Polynomial representations of Boolean functions over various rings such as $\mathbb{Z}$ and $\mathbb{Z}_m$ have been studied since Minsky and Papert (1969). From then on, they have been employed in a large variety of areas including communication complexity, circuit complexity, learning theory, coding theory and so on. For any integer $m \geq 2$, each Boolean function has a unique multilinear polynomial representation over ring $\mathbb{Z}_m$. The degree of such polynomial is called *modulo-m degree*, denoted as $\deg_m(\cdot)$.

In this paper, we investigate the lower bound of modulo-m degree of Boolean functions. When $m = p^k$ ($k \geq 1$) for some prime p, we give a tight lower bound $\deg_m(f) \geq k(p-1)$ for any non-degenerate function $f : \{0,1\}^n \to \{0,1\}$, provided that n is sufficient large. When m contains two different prime factors p and q, we give a nearly optimal lower bound for any symmetric function $f : \{0,1\}^n \to \{0,1\}$ that $\deg_m(f) \geq \frac{n}{2+\frac{1}{p-1}+\frac{1}{q-1}}$.

1 Introduction

Given a Boolean function $f : \{0,1\}^n \to \{0,1\}$, the *degree* (resp., *modulo-m degree*), denoted as $\deg(f)$ (resp., $\deg_m(f)$), is the degree of the unique[1] multilinear polynomial representation of f over $\mathbb{R}$ (resp., $\mathbb{Z}_m$). These complexity measures and related notions have been studied extensively since the work of Minsky and Papert [23]. The polynomial representation of a Boolean function has found numerous applications in the study of query complexity (see e.g. [5]), communication complexity [4, 28, 31, 30, 29, 24, 10], learning theory [17, 20, 16, 25], explicit combinatorial constructions [13, 14, 11, 7], circuit lower bounds [33, 27, 1, 12] and coding theory [36, 37, 15, 21], etc.

In this paper, we focus on modulo-m degree of Boolean functions. Throughout, all Boolean functions are assumed to be *non-degenerate*[2], if not specifically mentioned. One of the complexity theoretic motivations of studying $\deg_m(f)$ is to understand the power of modular counting. For example, the famous Razborov–Smolensky polynomial method [27, 33] reduces the task of proving size lower bounds for $\mathsf{AC}^0[p]$ circuits to proving a lower bound of approximate modulo-p degree of the target Boolean function. However, this approach mainly works when p is a prime.[3] Another example, in which m can be composite, is that a $(1/2 + o(1))$-inapproximability of a Boolean function f by degree-$O(1)$ polynomials over $\mathbb{Z}_m$ implies that f cannot be computed by $\mathsf{MAJ}_{O(1)} \circ \mathsf{MOD}_m \circ \mathsf{AND}_{O(1)}$ circuits [1]. In general, it has been proved important to understand the computational power of polynomials over $\mathbb{Z}_m$ for general m.

Towards the complexity measure $\deg_m(f)$ itself, the case when m is a prime has been studied a lot in previous works. For example, one natural question is whether $\deg_m(f)$ is polynomially related to $\deg(f)$ for general m, as other complexity measures like decision tree complexity $\mathrm{D}(f)$ do? The answer is NO according to the parity function $\mathsf{PARITY}(x) := \bigoplus_{i=1}^n x_i$. That is, $\deg_2(\mathsf{PARITY}) = 1$ but $\deg(\mathsf{PARITY}) = n$. Though this function works as a counterexample for the relationship between $\deg_2(f)$ and $\deg(f)$, it is still inspiring because its modulo-3 degree is large. By writing PARITY as $\frac{1}{2} - \frac{1}{2}\prod_{i=1}^n(1 - 2x_i)$ and taking modulo 3, one can get $\deg_3(\mathsf{PARITY}) = n$. Actually, Gopalan et al. [12] give the following relationship between the polynomial degrees modulo two different primes p and q:

$$\deg_q(f) \geq \frac{n}{\lceil \log_2 p \rceil \deg_p(f) p^{2\deg_p(f)}}.$$

Daunting at the first glance, the inequality implies an essential fact that, as long as $\deg_p(f) = o(\log n)$, a lower bound of $\Omega(n^{1-o(1)})$ for $\deg_q(f)$ follows. Moreover, if m has at least two different prime factors p and q, then $\deg_m(f) \geq \max\left\{\deg_p(f), \deg_q(f)\right\} = \Omega(\log n)$.

Having negated the possibility for the case of prime m, it is natural to study the case of composite number. The systematic study of this case was initiated by Barrington et al. [3]. Alas, whether $\deg_m(f)$ is polynomially related to $\deg(f)$ is still a widely open problem. Though the case m being a prime power is proved to be not true in Gopalan's thesis [10], we are unable to find better separation between $\deg_m(f)$ and $\deg(f)$, for $m = pq$ with p and q being two distinct primes, than the quadratic one given by Li and Sun [19]. This leads to the following conjecture:

[1] The existence and uniqueness are guaranteed by the Möbius inversion, see e.g. [12].

[2] A Boolean function is called non-degenerate if it depends on all its n variables.

[3] It is a folklore that $\mathsf{AC}^0[m] = \mathsf{AC}^0[\mathrm{rad}(m)]$, where $\mathrm{rad}(m)$ is the square-free part of m. Therefore in fact we are able to handle $\mathsf{AC}^0[q]$ circuits for any prime power q.

▶ **Conjecture 1.1.** *Let f be a Boolean function. If m has at least two distinct prime factors, then*

$$\deg(f) = O(\mathrm{poly}(\deg_m(f))).$$

Towards this conjecture, the first step is to deal with *symmetric* Boolean functions. Lee et al. [18] proves that $2\deg_p(f)\deg_q(f) > n$ for any distinct primes p, q and non-trivial symmetric Boolean function $f : \{0,1\}^n \to \{0,1\}$, implying the correctness of Conjecture 1.1 in symmetric cases. Li and Sun [19] improved their bound to $p\deg_p(f) + q\deg_q(f) > n$, which implies $\deg_{pq}(f) > \frac{n}{p+q}$. This is far from being tight; actually, as we will present later, the denominator $p + q$ can be reduced to 3.5.

On the tight lower bound of $\deg(f)$, Nisan and Szegedy [26] give the bound $\deg(f) \geq \log_2 n - O(\log\log n)$ as long as f is non-degenerate. Very recently, this bound is improved to $\deg(f) \geq \log_2 n - O(1)$ by [6, 35], which is tight up to the additive $O(1)$-term by the *address function*. Gathen and Roche [34] show that $\deg(f) \geq \deg_{p(n)}(f) \geq p(n) - 1$ for any non-trivial *symmetric* Boolean function, where $p(n)$ is the largest prime below $n + 2$. (Notice that the module degree gives a lower bound on the degree.) Using the currently best result on prime gaps [2], this gives an $n - O(n^{0.525})$ lower bound. On the other side, Gathen and Roche give a polynomial family with $\deg(f) = n - 3$, and they propose Conjecture 1.2 below with a probabilistic heuristic argument:

▶ **Conjecture 1.2.** *For any non-trivial symmetric Boolean function $f : \{0,1\}^n \to \{0,1\}$,*

$$\deg(f) \geq n - O(1).$$

Our Results. In this work, we prove the following four theorems, giving better lower bounds for $\deg_m(f)$. As we have already mentioned, the gap between $\deg(f)$ and $\deg_{p^k}(f)$ can be arbitrarily large. Nevertheless, we claim that $\deg_{p^k}(f)$ cannot be too small either. This begins with symmetric functions:

▶ **Theorem 1.3.** *For any prime p, positive integer k, and non-trivial symmetric function $f : \{0,1\}^n \to \{0,1\}$,*

$$\deg_{p^k}(f) \geq (p-1)\cdot k$$

when $n \geq (k-1)\varphi(p^\mu) + p^\mu - 1 \in O(p^2k^2)$ where $\mu = \lceil \log_p((p-1)k - 1)\rceil$. The bound $(p-1)\cdot k$ is tight.

The proof of Theorem 1.3 is centered around Mahler expansion [22], which has been deemed useful in several fields of study, from analytic functions to combinatorics. Wilson [36] studied Mahler coefficients and related degree to period of symmetric functions. However, by introducing some more insights, we are able to give a stronger analysis to settle this case once for all. To be a bit more concrete, our argument (i) introduces the base-p period to replace normal period, and then (ii) spans every symmetric functions into two fashions, by MODs or binomials, and then (iii) introduces Mahler coefficient matrix and determines its kernel.

In addition, Theorem 1.3 can be extended to non-degenerate Boolean functions. We achieve this by showing that one can embed an $\omega(1)$-size non-trivial symmetric Boolean function into any non-degenerate functions by applying Erdős–Rado Theorem from Ramsey theory.[4] This leads to the same tight bound, provided that the input size is sufficiently large.

[4] We note that a similar embedding argument has appeared before in [1].

▶ **Theorem 1.4.** *For any prime p, positive integer k, and non-degenerate function $f : \{0,1\}^n \to \{0,1\}$ with sufficiently large n,*

$$\deg_{p^k}(f) \geq (p-1) \cdot k.$$

The bound $(p-1) \cdot k$ is tight.

Now turn to the case of non-prime-power composite m. The following theorem provides a lower bound on $\deg_m(f)$.

▶ **Theorem 1.5.** *For any composite number m with at least two different prime factors p, q and any non-trivial symmetric Boolean function $f : \{0,1\}^n \to \{0,1\}$,*

$$\deg_m(f) \geq \frac{1}{2 + \frac{1}{p-1} + \frac{1}{q-1}} \cdot n.$$

Note that this bound approaches $n/2$ when p and q become larger and larger. It improves the $n/(p+q)$ bound in [19]. To prove this theorem, we show a stronger version of Theorem 1.3 for $k = 1$, which requires a more elaborate analysis. Then we utilizes Periodicity Lemma [9] to obtain the desired lower bound.

On the other hand, the next theorem shows that the bound in Theorem 1.5 cannot be larger than $(1 + o(1))n/2$:

▶ **Theorem 1.6.** *Let m be a square-free composite number. There exists a symmetric Boolean function $f : \{0,1\}^n \to \{0,1\}$ with arbitrarily large n, such that $\deg_m(f) \leq n/2 + o_m(n)$.*[5]

Organization. In Section 2, we give necessary definitions and concepts. Then we give the proofs of Theorem 1.3 and Theorem 1.4 respectively in Section 3.1 and Section 3.2. In Section 4.2 we prove Theorem 1.5, and in Section 4.3 we prove Theorem 1.6. Finally, we conclude the paper in Section 5.

2 Preliminaries

We denote $\{1, 2, \ldots, n\}$ as $[n]$ throughout this paper. $\varphi(\cdot)$ denotes Euler's totient function. Notation $\log^{\circ k}(n)$ is defined as $\underbrace{\log\log\cdots\log}_{k} n$, and $\log^*(n)$ is for the iterated logarithm, that is, $\min\{k : \log^{\circ k}(n) \leq 1\}$.

2.1 Basics of Boolean Functions

An n-bit *Boolean function* $f(x)$ is a mapping from $\{0,1\}^n$ to $\{0,1\}$. Sometimes we write $\boldsymbol{x}$ to indicate the n-dimensional 0-1 vector corresponding to string $x \in \{0,1\}^n$. The following operation will be frequently used: Suppose $x \in \{0,1\}^n$ is a (input) string, and $S \subseteq [n]$ is a set of indices. Denote the string obtained by flipping all bits in x whose indices are in S as $x^{\oplus S}$. As a common practice, $x^{\oplus\{i\}}$ is abbreviated as $x^{\oplus i}$.

[5] The subscript "m" in the $o(\cdot)$ notation means that the hidden factor depends on m.

Here we list some subclasses of Boolean functions, which we will frequently deal with later:

- A Boolean function is called *non-trivial* if it is not a constant.
- A Boolean function is called *non-degenerate* if its value depends on all input bits. In other words, there does not exist such t that, for every $x \in \{0,1\}^n$ the equality $f(x) = f(x^{\oplus t})$ holds. Such bit, if exists, is also known as *dumb* bit.
- A Boolean function is called *symmetric*, if $f(x) = f(y)$ for any x, y satisfying $|x| = |y|$. Here $|x|$ denotes the Hamming weight of x, i.e., number of 1's.

There exists a unique polynomial representing f over $\mathbb{Z}_m$ or $\mathbb{Z}$. More formally:

▶ **Fact 2.1.** *For any Boolean function $f : \{0,1\}^n \to \{0,1\}$, the unique polynomial*

$$\sum_{a\in\{0,1\}^n} f(a) \prod_{i=1}^{n} ((2a_i - 1)x_i + 1 - a_i) =: \sum_{S\subseteq[n]} c_S \prod_{i\in S} x_i$$

represents f over $\mathbb{Z}$. On top of this, the polynomial $\sum_{S\subseteq[n]}(c_S \bmod m)\prod_{i\in S} x_i$ represents f over $\mathbb{Z}_m$.

▶ **Definition 2.2.** *The degree (resp., modulo-m degree) of a Boolean function f, denoted by* $\deg(f)$ *(resp.,* $\deg_m(f)$*), is the degree of the polynomial representing f over $\mathbb{Z}$ (resp., $\mathbb{Z}_m$).*

This measure has some simple but useful properties. The following fact is a consequence of the Chinese Remainder Theorem; see [19, Fact 5].

▶ **Fact 2.3.** *Suppose $f : \{0,1\}^n \to \{0,1\}$ is a Boolean function, and m, m' are coprime. Then* $\deg_{m'm}(f) = \max\{\deg_m(f), \deg_{m'}(f)\}$.

With some input bits fixed, the degree of a Boolean function may decrease. This can be easily derived by substituting those variables with their values. More formally, we define the *restriction* of Boolean functions and restate this fact below.

▶ **Definition 2.4** (Restriction). *Suppose $f : \{0,1\}^n \to \{0,1\}$ is a Boolean function, $S \subseteq [n]$ is a set of indices, and there is a mapping $\sigma : [n]\backslash S \to \{0,1\}$. For every $i \notin S$, fix the i-th bit in the input of f to be $\sigma(i)$ to obtain a new Boolean function with input size $|S|$. We call it the restriction of f over σ, denoted as $f|_\sigma$.*

▶ **Fact 2.5.** *Suppose $f : \{0,1\}^n \to \{0,1\}$ is a Boolean function. For any integer $m \geq 2$ and restriction $f|_\sigma$, we have* $\deg_m(f) \geq \deg_m(f|_\sigma)$.

A common complexity measure, the *sensitivity*, will be used in Section 3.2. Simon gave a lower bound on this measure [32].

▶ **Definition 2.6** (Sensitivity). *Given a Boolean function $f : \{0,1\}^n \to \{0,1\}$ and an input x, we say bit i is sensitive if $f(x) \neq f(x^{\oplus i})$. The sensitivity of f on input x is $s(f,x) := |\{i : i \in [n], f(x) \neq f(x^{\oplus i})\}|$. The sensitivity of f is then defined as $s(f) := \max_x s(f,x)$.*

▶ **Theorem 2.7** ([32]). *For any non-degenerate Boolean function $f : \{0,1\}^n \to \{0,1\}$, we have*

$$s(f) \geq \frac{1}{2}\log n - \frac{1}{2}\log\log n + \frac{1}{2}.$$

2.2 Periodicity and Mahler Expansion

We consider symmetric Boolean functions in this section. For a symmetric function $f : \{0,1\}^n \to \{0,1\}$, clearly there exists a unique $F : \{0,\dots,n\} \to \{0,1\}$, called the *univariate version of* f, such that $f(x) = F(|x|)$ for every x. We call f (and F) *ℓ-periodic*, if $F(a) = F(b)$ for any $0 \le a, b \le n$ satisfying $\ell \,|\, a - b$. For example, f is trivially ℓ-periodic for any $\ell > n$. We are also interested in integer power period length. Hence we introduce the following definition.

▶ **Definition 2.8** (Base-m period). *Assume $f : \{0,1\}^n \to \{0,1\}$ is a symmetric Boolean function. The base-m period is the minimum ℓ such that ℓ is a power of m, and f is ℓ-periodic. Denote it as $\pi_m(f)$.*

Here are some concrete examples for a clearer illustration.

- The not-all-equal NAE function is defined as $\mathsf{NAE}_n(x_1,\dots,x_n) := \mathbb{I}[\exists i,j \text{ s.t. } x_i \ne x_j]$. Then $\pi_3(\mathsf{NAE}_3) = 3$ while $\pi_3(\mathsf{NAE}_4) = 9$. That is, $\pi_m(f)$ may be larger than n.
- If f is a trivial function, then $\pi_3(f) = 1$.

One may write F as a univariate polynomial over $\mathbb{Q}$, but it will not always induce a polynomial when we move to work on $\mathbb{Z}_m$, like what f does. Fortunately, the following representation, also known as *Mahler expansion* [36], serves the purpose similar to polynomial representation.

▶ **Theorem 2.9** (Mahler expansion). *Assume that $f : \{0,1\}^n \to \{0,1\}$ is a symmetric Boolean function, and F is the corresponding univariate version. Let $d := \max\{n, m-1\}$. Then there exists a unique sequence $\alpha_0, \alpha_1, \cdots, \alpha_d \in \mathbb{Z}_m$ such that*

$$\sum_{j=0}^{d} \alpha_j \binom{t}{j} = \begin{cases} F(t), & 0 \le t \le n; \\ 0, & n < m-1 \text{ and } n < t < m. \end{cases}$$

We call $\sum_{j=0}^{d} \alpha_j \binom{t}{j}$ the Mahler expansion of F over $\mathbb{Z}_m$, and α_j the j-th Mahler coefficient.

There are some connections between polynomial degree and Mahler expansion. Over ring $\mathbb{Z}_m$, let $d^* := \max\{\ell : \alpha_\ell \not\equiv 0 \pmod m, \ell \le n\}$. If we only take 0-th to d^*-th terms in the Mahler expansion to get $\hat{F}(t) = \sum_{j=0}^{d^*} \alpha_j \binom{t}{j}$, then $\hat{F}(|x|) = F(|x|)$ for all $x \in \{0,1\}^n$, which implies

▶ **Fact 2.10.** $\deg_m(f) = \max\{\ell : \alpha_\ell \not\equiv 0 \pmod m, \ell \le n\}$.

▶ Remark. The fact above does not hold if we take away the condition $\ell \le n$. The next example shows that on $\mathbb{Z}_m$, the existence of high-order non-zero Mahler coefficient does not imply high degree, if the input length is too short.

▶ Example 2.11. Let $n = 2$ and $f(x) = -x_0x_1 + x_0 + x_1 = x_0 \vee x_1$. On $\mathbb{Z}_5$, one can verify its Mahler expansion is

$$f(x) = \binom{|x|}{1} + 4\binom{|x|}{2} + 2\binom{|x|}{4}.$$

But $\deg_5(f) = 2$.

This phenomenon does not come from nowhere; intuitively speaking, in the Mahler expansion over $\mathbb{Z}_m$, one may need to imitate Lagrange-style interpolation for $|x| > n$, and hence introduce some high-order terms. (Although $|x|$ can never be above n, we need to utilize MOD functions later in this paper, which requires $F(t)$ to be zero for $n < t < m$.)

Wilson [36] showed the following result about the degree and Mahler expansion of symmetric Boolean functions, given the base-p period.

▶ **Theorem 2.12** ([36, Lemma 1]). *Let p be a prime, and t, k be positive integers. Assume $f : \{0,1\}^n \to \{0,1\}$ is a symmetric Boolean function, and $\{\alpha_\ell\}$ are its Mahler coefficients over $\mathbb{Z}_{p^k}$. If f is p^t-periodic, then*

$$\deg_{p^k}(f) \le (k-1)\cdot\varphi(p^t) + p^t - 1.$$

In addition, for any positive integer j and $\ell \ge j\cdot\varphi(p^t) + p^t$, we have $\alpha_\ell \equiv 0 \pmod{p^j}$.

2.3 MOD and Its Mahler Expansion over $\mathbb{Z}_{p^k}$

We first look into the Mahler expansion of weight modular functions. This special case is illuminating in our later proofs. The MOD function is defined as

$$\mathsf{MOD}_n^{c,m}(x) := \mathbb{I}\big[|x| \equiv c \pmod{m}\big] \in \{0,1\},$$

where $n \ge m-1$ denotes the length of input x, and $\mathbb{I}[\cdot]$ is the indicator function. The following theorem gives the degree of MOD_n^{0,p^t}.

▶ **Theorem 2.13** ([36, Theorem 10]). *Let p be a prime, and t, k be positive integers. Denote $d := (k-1)\cdot\varphi(p^t) + p^t - 1$. Then for any $n \ge d$, we have*

$$\deg_{p^k}(\mathsf{MOD}_n^{0,p^t}) = d.$$

In fact, we can achieve a more general result by further analysis. Fix n, p, t and k. Notate the Mahler coefficient of MOD_n^{a,p^t} over $\mathbb{Z}_{p^k}$ as $\alpha_\ell^{(a,p^t)}$ i.e., $\mathsf{MOD}_n^{a,p^t}(x) = \sum_{j=0}^{d} \alpha_j^{(a,p^t)}\binom{|x|}{j}$. Moreover, MOD_n^{a,p^t} can also be represented with $\alpha_\ell^{(0,p^t)}$ as

$$\mathsf{MOD}_n^{a,p^t}(x) = \sum_{j=0}^{d} \alpha_j^{(0,p^t)}\binom{|x|-a}{j}.$$

Then expand each $\binom{|x|-a}{j}$ by Vandermonde convolution to get

$$\alpha_\ell^{(a,p^t)} = \sum_{i=0}^{d-\ell}\binom{-a}{i}\alpha_{i+\ell}^{(0,p^t)}. \tag{1}$$

Specially, by setting $\ell = d$, we get $\alpha_d^{(a,p^t)} = \alpha_d^{(0,p^t)}$. This equation generalizes the theorem to all remainders.

▶ **Corollary 2.14.** *Let p be a prime, and t and k be positive integers. Denote $d := (k-1)\cdot\varphi(p^t) + p^t - 1$. For any $n \ge d$ and $0 \le a < p^t$, we have*

$$\deg_{p^k}(\mathsf{MOD}_n^{a,p^t}) = d.$$

3 Lower Bound of $\deg_{p^k}(f)$

By identifying the degree of MOD_n^{i,p^t} over $\mathbb{Z}_{p^k}$, we show that the degree of all p^t-periodic functions is constantly small since they can be spanned by $\{\mathsf{MOD}_n^{j,p^t}\}_{j=0}^{p^t-1}$. In Section 3.1, we prove that the degree of any p^t-periodic (but not p^{t-1}-periodic) function will not decrease too much from $(k-1)\cdot\varphi(p^t) + p^t - 1$ during the spanning, despite the cancellation of the high-order coefficients. By a Ramsey-type argument in Section 3.2, we further extend our lower bound to all non-degenerate Boolean function with sufficiently many input bits.

3.1 Symmetric Functions – Proof of Theorem 1.3

We begin with the periodicity of symmetric Boolean functions with low degree. In our proof, the following Lucas's Theorem is important.

▶ **Theorem 3.1** (Lucas). *Let $n, m \in \mathbb{N}$, and p be a prime. Assume in base p, n and m can be represented as $n = (n_v n_{v-1} \cdots n_0)_p$ and $m = (m_v m_{v-1} \cdots m_0)_p$ (the number with fewer digits are padded with 0). Then*

$$\binom{n}{m} \equiv \binom{n_v}{m_v}\binom{n_{v-1}}{m_{v-1}} \cdots \binom{n_0}{m_0} \pmod{p}.$$

The next lemma indicates the periodicity of symmetric Boolean functions with low degree.

▶ **Lemma 3.2.** *Let $f : \{0,1\}^n \to \{0,1\}$ be a symmetric Boolean function. For prime p and positive integers t and k, if $\deg_{p^k}(f) \le p^t - 1$, then f is p^t-periodic.*

Proof. Denote $d := \deg_{p^k}(f)$, and suppose α_ℓ are the Mahler coefficients of f over ring $\mathbb{Z}_{p^k}$, i.e., $f(x) = \sum_{j=0}^{d} \alpha_j \binom{|x|}{j} \bmod p^k$. According to Lucas's Theorem, if $a \equiv b \pmod{p^t}$, then for any $0 \le j \le p^t - 1$, we have $\binom{a}{j} \equiv \binom{a_v}{j_v} \cdots \binom{a_t}{j_t}\binom{a_{t-1}}{j_{t-1}} \cdots \binom{a_0}{j_0} \pmod{p}$. Here, a_i (resp. b_i and j_i) is the representation of a (resp. b and j) in the base p. Note that $j_i = 0$ for any $i \ge t$. Hence $\binom{a}{j} \equiv \binom{a_{t-1}}{j_{t-1}} \cdots \binom{a_0}{j_0} \pmod{p}$. For the same reason, $\binom{b}{j} \equiv \binom{b_{t-1}}{j_{t-1}} \cdots \binom{b_0}{j_0} \pmod{p}$. In addition, a and b's last t digits are the same as $a \equiv b \pmod{p^t}$. Thus $\sum_{j=0}^{d} \alpha_j \binom{a}{j} \bmod p = \sum_{j=0}^{d} \alpha_j \binom{b}{j} \bmod p$. By the definition that $f(x) \in \{0,1\}$, we get $\sum_{j=0}^{d} \alpha_j \binom{a}{j} \bmod p^k = \sum_{j=0}^{d} \alpha_j \binom{b}{j} \bmod p^k$. ◀

Next, provided $\pi_p(f)$, we give some lower bounds on the degree by the following two lemmas, conditioned on that n is large enough. Together with the lemma above we lead to a contradiction, and our theorem follows eventually. Before continuing, notice again that the value $f(x)$ is related only to the Hamming weight of x, and thus $f(x) = \sum_{0 \le i \le n : F(i)=1} \mathsf{MOD}_n^{i,n+1}(x)$. Specially, if $f(x)$ is t-periodic, then we can write $f(x)$ as $f(x) = \sum_{0 \le i \le t-1 : F(i)=1} \mathsf{MOD}_n^{i,t}(x)$ and apply Corollary 2.14.

▶ **Lemma 3.3.** *Assume p is a prime, and $f : \{0,1\}^n \to \{0,1\}$ is a symmetric Boolean function of period p. If for some positive integer k, it holds that $n \ge (p-1) \cdot k$, then*

$$\deg_{p^k}(f) = (p-1) \cdot k.$$

Proof. Expand $f(x)$ to get $\sum_{0 \le i \le p-1 : F(i)=1} \mathsf{MOD}_n^{i,p}(x)$. According to Corollary 2.14, the degree of each term in the summation is $\deg_{p^k}\left(\mathsf{MOD}_n^{i,p}\right) = (p-1) \cdot k =: d$. On the other hand, Section 2.3 says the coefficient of degree d term is identical in the polynomial of every MOD. As $f(x)$ is non-trivial, the number of terms in the summation, denoted as N, is neither 0 nor p. Therefore, the degree d term in $f(x)$ has coefficient $N \cdot \alpha_d^{(0,p)} \not\equiv 0 \pmod{p}$, implying $\deg_{p^k}(f) = d$ as desired. ◀

▶ **Lemma 3.4.** *Assume p is a prime, and $f : \{0,1\}^n \to \{0,1\}$ is a symmetric Boolean function with $\pi_p(f) = p^t$. Here $t \ge 1$ and $n \ge (k-1) \cdot \varphi(p^t) + p^t - 1$. Then*

$$\deg_{p^k}(f) \ge (k-2) \cdot \varphi(p^t) + p^t.$$

Proof. Consider over the ring $\mathbb{Z}_{p^k}$. Let $d := (k-1) \cdot \varphi(p^t) + p^t - 1$. Provided p^t, we abbreviate $\alpha_\ell^{(j,p^t)}$, the ℓ-th Mahler coefficients of MOD_n^{j,p^t}, as $\alpha_\ell^{(j)}$ for convenience. According to Corollary 2.14, we have $\deg_{p^k}\left(\mathsf{MOD}_n^{j,p^t}\right) = d$.

For all $0 \le i \le p^t - 1$, Theorem 2.12 implies the fact that $\alpha_\ell^{(i)}$ can be divided by p^{k-2} when $\ell \ge (k-2)\cdot\varphi(p^t) + p^t = d - \varphi(p^t) + 1$. Therefore, we divide every such coefficient by p^{k-2}, and then take the remainder modulo p to get $\tilde{\alpha}_\ell^{(i)} := \left(\alpha_\ell^{(i)}/p^{k-2}\right) \bmod p$, where $d - \varphi(p^t) + 1 \le \ell \le d$. All these $\tilde{\alpha}_\ell^{(i)}$ forms the matrix

$$\boldsymbol{S} := \begin{bmatrix} \tilde{\alpha}_d^{(0)} & \cdots & \tilde{\alpha}_d^{(p^t-1)} \\ \vdots & \ddots & \vdots \\ \tilde{\alpha}_{d-\varphi(p^t)+1}^{(0)} & \cdots & \tilde{\alpha}_{d-\varphi(p^t)+1}^{(p^t-1)} \end{bmatrix} \in \mathbb{F}_p^{\varphi(p^t)\cdot p^t}.$$

Take its first $\varphi(p^t)$ columns to get a square matrix

$$\boldsymbol{S}' := \begin{bmatrix} \tilde{\alpha}_d^{(0)} & \cdots & \tilde{\alpha}_d^{(\varphi(p^t)-1)} \\ \vdots & \ddots & \vdots \\ \tilde{\alpha}_{d-\varphi(p^t)+1}^{(0)} & \cdots & \tilde{\alpha}_{d-\varphi(p^t)+1}^{(\varphi(p^t)-1)} \end{bmatrix}.$$

When $d - \varphi(p^t) + 1 \le \ell \le d$, divide both sides of Equation (1) by p^{k-2} and take the remainder modulo p to get

$$\tilde{\alpha}_\ell^{(a)} = \sum_{j=0}^{d-\ell} \binom{-a}{j} \tilde{\alpha}_{j+\ell}^{(0)},$$

which leads to the following decomposition of matrix $\boldsymbol{S}'$:

$$\boldsymbol{S}' = \begin{bmatrix} \tilde{\alpha}_d^{(0)} & & \\ \vdots & \ddots & \\ \tilde{\alpha}_{d-\varphi(p^t)+1}^{(0)} & \cdots & \tilde{\alpha}_d^{(0)} \end{bmatrix} \cdot \begin{bmatrix} \binom{0}{0} & \cdots & \binom{1-\varphi(p^t)}{0} \\ \vdots & \ddots & \vdots \\ \binom{0}{\varphi(p^t)-1} & \cdots & \binom{1-\varphi(p^t)}{\varphi(p^t)-1} \end{bmatrix} =: \boldsymbol{T}\cdot\boldsymbol{C}.$$

As $\tilde{\alpha}_d^{(0)} \ne 0$, the first matrix has determinant $\det(\boldsymbol{T}) \ne 0$. The latter one, consisting of binomial coefficients, is also invertible. We will prove this fact later. Eventually, $\operatorname{rank}(\boldsymbol{S}') = \varphi(p^t)$, so the kernel of $\boldsymbol{S}$ has dimension $\dim\ker\boldsymbol{S} = (p^t) - \varphi(p^t) = p^{t-1}$.

On one hand, because $f(x)$ is p^t-periodic, we can expand it by $\{\mathsf{MOD}_n^{j,p^t}\}_{j=0}^{p^t-1}$ with coefficients w_j.

$$f(x) = \sum_{j=0}^{p^t-1} w_j \mathsf{MOD}_n^{j,p^t}(x) = \sum_{j=0}^{p^t-1}\left(w_j \sum_{\ell=0}^{d} \alpha_\ell^{(j)}\binom{|x|}{\ell}\right) = \sum_{\ell=0}^{d}\left(\left(\sum_{j=0}^{p^t-1} w_j\alpha_\ell^{(j)}\right)\binom{|x|}{\ell}\right). \quad (2)$$

On the other hand, $\mathsf{MOD}_n^{i,p^{t-1}}$ can also be spanned by $\{\mathsf{MOD}_n^{j,p^t}\}$. In other words, assume $w_j^{(i)} := \mathbb{I}[i \equiv j \pmod{p^{t-1}}]$, then

$$\mathsf{MOD}_n^{i,p^{t-1}} = \sum_{j=0}^{p^t-1} w_j^{(i)}\mathsf{MOD}_n^{j,p^t} = \sum_{\ell=0}^{d}\left(\left(\sum_{j=0}^{p^t-1} w_j^{(i)}\alpha_\ell^{(j)}\right)\binom{|x|}{\ell}\right). \quad (3)$$

We claim $\deg_{p^k}(\mathsf{MOD}_n^{i,p^{t-1}}) \le d - \varphi(p^t)$, and because $n \ge d$, the coefficients of highest $\varphi(p^t)$ terms in its Mahler expansion (i.e., from degree $d - \varphi(p^t) + 1$ to degree d) are all zero. This is due to Corollary 2.14, where we have

$$\begin{aligned}\deg_{p^k}(\mathsf{MOD}_n^{i,p^{t-1}}) &= (k-1)\varphi(p^{t-1}) + p^{t-1} - 1\\ &= p^{t-2}\left((k-1)(p-1)+p\right) - 1\\ &\le p^{t-2}\left((k-1)(p^2-p)+p\right) - 1\\ &= d - \varphi(p^t).\end{aligned}$$

Further, if we set column vector $\boldsymbol{w}^{(i)} = \left(w_0^{(i)}, ..., w_{p^t-1}^{(i)}\right)^\top$ where $0 \le i \le p^{t-1} - 1$, then the above fact, together with Equation (3), indicates the following equation:

$$\boldsymbol{S}\boldsymbol{w}^{(i)} = \left[\sum_{j=0}^{p^t-1} w_j^{(i)} \tilde{\alpha}_d^{(j)}, \sum_{j=0}^{p^t-1} w_j^{(i)} \tilde{\alpha}_{d-1}^{(j)}, \cdots, \sum_{j=0}^{p^t-1} w_j^{(i)} \tilde{\alpha}_{d-\varphi(p^t)+1}^{(j)}\right]^\top = \mathbf{0}.$$

One can verify that $\left\{\boldsymbol{w}^{(0)}, \cdots, \boldsymbol{w}^{(p^{t-1}-1)}\right\}$ is linear independent, and therefore they form a base of the kernel of $\boldsymbol{S}$ i.e., $\ker \boldsymbol{S} = \operatorname{span}\left\{\boldsymbol{w}^{(0)}, \cdots, \boldsymbol{w}^{(p^{t-1}-1)}\right\}$.

However, $f(x)$ is not p^{t-1}-periodic because $\pi_p(f) = p^t$. This means $f(x)$ cannot be written as the sum of some $\mathsf{MOD}_n^{i,p^{t-1}}$. Thus $\boldsymbol{w} := (w_0, ..., w_{p^t-1})^\top \notin \operatorname{span}\left\{\boldsymbol{w}^{(0)}, \cdots, \boldsymbol{w}^{(p^{t-1}-1)}\right\}$ i.e., $\boldsymbol{S}\boldsymbol{w} \neq \mathbf{0}$. This leads to the existence of $D \in [d - \varphi(p^t) + 1, d]$ such that $\sum_{j=0}^{p^t-1} w_j^{(i)} \tilde{\alpha}_D^{(j)} \neq 0$. Namely, the degree D term in Equation (2) exists as desired. ◀

To finish the proof of this lemma, we show that the matrix $\boldsymbol{C}$ is invertible, due to the following proposition.

▶ **Proposition 3.5.** $\det(\boldsymbol{C}) = \pm 1$.

Proof. In fact,

$$\boldsymbol{C} = \operatorname{diag}\{1, -1, 1, -1, ...(-1)^{m-1}\} \cdot \begin{bmatrix} 1 & 1 & \binom{1}{1} & \cdots & \binom{m-2}{m-2} \\ 0 & \binom{1}{0} & \binom{2}{1} & \cdots & \binom{m-1}{m-2} \\ 0 & \binom{2}{0} & \binom{3}{1} & \cdots & \binom{m}{m-2} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & \binom{m-1}{0} & \binom{m}{1} & \cdots & \binom{2m-3}{m-2} \end{bmatrix}$$

where $m := \varphi(p^t)$. Denote the second matrix as $\boldsymbol{C}'$. Take Row m of $\boldsymbol{C}'$ and subtract Row $m-1$ from it. Then take Row $m-1$ and subtract Row $m-2$ from it. $\cdots$ Take Row 3 and subtract Row 2 from it. Then C' has been transformed to

$$\begin{bmatrix} 1 & 1 & \binom{1}{1} & \cdots & \binom{m-2}{m-2} \\ 0 & \binom{1}{0} & \binom{2}{1} & \cdots & \binom{m-1}{m-2} \\ 0 & 0 & \binom{2}{0} & \cdots & \binom{m-1}{m-3} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \binom{m-1}{0} & \cdots & \binom{2m-4}{m-3} \end{bmatrix}.$$

Keep repeating this step, and $\boldsymbol{C}'$ will be transformed into an upper triangular matrix, whose diagonal elements are all 1. ◀

Now we are ready to prove Theorem 1.3.

Proof of Theorem 1.3. Note that Lemma 3.3 provides tight instances, so below we are going to prove the inequality.

Assume towards contradiction that there exists $f : \{0,1\}^n \to \{0,1\}$ satisfying $\deg_{p^k}(f) < (p-1)\cdot k$, and $n \geq (k-1)\cdot\varphi(p^\mu) + p^\mu - 1$ where $\mu = \lceil \log_p((p-1)k-1)\rceil$. Lemma 3.2 tells us that f is p^μ-periodic. The non-triviality of f indicates that there exists $1 \leq t \leq \mu$ such that $\pi_p(f) = p^t$.

If $t = 1$, then according to Lemma 3.3 we have $\deg_{p^k}(f) = (p-1)\cdot k$. If $t \geq 2$, then Lemma 3.4 indicates

$$\begin{aligned}\deg_{p^k}(f) &\geq (k-2)\cdot\varphi(p^t) + p^t\\ &\geq (k-2)\cdot\varphi(p^2) + p^2\\ &= k\cdot(p-1)^2 + 2p - p^2 + (p-1)\cdot k\\ &\geq (p-1)^2 + 2p - p^2 + (p-1)\cdot k\\ &> (p-1)\cdot k.\end{aligned}$$

Both cases lead to contradiction. ◀

3.2 Non-degenerate Functions – Proof of Theorem 1.4

For the general non-degenerate case, our key idea is to embed a symmetric Boolean function into it, and then apply Theorem 1.3. The following lemma is crucial.

▶ **Lemma 3.6.** *There exists a monotone increasing function $r(n) = \omega(1)$ such that the following holds. Let $f : \{0,1\}^n \to \{0,1\}$ be a non-degenerate Boolean function. Then there exists a set of indices $S \subseteq [n]$ with $|S| \geq r(n)$, and a mapping $\sigma : [n]\backslash S \to \{0,1\}$ such that $f|_\sigma$ is a non-trivial symmetric Boolean function.*

Generally speaking, with this lemma in hand, every $h(n)$ lower bound on complexity measure of symmetric functions that is monotone decreasing w.r.t. restriction (e.g., Fact 2.5) can yield an $h(r(n))$ lower bound on that of all non-degenerate functions. In the setting of modulo-p^k degree, the bound $h(n)$ is a constant function (when n is large than some threshold), so we can get the same bound, except that the threshold for n blows up. However, as indicated by our proof, the function $r(n)$ grows extraordinary slow (approximately the square root of iterated logarithm of n).

First, let us see how to utilize this lemma in proving Theorem 1.4.

Proof of Theorem 1.4. As long as Lemma 3.6 holds, by Fact 2.5 and Theorem 1.3, if $n \geq r^{-1}((k-1)\cdot\varphi(p^\mu) + p^\mu - 1)$, then $\deg_{p^k}(f) \geq (p-1)\cdot k$, deriving the desired lower bound. In addition, any symmetric function with period p (and input long enough) still serves as an instance with $\deg_{p^k}(f) = (p-1)\cdot k$. ◀

In the rest part of this section we prove Lemma 3.6.

For convenience, we introduce the following notation. If $x_i = 1$ for every $i \in S \subseteq [n]$, then define $\mathrm{DOWN}(S,x,k) := \left\{x^{\oplus T} \mid T \subseteq S, |T| = k\right\}$. Intuitively speaking, it is the set of strings obtained by flipping k bits, whose indices are in S, of x from 1 to 0.

According to Theorem 2.7, there exists $\tilde{x}$ such that $s(f,\tilde{x}) = \Omega(\log n)$. Without loss of generality we assume the set $\{i \in [n] : \tilde{x}_i = 1, f(\tilde{x}) \neq f(\tilde{x}^{\oplus i})\}$, defined as S_0, is of cardinality $\Omega(\log n)$. Recursively define S_t to be the largest set satisfying the following two conditions:

- $S_t \subseteq S_{t-1}$.
- The value $f(y)$ are identical for any $y \in \mathrm{DOWN}(S_t, \tilde{x}, t)$.

We then make the following claim, and prove it.

▷ Claim 3.7.

$$|S_t| = \Omega\left(\log^{\circ(t-1)}(|S_{t-1}|)\right).$$

Our proof relies on Erdős–Rado Theorem [8] from Ramsey theory on hypergraphs.

▶ **Definition 3.8** (k-Uniform Hypergraph Ramsey Number)**.** *Suppose V is a set of vertices, and all size-k subsets of V forms $\mathcal{F}_k(V)$. If $E \subseteq \mathcal{F}_k(V)$, then we call (V, E) as a k-uniform hypergraph of order $|V|$. Naturally, we call $(V, \mathcal{F}_k(V))$ a complete k-uniform hypergraph.*

If the following property holds for complete k-uniform hypergraph of order M but not $M-1$, then $r_k(s,t) := M$ is called the k-uniform hypergraph Ramsey number: color every k-hyperedge red or blue arbitrarily, then there must exist a complete red hyper-subgraph of order s, or a complete blue hyper-subgraph of order t.

▶ **Theorem 3.9** ([8])**.** *$r_2(s,t) \le \binom{s+t-2}{t-1}$ and*

$$r_k(s,t) \le 2^{\binom{r_{k-1}(s-1,t-1)}{k-1}}, \quad (k > 2).$$

This theorem implies the following fact: if we color k-uniform hypergraph of order n with two colors, then there exists a monochromatic clique of size $\Omega(\log^{\circ k}(n))$.

Proof of Claim 3.7. Construct the following complete t-uniform hypergraph. The vertex set is S_{t-1}. For any $x \in \mathrm{DOWN}(S_{t-1}, \tilde{x}, t)$, we color the hyperedge $\{i : x_i \neq \tilde{x}_i\}$ with red if $f(x) = 1$, or blue otherwise. Take the largest monochromatic clique and suppose its vertex set is S. According to Theorem 3.9, $|S| = \Omega(\log^{\circ k}(n))$. Furthermore, the monochromaticity implies the value $f(z)$ is identical for any $z \in \mathrm{DOWN}(S, \tilde{x}, t)$. Hence S satisfies the desired conditions where our claim follows immediately. ◁

With the help of the claim and notations above, we can complete our proof of Lemma 3.6.

Proof of Lemma 3.6. By invoking Claim 3.7 iteratively,

$$|S_t| \ge Z \cdot \log^{\circ((t-1)t/2+1)}(n),$$

where Z is a positive constant irrelevant to n. Take $t' = t'(n) := \lfloor \sqrt{\log^*(n) - 2} \rfloor$. Then $(t'-1)t'/2 + 1 < \log^*(n)$ and $|S_{t'}| = \omega(1)$. In addition, define

$$r = r(n) := \min\left\{Z \cdot \log^{\circ(t'(t'-1)/2+1)}(n), t'(n)\right\} = \omega(1).$$

Then we have $r(n) \le |S_{r(n)}|$. This is because

- if $t'(n) \le Z \cdot \log^{\circ(t'(t'-1)/2+1)}(n)$, then we have $r(n) = t'(n) \le Z \cdot \log^{\circ(r(r-1)/2+1)}(n) \le |S_{r(n)}|$;
- if $t'(n) > Z \cdot \log^{\circ(t'(t'-1)/2+1)}(n)$, then $t'(n) > r(n)$, so $r(n) = Z \cdot \log^{\circ(t'(t'-1)/2+1)}(n) \le Z \cdot \log^{\circ(r(r-1)/2+1)}(n) \le |S_{r(n)}|$.

Now take a size $r(n)$ subset T of $S_{r(n)}$ arbitrarily. Define the mapping $\sigma : [n] \backslash T \to \{0,1\}$ such that $\sigma(i) = \tilde{x}_i$. Restrict f over σ to obtain a new function $g := f|_\sigma$. We will prove g is symmetric and non-trivial, and then the lemma follows immediately.

Symmetric. Assume $x, y \in \{0,1\}^{r(n)}$ such that $|x| = |y|$. Define x' (resp. y') to be the string of size n obtained from x (resp. y) and σ. Recall the definition of $S_{r(n)}$. That is, for any $i \in S_{r(n)}$, it holds that $\tilde{x}_i = 1$. Therefore,

$$x', y' \in \mathrm{DOWN}(S_{r(n)}, \tilde{x}, |x|) \subseteq \mathrm{DOWN}(S_{|x|}, \tilde{x}, |x|).$$

By definition of DOWN, we have $f(x') = f(y')$ i.e., $g(x) = g(y)$.

Non-trivial. Assume $z, w \in \{0,1\}^{r(n)}$ such that $|z| = 0$ and $|w| = 1$. We define z' and w' similarly to x' and y'. Suppose $z' = w' \oplus e_i$. As $i \in T \subseteq S_0$, the i-th bit is sensitive. Therefore, $f(z') \neq f(w')$ i.e., $g(z) \neq g(w)$. ◀

4 Lower Bounds of $\deg_{pq}(f)$ for Symmetric Functions

We first go further with the analysis of Mahler coefficients of MOD functions, then prove Theorem 1.5 in Section 4.2, and give an instance in Section 4.3, showing one can never improve the constant factor 1/2.

4.1 More Analyses of MOD and Its Mahler Coefficients

Let p be a prime and t be a positive integer. Consider over the ring $\mathbb{Z}_p$. Recall the notation $\alpha_\ell^{(a,p^t)}$: it is the ℓ-th Mahler coefficient of MOD_n^{a,p^t}. Since $\deg_p(\mathsf{MOD}_n^{a,p^t}) = p^t - 1$, the following $p^t \times p^t$ matrix collects all the coefficients of MOD_n^{a,p^t}:

$$\boldsymbol{A}_{p^t} := \begin{bmatrix} \alpha_0^{(0,p^t)} & \cdots & \alpha_0^{(p^t-1,p^t)} \\ \vdots & \ddots & \vdots \\ \alpha_{p^t-1}^{(0,p^t)} & \cdots & \alpha_{p^t-1}^{(p^t-1,p^t)} \end{bmatrix}.$$

In fact,

$$(\boldsymbol{A}_{p^t})_{i,j} = \alpha_i^{(j,p^t)} = \binom{p^t-1-j}{p^t-1-i}.$$

This is because

$$\sum_{i=0}^{p^t-1} \binom{p^t-1-j}{p^t-1-i}\binom{|x|}{i} = \binom{p^t-1-j+|x|}{p^t-1} = \begin{cases} 1 & \text{if } |x| \equiv j \pmod{p^t}, \\ 0 & \text{otherwise}, \end{cases} \tag{4}$$

by Vandermonde's convolution.

The matrix $\boldsymbol{A}_{p^t}$ has many elegant properties. For example, the following one shows the relationship between $\boldsymbol{A}_{p^t}$ and $\boldsymbol{A}_p$. We use $\otimes$ to denote matrix tensor product.

▶ **Proposition 4.1.** *On the ring $\mathbb{Z}_p$,*

$$\boldsymbol{A}_{p^t} = \boldsymbol{A}_p^{\otimes t} := \underbrace{\boldsymbol{A}_p \otimes \boldsymbol{A}_p \otimes \cdots \otimes \boldsymbol{A}_p}_{t}.$$

Proof. Let i_ℓ and j_ℓ be the representation of i and j in base p. Then by Lucas's Theorem,

$$\binom{p^t-1-j}{p^t-1-i} \equiv \binom{\sum_{\ell=0}^{t-1}(p-1-j_\ell)\cdot p^\ell}{\sum_{\ell=0}^{t-1}(p-1-i_\ell)\cdot p^\ell} \equiv \prod_{\ell=0}^{t-1}\binom{p-1-j_\ell}{p-1-i_\ell} \equiv \prod_{\ell=0}^{t-1}(\boldsymbol{A}_p)_{i_\ell,j_\ell} \pmod{p}. ◀$$

Below we give another observation, which assists with our proof of Theorem 1.5.

▶ **Lemma 4.2.** *Suppose p is a prime, and $n < p - 1$ is a positive integer. Then for any $v \in \{0,1\}^p$ satisfying $v_i \neq v_j$ for some $0 \leq i < j \leq n$, there exists $\lfloor n/2 \rfloor + 1 \leq \ell \leq n$ such that $(\boldsymbol{A}_p \boldsymbol{v})_\ell \neq 0$.*

Our proof of Lemma 4.2 utilizes the following proposition on another binomial coefficient matrix.

▶ **Proposition 4.3.** *For any prime p, integers j, k with $j + k < p$ and distinct $a_0, \dots, a_k \in \mathbb{F}_p$ satisfying $a_0, \dots, a_k \geq j$, the matrix*

$$\begin{bmatrix} \binom{a_0}{j} & \binom{a_1}{j} & \cdots & \binom{a_k}{j} \\ \binom{a_0}{j+1} & \binom{a_1}{j+1} & \cdots & \binom{a_k}{j+1} \\ \vdots & \vdots & \ddots & \vdots \\ \binom{a_0}{j+k} & \binom{a_1}{j+k} & \cdots & \binom{a_k}{j+k} \end{bmatrix}$$

is invertible over $\mathbb{F}_p$.

Proof. One can verify that

$$\operatorname{diag}\left\{ \frac{(j+0)^{\underline{0}}}{\binom{a_0}{j}}, \dots, \frac{(j+k)^{\underline{k}}}{\binom{a_k}{j}} \right\} \cdot S \cdot \begin{bmatrix} \binom{a_0}{j} & \cdots & \binom{a_k}{j} \\ \vdots & \ddots & \vdots \\ \binom{a_0}{j+k} & \cdots & \binom{a_k}{j+k} \end{bmatrix} = \begin{bmatrix} (a_0 - j)^0 & \cdots & (a_k - j)^0 \\ \vdots & \ddots & \vdots \\ (a_0 - j)^k & \cdots & (a_k - j)^k \end{bmatrix},$$

where S is the second Stirling number matrix, i.e., $S_{ij} = \left\{ {i \atop j} \right\}$, and the notation $x^{\underline{y}}$ stands for the falling factorial power $x(x-1)\cdots(x-y+1)$. The Vandermonde matrix on the R.H.S. is also invertible because $a_0, \dots, a_k$ are distinct. ◀

Proof of Lemma 4.2. Assume towards contradiction that there exists some v satisfying the condition, but $(\boldsymbol{A}_p v)_\ell = 0$ for all $\lfloor n/2 \rfloor + 1 \leq \ell \leq n$. In other words, if we take row $\lfloor n/2 \rfloor + 1$ to n and column 0 to n from $\boldsymbol{A}_p$ to get another $\lceil n/2 \rceil \times (n+1)$ matrix $\boldsymbol{B}$ i.e.,

$$\boldsymbol{B} := \begin{bmatrix} \binom{p-1-0}{p-1-(\lfloor n/2 \rfloor + 1)} & \binom{p-1-1}{p-1-(\lfloor n/2 \rfloor + 1)} & \cdots & \binom{p-1-n}{p-1-(\lfloor n/2 \rfloor + 1)} \\ \vdots & \vdots & \ddots & \vdots \\ \binom{p-1-0}{p-1-n} & \binom{p-1-1}{p-1-n} & \cdots & \binom{p-1-n}{p-1-n} \end{bmatrix},$$

then $\boldsymbol{B}\boldsymbol{v}' = \boldsymbol{0}$ where $\boldsymbol{v}' = \{v_0, ..., v_n\}^T$. (This is because $(\boldsymbol{A}_p)_{i,j} = \binom{p-1-j}{p-1-i} = 0$ for all $\lfloor n/2 \rfloor + 1 \leq i \leq n$ and $n + 1 \leq j \leq p - 1$.)

Next, for any $t \in [(\lfloor n/2 \rfloor + 1), n]$, the sum of row t is $\binom{p-1-0}{p-1-t} + \binom{p-1-1}{p-1-t} + \cdots + \binom{p-1-n}{p-1-t} = \binom{p}{p-t} \equiv 0 \pmod{p}$. Therefore $\boldsymbol{B}\boldsymbol{1} = \boldsymbol{0}$, so we can assume the number of 1's in $\boldsymbol{v}'$ is no more that $\lceil n/2 \rceil$, without loss of generality. (Otherwise, subtract $\boldsymbol{v}'$ from $\boldsymbol{1}$.) This means that we can take $s \leq \lceil n/2 \rceil$ column vectors of $\boldsymbol{B}$, the summation of which is $\boldsymbol{0}$, and furthermore, the last s dimensions of these vectors form a singular matrix with form $\boldsymbol{B}'_{i,j} = \binom{a_j}{p-1-n+s-1+i}$. However, by flipping it upside down and applying Proposition 4.3, this matrix is invertible. ◀

4.2 Proof of Theorem 1.5

Our proof requires the following two lemmas. The first one is often referred to as Periodicity Lemma. It says any function with coprime periods is constant, if the domain is large enough.

▶ **Lemma 4.4** (Periodicity Lemma, [9]). *Let g be an a-periodic and b-periodic function on domain $\{0,1,\dots,n\}$ with $\gcd(a,b)=1$ and $n \geq a+b-2$. Then g is a constant function.*

The next one can be regarded as a stronger version of Theorem 1.3 with $k=1$.

▶ **Lemma 4.5.** *Assume p is a prime. For any non-trivial symmetric $f:\{0,1\}^n \to \{0,1\}$,*

$$\deg_p(f) \geq \min\left\{\frac{n}{2}, \left(1-\frac{1}{p}\right)\pi_p(f)\right\}.$$

Note that the base-p period appear explicitly in the lower bound. This allows us to apply Lemma 4.4. We prove Theorem 1.5 first.

Proof of Theorem 1.5. If $\max\{\deg_p(f), \deg_q(f)\} \geq \frac{n}{2}$, the theorem then follows naturally. Otherwise, according to Fact 2.3 and Lemma 4.5, we have

$$\deg_m(f) \geq \deg_{pq}(f) = \max\{\deg_p(f), \deg_q(f)\} \geq \max\left\{\left(1-\frac{1}{p}\right)\pi_p(f), \left(1-\frac{1}{q}\right)\pi_q(f)\right\}. \tag{5}$$

On the other hand, the non-triviality of $f(x)$ implies $\pi_p(f)+\pi_q(f) > n+2$ owing to Lemma 4.4. The last term in Inequality (5) is $> \frac{n+2}{2+1/(p-1)+1/(q-1)} > \frac{n}{2+1/(p-1)+1/(q-1)}$, and hence the theorem is also true. ◀

It remains to show why Lemma 4.5 is true.

Proof of Lemma 4.5. Consider over the ring $\mathbb{Z}_p$. Suppose $\pi_p(f)=p^t$. We write $f(x)$ as we did in Equation (2), and let α_ℓ be the ℓ-th Mahler coefficient of $f(x)$. Then $\sum_{j=0}^{p^t-1} w_j \alpha_\ell^{(j,p^t)} = \alpha_\ell$, or

$$\boldsymbol{\alpha} = \boldsymbol{A}_{p^t}\boldsymbol{w} \tag{6}$$

if we set $\boldsymbol{w} := (w_0, ..., w_{p^t-1})^\top$ and $\boldsymbol{\alpha} := (\alpha_0, ..., \alpha_{p^t-1})^\top$.

Divide $\boldsymbol{w}$ and $\boldsymbol{\alpha}$ into blocks of length p^{t-1} as $\boldsymbol{w} = (\boldsymbol{w}^{\langle 0\rangle}, \dots, \boldsymbol{w}^{\langle p-1\rangle})^\top$ and $\boldsymbol{\alpha} = (\boldsymbol{\alpha}^{\langle 0\rangle}, \dots, \boldsymbol{\alpha}^{\langle 0\rangle})^\top$ where $\boldsymbol{w}^{\langle i\rangle} \in \{0,1\}^{p^{t-1}}, \boldsymbol{\alpha}^{\langle i\rangle} \in \mathbb{F}_p^{p^{t-1}}$. By Proposition 4.1, we have

$$\boldsymbol{\alpha}^{\langle i\rangle} = \boldsymbol{A}_{p^{t-1}} \sum_{j=0}^{p-1}\left((\boldsymbol{A}_p)_{ij}\boldsymbol{w}^{\langle j\rangle}\right). \tag{7}$$

Consider two cases. One deals with the case $\pi_p(f)=p^t<n$, where we show $\deg_p(f) > \frac{p-1}{p}\cdot\pi_p(f)$; another deals with $\pi_p(f) \geq n$, where we can obtain $\deg_p(f) \geq n/2$.

Case I ($\boldsymbol{p^t < n}$). First, assume $\boldsymbol{\alpha}^{\langle p-1\rangle} = \boldsymbol{0}$. Note that $\boldsymbol{A}_{p^{t-1}}$ is full-rank according to Proposition 4.3, which allows Equation (7) to be transformed into

$$\boldsymbol{A}_{p^{t-1}}^{-1}\boldsymbol{\alpha}^{\langle p-1\rangle} = \sum_{j=0}^{p-1}\left((\boldsymbol{A}_p)_{p-1,j}\boldsymbol{w}^{\langle j\rangle}\right).$$

Since $(\boldsymbol{A}_p)_{p-1,j}=1$, we have $\sum_{j=0}^{p-1}\boldsymbol{w}^{\langle j\rangle}=\boldsymbol{0}$. This implies $\boldsymbol{w}^{\langle 0\rangle} = \dots = \boldsymbol{w}^{\langle p-1\rangle}$ as $\boldsymbol{w}^{\langle i\rangle} \in \{0,1\}^{p^{t-1}}$, and further, $f(x)$ becomes p^{t-1}-periodic, conflicting with $\pi_p(f)=p^t$. Eventually, we have $\boldsymbol{\alpha}^{\langle p-1\rangle} \neq \boldsymbol{0}$. Because $n > p^t$, the highest non-zero Mahler coefficient indicates the degree of f (see the remark below Fact 2.10), and then $\deg_p(f) > (p-1)p^{t-1} = \frac{p-1}{p}\cdot\pi_p(f)$.

Case II ($p^t \geq n$). By Equation (6),

$$\left(\boldsymbol{I}_p \otimes (\boldsymbol{A}_{p^{t-1}})^{-1}\right) \boldsymbol{A}_{p^t} \boldsymbol{w} = \left(\boldsymbol{I}_p \otimes (\boldsymbol{A}_{p^{t-1}})^{-1}\right) \boldsymbol{\alpha}. \tag{8}$$

The R.H.S. of (8) is just

$$\left(\boldsymbol{I}_p \otimes (\boldsymbol{A}_{p^{t-1}})^{-1}\right) \boldsymbol{\alpha} = \begin{bmatrix} (\boldsymbol{A}_{p^{t-1}})^{-1}\boldsymbol{\alpha}^{\langle 0\rangle} \\ \vdots \\ (\boldsymbol{A}_{p^{t-1}})^{-1}\boldsymbol{\alpha}^{\langle p-1\rangle} \end{bmatrix} =: \begin{bmatrix} \boldsymbol{\beta}^{\langle 0\rangle} \\ \vdots \\ \boldsymbol{\beta}^{\langle p-1\rangle} \end{bmatrix}.$$

The L.H.S. of (8) can be written as

$$\begin{aligned} \left(\boldsymbol{I}_p \otimes (\boldsymbol{A}_{p^{t-1}})^{-1}\right) \boldsymbol{A}_{p^t} \boldsymbol{w} &= \left(\boldsymbol{I}_p \otimes (\boldsymbol{A}_{p^{t-1}})^{-1}\right) (\boldsymbol{A}_p \otimes \boldsymbol{A}_{p^{t-1}})\boldsymbol{w} \\ &= (\boldsymbol{I}_p\boldsymbol{A}_p) \otimes ((\boldsymbol{A}_{p^{t-1}})^{-1}\boldsymbol{A}_{p^{t-1}})\boldsymbol{w} \\ &= (\boldsymbol{A}_p \otimes \boldsymbol{I}_{p^{t-1}})\boldsymbol{w}. \end{aligned}$$

Therefore,

$$(\boldsymbol{A}_p \otimes \boldsymbol{I}_{p^{t-1}})\boldsymbol{w} = \left(\boldsymbol{\beta}^{\langle 0\rangle}, \cdots, \boldsymbol{\beta}^{\langle p-1\rangle}\right)^\top. \tag{9}$$

For $0 \leq j < p^{t-1}$ we define

$$\tilde{\boldsymbol{\beta}}^{\langle j\rangle} := \left(\boldsymbol{\beta}_j^{\langle 0\rangle}, \cdots, \boldsymbol{\beta}_j^{\langle p-1\rangle}\right)^\top \text{ and } \tilde{\boldsymbol{w}}^{\langle j\rangle} := \left(\boldsymbol{w}_j^{\langle 0\rangle}, \cdots, \boldsymbol{w}_j^{\langle p-1\rangle}\right)^\top,$$

Intuitively, vectors with tildes here contain entries taken from the original vector with stride p^{t-1}. Then Equation (9) implies

$$\boldsymbol{A}_p\tilde{\boldsymbol{w}}^{\langle j\rangle} = \tilde{\boldsymbol{\beta}}^{\langle j\rangle}.$$

Let $n' = \lfloor (n+1)/p^{t-1}\rfloor - 1$, $n'' = \lceil (n+1)/p^{t-1}\rceil - 1$, and $m' = n \bmod p^{t-1}$. Consider the following two subcases:

Subcase II-1. Suppose there exists $\ell \leq m'$ and $i, j \in [0, n'']$ such that $\tilde{\boldsymbol{w}}_i^{\langle \ell\rangle} \neq \tilde{\boldsymbol{w}}_j^{\langle \ell\rangle}$. According to Lemma 4.2, there exists $i' \in [\lfloor n''/2\rfloor + 1, n'']$ satisfying $0 \neq \left(\boldsymbol{A}_p\tilde{\boldsymbol{w}}^{\langle j\rangle}\right)_{i'} = \tilde{\boldsymbol{\beta}}_{i'}^{\langle \ell\rangle} = \boldsymbol{\beta}_\ell^{\langle i'\rangle}$. Because $\boldsymbol{A}_{p^{t-1}}$ is invertible, we have $\boldsymbol{\alpha}^{\langle i'\rangle} = \boldsymbol{A}_{p^{t-1}}\boldsymbol{\beta}^{\langle i'\rangle} \neq \boldsymbol{0}$. What's more,

- if $i' < n''$ and recall Fact 2.10, we have $\deg_p(f) \geq (\lfloor n''/2\rfloor + 1) \cdot p^{t-1} \geq n/2$;
- if $i' = n''$, we select the minimum ℓ such that $\boldsymbol{\beta}_\ell^{\langle i'\rangle} \neq 0$. Due to the fact $(\boldsymbol{A}_{p^{t-1}})_{\ell,j} = \binom{p^{t-1}-1-j}{p^{t-1}-1-\ell} = 0$ when $j > \ell$, it follows that

$$\boldsymbol{\alpha}_\ell^{\langle i'\rangle} = \sum_{j=0}^{\ell} (\boldsymbol{A}_{p^{t-1}})_{\ell,j}\boldsymbol{\beta}_j^{\langle i'\rangle} = (\boldsymbol{A}_{p^{t-1}})_{\ell,\ell}\boldsymbol{\beta}_\ell^{\langle i'\rangle} \neq 0. \tag{10}$$

Eventually $\deg_p(f) \geq n'' \cdot p^{t-1} \geq n/2$.

Subcase II-2. Otherwise, there exists a minimum $\ell \in [m'+1, p^{t-1}-1]$ and $i, j \in [0, n']$ such that $\tilde{\boldsymbol{w}}_i^{\langle \ell\rangle} \neq \tilde{\boldsymbol{w}}_j^{\langle \ell\rangle}$ as $f(x)$ is non-trivial. The same argument shows that there exists $i' \in [\lfloor n'/2\rfloor + 1, n']$ satisfying $\boldsymbol{\beta}_\ell^{\langle i'\rangle} \neq 0$. In addition, the condition $\tilde{\boldsymbol{w}}_0^{\langle \ell'\rangle} = \cdots = \tilde{\boldsymbol{w}}_{n'}^{\langle \ell'\rangle}$ for all $\ell' < \ell$ implies

$$\boldsymbol{\beta}_{\ell'}^{\langle i'\rangle} = \tilde{\boldsymbol{\beta}}_{i'}^{\langle \ell'\rangle} = \sum_{j=0}^{p-1} (\boldsymbol{A}_p)_{i',j}\tilde{\boldsymbol{w}}_j^{\langle \ell'\rangle} = \boldsymbol{w}_0^{\langle \ell'\rangle} \cdot \sum_{j=0}^{i'} \binom{p-1-j}{p-1-i'} = \boldsymbol{w}_0^{\langle \ell'\rangle} \cdot \binom{p}{p-i'} = 0.$$

Hence, by imitating (10) we can obtain $\boldsymbol{\alpha}_\ell^{\langle i'\rangle} \neq 0$, which leads to $\deg_p(f) \geq \lfloor n'/2\rfloor \cdot p^{t-1} + m' + 1 \geq n/2$. ◀

4.3 Proof of Theorem 1.6

We will later apply the following lemma about Diophantine approximation, which is an immediate corollary of Kronecker's Theorem.

▶ **Lemma 4.6.** *Suppose real numbers $a_1, \dots, a_k$ satisfy that $1, a_1, \dots, a_k$ are linearly independent over $\mathbb{Q}$. Then, for any $\varepsilon > 0$, there exist infinitely many positive integers ℓ such that $\ell a_i \bmod 1 \in (1-\varepsilon, 1)$ for each $i = 1, \dots, k$.*

Now we prove Theorem 1.6.

Proof of Theorem 1.6. Write $m = p_1 p_2 \cdots p_k$ for p_i being primes. Choose a prime q different from all p_i. Fix an arbitrary $\varepsilon > 0$. Let $a_i = \log q / \log p_i$ for $i = 1, \dots, k$. Then $1, a_1, \dots, a_k$ are linearly independent over $\mathbb{Q}$, otherwise a nontrivial linear relation can be exponentiated to contradict the unique factorization theorem over $\mathbb{Z}^+$. Applying Lemma 4.6 we get infinitely many ℓ that satisfy the condition $\ell \cdot \log q / \log p_i \bmod 1 \in (1-\varepsilon, 1)$, which implies $p_i^{r_i}/q^\ell \in (1, p_i^\varepsilon)$ where $r_i = \lceil \ell \log q / \log p_i \rceil$.

Now, choose a sufficiently large ℓ, let $n = 2q^\ell$ and define $f : \{0,1\}^n \to \{0,1\}$ by $f(x) = \mathbb{I}[|x| = q^\ell]$. Then f is $p_i^{r_i}$-periodic since $p_i^{r_i} > q^\ell$. Therefore $\deg_{p_i}(f) \leq p_i^{r_i} - 1$ by Theorem 2.12. Thus,

$$\deg_m(f) \leq \max_{1 \leq i \leq k} \{p_i^{r_i}\} \leq \frac{n}{2} \max_{1 \leq i \leq k} \{p_i^\varepsilon\}.$$

The theorem follows by letting $\varepsilon \to 0$. ◀

5 Conclusion

In a nutshell, we explore and exploit the matrices consisting of Mahler coefficients of the MOD function, serving as a significant extension of Wilson's arguments. This approach fully characterizes the modulo degree of Boolean functions when the base is prime or prime power, and provides good lower bounds for the composite case with the help of periodicity lemma. In addition, we also show a practical way to generalize properties of symmetric functions to non-degenerate ones by a Ramsey-type argument.

Nevertheless, there is still ample room for further discussion. First and foremost, we conjecture that the constant factor in Theorem 1.5 can be improved to 1/2 in correspondence with Theorem 1.6. Moreover, an anonymous reviewer also raises a good question with regard to Theorem 1.4: Could the extraordinary large prerequisite $n \geq \mathrm{tower}(\mathrm{poly}(p,k))$ (which is implicit in the proof) be improved to something like $n \geq \exp(\mathrm{poly}(p,k))$? We also wonder if it is possible to embed other kinds of functions to derive similar results. Above all, both Conjecture 1.1 and Conjecture 1.2 remain open.

On Quasipolynomial Multicut-Mimicking Networks and Kernelization of Multiway Cut Problems

Magnus Wahlström
Department of Computer Science, Royal Holloway, University of London, UK
Magnus.Wahlstrom@rhul.ac.uk

Abstract

We show the existence of an exact mimicking network of $k^{O(\log k)}$ edges for minimum multicuts over a set of terminals in an undirected graph, where k is the total capacity of the terminals. Furthermore, if Small Set Expansion has an approximation algorithm with a ratio slightly better than $\Theta(\log n)$, then a mimicking network of quasipolynomial size can be computed in polynomial time. As a consequence of the latter, several problems would have quasipolynomial kernels, including Edge Multiway Cut, Group Feedback Edge Set for an arbitrary group, 0-Extension for integer-weighted metrics, and Edge Multicut parameterized by the solution and the number of cut requests. The result works via a combination of the matroid-based irrelevant edge approach used in the kernel for s-Multiway Cut with a recursive decomposition and sparsification of the graph along sparse cuts. The main technical contribution is a matroid-based marking procedure that we can show will mark all non-irrelevant edges, assuming that the graph is sufficiently densely connected. The only part of the result that is not currently constructive and polynomial-time computable is the detection of such sparse cuts.

This is the first progress on the kernelization of Multiway Cut problems since the kernel for s-Multiway Cut for constant value of s (Kratsch and Wahlström, FOCS 2012).

1 Introduction

Graph separation questions are home to some of the most intriguing open questions in theoretical computer science. In approximation algorithms, the well-known *unique games conjecture* (UGC) has been central to the area for close to two decades, and is closely related to graph separation problems. Even more directly, the *small set expansion hypothesis*, proposed by Raghavendra and Steurer [31], roughly states that it is NP-hard to approximate the Small Set Expansion problem (SSE) up to a constant factor, where SSE is the problem of finding a small-sized set in a graph with minimum expansion. (More precise statements are given in Section 2.2.) Despite significant research, the best result available in polynomial time is an $O(\log n)$-approximation due to Räcke [30].

Another interesting notion from parameterized complexity is *kernelization*. Informally, a kernelization algorithm is a procedure that takes an input of a parameterized, usually NP-hard problem and *reduces* it to an equivalent instance of size bounded in the parameter, e.g., by discarding irrelevant parts of the input or transforming some part of the input into a smaller object with equivalent behaviour. For example, the seminal Nemhauser-Trotter theorem on the half-integrality of Vertex Cover [27] implies that an instance of Vertex Cover can be reduced to have at most $2k$ vertices, where k is the bound given on the

solution size. On the flip side, Fortnow and Santhanam [10] and Bodlaender et al. [3] gave a framework to exclude the existence of a kernel of any polynomial size, under a standard complexity-theoretic conjecture. An extensive collection of upper and lower bounds for kernelization exists (see, e.g., the recent book of Fomin et al. [9]), but a handful of central "hard questions" remain unanswered. One of the most notorious is Multiway Cut.

Let $G = (V, E)$ be a graph and $T \subseteq V$ a set of terminals in G. An *(edge) multiway cut* for T in G is a set of edges $X \subseteq E$ such that no two terminals are connected in $G - X$, and Multiway Cut is the problem of finding a multiway cut of at most k edges, given a parameter k. The problem is FPT [24] and NP-hard for $|T| \geq 3$ [6]. Using methods from matroid theory, Kratsch and Wahlström [17] were able to show that if $|T| \leq s$, then Multiway Cut has a kernel with $O(k^{s+1})$ vertices, hence the problem has a polynomial kernel for every constant s. However, if $|T|$ is unbounded, the only known size bound for a kernel is $2^{O(k)}$, following from the FPT algorithm [24], and the question of whether Multiway Cut has a polynomial kernel in the general case is completely open.

We show a connection between kernelization of Multiway Cut-type problems and approximation algorithms for Small Set Expansion. Specifically, we show the existence of a kind of *mimicking network* for the problem, of size quasipolynomial in k; and if SSE has approximation algorithms slightly better than current state of the art, then it can be computed in polynomial time and Multiway Cut has a quasipolynomial kernel.

1.1 Mimicking networks and multiway cut sparsifiers

Although kernelization is most commonly described in terms of polynomial-time preprocessing as above, there is also a clear connection with *succinct information representation*. For example, consider a graph $G = (V, E)$ with a set of k terminals $T \subseteq V$. The pair (G, T) is referred to as a *terminal network*. A *mimicking network* for (G, T) is a graph $G' = (V', E')$ with $T \subseteq V'$ such that for any sets $A, B \subseteq T$, the min-cut between A and B in G and G' have the same value. A mimicking network of size bounded in k always exists, but the size of G' can be significant. The best known general upper bound is double-exponential in k [12, 15], and there is an exponential lower bound [20]. Better bounds are known for special graph classes, but even for planar graphs the best possible general bound has $2^{\Theta(k)}$ vertices [20, 14] (see also recent improvements by Krauthgamer and Rika [19]).

A related notion is *cut sparsifiers*, which solve the same task up to some approximation factor $q \geq 1$ [26, 21], typically $q = \omega(1)$ in the general case. We focus on mimicking networks; see Krauthgamer and Rika [19] for an overview of cut sparsifiers.

However, if we include the capacity of the set of terminals in the bound (and if edges have integer capacity), then significantly stronger results are possible. Chuzhoy [4] showed that if the total capacity of T is $\text{cap}_G(T) = \sum_{t \in T} d(t) = k$, then there exists an $O(1)$-approximate cut sparsifier of size $O(k^3)$. Kratsch and Wahlström [17] sharpened this to an exact mimicking network with $O(k^3)$ edges, which furthermore can be computed in randomized polynomial time. This is particularly remarkable given that the network has to replicate the exact cut-value for exponentially many pairs (A, B). The network can be constructed via contractions on G.[1] This built on an earlier result that used linear representations of matroids to encode the sizes of all (A, B)-min cuts into an object using $\tilde{O}(k^3)$ bits of space [18], although this earlier version did not produce an explicit graph, i.e., not a mimicking network.

[1] The results of [17] are phrased in terms of vertex cuts, but the above follows easily from [17].

These results had significant consequences for kernelization. The succinct representation in [18] was used to produce a (randomized) polynomial kernel for the Odd Cycle Transversal problem, thereby solving a notorious open problem in parameterized complexity [18]; and the mimicking network of [17] brought further (randomized) polynomial kernels for a range of problems, in particular including Almost 2-SAT, i.e., the problem of satisfying all but at most k clauses of a given 2-CNF formula.

Similar methods are relevant for the question of separating a set of terminals into more than two parts. Let (G, T) be a terminal network, and let $\mathcal{T} = T_1 \cup \ldots \cup T_s$ be a partition of T. A *multiway cut for* $\mathcal{T}$ is a set of edges $X \subseteq E(G)$ such that $G - X$ contains no path between any pair of terminals $t \in T_i$ and $t' \in T_j$ for $t, t' \notin X$ and $i \neq j$. Let us define a *multicut-mimicking network* for (G, T) as a terminal network (G', T) where $T \subseteq V(G')$ and for every partition $\mathcal{T} = T_1 \cup \ldots \cup T_s$ of T, the size of a minimum multiway cut for $\mathcal{T}$ is identical in G and G'. (The term *multicut-mimicking*, as opposed to *multiway cut-mimicking*, is justified; see Section 2.1.) The minimum size of a multicut-mimicking network, in terms of $k = \mathrm{cap}_G(T)$, appears to lie at the core of the difficulty of the question of a polynomial kernelization of Multiway Cut. The kernel for s-Multiway Cut mentioned above builds on the computation of a mimicking network of size $O(k^{s+1})$ for partitions of T into at most s parts [17]. The kernel for s-Multiway Cut then essentially follows from considering the partition $\mathcal{T} = \{t_1\} \cup \ldots \cup \{t_s\}$ of a set T of $|T| = s$ terminals (along with known reduction rules bounding $\mathrm{cap}_G(T)$). We are not aware of any non-trivial lower bounds on the size of a multicut-mimicking network in terms of k; it seems completely consistent with known bounds that every terminal network (G, T) would have a multicut-mimicking network of size $\mathrm{poly}(k)$, even for partitions into an unbounded number of sets.

In this paper, we show that any terminal network (G, T) with $\mathrm{cap}_G(T) = k$ admits a multicut-mimicking network (G', T) where $|V(G')| = k^{O(\log k)}$; and furthermore, such a network could be computed in randomized polynomial time, given a polynomial number of queries to a sufficiently good approximation algorithm for a graph separation problem similar to Small Set Expansion. We also see a tradeoff between the quality of the approximation algorithm and the size of (G', T). In particular, if Small Set Expansion has an approximation algorithm with a ratio of $\alpha(n, k) = \log^{1-\varepsilon} n \cdot \log^{O(1)} k$ for some $\varepsilon > 0$, where k is the number of edges cut in the optimal solution, then (G', T) can be computed efficiently, with $|V(G')|$ being quasipolynomial in k. Such an algorithm goes beyond the bounds of what is currently known – namely, a ratio of $O(\log n)$ due to Räcke [30], improved for certain regimes by Bansal et al. [2] – but does not appear to be excluded by any established hardness conjecture. We also consider the existence result very interesting in its own right, and invite further study of capacity-based bounds for multicut-mimicking networks; in particular, whether a $\mathrm{poly}(k)$-sized multicut-mimicking network always exists. The results strongly suggest the existence of a quasipolynomial kernel for Edge Multiway Cut.

Flow sparsifiers. Finally, similarly to cut sparsifiers, there is a notion of a *flow sparsifier* of a terminal network (G, T). Here the goal is to approximately preserve the minimum congestion for any multicommodity flow on (G, T). Chuzhoy [4] showed flow sparsifiers with quality $O(1)$ and with $k^{O(\log \log k)}$ vertices, where k is the total terminal capacity; for further results on achievable bounds for flow sparsifiers, see [1, 7]. However, the notion is incomparable to multicut-mimicking networks, because even an exact flow sparsifier would be subject to the corresponding multicommodity flow-multicut approximation gap, which is $\Theta(\log k)$ in the worst case [11].

Further related work. The general approach of decomposing a graph along sparse cuts is well established; cf. Räcke [29] and follow-up work. For further applications of matroid tools to kernelization, see Hols and Kratsch [13], Kratsch [16], and Reidl and Wahlström [32].

1.2 Our results

More formally, we have the following.

▶ **Theorem 1.** *Let A be an approximation algorithm for* Small Set Expansion *with an approximation ratio of $\alpha(n,k) = O(\log^{1-\varepsilon} n \log^d k)$, where $\varepsilon > 0$, $d = O(1)$, and k is the number of edges cut in the optimal solution. Let (G,T) be a terminal network with $\mathrm{cap}_G(T) = k$. Then there is a set $Z \subseteq E(G)$ with $|Z| = k^{O(\alpha(n,k)\log k)}$ such that for every partition $\mathcal{T} = T_1 \cup \ldots \cup T_s$ of T, there is a minimum multiway cut X for $\mathcal{T}$ such that $X \subseteq Z$. Furthermore, Z can be computed in randomized polynomial time using calls to A.*

The precise requirement for the approximation algorithm is slightly relaxed from the above. We refer to the precise algorithm we need as a *sublogarithmic terminal expansion tester*; see Definition 5. Simplifying the statement a bit gives us the following.

▶ **Corollary 2.** *Let (G,T) be a terminal network with $\mathrm{cap}_G(T) = k$. The following holds.*

1. *There is a multicut-mimicking network for (G,T) with $k^{O(\log k)}$ edges.*
2. *If there is a sublogarithmic terminal expansion tester – in particular, if* Small Set Expansion *has an approximation ratio as in Theorem 1 – then a multicut-mimicking network of size quasipolynomial in k can be computed in randomized polynomial time.*

This would give us the following selection of conditional breakthrough results in kernelization. We refer to previous kernelization work [17, 32] for the necessary definitions.

▶ **Corollary 3.** *If there is a sublogarithmic terminal expansion tester, then the following problems have randomized quasipolynomial kernels.*

1. Edge Multiway Cut *parameterized by solution size.*
2. Edge Multicut *parameterized by the solution size and the number of cut requests.*
3. Group Feedback Edge Set *parameterized by solution size, for any group.*
4. Subset Feedback Edge Set *with undeletable edges, parameterized by solution size.*
5. *0-*Extension *for integer-weighted graphs, parameterized by solution cost.*

Preliminaries. A *parameterized problem* is a decision problem where inputs are given as pairs $I = (X,k)$, where k is the *parameter*. A *polynomial kernelization* is a polynomial-time procedure that maps an instance (X,k) to an instance (X',k') where (X,k) is positive if and only if (X',k') is positive, and $|X'|, k' \leq g(k)$ for some function $g(k)$ referred to as the *size* of the kernel. A problem has a *polynomial kernel* if it has a kernel where $g(k) = k^{O(1)}$. We extend this to discuss *quasipolynomial kernels*, which is the case that $g(k) = k^{\log^{O(1)} k}$.

We use standard terminology from graph theory and parameterized complexity; see, e.g., [5, 9] for references.

2 Terminal separation notions

For a graph $G = (V,E)$ and sets $A, B \subseteq V$, we let $E_G(A,B) = \{uv \in E \mid u \in A, v \in B\}$. As shorthand for $S \subseteq V$ we also write $E(S) = E(S,S)$, $\partial_G(S) = E_G(S, V \setminus S)$, and $\delta_G(S) = |\partial_G(S)|$. The *total capacity* of a set of vertices S in a graph G is $\mathrm{cap}_G(S) := \sum_{v \in S} d(v)$. In all cases, we may omit the index G if understood from context.

2.1 Multicut-mimicking networks

Let $G = (V, E)$ be a graph and $T \subseteq V$ a set of terminals with $\text{cap}_G(T) = k$. An *(edge) multiway cut* for T in G is a set of edges $X \subseteq E$ such that no two vertices in T are connected in $G - X$. More generally, let $\mathcal{T} = \{T_1, \ldots, T_r\}$ be a partition of T. Then an *(edge) multiway cut for $\mathcal{T}$ in G* is a set of edges $X \subseteq E$ such that in $G - X$ every connected component contains terminals from at most one part of $\mathcal{T}$. Hence a multiway cut for (G, T) is equivalent to a multiway cut for $(G, \{\{t\} \mid t \in T\})$. Furthermore, let $R \subseteq \binom{T}{2}$ be a set of pairs over T, referred to as *cut requests*. A *multicut for R in G* is a set of edges $X \subseteq E$ such that every connected component in $G - X$ contains at most one member of every pair $\{u, v\} \in R$. A *minimum multicut for R in G* is a multicut for R in G of minimum cardinality. Similarly, a *minimum multiway cut for $\mathcal{T}$ in G* is a multiway cut for $\mathcal{T}$ in G of minimum cardinality.

We define a *multicut-mimicking network* for T in G as a graph $G' = (V', E')$ such that $T \subseteq V'$ and such that for every set of cut requests $R \subseteq \binom{T}{2}$, the size of a minimum multicut for R is equal in G and in G'. We observe that this is equivalent to preserving the sizes of minimum multiway cuts over all partitions of T.

▶ **Proposition 4** (★[2]). *A graph G' with $T \subseteq V(G')$ is a multicut-mimicking network for T in G if and only if, for every partition $\mathcal{T}$ of T, the size of a minimum multiway cut for $\mathcal{T}$ is equal in G and in G'.*

As a slightly sharper notion, a *multicut-covering set* for (G, T) is a set $Z \subseteq E(G)$ such that for every set of cut requests $R \subseteq \binom{T}{2}$, there is a minimum multicut X for R in G such that $X \subseteq Z$. Note that a multicut-covering set Z is essentially equivalent to a multicut-mimicking network formed by contraction (contracting all edges of $E(G) \setminus Z$). Our main result in this paper is the existence of a multicut-covering set of size quasipolynomial in $k = \text{cap}(T)$ in any undirected graph G. Furthermore, such a set can be computed in polynomial time, subject to the existence of certain approximation algorithms that we will make precise later in this section. The term is a generalization of a *cut-covering set*, used in previous work [17].

2.2 Graph separation algorithms

The central technical approximation assumption needed in this paper is the following. For a graph G with a set of terminals T, define the *T-capacity of S in G* as $\text{cap}_T(S) = \text{cap}_G(T \cap S) + \delta_G(S)$. Then we define the following notion.

▶ **Definition 5** (Sublogarithmic terminal expansion tester). *Let (G, T) be a terminal network with* $\text{cap}_G(T) = k$. *A* terminal polynomial expansion tester *(with approximation ratio α) is a (possibly randomized) algorithm that, given as input (G, T) and an integer $c \in \mathbb{N}$, with $c = \Omega(\log k)$, does one of the following.*

1. *Either returns a set $S \subset V$ such that $N_G[S] \neq V(G)$ and $\text{cap}_T(S) < |S|^{1/c}$,*
2. *or guarantees that for every set S with $\emptyset \subset (S \cap T) \subset T$ and $|S| \leq |V(G)|/2$ we have $\text{cap}_T(S) \geq |S|^{1/c}/\alpha$.*

A sublogarithmic terminal expansion tester *is a terminal polynomial expansion tester with an approximation ratio $\alpha = O(\log^{1-\varepsilon} n \log^{O(1)} k)$ for some $\varepsilon > 0$. We say that (G, T) is (α, c)-*dense *if case 2 above applies, i.e., for every set S with $S \cap T \notin \{\emptyset, T\}$ and $|S| \leq |V(G)|/2$ we have $\text{cap}_T(S) \geq |S|^{1/c}/\alpha$.*

[2] Proofs marked with ★ are found in the full version of the paper

The conditions can be relaxed somewhat. It is sufficient if the algorithm works with parameters $c = \Omega(\alpha \log k)$. It is also possible to put a lower bound on the size of sets S for which the guarantee needs to apply. However, these relaxed assumptions do not seem to make a difference for any algorithms we are aware of for the problem.

We note that such an algorithm would follow from a slightly improved approximation algorithm for Small Set Expansion. Let $G = (V, E)$ be a graph and $S \subseteq V$ a set of vertices. The *edge expansion* of S is $\Phi(S) := \frac{\delta(S)}{|S|}$. For a real number $\rho \in (0, 1/2]$, one also defines the *small set expansion* $\Phi_\rho(G) := \min_{S \subseteq V, |S| \leq \rho n} \Phi(S)$. In particular, for a value $s \in [n/2]$, $\Phi_{s/n}(G)$ denotes the worst (i.e., minimum) expansion among subsets of G of size at most s. A sufficiently good approximation algorithm for Small Set Expansion implies a sublogarithmic terminal expansion tester, as follows.

▶ **Lemma 6 (★).** *Assume that* Small Set Expansion *has a bicriteria approximation algorithm that on input (G, ρ) returns a set S with $|S| \leq \beta \rho n$ and $\Phi(S) \leq \alpha \cdot \Phi_\rho$, for some $\alpha, \beta \geq 1$. If $\alpha\beta = O(\log^{1-\varepsilon} n \log^{O(1)}(n \cdot \Phi_\rho))$, for some $\varepsilon > 0$, then there is a sublogarithmic terminal expansion tester with ratio $\Theta(\alpha\beta)$ (with $n \cdot \Phi_\rho$ replaced by k).*

Existing approximation algorithms do not meet this threshold; the best known results are an $O(\log n)$-approximation due to Räcke [30] and a bicriteria algorithm of Bansal et al. [2] which achieves a ratio of $O(\sqrt{\log n \log(1/\rho)})$. Unfortunately, the latter improvement is insufficient to make the analysis in the next section work. However, it seems clear that no existing hardness conjecture could possibly rule out the existence of such an algorithm. Furthermore, testing for (α, c)-denseness when $c = \Omega(\alpha \log k)$ corresponds to looking for significantly worse expanding sets than the regime usually focused on in the approximation literature. Hence we proceed with conditional results in the rest of the paper.

3 Multicut-covering sets

We now present the main result of the paper, namely the existence of quasipolynomial multicut-mimicking networks for terminal networks (G, T), and the conditional efficient computability of such objects given a sublogarithmic terminal expansion tester.

At a high level, the process works through recursive decomposition of the graph G across very sparse cuts, treating each piece $G[S]$ of the recursion as a new instance of multicut-covering set computation, where the edges of $\partial(S)$ are considered as additional terminals. The process repeatedly finds a single edge $e \in E(G)$ with a guarantee that for every set of cut requests $R \subseteq \binom{T}{2}$ there is a minimum multicut X for R in G such that $e \notin X$. We may then contract the edge e and repeat the process. Thus the end product is a multicut-mimicking network, and the edges that survive until the end of the process form a multicut-covering set.

In somewhat more detail, the process uses a novel variant of the representative sets approach, which was previously used in the kernel for s-Multiway Cut [17]. Refer to an edge e as *essential for* R, for some $R \subseteq \binom{T}{2}$, if every minimum multicut for R in G contains e, and *essential for* (G, T) if it is essential for R for some $R \subseteq \binom{T}{2}$. We use a representative sets approach to return a set of at most k^c edges which is guaranteed to contain every essential edge, *if* (G, T) is already (α, c)-dense, for an appropriate value $c = \Theta(\alpha \log k)$. On the other hand, if (G, T) is not (α, c)-dense, then (by careful choice of parameters) we can identify a cut through G which is sufficiently sparse that we can reduce the size of one side of this cut via a recursive call. This gives a tradeoff between the size of the resulting multicut-covering set and the denseness-guarantee we may assume through the approximation algorithm. The threshold for feasibility for this tradeoff is precisely the existence of a sublogarithmic terminal expansion tester.

3.1 Recursive replacement

We now present the recursive decomposition step in detail. Let (G,T) be a terminal network with $\mathrm{cap}_G(T)=k$. For a set $S \subseteq V$, we define the graph $G_S = G[N_G[S]] - E(S)$, i.e., G_S equals the graph $G[S]$ with the edges of $\partial(S)$ added back in. We also denote $T(S) = (T \cap S) \cup N_G(S)$ as the *terminals of* S. Under these definitions, the T*-capacity of* S *in* G has two equivalent definitions as $\mathrm{cap}_T(S) = \mathrm{cap}_{G_S}(T(S)) = \mathrm{cap}_G(T \cap S) + \delta_G(S)$. The *recursive instance at* S consists of the terminal network $(G_S, T(S))$. This is the basis of our recursive replacement procedure. Indeed, we show the following. Note that we consider $E(G_S) \subseteq E(G)$ in the following.

▶ **Lemma 7** (★). *Let $(G_S, T(S))$ be the recursive instance at S for some $S \subseteq V(G)$. Let Z_S be a multicut-covering set for $(G_S, T(S))$ and let $e \in E(G_S) \setminus Z_S$. Then e is not essential for (G,T).*

Let us also briefly note the formal correctness of contracting a non-essential edge.

▶ **Proposition 8** (★). *Let $e \in E(G)$ be a non-essential edge. Then for every $X \subseteq E(G)$ with $e \notin X$, and every partition $\mathcal{T}$ of T, X is a multiway cut for $\mathcal{T}$ in G if and only if it is a multiway cut for $\mathcal{T}$ in G/e. Furthermore, G/e is a multicut-mimicking network for (G,T), and any multicut-covering set $Z \subseteq E(G/e)$ for $(G/e,T)$ is also multicut-covering for (G,T).*

The process now works as follows. Recall that (G,T) is (α,c)-dense if $\mathrm{cap}_T(S) \geq |S|^{1/c}/\alpha$ for every set S with $S \cap T \neq \emptyset$ and $|S| \leq |V|/2$. The main technical result is a marking process that marks all essential edges for (G,T) on the condition that (G,T) is (α,c)-dense, and which marks at most k^c edges in total. In such a case, we are clearly allowed to select and contract any unmarked edge of G. Now, assume that (G,T) is not (α,c)-dense. Then by definition there exists a set $S \subset V$ such that $\mathrm{cap}_T(S) < |S|^{1/c}/\alpha$. If we can detect a set S such that $\mathrm{cap}_T(S) < |S|^{1/c}$, then we can recursively compute a multicut-covering set Z_S for $(G_S, T(S))$, consisting of at most $\mathrm{cap}_T(S)^c < |S|$ edges. By the above, we may again select any single edge $e \in E(G_S) \setminus Z_S$ and contract e in G. In either case, we replace G by a strictly smaller graph until $|E(G)| \leq k^c$, at which point we are done.

The two ingredients in the above are thus the marking process for (α,c)-dense graphs, which we present next, and the ability to distinguish the two cases, which is precisely the assumption of the existence of a sublogarithmic terminal expansion tester.

3.2 The (α,c)-dense case

Let us now focus on the marking procedure. Let a terminal network (G,T) with $\mathrm{cap}_G(T)=k$ and an integer c be given, and assume that $c = \Omega(\alpha \log k)$ for some α. We show a process that marks a set of at most k^c edges that contains every essential edge, assuming that (G,T) is (α,c)-dense. (A more precise bound on the relationship between c and α is given later, but the constant factors involved are not important to our main result.)

We will prove the following result. The proof takes up the rest of the subsection.

▶ **Lemma 9.** *Assume that (G,T) is (α,c)-dense where $c = \Omega(\alpha \log k)$. A multicut-covering set $Z \subseteq E(G)$ of size less than k^c can be computed in randomized polynomial time.*

The basis is the following. If (G,T) is (α,c)-dense then for every partition $\mathcal{T}$ of T, every minimum multiway cut X for $\mathcal{T}$, and every connected component H of $G-X$ except possibly the largest one, it holds that $\mathrm{cap}_T(V(H)) \geq |V(H)|^{1/c}/\alpha$. We also have

$$\sum_{H \in G-X} \mathrm{cap}_T(V(H)) = \mathrm{cap}_G(T) + 2|X| < 3k,$$

where the sum ranges over connected components H. This implies restrictions on the possible sizes of components of $G - X$, which will help in the marking process (as we shall see). Essentially, if too many components are too large, then the above sum will exceed $3k$ and we can conclude non-optimality of the corresponding multiway cut.

Finally, let us eliminate a silly edge case to assume $c \leq k$.

▶ **Lemma 10** (★). *If $c > k$ then a multicut-covering set of at most k^c edges can be marked deterministically.*

3.2.1 Matroid constructions

Before we show the marking procedure, we need some additional preliminaries. We refer to Oxley [28] and Marx [25] for further relevant background on matroids.

A *matroid* is a pair $M = (E, \mathcal{I})$ where $\mathcal{I} \subseteq 2^E$ is the *independent sets* of M, subject to the following axioms.

1. $\emptyset \in \mathcal{I}$;
2. if $B \in \mathcal{I}$ and $A \subseteq B$ then $A \in \mathcal{I}$; and
3. if $A, B \in \mathcal{I}$ with $|B| > |A|$ then there exists an element $x \in B \setminus A$ such that $A + x \in \mathcal{I}$.

A *basis* of M is a maximum independent set of M; the *rank* of M is the size of a basis.

Let A be a matrix, and let E label the columns of A. The *column matroid* of A is the matroid $M = (E, \mathcal{I})$ where $S \in \mathcal{I}$ for $S \subseteq E$ if and only if the columns indexed by S are linearly independent. A matrix A *represents* a matroid M if M is isomorphic to the column matroid of A. We refer to A as a *linear representation* of M.

We need three classes of matroids to build from. First, for a set E, the *uniform matroid* over E of rank r is the matroid $U(E, r) := (E, \{S \subseteq E \mid |S| \leq r\})$. Uniform matroids are representable over any sufficiently large field.

The second class is a *truncated graphic matroid.* Given a graph $G = (E, V)$, the *graphic matroid* of G is the matroid $M(G) = (E, \mathcal{I})$ where a set $F \subseteq E$ is independent if and only if F is the edge set of a forest in G. Graphic matroids can be deterministically represented over all fields. The *r-truncation* of a matroid $M = (E, \mathcal{I})$ for some $r \in \mathbb{N}$ is the matroid $M' = (E, \mathcal{I}')$ where $S \in \mathcal{I}'$ if and only if $S \in \mathcal{I}$ and $|S| \leq r$. Given a linear representation of M, over some field $\mathbb{F}$, a truncation of M can be computed in randomized polynomial time, possibly by moving to an extension field of $\mathbb{F}$ [25]. There are also methods for doing this deterministically [22], but the basic randomized form will suffice for us.

The final class is more involved. Let $D = (V, A)$ be a directed graph and $S \subseteq V$ a set of source vertices. A set $T \subseteq V$ is *linked to S in D* if there are $|T|$ pairwise vertex-disjoint paths starting in S and ending in T. Let $U \subseteq V$. Then $M(D, S, U) = (U, \{T \subseteq U \mid T \text{ is linked to } S \text{ in } D\})$ defines a matroid over U, referred to as a *gammoid.* Note that by Menger's theorem, a set T is dependent in M if and only if there is an (S, T)-vertex cut in D of cardinality less than $|T|$ (where the cut is allowed to overlap S and T). Like uniform matroids, gammoids are representable over any sufficiently large field, and a representation can be computed in randomized polynomial time [28, 25]. We will work over a variant of gammoids we refer to as *edge-cut gammoids*, which are defined as gammoids, except in terms of edge cuts instead of vertex cuts. Informally, for a graph $G = (V, E)$ and a set of source vertices $S \subseteq V$, the edge-cut gammoid of (G, S) is a matroid on a ground set of edges, where a set F of edges is independent if and only if it can be linked to S via pairwise edge-disjoint paths. However, we also need to introduce the "edge version" of *sink-only copies* of vertices, as used in previous work [17]. That is, we introduce a second set $E' = \{e' \mid e \in E\}$ containing copies of edges $e \in E$ which can only be used as the endpoints of linkages, not as initial or intermediate edges.

More formally, for a graph $G = (V, E)$ and a set of source vertices $S \subseteq E$ we perform the following transformation.

1. Subdivide every edge $e \in E$ by a new vertex z_e.
2. Let $p = \text{cap}_G(S)$. Inflate every vertex $v \in V$ into a twin class of $p + 1$ vertices (but do not inflate vertices z_e introduced in the previous step).
3. Replace every edge uv in the resulting graph by the two directed edges (u, v), (v, u), creating a directed graph D_G.
4. For every edge $e = uv \in E$, introduce a further new vertex z'_e, and create directed edges (u_i, z'_e) and (v_j, z'_e) for every copy u_i, v_j in D_G of the vertices u, v of G.

Slightly abusing notation, we let E refer to the vertices z_e in D_G, and we let E' refer to the vertices z'_e in D_G. The *edge-cut gammoid of* (G, S) is the gammoid $(D_G, \partial(S), E \cup E')$. Let us observe the resulting notion of independence.

▶ **Proposition 11.** *Let $G = (V, E)$ and $S \subseteq V$ be given. Let $M = (E \cup E', \mathcal{I})$ be the edge-cut gammoid of (G, S). Let $X \subseteq E \cup E'$ be given, and let $F = (X \cap E) \cup \{e \mid e' \in F \cap E'\}$. Then X is independent in M if and only if there exists a set $\mathcal{P}$ of $|X|$ paths linking X to S, where paths are pairwise edge-disjoint except that if $\{e, e'\} \subseteq X$ for some edge e, then two distinct paths in $\mathcal{P}$ end in e.*

We let $U(E, p)$ denote the uniform matroid of rank p on ground set $E(G)$, $M_G(p)$ the p-truncated graphic matroid of G, and $M(T)$ the edge-cut gammoid of (G, T).

If $M_1 = (E_1, \mathcal{I}_1)$ and $M_2 = (E_2, \mathcal{I}_2)$ are two matroids with $E_1 \cap E_2 = \emptyset$, then their *disjoint union* is the matroid $M_1 \uplus M_2 = (E_1 \cup E_2, \{I_1 \cup I_2 \mid I_1 \in \mathcal{I}_1, I_2 \in \mathcal{I}_2\})$. If M_1 and M_2 are represented by matrices A_1 and A_2 over the same field, then $M_1 \uplus M_2$ is represented by the matrix $A = \begin{pmatrix} A_1 & 0 \\ 0 & A_2 \end{pmatrix}$. We will define matroids M as the disjoint union over several copies of the base matroids $M(T)$, $M_G(p)$ and $U(E, p)$ defined above. In such a case, we refer to the individual base matroids making up M as the *layers* of M.

Representative sets

Our main technical tool is the representative sets lemma, due to Lovász [23] and Marx [25]. This result has been important in FPT algorithms [25, 8] and has been central to the previous kernelization algorithms for cut problems, including variants of Multiway Cut [17]. We also introduce some further notions.

▶ **Definition 12.** *Let $M = (E, \mathcal{I})$ be a matroid and $X, Y \in \mathcal{I}$. We say that Y* extends *X* in *M if $r(X \cup Y) = |X| + |Y|$, or equivalently, if $X \cap Y = \emptyset$ and $X \cup Y \in \mathcal{I}$. Furthermore, let $c = O(1)$ be a constant and let $\mathcal{Y} \subseteq \binom{E}{c}$. We say that a set $\hat{\mathcal{Y}} \subseteq \mathcal{Y}$* represents *$\mathcal{Y}$* in *$M$ if the following holds: For every $X \in \mathcal{I}$ for which there exists some $Y \in \mathcal{Y}$ such that Y extends X in M, then there exists some $Y' \in \hat{\mathcal{Y}}$ such that Y' extends X in M.*

▶ **Lemma 13** (representative sets lemma [23, 25])**.** *Let $M = (E, \mathcal{I})$ be a linear matroid represented by a matrix A of rank $r + s$, and let $\mathcal{Y} \subseteq \binom{E}{s}$ be a collection of independent sets of M, where $s = O(1)$. In time polynomial in the size of A and the size of $\mathcal{Y}$, we can compute a set $\hat{\mathcal{Y}} \subseteq \mathcal{Y}$ of size at most $\binom{r+s}{s}$ which represents $\mathcal{Y}$ in M.*

We will use the following *product form* of the representative sets lemma, with stronger specialized bounds. Assume that the rank of M is $r = r_1 + \ldots + r_c$, where r_i is the rank of layer i of M. Then Lemma 13 gives a bound on $|\hat{\mathcal{Y}}|$ as $\Theta((r_1 + \ldots + r_c)^c)$, but the following bound is significantly better when the layers of M have different rank.

▶ **Lemma 14** ([17]). *Let $M = (E, \mathcal{I})$ be a linear matroid, given as the disjoint union of c matroids $M_i = (E_i, \mathcal{I}_i)$, where M_i has rank r_i. Let $\mathcal{Y} \subseteq \binom{E}{c}$ be such that every set $Y \in \mathcal{Y}$ contains precisely one member in each layer M_i of M. Then the representative set $\hat{\mathcal{Y}} \subseteq \mathcal{Y}$ computed by the representative sets lemma will have $|\hat{\mathcal{Y}}| \leq \prod_{i=1}^{c} r_i$.*

3.2.2 The marking process

We are now ready to present the marking process.

Let $r = c - 2$. We define a process that marks edges of G in r passes, where each pass is a call to the representative sets lemma with a different matroid construction. Specifically, for each $i \in [r]$, define the following. The matroid M_i is the disjoint union of i copies of the edge-cut gammoid $M(T)$, one copy of $M_G(k^{r-i})$, and one copy of $U(E, k)$, where for $i = r$ we simply skip the copy of $M_G(k^0)$. We refer to the first i layers in M_i as the *gammoid layers* and the remaining as the *additional layers.* Note that a linear representation of M_i over some common field $\mathbb{F}$ can be computed in randomized polynomial time, since every layer of M_i can be represented over any sufficiently large field.

For each edge $e \in E$, let $t_i(e)$ be the set that contains a copy of z'_e in every gammoid layer, and a copy of e in every additional layer. Let $E_i = \{t_i(e) \mid e \in E\}$. For each pass $i \in [r]$, we compute a representative set $\hat{E}_i \subseteq E_i$ in the matroid M_i, and let $Z_i \subseteq E$ be the set of edges represented in $\hat{E}_i$. Let $Z = Z_1 \cup \ldots \cup Z_r$. We consider an edge $e \in E$ *marked* if $e \in Z$. We finish the description by observing the bound on the number of marked edges.

▶ **Lemma 15.** *The total number of marked edges is at most $rk^{r+1} < k^c$.*

Proof. By the product form of the representative sets lemma, $|Z_i| \leq k^{r+1}$ for every $i \in [r]$. ◀

Our main correctness condition for the marking is as follows. Consider a partition $\mathcal{T}$ of T and a corresponding minimum multiway cut $X \subseteq E$. Note that $|X| \leq k$ since $E(T, V)$ is a multiway cut for every partition. Say that X is *p-way plus q* if the p largest connected components of $G - X$ together cover all but q of the vertices. Say that X is *covered* if all edges essential for $\mathcal{T}$ are marked. We then have the following.

▶ **Lemma 16** (★). *If X is p-way plus k^{r-p} for $p \in [r]$, then X is covered in pass p above.*

Proof sketch. We define a set F_e such that $t_p(f)$ extends F_e if and only if $f = e$. By the existence of the set F_e, we then have a guarantee that $e \in Z_p$. To construct F_e, we follow [17] in the first p layers by letting F_e contain $X \cup \partial(T_i)$, where T_i is the set of vertices of T contained in the ith largest layer, thereby "blocking out" any edge contained in the p largest components from extending F_e. We use the two additional layers to block out edges containing in small components, respectively edges of $X - e$. Then by construction $t_p(f)$ fails to extend F_e for every edge $f \neq e$. Furthermore, as as in [17], we show that $t_p(e)$ extends F_e: if $t_p(e)$ fails to extend F_e in a gammoid layer, then this yields a "pushed solution" X_2 which is a minimum multiway cut for $\mathcal{T}$ with $e \notin X_2$, contradicting that e is essential for $\mathcal{T}$. In the additional layers, the argument for why e extends F_e is trivial. ◀

3.2.3 Correctness

We now argue that if (G, T) is (α, c)-dense for $c = \Omega(\alpha \log k)$ then every partition of T has a minimum multiway cut that is p-way plus k^{r-p} for some $p \in [r]$. For this, assume for a contradiction that for some partition $\mathcal{T}$ of T the minimum multiway cut X of $\mathcal{T}$ is not covered in any of the above passes. We will derive that $|X| > k$, contradicting that X is minimum. Assume that $G - X$ has p components, and let $n_1 \geq \ldots \geq n_p$ be the number of vertices in each component, sorted by size. The converse to Lemma 16 is the following.

▶ **Corollary 17.** *If X is not covered, then for every $i \in [r]$ it holds that $\sum_{j=i+1}^{p} n_j > k^{r-i}$.*

For $i \in [r]$, let us write $n_{\geq i} = \sum_{j=i}^{p} n_j$. Hence for each $i \in [r]$, $n_{\geq i+1} > k^{r-i}$.

Now, refer as previously to the vertex sets of the connected components of $G - X$ in order as $V_1, \ldots, V_p$, where $|V_i| = n_i$, $i \in [p]$. By the density assumption, for every $i \geq 2$, $\mathrm{cap}_T(V_i) \geq n_i^{1/c}/\alpha$. On the other hand, as previously noted, if X is minimum we have

$$\sum_{i=1}^{p} \mathrm{cap}_T(V_i) = \sum_{i=1}^{p} (\mathrm{cap}_G(T \cap V_i) + \delta(V_i)) = k + 2|X| \leq 3k. \tag{1}$$

It now remains to estimate the value of the following system:

$$\begin{array}{rl} \min & \sum_{i=2}^{p} n_i^{1/c}/\alpha \\ \text{s.t.} & \sum_{j=i+1}^{p} n_j > k^{r-i} \quad \forall i \in [r] \\ & \sum_{i=1}^{p} n_i = n \\ & n_1 \geq \ldots \geq n_p \geq 0 \end{array} \tag{2}$$

If we can determine that this value is greater than $3k$, then we will have derived a contradiction, showing that the cut X is covered. This is somewhat intricate, but not very difficult.

▶ **Lemma 18 (★).** *There is a $c = \Theta(\alpha \log k)$ such that the following holds: If (G, T) is (α, c)-dense, and if X is a multiway cut for some partition $\mathcal{T}$ of T such that X is not covered, then $|X| > k$.*

Proof sketch. Through concavity, one can show that the worst-case component sizes (i.e., the distribution n_i for which the system above achieves its minimum value) is when $n_i = k^{r-i+1}(1 - o(1))$ for every $i \geq 2$. The value of the system then becomes a geometric sum with ratio $k^{1/c} = 2^{\Theta(1/\alpha)}$, hence the total contribution is $\Theta((1/\alpha)k/(k^{1/c} - 1))$. Computing the asymptotics of the contributing factor $k^{1/c} - 1$ shows that it defeats $1/\alpha$, and establishes the result. ◀

3.3 Completing the result

By the above, every terminal network (G, T) that is (α, c)-dense for some $c = \Theta(\alpha \log k)$ has a multicut-covering set of at most k^c edges, which can be computed in randomized polynomial time. We extend the result to any (G, T), using a sublogarithmic terminal expansion tester.

▶ **Theorem 19** (Theorem 1 restated). *Let A be a sublogarithmic terminal expansion tester with ratio $\alpha(n, k)$. Let (G, T) be a terminal network with $\mathrm{cap}_G(T) = k$. There is a multicut-covering set $Z \subseteq E(G)$ with $|Z| \leq k^{O(\alpha(n,k) \log k)}$, which furthermore can be computed in randomized polynomial time using calls to A.*

Proof. Set $c = \Theta(\alpha \log k)$ as in Lemma 18. If $|E(G)| < k^c$ then return $Z = E(G)$, otherwise call A on (G, T, c). If (G, T) is (α, c)-dense, then Lemma 9 applies and we are done. Otherwise, let $S \subseteq V(G)$ be the set returned by A, and let $k_S = \mathrm{cap}_T(S)$. Let $(G_S, T(S))$ be the recursive instance at S, and note that $|V(G_S)| = |N_G[S]| < |V|$ and $|S| > k_S^c$ by definition of A. We may now proceed by induction on $|V|$ and assume that we can compute a multicut-covering set $Z_S \subseteq E(G_S)$ of size $|Z_S| < k_S^c$. To eliminate a corner case, if there is a vertex $v \in V(G_S)$ with $v \notin T(S)$ and $d_{G_S}(v) \leq 2$, then delete v if v is a leaf, otherwise contract one edge incident with v. Note that since $v \notin T(S)$ we have $d_G(v) = d_{G_S}(v)$ and $v \notin T$, hence these reduction rules are clearly correct. If this rule does not apply, there must be some edge $e \in E(G_S) \setminus Z_S$, and by construction e corresponds directly to an edge in G. Hence by

Prop. 8 we may contract e in G and repeat. This yields a graph G' with $|V(G')| < |V|$, hence by induction we can create a multicut-covering set Z for G', which is also a multicut-covering set of G by Prop. 8. Hence we can compute a multicut-covering set Z with $|Z| < k^c$. ◀

We observe the following consequences.

▶ **Corollary 20.** *Let (G,T) be a terminal network with $\text{cap}_G(T) = k$. The following holds.*

1. *There is a multicut-mimicking network for (G,T) with $k^{O(\log k)}$ edges.*
2. *If there is a sublogarithmic terminal expansion tester – in particular, if* Small Set Expansion *has an approximation ratio as in Theorem 19 – then a multicut-mimicking network of size quasipolynomial in k can be computed in randomized polynomial time.*

Proof. The first is immediate using $\alpha(n,k) = 1$. For the second, all that remains is to clean up the value $|Z|$. For this, let $\alpha(n,k) \leq \log^{1-\varepsilon} n \log^d k$ and $c = b\alpha \log k$, for some bounded values b, d, and first assume that $|Z| \geq |V(G)| = n$. Then

$$\begin{aligned} n \leq |Z| < k^{b\alpha \log k} &\Rightarrow \\ \log n < b\alpha \log^2 k &\Rightarrow \\ \log n < b \log^{1-\varepsilon} n \log^{d+2} k &\Rightarrow \\ \log^{\varepsilon} n < b \log^{d+2} k &\Rightarrow \\ \log n < (b \log^{d+2} k)^{1/\varepsilon}&, \end{aligned}$$

hence $|Z| \leq k^{\log^{O(1)} k}$, as promised. Otherwise, we contract all edges not present in Z and compute a new multicut-covering set Z' for the new system (G', T). Eventually, this process halts, and at this point we will have a multicut-covering set Z with $|Z| \leq k^{\log^{O(1)} k}$ for some graph G'' created by contractions from G, and by Prop. 8 this set Z is also a multicut-covering set for (G,T). ◀

3.4 Kernelization extensions and consequences

As noted, we get the following consequences.

▶ **Corollary 21 (★).** *If there is a sublogarithmic terminal expansion tester, then the following problems have randomized quasipolynomial kernels.*

1. Edge Multiway Cut *parameterized by solution size.*
2. Edge Multicut *parameterized by the solution size and the number of cut requests.*
3. Group Feedback Edge Set *parameterized by solution size, for any group.*
4. Subset Feedback Edge Set *with undeletable edges, parameterized by solution size.*
5. 0-Extension *for integer-weighted graphs, parameterized by solution cost.*

Finally, as in [32], the latter result extends to "0-Extension sparsifiers" which hold independent of the choice of metric. Let us briefly recall some details. An instance of 0-Extension can be defined as a terminal network (G,T), a metric $\mu\colon D \times D \to \mathbb{R}^+$ for some label set D, and a partial labelling $\tau\colon T \to D$. The goal is to find $\lambda\colon V(G) \to D$ extending τ, to minimize the cost $\sum_{uv \in E(G)} \mu(\lambda(u), \lambda(v))$. We note that the "kernel" in the previous result can be constructed without needing access to μ or τ, i.e., it is valid for every metric μ and every partial labelling τ.

▶ **Theorem 22 (★).** *Let $G = (V,E)$ be an undirected, unweighted graph and $T \subseteq V$ a set of terminals, $|T| = r$. For any integer $p \in \mathbb{N}$, let $k = p + r$; there exists a set $Z \subseteq E$ with $|Z| = k^{O(\log k)}$ such that the following holds. For any metric $\mu\colon D \times D \to \mathbb{R}^+$ and any labelling $\tau\colon T \to D$, if there exists a labelling $\lambda\colon V \to D$ extending τ where $\lambda(u) \neq \lambda(v)$ for at most p edges $uv \in E$, then there exists such a labelling λ, of minimum cost among all such labellings, such that $\lambda(u) = \lambda(v)$ for every edge $uv \in E \setminus Z$.*

4 Discussion

We defined the notion of a *multicut-mimicking network*, and showed that every terminal network (G, T) with $k = \text{cap}_G(T)$ admits one of size $k^{O(\log k)}$, which furthermore may be computable in randomized polynomial time, subject to the precise approximation guarantees available for a restricted variant of Small Set Expansion. The mimicking network can be constructed via contractions on G, i.e., it simply consists of a set of edges which form a *multicut-covering set.* As a consequence of such a result, a range of parameterized problems, starting from Edge Multiway Cut, would have quasipolynomial kernels. Unfortunately, the approximation guarantee required for this latter result appears to go just below the range of available guarantees from the literature.

A natural question is whether an appropriate approximation algorithm can be constructed. We note that an approximation ratio of polylog(k) for Small Set Expansion is sufficient, where $k = \delta(S)$ is the number of edges cut in the optimal solution S. We are not aware of approximation ratios in term of this parameter having been investigated. Also note that it is sufficient if the approximation algorithm has a running time quasipolynomial in k (but polynomial in n).

Another question is whether the existence of a polynomial-sized multicut-mimicking network can be established. Can such a result be excluded, even for the apparently more demanding situation of sparsifiers for 0-Extension instances (as in Theorem 22)?

We also have not investigated the vertex-deletion versions of these problems, which seem likely to bring significant additional difficulty (if such a generalization is possible).

In either case, the existence of a quasipolynomial multicut-covering set appears to rule out any possibility of a lower bound against the kernelizability of Edge Multiway Cut for any size better than quasipolynomial, given the nature of the lower bound results against kernelization. We hope, therefore (but dare not explicitly conjecture) that Edge Multiway Cut and related problems have quasipolynomial (randomized) kernels or better, unconditionally.

Hardness of Equations over Finite Solvable Groups Under the Exponential Time Hypothesis

Armin Weiß
Universität Stuttgart, Institut für Formale Methoden der Informatik (FMI), Germany
armin.weiss@fmi.uni-stuttgart.de

Abstract

Goldmann and Russell (2002) initiated the study of the complexity of the equation satisfiability problem in finite groups by showing that it is in P for nilpotent groups while it is NP-complete for non-solvable groups. Since then, several results have appeared showing that the problem can be solved in polynomial time in certain solvable groups of Fitting length two. In this work, we present the first lower bounds for the equation satisfiability problem in finite solvable groups: under the assumption of the exponential time hypothesis, we show that it cannot be in P for any group of Fitting length at least four and for certain groups of Fitting length three. Moreover, the same hardness result applies to the equation identity problem.

Acknowledgements I am grateful to Moses Ganardi for bringing my attention both to the AND-weakness conjecture and to the exponential time hypothesis. I am also thankful to David A. Mix Barrington for an interesting email exchange concerning the AND-weakness conjecture and the idea to include steps of the lower central series in Proposition 8 to get a more refined upper bound. Furthermore, I am indebted to Caroline Mattes and Jan Philipp Wächter for many helpful discussions. Finally, I want to thank the anonymous referees for their valuable comments.

1 Introduction

The study of equations over algebraic structures has a long history in mathematics. Some of the first explicit decidability results in group theory are due to Makanin [33], who showed that equations over free groups are decidable. Subsequently several other decidability and undecidability results as well as complexity results on equations over infinite groups emerged (see [11, 14, 32, 37] for a random selection). For a fixed group G, the equation satisfiability problem EQN-SAT is as follows: given an expression $\alpha \in (G \cup \mathcal{X} \cup \mathcal{X}^{-1})^*$ where $\mathcal{X}$ is some set of variables, the question is whether there exists some assignment $\sigma : \mathcal{X} \to G$ such that $\sigma(\alpha) = 1$ (here σ is extended to expressions in the natural way – $\mathcal{X}^{-1}$ is a disjoint copy of $\mathcal{X}$ representing the inverses of $\mathcal{X}$). Likewise EQN-ID is the problem, given an expression, decide whether it evaluates to 1 under *all* assignments.

Henceforth, all groups we consider are finite. In this case, equation satisfiability and related questions are clearly decidable by an exhaustive search. Still the complexity is an interesting topic of research: its study has been initiated by Goldmann and Russell [15], who showed that satisfiability of systems of equations can be decided in P if and only if the group is abelian (assuming P ≠ NP) – otherwise, the problem is NP-complete. They also obtained

47th International Colloquium on Automata, Languages, and Programming (ICALP 2020).

some results for single equations: EQN-SAT is NP-complete for non-solvable groups, while for nilpotent groups it is in P. This left the case of solvable but non-nilpotent groups open. Indeed, Burris and Lawrence raised the question whether EQN-ID$(G) \in$ P for all finite solvable groups G [9, Problem 1]. Moreover, Horváth [18] conjectured a positive answer.

Contribution. In this work we give a negative answer to this question assuming the exponential time hypothesis by showing the following result:

▶ **Corollary A.** *Let G be finite solvable group and assume that either*

- *the Fitting length of G is at least four, or*
- *the Fitting length of G is three and there is no Fitting-length-two normal subgroup whose index is a power of two.*

Then EQN-SAT(G) and EQN-ID(G) are not in P *under the exponential time hypothesis.*

To the best of our knowledge, this constitutes the first hardness results for EQN-SAT(G) and EQN-ID(G) if G is solvable.[1] The Fitting length of a group G is the minimal d such that there is a sequence $1 = G_0 \trianglelefteq \cdots \trianglelefteq G_d = G$ with all quotients G_{i+1}/G_i nilpotent.

Moreover, we show that if S is a semigroup with a group divisor (i.e., a group which is a quotient of a subsemigroup of S) meeting the requirements of Corollary A, EQN-SAT(S) (here the input consists of two expressions) is also not in P under the exponential time hypothesis. Finally, using the same ideas as for our main result, we derive an upper bound of $2^{\mathcal{O}(n^{1/(d-1)})}$ for the length of the shortest G-program (definition see below) for the n-input AND function in a finite solvable group of Fitting length $d \geq 2$. Notice that a corresponding $2^{n^{\Omega(1)}}$ lower bound would imply that EQN-SAT(G) and EQN-ID(G) can be solved in quasipolynomial time for finite solvable groups G.

General approach. The complexity of EQN-SAT is closely related to the complexity of the satisfiability problem for G-programs (denoted by ProgramSAT – for a definition see Section 3). Indeed, [5] gives a reduction from EQN-SAT to ProgramSAT (be aware that, while the problems EQN-SAT and ProgramSAT are well-defined for finitely generated infinite groups, in general, such a reduction exists only in the case of finite groups). Moreover, also ProgramSAT is in P for nilpotent groups and NP-complete for non-solvable groups [6].

In order to show hardness of these problems, one usually reduces some NP-complete problem like 3SAT or C-Coloring to them. Typically, this requires to encode big logical conjunctions into the group G. Therefore, the complexity of these problems is linked to the length of the shortest G-program for the AND function. Indeed, [5, Theorem 4] shows that, if the AND function can be computed by a P-uniform family of G-programs of polynomial length, then ProgramSAT$(G \wr C_k)$ for $k \geq 4$ is NP-complete (here C_k denotes the cyclic group of order k; P-uniform means that the n-input G-program can be computed in time polynomial in n). Thus, if there exists a solvable group with efficiently computable polynomial length G-programs for the AND function, then there is a solvable group with an NP-complete ProgramSAT problem.

[1] Recently (a preprint appeared only days after the submission of this paper), in [24] Idziak, Kawałek, and Krzaczkowski succeeded to show that EQN-SAT(S_4) is not in P under the exponential time hypothesis (S_4 denotes the symmetric group over four elements). Moreover, they proved similar results as in this work for the case of algebras from congruence modular varieties. This complements our main result Corollary A. Indeed, a joint paper proving a quasipolynomial lower bound on EQN-SAT and EQN-ID for *all* finite groups of Fitting length three is under preparation.

It is well-known that G-programs describe the circuit complexity class CC^0 [34] with the depth of the circuit relating to the Fitting length of the group. One can make a depth size trade-off for the AND function using a divide-and-conquer approach: Assume there is a circuit of depth two and size 2^n for the n-input AND (which is the case by [3]). Since the n-input AND can be decomposed as $\sqrt{n}$-input AND of $\sqrt{n}$ many $\sqrt{n}$-input ANDs, we obtain a CC^0 circuit of depth 4 and size roughly $2^{\sqrt{n}}$.

This observation plays a crucial role for our results: it allows us to reduce an m-edge C-Coloring instance to an equation of size roughly $2^{\sqrt{m}}$. We compare this to the exponential time hypothesis (ETH), which conjectures that n-variable 3SAT cannot be solved in time $2^{o(n)}$. ETH implies that C-Coloring cannot be solved in time $2^{o(m)}$, which gives us a quasipolynomial lower bound on EQN-SAT and EQN-ID. Notice that in the literature there are several other quasipolynomial lower bounds building on the exponential time hypothesis – see [1, 7, 8] for some examples.

Outline. In Section 2, we fix our notation and state some basic results on inducible and atomically universally definable subgroups. Some of these observations are well-known, while others, to the best of our knowledge, have not been stated explicitly. Section 3 gives a little excursion to the complexity of the AND-function in terms of G-programs over finite solvable groups deriving an upper bound $2^{\mathcal{O}(n^{1/(d-1)})}$ if $d \geq 2$ is the Fitting length of G.

Section 4 and Section 5 are the main part of our paper: we reduce the C-Coloring problem to EQN-SAT and EQN-ID. For the reduction, we need some special requirements on the group G. In Section 5 we show that actually the requirements of Corollary A are enough using the concept of inducible and atomically universally definable subgroups. Finally, in Corollary 22 we examine consequences to EQN-SAT in semigroups.

Related work on equations. Since the work of Goldman and Russell [15] and Barrington et al. [5], a long list of literature has appeared investigating EQN-ID and EQN-SAT in groups and other algebraic structures. In [9] it is shown that EQN-ID is in P for nilpotent groups as well as for dihedral groups D_k where k is odd. Horváth resp. Horváth and Szabó [19, 22] extended these results by showing the following among other results: EQN-SAT(G) is in P for $G = C_n \rtimes B$ with B abelian, $n = p^k$ or $n = 2p^k$ for some prime p and EQN-ID is in P for semidirect products $G = C_{n_1} \rtimes (C_{n_2} \rtimes \cdots \rtimes (C_{n_k} \rtimes (A \rtimes B)))$ with A, B abelian (be aware that such a group is two-step solvable). Furthermore, in [12] it is proved that EQN-SAT$(G) \in \mathsf{P}$ for so-called semi-pattern groups. Finally, in [13] Földvári and Horváth established that EQN-SAT is in P for the semidirect product of a p-group and an abelian group and that EQN-ID is in P for the semidirect product of a nilpotent group with an abelian group. Notice that all these groups have in common that their Fitting length is at most two.

In [20, 21] the EQN-SAT and EQN-ID problems for generalized terms are introduced. Here a generalized term means an expression which may also use commutators or even more complicated terms inside the input expression. Using commutators is a more succinct representation, which allows for showing that EQN-SAT is NP-complete and EQN-ID is coNP-complete in the alternating group A_4 [21]. In [31] this result is extended by showing that, with commutators and the generalized term $w(x, y_1, y_2, y_3) = x^8[x, y_1, y_2, y_3]$, EQN-SAT is NP-complete and EQN-ID is coNP-complete for all non-nilpotent groups.

There is also extensive literature on equations in other algebraic structures – for instance, [2, 5, 26, 27, 28, 29, 38, 39, 40] in semigroups. We only mention two of them explicitly: [27] showed that identity checking (EQN-ID without constants in the input) in semigroups is coNP complete. Moreover, among other results, [2] reduces the identity checking problem in the direct product of maximal subgroups to identity checking in some semigroup.

2 Preliminaries

The set of words over some alphabet Σ is denoted by Σ^*. The length of a word $w \in \Sigma^*$ is denoted by $|w|$. We denote the interval of integers $\{ i, \dots, j \}$ by $[i \mathinner{..} j]$.

Complexity. We use standard notation from complexity theory. In several cases we use the notion of AC^0 many-one reductions (denoted by $\leq_{\mathrm{m}}^{\mathsf{AC}^0}$) meaning that the reducing function can be computed in AC^0 (i.e., by a polynomial-size, constant-depth Boolean circuit). The reader unfamiliar with this terminology may think about logspace or polynomial time reductions. Also be aware that in order to obtain AC^0 many-one reductions in most cases we need the presence of a letter representing the group identity for padding reasons.

Exponential time hypothesis. The exponential time hypothesis (ETH) is the conjecture that there is some $\delta > 0$ such that every algorithm for 3SAT needs time $\Omega(2^{\delta n})$ in the worst case where n is the number of variables of the given 3SAT instance. By the sparsification lemma [25, Thm. 1] this is equivalent to the existence of some $\epsilon > 0$ such that every algorithm for 3SAT needs time $\Omega(2^{\epsilon(m+n)})$ in the worst case where m is the number of clauses of the given 3SAT instance (see also [10, Thm. 14.4]). In particular, under ETH there is no algorithm for 3SAT running in time $2^{o(n+m)}$.

***C*-Coloring.** A C-coloring for $C \in \mathbb{N}$ of a graph $\Gamma = (V, E)$ is a map $\chi : V \to [1 \mathinner{..} C]$. A coloring χ is called *valid* if $\chi(u) \neq \chi(v)$ whenever $\{ u, v \} \in E$. The problem C-Coloring is as follows: given an undirected graph $\Gamma = (V, E)$, the question is whether there is a valid C-coloring of Γ. The C-Coloring problem is one of the classical NP-complete problems for $C \geq 3$. Moreover, by [10, Thm. 14.6], 3-Coloring cannot be solved in time $2^{o(|V|+|E|)}$ unless ETH fails. Since 3-Coloring can be reduced to C-Coloring for fixed $C \geq 3$ by introducing only a linear number of additional edges and a constant number of vertices, it follows for every $C \geq 3$ that also C-Coloring cannot be solved in time $2^{o(|V|+|E|)}$ unless ETH fails.

Commutators and Fitting series. Throughout, we only consider finite groups G. We use notation similar to [36]. We write $[x, y] = x^{-1}y^{-1}xy$ for the commutator and $x^y = y^{-1}xy$ for the conjugation. Moreover, we write $[x_1, \dots, x_n] = [[x_1, \dots, x_{n-1}], x_n]$ for $n \geq 3$.

As usual for subsets $X, Y \subseteq G$, we write $\langle X \rangle$ for the subgroup generated by X and we define $[X, Y] = \langle\, [x, y] \mid x \in X, y \in Y \,\rangle$ and $[X_1, \dots, X_k] = [[X_1, \dots, X_{k-1}], X_k]$ for $X_1, \dots, X_k \subseteq G$. In contrast, we write $[X, Y]_{\mathrm{set}} = \{ [x, y] \mid x \in X, y \in Y \}$ (thus, $[X, Y] = \langle [X, Y]_{\mathrm{set}} \rangle$) and $[X_1, \dots, X_k]_{\mathrm{set}} = [[X_1, \dots, X_{k-1}]_{\mathrm{set}}, X_k]_{\mathrm{set}}$.

Finally, we denote the set $\{ g^x \mid x \in X \}$ with g^X (be aware that here we differ from [36]) and define $X^Y = \{ x^y \mid x \in X, y \in Y \}$.

▶ **Lemma 1.** *If $X_i^G = X_i \subseteq G$ for $i = 1, \dots, k$, then*

$$[\langle X_1 \rangle, \dots, \langle X_k \rangle] = \langle [X_1, \dots, X_k]_{\mathrm{set}} \rangle .$$

Proof. By [36, 5.1.7], we have $[\langle X \rangle, \langle Y \rangle] = [X, Y]^{\langle X \rangle \langle Y \rangle}$ for arbitrary $X, Y \subseteq G$. Thus, if $X = X^G$ and $Y = Y^G$, we have $[\langle X \rangle, \langle Y \rangle] = [X, Y]$. We use this to show the lemma by induction:

$$\begin{aligned}
[\langle X_1 \rangle, \dots, \langle X_k \rangle] &= \big[[\langle X_1 \rangle, \dots, \langle X_{k-1} \rangle], \langle X_k \rangle\big] \\
&= \big[\langle [X_1, \dots, X_{k-1}]_{\mathrm{set}} \rangle, \langle X_k \rangle\big] && \text{(by induction)} \\
&= \big[[X_1, \dots, X_{k-1}]_{\mathrm{set}}, X_k\big] && \text{(by [36, 5.1.7])} \\
&= \langle [X_1, \dots, X_k]_{\mathrm{set}} \rangle
\end{aligned}$$

◀

For $x, y \in G$, we write $[x, {}_k\, y] = [x, \underbrace{y, \dots, y}_{k \text{ times}}]$ and likewise for $X, Y \subseteq G$, we write $[X, {}_k\, Y] = [X, \underbrace{Y, \dots, Y}_{k \text{ times}}]$ and $[{}_k\, Y] = [\underbrace{Y, \dots, Y}_{k \text{ times}}]$ and analogously $[X, {}_k\, Y]_{\text{set}}$ and $[{}_k\, Y]_{\text{set}}$.

Since G is finite, there is some $M = M(G) \in \mathbb{N}$ such that $[X, {}_M\, Y] = [X, {}_i\, Y]$ for all $i \geq M$ and all $X, Y \subseteq G$ with $X^G = X$ and $Y^G = Y$ (notice that $[X, {}_i\, Y] \leq [X, {}_j\, Y]$ for $j \leq i$ due to the normality of $[X, Y]$). It is clear that $M = |G|$ is large enough, but typically much smaller values suffice.

▶ **Lemma 2.** *For all $X, Y \subseteq G$ with $X^G = X$ we have $[X, {}_M\, Y] = [[X, G], {}_M\, Y]$.*

Proof. We have $[X, G] \leq \langle X \rangle$ because $[x, g] = x^{-1}x^g \in X$. Thus, the inclusion right to left follows. The other inclusion is because $[X, {}_M\, Y] = [X, {}_{M+1}\, Y] \leq [X, G, {}_M Y] = [[X, G], {}_M\, Y]$. ◀

The k-th term of the lower central series is $\gamma_k G = [G, {}_k\, G]$. The *nilpotent residual* of G is defined as $\gamma_\infty G = \gamma_M G$ where M is as above (i.e., $\gamma_\infty G = \gamma_i G$ for every $i \geq M$). Recall that a finite group G is nilpotent if and only if $\gamma_\infty G = 1$.

The *Fitting* subgroup $\mathrm{Fit}(G)$ is the union of all nilpotent normal subgroups. Let G be a finite solvable group. It is well-known that $\mathrm{Fit}(G)$ itself is a nilpotent normal subgroup (see e.g. [23, Satz 4.2]). The *upper Fitting series*

$$1 = \mathcal{U}_0 G \lhd \mathcal{U}_1 G \lhd \cdots \lhd \mathcal{U}_k G = G$$

is defined by $\mathcal{U}_{i+1}G / \mathcal{U}_i G = \mathrm{Fit}(G/\mathcal{U}_i G)$. The *lower Fitting series*

$$1 = \mathcal{L}_d G \lhd \cdots \lhd \mathcal{L}_1 G \lhd \mathcal{L}_0 G = G$$

is defined by $\mathcal{L}_{i+1} G = \gamma_\infty(\mathcal{L}_i G)$. We have $d = k$ (see e.g. [23, Satz 4.6]) and this number is called the *Fitting length* $\mathrm{FitLen}(G)$ (sometimes also referred to as *nilpotent length*). The following fact can be derived by a straightforward induction from the characterization of $\mathrm{Fit}(G)$ as largest nilpotent normal subgroup (for a proof see e.g. [41]):

▶ **Lemma 3.** *Let $H \trianglelefteq G$ be a normal subgroup. Then for all i, we have $\mathcal{U}_i H = \mathcal{U}_i G \cap H$. In particular,*

(i) *if $\mathrm{FitLen}(H) = i$, then $H \leq \mathcal{U}_i G$,*
(ii) *if $g \in \mathcal{U}_i G \setminus \mathcal{U}_{i-1} G$, then $\mathrm{FitLen}(\langle g^G \rangle) = i$.*

Equations in groups. An *expression* (also called a *polynomial* in [39, 22, 31]) over a group G is a word α over the alphabet $G \cup \mathcal{X} \cup \mathcal{X}^{-1}$ where $\mathcal{X}$ is a set of variables. Here $\mathcal{X}^{-1}$ denotes a formal set of inverses of the variables. Since we are dealing with finite groups only, a variable $X^{-1} \in \mathcal{X}^{-1}$ for $X \in \mathcal{X}$ can be considered as an abbreviation for $X^{|G|-1}$. Sometimes we write $\alpha(X_1, \dots, X_n)$ for an expression α to indicate that the variables occurring in α are from the set $\{ X_1, \dots, X_n \}$. Moreover, if $\beta_1, \dots, \beta_n$ are other expressions, we write $\alpha(\beta_1, \dots, \beta_n)$ for the expression obtained by substituting each occurrence of a variable X_i by the expression β_i.

An assignment for an expression α is a mapping $\sigma : \mathcal{X} \to G$ – here σ is canonically extended by $\sigma(X^{-1}) = \sigma(X)^{-1}$ and $\sigma(g) = g$ for $g \in G$. An assignment σ is *satisfying* if $\sigma(\alpha) = 1$ in G. The problems EQN-SAT(G) and EQN-ID(G) are as follows: for both of them the input is an expression α. For EQN-SAT(G) the question is whether there *exists* a satisfying assignment, for EQN-ID(G) the question is whether *all* assignments are satisfying.

Notice that in the literature EQN-SAT is also denoted by POL-SAT [39, 22] or Eq [31], while EQN-ID is also referred to as POL-EQ (e.g. in [39, 22, 28]) or Id [31].

If $\mathcal{X} = \mathcal{Y} \cup \mathcal{Z}$ with $\mathcal{Y} \cap \mathcal{Z} = \emptyset$ and we are given assignments $\sigma_1 : \mathcal{Y} \to G$ and $\sigma_2 : \mathcal{Z} \to G$, we obtain a new assignment $\sigma_1 \cup \sigma_2$ defined by $(\sigma_1 \cup \sigma_2)(X) = \sigma_1(X)$ if $X \in \mathcal{Y}$ and $(\sigma_1 \cup \sigma_2)(X) = \sigma_2(X)$ if $X \in \mathcal{Z}$. We write $[X \mapsto g]$ for the assignment $\{ X \} \to G$ mapping X to g.

Inducible subgroups. According to [15], we call a subset $S \subseteq G$ *inducible* if there is some expression $\alpha \in (G \cup \mathcal{X} \cup \mathcal{X}^{-1})^*$ such that $S = \{ \sigma(\alpha) \mid \sigma \colon \mathcal{X} \to G \}$. In this case we say that α *induces* S. Notice that in a finite group every verbal subgroup is inducible. (A subgroup is called *verbal* if it is generated by a set of the form $\{ \sigma(\alpha) \mid \sigma \colon \mathcal{X} \to G, \alpha \in \mathcal{A} \}$ where $\mathcal{A} \subseteq (\mathcal{X} \cup \mathcal{X}^{-1})^*$ is a *finite* set of expressions without constants.) This shows the first three points of the following lemma (for $\gamma_1 G$, see also [15, Lemma 5]):

▶ **Lemma 4.** *Let G be a finite group. Then*

(i) *for every $k \in \mathbb{N}$, the subgroup generated by all k-th powers is inducible,*

(ii) *every element $\gamma_k G$ of the lower central series is inducible,*

(iii) *every element $\mathcal{L}_k G$ of the lower Fitting series is inducible,*

(iv) *if $K \leq H \leq G$ and K is inducible in H and H inducible in G, then K is also inducible in G,*

(v) *if $H \leq G$ with $H = [G, H]$, then H is inducible.*

The fourth point follows simply by "plugging in" an expression for H inside an expression for K. The last point follows from the proof of [31, Lemma 9].

The notion of inducible subgroup turns out to be very useful for proving lower bounds on the complexity. Indeed, the following facts are straightforward:

▶ **Lemma 5** ([15, Lemma 8], [20, Lemma 9, 10]). *Let $H \leq G$ be an inducible subgroup. Then*

- *EQN-SAT(H) $\leq_{\mathrm{m}}^{\mathsf{AC}^0}$ EQN-SAT(G), and*
- *EQN-ID(H) $\leq_{\mathrm{m}}^{\mathsf{AC}^0}$ EQN-ID(G).*
- *If, moreover, H is normal in G, then EQN-SAT(G/H) $\leq_{\mathrm{m}}^{\mathsf{AC}^0}$ EQN-SAT(G).*

Let us briefly sketch the ideas to see this lemma: Fix an expression β inducing H. For first and second reduction, replace every occurring variable of a given equation by a copy of β with disjoint variables. The third reduction simply appends β to an input equation.

Atomically universally definable subgroups. The situation for reducing EQN-ID(G/H) to EQN-ID(G) is slightly more complicated. For this we need a new definition: We call a subset $S \subseteq G$ *atomically universally definable* if there is some expression $\alpha \in (G \cup \mathcal{X} \cup \mathcal{X}^{-1})^*$ where $\mathcal{X} = \{ X \} \cup \{ Y_1, Y_2, \ldots \}$ such that

$$S = \{ g \in G \mid (\sigma \cup [X \mapsto g])(\alpha) = 1 \text{ for all } \sigma \colon \{ Y_1, Y_2, \ldots \} \to G \} .$$

In this case we say that α *atomically universally defines* S. (Notice that *universally definable* usually is defined analogously but instead of a single equation α one allows a Boolean formula of equations.) It is clear that the center of a group is atomically universally definable by the expression $[X, Y]$. This generalizes as follows:

▶ **Lemma 6.** *Let G be a finite group.*

- *The Fitting group* $\mathrm{Fit}(G)$ *is atomically universally definable.*
- *If $N \leq H \leq G$ and N is normal in G and H/N is atomically universally definable in G/N and N is atomically universally definable in G, then H is atomically universally definable in G.*
- *All terms $\mathcal{U}_i G$ of the upper Fitting series are atomically universally definable.*
- *If $H \leq G$ is inducible, then the centralizer $C_G(H) = \{ g \in G \mid gh = hg \text{ for all } h \in H \}$ is atomically universally definable.*

Proof. By Lemma 3, the normal subgroup $\langle g^G \rangle$ generated by $g \in G$ is nilpotent if and only if $g \in \mathrm{Fit}(G)$. Therefore, $g \in \mathrm{Fit}(G)$ if and only if $\left[_M \langle g^G \rangle\right] = 1$ (M as in Section 2 large enough), which, by Lemma 1, is the case if and only if $\left[_M\, g^G\right]_{\mathrm{set}} = 1$. Hence, the expression $[X^{Y_1}, \dots, X^{Y_M}]$ atomically universally defines $\mathrm{Fit}(G)$.

Now, suppose that $\beta \in (G \cup \mathcal{X}_\beta \cup \mathcal{X}_\beta^{-1})^*$ with $\mathcal{X}_\beta = \{ X, Y_1, \dots, Y_k \}$ atomically universally defines H/N in G/N and that $\alpha \in (G \cup \mathcal{X}_\alpha \cup \mathcal{X}_\alpha^{-1})^*$ with $\mathcal{X}_\alpha = \{ Z, Y_{k+1}, \dots, Y_m \}$ atomically universally defines N in G. Thus, $g \in H$ if and only if $\beta(g, Y_1, \dots, Y_k) \in N$ for all $Y_1, \dots, Y_k \in G$ and $h \in N$ if and only if $\alpha(h, Y_{k+1}, \dots, Y_m) = 1$ for all $Y_{k+1}, \dots, Y_m \in G$. Hence, $\alpha(\beta(g, Y_1, \dots, Y_k), Y_{k+1}, \dots, Y_m) = 1$ for all $Y_1, \dots, Y_m \in G$ if and only if $g \in H$ and so H is atomically universally definable.

The third point follows by induction from the first and second point. The fourth point is essentially due to [20, Lemma 10]: if β is an expression inducing H, then $[X, \beta]$ atomically universally defines $C_G(H)$. ◀

▶ **Lemma 7.** *Let $H \trianglelefteq G$ be an atomically universally definable normal subgroup. Then*

$$\text{EQN-ID}(G/H) \leq_{\mathrm{m}}^{\mathsf{AC}^0} \text{EQN-ID}(G).$$

Proof. Denote $Q = G/H$. Let $\beta \in (G \cup \mathcal{X}_\beta \cup \mathcal{X}_\beta^{-1})^*$ with $\mathcal{X}_\beta = \{ Z, Y_1, \dots, Y_k \}$ atomically universally define H and let $\alpha \in (Q \cup \mathcal{X} \cup \mathcal{X}^{-1})^*$ be an instance for EQN-ID(Q) (with $\mathcal{X} \cap \mathcal{X}_\beta = \emptyset$). Let $\tilde{\alpha}$ denote the expression obtained from α by replacing every constant of Q by an arbitrary preimage in G. Then $\sigma(\alpha) = 1$ in Q for all assignments $\sigma : \mathcal{X} \to Q$ if and only if $\tilde{\sigma}(\tilde{\alpha}) \in H$ for all assignments $\tilde{\sigma} : \mathcal{X} \to G$. By the choice of β, the latter is the case if and only if $\hat{\sigma}(\beta(\tilde{\alpha}, Y_1, \dots, Y_k)) = 1$ for all assignments $\hat{\sigma} : \mathcal{X} \cup \{ Y_1, \dots, Y_k \} \to G$. ◀

3 G-programs and AND-weakness

Let G be a finite group. An n-input G-program of length ℓ with variables (input bits) from $\{ B_1, \dots, B_n \}$ is a sequence

$$P = \langle B_{i_1}, a_1, b_1 \rangle \langle B_{i_2}, a_2, b_2 \rangle \cdots \langle B_{i_\ell}, a_\ell, b_\ell \rangle \in (\{ B_1, \dots, B_n \} \times G \times G)^*.$$

For a mapping $\sigma : \{ B_1, \dots, B_n \} \to \{0, 1\}$ (called an assignment) we define $\sigma(P) \in G$ as the group element $c_1 c_2 \cdots c_\ell$, where $c_j = a_j$ if $B_{i_j} = 0$ and $c_j = b_j$ if $B_{i_j} = 1$ for all $1 \leq j \leq \ell$. We say that an n-input G-program P *computes* a function $f : \{0, 1\}^n \to \{0, 1\}$ if P is over the variables $B_1, \dots, B_n$ and there is some $S \subseteq G$ such that $\sigma(P) \in S$ if and only if $f(\sigma) = 1$.

ProgramSAT is the following problem: given a G-program P with variables $B_1, \dots, B_n$, decide whether there is an assignment $\sigma : \{ B_1, \dots, B_n \} \to G$ such that $\sigma(P) = 1$.

The AND-weakness conjecture. In [6], Barrington, Straubing and Thérien conjectured that, if G is finite and solvable, every G-program computing the n-input AND requires length exponential in n. This is called the AND-*weakness conjecture*.

Unfortunately, the term "exponential" seems to be a source of a possible misunderstanding: while often it means $2^{\Omega(n)}$, in other occasions it is used for $2^{n^{\Omega(1)}}$. Indeed, in [15, 5], the conjecture is restated as its *strong version*: "every G-program over a solvable group G for the n-input AND requires length $2^{\Omega(n)}$." However, already in the earlier paper [4], it is remarked that the n-input AND can be computed by depth-k CC^0 circuits of size $2^{\mathcal{O}(n^{1/(k-1)})}$ for every $k \geq 2$ (a CC^0 circuit is a circuit consisting only of MOD_m gates for some $m \in \mathbb{N}$) – thus, disproving the strong version of the AND-weakness conjecture. For a recent discussion about the topic also referencing the cases where the conjecture actually is proved, we refer to [30].

In this section we provide a more detailed upper bound on the length of G-programs for the AND function in terms of the Fitting length of G. We can view our upper bound as a refined version of the $2^{\mathcal{O}(n^{1/(k-1)})}$ upper bound for depth-k CC^0 circuits. This is because, by [34, Theorem 2.8], for every depth-k CC^0 circuit family there is a fixed group G of Fitting length k (indeed, of derived length k) such that the n-input circuit can be transformed into a G-program of length polynomial in n.

▶ **Proposition 8.** *Let G be a finite solvable group and consider a strictly ascending series $1 = H_0 \lhd H_1 \lhd \cdots \lhd H_m = G$ of normal subgroups where $H_i = \gamma_{k_i}(H_{i+1})$ with $k_i \in \mathbb{N} \cup \{ \infty \}$ for $i \in [1 \mathinner{..} m-1]$ and $k_0 = \infty$. Denote $c = |\{ i \in [1 \mathinner{..} m-1] \mid k_i = \infty \}|$ and $C = \prod_{k_i < \infty}(k_i + 1)$.*

Then the n-input AND *function can be computed by a G-program of length $\mathcal{O}(2^{Dn^{1/c}})$ where $D = \frac{c}{C^{1/c}}$. More precisely, for every $n \in \mathbb{N}$ there is some $1 \neq g \in G$ and a G-program Q_n of length $\mathcal{O}(2^{Dn^{1/c}})$ such that*

$$\sigma(Q_n) = \begin{cases} g & \textit{if } \sigma(B_1) = \cdots = \sigma(B_n) = 1, \\ 1 & \textit{otherwise.} \end{cases}$$

Clearly we have $c \leq d - 1$ if d is the Fitting length of G. The lower Fitting series is the special example of such a series where $H_i = \mathcal{L}_{d-i}G$ and $k_i = \infty$ for all $i \in \{ 0, \ldots, d \}$. Thus, we get the following corollary:

▶ **Corollary 9.** *Let G be a finite solvable group of Fitting length $d \geq 2$. Then the n-input* AND *function can be computed by a G-program of length $2^{\mathcal{O}(n^{1/(d-1)})}$.*

▶ **Example 10.** The symmetric group on four elements S_4 has Fitting length 3 with $S_4 \geq A_4 \geq C_2 \times C_2 \geq 1$ being both the upper and lower Fitting series. Therefore, we obtain a length-$\mathcal{O}(2^{2\sqrt{n}})$ program for the n-input AND by Proposition 8. In particular, the strong version of the AND-weakness conjecture does not hold for the group S_4. Note that according to [6], S_4 is the smallest group for which the $2^{\Omega(n)}$ lower bound from [6] does not apply.

On the other hand, consider the group $G = (C_3 \times C_3) \rtimes D_4$ where D_4 (the dihedral group of order eight) acts faithfully on $C_3 \times C_3$[2]. It has Fitting length two. Moreover, its derived subgroup $G' = (C_3 \times C_3) \rtimes C_2$ still has Fitting length two. Hence, we have a series $H_3 = G$, $H_2 = G' = \gamma_1 G$, $H_1 = \gamma_\infty G' = C_3 \times C_3$, and $H_0 = 1$. Therefore, we get an upper bound of $\mathcal{O}(2^{n/2})$ for the length of a program for the n-input AND.

Proof of Proposition 8. We choose $K = (n/C)^{1/c}$. For simplicity, let us first assume that K is an integer. Moreover, we assume that K is large enough such that $H_i = [_K\, H_{i+1}]$ holds whenever $k_i = \infty$ and that $K \geq k_i + 1$ for all $k_i < \infty$.

We define sets $A_i \subseteq G$ inductively by $A_m = G$ and $A_i = [_K\, A_{i+1}]_{\mathrm{set}}$ if $k_i = \infty$ and $A_i = [_{k_i+1}\, A_{i+1}]_{\mathrm{set}}$ if $k_i < \infty$. By Lemma 1 and induction it follows that $H_i = \langle A_i \rangle$ for all $i \in 0, \ldots, m$. Since $H_1 \neq 1$, we find a non-trivial element $g \in A_1$. We can decompose g recursively. For this, we need some more notation: for $\ell \in [1 \mathinner{..} m]$ consider the set of words

$$V_\ell = \left\{ v = v_1 \cdots v_{\ell-1} \in [1 \mathinner{..} K]^{\ell-1} \;\middle|\; v_i \leq k_i + 1 \text{ for all } i \in [1 \mathinner{..} \ell-1] \right\}.$$

We have $|V_m| = C \cdot K^c = n$, so we can fix a bijection $\kappa \colon V_m \to [1 \mathinner{..} n]$.

Now, we can describe the recursive decomposition of $g = g_\epsilon$:

[2] This group can be found in the GAP small group library under the index [72, 40]. It has been suggested as an example by Barrington (private communication).

- g_v for $v \in V_m$ are arbitrary element from G, and
- $g_v = [g_{v1}, \dots, g_{vK}]$ for $v \in V_\ell$ with $k_\ell = \infty$, and
- $g_v = [g_{v1}, \dots, g_{v(k_\ell+1)}]$ for $v \in V_\ell$ with $k_\ell < \infty$.

For $v \in V_\ell$ we have $|g_v| \leq \sum_{i=1}^{K} 2^{K+1-i} |g_{vi}| \leq 2^{K+1} \max_i |g_{vi}|$ whenever $k_\ell = \infty$ and $|g_v| \leq 2^{k_\ell+2} \max_i |g_{vi}|$ if $k_\ell < \infty$. Therefore, setting $D = \frac{c}{C^{1/c}}$ we obtain by induction

$$|g_\varepsilon| \leq 2^{\sum_{k_\ell<\infty}(k_\ell+2)}(2^{K+1})^c \in \mathcal{O}(2^{Dn^{1/c}}).$$

In order to obtain a G-program for the n-input AND, we define G-programs P_v for $v \in \bigcup_{\ell \leq m} V_\ell$. In the commutators we need also programs for inverses: for a G-program $P = \langle B_{i_1}, a_1, b_1 \rangle \langle B_{i_2}, a_2, b_2 \rangle \cdots \langle B_{i_\ell}, a_\ell, b_\ell \rangle$ we set $P^{-1} = \langle B_{i_\ell}, a_\ell^{-1}, b_\ell^{-1} \rangle \cdots \langle B_{i_1}, a_1^{-1}, b_1^{-1} \rangle$. Clearly $(\sigma(P))^{-1} = \sigma(P^{-1})$ for all assignments σ.

- for $v \in V_m$ we set $P_v = \langle B_{\kappa(v)}, 1, g_v \rangle$,
- for $v \in V_\ell$ with $1 \leq \ell < m$ we set $P_v = [P_{v1}, \dots, P_{vK}]$ if $k_\ell = \infty$, and
- for $v \in V_\ell$ with $1 \leq \ell < m$ we set $P_v = [P_{v1}, \dots, P_{v(k_\ell+1)}]$ if $k_\ell < \infty$.

For $v \in V_\ell$ let $V(v)$ denote the set of those words $w \in V_m$ having v as a prefix. By induction we see that

$$\sigma(P_v) = \begin{cases} g_v & \text{if } \sigma(B_{\kappa(w)}) = 1 \text{ for all } w \in V(v), \\ 1 & \text{otherwise.} \end{cases}$$

This shows the correctness of our construction.

It remains to consider the case that $(n/C)^{1/c}$ is not an integer. Then we set $K = \lceil (n/C)^{1/c} \rceil$. It follows that $|V_{m-1}| = C \cdot K^c \geq n$, so we can fix a bijection $\kappa \colon U \to [1 \,..\, n]$ for some subset $U \subseteq V_{m-1}$. We still have $|g_\varepsilon| \leq 2^{\sum_{k_i<\infty}(k_i+1)}(2^{K+1})^c \in \mathcal{O}(2^{cK}) = \mathcal{O}(2^{Dn^{1/c}})$ with D as above. This concludes the proof of Proposition 8. ◀

▶ Remark 11. In the light of Proposition 8 it is natural to ask for a refined version of the AND-weakness conjecture. A natural candidate would be to conjecture that every G-program for the n-input AND has length $2^{\Omega(n^{1/(d-1)})}$ where d is the Fitting length of G.

However, this also weaker version of the AND-weakness conjecture is wrong! Indeed, in [4, Section 2.4] Barrington, Beigel and Rudich show that the n-input AND can be computed by circuits using only MOD_m gates of depth 3 and size $2^{\mathcal{O}(n^{1/r} \log n)}$ where r is the number of different prime factors of m. Translating the circuit into a G-program yields a group G of Fitting length 3. Since there is no bound on r, we see that there is no lower bound on the exponent δ such that there are G-programs of length $2^{\mathcal{O}(n^\delta)}$ for the n-input AND in groups of Fitting length 3.

In [17] it is shown that the AND function can be computed by probabilistic CC^0 circuits using only a logarithmic number of random bits, which "may be viewed as evidence contrary to the conjecture" [17]. In the light of this, we do not feel confident to judge which form of the AND-weakness conjecture might be true. The following version seems possible.

▶ **Conjecture 1** (AND-weakness [6]). *Let G be finite solvable. Then every G-program for the n-input* AND *has length $2^{n^{\Omega(1)}}$.*

Notice that [5, Theorem 2] (if G is AND-weak, ProgramSAT over G can be decided in quasi-polynomial time) still holds with this version of the AND-weakness conjecture.

4 Reducing C-Coloring to equations

In this section we describe the reduction of C-Coloring to EQN-SAT(G) and EQN-ID(G) in the spirit of [15, 31]. For this, we rely on the fact that G has some normal subgroups meeting some special requirements. In Section 5, we show that all sufficiently complicated finite solvable groups meet the requirements of Theorem 14.

For a normal subgroup $H \trianglelefteq G$ and $g \in G$, we define $\eta_g(H) = \left[H, {}_M\, g^G\right]$. Recall that M is chosen large enough such that $[X, {}_M\, Y] = [X, {}_i\, Y]$ for all $i \geq M$ and all $X, Y \subseteq G$ with $X^G = X$ and $Y^G = Y$. Since H is normal, we have $\eta_g(H) \leq H$ and $\eta_g(H)$ is normal in G.

▶ **Lemma 12.** *Let $H \trianglelefteq G$ be a normal subgroup and $g, h \in G$. Then*

(i) $\eta_g(\eta_g(H)) = \eta_g(H)$, *and*

(ii) $\eta_{gh}(H) \leq \eta_g(H)\eta_h(H)$, *and*

(iii) $\mathrm{FitLen}(\eta_{gh}(H)) \leq \max\{\, \mathrm{FitLen}(\eta_g(H)), \mathrm{FitLen}(\eta_h(H))\,\}$.

Proof. We use the fact that M is chosen such that $[X, {}_M\, Y] = [X, {}_i\, Y]$ for all $i \geq M$ and all $X, Y \subseteq G$ with $X^G = G$ and $Y^G = Y$:

$$\eta_g(H) = \left[H, {}_M\, g^G\right] = \left[H, {}_{2M}\, g^G\right] = \left[\left[H, {}_M\, g^G\right], {}_M\, g^G\right] = \eta_g(\eta_g(H)).$$

The second point follows with the same kind of argument:

$$\begin{aligned} \eta_{gh}(H) &= [H, {}_{2M} (gh)^G] \leq [H, {}_{2M} \left\langle g^G \cup h^G \right\rangle] \\ &= \left\langle [H, {}_{2M} g^G \cup h^G]_{\mathrm{set}} \right\rangle && \text{(by Lemma 1)} \\ &\leq \eta_g(H)\eta_h(H). \end{aligned}$$

The last step is because each of the commutators in $[H, {}_{2M} g^G \cup h^G]_{\mathrm{set}}$ either contains at least M terms from g^G and, thus, is in $\eta_g(H)$ or it contains at least M terms from h^G.

The third point is an immediate consequence of the second point and Lemma 3. ◀

▶ **Lemma 13.** *Suppose that $K \trianglelefteq G$ is a normal subgroup satisfying $\eta_g(K) = K$ for some $g \in G$. Then K is inducible.*

Proof. Because $\eta_g(K) = K$ for some $g \in G$ implies that $K = [K, G]$, it follows from Lemma 4 that K is inducible. ◀

▶ **Theorem 14.** *Let G be a finite solvable group of Fitting length three and assume there are normal subgroups $K \trianglelefteq H \trianglelefteq G$ such that $\mathrm{FitLen}(K) = 2$, $\mathcal{U}_2 G \leq H$, and $|G/H| \geq 3$. Moreover, assume that*

(I) *for all $g \in G \setminus H$ we have $\eta_g(K) = K$,*

(II) *for all $h \in H$ we have $\mathrm{FitLen}(\eta_h(K)) \leq 1$.*

Then EQN-SAT(G) and EQN-ID(G) cannot be decided in deterministic time $2^{o(\log^2 N)}$ under ETH where N is the length of the input expression. In particular, EQN-SAT(G) and EQN-ID(G) are not in P *under ETH.*

Proof outline. The crucial observation for this theorem is the same as for Proposition 8: that, roughly speaking, the n-input AND can be decomposed into the conjunction of $\sqrt{n}$ many $\sqrt{n}$-input ANDs. We use this observation in order to reduce the C-Coloring problem to EQN-SAT. More precisely, given a graph Γ with n vertices and m edges, we construct an expression δ and an element $\tilde{h} \in G$ such that

(A) the length of δ is in $2^{\mathcal{O}(\sqrt{m+n})}$,
(B) δ can be computed in time polynomial in its length,
(C) $\delta = \tilde{h}$ is satisfiable if and only if Γ has a valid C-coloring, and
(D) $\sigma(\delta) = 1$ holds for all assignments σ if and only if Γ does *not* have a valid C-coloring.

For the number of colors we use $C = |G/H|$. Let N denote the input length for EQN-SAT (resp. EQN-ID). A $2^{o(\log^2 N)}$-time algorithm for EQN-SAT (resp. EQN-ID), thus, would imply a $2^{o(n+m)}$-time algorithm for C-Coloring contradicting ETH. Hence, it is enough to show points (A)–(D).

In order to construct the expression δ, we assign a variable X_i to every vertex v_i of Γ. Every assignment σ to the variables X_i will give us a coloring χ_σ of Γ (to be defined later). During the proof, we also introduce some auxiliary variables. The aim is to construct δ in a way that an assignment σ to the variables X_i can be extended to a satisfying assignment for $\delta = \tilde{h}$ if and only if χ_σ is a valid coloring of Γ (see Lemma 17).

We start by grouping the edges into roughly $\sqrt{m}$ batches of $\sqrt{m}$ edges each. For each batch of edges, we construct an expression γ_r (where r is the number of the batch) such that for every assignment σ to the variables X_i we have

- if χ_σ assigns the same color to two endpoints of an edge in the r-th batch, then for every assignment to the auxiliary variables, γ_r evaluates to something in $\mathcal{U}_1 K$,
- otherwise, for every element $h \in K$, there is an assignment to the auxiliary variables such that γ_r evaluates to h.

A more formal statement of this can be found in Lemma 15. The expression δ combines all the γ_r as an iterated commutator such that if one of the γ_r evaluates to something in $\mathcal{U}_1 K$, then δ evaluates to 1, and, otherwise, there is some assignment to the auxiliary variables such that δ evaluates to the fixed element $\tilde{h}$.

Proof. Let $C = |G/H|$. Let us describe how the C-Coloring problem for a given graph $\Gamma = (V, E)$ is reduced to an instance of EQN-SAT (resp. EQN-ID). We denote $V = \{ v_1, \dots, v_n \}$. For every vertex v_i we introduce a variable X_i and we set $\mathcal{X} = \{ X_1, \dots, X_n \}$. By fixing a bijection $|G/H| \to [1 .. C]$, we obtain a correspondence between assignments $\mathcal{X} \to G$ and colorings $V \to [1 .. C]$ (be aware that it is *not* one-to-one). During the construction we will also introduce a set $\mathcal{Y}$ of auxiliary variables. As outlined above, the idea is that an assignment $\mathcal{X} \to G$ represents a valid coloring if and only if there is an assignment to the auxiliary variables under which the equation evaluates to a non-identity element.

For each edge $\{ v_i, v_j \} \in E$, we introduce one edge gadget $X_i X_j^{-1}$ (it does not matter which one is the positive variable). Now, we group these gadgets into R batches of R elements each (if the number of gadgets is not a square, we duplicate some gadgets) – i.e., we choose $R = \lceil \sqrt{m} \rceil$. How the gadgets exactly are grouped together does not matter.

For $r \in [1 .. R]$ and $k \in [1 .. |K|]$ let $\alpha_{r,k}$ be an expression which induces K (i.e., all $\alpha_{r,k}$ are the same expressions but with disjoint sets of variables). Such expressions exist by Lemma 13. Let the variables of $\alpha_{r,k}$ be $Y_{r,k,t}$ for $t \in [1 .. T]$ for some $T \in \mathbb{N}$. Moreover, we introduce more auxiliary variables $Z_{r,k,s,\nu}$ for $r \in [1 .. R]$, $k \in [1 .. |K|]$, $s \in [1 .. R]$, and $\nu \in [1 .. M]$ (recall that M is chosen such that, in particular, $[H_1, {}_M\, H_2] = [H_1, {}_{M+1}\, H_2]$ for arbitrary normal subgroups H_1, H_2 of G) and we set

$$\mathcal{Y}'_r = \left\{ Z_{r,k,s,\nu},\ Y_{r,k,t} \;\middle|\; k \in [1 .. |K|], s \in [1 .. R], \nu \in [1 .. M], t \in [1 .. T] \right\}.$$

Let $\beta_{r,1}, \dots, \beta_{r,R}$ be the gadgets of the r-th batch for some $r \in [1 .. R]$. We define

$$\gamma_r = \prod_{k=1}^{|K|} \left[\alpha_{r,k}, \beta_{r,1}^{Z_{r,k,1,1}}, \dots, \beta_{r,1}^{Z_{r,k,1,M}}, \dots, \beta_{r,R}^{Z_{r,k,R,1}}, \dots, \beta_{r,R}^{Z_{r,k,R,M}} \right]. \tag{1}$$

We do this for every batch of gadgets. The following observation is crucial:

▶ **Lemma 15.** *Let $\sigma\colon \mathcal{X} \to G$ be an assignment and let $r \in [1 \mathinner{..} R]$.*

- *If $\sigma(\beta_{r,s}) \in G \setminus H$ for all s, then $\left\{\, (\sigma \cup \sigma')(\gamma_r) \;\middle|\; \sigma' : \mathcal{Y}'_r \to G \,\right\} = K$,*
- *Otherwise, $\left\{\, (\sigma \cup \sigma')(\gamma_r) \;\middle|\; \sigma' : \mathcal{Y}'_r \to G \,\right\} \leq \mathcal{U}_1 K$.*

Proof. By construction, we have $(\sigma \cup \sigma')(\alpha_{r,k}) \in K$ for all r and k and all assignments σ and σ'. Since K is normal, it follows that $(\sigma \cup \sigma')(\gamma_r) \in K$ for all assignments σ and σ'.

Consider the case that $g_s \coloneqq \sigma(\beta_{r,s}) \in G \setminus H$ for all $s \in [1 \mathinner{..} R]$. By assumption (I), we have $K = \eta_{g_1}(K) = \eta_{g_2}(\eta_{g_1}(K)) = \cdots = \eta_{g_R} \ldots \eta_{g_2}(\eta_{g_1}(K)) \cdots)$. By Lemma 1, it follows that $K = \left\langle [K, {}_M\, g_1^G, \ldots, {}_M\, g_R^G]_{\mathrm{set}} \right\rangle$. Since $1 \in [K, {}_M\, g_1^G, \ldots, {}_M\, g_R^G]_{\mathrm{set}}$ and every element in K can be written as a product of length at most $|K|$ over any generating set, we conclude $K = \left([K, {}_M\, g_1^G, \ldots, {}_M\, g_R^G]_{\mathrm{set}}\right)^{|K|}$. This is exactly the form how γ_r was defined in Equation (1) (recall that $\alpha_{r,s}$ can evaluate to every element of K). Therefore, for each $h \in K$, there is an assignment $\sigma'\colon \mathcal{Y}'_r \to G$ such that $(\sigma \cup \sigma')(\gamma_r) = h$.

On the other hand, let $g_s \coloneqq \sigma(\beta_{r,s}) \in H$ for some s. Then, by assumption (II) we have $\mathrm{FitLen}(\eta_{g_s}(K)) \leq 1$. Since $(\sigma \cup \sigma')(\gamma_r) \in \eta_{g_s}(K)$, we obtain $(\sigma \cup \sigma')(\gamma_r) \in \mathcal{U}_1 K$ by Lemma 3. ◀

Now, for every set of auxiliary variables $\mathcal{Y}'_r$ we introduce M disjoint copies, which we call $\mathcal{Y}_r^{(\mu)}$ for $\mu \in [1 \mathinner{..} M]$. We write $\gamma_r^{(\mu)}$ for the copy of γ_r where the variables of $\mathcal{Y}'_r$ are substituted by the corresponding ones in $\mathcal{Y}_r^{(\mu)}$ (the variables $\mathcal{X}$ are shared over all $\gamma_r^{(\mu)}$). We set

$$\delta = \left[\gamma_1^{(1)}, \ldots, \gamma_1^{(M)}, \ldots, \gamma_R^{(1)}, \ldots, \gamma_R^{(M)}\right].$$

Finally, fix some $\tilde{h} \in K \setminus 1$ with $\tilde{h} \in [{}_{M \cdot R}\, K]_{\mathrm{set}}$ and set $\mathcal{Y} = \bigcup_{r,\mu} \mathcal{Y}_r^{(\mu)}$.

▶ **Lemma 16.** *Let $\sigma\colon \mathcal{X} \to G$ be an assignment. If $\sigma(\beta_{r,s}) \in G \setminus H$ for all r and s, then there is some assignment $\sigma'\colon \mathcal{Y} \to G$ such that $(\sigma \cup \sigma')(\delta) = \tilde{h}$. Otherwise $(\sigma \cup \sigma')(\delta) = 1$ for all $\sigma'\colon \mathcal{Y} \to G$.*

Proof. If $\sigma(\beta_{r,s}) \in G \setminus H$ for all r and s, then by Lemma 15, $\left\{(\sigma \cup \sigma')(\gamma_r^{(\mu)}) \;\middle|\; \sigma' : \mathcal{Y}_r^{(\mu)} \to G\right\} = K$ for all $r \in [1 \mathinner{..} R]$ and $\mu \in [1 \mathinner{..} M]$. Hence, since we chose the auxiliary variables $\mathcal{Y}_r^{(\mu)}$ to be all disjoint, we obtain

$$\tilde{h} \in [{}_{M \cdot R}\, K]_{\mathrm{set}} \subseteq \left\{\, (\sigma \cup \sigma')(\delta) \;\middle|\; \sigma' : \mathcal{Y}_r^{(\mu)} \to G \,\right\}.$$

On the other hand, if $\sigma(\beta_{r,s}) \in H$, then, by Lemma 15, for all $\sigma'\colon \mathcal{Y} \to G$ and all $\mu \in [1 \mathinner{..} M]$ we have $(\sigma \cup \sigma')(\gamma_r^{(\mu)}) \in \mathcal{U}_1 K$. Hence, $(\sigma \cup \sigma')(\delta) \in [{}_M\, \mathcal{U}_1 K] = 1$. ◀

Now we are ready to define our equation as $\delta \tilde{h}^{-1}$ for the reduction of C-Coloring to EQN-SAT(G) and δ for the reduction to EQN-ID(G).

The final step is to show points (A)–(D) from above.

For (A) observe that the length of γ_r is $\mathcal{O}(2^{M \cdot R})$ for all r. Thus, the length of δ is $\mathcal{O}(2^{M \cdot R}) \cdot \mathcal{O}(2^{M \cdot R}) \subseteq 2^{\mathcal{O}(R)} = 2^{\mathcal{O}(\sqrt{m})}$ as desired. Point (B) is straightforward from the construction of δ.

In order to see (C) and (D), we use Lemma 16 to prove another lemma. We fix a bijection $\xi : G/H \to [1 \mathinner{..} C]$. For an assignment $\sigma : \mathcal{X} \to G$, we define a corresponding coloring $\chi_\sigma : V \to [1 \mathinner{..} C]$ by $\chi_\sigma(v_i) = \xi(\sigma(X_i)H)$.

▶ **Lemma 17.** *Let $\sigma : \mathcal{X} \to G$ be an assignment. Then*

- *if χ_σ is valid, then there is an assignment $\sigma' : \mathcal{Y} \to G$ such that $(\sigma \cup \sigma')(\delta) = \tilde{h} \neq 1$,*
- *if χ_σ is* not *valid, then for all assignments $\sigma' : \mathcal{Y} \to G$ we have $(\sigma \cup \sigma')(\delta) = 1$.*

Proof. Let χ_σ be a valid coloring. First, observe that the gadgets all evaluate to some element outside of H under σ. This is because, if there is a gadget $X_i X_j^{-1}$ that means that $\{ v_i, v_j \} \in E$ and so $\chi_\sigma(v_i) \neq \chi_\sigma(v_j)$; hence, $\sigma(X_i) \neq \sigma(X_j)$ in G/H (since ξ is a bijection). Therefore, by Lemma 16, it follows that δ evaluates to $\tilde{h}$ under some proper assignment for $\mathcal{Y}$.

On the other hand, if χ_σ is not a valid coloring, then there is an edge $\{ v_i, v_j \} \in E$ with $\chi_\sigma(v_i) = \chi_\sigma(v_j)$. Then we have $\sigma(X_i)H = \sigma(X_j)H$. Hence, by Lemma 16, we obtain that $(\sigma_\chi \cup \sigma')(\delta) = 1$ in G for every $\sigma' : \mathcal{Y} \to G$. ◀

This concludes the proof of Theorem 14. ◀

5 Consequences

In this section we derive our main result Corollary A. We start again with a lemma.

▶ **Lemma 18.** *For every finite solvable, non-nilpotent group G of Fitting length d, there are proper normal subgroups $K \trianglelefteq H \triangleleft G$ with $\mathrm{FitLen}(K) = d - 1$ and $\mathcal{U}_{d-1}G \leq H$ such that*

- *for all $g \in G \setminus H$ we have $\eta_g(K) = K$,*
- *for all $h \in H$ we have $\mathrm{FitLen}(\eta_h(K)) < \mathrm{FitLen}(K)$.*

The construction for Lemma 18 resembles the ones in Lemmas 5 and 6 of [31]. However, while in [31] a minimal normal subgroup N of a quotient G/K is constructed such that r_g with $r_g(x) = [x, g]$ is an automorphism of N (and N is abelian), in our case this is not enough since we need to apply commutator constructions to our analog of N in the spirit of the divide-and-conquer approach of Proposition 8.

Proof. Let $g_1 \in G \setminus \mathcal{U}_{d-1}G$ where d is the Fitting length of G. We construct a sequence of normal subgroups $K_1, K_2, \ldots$ of G as follows: we set $K_1 = \eta_{g_1}(G)$. By Lemma 2, $K_1 = \gamma_\infty \langle g_1^G \rangle$, so it has Fitting length $d - 1$.

Now, while there is some $g_i \in G$ such that $\eta_{g_i}(K_{i-1}) < K_{i-1}$ and $\mathrm{FitLen}(\eta_{g_i}(K_{i-1})) = \mathrm{FitLen}(K_{i-1})$, we set $K_i = \eta_{g_i}(K_{i-1})$ and continue. Since K_i is a proper subgroup of K_{i-1}, this process eventually terminates. We call the last term K. We claim that K satisfies the statement of Lemma 18. By construction for every $g \in G$ one of the two cases

- $\eta_g(K) = K$ or
- $\mathrm{FitLen}(\eta_g(K)) < \mathrm{FitLen}(K)$

applies. Moreover, since $K = \eta_g(K')$ for some $K' \leq G$ and some $g \in G$, we have $K = \eta_g(K') = \eta_g(\eta_g(K')) = \eta_g(K)$ by Lemma 12 (i). By Lemma 12 (iii), the elements $\{ h \in G \mid \mathrm{FitLen}(\eta_h(K)) < \mathrm{FitLen}(K) \}$ form a subgroup H of G. Clearly H is normal (by the definition of η_h) and $\mathcal{U}_{d-1}G \leq H$ because $\mathrm{FitLen}([K, {}_M\, \mathcal{U}_{d-1}G]) = \mathrm{FitLen}(K) - 1$. Since there is some $g \in G$ with $K = \eta_g(K)$, we have $H \neq G$. ◀

Be aware that K depends on the order the g_i were chosen. Indeed, if G is a direct product of two groups G_1 and G_2 of equal Fitting length, then K will either be contained in G_1 or in G_2 – in which factor depends on the choice of the g_i.

▶ **Theorem 19** (Corollary A). *Let G be a finite solvable group such that either* $\mathrm{FitLen}(G) = 3$ *and $|G/\mathcal{U}_2G|$ has a prime divisor 3 or greater (i.e., $G/\mathcal{U}_2G$ is not a 2-group) or* $\mathrm{FitLen}(G) \geq 4$. *Then EQN-SAT$(G)$ and EQN-ID(G) cannot be decided in deterministic time $2^{o(\log^2 N)}$ under ETH. In particular, EQN-SAT(G) and EQN-ID(G) are not in* P *under ETH.*

Proof. Consider the case that G has Fitting length 3 and $|G/\mathcal{U}_2G|$ has a prime divisor 3 or greater. Let 2^ν for some $\nu \in \mathbb{N}$ be the greatest power of two dividing $|G/\mathcal{U}_2G|$. Then, the subgroup $\widetilde{G}$ generated by all 2^ν-th powers is normal and it is not contained in $\mathcal{U}_2G$. Therefore, by Lemma 3 it has Fitting length 3 as well. Also, by Lemma 3, we know that $\mathcal{U}_2\widetilde{G} = \widetilde{G} \cap \mathcal{U}_2G$. Hence, $\widetilde{G}/\mathcal{U}_2\widetilde{G}$ is a subgroup of $G/\mathcal{U}_2G$. Moreover, since $\widetilde{G}$ is generated by 2^ν-th powers, the generators of $\widetilde{G}$ have odd order in $\widetilde{G}/\mathcal{U}_2\widetilde{G}$. Since $\widetilde{G}/\mathcal{U}_2\widetilde{G}$ is nilpotent, it follows that $|\widetilde{G}/\mathcal{U}_2\widetilde{G}|$ is odd (recall that a nilpotent group is a direct product of p-groups).

Since $\widetilde{G}$ is inducible in G, by Lemma 5, it suffices to show that $\widetilde{G}$ satisfies the requirements of Theorem 14. For this, we use Lemma 18, which gives us normal subgroups $K \trianglelefteq H \triangleleft \widetilde{G}$ with $\mathcal{U}_2\widetilde{G} \leq H$, $\mathrm{FitLen}(K) = 2$ and such that for all $g \in \widetilde{G} \setminus H$ we have $\eta_g(K) = K$, and for all $h \in H$ we have $\mathrm{FitLen}(\eta_h(K)) \leq 1$.

It only remains to show that $|\widetilde{G}/H| \geq 3$. Since $H \neq \widetilde{G}$ and $|\widetilde{G}/H|$ is odd, this holds trivially. Thus, both EQN-SAT(G) and EQN-ID(G) are not in P under ETH if G has Fitting length 3 and $|G/\mathcal{U}_2G|$ a prime divisor 3 or greater.

The second case can be reduced to the first case as follows: Assume that G has Fitting length $d \geq 4$. If $|G/\mathcal{U}_{d-1}G|$ has a prime factor 3 or greater, we can apply the Fitting length 3 case to $G/\mathcal{L}_3G$ for EQN-SAT and to $G/\mathcal{U}_{d-3}G$ for EQN-ID. By Lemma 4 and Lemma 5 this implies the corollary for EQN-SAT. For EQN-ID, the statement follows form Lemma 6 and Lemma 7.

On the other hand, if $|G/\mathcal{U}_{d-1}G| = 2^\nu$ for some $\nu \geq 1$, as in the first case, we consider the subgroup $\widetilde{G}$ generated by all 2^ν-th powers. Then the index of $\widetilde{G}$ in G is again a power of two (since the order of every element in $G/\widetilde{G}$ is a power of two). Moreover, $\widetilde{G} \leq \mathcal{U}_{d-1}G$ and, by Lemma 3, we have

$$\widetilde{G}/\mathcal{U}_{d-2}\widetilde{G} = \widetilde{G}/(\mathcal{U}_{d-2}G \cap \widetilde{G}) \cong (\widetilde{G} \cdot \mathcal{U}_{d-2}G)/\mathcal{U}_{d-2}G \leq \mathcal{U}_{d-1}G/\mathcal{U}_{d-2}G.$$

Now, $|\mathcal{U}_{d-1}G/\mathcal{U}_{d-2}G|$ cannot be a power of two because, otherwise, $G/\mathcal{U}_{d-2}G$ would be a 2-group and, thus, nilpotent – contradicting the fact that the upper Fitting series is a shortest Fitting series. Since the index of $\widetilde{G}$ in $\mathcal{U}_{d-1}G$ is a power of two, we see that $\widetilde{G} \not\subseteq \mathcal{U}_{d-2}G$ and that the index of $\mathcal{U}_{d-2}\widetilde{G}$ in $\widetilde{G}$ has a prime factor other than 2. Therefore, we can apply the Fitting length 3 case to $\widetilde{G}/\mathcal{L}_3\widetilde{G}$ (resp. $\widetilde{G}/\mathcal{U}_{d-3}\widetilde{G}$). ◀

The case that $G/\mathcal{U}_2G$ is a 2-group. As mentioned above, in the recent paper [24] Idziak, Kawałek, and Krzaczkowski proved a $2^{\mathcal{O}(\log^2(n))}$-lower bound under ETH for EQN-SAT(S_4). They apply a reduction of 3SAT to EQN-SAT(S_4). Instead of using commutators to simulate conjunctions in the group, the more complicated logical function $(X, Y_1, Y_2, Y_3) \mapsto X \wedge (Y_1 \vee Y_2 \vee Y_3)$ is encoded into the group. Indeed, under suitable assumptions on the group and the range of the variables, both the expressions $w(X, Y_1, Y_2, Y_3) = X^8[X, Y_1, Y_2, Y_3]$ (see [31]) and $s(X, Y_1, Y_2, Y_3) = X\,[X, Y_1, Y_2, Y_3]^{-1}$ (see [16] – referred to by [24]) simulate this logical function. A new paper unifying our approaches and proving Theorem 19 for *all* groups of Fitting length 3 is under preparation.

Consequences for ProgramSAT. We have EQN-SAT$(G) \leq_{\mathrm{m}}^{\mathsf{AC}^0}$ ProgramSAT(G) for every finite group G by [5, Lem. 1] (while not explicitly stated, it is clear that this reduction is an AC^0-reduction). Thus, by Theorem 14, ProgramSAT(G) is not in P under ETH if G is of Fitting length at least 4 or G is of Fitting length 3 and $G/\mathcal{U}_2G$ is not a 2-group.

Table 1 Groups up to order 767 for which Theorem 19 gives lower bounds.

Small groups for which Theorem 19 gives a lower bound. In [19] lists of groups are given where the complexity of EQN-SAT and EQN-ID is unknown. The paper refers to a more comprehensive list available on the author's website `http://math.unideb.hu/horvath-gabor/research.html`. We downloaded the lists of groups and ran tests in GAP for which of these groups Theorem 19 provides lower bounds. In the list with unknown complexity for EQN-ID there are 2331 groups of order less than 768 out of which 1559 are of Fitting length three or greater. Theorem 19 applies to 22 of them: 3 groups of Fitting length 4 and 19 groups G of Fitting length 2 where $G/\mathcal{U}_2G$ is not a 2-group. A list of the groups for which we could prove lower bounds can be found in Table 1.

5.1 Equations in finite semigroups

For a semigroup S, the problems EQN-SAT(S) and EQN-ID(S) both receive two expressions as input. The questions is whether the two expressions evaluate to the same element under some (resp. all) assignments. For semigroups R, S we say that R *divides* S if R is a quotient of a subsemigroup of S. The following lemmas are straightforward to prove using basic semigroup theory.

For the proofs, we need Green's relations $\mathcal{H}$ and $\mathcal{J}$. For a definition, we refer to [35, Appendix A]. For a semigroup S we write S^1 for S with an identity adjoined if there is none.

▶ **Lemma 20.** *If G is a maximal subgroup of a finite semigroup S, then EQN-SAT$(G) \le_{\mathrm{m}}^{\mathsf{AC}^0}$ EQN-SAT(S).*

Proof. Let $e \in G$ denote the identity of G. Clearly, $G = eGe \le eSe$ and eSe is a submonoid of S with identity e. The reduction simply replaces every variable X by eXe (and likewise for constants). Let $\tilde{\alpha}$ denote the equation we obtain from an input equation α this way. Now the question is whether $\tilde{\alpha} = e$ in S. Clearly, if α has a solution in G, the resulting equation $\tilde{\alpha}$ has a solution in S. On the other hand, if $\tilde{\alpha}$ has a solution in S, we obtain a solution of $\alpha = e$ in S where every variable takes values in eSe.

Assume we have $\sigma(X) = x \notin G$ for a satisfying assignment σ and some variable X of α. Since $\sigma(\alpha) = e$, we have that e is in the two-sided ideal $S^1 x S^1$ generated by $x = exe$. By point 2. of [35, Exercise A.2.2] it follows that $x \in H_e = G$ where H_e denotes the $\mathcal{H}$-class of e under Green's relations (for a definition, we refer to [35]) and G agrees with H_e because G is a maximal subgroup. ◀

▶ **Lemma 21.** *If a group G divides a semigroup S, then G divides already one of the maximal subgroups (i.e., regular $\mathcal{H}$-classes) of S.*

Proof. Let $U \leq S$ a subsemigroup and $\varphi : U \to G$ a surjective semigroup homomorphism. Pick some arbitrary element $s \in U$ and let $e = s^{\omega}$ be the idempotent generated by s. Clearly, we have $\varphi(e) = 1$. Now, the subsemigroup $eUe \leq U$ still maps surjectively onto G under φ: by assumption for every $g \in G$ there is some $u_g \in U$ with $\varphi(u_g) = g$; hence, $g = 1g1 = \varphi(e)\varphi(u_g)\varphi(e) \in \varphi(eUe)$.

If eUe is not contained in a maximal subgroup, then by point 2. of [35, Exercise A.2.2], there is some $t \in eUe$ which is not $\mathcal{J}$-equivalent to e. Now, we can repeat the above process starting with t. This will decrease the size of U, so it eventually terminates. ◀

▶ **Corollary 22.** *Let S be a finite semigroup and G a group dividing S. If $\mathrm{FitLen}(G) \geq 4$ or $\mathrm{FitLen}(G) = 3$ and $G/\mathcal{U}_2 G$ is not a 2-group, then EQN-SAT(S) is not in P under ETH.*

Proof. If G with $\mathrm{FitLen}(G) \geq 4$ or $\mathrm{FitLen}(G) = 3$ and $G/\mathcal{U}_2 G$ divides S, then it follows from Lemma 21 that there is a group $\widetilde{G}$ with the same properties and which is a maximal subgroup of S. Hence, the statement follows from Lemma 20. ◀

[2, Theorem 1] states that identity checking over $\widetilde{G}$ reduces to identity checking over S where $\widetilde{G}$ is the direct product of all maximal subgroups of S. However, be aware that in this context the identity checking problem does not allow constants. Since the proof of Theorem 14 essentially relies on the fact that the subgroup K is inducible and this can be only shown using constants, this does not allow us to show hardness of EQN-ID(S).

6 Conclusion

We have shown that assuming the exponential time hypothesis there are solvable groups with equation satisfiability problem not decidable in polynomial time. Thus, under standard assumptions from complexity theory this means a negative answer to [9, Problem 1] (also conjectured in [18]). Theorem 19 yields a quasipolynomial time lower bound under ETH. Thus, a natural weakening of [9, Problem 1] is as follows:

▶ **Conjecture 2.** *If G is a finite solvable group, then EQN-SAT(G) and EQN-ID(G) are decidable in quasipolynomial time.*

In [5, Theorem 2] it is proved that ProgramSAT(G) and, hence, also EQN-SAT(G) can be decided in quasipolynomial time given that G is AND-weak. As remarked in Section 3 this theorem remains valid with our slightly less restrictive definition of AND-weakness in Conjecture 1. Thus, Conjecture 1 implies Conjecture 2. In particular, under the assumption of both ETH and the AND-weakness conjecture (Conjecture 1), for every finite solvable group G meeting the requirements of Theorem 19 there are quasipolynomial upper and lower bounds for EQN-SAT(G) and EQN-ID(G) – so under these assumptions both problems are neither in P nor NP-complete. This contrasts the situation for solving systems of equations: there is a clear P versus NP-complete dichotomy [15].

Theorem 19 proves lower bounds on EQN-SAT and EQN-ID for all sufficiently complicated finite solvable groups. As outlined above, together with the authors of [24] the extension to *all* groups of Fitting length three is under preparation. As a refinement we plan to show that under ETH there is no $2^{o(n^{1/(d-1)})}$-time algorithm for EQN-SAT(G) and EQN-ID(G) where d is the Fitting length of G. Possible further research might address the complexity of EQN-SAT and EQN-ID in groups of Fitting length two. The results presented in the introduction suggest that these cases can be solved in polynomial time.

▶ **Conjecture 3.** *If G is a finite solvable group of Fitting length two, then EQN-SAT(G) and EQN-ID(G) are decidable in polynomial time.*

Another direction for future work is the complexity of EQN-ID for expressions without constants.

Graph Isomorphism in Quasipolynomial Time Parameterized by Treewidth

Daniel Wiebking
RWTH Aachen University, Germany
wiebking@informatik.rwth-aachen.de

Abstract

We extend Babai's quasipolynomial-time graph isomorphism test (STOC 2016) and develop a quasipolynomial-time algorithm for the multiple-coset isomorphism problem. The algorithm for the multiple-coset isomorphism problem allows to exploit graph decompositions of the given input graphs within Babai's group-theoretic framework.

We use it to develop a graph isomorphism test that runs in time $n^{\operatorname{polylog}(k)}$ where n is the number of vertices and k is the minimum treewidth of the given graphs and $\operatorname{polylog}(k)$ is some polynomial in $\log(k)$. Our result generalizes Babai's quasipolynomial-time graph isomorphism test.

1 Introduction

The graph isomorphism problem asks for a structure preserving bijection between two given graphs G and H, i.e., a bijection $\varphi : V(G) \to V(H)$ such that $vw \in E(G)$ if and only if $\varphi(v)\varphi(w) \in E(H)$. One central open problem in theoretical computer science is the question whether the graph isomorphism problem can be solved in polynomial time. There are a few evidences that the problem might not be NP-hard. For example, NP-hardness of the problem implies a collapse of the polynomial hierarchy [32]. Moreover, NP-hardness of the graph isomorphism problem would refute the exponential time hypothesis since the problem can be decided in quasipolynomial time [1].

The research of the graph isomorphism problem started with two fundamental graph classes, i.e., the class of trees and the class of planar graphs. In 1970, Zemlyachenko gave a polynomial-time isomorphism algorithm for trees [37]. One year later, Hopcroft and Tarjan extended a result of Weinberg and designed a polynomial-time isomorphism algorithm for planar graphs [16],[34]. In 1980, Filotti, Mayer and Miller extended the polynomial-time algorithm to graphs of bounded genus [24],[10][1]. The genus is a graph parameter that measures how far away the graph is from being planar.

In Luks's pioneering work in 1982, he gave a polynomial-time isomorphism algorithm for graphs of bounded degree [22]. His group-theoretic approach laid the foundation of many other algorithms that were developed ever since. It turns out that the research in the

[1] Myrvold and Kocay pointed out an error in Filotti's techniques [26]. However, different algorithms have been given which show that the graph isomorphism problem for graphs of bounded genus is indeed decidable in polynomial time [25, 11, 17].

graph isomorphism problem for restricted graph classes was a promising approach in tackling the graph isomorphism problem in general. Shortly after Luks's result, a combinatorial partitioning lemma by Zemlyachenko was combined with Luks's framework. This resulted in an isomorphism algorithm for graphs with n vertices in general that runs in time $2^{\mathcal{O}(\sqrt{n \log n})}$ [38],[4]. This algorithm was the fastest for decades.

In 1983, the seminal work of Robertson and Seymour in graph minors started a new era of graph theory [30]. At the same time, Miller extended Luks's group-theoretic framework to hypergraphs [25]. It turned out that the study of general structures such as hypergraphs was also a promising approach in tackling the graph isomorphism problem. In 1991, Ponomarenko could in fact use Miller's hypergraph algorithm to design a polynomial-time isomorphism algorithm for graphs excluding a minor [29].

The work of Robertson and Seymour also rediscovered the notion of treewidth [8], a graph parameter that measures how far away the graph is from being a tree. The treewidth parameter was reborn and has been studied ever since. So, researchers went back to the roots and studied the isomorphism problem for graphs of bounded treewidth. In 1990, Bodlaender gave a simple isomorphism-algorithm for graphs of treewidth k with n vertices that runs in time $n^{\mathcal{O}(k)}$ [5]. However, no FPT-algorithm was known, i.e., an isomorphism algorithm with a running time of the form $f(k) \cdot n^{\mathcal{O}(1)}$. The search of a FPT-algorithm occupied researchers over years and this open problem was explicitly stated by several authors [36, 6, 18, 19, 28, 7, 9, 12]. In 2017, Lokshtanov, Pilipczuk, Pilipczuk and Saurabh finally solved this open problem and designed a FPT-algorithm for the graph isomorphism problem [21]. Their algorithm runs in time $2^{\mathcal{O}(k^5 \log k)} n^{\mathcal{O}(1)}$ where n is the number of vertices and k is the minimum treewidth of the given graphs.

At the same time, Babai made a breakthrough and designed a quasipolynomial-time algorithm for the graph isomorphism problem in general [1]. His algorithm runs in time $n^{\mathrm{polylog}(n)}$ where n is the number of vertices and $\mathrm{polylog}(n)$ is some polynomial in $\log(n)$ (according to Helfgott's analysis the function $\mathrm{polylog}(n)$ can chosen to be quadratic in $\log(n)$ [15]). To achieve this result, Babai built on Luks's group-theoretic framework, which actually solves the more general string isomorphism problem. One of the main questions is how to combine Babai's group-theoretic algorithm with the graph-theoretic techniques that have been developed. For example, it is unclear how to exploit a decomposition of the given graphs within Babai's framework since his algorithm actually processes strings rather than graphs.

Recently, Grohe, Neuen and Schweitzer were able to extend Babai's algorithm to graphs of maximum degree d and an isomorphism algorithm was developed that runs in time $n^{\mathrm{polylog}(d)}$ [13]. They suggest that their techniques might be useful also for graphs parameterized by treewidth and conjectured that the isomorphism problem for graphs of treewidth k can be decided in time $n^{\mathrm{polylog}(k)}$.

In [14], the graph-theoretic FPT-algorithm of Lokshtanov et al. was improved by using Babai's group-theoretic algorithm and the extension given by Grohe et al. as a black box. They decomposed a graph of bounded treewidth into subgraphs with particular properties. They were able to design a faster algorithm that computes the isomorphisms between these subgraphs. However, they pointed out a central problem that arises when dealing with graph decompositions: When the isomorphisms between these subgraphs are already computed, how can they be efficiently merged in order to compute the isomorphisms between the entire graphs? This problem was named as *multiple-coset isomorphism problem* and is formally defined as follows. Given two sets $J = \{\rho_1 \Delta_1^{\mathrm{Can}}, \ldots, \rho_t \Delta_t^{\mathrm{Can}}\}$ and $J' = \{\rho'_1 \Delta'^{\mathrm{Can}}_1, \ldots, \rho'_t \Delta'^{\mathrm{Can}}_t\}$ where $\rho_i : V \to n, \rho'_i : V' \to n$ are bijections and $\Delta_i^{\mathrm{Can}}, \Delta'^{\mathrm{Can}}_i \leq \mathrm{Sym}([n])$ are permutation groups for all $i \in [t]$, the problem is to decide whether there are bijections $\varphi : V \to V', \psi : [t] \to [t]$ such that $\Delta_i^{\mathrm{Can}} = \Delta'^{\mathrm{Can}}_{\psi(i)}$ and $\varphi \in \rho_i \Delta_i^{\mathrm{Can}}(\rho'_{\psi(i)})^{-1}$ for all $i \in [t]$. By applying the group-theoretic black box algorithms, they achieved an improved isomorphism test for graphs of treewidth k that runs in time $2^{k \cdot \mathrm{polylog}(k)} n^{\mathcal{O}(1)}$. However, for further improvements, it did not seem to be enough to use the group-theoretic algorithms as a black box only. The question of an isomorphism algorithm that runs in time $n^{\mathrm{polylog}(k)}$ remained open.

In [31], the study of the multiple-coset isomorphism problem continued. Rather than using group-theoretic algorithms as a black box, they were able to extend Luks's group-theoretic framework to the multiple-coset isomorphism problem. In order to facilitate their recursion, they introduced the class of combinatorial objects. Their class of combinatorial objects contains hypergraphs, colored graphs, relational structures, explicitly given codes and more. However, the key idea in order to handle the involved structures recursively, was to add so-called labeling cosets to their structures. By doing so, they could combine combinatorial decomposition techniques with Luks's group-theoretic framework. This led to a simply-exponential time algorithm for the multiple-coset isomorphism problem. Although the achieved running time was far away from being quasipolynomial, their result led to improvements of several algorithms. For example, it led to the currently best algorithm for the normalizer problem (a central problem in computational group theory) [35]. However, they were not able to extend also Babai's techniques to their framework and the question of a graph isomorphism algorithm running in time $n^{\mathrm{polylog}(k)}$ remained open.

Our Contribution. In this paper, we give a quasipolynomial-time algorithm for the multiple-coset isomorphism problem. This leads to an answer of the conjecture in [13] mentioned above.

▶ **Theorem** (Theorem 10). *The graph isomorphism problem can be decided in time $n^{\mathrm{polylog}(k)}$ where n is the number of vertices and k is the minimum treewidth of the input graphs.*

When $k = \mathrm{polylog}(n)$, our algorithm runs in time $n^{\mathcal{O}(\log(\log n)^c)}$ (for some constant c) and is significantly faster than Babai's algorithm and existing FPT-algorithms for graphs parameterized by treewidth.

For the present work, we exploit the fact that Babai's algorithm was recently extended to canonization [3]. A canonical labeling of a graph is a function that labels the vertices V of the graph with integers $1, \dots, |V|$ in such a way that the labeled versions of two isomorphic graphs are equal (rather than isomorphic). The computation of canonical forms and labelings, rather than isomorphism testing, is an important task in the area of graph isomorphism and is especially useful for practical applications. Also the framework given in [31] is actually designed for the canonization problem. The present paper is based on these works and our algorithms provide canonical labelings as well. Only the algorithm given in the last section depends on the bounded-degree isomorphism algorithm of Grohe et al. for which no adequate canonization version is known.

The first necessary algorithm that we provide in our work is a simple canonization algorithm for hypergraphs.

▶ **Theorem** (Theorem 6). *Canonical labelings for hypergraphs (V, H) can be computed in time $(|V| + |H|)^{\mathrm{polylog}|V|}$.*

There is a simple argument why this algorithm is indeed necessary for our main result. It is well-known that a hypergraph $X = (V, H)$ can be encoded as a bipartite graph $G_X = (V \cup H, E)$ (the bipartite graph G_X has an edge $(v, S) \in E$, if and only if $v \in S$). It is not hard to show that the treewidth k of this bipartite graph G_X is at most $|V|$. The bipartite graph G_X uniquely encodes the hypergraph X, in particular, two hypergraphs are isomorphic if and only if their corresponding bipartite graphs are isomorphic. This means that an isomorphism algorithm for graphs of treewidth k running in time $n^{\mathrm{polylog}(k)}$ would imply an isomorphism algorithm for hypergraphs running in time $(|V|+|H|)^{\mathrm{polylog}|V|}$. However, applying Babai's algorithm to the bipartite graph would lead to a running time of $(|V|+|H|)^{\mathrm{polylog}(|V|+|H|)}$. Instead of applying Babai's algorithm to the bipartite graph directly, we decompose the hypergraph and canonize the substructures recursively. To merge the canonical labelings of all subhypergraphs, we use a canonical version of the multiple-coset isomorphism problem. However, for the hypergraph algorithm, it suffices to use Babai's algorithm as a black box only.

Our decomposition technique for hypergraphs can also be used to design a simple canonization algorithm for k-ary relations.

▶ **Theorem** (Theorem 5). *Canonical labelings for k-ary relations $R \subseteq V^k$ can be computed in time $2^{\mathrm{polylog}|V|}|R|^{\mathcal{O}(1)}$.*

The algorithm improves the currently best algorithm from [13]. As graphs can be seen as binary relations, our algorithm generalizes the quasipolynomial-time bound for graphs. The achieved running time is the best one can hope for as long as the graph isomorphism problem has no solution better than quasipolynomial time.

Our main algorithm finally solves the multiple-coset isomorphism problem. In fact, the algorithm computes canonical labelings as well.

▶ **Theorem** (Theorem 7). *Canonical labelings for a set J consisting of labeling cosets can be computed in time $(|V|+|J|)^{\mathrm{polylog}|V|}$.*

This result is actually of independent interest as it also implies a faster canonization algorithm for the entire class of combinatorial objects.

To solve this problem, the simple hypergraph canonization algorithm can be used as a subroutine in some places. However, we do not longer use Babai's and Luks's techniques as a black box only. To extend their methods, we follow the route of [31] and consider combinatorial objects that allows to combine combinatorial structures with permutation group theory. In particular, we can extend Luks's subgroup reduction and Babai's method and aggregation of local certificates to our framework. All these methods were designed for the string isomorphism problem and need non-trivial extensions when dealing with a set of labeling cosets rather than a string.

Related Work. Another extension of Babai's quasipolynomial time algorithm has been independently proposed by Daniel Neuen [27] who provided another algorithm for the isomorphism problem of hypergraphs. However, Neuen can exploit groups with restricted composition factors that are given as additional input in order to speed up his algorithm. This can be exploited in the setting of graphs of bounded Euler genus. He provides a graph isomorphism algorithm that runs in time $n^{\mathrm{polylog}(g)}$ where n is the number of vertices and g is the minimum genus of the given graphs.

On the other hand, his algorithm is not able to handle labeling cosets occurring in the combinatorial structures. In particular, his algorithm is not able to solve the multiple-coset isomorphism problem in the desired time bound, which we require for our isomorphism algorithm for graphs parameterized by treewidth. Moreover, his techniques do not provide canonical labelings.

We hope that both algorithms can be combined to give a faster isomorphism test for the large class of graphs excluding a topological subgraph. This large class of graphs includes the graphs of bounded treewidth, graphs of bounded genus, graphs of bounded degree and graphs excluding a minor. In fact, Grohe and Marx provide a structure theorem which shows that the graph classes mentioned above also characterize graphs excluding a topological subgraph. Informally, they showed that graphs excluding a topological subgraph can be decomposed into almost bounded-degree parts and minor-free parts which in turn can be decomposed into almost-embeddable parts [12]. Therefore, we hope that the improved algorithms for the isomorphism problem for bounded-degree graphs and bounded-genus graphs can be combined with our algorithm to exploit the occurring graph decomposition.

Organization of the Paper. In Section 3, we show how (sufficiently small) instances of the multiple-coset isomorphism and canonization problem can be processed with Babai's algorithm. In Section 4, we present a partitioning technique to reduce the canonization problem for k-ary relations to instances of small size in each decomposition level. In Section 5, we extend our technique to canonization of hypergraphs, which is an important subroutine used in the next section. In Section 6, we finally present our main algorithm which canonizes a set of labeling cosets and is divided into five subroutines. In the first subroutine, we extend the partitioning technique to families of partitions. The second and third subroutine extends Luks's subgroup reduction to our framework and reduces the problem to the barrier configuration characterized by a giant representation. The fourth and fifth subroutine extend Babai's method and aggregation of local certificates to our framework. In Section 7, a straightforward application of the multiple-coset isomorphism problem leads to an isomorphism algorithm that runs in time $n^{\mathrm{polylog}(k)}$ where n is the number of vertices and k is the treewidth of the given graphs.

2 Preliminaries

For an integer t, we write $[t]$ for $\{1,\dots,t\}$. For a set S and an integer k, we write $\binom{S}{k}$ for the k-element subsets of S and 2^S for the power set of S. The composition of two functions $f : V \to U$ and $g : U \to W$ is denoted by fg and is defined as the function that first applies f and then applies g.

Labeling Cosets. A *labeling* of a set V is a bijection $\rho : V \to \{1,\dots,|V|\}$. A *labeling coset* of a set V is a set of bijections Λ such that $\Lambda = \Delta\rho = \{\delta\rho \mid \delta \in \Delta\}$ for some subgroup $\Delta \le \mathrm{Sym}(V)$ and some labeling $\rho : V \to \{1,\dots,|V|\}$. We write $\mathrm{Label}(V)$ to denote the labeling coset $\mathrm{Sym}(V)\rho = \{\sigma\rho \mid \sigma \in \mathrm{Sym}(V)\}$ where ρ is an arbitrary labeling of V. Analogous to subgroups, a set $\Theta\tau$ is called a *labeling subcoset* of $\Delta\rho$, written $\Theta\tau \le \Delta\rho$, if the labeling coset $\Theta\tau$ is a subset of $\Delta\rho$.

Generating Sets. For the basic theory of handling permutation groups given by generating sets, we refer to [33]. Indeed, most algorithms are based on strong generating sets. However, given an arbitrary generating set, the Schreier-Sims algorithm is used to compute a strong generating set (of size quadratic in the degree) in polynomial time.

Hereditarily Finite Sets and Combinatorial Objects. Inductively, we define *hereditarily finite sets*, denoted by $\mathrm{HFS}(V)$, over a ground set V.

- A vertex $v \in V$ is an atom and a hereditarily finite set $v \in \mathrm{HFS}(V)$,
- a labeling coset $\Delta\rho \le \mathrm{Label}(V)$ is an atom and a hereditarily finite set $\Delta\rho \in \mathrm{HFS}(V)$,
- if $X_1,\dots,X_t \in \mathrm{HFS}(V)$, then also $\mathcal{X} = \{X_1,\dots,X_t\} \in \mathrm{HFS}(V)$ where $t \in \mathbb{N} \cup \{0\}$, and
- if $X_1,\dots,X_t \in \mathrm{HFS}(V)$, then also $\mathcal{X} = (X_1,\dots,X_t) \in \mathrm{HFS}(V)$ where $t \in \mathbb{N} \cup \{0\}$.

A *(combinatorial) object* is a pair $(V,\mathcal{X})$ consisting of a ground set V and a hereditarily finite set $\mathcal{X}\in\mathrm{HFS}(V)$. The ground set V is usually apparent from context and the combinatorial object $(V,\mathcal{X})$ is identified with the hereditarily finite set $\mathcal{X}$. The set $\mathrm{Obj}(V)$ denotes the set of all objects over V. The *transitive closure* of an object $\mathcal{X}$, denoted by $\mathrm{TC}(\mathcal{X})$, is defined as all objects that recursively occur in $\mathcal{X}$. All labeling cosets that occur in $\mathcal{X}$ are succinctly represented via generating sets. The encoding size of an object $\mathcal{X}$ can be chosen polynomial in $|\mathrm{TC}(\mathcal{X})|+|V|+t_{\max}$ where $t_{\max}$ is the maximal length of a tuple in $\mathrm{TC}(\mathcal{X})$.

Isomorphisms and Automorphisms of Objects. The image of an object $\mathcal{X}\in\mathrm{Obj}(V)$ (where V is disjoint from $\mathbb{N}$) under a bijection $\mu:V\to V'$ is an object $\mathcal{X}^{\mu}\in\mathrm{Obj}(V')$ that is defined as follows. Define $v^{\mu}:=\mu(v)$ for an atom $\mathcal{X}=v$ and define $(\Delta\rho)^{\mu}:=\mu^{-1}\Delta\rho$ for an atom $\mathcal{X}=\Delta\rho$, and inductively define $\{X_1,\dots,X_t\}^{\mu}:=\{X_1^{\mu},\dots,X_t^{\mu}\}$ and $(X_1,\dots,X_t)^{\mu}:=(X_1^{\mu},\dots,X_t^{\mu})$.

The set of all isomorphisms from an object $\mathcal{X}\in\mathrm{Obj}(V)$ and to an object $\mathcal{X}'\in\mathrm{Obj}(V')$ is denoted by $\mathrm{Iso}(\mathcal{X};\mathcal{X}'):=\{\varphi:V\to V'\mid\mathcal{X}^{\varphi}=\mathcal{X}'\}$. The set of all automorphisms of an object $\mathcal{X}$ is denoted by $\mathrm{Aut}(\mathcal{X}):=\mathrm{Iso}(\mathcal{X};\mathcal{X})$.

▶ **Definition 1** ([31]). *Let $\mathcal{C}$ be an isomorphisms-closed class of (unordered) objects, i.e., for all $\mathcal{X}\in\mathcal{C}$ over a set V and all bijections $\varphi:V\to V'$ it holds that $\mathcal{X}^{\varphi}\in\mathcal{C}$. A* canonical labeling function CL *is a function that assigns each object in $\mathcal{C}$ a labeling coset $\mathrm{CL}(\mathcal{X})=\Lambda\le\mathrm{Label}(V)$ such that:*

(CL1) $\mathrm{CL}(\mathcal{X})=\varphi\,\mathrm{CL}(\mathcal{X}^{\varphi})$ *for all $\varphi\in\mathrm{Iso}(V;V')$ (the set of bijections from V to V'), and*

(CL2) $\mathrm{CL}(\mathcal{X})=\mathrm{Aut}(\mathcal{X})\pi$ *for some (and thus for all) $\pi\in\mathrm{CL}(\mathcal{X})$.*

In this case, the labeling coset Λ is also called a canonical labeling *for $\mathcal{X}$.*

3 Handling Small Objects via String Canonization

Next, we define the central problem of this paper which is introduced in [14],[31]. This problem is a canonical version of the multiple-coset isomorphism problem.

▶ **Problem 2.** *Compute a function $\mathrm{CL}_{\mathrm{Set}}$ with the following properties:*

Input $J\in\mathrm{Obj}(V)$ *where* $J=\{\Delta_1\rho_1,\dots,\Delta_t\rho_t\}$, $\Delta_i\rho_i\le\mathrm{Label}(V), i\in[t]$ *and V is an (unordered) set.*

Output *A labeling coset* $\mathrm{CL}_{\mathrm{Set}}(J)=\Lambda\le\mathrm{Label}(V)$ *such that:*

(CL1) $\mathrm{CL}_{\mathrm{Set}}(J)=\varphi\,\mathrm{CL}_{\mathrm{Set}}(J^{\varphi})$ *for all* $\varphi\in\mathrm{Iso}(V;V')$.

(CL2) $\mathrm{CL}_{\mathrm{Set}}(J)=\mathrm{Aut}(J)\pi$ *for some (and thus for all)* $\pi\in\Lambda$.

Following the definition of the automorphism group for objects in general, we have that $\mathrm{Aut}(J)=\{\sigma\in\mathrm{Sym}(V)\mid\exists\psi\in\mathrm{Sym}(t)\forall i\in[t]:\sigma^{-1}\Delta_i\rho_i=\Delta_{\psi(i)}\rho_{\psi(i)}\}$.

To clarify the complexity status of Problem 2, it is important to note that the problem is actually polynomial-time equivalent to the string canonization problem. The string canonization problem in turn can be solved in quasipolynomial-time with Babai's algorithm [3]. However, the reduction increases the permutation domain V by a factor $|J|$, which leads to a running time of $2^{\mathrm{polylog}(|V|+|J|)}$ as stated in the following lemma.

▶ **Lemma 3.** *Canonical labelings for sets J can be computed in time $2^{\mathrm{polylog}(|V|+|J|)}$.*

The main task in this work is to remove the dependency of $|J|$ in the exponent. The main algorithm (Theorem 7) solves Problem 2 in a running time of $(|V|+|J|)^{\mathrm{polylog}|V|}$ and is presented in Section 6. This improvement will finally lead to an improved algorithm for the graph isomorphism problem from $n^{\mathrm{polylog}(n)}$ to $n^{\mathrm{polylog}(k)}$ where n is the number of vertices and k is the minimum treewidth of the input graphs. However, Lemma 3 is still used in our algorithms. Especially, when $|J|$ is bounded by some quasipolynomial in $|V|$, the algorithm from Lemma 3 already runs in the desired time bound.

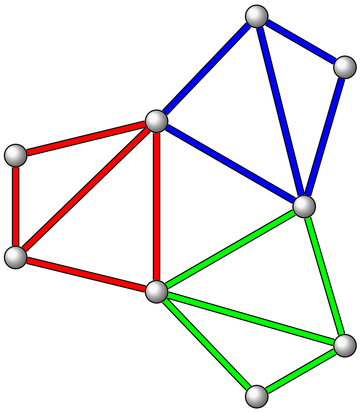

Figure 1 We see a graph G decomposed into 3 isomorphic subgraphs $H_1, H_2, H_3 \subseteq G$ shown in distinct colors.

The Intuition Behind this Central Problem. We explain why Problem 2 is the central problem when dealing with graph decompositions. We want to keep this subsection as simple as possible and do not want to introduce tree decompositions yet. For our purpose, we consider a simplified formulation of a graph decomposition. In this subsection, a graph decomposition of a graph $G = (V, E)$ is a family of subgraphs $\{H_i\}_{i \in [t]}$ that covers the edges of the entire graph, i.e., $E(G) = E(H_1) \cup \ldots \cup E(H_t)$. We say that a graph decomposition is defined in an isomorphism-invariant way if for two isomorphic graphs G, G' the decompositions $\{H_i\}_{i \in [t]}, \{H'_i\}_{i \in [t]}$ are defined in such a way that each isomorphism $\varphi \in \text{Iso}(G; G')$ also maps each subgraph H_i of the decomposition of G to a subgraph H'_j of the decomposition of G'. In particular, such a decomposition has to be invariant under automorphisms of the graph. A prime example of such a isomorphism-invariant decomposition in the setting of bounded-treewidth graphs is the decomposition into clique-separator-free parts. The clique-separator decomposition goes back to Leimer [20] and is also used in our final isomorphism algorithm.

Assume we have given a graph G for which we can construct a graph decomposition $\{H_i\}_{i \in [t]}$ in an isomorphism-invariant way and our task is the computation of a canonical labeling for G. A priori, it is unclear how to exploit our graph decomposition. In a first step, we could compute canonical labelings $\Delta_i \rho_i := \text{CL}(H_i)$ for each subgraph H_i recursively. The central question is how to merge these labeling cosets $\Delta_i \rho_i$ for H_i in order to obtain a canonical labeling $\Delta \rho$ for the entire graph G.

The easy case occurs when all subgraphs H_i, H_j are pairwise non-isomorphic. In this case, the subgraphs cannot be mapped to each other and indeed $\text{Aut}(G) = \text{Aut}(H_1) \cap \ldots \cap \text{Aut}(H_t)$. Therefore, the computation of $\Delta \rho$ reduces to a canonical intersection-problem. In fact, Babai's quasipolynomial-time algorithm [3] can be used to intersect labeling cosets canonically.

We consider the second extreme case in which all subgraphs H_i, H_j are pairwise isomorphic, see Figure 1.

In such a case, we have that $\text{Aut}(G) = \{\sigma \in \text{Sym}(V) \mid \exists \psi(t) \forall i \in [t] : \sigma \in \text{Iso}(H_i; H_{\psi(i)})\}$. Equivalently, we have that $\text{Aut}(G) = \text{Aut}(\{\Delta_1 \rho_1, \ldots, \Delta_t \rho_t\})$. Therefore, by the definition of Problem 2, the canonical labeling $\Delta \rho := \text{CL}_{\text{Set}}(\{\Delta_1 \rho_1, \ldots, \Delta_t \rho_t\})$ defines a canonical labeling for the entire graph G.

Alternatively, one can use the following lemma which intuitively says that for the purpose of canonization the subgraphs H_i can be replaced with their labeling cosets $\Delta_i \rho_i$ while preserving all symmetry information. Formally, it says the following.

▶ **Lemma 4** ([31], Object Replacement Lemma)**.** *Let $\mathcal{X} = \{X_1, \ldots, X_t\}$ be an object and let* CL *and* $\mathrm{CL}_{\mathrm{Set}}$ *be canonical labeling functions. Define $\mathcal{X}^{\mathrm{Set}} := \{\Delta_1\rho_1, \ldots, \Delta_t\rho_t\}$ where $\Delta_i\rho_i := \mathrm{CL}(X_i)$ is a canonical labeling for $X_i \in \mathcal{X}$. Assume that $X_i, X_j \in \mathcal{X}$ are pairwise isomorphic. Then, $\mathrm{CL}_{\mathrm{Object}}(\mathcal{X}) := \mathrm{CL}_{\mathrm{Set}}(\mathcal{X}^{\mathrm{Set}})$ defines a canonical labeling for $\mathcal{X}$.*

Roughly speaking, Problem 2 can be seen as the task of merging the given labeling cosets. The mixed case in which some (but not all) subgraphs H_i, H_j are isomorphic can be handled by a mixture of the above cases.

In Section 7, we apply this problem to graphs G with n vertices of treewidth k. By exploiting that the subgraphs in our application can only intersect in cliques of size at most k, we are able to restrict our attention to vertex sets of size $|V| \leq k$ (with at most $|J| \leq n$ labeling cosets). This finally leads to the desired running time of $n^{\mathrm{polylog}(k)}$.

Application to Combinatorial Objects. A second application of Problem 2 is the canonization framework for combinatorial objects in general given in [31]. In fact, our algorithms build on this canonization framework as it allows a recursive approach to solve the problem. Our improved running time for Problem 2 then implies an improved canonization algorithm for combinatorial objects in general that runs in time $n^{\mathrm{polylog}|V|}$ (Corollary 8).

4 Canonization of k-ary Relations

In this section, we provide an algorithm for canonical labeling of k-ary relations $R \subseteq V^k$. As graphs can be seen as binary relations, this problem clearly generalizes the graph canonization problem. One way to canonize k-ary relations is by using a well-known reduction to the graph canonization problem [23]. However, this approach leads to a running time that is quasipolynomial in $|V| + |R|$. In this section, we will give a polynomial-time reduction to the canonization problem for objects that are of input size polynomial in $|V|$ (which does not depend on $|R|$). With this reduction, we obtain an improved algorithm that runs in time $2^{\mathrm{polylog}|V|}|R|^{\mathcal{O}(1)}$. Our bound improves the currently best algorithm from [13]. Moreover, our time bound is also optimal (when measured in $|V|$ and $|R|$) as long as the graph isomorphism problem can not be solved faster than quasipolynomial time.

A *partition* of a set $\mathcal{X} \in \mathrm{Obj}(V)$ is a set $\mathcal{P} = \{P_1, \ldots, P_p\}$ such that $\mathcal{X} = P_1 \cup \ldots \cup P_p$ where $\emptyset \neq P_i \subseteq \mathcal{X}$ for all $P_i \in \mathcal{P}$. We suggest a general technique for exploiting partitions.

The Partitioning Technique. In this setting, we assume that we are given some object $\mathcal{X} \in \mathrm{Obj}(V)$ for which we can construct a partition $\mathcal{P} = \{P_1, \ldots, P_p\}$ in an isomorphism-invariant way such that $2 \leq |\mathcal{P}| \leq 2^{\mathrm{polylog}|V|}$. The goal is the computation of a canonical labeling for $\mathcal{X}$ by using an efficient recursion.

For example, $\mathcal{X} = R \subseteq V^k$ might be a k-ary relation for which we can easily construct a partition in an isomorphism-invariant way, as seen next. Assume $|R| \geq 2$ (otherwise the canonization problem is easy to solve) and let r be the first position in which R differs, i.e., the smallest $r \in [k]$ such that there are $(x_1, \ldots, x_k), (y_1, \ldots, y_k) \in R$ with $x_r \neq y_r$. Then, we partition $R = P_1 \cup \ldots \cup P_p$ by saying that two tuples $(x_1, \ldots, x_k), (y_1, \ldots, y_k)$ are in the same part P_i if and only if $x_r = y_r$. This gives a non-trivial partition $\mathcal{P} = \{P_1, \ldots, P_p\}$ with $2 \leq |\mathcal{P}| \leq |V| \leq 2^{\mathrm{polylog}|V|}$ which is preserved under automorphisms and isomorphisms.

Using recursion, we compute a canonical labeling $\Delta_i\rho_i$ for each part $P_i \subseteq \mathcal{X}$ recursively (assumed that we can define a partition for each part again). In our example, $P_i \subseteq R$ is a subrelation and therefore we can apply our approach recursively.

So far, we computed canonical labelings for each part $P_i \subseteq \mathcal{X}$ independently. The main idea is to use our central problem (Problem 2) to merge all these labeling cosets. Let us restrict our attention to the case in which the parts $P_i, P_j \in \mathcal{P}$ are pairwise isomorphic. In this case, we define the set $\mathcal{P}^{\text{Set}} := \{\Delta_i \rho_i \mid P_i \in \mathcal{P}\}$ consisting of the canonical labelings $\Delta_i \rho_i$ for each part. Moreover, by object replacement (Lemma 4), a canonical labeling for $\mathcal{P}^{\text{Set}}$ defines a canonical labeling for $\mathcal{P}$ as well. A canonical labeling for $\mathcal{P}$ in turn defines a canonical labeling for $\mathcal{X}$ since we assume the partition to be defined in an isomorphism-invariant way. Therefore, it is indeed true that a canonical labeling for $\mathcal{P}^{\text{Set}}$ would define a canonical labeling for $\mathcal{X}$. For this reason, we can use the algorithm from Lemma 3 to compute a canonical labeling for $\mathcal{P}^{\text{Set}}$. Intuitively, this algorithm merges all the labeling cosets in $\mathcal{P}^{\text{Set}}$ into one single canonical labeling. In our example, this single labeling coset is a canonical labeling for the relation R. The algorithm Lemma 3 runs in the desired time bound since $|\mathcal{P}^{\text{Set}}| = |\mathcal{P}| \leq 2^{\text{polylog}|V|}$ is bounded by some quasipolynomial.

Let us consider the number of recursive calls $R(\mathcal{X})$ of this approach for a given object $\mathcal{X}$. Since we recurse on each part $P_i \in \mathcal{P}$, we have a recurrence of $R(\mathcal{X}) = 1 + \sum_{P_i \in \mathcal{P}} R(P_i)$ leading to at most $|\mathcal{X}|^{\mathcal{O}(1)}$ recursive calls. The running time for one single recursive call is bounded by $2^{\text{polylog}|V|}$. For this reason, the total running time is bounded by $2^{\text{polylog}|V|}|\mathcal{X}|^{\mathcal{O}(1)}$.

▶ **Theorem 5.** *Canonical labelings for k-ary relations $R \subseteq V^k$ can be computed in time $2^{\text{polylog}|V|}|R|^{\mathcal{O}(1)}$.*

5 Canonization of Hypergraphs

In this section, we provide an algorithm for canonical labeling of hypergraphs (V, H) where $H \subseteq 2^V$.

We want to extend the previous partitioning technique to hypergraphs. However, for hypergraphs a non-trivial isomorphism-invariant partition $H = H_1 \uplus \ldots \uplus H_s$ of the edge set does not always exist, e.g., the hypergraph $(V, \{S \subseteq V \mid |S| = 2\})$ does not have a non-trivial partition of the edge set that is preserved under automorphisms. Therefore, we can not apply the partitioning technique to this setting. For this reason, we introduce a generalized technique in order to solve this problem. This generalized technique results in a slightly weaker time bound of $(|V| + |H|)^{\text{polylog}|V|}$ (where the dependency on $|H|$ is not polynomial). Indeed, it is an open problem whether the running time for the hypergraph isomorphism problem can be improved to $2^{\text{polylog}|V|} \cdot |H|^{\mathcal{O}(1)}$ [2].

A *cover* of a set $\mathcal{X} \in \text{Obj}(V)$ is a set $\mathcal{C} = \{C_1, \ldots, C_c\}$ such that $\mathcal{X} = C_1 \cup \ldots \cup C_c$ where $\emptyset \neq C_i \subseteq \mathcal{X}$ for all $C_i \in \mathcal{C}$. In contrast to a partition, the sets C_i, C_j are not necessarily disjoint for $i \neq j$. A cover $\mathcal{C}$ of $\mathcal{X}$ is called *sparse* if $|C_i| \leq \frac{1}{2}|\mathcal{X}|$ for all $C_i \in \mathcal{C}$. Extending the partitioning technique, we suggest a technique to handle covers.

The Covering Technique. In this setting, we assume that we have given some object $\mathcal{X} \in \text{Obj}(V)$ for which we can define a cover $\mathcal{C} = \{C_1, \ldots, C_c\}$ in an isomorphism-invariant way. Also here, we assume that $2 \leq |\mathcal{C}| \leq 2^{\text{polylog}|V|}$. The goal is the computation of a canonical labeling of $\mathcal{X}$ using an efficient recursion.

For example, $\mathcal{X} = H$ is a hypergraph for which we can easily define a cover in an isomorphism-invariant way, as seen next. We assume that $|H| \geq 2$ (otherwise the canonization problem is easy to solve) and that $\emptyset \notin H$ (otherwise we remove the empty set from H). Then, we cover $H = \bigcup_{v \in V} C_v$ by setting $C_v := \{S \in H \mid v \in S\}$ and define a cover $\mathcal{C} := \{C_v \mid v \in V\}$. Since each hyperedge $S \in H$ contains at least one vertex $v \in V$, each hyperedge S is contained in at least one set $C_v \in \mathcal{C}$. Moreover, the cover $\mathcal{C}$ is preserved under automorphisms and isomorphisms.

First, we reduce to the setting in which $\mathcal{C}$ is a sparse cover of $\mathcal{X}$. This can be done as follows. We define $C_i^* := C_i$ if $|C_i| \leq \frac{1}{2}|\mathcal{X}|$ and we define $C_i^* := \mathcal{X} \setminus C_i$ if $|C_i| > \frac{1}{2}|\mathcal{X}|$. By definition, we ensured that $|C_i^*| \leq \frac{1}{2}|\mathcal{X}|$ for all $i \in [c]$. Let $\mathcal{X}^* := \bigcup_{i \in [c]} C_i^*$. Next, we consider two cases.

If $\mathcal{X}^* \subsetneq \mathcal{X}$, then we have found a non-trivial partition $\mathcal{X} = \mathcal{X}^* \uplus \mathcal{X}^\circ$ where $\mathcal{X}^\circ := \mathcal{X} \setminus \mathcal{X}^*$. In the hypergraph example, we would have a non-trivial partition of the hyperedges defined in an isomorphism-invariant way (which can be exploited very easily). We proceed analogously as in the partitioning technique explained in Section 4.

Otherwise, if $\mathcal{X}^* = \mathcal{X}$, then $\mathcal{C}^* := \{C_1^*, \dots, C_c^*\}$ is also a cover of $\mathcal{X}$. But more importantly, the cover $\mathcal{C}^*$ is indeed sparse. In the case of a sparse cover, we also proceed analogously as in the partition technique explained in Section 4. However, the key difference of the covering technique compared to the partitioning technique lies in the recurrence for the number of recursive calls since the sets $C_i^*, C_j^* \in \mathcal{C}^*$ are not necessarily pairwise disjoint. The recurrence we have is $R(\mathcal{X}) = 1 + \sum_{C_i^* \in \mathcal{C}^*} R(C_i^*)$. By using that $|\mathcal{C}^*| = |\mathcal{C}| \leq 2^{\operatorname{polylog}|V|}$ and that $|C_i^*| \leq \frac{1}{2}|\mathcal{X}|$, we obtain at most $|\mathcal{X}|^{\operatorname{polylog}|V|}$ recursive calls. This is exactly the reason why the algorithm for relations is faster than the algorithm for hypergraphs.

▶ **Theorem 6.** *Canonical labelings for hypergraphs* (V, H) *can be computed in time* $(|V| + |H|)^{\operatorname{polylog}|V|}$.

6 Canonization of Sets and Objects

Our main theorem provides an algorithm that canonizes a set $J = \{\Delta_1\rho_1, \dots, \Delta_t\rho_t\}$ consisting of labelings cosets $\Delta_i\rho_i \leq \operatorname{Label}(V), i \in [t]$.

▶ **Theorem 7.** *A function* $\mathrm{CL}_{\mathrm{Set}}$ *solving Problem 2 can be computed in time* $(|V|+|J|)^{\operatorname{polylog}|V|}$.

▶ **Corollary 8.** *Canonical labelings for combinatorial objects can be computed in time* $n^{\operatorname{polylog}|V|}$ *where* n *is the input size and* V *is the ground set of the object.*

Proof Outline. For the purpose of recursion, our main algorithm $\mathrm{CL}_{\mathrm{Set}}$ needs some additional input parameters. The input of the main algorithm is a tuple $(J, A, \Delta^{\mathrm{Can}}, g^{\mathrm{Can}})$ consisting of the following input parameters.

- J is a set consisting of labeling cosets,
- $A \subseteq V$ is a subset which is Δ_i-invariant for all $\Delta_i\rho_i \in J$. We require that Property (A) holds: $(\Delta_i\rho_i)|_{V \setminus A} = (\Delta_j\rho_j)|_{V \setminus A}$ for all $\Delta_i\rho_i, \Delta_j\rho_j \in J$ (initially, we set $A := V$),
- $\Delta^{\mathrm{Can}} \leq \operatorname{Sym}(V^{\mathrm{Can}})$ is a group over the linearly ordered set $V^{\mathrm{Can}} = \{1, \dots, |V|\}$. We require that for all $\Delta_i\rho_i \in J$ it holds that $\rho_i^{-1}\Delta_i\rho_i = \Delta^{\mathrm{Can}}$ (if this would not be the case, in can be shown that J can be partitioned such that progress can be measured), and
- $g^{\mathrm{Can}} : \Delta^{\mathrm{Can}} \to \operatorname{Sym}(W^{\mathrm{Can}})$ is a giant representation where $W^{\mathrm{Can}} = \{1, \dots, |W^{\mathrm{Can}}|\}$ is a linearly ordered set (a homomorphism $h : \Delta \to \operatorname{Sym}(W)$ is called a *giant representation* if the image of Δ under h is a giant, i.e., $\operatorname{Alt}(W) \leq h(\Delta) \leq \operatorname{Sym}(W)$). It is allowed that g^{Can} is undefined ($g^{\mathrm{Can}} = \bot$).

The Subgroup Recursion. First of all we design a subgroup reduction that, given a tuple $(J, A, \Delta^{\mathrm{Can}}, \bot)$ and a subgroup $\Psi^{\mathrm{Can}} \leq \Delta^{\mathrm{Can}}$, reduces the canonical labeling problem of $(J, A, \Delta^{\mathrm{Can}}, \bot)$ to s-many instances $(\widehat{J}_i, A, \Psi^{\mathrm{Can}}, \bot)$ where $|\widehat{J}_i| \leq |J|$. Here, s corresponds to the index of Ψ^{Can} in Δ^{Can}. In contrast to Luks's subgroup reduction, the present reduction splits all labeling cosets in J simultaneously. We describe the idea of this algorithm.

Figure 2 Flowchart of the algorithm for Theorem 7.

We consider the decomposition into left cosets of $\Delta^{\mathrm{Can}} = \bigcup_{\ell\in[s]} \delta_\ell^{\mathrm{Can}}\Psi^{\mathrm{Can}}$ and define $\widehat{\mathcal{J}} := \{\rho_i\delta_\ell^{\mathrm{Can}}\Psi^{\mathrm{Can}} \mid i \in [t], \ell \in [s]\}$. Surprisingly, we can show that $\mathrm{Aut}(\widehat{\mathcal{J}}) = \mathrm{Aut}(J)$. This means that a canonical labeling for $\widehat{\mathcal{J}}$ defines a canonical labeling for J as well and vice versa. Therefore, the first idea that comes to mind would be a recursion on the instance $(\widehat{\mathcal{J}}, A, \Psi^{\mathrm{Can}}, \bot)$. However, there are two problems when recursing on $\widehat{\mathcal{J}}$. First, the instance $\widehat{\mathcal{J}}$ does not necessarily preserve Property (A) that we have for the subset $A \subseteq V$ (this requirement is important for the subroutines that follow).

Second, it holds that $|\widehat{\mathcal{J}}| > |J|$ (assumed that $\Psi^{\mathrm{Can}} < \Delta^{\mathrm{Can}}$ is a proper subgroup). Also this blow-up in the instance size would not lead to the desired recursion. However, we are able to construct a decomposition of $\widehat{\mathcal{J}} = \widehat{\mathcal{J}}_1 \uplus \ldots \uplus \widehat{\mathcal{J}}_r$ such that $r \le s$ and $|\widehat{\mathcal{J}}_i| \le |J|$ and such that Property (A) holds for each instance $(\widehat{\mathcal{J}}_i, A, \Psi^{\mathrm{Can}}, \bot)$.

The Johnson Reduction. We design an algorithm that, given an instance $(J, A, \Delta^{\mathrm{Can}}, \bot)$, either finds a giant representation $g^{\mathrm{Can}} : \Delta^{\mathrm{Can}} \to \mathrm{Sym}(W^{\mathrm{Can}})$ or reduces the canonical labeling problem of $(J, A, \Delta^{\mathrm{Can}}, \bot)$ to instances that are smaller (according to some function that measures progress).

First of all, we want to reduce to the case in which all $\Delta_i \le \mathrm{Sym}(V)$ are transitive on $A \subseteq V$. To achieve transitivity, Babai's algorithm uses Luks's idea of orbit-by-orbit processing. However, the orbit-by-orbit recursion is a tool that is developed for strings and needs a non-trivial adaption when dealing with a set of labeling cosets J. To achieve transitivity, the present algorithm uses an extension of the orbit-by-orbit recursion that was developed in [31]. In the transitive case, we follow Babai's idea. First, we define a block system $\mathcal{B}^{\mathrm{Can}}$ on which Δ^{Can} acts primitively. If the primitive group acting on $\mathcal{B}^{\mathrm{Can}}$ is small, we use the subgroup reduction to reduce to a subgroup $\Psi^{\mathrm{Can}} \le \Delta^{\mathrm{Can}}$ that is defined as the kernel of that action. In case that the primitive group is large, we use Cameron's classification of large primitive groups which implies that the primitive group is a Cameron group. We reduce the Cameron group to a Johnson group by using the subgroup reduction again. The Johnson group (acting on subsets of a set W^{Can}) in turn can be used to define a giant representation $g^{\mathrm{Can}} : \Delta^{\mathrm{Can}} \to \mathrm{Sym}(W^{\mathrm{Can}})$.

▶ **Definition 9** (Certificates of Fullness). *A group $G \le \mathrm{Sym}(V)$ is called* certificate of fullness *for an instance $(J, A, \Delta^{\mathrm{Can}}, g^{\mathrm{Can}})$ if*

1. $G \le \mathrm{Aut}(J)$,
2. $G^{\mathrm{Can}} := G^{\rho_i} \le \Delta^{\mathrm{Can}}$ *does not depend on the choice of $\Delta_i\rho_i \in J$, and*
3. $g^{\mathrm{Can}} : G^{\mathrm{Can}} \to \mathrm{Sym}(W^{\mathrm{Can}})$ *is still a giant representation.*

The Certificate Producing Algorithm. We design an algorithm that, given an instance $(J, A, \Delta^{\mathrm{Can}}, g^{\mathrm{Can}})$ (where g^{Can} is defined), either finds a certificate of fullness or makes progress (according to some function that measures progress).

The algorithm picks a subset $T^{\mathrm{Can}} \subseteq W^{\mathrm{Can}}$ of logarithmic size. We call this set T^{Can} a *canonical test set.* Next, we define the group $\Delta_T^{\mathrm{Can}} \leq \Delta^{\mathrm{Can}}$ which stabilizes T^{Can} in the image under g^{Can}. By doing so, we can define a giant representation $g_T^{\mathrm{Can}} : \Delta_T^{\mathrm{Can}} \to \mathrm{Sym}(T^{\mathrm{Can}})$. We say that $v^{\mathrm{Can}} \in V^{\mathrm{Can}}$ is *affected* by g_T^{Can} if g_T^{Can} is not a giant representation when restricted to $(\Delta_T^{\mathrm{Can}})_{(v^{\mathrm{Can}})}$. Let $S^{\mathrm{Can}}, U^{\mathrm{Can}} \subseteq V^{\mathrm{Can}}$ be set of elements affected and unaffected by g_T^{Can}, respectively. We have a technical difference in our algorithm in contrast to Babai's method. In Babai's method of local certificates, he processes a giant representation $g : \Delta \to \mathrm{Sym}(W)$ and considers multiple test sets $T \subseteq W$ (one test set for each subset of logarithmic size). In our framework, we define the giant representation for a group Δ^{Can} over a linearly ordered set V^{Can}. This allows us to choose one single (canonical) test set $T^{\mathrm{Can}} \subseteq W^{\mathrm{Can}}$ only. Here, canonical means that the subset is chosen minimal with respect to the ordering of the natural numbers. However, when we translate the ordered structures V^{Can} to unordered structures over V, we implicitly consider multiple test sets and giant representations. More precise, by applying inverses of labelings in $\Delta_i\rho_i \in J$ to the ordered group $\Delta_T^{\mathrm{Can}} \leq \mathrm{Sym}(V^{\mathrm{Can}})$, we obtain a set of groups over V, i.e., $\{\lambda_i \Delta_T^{\mathrm{Can}} \lambda_i^{-1} \mid \lambda_i \in \Delta_i\rho_i\}$. Similarly, we can define a set of giant representations $\{(g_T^{\mathrm{Can}})^{\lambda_i^{-1}} \mid \lambda_i \in \Delta_i\rho_i\}$ (where $(g_T^{\mathrm{Can}})^{\lambda_i^{-1}}(\delta_i) := g_T^{\mathrm{Can}}(\lambda_i^{-1}\delta_i\lambda_i)$ for $\delta_i \in \Delta_i$) and a set of affected points $H_i := \{S \subseteq V \mid S^{\lambda_i} = S^{\mathrm{Can}}$ for some $\lambda_i \in \Delta_i\rho_i\}$. Therefore, when dealing over unordered structures, we need to consider multiple groups and homomorphisms. It becomes even more complex, since we are dealing with a set J consisting of labeling cosets rather than one single group only. In fact, we obtain a set of affected point sets H_i for each labeling coset $\Delta_i\rho_i \in J$. However, it turns out that the hardest case occurs when $H_i = H_j$ for all $\Delta_i\rho_i, \Delta_j\rho_j \in J$. Roughly speaking, we will apply the following strategy.

We restrict each labeling coset in J to some set of affected points $S \in H_i$ and define a set of local restrictions J_S^* that ignore the vertices outside S. The precise definition of J_S^* is given in our algorithm. Intuitively, the algorithms tries to analyze the labeling cosets locally.

Case 1: The local restrictions J_S^* are pairwise distinct. In this case, we canonize the local restrictions J_S^* recursively. Observe that a canonical labeling $\Delta\rho$ for J_S^* does not necessarily define a canonical labeling for J. However, we can define a function $\alpha : J_S^* \to J$ that assigns each local restriction its corresponding labeling coset $\Delta_i\rho_i \in J$. This function is well-defined since we assumed the local restrictions to be pairwise distinct. Now, each automorphism in $\mathrm{Aut}(J_S^*)$ induces a permutation of J_S^* which in turn induces a permutation of J. We are able to use the permutations on J to canonize the set J efficiently (without even applying further recursive calls).

Case 2: Some local restrictions in J_S^* are pairwise different and some local restrictions in J_S^* are pairwise equal. In this case, we can define a non-trivial partition of J in the following way. We say that two labeling cosets $\Delta_i\rho_i, \Delta_j\rho_j$ are in the same part, if and only if the corresponding local restrictions in J_S^* coincide. Actually, this leads to a family of partitions since we obtain one partition for each choice of an affected set $S \in H_i$. We exploit this partition family by using an extension of the partitioning techniques from Sections 4 and 5.

Case 3: The local restrictions J_S^* are pairwise equal. In this case, it is possible to find automorphisms $G_S \leq \mathrm{Sym}(V)$ of J which fix the unaffected points $V \setminus S$. In fact, we can find such automorphisms for all choices of $S \in H_i$, otherwise we are in a situation of a previous case. Finally, we consider the group of automorphisms $G \leq \mathrm{Aut}(J)$ generated by all G_S for $S \in H_i$. We can show that G is indeed a certificate of fullness.

The Certificate Aggregation. We finally design an algorithm that, given an instance $(J, A, \Delta^{\mathrm{Can}}, g^{\mathrm{Can}})$ and a certificate of fullness $G \leq \mathrm{Sym}(V)$ makes progress (according to some function that measures progress).

Let us consider the less technical case in which $g^{\mathrm{Can}}(G^{\mathrm{Can}})$ is the symmetric group (rather than the alternating group). In this case, it holds that $G^{\mathrm{Can}}\Psi^{\mathrm{Can}} = \Delta^{\mathrm{Can}}$ where Ψ^{Can} is the kernel of g^{Can}. Similarly to the subgroup recursion, we consider the decomposition of $\Delta^{\mathrm{Can}} = \bigcup_{\ell\in[s]} \delta_\ell^{\mathrm{Can}}\Psi^{\mathrm{Can}}$ into left cosets of the kernel and define $\widehat{J} := \{\rho_i\delta_\ell^{\mathrm{Can}}\Psi^{\mathrm{Can}} \mid i \in [t], \ell \in [s]\}$. Again, we have $\mathrm{Aut}(\widehat{J}) = \mathrm{Aut}(J)$. The key observation is that G is transitive on $\widehat{J}$ since $(\rho_i\delta_\ell^{\mathrm{Can}}\Psi^{\mathrm{Can}})^{g^{-1}} = \rho_i g^{\rho_i}\delta_\ell^{\mathrm{Can}}\Psi^{\mathrm{Can}}$ for all $g \in G$ and $G^{\mathrm{Can}}\Psi^{\mathrm{Can}} = \Delta^{\mathrm{Can}}$.

First, consider an easy case in which $J = \{\Delta_1\rho_1\}$ consists of one single labeling coset. In this case, we have a set of automorphisms G acting transitively on the subcosets $\widehat{J} = \{\rho_1\delta_\ell^{\mathrm{Can}}\Psi^{\mathrm{Can}} \mid \ell \in [s]\}$. Moreover, each subcoset satisfies $\mathrm{Aut}(\rho_1\delta_\ell^{\mathrm{Can}}\Psi^{\mathrm{Can}}) \leq \mathrm{Aut}(J)$ and can be seen as an individualization of J. This means, we can choose (arbitrarily) a subcoset $\rho_1\delta_\ell^{\mathrm{Can}}\Psi^{\mathrm{Can}} \leq \Delta_1\rho_1$ and recurse on that. Since the automorphisms in G can map each subcoset to each other subcoset it does not matter which subcoset we choose. By recursing on one single subcoset only, we can measure significant progress. At the end, we return $G\widehat{\Lambda}$ where $\widehat{\Lambda}$ is a canonical labeling for the (arbitrarily) chosen subcoset and G is the group of automorphisms (acting transitively on the set of all subcosets).

However, the situation becomes more difficult when dealing with more labeling cosets $J = \{\Delta_1\rho_1,\dots,\Delta_t\rho_t\}$ for $t \geq 2$. The first idea that comes to mind is the following generalization. We choose (arbitrarily) some $\ell \in [s]$ and define the set of subcosets $\widehat{J_\ell} := \{\rho_i\delta_\ell^{\mathrm{Can}}\Psi^{\mathrm{Can}} \mid i \in [t]\} \subseteq \widehat{J}$. The set $\widehat{J_\ell}$ contains exactly one subcoset $\rho_i\delta_\ell^{\mathrm{Can}}\Psi^{\mathrm{Can}} \leq \Delta_i\rho_i$ of each $\Delta_i\rho_i \in J$. However, the partition $\widehat{\mathcal{J}} := \{\widehat{J_\ell} \mid \ell \in [s]\}$ might not be G-invariant and G might not be transitive on it. In fact, we are able to find a suitable partition $\widehat{\mathcal{J}} := \{\widehat{J}_1,\dots,\widehat{J}_r\}$ of the subcosets $\widehat{J}$ on which G is transitive.

7 Isomorphism of Graphs Parameterized by Treewidth

▶ **Theorem 10.** *Let G_1, G_2 be two connected graphs. There is an algorithm that, given a pair (G_1, G_2), computes the set of isomorphisms $\mathrm{Iso}(G_1; G_2)$ in time $|V(G_1)|^{\mathrm{polylog}(\mathrm{tw}\, G_1)}$.*

Proof Outline. We follow the graph decomposition approach from [14] building on [21]. It was shown that graphs of treewidth k can be decomposed in an isomorphism-invariant way into parts that have restrictions on their automorphism groups. More precisely, the automorphism group of each part has composition-width at most k after fixing one vertex (the composition-width of a group Δ is the smallest integer k such that all composition factors of Δ are isomorphic to a subgroup of $\mathrm{Sym}(k)$). This fact allows us to use the bounded-degree graph isomorphism algorithm given in [13] to compute the isomorphisms between the parts. Finally, we use our main theorem (Theorem 7) to merge the isomorphisms.

Since Grohe, Neuen and Schweitzer provide an isomorphism algorithm, rather than a canonization algorithm, our final algorithm from the previous theorem does not lead to canonical forms. However, this is the only part that depends on their isomorphism algorithm.

8 Outlook and Open Questions

One could ask the question whether our isomorphism algorithm for graphs can be improved to a FPT-algorithm that runs in time $2^{\mathrm{polylog}(k)}n^{\mathcal{O}(1)}$ where n is the number of vertices and k is the maximum treewidth of the given graphs. There are various reasons why this might be difficult. One reason is that our approach would require a FPT-algorithm for the isomorphism problem of graphs of maximum degree d that runs in time $2^{\mathrm{polylog}(d)}n^{\mathcal{O}(1)}$. However, it is an open question whether any FPT-algorithm for the graph isomorphism problem parameterized by maximum degree exists. Another reason is that an algorithm for graphs running in time $2^{\text{polylog}(k)}n^{\mathcal{O}(1)}$ would imply an isomorphism algorithm for hypergraphs (V,H) running in time $2^{\text{polylog}|V|}|H|^{\mathcal{O}(1)}$. It is also an open question, whether such a hypergraph isomorphism algorithm exists [2]. If this were indeed the case, one could hope for an improvement of our canonization algorithm for a set J consisting of labeling cosets that runs in time $2^{\text{polylog}|V|}|J|^{\mathcal{O}(1)}$.

Recently, Babai extended his quasipolynomial-time algorithm to the canonization problem for graphs [3]. With Babai's result, it is a natural question whether the bounded-degree isomorphism algorithm of [13] extends to canonization as well. The present isomorphism algorithm for graphs parameterized by treewidth should then be amenable to canonization as well.

Another question that arises is about permutation groups $G \leq \text{Sym}(V)$. The canonical labeling problem for permutation groups is of great interest because it also solves the normalizer problem. In our recent work, we gave a canonization algorithm for explicitly given permutation groups running in time $2^{\mathcal{O}(|V|)}|G|^{\mathcal{O}(1)}$ [31]. Recently, the framework was extended to permutation groups that are implicitly given and the running time was improved to $2^{\mathcal{O}(|V|)}$ [35]. The present work implies a canonization algorithm running in time $(|V|+|G|)^{\text{polylog}|V|}$. An important question is whether the present techniques can be combined with the canonization techniques for implicitly given permutation groups to obtain a canonization algorithm running in time $2^{\text{polylog}|V|}$.

Finally, we ask whether the isomorphism problem can be solved in time $n^{\text{polylog}(|V(H)|)}$ where n is the number of vertices and H is an excluded topological subgraph H of the given graphs. Even for excluded minors H, we do not have such an algorithm.

Parameterized Inapproximability for Steiner Orientation by Gap Amplification

Michał Włodarczyk
Eindhoven University of Technology, The Netherlands
m.wlodarczyk@tue.nl

Abstract

In the k-Steiner Orientation problem, we are given a mixed graph, that is, with both directed and undirected edges, and a set of k terminal pairs. The goal is to find an orientation of the undirected edges that maximizes the number of terminal pairs for which there is a path from the source to the sink. The problem is known to be W[1]-hard when parameterized by k and hard to approximate up to some constant for FPT algorithms assuming Gap-ETH. On the other hand, no approximation factor better than $\mathcal{O}(k)$ is known.

We show that k-Steiner Orientation is unlikely to admit an approximation algorithm with any constant factor, even within FPT running time. To obtain this result, we construct a self-reduction via a hashing-based gap amplification technique, which turns out useful even outside of the FPT paradigm. Precisely, we rule out any approximation factor of the form $(\log k)^{o(1)}$ for FPT algorithms (assuming FPT $\neq$ W[1]) and $(\log n)^{o(1)}$ for purely polynomial-time algorithms (assuming that the class W[1] does not admit randomized FPT algorithms). This constitutes a novel inapproximability result for polynomial-time algorithms obtained via tools from the FPT theory. Moreover, we prove k-Steiner Orientation to belong to W[1], which entails W[1]-completeness of $(\log k)^{o(1)}$-approximation for k-Steiner Orientation. This provides an example of a natural approximation task that is complete in a parameterized complexity class.

Finally, we apply our technique to the maximization version of directed multicut – Max (k,p)-Directed Multicut – where we are given a directed graph, k terminals pairs, and a budget p. The goal is to maximize the number of separated terminal pairs by removing p edges. We present a simple proof that the problem admits no FPT approximation with factor $\mathcal{O}(k^{\frac{1}{2}-\varepsilon})$ (assuming FPT $\neq$ W[1]) and no polynomial-time approximation with ratio $\mathcal{O}(|E(G)|^{\frac{1}{2}-\varepsilon})$ (assuming NP $\not\subseteq$ co-RP).

1 Introduction

In the recent years new research directions emerged in the intersection of the two theories aimed at tackling NP-hard problem: parameterized complexity and approximation algorithms. This led to numerous results combining techniques from both toolboxes. The main goal in this area is to obtain an algorithm running in time $f(k) \cdot |I|^{\mathcal{O}(1)}$ for an instance I with

parameter k, that finds a solution of value not worse than α (the approximation factor) times the value of the optimal solution. They are particularly interesting for problems that are both W[1]-hard and at the same time cannot be well approximated in polynomial time [1, 10, 13, 22, 30]. On the other hand, some problems remain resistant to approximation even in this paradigm.

Obtaining polynomial-time approximation lower bounds under the assumption of P $\neq$ NP is challenging, because it usually requires to prove NP-hardness of a *gap problem.* In a gap problem one only needs to distinguish instances with the value of optimal solution at least C_1 from those with this value at most C_2. This provides an argument that one cannot obtain any approximation factor better than the gap, i.e., $\frac{C_1}{C_2}$, as long as P $\neq$ NP.

A road to such lower bounds has been paved by the celebrated PCP theorem [4], which gives an alternative characterization of the class NP. The original complicated proof has been simplified by Dinur [16] via the technique of *gap amplification*: an iterated reduction from a gap problem with a small gap to one with a larger gap. When the number of iterations depends on the input size, this allows us to start the chain of reductions from a problem with no constant gap. However, this is only possible when we can guarantee that the size of all created instances does not grow super-polynomially.

The process of showing approximation lower bounds becomes easier with an additional assumption of the *Unique Games Conjecture* [28], which states that a particular gap version of the Unique Games problem is NP-hard. This makes it possible to start a reduction from a problem with an already relatively large gap. The reductions based on Unique Games Conjecture provided numerous tight approximation lower bounds [5, 23, 31].

A parameterized counterpart of the hardness assumption P $\neq$ NP is FPT $\neq$ W[1], which is equivalent to the statement that k-Clique $\notin$ FPT, that is, k-Clique[1] does not admit an algorithm with running time of the form $f(k) \cdot |I|^{\mathcal{O}(1)}$. Similarly to the classical complexity theory, proving hardness of an approximate task relying only on FPT $\neq$ W[1] is difficult but possible. A recent result stating that the gap version of k-Dominating Set is W[1]-hard (for the gap being any computable function $F(k)$) required gap amplification through a distributed PCP theorem [26].

Again, the task becomes easier when working with a stronger hardness assumption: *Gap Exponential Time Hypothesis*[2] (Gap-ETH) states that there exists $\varepsilon > 0$ so that one requires exponential time to distinguish satisfiable 3-CNF-SAT formulas from those where only a fraction of $(1-\varepsilon)$ clauses can be satisfied at once [17, 34]. Gap-ETH is a stronger assumption than FPT $\neq$ W[1], i.e., the first implies the second, and it sometimes turns out more convenient since it already provides hardness for a problem with a gap. There are many recent examples of using Gap-ETH for showing hardness of parameterized approximation [6, 9, 10, 11, 13, 30].

Our contribution is a novel gap amplification technique which exploits the fact that in a parameterized reduction we can afford an exponential blow-up with respect to the parameter. It circumvents the obstacles related to PCP protocols and, together with a hashing-based lemma, allows us to construct relatively simple self-reductions for problems on directed graphs.

[1] We attach the parameter to the problem name when we refer to a parameterized problem.

[2] Gap-ETH is a stronger version of the *Exponential Time Hypothesis* (ETH), according to which one requires exponential time to solve 3-CNF-SAT [25].

Steiner Orientation

In the k-Steiner Orientation problem we are given a mixed graph, that is, with both directed and undirected edges, and a set of k terminal pairs. The goal is to find an orientation of the undirected edges that maximizes the number of terminal pairs for which there is a path from the source to the sink.

Some of the first studies on the k-Steiner Orientation problem (also referred to as the Maximum Graph Orientation problem) were motivated by modeling protein-protein interactions (PPI) [36] and protein-DNA interactions (PDI) [19, 20]. Whereas PPIs interactions could be represented with undirected graphs, PDIs required introducing mixed graphs. Arkin and Hassin [3] showed the problem to be NP-hard, but polynomially solvable for $k = 2$. This result was generalized by Cygan et al. [15], who presented an $n^{\mathcal{O}(k)}$-time algorithm, which implies that the problem belongs to the class XP (see Section 3) when parameterized by k (cf. [18] for different choices of parameterization).

The k-Steiner Orientation problem has been proved to be W[1]-hard by Pilipczuk and Wahlström [38], which makes it unlikely to be solvable in time $f(k)\cdot|I|^{\mathcal{O}(1)}$. The W[1]-hardness proof has been later strengthened to work on planar graphs and to give a stronger running time lower bound based on ETH [11], which is essentially tight with respect to the $n^{\mathcal{O}(k)}$-time algorithm.

The approximation of Steiner Orientation has been mostly studied on undirected graphs, where the problem reduces to optimization over trees by contracting 2-connected components [15]. Medvedovsky et al. [36] presented an $\mathcal{O}(\log n)$-approximation and actually proved that one can always find an orientation satisfying $\Omega(\frac{k}{\log n})$ terminal pairs. The approximation factor has been improved to $\mathcal{O}(\log n/\log\log n)$ [20] and later to $\mathcal{O}(\log k/\log\log k)$ [15] by observing that one can compress an undirected instance to a tree of size $\mathcal{O}(k)$. A lower bound of $\frac{12}{11} - \varepsilon$ (based on P $\neq$ NP) has been obtained via a reduction from Max Directed Cut [36]. Medvedovsky et al. [36] posed a question of tackling the maximization problem on mixed graphs, which was partially addressed by Gamzu et al. [20] who provided a polylogarithmic approximation in the case where the number of undirected components on each source-sink path is bounded by a constant.

The decision problem whether all the terminal pairs can be satisfied is polynomially solvable when restricting input graphs to be undirected [24], which makes the maximization version fixed-parameter tractable, by simply enumerating all subsets of terminals. The maximization version on mixed graphs is far less understood from the FPT perspective. It is unlikely to be exactly solvable since the decision problem is W[1]-hard, but can we approximate it within a reasonable factor? The reduction by Chitnis et al. [11] implies that, assuming Gap-ETH, k-Steiner Orientation cannot be approximated within factor $\frac{20}{19} - \varepsilon$ on mixed graphs, in running time $f(k) \cdot n^{\mathcal{O}(1)}$. Using new techniques introduced in this paper, we are able to provide stronger lower bounds based on a weaker assumption.

Related work

Some examples of the new advancements in parameterized approximations are 1.81-approximation for k-Cut [22] (recently improved to $(\frac{5}{3} + \varepsilon)$ [27]), which beats the factor 2 that is believed to be optimal within polynomial running time [33], or $(1 + \frac{2}{e} + \varepsilon)$-approximation for k-Median [13], all running in time $f(k) \cdot n^{\mathcal{O}(1)}$. For Capacitated k-Median, a constant factor FPT approximation has been obtained [1, 14], whereas the best-known polynomial-time approximation factor is $\mathcal{O}(\log k)$. Another example is an FPT approximation scheme for the planar case of Bidirected Steiner Network, which does not admit a polynomial-time approximation scheme unless P = NP [10].

On the other hand several problems have proven resistant to such improvements. Chalermsook et al. [9] showed that under the assumption of Gap-ETH there can be no parameterized approximations with ratio $o(k)$ for k-Clique or k-Biclique and none with ratio $F(k)$ for k-Dominating Set (for any computable function F). They have also ruled out $k^{o(1)}$-approximation for Densest k-Subgraph. The cited FPT approximation for k-Median has a tight approximation factor assuming Gap-ETH [13].

Subsequently, efforts have been undertaken to weaken the complexity assumptions on which the lower bounds are based. For the k-Dominating Set problem Gap-ETH has been replaced with a more established hardness assumption that FPT $\neq$ W[1] [26]. Marx [35] has proven parameterized inapproximability of Monotone k-Circuit SAT under the even weaker assumption that FPT $\neq$ W[P]. Lokshtanov et al. [30] introduced the *Parameterized Inapproximability Hypothesis* (PIH), that is weaker than Gap-ETH and stronger than FPT $\neq$ W[1], and used it to rule out an FPT approximation scheme for Directed k-Odd Cycle Transversal. PIH turned out to be a sufficient assumption to argue there can be no FPT algorithm for k-Even Set [6].

2 Overview of the results

Our main inapproximability result is a W[1]-hardness proof for the gap version of k-Steiner Orientation with the gap $q = (\log k)^{o(1)}$. This means that the problem is unlikely to admit a $(\log k)^{o(1)}$-approximation algorithm with running time $f(k) \cdot |I|^{\mathcal{O}(1)}$.

▶ **Theorem 2.1.** *Consider a function $\alpha(k) = (\log k)^{\beta(k)}$, where $\beta(k) \to 0$ is computable and non-increasing. It is* W[1]*-hard to distinguish whether for a given instance of k-Steiner Orientation:*

1. *there exists an orientation satisfying all k terminal pairs, or*
2. *for all orientations the number of satisfied pairs is at most $\frac{1}{\alpha(k)} \cdot k$.*

The previously known approximation lower bound for FPT algorithms, $\frac{20}{19} - \varepsilon$, was obtained via a linear reduction from k-Clique and was based on Gap-ETH [11]. Our reduction not only raises the inapproximability bar significantly, but also weakens the hardness assumption (although we are not able to enforce the planarity of the produced instances, as in [11]). In fact, we begin with the decision version of k-Steiner Orientation and introduce a gap inside the self-reduction. What is interesting, we rely on totally different properties of the problem than in the W[1]-hardness proof [38]: that one required gadgets with long undirected paths and we introduce only new directed edges.

This result is also interesting from the perspective of the classical (non-parameterized) approximation theory. The best approximation lower bound known so far has been $\frac{12}{11} - \varepsilon$ [36], valid also for undirected graphs. Therefore we provide a new inapproximability result for polynomial algorithms, which is based on an assumption from parameterized complexity. Restricting to a purely polynomial running time allows us to rule out also approximation factors depending on n (rather than on k) with a slightly stronger assumption, which is required because the reduction is randomized (see Section 3 for the formal definition of a false-biased FPT algorithm).

▶ **Theorem 2.2.** *Consider a function $\alpha(n) = (\log n)^{\beta(n)}$, where $\beta(n) \to 0$ is computable and non-increasing. Unless the class W[1] admits false-biased FPT algorithms, there is no polynomial-time algorithm that, given an instance of Steiner Orientation with n vertices and k terminal pairs, distinguishes between the following cases:*

1. *there exists an orientation satisfying all k terminal pairs, or*
2. *for all orientations the number of satisfied pairs is at most $\frac{1}{\alpha(n)} \cdot k$.*

A similar phenomenon, that is, novel polynomial-time hardness based on an assumption from parameterized complexity, has appeared in the work on Monotone k-Circuit SAT [35]. Another example of this kind is polynomial-time approximation hardness for Densest k-Subgraph based on ETH [32].

W[1]-completeness

So far, the decision version of k-Steiner Orientation has only been known to be W[1]-hard [38] and to belong to XP [15]. We establish its exact location in the W-hierarchy. A crucial new insight is that we can assume the solution to be composed of $f(k)$ pieces, for which we only need to check if they match each other, and this task reduces to k-Clique.

▶ **Theorem 2.3.** *k-Steiner Orientation is* W[1]*-complete.*

We hereby solve an open problem posted by Chitnis et al. [11]. What is more, this implies that $(\log k)^{o(1)}$-Gap k-Steiner Orientation belongs to W[1] (see Section 3 for formal definitions of problems). Together with Theorem 2.1 this entails W[1]-completeness. Another gap problem with this property is Maximum k-Subset Intersection[3], introduced for the purpose of proving W[1]-hardness of k-Biclique [29]. We are not aware of any other natural gap problem being complete in a parameterized complexity class. Note that although W[1]-hardness of the gap version of k-Dominating Set is known [26], k-Dominating Set is W[2]-complete.

Directed Multicut

As another application of our technique, we present a simple hardness result for the gap version of Max (k,p)-Directed Multicut with the gap $q = k^{\frac{1}{2}-\varepsilon}$. We show that even if we parameterize the problem with both the number of terminal pairs k and the size of the cutset p, then we essentially cannot obtain any approximation ratio better than $\sqrt{k}$.

▶ **Theorem 2.4.** *For any $\varepsilon > 0$ and function $\alpha(k) = \mathcal{O}\left(k^{\frac{1}{2}-\varepsilon}\right)$, it is* W[1]*-hard to distinguish whether for a given instance of Max (k,p)-Directed Multicut:*

1. *there is a cut of size p that separates all k terminal pairs, or*
2. *all cuts of size p separate at most $\frac{1}{\alpha(k)} \cdot k$ terminal pairs.*

When restricted to polynomial running time, the lower bound of $\Omega(k^{\frac{1}{2}-\varepsilon})$ can be improved to $\Omega(|E(G)|^{\frac{1}{2}-\varepsilon})$, however unlike the case of k-Steiner Orientation, this time the reduction is polynomial and we need to assume only NP $\not\subseteq$ co-RP (recall that a problem is in co-RP if it admits a polynomial-time false-biased algorithm, i.e., an algorithm which is always correct for YES-instances and for NO-instances returns the correct answer with probability greater than some constant).

▶ **Theorem 2.5.** *Assuming* NP $\not\subseteq$ co-RP*, for any $\varepsilon > 0$ and function $\alpha(m) = \mathcal{O}\left(m^{\frac{1}{2}-\varepsilon}\right)$, there is no polynomial-time algorithm that, given an instance $(G, \mathcal{T}, p)$, $|\mathcal{T}| = k$, $|E(G)| = m$, of Max Directed Multicut, distinguishes between the following cases:*

1. *there is a cut of size p that separates all k terminal pairs, or*
2. *all cuts of size p separate at most $\frac{1}{\alpha(m)} \cdot k$ terminal pairs.*

[3] To give a concrete example of a W[1]-complete gap problem, consider the task of distinguishing graphs with $K_{k,F_1(k)}$ from those with no $K_{k,F_2(k)}$. The reduction in [29] implies that this is W[1]-hard for functions F_1, F_2 with large gap. On the other hand, the problem of finding $K_{k,F_1(k)}$ belongs to W[1] via a color-coding reduction to $(F_1(k)+k)$-Clique.

As far as we know, the approximation status of this variant has not been studied yet. If we want to minimize the number of removed edges to separate all terminal pairs or minimize the ratio of the cutset size to the number of separated terminal pairs (this problem is known as Directed Sparsest Multicut), those cases admit a polynomial-time $\tilde{\mathcal{O}}(n^{\frac{11}{23}})$-approximation algorithm [2] and a lower bound of $2^{\Omega(\log^{1-\varepsilon} n)}$ [12]. Since $\frac{11}{23} < \frac{1}{2}$ and $n \le m$, the maximization variant with a hard constraint on the cutset size turns out to be harder.

In the undirected case p-Multicut is FPT, even when parameterized only by the size of the cutset p and allowing arbitrarily many terminals [7]. This is in contrast with the directed case, which becomes W[1]-hard already for 4 terminals, when parameterized by p. It is worth mentioning that k-Steiner Orientation and p-Directed Multicut were proven to be W[1]-hard with a similar gadgeting machinery [38].

Organization of the paper

We begin with the necessary definitions in Section 3. As our gap amplification technique is arguably the most innovative ingredient of the paper, we precede the proofs with informal Section 4, which introduces the ideas gradually. It is followed by the detailed constructions for k-Steiner Orientation in Section 5 and for Max (k, p)-Directed Multicut in Section 6. Each contains a self-reduction lemma and applications to polynomial and FPT running time. The proof of W[1]-completeness of k-Steiner Orientation can be found in the full version of the article.

3 Preliminaries

Fixed parameter tractability

A parameterized problem instance is created by associating an integer parameter k with an input instance. Formally, a parameterized language is a subset of $\Sigma^* \times \mathbb{N}$. We say that a language (or a problem) is *fixed parameter tractable* (FPT) if it admits an algorithm solving an instance (I, k) (i.e., deciding if it belongs to the language) in running time $f(k) \cdot |I|^{\mathcal{O}(1)}$, where f is a computable function. Such a procedure is called an *FPT algorithm* and we say concisely that it runs in *FPT time*. A language belongs to the broader class XP if it admits an algorithm with running time of the form $|I|^{f(k)}$.

There is no widely recognized class describing problems which admit randomized FPT algorithms. Instead of defining such a class, we will directly use the notion of a *false-biased* algorithm, which is always correct for YES-instances and for NO-instances returns the correct answer with probability greater than some constant (equivalently, when the algorithm returns *false* then it is always correct). Similarly, a *true-biased* algorithm is always correct for NO-instances but may be wrong for YES-instances with bounded probability. A false-biased (resp. true-biased) FPT algorithm satisfies the condition above and runs in FPT time.

To argue that a problem is unlikely to be FPT, we use parameterized reductions analogous to those employed in the classical complexity theory. Here, the concept of W-hardness replaces NP-hardness, and we need not only to construct an equivalent instance in FPT time, but also ensure that the parameter in the new instance depends only on the parameter in the original instance. If there exists a parameterized reduction from a W[1]-hard problem (e.g., k-Clique) to another problem Π, then the problem Π is W[1]-hard as well. This provides an argument that Π does not admit an algorithm with running time $f(k) \cdot |I|^{\mathcal{O}(1)}$ under the assumption that FPT $\neq$ W[1].

Approximation algorithms and gap problems

We define an optimization problem (resp. parameterized optimization problem) as a task of optimizing function $L \to \mathbb{N}$, where $L \subseteq \Sigma^*$ (resp. $L \subseteq \Sigma^* \times \mathbb{N}$), representing the value of the optimal solution. An α-approximation algorithm for a maximization task must return a solution of value no less than the optimum divided by α (we follow the convention with $\alpha \ > 1$). The approximation factor α can be a constant or it can depend on the input size. In the most common setting, the running time is required to be polynomial. An FPT approximation algorithm works with a parameterized optimization problem and is required to run in FPT time. It is common that its approximation factor can depend on the parameter.

A gap problem (resp. parameterized gap problem) is given by two disjoint languages $L_1, L_2 \subseteq \Sigma^*$ (resp. $L_1, L_2 \subseteq \Sigma^* \times \mathbb{N}$). An algorithm should decide whether the input belongs to L_1 or to L_2. If neither holds, then the algorithm is allowed to return anything. Usually L_1, L_2 are defined respectively as the sets of instances (of an optimization problem) with a solution of value at least C_1 and instances with no solution with value greater than C_2. An α-approximation algorithm with $\alpha \ < \frac{C_1}{C_2}$ can distinguish L_1 from L_2, therefore hardness of an approximation task is implied by hardness for the related gap problem.

Problem definitions

We now formally describe the problems we work with. Since we consider parameterized algorithms it is important to specify how we define the parameter of an instance.

A mixed graph is a triple (V, A, E), where V is the vertex set, A is the set of directed edges, and E stands for the set of undirected edges. An orientation of a mixed graph is given by replacing each undirected edge $uv \in E$ with one of the directed ones: (u, v) or (v, u). This creates a directed graph $\tilde{G} = (V, A \cup \tilde{E})$, where $\tilde{E}$ is the set of newly created directed edges. We assume that $uv \notin E$ for each $(u, v) \in A$, so $\tilde{G}$ is always a simple graph.

k-Steiner Orientation

Input: mixed graph $G = (V, A, E)$, list of terminal pairs $\mathcal{T} = ((s_1, t_1), \ldots, (s_k, t_k))$,
Parameter: k
Task: find an orientation $\tilde{G}$ of G that maximizes the number of pairs (s_i, t_i), such that t_i is reachable from s_i in $\tilde{G}$

We add „Max" to the name of the following problem in order to distinguish it from the more common version of Directed Multicut, where one minimizes the number of edges in the cut.

Max (k, p)-Directed Multicut

Input: directed graph $G = (V, A)$, list of terminal pairs $\mathcal{T} = ((s_1, t_1), \ldots, (s_k, t_k))$, integer p
Parameter: $k + p$
Task: find a subset of edges $A' \subseteq A$, $|A'| \leq p$, in order to maximize the number of pairs (s_i, t_i), such that t_i is unreachable from s_i in $G \setminus A'$

If a solution to either problem satisfies the reachability (resp. unreachability) condition for a particular terminal pair, we say that this pair is satisfied by this solution. The decision versions of both problems ask whether there is a solution of value k, that is, satisfying all the terminal pairs. We call such an instance fully satisfiable, or a YES-instance, and a NO-instance otherwise. For the sake of proving approximation hardness we introduce the gap versions: q-Gap k-Steiner Orientation and q-Gap Max (k,p)-Directed Multicut, where we are promised that the value of the optimal solution is either k or at most $\frac{k}{q}$, and we have to distinguish between these cases.

When referring to non-parameterized problems, we drop the parameters in the problem name. We use notation $[n] = \{1, 2, \dots, n\}$. All logarithms are 2-based.

4 The gap amplification technique

We begin with an informal thought experiment that helps to understand the main ideas behind the reduction. For an instance $(G, \mathcal{T} = ((s_1, t_1), \dots, (s_k, t_k)))$ of k-Steiner Orientation we refer to the vertices $s_i, t_i \in V(G)$ as $G\{s, i\}$ and $G\{t, i\}$. We want to construct a larger instance $(H, \mathcal{T}_H)$ so that if $(G, \mathcal{T})$ is fully satisfiable then $(H, \mathcal{T}_H)$ is as well, but otherwise the maximal fraction of satisfiable pairs in $(H, \mathcal{T}_H)$ is strictly less than $\frac{k-1}{k}$. Consider k vertex-disjoint copies of the original instance: $(G_1, \mathcal{T}_1), (G_2, \mathcal{T}_2), \dots, (G_k, \mathcal{T}_k)$, that will be treated as the first layer. Assume that $(G, \mathcal{T})$ is a NO-instance (i.e., one cannot satisfy all pairs at once), so for any orientation of the copies $\tilde{G}_1, \tilde{G}_2, \dots, \tilde{G}_k$, there is a tuple $(j_1, j_2, \dots, j_k)$ such that $\tilde{G}_i\{t, j_i\}$ is unreachable from $\tilde{G}_i\{s, j_i\}$ in $\tilde{G}_i$. Suppose for now that we have fixed the values of (j_i), even before we have finished building our instance.

Let $R = (r_1, r_2, \dots, r_k)$ be a tuple sampled randomly from $[k]^k$. We connect the sinks in the first layer to the sources in another copy of the same instance – let us refer to it as $(G_R, \mathcal{T}_R)$. We add a directed edge from $G_i\{t, r_i\}$ to $G_R\{s, i\}$ for each $i \in [k]$, thus connecting a random sink of G_i to the source $G_R\{s, i\}$, as shown in Figure 1. We refer to the union of all $k+1$ copies of G with k added connecting edges as the graph H. We define $\mathcal{T}_H = ((G_1\{s, r_1\}, G_R\{t, 1\}), \dots, (G_k\{s, r_k\}, G_R\{t, k\}))$, so we want to satisfy those k terminal pairs that got connected randomly. Let X be a random variable equal to the value of the optimal solution for $(H, \mathcal{T}_H)$ under the restriction that the solution orients $G_1, G_2 \dots, G_k$ as $\tilde{G}_1, \tilde{G}_2, \dots, \tilde{G}_k$. What would be the expected value of X?

Let Y denote another random variable being the number of indices i for which $r_i \neq j_i$. By linearity of expectation we have $\mathbb{E}Y = k - 1$. It holds that $X \leq Y$ and so far we still have only the bound $\mathbb{E}X \leq k - 1$. However, with probability $(\frac{k-1}{k})^k$ we have $r_i \neq j_i$ for all i, therefore $Y = k$, but we cannot connect all pairs within G_R (because it is a copy of a NO-instance), so $X \leq k - 1$. This means that $\mathbb{E}(Y - X) \geq (\frac{k-1}{k})^k$ and so $\mathbb{E}X \leq k - 1 - (\frac{k-1}{k})^k$: the gap has been slightly amplified.

Of course in the proper reduction we cannot fix the orientation before adding the connecting edges. However, we can afford an exponential blow-up with respect to k. We can include in the second layer the whole probabilistic space, that is, k^k copies of $(G, \mathcal{T})$ (rather than a single $(G_R, \mathcal{T}_R)$), each connected to the first layer with respect to a different tuple $(r_1, r_2, \dots, r_k)$, thus creating a large instance $(H, \mathcal{T}_H)$ with $k^k \cdot k$ terminal pairs (see Figure 1). For any orientation of H the fraction of satisfied terminal pairs equals the average over the fractions for all k^k groups of terminal pairs, so we can emulate the construction above without fixing $(j_1, j_2, \dots, j_k)$. The maximal fraction of satisfiable terminal pairs in such (no longer random) $(H, \mathcal{T}_H)$ would be the same as before, that is, $\frac{\mathbb{E}X}{k} < k - 1$. However, the smaller instance we create the better lower bounds we get, so we will try to be more economical while constructing $(H, \mathcal{T}_H)$.

An important observation is that we do not have to include all k^k choices of R in the construction. We just need a sufficient combination of them, so that the gap amplification occurs for any choice of $(j_1, j_2, \dots, j_k)$. This can be ensured by picking just $k^{\mathcal{O}(1)}$ choices of R and using an argument based on the Chernoff bound (see Section 5 for a detailed construction).

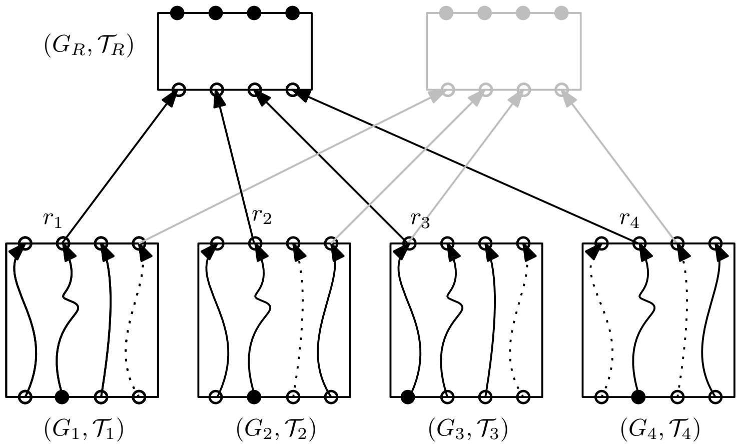

Figure 1 The construction of $(H, \mathcal{T}_H)$ for $k = 4$. The black copy $(G_R, \mathcal{T}_R)$ is connected according to the choice of $R = (r_1, r_2, r_3, r_4) = (2, 2, 1, 2)$ and the terminals (sources and sinks) are marked with black dots. The dotted lines indicate which pairs of terminals are unreachable in each $\tilde{G}_i$ and we can set $(j_1, j_2, j_3, j_4) = (4, 3, 4, 3)$ (another valid choice is $(4, 3, 4, 1)$). We have $r_i \neq j_i$ for each i, so $Y = 4$ but $X \leq 3$. The grey copy illustrates another random choice of connection: $R' = (r_1, r_2, r_3, r_4) = (4, 4, 1, 3)$ and $X \leq Y = 2$. If we wanted to construct $(H, \mathcal{T}_H)$ emulating the whole probabilistic space, we would include all 4^4 copies of $(G_R, \mathcal{T}_R)$ for all choices of $R = (r_1, r_2, r_3, r_4)$ in the same way as the black and the grey copy.

We can iterate this construction by treating $(H, \mathcal{T}_H)$ as a new input and amplifying the gap further in each step. In further steps we need to add an exponential number of copies to the new layer, even when compressing the probabilistic space as above. This is why we get an exponential blow-up with respect to k and we need to work with a parameterized hardness assumption, even for ruling out polynomial-time approximations.

The construction for Max (k, p)-Directed Multicut is simpler because the layer stacking does not have to be iterated. Therefore to achieve polynomial-time hardness it suffices to assume that NP $\not\subseteq$ co-RP. The phenomenon that both problems admit such strong self-reduction properties can be explained by the fact that when dealing with directed reachability one can compose instances sequentially, which is the first step in both reductions.

5 Inapproximability of Steiner Orientation

We are going to present a formal construction of the argument sketched in Section 4. We first formulate and discuss the properties of the construction. Then we introduce a probabilistic tool, called a δ-biased sampler family, describe the reduction step, and prove the gap amplifying property. At the end of this section we present the proof of the following lemma. Let $S(G, \mathcal{T})$ denote the maximal number of pairs that can be satisfied by some orientation in an instance $(G, \mathcal{T})$.

▶ **Lemma 5.1.** *There is a procedure that, for an instance $(G, \mathcal{T}_G)$, $k = |\mathcal{T}_G|$, of Steiner Orientation, and a parameter q, constructs a new instance $(H, \mathcal{T}_H)$, $k_0 = |\mathcal{T}_H|$, such that:*
1. $k_0 = 2^{q^{\mathcal{O}(k)}}$,
2. $|V(H)| \leq |V(G)| \cdot k_0^2$,
3. *if $S(G, \mathcal{T}_G) = k$, then $S(H, \mathcal{T}_H) = k_0$ always (Completeness),*
4. *if $S(G, \mathcal{T}_G) < k$, then $S(H, \mathcal{T}_H) \leq \frac{1}{q} \cdot k_0$ with probability at least $\frac{1}{k_0}$ (Soundness).*

The randomized construction runs in time proportional to $|H|$. It can be derandomized within running time $f(k, q) \cdot |G|$.

It easily follows from these properties that the gap can get amplified to any constant q. It is more complicated though to rule out a superconstant approximation factor, e.g., $\alpha(k) = \log\log k$, because we need to keep track of the growth of $\alpha(k_0)$ when increasing q. We address this issue after proving Lemma 5.1.

Sampler families

As sketched in Section 4, given fixed orientations of the k copies of G, we are able to randomly sample k sinks and insert additional edges so that the expected optimum of the new instance is sufficiently upper bounded. We want to reverse this idea, so we could randomly sample a moderate number of additional connections once to ensure the upper bound works for any orientation. To this end, we need some kind of a hashing technique to mimic the behaviour of the probabilistic space with a structure of moderate size. Examples of such constructions are (generalized) universal hash families [8, 39, 40] or expander random walk sampling [21]. Even though the construction presented below is relatively simple, we are not aware of any occurrences of it in the literature.

For a set X_1 and a multiset X_2, we write $X_2 \subseteq X_1$ if every element from X_2 appears in X_1. Let $U(X)$ denote the uniform distribution over a finite multiset X. In particular, each distinct copy of the same element in X has the same probability of being chosen: $\frac{1}{|X|}$.

▶ **Definition 5.2.** *For a family $\mathcal{F}$ of functions $X \to [0,1]$, a δ-biased sampler family is a multiset $X_H \subseteq X$, such that for every $f \in \mathcal{F}$ it holds*

$$\left|\mathbb{E}_{x\sim U(X_H)} f(x) - \mathbb{E}_{x\sim U(X)} f(x)\right| \le \delta.$$

▶ **Lemma 5.3.** *For a given X, $\mathcal{F}$, and $\delta\ > 0$, a sample of $\mathcal{O}(\delta^{-2}\log(|\mathcal{F}|))$ elements from X (sampled independently with repetitions) forms a δ-biased sampler family with probability at least $\frac{1}{2}$.*

Proof. We sample independently $M = 10\cdot\delta^{-2}\log(|\mathcal{F}|)$ elements from X with repetitions. For the sake of analysis, note that this is a single sample from the space $\Omega_{X,M}$ being the family of all M-tuples of elements from X, equipped with a uniform distribution. Let X_H denote the random multiset of all elements in this M-tuple. For each $f \in \mathcal{F}$ we define $A_f \subseteq \Omega_{X,M}$ as the family of tuples for which $\left|\mathbb{E}_{x\sim U(X_H)} f(x) - \mathbb{E}_{x\sim U(X)} f(x)\right| > \delta$. For a fixed f we apply the Hoeffding's inequality.

$$\mathbb{P}(A_f) = \mathbb{P}\left(\left|\mathbb{E}_{x\sim U(X_H)} f(x) - \mathbb{E}_{x\sim U(X)} f(x)\right| > \delta\right) \le 2\exp(-2\delta^2 M).$$

For our choice of M this bound gets less than $\frac{1}{2|\mathcal{F}|}$. By union bound, the probability that X_F is not a δ-biased sampler family is $\mathbb{P}\left(\bigcup_{f\in\mathcal{F}} A_f\right) \le \sum_{f\in\mathcal{F}} \mathbb{P}(A_f) \le \frac{1}{2}$. The claim follows. ◀

We keep the concise notation from Section 4: for an instance $(G,\mathcal{T})$, $\mathcal{T} = ((s_1,t_1),\dots,(s_k,t_k))$ of k-Steiner Orientation we refer to the vertices $s_i, t_i \in V(G)$ as $G\{s,i\}$ and $G\{t,i\}$.

Building the layers

Given an instance $(G,\mathcal{T}_G)$, our aim is to build a larger instance, so that if $S(G,\mathcal{T}) = k$ then the new one is also fully satisfiable, but otherwise the maximal fraction of terminal pairs being simultaneously satisfiable in the new instance is at most $\frac{1}{q}$.

$(H_4^i, \mathcal{T}_4^i)$

Figure 2 The construction of $(H^{i+1}, \mathcal{T}^{i+1})$ for $k = 4$. The first copy of $(H^i, \mathcal{T}^i)$ is shown in greater detail to highlight the recursive construction, with circles representing its terminal pairs. The new layer consists of p_{i+1} copies of $(G, \mathcal{T})$. The vector $R = (r_1, r_2, r_3, r_4) \in [p_i]^4$ indicates which sinks are connected to the sources in $(G_R, \mathcal{T}_R)$. The black dots show 4 terminal pairs associated with this copy. For the sake of legibility only the edges incident to G_R (the black ones) and neighboring copies (the grey ones) are sketched.

We inductively construct a family of instances $(H^i, \mathcal{T}^i)_{i=1}^B$ with $(H^1, \mathcal{T}^1) = (G, \mathcal{T}_G)$. Let $k_i = |\mathcal{T}^i|$ and p_i indicate the number of copies of $(G, \mathcal{T}_G)$ in the last layer (to be explained below) of $(H^i, \mathcal{T}^i)$. We will have that $p_1 = 1$ and $k_i = |\mathcal{T}^i| = k \cdot p_i$. We construct $(H^{i+1}, \mathcal{T}^{i+1})$ by taking k vertex-disjoint copies of the i-th instance, denoted $(H_1^i, \mathcal{T}_1^i), \ldots, (H_k^i, \mathcal{T}_k^i)$ and forming a new layer of copies of $(G, \mathcal{T}_G)$ which will be randomly connected to the i-th layer through directed edges. Therefore graph H^{i+1} will have $i + 1$ layers of copies of G.

Let $\mathcal{R} = [k_i]^k$ be the family of k-tuples $(r_1, r_2, \ldots r_k)$ with elements from the set $[k_i]$. We sample a random tuple $R = (r_1, r_2, \ldots r_k)$ from $\mathcal{R}$ and create a new copy of the original instance – let us refer to it as $(G_R, \mathcal{T}_R)$. We add a directed edge from $H_j^i\{t, r_j\}$ to $G_R\{s, j\}$ for each $j \in [k]$, thus connecting a random sink of H_j^i to the source $G_R\{s, i\}$. We insert k pairs to $\mathcal{T}^{i+1}$: $(H_1^i\{s, r_1\}, G_R\{t, 1\}), \ldots, (H_k^i\{s, r_k\}, G_R\{t, k\})$. We iterate this subroutine $p_{i+1} = \mathcal{O}(k^4 q^{2k} p_i)$ times (a derivation of this quantity is postponed to Lemma 5.4), as shown in Figure 2.

▶ **Lemma 5.4.** *Let $y_i = S(H^i, \mathcal{T}^i) \,/\, k_i$ be the maximal fraction of terminal pairs that can be simultaneously satisfied in $(H^i, \mathcal{T}^i)$. Suppose that $S(G, \mathcal{T}_G) < k$ and $y_i \geq \frac{1}{q}$. Then with probability at least $\frac{1}{2}$ it holds $y_{i+1} \leq y_i - \frac{1}{2k} \cdot q^{-k}$.*

Proof. First observe that for each $(s_j, t_j) \in \mathcal{T}^i$, any (s_j, t_j)-path in $(H^i, \mathcal{T}^i)$ runs through i unique copies of $(G, \mathcal{T}_G)$. Therefore an (s_j, t_j)-pair is satisfied only if the corresponding i terminal pairs in those copies are satisfied. Recall that we have connected each copy of $(G, \mathcal{T}_G)$ in the i-th layer to the terminals from the previous layer according to a random tuple $R = (r_1, r_2, \ldots r_k) \in \mathcal{R}$.

We will now analyze how the possible orientations $\tilde{H}_1^i, \ldots, \tilde{H}_k^i$ influence the status of the terminal pairs in $\mathcal{T}^{i+1}$. Let $C_j \subseteq [k_i]$ encode which of the terminal pairs are reachable in $\tilde{H}_j^i$, that is, $C_j = \{\ell \in [k_i] \colon \tilde{H}_j^i\{t, \ell\}$ is reachable from $\tilde{H}_j^i\{s, \ell\}\}$. A tuple $C = (C_1, \ldots C_k)$ is called a *configuration* and we denote the family of all feasible configurations as $\mathcal{C}$. We have $|\mathcal{C}| \leq (2^{k_i})^k = 2^{p_i k^2}$. For a configuration $C \in \mathcal{C}$ let $f_C : \mathcal{R} \to [0, 1]$ be a function describing the maximal fraction of satisfiable terminal pairs from those with sinks in G_R connected through a tuple $R \in \mathcal{R}$. Note that $f_C(R)$ depends on C, R and the best possible orientation of G_R, whereas it is oblivious to the rest of the structure of $(\tilde{H}^i_j)_{j=1}^k$. We can thus think of C as an interface between the first i layers and G_R.

For fixed orientations $\tilde{H}^i_1, \dots, \tilde{H}^i_k$, and therefore fixed configuration $C \in \mathcal{C}$, we estimate the expected value of f_C. Let Y_j be a random Boolean variable indicating that $\tilde{H}^i_j[t, r_j]$ is reachable from $\tilde{H}^i_j[s, r_j]$ for a random $(r_1, r_2, \dots r_k) \in \mathcal{R}$, i.e., that $r_j \in C_j$. Let $Y = \sum_{j=1}^k Y_j/k$, so that we always have $f_C(R) \le Y$.

Let $c_j = |C_j|/k_i$. By linearity of expectation $\mathbb{E}Y = \sum_{j=1}^k c_j/k$ and by the assumption $c_j \le y_i$ for all $j \in [k]$. However, with probability $\prod_{j=1}^k c_j$ we have $r_j \in C_j$ for all j, so $Y = 1$, but we cannot connect all pairs within $(G_R, \mathcal{T}_R)$ (since we assumed $S(G, \mathcal{T}_G) < k$), so $f_C(R) \le 1 - \frac{1}{k}$. This means that

$$\mathbb{E}\left(Y - f_C(R)\right) \ge \frac{1}{k} \cdot \prod_{j=1}^k c_j, \quad \text{and so} \quad \mathbb{E}f_C(R) \le \frac{1}{k} \cdot \left(\sum_{j=1}^k c_j - \prod_{j=1}^k c_j \right).$$

The quantity $\sum_{j=1}^k c_j - \prod_{j=1}^k c_j$ can only increase when we increase some c_ℓ, because the ℓ-th partial derivative is $1 - \prod_{j \in [k],\, j \neq \ell} c_j \ge 0$. By the assumption $c_j \le y_i$ and $y_i \ge \frac{1}{q}$, hence

$$\mathbb{E}f_C(R) \le \frac{1}{k} \cdot \left(\sum_{j=1}^k y_i - \prod_{j=1}^k y_i \right) \le y_i - \frac{1}{k} \cdot q^{-k}.$$

Now we apply Lemma 5.3 for $\mathcal{F} = \{f_C : C \in \mathcal{C}\}$ and $\delta = \frac{1}{2k} \cdot q^{-k}$ to argue that for our choice of p_{i+1} – the number of copies in the last layer – the estimation works for all $C \in \mathcal{C}$ at once. The quantity $M = \mathcal{O}(\delta^{-2} \log(|\mathcal{F}|))$ in Lemma 5.3 becomes $\mathcal{O}(k^4 q^{2k} p_i)$, which is exactly as we defined p_{i+1}. We have sampled p_{i+1} tuples from $\mathcal{R}$ (let us denote this multiset as $\mathcal{R}_H \subseteq \mathcal{R}$) and added a copy $(G_R, \mathcal{T}_R)$ for each $R \in \mathcal{R}_H$. For a fixed $C \in \mathcal{C}$, the maximal fraction of satisfiable terminal pairs in $(H^{i+1}, \mathcal{T}^{i+1})$ equals the average of $f_C(R)$ over $R \in \mathcal{R}_H$. By Lemma 5.3 we know that, regardless of the choice of C, this quantity is at most

$$\mathbb{E}_{R \sim U(\mathcal{R}_H)} f_C(R) \le \mathbb{E}_{R \sim U(\mathcal{R})} f_C(R) + \frac{1}{2k} \cdot q^{-k} \le y_i - \frac{1}{2k} \cdot q^{-k},$$

with probability at least $\frac{1}{2}$ (that is, if we have chosen $\mathcal{R}_H$ correctly). Since the upper bound works for all $C \in \mathcal{C}$ simultaneously, the claim follows. ◀

Proof of Lemma 5.1. We define $(H, \mathcal{T}_H) = (H^B, \mathcal{T}^B)$ for $B = 2kq^k$. The completeness is straightforward: if $S(G, \mathcal{T}_G) = k$, then we can orient all copies of G so that $G\{t, j\}$ is always reachable from $G\{s, j\}$ and each requested path in $S(H^i, \mathcal{T}^i)$ is given as a concatenation of respective paths in B copies of G.

To see the soundness, suppose that $S(G, \mathcal{T}_G) < k$. The sequence $(y_i)_{i=0}^B$ is non-increasing and the value of y_i is being decreased by at least $\frac{i}{2k} \cdot q^{-k}$ in each iteration, as long as $y_i \ge \frac{1}{q}$, due to Lemma 5.4. Therefore after $B = 2kq^k$ iterations we are sure to have $y_B \le \frac{1}{q}$.

To estimate the size of the instance, recall that we have $k_i = p_i k$ and $p_{i+1} = \mathcal{O}(k^4 q^{2k} p_i)$. We can assume $q \ge 2$ and so $k \le q^k$. For $B = 2kq^k$, the value of p_B becomes $\left(k^4 q^{2k}\right)^{\mathcal{O}(kq^k)} = 2^{q^{\mathcal{O}(k)} \mathcal{O}(\log q)} = 2^{q^{\mathcal{O}(k)}}$. The size of $V(H)$ is at most $k_B \cdot |V(G)|$ times the number of layers, which is B. We trivially bound $B \le 2^B \le k_B$ to obtain $|V(H)| \le |V(G)| \cdot k_B^2$.

The presented construction is randomized because we randomly choose a biased sampler family in each of the B steps. If we start with a YES-instance, then we produce a YES instance regardless of these choices, and otherwise we produce a NO instance with probability at least $2^{-B} \geq \frac{1}{k_B}$. The construction can be derandomized within running time $f(k,q) \cdot |V(G)|$ as follows. In each application of Lemma 5.3 the sizes of X and $\mathcal{F}$ are $(k_i)^k$ and $2^{p_i k^2}$, respectively, and $\delta = \frac{1}{2k} \cdot q^{-k}$, which are all bounded by a function of k and q. Therefore instead of sampling a biased sampler family, we can enumerate all $\mathcal{O}(\delta^{-2}\log(|\mathcal{F}|))$-tuples of elements from X and find one giving a biased sampler family. ◀

Adjusting the parameters

The construction above implies that we can amplify the gap to any constant q by multiplying the size of an instance by a factor depending on k and q. However, when we want to rule out a superconstant approximation factor, e.g., $\alpha(k) = \log\log k$, we would like to apply the hypothetical approximation algorithm to the instance $(H, \mathcal{T}_H)$ with parameter k_0 depending on k and q, so we additionally need to adjust q so that $\alpha(k_0(k,q)) \leq q$.

▶ **Theorem 2.1.** *Consider a function $\alpha(k) = (\log k)^{\beta(k)}$, where $\beta(k) \to 0$ is computable and non-increasing. It is* W[1]*-hard to distinguish whether for a given instance of k-*Steiner Orientation*:*

1. *there exists an orientation satisfying all k terminal pairs, or*
2. *for all orientations the number of satisfied pairs is at most $\frac{1}{\alpha(k)} \cdot k$.*

Proof. We are going to reduce the exact version of k-Steiner Orientation, which is W[1]-hard, to the version with a sufficiently large gap, with Lemma 5.1. For a fixed k we can bound k_0 by a function of q: $k_0(q) \leq 2^{q^{c \cdot k}}$ for some constant c. On the other hand, $k_0(q) \to \infty$. Given an instance $(G, \mathcal{T}_G)$ we use Lemma 5.1 with q large enough, so that $\beta(k_0(q)) \cdot c \cdot k \leq 1$. The dependency $q(k)$ is also a computable function. We get $\alpha(k_0) = (\log k_0)^{\beta(k_0)} \leq q^{c \cdot k \cdot \beta(k_0)} \leq q$.

We have obtained a new instance $(H, \mathcal{T}_H)$ of k_0-Steiner Orientation of size $f(k) \cdot |V(G)|$ and k_0 being a function of k. If the original instance is fully satisfiable then the same holds for $(H, \mathcal{T}_H)$ and otherwise $S(H, \mathcal{T}_H) \leq \frac{1}{q} \cdot k_0 \leq \frac{1}{\alpha(k_0)} \cdot k_0$, which finishes the reduction. ◀

If we restrict the running time to be purely polynomial, we can slightly strengthen the lower bound, i.e., replace k with n in the approximation factor, while working with a similar hardness assumption. To make this connection, we observe that in order to show that a problem is in FPT, it suffices to solve it in polynomial time for some superconstant bound on the parameter.

▶ **Proposition 5.5.** *Consider a parameterized problem $\Pi \in$ XP that admits a polynomial-time algorithm (resp. false-biased polynomial-time algorithm) for the case $f(k) \leq |I|$, where f is some computable function. Then Π admits an* FPT *algorithm (resp. false-biased* FPT *algorithm).*

Proof. Since $\Pi \in$ XP, it admits a deterministic algorithm with running time $|I|^{g(k)}$. Whenever $f(k) \leq |I|$, we execute the polynomial-time algorithm. Otherwise we can solve it in time $f(k)^{g(k)}$. ◀

The hardness assumption below is slightly stronger than in Theorem 2.1, because the quantity 2^{k_0} can be super-polynomial and we cannot afford the time-expensive derandomization.

▶ **Theorem 2.2.** *Consider a function $\alpha(n) = (\log n)^{\beta(n)}$, where $\beta(n) \to 0$ is computable and non-increasing. Unless the class W[1] admits false-biased FPT algorithms, there is no polynomial-time algorithm that, given an instance of* Steiner Orientation *with n vertices and k terminal pairs, distinguishes between the following cases:*

1. *there exists an orientation satisfying all k terminal pairs, or*
2. *for all orientations the number of satisfied pairs is at most $\frac{1}{\alpha(n)} \cdot k$.*

Proof. Suppose there is such an algorithm with approximation factor $\alpha(n) = (\log n)^{\beta(n)}$. Let $\beta^*(\ell)$ be the smallest integer L, for which $\beta(L) \le \frac{1}{\ell}$. The function β^* is well defined and computable, because β is computable. Again, for fixed k and some constant c we have dependency $k_0(q) \le 2^{q^{c \cdot k}}$.

We are going to use the polynomial-time algorithm to solve k-Steiner Orientation in randomized $f(k) \cdot n^{\mathcal{O}(1)}$ time, which would imply the claim. Since the problem is in XP [15], by Fact 5.5 it suffices to solve instances satisfying $\beta^*((ck)^2) \le n$ in polynomial time. We can thus assume $(ck)^2 \cdot \beta(n) \le 1$, or equivalently $ck \cdot \beta(n) \le \sqrt{\beta(n)}$.

Given an instance of k-Steiner Orientation, we apply Lemma 5.1 with $q = (2 \log n)^{\beta(n)}$.

$$k_0 \le 2^{q^{ck}} = 2^{(2\log n)^{ck \cdot \beta(n)}} \le 2^{(2\log n)^{\sqrt{\beta(n)}}} = n^{o(1)},$$

$$\alpha(|V(H)|) \le \alpha(n \cdot k_0^2) = \alpha(n^{1+o(1)}) = ((1 + o(1)) \cdot \log n)^{\beta(n)}.$$

For large n we obtain $\alpha(|V(H)|) \le q$. Since $|V(H)| \le n \cdot k_0^2 = n^{1+o(1)}$, the size of the new instance of polynomially bounded and thus the randomized construction takes polynomial time. If we started with a YES instance, we always produce a YES instance, and otherwise $S(H, \mathcal{T}_H) \le \frac{1}{q} \cdot k_0 \le \frac{1}{\alpha(|V(H)|)} \cdot k_0$ with probability at least $\frac{1}{k_0}$, so we need to repeat the procedure $k_0 = n^{o(1)}$ times to get a constant probability of creating an instance with a small optimum. A hypothetical algorithm distinguishing these cases would therefore entail a false-biased polynomial-time algorithm for Steiner Orientation for the case $\beta^*((ck)^2) \le n$. The claim follows from Proposition 5.5. ◀

6 Inapproximability of Directed Multicut

We switch our attention to the Max (k,p)-Directed Multicut problem, for which we provide a slightly simpler reduction. We keep the same convention as before: within graph G we refer to sources and sinks $(s_i, t_i) \in \mathcal{T}$ shortly as $G\{s,i\}$, $G\{t,i\}$, and denote the maximal number of terminal pairs separable in $(G, \mathcal{T})$ by deleting p edges by $S(G, \mathcal{T}, p)$.

▶ **Lemma 6.1.** *There is a procedure that, for an instance $(G, \mathcal{T}_G, p)$, $|\mathcal{T}_G| = 4$ of* Directed Multicut *and parameter q, constructs a new instance $(H, \mathcal{T}_H, p_0)$, $k_0 = |\mathcal{T}_H|$, such that:*

1. *$k_0 = \Theta(p \cdot q^2 \log q)$,*
2. *$p_0 = \Theta(p^2 \log q)$,*
3. *$|E(H)| = |E(G)| \cdot p_0 + \mathcal{O}(k_0 \cdot p_0)$,*
4. *if $S(G, \mathcal{T}_G, p) = 4$, then $S(H, \mathcal{T}_H, p_0) = k_0$ always (Completeness),*
5. *if $S(G, \mathcal{T}_G, p) < 4$, then $S(H, \mathcal{T}_H, p_0) \le \frac{1}{q} \cdot k_0$ with probability at least $\frac{1}{2}$ (Soundness).*

The randomized construction takes time proportional to $|H|$. It can be derandomized in time $f(p,q) \cdot |G|$.

Proof. Consider $M = 3(p+1) \cdot \log q$ copies of $(G, \mathcal{T}_G)$, denoted $(G_1, \mathcal{T}_1), \dots, (G_M, \mathcal{T}_M)$. Let $\mathcal{R} = [4]^M$ be the family of all M-tuples with values in $[4]$. For a random sequence $R = (r_1, r_2, \dots r_M) \in \mathcal{R}$, we add a terminal pair s_R, t_R and for each $i \in [M]$ we add directed

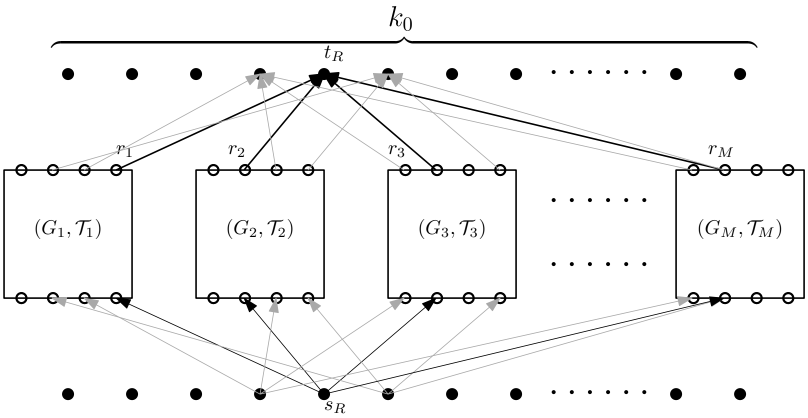

Figure 3 Building a new instance from M parallel copies of G. The tuple $R = (r_1, r_2, \dots r_M)$ encodes through which nodes the (s_R, t_R) pair is connected. For the sake of legibility only the edges incident to s_R, t_R (the black ones) and neighboring terminals (the grey ones) are sketched.

edges $(s_R, G_i\{s, r_i\})$ and $(G_i\{t, r_i\}, t_R)$. We repeat this subroutine $k_0 = \Theta(p \cdot q^2 \log q)$ times and create that many terminals pairs as depicted in Figure 3. We set the budget $p_0 = 3p(p+1) \cdot \log q$.

If $S(G, \mathcal{T}_G, p) = 4$, then the budget suffices to separate all terminal pairs in all copies of $(G, \mathcal{T}_G)$ (completeness). Otherwise, one needs to remove at least $p+1$ edges from each copy of $(G, \mathcal{T}_G)$ to separate all 4 pairs so we can afford that in at most $3p \cdot \log q$ copies. Therefore for any solution there are at least $3 \log q$ copies, where there is at least one terminal pair that is not separated.

Let $C_i \subseteq [4]$ represent information about the status of solution within $(G_i, \mathcal{T}_i)$: there is path from $G_i\{s, j\}$ to $G_i\{t, j\}$ only if $j \in C_i$. A tuple $C = (C_1, \dots, C_M)$ is called a configuration and we refer to the family of configurations induced by possible solutions as $\mathcal{C}$. Clearly, $|\mathcal{C}| \le 16^M$.

Recall that each terminal pair can be represented by a tuple $R = (r_1, r_2, \dots r_M) \in \mathcal{R}$ encoding through which terminal pair in G_i a path from s_R to t_R can go. For a fixed configuration $C \in \mathcal{C}$, function $f_C : \mathcal{R} \to \{0, 1\}$ is set to 1 if the pair s_R, t_R is separated, or equivalently: if for each $i \in [M]$ we have $r_i \notin C_i$. For $S(G, \mathcal{T}_G, p) < 4$ there are at least $3 \log q$ copies of G_i with $C_i \neq \emptyset$, therefore $\mathbb{E}_{R \sim U(\mathcal{R})} f_C(R) \le (\frac{3}{4})^{3 \log q} \le 2^{-\log(2q)} = \frac{1}{2q}$.

The size of $\mathcal{C}$ is at most $16^M = 2^{\mathcal{O}(p \log q)}$. We apply Lemma 5.3 for $\mathcal{F} = \{f_C : C \in \mathcal{C}\}$ and $\delta = \frac{1}{2q}$. It follows that $\mathcal{O}(\delta^{-2} \log(|\mathcal{F}|)) = \mathcal{O}(p \cdot q^2 \log q)$ random samples from $\mathcal{R}$ suffice to obtain a rounding error of at most $\frac{1}{2q}$ for all $C \in \mathcal{C}$ at once. Therefore with probability at least $\frac{1}{2}$ we have constructed an instance in which for any cutset of size p_0 (and thus for any configuration C) the fraction of separated terminal pairs is at most $\mathbb{E}_{R \sim U(\mathcal{R})} f_C(R) + \frac{1}{2q} \le \frac{1}{q}$. ◀

Remark on derandomization

As before, if we allow exponential running time with respect to p and q, we can find a correct sampler family by enumeration and derandomize the reduction. However, we cannot afford that in a polynomial-time reduction. To circumvent this, observe that we upper bound the expected value of f_C using independence of $3 \log q$ variables. We could alternatively take advantage of δ-biased ℓ-wise independent hashing [37] (cf. [8, 39, 40]) to construct biased ℓ-wise independent binary random variables with few random bits, instead of relying on Lemma 5.3. This technique provides an analogous bound on additive estimation error as in Lemma 5.3 for events that depend on at most ℓ variables. A family of N such variables can be constructed using $\mathcal{O}(\ell + \log\log N + \log(\frac{1}{\delta}))$ random bits [37, Lemma 4.2].

Since we are interested in having $N = \mathcal{O}(p \cdot \log q)$ variables, $\delta = \frac{1}{2q}$, and $(3\log q)$-wise independency, the size of the whole probabilistic space becomes $2^{\mathcal{O}(\log q + \log\log p)} = q^{\mathcal{O}(1)}(\log p)^{\mathcal{O}(1)}$. The problem is that we need to optimize the exponent at q in order to obtain better lower bounds. Unfortunately, we are not aware of any construction of a δ-biased ℓ-wise independent hash family, that would optimize this constant.

▶ **Theorem 2.4.** *For any $\varepsilon > 0$ and function $\alpha(k) = \mathcal{O}\left(k^{\frac{1}{2}-\varepsilon}\right)$, it is* W[1]*-hard to distinguish whether for a given instance of* Max (k,p)-Directed Multicut*:*

1. *there is a cut of size p that separates all k terminal pairs, or*
2. *all cuts of size p separate at most $\frac{1}{\alpha(k)} \cdot k$ terminal pairs.*

Proof. Let us fix $\varepsilon > 0$. We are going to reduce the exact version of p-Directed Multicut with 4 terminals, which is W[1]-hard, to the version with a sufficiently large gap, parameterized by both p and $k = |\mathcal{T}|$. Let L be an integer larger than $\frac{2}{\varepsilon}$.

For an instance $(G, \mathcal{T}, p)$ of p-Directed Multicut we apply Lemma 6.1 with $q = p^L$. If the original instance is fully solvable, the new one is as well. Otherwise the maximal fraction of separated terminal pairs is $\frac{k_0}{q} = \mathcal{O}(p \cdot q \log q) = \mathcal{O}(p^{L+2})$. On the other hand, $\frac{k_0}{\alpha(k_0)} = \Omega\left(k_0^{(\frac{1}{2}+\varepsilon)}\right) \geq \Omega\left(p^{2L\cdot(\frac{1}{2}+\varepsilon)}\right)$. The exponent at p in the latter formula is $L + 2\varepsilon L > L + 2$, so for large p it holds $\frac{k_0}{\alpha(k_0)} \geq \frac{k_0}{q}$, therefore the reduction maps NO-instances into those where all cuts of size p_0 separate at most $\frac{k_0}{\alpha(k_0)}$ terminal pairs. Both k_0 and p_0 are functions of p, therefore we have obtained a parameterized reduction. ◀

▶ **Theorem 2.5.** *Assuming* NP $\not\subseteq$ co-RP*, for any $\varepsilon > 0$ and function $\alpha(m) = \mathcal{O}\left(m^{\frac{1}{2}-\varepsilon}\right)$, there is no polynomial-time algorithm that, given an instance $(G, \mathcal{T}, p)$, $|\mathcal{T}| = k$, $|E(G)| = m$, of* Max Directed Multicut*, distinguishes between the following cases:*

1. *there is a cut of size p that separates all k terminal pairs, or*
2. *all cuts of size p separate at most $\frac{1}{\alpha(m)} \cdot k$ terminal pairs.*

Proof. Suppose there is such an algorithm for some $\varepsilon > 0$ and proceed as in the proof of Theorem 2.4 with L sufficiently large, so that $2\varepsilon L \geq 5$ and $q = m^L$. The reduction is polynomial because L is constant for fixed ε. We have $m_0 = |E(H)| = m \cdot p_0 + \mathcal{O}(k_0 \cdot p_0) = mp^2 \log q + \mathcal{O}(p^3 q^2 \log^2 q) = \mathcal{O}(m^{2L+5})$ because $p \leq m$. If the initial instance is fully satisfiable, then always $S(H, \mathcal{T}_H, p_0) = k_0$. For a NO-instance, we have $S(H, \mathcal{T}_H, p_0) \leq \frac{k_0}{q} = \mathcal{O}(m^{L+2})$ with probability at least $\frac{1}{2}$. On the other hand, $k_0 = \Omega(m^{2L})$ and

$$\frac{k_0}{\alpha(m_0)} = \Omega\left(\frac{1}{m_0^{\frac{1}{2}-\varepsilon}}\right) \cdot k_0 = \Omega\left(m^{2L-(2L+5)\cdot(\frac{1}{2}-\varepsilon)}\right) = \Omega(m^{L-\frac{5}{2}+2\varepsilon L}).$$

We have adjusted L to have $L - \frac{5}{2} + 2\varepsilon L > L + 2$, so for large m we get $\frac{k_0}{\alpha(m_0)} \geq \frac{k_0}{q}$. Therefore the reduction maps NO-instances into those where all cuts of size p_0 separate at most $\frac{k_0}{\alpha(m_0)}$ terminal pairs. When the reduction from Lemma 6.1 is correct (with probability at least $\frac{1}{2}$), we are able to detect the NO-instances. This implies that Directed Multicut $\in$ co-RP. ◀

7 Final remarks and open problems

I would like to thank Pasin Manurangsi for helpful discussions and, in particular, for suggesting the argument based on Chernoff bound in Lemma 5.1, which is surprisingly simple and powerful. A question arises whether one can derandomize this argument efficiently and construct a δ-biased sampler family in an explicit way. This would allow us to replace the assumption NP $\not\subseteq$ co-RP with P $\neq$ NP for Directed Multicut. This technique may also find use in other reductions in parameterized inapproximability.

An obvious question is if any of the studied problems admits an $o(k)$-approximation, or if the lower bounds can be strengthened. Note that for the maximization version of Directed Multicut we do not know anything better than $\frac{k}{2}$-approximation as we cannot solve the exact problem for $k > 2$. For Steiner Orientation, the reason why the value of the parameter in the self-reduction becomes so large, is that in each step we can add only an exponentially small term to the gap. Getting around this obstacle should lead to better lower bounds. Also, the approximation status for k-Steiner Orientation on planar graphs remains unclear [11]. Here we still cannot rule out a constant approximation and there are no upper bounds known.

Finally, it is an open quest to establish relations between other hard parameterized problems and their gap versions. Is $F(k)$-Gap k-Clique W[1]-hard for $F(k) = o(k)$ and is $F(k)$-Gap k-Dominating Set W[2]-hard for any function F (open questions in [26])? Or can it be possible that $F(k)$-Gap k-Dominating Set is in W[1] for some function F?

Near-Optimal Algorithm for Constructing Greedy Consensus Tree

Hongxun Wu
Institute for Interdisciplinary Information Sciences, Tsinghua University, Beijing, China
wuhx18@mails.tsinghua.edu.cn

Abstract

In biology, phylogenetic trees are important tools for describing evolutionary relations, but various data sources may result in conflicting phylogenetic trees. To summarize these conflicting phylogenetic trees, consensus tree methods take k conflicting phylogenetic trees (each with n leaves) as input and output a single phylogenetic tree as consensus.

Among the consensus tree methods, a widely used method is the greedy consensus tree. The previous fastest algorithms for constructing a greedy consensus tree have time complexity $\tilde{O}(kn^{1.5})$ [Gawrychowski, Landau, Sung, Weimann 2018] and $\tilde{O}(k^2n)$ [Sung 2019] respectively. In this paper, we improve the running time to $\tilde{O}(kn)$. Since k input trees have $\Theta(kn)$ nodes in total, our algorithm is optimal up to polylogarithmic factors.

1 Introduction

The problem of constructing consensus trees arises from bioinformatics. In biology, phylogenetic trees describe the biological evolutionary relations between species. But the phylogenetic trees from different biological data may conflict with each other. As mentioned in [22], even from the same data set, when certain resampling techniques are used, we could still get many different phylogenetic trees. This problem has long been studied, to name a few [1, 14, 28, 17, 13, 12, 18, 5].

Motivated by this, consensus tree methods were proposed [1] to summarize these phylogenetic trees into a single phylogenetic tree, which is viewed as the consensus of these phylogenetic trees and is called the consensus tree. Since then, many different consensus tree methods were proposed. As mentioned in [22], the majority rule consensus tree [28], the loose consensus tree [8], and the greedy consensus tree [9] are the most frequently used consensus trees.

As discussed in [11], while increasing the number of phylogenetic trees in the input, the greedy consensus tree converges faster than majority rule consensus tree and R^* consensus tree. Although the greedy consensus tree is not a consistent estimator, the region of parameter space in which greedy consensus tree fails is relatively small, hence greedy consensus tree offers more robustness [11]. The greedy consensus tree method is implemented in many software packages, such as PHYLIP [15], PAUP* [40], MrBayes [32], RAxML [37], and also widely used in numerous works in biology [6, 7, 11, 24, 26, 27, 30, 31, 33, 34, 36, 38].

For most consensus tree methods, optimal or near-optimal algorithms for construction have been found. One exception is the greedy consensus tree (See Table 1). For greedy consensus tree construction, the naïve algorithm takes $\tilde{O}(kn^3)$ time [9]. Then it was improved to $O(kn^2)$ time by [22]. Recently there are $\tilde{O}(kn^{1.5})$ [16] and $\tilde{O}(k^2n)$ [39] algorithms proposed for it.

Table 1 Running time of construction algorithms for different consensus tree methods.

Consensus tree method	Running time	Reference
Adam's consensus tree	$O(kn \log n)$	[19]
Strict consensus tree	$O(kn)$	[10]
Loose consensus tree	$O(kn)$	[22]
Frequency difference consensus tree	$O(kn \log^2 n)$	[16]
Majority-rule consensus tree	$O(kn \log k)$, Randomized $O(kn)$	[4, 22]
Majority-rule (+) consensus tree	$O(kn)$	[21]
Local consensus tree	$O(kn^3)$	[25, 20]
R^* consensus tree	$O(n^2 \log^{k+2} n)$	[23]
Greedy consensus tree	$O(kn^{1.5})$, $O(k^2 n)$	[16, 39]

In this paper, we present a near-optimal $\tilde{O}(kn)$ time algorithm for greedy consensus tree construction.

▶ **Theorem 1.** *Greedy consensus tree of k phylogenetic trees for n species can be constructed in $\tilde{O}(kn)$ time.*

High Level Idea

The previous $\tilde{O}(kn^{1.5})$ algorithm [16] builds the consensus tree by dynamically adding nodes to it. To find out the position to add a new node, they need to support least common ancestor query on the consensus tree. Since the consensus tree is dynamically changing, answering such queries is time-consuming and becomes the bottleneck of this previous algorithm. Motivated by it, we came up with an alternative approach that only requires least common ancestor query on the phylogenetic trees in the input. Since these are static trees, such queries can be efficiently answered. This leads to our improved algorithm.

2 Preliminaries

2.1 Phylogenetic Tree

Phylogenetic trees represent the evolution of species. Different leaves of a phylogenetic tree represent different species. From biological data, we can infer that some of these species share common ancestors. These common ancestors are represented by the nonleaf nodes, also called inner nodes. Each inner node represents the common ancestor of all leaves in its subtree.

Formally, a tree with n leaves is leaf-labeled if and only if its n leaves have distinct labels from 1 to n. A phylogenetic tree T is a rooted, unordered, leaf-labeled tree in which every inner node has at least two children. If there is a directed path from node u to node v, u is a descendant of v, and v is an ancestor of u. Thus node u is a descendant of itself. If $u \neq v$ and v is a descendant of u, v is a proper descendant of u, and u is a proper ancestor of v.

The subtree tree of an inner node u is the subtree rooted at u and formed by all its descendants. In the rest of the paper, whenever we say a subtree, we always refer to the subtree of an inner node.

Cluster and Signature

For inner node v in phylogenetic tree T, we define $L(v)$ to be the set of species within its subtree. Namely, $L(v) = \{x \in [n] : \text{There is a leaf labeled } x \text{ in the subtree of } v\}$. The set $L(v)$ is called a cluster.

Based on $L(v)$, we define the signature of phylogenetic tree T to be the set of all clusters in it. Namely, $\text{sign}(T) = \{L(v) : v \text{ is an inner node in } T\}$.

▶ **Observation 2.** *The signature of a phylogenetic tree completely captures its structure. Namely, given $sign(T)$, the phylogenetic tree T is uniquely determined.*

More specifically, suppose the cluster $c_1 \in sign(T)$ corresponds to node u on T. Namely, $c_1 = L(u)$. Let $par(u)$ denote the parent of u on T. $L(par(u))$ is the smallest cluster $c_2 \in sign(T)$ such that $c_1 \subset c_2$. This determines the parent of each node.

Consistency

But not every set S of clusters can be the signature of a phylogenetic tree. S is a valid signature if and only if it is a laminar family. In this case, we say S is consistent. Namely, S is consistent if and only if for every pair of distinct clusters $c_1, c_2 \in S$, one of the following holds:

- $c_1 \cap c_2 = \emptyset$
- $c_1 \subset c_2$
- $c_1 \supset c_2$

We say a cluster c is consistent with S if and only if $S \cup \{c\}$ is consistent.

2.2 Greedy Consensus Tree

Recall that the greedy consensus tree method takes k phylogenetic trees $T_1, T_2, \cdots, T_k$ as inputs. These k trees are over the same set of n species. Its objective is to output a single phylogenetic tree to be the consensus tree.

Definition

As its name suggests, a greedy consensus tree is defined as the output of a simple greedy algorithm. Let $\mathcal{F}$ be the set of all clusters that have appeared in $T_1, T_2, \cdots, T_k$. The frequency $f(c)$ of a cluster c is the number of times c appears in $\mathcal{F}$.

Let S denote the signature of the current consensus tree. Initially, the consensus tree only contains a root and n leaves. Thus $S = \{\{1, 2, \ldots, n\}, \{1\}, \{2\}, \ldots, \{n\}\}$. Each time we pick the cluster with the highest frequency in $\mathcal{F}$ and add it to S if they are consistent. From the tree point of view, we are adding a new inner node to the consensus tree. For the details, see Algorithm 1.

Algorithm 1 Greedy consensus tree.

```
1: Initially signature $S \leftarrow \{\{1, 2, \ldots, n\}, \{1\}, \{2\}, \ldots, \{n\}\}$
2: $\mathcal{F} \leftarrow \text{sign}(T_1) \cup \text{sign}(T_2) \cup \cdots \cup \text{sign}(T_k)$
3: For all clusters $c \in \mathcal{F}$, count its frequency $f(c) \leftarrow |\{i | c \in \text{sign}(T_i)\}|$
4: while $\mathcal{F} \neq \emptyset$ do
5:     Pick $c_0 \leftarrow \arg\max_{c \in \mathcal{F}} f(c)$ with the highest frequency (ties are broken arbitrarily)
6:     if $c_0$ is consistent with $S$ then $S \leftarrow S \cup \{c_0\}$
7:     $\mathcal{F} \leftarrow \mathcal{F} \backslash \{c_0\}$
8: $S$ is the signature of a greedy consensus tree
```

Since at Line 5, Algorithm 1, ties are broken arbitrarily, the output of the algorithm may not be unique. There may be more than one greedy consensus tree for a fixed input.

Running Time

Algorithm 1 is a naïve algorithm for constructing greedy consensus trees. Here we discuss this algorithm and its complexity in more detail. It essentially contains two phases:

1. Count the frequency $f(c)$ of clusters and sort them. (Line $1 \sim 3$ of Algorithm 1)
2. Repeatedly run the greedy procedure. (Line $4 \sim 7$ of Algorithm 1)

The first phase is easy to be handled in $\tilde{O}(kn)$ time. Suppose $|\mathcal{F}| = m$. Namely, there are m distinct clusters. For each of them, we assign a unique number in $[m]$ to it as its identifier. For each $u \in T_i$, let $id(u) \in [m]$ be the identifier of $L(u)$. Then, for $u \in T_i$ and $v \in T_j$, $id(u) = id(v)$ if and only if $L(u) = L(v)$.

In [16], they showed that these identifiers can be computed in $O(kn \log^2 n)$ time. To be self-contained, we state it in Lemma 4 and present a short proof here. We first need a data structure for dynamic set equality.

▶ **Lemma 3** (Lemma 1, [16]). *There is a deterministic dynamic set equality structure that supports:*

- $\textsc{Create}(s)$*: Create a new empty set* s*.*
- $\textsc{Add}(s, x)$*: Add an element* x *to set* s*. (create a new set* $s \cup \{x\}$ *without destroying* s*)*
- $ID(s)$*: Return the identifier of set* s *which is a positive integer smaller than the number of sets we have created. Two sets have the same identifier if and only if they are equal.*

Let n *denote the size of all sets created. Each operation takes* $\tilde{O}(1)$ *time.*

Proof. We apply the dynamic string equality structure in [29]. It supports the following operations in $\tilde{O}(1)$ time: (1) create a new string with a single character, (2) test if two strings are equal, (3) split a string into two new strings without destroying it, (4) concatenate two strings to form a new string without destroying them, (5) given i, return the i-th character in a string. Modifying a character of a string can be reduced to $O(1)$ split, create, and concatenate operations. Comparing the lexicographical order of two strings can be reduced to $O(\log n)$ split and equality testing operations using binary search. Thus they all take $\tilde{O}(1)$ time.

We encode each set s into a binary string. The i-th bit of the string is 1 if and only if $i \in s$. For empty set, we create a new string with n zeros in beginning. To add an element x to s, we only need to modify the x-th bit in the string which take $\tilde{O}(1)$ time.

To maintain the identifier of each set s, we maintain a global balanced binary search tree of the strings of all sets in their lexicographical order. When a new set is created, we add its string to this balanced binary search tree, and attach a new identifier to it. Since comparing lexicographical order takes $\tilde{O}(1)$ time, maintaining this binary search tree and finding the identifier of a set also takes $\tilde{O}(1)$ time. ◀

▶ **Lemma 4** (Theorem 3, [16]). *The identifier* $id(u)$ *can be found for every node* u *of phylogenetic trees* $T_1, T_2, \cdots, T_k$ *in* $\tilde{O}(kn)$ *time.*

Proof. We process each tree T_i bottom-up. For each inner node u, we obtain $L(u)$ and its identifier in the dynamic set equality structure by the following procedure:

1. Let v be the children of u with the largest subtree. If v is a leaf, we let s be the singleton $\{\text{label}(v)\}$. Otherwise, let $s = L(v)$ in dynamic set equality structure.
2. We traverse the subtrees of all other children of u and add the leaves we visited into s. Now s equals $L(u)$
3. $id(u) \leftarrow \text{ID}(s)$.

Since each time a node is visited at Step 2, the subtree it belongs to is doubled. Each node can be visited at most $O(\log n)$ times throughout the procedure. Thus this procedure takes $\tilde{O}(kn)$ time in total. ◀

After we get the identifiers $id(u)$, counting the frequency of identifiers and sorting within $\tilde{O}(kn)$ time are straight-forward.

The bottleneck of the naïve algorithm is the second phase. To test whether the signature S of the consensus tree is consistent with c_0, the naïve algorithm enumerates all clusters in S. There can be at most $O(n)$ clusters in S since each of them corresponds to a node in the consensus tree.

For every cluster in S testing whether it is consistent with c_0 takes $O(n)$ time. There are $O(n)$ clusters in S. Thus for each c_0, it takes at most $O(n^2)$ time. There are $O(kn)$ clusters in $\mathcal{F}$ (since each of them corresponds to at least one node in $T_1, T_2, \ldots, T_k$).

So in total, the naïve algorithm takes $O(kn^3)$ time. We will present our algorithm for the second phase in Section 3 and show how to make it efficient in Section 4.

2.3 Data Structures

Our algorithm relies on some classical data structure techniques introduced here.

DFS Sequence

Let T be a rooted tree. The Euler tour of T starts from its root, passing by each edge exactly twice (from opposite directions), and return to the root. We define $E(T)$ to be the Euler tour of T in which we only keep the first occurrence of each node. Or equivalently, $E(T)$ is the sequence produced by the following depth-first search: Initially let the sequence be empty. When we perform a depth-first search on T, each time we visit a node for the first time, we add it to the end of our sequence. In the end, this sequence equals $E(T)$.

▶ **Observation 5.** *Suppose v is a node on T. All nodes within the subtree of v form a continuous interval in $E(T)$.*

For the subtree of v on T, we denote its corresponding interval by $[l_T(v), r_T(v)]$. Here $l_T(v)$ is the position of v in $E(T)$, and $r_T(v)$ is the position of the last node that belongs to the subtree of v in $E(T)$.

Top Tree

A dynamic forest is a set of trees over disjoint sets of nodes that supports dynamic edge connection and deletion. Top tree [3] is a useful data structure for maintaining information in a dynamic forest. k-th ancestor of node u is the ancestor which is higher than u by k edges. When $k = 1$, it is the parent of u.

▶ **Lemma 6** ([3])**.** *Top tree supports the following operations in $\tilde{O}(1)$ time:*

1. *$connect(u, v)$: Add an edge connecting nodes u and v that belong to different trees.*
2. *$delete(u, v)$: Delete the edge connecting nodes u and v.*
3. *$lca(u, v)$: Return the least common ancestor of u and v.*
4. *$ancestor(u, k)$: Return the k-th ancestor of u.*

Splay tree

Splay tree [35] is a classical binary search tree maintaining a dynamic sequence. Each element in the sequence has two attributes, its key and value. The elements in a dynamic sequence are arranged in the increasing order of their keys. While keys specify the order of the elements, values are the information related to our queries.

▶ **Lemma 7.** *Let K be an ordered set, and let $G = (S, +)$ be a semigroup. Splay tree maintains n nodes each with its key and value, supporting the following operations:*

1. *$Insert(k, v)$: Insert a new node with key $k \in K$ and value $v \in S$.*
2. *$Delete(k)$: Delete the elements with key $k \in K$.*
3. *$Split(k)$: Return two splay trees T_1, T_2. T_1 contains all nodes whose keys are smaller than k, and T_2 contains all other nodes. The original splay tree is destroyed after the operation.*
4. *$Size()$: Return the number of nodes in the splay tree.*
5. *$Merge(T_1, T_2)$: Merge two splay trees T_1, T_2 where all nodes in T_1 have smaller keys than those in T_2.*
6. *$Sum(k_1, k_2)$: Suppose the values of nodes with keys $k \in [k_1, k_2]$ are $v_1, v_2, \ldots, v_t$ in the order of increasing keys. Then it returns $v_1 + v_2 + \cdots + v_t$.*

Suppose the $+$ operation of semigroup G takes $\tilde{O}(1)$ time. Then each operation here takes $\tilde{O}(1)$ time.

Specifically, it has the following two applications:

- *Let S be the set of integers, and let $+$ be addition. We can answer the summation of a continuous subsequence in $\tilde{O}(1)$ time.*
- *Let S be the set of nodes in a static tree, and let $a + b$ be the least common ancestor of a and b. We can answer the least common ancestor of a continuous subsequence in $\tilde{O}(1)$ time.*

Proof. The original paper [35] for splay tree showed how to handle insert, delete, split, and merge operations when nodes only have keys but no values.

Here at each node, in addition to its key, we also maintain its value and the summation of all values in its subtree. (Here summation refers to the operation of the semigroup) This summation can be calculated from the summation of its children by a $+$ operation. Whenever the children of a node in splay tree changes, we update its summation. Since for each operation, we only change the children of $O(\log n)$ nodes. Update the summation for them takes $O(\log n)$ many $+$ operations only.

To evaluate $Sum(k_1, k_2)$, we first split the splay tree into three trees T_1, T_2, T_3 using two splits. T_1 contains all nodes with keys smaller than k_1. T_2 contains all elements with keys in $[k_1, k_2]$. T_3 contains all other elements. Then we return the summation maintained at the root of T_2, and merge them back.

For $Size()$ query, we can let the value of each node be one and reduce it to the value summation query.

For the applications, since LCA operation is associative, $(S, +)$ is a semigroup. The LCA of two nodes can be answered in $\tilde{O}(1)$ time [2]. Thus each operation takes only $\tilde{O}(1)$ time, and we can answer the least common ancestor of a continuous subsequence by $Sum(k_1, k_2)$.

Similarly, we can answer the summation of a continuous subsequence in $\tilde{O}(1)$ time by $Sum(k_1, k_2)$. ◀

3 Algorithm

In the naïve algorithm, checking whether a cluster c_0 is consistent with signature S takes $O(n^2)$ time. To speed it up, the first step is to find a characterization of consistency that utilizes the tree structure. Here we start with the characterization from the previous $\tilde{O}(kn^{1.5})$ algorithm [16]. Then we develop it into an improved algorithm.

From this section, we will be using the following notations. $\mathcal{T}$ denotes the phylogenetic tree corresponding to signature S, namely our consensus tree. $\mathrm{LCA}_{\mathcal{T}}(c_0)$ is the least common ancestor of all species in cluster c_0 on consensus tree $\mathcal{T}$, while $LCA_i(c_0)$ is that on the input phylogenetic tree T_i. $subtree(v)$ denotes the set of all nodes (both inner nodes and leaves) within the subtree of v.

3.1 Characterization of consistency

In this subsection, the proof of Lemma 8 and 9 are already known from [16], but for clarity, we formally state and prove them here.

To utilize the tree structure, we will focus on consensus tree $\mathcal{T}$ instead of its signature S. The cluster c_0 is consistent with S if and only if for all nodes $u \in \mathcal{T}$, $L(u)$ is consistent with c_0. First, we begin with a lemma that says only those nodes within the subtree of $LCA_{\mathcal{T}}(c_0)$ matters.

▶ **Lemma 8** ([16]). *For node $u \in \mathcal{T}$ outside the subtree of $LCA_{\mathcal{T}}(c_0)$, $L(u)$ is always consistent with c_0.*

Proof. For simplicity, we use lca to denote $LCA_{\mathcal{T}}(c_0)$ here. By the definition of lca, we know $c_0 \subseteq L(lca)$. $u \notin subtree(lca)$ implies that $L(u) \not\subset L(lca)$. Since signature S is consistent, there are two possibilities, either $L(lca) \subset L(u)$ or $L(lca) \cap L(u) = \emptyset$.

- $L(lca) \subset L(u)$: Then $c_0 \subseteq L(lca) \subset L(u)$.
- $L(lca) \cap L(u) = \emptyset$: Then $c_0 \cap L(u) \subseteq L(lca) \cap L(u) = \emptyset$.

In both cases, $L(u)$ is consistent with c_0. ◀

Then we focus on nodes within the subtree of $LCA_{\mathcal{T}}(c_0)$, more specifically, the children of $LCA_{\mathcal{T}}(c_0)$. Following is the characterization.

▶ **Lemma 9** ([16]). *Cluster c_0 is consistent with the signature S of $\mathcal{T}$ if and only if every child w of $LCA_{\mathcal{T}}(c_0)$ satisfies one of the following:*

- $L(w) \subset c_0$
- $L(w) \cap c_0 = \emptyset$

Equivalently, $S \cup \{c_0\}$ is consistent if and only if

$$\sum_{\substack{\text{child } w \text{ of } LCA_{\mathcal{T}}(c_0) \\ L(w) \subset c_0}} |L(w)| = |c_0|$$

Proof. For simplicity, we use lca to denote $LCA_{\mathcal{T}}(c_0)$ here. By Lemma 8, we only have to consider every node u within the subtree of lca. If $c_0 = L(lca)$, c_0 is consistent with S (since $S \cup \{c_0\} = S$), and all children w satisfies $L(w) \subset c_0$. Now we assume $c_0 \neq L(lca)$ which implies $c_0 \subset L(lca)$.

We first prove that this condition is sufficient. For inner node u within the subtree of lca, if $u = lca$, we know $c_0 \subset L(u)$ which means they are consistent. Otherwise, u must belong to the subtree of a child of lca. Let us call this child w_0.

By the condition of this lemma, either $L(w_0) \cap c_0 = \emptyset$ or $L(w_0) \subset c_0$. If $L(w_0) \cap c_0 = \emptyset$, since $L(u) \subseteq L(w_0)$, we know $L(u) \cap c_0 = \emptyset$. Otherwise $L(u) \subseteq L(w_0) \subset c_0$. In either case, $L(u)$ is consistent with c_0.

Then we prove the necessity. For every child w of lca, since $L(w)$ has to be consistent with c_0, either one of two conditions in this lemma holds, or $c_0 \subset L(w)$. If $c_0 \subset L(w)$, then w is either lca or a proper ancestor of lca, which contradicts the fact that w is a child of lca. ◀

3.2 Our Algorithm

Algorithm

We begin with a corollary of the characterization to replace $LCA_{\mathcal{T}}(c_0)$.

▶ **Corollary 10.** *c_0 is consistent with the signature S of $\mathcal{T}$ if and only if, there exists a node $u_0 \in T$, such that $c_0 \subseteq L(u_0)$, and every child w of u_0 satisfies one of the following:*

- $L(w) \subseteq c_0$
- $L(w) \cap c_0 = \emptyset$

Equivalently, $S \cup \{c_0\}$ is consistent if and only if $\exists u_0 \in T$ such that

$$\sum_{\substack{child\ w\ of\ u_0 \\ L(w) \subseteq c_0}} |L(w)| = |c_0|$$

Proof. For necessity, let $u_0 = LCA_{\mathcal{T}}(c)$.

For sufficiency, if $u_0 = LCA_{\mathcal{T}}(c_0)$, it follows from Lemma 9. If $u_0 \neq LCA_{\mathcal{T}}(c_0)$, since $c_0 \subseteq L(u_0)$, there must be a child w_0 of u_0 such that $c_0 \subseteq L(w_0)$. Otherwise, $LCA_{\mathcal{T}}(c_0)$ should have been u_0. On the other hand, because $L(w_0) \cap c_0 \neq \emptyset$, $L(w_0) \subseteq c_0$. Thus $c_0 = L(w_0)$. Namely, if $u_0 \neq LCA_{\mathcal{T}}(c_0)$, it must be the parent of $w_0 = LCA_{\mathcal{T}}(c_0)$, and $c_0 = L(w_0)$. c_0 is then consistent with S since $L(w_0) \in S$. ◀

We have the following lemma to help us find such u_0.

▶ **Lemma 11.** *Suppose x is an arbitrary leaf of $\mathcal{T}$ such that $x \in c_0$. Let u_0 be the lowest ancestor of x that $L(u_0) \nsubseteq c_0$. c_0 is consistent with the signature S of $\mathcal{T}$ if and only if u_0 satisfies the conditions in Corollary 10.*

Besides, let p be the path from the root to u_0. If c_0 is consistent with signature S, for each proper ancestors u of u_0, $L(u) \nsubseteq c_0$, and for each proper descendant u of u_0 on path p, $L(u) \subseteq c_0$.

Proof. If c_0 is consistent with S, by Corollary 10, there is a node $u_0 \in T$ satisfying the conditions. Then by $c_0 \subseteq L(u_0)$, we know x is in the subtree of u_0. In other words, u_0 is on path p.

For each proper ancestor u of u_0, $c_0 \subseteq L(u_0) \subset L(u)$. Thus $L(u) \nsubseteq c_0$. Suppose the child of u_0 on path p is w_0. Since leaf $x \in c_0 \cap L(w_0)$, we know $L(w_0) \subseteq c_0$ from the conditions in Corollary 10. For all proper descendants u of u_0 on path p, $L(u) \subseteq L(w_0) \subseteq c_0$. Thus u_0 is the lowest ancestor of x that $L(u_0) \nsubseteq c_0$. ◀

By Lemma 11, we can perform a binary search on path p to find the lowest ancestor u_0 of x that $L(u_0) \nsubseteq c_0$. We will show how to check whether $L(u) \nsubseteq c_0$ for an arbitrary node $u \in \mathcal{T}$ efficiently in Section 4.

Finally, we discuss how $\mathcal{T}$ should change when we add c_0.

▶ **Lemma 12.** *Suppose S is consistent with c_0 and $c_0 \notin S$. When adding c_0 to S and adding the new node (corresponding to c_0) to $\mathcal{T}$, the u_0 in Lemma 11 should be the parent of the new node on $\mathcal{T}$. The children of the new node should be all children w of u_0 such that $L(w) \subset c_0$.*

Proof. Since the leaf $x \in c_0$ (in Lemma 11), all inner nodes u with $c_0 \subset L(u)$ are on path p, the path from the root to x. Thus by Lemma 11, $L(u_0)$ is the smallest set in S that contains c_0. Then the first claim follows from Observation 2. For those children w of u_0 such that $L(w) \subset c_0$, c_0 becomes the smaller set containing them. Thus they must change their parent. For other nodes u, such that $L(u) \subset c_0$, by the conditions of Corollary 10, u must be within the subtree of a child of u_0. Then that child is a smaller set containing it. Thus their parents stay unchanged. ◀

Algorithm 2 Our algorithm to check consistency and update $\mathcal{T}$.

```
1:  Pick an arbitrary species in $c_0$, and $x \leftarrow$ the corresponding leaf of $\mathcal{T}$
2:  Binary search the path from root to $x$.
3:  $u_0 \leftarrow$ the lowest node $u$ on the path that $L(u) \nsubseteq c_0$
4:  $sum \leftarrow \sum_{\text{child } w \text{ of } u_0, L(w) \subseteq c_0} |L(w)|$
5:  if $sum = |c_0|$ then
6:      $c_0$ is consistent with $S$, and we add it to consensus.
7:      We add a new node $w'$ (corresponding to $c_0$) to $\mathcal{T}$
8:      for child $w$ of $u_0$ do
9:          if $L(w) \subset c_0$ then
10:             Move $w$ to be a child of $w'$
11:     Let $w'$ be a child of $u_0$
```

Details of our algorithm are presented in Algorithm 2.

▶ **Lemma 13.** *$sum = |c_0|$ at Line 5, Algorithm 2 if and only if c_0 is consistent with S.*

Proof. If c_0 is consistent with S, by Lemma 11 we must find such a node u_0. On the other hand, if c_0 is not consistent with S, by Corollary 10, there is no such u_0. [1] ◀

To test whether $L(u) \subseteq c_0$ at Line 3, we need the following lemma. Recall $LCA_i(c)$ is the least common ancestor on tree T_i for cluster c.

▶ **Lemma 14.** *Suppose $c_0 = L(v)$ where v is a node in T_i. For a node u in $\mathcal{T}$, $L(u) \subseteq c_0$ if and only if $LCA_i(L(u))$ is in the subtree of v.*

Proof. If $L(u) \subseteq c_0 = L(v)$, every leaf in $L(u)$ is a descendant of v. So $LCA_{T_i}(L(u))$ is in the subtree of v. (note when $c_0 = L(u)$, it is still true since $LCA_i(L(u)) = v$)

Conversely, if $LCA_i(L(u))$ is a descendant of v, since leaves in $L(u)$ are in the subtree of $LCA_i(L(u))$ on T_i, they are also in the subtree of $L(v)$. Thus $L(u) \subseteq L(v) = c_0$. ◀

Thus the subset queries at Line 11 of Algorithm 2 are turned into LCA queries on phylogenetic tree T_i. Also for the summation query at Line 4, $L(w) \subseteq c_0$ if and only if $LCA_i(L(w))$ is in the subtree of v.

Since T_i is a fixed static tree, finding $LCA_i(L(w))$ is tractable in polylogarithmic time. Details are presented in the next section.

[1] Note if c_0 is not consistent with S, u_0 may not equal to $LCA_{\mathcal{T}}(c)$. In this case, we have to refer back to Corollary 10 instead of Lemma 9.

4 Efficiency

In this section, we will show that our algorithm can be implemented efficiently. There are two kinds of queries in Algorithm 2:

1. $\boldsymbol{lca(u, i)}$: Given $u \in \mathcal{T}$, return $LCA_i(L(u))$ on tree T_i. (At Line 3, to see whether $L(u) \subseteq c_0$, by Lemma 14, we need to find out $LCA_i(L(u))$)
2. $\boldsymbol{sum(u, v, i)}$: Given $u \in \mathcal{T}$ and $v \in T_i$, evaluate the summation

$$\sum_{\substack{\text{child } w \text{ of } u \\ LCA_i(L(w)) \in subtree(v) \text{ on } T_i}} |L(w)|$$

   (By Lemma 14, it equals the summation sum at Line 4)

After checking consistency, in Line 7 $\sim$ 11, Algorithm 2, the consensus tree is dynamically updated. The following update operation is needed:

1. $\boldsymbol{add(u, v, i)}$: Given $u \in \mathcal{T}$ and $v \in T_i$, add a new node w' to be a child of u. For all children w of u such that $LCA_i(L(w))$ is in the subtree of v, move them to be the children of the new node w'.

4.1 Data Structures

Recall $E(T)$ is the Euler tour of T where we only keep the first occurrence of each node. For node $v \in T_i$, the subtree of $L(v)$ corresponds to a continuous interval $[l_{T_i}(v), r_{T_i}(v)]$ in $E(T_i)$. Let $l_i(v)$ and $r_i(v)$ be the shorthands for $l_{T_i}(v)$ and $r_{T_i}(v)$.

The data structures we use have three components:

1. For each phylogenetic tree T_i, we maintain a top tree T_i'. Thus by Lemma 6, we can answer the least common ancestor of two nodes in $\tilde{O}(1)$ time.
2. For the consensus tree $\mathcal{T}$, we maintain its structure with a top tree $\mathcal{T}'$. By Lemma 6, we can answer k-th ancestor query in $\tilde{O}(1)$ time. This is for the binary search at Line 3, Algorithm 2.
3. For each node $u \in \mathcal{T}$, we use k splay trees $S_1, \ldots, S_k$ to maintain all its children w. The key of child w in the i-th tree is $l_i(LCA_i(L(w)))$, the position of $LCA_i(L(w))$ in $E(T_i)$. We maintain the following two values for each child w:
   - $|L(w)|$: The corresponding operation is integer additions.
   - $LCA_i(L(w))$: The corresponding operation is the least common ancestor of two nodes on T_i.

   Thus the splay trees support the following two kinds of queries:
   - $Sum\_Size(k_1, k_2)$: return the summation of the first value of each w whose key is in range $[k_1, k_2]$.
   - $Sum\_LCA(k_1, k_2)$: return the LCA of the second value of each w whose key is in range $[k_1, k_2]$.

Here the splay trees can be replaced with any balanced search trees with merge and split operations.

For each node $u \in \mathcal{T}$, we compute $LCA_i(L(u))$ for all i once we add u to our consensus tree and store these k numbers at node u. Namely, we compute them during the updates, not the queries.

4.2 Handle Update

Recall $add(u, v, i)$ requires us to do the following:

- add a new node w' to be a child of u on the consensus tree $\mathcal{T}$
- move some children of u to be children of w'

Let the set of all children of u be C and those children need to move be W. $par(u)$ denotes the parent of u.

Here we use the following idea from [16]:

- If $|W| \leq |C|/2$, we add a new node w' to be a child of u. Then we move nodes in W to be the children of w' one by one.
- If $|W| > |C|/2$, instead of moving nodes in W, we move nodes in $C \backslash W$. We disconnect u from $par(u)$ and connect w' with $par(u)$. Namely, replace u with w'. Then we make u a child of w'. For all children of u in $C \backslash W$, we move them to be the children of w'.

In this way, we need to move at most $\min\{|W|, |C| - |W|\}$ nodes. The details are presented in Algorithm 3.

Algorithm 3 Handle update $add(u, v, i)$.

```
1:  $C \leftarrow$ the set of all children of $u$
2:  $W \leftarrow \{w \in C | LCA_i(L(w)) \in subtree(v)$ on $T_i\}$
3:  if $|W| \leq |C|/2$ then
4:      Add a new node $w'$ to be a child of $u$ on Top tree $\mathcal{T}'$
5:      for $w \in W$ do
6:          Cut the edge between $w$ and $u$ on $\mathcal{T}'$ and connect $w$ with $w'$
7:          Remove $w$ from the splay trees at $u$. Insert $w$ into splay trees at $w'$
8:      for $i \in k$ do
9:          Compute $LCA_i(L(w')) \leftarrow Sum\_LCA(1, n)$ by query the splay tree $S_i$ at node $w'$
10: else
11:     Add a new node $w'$ to replace $u$, and make $u$ a child of $w'$ on Top tree $\mathcal{T}'$
12:     for $w \in C - W$ do
13:         Cut the edge between $w$ and $u$ on $\mathcal{T}'$ and connect $w$ with $w'$
14:         Remove $w$ from the splay trees at $u$. Insert $w$ into splay trees at $w'$
15:     for $i \in k$ do
16:         $LCA_i(L(w))$ gets the answer we stored at node $u$ before
17:         Compute $LCA_i(L(u)) \leftarrow Sum\_LCA(1, n)$ by query the splay tree $S_i$ at node $u$
```

▶ **Lemma 15.** *Each node is moved at most $O(\log n)$ times.*

Proof. No matter we move children in W or $C \backslash W$, the set C is eventually divided into two sets $C \backslash W$ and W after the procedure. Since we always move the nodes in the smaller set, each time we move a node, the size of the set containing it is at least halved. Or equivalently, the number of its siblings is at least halved. Since initially the root has n children, every node is in a set of size n. Each node can be moved at most $O(\log n)$ times. ◀

▶ **Lemma 16.** *All updates $add(u, v, i)$ take $\tilde{O}(kn)$ time in total.*

Proof. See Algorithm 3.

At Line 2, we need to implicitly find out the set W and get its size. By Observation 5, the subtree of v forms a continuous interval in $E(T_i)$. Then the size of W is just the number of nodes with keys within $[l_i(v), r_i(v)]$ in splay tree S_i. We can split this part out from S_i into a splay tree S'. The size of S' is just the size of W.

Then at Line 6, 7, 13, 14, each time we move a node, by Lemma 6 and Lemma 7, it takes $\tilde{O}(k)$ time. (The bottleneck is to delete and insert nodes at all k splay trees) By Lemma 15, each node is moved at most $O(\log n)$ times. Since the consensus tree has at most n nodes in the end, in total this part takes $\tilde{O}(kn)$ time.

At Line 9, and 17, we need to query k splay trees for each node inserted to the consensus tree. By Lemma 7, this takes $\tilde{O}(k)$ time for each node inserted. Thus in total, we need $\tilde{O}(kn)$ time. ◀

4.3 Handle Queries

▶ **Lemma 17.** *The queries $lca(u, i)$ and $sum(u, v, i)$ can be answered in $\tilde{O}(1)$ time.*

Proof. For query $lca(u, i)$, we return the $LCA_i(L(w))$ we computed at Line 17, Algorithm 3 when adding u.

For $sum(u, v, i)$, by Observation 5, all children w that $LCA_i(L(w)) \in subtree(v)$ on T_i are in a continuous interval of $E(T_i)$, namely $[l_i(v), r_i(v)]$. To answer $sum(u, v, i)$, we perform $Sum(l_i(v), r_i(v))$ on splay tree S_i for the second value, namely $|L(w)|$, and we return the summation to be the answer. ◀

4.4 Time complexity

▶ **Theorem 18.** *Greedy consensus tree of k phylogenetic trees for n species can be constructed in $\tilde{O}(kn)$ time.*

Proof. Recall the construction of greedy consensus tree contains two phases:

1. Count the frequency $f(c)$ of clusters and sort them. (Line 1 $\sim$ 3 of Algorithm 1)
2. Repeatedly run the greedy procedure. (Line 4 $\sim$ 7 of Algorithm 1)

By Lemma 4, we can get the identifier of each cluster and handle the first phase in $\tilde{O}(kn)$ time.

To handle the second phase, we run our Algorithm 2.

- For the binary search at Line 3, by Lemma 6, we can randomly access the path by k-th ancestor query in $\tilde{O}(1)$ time. By Lemma 14 and Lemma 17, we can check whether $L(u) \subseteq c_0$ in $\tilde{O}(1)$ time.
- For the summation at Line 4, by Lemma 17, can also be evaluated in $\tilde{O}(1)$ time.

Thus for each of the kn clusters, checking consistency takes $\tilde{O}(1)$ time. Then it takes $\tilde{O}(kn)$ time in total.

For Line 7 $\sim$ 11 of Algorithm 2, we run Algorithm 3. By Lemma 3, this part takes $\tilde{O}(kn)$ time in total.

Thus our algorithm takes $\tilde{O}(kn)$ time. ◀

Abstract

Constraints on entropies are considered to be the laws of information theory. Even though the pursuit of their discovery has been a central theme of research in information theory, the algorithmic aspects of constraints on entropies remain largely unexplored. Here, we initiate an investigation of decision problems about constraints on entropies by placing several different such problems into levels of the arithmetical hierarchy. We establish the following results on checking the validity over all almost-entropic functions: first, validity of a Boolean information constraint arising from a monotone Boolean formula is co-recursively enumerable; second, validity of "tight" conditional information constraints is in Π^0_3. Furthermore, under some restrictions, validity of conditional information constraints "with slack" is in Σ^0_2, and validity of information inequality constraints involving max is Turing equivalent to validity of information inequality constraints (with no max involved). We also prove that the classical implication problem for conditional independence statements is co-recursively enumerable.

1 Introduction

The study of constraints on entropies is a central topic of research in information theory. In fact, more than 30 years ago, Pippenger [40] asserted that constraints on entropies are the "*laws of information theory*" and asked whether the *polymatroidal axioms* form the complete laws of information theory, i.e., whether every constraint on entropies can be derived from the polymatroidal axioms. These axioms consist of the following three types of constraints: (1) $H(\varnothing) = 0$, (2) $H(X) \leq H(X \cup Y)$ (monotonicity), and (3) $H(X) + H(Y) \geq H(X \cap Y) + H(X \cup Y)$ (submodularity). It is known that the polymatroidal axioms are

equivalent to Shannon's basic inequalities, that is, to the non-negativity of the entropy, conditional entropy, mutual information, and conditional mutual information [46]. In a celebrated result published in 1998, Zhang and Yeung [51] answered Pippenger's question negatively by finding a linear inequality that is satisfied by all entropic functions, but cannot be derived from the polymatroidal axioms.

Zhang and Yeung's result became the catalyst for the discovery of other information laws that are not captured by the polymatroidal axioms (e.g., [25, 34]). In particular, we now know that there are more elaborate laws, such as conditional inequalities, or inequalities expressed using max, which find equally important applications in a variety of areas. For example, implications between conditional independence statements of discrete random variables can be expressed as conditional information inequalities. In another example, we have recently shown that conjunctive query containment under bag semantics is at least as hard as checking information inequalities using max [1]. Despite the extensive research on various kinds of information inequalities, to the best of our knowledge nothing is known about the algorithmic aspects of the associated decision problem: check whether a given information law is valid.

In this paper, we initiate a study of algorithmic problems that arise naturally in information theory, and establish several results. To this effect, we introduce a generalized form of information inequalities, which we call *Boolean information constraints*, consisting of Boolean combinations of linear information inequalities, and define their associated decision problems. Since it is still an open problem whether linear information inequalities, which are the simplest kind of information laws, are decidable, we focus on placing these decision problems in the arithmetical hierarchy, also known as the Kleene-Mostowski hierarchy [41]. The arithmetical hierarchy has been studied by mathematical logicians since the late 1940s; moreover, it directly influenced the introduction and study of the polynomial-time hierarchy by Stockmeyer [43]. The first level of the arithmetical hierarchy consists of the collection Σ_1^0 of all recursively enumerable sets and the collection Π_1^0 of the complements of all recursively enumerable sets. The higher levels Σ_n^0 and Π_n^0, $n \geq 2$, are defined using existential and universal quantification over lower levels. We prove a number of results, including the following.

(1) Checking the validity of a Boolean information constraint arising from a monotone Boolean formula (in particular, a max information inequality) is in Π_1^0 (Theorem 7).
(2) Checking the validity of a conditional information inequality whose antecedents are "tight" is in Π_3^0 (Corollary 11). "Tight" inequalities are defined in Section 4.2.2, and include conditional independence assertions between random variables.
(3) Checking the validity of a conditional information inequality whose antecedents have "slack" and are group-balanced is in Σ_2^0 (Corollary 14).
(4) Checking the validity of a group-balanced, max information inequality is Turing equivalent to checking the validity of an information inequality (Corollary 17).

While the decidability of linear information inequalities (the simplest kind considered in this paper) remains open, a separate important question is whether more complex Boolean information constraints are any harder. For example, some conditional inequalities, or some max-inequalities can be proven from a simple linear inequality, hence they do not appear to be any harder. However, Kaced and Romashchenko [25] proved that there exist conditional inequalities that are *essentially conditional*, which means that they do not follow from a linear inequality. (We give an example in Equation (9).) We prove here that any conditional information inequality with slack is essentially *unconditioned* (Corollary 10; see also Equation(19)), and that any max-inequality also follows from a single linear inequality (Theorem 16).

A subtle complication involving these results is whether by “validity” it is meant that the given Boolean information constraint holds for the set of all entropic vectors over n variables, denoted by Γ_n^*, or for its topological closure, denoted by $\overline{\Gamma}_n^*$. It is well known that these two spaces differ for all $n \geq 3$. With the exception of (1) above, which holds for both Γ_n^* and $\overline{\Gamma}_n^*$, our results are only for $\overline{\Gamma}_n^*$. A problem of special interest is the implication between conditional independence statements of discrete random variables, and this amounts to checking the Γ_n^*-validity of a tight conditional information inequality; it is known that this problem is not finitely axiomatizable [44], and its decidability remains open. Our result (2) above does not apply here because it is a statement about $\overline{\Gamma}_n^*$-validity. However, we prove that the implication problem for conditional independence statements is in Π_1^0 (Theorem 8).

2 Background and Notations

Throughout this paper, vectors and tuples are denoted by bold-faced letters, and random variables are capitalized. We write $\boldsymbol{x} \cdot \boldsymbol{y} \stackrel{\text{def}}{=} \sum_i x_i y_i$ for the dot product of $\boldsymbol{x}, \boldsymbol{y} \in \mathbb{R}^m$. For a given set $S \subseteq \mathbb{R}^m$, S is *convex* if $\boldsymbol{x}, \boldsymbol{y} \in S$ and $\theta \in [0,1]$ implies $\theta\boldsymbol{x} + (1-\theta)\boldsymbol{y} \in S$; S is called a *cone* if $\boldsymbol{x} \in S$ and $\theta \geq 0$ implies $\theta\boldsymbol{x} \in S$; the topological closure of S is denoted by $\overline{S}$; and, finally, $S^* \stackrel{\text{def}}{=} \{\boldsymbol{y} \mid \forall \boldsymbol{x} \in S, \boldsymbol{x} \cdot \boldsymbol{y} \geq 0\}$ denotes the *dual cone* of S. It is known that S^* is always a closed, convex cone. We provide more background in the full version [2].

For a random variable X with a fixed finite domain D and a probability mass function (pmf) p, its (binary) *entropy* is defined by

$$H(X) \stackrel{\text{def}}{=} -\sum_{x \in D} p(x) \cdot \log p(x) \tag{1}$$

In this paper all logarithms are in base 2.

Fix a joint distribution over n finite random variables $\boldsymbol{V} \stackrel{\text{def}}{=} \{X_1, \ldots, X_n\}$. For each $\alpha \subseteq [n]$, let $\boldsymbol{X}_\alpha$ denote the random (vector-valued) variable $(X_i : i \in \alpha)$. Define the set function $h : 2^{[n]} \to \mathbb{R}_+$ by setting $h(\alpha) \stackrel{\text{def}}{=} H(\boldsymbol{X}_\alpha)$, for all $\alpha \subseteq [n]$. With some abuse, we blur the distinction between the set $[n]$ and the set of variables $\boldsymbol{V} = \{X_1, \ldots, X_n\}$, and write $H(\boldsymbol{X}_\alpha)$, $h(\boldsymbol{X}_\alpha)$, or $h(\alpha)$ interchangeably. We call the function h an *entropic function*, and also identify it with a vector $\boldsymbol{h} \stackrel{\text{def}}{=} (h(\alpha))_{\alpha \subseteq [n]} \in \mathbb{R}_+^{2^n}$, which is called an *entropic vector*. Note that most texts and papers on this topic drop the component $h(\emptyset)$, which is always 0, leading to entropic vectors in $\mathbb{R}^{2^n - 1}$. We prefer to keep the $\emptyset$-coordinate to simplify notations. The implicit assumption $h(\emptyset) = 0$ is used through the rest of the paper.

The set of entropic functions/vectors is denoted by $\Gamma_n^* \subseteq \mathbb{R}_+^{2^n}$. Its topological closure, denoted by $\overline{\Gamma}_n^*$, is the set of *almost entropic* vectors (or functions). It is known [46] that $\Gamma_n^* \subsetneq \overline{\Gamma}_n^*$ for $n \geq 3$. In general, Γ_n^* is neither a cone nor convex, but its topological closure $\overline{\Gamma}_n^*$ is a closed convex cone [46].

Every entropic function h satisfies the following *basic Shannon inequalities*:

$$h(\boldsymbol{Y} \cup \boldsymbol{X}) \geq h(\boldsymbol{X}) \qquad\qquad h(\boldsymbol{X}) + h(\boldsymbol{Y}) \geq h(\boldsymbol{X} \cup \boldsymbol{Y}) + h(\boldsymbol{X} \cap \boldsymbol{Y})$$

called *monotonicity* and *submodularity* respectively. Any inequality obtained by taking a positive linear combination of Shannon inequalities is called a *Shannon-type inequality.*

Throughout this paper we will abbreviate the union $\boldsymbol{X} \cup \boldsymbol{Y}$ of two sets of variables as $\boldsymbol{XY}$. The quantities $h(\boldsymbol{Y}|\boldsymbol{X}) \stackrel{\text{def}}{=} h(\boldsymbol{XY}) - h(\boldsymbol{X})$ and $I_h(\boldsymbol{Y};\boldsymbol{Z}|\boldsymbol{X}) \stackrel{\text{def}}{=} h(\boldsymbol{XY}) + h(\boldsymbol{XZ}) - h(\boldsymbol{XYZ}) - h(\boldsymbol{X})$ are called the *conditional entropy* and the *conditional mutual information* respectively. It can be easily checked that $h(\boldsymbol{Y}|\boldsymbol{X}) \geq 0$ and $I_h(\boldsymbol{Y};\boldsymbol{Z}|\boldsymbol{X}) \geq 0$ are Shannon-type inequalities.

▶ Remark 1. The established notation Γ_n^* [47, 50, 11] for the set of entropic vectors is unfortunate, because the star in this context does **not** represent the dual cone. We will continue to denote by Γ_n^* the set of entropic vectors (which is not a cone!), and use explicit parentheses, as in $(\Gamma_n^*)^*$, to represent the dual cone.

3 Boolean information Constraints

Most of this paper considers the following problem: given a Boolean combination of information inequalities, check whether it is valid. However in Section 5 we briefly discuss the dual problem, namely, recognizing whether a given vector $\boldsymbol{h}$ is an entropic vector (or an almost entropic vector).

A *Boolean function* is a function $F : \{0,1\}^m \to \{0,1\}$. We often denote its inputs with variables $Z_1, \dots, Z_m \in \{0,1\}$, and write $F(Z_1, \dots, Z_m)$ for the value of the Boolean function.

3.1 Problem Definition

A vector $\boldsymbol{c} \in \mathbb{R}^{2^n}$ defines the following (linear) *information inequality*:

$$\boldsymbol{c} \cdot \boldsymbol{h} = \sum_{\alpha \subseteq [n]} c_\alpha h(X_\alpha) \geq 0. \tag{2}$$

The information inequality is said to be *valid* if it holds for all vectors $\boldsymbol{h} \in \Gamma_n^*$; equivalently, $\boldsymbol{c}$ is in the dual cone, $\boldsymbol{c} \in (\Gamma_n^*)^*$. By continuity, an information inequality holds $\forall \boldsymbol{h} \in \Gamma_n^*$ iff it holds $\forall \boldsymbol{h} \in \overline{\Gamma}_n^*$. In 1986, Pippenger [40] defined the "*laws of information theory*" as the set of all information inequalities, and asked whether all of them are Shannon-type inequalities. This was answered negatively by Zhang and Yeung in 1998 [51]. We know today that several applications require more elaborate laws, such as max-inequalities and conditional inequalities. Inspired by these new laws, we define the following generalization.

▶ **Definition 2.** *To each Boolean function F with m inputs, and every m vectors $\boldsymbol{c}_j \in \mathbb{R}^{2^n}, j \in [m]$, we associate the following* Boolean information constraint*:*

$$F(\boldsymbol{c}_1 \cdot \boldsymbol{h} \geq 0, \dots, \boldsymbol{c}_m \cdot \boldsymbol{h} \geq 0). \tag{3}$$

For a set $S \subseteq \mathbb{R}^{2^n}$, a Boolean information constraint is said to be *S-valid* if it holds for all $\boldsymbol{h} \in S$. Thus, we will distinguish between Γ_n^*-validity and $\overline{\Gamma}_n^*$-validity. Unlike in the case of information inequalities, these two notions of validity no longer coincide for arbitrary Boolean information constraints in general, as we explain in what follows.

▶ **Definition 3.** *Let F be a Boolean function. The* entropic Boolean information constraint *problem parameterized by F, denoted by $\mathsf{EBIC}(F)$, is the following: given m integer vectors $\boldsymbol{c}_j \in \mathbb{Z}^{2^n}$, where $j \in [m]$, check whether the constraint (3) holds for all entropic functions $\boldsymbol{h} \in \Gamma_n^*$. In the* almost-entropic *version, denoted by $\mathsf{AEBIC}(F)$, we replace Γ_n^* by $\overline{\Gamma}_n^*$.*

The inputs $\boldsymbol{c}_j, j \in [m]$, to these problems are required to be integer vectors in order for $\mathsf{EBIC}(F)$ and $\mathsf{AEBIC}(F)$ to be meaningful computational problems. Equivalently, one can require the inputs to be rational vectors $\boldsymbol{c}_j \in \mathbb{Q}^{2^n}, j \in [m]$.

Let F be a Boolean function. F can be written as a conjunction of clauses $F = C_1 \wedge C_2 \wedge \cdots$, where each clause is a disjunction of literals. Equivalently, a clause C has this form:

$$(Z_1' \wedge \cdots \wedge Z_k') \Rightarrow (Z_1 \vee \cdots \vee Z_\ell) \tag{4}$$

Problem	Abbreviation		Simple Example
	Entropic	Almost-entropic	
Boolean information constraint	EBIC(F)	AEBIC(F)	$h(XY) \le \frac{2}{3}h(XYZ) \Rightarrow$ $\max(h(YZ), h(XZ)) \ge \frac{2}{3}h(XYZ)$
Information Inequality	IIP		$h(XY) + h(YZ) + h(XZ) \ge 2h(XYZ)$
Max-Information Inequality	MaxIIP		$\max(h(XY), h(YZ), h(XZ)) \ge \frac{2}{3}h(XYZ)$
Conditional Information Inequality	ECIIP	AECIIP	$((h(XY) \le \frac{2}{3}h(XYZ)) \wedge (h(YZ) \le \frac{2}{3}h(XYZ)))$ $\Rightarrow h(XZ) \ge \frac{2}{3}h(XYZ)$
Conditional Independence	CI	(no name)	$(I(X;Y) = 0 \wedge I(X;Z\vert Y) = 0) \Rightarrow I(X;Z) = 0$

Figure 1 Notations for various Boolean Information Constraint Problems.

where $Z_1', \dots, Z_k', Z_1, \dots, Z_\ell$ are distinct Boolean variables. Checking EBIC(F) is equivalent to checking EBIC(C), for each clause of F (and similarly for AEBIC(F)); therefore and without loss of generality, we will assume in the rest of the paper that F consists of a single clause (4) and study the problem along these dimensions:

Conditional and Unconditional Constraints. When $k = 0$ (i.e., when the antecedent is empty), the formula F is *monotone*, and we call the corresponding Boolean information constraint *unconditional*. When $k > 0$, the formula F is *non-monotone*, and we call the corresponding constraint *conditional*.

Simple and Max Constraints. When $k = 0$ and $\ell = 1$, then we say that F defines a *simple* inequality; when $k = 0$ and $\ell > 1$, then we say that F defines a max-*inequality*. The case when $\ell = 0$ and $k > 0$ is not interesting because F is not valid, since the zero-vector $\boldsymbol{h} = \boldsymbol{0}$ violates the constraint.

3.2 Examples and Applications

This section presents examples and applications of Boolean Function Information Constraints and their associated decision problems. A summary of the notations is in Fig. 1.

3.2.1 Information Inequalities

We start with the simplest form of a Boolean information constraint, namely, the linear information inequality in Eq. (2), which arises from the single-variable Boolean formula Z_1. We will call the corresponding decision problem the *information-inequality problem*, denoted by IIP: given a vector of integers $\boldsymbol{c}$, check whether Eq. (2) is Γ_n^*-valid or, equivalently, $\overline{\Gamma}_n^*$-valid. Pippenger's question from 1986 was essentially a question about decidability. Shannon-type inequalities are decidable in exponential time using linear programming methods, and software packages have been developed for this purpose [46, Chapter 13] (it is not known, however, if there is a matching lower bound in the complexity of this problem). Thus, if every information inequality were a Shannon-type inequality, then information inequalities would be decidable. However, Zhang and Yeung's gave the first example of a non-Shannon-type information inequality [51]. Later, Matúš [34] proved that, when $n \ge 4$ variables, there exists infinitely many inequivalent non-Shannon entropic inequalities. More precisely, he proved that the following is a non-Shannon inequality, for every $k \ge 1$:

$$I_h(C;D|A) + \frac{k+3}{2}I_h(C;D|B) + I_h(A;B) + \frac{k-1}{2}I_h(B;C|D) + \frac{1}{k}I_h(B;D|C) \ge I_h(C;D) \tag{5}$$

This ruined any hope of proving decidability of information inequalities by listing a finite set of axioms. To date, the study of non-Shannon-type inequalities is an active area of research [49, 31, 48], and the question whether IIP is decidable remains open.

Hammer et al. [23], showed that, up to logarithmic precision, information inequalities are equivalent to linear inequalities in Kolmogorov complexity (see also [20, Theorem 3.5]).

3.2.2 Max Information Inequalities

Next, we consider constraints defined by a disjunction of linear inequalities, in other words $(\boldsymbol{c}_1 \cdot \boldsymbol{h} \geq 0) \vee \cdots \vee (\boldsymbol{c}_m \cdot \boldsymbol{h} \geq 0)$, where $\boldsymbol{c}_j \in \mathbb{R}^{2^n}$. This is equivalent to:

$$\max(\boldsymbol{c}_1 \cdot \boldsymbol{h}, \boldsymbol{c}_2 \cdot \boldsymbol{h}, \dots, \boldsymbol{c}_m \cdot \boldsymbol{h}) \geq 0 \tag{6}$$

and, for that reason, we call them *Max information inequalities* and denote the corresponding decision problem by MaxIIP. As before, Γ_n^*-validity and $\overline{\Gamma}_n^*$-validity coincide.

Application to Constraint Satisfaction and Database Theory. Given two finite structures $\boldsymbol{A}$ and $\boldsymbol{B}$, we write $\mathsf{HOM}(\boldsymbol{A}, \boldsymbol{B})$ for the set of homomorphisms from $\boldsymbol{A}$ to $\boldsymbol{B}$. We say that $\boldsymbol{B}$ *dominates* structure $\boldsymbol{A}$, denote by $\boldsymbol{A} \preceq \boldsymbol{B}$, if for every finite structure $\boldsymbol{C}$, we have that $|\mathsf{HOM}(\boldsymbol{A}, \boldsymbol{C})| \leq |\mathsf{HOM}(\boldsymbol{B}, \boldsymbol{C})|$. The *homomorphism domination problem* asks whether $\boldsymbol{A} \preceq \boldsymbol{B}$, given $\boldsymbol{A}$ and $\boldsymbol{B}$. In database theory this problem is known as the *query containment problem under bag semantics* [13]. In that setting we are given two Boolean conjunctive queries Q_1, Q_2, which we interpret using bag semantics, i.e., given a database D, the answer $Q_1(D)$ is the number of homomorphisms $Q_1 \to D$ [28]. Q_1 *is contained in* Q_2 *under bag semantics* if $Q_1(D) \leq Q_2(D)$ for every database D. It is open whether the homomorphism domination problem is decidable.

Kopparty and Rossman [29] described a MaxIIP problem that yields a sufficient condition for homomorphism domination. In recent work [1] we proved that, when $\boldsymbol{B}$ is acyclic, then that condition is also necessary, and, moreover, the domination problem for acyclic $\boldsymbol{B}$ is Turing-equivalent to MaxIIP. Hence, any result on the complexity of MaxIIP immediately carries over to the homomorphism domination problem for acyclic $\boldsymbol{B}$, and vice versa.

We illustrate here Kopparty and Rossman's MaxIIP condition on a simple example. Consider the following two Boolean conjunctive queries: $Q_1() = R(u,v) \wedge R(v,w) \wedge R(w,u)$, $Q_2() = R(x,y) \wedge R(x,z)$; interpreted using bag semantics, Q_1 returns the number of triangles and Q_2 the number of V-shaped subgraphs. Kopparty and Rossman proved that $Q_1 \preceq Q_2$ follows from the following max-inequality:

$$\max\{2h(XY) - h(X) - h(XYZ), 2h(YZ) - h(Y) - h(XYZ), 2h(XZ) - h(Z) - h(XYZ)\} \geq 0 \tag{7}$$

3.2.3 Conditional Information Inequalities

A *conditional information inequality* has the form:

$$(\boldsymbol{c}_1 \cdot \boldsymbol{h} \geq 0 \wedge \cdots \wedge \boldsymbol{c}_k \cdot \boldsymbol{h} \geq 0) \Rightarrow \boldsymbol{c}_0 \cdot \boldsymbol{h} \geq 0 \tag{8}$$

Here we need to distinguish between Γ_n^*-validity and $\overline{\Gamma}_n^*$-validity, and denote by ECIIP and AECIIP the corresponding decision problems. Notice that, without loss of generality, we can allow equality in the antecedent, because $\boldsymbol{c}_i \cdot \boldsymbol{h} = 0$ is equivalent to $\boldsymbol{c}_i \cdot \boldsymbol{h} \geq 0 \wedge -\boldsymbol{c}_i \cdot \boldsymbol{h} \geq 0$.

Suppose that there exist $\lambda_1 \geq 0, \dots, \lambda_m \geq 0$ such that the inequality $\boldsymbol{c}_0 \cdot \boldsymbol{h} - (\sum_i \lambda_i \boldsymbol{c}_i \cdot \boldsymbol{h}) \geq 0$ is valid; then Eq. (8) is, obviously, also valid. Kaced and Romashchenko [25] called Eq. (8) an *essentially conditioned inequality* if no such λ_i's exist, and discovered several valid conditional inequalities that are essentially conditioned.

Application to Conditional Independence. Fix three set of random variables $\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z}$. A *conditional independence* (CI) statement is a statement of the form $\phi = (\boldsymbol{Y} \perp\!\!\!\perp \boldsymbol{Z} \mid \boldsymbol{X})$, and it asserts that $\boldsymbol{Y}$ and $\boldsymbol{Z}$ are independent conditioned on $\boldsymbol{X}$. A *CI implication* is a statement $\varphi_1 \wedge \cdots \wedge \varphi_k \Rightarrow \varphi_0$, where $\varphi_i, i \in \{0, \dots, k\}$ are CI statements. The *CI implication problem* is: given an implication, check if it is valid for all discrete probability distributions. Since $(\boldsymbol{Y} \perp\!\!\!\perp \boldsymbol{Z} \mid \boldsymbol{X}) \Leftrightarrow I_h(\boldsymbol{Y}; \boldsymbol{Z}|\boldsymbol{X}) = 0 \Leftrightarrow -I_h(\boldsymbol{Y}; \boldsymbol{Z}|\boldsymbol{X}) \geq 0$, the CI implication problem is a special case of ECIIP.

The CI implication problem has been studied extensively in the literature [30, 44, 18, 27]. Pearl and Paz [39] gave a sound, but incomplete, set of *graphoid axioms*, Studený [44] proved that no finite axiomatization exists, while Geiger and Pearl [18] gave a complete axiomatization for two restricted classes, called saturated, and marginal CIs. See [16, 21, 38] for some recent work on the CI implication problem. The decidability of the CI implication problem remains open to date.

Results in [25] imply that the following CI implication is essentially conditioned (see [27]):

$$I_h(C; D|A) = I_h(C; D|B) = I_h(A; B) = I_h(B; C|D) = 0 \Longrightarrow I_h(C; D) = 0 \tag{9}$$

While a CI implication problem is an instance of an *entropic* conditional inequality, one can also consider the question whether a CI implication statement holds for all *almost entropic* functions; for example the implication (9) holds for all almost entropic functions. Kaced and Romashchenko [25] proved that these two problems differ, by giving examples of CI implications that hold for all entropic functions but fail for almost entropic functions.

3.2.4 Group-Theoretic Inequalities

There turns out to be a way to "rephrase" IIP as a decision problem in group theory; This was a wonderful result by Chan and Yeung [12] (see also [11]). A tuple $(G; G_1, \dots, G_n)$ is called a *group system* if G is a finite group and $G_1, \dots, G_n \subseteq G$ are n subgroups. For any $\alpha \subseteq [n]$, define $G_\alpha := \bigcap_{i \in \alpha} G_i$; implicitly, we set $G_\varnothing := G$. A vector $\boldsymbol{c} \subseteq \mathbb{R}^{2^n}$ defines the following *group-theoretic inequality*:

$$\sum_{\alpha \subseteq [n]} c_\alpha \log \frac{|G|}{|G_\alpha|} \geq 0 \tag{10}$$

▶ **Theorem 4** ([12]). *An information inequality* (2) *is* Γ_n^**-valid if and only if the corresponding group-theoretic inequality* (10) *holds for all group systems* $(G, G_1, \dots, G_n)$*,*

In particular, a positive or negative answer to the decidability problem for IIP immediately carries over to the validity problem of group-theoretic inequalities of the form (10). We note that the group-theoretic inequalities considered here are different from the word problems in group, see e.g. the survey [35]; the undecidability results for word problems in groups do not carry over to the group-theoretic inequalities and, thus, to information inequalities.

3.2.5 Application to Relational Query Evaluation

The problem of bounding the number of copies of a graph inside of another graph has a long and interesting history [17, 5, 14, 36]. The subgraph homomorphism problem is a special case of the relational query evaluation problem, in which case we want to find an upper bound on the output size of a full conjunctive query. Using the entropy argument from [14], *Shearer's lemma* in particular, Atserias, Grohe, and Marx [6] established a tight upper bound on the answer to a full conjunctive query over a database. Note that Shearer's lemma is a Shannon-type inequality. Their result was extended to include functional dependencies and more generally degree constraints in a series of recent work in database theory [19, 3, 4]. All these results can be cast as applications of Shannon-type inequalities. For a simple example, let $R(X,Y), S(Y,Z), T(Z,U)$ be three binary relations (tables), each with N tuples, then their join $R(X,Y) \bowtie S(Y,Z) \bowtie T(Z,U)$ can be as large as N^2 tuples. However, if we further know that the functional dependencies $XZ \to U$ and $YU \to X$ hold in the output, then one can prove that the output size is $\leq N^{3/2}$, by using the following Shannon-type information inequality:

$$h(XY) + h(YZ) + h(ZU) + h(X|YU) + h(U|XZ) \geq 2h(XYZU) \tag{11}$$

While the tight upper bound of any conjunctive query can be proven using only Shannon-type inequalities, this no longer holds when the relations used in the query are constrained to satisfy functional dependencies. In that case, the tight upper bound can always be obtained from an information inequality, but Abo Khamis et al. [4] gave an example of a conjunctive query for which the tight upper bound requires a non-Shannon inequality.

3.2.6 Application to Secret Sharing

An interesting application of conditional information inequalities is secret sharing, which is a classic problem in cryptography, independently introduced by Shamir [42] and Blakley [8]. The setup is as follows. There is a set P of *participants*, a *dealer* $d \notin P$, and an *access structure* $\mathcal{F} \subset 2^P$. The access structure is closed under taking superset: $A \in \mathcal{F}$ and $A \subseteq B$ implies $B \in \mathcal{F}$. The dealer has a secret s, from some finite set K, which she would like to share in such a way that every set $F \in \mathcal{F}$ of participants can recover the secret s, but every set $F \notin \mathcal{F}$ knows *nothing* about s. The dealer shares her secret by using a *secret sharing scheme*, in which she gives each participant $p \in P$ a *share* $s_p \in K_p$, where K_p is some finite domain. The scheme is designed in such a way that from the tuple $(s_p)_{p \in F}$ one can recover s if $F \in \mathcal{F}$, and conversely one cannot infer any information about s if $F \notin \mathcal{F}$.

One way to formalize secret sharing uses information theory (for other formalisms, see [7]). We identify the participants P with the set $[n-1]$, and the dealer with the number n. A secret sharing scheme on P with access structure $\mathcal{F} \subseteq 2^P$ is a joint distribution on n discrete random variables $(X_1, \ldots, X_n)$ satisfying:

(i) $H(X_n) > 0$
(ii) $H(X_n \mid \boldsymbol{X}_F) = 0$ if $F \in \mathcal{F}$
(iii) $H(X_n \mid \boldsymbol{X}_F) = H(X_n)$ if $F \notin \mathcal{F}$; equivalently, $I_H(X_n; \boldsymbol{X}_F) = 0$.

Intuitively, X_i denotes the share given to the ith participant, and X_n is the unknown secret. It can be shown, without loss of generality, that (i) can be replaced by the assumption that the marginal distribution on X_n is uniform [9], which encodes the fact that the scheme does not reveal any information about the secret X_n. Condition (ii) means one can recover the secret from the shares of qualified participants, while condition (iii) guarantees the complete opposite. A key challenge in designing a good secret sharing scheme is to reduce the total size of the shares. The only known [15, 10, 26] way to prove a *lower bound* on share sizes is to lower bound the *information ratio* $\frac{\max_{p \in P} H(X_p)}{H(X_n)}$. In order to prove that some number ℓ is a lower bound on the information ratio, we need to check that $\max_{i \in [n-1]} \{ h(X_i) - \ell \cdot h(X_n) \} \geq 0$ holds for all entropic functions $\boldsymbol{h} \in \Gamma_n^*$ satisfying the extra conditions (i), (ii), and (iii) above. Equivalently, ℓ is a lower bound on the information ratio if and only if the following Boolean information constraint is Γ_n^*-valid:

$$\bigwedge_{F \in \mathcal{F}} (h(X_n \mid \boldsymbol{X}_F) = 0) \wedge \bigwedge_{F \notin \mathcal{F}} (I_h(X_n; \boldsymbol{X}_F) = 0) \Longrightarrow (h(X_n) = 0) \vee \Big[\bigvee_{i \in [n-1]} (h(X_i) \geq \ell \cdot h(X_n)) \Big]$$

4 Placing EBIC and AEBIC in the Arithmetical Hierarchy

What is the complexity of EBIC(F) / AEBIC(F)? Is it even decidable? As we have seen there are numerous applications of the Boolean Information Constraint problem, hence any positive or negative answer, even for special cases, would shed light on these applications. While their (un)decidability is currently open, in this paper we provide several upper bounds on their complexity, by placing them in the arithmetical hierarchy.

We briefly review some concepts from computability theory. In this setting it is standard to assume objects are encoded as natural numbers. A set $A \subseteq \mathbb{N}^k$, for $k \geq 1$, is *Turing computable*, or *decidable*, if there exists a Turing machine that, given $x \in \mathbb{N}^k$ decides whether $x \in A$. A set A is *Turing reducible* to B if there exists a Turing machine with an oracle for B that can decide membership in A. The *arithmetical hierarchy* consists of the classes of sets Σ_n^0 and Π_n^0 defined as follows. The class Σ_n^0 consists of all sets of the form $\{x \mid \exists y_1 \forall y_2 \exists y_3 \cdots \mathsf{Q} y_n R(x, y_1, \ldots, y_n)\}$, where R is an $(n+1)$-ary decidable predicate, $\mathsf{Q} = \exists$ if n is odd, and $Q = \forall$ if n is even. In a dual manner, the class Π_n^0 consists of sets of the form $\{x \mid \forall y_1 \exists y_2 \forall y_3 \cdots \mathsf{Q} y_n R(x, y_1, \ldots, y_n)\}$. Then $\Sigma_0^0 = \Pi_0^0$ are the decidable sets, while Σ_1^0 consists of the *recursively enumerable* sets, and Π_1^0 consists of the *co-recursively enumerable* sets. It is known that these classes are closed under union and intersection, but not under complements, and that they form a strict hierarchy, $\Sigma_n^0, \Pi_n^0 \subsetneq (\Sigma_{n+1}^0 \cap \Pi_{n+1}^0)$. For more background, we refer to [41]. Our goal is to place the problems EBIC(F), AEBIC(F), and their variants in concrete levels of the arithmetical hierarchy.

4.1 Unconditional Boolean Information Constraints

We start by discussing unconditional Boolean information constraints, or, equivalently, a Boolean information constraint defined by a monotone Boolean formula F. The results here are rather simple; we include them only as a warmup for the less obvious results in later sections. Based on our discussion in Sections 3.2.1 and 3.2.2, we have the following result.

▶ **Theorem 5.** *If F is monotone, then EBIC(F) and AEBIC(F) are equivalent problems.*

Next, we prove that these problems are co-recursively enumerable, by using the following folklore fact. A *representable set of n random variables* is a finite relation Ω with N rows and $n+1$ columns $X_1, \ldots, X_n, p$, where column p contains rational probabilities in $[0,1] \cap \mathbb{Q}$ that sum to 1. Thus, Ω defines n random variables with finite domain and probability mass given by rational numbers. We denote $\boldsymbol{h}^\Omega$ its entropic vector. By continuity of Eq.(1), we obtain:

▶ **Proposition 6.** *For every entropic vector $\boldsymbol{h} \in \Gamma_n^*$ and every $\varepsilon > 0$, there exists a representable space Ω such that $\|\boldsymbol{h} - \boldsymbol{h}^\Omega\| < \varepsilon$.*

The group-characterization proven by Chan and Yeung [12] implies a much stronger version of the proposition; we do not need that stronger version in this paper.

▶ **Theorem 7.** *Let F be a monotone Boolean formula. Then* $\mathsf{EBIC}(F)$ *(and, hence,* $\mathsf{AEBIC}(F)$*) is in Π^0_1, i.e., it is co-recursively enumerable.*

Proof. Fix $F = Z_1 \vee \cdots \vee Z_m$ and $\boldsymbol{c}_i \in \mathbb{Z}^{2^n}$, $i \in [m]$. We need to check:

$$\forall \boldsymbol{h} \in \Gamma^*_n : \qquad \boldsymbol{c}_1 \cdot \boldsymbol{h} \geq 0 \vee \cdots \vee \boldsymbol{c}_m \cdot \boldsymbol{h} \geq 0 \tag{12}$$

We claim that (12) is equivalent to:

$$\forall \Omega \qquad \boldsymbol{c}_1 \cdot \boldsymbol{h}^{\Omega} \geq 0 \vee \cdots \vee \boldsymbol{c}_m \cdot \boldsymbol{h}^{\Omega} \geq 0 \tag{13}$$

Obviously (12) implies (13), and the opposite follows from Prop. 6: if (12) fails on some entropic vector $\boldsymbol{h}$, then it also fails on some representable $\boldsymbol{h}^{\Omega}$ close enough to $\boldsymbol{h}$. Finally, (13) is in Π^0_1 because, the property after $\forall\Omega$ is decidable, by expanding the definition of entropy (1) in each condition $\boldsymbol{c}_i \cdot \boldsymbol{h}^{\Omega} \geq 0$, and writing the latter as $\sum_j a_j \log b_j \geq 0$, or, equivalently, $\prod_j (b_j)^{a_j} \geq 1$, where a_j, b_j are rational numbers, which is decidable. ◀

4.2 Conditional Boolean Information Constraints

We now consider non-monotone Boolean functions, in other words, conditional information constraints (8). Since Γ^*_n- and $\overline{\Gamma}^*_n$-validity no longer coincide, we study $\mathsf{EBIC}(F)$ and $\mathsf{AEBIC}(F)$ separately. The results here are non-trivial, and some proofs are deferred to [2].

4.2.1 The Entropic Case

Our result for $\mathsf{EBIC}(F)$ is restricted to the CI implication problem. Recall from Sec. 3.2.3 that this problem consists of checking whether an implication between statements of the form $(\boldsymbol{Y} \perp\!\!\!\perp \boldsymbol{Z} \mid \boldsymbol{X})$ holds for all random variables with finite domain, and this is equivalent to checking whether a certain conditional inequality holds for all entropic functions. We prove that this problem is in Π^0_1 by using Tarski's theorem of the decidability of the theory of reals with $+, *$ [45].

▶ **Theorem 8.** *The CI implication problem (Section 3.2.3) is in Π^0_1.*

Proof. Tarski has proven that the theory of reals with $+, *$ is decidable. More precisely, given a formula Φ in FO with symbols $+$ and $*$, it is decidable whether that formula is true in the model of real numbers $(\mathbb{R}, +, *)$; for example, it is decidable whether[1] $\Phi \equiv \forall x \exists y \forall z (x^2 + 3y \geq z \wedge (y^3 + yz \leq xy^2))$ is true. We will write $(\mathbb{R}, +, *) \models \Phi$ to denote the fact that Φ is true in the model of reals.

Consider a conditional inequality over a set of n joint random variables:

$$I_h(Y_1; Z_1|X_1) = 0 \wedge \cdots \wedge I_h(Y_k; Z_k|X_k) = 0 \Rightarrow I_h(Y; Z|X) = 0$$

The following algorithm returns *false* if the inequality fails on some entropic function h, and runs forever if the inequality holds for all h, proving that the problem is in Π^0_1:

- Iterate over all $N \geq 0$. For each N, do the following steps.

[1] $3y$ is a shorthand for $y + y + y$ and $x \geq y$ is a shorthand for $\exists u(x = y + u^2)$.

- Consider n joint random variables $X_1, \dots, X_n$ where each has outcomes in the domain $[N]$; thus there are N^n possible outcomes. Let $p_1, \dots, p_{N^n}$ be real variables representing the probabilities of these outcomes.
- Construct a formula Δ stating "there exist probabilities $p_1, \dots, p_{N^n}$ for these outcomes, whose entropy fails the conditional inequality". More precisely, the formula consists of the following:
  - Convert each conditional independence statement in the antecedent $I_h(Y_i; Z_i|X_i) = 0$ into its equivalent statement on probabilities: $p(X_iY_iZ_i)p(X_i) = p(X_iY_i)p(X_iZ_i)$.
  - Replace each such statement with a conjunction of statements of the form $p(X_i = x, Y_i = y, Z_i = z) \cdot p(X_i = x) = p(X_i = x, Y_i = y) \cdot p(X_i = x, Z_i = z)$, for all combinations of values x, y, z. If X_i, Y_i, Z_i have in total k random variables, then there are N^k combinations of values x, y, z, thus we create a conjunction of N^k equality statements.
  - Each marginal probability is a sum of atomic probabilities, for example $p(X_i = x, Y_i = y) = p_{k_1} + p_{k_2} + \cdots$ where $p_{k_1}, p_{k_2}, \dots$ are the probabilities of all outcomes that have $X_i = x$ and $Y_i = y$. Thus, the equality statement in the previous step becomes the following formula: $(p_{i_1} + p_{i_2} + \cdots)(p_{j_1} + p_{j_2} + \cdots) = (p_{k_1} + p_{k_2} + \cdots)(p_{\ell_1} + p_{\ell_2} + \cdots)$. There is one such formula for every combination of values x, y, z; denote Φ_i the conjunction of all these formulas. Thus, Φ_i asserts $I_h(Y_i; Z_i|X_i) = 0$.
  - Let $\Phi = \Phi_1 \wedge \cdots \wedge \Phi_k$. Let Ψ be the similar formula for the consequent: thus, Ψ asserts $I_h(Y; Z|X) = 0$.
  - Finally, construct the formula $\Delta \overset{\text{def}}{=} \exists p_1, \dots, \exists p_{N^n}, (\Phi \wedge \neg\Psi)$.
- Check whether $(\mathbb{R}, +, *) \vDash \Delta$. By Tarski's theorem this step is decidable.
- If Δ is true, then return *false*; otherwise, continue with $N + 1$. ◀

Tarski's exponential function problem

One may attempt to extend the proof above from the CI implication problem to arbitrary conditional inequalities (8). To check if a conditional inequality is valid for all entropic functions, we can repeat the argument above: iterate over all domain sizes $N = 1, 2, 3, \dots$, and check if there exists probabilities $p_1, \dots, p_{N^n}$ that falsify the implication $(\boldsymbol{c}_1 \cdot \boldsymbol{h} \geq 0 \wedge \cdots \wedge \boldsymbol{c}_k \cdot \boldsymbol{h} \geq 0) \Rightarrow \boldsymbol{c}_0 \cdot \boldsymbol{h} \geq 0$. The problem is that in order to express $\boldsymbol{c}_i \cdot \boldsymbol{h} \geq 0$ we need to express the vector $\boldsymbol{h}$ in terms of the probabilities $p_1, \dots, p_{N^n}$. To apply directly the definition of entropy in (1) we need to use the log function, or, alternatively, the exponential function, and this takes us outside the scope of Tarski's theorem. A major open problem in model theory, originally formulated also by Tarski, is whether decidability continues to hold if we augment the structure of the real numbers with the exponential function (see, e.g., [32] for a discussion). Decidability of the first-order theory of the reals with exponentiation would easily imply that the entropic conditional information inequality problem ECIIP (not just the entropic conditional independence (CI) implication problem) is in Π^0_1, because every condition $\boldsymbol{c} \cdot \boldsymbol{h} \geq 0$ can be expressed using $+, *$ and the exponential function, by simply expanding the definition of entropy in Equation (1).

4.2.2 The Almost-Entropic Case

Suppose the antecedent of (8) includes the condition $\boldsymbol{c} \cdot \boldsymbol{h} \geq 0$. Call $\boldsymbol{c} \in \mathbb{R}^{2^n}$ *tight* if $\boldsymbol{c} \cdot \boldsymbol{h} \leq 0$ is $\overline{\Gamma}^*_n$-valid. When $\boldsymbol{c}$ is tight, we can rewrite $\boldsymbol{c} \cdot \boldsymbol{h} \geq 0$ as $\boldsymbol{c} \cdot \boldsymbol{h} = 0$. If $\boldsymbol{c}$ is not tight, then there exists $\boldsymbol{h} \in \overline{\Gamma}^*_n$ such that $\boldsymbol{c} \cdot \boldsymbol{h} > 0$; in that case we say that $\boldsymbol{c}$ *has slack*. For example, all conditions occurring in CI implications are tight, because they are of the form $-I_h(Y; Z|X) \geq 0$, and more conveniently written $I_h(Y; Z|X) = 0$, while a condition like $3h(X) - 4h(YZ) \geq 0$ has slack. We extend the definition of slack to a set. We say that the set $\{\boldsymbol{c}_1, \dots, \boldsymbol{c}_k\} \subset \mathbb{R}^{2^n}$ has slack if there exists $\boldsymbol{h} \in \overline{\Gamma}^*_n$ such that $\boldsymbol{c}_i \cdot \boldsymbol{h} > 0$ for all $i = 1, k$; notice that this is more restricted than requiring each of $\boldsymbol{c}_i$ to have slack. We present below results on the complexity of $\mathsf{AEBIC}(F)$ in two special cases: when all antecedents are tight, and when the set of antecedents has slack. Both results use the following theorem, which allows us to move one condition $\boldsymbol{c}_k \cdot \boldsymbol{h} \geq 0$ from the antecedent to the consequent:

▶ **Theorem 9.** *The following statements are equivalent:*

$$\forall \boldsymbol{h} \in \overline{\Gamma}^*_n : \qquad \bigwedge_{i \in [k]} \boldsymbol{c}_i \cdot \boldsymbol{h} \geq 0 \Rightarrow \boldsymbol{c} \cdot \boldsymbol{h} \geq 0 \tag{14}$$

$$\forall \varepsilon > 0, \exists \lambda \geq 0, \forall \boldsymbol{h} \in \overline{\Gamma}^*_n : \qquad \bigwedge_{i \in [k-1]} \boldsymbol{c}_i \cdot \boldsymbol{h} \geq 0 \Rightarrow \boldsymbol{c} \cdot \boldsymbol{h} + \varepsilon h([n]) \geq \lambda \boldsymbol{c}_k \cdot \boldsymbol{h} \tag{15}$$

Moreover, if the set $\{\boldsymbol{c}_1, \dots, \boldsymbol{c}_k\}$ has slack, then one can set $\varepsilon = 0$ in Eq.(15)*.*

Proof. We prove here only the implication from (15) to (14); the other direction is non-trivial and is proven in the full version [2] using only the properties of closed convex cones. Assume condition (15) holds, and consider any $\boldsymbol{h} \in \overline{\Gamma}^*_n$ s.t. $\bigwedge_{i \in [k]} \boldsymbol{c}_i \cdot \boldsymbol{h} \geq 0$. We prove that $\boldsymbol{c} \cdot \boldsymbol{h} \geq 0$. For any $\varepsilon > 0$, condition (15) states that there exists $\lambda > 0$ such that $\boldsymbol{c} \cdot \boldsymbol{h} + \varepsilon h([n]) \geq \lambda \boldsymbol{c}_k \cdot \boldsymbol{h}$ and therefore $\boldsymbol{c} \cdot \boldsymbol{h} + \varepsilon h([n]) \geq 0$. Since $\varepsilon > 0$ is arbitrary, we conclude that $\boldsymbol{c} \cdot \boldsymbol{h} \geq 0$, as required. ◀

By applying the theorem repeatedly, we can move all antecedents to the consequent:

▶ **Corollary 10.** *Condition* (14) *is equivalent to:*

$$\forall \varepsilon > 0, \exists \lambda_1 \geq 0, \cdots, \exists \lambda_k \geq 0, \forall \boldsymbol{h} \in \overline{\Gamma}^*_n : \qquad \boldsymbol{c} \cdot \boldsymbol{h} + \varepsilon h([n]) \geq \sum_{i \in [k]} \lambda_i \boldsymbol{c}_i \cdot \boldsymbol{h} \tag{16}$$

Moreover, if the set $\{\boldsymbol{c}_1, \dots, \boldsymbol{c}_k\}$ has slack, then one can set $\varepsilon = 0$ in Eq.(16)*.*

Antecedents Are Tight. We consider now the case when all antecedents are tight, a condition that can be verified in Π^0_1, by Th.7. In that case, condition (14) is equivalent to:

$$\forall p \in \mathbb{N}, \exists q \in \mathbb{N}, \forall \boldsymbol{h} \in \overline{\Gamma}^*_n : \qquad \boldsymbol{c} \cdot \boldsymbol{h} + \frac{1}{p} h([n]) \geq q \sum_{i \in [k]} \boldsymbol{c}_i \cdot \boldsymbol{h} \tag{17}$$

Indeed, the non-trivial direction (16)⇒ (17) follows by setting $q \overset{\text{def}}{=} \lceil \max(\lambda_1, \dots, \lambda_k) \rceil \in \mathbb{N}$ and noting that $\boldsymbol{c}_i$ is tight, hence $\boldsymbol{c}_i \cdot \boldsymbol{h} \leq 0$ and therefore $\lambda_i \boldsymbol{c}_i \cdot \boldsymbol{h} \geq q \boldsymbol{c}_i \cdot \boldsymbol{h}$.

▶ **Corollary 11.** *Consider a conditional inequality* (8)*. If all antecedents are tight, then the corresponding decision problem* AECIIP *is in* Π^0_3

Proof. Based on our discussion, the inequality (8) is equivalent to condition (17), which is of the form $\forall p \exists q \forall \boldsymbol{h}$. Replace $\boldsymbol{h}$ with a representable entropic vector $\boldsymbol{h}^\Omega$, as in the proof of Theorem 7, and it becomes $\forall p \exists q \forall \boldsymbol{h}^\Omega$, placing it in Π^0_3. ◀

Recall that the implication problem for CI is a special case of a conditional inequality with tight antecedents. We have seen in Theorem 8 that the *entropic* version of the CI implication problem is in Π^0_1; Corollary 11 proves that the *almost entropic* version is in Π^0_3.

Consider any conditional inequality (8) where the antecedents are tight. If this inequality holds for all almost entropic functions, then it can be proven by proving a family of (unconditional) inequalities (17). In fact, some conditional inequalities in the literature have been proven precisely in this way. For example, consider the CI implication (9) (Sec. 3.2.3), and replace each antecedent $I_h(\boldsymbol{Y};\boldsymbol{Z}|\boldsymbol{X}) = 0$ with $-I_h(\boldsymbol{Y};\boldsymbol{Z}|\boldsymbol{X}) \geq 0$. By Eq. (17), the following condition holds: $\forall p \in \mathbb{N}, \exists q \in \mathbb{N}$ such that

$$q(I_h(C;D \mid A) + I_h(C;D \mid B) + I_h(A;B) + I_h(B;C \mid D)) + \frac{1}{p}h(ABCD) \geq I_h(C;D) \tag{18}$$

Thus, in order to prove (9), it suffices to prove (18). Matúš's inequality (5) provides precisely the proof of (18) (by setting $k \stackrel{\text{def}}{=} p$, $q \stackrel{\text{def}}{=} \max(\lceil \frac{k+3}{2} \rceil, 1)$, and observing that $I_h(B;D \mid C) \leq h(ABCD)$).

Antecedents Have Slack. Next, we consider the case when the antecedents have slack, which is a recursively enumerable condition. In that case, condition (16) is equivalent to:

$$\exists\lambda_1 \geq 0, \cdots, \exists\lambda_k \geq 0, \forall \boldsymbol{h} \in \overline{\Gamma}^*_n : \qquad \boldsymbol{c}\cdot\boldsymbol{h} \geq \sum_{i\in[k]} \lambda_i \boldsymbol{c}_i \cdot \boldsymbol{h} \tag{19}$$

In other words, we have proven the following result of independent interest: any conditional implication with slack is essentially unconditioned. However, we cannot immediately use (19) to prove complexity bounds for $\mathsf{AEBIC}(F)$, because the λ_i's in (19) are not necessarily rational numbers. When we derived Eq. (17) we used the fact that the antecedents are tight, hence $\boldsymbol{c}_i \cdot \boldsymbol{h} \leq 0$, hence we could replace the λ_i's with some natural number q larger than all of them. But now, the sign of $\boldsymbol{c}_i \cdot \boldsymbol{h}$ is unknown. We prove below that, under a restriction called *group balance*, the λ_i's can be chosen in $\mathbb{Q}$, placing the decision problem in Σ^0_2. Group balance generalizes Chan's notion of a *balanced inequality*, which we review below. In the full version [2] we give evidence that some restriction is necessary to ensure the λ_i's are rationals, and also show that every conditional inequality can be strengthened to be group balanced.

A vector $\boldsymbol{h} \in \mathbb{R}^{2^n}$ is called *modular* if $h(\boldsymbol{X}) + h(\boldsymbol{Y}) = h(\boldsymbol{X}\cup\boldsymbol{Y}) + h(\boldsymbol{X}\cap\boldsymbol{Y})$ forall sets of variables $\boldsymbol{X},\boldsymbol{Y} \subseteq \boldsymbol{V}$. Every non-negative modular function is entropic [46], and is a non-negative linear combination of the *basic modular functions* $\boldsymbol{h}^{(1)},\dots,\boldsymbol{h}^{(n)}$, where $h^{(j)}(\alpha) \stackrel{\text{def}}{=} 1$ when $j \in \alpha$ and is $h^{(j)}(\alpha) \stackrel{\text{def}}{=} 0$ otherwise. Chan [22] called an inequality $\boldsymbol{c}\cdot\boldsymbol{h} \geq 0$ *balanced* if $\boldsymbol{c}\cdot\boldsymbol{h}^{(j)} = 0$ for every $j \in [n]$. He proved that *any* valid inequality can be strengthened to a balanced one. More precisely: $\boldsymbol{c}\cdot\boldsymbol{h} \geq 0$ is valid iff $\boldsymbol{c}\cdot\boldsymbol{h}^{(i)} \geq 0$ for all $i \in [n]$ and $\boldsymbol{c}\cdot\boldsymbol{h} - \sum_i(\boldsymbol{c}\cdot\boldsymbol{h}^{(i)})h(X_i \mid X_{[n]-\{i\}}) \geq 0$ is valid; notice that the latter inequality is balanced. For example, $h(XY) + h(XZ) - h(X) - h(XYZ) \geq 0$ is balanced, while $h(XY) - h(X) \geq 0$ is not balanced, and can be strengthened to $h(XY) - h(X) - h(Y|X) \geq 0$. We generalize Chan's definition:

▶ **Definition 12.** *Call a set* $\{\boldsymbol{d}_1,\dots,\boldsymbol{d}_k\} \subseteq \mathbb{R}^{2^n}$ group balanced *if (a)* $\text{rank}(\boldsymbol{A}) = k-1$ *where* $\boldsymbol{A}$ *is the* $k \times n$ *matrix* $A_{ij} = \boldsymbol{d}_i \cdot \boldsymbol{h}^{(j)}$*, and (b) there exists a non-negative modular function* $\boldsymbol{h}^{(*)} \neq 0$ *such that* $\boldsymbol{d}_i \cdot \boldsymbol{h}^{(*)} = 0$ *for all* i*.*

If $k = 1$ then $\{\boldsymbol{d}_1\}$ is group balanced iff $\boldsymbol{d}_1$ is balanced, because the matrix $\boldsymbol{A}$ has a single row $\left(\boldsymbol{d}\cdot\boldsymbol{h}^{(1)} \cdots \boldsymbol{d}\cdot\boldsymbol{h}^{(n)}\right)$, and its rank is 0 iff all entries are 0. We prove in [2]:

▶ **Theorem 13.** *Consider a group balanced set of* n *vectors with rational coefficients,* $D = \{\boldsymbol{d}_1,\dots,\boldsymbol{d}_n\} \subseteq \mathbb{Q}^{2^n}$*. Suppose the following condition holds:*

$$\exists\lambda_1 \geq 0, \cdots, \exists\lambda_n \geq 0, \sum_{i\in[n]} \lambda_i = 1, \forall \boldsymbol{h} \in \overline{\Gamma}^*_n : \qquad \sum_{i\in[n]} \lambda_i \boldsymbol{d}_i \cdot \boldsymbol{h} \geq 0 \tag{20}$$

Then there exists rational $\lambda_1,\dots,\lambda_k \geq 0$ *with this property.*

This implies that, if $\boldsymbol{c}_1,\dots,\boldsymbol{c}_k$ have slack and $\{\boldsymbol{c},-\boldsymbol{c}_1,\dots,-\boldsymbol{c}_k\}$ is group balanced, then there exist rational λ_i's for inequality (19). In particular:

▶ **Corollary 14.** *Consider a conditional inequality* (8)*. If the antecedents have slack and* $\{\boldsymbol{c},-\boldsymbol{c}_1,\dots,-\boldsymbol{c}_k\}$ *is group balanced, then the corresponding decision problem is in* Σ_2^0*.*

We end this section by illustrating with an example:

▶ **Example 15.** Consider the following conditional inequality:

$$h(XYZ)+h(X)\geq 2h(XY)\wedge h(XYZ)+h(Y)\geq 2h(YZ) \quad\Rightarrow\quad 2h(XZ)\geq h(XYZ)+h(Z) \tag{21}$$

The antecedents have slack, because, by setting[2] $\boldsymbol{h}\overset{\text{def}}{=}2\boldsymbol{h}^{(X)}+\boldsymbol{h}^{(Z)}$, both antecedents become strict inequalities: $h(XYZ)+h(X)-2h(XY)=3+2-4>0$ and $h(XYZ)+h(Y)-2h(YZ)=3+0-2>0$. To check validity, we prove in Example 18 the following inequality:

$$(2h(XY)-h(XYZ)-h(X))+(2h(YZ)-h(XYZ)-h(Y))+(2h(XZ)-h(XYZ)-h(Z))\geq 0$$

and this immediately implies (21).

Consider now the following set $D=\{\boldsymbol{d}_1,\boldsymbol{d}_2,\boldsymbol{d}_3\}$, where the vectors $\boldsymbol{d}_1,\boldsymbol{d}_2,\boldsymbol{d}_3$ represent the expressions $2h(XY)-h(XYZ)-h(X)$, $2h(YZ)-h(XYZ)-h(Y)$, and $2h(XZ)-h(XYZ)-h(Z)$ respectively. We prove that D is group balanced. To check condition (a) of Def. 12 we verify that the matrix $\boldsymbol{A}$ has rank 2; in our example the matrix is $\boldsymbol{A}=\begin{pmatrix}0&1&-1\\-1&0&1\\-1&1&0\end{pmatrix}$ and its rank is 2 as required. To check condition (b), we define $\boldsymbol{h}^{(*)}=h^{(X)}+h^{(Y)}+h^{(Z)}$ and verify that $\boldsymbol{d}_1\cdot\boldsymbol{h}^{(*)}=\boldsymbol{d}_2\cdot\boldsymbol{h}^{(*)}=\boldsymbol{d}_3\cdot\boldsymbol{h}^{(*)}=4-3-1=0$. Thus, D is group balanced.

4.3 Discussion on the Decidability of MaxIIP

A proof of the decidability of MaxIIP would immediately imply that the domination problem $\boldsymbol{A}\leq\boldsymbol{B}$ for acyclic structures $\boldsymbol{B}$ is also decidable [1]. It is currently open whether MaxIIP is decidable, or even if the special case IIP is decidable. But what can we say about the domination problem if IIP were decidable? Theorem 7 only says that both problems are in Π_1^0, and does not tell us anything about MaxIIP if IIP were decidable. We prove here that, the decidability of IIP implies the decidability of group-balanced MaxIIP. We start with a result of general interest, which holds even for conditional Max-Information constraints.

▶ **Theorem 16.** *The following two statements are equivalent:*

$$\forall\boldsymbol{h}\in\overline{\Gamma}_n^*: \qquad \bigwedge_{i\in[k]}\boldsymbol{c}_i\cdot\boldsymbol{h}\geq 0\Rightarrow\bigvee_{j\in[m]}\boldsymbol{d}_j\cdot\boldsymbol{h}\geq 0 \tag{22}$$

$$\exists\lambda_1,\dots,\lambda_m\geq 0,\sum_j\lambda_j=1,\forall\boldsymbol{h}\in\overline{\Gamma}_n^*: \qquad \bigwedge_{i\in[k]}\boldsymbol{c}_i\cdot\boldsymbol{h}\geq 0\Rightarrow\sum_{j\in[m]}\lambda_j\boldsymbol{d}_j\cdot\boldsymbol{h}\geq 0 \tag{23}$$

The theorem says that every max-inequality is essentially a linear inequality. The proof of (23) ⇒ (22) is immediate; we prove the reverse in [2]. As before, we don't know whether these coefficients λ_i can be chosen to be rational numbers in general, but by Theorem 13 this is the case when $\{\boldsymbol{c}_1,\dots,\boldsymbol{c}_k\}$ is group-balanced, and this implies:

▶ **Corollary 17.** *The MaxIIP problem where the inequalities* $\boldsymbol{c}_1,\dots,\boldsymbol{c}_n$ *are group balanced is Turing equivalent to the IIP problem.*

[2] Where $\boldsymbol{h}^{(X)}$ denotes the basic modular function at X, i.e. $h^{(X)}(X)=1$, $h^{(X)}(Y)=h^{(X)}(Z)=0$.

Proof. We describe a Turing reduction from MaxIIP to IIP. Consider a MaxIIP problem, $\bigvee_{j\in[m]}(\boldsymbol{c}_j \cdot \boldsymbol{h} \geq 0)$. We run two computations in parallel. The first computation iterates over all representable spaces Ω, and checks whether $\bigwedge_j(\boldsymbol{c}_j \cdot \boldsymbol{h}^\Omega < 0)$; if we find such a space then we stop and we return *false*. If the inequality is invalid then this computation will eventually terminate because in that case there exists a representable counterexample Ω. The second computation iterates over all m-tuples of natural numbers $(\lambda_1,\dots,\lambda_m) \in \mathbb{N}^m$ and checks $\forall \boldsymbol{h} \in \Gamma_n^*, \sum_j \lambda_j \boldsymbol{c}_j \cdot \boldsymbol{h} \geq 0$ by using the oracle for IIP: if it finds such λ_j's, then it stops and returns *true*. If the inequality is valid then this computation will eventually terminate, by Theorems 16 and 13. ◀

We illustrate with an example.

▶ **Example 18.** Consider Kopparty and Rossman's inequality (7), which can be stated as $\max(\boldsymbol{c}_1,\boldsymbol{c}_2,\boldsymbol{c}_3) \geq 0$, where $\boldsymbol{c}_1,\boldsymbol{c}_2,\boldsymbol{c}_3$ define the three expressions in (7). To prove that it is valid, it suffices to prove that their sum is ≥ 0; we show this briefly here[3]:

$$\begin{aligned}
&(2h(XY)-h(X))+(2h(YZ)-h(Y))+(2h(XZ)-h(Z))-3h(XYZ)\\
&=(h(XY)+h(YZ)+h(XZ))+(h(XY)-h(X))+(h(YZ)-h(Y))+(h(XZ)-h(Z))\\
&\quad -3h(XYZ)\\
&\geq (h(XY)+h(YZ)+h(XZ))+(h(XYZ)-h(XZ))+(h(XYZ)-h(XY))\\
&\qquad +(h(XYZ)-h(YZ))-3h(XYZ)=0
\end{aligned}$$

Theorem 16 proves that *any* max-inequality necessarily follows from such a linear inequality; we just have to find the right λ_i's. In this example, the set $\boldsymbol{c}_1,\boldsymbol{c}_2,\boldsymbol{c}_3$ is group balanced (as we showed in Example 15), therefore there exists rational λ_i's; indeed, our choice here is $\lambda_1=\lambda_2=\lambda_3=1$.

5 The Recognizability Problems

We study here two problems that are the dual of the Boolean information constraint problem. The *entropic-recognizability problem* takes as input a vector $\boldsymbol{h}$ and checks if $\boldsymbol{h} \in \Gamma_n^*$. The *almost-entropic-recognizability problem* checks if $\boldsymbol{h} \in \overline{\Gamma}_n^*$. We will prove that the latter is in Π_2^0, and leave open the complexity of the former.

Before we define these problems formally, we must first address the question of how to represent the input $\boldsymbol{h}$. One possibility is to represent $\boldsymbol{h}$ as a vector of rational numbers, but this is unsatisfactory, because usually entropies are not rational numbers. Instead, we will allow a more general representation. To justify it, assume first that $\boldsymbol{h}$ were given by some representable space Ω (Sec. 4.1), where all probabilities are rational numbers. In that case, every term $p_i \log p_i$ in the definition of the entropy can be written as $\log(p_i^{p_i})$, hence the quantity $h(\boldsymbol{X})$ has the form $h(\boldsymbol{X}) = \log\prod_i p_i^{p_i}$. In general, any product $\prod_i m_i^{n_i}$ where $m_i, n_i \in Q$, for $i = 1, n$, can be rewritten as $\left(\frac{a}{b}\right)^{\frac{1}{c}}$, where $a,b,c \in \mathbb{N}$. Indeed, writing $m_i = u_i/v_i$ and $n_i = s_i/t_i$ where $u_i, v_i, s_i, t_i \in \mathbb{N}$, we have:

$$\prod_i\left(\frac{u_i}{v_i}\right)^{\frac{s_i}{t_i}} = \prod_i\left(\frac{u_i^{s_i}}{v_i^{s_i}}\right)^{\frac{1}{t_i}} = \left(\prod_i \frac{u_i^{s_i\cdot\prod_{j\neq i}t_j}}{v_i^{s_i\cdot\prod_{j\neq i}t_j}}\right)^{\frac{1}{\prod_i t_i}} = \left(\frac{a}{b}\right)^{\frac{1}{c}} \qquad a,b,c\in\mathbb{N}$$

[3] We apply submodularity: $h(XY) - h(X) \geq h(XYZ) - h(XZ)$ etc.

Justified by this observation, we assume that the input to our problem consists of three vectors $(a_{\boldsymbol{X}})_{\boldsymbol{X}\subseteq\boldsymbol{V}}$, $(b_{\boldsymbol{X}})_{\boldsymbol{X}\subseteq\boldsymbol{V}}$, and $(c_{\boldsymbol{X}})_{\boldsymbol{X}\subseteq\boldsymbol{V}}$ in $\mathbb{N}^{2^n}$, with the convention that $h(\boldsymbol{X}) \overset{\text{def}}{=} \frac{1}{c_{\boldsymbol{X}}} \log \frac{a_{\boldsymbol{X}}}{b_{\boldsymbol{X}}}$. Thus, we do not assume that these vectors come from a representable space Ω, we only assume their entropies can be represented in this form.

▶ **Definition 19** ((Almost-)Entropic Recognizability Problem)**.** *Given natural numbers $(a_{\boldsymbol{X}})_{\boldsymbol{X}\subseteq\boldsymbol{V}}$, $(b_{\boldsymbol{X}})_{\boldsymbol{X}\subseteq\boldsymbol{V}}$ and $(c_{\boldsymbol{X}})_{\boldsymbol{X}\subseteq\boldsymbol{V}}$, check whether the vector $h(\boldsymbol{X}) \overset{\text{def}}{=} \frac{1}{c_{\boldsymbol{X}}} \log \frac{a_{\boldsymbol{X}}}{b_{\boldsymbol{X}}}$, $\boldsymbol{X} \subseteq \boldsymbol{V}$, represents an entropic vector, or an almost-entropic vector.*

Our result in this section is (see [2] for a proof):

▶ **Theorem 20.** *The almost entropic recognizability problem is in Π_2^0.*

We end with a brief comment on the complexity of the entropic-recognizability problem: given $\boldsymbol{h}$ (represented as in Def. 19) check if $\boldsymbol{h} \in \Gamma_n^*$. Consider the following restricted form of the problem: check if $\boldsymbol{h}$ is the entropic vector of a representable space Ω (i.e. finite space with rational probabilities). This problem is in Σ_1^0, because one can iterate over all representable spaces Ω and check that their entropies are those required. However, in the general setting we ask whether *any* finite probability space has these entropies, not necessarily one with rational probabilities. This problem would remain in Σ_1^0 if the theory of reals with exponentiation were decidable. Recall that Tarski's theorem states that the theory of reals $\text{FO}(\mathbb{R}, 0, 1, +, *)$ is decidable. A major open problem in model theory is whether the theory remains decidable if we add exponentiation. If that were decidable, then the entropic-recognizability problem would be in Σ_1^0. To see this, consider the following semi-decision problem. Iterate over $N = 1, 2, 3, \ldots$ and for each N check if there exists a probability space whose active domain has size N (thus, there are N^n outcomes, where $n = |\boldsymbol{V}|$ is the number of variables) and whose entropies are precisely those given. This statement that can be expressed using the exponential function (which we need in order to express the entropy as $\sum_i p_i \log p_i$). If there exists any finite probability space with the required entropies, then this procedure will find it; otherwise it will run forever, placing the problem in Σ_1^0.

6 Discussion

CI Implication Problem. The implication problem for Conditional Independence statements has been extensively studied in the literature, but its complexity remains an open problem. It is not even known whether this problem is decidable [18, 37, 38]. Our Theorem 8 appears to be the first upper bound on the complexity of the CI implication problem, placing it in Π_1^0. Hannula et al. [24] prove that, if all random variables are restricted to be binary random variables, then the CI implication problem is in EXPSPACE; the implication problem for binary random variables differs from that for general discrete random variables; see the discussion in [18].

Finite, infinite, continuous random variables. In this paper, all random variables have a finite domain. There are two alternative choices: discrete random variables (possibly infinite), and continuous random variables. The literature on entropic functions has mostly alternated between defining entropic functions over finite random variables, or over discrete infinite random variables with finite entropy. For example discrete (possibly infinite) random variables are considered by Zhang and Yeung, [50], by Chan and Yeung [12], and by Chan [22], while random variables with finite domains are considered by Matúš [33, 34] and by Kaced and Romashchenko [25]. The reason for this inconsistency is that for information inequalities the distinction doesn't matter: every entropy of a set of discrete random variables can be approximated arbitrarily well by the entropy of a set of random variables with finite domain, and Prop. 6 extends immediately to discrete random variables[4]. However, the distinction is significant for conditional inequalities, and here the choice in the literature is always for finite domains. For example, the implication problem for conditional independence, i.e. the graphoid axioms, is stated for finite probability spaces by Geiger and Pearl [18], while Kaced and Romashchenko [25] also use finite distributions to prove the existence of conditional inequalities that hold over entropic but fail for almost-entropic functions. One could also consider continuous distributions, whose entropy is $\int p(x)\log(1/p(x))dx$, where p is the probability density function. Chan [22] showed that an information inequality holds for all continuous distributions iff it is balanced and it holds for all discrete distributions. For example, $h(X) \geq 0$ is not balanced, hence it fails in the continuous, because the entropy of the uniform distribution in the interval $[0, c]$ is $\log c$, which is < 0 when $c < 1$.

Strict vs. non-strict inequalities. The literature on information inequalities always defines inequalities using ≥ 0, in which case validity for entropic functions is the same as validity for almost entropic functions. One may wonder what happens if one examines strict inequalities $\boldsymbol{c} \cdot \boldsymbol{h} > 0$ instead. Obviously, each such inequality fails on the zero-entropic vector, but we can consider the conditional version $\boldsymbol{h} \neq 0 \Rightarrow \boldsymbol{c} \cdot \boldsymbol{h} > 0$, which we can write formally as $\boldsymbol{c} \cdot \boldsymbol{h} \leq 0 \Rightarrow h(\boldsymbol{V}) \leq 0$. This a special case of a conditional inequality as discussed in this paper. An interesting question is whether for this special case Γ_n^*-validity and $\overline{\Gamma}_n^*$-validity coincide; a negative answer would represent a significant extension of Kaced and Romashchenko's result [25].

[4] The idea of the proof relies on the fact that every entropy is required to converge, i.e. $h(X_\alpha) = \sum_i p_i \log 1/p_i$, hence there exists a finite subspace of outcomes $\{1, 2, \ldots, N\}$ for which the sum is ε-close to $h(X_\alpha)$. The union of these spaces over all $\alpha \subseteq [n]$ suffices to approximate h well enough.

Abstract

Continuous linear dynamical systems are used extensively in mathematics, computer science, physics, and engineering to model the evolution of a system over time. A central technique for certifying safety properties of such systems is by synthesising inductive invariants. This is the task of finding a set of states that is closed under the dynamics of the system and is disjoint from a given set of error states. In this paper we study the problem of synthesising inductive invariants that are definable in o-minimal expansions of the ordered field of real numbers. In particular, assuming Schanuel's conjecture in transcendental number theory, we establish effective synthesis of o-minimal invariants in the case of semi-algebraic error sets. Without using Schanuel's conjecture, we give a procedure for synthesizing o-minimal invariants that contain all but a bounded initial segment of the orbit and are disjoint from a given semi-algebraic error set. We further prove that effective synthesis of semi-algebraic invariants that contain the whole orbit, is at least as hard as a certain open problem in transcendental number theory.

1 Introduction

A *continuous linear dynamical system* (CDS) is a system whose evolution is governed by a differential equation of the form $\dot{\mathbf{x}}(t) = A\mathbf{x}(t)$, where A is a matrix with real entries. CDSs are ubiquitous in mathematics, physics, and engineering; they have been extensively studied as they describe the evolution of many types of systems (or abstractions thereof) over time. More recently, CDSs have become central in the study of cyber-physical systems (see, e.g., the textbook [4]).

In the study of CDSs, particularly from the perspective of control theory, a fundamental problem is *reachability* – namely whether the orbit $\{\mathbf{x}(t) \ : \ t \geq 0\}$ intersects a given target set $Y \subseteq \mathbb{R}^d$. For example, when $\mathbf{x}(t)$ describes the state of an autonomous car (i.e., its location, velocity, etc.). Y may describe situations where the car is not able to stop in time to respond to a hazard.

When Y is a singleton set, reachability is decidable [14, Theorem 2]. However, already when Y is a half-space it is open whether or not reachability is decidable. The latter decision problem is known in the literature as the *continuous Skolem problem.* Some partial positive results were given in [6] and [10]. The continuous Skolem problem is related to notoriously difficult problems in the theory of Diophantine approximation: specifically a procedure for the continuous Skolem problem would yield one for computing to arbitrary precision the *Diophantine-approximation types* of all real algebraic numbers [10].

In lieu of an algorithm to decide reachability, a popular approach to certifying non-reachability is by finding an *inductive invariant*, that is, a set X that is closed under the dynamics of the system and disjoint from the target Y. For such a set, it is immediate that the orbit of any point in X does not reach Y. In order to make this approach effective it is natural to seek invariants among suitably tame classes of sets (e.g., polyhedra, semi-algebraic sets, *etc*). In this work we take a very general approach – we consider *o-minimal invariants*, that is, invariants definable in *some* o-minimal expansion of the ordered set of real numbers. The class of o-minimal invariants includes those defined by Boolean combinations of inequalities involving polynomials, the real exponential function, and bounded versions of the trigonometric functions. One can potentially use many other functions to define o-minimal invariants, but the key to our approach is to show that the ingredients just listed suffice in the case of a CDS and semi-algebraic target Y.

The papers [2, 1] study o-minimal invariants for *discrete* linear dynamical systems. There it is proved that when the target Y is a semi-algebraic set, the question of whether there exists an o-minimal invariant disjoint from Y is decidable. Furthermore, if there is an o-minimal invariant then there is in fact a semi-algebraic invariant which can moreover be constructed effectively. The present paper uses similar ideas, although the case of continuous linear dynamical systems differs in several important ways.

Main Contributions. We consider the following problem: given a CDS by means of a matrix A with rational entries, an initial point $\mathbf{x}_0 = \mathbf{x}(0)$, and a semi-algebraic set Y of error states, decide whether there exists a set that is definable in some o-minimal expansion of the ordered real field and is (1) disjoint from Y, (2) invariant under the dynamics of the system, and (3) contains the initial point $\mathbf{x}_0$. We show that in searching for such invariants it suffices to look among sets definable in the expansion of the reals with the real exponential function and trigonometric functions restricted to bounded domains. Moroever, assuming Schanuel's conjecture (a unifying conjecture in transcendental number theory), we prove that the existence of such an invariant is decidable, and that invariants can effectively be constructed when they exist.

Without assuming Schanuel's conjecture we can decide a related problem, namely the question of whether there exists a set that is definable in an o-minimal expansion of the real field and is (1) disjoint from Y, (2) invariant under the dynamics of the system, and (3) meets the orbit of the initial point $\mathbf{x}_0$. Notice that such a set – which could be called an *eventual invariant* – must contain all but a bounded initial segment of the orbit. We show that when such a set exists, it can be effectively constructed and moreover that it can be chosen to be a semi-algebraic set. Such an invariant can serve as a certificate that the orbit does not enter the error set Y infinitely often. The latter is a very difficult problem to decide, even when the target set is a half-space [9].

As mentioned earlier, for discrete linear dynamical systems the question of whether there exists a semi-algebraic invariant that contains the *whole* orbit is decidable [2, 1]. We provide an explanation of why the analogous result for continuous systems is not easy to prove; this is by way of a reduction from a difficult problem that highlights the complications of continuous systems. The problem asks whether a given exponential polynomial of the form

$$f(t) = a_1 e^{b_1 t} + \cdots + a_n e^{b_n t}$$

has zeros in a bounded interval, where a_i, b_i are real algebraic numbers. Deciding whether f has zeros in a bounded region seems to be difficult because all the zeros have to be transcendental (a consequence of Hermite-Lindemann Theorem), and they can be tangential, i.e., f never changes its sign, yet it has a zero.

Related Work. Invariant synthesis is a central technique for establishing safety properties of hybrid systems. It has long been known how to compute a strongest *algebraic* invariant [20] (i.e., a smallest algebraic set that contains the collection of reachable states) for an arbitrary CDS. Here an algebraic invariant is one that is specified by a conjunction of polynomial equalities. If one moves to the more expressive setting of semi-algebraic invariants, which allow inequalities, then there is typically no longer a strongest (or smallest) invariant, but one can still ask to decide the existence of an invariant that avoids a given target set of configurations. This is the problem that is addressed in the present paper.

Partial positive results are known, for example when strong restrictions on the matrix A are imposed, such as when all the eigenvalues are real and rational, or purely imaginary with rational imaginary part [15].

A popular approach in previous work has been to seek invariants that match a given syntactic *template*, which allows to reduce invariant synthesis to constraint solving [13, 23, 16]. While this technique can be applied to much richer classes of systems than those considered here (e.g., with discrete control modes and non-linear differential equations), it does not appear to offer a way to decide the existence of arbitrary semi-algebraic invariants. An alternative to the template approach for invariant generation involves obtaining candidate invariants from semi-algebraic abstractions of a system [21]. Another active area of current research lies in developing powerful techniques to check whether a given semi-algebraic set is actually an invariant [12, 16].

Other avenues for analysing dynamical systems in the literature include bisimulations [7], forward/backward reach-set computation [5], and methods for directly proving liveness properties [22]. The latter depends on constructing *staging sets*, which are essentially semi-algebraic invariants.

Often, questions about dynamical systems can be reduced to deciding whether a sentence belongs to the elementary theory of an appropriate expansion of the ordered field of real numbers. While the latter is typically undecidable, there are partial positive results, namely quasi-decidability in bounded domains, see [11] and the references therein. This can be used to reason about the dynamics of a system in a bounded time interval, under the assumption that it does not tangentially approach the set that we want to avoid. However, it seems unlikely that such results can be easily applied to the problems considered here.

The rest of the paper is organised as follows. In Section 2, we give the necessary definitions and terminology. In Section 3, we define *cones*, which are over-approximations of the orbit, and prove that they are in a certain sense canonical. The positive results assuming Schanuel's conjecture are subsequently given in this section. Section 4 is devoted to the effective construction of the semi-algebraic invariants which allows us to state and prove the unconditional positive results. In Section 5, we give the aforementioned reduction, from finding zeros of exponential polynomials.

See [3] for the complete proofs.

2 Preliminaries

A *continuous-time linear dynamical system* is a pair

$$\langle A, \mathbf{x}_0 \rangle$$

where $A \in \mathbb{Q}^{d \times d}$ and $\mathbf{x}_0 \in \mathbb{Q}^d$. The system evolves in time according the function $x(t)$ which is the unique solution to the differential equation $\dot{\mathbf{x}}(t) = A\mathbf{x}(t)$ with $\mathbf{x}(0) = \mathbf{x}_0$. Explicitly this solution can be written as:

$$\mathbf{x}(t) = e^{At}\mathbf{x}_0.$$

The *orbit of* $\langle A, \mathbf{x}_0 \rangle$ *from time* t_0 is the set $\mathcal{O}(t_0) = \{e^{At}\mathbf{x}_0 \ : \ t \geq t_0\}$. An *invariant for* $\langle A, \mathbf{x}_0 \rangle$ *from time* t_0 is a set $\mathcal{I} \subseteq \mathbb{R}^d$ that contains $e^{At_0}\mathbf{x}_0$ and is stable under applications of e^{At}, i.e., $e^{At}\mathcal{I} \subseteq \mathcal{I}$ for every $t \geq 0$. Note that an invariant from time t_0 contains $\mathcal{O}(t_0)$. Given a set $Y \subseteq \mathbb{R}^d$ (referred to henceforth as an *error set*), we say that the invariant $\mathcal{I}$ *avoids* Y if the two sets are disjoint.

We denote by $\mathfrak{R}_0$ the structure $\langle \mathbb{R}, 0, 1, +, \cdot, < \rangle$. This is the ordered field of real numbers with constants 0 and 1. A sentence in the corresponding first-order language is a quantified Boolean combination of atomic propositions of the form $P(x_1, \dots, x_n) > 0$, where P is a polynomial with integer coefficients and $x_1, \dots, x_n$ are variables. In addition to $\mathfrak{R}_0$, we also consider its following expansions:

- $\mathfrak{R}_{\exp}$, obtained by expanding $\mathfrak{R}_0$ with the real exponentiation function $x \mapsto e^x$.
- $\mathfrak{R}^{\mathrm{RE}}$, obtained by expanding $\mathfrak{R}_0$ with the *restricted elementary functions*, namely $x \mapsto e^x|_{[0,1]}$, $x \mapsto \sin x|_{[0,1]}$, and $x \mapsto \cos x|_{[0,1]}$.
- $\mathfrak{R}^{\mathrm{RE}}_{\exp}$, obtained by expanding $\mathfrak{R}_{\exp}$ with the restricted elementary functions.

Tarski famously showed that the first-order theory of $\mathfrak{R}_0$ admits quantifier elimination, moreover the elimination is effective and therefore the theory is decidable [24, Theorem 37].

It is an open question whether the theory of the reals with exponentiation ($\mathfrak{R}_{\exp}$) is decidable; however decidability was established subject to Schanuel's conjecture by MacIntyre and Wilkie [18, Theorem 1.1]. MacIntyre and Wilkie further showed in [18, Section 5] that decidability of the theory of $\mathfrak{R}_{\exp}$ implies a weak form of Schanuel's conjecture.

Similarly, it is an open question whether $\mathfrak{R}^{\mathrm{RE}}$ and $\mathfrak{R}^{\mathrm{RE}}_{\exp}$ are decidable, but they are also known to be decidable subject to Schanuel's conjecture [17, Theorem 3.1][1].

[1] More precisely, the decidability of $\mathfrak{R}_{\exp}$ requires Schanuel's conjecture over $\mathbb{R}$, whereas that of $\mathfrak{R}^{\mathrm{RE}}_{\exp}$ requires it over $\mathbb{C}$.

Let $\mathfrak{R}$ be an expansion of the structure $\mathfrak{R}_0$. A set $S \subseteq \mathbb{R}^d$ is *definable* in $\mathfrak{R}$ if there exists a formula $\phi(x_1, \ldots, x_d)$ in $\mathfrak{R}$ with free variables $x_1, \ldots, x_d$ such that $S = \{(c_1, \ldots, c_d) \in \mathbb{R}^d \mid \mathfrak{R} \models \phi(c_1, \ldots, c_d)\}$. For $\mathfrak{R} = \mathfrak{R}_0$, the ordered field of real numbers, $\mathfrak{R}_0$-definable sets are known as *semi-algebraic* sets.

▶ Remark 2.1. There is a natural first-order interpretation of the field of complex numbers $\mathbb{C}$ in the field of real numbers $\mathbb{R}$. We shall say that a set $S \subseteq \mathbb{C}^d$ is $\mathfrak{R}$-*definable* if the image $\{(x, y) \in \mathbb{R}^d \times \mathbb{R}^d \mid x + iy \in S\}$ of S under this interpretation is $\mathfrak{R}$-definable.

A totally ordered structure $\langle M, <, \ldots \rangle$ is said to be *o-minimal* if every definable subset of M is a finite union of intervals. Tarski's result on quantifier elimination implies that $\mathfrak{R}_0$ is o-minimal. The o-minimality of $\mathfrak{R}_{\exp}$ and $\mathfrak{R}^{\text{RE}}$ is shown in [27], and the o-minimality of $\mathfrak{R}^{\text{RE}}$ and $\mathfrak{R}^{\text{RE}}_{\exp}$ is due to [25, 26].

A *semi-algebraic invariant* is one that is definable in $\mathfrak{R}_0$. An *o-minimal invariant* is one that is definable in an o-minimal expansion of $\mathfrak{R}_{\exp}$.

3 Orbit Cones

In this section we define orbit cones, an object that plays a central role in the subsequent results. They can be thought of as over-approximations of the orbit that has certain desirable properties, and moreover it is canonical in the sense that any other invariant must contain a cone.

3.1 Jordan Normal Form

Let $\langle A, \mathbf{x}_0 \rangle$ be a continuous linear dynamical system. The exponential of a square matrix A is defined by its formal power series as

$$e^A \stackrel{\text{def}}{=} \sum_{n=0}^{\infty} \frac{A^n}{n!}.$$

Let $\lambda_1, \ldots, \lambda_k$ be the eigenvalues of A, and recall that when $A \in \mathbb{Q}^{d \times d}$, all the eigenvalues are algebraic. We can write A in *Jordan Normal Form* as $A = PJP^{-1}$ where $P \in \mathbb{C}^{d \times d}$ is an invertible matrix with algebraic entries, and $J = \text{diag}(B_1, \ldots, B_k)$ is a block-diagonal matrix where each block B_l is a Jordan block that corresponds to eigenvalue λ_l, and it has the form

$$B_l = \begin{pmatrix} \lambda_l & 1 & 0 & \cdots & 0 \\ 0 & \lambda_l & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & \lambda_l \end{pmatrix} \in \mathbb{C}^{d_l \times d_l}$$

with $\sum_{l=1}^{k} d_l = d$.

From the power series, we can write $e^{At} = Pe^{Jt}P^{-1}$. Further, $e^{Jt} = \text{diag}(e^{B_1}, \ldots, e^{B_k})$. For each $1 \leq l \leq k$, write $B_l = \Lambda_l + N_l$, where Λ_l is the $d_l \times d_l$ diagonal matrix $\text{diag}(\lambda_l, \ldots, \lambda_l)$ and N_l is the $d_l \times d_l$ matrix $\text{diag}_2(1, \ldots, 1)$; where $\text{diag}_j(\cdot)$ is the j-th diagonal matrix, with other entries zero.

The matrices Λ_l and N_l commute, since the former is a diagonal matrix. A fundamental property of matrix exponentiation is that if matrices A, B commute, then $e^{A+B} = e^A e^B$. Thus, we have

$$e^{Jt} = e^{\text{diag}(\Lambda_1 t + N_1 t, \ldots, \Lambda_k t + N_k t)} = \text{diag}(e^{\lambda_1 t}, \ldots, e^{\lambda_k t}) e^{\text{diag}(N_1 t, \ldots, N_k t)},$$

where by $\mathrm{diag}(e^{\lambda_1 t}, \ldots, e^{\lambda_k t})$ we mean the $d \times d$ diagonal matrix that has the entry $e^{\lambda_1 t}$ written d_1 times, the entry $e^{\lambda_2 t}$ written d_2 times and so on. It will always be clear from the context whether we repeat the entries because of their multiplicity or not.

Matrices N_l are nilpotent, so its power series expansion is a finite sum, i.e. a polynomial in $N_l t$. More precisely, one can verify that:

$$e^{N_l t} = I + \mathrm{diag}_2(t, \ldots, t) + \mathrm{diag}_3(\frac{t^2}{2}, \ldots, \frac{t^2}{2}) + \ldots + \mathrm{diag}_{d_l}\left(\frac{t^{(d_l-1)}}{(d_l-1)!}\right).$$

Set $Q(t) \overset{\text{def}}{=} \mathrm{diag}(e^{N_1 t}, \ldots, e^{N_k t})$. From the equation above, the entries of $Q(t)$ are polynomials in t with rational coefficients.

Write the eigenvalues as $\lambda_l = \rho_l + \mathrm{i}\omega_l$, so that

$$\mathrm{diag}(e^{\lambda_1 t}, \ldots, e^{\lambda_k t}) = \underbrace{\mathrm{diag}(e^{\rho_1 t}, \ldots, e^{\rho_k t})}_{E(t)} \cdot \underbrace{\mathrm{diag}(e^{\omega_1 \mathrm{i} t}, \ldots, e^{\omega_k \mathrm{i} t})}_{R(t)}$$

We have in this manner decomposed the orbit

$$\mathcal{O}(t_0) = \{P \quad E(t)\ R(t)\ Q(t) \quad P^{-1}\mathbf{x}_0 \ : \ t \geq t_0\},$$

into an exponential $E(t)$, a rotation $R(t)$, and a simple polynomial $Q(t)$ matrices that commute with one another. Having the orbit in such a form will facilitate the analysis done in the sequel.

3.2 Cones as Canonical Invariants

In a certain sense, the rotation matrix $R(t)$ is the most complicated, because of it, the orbit is not even definable in $\mathfrak{R}_{\exp}$. The purpose of cones is to abstract away this matrix by a much simpler subgroup of the complex torus

$$\mathbb{T} \overset{\text{def}}{=} \{\mathbf{z} \in \mathbb{C}^k \ : \ |z_i| = 1, 1 \leq i \leq k\}.$$

To this end, consider the group of additive relations among the frequencies $\omega_1, \ldots, \omega_k$:

$$S \overset{\text{def}}{=} \{\mathbf{a} \in \mathbb{Z}^k \ : \ a_1\omega_1 + \cdots + a_k\omega_k = 0\}.$$

The subgroup of the torus of interest, respects the additive relations as follows:

$$\mathbb{T}_\omega \overset{\text{def}}{=} \{(\tau_1, \ldots, \tau_k) \in \mathbb{T} \ : \ \text{for all } \mathbf{a} \in S,\ \tau_1^{a_1} \cdots \tau_k^{a_k} = 1\}.$$

Its desirable properties are summarised in the following proposition:

▶ **Proposition 3.1.** *For algebraic numbers $\omega_1, \ldots, \omega_k$,*

1. *$\mathbb{T}_\omega$ is semi-algebraic,*
2. *diagonals of $\{R(t) \ : \ t \geq 0\}$ form a dense subset of $\mathbb{T}_\omega$.*

Proof. Being an Abelian subgroup of $\mathbb{Z}^k$, S has a finite basis, moreover this basis can be computed because of effective bounds, [19, Section 3]. To check that $(\tau_1, \ldots, \tau_k)$ belongs to $\mathbb{T}_\omega$, it suffices to check that $\tau_1^{a_1} \cdots \tau_k^{a_k} = 1$ for $(a_1, \ldots, a_k)$ in the finite basis. This forms a finite number of equations, therefore $\mathbb{T}_\omega$ is semi-algebraic. The fact that this is a subset of vectors of complex numbers is not problematic in this case because of the simple first-order interpretation in the theory of reals, see Remark 2.1.

The second statement of the proposition is a consequence of Kronecker's theorem on inhomogeneous simultaneous Diophantine approximations, see [8, Page 53, Theorem 4]. The proof of a slightly stronger statement can also be found in [9, Lemma 4]. Examples can be found where the set of diagonals of $\{R(t) \ : \ t \geq 0\}$ is a strict subset of $\mathbb{T}_\omega$. ◀

The orbit cone can now be defined by replacing the rotations with the subgroup of the torus. As it turns out, for our purposes this approximation is not too rough.

▶ **Definition 3.2.** *The* orbit cone *from* $t_0 \geq 0$ *is*

$$\mathcal{C}_{t_0} \overset{\text{def}}{=} \left\{ P\ E(t)\ \mathrm{diag}(\boldsymbol{\tau})\ Q(t)\ P^{-1}\mathbf{x}_0\ :\ \boldsymbol{\tau} \in \mathbb{T}_\omega, t \geq t_0 \right\}.$$

We prove that the cone is an inductive invariant and also a subset of $\mathbb{R}^d$.

▶ **Lemma 3.3.** *For all* $\delta, t_0 \geq 0$*,* $e^{A\delta}\mathcal{C}_{t_0} \subseteq \mathcal{C}_{t_0}$*.*

Proof. Fix $t \geq t_0$ and $\boldsymbol{\tau} \in \mathbb{T}_\omega$, and consider the point

$$\mathbf{v} = P\ E(t)\ \mathrm{diag}(\boldsymbol{\tau})\ Q(t)\ P^{-1}\mathbf{x}_0 \in \mathcal{C}_{t_0},$$

then we can write $e^{A\delta}\mathbf{v}$ as

$$\begin{aligned} e^{A\delta}\mathbf{v} &= P\ E(\delta)R(\delta)Q(\delta) \cdot E(t)\mathrm{diag}(\boldsymbol{\tau})Q(t)\ P^{-1}\mathbf{x}_0 \\ &= P\ E(\delta+t)\ R(\delta)\mathrm{diag}(\boldsymbol{\tau})\ Q(\delta)Q(t)\ P^{-1}\mathbf{x}_0. \end{aligned}$$

The matrix $R(\delta)\mathrm{diag}(\boldsymbol{\tau})$ is equal to $\mathrm{diag}(\boldsymbol{\tau}')$ for some $\boldsymbol{\tau}' \in \mathbb{T}_\omega$. Otherwise said, the vector $(e^{\delta\omega_1 \mathrm{i}}\tau_1, \ldots, e^{\delta\omega_k \mathrm{i}}\tau_k)$ belongs to $\mathbb{T}_\omega$. Indeed this is the case because for any $\mathbf{a} \in S$ we have

$$e^{a_1\delta\omega_1\mathrm{i}}\tau_1^{a_1} \cdots e^{a_k\delta\omega_k\mathrm{i}}\tau_k^{a_k} = e^{\delta\mathrm{i}\ (a_1\omega_1+\cdots+a_k\omega_k)} \cdot \tau_1^{a_1} \cdots \tau_k^{a_k} = 1.$$

Finally, by induction on the dimension d one can verify that $Q(\delta)Q(t) = Q(\delta + t)$. ◀

The fact that cones are subsets of $\mathbb{R}^d$ comes as a corollary of the following proposition whose proof can be found in Appendix A of the full version of the paper [3].

▶ **Proposition 3.4.** *Let* $A = PJP^{-1}$ *as above, and let* $C_i \in \mathbb{C}^{d_i \times d_i}$ *for* $i = 1, \ldots, k$*, with dimensions compatible to the Jordan blocks of* A*, and such that for every* i_1, i_2*, if* $B_{i_1} = \overline{B_{i_2}}$*, then* $C_{i_1} = \overline{C_{i_2}}$*. Then* $P\mathrm{diag}(C_1, \ldots, C_k)P^{-1}$ *has real entries.*

The matrix $E(t)\mathrm{diag}(\tau)Q(t)$ can be written as $\mathrm{diag}(C_1, \ldots, C_k)$ where the C_i matrices satisfy the conditions of Proposition 3.4, hence the following corollary.

▶ **Corollary 3.5.** *For all* $t_0 \geq 0$ *we have* $\mathcal{C}_{t_0} \subseteq \mathbb{R}^d$*.*

It is surprising that, already, the cones are a complete characterisation of o-minimal inductive invariants in the following sense.

▶ **Theorem 3.6.** *Let* $\mathcal{I}$ *be an o-minimal invariant that contains the orbit* $\mathcal{O}(u)$ *from some time* $u \geq 0$*, then there exists* $t_0 \geq u$ *such that:*

$$\mathcal{C}_{t_0} \subseteq \mathcal{I}.$$

Proof sketch. Conceptually, the proof follows along the lines of its analogue in [1]. There are a few differences, namely that the entries of the matrix A in [1] are assumed to be algebraic, while this is not true for the entries of e^A.

We define rays of the cone, which are subsets where $\boldsymbol{\tau} \in \mathbb{T}_\omega$ is fixed. Then we prove that for every ray, all but a finite part of it, is contained in the invariant. This is done by contradiction: if a ray is not contained in the invariant, a whole dense subset of the cone can be shown not to be contained in the invariant, leading to a contradiction, since the invariant is assumed to contain the orbit. We achieve this using some results on the topology of o-minimal sets.

The complete proof can be found in Appendix B of [3]. ◀

Another desirable property of cones is that they are $\mathfrak{R}_{\exp}$-definable. Also, one can observe that for every t_0, the set $\{e^{At}\mathbf{x}_0 : 0 \le t \le t_0\}$ is definable in $\mathfrak{R}_{\exp}^{\mathrm{RE}}$ (as we only need bounded restrictions of sin and cos to capture e.g. $e^{\mathrm{i}\omega_i}$ up to time t_0). As an immediate corollary of Theorem 3.6, we have the following theorems.

▶ **Theorem 3.7.** *Let $\langle A, \mathbf{x}_0\rangle$ be a CDS. For every $t_0 \ge 0$, the set $\mathcal{C}_{t_0} \cup \{e^{At}\mathbf{x}_0 : 0 \le t \le t_0\}$ is an invariant that contains the whole orbit of $\langle A, \mathbf{x}_0\rangle$. Moreover, this invariant is definable in $\mathfrak{R}_{\exp}^{\mathrm{RE}}$ (and in particular is o-minimal).*

▶ **Theorem 3.8.** *Let $\langle A, \mathbf{x}_0\rangle$ be a CDS and let $Y \subseteq \mathbb{R}^d$ be an error set. There exists an o-minimal invariant $\mathcal{I}$ that contains the orbit and is disjoint from Y if and only if there exists t_0 such that $\mathcal{C}_{t_0} \cup \{e^{At}\mathbf{x}_0 : 0 \le t \le t_0\}$ is such an invariant.*

Theorem 3.8 now allows us to provide an algorithm for deciding the existence of an invariant, subject to Schanuel's conjecture:

▶ **Theorem 3.9.** *Assuming Schanuel's conjecture, given a CDS $\langle A, \mathbf{x}_0\rangle$ and an $\mathfrak{R}_{\exp}^{\mathrm{RE}}$ definable error set Y, it is decidable whether there exists an o-minimal invariant for $\langle A, \mathbf{x}_0\rangle$ that avoids Y. Moreover, if such an invariant exists, we can compute a representation of it.*

Proof. By Theorem 3.8, there exists an o-minimal invariant $\mathcal{I}$ that avoids Y if and only if there exists some $t_0 \in \mathbb{R}$ such that $\mathcal{C}_{t_0} \cup \{e^{At}\mathbf{x}_0 : 0 \le t \le t_0\}$ is such an invariant. Thus, the problem reduces to deciding the truth value of the following $\mathfrak{R}_{\exp}^{\mathrm{RE}}$ sentence:

$$\exists t_0 \;:\; (\mathcal{C}_{t_0} \cup \{e^{At}\mathbf{x}_0 : 0 \le t \le t_0\}) \cap Y = \emptyset$$

The theory of $\mathfrak{R}_{\exp}^{\mathrm{RE}}$ is decidable subject to Schanuel's conjecture, and therefore we can decide the existence of an invariant. Moreover, if an invariant exists, we can compute a representation of it by iterating over increasing values of t_0, until we find a value for which the sentence $\left(\mathcal{C}_{t_0} \cup \{e^{At}\mathbf{x}_0 : 0 \le t \le t_0\}\right) \cap Y = \emptyset$ is true. ◀

4 Semi-algebraic Error Sets and Fat Trajectory Cones

In this section, we restrict attention to semi-algebraic invariants and semi-algebraic error sets, in order to regain unconditional decidability.

Substitute $s = e^t$ in the definition of the cone to get:

$$\mathcal{C}_{t_0} = \left\{P \; E(\log s) \; \mathrm{diag}(\boldsymbol{\tau}) \; Q(\log s) \; P^{-1}\mathbf{x}_0 \;:\; \boldsymbol{\tau} \in \mathbb{T}_\omega, \; s \ge e^{t_0}\right\}.$$

Written this way, observe that $E(\log s) = \mathrm{diag}(s^{\rho_1}, \ldots, s^{\rho_k})$, which is almost semi-algebraic, apart from the fact that the exponents need not be rational.

4.1 Unconditional Decidability

We give the final, yet crucial property of the cones. When the error set is semi-algebraic, it is possible to decide, unconditionally, whether there exists some cone that avoids the error set. Moreover the proof is constructive, it will produce the cone for which this property holds.

▶ **Theorem 4.1.** *For a semi-algebraic error set Y, it is (unconditionally) decidable whether there exists $t_0 \ge 0$ such that $\mathcal{C}_{t_0} \cap Y = \emptyset$. Moreover, such a t_0 can be computed.*

Proof. Define the set

$$U \overset{\text{def}}{=} \left\{ \mathcal{V} \in \mathbb{R}^{d\times d} \ : \ \forall \boldsymbol{\tau} \in \mathbb{T}_\omega, \quad P\ \mathcal{V}\ \text{diag}(\boldsymbol{\tau})\ P^{-1}\mathbf{x}_0 \in \mathbb{R}^d \setminus Y \right\}.$$

The set U can be seen to be semi-algebraic and thus is expressed by a quantifier-free formula that is a finite disjunction of formulas of the form $\bigwedge_{l=1}^m R_l(\mathcal{V}) \sim_l 0$, where each R_l is a polynomial with integer coefficients, over $d \times d$ variables of the entries of the matrix $\mathcal{V}$, and$\sim_l \in \{>, =\}$. Define the matrix

$$\Lambda(s) \overset{\text{def}}{=} \text{diag}(s^{\rho_1}, \ldots, s^{\rho_k}) Q(\log s) \in \mathbb{R}^{d\times d},$$

and notice that $\mathcal{C}_{t_0} \cap Y = \emptyset$ if and only if $\Lambda(s) \in U$ for every $s \geq e^{t_0}$. Thus, it is enough to decide whether there exists $s_0 \geq 1$ such that for every $s \geq s_0$, at least one of the disjuncts $\bigwedge_{l=1}^m R_l(\Lambda(s)) \sim_l 0$ is satisfied.

Since $R_l(\Lambda(s))$ are polynomials in entries of the form s^{ρ_i} and $\log(s)$, there is an effective bound s_0 such that for all $s \geq s_0$, none of the values $R_l(\Lambda(s))$ change sign for any $1 \leq l \leq m$. Hence we only need to decide whether there exists some $s_0' \geq s_0$ such that for all $s \geq s_0'$ we have $R_l(\Lambda(s)) \sim_l 0$ for every $1 \leq l \leq m$.

Fix some l. The polynomial $R_l(v_1, \ldots, v_D)$ has the form $\sum_i a_i v_1^{n_{i,1}} \cdots v_D^{n_{i,D}}$. After identifying the matrix $\Lambda(s)$ with a vector in $\mathbb{R}^D$ for $D = d^2$, we see that $R_l(\Lambda(s))$ is a sum of terms of the form

$$a_i s^{n'_{i,1}\rho_1 + \ldots n'_{i,k}\rho_k} \cdot Q_{i,1}(\log s) \cdots Q_{i,D}(\log s)$$

where the $n'_{i,j}$ are aggregations of the $n_{i,j}$ for identical entries of $\text{diag}(s_1^\rho, \ldots, s_k^\rho)$, and $Q_{i,j}(\log s)$ are polynomials obtained from the entries of $Q(\log s)$ under R_l. We can join the polynomials $Q_1, \ldots, Q_D$ into a single polynomial f_i, which would also absorb a_i. Thus, we rewrite R_l in the form $\sum_i s^{n'_{i,1}\rho_1 + \ldots n'_{i,k}\rho_k} f_i(\log s)$ where each f_i is a polynomial with rational coefficients (as the coefficients in $Q(\log s)$ are rational).

In order to reason about the sign of this expression as $s \to \infty$, we need to find the leading term of $R_l(\Lambda(s))$. This, however, is easy: the exponents $n'_{i,1}\rho_1 + \ldots + n'_{i,k}\rho_k$ are algebraic numbers, and are therefore susceptible to effective comparison. Thus, we can order the terms by magnitude. Then, we can determine the asymptotic sign of each coefficient $f_i(\log s)$ by looking at the leading term in f_i.

We can thus determine the asymptotic behaviour of each $R_l(\Lambda(s))$, to conclude whether $\bigwedge_{l=1}^m R_l(\Lambda(s)) \sim_l 0$ eventually holds. Moreover, for rational s, every quantity above can be computed to arbitrary precision, therefore it is possible to compute a threshold s_0', after which, for all $s \geq s_0'$, $\bigwedge_{l=1}^m R_l(\Lambda(s)) \sim_l 0$ holds. This completes the proof. ◀

▶ **Theorem 4.2.** *For a semi-algebraic set Y, it is decidable whether there exists a o-minimal invariant, disjoint from Y, that contains the orbit $\mathcal{O}(u)$ after some time $u \geq 0$. Moreover in the positive instances an invariant that is $\mathfrak{R}_{\exp}$-definable can be constructed.*

Proof. If there is an invariant $\mathcal{I}$ that contains $\mathcal{O}(u)$, for some $u \geq 0$, then Theorem 3.6 implies that there exists some $t_0 \geq u$ such that $\mathcal{C}_{t_0}$ is contained in $\mathcal{I}$. Consequently, the question that we want to decide is equivalent to the question of whether there exists a t_0, such that $\mathcal{C}_{t_0} \cap Y = \emptyset$. The latter is decidable thanks to Theorem 4.1. The effective construction follows from the fact that such a t_0 is computable and that the cone is $\mathfrak{R}_{\exp}$-definable. ◀

4.2 Effectively Constructing the Semi-algebraic Invariant

We now turn to show that in fact, for semi-algebraic error sets Y, we can approximate $\mathcal{C}_{t_0}$ with a semi-algebraic set such that if $\mathcal{C}_{t_0}$ avoids Y, so does the approximation. Intuitively, this is done by relaxing the "non semi-algebraic" parts of $\mathcal{C}_{t_0}$ in order to obtain a *fat cone.* This relaxation has two parts: one is to "rationalize" the (possibly irrational) exponents $\rho_1, \dots, \rho_k$, and the other is to approximate the polylogs in $Q(\log s)$ by polynomials.

Relaxing the exponents. We start by approximating the exponents $\rho_1, \dots, \rho_k$ with rational numbers. We remark that naively taking rational approximations is not sound, as the approximation must also adhere to the additive relationships of the exponents.

Let $\boldsymbol{\ell} = (\ell_1, \dots, \ell_k)$ and $\mathbf{u} = (u_1, \dots, u_k)$ be tuples of rational numbers such that $\ell_i \le \rho_i \le u_i$ for $i = 1, \dots, k$. Define $\mathbb{S} \subseteq \mathbb{R}^k$ as:

$$\mathbb{S} \overset{\text{def}}{=} \left\{ (q_1, \dots, q_k) \in \mathbb{R}^k \ : \ \forall n_1, \dots, n_k \in \mathbb{Z}, \quad \left(\sum_{i=1}^{k} n_i \rho_i = 0 \Rightarrow \sum_{i=1}^{k} n_i q_i = 0 \right) \right\}$$

Thus, $\mathbb{S}$ captures the integer additive relationships among the ρ_i. Define

$$\mathrm{Box}(\boldsymbol{\ell}, \mathbf{u}) \overset{\text{def}}{=} \{ \mathrm{diag}(\mathbf{q}) \ : \ \boldsymbol{\ell} \le \mathbf{q} \le \mathbf{u}, \mathbf{q} \in \mathbb{S} \}.$$

Approximating polylogs. Let $\epsilon, \delta > 0$. We simply replace $\log s$ by r such that $\delta \le r \le s^\epsilon$. Note that it is not necessarily the case that $\delta \le \log s \le s^\epsilon$, so this replacement is a-priori not sound. However, for large enough s the inequalities do hold, which will suffice for our purposes.

We can now define the fat cone. Let $\epsilon, \delta > 0$ and $\boldsymbol{\ell} = (\ell_1, \dots, \ell_k)$ and $\mathbf{u} = (u_1, \dots, u_k)$ as above, the fat orbit cone $\mathcal{F}_{s_0, \epsilon, \delta, \boldsymbol{\ell}, \mathbf{u}}$ is the set:

$$\left\{ P \ \mathrm{diag}(s^{q_1}, \dots, s^{q_k}) \mathrm{diag}(\boldsymbol{\tau}) \ Q(r) P^{-1} \mathbf{x}_0 \ : \ \boldsymbol{\tau} \in \mathbb{T}_\omega, \ s \ge s_0, \ \delta \le r \le s^\epsilon, \ \mathbf{q} \in \mathrm{Box}(\boldsymbol{\ell}, \mathbf{u}) \right\}.$$

That is, the fat cone is obtained from $\mathcal{C}_{t_0}$ with the following changes:

- $R(\log s) = \mathrm{diag}(s^{\rho_1}, \dots, s^{\rho_k})$ is replaced with $\mathrm{diag}(s^{q_1}, \dots, s^{q_k})$, where the q_i are rational approximations of the ρ_i, and maintain the additive relationships.
- $Q(\log s)$ is replaced with $Q(r)$ where $\delta \le r \le s^\epsilon$.
- The variable s starts from s_0 (as opposed to e^{t_0}).

We first show that the fat cone is semi-algebraic (the proof is in [3] Appendix C), then proceed to prove that if there is a cone that avoids the error set, then there is a fat one that avoids it as well.

▶ **Lemma 4.3.** *$\mathcal{F}_{s_0, \epsilon, \delta, \boldsymbol{\ell}, \mathbf{u}}$ is definable in $\mathfrak{R}_0$, and we can compute a representation of it.*

▶ **Lemma 4.4.** *Let $Y \subseteq \mathbb{R}^d$ be a a semi-algebraic error set such that $\mathcal{C}_{t_0} \cap Y = \emptyset$ for some $t_0 \in \mathbb{R}$, then there exists $\delta, \epsilon, s_0, \boldsymbol{\ell}, \boldsymbol{u}$ as above such that*

1. *$\mathcal{F}_{s_0, \epsilon, \delta, \boldsymbol{\ell}, \boldsymbol{u}} \cap Y = \emptyset$, and*
2. *for every $t \ge 0$ it holds that $e^{At} \cdot \mathcal{F}_{s_0, \epsilon, \delta, \boldsymbol{\ell}, \boldsymbol{u}} \subseteq \mathcal{F}_{s_0, \epsilon, \delta, \boldsymbol{\ell}, \boldsymbol{u}}$.*

The result is constructive, so when t_0 is given, the constants $s_0, \epsilon, \delta, \boldsymbol{\ell}, \mathbf{u}$ can be computed. It follows that a corollary of this lemma, and Lemma 4.3, is a stronger statement than that of Theorem 4.2, namely one where $\mathfrak{R}_{\exp}$ is replaced by $\mathfrak{R}_0$. We state it here before moving on with the proof of Lemma 4.4.

▶ **Theorem 4.5.** *For a semi-algebraic set Y, it is decidable whether there exists a o-minimal invariant, disjoint from Y, that contains the orbit $\mathcal{O}(u)$ after some time $u \geq 0$. Moreover in the positive instances an invariant that is $\mathfrak{R}_0$-definable can be constructed.*

The proof of Lemma 4.4 is given by the two corresponding steps. The second step, proving the invariance of the fat cone, can be found in [3]. We turn our attention to the first step.

▶ **Lemma 4.6.** *Let $Y \subseteq \mathbb{R}^d$ be a semi-algebraic error set, and let $t_0 \in \mathbb{R}$ be such that $\mathcal{C}_{t_0} \cap Y = \emptyset$, then there exists $\delta, \epsilon, s_0, \boldsymbol{\ell}, \mathbf{u}$ as above such that $\mathcal{F}_{s_0,\epsilon,\delta,\boldsymbol{\ell},\mathbf{u}} \cap Y = \emptyset$.*

Proof. We use the same analysis and definitions of U, R_l, $\sim_l$, $\Lambda(s)$ as in the proof of Theorem 4.1 and focus on a single polynomial R_l. Recall that we had

$$R_l(\Lambda(s)) = \sum_i s^{n_{i,1}\rho_1 + \dots n_{i,k}\rho_k} f_i(\log s) \tag{1}$$

where each f_i is a polynomial with rational coefficients.

Denote $\boldsymbol{\rho} = (\rho_1, \dots, \rho_k)$. We show, first, how to replace the exponents vector $\boldsymbol{\rho}$ by any exponents vector in $\mathrm{Box}(\boldsymbol{\ell}, \mathbf{u})$ for appropriate $\boldsymbol{\ell}, \mathbf{u}$, and second, how to replace $\log s$ by r where $\delta \leq r \leq s^\epsilon$ for some appropriate δ and ϵ, while maintaining the inequality or equality prescribed by $\sim_l$.

Denote by N the set of vectors $\mathbf{n_i} = (n_{i,1}, \dots, n_{i,k})$ of exponents in (1). Let $\mu > 0$, such that for every $\mathbf{n}, \mathbf{n'} \in N$, if $\boldsymbol{\rho} \cdot (\mathbf{n} - \mathbf{n'}) \neq 0$ then $|\boldsymbol{\rho} \cdot (\mathbf{n} - \mathbf{n'})| > \mu$. That is, μ is a lower bound on the minimal difference between distinct exponents in (1). Observe that we can compute a description of μ, as the exponents are algebraic numbers.

Let $M = \max_{\mathbf{n},\mathbf{n'} \in N} \|\mathbf{n} - \mathbf{n'}\|$ (where $\|\cdot\|$ is the Euclidean norm in $\mathbb{R}^k$).

▷ Claim 4.7. Let $\mathbf{c} \in \mathbb{R}^k$ be such that $\|\boldsymbol{\rho} - \mathbf{c}\| \leq \frac{\mu}{2M}$, then, for all $\mathbf{n}, \mathbf{n'} \in N$, if $\boldsymbol{\rho} \cdot (\mathbf{n} - \mathbf{n'}) > 0$ then $\mathbf{c} \cdot (\mathbf{n} - \mathbf{n'}) > \frac{\mu}{2}$.

Proof of Claim 4.7. Suppose that $\boldsymbol{\rho} \cdot (\mathbf{n} - \mathbf{n'}) > 0$, then by the above we have $\boldsymbol{\rho} \cdot (\mathbf{n} - \mathbf{n'}) > \mu$, and hence

$$\mathbf{c} \cdot (\mathbf{n} - \mathbf{n'}) = \boldsymbol{\rho} \cdot (\mathbf{n} - \mathbf{n'}) + (\mathbf{c} - \boldsymbol{\rho}) \cdot (\mathbf{n} - \mathbf{n'}) \geq \mu - \|\mathbf{c} - \boldsymbol{\rho}\| \cdot \|\mathbf{n} - \mathbf{n'}\| \geq \mu - \frac{\mu}{2M} M = \frac{\mu}{2}. \blacktriangleleft$$

We can now choose $\boldsymbol{\ell}$ and $\mathbf{u}$ such that $u_i - \ell_i \leq \frac{\mu}{2M\sqrt{k}}$ and for all $\mathbf{c} \in \mathrm{Box}(\boldsymbol{\ell}, \mathbf{u})$ we have

$$\|\boldsymbol{\rho} - \mathbf{c}\| \leq \sqrt{\sum_{i=1}^{k} (u_i - \ell_i)^2} \leq \sqrt{\frac{\mu^2}{(2M)^2}} = \frac{\mu}{2M}.$$

It follows from Claim 4.7 and from the definition of $\mathrm{Box}(\boldsymbol{\ell}, \mathbf{u})$ that, intuitively, every $\mathbf{c} \in \mathrm{Box}(\boldsymbol{\ell}, \mathbf{u})$ maintains the order of magnitude of the monomials $s^{n_{i,1}\cdot\rho_1 + \dots + n_{i,k}\cdot\rho_k}$ in $R_l(\Lambda(s))$.

More precisely, let $\Lambda'(s) = \mathrm{diag}(s^{c_1}, \dots, s^{c_k})Q(\log s)$ for some $\mathbf{c} \in \mathrm{Box}(\boldsymbol{\ell}, \mathbf{u})$, then the exponent of the ratio of every two monomials in $R_l(\Lambda'(s))$ has the same (constant) sign as the corresponding exponent in $R_l(\Lambda(s))$. Moreover, the exponents of distinct monomials in $R_l(\Lambda(s))$ differ by at least $\frac{\mu}{2}$ in $R_l(\Lambda'(s))$.

We now turn our attention to the $\log s$ factor. First, let s_0 be large enough that $f_i(\log s)$ has constant sign for every $s \geq s_0$. We can now let δ be large enough such that for every $r \geq \delta$, the sign of $f_i(\log s)$ coincides with the sign of $f_i(r)$ for every $s \geq s_0$. It remains to give an upper bound on r of the form s^ϵ such that plugging $f_i(r)$ instead of $f_i(\log s)$ does not change the ordering of the terms (by their magnitude) in $R_l(\Lambda'(s))$.

Let B be the maximum degree of all polynomials f_i in (1), and define $\epsilon = \frac{\mu}{3B}$ (in fact, any $\epsilon < \frac{\mu}{2B}$ would suffice), then we have that, for $s \geq s_0$, $f_i(r)$ has the same sign as $f_i(\log s)$ for every $\delta \leq r \leq s^\epsilon$ (by our choice of δ), and guarantees that plugging s^ϵ instead of s does not change the ordering of the terms (by their magnitude) in R_l. Since the exponents of the monomials in $R_l(\Lambda'(s))$ differ by at least $\frac{\mu}{2}$, it follows that their order is maintained when replacing $\log s$ by $\delta \leq r \leq s^\epsilon$.

Let $\Lambda''(s) = \mathrm{diag}(s^{c_1}, \dots, s^{c_k})Q(r)$ for some $\mathbf{c} \in \mathrm{Box}(\boldsymbol{\ell}, \mathbf{u})$ and $\delta \leq r \leq s^\epsilon$, then by our choice of ϵ, the dominant term in $R_l(\Lambda''(s))$ is the same as that in $R_l(\Lambda(s))$. Therefore, for large enough s, the signs of $R_l(\Lambda''(s))$ and $R_l(\Lambda(s))$ are the same.

Note that since $\mathcal{C}_{t_0} \cap Y = \emptyset$, then w.l.o.g. $R_l(\Lambda(s)) \sim_l 0$ for every l. Thus, by repeating the above argument for each R_l, we can compute $s_0 \in \mathbb{R}$, $\epsilon > 0$, $\delta \in \mathbb{R}$, and $\boldsymbol{\ell}, \mathbf{u} \in \mathbb{Q}^k$ such that $\mathcal{F}_{s_0,\epsilon,\delta,\boldsymbol{\ell},\mathbf{u}} \cap Y = \emptyset$, and we are done. ◀

5 A Reduction from Zeros of an Exponential Polynomial

In Theorem 4.5, we showed unconditional decidability for the question of whether there exists an invariant containing the orbit $\mathcal{O}(u)$, for some $u \geq 0$. Even though we construct such an invariant, it cannot be used as a certificate proving that the orbit never enters the error set; however it is a certificate that the orbit of the system does not enter Y *after* time u.

In this section we give indications that deciding whether there exists an invariant that takes into account the orbit $\leq u$ is difficult. More precisely, we will reduce a problem about zeros of a certain exponential polynomial to the question of whether there exists a semi-algebraic invariant disjoint from Y containing $\mathcal{O}(0)$.

▶ Remark 5.1. In the setting of discrete linear dynamical systems, the existence of a semi-algebraic invariant from time t_0 immediately implies the existence of one from time 0. This is because the system goes through finitely many points from 0 to t_0, which can be added one by one to the semi-algebraic set. In this respect CDSs are more complicated to analyse.

The problem that we reduce from, can be stated as follows. We are given as input real algebraic numbers $a_1, \dots, a_n, \rho_1, \dots, \rho_n$, and $t_0 \in \mathbb{Q}$, and asked to decide whether the exponential function:

$$f(t) \stackrel{\text{def}}{=} a_1 e^{\rho_1 t} + \cdots + a_n e^{\rho_n t},$$

has any zeros in the interval $[0, t_0]$. This is a special case of the so-called Continuous Skolem Problem [6, 10].

While there has been progress on characterising the asymptotic distribution of complex zeros of such functions, less is known about the real zeros, and we lack any effective characterisation, see [6, 10] and the references therein. The difficulty of knowing whether f has a zero in the specified region is because (a) all the zeros have to be transcendental (a consequence of Hermite-Lindemann Theorem) and (b) there can be tangential zeros, that is f has a zero but it never changes its sign. See the discussion in [6, Section 6]. Finding the zeros of such a polynomial is a special case of the *bounded* continuous Skolem problem. We note that when ρ_i are all rational the problem is equivalent to a sentence of $\mathfrak{R}_0$ (and hence decidable) by replacing $t = \log s$.

The rest of this section is devoted to the proof of the following theorem.

▶ **Theorem 5.2.** *For every exponential polynomial f we can construct a CDS $\langle A, \mathbf{x}_0 \rangle$ and semi-algebraic set Y such that the following two statements are equivalent:*

- *there exists a semi-algebraic invariant disjoint from Y that contains $\mathcal{O}(0)$,*
- *f does not have a zero in $[0, t_0]$.*

Fix the function f, *i.e.* real algebraic numbers $a_1, \ldots, a_n, \rho_1, \ldots, \rho_n$ and $t_0 \in \mathbb{Q}$. Without loss of generality we can assume that $\rho_1, \ldots, \rho_n$ are all nonnegative, since $e^{\rho t} f(t) = 0$ if and only if $f(t) = 0$ where ρ is larger than all $\rho_1, \ldots, \rho_n$.

Since every ρ_i is algebraic, there is a minimal polynomial p_i, that has ρ_i as a simple root. Let A be the $d \times d$ companion matrix of the polynomial $p_1(x) \cdots p_n(x) x^2$. The numbers ρ_i are eigenvalues A of multiplicity one, and the latter also has zero as an eigenvalue of multiplicity two. In addition to those, the matrix A generally has other (complex) eigenvalues as well. We put A in Jordan normal form, $P^{-1}AP = J$ where J is made of two block diagonals: $\tilde{A}$ and B, where

$$\tilde{A} \stackrel{\text{def}}{=} \begin{pmatrix} \operatorname{diag}(\rho_1, \ldots, \rho_n) & & \\ & 0 & 1 \\ & 0 & 0 \end{pmatrix},$$

and B is some $(d-n-2) \times (d-n-2)$ matrix. Define:

$$\tilde{\mathbf{x}}_0 \stackrel{\text{def}}{=} (\underbrace{1, \ldots, 1}_{n+2}, 0, \ldots, 0),$$

the vector that has $n+2$ ones and the rest, $d-(n+2)$ zeros, whose purpose is to ignore the contribution of the eigenvalues in matrix B in the system. To simplify notation, since $\tilde{\mathbf{x}}_0$ is ignoring the contribution of the matrix B, the dynamics of the system $\langle J, \tilde{\mathbf{x}}_0 \rangle$ can be assume to be the same as:

$$e^{\tilde{A}t}(1, \ldots, 1) = (e^{\rho_1 t}, \ldots, e^{\rho_n t}, t).$$

Focus on a single eigenvalue, *i.e.* on the graph $\{(e^{\rho t}, t) \ : \ t \geq 0\}$, as the analysis will easily generalise to the CDS in question. This is itself a CDS, so terminology such as orbits *etc.* make sense. The challenge is to find a family of *tubes* around this exponential curve such that (a) all the tubes together with $\{(y, t) \ : \ t \geq t_0\}$ are invariants and (b) the tubes are arbitrarily close approximations of the curve.

We achieve this by the following families of polynomials:

- under-approximations are given by the family indexed by $n \in \mathbb{N}$:

$$P_n(t) \stackrel{\text{def}}{=} \sum_{k=0}^{n} \frac{(\rho t)^k}{k!}.$$

- over-approximations are given by a family indexed by $n \in \mathbb{N}$ and $\mu > 1$:

$$Q_{n,\mu}(t) \stackrel{\text{def}}{=} P_n(\mu t).$$

Define:

$$\mathcal{I}_{n,\mu} \stackrel{\text{def}}{=} \{(y, t) \ : \ P_n(t) \leq y \leq Q_{n,\mu}(t) \text{ and } 0 \leq t \leq t_0\}.$$

It is clear from Taylor's theorem and the assumption that $\rho > 0$, that by taking $n \to \infty$, and $\mu \to 1^+$ the sets $\mathcal{I}_{n,\mu}$ are arbitrary precise approximations of the graph $\{(e^{\rho t}, t) \ : \ t \geq 0\}$, what remains to show is that they are invariant.

▶ **Lemma 5.3.** *For every $\mu > 1$ there exists $n_0 \in \mathbb{N}$ such that for all $n \geq n_0$ the set*

$$\mathcal{I}_{n,\mu} \cup \{(y, t) \ : \ t > t_0\}$$

is an invariant containing the whole orbit, i.e. $\{(e^{\rho t}, t) \ : \ t \geq 0\}$.

The proof is in Appendix D of [3].

We can construct such invariants for every curve $e^{\rho_i t}$, and thus build $\tilde{\mathcal{I}}_{n,\mu}$ for

$$\left\{(e^{\rho_1 t}, \dots, e^{\rho_n t}, t) \ : \ t \geq 0\right\}.$$

To prove Theorem 5.2 we define $\tilde{Y}$ by the formula

$$\Phi(x_1, \dots, x_n, x_{n+1}) \overset{\text{def}}{=} a_1 x_1 + \cdots + a_n x_n = 0 \text{ and } 0 \leq x_{n+1} \leq t_0.$$

Since the analysis was done on the CDS $\langle J, \tilde{\mathbf{x}}_0 \rangle$, whose entries are not rational in general, before proceeding with the proof of Theorem 5.2, we need the following lemma to say that changing basis does not have an effect in the decision problem at hand:

▶ **Lemma 5.4.** *For every $\tilde{Y}$ semi-algebraic, there exists another semi-algebraic set Y and $\mathbf{x}_0$ with rational entries such that the following two statements are equivalent:*

- *$\langle J, \tilde{\mathbf{x}}_0 \rangle$ has a semi-algebraic invariant disjoint from $\tilde{Y}$, containing the whole orbit,*
- *$\langle PJP^{-1}, \mathbf{x}_0 \rangle$ has a semi-algebraic invariant disjoint from Y, containing the whole orbit.*

The proof can be found in [3]. Thanks to this lemma, we can prove Theorem 5.2 for the CDS $\langle J, \tilde{\mathbf{x}}_0 \rangle$ and the set $\tilde{Y}$ instead. This is done as follows. The direct implication is trivial. For the converse, observe that $f(t)$ does not have a zero in $[0, t_0]$ if and only if the $\mathcal{O}(0)$ and $\tilde{Y}$ are disjoint. Since both $\mathcal{O}(0)$ and $\tilde{Y}$ are closed sets, we can find a tube that contains $\mathcal{O}(0)$ and is disjoint from $\tilde{Y}$, *i.e.* there exists some $\mu > 1$ and $n \in \mathbb{N}$ such that

$$\tilde{\mathcal{I}}_{n,\mu} \cup \{(y, t) \ : \ t > t_0\},$$

is an invariant that is disjoint from $\tilde{Y}$ but contains $\mathcal{O}(0)$.

Abstract

Type-two constructions abound in cryptography: adversaries for encryption and authentication schemes, if active, are modeled as algorithms having access to oracles, i.e. as second-order algorithms. But how about making cryptographic schemes *themselves* higher-order? This paper gives an answer to this question, by first describing why higher-order cryptography is interesting as an object of study, then showing how the concept of probabilistic polynomial time algorithm can be generalized so as to encompass algorithms of order strictly higher than two, and finally proving some positive and negative results about the existence of higher-order cryptographic primitives, namely authentication schemes and pseudorandom functions.

1 Introduction

Higher-order computation generalizes classic first-order one by allowing algorithms and functions to not only take *strings* but also *functions* in input. It is well-known that this way of computing gives rise to an interesting computability and complexity theory [26, 25, 31], and that it also constitutes a conceptual basis for the functional programming paradigm, in which higher-order subroutines allow for a greater degree of modularity and conciseness in programs.

In cryptography [19, 20, 24], computation is necessarily randomized, and being able to restrict the time complexity of adversaries is itself crucial: most modern cryptographic schemes are insecure against computationally *unbounded* adversaries. Noticeably, higher-order constructions are often considered in cryptography, in particular when modeling active adversaries, which have access to oracles for the underlying encryption, decryption, or authentication functions, and can thus naturally be seen as second-order algorithms. Another example of useful cryptographic constructions which can be spelled out at different type orders, are *pseudorandom* primitives. Indeed, pseudorandomness can be formulated on (families of) strings, giving rise to so-called pseudorandom *generators* [5], but also on (families of) first-order functions on strings, giving rise to the so-called pseudorandom *functions* [21]. In the former case, again, adversaries (i.e., distinguishers) are ordinary polynomial time algorithms, while in the latter case, they are polytime oracle machines.

Given the above, it is natural to wonder whether standard primitives like encryption, authentication, hash functions, or pseudorandom functions, could be made higher-order. As discussed in Section 2 below, that would represent a way of dealing with code-manipulating programs and their security in a novel, fundamentally interactive, way. Before even looking at the feasibility of this goal, there is one challenge we are bound to face, which is genuinely definitional: how could we even *give* notions of security (e.g. pseudorandomness, unforgeability, and the like) for *second-order* functions, given that those definitions would rely on a notion of *third-order* probabilistic polynomial time adversary, itself absent from the literature? Indeed, although different proposals exist for classes of feasible *deterministic* functionals [9, 25], not much is known if the underlying algorithm has access to a source of randomness. Moreover, the notion of feasibility cryptography relies on is based on the so-called *security parameter*, a global numerical value which controls the complexity of all the involved parties. In Section 3, we give a definition of higher-order probabilistic polynomial time by way of concepts borrowed from game semantics [22, 23, 2], and being inspired by recent work by Ferée [13]. We give evidence to the fact that the provided definition is general enough to capture a broad class of adversaries of order strictly higher than two.

After having introduced the model, we take a look at whether any concrete instance of a secure higher-order cryptographic primitive can be given. The results we provide are about pseudorandom functions and (deterministic) authentication. We prove on the one hand that those constructions are *not* possible if one insists on them having the expected type (see Section 4.2). On the other hand, we prove (in Section 4.3 below) that second-order pseudorandomness *is* possible if the argument function takes as input a string of *logarithmic* length.

2 The Why and How of Authenticating Functions

Encryption and authentication, arguably the two simplest cryptographic primitives, are often applied to *programs* rather than mere data. But when this is done, programs are treated as ordinary data, i.e., as *strings of symbols*. In particular, two different but equivalent programs are seen as different strings, and their encryptions or authentication tags can be completely different objects. It is natural to ask the following: would it be possible to deal with programs as *functions* and not as *strings*, in a cryptographic scenario? Could we, e.g., encrypt or authenticate programs seeing them as *black boxes*, thus without any access to their code?

For the sake of simplicity, suppose that the program `P` we deal with has a very simple IO behaviour, i.e. it takes as input a binary string of length n and returns a boolean. Authenticating `P` could in principle be done by querying `P` on some of its inputs and, based on the outputs to the queries, compute a tag for $\mathtt{P}$. As usual, such an authenticating scheme would be secure if no efficient adversary $\mathcal{A}$ could produce a tag for $\mathtt{P}$ without knowing the underlying secret key k (such that $|k| = n$), unless with negligible probability. Please notice that the adversary, contrarily to the scheme itself, could have access to the code of $\mathtt{P}$, even if that code has not been used during the authenticating process.

But how could security be *defined* in a setting like the above? The three entities at hand have the following types, where $\mathtt{MAC}$ is the authentication algorithm, $\mathbb{S} = \{0,1\}^*$ is the set of binary strings, and $\mathbb{B} = \{0,1\}$ is the set of boolean values:

$$\begin{aligned}\mathtt{P} &: \mathbb{S} \to \mathbb{B}\\ \mathtt{MAC} &: \mathbb{S} \to (\mathbb{S} \to \mathbb{B}) \to \mathbb{S}\\ \mathcal{A} &: ((\mathbb{S} \to \mathbb{B}) \to \mathbb{S}) \to (\mathbb{S} \to \mathbb{B}) \times \mathbb{S}\end{aligned}$$

The first argument of $\mathtt{MAC}$ is the key k, which is of course not passed to the adversary $\mathcal{A}$. The latter can query $\mathtt{MAC}_k$ and produce a function and its tag. Its type, as expected, has order three. The above is not an accurate description of the input-output behaviour of the involved algorithms, and in particular of the fact that the length of the input string to $\mathtt{P}$ might be in a certain relation to the length of k, i.e., the underlying security parameter. Reflecting all this in the types above is however possible by replacing occurrences of the type $\mathbb{S}$ with *refinements* of $\mathbb{S}$, as follows:

$$\begin{aligned}\mathtt{P} &: \mathbb{S}[n] \to \mathbb{B}\\ \mathtt{MAC} &: \mathbb{S}[n] \to (\mathbb{S}[r(n)] \to \mathbb{B}) \to \mathbb{S}[p(n)]\\ \mathcal{A} &: ((\mathbb{S}[r(n)] \to \mathbb{B}) \to \mathbb{S}[p(n)]) \to (\mathbb{S}[r(n)] \to \mathbb{B}) \times \mathbb{S}[p(n)]\end{aligned}$$

But how could the time complexity of the three algorithms above be defined? While polynomial time computability of the function $\mathtt{P}$ and the authenticating algorithm $\mathtt{MAC}$ can be captured in a standard way using, e.g., oracle Turing machines, the same cannot be said about $\mathcal{A}$. How to, e.g., appropriately account for the time $\mathcal{A}$ needs to "cook" a function f in $\mathbb{S}[n] \to \mathbb{B}$ to be passed to its argument functional? Appealing as it is, our objective of studying higher-order forms of cryptography is actually bound to be nontrivial, even from a purely *definitional* perspective.

Given the above discussion, the contributions of this paper can be described in greater detail, as follows:

- On the one hand, we give a *definition* of a polynomial-time higher-order probabilistic algorithm whose time complexity depends on a global security parameter and which is based on games and strategies, in line with game semantics [22, 23, 2]. This allows to discriminate satisfactorily between efficient and non-efficient adversaries, and accounts for the complexity of first-and-second-order algorithms consistently with standard complexity theory.
- On the other hand, we give some *positive* and *negative* results about the possibility of designing second-order cryptographic primitives, and in particular pseudorandom functions and authentication schemes. In particular we prove, by an essentially information-theoretic argument, that secure deterministic second-order authentication schemes of the kind sketched above *cannot* exist. A simple and direct reduction argument shows that a more restricted form of pseudorandom function exists under standard cryptographic assumptions. Noticeably, the adversaries we prove the existence of are of a very peculiar form, while the ones which we prove impossible to build are quite general.

3 Higher-Order Probabilistic Polynomial Time Through Parametrized Games

In this section, we introduce a framework inspired by game semantics, in which one can talk about the efficiency of probabilistic higher-order programs in presence of a global security parameter. While the capability of interpreting higher-order programs is a well-established feature of game semantics, dealing *at the same time* with probabilistic behaviors *and* efficiency constraints has – to the best of the authors' knowledge – not been considered so far. The two aspects have however been tackled *independently.* Several game models of probabilistic languages have been introduced: we can cite here, for instance, the fully abstract model of probabilistic Idealized Algol by Danos and Harmer [11], or the model of probabilistic PCF by Clairambault at al. [8]. About efficiency, we can cite the work by Férée [13] on higher-order complexity and game semantics, in which the cost of evaluating higher-order programs is measured parametrically on the size of *all* their inputs, including functions, thus in line with type-two complexity [9]. We are instead interested in the efficiency of higher-order definitions with respect to the *security parameter.* Unfortunately, existing probabilistic game models do not behave well when restricted to capture feasibility: *polytime computable* probabilistic strategies in the spirit of Danos and Harmer do not *compose* (see the Extended Version of this paper [3] for more details).

Contrary to most works in game semantics, we do not aim at building a model of a *particular* programming language, but we take game semantics as our model of computation. As a consequence, we are not bound by requirements to interpret particular programming features or to reflect their discriminating power, and the resulting notions of games and strategies will be very simple.

We present our game-based model of computation in three steps: first, we define a category of deterministic games and strategies called $\mathcal{PG}$ – for *parametrized games* – which capture computational agents whose behavior is parametrized by the security parameter. This model ensures that computational agents are *total*: they *always* answer any request by the opponent. In a second step, we introduce $\mathcal{PPG}$, as a sub-category of $\mathcal{PG}$ designed to model those agents whose time complexity is *polynomially bounded* with respect to the security parameter. Finally, we deal with *randomized agents* by allowing them to interact with a *probabilistic oracle*, that outputs (a bounded amount of) random bits.

3.1 Parametrized Deterministic Games

Our game model has been designed so as to be able to deal with security properties that – as exemplified by *computational indistinguishability* – are expressed by looking at the behavior of adversaries *at the limit*, i.e., when the security parameter tends towards infinity. The *agents* we consider are actually *families* of functions, indexed by the security parameter. As such, our game model can be seen as a parametrized version of Hyland's simple games [22], where the set of plays is replaced by a *family* of sets of plays, indexed by the natural numbers. Moreover, we require the total length of any interaction between the involved parties to be polynomially bounded in the security parameter.

We need a few preliminary definitions before delving into the definition of a game. Given two sets X and Y, we define $\mathrm{Alt}(X,Y)$ as $\{(a_1,\ldots,a_n) \mid a_i \in X \text{ if } i \text{ is odd}, a_i \in Y \text{ if } i \text{ is even}\}$, i.e., as the set of finite alternating sequences whose first element is in X. Given any set of sequences X, $\mathsf{Odd}(X)$ (respectively, $\mathsf{Even}(X)$) stands for the subset of X containing the sequences of odd (respectively, even) length. From now on, we implicitly assume that any (opponent or player) move m can be faithfully encoded as a string in an appropriate, fixed alphabet. This way, moves and plays implicitly have a length, that we will indicate through the unary operator $|\cdot|$. We fix a set **Pol** of unary polynomially-bounded total functions on the natural numbers, which includes the identity ι, base-2 logarithm $\lfloor \lg \rfloor$, addition, multiplication, and closed under composition. **Pol** can be equipped with the pointwise partial order: $p \leq q$ when $\forall n \in \mathbb{N}, p(n) \leq q(n)$.

▶ **Definition 1** (Parametrized Games). *A* parametrized game $G = (O_G, P_G, L_G)$ *consists of sets* O_G, P_G *of opponent and player moves, respectively, together with a family of non-empty prefix-closed sets* $L_G = \{L^n_G\}_{n\in\mathbb{N}}$, *where* $L^n_G \subseteq \mathit{Alt}(O_G, P_G)$, *such that there is* $p \in \mathbf{Pol}$ *with* $\forall n \in \mathbb{N}.\forall s \in L^n_G.|s| \leq p(n)$. *The union of* O_G *and* P_G *is indicated as* M_G, *and is said to be set of* moves *of* G.

For every $n \in \mathbb{N}$, L^n_G represents the set of legal plays, when n is the current value of the security parameter. Observe that the first move is always played by *the opponent*, and that for any fixed value of the security parameter n, the length of legal plays is bounded by $p(n)$, where $p \in \mathbf{Pol}$. In the following, we often form plays from moves coming from different games or from different copies of the same game. If s is such a play, we indicate, e.g., the sub-play of s consisting of the moves from G as s_G.

▶ **Example 2** (Ground Games). We present here some games designed to model *data-types*. The simplest game is probably the *unit game* $\mathbf{1} = (\{?\}, \{*\}, \{L^n_{\mathbf{1}}\}_{n\in\mathbb{N}})$ with just one opponent move and one player move, where $L^n_{\mathbf{1}} = \{\varepsilon, ?, ?*\}$ for every n. Just slightly more complicated than the unit game is the *boolean game* $\mathbf{B}$ in which the two moves 0 and 1 take the place of $*$. In the two games introduced so far, parametrization is not really relevant, since $L^n_G = L^m_G$ for every $n, m \in \mathbb{N}$. The latter is not true in $\mathbf{S}[p] = (\{?\}, \{0,1\}^*, \{L^n_{\mathbf{S}[p]}\}_{n\in\mathbb{N}})$ with $L^n_{\mathbf{S}[p]} = \{\varepsilon, ?\} \cup \{?s \mid |s| = p(n)\}$, which will be our way of capturing strings. A slight variation of $\mathbf{S}[p]$ is $\mathbf{L}[p]$, in which the returned string can have length *smaller or* equal to $p(n)$.

▶ **Example 3** (Oracle Games). As another example, we describe how to construct *polynomial boolean oracles* as games. For every polynomial $p \in \mathbf{Pol}$ we define a game $\mathbf{O}^p$ as $(\{?\}, \{0,1\}, \{L^n_{\mathbf{O}^p}\}_{n\in\mathbb{N}})$ with

$$\begin{aligned} L^n_{\mathbf{O}^p} = \{?\} &\cup \{?b_1?b_2\ldots?b_m \mid b_i \in \{0,1\} \wedge m \leq p(n)\} \\ &\cup \{?b_1?b_2\ldots?b_m? \mid b_i \in \{0,1\} \wedge m < p(n)\}. \end{aligned}$$

Our oracle games are actually a special case of a more general construction, that amounts to building, from any game G, and any polynomial p, a game which consists in playing G at most $p(n)$ times. That is itself nothing more than a bounded version [18] of the exponential construction from models of linear logic [16].

▶ **Definition 4** (Bounded Exponentials). *Let* $G = (O_G, P_G, L_G)$ *be a parametrized game. For every* $p \in \mathbf{Pol}$, *we define a new parametrized game* $!_pG := (O_{!_pG}, P_{!_pG}, L_{!_pG})$ *as follows:*

- $O_{!_pG} = \mathbb{N}_{>0} \times O_G$, *and* $P_{!_pG} = \mathbb{N}_{>0} \times P_G$;
- *For* $n \in \mathbb{N}$, $L^n_{!_pG}$ *is the set of those plays* $s \in \mathit{Alt}(O_{!_pG}, P_{!_pG})$ *such that:*
  - *for every* i, *the* i*-th projection* s_i *of* s *is in* L^n_G;
  - *if a move* $(i+1, z)$ *appears in* s *for* $i \in \mathbb{N}_{>0}$, *then a move* (i, x) *appears at some earlier point of* s, *and* $i + 1 \leq p(n)$.

We do not need any switching condition as in so-called AJM games [1]: the impossibility for the observer to switch between the various copies of G when playing in $!_pG$ is a byproduct of our very definition of a game. Observe that the game $\mathbf{O}^p$ is isomorphic to the game $!_p\mathbf{B}$ – we can build a bijection between legal plays having the same length.

Games specify *how* agents could play in a certain interactive scenario. As such, they do not represent *one* such agent, this role being the one of *strategies*. Indeed, a strategy on a game is precisely a way of specifying the *deterministic* behavior of an agent, i.e. how the agent plans to react to any possible move by the opponent. We moreover ask our strategies to be total, i.e., that the player cannot refuse to play when it is her turn.

▶ **Definition 5** (Strategies). *A* strategy *on a parametrized game $G = (O_G, P_G, L_G)$ consists of a family $\mathsf{f} = \{\mathsf{f}_n\}_{n\in\mathbb{N}}$, where f_n is a partial function from $\mathsf{Odd}(L_G^n)$ to P_G such that:*

- *for every $s \in \mathsf{Odd}(L_G^n)$, if $\mathsf{f}_n(s) = x$ is defined, then $sx \in L_G^n$;*
- *$sxy \in Dom(\mathsf{f}_n)$ implies that $x = \mathsf{f}_n(s)$;*
- *for every $s \in \overline{\mathsf{f}}_n$, if $sx \in L_G^n$ then $sx \in Dom(\mathsf{f}_n)$;*

where $\overline{\mathsf{f}}$ represents the set of plays characterising f, *defined as the family $\{\overline{\mathsf{f}}_n\}$ where $\overline{\mathsf{f}}_n = \{\varepsilon\} \cup \{s\mathsf{f}_n(s) \mid s \in Dom(\mathsf{f}_n)\} \subseteq L_G^n$.*

Any strategy f is entirely characterized by its set of plays $\overline{\mathsf{f}}$. As such, it does not need to be effective, i.e., it is entirely possible that f, seen as a function of the history and the security parameter, is an uncomputable function.

Up to now, the games we have described are such that their strategies are meant to represent concrete data: think about how a strategy for, e.g., $\mathbf{B}$ or $\mathbf{O}^p$ could look like. It is now time to build games modeling *functions*, this being embodied by the following construction on games:

▶ **Definition 6** (Constructing Functional Games). *The game $G \multimap H$ is given as $O_{G\multimap H} = P_G + O_H$, $P_{G\multimap H} = O_G + P_H$, and $L_{G\multimap H} = \{s \in Alt(O_{G\multimap H}, P_{G\multimap H}) \mid s_G \in L_G, s_H \in L_H\}$.*

Strategies for the game $G \multimap H$ are meant to model any agent that, when interacting with a strategy in G, behaves like a strategy for H. When G and H are ground games, this can indeed be seen as a function between the corresponding sets.

▶ **Example 7.** As an example, we look at the game $\mathbf{O}^p \multimap \mathbf{S}[p]$, which captures functions returning a string of size $p(n)$ after having queried a binary oracle at most $p(n)$ times. First, observe that:

$$\mathbf{O}^p \multimap \mathbf{S}[p] = (\{?_{\mathbf{S}[p]}, 0, 1\}, \{?_{\mathbf{O}^p}\} \cup \{0,1\}^\star, \{L^n_{\mathbf{O}^p\multimap\mathbf{S}[p]}\}_{n\in\mathbb{N}}),$$

where $L_n^{\mathbf{O}^p\multimap\mathbf{S}[p]}$ is generated by the following grammar:

$$\begin{aligned} q \in L_n^{\mathbf{O}^p\multimap\mathbf{S}[p]} &::= ?_{\mathbf{S}[p]}o \;\big|\; ?_{\mathbf{S}[p]}e \;\big|\; ?_{\mathbf{S}[p]}es && s \in \{0,1\}^* \text{ with } |s| \leq p(n) \\ e &::= \epsilon \;\big|\; ?_{\mathbf{O}^p}b_1 \ldots ?_{\mathbf{O}^p}b_m && b_i \in \{0,1\}, m \leq p(n) \\ o &::= ?_{\mathbf{O}^p} \;\big|\; ?_{\mathbf{O}^p}b_1 \ldots ?_{\mathbf{O}^p}b_{m-1}?_{\mathbf{O}^p} && b_i \in \{0,1\}, m \leq p(n) \end{aligned}$$

Of course there are *many* strategies for this game, and we just describe two of them here, both making use of the oracle: the first one – that we will call once_p – queries the oracle for a random boolean, and returns the string $0^{p(n)}$ or the string $1^{p(n)}$ depending on the obtained value. It is represented in Figure 1a. The second strategy – denoted mult_p and represented in Figure 1b – generates a random key of length $p(n)$ by making $p(n)$ calls to the probabilistic oracle.

We now look at how to *compose* strategies: given a strategy on $G \multimap H$, and $H \multimap K$, we want to build a strategy on $G \multimap K$ that combines them. We define composition as in [22, 32], except that we need to take into account the security parameter n.

	$\mathbf{O}^p$	$\multimap$	$\mathbf{S}[p]$
O			$?_{\mathbf{S}[p]}$
P	$?_{\mathbf{O}^p}$		
O	b		
P			$b^{p(n)}$

(a) The strategy once_p.

	$\mathbf{O}^p$	$\multimap$	$\mathbf{S}[p]$
O			$?_{\mathbf{S}[p]}$
P	$?_{\mathbf{O}^p}$		
O	b_1		
$\vdots$			
P	$?_{\mathbf{O}^p}$		
O	$b_{p(n)}$		
P			$b_1 \dots b_{p(n)}$

(b) The strategy mult_p.

Figure 1 Two Distinct Strategies on the Game $\mathbf{O}^p \multimap \mathbf{S}[p]$.

▶ **Definition 8** (Composition of Strategies). *Let G, H, K be parametrized games, and let f, g be two strategies on $G \multimap H$ and $H \multimap K$ respectively. We first define the set of* interaction sequences of f and g *as:*

$$(\mathsf{f} \parallel\!\mid \mathsf{g})_n = \{s \in (M_G + M_H + M_K)^\star \mid s_{G,H} \in \bar{\mathsf{f}}_n \wedge s_{H,K} \in \bar{\mathsf{g}}_n\}.$$

From there, we define the composition of f *and* g *as the unique strategy* $\mathsf{f};\mathsf{g}$ *such that:*

$$\overline{\mathsf{f};\mathsf{g}}_n = \{s_{G,K} \mid s \in (\mathsf{f} \parallel\!\mid \mathsf{g})_n\}.$$

We can check that $\mathsf{f};\mathsf{g}$ is indeed a strategy on $G \multimap K$, and that moreover composition, seen as an operation on strategies, is associative and admits an identity. We can thus define $\mathcal{PG}$ as the category whose objects are parametrized games, and whose set of morphisms $\mathcal{PG}(G, H)$ consists of the parametrized strategies on the game $G \multimap H$.

3.2 Polytime Computable Strategies

Parametrized games have been defined so as to have polynomially bounded *length*. However, there is no guarantee on the effectiveness of its strategies, i.e., that the next player move, can be computed algorithmically from the history, uniformly in the security parameter. This can be however tackled by considering a subcategory of $\mathcal{PG}$ in which strategies are not merely functions, but can be (efficiently) computed:

▶ **Definition 9** (Polytime Computable Strategies). *Let G be a parametrized game, and* f *be a strategy on G. We say that* f *is* polytime computable *when there exists a polynomial time Turing machine which on input $(1^n, s)$ returns* $\mathsf{f}(n)(s)$.

All strategies we have given as examples in the previous section are polytime computable. For example, the two strategies from Example 7 are both computable in linear time.

▶ **Proposition 10** (Stability of Polytime Computable Strategies). *Let G, H, K be polynomially bounded games. If f, g are polytime computable strategies, respectively on $G \multimap H$, and $H \multimap K$, then $\mathsf{f};\mathsf{g}$ is itself a polytime computable strategy.*

For elementary reasons, the identity strategy on any game G is polytime computable. We can thus write $\mathcal{PPG}$ for the the sub-category of $\mathcal{PG}$ whose objects are paramterized games, and whose morphisms are polytime computable strategies.

Let us now consider the algorithm `MAC` from Section 2. Its type can be turned into the parametrized game $\mathbf{S}[\iota] \multimap !_q(\mathbf{S}[r] \multimap \mathbf{B}) \multimap \mathbf{S}[p]$. The bounded exponential $!_q$ serves to model the fact that the argument function can be accessed a number of times which is *polynomially bounded* on n. As a consequence, `MAC` can only query the argument function a number of times which is negligibly smaller than the number of possible queries, itself exponential in n (if $r(n) \geq n$). As we will see in Section 4, this is the key ingredient towards proving security of such a message authentication code to be unattainable.

3.3 Probabilistic Strategies

Both in $\mathcal{PG}$ and in $\mathcal{PPG}$, strategies on any game G are ultimately *functions*, and the way they react to stimuli from the environment is completely deterministic. How could we reconcile all this with our claim that the framework we are introducing adequately models *randomized* higher-order computation? Actually, one could be tempted to define a notion of *probabilistic strategy* in which the underlying function family $\{f_n\}_{n\in\mathbb{N}}$ is such that f_n returns *a probability distribution* $f_n(s)$ of player moves when fed with the history s. This, however, would lead to some technical problems when *composing strategies*: it would be hard to keep the composition of two efficient strategies itself efficient (see [3]).

It turns out that a much more convenient route consists, instead, in defining a *probabilistic* strategy on G simply as a *deterministic* polytime strategy on $\mathbf{O}^p \multimap G$, namely as an ordinary strategy having access to polynomially many random bits. Actually, we have already encountered strategies of this kind, namely once_p and mult_p from Example 7. This will be our way of modeling higher-order probabilistic computations.

But in which sense does any probabilistic strategy behave *probabilistically*, given that, after all, behind it there is a *deterministic* (polytime) Turing machine? The following definition gives an answer to this question, in the particular case of probabilistic strategies on the game $\mathbf{B}$.

▶ **Definition 11.** *Let* f *be a strategy on the game* $\mathbf{O}^p \multimap \mathbf{B}$*. For every* $b \in \mathbb{B}$*, we define the* probability of observing b when executing f *as follows:*

$$\Pr(\mathsf{f} \Downarrow^n b) = \sum_{\substack{(b_1,\ldots,b_k)\in\mathbb{B}^k \\ \textit{with } (?_{\mathbf{B}}\cdot ?_{\mathbf{O}^p}\cdot b_1 \ldots ?_{\mathbf{O}^p}\cdot b_k\cdot b)\in\bar{\mathsf{f}}_n}} \frac{1}{2^k}.$$

Parametrized games and probabilistic strategies can be themselves seen as a category whose morphisms (from the game G to the game H) are pairs in the form (q, f), where f is a strategy in $\mathbf{O}^q \multimap (G \multimap H)$. This category can be proved to be symmetric monoidal closed, although cartesian closure fails: duplication is not available in its full generality, but only in bounded form, which, we conjecture, is enough to get the structure of a bounded exponential situation [6].

Given a probabilistic strategy f on G (i.e. a strategy on $\mathbf{O}^q \multimap G$) and $p \in \mathbf{Pol}$, we indicate as $!_p\mathsf{f}$ the strategy in which $p(n)$ copies of f are played, *but in which* randomness is resolved just once and for all, i.e. $!_p\mathsf{f}$ is the naturally defined strategy on $\mathbf{O}^q \multimap !_pG$ in which the $q(n)$ random bits are all queried for at the beginning of the play, after the first opponent move.

3.4 On the Expressive Power of Probabilistic Strategies

A few words about the expressive power of probabilistic strategies – seen as a model of higher-order randomized computation – are now in order. For trivial reasons, every probabilistic strategy for the game $\mathbf{S}[\iota] \multimap \mathbf{L}[p]$ can be precisely simulated by a probabilistic Turing machine

	$!_q(\mathbf{S}[r]$	$\multimap$	$\mathbf{B})$	$\multimap$	$\mathbf{S}[p]$
O					$?_{\mathbf{S}[p]}$
P			$(1, ?_{\mathbf{B}})$		
O	$(1, ?_{\mathbf{S}[r]})$				
P	$(1, s_1)$				
O			$(1, t_1)$		
		$\vdots$			
P			$(m, ?_{\mathbf{B}})$		
O	$(m, ?_{\mathbf{S}[r]})$				
P	(m, s_m)				
O			(m, t_m)		
P					v

Figure 2 Plays (of Maximal Length) for the game $!_q(\mathbf{S}[r] \multimap \mathbf{B}) \multimap \mathbf{S}[p]$.

working in polynomial time. Conversely, every such machine can be turned into a probabilistic strategy for the aforementioned game, once p is chosen as a sufficiently large polynomial. Similarly, behind any probabilistic strategy for the game $\mathbf{S}[\iota] \multimap !_q(\mathbf{L}[p] \multimap \mathbf{L}[r]) \multimap \mathbf{L}[s]$ there is an probabilistic *oracle* Turing machine working in polynomial time. The converse statement, however, can be proved *only assuming* the oracle with which the machine interacts to produce outputs polynomially related (in size) to the inputs.

More generally, the intrinsic restriction parametrized games impose on the *length* of any interaction indeed poses some limitations as to what strategies can do, and in particular to how they can interact with the environment. This implies that our framework is fundamentally inadequate as a characterization of, say, the basic feasible functionals [9]. We claim, however, that cryptography most often deals with situations in which, even if some of the parties can be computationally *unbounded*, the length of the interaction between them, but also the size of the exchanged messages, are *polynomially* bounded. The interested reader is invited to take a look at, e.g., the cryptographic experiments in [24]. Even in interactive proofs, in which no restrictions is put on complexity of the prover, the amount and size of the exchanged messages is by definition polynomially bounded.

4 The (In)feasibility of Higher-Order Cryptography

In this section, we give both negative and positive results about the possibility of defining a deterministic polytime strategy for the game $\mathbf{S}[\iota] \multimap !_q(\mathbf{S}[r] \multimap \mathbf{B}) \multimap \mathbf{S}[p]$ which could serve to authenticate functions. When r is linear, this is impossible, as proved in Section 4.2 below. When, instead, r is logarithmic (and q is at least linear), a positive result can be given, see Section 4.3.

But how would a strategy for the game $!_q(\mathbf{S}[r] \multimap \mathbf{B}) \multimap \mathbf{S}[p]$ look like? Plays for this game are in Figure 2. A strategy for such a game is required to determine the value of the query $s_{i+1} \in \mathbb{S}[r(n)]$ based on $t_1, \ldots, t_i \in \mathbb{B}$. Moreover, based on $t_1, \ldots, t_m$ (where $m \leq q(n)$), the strategy should be able to produce the value $v \in \mathbb{S}[p(n)]$. Strictly speaking, the strategy should also be able to respond to a situation in which the opponent directly replies to a move $(i, ?_{\mathbf{B}})$ by way of a truth value (i, t_i), without querying the argument. This is however a signal that the agent with which the strategy is interacting represents a *constant* function, and we will not consider it in the following.

The way we will prove deterministic authentication impossible when r is linear consists in showing that since q is polynomially bounded (thus negligibly smaller than the number of possible queries of type $\mathbf{S}[r]$ any function is allowed to make to its argument), there are many argument functions $\mathbb{S}[r(n)] \to \mathbb{B}$ which are indistinguishable, and would thus receive the same tag. In the following, we prove that the (relatively few) coordinates on which the argument function is queried can even be efficiently determined.

4.1 Efficiently Determining Influential Variables

A key step towards proving our negative result comes from the theory of influential variables in decision trees. In this section, we are going to give some preliminary definitions about it, without any aim at being comprehensive (see, e.g., [29]).

From now on, metavariables like N, M, L stand for natural number unrelated to the security parameter, unless otherwise specified. Given a natural number $N \in \mathbb{N}$, $[N]$ denotes the set $\{1, \dots, N\}$. Whenever $j \in [N]$, $e_j \in \mathbb{S}[N]$ is the binary string which is everywhere 0 except on the j-th component, in which it is 1.

▶ **Definition 12** (Variance and Influence). *For every distribution $\mathcal{D}$ over $\mathbb{S}[N]$, and $F : \mathbb{S}[N] \to \mathbb{B}$, we write $\mathbf{Var}_{\mathcal{D}}(F)$ for the value $\mathbb{E}(F(\mathcal{D})^2) - \mathbb{E}(F(\mathcal{D}))^2 = \Pr_{x,y\sim\mathcal{D}}(F(x) \neq F(y))$, called the* variance of F under $\mathcal{D}$. *For every distribution $\mathcal{D}$ over $\mathbb{S}[N]$, $F : \mathbb{S}[N] \to \mathbb{B}$, and $j \in [N]$, we define the* influence of j on F under $\mathcal{D}$, *written $\mathbf{Inf}^j_{\mathcal{D}}(F)$, as $\Pr_{x\sim D}[F(x) \neq F(x \oplus e_j)]$.*

The quantity $\mathbf{Inf}^j_{\mathcal{D}}(F)$ measures how much, on the average, changing the j-th input to F influences its output. If F does not depend too much on the j-th input, then $\mathbf{Inf}^j_{\mathcal{D}}(F)$ is close to 0, while it is close to 1 when switching the j-th input has a strong effect on the output.

▶ **Example 13.** Let $PARITY_N : \mathbb{S}[N] \to \mathbb{B}$ be the parity function on N bits. It holds that

$$\begin{aligned}\mathbf{Inf}^j_{\mathcal{D}}(PARITY_N) &= \Pr_{x\sim\mathcal{D}}[PARITY_N(x) \neq PARITY_N(x \oplus e_j)] \\ &= \sum_x \mathcal{D}(x) \cdot |PARITY_N(x) - PARITY_N(x \oplus e_j)| = \sum_x \mathcal{D}(x) = 1.\end{aligned}$$

This indeed matches the intuition: changing any one coordinate makes the output to change, independently on the distribution from which the input is drawn.

If $F : A \to \mathbb{S}[L]$, and $t \in [L]$, we define $F_t : A \to \mathbb{B}$ to be the function that on input $x \in A$ outputs the t-th bit of $F(x)$. The kind of distributions over $\mathbb{S}[N]$ we will be mainly interested at are the so-called *semi-uniform* ones, namely those in which some of the N bits have a fixed value, while the others take all possible values with equal probability. It is thus natural to deal with them by way of partial functions. For every partial function $g : [N] \to \mathbb{B}$ we define $Dom(g) \subseteq [N]$ to be the set of inputs on which g is defined, and U_g to be the uniform distribution of x over $\mathbb{S}[N]$ *conditioned on* $x_j = g(j)$ for every $j \in Dom(g)$, i.e., the distribution defined as follows:

$$U_g(x) = \begin{cases} \frac{1}{2^{N-|Dom(g)|}} & \text{if } x_j = g(j) \text{ for every } j \in Dom(g); \\ 0 & \text{otherwise.} \end{cases}$$

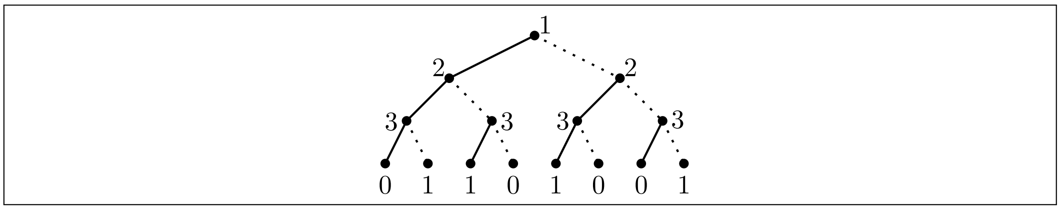

Figure 3 A Decision Tree for $PARITY_3$.

If a distribution $\mathcal{D}$ can be written as U_g, where $g : [N] \to \mathbb{B}$, we say that $\mathcal{D}$ is an $Dom(g)$-*distribution*, or a *semi-uniform* distribution. Given a distribution $\mathcal{D} : \mathbb{S}[N] \to \mathbb{R}_{[0,1]}$, some index $j \in [N]$ and a bit $b \in \mathbb{B}$, the expression $\mathcal{D}[j \leftarrow b]$ stands for the conditioning of $\mathcal{D}$ to the fact that the j-th boolean argument is b. Note that if $\mathcal{D}$ is an S-distribution and $j \in [N] \setminus S$, then $\mathcal{D}[j \leftarrow b]$ is an $S \cup \{j\}$-distribution.

A crucial concept in the following is that of a decision tree, which is a model of computation for boolean functions in which the interactive aspects are put upfront, while the merely computational aspects are somehow abstracted away.

▶ **Definition 14** (Decision Tree). *Given a function F, a* decision tree T for F *is a finite ordered binary tree whose internal nodes are labelled with an index $i \in [N]$, whose leaves are labelled with a bit $b \in \mathbb{B}$, and such that whenever a path ending in a leaf labelled with b is consistent with $x \in \mathbb{S}[N]$, it holds that $F(x) = b$. The* depth *of any decision tree T is defined the same as that of any tree.*

▶ **Example 15.** An example of a decision tree that computes the function $PARITY_3 : \mathbb{S}[3] \to \mathbb{B}$ defined in Example 13 can be found in Figure 3.

The following result, which is an easy corollary of some well-known results in the literature (i.e. Corollary 1.2 from [29]), put the variance and the influence in relation whenever the underlying function can be computed by way of a decision tree of limited depth.

▶ **Lemma 16.** *Suppose that F is computable by a decision tree of depth at most q and $g : [N] \to \mathbb{B}$ is a partial function. Then there exists $j \in [N] \setminus Dom(g)$ such that*

$$\mathbf{Inf}^j_{U_g}(F) \geq \frac{\mathbf{Var}_{U_g}(F)}{q}.$$

Every decision tree T makes on any input a certain number of queries, which of course can be different for different inputs. If $\mathcal{D}$ is a distribution, S is a subset of $[N]$ and T is a decision tree, we define $\Delta_{\mathcal{D},S}(T)$ as the expectation over $x \sim \mathcal{D}$ of the number of queries that T makes on input x outside of S, which is said to be *the average query complexity of T on $\mathcal{D}$ and S*. The following result relates the query complexity before and after the underlying semi-uniform distribution is updated: if we fix the value of a variable, then the average query complexity goes down (on the average) by at least the variable's influence:

▶ **Lemma 17.** *For every decision tree T computing a function F, $S \subseteq [N]$, $j \in [N] \setminus S$, and S-distribution $\mathcal{D}$, it holds that*

$$\tfrac{1}{2}\Delta_{\mathcal{D}[j \leftarrow 0], S \cup \{j\}}(T) + \tfrac{1}{2}\Delta_{\mathcal{D}[j \leftarrow 1], S \cup \{j\}}(T) \leq \Delta_{\mathcal{D},S}(T) - \mathbf{Inf}^j_{\mathcal{D}}(F).$$

By somehow iterating over Lemma 17, we can get the following result, which states that fixing enough coordinates, the variance can be made arbitrarily low, and that those coordinates can be efficiently determined:

▶ **Theorem 18.** *For every $F : \mathbb{S}[N] \to \mathbb{S}[L]$ such that for every $t \in [L]$, F_t is computable by a decision tree of depth at most Q, and every $\varepsilon > 0$, there exist a natural number $m \leq LQ^2/\varepsilon$ and a partial function $g : [N] \to \mathbb{B}$ where $|Dom(g)| \leq m$ such that $\mathbf{Var}_{U_g}(F_t) \leq \varepsilon$ for every $t \in \{1, \ldots, L\}$. Moreover, there is a polytime randomized algorithm A that on input F, $\delta > 0$, and $\varepsilon > 0$, makes at most $\mathcal{O}(LN) \cdot poly(Q/(\delta\varepsilon))$ queries to F and outputs such a partial function g with $|Dom(g)| \leq \mathcal{O}((LQ^2)/(\varepsilon\delta))$ with probability at least $1 - \delta$.*

Proof. We here give the main ingredients of the proof, referring to [3] for a more detailed account. The algorithm A proceeds by iteratively fixing new coordinates between the N many ones the function F depends on, stopping when the variance of all the functions F_t on the obtained semi-uniform distribution falls significantly below ε. The next coordinate to be fixed is chosen by estimating, using statistical methods, the influence of *all* the possible coordinates. Using similar methods, A can also estimate accurately the variance, and stop when enough coordinates are fixed. The role of Lemma 16 is to guarantee that if the variance is not too low, an influential variable can always be found, while the one of Lemma 17 consists in guaranteeing that a bounded number of iterations is enough. ◀

4.2 On the Impossibility of Authenticating Functions

Theorem 18 tells us that for every first-order boolean function which can be computed by a decision tree of low depth, there exist relatively few of its coordinates that, once fixed, determine the function's output with very high probability. If N is exponentially larger than Q, in particular, there is no hope for such a function to be a secure message authentication code. In this section, we aim at proving the aforementioned claim. In order to do it, we build a third-order randomized algorithm, which will be shown to fit into our game-theoretic framework.

More specifically, we are concerned with the cryptographic properties of strategies for the parametrized game $SOF_{q,r,p} =!_q(\mathbf{S}[r] \multimap \mathbf{B}) \multimap \mathbf{S}[p]$ and, in particular, with the case in which r is the identity ι, i.e. we are considering the game $LINSOF_{q,p} = SOF_{q,\iota,p}$. Any such strategy, when deterministic, can be seen as computing a family of functions $\{F_n\}_{n\in\mathbb{N}}$ where $F_n : (\mathbb{S}[n] \to \mathbb{B}) \to \mathbb{S}[p(n)]$. How could we fit all this into the hypotheses of Theorem 18?

The definitions of variance, influence, and decision tree can be easily generalised to functions in the form $F : (\mathbb{S}[N] \to \mathbb{B}) \to \mathbb{S}[M]$. Of course the underlying distribution $\mathcal{D}$ must be a distribution over functions $\mathbb{S}[N] \to \mathbb{B}$. The parameter N can be fixed in such a way that $n < N < 2^n$, where n is the security parameter. For simplicity we will choose N to be a power of 2, which hence divides 2^n.

▶ **Definition 19** (Extensions). *For every $x \in \mathbb{S}[N]$, we define the* extension *of x, denoted by f_x as the function $f_x : \mathbb{S}[n] \to \mathbb{B}$ such that for every $i \in [2^n]$ (identifying $\mathbb{S}[n]$ with the numbers $\{0, \ldots, 2^n - 1\}$ in the natural way), it holds that $f_x(i) = x_{\lfloor i/N \rfloor + 1}$. That is, f_x is the function that outputs x_1 on the first $2^n/N$ inputs, outputs x_2 on the second $2^n/N$ inputs, and so on and so forth. Given a distribution $\mathcal{D}$ over $\mathbb{S}[N]$, a distribution over functions $\mathbb{S}[n] \to \mathbb{B}$ can be formed in the natural way as $f_{\mathcal{D}}$.*

We will also make use of the following slight variation on the classic notion of Hamming distance: define $H(\cdot, \cdot)$ to be the so-called *normalized Hamming distance.* In fact, we overload the symbol H and use it for both *strings* in $\mathbb{S}[N]$ and *functions* in $\mathbb{S}[n] \to X$ for some set X. That is, if $x, y \in \{0, 1\}^N$ then $H(x, y) = \Pr_{j\in[N]}[x_j \neq y_j]$ while if $f, g \in \mathbb{S}[n] \to X$ then $H(f, g) = \Pr_{i\in\mathbb{S}[n]}[f(i) \neq g(i)]$.

Finally, the following ground game will be useful in the following as a way to represent partial functions as ground objects. The game $\mathbf{T}[q]$ is a slight variation on $\mathbf{S}[q]$ in which the returned string is in the ternary alphabet $\{0,1,\bot\}$. Any strategy for $\mathbf{T}[q]$ can thus be seen as representing a (family of) partial functions from $[q(n)]$ to $\mathbb{B}$.

▶ **Theorem 20.** *For every $\varepsilon,\delta>0$, there is a polytime probabilistic strategy* $\mathsf{infvar}_{\varepsilon,\delta}$ *on the game $!_s(\mathit{LINSOF}_{q,p})\multimap\mathbf{T}[t]$ such that for every deterministic strategy* f *on $\mathit{LINSOF}_{q,p}$ computing $\{F_n\}_{n\in\mathbb{N}}$, the composition $(!_s\mathsf{f});\mathsf{infvar}_{\varepsilon,\delta}$, with probability at least $1-\delta$, computes some functions $g_n:[t(n)]\to\mathbb{B}$ such that $\mathbf{Var}_{f_{U_{g_n}}}(F_n)\leq\varepsilon$ and $|\mathit{Dom}(g_n)|\leq\mathcal{O}(p(n)q^2(n)/(\delta\epsilon))$.*

Proof. This is a corollary to Theorem 18, since the functions F_n can be seen as first-order functions, and can thus be queried on functions in the form f_x (see Definition 19), where $x\in\mathbb{S}[N]$, and N is appropriately chosen so as to be significantly smaller than 2^n. Since F_n is computed by f, it can be computed by a decision tree having depth $q(n)$. Please refer to [3] for a more detailed proof. ◀

Remarkably, the strategy $\mathsf{infvar}_{\varepsilon,\delta}$ infers the "influential variables" of f *without* looking at how the latter queries its argument function, something which would anyway be available in the history of the interaction. This is reminiscent of *innocence* [23], a key concept in game semantics. We can now state the main result of this section.

▶ **Theorem 21.** *For every δ there is a polytime probabilistic strategy* coll_δ *on a game $!_s(\mathit{LINSOF}_{q,p})\multimap(\mathbf{S}[\iota]\multimap\mathbf{B})\otimes(\mathbf{S}[\iota]\multimap\mathbf{B})$ such that for every deterministic strategy* f *on $\mathit{LINSOF}_{q,p}$ computing $\{F_n\}_{n\in\mathbb{N}}$, the composition $(!_s\mathsf{f});\mathsf{coll}_\delta$, with probability at least $1-\delta$, computes two function families g,h with $g_n,h_n:\mathbb{S}[n]\to\mathbb{B}$ such that*
1. *$H(g_n,h_n)\geq 0.1$ for every n.*
2. *$F_n(g_n)=F_n(h_n)$ for every n.*
3. *For every function f on which* coll_δ *queries its argument, it holds that $H(f,g_n)\geq 0.1$ and $H(f,h_n)\geq 0.1$.*

Proof. The strategy coll_δ can be easily built from $\mathsf{infvar}_{\varepsilon,\delta}$: the former calls the latter, and then draws two strings independently at random from U_{k_n}, where k_n is the function the latter produces in output, and obtaining x,y. The two required outputs are thus f_x and f_y, and have all the required properties. ◀

This shows that coll_δ finds a *collision* for F_n as a pair of functions that are different from each other (and in fact significantly different in Hamming distance) but for which F_n outputs the same value, and hence F cannot be a collision-resistant hash function. Moreover, because the functions are far from those queried, this means that F_n cannot be a secure message authentication code either, since by querying F_n on g_n, the adversary can predict the value of the tag on h_n.

4.3 A Positive Result on Higher-Order Pseudorandomness

We conclude this paper by giving a positive result. More specifically, we prove that pseudorandomness can indeed be attained at second order, but at a high price, namely by switching to the type $\mathit{LOGSOF}_p=\mathit{SOF}_{\iota,\lfloor\lg\rfloor,p}$. This indeed has the same structure of $\mathit{LINSOF}_{q,p}$, but the argument function takes in input strings of *logarithmic size* rather than linear size. Moreover, the argument function can be accessed a linear number of times, which is enough to query it on *every possible* coordinate.

The fact that a strategy on LOGSOF_p can query its argument on every possible coordinate renders the attacks described in the previous section unfeasible. Actually, LOGSOF_p can be seen as an *interactive* variation of the game $\mathbf{S}[\iota]\multimap\mathbf{S}[p]$, for which pseudorandomness is

	$!_{\iota+1}(\mathbf{L}[\iota]$	$\multimap$	$\mathbf{S}[w])$	$\multimap$	$!_{\iota}(\mathbf{S}[\lfloor\lg\rfloor]$	$\multimap$	$\mathbf{B})$	$\multimap$	$\mathbf{S}[p])$
O									$?_{\mathbf{S}[p]}$
			$\vdots$						
P			$(i, ?_{\mathbf{S}[w]})$						
O	$(i, ?_{\mathbf{L}[\iota]})$								
P	$(i, (z_1 \cdots z_{i-1})$								
O			$(i, j_i))$						
P							$(i, ?_{\mathbf{B}})$		
O					$(i, ?_{\mathbf{S}[\lfloor\lg\rfloor]})$				
P					$(i, \alpha(j_i, \{j_1, \ldots, j_{i-1}\})$				
O							(i, z_i)		
			$\vdots$						
P			$(n, ?_{\mathbf{S}[w]})$						
O	$(n, ?_{\mathbf{L}[\iota]})$								
P	$(n, (z_1 \cdots z_n))$								
O			(n, v)						
P									$\beta(v)$

Figure 4 Plays in $\overline{\mathsf{fo2so}}$.

well known to be attainable starting from standard cryptographic assumptions [19]: simply, instead of taking in input *the whole* string *at once*, it queries it *bit by bit*, in a certain order. A *random strategy* of that type, then, would be one that, using the notation from Figure 2,

- Given $t_1, \ldots, t_i \in \mathbb{B}$, returns a string s_{i+1} uniformly chosen at random from $\mathbb{S}[r(n)] - \{s_1, \ldots, s_i\}$, this for every $i < q(n)$.
- Moreover, based on $t_1, \ldots, t_{r(n)}$, it produces a string v chosen uniformly at random from $\mathbb{S}[p(n)]$.

Please notice that this random strategy can be considered as a *random* functional in $(\mathbb{S}[r(n)] \to \mathbb{B}) \to \mathbb{S}[p(n)]$ only if $r(n)$ is logarithmic, because this way the final result v is allowed to depend on the value of the input function in *all possible coordinates.* The process of generating such a random strategy uniformly can be seen[1] as a probabilistic strategy $\mathsf{randsof}$. We are now ready to formally define pseudorandom functions:

▶ **Definition 22** (Second-Order Pseudorandom Function). *A deterministic polytime strategy* f *on* $\mathbf{S}[\iota] \multimap LOGSOF_p$ *is said to be* pseudorandom *iff for every probabilistic polytime strategy* $\mathcal{A}$ *on* $!_s LOGSOF_p \multimap \mathbf{B}$ *there is a negligible function* $\varepsilon : \mathbb{N} \to \mathbb{R}_{[0,1]}$ *such that*

$$|\Pr(!_s(\mathsf{mult}_\iota; \mathsf{f}); \mathcal{A} \Downarrow^n 1) - \Pr(!_s\mathsf{randsof}; \mathcal{A} \Downarrow^n 1)| \leq \varepsilon(n).$$

The way we build a pseudorandom function consists in constructing a *deterministic* polytime strategy $\mathsf{fo2so}$ for the game $!_{\iota+1}(\mathbf{L}[\iota] \multimap \mathbf{S}[w]) \multimap LOGSOF_p$, where $w \in \mathbf{Pol}$ is such that $w \geq \lfloor\lg\rfloor$ and $w \geq p$. The strategy is represented in Figure 4. The function α interprets its first argument (a string in $\mathbb{S}[w(n)]$), as an element of $\mathbb{S}[\lfloor\lg\rfloor(n)]$ distinct from those it takes as second argument, and distributing the probabilities uniformly. The function β, instead, possibly discards some bits of the input and produces a possibly shorter string.

[1] the strategy at hand would, strictly speaking, need exponentially many random bits, which are not allowed in our model; this could be accomodated without any major problem.

The way the strategy $\mathsf{fo2so}$ is defined makes the composition $\mathsf{f};\mathsf{fo2so}$ statistically very close to the random strategy whenever f is chosen uniformly at random among the strategies for the parametric game $\mathbf{L}[\iota] \multimap \mathbf{S}[w]$. This allows us to prove the following:

▶ **Theorem 23.** *Let $F : \{0,1\}^n \times \{0,1\}^{\leq n} \to \{0,1\}^{w(n)}$ be a pseudorandom function and let f_F be the deterministic polytime strategy for the game $\mathbf{S}[\iota] \multimap !_{\iota+1}(\mathbf{L}[\iota] \multimap \mathbf{S}[w])$ obtained from F. Then, $\mathsf{f}_F;\mathsf{fo2so}$ is second-order pseudorandom.*

5 Related Work

Game semantics and the geometry of interaction are among the best-studied program semantic frameworks (see, e.g. [17, 2, 23]), and can also be seen as computational models, given their operational flavor. This is particularly apparent in the work on abstract machines [10, 14], but also in the so-called geometry of synthesis [15]. In this paper, we are particularly interested in the latter use of game semantics, and take it as the underlying computational model. The definition of our game model has been strongly inspired by works by Hyland [22] and Wolverson [32], the main novelties being parametrization and the bounded exponential construction, which together allow us to account for efficient randomized higher-order computations of the kinds used in cryptography. As a consequence, our definition of an acceptable strategy is more permissive than the ones from so-called AJM games [2] and HO games [23], the former being history-free, the latter essentially relying on so-called justification pointers.

This is certainly not the first paper in which cryptography is generalized to computational models beyond the one of first-order functions. One should of course cite Canetti's universally composable security [7], but also Mitchell et al.'s framework, the latter based on process algebras [28]. None of them deals with security properties of higher-order functions, though. A precursor of the aforementioned work [27] deals with first-order probabilistic polynomial time by way of oracles in an higher-order calculus, but lacks any claim about how probabilistic polynomial time would look like for genuinely higher-order functions.

Various ways to generalize the so-called formal model [12] to higher-order computation have been proposed. As an example, this is what Sumii and Pierce [30] do with their system of logical relations, which is shown to guarantee a form of non-interference. Similarly for Bhargavan et al.'s type system [4] in which cryptographic primitives are seen as libraries for the language F#. All this is is however fundamentally different from what we do here, namely extending the so-called *computational* model to higher-order computation: randomized behaviours and time-bounds are abstracted away.

Abstract

Higher-order recursion schemes are an expressive formalism used to define languages of possibly infinite ranked trees. They extend regular and context-free grammars, and are equivalent to simply typed λY-calculus and collapsible pushdown automata. In this work we prove, under a syntactical constraint called safety, decidability of the model-checking problem for recursion schemes against properties defined by alternating B-automata, an extension of alternating parity automata for infinite trees with a boundedness acceptance condition. We then exploit this result to show how to compute downward closures of languages of finite trees recognized by safe recursion schemes.

1 Introduction

Higher-order functions are nowadays widely used not only in functional programming languages such as Haskell and the OCAML family, but also in mainstream languages such as Java, JavaScript, Python, and C++. *Recursion schemes* are faithful and algorithmically

47th International Colloquium on Automata, Languages, and Programming (ICALP 2020).

manageable abstractions of the control flow of higher-order programs [36]. A deterministic recursion scheme normalises into a possibly infinite Böhm tree, and in this respect recursion schemes can equivalently be presented as simply-typed lambda-terms using a higher-order fixpoint combinator Y [50]. There are also nontrivial inter-reductions between recursion schemes and the equi-expressive collapsible higher-order pushdown automata [30] and ordered tree-pushdown automata [13]. In another semantics, also used in this paper, nondeterminstic recursion schemes are recognisers of languages of finite trees, and in this view they are also known as higher-order OI grammars [23, 38], generalising indexed grammars [2] (which are recursion schemes of order two) and ordered multi-pushdown automata [8].

The most celebrated algorithmic result in the analysis of recursion schemes is the decidability of the model-checking problem against properties expressed in monadic second-order logic (MSO): given a recursion scheme $\mathcal{G}$ and an MSO sentence φ, one can decide whether the Böhm tree generated by $\mathcal{G}$ satisfies φ [43]. This fundamental result has been reproved several times, that is, using collapsible higher-order pushdown automata [30], intersection types [37], Krivine machines [48], and it has been extended in diverse directions such as global model checking [11], logical reflection [9], effective selection [12], and a transfer theorem via models of lambda-calculus [49]. When the input property is given as an MSO formula, the model-checking problem is non-elementary already for trees of order 0 (regular trees) [51]; when the input property is presented as a parity tree automaton (which is equi-expressive with MSO on trees, but less succinct), the MSO model-checking problem for recursion schemes of order n is complete for n-fold exponential time [43]. Despite these hardness results, the model-checking problem can be solved efficiently on multiple nontrivial examples, thanks to the development of several recursion-scheme model checkers [36, 35, 10, 47, 42].

Unboundedness problems. Recently, an increasing interest has arose for model checking quantitative properties going beyond the expressive power of MSO. The *diagonal problem* is an example of a quantitative property not expressible in MSO. Over words, the problem asks, for a given set of letters Σ and a language of finite words $\mathcal{L}$, whether for every $n \in \mathbb{N}$ there is a word in $\mathcal{L}$ where every letter from Σ occurs at least n times. Over full trios (classes of languages closed under regular transductions), decidability of the diagonal problem over finite words has interesting algorithmic consequences, such as computability of downward closures [54] and decidability of separability by piecewise testable languages [21]. The diagonal problem for languages of words recognised by recursion schemes is decidable [29, 14, 45].

Over full trios of finite words, the diagonal problem is equivalent to the computability of downward closures [22], which is an important problem in its own right. The *downward closure* of a language $\mathcal{L}$ of finite trees is the set $\mathcal{L}{\downarrow}$ of all trees that can be homeomorphically embedded into some tree in $\mathcal{L}$. By Higman's lemma [31], the embedding relation on finite ranked trees is a well quasi-order. Consequently, the downward closure $\mathcal{L}{\downarrow}$ of an arbitrary set of trees $\mathcal{L}$ is always a regular language. The downward closure of a language offers a nontrivial regular abstraction thereof: even though the actual count of letters is lost, their limit properties are preserved, as well as their order of appearance.

We say that the downward closure is *computable* when a finite automaton for $\mathcal{L}{\downarrow}$ can be effectively constructed (which is not true in general). Downward closures are computable for a wide class of languages of finite words such as those recognised by context-free grammars [20, 41, 3], Petri nets [27], stacked counter automata [55], context-free FIFO rewriting systems and 0L-systems [1], second-order pushdown automata [54], higher-order pushdown automata [29], and (possibly unsafe) recursion schemes over words [14]. Over finite trees, it is known that downward closures are computable for the class of regular tree languages [25]. We are not aware of other such computability results for other classes of languages of finite trees.

In another line of research, B-automata, and among them *alternating B-automata*, have been put forward as a quantitative extension to MSO [15, 18, 52, 39]. They extend alternating automata over infinite trees [26, Chapter 9] by nonnegative integer counters that can be incremented or reset to zero. The extra counters do not constrain the availability of transitions during a run (unlike in other superficially similar models, such as counter machines), but are used in order to define the acceptance condition: an infinite tree is *n-accepted* if n is a bound on the values taken by the counters during an accepting run of the automaton over it.

The *universality problem* consists in deciding whether for every tree there is a bound n for which it is n-accepted. The *boundedness problem* asks whether there exists a bound n for which all trees are n-accepted. These two problems are closely related. Their decidability is an important open problem in the field, and proving the decidability of the boundedness problem would solve the long standing nondeterministic Mostowski index problem [17]. However, though open in general, the boundedness problem is known to be decidable over finite words [15] and trees [18] and infinite words [39], as well as over infinite trees for its weak [53] and the more general quasi-weak [40] version.

Another expressive formalism expressing unboundedness properties beyond MSO is MSO+U, which extends MSO by a new quantifier "$\mathsf{U}X.\varphi$" [7] stating that there exist arbitrarily large finite sets X satisfying φ. This logic is incomparable with B-automata. The model-checking problem of recursion schemes against its weak fragment WMSO+U, where monadic second-order quantifiers are restricted to finite sets, is decidable [46].

Contributions. Our first contribution is the decidability of the model-checking problem of properties expressed by alternating B-automata for an expressive class of recursion schemes called *safe recursion schemes*. As generators of infinite trees, safe recursion schemes are equivalent to higher-order pushdown automata without the collapse operation [34] and are strictly less expressive than general (unsafe) recursion schemes [44, Corollary I.2]. Here, the model-checking problem asks whether a concrete infinite tree (the Böhm tree generated by the safe recursion scheme) is accepted by the B-automaton for some bound. This problem happens to be significantly simpler than the universality/boundedness problem above described. The proof goes by reducing the order of the safe recursion scheme similarly as done in Knapik, Niwiński, and Urzyczyn [34] to show decidability of the MSO model-checking problem, at the expense of making the property automaton two-way. We then rely on the fact that two-way alternating B-automata can be converted to equivalent one-way alternating B-automata [6]. Our result is incomparable with the result of Ong [43], since

(1) alternating B-automata are strictly more expressive than MSO, however

(2) we obtain it under the more restrictive safety assumption.

Whether the safety assumption can be dropped while preserving decidability of the model-checking problem against B-automata properties remains open.

Our second contribution is to define the following generalization of the diagonal problem from words to trees: given a language of finite trees $\mathcal{L}$ and a set of letters Σ, decide whether for every $n \in \mathbb{N}$ there is a tree $T \in \mathcal{L}$ such that every letter from Σ occurs at least n times on every branch of T. This generalization is designed in order to reduce the computation of downward closures to the diagonal problem, in the same fashion as for finite words. Our proof strategy is to represent downward-closed sets of trees $\mathcal{L}\downarrow$ by simple tree regular expressions, which are a subclass of regular expressions for finite trees [24, 25]. By further analysing and simplifying the structure of these expressions, the computation of the downward closure can be reduced to finitely many instances of the diagonal problem. Unlike in the case of finite words, we do not know whether for full trios there exists a converse reduction from the diagonal problem to the problem of computing downward closures.

Our third contribution is decidability of the diagonal problem for languages of finite trees recognised by safe recursion schemes (and thus computability of downward closures of those languages). The diagonal problem can directly be expressed in a logic called *weak cost monadic second order logic* (WCMSO) [53], which extends weak MSO with atomic formulae of the form $|X| \leq N$ stating that the cardinality of the monadic variable X is at most N. Since WCMSO can be translated to alternating B-automata [53], the diagonal problem reduces to the model-checking problem of safe recursion schemes against alternating B-automata, which we have shown decidable in the first part. Note that it seems difficult to express the diagonal problem using alternating B-automata directly, and indeed the fact that alternating B-automata can express all WCMSO properties is nontrivial.

Outline. In Section 2, we define recursion schemes and B-automata. In Section 3, we present our first result, namely decidability of model checking of safe recursion schemes against B-automata. In Section 4, we introduce the diagonal problem, and we show how it can be used to compute downward closures. In Section 5, we solve the diagonal problem for schemes. We conclude in Section 6 with some open problems. A full technical report containing full proofs it also available [4].

2 Preliminaries

Recursion schemes. A *ranked alphabet* is a (usually finite) set $\mathbb{A}$ of letters, together with a function *rank*: $\mathbb{A} \to \mathbb{N}$, assigning a *rank* to every letter. When we define trees below, we require that a node labeled by a letter a has exactly $\mathit{rank}(a)$ children. In the sequel, we usually assume some fixed finite ranked alphabet $\mathbb{A}$. The set of *(simple) types* is constructed from a unique ground type o using a binary operation $\to$; namely o is a type, and if α and β are types, so is $\alpha \to \beta$. By convention, $\to$ associates to the right, that is, $\alpha \to \beta \to \gamma$ is understood as $\alpha \to (\beta \to \gamma)$. A type $\mathsf{o} \to \dots \to \mathsf{o}$ with k occurrences of $\to$ is also written as $\mathsf{o}^k \to o$. The *order* of a type α, denoted $\mathit{ord}(\alpha)$ is defined by induction: $\mathit{ord}(\mathsf{o}) = 0$ and $\mathit{ord}(\alpha_1 \to \dots \to \alpha_k \to \mathsf{o}) = \max_i(\mathit{ord}(\alpha_i)) + 1$ for $k \geqslant 1$.

We coinductively define both *lambda-terms* and the two-argument relation "M is a *lambda-term of type* α" as follows (cf. [32, 5]):

- a letter $a \in \mathbb{A}$ is a lambda-term of type $\mathsf{o}^{\mathit{rank}(a)} \to \mathsf{o}$;
- for every type α there is a countable set $\{x, y, \dots\}$ of *variables of type* α which can be used as lambda-terms of type α;
- if M is a lambda-term of type β and x a variable of type α, then $\lambda x.M$ is a lambda-term of type $\alpha \to \beta$; this construction is called a *lambda-binder*;
- if M is a lambda-term of type $\alpha \to \beta$, and N is a lambda-term of type α, then $M\,N$ is a lambda-term of type β, called an *application*.

As usual, we identify lambda-terms up to *alpha-conversion* (i.e., renaming of bound variables). We use here the standard notions of *free variable*, *subterm*, (capture-avoiding) *substitution*, and *beta-reduction* (see for instance [32, 5]). A *closed* lambda-term does not have free variables. For a lambda-term M of type α, the *order* of M, denoted $\mathit{ord}(M)$, is defined as $\mathit{ord}(\alpha)$. It is *first-order* if its order is one. An *applicative term* is a lambda-term not containing lambda-binders (it contains only letters, applications, and variables).

A lambda-term M is *superficially safe* if all its free variables x have order $\mathit{ord}(x) \geqslant \mathit{ord}(M)$. A lambda-term M is *safe* if it is superficially safe, and if for every subterm of the form $K\,L_1\,\dots\,L_k$, where K is not an application and $k \geqslant 1$, all subterms $K, L_1, \dots, L_k$ are superficially safe.

A *(higher-order, deterministic) recursion scheme* over the alphabet $\mathbb{A}$ is a tuple $\mathcal{G} = \langle \mathbb{A}, \mathcal{N}, X_0, \mathcal{R} \rangle$, where $\mathcal{N}$ is a finite set of typed *nonterminals*, $X_0 \in \mathcal{N}$ is the *initial nonterminal*, and $\mathcal{R}$ is a function assigning to every nonterminal $X \in \mathcal{N}$ of type $\alpha_1 \to \cdots \to \alpha_k \to \mathsf{o}$ a finite lambda-term of the form $\lambda x_1 . \cdots . \lambda x_k . K$, of the same type $\alpha_1 \to \cdots \to \alpha_k \to \mathsf{o}$, in which K is an applicative term with free variables in $\mathcal{N} \uplus \{x_1, \ldots, x_k\}$. We refer to $\mathcal{R}(X)$ as the *rule* for X. The *order* of a recursion scheme $\mathit{ord}(\mathcal{G})$ is the maximum order of its nonterminals.

The lambda-term *represented* by a recursion scheme $\mathcal{G}$ as above, denoted $\Lambda(\mathcal{G})$, is the limit of applying recursively the following operation to X_0: take an occurrence of some nonterminal X, and replace it with $\mathcal{R}(X)$ (the nonterminals should be chosen in a fair way, so that every nonterminal is eventually replaced). Thus, $\Lambda(\mathcal{G})$ is a (usually infinite) regular lambda-term obtained by unfolding the nonterminals of $\mathcal{G}$ according to their definition. We remark that when substituting $\mathcal{R}(X)$ for a nonterminal X there is no need for any renaming of variables (capture-avoiding substitution), since $\mathcal{R}(X)$ does not contain free variables other than nonterminals. We only consider recursion schemes for which $\Lambda(\mathcal{G})$ is well-defined (e.g. by requiring that $\mathcal{R}(X)$ is not a single nonterminal). A recursion scheme $\mathcal{G}$ is *safe* if $\Lambda(\mathcal{G})$ is safe.

A *tree* is a closed applicative term of type o. Such lambda-terms are coinductively of the form $a\, M_1 \cdots M_r$, where $a \in \mathbb{A}$ is of rank r, and where $M_1, \ldots, M_r$ are again trees. Thus, such a lambda-term can be identified with a tree understood in the traditional sense: a is the label of its root, and $M_1, \ldots, M_r$ describe subtrees attached in the r children of the root, from left to right. For trees we also use the notation $a(M_1, \ldots, M_r)$ instead of $a\, M_1 \ldots M_r$. A tree is *regular* if it has finitely many subtrees (subterms) up to isomorphism.

The *Böhm tree* of a lambda-term M of type o, denoted $BT(M)$, is defined coinductively as follows: if there is a sequence of beta-reductions from M to a lambda-term of the form $a\, M_1 \ldots M_r$ (where $a \in \mathbb{A}$ is a letter), then $BT(M) = a(BT(M_1), \ldots, BT(M_r))$; otherwise $BT(M) = \bot()$, where $\bot \in \mathbb{A}$ is a distinguished letter of rank 0. It is a classical result that $BT(M)$ exists, and is uniquely defined [32, 5]. Clearly, $BT(M)$ is indeed a tree. The tree *generated* by a recursion scheme $\mathcal{G}$, denoted $BT(\mathcal{G})$, is $BT(\Lambda(\mathcal{G}))$.

A lambda-term N is *normalizing* if $BT(N)$ does not contain the special letter $\bot$; a recursion scheme $\mathcal{G}$ is *normalizing* if $\Lambda(\mathcal{G})$ is normalizing. In other words, in a normalizing recursion scheme/lambda-term beta-reduction always produces a letter. It is possible to transform every recursion scheme $\mathcal{G}$ into a normalizing recursion scheme $\mathcal{G}'$ generating the same tree as $\mathcal{G}$, up to renaming $\bot$ into some non-special letter $\bot'$ (cf. [28, Section 5]). Moreover, the construction preserves safety and the order.

Recursion schemes as recognizers of languages of finite trees. The standard semantics of a recursion scheme $\mathcal{G} = \langle \mathbb{A}, \mathcal{N}, X_0, \mathcal{R} \rangle$ is the single infinite tree $BT(\mathcal{G})$ generated by the scheme. An alternative view is to consider a recursion scheme as a recognizer of a language of finite trees $\mathcal{L}(\mathcal{G})$. This alternative view is relevant when discussing downward closures of languages of finite trees. We employ a special letter $\mathsf{nd} \in \mathbb{A}$ of rank 2 in order to represent $\mathcal{L}(\mathcal{G})$ by resolving the nondeterministic choice of nd in the infinite tree $BT(\mathcal{G})$ in all possible ways. Formally, for two trees T, U, we write $T \to_{\mathsf{nd}} U$ if U is obtained from T by choosing an nd-labeled node u of T and a child v thereof, and replacing the subtree rooted at u with the subtree rooted at v. The relation $\to_{\mathsf{nd}}^*$ is the reflexive and transitive closure of $\to_{\mathsf{nd}}$. We define the language of finite trees *recognized* by $\mathcal{G}$ as $\mathcal{L}(\mathcal{G}) = \mathcal{L}(BT(\mathcal{G}))$, where

$$\mathcal{L}(T) = \{U \mid T \to_{\mathsf{nd}}^* U, \text{ with } U \text{ finite and not containing “}\mathsf{nd}\text{” or “}\bot\text{”}\}\,.$$

For an illustration of this encoding, and simultaneously for an example of a recursion scheme, consider the ranked alphabet $\mathbb{A}$ containing a letter a of rank 2, two letters b_1, b_2 of rank 1, and a letter c of rank 0. We use an initial nonterminal S of order-0 type o, and an additional nonterminal A of order-2 type $(\mathsf{o} \to \mathsf{o}) \to (\mathsf{o} \to \mathsf{o}) \to \mathsf{o} \to \mathsf{o} \to \mathsf{o}$, together with the following two rules:

$$\mathcal{R}(S) = A\, b_1\, b_2\, c\, c,$$
$$\mathcal{R}(A) = \lambda f.\lambda g.\lambda x.\lambda y.\mathsf{nd}\,(a\, x\, y)\,(A\, f\, g\,(f\, x)\,(g\, x)).$$

Then, $BT(\mathcal{G})$ is the infinite non-regular tree $\mathsf{nd}\,(a\, c\, c)\,(\mathsf{nd}\,(a\,(b_1\, c)\,(b_2\, c))\,(\cdots))$, and $\mathcal{L}(\mathcal{G})$ is the non-regular language of all finite trees of the form $a\,(b_1^n\, c)\,(b_2^n\, c)$ with $n \in \mathbb{N}$.

Alternating B-automata. We introduce the model of automata used in this paper, namely *alternating one-way/two-way B-automata* over trees (over a ranked alphabet). We consider counters which can be *incremented* $\mathtt{i}$, *reset* $\mathtt{r}$, or left *unchanged* ε. Let Γ be a finite set of *counters* and let $\mathbb{C} = \{\mathtt{i}, \mathtt{r}, \varepsilon\}$ be the *alphabet of counter actions*. Each counter starts with value zero, and the *value of a sequence* of actions is the supremum of the values achieved during this sequence. For instance $\mathtt{iir}\varepsilon\mathtt{i}\varepsilon$ has value 2, $(\mathtt{ir})^\omega$ has value 1, and $\mathtt{iri}^2\mathtt{ri}^3\mathtt{r}\cdots$ has value ∞. For an infinite sequence of counter actions $w \in \mathbb{C}^\omega$, let $val(w) \in \mathbb{N} \cup \{\infty\}$ be its *value*. In case of several counters, $w = c_1 c_2 \cdots \in (\mathbb{C}^\Gamma)^\omega$, we take the counter with the maximal value: $val(w) = \sup_{c \in \Gamma} val(w(c))$, where $w(c) = c_1(c) c_2(c) \cdots$.

An *(alternating, two-way) B-automaton* over a finite ranked alphabet $\mathbb{A}$ is a tuple $\langle \mathbb{A}, Q, q_0, pr, \Gamma, \delta \rangle$ consisting of a finite set of *states* Q, an *initial state* $q_0 \in Q$, a function $pr \colon Q \to \mathbb{N}$ assigning *priorities* to states, a finite set Γ of counters, and a *transition function*

$$\delta : Q \times \mathbb{A} \to \mathcal{B}^+(\{\uparrow, \circlearrowleft, \downarrow_1, \downarrow_2, \ldots\} \times \mathbb{C}^\Gamma \times Q)$$

mapping a state and a letter a to a (finite) positive Boolean combination of triples of the form (d, c, q); it is assumed that if $d = \downarrow_i$ then $i \leqslant rank(a)$. Such a triple encodes the instruction to send the automaton to state q in direction d while performing action c. The direction $\downarrow_i$ moves to the i-th child, $\uparrow$ moves to the parent, and $\circlearrowleft$ stays in place. We assume that $\delta(q, a)$ is written in disjunctive normal form for all q and a.

The acceptance of an infinite input tree T by an alternating B-automaton $\mathcal{A}$ is defined in terms of a game $(\mathcal{A}, T)$ between two players, called Eve and Adam. Eve is in charge of disjunctive choices and tries to minimize the counter values while satisfying the parity condition. Adam, on the other hand, is in charge of conjunctive choices and tries to either maximize counter values, or to sabotage the parity condition. Since the transition function is given in disjunctive normal form, each turn of the game consists of Eve choosing a disjunct and Adam selecting a single tuple (d, c, q) thereof. In order to guarantee that from every position there is some move, we assume that each disjunction is nonempty and that each disjunct contains a tuple with some direction other than $\uparrow$. A *play* of $\mathcal{A}$ on the tree T is a sequence $q_0, (d_1, c_1, q_1), (d_2, c_2, q_2), \ldots$ compatible with T and δ: q_0 is the initial state, and for all $i \in \mathbb{N}$, $(d_{i+1}, c_{i+1}, q_{i+1})$ appears in $\delta(q_i, T(x_i))$ where x_i is the node of T after following the directions $d_1 d_2 \ldots d_i$ starting from the root. The value $val(\pi)$ of a play π is the value $val(c_1 c_2 \cdots)$ as defined above if the largest number appearing infinitely often among the priorities $pr(q_0), pr(q_1), \ldots$ is even; otherwise, $val(\pi) = \infty$. We say that the play π is *n-winning* (for Eve) if $val(\pi) \leqslant n$.

A *strategy* for one of the players in the game $(\mathcal{A}, T)$ is a function that returns the next choice given the history of the play. Note that choosing a strategy for Eve and a strategy for Adam fixes a play in $(\mathcal{A}, T)$. We say that a play π is *compatible* with a strategy σ if there is some strategy σ' for the other player such that σ and σ' together yield the play π. A strategy for Eve is *n-winning* if every play compatible with it is n-winning. We say that Eve *n-wins* the game if there is some n-winning strategy for Eve. A B-automaton *n-accepts* a tree T if Eve n-wins the game $(\mathcal{A}, T)$; it *accepts* T if it n-accepts T for some $n \in \mathbb{N}$. The language *recognized* by $\mathcal{A}$ is the set of all trees accepted by $\mathcal{A}$.

If no $\delta(q, a)$ uses the direction $\uparrow$, then we call $\mathcal{A}$ *one-way*. The following theorem essentially follows from a result of Blumensath, Colcombet, Kuperberg, Parys, and Vanden Boom [6, Theorem 6] modulo some cosmetic changes (c.f. [4, Appendix A] for more details).

▶ **Theorem 2.1** (c.f. [6, Theorem 6]). *Given an alternating two-way B-automaton, one can compute an alternating one-way B-automaton that recognizes the same language.*

As a special case of a result by Colcombet and Göller [16] we obtain the following fact.

▶ **Fact 2.2.** *One can decide whether a given B-automaton accepts a given regular tree.*

3 Model-checking safe recursion schemes against alternating B-automata

In this section we prove the first main theorem of our paper, the decidability of the *model-checking problem* of safe recursion schemes against properties described by B-automata:

▶ **Theorem 3.1.** *Given an alternating B-automaton $\mathcal{A}$ and a safe recursion scheme $\mathcal{G}$, one can decide whether $\mathcal{A}$ accepts the tree generated by $\mathcal{G}$.*

It is worth noticing that this theorem generalises the result of Knapik et al. [34] on safe recursion schemes from regular (MSO) properties to the more general quantitative realm of properties described by B-automata. On the other hand, our result is incomparable with the celebrated theorem of Ong [43] showing decidability of model checking regular properties of possibly unsafe recursion schemes. Whether model checking of possibly unsafe recursion schemes against properties described by B-automata is decidable remains an open problem.

By Theorem 2.1, every B-automaton can be effectively transformed into an equivalent one-way B-automaton, so it is enough to prove Theorem 3.1 for a one-way B-automaton $\mathcal{A}$. The proof of Theorem 3.1 is based on the following lemma, where we use in an essential way the assumption that the recursion scheme is safe.

▶ **Lemma 3.2.** *For every safe recursion scheme $\mathcal{G}$ of order m and for every alternating one-way B-automaton $\mathcal{A}$, one can effectively construct a safe recursion scheme $\mathcal{G}'$ of order $m - 1$ and an alternating two-way B-automaton $\mathcal{A}'$ such that*

$$\mathcal{A} \text{ accepts } BT(\mathcal{G}) \quad \text{if and only if} \quad \mathcal{A}' \text{ accepts } BT(\mathcal{G}').$$

Theorem 3.1 follows easily: Using Lemma 3.2 we can reduce the order of the considered safe recursion scheme by one. We obtain a two-way B-automaton, which we convert back to a one-way B-automaton using Theorem 2.1. It is then sufficient to repeat this process, until we end up with a recursion scheme of order 0. A recursion scheme of order 0 generates a regular tree and, by Fact 2.2, we can decide whether the resulting B-automaton accepts this tree, answering our original question.

Lambda-trees. We now come to the proof of Lemma 3.2. The construction of $\mathcal{G}'$ from of $\mathcal{G}$ follows an analogous result for MSO [33, 34], which we generalise to B-automata. We represent some lambda-terms as trees. For a *finite* set $\mathcal{X}$ of variables of type o, we define a new ranked alphabet $\mathbb{A}_{\mathcal{X}}$ that contains

1) a letter $\overline{a}$ of rank 0 for every letter $a \in \mathbb{A}$;
2) a letter $\overline{x}$ of rank 0 for every variable $x \in \mathcal{X}$;
3) a letter $\overline{\lambda x}$ of rank 1 for every variable $x \in \mathcal{X}$;
4) a letter @ of rank 2.

We remark that $\mathbb{A}_{\mathcal{X}}$ is a usual finite ranked alphabet. A *lambda-tree* is a tree over the alphabet $\mathbb{A}_{\mathcal{X}}$, where $\mathcal{X}$ is clear from the context. Intuitively, a lambda-tree is a tree representation of a first-order lambda-term.

The semantics $[\![T]\!]_{\mathcal{X},s}$ of a lambda-tree T is defined in such a way that if T "corresponds" to the lambda-term M, then $[\![T]\!]_{\mathcal{X},s} = BT(M)$. Since T uses only variables of type o we can read the resulting Böhm tree directly, without performing any reduction. Essentially, we walk down through T, skipping all lambda-binders and choosing the left branch in all applications. Whenever we reach some variable x, we go up to the corresponding lambda-binder, then up to the corresponding application, and then we again start going down in the argument of this application. Formally, let $\mathcal{X}$ be a finite set of variables of type o, and let $s \in \mathbb{N}$. The intended meaning is that $\mathcal{X}$ contains variables that may potentially appear in the considered lambda-tree T, and that s is a bound for the arity of types in the lambda-term represented by T (types of all its subterms should be of the form $\mathsf{o}^k \to \mathsf{o}$ for $k \leq s$). We take $\mathit{Dirs}_{\mathcal{X},s} = \{\downarrow\} \cup \{\uparrow_x \mid x \in \mathcal{X}\} \cup \{\uparrow_i \mid 1 \leq i \leq s\}$. Intuitively, $\downarrow$ means to go down to the left child, $\uparrow_x$ means that we are looking for the value of (lambda)variable x, and $\uparrow_i$ means that we are looking for the i-th argument of an application. For a node v of T denote its parent by $\mathit{par}(v)$, and its i-th child by $\mathit{ch}_i(v)$. For $d \in \mathit{Dirs}_{\mathcal{X},s}$, and for a node v of T labeled by $a \in \mathbb{A}$, we define the $(\mathcal{X}, s)$*-successor* of (d, v) as

1. $(\downarrow, \mathit{ch}_1(v))$ if $d = \downarrow$ and $a = \overline{\lambda x}$ (for some x) or @,
2. $(\uparrow_x, v)$ if $d = \downarrow$ and $a = \overline{x}$ (for some x),
3. $(\uparrow_x, \mathit{par}(v))$ if $d = \uparrow_x$ and $a \neq \overline{\lambda x}$ (including the case when $a = \overline{\lambda y}$ for $y \neq x$),
4. $(\uparrow_1, \mathit{par}(v))$ if $d = \uparrow_x$ and $a = \overline{\lambda x}$,
5. $(\uparrow_{i+1}, \mathit{par}(v))$ if $d = \uparrow_i$ for $i < s$ and $a = \overline{\lambda y}$ (for some y),
6. $(\uparrow_{i-1}, \mathit{par}(v))$ if $d = \uparrow_i$ for $i > 1$ and $a =$ @,
7. $(\downarrow, \mathit{ch}_2(v))$ if $d = \uparrow_1$ and $a =$ @.

Rule 1 allows us go to down to the first child in the case of lambda-binders and applications. Rule 2 records that we have seen x, and thus we need to find its value by going up. Rule 3 climbs the tree upwards as long as we do not see the corresponding binder $\overline{\lambda x}$. Rule 4 records that we have seen $\overline{\lambda x}$ and initialises its level to 1. We now need to find the corresponding application. Rule 5 increments the level and goes up when we encounter a binder $\overline{\lambda y}$, and Rule 6 decrements it for applications @. Finally, when we see an application at level 1 we apply Rule 7 which searches for the value of x in the right child. An $(\mathcal{X}, s)$*-maximal path* from (d_1, v_1) is a sequence of pairs $(d_1, v_1), (d_2, v_2), \ldots$ in which every (d_{i+1}, v_{i+1}) is the $(\mathcal{X}, s)$-successor of (d_i, v_i), and which is either infinite or ends in a pair that has no $(\mathcal{X}, s)$-successor. For $d \in \mathit{Dirs}_{\mathcal{X},s}$, and for a node v of T, we define the $(\mathcal{X}, s)$*-derived tree* from (T, d, v), denoted by $[\![T, d, v]\!]_{\mathcal{X},s}$, by coinduction:

- if the $(\mathcal{X}, s)$-maximal path from (d, v) is finite and ends in $(\downarrow, w)$ for a node w labeled by $\overline{a}$, then $[\![T, d, v]\!]_{\mathcal{X},s} = a([\![T, \uparrow_1, w]\!]_{\mathcal{X},s}, \ldots, [\![T, \uparrow_{\mathit{rank}(a)}, w]\!]_{\mathcal{X},s})$;
- otherwise, $[\![T, d, v]\!]_{\mathcal{X},s} = \bot$.

The $(\mathcal{X}, s)$*-derived tree* from T is $[\![T]\!]_{\mathcal{X},s} = [\![T, \downarrow, v_0]\!]_{\mathcal{X},s}$, where v_0 is the root of T. We say that T is *normalizing* if $[\![T]\!]_{\mathcal{X},s}$ does not contain $\bot$.

The following lemma performs the order reduction. It crucially relies on the safety assumption. It is a variant of results proved in Knapik et al. [33, 34] (c.f. [4, Appendix C] for more details). Intuitively, it says that a lambda-tree representation T of a safe recursion scheme $\mathcal{G}$ of order m can be computed by a safe recursion scheme of order $m - 1$ in a semantic-preserving way.

▶ **Lemma 3.3** ([33, 34])**.** *For every safe recursion scheme $\mathcal{G}$ of order $m \geq 1$ one can construct a safe recursion scheme $\mathcal{G}'$ of order $m-1$, a finite set of variables $\mathcal{X}$, and a number $s \in \mathbb{N}$ such that*

$$[\![BT(\mathcal{G}')]\!]_{\mathcal{X},s} = BT(\mathcal{G}).$$

▶ Remark 3.4. In Knapik et al. [33, 34] the lambda-tree T is denoted $\daleth_{\mathcal{G}}(X_0)$ (where X_0 is the starting nonterminal of $\mathcal{G}$), and the recursion scheme $\mathcal{G}'$ is denoted $\mathcal{G}^\alpha$. The set $\mathcal{X}$ is just the set of variables appearing in the letters used in $\mathcal{G}^\alpha$; the number s can be also read out of $\mathcal{G}^\alpha$. They prove that the $(\mathcal{X}, s)$-derived tree of $\daleth_{\mathcal{G}}(X_0)$ equals the tree generated by $\mathcal{G}$ [33, Proposition 4], that $\mathcal{G}^\alpha$ is safe [34, Lemma 3.5], and that $\mathcal{G}^\alpha$ generates $\daleth_{\mathcal{G}}(X_0)$.

In order to prove Lemma 3.3, one needs to replace in $\mathcal{G}$ every variable x of type o by $\overline{x}$, every lambda-binder concerning such a variable by $\overline{\lambda x}$, and every application with an argument of type o by a construct creating a @-labeled node. Types of subterms change and the order of the recursion scheme decreases by one. Notice, however, that while computing $BT(\Lambda(\mathcal{G}))$ we may need to rename variables during capture-avoiding substitutions, while in the tree generated by the modified recursion scheme we leave original variable names. In general (i.e., when the transformation is applied to an arbitrary recursion scheme) this causes a problem of overlapping variable names. The assumption that $\mathcal{G}$ is safe is crucial here and there is no need to rename variables when applying the transformation to a safe recursion scheme.

Having Lemma 3.3, it remains to transform a one-way B-automaton $\mathcal{A}$ operating on the tree generated by $\mathcal{G}$ into a two-way B-automaton $\mathcal{A}'$ operating on the lambda-tree generated by $\mathcal{G}'$, as described by the following lemma (as mentioned on page 5, we can assume that $\mathcal{G}$ is normalizing, which implies that $BT(\mathcal{G}')$ is normalizing: the tree $[\![BT(\mathcal{G}')]\!]_{\mathcal{X},s} = BT(\mathcal{G})$ does not contain $\perp$).

▶ **Lemma 3.5.** *Let $\mathcal{A}$ be an alternating one-way B-automaton over a finite alphabet $\mathbb{A}$, let $\mathcal{X}$ be a finite set of variables, and let $s \in \mathbb{N}$. One can construct an alternating two-way B-automaton $\mathcal{A}'$ such that for every normalizing lambda-tree T over $\mathbb{A}_{\mathcal{X}}$,*

$$\mathcal{A} \text{ accepts } [\![T]\!]_{\mathcal{X},s} \quad \text{if and only if} \quad \mathcal{A}' \text{ accepts } T.$$

Proof. The B-automaton $\mathcal{A}'$ simulates $\mathcal{A}$ on the lambda-tree. Whenever $\mathcal{A}$ wants to go down to the i-th child, $\mathcal{A}'$ has to follow the $(\mathcal{X}, s)$-maximal path from $(\uparrow_i, v)$ (where v is the current node). To this end, it has to remember the current pair (d, v), and repeatedly find its $(\mathcal{X}, s)$-successor. Here v is always just the current node visited by the B-automaton; the d component comes from the (finite) set $\mathit{Dirs}_{\mathcal{X},s}$, and thus it can be remembered in the state. It is straightforward to encode the definition of an $(\mathcal{X}, s)$-successor in transitions of an automaton. We do not have to worry about infinite $(\mathcal{X}, s)$-maximal paths, because by assumption the $(\mathcal{X}, s)$-derived tree does not contain $\perp$-labeled nodes. ◀

4 Downward closures of tree languages

In this section we lay down a method for the computation of the downward closure for classes of languages of finite trees closed under linear FTT transductions. This method is analogous to the one of Zetzsche [54] for the case of finite words. In Section 4.1 we define the downward closure of languages of finite ranked trees with respect to the embedding well-quasi order and in Section 4.2 we define the simultaneous unboundedness problem for trees and show how computing the downward closure reduces to it. In Section 4.3 we define the diagonal problem for finite trees and show how the previous problem reduces to it. We will then solve the diagonal problem for languages of finite trees recognized by safe recursion schemes in Section 5.

Let us emphasize that this section can be applied to any class of languages of finite trees closed under linear FTT transductions, not just those recognized by safe recursion schemes.

4.1 Preliminaries

Given two finite trees $S = a(S_1, \dots, S_k)$ and $T = b(T_1, \dots, T_r)$, we say that S *homeomorphically embeds into* T, written $S \sqsubseteq T$, if, either

1) there exists $i \in \{1, \dots, r\}$ such that $S \sqsubseteq T_i$, or

2) $a = b$, $k = r$, and $S_i \sqsubseteq T_i$ for all $i \in \{1, \dots, r\}$.

For a language of finite trees $\mathcal{L}$, its *downward closure*, denoted by $\mathcal{L}{\downarrow}$, is the set of trees S such that $S \sqsubseteq T$ for some tree $T \in \mathcal{L}$.

Pure products. Goubault-Larrecq and Schmitz [25] describe downward-closed sets of trees using so-called *simple tree regular expressions*. Among those expressions they distinguish *products*, which describe *ideals* of trees. Because every downward-closed set of trees is a finite union of ideals, such a set can be described by a finite list of products. Since their definition of a product is rather indirect, we consider the stronger notion of *pure products*.

A *context* is a tree possibly containing one or more occurrences of a special leaf $\square$, called a *hole*. Given a context C and a set of trees $\mathcal{L}$, we write $C[\mathcal{L}]$ for the set of trees obtained from C by replacing every occurrence of the hole $\square$ by some tree from $\mathcal{L}$. Different occurrences of $\square$ are replaced by possibly different trees from $\mathcal{L}$. The definition readily extends to a set of contexts $\mathcal{C}$, by writing $\mathcal{C}[\mathcal{L}]$ for $\bigcup_{C \in \mathcal{C}} C[\mathcal{L}]$. If C does not have any $\square$, then $C[\mathcal{L}]$ is just $\{C\}$. A *pure product* is defined according to the following abstract syntax:

$$P ::= a^?(P, \dots, P) \mid I^*.P, \qquad C ::= a(P_\square, \dots, P_\square),$$
$$I ::= C + \dots + C, \qquad P_\square ::= \square \mid P,$$

where the sum of contexts is nonempty, and where in a context $C = a(P_{\square,1}, \dots, P_{\square,r})$ it is required that at least one $P_{\square,i}$ is a hole $\square$. A pure product P denotes a set of trees $[\![P]\!]$ downward-closed for $\sqsubseteq$, which is defined recursively as follows:

$$\begin{aligned}
[\![a^?(P_1, \dots, P_r)]\!] &= \{a(T_1, \dots, T_r) \mid \forall i \,.\, T_i \in [\![P_i]\!]\} \cup [\![P_1]\!] \cup \dots \cup [\![P_r]\!],\\
[\![I^*.P]\!] &= \bigcup_{n \in \mathbb{N}} \underbrace{[\![I]\!][\dots[[\![I]\!]}_{n}[\![P]\!]]]\dots],\\
[\![C_1 + \dots + C_k]\!] &= [\![C_1]\!] \cup \dots \cup [\![C_k]\!],\\
[\![a(P_{\square,1}, \dots, P_{\square,r})]\!] &= \{a(T_1, \dots, T_r) \mid \forall i \,.\, T_i \in [\![P_{\square,i}]\!]\} \cup [\![P_{\square,1}]\!] \cup \dots \cup [\![P_{\square,r}]\!],\\
[\![\square]\!] &= \{\square\}\,.
\end{aligned}$$

For example, $[\![(a(b(), \square))^*.c^?()]\!]$ is the set of trees of the form either $b()$, or $c()$, or $a(b(), a(b(), \dots a(b(), x) \dots))$ with x either $b()$ or $c()$. Based on the results of Goubault-Larrecq and Schmitz [25] it is not difficult to deduce the following lemma (see [4, Appendix D] for a proof).

▶ **Lemma 4.1.** *Every set of trees $\mathcal{L}$ downward-closed for $\sqsubseteq$ can be represented as $\mathcal{L} = [\![P_1]\!] \cup \dots \cup [\![P_k]\!]$, in which $P_1, \dots, P_k$ are pure products.*

This decomposition result strengthens the results of Goubault-Larrecq and Schmitz [25] by showing that pure products (instead of just products) suffice in order to represent downward-closed sets of trees.

Transductions. A (nondeterministic) *finite tree transducer* (*FTT*) is a tuple $\mathcal{A} = (\mathbb{A}_{in}, \mathbb{A}_{out}, S, p^I, \delta)$, where $\mathbb{A}_{in}, \mathbb{A}_{out}$ are the input and output alphabets (finite, ranked), S is a finite set of *control states*, $p^I \in S$ is an *initial state*, and δ is a finite set of *transition rules* of the form either $(p, a(\mathsf{x}_1, \ldots, \mathsf{x}_r)) \to T$ or $(p, \mathsf{x}) \to T$, where $p \in S$ is a control state, $a \in \mathbb{A}_{in}$ is a letter of rank r, and T is a finite tree over the alphabet $\mathbb{A}_{out} \cup (S \times \{\mathsf{x}_1, \ldots, \mathsf{x}_r\})$ or $\mathbb{A}_{out} \cup (S \times \{\mathsf{x}\})$, respectively. The rank of all the pairs from $S \times \{\mathsf{x}_1, \ldots, \mathsf{x}_r\}$ or $S \times \{\mathsf{x}\}$ is 0. An FTT is *linear* if for each rule of the form $(p, a(\mathsf{x}_1, \ldots, \mathsf{x}_r)) \to T$ and for each $i \in \{1, \ldots, r\}$, in T there is at most one letter from $S \times \{\mathsf{x}_i\}$, and moreover for each rule of the form $(p, \mathsf{x}) \to T$, in T there is at most one letter from $S \times \{\mathsf{x}\}$. An FTT $\mathcal{A}$ defines in a natural way a relation between finite trees, also denoted $\mathcal{A}$ (c.f. Comon et al. [19]). For a language $\mathcal{L}$ we write $\mathcal{A}(\mathcal{L})$ for the set of trees U such that $(T, U) \in \mathcal{A}$ for some $T \in \mathcal{L}$. A function that maps $\mathcal{L}$ to $\mathcal{A}(\mathcal{L})$ for some linear FTT $\mathcal{A}$ is called a *linear FTT transduction.*

▶ **Fact 4.2.** *The downward closure operation $\mathcal{L} \mapsto \mathcal{L}{\downarrow}$ and the regular restriction operation $\mathcal{L} \mapsto \mathcal{L} \cap \mathcal{R}$ (for every regular language $\mathcal{R}$) are effectively linear FTT transductions.*

▶ **Lemma 4.3** (c.f. [4, Appendix E]). *The class of languages of finite trees recognized by safe recursion schemes is effectively closed under linear FTT transductions.*

4.2 The simultaneous unboundedness problem for trees

We say that a pure product P is *diversified*, if no letter appears in P more than once. The *simultaneous unboundedness problem* (*SUP*) for a class $\mathfrak{C}$ of finite trees asks, given a diversified pure product P and a language $\mathcal{L} \in \mathfrak{C}$ such that $\mathcal{L} \subseteq [\![P]\!]$, whether $[\![P]\!] \subseteq \mathcal{L}{\downarrow}$.

▶ Remark 4.4. This is a generalization of SUP over finite words. In the latter problem, one is given a language of finite words $\mathcal{L}$ such that $\mathcal{L} \subseteq a_1^* \ldots a_k^*$, and must check whether $a_1^* \ldots a_k^* \subseteq \mathcal{L}{\downarrow}$. A word in $a_1^* \ldots a_k^*$ can be represented as a linear tree by interpreting $a_1, \ldots, a_k$ as unary letters and by appending a new leaf e at the end. Thus $a_1^* \ldots a_k^*$ can be represented as the language of the diversified pure product $(a_1(\Box))^*.(a_2(\Box))^*. \cdots .(a_k(\Box))^*.e^?()$.

Following Zetzsche [54], we can reduce the computation of the downward closure to SUP.

▶ **Theorem 4.5** (c.f. [4, Appendix F]). *Let $\mathfrak{C}$ be a class of languages of finite trees closed under linear FTT transductions. One can compute a finite tree automaton recognizing the downward closure of a given language from $\mathfrak{C}$ if and only if SUP is decidable for $\mathfrak{C}$.*

▶ Remark 4.6. Pure products for trees correspond to expressions of the form $a_0^? A_1^* a_1^? \ldots A_k^* a_k^?$ for words (where A_i are sets of letters). In SUP for words simpler expressions of the form $b_1^* \ldots b_k^*$ suffice. This is not possible for trees:

1) expressions of the form $a^?(\cdot, \cdot)$ cannot be removed since they are responsible for branching, and
2) reducing the two contexts in $(a(P_1, \Box) + b(P_2, \Box))^*.P_3$ to a single one would require changing trees of the form $a(T_1, b(T_2, T_3))$ into trees of the form $c(T_1, T_2, T_3)$, which is not a linear FTT transduction.

4.3 The diagonal problem for trees

In SUP for words, instead of checking whether $a_1^* \dots a_k^* \subseteq \mathcal{L}{\downarrow}$, one can equivalently check whether, for each $n \in \mathbb{N}$, there is a word $a_1^{x_1} \dots a_k^{x_k} \in \mathcal{L}$ such that $x_1, \dots, x_k \geq n$. The latter problem is known as the *diagonal problem* for words. In this section, we define an analogous diagonal problem for trees, and we show how to reduce SUP to it.

Given a set of letters Σ, we say that a language of finite trees $\mathcal{L}$ is Σ-*diagonal* if, for every $n \in \mathbb{N}$, there is a tree $T \in \mathcal{L}$ such that for every letter $a \in \Sigma$ and every branch B of T there are at least n occurrences a in B. The *diagonal problem* for a class $\mathfrak{C}$ of finite trees asks, given a language $\mathcal{L} \in \mathfrak{C}$ and a set of letters Σ, whether $\mathcal{L}$ is Σ-diagonal.

Versatile trees. Contrary to the case of words, the presence of sums in our expressions creates some complications in reducing from SUP to the diagonal problem. We deal with these sums by introducing the notion of *versatile trees*. Intuitively, in order to obtain a versatile tree of a pure product P, for every sum $I = C_1 + \dots + C_k$ in P we fix some order of the contexts $C_1, \dots, C_k$, and we allow the contexts to be appended in this order. Formally, the set $(\!|P|\!)$ of versatile trees of a pure product P is defined by structural induction on P:

$$\begin{aligned}
(\!|I^*.P|\!) &= \bigcup_{n\in\mathbb{N}} (\!|I|\!)[\underbrace{((\!|I|\!) \cup \{\square\})[\dots[((\!|I|\!) \cup \{\square\})[}_{n}(\!|P|\!)]]\dots]],\\
(\!|a^?(P_1, \dots, P_r)|\!) &= (\!|a(P_1, \dots, P_r)|\!),\\
(\!|C_1 + \dots + C_k|\!) &= (\!|C_1|\!)[\dots[(\!|C_k|\!)]\dots],\\
(\!|a(P_{\square,1}, \dots, P_{\square,r})|\!) &= \{a(T_1, \dots, T_r) \mid \forall i\,.\,T_i \in (\!|P_{\square,i}|\!)\}\,,\\
(\!|\square|\!) &= \{\square\}\,.
\end{aligned}$$

For example, if $I = a(S_1, \square, \square) + b(\square, S_2)$, then $(\!|I|\!) = \{a(S_1, b(\square, S_2), b(\square, S_2))\}$. Notice that all trees in $(\!|P|\!)$ have the same root's label; denote this label by *root*(P).

From SUP to the diagonal problem. Assuming that P is diversified, for a number $n \in \mathbb{N}$ we say that a tree T is *n-large with respect to P* if, for every subexpression of P of the form $I^*.P'$, above every occurrence of *root*(P') in T there are at least n ancestors labeled by *root*$(I^*.P')$. In other words, for $T \in (\!|P|\!)$ this means that in T every context appearing in P was appended at least n times, on all branches where it was possible to append it. Clearly $(\!|P|\!) \subseteq [\![P]\!]$. On the other hand, every tree from $[\![P]\!]$ can be embedded into every large enough versatile tree. We thus obtain the following lemma.

▶ **Lemma 4.7.** *For every diversified pure product P, and for every sequence of trees $T_1, T_2, \dots \in (\!|P|\!)$ such that every T_n is n-large, $\{T_n \mid n \in \mathbb{N}\}{\downarrow} = [\![P]\!]$.*

Using versatile trees we can reduce from SUP to the diagonal problem.

▶ **Lemma 4.8** (c.f. [4, Appendix G]). *Let $\mathfrak{C}$ be a class of languages of finite trees closed under linear FTT transductions. SUP for $\mathfrak{C}$ reduces to the diagonal problem for $\mathfrak{C}$.*

▶ Remark 4.9. Another formulation of the diagonal problem for languages of finite trees [29, 14, 45] requires that, for every $n \in \mathbb{N}$, there is a tree $T \in \mathcal{L}$ containing at least n occurrences of every letter $a \in \Sigma$ (not necessarily on the same branch, unlike in our case). Such a formulation of the diagonal problem seems too weak to compute downward closures for languages of finite trees.

5 Languages of safe recursion schemes

In the previous section, we have developed a general machinery allowing one to compute downward closures for classes of languages of finite trees closed under linear FTT transductions. In this section, we apply this machinery to the particular case of languages recognized by safe recursion schemes. The following is the main theorem of this section.

▶ **Theorem 5.1.** *Finite tree automata recognizing downward closures of languages of finite trees recognised by safe recursion schemes are computable.*

In order to prove the theorem we need to recall a formalism necessary to express the diagonal problem in logic.

Cost logics. *Cost monadic logic* (*CMSO*) was introduced in Colcombet [15] as a quantitative extension of monadic second-order logic. As usual, the logic can be defined over any relational structure, but we restrict our attention to CMSO over trees. In addition to *first-order variables* ranging over nodes of the tree and *monadic second-order variables* (also called *set variables*) ranging over sets of nodes, CMSO uses a single additional variable N, called the *numeric variable*, which ranges over $\mathbb{N}$. The atomic formulas in CMSO are those from *MSO* (the membership relation $x \in X$ and relations $a(x, x_1, \dots, x_r)$ asserting that $a \in \mathbb{A}$ of rank r is the label at node x with children $x_1, \dots, x_r$ from left to right), as well as a new predicate $|X| \leqslant N$, where X is any set variable and N is the numeric variable. Arbitrary CMSO formulas are built inductively by applying Boolean connectives and by quantifying (existentially or universally) over first-order or set variables. We require that any predicates of the form $|X| \leqslant N$ appear positively in the formula (i.e., within the scope of an even number of negations). We regard N as a parameter. As usual, a *sentence* is a formula without first-order or monadic *free variables*; however, the parameter N is allowed to occur in a sentence. If we fix a value $n \in \mathbb{N}$ for N, the semantics of $|X| \leqslant N$ is what one would expect: the predicate holds when X has cardinality at most n. We say that a sentence φ *n-accepts* a tree T if it holds in T when n is used as value of N; it *accepts* T if it n-accepts T for some $n \in \mathbb{N}$. The language *defined* by φ is the set of all trees (over a fixed alphabet $\mathbb{A}$) accepted by φ.

Weak cost monadic logic (*WCMSO* for short) is the variant of CMSO where the second-order quantification is restricted to finite sets. Vanden Boom [53, Theorem 2] proves that WCMSO is effectively equivalent to a subclass of alternating B-automata, called *weak B-automata*. Thanks to Theorem 3.1, we obtain the following corollary.

▶ **Corollary 5.2.** *The model-checking problem of safe recursion schemes against WCMSO properties is decidable.*

▶ Remark 5.3. The same holds for a more expressive logic called *quasi-weak cost monadic logic* (*QWCMSO*) [6], whose expressive power lies between WCMSO and the CMSO. Indeed, Blumensath et al. [6, Theorem 2] prove that QWCMSO is effectively equivalent to a subclass of alternating B-automata called *quasi-weak B-automata*, and thus by Theorem 3.1 even model checking of safe recursion schemes against QWCMSO properties is decidable.

Solving the diagonal problem. By Theorem 4.5 and Lemma 4.8, all we need to do is to show that the diagonal problem is decidable for languages recognized by safe recursion schemes, that is, that given a safe recursion scheme $\mathcal{G}$ and a set of letters Σ, one can check whether for every $n \in \mathbb{N}$ there is a tree $T \in \mathcal{L}(\mathcal{G})$ such that there are at least n occurrences of every letter $a \in \Sigma$ on every branch of T (we say that such a tree T is *n-large with respect* *to* Σ). In order to do this, given a set of letters Σ, we write a WCMSO sentence φ_Σ that n-accepts an (infinite) tree T if and only if no tree in $\mathcal{L}(T)$ is n-large with respect to Σ. Consequently, φ_Σ accepts T if for some n no tree in $\mathcal{L}(T)$ is n-large with respect to Σ, that is, if $\mathcal{L}(T)$ is not Σ-diagonal. Thus, in order to solve the diagonal problem, it is enough to check whether φ_Σ accepts $BT(\mathcal{G})$ (recall that $\mathcal{L}(\mathcal{G})$ is defined as $\mathcal{L}(BT(\mathcal{G}))$), which is decidable by Corollary 5.2. It remains to construct the aforementioned sentence φ_Σ.

First, observe that the process of producing a finite tree recognized by $\mathcal{G}$ from the infinite tree $BT(\mathcal{G})$ generated by $\mathcal{G}$ is expressible by a formula of WCMSO (actually, by a first-order formula). More precisely we can write a WCMSO formula $\mathsf{tree}(X)$ that holds in a tree T if and only if X is instantiated to a set of nodes of a tree $T' \in \mathcal{L}(T)$, together with their nd-labeled ancestors. See [4, Appendix H] for more details. Using $\mathsf{tree}(X)$ we now construct the desired formula φ_Σ, and thus we finish the proof of Theorem 5.1.

▶ **Lemma 5.4.** *Given a set of letters Σ, one can compute a WCMSO sentence φ_Σ that, for every $n \in \mathbb{N}$, n-accepts a tree T if and only if no tree in $\mathcal{L}(T)$ is n-large with respect to Σ.*

Proof. We can reformulate the property as follows: for every tree $T' \in \mathcal{L}(T)$ there is a letter $a \in \Sigma$, and a leaf x that has less than n a-labeled ancestors. This is expressed by the following formula of WCMSO (where $\mathsf{leaf}(x)$ states that the node x is a leaf, $a(x)$ that x has label a, and $z \le x$ that z is an ancestor of x, all being easily expressible):

$$\forall X.\Big(\mathsf{tree}(X) \to \bigvee_{a\in\Sigma} \exists x \exists Z.\big(x \in X \wedge \mathsf{leaf}(x) \wedge \forall z.(z \le x \wedge a(z) \to z \in Z) \wedge |Z| < N\big)\Big). \quad ◀$$

6 Conclusions

A tantalising direction for further work is to drop the safety assumption from Theorem 3.1, that is, to establish whether the model-checking problem against B-automata is decidable for trees generated by (not necessarily safe) recursion schemes. We also leave open whether downward closures are computable for this more expressive class. Another direction for further work is to analyse the complexity of the considered model-checking problem. The related problem described in Remark 4.9 is k-EXP-complete for languages of finite trees recognised by recursion schemes of order k [45], and thus not harder than the nonemptiness problem [43]. Does the same upper bound hold for the more general diagonal problem that we consider in this paper? Zetzsche [56] has shown that the downward closure inclusion problem is co-k-NEXP-hard for languages of finite trees recognised by safe recursion schemes of order k. Is it possible to obtain a matching upper bound?

Abstract

We investigate the impact of modifying the constraining relations of a Constraint Satisfaction Problem (CSP) instance, with a fixed template, on the set of solutions of the instance. More precisely we investigate sensitive instances: an instance of the CSP is called sensitive, if removing any tuple from any constraining relation invalidates some solution of the instance. Equivalently, one could require that every tuple from any one of its constraints extends to a solution of the instance.

Clearly, any non-trivial template has instances which are not sensitive. Therefore we follow the direction proposed (in the context of strict width) by Feder and Vardi in [13] and require that only the instances produced by a local consistency checking algorithm are sensitive. In the language of the algebraic approach to the CSP we show that a finite idempotent algebra $\mathbf{A}$ has a $k+2$ variable near unanimity term operation if and only if any instance that results from running the $(k,k+1)$-consistency algorithm on an instance over $\mathbf{A}^2$ is sensitive.

A version of our result, without idempotency but with the sensitivity condition holding in a variety of algebras, settles a question posed by G. Bergman about systems of projections of algebras that arise from some subalgebra of a finite product of algebras.

Our results hold for infinite (albeit in the case of $\mathbf{A}$ idempotent) algebras as well and exhibit a surprising similarity to the strict width k condition proposed by Feder and Vardi. Both conditions can be characterized by the existence of a near unanimity operation, but the arities of the operations differ by 1.

1 Introduction

One important algorithmic approach to deciding if a given instance of the Constraint Satisfaction Problem (CSP) has a solution is to first consider whether it has a consistent set of local solutions. Clearly, the absence of local solutions will rule out having any (global) solutions, but in general having local solutions does not guarantee the presence of a solution. A major thrust of the recent research on the CSP has focused on coming up with suitable notions of local consistency and then characterizing those CSPs for which local consistency implies outright consistency or some stronger property. A good source for background material is the survey article [7].

Early results of Feder and Vardi [13] and also Jeavons, Cooper, and Cohen [15] establish that when a template (i.e., a relational structure) $\mathbb{A}$ has a special type of polymorphism, called a near unanimity operation, then not only will an instance of the CSP over $\mathbb{A}$ that has a suitably consistent set of local solutions have a solution, but that any partial solution of it can always be extended to a solution. The notion of local consistency that we investigate in this paper is related to that considered by these researchers but that, as we shall see, is weaker.

The following operations are central to our investigation.

▶ **Definition 1.** *An operation $n(x_1, \dots, x_{k+1})$ on a set A of arity $k+1$ is called a* near unanimity operation on A *if it satisfies the equalities*

$$n(b, a, a, \dots, a) = n(a, b, a, \dots, a) = \dots = n(a, a, \dots, a, b) = a$$

for all a, $b \in A$.

Near unanimity operations have played an important role in the development of universal algebra and first appeared in the 1970's in the work of Baker and Pixley [1] and Huhn [14]. More recently they have been used in the study of the CSP [13, 15] and related questions [2, 12]. The main results of this paper can be expressed in terms of the CSP and also in algebraic terms and we start by presenting them from both perspectives. In the concluding section, Section 6, a translation of parts of our results into a relational language is provided, along with some open problems.

1.1 CSP viewpoint

In their seminal paper, Feder and Vardi [13] introduced the notion of bounded width for the class of CSP instances over a finite template $\mathbb{A}$. Their definition of bounded width was presented in terms of the logic programming language DATALOG but there is an equivalent formulation using local consistency algorithms, also given in [13]. Given a CSP instance $\mathcal{I}$ and $k < l$, the (k, l)-consistency algorithm will produce a new instance having all k variable constraints that can be inferred by considering l variables at a time of $\mathcal{I}$. This algorithm rejects $\mathcal{I}$ if it produces an empty constraint. The class of CSP instances over a finite template $\mathbb{A}$ will have width (k, l) if the (k, l)-consistency algorithm rejects all instances from the class that do not have solutions, i.e., the (k, l)-consistency algorithm can be used to decide if a given instance from the class has a solution or not. The class has bounded width if it has width (k, l) for some $k < l$.

A lot of effort, in the framework of the algebraic approach to the CSP, has gone in to analyzing various properties of instances that are the outputs of these types of local consistency algorithms. On one end of the spectrum of the research is a rather wide class of templates of bounded width [5] and on the other a very restrictive class of templates having bounded strict width [13].

To be more precise, we now formally introduce instances of the CSP.

▶ **Definition 2.** *An* instance $\mathcal{I}$ *of the* CSP *is a pair* $(V, \mathcal{C})$ *where* V *is a finite set of variables, and* $\mathcal{C}$ *is a set of constraints of the form* $((x_1, \dots, x_n), R)$ *where all* x_i *are in* V *and* R *is an* n*-ary relation over (possibly infinite) sets* A_i *associated to each variable* x_i*.*

A solution *of* $\mathcal{I}$ *is an evaluation* f *of variables such that, for every* $((x_1, \dots, x_n), R) \in \mathcal{C}$ *we have* $(f(x_1), \dots, f(x_n)) \in R$*;* a partial solution *is a partial function satisfying the same condition.*

The CSP over a relational structure $\mathbb{A}$*, written* $\mathsf{CSP}(\mathbb{A})$*, is the class of* CSP *instances whose constraint relations are from* $\mathbb{A}$*.*

▶ **Example 3.** For $k > 1$, the template associated with the graph k-colouring problem is the relational structure $\mathbb{D}_{k\text{colour}}$ that has universe $\{0, 1, \dots, k-1\}$ and a single relation $\neq_k = \{(x, y) \mid x, y < k \text{ and } x \neq y\}$. The template associated with the HORN-3-SAT problem is the relational structure $\mathbb{D}_{\text{horn}}$ that has universe $\{0, 1\}$ and two ternary relations R_0, R_1, where R_i contains all the triples but $(1, 1, i)$. It is known that $\mathsf{CSP}(\mathbb{D}_{\text{horn}})$ has width $(1, 2)$, that $\mathsf{CSP}(\mathbb{D}_{2\text{colour}})$ has width $(2, 3)$, and that for $k > 2$, $\mathsf{CSP}(\mathbb{D}_{k\text{colour}})$ does not have bounded width (see [7]).

Instances produced by the (k, l)-consistency algorithm have uniformity and consistency properties that we highlight.

▶ **Definition 4.** *The* CSP *instance* $\mathcal{I}$ *is* k-uniform *if all of its constraints are* k*-ary and every set of* k *variables is constrained by a single constraint.*

An instance is a (k, l)-instance *if it is* k*-uniform and for every choice of a set* W *of* l *variables no additional information about the constraints can be derived by restricting the instance to the variables in* W*.*

This last, very important, property can be rephrased in the following way: for every set $W \subseteq V$ of size l, every tuple in every constraint of $\mathcal{I}_{|W}$ participates in a solution to $\mathcal{I}_{|W}$ (where $\mathcal{I}_{|W}$ is obtained from $\mathcal{I}$ by removing all the variables outside of W and all the constraints that contain any such variables).

Consider the notion of strict width k introduced by Feder and Vardi [13, Section 6.1.2]. Let $\mathbb{A}$ be a template and let us assume, to avoid some technical subtleties, that every relation in $\mathbb{A}$ has arity at most k. The class $\mathsf{CSP}(\mathbb{A})$ has *strict width* (k, l) if whenever the (k, l)-consistency algorithm does not reject an instance $\mathcal{I}$ from the class then “it should be possible to obtain a solution by greedily assigning values to the variables one at a time while satisfying the inferred k-constraints.” In other words, if $\mathcal{I}$ is the result of applying the (k, l)-consistency algorithm to an instance of $\mathsf{CSP}(\mathbb{A})$, then any partial solution of $\mathcal{I}$ over at least k variables can be extended to a solution. The template $\mathbb{A}$ is said to have *strict width* k if it has strict width (k, l) for some $l > k$.

A *polymorphism* of a template $\mathbb{A}$ is a function on A that preserves all of the relations of $\mathbb{A}$. Feder and Vardi prove the following.

▶ **Theorem 5** (see Theorem 25, [13])**.** *Let* $k > 1$ *and let* $\mathbb{A}$ *be a finite relational structure with relations of arity at most* k*. The class* $\mathsf{CSP}(\mathbb{A})$ *has strict width* k *if and only if it has strict width* $(k, k+1)$ *if and only if* $\mathbb{A}$ *has a* $(k+1)$*-ary near unanimity operation as a polymorphism.*

Using this Theorem we can conclude that $\mathsf{CSP}(\mathbb{D}_{\mathrm{2colour}})$ from Example 3 has strict width 2 since the ternary majority operation preserves the relation $\neq_2$. In fact this operation preserves all binary relations over the set $\{0,1\}$. On the other hand, $\mathsf{CSP}(\mathbb{D}_{\mathrm{horn}})$ does not have strict width k for any $k \geq 3$.

Following the algebraic approach to the CSP we replace templates $\mathbb{A}$ with algebras $\mathbf{A}$.

▶ **Definition 6.** *An* algebra $\mathbf{A}$ *is a pair* $(A, \mathcal{F})$ *where* A *is a non-empty set, called the* universe *of* $\mathbf{A}$ *and* $\mathcal{F} = (f_i \mid i \in I)$ *is a set of finitary operations on* A *called the* set of basic operations of $\mathbf{A}$. *The function that assigns the arity of the operation* f_i *to* i *is called the* signature of $\mathbf{A}$. *If* $t(x_1, \dots, x_n)$ *is a term in the signature of* $\mathbf{A}$ *then the interpretation of* t *by* $\mathbf{A}$ *as an operation on* A *is called a* term operation of $\mathbf{A}$ *and is denoted by* $t^{\mathbf{A}}$.

The CSP over $\mathbf{A}$, *written* $\mathsf{CSP}(\mathbf{A})$, *is the class of* CSP *instances whose constraint relations are amongst those relations over* A *that are preserved by the operations of* $\mathbf{A}$ *(i.e., they are subuniverses of powers of* $\mathbf{A}$*).*

A number of important questions about the CSP can be reduced to considering templates that have all of the singleton unary relations [7]; the algebraic counterpart to these types of templates are the *idempotent algebras.*

▶ **Definition 7.** *An operation* $f : A^n \to A$ *on a set* A *is* idempotent *if* $f(a, a, \dots, a) = a$ *for all* $a \in A$. *An algebra* $\mathbf{A}$ *is* idempotent *if all of its basic operations are.*

It follows that if $\mathbf{A}$ is idempotent then every term operation of $\mathbf{A}$ is an idempotent operation. As demonstrated in Example 22, several of the results in this paper do not hold in the absence of idempotency.

The characterization of strict width in Theorem 5 has the following consequence in terms of algebras.

▶ **Corollary 8.** *Let* $k > 1$ *and let* $\mathbb{A}$ *be a finite relational structure with relations of arity at most* k. *Let* $\mathbf{A}$ *be the algebra with the same universe as* $\mathbb{A}$ *whose basic operations are exactly the polymorphisms of* $\mathbb{A}$. *The following are equivalent:*

1. $\mathbf{A}$ *has a near unanimity term operation of arity* $k+1$*;*
2. *in every* $(k, k+1)$*-instance over* $\mathbf{A}$, *every partial solution extends to a solution.*

The implication “1 implies 2” in Corollary 8 remains valid for general algebras, not necessarily coming from finite relational structures with restricted arities of relations. However, the converse implication fails even if $\mathbf{A}$ is assumed to be finite and idempotent.

▶ **Example 9.** Consider the rather trivial algebra $\mathbf{A}$ that has universe $\{0,1\}$ and no basic operations. If $\mathcal{I}$ is a $(2,3)$-instance over $\mathbf{A}$ then since, as noted just after Theorem 5, every binary relation over $\{0,1\}$ is invariant under the ternary majority operation on $\{0,1\}$ it follows that every partial solution of $\mathcal{I}$ can be extended to a solution. Of course, $\mathbf{A}$ does not have a near unanimity term operation of any arity.

What this example demonstrates is that in general, for a fixed k, the k-ary constraint relations arising from an algebra do not capture that much of the structure of the algebra. Example 22 provides further evidence for this.

Our first theorem shows that for finite idempotent algebras $\mathbf{A}$, by considering a slightly bigger set of $(k, k+1)$-instances, over $\mathsf{CSP}(\mathbf{A}^2)$, rather than over $\mathsf{CSP}(\mathbf{A})$, we can detect the presence of a $(k+1)$-ary near unanimity term operation. Moreover, it is enough to consider only instances with $k+2$ variables. We note that every $(k, k+1)$-instance over $\mathbf{A}$ can be easily encoded as a $(k, k+1)$-instance over $\mathbf{A}^2$.

▶ **Theorem 10.** *Let* $\mathbf{A}$ *be a finite, idempotent algebra and* $k > 1$*. The following are equivalent:*

1. $\mathbf{A}$ *(or equivalently* $\mathbf{A}^2$*) has a near unanimity term operation of arity* $k + 1$*;*
2. *in every* $(k, k + 1)$*-instance over* $\mathbf{A}^2$*, every partial solution extends to a solution;*
3. *in every* $(k, k + 1)$*-instance over* $\mathbf{A}^2$ ***on*** $k + 2$ ***variables****, every partial solution extends to a solution.*

In Theorem 20 we extend our result to infinite idempotent algebras by working with local near unanimity term operations.

Going back the original definition of strict width: “it should be possible to obtain a solution by greedily assigning values to the variables one at a time while satisfying the inferred k-constraints” we note that the requirement that the assignment should be greedy is rather restrictive. The main theorem of this paper investigates an arguably more natural concept where the assignment need not be greedy.

▶ **Definition 11.** *An instance of the* CSP *is called* sensitive*, if removing any tuple from any constraining relation invalidates some solution of the instance.*

In other words, an instance is sensitive if every tuple in every constraint of the instance extends to a solution. For $(k, k + 1)$-instances, being sensitive is equivalent to the instance being a (k, n)-instance, where n is the number of variables present in the instance. We provide the following characterization.

▶ **Theorem 12.** *Let* $\mathbf{A}$ *be a finite, idempotent algebra and* $k > 1$*. The following are equivalent:*

1. $\mathbf{A}$ *(or equivalently* $\mathbf{A}^2$*) has a near unanimity term operation of arity* $k + 2$*;*
2. *every* $(k, k + 1)$*-instance over* $\mathbf{A}^2$ *is sensitive;*
3. *every* $(k, k + 1)$*-instance over* $\mathbf{A}^2$ ***on*** $\boldsymbol{k + 2}$ ***variables*** *is sensitive.*

Exactly as in Theorem 10 we can consider infinite algebras at the cost of using local near unanimity term operations (see Theorem 21).

In conclusion we investigate a natural property of instances motivated by the definition of strict width and provide a characterization of this new condition in algebraic terms. A surprising conclusion is that the new concept is, in fact, very close to the strict width concept, i.e., for a fixed k one characterization is equivalent to a near unanimity operation of arity $k + 1$ and the second of arity $k + 2$.

1.2 Algebraic viewpoint

Our work has as an antecedent the papers of Baker and Pixley [1] and of Bergman [8] on algebras having near unanimity term operations. In these papers the authors considered subalgebras of products of algebras and systems of projections associated with them. Baker and Pixley showed that in the presence of a near unanimity term operation, such a subalgebra is closely tied with its projections onto small sets of coordinates.

▶ **Definition 13.** *A* variety of algebras *is a class of algebras of the same signature that is closed under taking homomorphic images, subalgebras, and direct products. For* $\mathbf{A}$ *an algebra,* $\mathcal{V}(\mathbf{A})$ *denotes the smallest variety that contains* $\mathbf{A}$ *and is called the* variety generated by $\mathbf{A}$*. A variety* $\mathcal{V}$ *has a near unanimity term of arity* $k + 1$ *if there is some* $(k + 1)$*-ary term in the signature of* $\mathcal{V}$ *whose interpretation in each member of* $\mathcal{V}$ *is a near unanimity operation.*

Here is one version of the Baker-Pixley Theorem:

▶ **Theorem 14** (see Theorem 2.1 from [1]). *Let $\mathbf{A}$ be an algebra and $k > 1$. The following are equivalent:*

1. $\mathbf{A}$ *has a $(k+1)$-ary near unanimity term operation;*
2. *for every $r > k$ and every $\mathbf{A}_i \in \mathcal{V}(\mathbf{A})$, $1 \leq i \leq r$, every subalgebra $\mathbf{R}$ of $\prod_{i=1}^{r} \mathbf{A}_i$ is **uniquely** determined by the projections of R on all products $A_{i_1} \times \cdots \times A_{i_k}$ for $1 \leq i_1 < i_2 < \cdots < i_k \leq r$;*
3. *the same as condition 2, with r set to $k+1$.*

In other words, an algebra has a $(k+1)$-ary near unanimity term operation if and only if every subalgebra of a product of algebras from $\mathcal{V}(\mathbf{A})$ is uniquely determined by its system of k-fold projections into its factor algebras. A natural question, extending the result above, was investigated by Bergman [8]: when does a given "system of k-fold projections" arise from a product algebra?

Note that such a system can be viewed as a k-uniform CSP instance: indeed, following the notation of Theorem 14, we can introduce a variable x_i for each $i \leq r$ and a constraint $((x_{i_1}, \ldots, x_{i_k}); \mathrm{proj}_{i_1,\ldots,i_k} R)$ for each $1 \leq i_1 < i_2 < \cdots < i_k \leq r$. In this way the original relation R consists of solutions of the created instance (but in general will not contain all of them). In this particular instance, different variables can be evaluated in different algebras. Note that the instance is sensitive, if and only if it "arises from a product algebra" in the sense investigated by Bergman.

We will say that $\mathcal{I}$ is a CSP instance *over the variety $\mathcal{V}$ (denoted $\mathcal{I} \in \mathsf{CSP}(\mathcal{V})$)* if all the constraining relations of $\mathcal{I}$ are algebras in $\mathcal{V}$. In the language of the CSP, Bergman proved the following:

▶ **Theorem 15** ([8]). *If $\mathcal{V}$ is a variety that has a $(k+1)$-ary near unanimity term then every $(k, k+1)$-instance over $\mathcal{V}$ is sensitive.*

In commentary that Bergman provided on his proof of this theorem he noted that a stronger conclusion could be drawn from it and he proved the following theorem. We note that this theorem anticipates the results from [13] and [15] dealing with templates having near unanimity operations as polymorphisms.

▶ **Theorem 16** ([8]). *Let $k > 1$ and $\mathcal{V}$ be a variety. The following are equivalent:*

1. $\mathcal{V}$ *has a $(k+1)$-ary near unanimity term;*
2. *any partial solution of a $(k, k+1)$-instance over $\mathcal{V}$ extends to a solution.*

Theorem 15 provides a partial answer to the question that Bergman posed in [8], namely that in the presence of a $(k+1)$-ary near unanimity term, a necessary and sufficient condition for a k-fold system of algebras to arise from a product algebra is that the associated CSP instance is a $(k, k+1)$-instance.

In [8] Bergman asked whether the converse to Theorem 15 holds, namely, that if all $(k, k+1)$-instances over a variety are sensitive, must the variety have a $(k+1)$-ary near unanimity term? He provided examples that suggested that the answer is no, and we confirm this by proving that the condition is actually equivalent to the variety having a near unanimity term of arity $k+2$. The main result of this paper, viewed from the algebraic perspective (but stated in terms of the CSP), is the following:

▶ **Theorem 17.** *Let $k > 1$. A variety $\mathcal{V}$ has a $(k+2)$-ary near unanimity term if and only if each $(k, k+1)$-instance of the* CSP *over $\mathcal{V}$ is sensitive.*

The "if" direction of this theorem is proved in Section 3, while a sketch of a proof of the "only if" direction can be found in Section 5 (the complete reasoning is included in the full version of this paper). We note that a novel and significant feature of this result is that it does not assume any finiteness or idempotency of the algebras involved.

1.3 Structure of the paper

The paper is structured as follows. In the next section we introduce local near unanimity operations and state Theorem 10 and Theorem 12 in their full power. In Section 3 we collect the proofs that establish the existence of (local) near unanimity operations. Section 4 contains a proof of a new loop lemma, which can be of independent interest, and is necessary in the proof in Section 5. In Section 5 we provide a sketch of the proof showing that, in the presence of a near unanimity operation of arity $k+2$, the $(k, k+1)$-instances are sensitive. A complete proof of this fact, which is our main contribution, can be found in the full version of this paper. Finally, Section 6 contains conclusions.

2 Details of the CSP viewpoint

In order to state our results in their full strength, we need to define local near unanimity operations. This special concept of local near unanimity operations is required, when considering infinite algebras.

▶ **Definition 18.** *Let $k > 1$. An algebra $\mathbf{A}$ has* local near unanimity term operations of arity $k+1$ *if for every finite subset S of A there is some $(k+1)$-ary term operation n_S of $\mathbf{A}$ such that*

$$n_S(b, a, \ldots, a, a) = n_S(a, b, a, \ldots, a) = \cdots = n_S(a, a, \ldots, b, a) = n_S(a, a, \ldots, a, b) = a.$$

for all a, $b \in S$.

It should be clear that, for finite algebras, having local near unanimity term operations of arity $k+1$ and having a near unanimity term operation of arity $k+1$ are equivalent, but for arbitrary algebras they are not. The following provides a characterization of when an idempotent algebra has local near unanimity term operations of some given arity; it will be used in the proofs of Theorems 20 and 21. It is similar to Theorem 14 and is proved in the full version of this paper.

▶ **Theorem 19.** *Let $\mathbf{A}$ be an idempotent algebra and $k > 1$. The following are equivalent:*

1. *$\mathbf{A}$ has local near unanimity term operations of arity $k+1$;*
2. *for every $r > k$, every subalgebra of $\mathbf{A}^r$ is uniquely determined by its projections onto all k-element subsets of coordinates;*
3. *every subalgebra of $\mathbf{A}^{k+1}$ is uniquely determined by its projections onto all k-element subsets of coordinates.*

We are ready to state Theorem 10 in its full strength:

▶ **Theorem 20.** *Let $\mathbf{A}$ be an idempotent algebra and $k > 1$. The following are equivalent:*

1. *$\mathbf{A}$ (or equivalently $\mathbf{A}^2$) has local near unanimity term operations of arity $k+1$;*
2. *in every $(k, k+1)$-instance over $\mathbf{A}^2$, every partial solution extends to a solution;*
3. *in every $(k, k+1)$-instance over $\mathbf{A}^2$ **on** $k+2$ **variables**, every partial solution extends to a solution.*

Proof. Obviously condition 2 implies condition 3. A proof of condition 3 implying condition 1 can be found in Section 3. The implication from 1 to 2 is covered by Theorem 16. ◀

Analogously, the main result of the paper, for idempotent algebras, and the full version of Theorem 12 states:

▶ **Theorem 21.** *Let* $\mathbf{A}$ *be an idempotent algebra and* $k > 1$. *The following are equivalent:*

1. $\mathbf{A}$ *(or equivalently* $\mathbf{A}^2$*) has local near unanimity term operations of arity* $k+2$*;*
2. *every* $(k, k+1)$*-instance over* $\mathbf{A}^2$ *is sensitive;*
3. *every* $(k, k+1)$*-instance over* $\mathbf{A}^2$ ***on*** $\boldsymbol{k+2}$ ***variables*** *is sensitive.*

Proof. Obviously condition 2 implies condition 3. For a proof that condition 3 implies condition 1 see Section 3. A sketch of the proof of the remaining implication can be found in Section 5 (see the full version of this paper for a complete proof). ◀

The following examples show that in Theorems 19, 20, and 21 the assumption of idempotency is necessary.

▶ **Example 22.** For $n > 2$, let $\mathbf{S}_n$ be the algebra with domain $[n] = \{1, 2, \dots, n\}$ and with basic operations consisting of all unary operations on $[n]$ and all non-surjective operations on $[n]$ of arbitrary arity. The collection of such operations forms a finitely generated clone, called the Słupecki clone. Relevant details of these algebras can be found in [16, Example 4.6] and [20]. It can be shown that for $m < n$, the subuniverses of $\mathbf{S}_n^m$ consist of all m-ary relations R_θ over $[n]$ determined by a partition θ of $[m]$ by

$$R_\theta = \{(a_1, \dots, a_m) \mid a_i = a_j \text{ whenever } (i, j) \in \theta\}.$$

These rather simple relations are preserved by any operation on $[n]$, in particular by any majority operation or more generally, by any near unanimity operation.

It follows from Theorem 16 that if $k > 1$ and $\mathcal{I}$ is a $(k, k+1)$-instance of $\mathsf{CSP}(\mathbf{S}_{2k+1}^2)$ then any partial solution of $\mathcal{I}$ extends to a solution. This also implies that $\mathcal{I}$ is sensitive. Furthermore any subalgebra of $\mathbf{S}_{k+2}^{k+1}$ is determined by it projections onto all k-element sets of coordinates. As noted in [16, Example 4.6], for $n > 2$, $\mathbf{S}_n$ does not have a near unanimity term operation of any arity, since the algebra $\mathbf{S}_n^n$ has a quotient that is a 2-element essentially unary algebra.

3 Constructing near unanimity operations

In this section we collect the proofs providing, under various assumptions, near unanimity or local near unanimity operations. That is: the proofs of “3 implies 1” in Theorems 20 and Theorem 21 as well as a proof of the “if” direction from Theorem 17.

In the following proposition we construct instances over $\mathbf{A}^2$ (for some algebra $\mathbf{A}$). By a minor abuse of notation, we allow in such instances two kinds of variables: variables x evaluated in A and variables y evaluated in A^2. The former kind should be formally considered as variables evaluated in A^2 where each constraint enforces that x is sent to $\{(b, b) \mid b \in A\}$.

Moreover, dealing with k-uniform instances, we understand the condition “every set of k variables is constrained by a single constraint” flexibly: in some cases we allow for more constraints with the same set of variables, as long as the relations are proper permutations so that every constraint imposes the same restriction.

▶ **Proposition 23.** *Let* $k > 1$ *and let* $\mathbf{A}$ *be an algebra such that, for every* $(k, k+1)$*-instance* $\mathcal{I}$ *over* $\mathbf{A}^2$ *on* $k+2$ *variables every partial solution of* $\mathcal{I}$ *extends to a solution. Then each subalgebra of* $\mathbf{A}^{k+1}$ *is determined by its* k*-ary projections.*

Proof. Let $\mathbf{R} \leq \mathbf{A}^{k+1}$ and we will show that it is determined by the system of projections $\mathrm{proj}_I(R)$ as I ranges over all k elements subsets of coordinates. Using $\mathbf{R}$ we define the following instance $\mathcal{I}$ of $\mathsf{CSP}(\mathbf{A}^2)$. The variables of $\mathcal{I}$ will be the set $\{x_1, x_2, \dots, x_{k+1}, y_{12}\}$ and the domain of each x_i is A, while the domain of y_{12} is A^2.

For $U \subseteq \{x_1, \ldots, x_{k+1}\}$ of size k, let C_U be the constraint with scope U and constraint relation $R_U = \mathrm{proj}_U(R)$. For U a $(k-1)$-element subset of $\{x_1, \ldots, x_{k+1}\}$, let $C_{U\cup\{y_{12}\}}$ be the constraint with scope $U \cup \{y_{12}\}$ and constraint relation $R_{U\cup\{y_{12}\}}$ that consists of all tuples $(b_v \mid v \in U \cup \{y_{12}\})$ such that there is some $(a_1, \ldots, a_{k+1}) \in R$ with $b_v = a_i$ if $v = x_i$ and with $b_{y_{12}} = (a_1, a_2)$.

The instance $\mathcal{I}$ is k-uniform and we will show that it is sensitive. Indeed every tuple in every constraining relation originates in some tuple $\mathbf{b} \in R$. Setting $x_i \mapsto b_i$ and $y_{12} \mapsto (b_1, b_2)$ defines a solution that extends such a tuple.

In particular $\mathcal{I}$ is a $(k, k+1)$-instance over $\mathbf{A}^2$ with $k+2$ variables and so any partial solution of it can be extended to a solution. Let $\mathbf{b} \in A^{k+1}$ such that $\mathrm{proj}_I(\mathbf{b}) \in \mathrm{proj}_I(R)$ for all k element subsets I of $[k+1]$. Then $\mathbf{b}$ is a partial solution of $\mathcal{I}$ over the variables $\{x_1, \ldots, x_{k+1}\}$ and thus there is some extension of it to the variable y_{12} that produces a solution of $\mathcal{I}$. But there is only one consistent way to extend $\mathbf{b}$ to y_{12} namely by setting y_{12} to the value (b_1, b_2). By considering the constraint with scope $\{x_3, \ldots, x_{k+1}, y_{12}\}$ it follows that $\mathbf{b} \in R$, as required. ◀

Now we are ready to prove the first implication tackled in this section: 3 implies 1 in Theorem 20.

Proof of "3 implies 1" in Theorem 20. By Theorem 19 it suffices to show that each subalgebra of $\mathbf{A}^{k+1}$ is determined by its k-ary projections. Fortunately, Proposition 23 provides just that. ◀

We move on to proofs of "3 implies 1" in Theorem 21 and the "if" direction of Theorem 17. Similarly, as in the theorem just proved, we start with a proposition.

▶ **Proposition 24.** *Let $k > 1$ and let $\mathbf{A}$ be an algebra such that every $(k, k+1)$-instance $\mathcal{I}$ over $\mathbf{A}^2$ on $k+2$ variables is sensitive. Then each subalgebra of $\mathbf{A}^{k+2}$ is determined by its $(k+1)$-ary projections.*

Proof. We will show that if $\mathbf{R}$ is a subalgebra of $\mathbf{A}^{k+2}$ then $R = R^*$ where

$$R^* = \{a \in A^{k+2} \mid \mathrm{proj}_I(a) \in \mathrm{proj}_I(R) \text{ whenever } |I| = k+1\}.$$

In other words, we will show that the subalgebra $\mathbf{R}$ is determined by its projections into all $(k+1)$-element sets of coordinates.

We will use R and R^* from the previous paragraph to construct a $(k, k+2)$-instance $\mathcal{I} = (V, \mathcal{C})$ with $V = \{x_5, \ldots, x_{k+2}, y_{12}, y_{34}, y_{13}, y_{24}\}$ where each x_i is evaluated in A while all the y's are evaluated in A^2.

The set of constraints is more complicated. There is a *special constraint* on a *special variable set* $((y_{12}, y_{34}, x_5, \ldots, x_{k+2}), C)$ where

$$C = \{((a_1, a_2), (a_3, a_4), a_5, \ldots, a_{k+2}) \mid (a_1, \ldots, a_{k+2}) \in R^*\}.$$

The remaining constraints are defined using the relation R. For each set of variables $S = \{v_1, \ldots, v_k\} \subseteq V$ (which is different than the set for the special constraint) we define a constraint $((v_1, \ldots, v_k), D_S)$ with $(b_1, \ldots, b_k) \in D_S$ if and only if there exists a tuple $(a_1, \ldots, a_{k+2}) \in R$ such that:

- if v_i is x_j then $b_i = a_j$, and
- if v_i is y_{lm} then $b_i = (a_l, a_m)$.

Note that the instance $\mathcal{I}$ is k-uniform.

▷ Claim 25. $\mathcal{I}$ is a $(k, k+1)$-instance.

Let $S \subseteq V$ be a set of size k. If S is not the special variable set, then every tuple in the relation constraining S originates in some $(b_1, \ldots, b_{k+2}) \in R$ and, as in Proposition 23, sending $x_i \mapsto b_i$ and $y_{lm} \mapsto (b_l, b_m)$ defines a solution that extends such a tuple. We immediately conclude, that the potential failure of the $(k, k+1)$ condition must involve the special constraint.

Thus $S = \{y_{12}, y_{34}, x_5, \ldots, x_{k+2}\}$ and if $\mathbf{b}$ is a tuple from the special constraint C then there is some $(a_1, \ldots, a_{k+2}) \in R^*$ with

$$\mathbf{b} = ((a_1, a_2), (a_3, a_4), a_5, \ldots, a_{k+2}).$$

The extra variable that we want to extend the tuple $\mathbf{b}$ to is either y_{13} or y_{24}. Both cases are similar and we will only work through the details when it is y_{13}. In this case, assigning the value (a_1, a_3) to the variable y_{13} will produce an extension $\mathbf{b}'$ of $\mathbf{b}$ to a tuple over $S \cup \{y_{13}\}$ that is consistent with all constraints of $\mathcal{I}$ whose scopes are subsets of $\{y_{12}, y_{34}, x_5, \ldots, x_{k+2}, y_{13}\}$.

To see this, consider a k element subset S' of $\{y_{12}, y_{34}, x_5, \ldots, x_{k+2}, y_{13}\}$ that excludes some variable x_j. Then, by the definition of R^* there exists some tuple of the form $(a_1, a_2, \ldots, a_{j-1}, a'_j, a_{j+1}, \ldots, a_{k+2}) \in R$. This tuple from R can be used to witness that the restriction of $\mathbf{b}'$ to S' satisfies the constraint $D_{S'}$ since the scope of this constraint does not include the variable x_j.

Suppose that S' is a k element subset of $\{y_{12}, y_{34}, x_5, \ldots, x_{k+2}, y_{13}\}$ that excludes y_{12}. By the definition of R^* there is some tuple of the form $(a_1, a'_2, a_3, \ldots, a_{k+2}) \in R$. Using this tuple it follows that the restriction of $\mathbf{b}'$ to S' satisfies the constraint $D_{S'}$. This is because neither of the variables y_{12} and y_{24} are in S' and so the value $a'_2 \in A_2$ does not matter. A similar argument works when S' is assumed to exclude y_{34} and the claim is proved.

Since $\mathcal{I}$ is a $(k, k+1)$-instance over $\mathbf{A}^2$ and it has $k+2$ variables then by assumption, $\mathcal{I}$ is sensitive. We can use this to show that $R^* \subseteq R$ to complete the proof of this proposition. Let $(a_1, \ldots, a_{k+2}) \in R^*$ and consider the associated tuple $\mathbf{b} = ((a_1, a_2), (a_3, a_4), a_5, \ldots, a_{k+2}) \in C$. Since $\mathcal{I}$ is sensitive then this k-tuple can be extended to a solution $\mathbf{b}'$ of $\mathcal{I}$. Using any constraints of $\mathcal{I}$ whose scopes include combinations of y_{12} or y_{34} with y_{13} or y_{24} it follows that the value of $\mathbf{b}'$ on the variables y_{13} and y_{24} are (a_1, a_3) and (a_2, a_4) respectively. Then considering the restriction of $\mathbf{b}'$ to $S = \{x_5, \ldots, x_{k+2}, y_{13}, y_{24}\}$ it follows that $(a_1, \ldots, a_{k+2}) \in R$ since this restriction lies in the constraint relation D_S. ◀

We are in a position to provide the two final proofs in this section.

Proof of "3 implies 1" in Theorem 21. By Theorem 19 it suffices to show that each subalgebra of $\mathbf{A}^{k+2}$ is determined by its $(k+1)$-ary projections. Fortunately Propositions 24 provides just that. ◀

Proof of the "if" direction in Theorem 17. For this direction we apply Proposition 24 to a special member of $\mathcal{V}$, namely the $\mathcal{V}$-free algebra freely generated by $\mathbf{x}$ and $\mathbf{y}$, which we will denote by $\mathbf{F}$. Up to isomorphism, this algebra is unique and its defining property is that $\mathbf{F} \in \mathcal{V}$ and for any algebra $\mathbf{A} \in \mathcal{V}$, any map $f : \{\mathbf{x}, \mathbf{y}\} \to A$ extends uniquely to a homomorphism from $\mathbf{F}$ to $\mathbf{A}$. Consequently, for any two terms $s(x, y)$ and $t(x, y)$ in the signature of $\mathcal{V}$ if $s^{\mathbf{F}}(\mathbf{x}, \mathbf{y}) = t^{\mathbf{F}}(\mathbf{x}, \mathbf{y})$ then the equation $s(x, y) \approx t(x, y)$ holds in $\mathcal{V}$.

Let $\mathbf{R}$ be the subalgebra of $\mathbf{F}^{k+2}$ generated by the tuples $(\mathbf{y}, \mathbf{x}, \mathbf{x}, \ldots, \mathbf{x})$, $(\mathbf{x}, \mathbf{y}, \mathbf{x}, \ldots, \mathbf{x})$, $\ldots$, $(\mathbf{x}, \ldots, \mathbf{x}, \mathbf{y})$. By Proposition 24, the algebra $\mathbf{R}$ is determined by its $(k+1)$-ary projections and so the constant tuple $(\mathbf{x}, \ldots, \mathbf{x})$ belongs to R. The term generating this tuple from the given generators of $\mathbf{R}$ defines the required $(k+2)$-ary near unanimity operation. ◀

4 New loop lemmata

A *loop lemma* is a theorem stating that a binary relation satisfying certain structural and algebraic requirements necessarily contains a *loop* – a pair (a, a). In this section we provide two new loop lemmata, Theorem 31 and Theorem 32, which generalize an "infinite loop lemma" of Olšák [18] and may be of independent interest. Theorem 32 is a crucial tool for the proof presented in Section 5.

The algebraic assumptions in the new loop lemmata concern absorption, a concept that has proven to be useful in the algebraic theory of CSPs and in universal algebra [6]. We adjust the standard definition to our specific purposes. We begin with a very elementary definition.

▶ **Definition 26.** *Let R and S be sets. We call a tuple $(a_1, \dots, a_n)$ a* one-S-in-R tuple *if for exactly one i we have $a_i \in S$ and all the other a_i's are in R.*

Next we proceed to define a relaxation of the standard absorbing notion. We follow a standard notation, silently extending operations of an algebra to powers (by computing them coordinate-wise).

▶ **Definition 27.** *Let $\mathbf{A}$ be an algebra, $\mathbf{R} \leq \mathbf{A}^k$ and $S \subseteq A^k$. We say that R locally n-absorbs S if, for every finite set $\mathcal{C}$ of one-S-in-R tuples of length n, there is a term operation t of $\mathbf{A}$ such that $t(\mathbf{a^1}, \dots, \mathbf{a^n}) \in R$ whenever $(\mathbf{a^1}, \dots, \mathbf{a^n}) \in \mathcal{C}$. We will say that R* locally absorbs *S, if R locally n-absorbs S for some n.*

Absorption, even in this form, is stable under various constructions. The following lemma lists some of them and we leave it without a proof (the reasoning is identical to the one in e.g. Proposition 2 in [6]).

▶ **Lemma 28.** *Let $\mathbf{A}$ be an algebra and $\mathbf{R} \leq \mathbf{A}^2$ such that R locally n-absorbs S. Then R^{-1} locally n-absorbs S^{-1}; and $R \circ R$ locally n-absorbs $S \circ S$, and $R \circ R \circ R$ locally n-absorbs $S \circ S \circ S$ etc.*

Let us prove a first basic property of local absorption.

▶ **Lemma 29.** *Let $\mathbf{A}$ be an idempotent algebra and $\mathbf{R} \leq \mathbf{A}^2$ such that R locally n-absorbs S. Let $(a_1, \dots, a_n)$ and $(b_1, \dots, b_n)$ be directed walks in R, and let $(a_i, b_i) \in S$ for each i (see Figure 1). Then there exists a directed walk from a_1 to b_n of length n in R.*

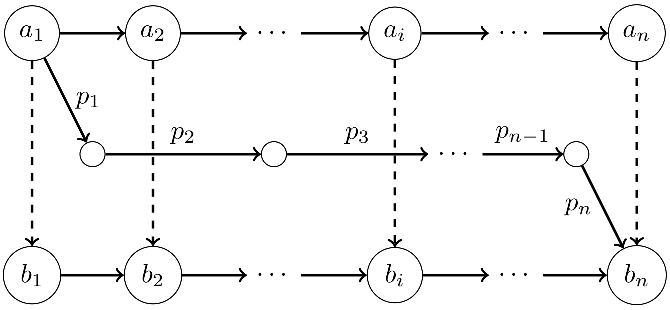

Figure 1 Solid arrows represent tuples from R and dashed arrows represent tuples from S.

Proof. We will show that there is a term operation t of the algebra $\mathbf{A}$ such that the following $(n+1)$-tuple of elements of A is a walk of length n in R from a_1 to b_n.

$$\begin{aligned}(a_1 =&t(a_1, a_1, a_1, \dots, a_1),\\ &t(b_1, a_2, a_2, \dots, a_2),\\ &t(b_2, b_2, a_3, \dots, a_3),\\ &\vdots\\ &t(b_{n-1}, b_{n-1}, \dots, b_{n-1}, a_n),\\ b_n =&t(b_n, b_n, b_n, \dots, b_n)).\end{aligned}$$

In order to choose a proper t we apply the definition of local absorption to the set of $(n+1)$ one-S-in-R tuples corresponding to the steps in the path. ◀

The loop lemma of Olšák concerns symmetric relations absorbing the equality relation $\{(a, a) \mid a \in A\}$, which is denoted $=_A$. The original result, stated in a slightly different language, does not cover the case of local absorption. However, a typographical modification of a proof mentioned in [18] shows that the theorem holds. For completeness sake, we present this proof in the full version of this paper.

▶ **Theorem 30** ([18])**.** *Let $\mathbf{A}$ be an **idempotent** algebra and $\mathbf{R} \leq \mathbf{A}^2$ be nonempty and symmetric. If R locally absorbs $=_A$, then R contains a loop.*

In order to apply this theorem in the case of sensitive instances, we need to generalize it. In the following two theorems we will gradually relax the requirement that R is symmetric. In the first step, we substitute it with a condition requiring a closed, directed walk in the graph (i.e., a sequence of possibly repeating vertices, with consecutive vertices connected by forward edges and the first and last vertex identical). Recall that R^{-1} is the inverse relation to R and let us denote by $R^{\circ l}$ the l-fold relational composition of R with itself.

▶ **Theorem 31.** *Let $\mathbf{A}$ be an **idempotent** algebra and $\mathbf{R} \leq \mathbf{A}^2$ contain a directed closed walk. If R locally absorbs $=_A$, then R contains a loop.*

Proof. Let n denote the arity of the absorbing operations. The proof is by induction on $l \geq 0$, where l is a number such that there exists a directed closed walk from a_1 to a_1 of length 2^l.

We start by verifying that such an l exists. Take a directed walk $(a_1, \dots, a_{k-1}, a_k = a_1)$ in R. We may assume that its length k is at least n, since we can, if necessary, traverse the walk multiple times. An application of Lemma 29 to the relations $R, =_A$ and tuples $(a_1, \dots, a_n)$, $(a_1, \dots, a_n)$ gives us a directed walk from a_1 to a_n of length n. Appending this walk with the walk $(a_n, a_{n+1}, \dots, a_k = a_1)$ yields a directed walk from a_1 to a_1 of length $k+1$. In this way, we can get a directed walk from a_1 to a_1 of any length greater than k.

Now we return to the inductive proof and start with the base of induction for $l = 0$ or $l = 1$. If $l = 0$, then we have found a loop. If $l = 1$ we have a closed walk of length 2, that is, a pair (a, b) which belongs to both R and R^{-1}. We set $R' = R \cap R^{-1}$ and observe that R' is nonempty and symmetric, and it is not hard to verify that R' locally absorbs $=_A$. Olšák's loop lemma, in the form of Theorem 30, gives us a loop in R.

Finally, we make the induction step from $l-1$ to l. Take a closed walk $(a_1, a_2, \dots)$ of length 2^l and consider $R' = R^{\circ 2}$. Observe that R' contains a directed closed walk of length 2^{l-1} (namely $(a_1, a_3, \dots)$), and that R' locally absorbs $=_A$ (by Lemma 28), so, by the inductive hypothesis, R' has a loop. In other words, R has a directed closed walk of length 2 and we are done by the case $l = 1$. ◀

Note that we cannot further relax the assumption on the graph by requiring that, for example, it has an infinite directed walk. Indeed the natural order of the rationals (taken for R) locally 2-absorbs the equality relation by the binary arithmetic mean operation $(a+b)/2$ (i.e., all the absorbing evaluations are realized by a single operation). The same relation locally 4-absorbs equality with the near unanimity operation $n(x,y,z,w)$ which, when applied to $a \leq b \leq c \leq d$, in any order, returns $(b+c)/2$.

Nevertheless, we can strengthen the algebraic assumption and still provide a loop; the following theorem is one of the key components in the proof sketch provided in Section 5 (albeit applied there with $l = 1$).

▶ **Theorem 32.** *Let* $\mathbf{A}$ *be an* ***idempotent*** *algebra and* $\mathbf{R} \leq \mathbf{A}^2$ *contain a directed walk of length* $n-1$*. If* R *locally* n*-absorbs* $=_A$ *and* $R^{\circ l}$ *locally* n*-absorbs* R^{-1} *for some* $l \in \mathbb{N}$ *then* R *contains a loop.*

Proof. By applying Lemma 29 similarly as in the proof of Theorem 31, we can get, from a directed walk of length $n-1$, a directed walk $(a_1, a_2, \dots)$ of an arbitrary length. Moreover, by the same reasoning, for each i and j with $j \geq i+n-1$, there is a directed walk from a_i to a_j of any length greater than or equal to $j-i$.

Consider the relations $R' = R^{\circ ln^2}$ and $S = (R^{-1})^{\circ n^2}$, and tuples

$$\mathbf{c} = (c_1, \dots, c_n) := (a_{n^2}, a_{(n+1)n}, \dots a_{(2n-1)n}), \text{ and}$$
$$\mathbf{d} = (d_1, \dots, d_n) := (a_n, a_{2n} \dots, a_{n^2})$$

By the previous paragraph and the definitions, both $\mathbf{c}$ and $\mathbf{d}$ are directed walks in R', and $(c_i, d_i) \in S$ for each i. Moreover, since $R^{\circ l}$ locally n-absorbs R^{-1}, Lemma 28 implies that R' locally absorbs S. We can thus apply Lemma 29 to the relations R', S and the tuples $\mathbf{c}, \mathbf{d}$ and obtain a directed walk from $c_1 = a_{n^2}$ to $d_{n-1} = a_{n^2}$ in R'. This closed walk in turn gives a closed directed walk in R and we are in a position to finish the proof by applying Theorem 31. ◀

5 Consistent instances are sensitive (sketch of a proof)

In this section we present the main ideas that are used to prove the "only if" direction in Theorem 17 and "1 implies 2" in Theorem 21. These ideas are shown in a very simplified situation, in particular, only the case that $k = 2$ and $\mathbf{A}$ is finite is considered. In the end of this section we briefly discuss the necessary adjustments in the general situation. A complete proof is given in the full version of this paper.

Consider a finite idempotent algebra $\mathbf{A}$ with a 4-ary near unanimity term operation and a $(2,3)$-instance $\mathcal{I} = (V, \mathcal{C})$ over $\mathbf{A}$. Each pair $\{x, y\}$ of variables is constrained by a unique constraint $((x,y), R_{xy})$ or $((y,x), R_{yx})$. For convenience we also define $R_{yx} = R_{yx}^{-1}$ (or $R_{xy} = R_{yx}^{-1}$ in the latter case) and R_{xx} to be the equality relation on A. Our aim is to show that every pair in every constraint relation extends to a solution. The overall structure of the proof is by induction on the number of variables of $\mathcal{I}$.

We fix a pair of variables $\{x_1, x_2\}$ and a pair $(a_1, a_2) \in R_{x_1 x_2}$ that we want to extend. The strategy is to consider the instance $\mathcal{J}$ obtained by removing x_1 and x_2 from the set of variables and shrinking the constraint relations R_{uv} to R'_{uv} so that only the pairs consistent with the fixed choice remain, that is,

$$R'_{uv} = \{(b,c) \in R_{uv} \mid (a_1, b) \in R_{x_1 u}, (a_2, b) \in R_{x_2 u}, (a_1, c) \in R_{x_1 v}, (a_2, c) \in R_{x_2 v}\}.$$

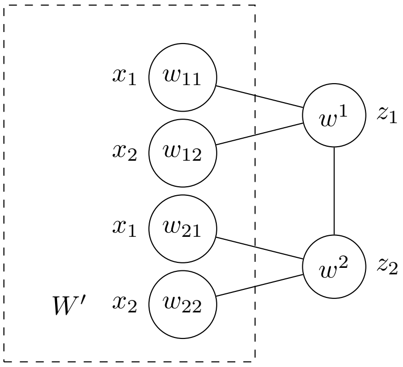

Figure 2 Pattern $\mathbb{P}$ in Lemma 35.

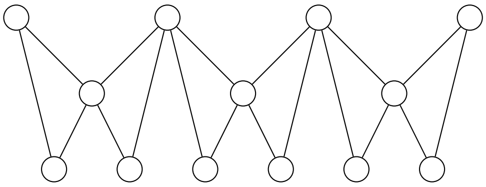

Figure 3 Path of three bow ties.

We will show that $\mathcal{J}$ contains a nonempty $(2,3)$-subinstance, that is, an instance whose constraint relations are nonempty subsets of the original ones. The induction hypothesis then gives us a solution to $\mathcal{J}$ which, in turn, yields a solution to $\mathcal{I}$ that extends the fixed choice.

Having a nonempty $(2,3)$-subinstance can be characterized by the solvability of certain relaxed instances. The following concepts will be useful for working with relaxations of $\mathcal{I}$ and $\mathcal{J}$.

▶ **Definition 33.** *A* pattern *is a triple $\mathbb{P} = (W; \mathcal{F}, l)$, where $(W; \mathcal{F})$ is an undirected graph, and l is a mapping $l : W \to V$. The variable $l(i)$ is referred to as the* label *of i.*

A realization *(*strong realization*, respectively) of $\mathbb{P}$ is a mapping $\alpha : W \to A$, which* satisfies *every edge $\{w_1, w_2\} \in \mathcal{F}$, that is, $(\alpha(w_1), \alpha(w_2)) \in R_{l(w_1),l(w_2)}$ $((\alpha(w_1), \alpha(w_2)) \in R'_{l(w_1),l(w_2)}$, respectively). (Strong realization only makes sense if $l(W) \subseteq V \setminus \{x_1, x_2\}$.)*

*A pattern is (*strongly*)* realizable *if it has a (strong) realization.*

The most important patterns for our purposes are *2-trees*, these are patterns obtained from the empty pattern by gradually adding triangles (patterns whose underlying graph is the complete graph on 3 vertices) and merging them along a vertex or an edge to the already constructed pattern. Their significance stems from the following well known fact.

▶ **Lemma 34.** *An instance (over a finite domain) contains a nonempty (2,3)-subinstance if and only if every 2-tree is realizable in it.*

The "only if" direction of the lemma applied to the instance $\mathcal{I}$ implies that every 2-tree is realizable. The "if" direction applied to the instance $\mathcal{J}$ tells us that our aim boils down to proving that every 2-tree is strongly realizable. This is achieved by an induction on a suitable measure of complexity of the tree using several constructions. We will not go into full technical details here, we rather present several lemmata whose proofs contain essentially all the ideas that are necessary for the complete proof.

▶ **Lemma 35.** *Every edge (i.e., a pattern whose underlying graph is a single edge) is strongly realizable.*

Proof sketch. Let $\mathbb{Q}$ be the pattern formed by an undirected edge with vertices w^1 and w^2 labeled z_1 and z_2, respectively. Let $\mathbb{P}$ be the pattern obtained from $\mathbb{Q}$ by adding a set of four fresh vertices $W' = \{w_{11}, w_{12}, w_{21}, w_{22}\}$ labeled x_1, x_2, x_1, x_2, respectively, and adding the edges $\{w^i, w_{i1}\}$ and $\{w^i, w_{i2}\}$ for $i = 1, 2$, see Figure 2. Observe that the restriction of a realization β of $\mathbb{P}$, such that $\beta(w_{ij}) = a_j$ for each $i, j \in \{1, 2\}$, to the set $\{w^1, w^2\}$ is a strong realization of $\mathbb{Q}$.

We consider the set T of restrictions of realizations of $\mathbb{P}$ to the set W'. Since constraint relations are subuniverses of $\mathbf{A}^2$, it follows that T is a subuniverse of $\mathbf{A}^4$.

$$T = \{(\beta(w_{11}), \beta(w_{12}), \beta(w_{21}), \beta(w_{22})) \mid \beta \text{ realizes } \mathbb{P}\} \leq \mathbf{A}^4$$

We need to prove that the tuple $\mathbf{a} = (a_1, a_2, a_1, a_2)$ is in T. By the Baker-Pixley theorem, Theorem 14, it is enough to show that for any 3-element set of coordinates, the relation T contains a tuple that agrees with $\mathbf{a}$ on this set. This is now our aim.

For simplicity, consider the set of the first three coordinates. We will build a realization β of $\mathbb{P}$ in three steps. After each step, β will satisfy all the edges where it is defined. First, since $(a_1, a_2) \in R_{x_1x_2}$ and $\mathcal{I}$ is a (2,3)-instance, we can find $b_1 \in A$ such that $(a_1, b_1) \in R_{x_1z_1}$ and $(a_2, b_1) \in R_{x_2z_1}$, and we set $\beta(w_{11}) = a_1$, $\beta(w_{12}) = a_2$, and $\beta(w^1) = b_1$. Second, we find $b_2 \in A$ such that $(a_1, b_2) \in R_{x_1z_2}$ and $(b_1, b_2) \in R_{z_1z_2}$ (here we use $(a_1, b_1) \in R_{x_1z_1}$ and that $\mathcal{I}$ is a (2,3)-instance), and set $\beta(w_{21}) = a_1$, $\beta(w^2) = b_2$. Third, using $(a_1, b_2) \in R_{x_1z_2}$ we find a_2' such that $(b_2, a_2') \in R_{z_2x_2}$ and set $\beta(w_{22}) = a_2'$. By construction, β is a realization of $\mathbb{P}$ and $(\beta(w_{11}), \beta(w_{12}), \beta(w_{21})) = (a_1, a_2, a_1)$, so our aim has been achieved. ◀

Using Lemma 35, one can go a step further and prove that every pattern built on a graph which is a triangle is strongly realizable. We are not going to prove this fact here.

▶ **Lemma 36.** *Every bow tie (a pattern whose underlying graph is formed by two triangles with a single common vertex) is strongly realizable.*

Proof sketch. Let $\mathbb{W}_1'$ and $\mathbb{W}_2'$ be two triangles (viewed as undirected graphs) with a single common vertex w. Let $\mathbb{Q}'$ be any pattern over $W_1' \cup W_2'$ with labelling l' sending $W_1' \cup W_2'$ to $V \setminus \{x_1, x_2\}$. Similarly as in the proof of Lemma 35 we form a pattern $\mathbb{Q}$ by adding to $\mathbb{Q}'$ ten additional vertices (five of them labeled x_1, the other five x_2) and edges so that the restriction of a realization α of $\mathbb{Q}$ to the set $W_1' \cup W_2'$ is a strong realization of $\mathbb{Q}'$ whenever the additional vertices have proper values (that is, value a_i for vertices labeled x_i).

We will gradually construct a realization α of $\mathbb{Q}$, which sends all the vertices labeled by x_1 to a_1, and all the vertices labeled by x_2 and adjacent to a vertex in W_1' to a_2. First use the discussion after Lemma 35 to find a strong realization of $\mathbb{Q}'$ restricted to W_1'. This defines α on W_1' and its adjacent vertices labeled by x_1 and x_2.

Next, we want to use Lemma 35 for assigning values to the two remaining vertices of W_2'. However, in order to accomplish that, we need to shift the perspective: the role of x_1 is played by x_1, but the role of x_2 is played by $l'(w)$; and the role of (a_1, a_2) is played by $(a_1, \alpha(w))$. In this new context, we use Lemma 35 to find a strong realization of the edge-pattern formed by the two remaining vertices of W_2' (with a proper restriction of l'). This defines α on all the vertices of $\mathbb{Q}$, except for the two vertices adjacent to $W_2' \setminus \{w\}$ and labeled by x_2. Finally, similarly as in the third step in the proof of Lemma 35, we define α on the remaining two vertices (labeled x_2) to get a sought after realization of $\mathbb{Q}$.

Now α assigns proper values (a_1 or a_2) to all additional vertices, except those two coming from the non-central vertices of W_2' and labeled by x_2. We apply the 4-ary near unanimity term operation to the realization α and its 3 variants obtained by exchanging the roles of W_1' and W_2' and x_1 and x_2. The result of this application is a realization of $\mathbb{Q}$ which defines a strong realization of $\mathbb{Q}'$. ◀

In the same way it is possible to prove strong realizability of further patterns, such as those in the following corollary.

▶ **Corollary 37.** *Every "path of 3 bow ties" (i.e., a pattern whose underlying graph is as in Figure 3) is strongly realizable.*

The application of the loop lemma is illustrated by the final lemma in this section.

▶ **Lemma 38.** *Every diamond (i.e., a pattern whose underlying graph is formed by two triangles with a single common edge) is strongly realizable.*

Proof sketch. The idea is to merge two vertices in a bow tie using the loop lemma. Let $\mathbb{Q}'$ be a pattern over a graph which is a bow tie on two triangles W_1' and W_2' (just like in the proof of Lemma 36). Let $w_1 \in W_1' \setminus W_2'$ and $w_2 \in W_2' \setminus W_1'$ be such that $l(w_1) = l(w_2)$.

Let $\mathbb{Q}$ be obtained from $\mathbb{Q}'$ exactly as in the proof of Lemma 36 and notice that a proper realization α of $\mathbb{Q}$ with $\alpha(w_1) = \alpha(w_2)$ gives us a strong realization of a diamond. Let $\mathbb{Q}^3$ be the pattern obtained by taking the disjoint union of 3 copies of $\mathbb{Q}$ and identifying the vertex w_2 in the i-th copy with the vertex w_1 in the $(i+1)$-first copy, for each $i \in \{1, 2\}$ (Figure 3 shows $\mathbb{Q}^3$ without the additional vertices).

Denote by T the set of all the realizations β of $\mathbb{Q}$ and denote by $S \subseteq T$ the set of those $\beta \in T$ that are proper. By a straightforward argument, both T and S are subuniverses of $\prod_{w \in Q} \mathbf{A}$. Using the near unanimity term operation of arity 4, S clearly 4-absorbs T.

The plan is to apply Theorem 32 to the binary relation $\mathrm{proj}_{w_1,w_2} S \subseteq A \times A$. As noted above, a loop in this relation gives us the desired strong realization of a diamond, so it only remains to verify the assumptions of Theorem 32. By Corollary 37, the pattern $\mathbb{Q}^3$ has a proper realization. The images of copies of vertices w_1 and w_2 in such a realization yield a directed walk in $\mathrm{proj}_{w_1,w_2}(S)$ of length 3. Next, since S 4-absorbs T, then $\mathrm{proj}_{w_1,w_2}(S)$ 4-absorbs $\mathrm{proj}_{w_1,w_2}(T)$, so it is enough to verify that the latter relation contains $=_A$ and $\mathrm{proj}_{w_1,w_2}(S)^{-1}$. We only look at the latter property. Consider any $(b_1, b_2) \in \mathrm{proj}_{w_1,w_2}(S)^{-1}$. By the definition of S, the pattern $\mathbb{Q}$ has a realization α such that $\alpha(w_1) = b_2$ and $\alpha(w_2) = b_1$. We flip the values $\alpha(w_1)$ and $\alpha(w_2)$, restrict α to $\{w_1, w_2\}$ together with the middle vertex of the bow tie, and then extend this assignment to a realization of $\mathbb{Q}$, giving us $(b_1, b_2) \in \mathrm{proj}_{w_1,w_2}(T)$. ◀

There are two major adjustments needed for the general case. First, the "if" direction of Lemma 34 (and its analogue for a general k) is no longer true over infinite domains. This is resolved by working directly with the realizability of k-trees and proving a more general claim by induction: instead of "a $(k, k+1)$-instance is sensitive" we prove, roughly, that any evaluation, which extends to a sufficiently deep k-tree, extends to a solution. Second, for higher values of k than 2 we do not prove strong realizability in one step as in, e.g., Lemma 35, but rather go through a sequence of intermediate steps between realizability and strong realizability.

6 Conclusion

We have characterized varieties that have sensitive $(k, k+1)$-instances of the CSP as those that possess a near unanimity term of arity $k + 2$. From the computational perspective, the following corollary is perhaps the most interesting consequence of our results.

▶ **Corollary 39.** *Let $\mathbb{A}$ be a finite* CSP *template whose relations all have arity at most k and which has a near unanimity polymorphism of arity $k+2$. Then every instance of the* CSP *over $\mathbb{A}$, after enforcing $(k, k+1)$-consistency, is sensitive.*

Therefore not only is the $(k, k+1)$-consistency algorithm sufficient to detect global inconsistency, we also additionally get the sensitivity property. Let us compare this result to some previous results as follows. Consider a template $\mathbb{A}$ that, for simplicity, has only unary and binary relations and that has a near unanimity polymorphism of arity $k + 2 \geq 4$. Then any instance of the CSP over $\mathbb{A}$ satisfies the following.

1. After enforcing $(2,3)$-consistency, if no contradiction is detected, then the instance has a solution [4] (this is the bounded width property).
2. After enforcing $(k,k+1)$-consistency, every partial solution on k variables extends to a solution (this is the sensitivity property).
3. After enforcing $(k+1,k+2)$-consistency, every partial solution extends to a solution [13] (this is the bounded strict width property).

For $k+2>4$ there is a gap between the first and the second item. Are there natural conditions that can be placed there?

The properties of a template $\mathbb{A}$ from the first and the third item (holding for every instance) can be characterized by the existence of certain polymorphisms: a near unanimity polymorphism of arity $k+2$ for the third item [13] and weak near unanimity polymorphisms of all arities greater than 2 for the first item [5, 11, 17]. This paper does not give such a direct characterization for the second item (essentially, since Theorem 21 involves a square). Is there any? Moreover, there are characterizations for natural extensions of the first and the third to relational structures with higher arity relations [13, 3]. This remains open for the second item as well.

In parallel with the flurry of activity around the CSP over finite templates, there has been much work done on the CSP over infinite ω-categorical templates [9, 19]. These templates cover a much larger class of computational problems but, on the other hand, share some pleasant properties with the finite ones. In particular, the $(k,k+1)$-consistency of an instance can still be enforced in polynomial time. Corollary 39 can be extended to this setting as follows.

▶ **Corollary 40.** *Let $\mathbb{A}$ be an ω-categorical* CSP *template whose relations all have arity at most k and which has local idempotent near unanimity polymorphisms of arity $k+2$. Then every instance of the* CSP *over $\mathbb{A}$, after enforcing the $(k,k+1)$-consistency, is sensitive.*

Bounded strict width k of an ω-categorical template was characterized in [10] by the existence of a *quasi-near unanimity* polymorphism n of arity $k+1$, i.e.,

$$n(y,x,\dots,x)\approx n(x,y,\dots,x)\approx\cdots\approx n(x,x,\dots,y)\approx n(x,x,\dots,x),$$

which is, additionally, *oligopotent*, i.e., the unary operation $x\mapsto n(x,x,\dots,x)$ is equal to an automorphism on every finite set. This result extends the characterization of Feder and Vardi since an oligopotent quasi-near unanimity polymorphism generates a near unanimity polymorphism as soon as the domain is finite. On an infinite domain, however, oligopotent quasi-near unanimity polymorphisms generate local near unanimity polymorphisms which, unfortunately, do not need to be idempotent on the whole domain. Our results thus fall short of proving the following natural generalization of Corollary 39 to the infinite.

▶ **Conjecture 41.** *Let $\mathbb{A}$ be an ω-categorical* CSP *template whose relations all have arity at most k and which has an oligopotent quasi-near unanimity polymorphism of arity $k+2$. Then every instance of the* CSP *over $\mathbb{A}$, after enforcing $(k,k+1)$-consistency, is sensitive.*

To confirm the conjecture, a new approach, that does not use a loop lemma, will be needed since there are examples of ω-categorical structures having oligopotent quasi-near unanimity polymorphisms for which the counterpart to Theorem 30 does not hold. Indeed, one such an example is the infinite clique.

Abstract

Dynamic networks of concurrent pushdown systems (DCPS) are a theoretical model for multi-threaded recursive programs with shared global state and dynamical creation of threads. The (global) state reachability problem for DCPS is undecidable in general, but Atig et al. (2009) showed that it becomes decidable, and is in 2EXPSPACE, when each thread is restricted to a fixed number of context switches. The best known lower bound for the problem is EXPSPACE-hard and this lower bound follows already when each thread is a finite-state machine and runs atomically to completion (i.e., does not switch contexts). In this paper, we close the gap by showing that state reachability is 2EXPSPACE-hard already with only one context switch. Interestingly, state reachability analysis is in EXPSPACE both for pushdown threads without context switches as well as for finite-state threads with arbitrary context switches. Thus, recursive threads together with a single context switch provide an exponential advantage.

Our proof techniques are of independent interest for 2EXPSPACE-hardness results. We introduce *transducer-defined* Petri nets, a succinct representation for Petri nets, and show coverability is 2EXPSPACE-hard for this model. To show 2EXPSPACE-hardness, we present a modified version of Lipton's simulation of counter machines by Petri nets, where the net programs can make explicit recursive procedure calls up to a bounded depth.

1 Introduction

There is a complexity gap between EXPSPACE and 2EXPSPACE that shows up in several problems in the safety verification of multithreaded programs.

Atig, Bouajjani, and Qadeer [1] study safety verification for *dynamic networks of concurrent pushdown systems* (DCPS), a theoretical model for multithreaded recursive programs with a finite shared global state, where threads can be recursive and can dynamically spawn additional threads. Unrestricted reachability is undecidable in this model. To ensure decidability, like many other works [16, 11, 14, 10], they assume a bound K that restricts each thread to have at most K context switches. For safety verification in this model, formulated as global state reachability, they show a lower bound of EXPSPACE and an upper bound of 2EXPSPACE, "closing the gap" is left open.

Kaiser, Kroening, and Wahl [8] study safety verification of multithreaded *non-recursive* programs with local and global Boolean variables. In this model, an arbitrary number of non-recursive threads execute over shared global state, but each thread can maintain local state in Boolean variables. Although their paper does not provide an explicit complexity bound, a lower bound of EXPSPACE and an upper bound of 2EXPSPACE can be derived from a reduction from Petri net coverability and their algorithm respectively.

Interestingly, when we restrict the models to disallow either context switches (i.e., each thread runs atomically to completion) or local state in the form of the pushdown stack or local variables (but allow arbitrary context switches), safety verification is in EXPSPACE [1, 7].

Thus, the complexity gap asks whether or not the combination of *local state* (maintained in local variables or in the stack) and bounded *context switching* provides additional power to computation. In this paper, we show that indeed it does. In fact, the combination of local state and just *one* context switch is sufficient to achieve 2EXPSPACE lower bounds for these problems. This closes the complexity gap.

We believe the constructions and models that we use along the way are of independent interest. We introduce *transducer-defined* Petri nets (TDPNs), a succinct representation for Petri nets. The places in a TDPN are encoded using words over a fixed alphabet, and the transitions are described by length-preserving transducers. We show that coverability for TDPNs is 2EXPSPACE-complete[1] and give a polynomial-time reduction from coverability for TDPNs to safety verification for DCPS with one context switch.

The idea of the latter reduction is to map a (compressed) place to the stack of a thread and a marking to the set of currently spawned threads. A key obstacle in the simulation is to "transfer" potentially exponential amount of information from before a transition to after it through a polynomial-sized global store. We present a "guess and verify" procedure, using non-determinism and the use of additional threads to verify a stack content letter-by-letter.

In order to show 2EXPSPACE-hardness for TDPNs, we introduce the model of *recursive net programs* (RNPs), which add the power of making possibly recursive procedure calls to the model of net programs (i.e., programs with access to Petri net counters). The addition of recursion enables us to replace the "copy and paste code" idea in Lipton's construction to show EXPSPACE-hardness of Petri net coverability [13] with a more succinct and cleaner program description where the copies are instead represented by different values of the local variables of the procedures. The net effect is to push the requirement for copies into the call stack of the RNP while maintaining a syntax which gives us a RNP which is polynomial in the

[1] After submitting this work, the authors were made aware of "(level 1) counter systems with chained counters" from [3], for which 2EXPSPACE-hardness of state reachability is shown in [3, Theorem 14]. The 2EXPSPACE-hardness of coverability in TDPN could also be deduced from that result.

size of a given counter program. When the stack size is bounded by an exponential function of the size of the program, we get a 2EXPSPACE-lower bound. We show that recursive net programs with exponentially large stacks can be simulated by TDPNs.

Finally, we note that the 2EXPSPACE lower bound holds for DCPS where each stack is bounded by a linear function of the size. Such stacks can be encoded by polynomially many local Boolean variables, giving us a 2EXPSPACE lower bound for the model of Kaiser et al.

In summary, we introduce a number of natural 2EXPSPACE-complete problems and, through a series of reductions, close an exponential gap in the complexity of safety verification for multithreaded recursive programs.

2 Dynamic Networks of Concurrent Pushdown Systems (DCPS)

In this section, we define the model of DCPS and then state our main result. Intuitively, a DCPS consists of a finite state control and several pushdown threads with local configurations, one of them being the active thread. A local configuration contains the number of context switches the thread has already performed, as well as the contents of its local stack. An action of a thread may specify a new thread with initially one symbol on the stack to be spawned as an inactive thread. The active thread can be switched out for one of the inactive threads at any time. When a thread is switched out, its context switch number increases by one. One can view this model as a collection of dynamically created recursive threads (with a call stack each), that communicate using some finite shared memory (the state control).

A *multiset* $\mathbf{m}\colon S \to \mathbb{N}$ over a set S maps each element of S to a natural number. Let $\mathbb{M}[S]$ be the set of all multisets over S. We treat sets as a special case of multisets where each element is mapped onto 0 or 1. We sometimes write $\mathbf{m} = [\![a_1, a_1, a_3]\!]$ for the multiset $\mathbf{m} \in \mathbb{M}[S]$ such that $\mathbf{m}(a_1) = 2$, $\mathbf{m}(a_3) = 1$, and $\mathbf{m}(a) = 0$ for each $a \in S \backslash \{a_1, a_3\}$. The empty multiset is denoted $\emptyset$. The *size* of a multiset $\mathbf{m}$, denoted $|\mathbf{m}|$, is given by $\sum_{a \in S} \mathbf{m}(a)$. Note that this definition applies to sets as well.

Given two multisets $\mathbf{m}, \mathbf{m}' \in \mathbb{M}[S]$ we define $\mathbf{m} \oplus \mathbf{m}' \in \mathbb{M}[S]$ to be a multiset such that for all $a \in S$, we have $(\mathbf{m} \oplus \mathbf{m}')(a) = \mathbf{m}(a) + \mathbf{m}'(a)$. We also define the natural order $\preceq$ on $\mathbb{M}[S]$ as follows: $\mathbf{m} \preceq \mathbf{m}'$ iff there exists $\mathbf{m}^{\Delta} \in \mathbb{M}[S]$ such that $\mathbf{m} \oplus \mathbf{m}^{\Delta} = \mathbf{m}'$. We also define $\mathbf{m} \ominus \mathbf{m}'$ for $\mathbf{m}' \preceq \mathbf{m}$ analogously: for all $a \in S$, we have $(\mathbf{m} \ominus \mathbf{m}')(a) = \mathbf{m}(a) - \mathbf{m}'(a)$.

A *Dynamic Network of Concurrent Pushdown Systems (*DCPS*)* $\mathcal{A} = (G, \Gamma, \Delta, g_0, \gamma_0)$ consists of a finite set of *(global) states* G, a finite alphabet of *stack symbols* Γ, an *initial state* $g_0 \in G$, an *initial stack symbol* $\gamma_0 \in \Gamma$, and a finite set of *transition rules* Δ. Elements of Δ have one of the two forms (1) $g|\gamma \hookrightarrow g'|w'$, or (2) $g|\gamma \hookrightarrow g'|w' \triangleright \gamma'$, where $g, g' \in G$, $\gamma, \gamma' \in \Gamma$, $w' \in \Gamma^*$, and $|w'| \leq 2$. Rules of the first kind allow the DCPS to take a single step in one of the pushdown threads while the second additionally spawn a new thread with top of stack symbol γ'. The *size* of $\mathcal{A}$ is defined as $|\mathcal{A}| = |G| + |\Gamma| + |\Delta|$.

The set of *configurations* of $\mathcal{A}$ is $G \times (\Gamma^* \times \mathbb{N}) \times \mathbb{M}[\Gamma^* \times \mathbb{N}]$. Given a configuration $\langle g, (w, i), \mathbf{m}\rangle$, we call g the *(global) state*, (w, i) the *local configuration* of the *active thread*, and $\mathbf{m}$ the multiset of the *local configurations* of the *inactive threads*. The initial configuration of $\mathcal{A}$ is $\langle g_0, (\gamma_0, 0), \emptyset\rangle$. For a configuration c of $\mathcal{A}$, we will sometimes write $c.g$ for the state of c and $c.\mathbf{m}$ for the multiset of threads of c (both active and inactive). The *size* of a configuration $c = \langle g, (w, i), \mathbf{m}\rangle$ is defined as $|c| = |w| + \sum_{(w',j) \in \mathbf{m}} |w'|$.

For $i \in \mathbb{N}$ we define the relation $\Rightarrow_i = \rightarrow_i \cup \mapsto_i$ on configurations of $\mathcal{A}$, where $\rightarrow_i$ and $\mapsto_i$ are defined as follows:

- $\langle g, (\gamma.w, i), \mathbf{m}\rangle \rightarrow_i \langle g', (w'.w, i), \mathbf{m}'\rangle$ for all $w \in \Gamma^*$ iff (1) there is a rule $g|\gamma \hookrightarrow g'|w' \in \Delta$ and $\mathbf{m}' = \mathbf{m}$ or (2) there is a rule $g|\gamma \hookrightarrow g'|w' \triangleright \gamma' \in \Delta$ and $\mathbf{m}' = \mathbf{m} \oplus [\![(\gamma', 0)]\!]$.

- $\langle g, (w, i), \mathbf{m} \oplus [\![(w', j)]\!]\rangle \mapsto_i \langle g, (w', j), \mathbf{m} \oplus [\![(w, i+1)]\!]\rangle$ for all $j \in \mathbb{N}$, $g \in G$, $\mathbf{m} \in \mathbb{M}[\Gamma^* \times \mathbb{N}]$, and $w, w' \in \Gamma^*$.

For $b \in \mathbb{N}$ we define the relation $\Rightarrow_{\leq b} := \bigcup_{i=0}^{b} \Rightarrow_i$. We use $\Rightarrow_i^*$ and $\Rightarrow_{\leq b}^*$ to denote the reflexive, transitive closure of $\Rightarrow_i$ and $\Rightarrow_{\leq b}$, respectively.

Given $K \in \mathbb{N}$, a state g of $\mathcal{A}$ is *K-bounded reachable* iff $\langle g_0, (\gamma_0, 0), \emptyset\rangle \Rightarrow_{\leq K}^* \langle g, (w, i), \mathbf{m}\rangle$ for some $(w, i) \in \Gamma^* \times \{0, \ldots, K\}$ and $\mathbf{m} \in \mathbb{M}[\Gamma^* \times \{0, \ldots, K+1\}]$.

Intuitively, a local configuration (w, i) describes a pushdown thread with stack content w that has already performed i context switches. The relation $\to_i$ corresponds to applying the two kinds of transition rules at i context switches. Both of them define pushdown transitions, which the active thread can perform. Type (2) also spawns a new inactive pushdown thread with 0 context switches, whose initial stack content consists of a single specified symbol. For each $i \in \mathbb{N}$, the relation $\mapsto_i$ corresponds to switching out the active thread and raising its number of context switches from i to $i+1$, while also switching in a previously inactive thread. For a fixed K, the *K-bounded state reachability problem* (SRP[K]) for a DCPS is :

Input A DCPS $\mathcal{A}$ and a global state g

Question Is g K-bounded reachable in $\mathcal{A}$?

This corresponds to asking whether the global state g is reachable if each thread can perform at most K context switches.

▶ **Theorem 1** (Main Result). *For each $K \geq 1$, the problem* SRP[K] *is* 2EXPSPACE*-complete.*

The fact that SRP[K] is in 2EXPSPACE for any fixed K follows from the results of Atig et al. [1]. They use a slightly different variant of DCPS. However, it is possible to show a reduction from SRP[K] for our variant to SRP[$K+2$] for theirs.

Our main result is to show 2EXPSPACE-hardness for SRP[1]. One may also adapt the results of Atig et al. to the problem where K is part of the input (encoded in unary), to derive an EXPSPACE lower bound and a 2EXPSPACE upper bound. Our result immediately implies 2EXPSPACE-hardness for this problem as well.

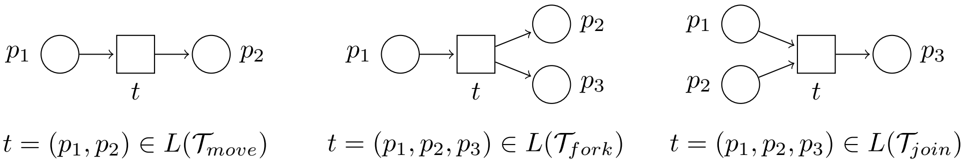
In the remaining sections we prove the lower bound in Theorem 1. In Section 3, we introduce *transducer-defined Petri nets* (TDPN), a succinct representation for Petri nets for which we prove the coverability problem is 2EXPSPACE-complete. Then, we show a reduction from the coverability problem for TDPNs to the SRP[1] problem. In Section 4, we prove hardness for coverability of TDPNs, completing the proof.

3 Transducer Defined Petri Nets (TDPN)

In this section, we prove the lower bound in Theorem 1 by reducing coverability for a succinct representation of Petri nets, namely TDPN, to SRP[1] for DCPS. We first recall some definitions about Petri nets, transducers and problems related to them.

▶ **Definition 2.** *A **Petri net** is a tuple $N = (P, T, F, p_0, p_f)$ where P is a finite set of* places, *T is a finite set of* transitions *with $T \cap P = \varnothing$, $F \subseteq (P \times T) \cup (T \times P)$ is its* flow relation, *and $p_0 \in P$ (resp. $p_f \in P$) its* initial place *(resp.* final place*). A* marking *of N is a multiset $\mathbf{m} \in \mathbb{M}[P]$. For a marking $\mathbf{m}$ and a place p we say that there are $\mathbf{m}(p)$* tokens *on p. Corresponding to the initial (resp. final) place we have the initial marking $\mathbf{m}_0 = [\![p_0]\!]$ (resp. final marking $\mathbf{m}_f = [\![p_f]\!]$). The* size *of N is defined as $|N| = |P| + |T|$.*

A transition $t \in T$ is enabled at a marking $\mathbf{m}$ if $\{p \mid (p, t) \in F\} \preceq \mathbf{m}$. If t is enabled in $\mathbf{m}$, t can be fired, which leads to a marking $\mathbf{m}'$ with $\mathbf{m}' = \mathbf{m} \oplus \{p \mid (t, p) \in F\} \ominus \{p \mid (p, t) \in F\}$. In this case we write $\mathbf{m} \xrightarrow{t} \mathbf{m}'$. A marking $\mathbf{m}$ is coverable *in N if there is a sequence $\mathbf{m}_0 \xrightarrow{t_1} \mathbf{m}_1 \xrightarrow{t_2} \ldots \xrightarrow{t_l} \mathbf{m}_l$ such that $\mathbf{m} \preceq \mathbf{m}_l$. We call such a sequence a* run *of N.*



$t = (p_1, p_2) \in L(\mathcal{T}_{move})$ $t = (p_1, p_2, p_3) \in L(\mathcal{T}_{fork})$ $t = (p_1, p_2, p_3) \in L(\mathcal{T}_{join})$

Figure 1 The types of transitions defined by the three transducers.

The *coverability problem* for Petri nets is defined as:
Input A Petri net N.
Question Is $\mathbf{m}_f$ coverable in N?

▶ **Definition 3.** *For $n \in \mathbb{N}$, a* (length preserving) ***n-ary transducer*** $\mathcal{T} = (\Sigma, Q, q_0, Q_f, \Delta)$ *consists of an alphabet Σ, a finite set of* states Q*, an* initial state $q_0 \in Q$*, a set of* final states $Q_f \subseteq Q$*, and a* transition relation $\Delta \subseteq Q \times \Sigma^n \times Q$*. For a* transition $(q, a_1, \dots, a_n, q') \in \Delta$ *we also write $q \xrightarrow{(a_1,\dots,a_n)} q'$. The size of $\mathcal{T}$ is defined as $|\mathcal{T}| = n \cdot |\Delta|$.*

The language *of $\mathcal{T}$ is the n-ary relation $L(\mathcal{T}) \subseteq (\Sigma^*)^n$ containing precisely those n-tuples $(w_1, \dots, w_n)$, for which there is a transition sequence $q_0 \xrightarrow{(a_{1,1},\dots,a_{n,1})} q_1 \xrightarrow{(a_{1,2},\dots,a_{n,2})} \dots \xrightarrow{(a_{1,m},\dots,a_{n,m})} q_m$ with $q_m \in Q_f$ and $w_i = a_{i,1}a_{i,2}\cdots a_{i,m}$ for all $i \in \{1, \dots, n\}$. Such a transition sequence is called an* accepting run *of $\mathcal{T}$.*

We note that in the more general (i.e. non-length-preserving) definition of a transducer, the transition relation Δ is a subset of $Q \times (\Sigma \cup \varepsilon)^n \times Q$. All transducers we consider in this paper are length-preserving.

▶ **Definition 4.** *A* ***transducer-defined Petri net*** $\mathcal{N} = (w_{init}, w_{final}, \mathcal{T}_{move}, \mathcal{T}_{fork}, \mathcal{T}_{join})$ *consists of two words $w_{init}, w_{final} \in \Sigma^l$ for some $l \in \mathbb{N}$, a binary transducer $\mathcal{T}_{move}$ and two ternary transducers $\mathcal{T}_{fork}$ and $\mathcal{T}_{join}$. Additionally, all three transducers share Σ as their alphabet. This defines an* explicit *Petri net $N(\mathcal{N}) = (P, T, F, p_0, p_f)$:*

- $P = \Sigma^l$.
- *T is the disjoint union of T_{move}, T_{join} and T_{fork}*[2] *where*
  - $T_{move} = \{(w, w') \in \Sigma^l \times \Sigma^l \mid (w, w') \in L(\mathcal{T}_{move})\}$,
  - $T_{fork} = \{(w, w', w'') \in \Sigma^l \times \Sigma^l \times \Sigma^l \mid (w, w', w'') \in L(\mathcal{T}_{fork})\}$, *and*
  - $T_{join} = \{(w, w', w'') \in \Sigma^l \times \Sigma^l \times \Sigma^l \mid (w, w', w'') \in L(\mathcal{T}_{join})\}$.
- *$p_0 = w_{init}$ and $p_f = w_{final}$.*
- $\forall t \in T$:
  - *If $t = (p_1, p_2) \in T_{move}$ then $(p_1, t), (t, p_2) \in F$.*
  - *If $t = (p_1, p_2, p_3) \in T_{fork}$ then $(p_1, t), (t, p_2), (t, p_3) \in F$.*
  - *If $t = (p_1, p_2, p_3) \in T_{join}$ then $(p_1, t), (p_2, t), (t, p_3) \in F$.*

An accepting run of one of the transducers, which corresponds to a single transition of N, is called a transducer-move*. The size of $\mathcal{N}$ is defined as $|\mathcal{N}| = l + |\mathcal{T}_{move}| + |\mathcal{T}_{fork}| + |\mathcal{T}_{join}|$.*

A Petri net defined by transducers in this way can only contain three different types of transitions, each type corresponding to one of the three transducers. These transition types are depicted in Figure 1. The *coverability problem* for TDPN is given by:
Input A TDPN $\mathcal{N}$.
Question Is $\mathbf{m}_f = [\![w_{final}]\!]$ coverable in the corresponding explicit Petri net $N(\mathcal{N})$?

[2] Note that a tuple $(w, w', w'') \in T_{join}$ is different from the same tuple in T_{fork}. In the interest of readability, we have chosen not to introduce a 4^{th} coordinate to distinguish the two.

Observe that the exlicit Petri net $N(\mathcal{N})$ has $|\Sigma|^l$ places, which is exponential in the size of $\mathcal{N}$. This means that TDPN are exponentially succinct representations of Petri nets.

It is a common theme in complexity theory to consider succinct versions of decision problems [12, 6, 15]. The resulting complexity is usually one exponent higher than the original version. In fact, certain types of hardness proofs can be lifted generically [15] (but such a simple argument does not seem to apply in our case). The hardness proof in the following is deferred to Section 4.

▶ **Theorem 5.** *The coverability problem for* TDPN *is* 2EXPSPACE*-complete.*

Traditionally, succinct versions of graphs and automata feature a compression using circuits [6, 15] or formulas [12]. One could also compress Petri nets by using circuits to accept binary encodings of elements (p, t) or (t, p) of the flow relation. It is relatively easy to reduce coverability for TDPN to this model by encoding transitions t as the pair or triple of places that they correspond to, yielding 2EXPSPACE-hardness. We consider transducers because they make the reduction to DCPS more natural. 2EXPSPACE-membership for any such representation follows by first unravelling the Petri net and then checking coverability [17].

We now show that coverability for TDPN can be reduced in polynomial time to SRP[1] for DCPS. The goal of the reduction is, given a TDPN $\mathcal{N} = (w_{init}, w_{final}, \mathcal{T}_{move}, \mathcal{T}_{fork}, \mathcal{T}_{join})$, to produce a DCPS $\mathcal{A}(\mathcal{N})$ with a global state *halt* such that w_{final} is coverable in $\mathcal{N}$ iff *halt* is 1-bounded reachable in $\mathcal{A}(\mathcal{N})$. We outline the main ideas and informally explain the solution to some technical issues that arise.

Representation of Markings. The main idea behind the simulation of a TDPN $\mathcal{N}$ by a DCPS $\mathcal{A}(\mathcal{N})$ is that a token on a place w of $\mathcal{N}$ is represented by a thread with stack content w. Extending this idea, a marking is represented by a multiset of threads, one for each token.

Initialization. The initial marking of $\mathcal{N}$ is $[\![w_{init}]\!]$ and $\mathcal{A}(\mathcal{N})$ starts by going into a special state where it always fills its stack with w_{init} and then moving to a global state *main*. We need $O(l)$ states in the global memory for the initialization.

Simulation of one Transducer-move. In the sequel, we explain the simulation of a single transducer-move from $\mathcal{T}_{move}$; the changes required to be made in the case of $\mathcal{T}_{join}$ and $\mathcal{T}_{fork}$ are explained at the end. Remembering the choice of transducer incurs a multiplicative cost of 3 in the global memory. The transducer-move requires us to do two things: Read the stack contents of a particular *input* thread which corresponds to a place w from which a token is removed; after which we need to create an *output* thread which corresponds to a place w' to which a token is added. This results in the following issue regarding input threads:

Issue 1: How can an input thread communicate its stack content w which comes from an exponentially large space of possibilities (since this space is Σ^l) given the requirement for the global state space to be polynomial in $|\mathcal{N}|$?

Solution 1: We pop the contents of the thread while simultaneously spawning *bit-threads*, each of which contains one letter of w along with the index $i \in \{1, \ldots, l\}$ of the letter and the information that w is a place from which a token is being removed; all of which is coded into a single *bit-symbol.*

Note that we have two types of threads: bit-threads and token-threads (i.e., those whose stack contents encode a token's position). Moreover, these two types of threads have disjoint sets of stack symbols: bit-symbols and *token-symbols.* The idea used to solve Issue 1 and read the stack contents, cannot be used in reverse to create an output token-thread since it is not possible to populate a stack with information from bit-threads.

Issue 2: How do we ensure the creation of appropriate output threads?

Solution 2: We implement a "guess-and-verify" procedure whereby we first guess the contents of an output token-thread while simultaneously producing bit-threads corresponding to w'; this is followed by a verification of the transition by comparing bit-threads produced corresponding to w and w', in a bit-by-bit fashion.

In particular, our simulation of a single transducer-move corresponds to a loop on the global state *main* which is broken up into three stages: Read, guess and verify. The implementation of this loop ensures that a configuration c of $\mathcal{A}(\mathcal{N})$ where $c.g = main$ has a multiset $c.\mathbf{m}$ of threads faithfully representing a marking $\tilde{\mathbf{m}}$ of $\mathcal{N}$ in that $c.\mathbf{m}$ contains exactly $\tilde{\mathbf{m}}(w'')$ token-threads with stack content w'' for each place w'' of $\mathcal{N}$ and no other threads.

We note that the discussion so far shows how the run of a $\mathcal{N}$ can be simulated when the schedule switches contexts at appropriate times. We must also ensure that new behaviors cannot arise due to context switches at arbitrary other points. We accomplish this by using global *locks* that ensure unwanted context switches get stuck.

Issue 3: How do we control the effect of arbitrary context switches?

Solution 3: The global state is partitioned in such a way as to only enable operations on bit-symbols while in some states and token-symbols in others. We ensure that for every bit-symbol γ, there is at most one thread with top of stack γ at any given time. Thus with the help of global control, we make sure unwanted context switches to bit-threads get the system stuck. The problem reduces to avoiding unwanted context switches between token-threads.

We use a *locking mechanism.* We add an extra $\top$ symbol at the top of every token-thread when it is first created. A read-stage always begins in a special state used for unlocking a thread (i.e. removing $\top$). While reading a particular thread, the global state disallows any transition on $\top$ or bit-symbols. Since all inactive token-threads have $\top$ as the top of stack symbol, this implies that the system cannot proceed until it switches back to the unlocked token-thread. Similarly, during the guess-stage where we are creating a new token-thread, transitions are disallowed on $\top$ and bit-symbols. The verify-stage only operates on bit-threads and switching to a token-thread is similarly pointless.

We now describe the three stages. Recall that the global state keeps the information that the current step is a transducer-move from $\mathcal{T}_{move}$.

Read-stage. We non-deterministically switch to a token-thread t_0 containing w as stack content, which we need to read. As explained earlier, we produce bit-threads decorated appropriately and at the end of this stage, we have popped all of t_0 and created l bit-threads; t_0 ceases to exist. The number of global states required in the stage is $O(l)$.

Guess-stage. Next, we create a new token-thread with w' as its stack contents by non-deterministic guessing, simultaneously spawning bit-threads for each letter of w'. At the end of this stage l more bit-threads have been added to the task buffer (for a total of $2l$ bit-threads) along with a token-thread containing w'. As in the read-stage, the number of global states used in this stage is $O(l)$.

Verify-stage. We guess a sequence of transitions $\delta_1 \ldots \delta_l$ of $\mathcal{T}_{move}$ on-the-fly; we guess δ_i which must be of the form $q_{i-1} \xrightarrow{(w_i, w_i')} q_i$ where w_i (resp. w_i') the i^{th} letter of w (resp. w'). We verify our guess by comparing each δ_i with the corresponding bit-threads b_i, b_i' with index i produced in the read-stage from w, w' respectively, before moving on to δ_{i+1}. During the verification, the bit-threads are *killed.* We enforce the condition that the target state of δ_i matches the source state of δ_{i+1}.

Claim. Killing a bit-thread t' with a single stack symbol γ' can be simulated by a DCPS. Consider the following sequence of operations starting from global state g with an active thread t which contains only one symbol γ on the stack:

1. Spawn a thread t'' with a special symbol γ_{spawn} and move to a special kill-state *kill* which contains information regarding the state g prior to the kill operation and stack symbols of t and t'.
2. Switch to a thread with symbol γ' and pop its contents while moving to a special state *return* which is forwarded the information contained in *kill*.
3. Switch to the thread with γ_{spawn} as top of stack and replace it with γ and at the same time go to global state g.

This concludes our proof sketch of the claim. Adding a kill operation to a DCPS only incurs a polynomial increase in the size of the DCPS.

In our setting, the net result of the sequence of operations simulating a kill-move is to remove the two bit-threads b_i, b_i' from the multiset of threads without changing the global state or the top of stack symbol γ. The special states *kill* (resp. *return*) ensure that if one switches to a thread whose top of stack is different from γ' in Step 2 (resp. γ_{spawn} in Step 3), no transition can be made. We return to our discussion regarding the sequence of transitions δ_i.

Since this process of checking the transducer-move occurs bit-by-bit, we require $O(l|\mathcal{T}_{move}|)$ many global states in this stage. At the end of the verification process, $\mathcal{A}(\mathcal{N})$ is once again in state *main* and the new multiset is the result of the addition of a w' thread and removal of the w thread from the old multiset of threads. We can now simulate the next transducer-move.

Checking for Coverability. At any point when $\mathcal{A}(\mathcal{N})$ is in the state *main*, it makes a non-deterministic choice between simulating the next transducer-move or checking for coverability. In the latter case, it goes into a special *check* state where the active thread is compared letter by letter with w_{final} in a process similar to initialization. At the end of the checking process, $\mathcal{A}(\mathcal{N})$ reaches the state *halt*. If the check fails at any intermediate point, $\mathcal{A}(\mathcal{N})$ terminates without reaching the *halt* state. We require a further $O(l)$ states for checking coverability.

Fork and Join. We have shown above how a single transducer-move is simulated assuming that it is a transducer-move from $\mathcal{T}_{move}$. In general, the transducer-move could be from $\mathcal{T}_{join}$ or $\mathcal{T}_{fork}$ as well. In these two cases, we have triples of the form (w, w', w'') accepted by the transducer. However, in the former, we read w, w' and guess w'' while in the latter, we read w and guess w', w''. In the case of $\mathcal{T}_{join}$, once we have read w, we non-deterministically switch to a thread containing w' as its contents. Whenever the threads picked during the read-stage and the threads created during the guess-stage do not agree with the guessed transitions of the transducer-move, we encounter a problem during the verify-stage and $\mathcal{A}(\mathcal{N})$ terminates without reaching the *halt* state.

Context Switches. Every thread (other than the initial one for w_{init}) is created during the guess-stage and then switched out once. The next time it is switched in, it is read and ceases to exist. This implies that there exists a run of $\mathcal{A}(\mathcal{N})$ simulating a run of $\mathcal{N}$ where every thread undergoes at most one context switch. Conversely, we show that a run of $\mathcal{A}(\mathcal{N})$ reaching *halt* where every thread is bounded by at most 1 context switch implies the existence of a run in $\mathcal{N}$ which covers the final marking as desired.

This concludes our overview of the construction of $\mathcal{A}(\mathcal{N})$ and completes the reduction of coverability for TDPN to SRP[1] for DCPS. The global memory is polynomial in the size of $\mathcal{N}$. Similarly, the stack alphabet is expanded to include $O(l \cdot |\Sigma|)$ bit symbols, hence the alphabet of $\mathcal{A}(\mathcal{N})$ is polynomial as well. In summary, $\mathcal{A}(\mathcal{N})$ can be produced in time polynomial in the size of the input.

▶ Remark 6. Our lower bound holds already for DCPS where the stack of each thread is bounded by a linear function of the size of the DCPS. Thus, as a corollary, we get 2EXPSPACE-hardness for a related model in which each thread is a *Boolean program*, i.e., where each thread has its stack bounded by a constant but has a polynomial number (in the size of $|G| + |\Gamma| + |\Delta|$) of local Boolean variables. This closes the gap from [8] as well as other similar models studied in the literature [2, 9, 4].

4 Recursive Net Programs (RNP)

We prove Theorem 5 by adapting the Lipton construction [13], as it is explained in [5], to our succinct representation of Petri nets. Our construction requires two steps. First we reduce termination for bounded counter programs to termination for *Petri net* programs which do not allow zero tests. Second, we reduce termination of net programs with to coverability for TDPN.

For the first step, we have to show how we can simulate the operation of a bounded counter program with one without zero tests. In the Lipton construction, this is achieved by constructing a gadget that performs zero tests for counters bounded by some bound B. These gadgets are obtained by transforming a gadget for bound B into a gadget for B^2. Starting with $B = 2$ and applying this transformation n times leads to a gadget for $B = 2^{2^n}$. One then has to argue that the resulting net program still has linear size in the parameter n. For a 2EXPSPACE lower bound, one would need to simulate a program where the bound is triply exponential in n. A naive implementation of the gadget would then lead to a program with triply exponential counter values, but exponential program size in n.

In order to argue later that the resulting program can be encoded in a small TDPN, we will present the Lipton construction in a different way. Instead of growing the program with every gadget transformation, we implement the gadgets recursively using a stack. We call these programs *recursive net programs* (RNP). This way, when we instantiate the model for a triply exponential bound on the counters (to get 2EXPSPACE-hardness instead of EXPSPACE-hardness), the resulting programs still have polynomial size control flow. Note that at run time, such programs can have an exponentially deep stack; however, this very large stack does not form part of the program description. We shall show that RNP have a natural encoding as TDPN.

For the second step, we reduce termination for RNP to coverability for TDPN. To this end, we borrow some techniques from the original construction to translate an RNP into an exponential sized Petri net. We then assign binary addresses to its places and construct transducers for those pairs and triples that correspond to transitions. This results in a TDPN of polynomial size. Finally, we argue that we do not need the whole exponential sized Petri net to reason about the transducers, and that just a polynomial size part suffices. This then gives us a polynomial time procedure.

4.1 From Bounded Counter Programs to RNP

Bounded Counter Programs. A *counter program* is a finite sequence of *labelled commands* separated by semicolons. Let l, l_1, l_2 be *labels* and x be a *variable* (also called a *counter*). The labelled commands have one of the following five forms:

(1) l : **inc** x; // increment
(2) l : **dec** x; // decrement
(3) l : **halt**
(4) l : **goto** l_1; // unconditional jump
(5) l : **if** $x = 0$ **then goto** l_1 **else goto** l_2; // conditional jump

Variables can hold values over the natural numbers, labels have to be pairwise distinct, but can otherwise come from some arbitrary set. For convenience, we require each program to contain exactly one **halt** command at the very end. The *size* $|C|$ of a counter program C is the number of its labelled commands.

During execution, all variables start with initial value 0. The semantics of programs follows from the syntax, except for the case of decrementing a variable whose value is already 0. In this case, the program aborts, which is different from proper termination, i.e., the execution of the **halt** command. It is easy to see that each counter program has only one execution, meaning it is deterministic. This execution is *k-bounded* if none of the variables ever reaches a value greater than k during it.

Let $\exp^{m+1}(x) := \exp(\exp^m(x))$ and $\exp^1(x) = \exp(x) := 2^x$. The N-fold exponentially bounded *halting problem* (also called *termination*) for counter programs ($\mathsf{HP}[N]$) is given by:
Input A unary number $n \in \mathbb{N}$ and a counter program C.
Question Does C have an $\exp^N(n)$-bounded execution that reaches the **halt** command?
We make use of the following well-known result regarding this problem:

▶ **Theorem 7.** *For each $N > 0$, the problem $\mathsf{HP}[N+1]$ is N-EXPSPACE-complete.*

The proof for arbitrary N matches the proof for $N = 1$, which the Lipton construction used.

Recursive Net Programs. The definition of *recursive net programs* (RNP) also involves sequences of labelled commands separated by semicolons. Let l, l_1, l_2 be labels, x be a variable, and `proc` be a procedure name. Then the labelled commands can still have one of the previous forms (1) to (4). However, form (5) changes from a conditional to a nondeterministic jump, and there are two new forms for procedure calls:

(1) l : **inc** x; // increment
(2) l : **dec** x; // decrement
(3) l : **halt**
(4) l : **goto** l_1; // unconditional jump
(5) l : **goto** l_1 **or goto** l_2; // nondeterministic jump
(6) l : **call** `proc`; // procedure call
(7) l : **return**; // end of procedure

In addition to labelled commands, these programs consist of a finite set PROC of procedure names and also a *maximum recursion depth* $k \in \mathbb{N}$. Furthermore, they not only contain one sequence of labelled commands to serve as the main program, but also include two additional sequences of labelled commands for each procedure name `proc` $\in$ PROC. The second sequence for each `proc` is not allowed to contain any **call** commands and serves as a sort of "base case" only to be called at the maximum recursion depth. Each label has to be unique among all sequences and each jump is only allowed to target labels of the sequence it belongs to. Each RNP contains exactly one **halt** command at the end of the main program.

For $\mathtt{proc} \in \mathsf{PROC}$ let $\#c(\mathtt{proc})$ be the number of commands in both of its sequences added together and let $\#c(\mathtt{main})$ be the number of commands in the main program. Then the *size* of an RNP R is defined as $|R| = \lceil \log k \rceil + \#c(\mathtt{main}) + \sum_{\mathtt{proc} \in \mathsf{PROC}} \#c(\mathtt{proc})$.

The semantics here is quite different compared to counter programs: If the command "l : **call** proc" is executed, the label l gets pushed onto the call stack. Then if the stack contains less than k labels, the first command sequence pertaining to proc, which we now call $\mathtt{proc}_{<\max}$, is executed. If the stack already contains k labels, the second command sequence, $\mathtt{proc}_{=\max}$, is executed instead. Since $\mathtt{proc}_{=\max}$ cannot call any procedures by definition, the call stack's height (i.e. the *recursion depth*) is bounded by k. On a return command, the last label gets popped from the stack and we continue the execution at the label occurring right after the popped one.

How increments and decrements are executed depends on the current recursion depth d as well. For each variable x appearing in a command, $k+1$ copies x_0 to x_k are maintained during execution. The commands **inc** x resp. **dec** x are then interpreted as increments resp. decrements on x_d (and not x or any other copy). As before, all these copies start with value 0 and decrements fail at value 0, which is different from proper termination.

Instead of a conditional jump, we now have a nondeterministic one, that allows the program execution to continue at either label. Regarding termination we thus only require there to be at least one execution that reaches the **halt** command. This gives us the following halting problem for RNP:

Input An RNP R

Question Is there an execution of R that reaches the **halt** command?

We now adapt the Lipton construction to recursive net programs. We start with a $\exp^2(n)$-bounded counter program C with a set of counters X and construct an RNP $R(C)$ with maximum recursion depth $n+1$ that terminates iff C terminates. The number of commands in $R(C)$ will be linear in $|C|$.

Auxiliary Variables. The construction of $R(C)$ involves simulating the zero test. To this end, we introduce for each counter $x \in X$ a complementary counter $\bar{x}$ and ensure that the invariant $x_0 + \bar{x}_0 = \exp^2(n)$ always holds. We can then simulate a zero test on x by checking that $\bar{x}$ can be decremented $\exp^2(n)$ times. This requires us to implement a decrement by $\exp^2(n)$ in linearly many commands and also a similar increment to reach a value of $\exp^2(n)$ for $\bar{x}$ from its initial value 0 at the start of the program. Furthermore, we need helper variables s, $\bar{s}$, y, $\bar{y}$, z, and $\bar{z}$. We also sometimes need to increment or decrement the $(d+1)$th copy of one of these six variables at recursion level d. As an example, for incrementing s_{d+1} in this way, we define the procedure s_inc:

$$\mathtt{s\_inc}_{<\max}: \ \textbf{inc } s; \textbf{return} \qquad \mathtt{s\_inc}_{=\max}: \ \textbf{inc } s; \textbf{return}$$

The analogous procedures for $\bar{s}$, y, $\bar{y}$, z, and $\bar{z}$ are defined similarly.

Program Structure. The program $R(C)$ consists of two parts: The initial part $R_{init}(C)$, which initializes all the complementary counters as mentioned above, followed by $R_{sim}(C)$, the part that simulates C. We construct $R_{sim}(C)$ from C by replacing some of its commands. Increments of the form **inc** x are replaced by **dec** $\bar{x}$;**inc** x, decrements **dec** x are replaced by **dec** x;**inc** $\bar{x}$. Unconditional jumps and the **halt** command stay the same. Each conditional jump (form (5) for counter programs) is replaced by

$$\begin{aligned} l &: \mathrm{Test}(x, l_{\text{continue}}, l_2); \\ l_{\text{continue}} &: \mathrm{Test}(\bar{x}, l_1, l_2) \end{aligned}$$

```
Test$(x, l_{\text{zero}}, l_{\text{nonzero}})$ :

                  goto $l_{\text{nztest}}$ or goto $l_{\text{loop}}$;
  $l_{\text{nztest}}$ : dec $x$; inc $x$; goto $l_{\text{nonzero}}$;
    $l_{\text{loop}}$ : dec $\bar{x}$; inc $x$; call $\bar{\texttt{s}}$_dec; call s_inc;
                  goto $l_{\text{exit}}$ or goto $l_{\text{loop}}$;
    $l_{\text{exit}}$ : call dec; goto $l_{\text{zero}}$

Test$_{+1}(v, l_{\text{zero}}, l_{\text{nonzero}})$ :

                  goto $l_{\text{nztest}}$ or goto $l_{\text{loop}}$;
  $l_{\text{nztest}}$ : call v_dec; call v_inc; goto $l_{\text{nonzero}}$;
    $l_{\text{loop}}$ : call $\bar{\texttt{v}}$_dec; call v_inc;
                  call $\bar{\texttt{s}}$_dec; call s_inc;
                  goto $l_{\text{exit}}$ or goto $l_{\text{loop}}$;
    $l_{\text{exit}}$ : call dec; goto $l_{\text{zero}}$
```

```
dec$_{<\text{max}}$ :

   $l_{\text{outer}}$ : call y_dec; call $\bar{\texttt{y}}$_inc;
   $l_{\text{inner}}$ : call z_dec; call $\bar{\texttt{z}}$_inc;
             dec $s$; inc $\bar{s}$;
             Test$_{+1}(z, l_{\text{next}}, l_{\text{inner}})$;
    $l_{\text{next}}$ : Test$_{+1}(y, l_{\text{exit}}, l_{\text{outer}})$;
    $l_{\text{exit}}$ : return

dec$_{=\text{max}}$ :

             dec $s$; inc $\bar{s}$; dec $s$; inc $\bar{s}$;
             return
```

Figure 2 Definitions of the macros Test and Test$_{+1}$ as well as the procedure `dec`. Regarding the second macro we require $v \in \{y, z\}$.

where Test$(x, l_{zero}, l_{nonzero})$ is what we call a *macro*. We use it as syntactic sugar to be replaced by its specification for the actual construction of $R(C)$. This is in contrast to procedures, which refer to specific parts of the program that can be called to increase the recursion depth.

Test Macros and Decrement Procedure. The macro Test is specified in the left part of Figure 2. It involves a call to the procedure `dec`, which is defined in the right part of the same figure. Below Test we have also specified the variant Test$_{+1}$, which is used in `dec`. The main difference is that Test$_{+1}$ can only be invoked on variables y or z and acts on their $(d+1)$th copy at recursion depth d.

Semantically, `dec` at recursion depth d decrements s_d by $\exp^2(n+1-d)$ (and increments $\bar{s}_d$ by the same amount). Both variants of Test simulate a conditional jump and have the side effect of switching the values x_d and $\bar{x}_d$ if the tested variable x_d was 0. Because of this, every conditional jump of C gets replaced by two instances of the Test macro, where the second one reverses the potential side effect.

The decrements of procedure `dec` are performed via two nested loops that each run $\exp^2(n-d)$-times. Each of these loops uses a helper variable y_{d+1} or z_{d+1} that has to be tested for zero at the end, using the Test$_{+1}$ macro. This involves transferring the helper variable's value to s_{d+1} and then calling `dec` at the next recursion depth. Essentially, any decrement by $\exp^2(j)$ for some j is implemented using $\exp^2(j-1)$ many decrements by $\exp^2(j-1)$ via the nested loops. This iterative squaring of the value by which we decrement continues down to the base case of $\exp^2(0) = 2$.

Semantics. Our construction is semantically very similar to the Lipton construction, barring two main differences: Firstly, instead of having $n+1$ different procedure definitions of `dec` (one per level d), we only need two because of recursion. The case for the Test macros is similar, as is the case of the helper variables s, y, z and their complements. Secondly, our variable copies start with index 0 counting upwards, whereas in the Lipton construction the variables start with index n and count downwards. This means that for some index d we have the invariant $s_d + \bar{s}_d = \exp^2(n+1-d)$ in our construction, where it is $s_d + \bar{s}_d = \exp^2(d)$ for Lipton. While the invariant of the Lipton construction is simpler, ours allows us to define the recursion depth starting at 0 and going upwards, which seemed more natural for recursion.

Let us give a more precise analysis regarding the effect of the Test macros and `dec` procedure. During the execution of `dec` at recursion depth d, we begin with $s_d = \exp^2(n+1-d)$, $y_{d+1} = z_{d+1} = \exp^2(n-d)$, and $\bar{s}_d = \bar{y}_{d+1} = \bar{z}_{d+1} = 0$. The invariants $s_d + \bar{s}_d = \exp^2(n+1-d)$, $y_{d+1} + \bar{y}_{d+1} = \exp^2(n-d)$, and $z_{d+1} + \bar{z}_{d+1} = \exp^2(n-d)$ are upheld throughout. At the end we have $s_d = \bar{y}_{d+1} = \bar{z}_{d+1} = 0$, $y_{d+1} = z_{d+1} = \exp^2(n-d)$, and $\bar{s}_d = \exp^2(n+1-d)$, meaning the decrements were performed correctly and all helper variables retain their initial values. The situation is quite similar for Test and Test$_{+1}$, if the variable to be tested was initially 0. In the non-zero case, the tested variable is just decremented and incremented once, whereas no other variables are touched. All executions that differ from the described behavior are guaranteed to get stuck.

Correctness of these semantics can be proven by induction on the recursion depth. It requires the assumptions $x_0 + \bar{x}_0 = \exp^2(n)$, $v_d + \bar{v}_d = \exp^2(n+1-d)$, and $\bar{v}_d = 0$ for all $x \in X$, $v \in \{\bar{s}, y, z\}$, and $d > 0$.

Initialization. We now have to construct $R_{init}(C)$ in such a way, that it performs all the necessary increments for these assumptions to hold at the start of $R_{sim}(C)$. Since this is again achieved using iterative squaring, we omit the precise construction. It involves calling a procedure `inc` to perform the increments on copies of variables at lower recursion depths, while x_0 is incremented in the main program for each $x \in X$.

Size Analysis. To give a brief size analysis of $R(C)$, PROC contains 14 procedure names, whose corresponding definitions have constant size. For each command in C, $R_{sim}(C)$ contains constantly many commands, and $R_{init}(C)$ has linearly many commands in the size of the variable set X. Since wlog. each variable of C is involved in at least one of its commands, the amount of commands in $R(C)$ is linear in $|C|$. Here, for doubly exponential counter values, we would not even need n to be given in unary since only $\lceil \log(n+1) \rceil$ factors into the size of $R(C)$.

Handling Triply Exponential Counter Values. The exact same construction with a maximum recursion depth of $2^n + 1$ can be used to simulate a counter program with counters bounded by $\exp^3(n)$: Starting with 2 and squaring n-times yields $\exp^2(n)$, therefore squaring 2^n times instead yields $\exp^3(n)$. The correctness follows from the same inductive proofs as before. For this changed maximum recursion depth, configurations contain exponentially in n many counter values and also maintain a call stack of size up to 2^n. However, since the maximum recursion depth can be encoded in binary, its size is still polynomial in the unary encoding of n. Thus, the halting problem for recursive net programs is 2EXPSPACE-hard.

4.2 From RNP to TDPN

Figure 3 and Figure 4 show how the commands of recursive net programs can be simulated by Petri net transitions. This is again done in similar fashion to Esparza's description [5] of the Lipton construction [13]. As we can see, this involves only the three types of transitions defined by our transducers.

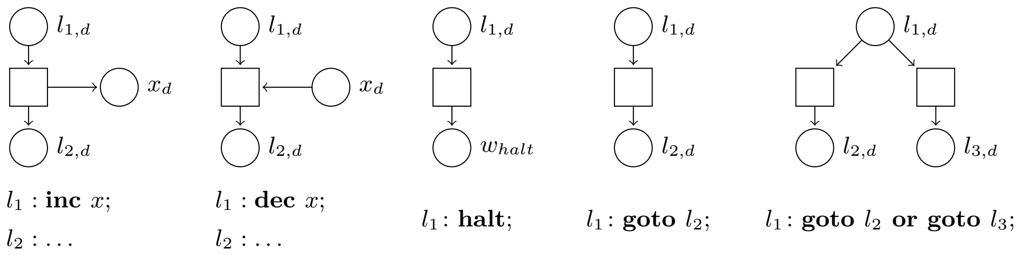


Figure 3 Petri net transitions for five of the seven command types found in recursive net programs. Here, $d \in \{0, \ldots, k\}$, where k is the maximum recursion depth.

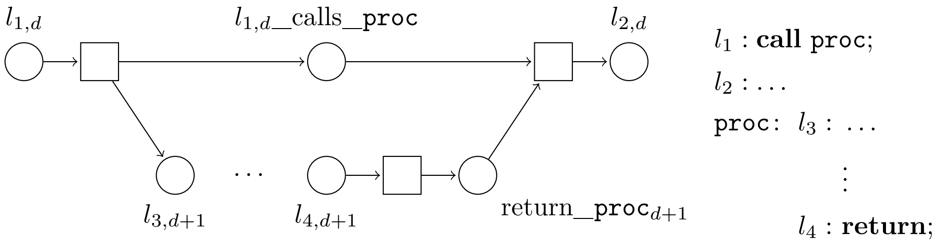

Figure 4 Petri net transitions for procedure calls found in recursive net programs. Here, $d \in \{0, \ldots, k-1\}$, where k is the maximum recursion depth.

Let us give more detail regarding the Petri net construction: Given an RNP R with maximum recursion depth k we construct a transducer-defined Petri net $\mathcal{N} = (w_{init}, w_{final}, \mathcal{T}_{move}, \mathcal{T}_{fork}, \mathcal{T}_{join})$, which defines the Petri net $N(\mathcal{N}) = (P, T, F, p_0, p_f)$, such that $[\![p_f]\!]$ is coverable in $N(\mathcal{N})$ iff there is a terminating execution of R. We begin by arguing about the shape of $N(\mathcal{N})$ and then construct our transducers afterwards.

The idea is for $N(\mathcal{N})$ to start with one place per variable and one place per label, as well as one auxiliary place for each **call** command and each proc $\in$ PROC, which can be seen in Figure 4. Additionally, there is also a single auxiliary place w_{halt} for the **halt** command. Let the number of all these places be h. Then each such place gets copied $k+1$ times, so that a copy exists for each possible recursion depth. Transitions get added at each recursion depth d according to Figure 3 and Figure 4, whereas some transitions in the latter also connect to places of recursion depth $d+1$.

Regarding the transducers, we use the alphabet $\{0, 1\}$. Every place address $w = u.v$ has a prefix u of length $\lceil \log h \rceil$ and a postfix v of length $\lceil \log k \rceil$. We assign each of the h places that $N(\mathcal{N})$ started with a number from 0 to $h-1$. The binary representation of this number (with leading zeros) is used for the u-part of its address. For the v-part, we use the binary representation of the recursion depth d (also with leading zeros), that a particular copy of this place corresponds to. The address of the place corresponding to the first label in the main program at recursion depth 0 is used for w_{init}, whereas the one corresponding to w_{halt} at recursion depth 0 is used for w_{final}.

To accept a particular pair or triple of addresses as a transition, each of the three transducers distinguishes between all possibilities regarding the u-parts. Any pair or triple of $\lceil \log h \rceil$-length words that matches a particular transition of the right type (move, fork, join) has a unique path in the transducer, while all non-matching pairs or triples do not. Then for the v-parts, the transducer needs to either check for equality, if all places correspond to the same recursion depth, or for one binary represented number to be one higher. Since it is clear from the u-parts, whether the recursion depths should all match or not, we can just connect the unique paths to the correct part of the transducer at the end.

The transducer parts for the first $\lceil \log h \rceil$ bits require to distinguish between up to $2^{3 \log h} = 8h$ possibilities, meaning they require polynomially in h many states. The parts for the last $\lceil \log k \rceil$ bits can easily be constructed using polynomially many states in $\log k$. Since h is linear in the number of commands in R and $\lceil \log k \rceil$ is the size of the binary encoding of the maximum recursion depth, $\mathcal{N}$ is of polynomial size compared to R. Because we can construct $\mathcal{N}$ by first constructing $N(\mathcal{N})$ without the copies for each recursion depth, this is feasible in polynomial time. Thus, the coverability problem for transducer-defined Petri nets is 2EXPSPACE-hard.

5 Discussion

The chain of reductions in Sections 3 and 4 complete the 2EXPSPACE lower bound for 1-bounded reachability for DCPS. In fact, an inspection of the reductions show a technical strengthening: the 2EXPSPACE lower bound already holds for SRP[1] of DCPS which satisfy two additional properties, *boundedness* and *local termination*.

▶ **Definition 8.** *A* DCPS $\mathcal{A}$ *is said to be* bounded *if there is a global bound* $B \in \mathbb{N}$ *on the size of every configuration of every run of* $\mathcal{A}$*. It is* locally terminating *if every infinite run of* $\mathcal{A}$ *contains infinitely many context switches.*

Consider the chain of reductions from the halting problem for bounded counter programs to RNP to TDPN to SRP[1]. The configurations of the counter programs, by definition, are bounded by a triply-exponential bound on the parameter n. This bound translates to bounds on the RNP and TDPN instances. In particular, the number of places in the TDPN produced in the reduction is exponentially bounded in n and the number of tokens on these places is triple-exponentially bounded in n. The DCPS constructed from the TDPN uses the stack of a thread to store an address of a place; thus, the height of a stack is bounded by a polynomial in n. In addition, since the number of tokens in the TDPN correspond to the number of in-progress threads in the DCPS, this implies a triple exponential (in n) bound on the number of threads in any execution of the DCPS. Thus, the size of every configuration in every run of the DCPS is bounded.

Second, the rules of the constructed DCPS do not allow any one thread to run indefinitely. In other words, any non-terminating run of the DCPS must involve infinitely many threads and the run contains infinitely many context switches.

▶ **Theorem 9.** *The* SRP[1] *problem for bounded, locally terminating* DCPS *is* 2EXPSPACE-*hard.*

Abstract

We consider the extension of FO^2 with quantifiers that state that the number of elements where a formula holds should belong to a given ultimately periodic set. We show that both satisfiability and finite satisfiability of the logic are decidable. We also show that the spectrum of any sentence is definable in Presburger arithmetic. In the process we present several refinements to the "biregular graph method". In this method, decidability issues concerning two-variable logics are reduced to questions about Presburger definability of integer vectors associated with partitioned graphs, where nodes in a partition satisfy certain constraints on their in- and out-degrees.

1 Introduction

In the search for expressive logics with decidable satisfiability problem, two-variable logic, denoted here as FO^2, is one yardstick. This logic is expressive enough to subsume basic modal logic and many description logics, while satisfiability and finite satisfiability coincide, and both are decidable [23, 15, 9]. However, FO^2 lacks the ability to count. Two-variable logic with counting, C^2, is a decidable extension of FO^2 that adds *counting quantifiers*. In C^2 one can express, for example, $\exists^5 x\ P(x)$ and $\forall x \exists^{\geqslant 5} y\ E(x, y)$ which, respectively, mean that there are exactly 5 elements in unary relation P, and that every element in a graph has at least 5 adjacent edges. Satisfiability and finite satisfiability do not coincide for C^2, but both are decidable [10, 16]. In [16] the problems were shown to be NEXPTIME-complete under a unary encoding of numbers, and this was extended to binary encoding in [18]. However, the numerical capabilities of C^2 are quite limited. For example, one can not express that the number of outgoing edges of each element in the graph is even.

A natural extension is to combine FO^2 with *Presburger arithmetic* where one is allowed to define collections of tuples of integers from addition and equality using boolean operators and quantifiers. The collections of k-tuples that one can define in this way are the *semi-linear sets*, and the collections of integers (when $k = 1$) definable are the *ultimately periodic sets.* Prior work has considered the addition of *Presburger quantification* to fragments of two-variable logic. For every definable set $\phi(x, y)$ and every ultimately periodic set S, one has a formula $\exists^S y\ \phi(x, y)$ that holds at x when the number of y such that $\phi(x, y)$ is in S. We let $\mathsf{FO}^2_{\mathrm{Pres}}$ denote the logic that adds this construct to FO^2.

On the one hand, the corresponding quantification over general k-tuples (allowing semi-linear rather than ultimately periodic sets) easily leads to undecidability [11, 3]. On the other hand, adding this quantification to modal logic has been shown to preserve decidability [1, 7]. Related *one-variable fragments* in which we have only a unary relational vocabulary and the main quantification is $\exists^S x\ \phi(x)$ are known to be decidable (see, e.g. [2]), and their decidability is the basis for a number of software tools focusing on integration of relational languages with Presburger arithmetic [14]. The decidability of full $\mathsf{FO}^2_{\mathrm{Pres}}$ is, to the best of our knowledge, still open [4]. There are a number of other extensions of C^2 that have been shown decidable; for example it has been shown that one can allow a distinguished equivalence relation [22] or a forest-structured relation [6, 5]. $\mathsf{FO}^2_{\mathrm{Pres}}$ is easily seen to be orthogonal to these other extensions.

In this paper we show that both satisfiability and finite satisfiability of $\mathsf{FO}^2_{\mathrm{Pres}}$ are decidable. Our result makes use of the *biregular graph method* introduced for analyzing C^2 in [13]. The method focuses on the problem of existence of graphs equipped with a partition of vertices based on constraints on the out- and in-degree. Such a partitioned graph can be characterized by the cardinalities of each partition component, and the key step in showing these decidability results is to prove that the set of tuples of integers representing valid sizes of partition components is definable by a formula in Presburger arithmetic. From this "graph constraint Presburger definability" result one can reduce satisfiability in the logic to satisfiability of a Presburger formula, and from there infer decidability using known results on Presburger arithmetic.

The approach is closely-related to the machinery developed by Pratt-Hartmann (the "star types" of [21]) for analyzing the decidability and complexity of C^2, its fragments [19], and its extensions [22, 5]. An advantage of the biregular graph approach is that it is transparent how to extract more information about the shape of witness structures. In particular we can infer that the *spectrum* of any formula is Presburger definable, where the spectrum of a formula ϕ is the set of cardinalities of finite models of ϕ. It is also interesting to note that a more restricted version of our biregular graph method is used to prove the decidability of FO^2 extended with two equivalence relations [12].

Characterising the spectrum for general first order formulas is quite a difficult problem, with ties to major open questions in complexity theory [8]. This work can be seen as a demonstration of the power of the biregular graph method to get new decidability results. We make heavy use of both techniques and results in [13], adapting them to the richer logic. We also require additional inductive arguments to handle the interaction of ordinary counting quantifiers and modulo counting quantification.

2 Preliminaries

Let $\mathbb{N} = \{0, 1, 2, \ldots\}$ and let $\mathbb{N}_\infty = \mathbb{N} \cup \{\infty\}$.

Linear and ultimately periodic sets. A set of the form $\{a + ip \mid i \in \mathbb{N}\}$, for some $a, p \in \mathbb{N}$ is a *linear set.* We will denote such a set by a^{+p}, where a and p are called the *offset* and *period* of the set, respectively. Note that, by definition, $a^{+0} = \{a\}$, which is a linear set. For convenience, we define $\emptyset$ and $\{\infty\}$ (which may be written as ∞^{+p}) to also be linear sets.

An *ultimately periodic set* (*u.p.s.*) S is a finite union of linear sets. Usually we write a u.p.s. $\{c_1\} \cup \cdots \cup \{c_m\} \cup a_1^{+p_1} \cup \cdots \cup a_n^{+p_n}$ as just $\{c_1, \ldots, c_m, a_1^{+p_1}, \ldots, a_n^{+p_n}\}$, and abusing notation, we write $a^{+p} \in S$ for a u.p.s. S if $a + ip \in S$ for every $i \in \mathbb{N}$.

Two-variable logic with ultimately periodic counting quantifiers. An *atomic formula* is either an atom $R(\vec{u})$, where R is a predicate, and $\vec{u}$ is a tuple of variables of appropriate size, or an equality $u = u'$, with u and u' variables, or one of the formulas $\top$ and $\bot$ denoting the True and False values. The logic $\mathsf{FO}^2_{\mathrm{Pres}}$ is a class of first-order formulas using only variables x and y, built up from atomic formulas and equalities using the usual boolean connectives and also *ultimately periodic counting quantification*, which is of the form $\exists^S x\ \phi$ where S is a u.p.s. One special case is where S is a singleton $\{a\}$ with $a \in \mathbb{N}_\infty$, which we write $\exists^a x\ \phi$; in case of $a \in \mathbb{N}$, these are *counting quantifiers.* The semantics of $\mathsf{FO}^2_{\mathrm{Pres}}$ is defined as usual except that, for every $a \in \mathbb{N}$, $\exists^a x\ \phi$ holds when there are *exactly* a number of x's such that ϕ holds, $\exists^\infty\ \phi$ holds when there are infinitely many x's such that ϕ holds, and $\exists^S x\ \phi$ holds when there is some $a \in S$ such that $\exists^a x\ \phi$ holds.

Note that when S is $\{\infty\} \cup 0^{+1} = \mathbb{N}_\infty$, $\exists^S x\ \phi$ is equivalent to $\top$. When S is 0^{+1}, $\exists^S x\ \phi$ semantically means that there are finitely many x such that ϕ holds. We define $\exists^\emptyset x\ \phi$ to be $\bot$ for any formula ϕ. We also note that $\exists^0 x\ \phi$ is equivalent to $\forall x\ \neg\phi$, and $\neg\exists^S x\ \phi$ is equivalent to $\exists^{\mathbb{N}_\infty - S} x\ \phi$.

For example, we can state in $\mathsf{FO}^2_{\mathrm{Pres}}$ that every node in a graph has even degree (i.e., the graph is Eulerian). Clearly $\mathsf{FO}^2_{\mathrm{Pres}}$ extends C^2, the fragment of the logic where only counting quantifiers are used, and FO^2, the fragment where only the classical quantifier $\exists x$ is allowed.

Presburger arithmetic. An *existential Presburger formula* is a formula of the form $\exists x_1 \ldots x_k\ \phi$, where ϕ is a quantifier-free formula over the signature including constants $0, 1$, a binary function symbol $+$, and a binary relation $\leqslant$. Such a formula is a *sentence* if it has no free variables. The notion of a sentence holding in a structure interpreting the function, relations, and constants is defined in the usual way. The structure $\mathcal{N} = (\mathbb{N}, +, \leqslant, 0, 1)$, is defined by interpreting $+, \leqslant, 0, 1$ in the standard way, while the structure $\mathcal{N}_\infty = (\mathbb{N}_\infty, +, \leqslant, 0, 1)$ is the same except that $a + \infty = \infty$ and $a \leqslant \infty$ for each $a \in \mathbb{N}_\infty$.

It is known that the satisfiability of existential Presburger sentences over $\mathcal{N}$ is decidable and belongs to NP [17]. Further, the satisfiability problem for $\mathcal{N}_\infty$ can easily be reduced to that for $\mathcal{N}$. Indeed, we can first guess which variables are mapped to ∞ and then which atoms should be true, then check whether each guessed atomic truth value is consistent with other guesses and determine additional variables which must be infinite based on this choice, and finally restrict to atoms that do not involve variables guessed to be infinite, and check that the conjunction is satisfiable by standard integers.

▶ **Theorem 1.** *The satisfiability problem for existential Presburger sentences over both $\mathcal{N}$ and $\mathcal{N}_\infty$ are both in NP.*

3 Main result

In this section we prove the decidability of $\mathsf{FO}^2_{\mathrm{Pres}}$ satisfiability. Our decision procedure is based on the key notion of regular graphs. Note that whenever we talk about graphs or digraphs (i.e., directed graphs), by default we allow both finite and infinite sets of vertices and edges.

3.1 Regular graphs

In the following we fix an integer $p \geqslant 0$. Let $\mathbb{N}_{\infty,+p}$ denote the set whose elements are either a or a^{+p}, where $a \in \mathbb{N}_\infty$. For integers $t, m \geqslant 1$, let $\mathbb{N}_{\infty,+p}^{t\times m}$ denote the set of matrices with t rows and m columns where each entry is an element from $\mathbb{N}_{\infty,+p}$.

A *t-color bipartite (undirected) graph* is $G = (U, V, E_1, \ldots, E_t)$, where U and V are sets of vertices and $E_1, \ldots, E_t$ are pairwise disjoint sets of edges between U and V. Edges in E_i are called *E_i-edges.* We will write an edge in a bipartite graph as $(u, v) \in U \times V$. For a vertex $u \in U \cup V$, the *E_i-degree* of u is the number of E_i-edges adjacent to u. The degree of u is the sum of the E_i-degrees for $i = 1 \ldots t$. We say that G is *complete*, if $U \times V = \bigcup_{i=1}^{t} E_i$.

For two matrices $A \in \mathbb{N}_{\infty,+p}^{t\times m}$ and $B \in \mathbb{N}_{\infty,+p}^{t\times n}$, the graph G is a *$A|B$-biregular* graph, if there exist partitions $U_1, \ldots, U_m$ of U and $V_1, \ldots, V_n$ of V such that for every $1 \leqslant i \leqslant t$, for every $1 \leqslant k \leqslant m$, for every $1 \leqslant l \leqslant n$, the E_i-degree of every vertex in U_k is $A_{i,k}$ and the E_i degree of every vertex in V_l is $B_{i,l}$.[1] For each such partition, we say that G *has size* $\bar{M}|\bar{N}$, where $\bar{M} = (|U_1|, \ldots, |U_m|)$ and $\bar{N} = (|V_1|, \ldots, |V_n|)$. The partition $U_1, \ldots, U_m$ and $V_1, \ldots, V_n$ is called a *witness partition.* We should remark that some U_i and V_i are allowed to be empty.

The above definition can be easily adapted for the case of directed graphs that are not necessarily bipartite. A t-color *directed graph* (or *digraph*) is $G = (V, E_1, \ldots, E_t)$, where $E_1, \ldots, E_t$ are pairwise disjoint set of directed edges on a set of vertices V. As before, edges in E_i are called E_i-edges. The E_i-indegree and -outdegree of a vertex u, is defined as the number of incoming and outgoing E_i-edges incident to u.

In a t-color digraph G we will assume that (i) there are no self-loops – that is, (v, v) is not an E_i-edge, for every vertex $v \in V$ and every E_i, and (ii) if (u, v) is an E_i-edge, then its inverse (v, u) is not an E_j-edge for any E_j. This will suffice for the digraphs that arise in our decision procedure. We say that a digraph G is *complete*, if for every $u, v \in V$ and $u \neq v$, either (u, v) or (v, u) is an E_i-edge, for some E_i.

We say that G is a *$A|B$-regular* digraph, where $A, B \in \mathbb{N}_{\infty,+p}^{t\times m}$, if there exists a partition $V_1, \ldots, V_m$ of V such that for every $1 \leqslant i \leqslant t$, for every $1 \leqslant k \leqslant m$, the E_i-indegree and -outdegree of every vertex in V_k is $A_{i,k}$ and $B_{i,k}$, respectively. We say that G has size $(|V_1|, \ldots, |V_m|)$, and call $V_1, \ldots, V_m$ a witness partition.

Lemma 2 below will be the main technical tool for our decidability result. Let $\bar{x}$ and $\bar{y}$ be vectors of variables of length m and n, respectively.

▶ **Lemma 2.** *For every $A \in \mathbb{N}_{\infty,+p}^{t\times m}$ and $B \in \mathbb{N}_{\infty,+p}^{t\times n}$, there exists (effectively computable) existential Presburger formula $\textsf{c-bireg}_{A|B}(\bar{x}, \bar{y})$ such that for every $(\bar{M}, \bar{N}) \in \mathbb{N}_\infty^m \times \mathbb{N}_\infty^n$, the following holds: there is complete $A|B$-biregular graph with size $\bar{M}|\bar{N}$ if and only if $\textsf{c-bireg}_{A|B}(\bar{M}, \bar{N})$ holds in $\mathcal{N}_\infty$.*

Lemma 3 below is the analog for digraphs.

▶ **Lemma 3.** *For every $A \in \mathbb{N}_{\infty,+p}^{t\times m}$ and $B \in \mathbb{N}_{\infty,+p}^{t\times m}$, there exists (effectively computable) existential Presburger formula $\textsf{c-reg}_{A|B}(\bar{x})$ such that for every $\bar{M} \in \mathbb{N}_\infty^m$, the following holds. There is complete $A|B$-regular digraph with size $\bar{M}$ if and only if $\textsf{c-reg}_{A|B}(\bar{M})$ holds in $\mathcal{N}_\infty$.*

[1] By abuse of notation, when we say that an integer z equals a^{+p}, we mean that $z \in a^{+p}$. Thus, when writing $A_{i,k} = a^{+p}$, we mean that the degree of the vertex is an element in a^{+p}.

Lemmas 2 and 3 can be easily readjusted when we are interested only in finite sizes, i.e., $\bar{M} \in \mathbb{N}^m$ and $\bar{N} \in \mathbb{N}^n$, by requiring the formulas to hold in $\mathcal{N}$, instead of $\mathcal{N}_\infty$. Alternatively, we can also state inside the formulas that none of the variables in $\bar{x}$ and $\bar{y}$ are equal to ∞.

The proofs of these two lemmas are discussed in Section 4.

3.2 Decision procedure

Theorem 4 below is the main result in this paper.

▶ **Theorem 4.** *For every FO^2_{Pres} sentence ϕ, there is an (effectively computable) existential Presburger formula $PRES_\phi$ such that (i) ϕ has a model iff $PRES_\phi$ holds in $\mathcal{N}_\infty$ and (ii) ϕ has a finite model iff $PRES_\phi$ holds in $\mathcal{N}$.*

From the decision procedure for existential Presburger formulas (Theorem 1) mentioned in Section 2, we immediately will obtain the following corollary.

▶ **Corollary 5.** *Both satisfiability and finite satisfiability for FO^2_{Pres} are decidable.*

We will sketch how Theorem 4 is proven, making use of Lemmas 2 and 3. We start by observing that satisfiability (and spectrum analysis) for an $\mathsf{FO}^2_{\mathrm{Pres}}$ sentence can be converted effectively into the same questions for a sentence in a variant of Scott normal form:

$$\phi := \forall x \forall y \; \alpha(x,y) \;\; \wedge \;\; \bigwedge_{i=1}^{k} \forall x \exists^{S_i} y \; \beta_i(x,y) \wedge x \neq y, \tag{1}$$

where $\alpha(x,y)$ is a quantifier free formula, each $\beta_i(x,y)$ is an atomic formula and each S_i is an u.p.s. The proof, which is fairly standard, will appear in the full version of this paper. By taking the least common multiple, we may assume that all the (non-zero) periods in all S_i are the same.

We recall some standard terminology. A 1-*type* is a maximally consistent set of atomic and negated atomic unary formulas using only variable x. A 1-type can be identified with the quantifier-free formula that is the conjunction of its constituent formulas. Thus, we say that an element a in a structure $\mathcal{A}$ has 1-type π, if π holds on the element a. We denote by A_π the set of elements in $\mathcal{A}$ with 1-type π. Clearly the domain A of a structure $\mathcal{A}$ is partitioned into the sets A_π. Similarly, a 2-*type* is a maximally consistent set of atomic and negated atomic binary formulas using only variables x, y, containing the predicate $x \neq y$. The notion of a pair of elements (a,b) in a structure $\mathcal{A}$ having 2-type E is defined as with 1-types. We denote by $\Pi = \{\pi_1, \pi_2, \ldots, \pi_n\}$ and $\mathcal{E} = \{E_1, \ldots, E_t, \overleftarrow{E_1}, \ldots, \overleftarrow{E_t}\}$ the sets of all 1-types and 2-types, respectively, where $\overleftarrow{E_i}(x,y) = E_i(y,x)$ for each $1 \leqslant i \leqslant t$ – that is, each $\overleftarrow{E_i}$ is the reversal of E_i.

Let $g : \mathcal{E} \times \Pi \to \mathbb{N}_{\infty,+p}$ be a function. We will use such a function g to describe the "behavior" of the elements in the following sense. Let $\mathcal{A}$ be a structure. We say that an element $a \in A$ *behaves according to* g, if for every $E \in \mathcal{E}$ and for every $\pi \in \Pi$, the number of elements $b \in A_\pi$ such that the 2-type of (a,b) is E belongs to $g(E,\pi)$. We denote by $A_{\pi,g}$ the set of all elements in A_π that behave according to g. The restriction of g on 1-type π is the function $g_\pi : \mathcal{E} \to \mathbb{N}_{\infty,+p}$, where $g_\pi(E) = g(E,\pi)$. We call the function g_π the *behavior* (function) towards 1-type π.

We are, of course, only interested in functions g that are consistent with the sentence ϕ in (1), and we formalize this as follows:

- A 1-type $\pi \in \Pi$ and a function $g : \mathcal{E} \times \Pi \to \mathbb{N}_{\infty,+p}$ are *incompatible* (w.r.t. $\forall x \forall y \; \alpha(x,y)$), if there is $E \in \mathcal{E}$ and $\pi' \in \Pi$ such that $\pi(x) \wedge E(x,y) \wedge \pi'(y) \models \neg\alpha(x,y)$ and $g(E,\pi') \neq 0$.

- A function $g : \mathcal{E} \times \Pi \to \mathbb{N}_{\infty,+p}$ is a *good* function (w.r.t. $\bigwedge_{i=1}^{k} \forall x \exists^{S_i} y\ \beta_i(x,y) \wedge x \neq y$), if for every $\pi \in \Pi$ and for every i the following holds:[2]

$$\sum_{E \models \beta_i(x,y)} \sum_{\pi \in \Pi} g(E,\pi) = a \qquad\qquad \text{for some } a \in S_i.$$

If $\mathcal{A} \models \phi$ then $A_{(\pi,g)} = \emptyset$, whenever π and g are incompatible, and in addition every element in A behaves only according to some good function.

The main idea is to construct the sentence PRES_ϕ that "counts" the cardinality $|A_{(\pi,g)}|$ in every structure $\mathcal{A} \models \phi$, for every π and g. Toward this end, let $\mathcal{G} = \{g_1, g_2, \ldots, g_m\}$ enumerate all good functions. Note that $\mathcal{G}$ can be computed effectively from the sentence ϕ, since it suffices to consider functions $g : \mathcal{E} \times \Pi \to \mathbb{N}_{\infty,+p}$ with codomain $\{0, \ldots, a, 0^{+p}, \ldots, a^{+p}, \infty\}$, where a is the maximal offset of the (non-∞) elements in $\bigcup_{i=1}^{k} S_i$.

The sentence PRES_ϕ will be of the form

$$\mathsf{PRES}_\phi := \exists \bar{X}\ \mathsf{consistent}_1(\bar{X})\ \wedge\ \mathsf{consistent}_2(\bar{X}) \tag{2}$$

where $\bar{X}$ is a vector of variables $(X_{(\pi_1,g_1)}, X_{(\pi_1,g_2)}, \ldots, X_{(\pi_n,g_m)})$. Intuitively, each $X_{(\pi_i,g_j)}$ represents $|A_{\pi_i,g_j}|$. By the formulas $\mathsf{consistent}_1(\bar{X})$ and $\mathsf{consistent}_2(\bar{X})$, we capture the consistency of the integers $\bar{X}$ with the formulas $\forall x \forall y\ \alpha(x,y)$ and $\bigwedge_{i=1}^{k} \forall x \exists^{S_i} y\ \beta_i(x,y) \wedge x \neq y$, respectively.

We start by defining the formula $\mathsf{consistent}_1(\bar{X})$. Letting H be the set of all pairs (π, g) where π and g are incompatible, the formula $\mathsf{consistent}_1(\bar{X})$ can be defined as

$$\mathsf{consistent}_1(\bar{X}) := \bigwedge_{(\pi,g) \in H} X_{(\pi,g)} = 0 \tag{3}$$

Towards defining the formula $\mathsf{consistent}_2(\bar{X})$, we introduce some notations. For $\pi \in \Pi$, define the matrices $M_\pi, \overleftarrow{M}_\pi \in \mathbb{N}_{\infty,+p}^{t \times m}$ as follows:

$$M_\pi := \begin{pmatrix} g_1(E_1,\pi) & \cdots & g_m(E_1,\pi) \\ \vdots & \ddots & \vdots \\ g_1(E_t,\pi) & \cdots & g_m(E_t,\pi) \end{pmatrix} \quad \text{and} \quad \overleftarrow{M}_\pi := \begin{pmatrix} g_1(\overleftarrow{E_1},\pi) & \cdots & g_m(\overleftarrow{E_1},\pi) \\ \vdots & \ddots & \vdots \\ g_1(\overleftarrow{E_t},\pi) & \cdots & g_m(\overleftarrow{E_t},\pi) \end{pmatrix}$$

The idea is that M_π captures all possible behavior towards 1-type π, where each column j represents the behavior of g_j towards π. Note that for a structure $\mathcal{A}$ and 1-type π, the restriction of $\mathcal{A}$ on the set A_π can be viewed as a t-color digraph $G = (V, E_1, \ldots, E_t)$. It is sufficient to consider only the 2-types $E_1, \ldots, E_t$, because each E_i determines its reversal $\overleftarrow{E_i}$. Moreover, an element a has an incoming E_i-edge if and only if it has an outgoing $\overleftarrow{E_i}$-edge. Thus, if $\mathcal{A} \models \phi$, the graph G is a complete $M_\pi|\overleftarrow{M}_\pi$-regular digraph.

Now, we explain how to capture the behavior between elements with distinct 1-types. Define matrices $L_\pi, \overleftarrow{L}_\pi \in \mathbb{N}_{\infty,+p}^{2t \times m}$ as follows:

$$L_\pi := \begin{pmatrix} M_\pi \\ \overleftarrow{M}_\pi \end{pmatrix} \quad \text{and} \quad \overleftarrow{L}_\pi := \begin{pmatrix} \overleftarrow{M}_\pi \\ M_\pi \end{pmatrix}$$

That is, in L_π the first t rows come from M_π with the next t rows from $\overleftarrow{M}_\pi$. On the other hand, in $\overleftarrow{L}_\pi$ the first t rows come from $\overleftarrow{M}_\pi$, followed by the t rows from M_π.

[2] Here the operation $+$ on $\mathbb{N}_{\infty,+p}$ is defined to be commutative operation where $a + \infty = a^{+p} + \infty = \infty$ and $a^{+p} + b = a^{+p} + b^{+p} = (a+b)^{+p}$. On integers from $\mathbb{N}$, it is the standard addition operation.

The idea is that for a structure $\mathcal{A}$, the 2-types that are realized between A_π and $A_{\pi'}$ can be viewed as a $2t$-color bipartite graph $G = (A_\pi, A_{\pi'}, E_1, \ldots, E_t, \overleftarrow{E_1}, \ldots, \overleftarrow{E_t})$, where the direction of the edges are ignored. Moreover, a pair (a, b) has 2-type E if and only if (b, a) has 2-type $\overleftarrow{E}$, Thus, if $\mathcal{A} \models \phi$, the graph G is a complete $L_{\pi'}|\overleftarrow{L}_{\pi}$-biregular graph.

Now we are ready to define the formula $\mathsf{consistent}_2(\bar{X})$. We enumerate all the 1-types $\pi_1, \ldots, \pi_n$ and define $\mathsf{consistent}_2$ as follows:

$$\mathsf{consistent}_2(\bar{X}) := \bigwedge_{1 \leqslant i \leqslant n} \mathsf{c\text{-}reg}_{M_{\pi_i}|\overleftarrow{M}_{\pi_i}}(\bar{X}_{\pi_i}) \ \wedge \ \bigwedge_{1 \leqslant i < j \leqslant n} \mathsf{c\text{-}bireg}_{L_{\pi_j}|\overleftarrow{L}_{\pi_i}}(\bar{X}_{\pi_i}, \bar{X}_{\pi_j}). \qquad (4)$$

The formula $\mathsf{consistent}_1(\bar{X})$ is Presburger definable by inspection, while $\mathsf{consistent}_2(\bar{X})$ is Presburger definable using Lemmas 2 and 3. The correctness comes directly from the following lemma.

▶ **Lemma 6.** *For every structure $\mathcal{A} \models \phi$, $\mathsf{consistent}_1(\bar{N}) \wedge \mathsf{consistent}_2(\bar{N})$ holds, where $\bar{N} = (|A_{\pi_1,g_1}|, \ldots, |A_{\pi_n,g_m}|)$. Conversely, for every $\bar{N}$ such that $\mathsf{consistent}_1(\bar{N}) \wedge \mathsf{consistent}_2(\bar{N})$ holds, there is $\mathcal{A} \models \phi$ such that $\bar{N} = (|A_{\pi_1,g_1}|, \ldots, |A_{\pi_n,g_m}|)$.*

Proof. Let ϕ be in Scott normal form as in (1). As before, $\Pi = \{\pi_1, \pi_2, \ldots, \pi_n\}$ denote the set of all 1-types and $\mathcal{E} = \{E_1, \ldots, E_t, \overleftarrow{E_1}, \ldots, \overleftarrow{E_t}\}$ the set of all 2-types, where $\overleftarrow{E_i}(x, y) = E_i(y, x)$ for each $1 \leqslant i \leqslant t$. Recall that each 2-type E contains the predicate $x \neq y$ and that $\mathcal{G} = \{g_1, \ldots, g_m\}$ is the set of all good functions.

Note that for $\pi, \pi' \in \Pi$ and $E \in \mathcal{E}$, the conjunction $\pi(x) \wedge E(x, y) \wedge \pi'(y)$ corresponds to a boolean assignment of the atomic predicates in $\alpha(x, y)$. Thus, either $\pi(x) \wedge E(x, y) \wedge \pi'(y) \models \alpha(x, y)$ or $\pi(x) \wedge E(x, y) \wedge \pi'(y) \models \neg\alpha(x, y)$. Similarly, $\pi(x) \wedge x = y \models \alpha(x, y)$ or $\pi(x) \wedge x = y \models \neg\alpha(x, y)$.

We first prove the first statement in the lemma. Let $\mathcal{A} \models \phi$. Partition A into $A_{\pi,g}$'s. We will show that $\mathsf{consistent}_1(\bar{X}) \ \wedge \ \mathsf{consistent}_2(\bar{X})$ holds when each $X_{\pi,g}$ is assigned with the value $|A_{\pi,g}|$.

Since $\mathcal{A} \models \forall x \forall y \ \alpha(x, y)$, by definition $A_{\pi,g} = \emptyset$, whenever π and g are incompatible. Thus, $\mathsf{consistent}_1(\bar{X})$ holds.

Next, we will show that $\mathsf{consistent}_2(\bar{X})$ holds. Let $\pi \in \Pi$. By definition of A_π, A_π is a complete $M_\pi|\overleftarrow{M}_\pi$-regular digraph $G = (V, E_1, \ldots, E_t)$, with size $(|A_{\pi,g_1}|, \ldots, |A_{\pi,g_m}|)$. Thus, by Lemma 3, $\mathsf{c\text{-}reg}_{M_\pi|\overleftarrow{M}_\pi}(\bar{X}_\pi)$ holds.

For $\pi_i, \pi_j \in \Pi$, where $i < j$, the structure $\mathcal{A}$ restricted to A_{π_i} and A_{π_j} can be viewed as a complete $L_{\pi_j}|\overleftarrow{L}_{\pi_i}$-biregular graph $G = (U, V, E_1, \ldots, E_t, \overleftarrow{E_1}, \ldots, \overleftarrow{E_t})$, where $U = A_{\pi_i}$ and $V = A_{\pi_j}$, and for each $1 \leqslant i \leqslant t$, we have the interpretation denoted (by a slight abuse of notation) as E_i consist of all pairs $(a, b) \in A_{\pi_i} \times A_{\pi_j}$ whose 2-type is E_i, and similarly for $\overleftarrow{E_i}$. By Lemma 2, $\mathsf{c\text{-}bireg}_{L_{\pi_j}|\overleftarrow{L}_{\pi_i}}(\bar{X}_{\pi_i}, \bar{X}_{\pi_j})$ holds.

Now we prove the second statement. Suppose PRES_ϕ holds. By definition, there exists an assignment to the variables in $\bar{X}$ such that $\mathsf{consistent}_1(\bar{X}) \wedge \mathsf{consistent}_2(\bar{X})$ holds. Abusing notation as we often do in this work, we denote the value assigned to each $X_{\pi,g}$ by the variable $X_{\pi,g}$ itself.

For each (π, g), we have a set $V_{\pi,g}$ with cardinality $X_{\pi,g}$. We denote by $V_\pi = \bigcup_g V_{\pi,g}$. We construct a structure $\mathcal{A}$ that satisfies ϕ as follows.

- The domain is $A = \bigcup_{\pi,g} V_{\pi,g}$.
- For each $\pi \in \Pi$, for each $a \in V_\pi$, the unary atomic formulas on a are defined such that the 1-type of a becomes π.

- For each $\pi \in \Pi$, the binary predicates on $(u, v) \in V_\pi \times V_\pi$ are defined as follows. Since $\mathsf{c\text{-}reg}_{M_\pi|\overleftarrow{M}_\pi}(\bar{X}_\pi)$ holds, there is a complete $M_\pi|\overleftarrow{M}_\pi$-regular digraph $G = (V_\pi, E_1, \ldots, E_t)$ with size $\bar{X}_\pi$. The edges $E_1, \ldots, E_t$ define precisely the 2-types among elements in V_π.
- For each π_i, π_j, where $i < j$, the binary predicates on $(u, v) \in V_{\pi_i} \times V_{\pi_j}$ are defined as follows. Since $\mathsf{c\text{-}bireg}_{L_{\pi_j}|\overleftarrow{L}_{\pi_i}}(\bar{X}_{\pi_i}, \bar{X}_{\pi_j})$ holds, there is a $L_{\pi'}|\overleftarrow{L}_\pi$-biregular graph $G = (V_{\pi_i}, V_{\pi_j}, E_1, \ldots, E_t, \overleftarrow{E}_1, \ldots, \overleftarrow{E}_t)$ with size $\bar{X}_\pi|\bar{X}_{\pi'}$. The edges $E_1, \ldots, E_t, \overleftarrow{E}_1, \ldots, \overleftarrow{E}_t$ define precisely the 2-types on $(u, v) \in V_{\pi_i} \times V_{\pi_j}$.

We first show that $\mathcal{A} \models \forall x \forall y\ \alpha(x, y)$. Indeed, suppose there exist $u, v \in A$ such that $\pi(u) \wedge E_(u, v) \wedge \pi'(v) \not\models \alpha(u, v)$. By definition, there is g such that $u \in V_{\pi,g}$ and $g(E, \pi') \neq 0$. Thus, $V_{\pi,g} \neq \emptyset$. This also means that π is incompatible with g, which implies that $X_{\pi,g} = 0$ by $\mathsf{consistent}_1(\bar{X})$, thus, contradicts the assumption that $V_{\pi,g} \neq \emptyset$.

Next, we show that $\mathcal{A} \models \bigwedge_{i=1}^{k} \forall x \exists^{S_i} y\ \beta_i(x, y) \wedge x \neq y$. Note that $\mathcal{G} = \{g_1, \ldots, g_m\}$ consists of only good functions. Thus, for every $g \in \mathcal{G}$, for every β_i, the sum $\sum_\pi \sum_{\beta_i(x,y) \in E}\ g(E, \pi)$ is an element in S_i. ◀

4 Proof ideas for Lemmas 2 and 3

We now discuss the proof of the main biregular graph lemmas. Due to space constraints, we deal only with the 1-color case, which gives the flavor of the arguments. The general case, which is much more involved, is deferred to the full version of this paper.

This section is organized as follows. In Subsection 4.1 we will focus on a relaxation of Lemma 2 where the requirement being complete is dropped. This will then be used to prove the complete case in Subsection 4.2. Finally, in Subsection 4.3 we present a brief explanation on how to modify the proof for the biregular graphs to the one for regular digraphs.

4.1 The case of incomplete 1-color biregular graphs

This subsection is devoted to the proof of the following lemma.

▶ **Lemma 7.** *For every $A \in \mathbb{N}^{1\times m}_{\infty,+p}$ and $B \in \mathbb{N}^{1\times n}_{\infty,+p}$, there exists (effectively computable) existential Presburger formula $\mathsf{bireg}_{A|B}(\bar{x}, \bar{y})$ such that for every $(\bar{M}, \bar{N}) \in \mathbb{N}^m_\infty \times \mathbb{N}^n_\infty$ the following holds: there is an $A|B$-biregular graph with size $\bar{M}|\bar{N}$ if and only if $\mathsf{bireg}_{A|B}(\bar{M}, \bar{N})$ holds in $\mathcal{N}_\infty$.*

The desired formula $\mathsf{c\text{-}bireg}_{A|B}(\bar{x}, \bar{y})$ for complete biregular graphs will be defined using the formula $\mathsf{bireg}_{A|B}(\bar{x}, \bar{y})$.

We will use the following notations. The term vectors always refers to row vectors, and we usually use $\bar{a}, \bar{b}, \ldots$ (possibly indexed) to denote them. We write $(\bar{a}, \bar{b})$ to denote the vector $\bar{a}$ concatenated with $\bar{b}$. Obviously 1-row matrices can be viewed as row vectors. For $\bar{a} = (a_1, \ldots, a_k) \in \mathbb{N}^k_\infty$, we write $\bar{a}^{+p}$ to denote the vector $(a_1^{+p}, \ldots, a_k^{+p})$.

Matrix entries of the form a^{+p} are called *periodic* entries. Otherwise, they are called *fixed* entries. By grouping the entries according to whether they are fixed/periodic, we write a 1-row matrix M as $(\bar{a}, \bar{b}^{+p})$, where $\bar{a}$ and $\bar{b}^{+p}$ correspond to the fixed and periodic entries in M. Matrices that contain only fixed (or, periodic) entries are written as $\bar{a}$ (or, $\bar{a}^{+p}$).

To specify $A|B$-biregular graphs, we write $(\bar{a}, \bar{b}^{+p})|(\bar{c}, \bar{d}^{+p})$-biregular graphs, where $A = (\bar{a}, \bar{b}^{+p})$ and $B = (\bar{c}, \bar{d}^{+p})$. Similarly, when, say, A contains only fixed entries, it is written as $\bar{a}|(\bar{c}, \bar{d}^{+p})$-biregular. The size of $(\bar{a}, \bar{b}^{+p})|(\bar{c}, \bar{d}^{+p})$-biregular graph is written as $(\bar{M}_0, \bar{M}_1)|(\bar{N}_0, \bar{N}_1)$, where the lengths of $\bar{M}_0, \bar{M}_1, \bar{N}_0, \bar{N}_1$ are the same as $\bar{a}, \bar{b}, \bar{c}, \bar{d}$, respectively. The other cases, when some of $\bar{a}, \bar{b}^{+p}, \bar{c}, \bar{d}^{+p}$ are omitted, are treated in similar manner.

As before, we will write $\bar{x}, \bar{y}$ (possibly indexed) to denote a vector of variables. We write $\bar{1}$ to denote the vector with all components being 1. We use $\cdot$ to denote the standard dot product between two vectors. To avoid being repetitive, when dot products are performed, it is implicit that the vector lengths are the same. In particular, $\bar{x} \cdot \bar{1}$ is the sum of all the components in $\bar{x}$.

We now outline the proof of Lemma 7, focusing only on the case where there is no ∞ degree in the matrices. The case where such a degree exists is similar but simpler. Without loss of generality, we can also assume that none of the fixed entries are zero. For vectors $\bar{M}_0, \bar{M}_1, \bar{N}_0, \bar{N}_1$ with the same length as $\bar{a}, \bar{b}, \bar{c}, \bar{d}$, respectively, we say that $(\bar{M}_0, \bar{M}_1)|(\bar{N}_0, \bar{N}_1)$ *is big enough for* $(\bar{a}, \bar{b}^{+p})|(\bar{c}, \bar{d}^{+p})$, if the following holds:

(a) $\bar{M}_0 \cdot \bar{1} + \bar{M}_1 \cdot \bar{1} + \bar{N}_0 \cdot \bar{1} + \bar{N}_1 \cdot \bar{1} \geqslant 2\delta_{\max}^2 + 3$,

(b) $\bar{M}_1 \cdot \bar{1} \geqslant \delta_{\max}^2 + 1$,

(c) $\bar{N}_1 \cdot \bar{1} \geqslant \delta_{\max}^2 + 1$.

Here $\delta_{\max}$ is $\max(p, \bar{a}, \bar{b}, \bar{c}, \bar{d})$ – that is, the maximal element among p and the components in $\bar{a}, \bar{b}, \bar{c}, \bar{d}$. When $\bar{b}^{+p}$ or $\bar{d}^{+p}$ are missing, the same notion can be defined by dropping condition (b) or (c), respectively. For example, we say that $\bar{M}|\bar{N}$ is big enough for $\bar{a}|\bar{b}$, if $\bar{M} \cdot \bar{1} + \bar{N} \cdot \bar{1} \geqslant 2\delta_{\max}^2 + 3$, where $\delta_{\max} = \max(\bar{a}, \bar{b})$. Similarly, $(\bar{M}_0, \bar{M}_1)|\bar{N}$ is big enough for $(\bar{a}, \bar{b}^{+p})|\bar{c}$, if $\bar{M}_0 \cdot \bar{1} + \bar{M}_1 \cdot \bar{1} + \bar{N} \cdot \bar{1} \geqslant 2\delta_{\max}^2 + 3$, and $\bar{M}_1 \cdot \bar{1} \geqslant \delta_{\max}^2 + 1$, where $\delta_{\max} = \max(p, \bar{a}, \bar{b}, \bar{c})$.

The proof idea is as follows. We first construct a formula that deals with big enough sizes. Then, we construct a formula for each of the cases when one of the conditions (a), (b) or (c) is violated. The interesting case will be when condition (b) is violated. This means that the number of vertices with degrees from $\bar{b}^{+p}$ is fixed, and they can be "encoded" inside the Presburger formula.

We start with the big enough case. When there are only fixed entries, we will use the following lemma.

▶ **Lemma 8.** *For $\bar{M}|\bar{N}$ big enough for $\bar{a}|\bar{b}$, there is a $\bar{a}|\bar{b}$-biregular graph with size $\bar{M}|\bar{N}$ if and only if $\bar{M} \cdot \bar{a} = \bar{N} \cdot \bar{b}$.*

Proof. Note that if we have a biregular graph with the desired outdegrees on the left, then the total number of edges must be $\bar{M} \cdot \bar{a}$, and similarly the total number of edges considering the requirement for vertices on the right, we see that the total number of edges must be $\bar{N} \cdot \bar{b}$. Thus this condition is always a necessary one, regardless of whether $\bar{M}|\bar{N}$ is big enough.

When both $\bar{M}$ and $\bar{N}$ do not contain ∞, [13, Lemma 7.2] shows that when $\bar{M}|\bar{N}$ is big enough for $\bar{a}|\bar{b}$, the converse holds: $\bar{M} \cdot \bar{a} = \bar{N} \cdot \bar{b}$ implies that there is a $\bar{a}|\bar{b}$-biregular graph with size $\bar{M}|\bar{N}$. We briefly mention the proof idea there, which we will also see later (e.g., in the proof of Lemma 9). There is a preliminary construction that handles the requirement on vertices on one side in isolation, leaving the vertices on the right with outdegree 1. A follow-up construction merges vertices on the right in order to ensure the necessary number of incoming edges on the right. In doing so we exploit the "big enough" property in order to avoid merging two nodes on the right with a common adjacent edge on the left.

We will now prove that the condition is also sufficient when either $\bar{M}$ or $\bar{N}$ contains ∞. So assume $\bar{M} \cdot \bar{a} = \bar{N} \cdot \bar{b}$, and thus both $\bar{M}, \bar{N}$ contain ∞.

We construct an $\bar{a}|\bar{b}$-biregular graph $G = (U, V, E)$ with size $\bar{M}|\bar{N}$ as follows. Let $\bar{a} = (a_1, \dots, a_m)$ and $\bar{b} = (b_1, \dots, b_n)$. Let $\bar{M} = (M_1, \dots, M_m)$ and $\bar{N} = (N_1, \dots, N_n)$. We pick pairwise disjoint sets $U_1, \dots, U_m$, where each $|U_i| = M_i$ and $V_1, \dots, V_n$, where $|V_i| = N_i$. We set $U = \bigcup_i U_i$ and $V = \bigcup_i V_i$.

The edges are constructed as follows. For each $i \leqslant i \leqslant m$, when $|U_i|$ is finite, we make each vertex $u \in U_i$ have degree a_i, as follows. For each $1 \leqslant j \leqslant t$, we pick a_i "new" vertices from some infinite set V_l – that is, vertices that are not adjacent to any edge, and connect them to u. Likewise, for each vertex $v \in V_i$ when $|V_i|$ is finite. After performing this, every vertex in finite U_i and V_i has degree a_i and b_i, respectively, and every vertex in infinite sets U_i and V_i has degree at most 1.

Finally, we iterate the following process. For every infinite U_i, if $u \in U_i$ has degree other than a_i, we change the degree to a_i by picking "new" vertices from some infinite set V_l, and connect them to u by an appropriate number of edges. Likewise, we can make each vertex v in infinite V_i to have degree b_i. Note that in any iteration, for every infinite set U_i, the degree of a vertex $u \in U_i$ is either a_i, 1, or 0. Likewise, in any iteration, for every infinite set V_i, the degree of a vertex $v \in V_i$ is either b_i, 1, or 0. Since there is an infinite supply of vertices, there are always new vertices that can be picked in any iteration. ◀

Now we move to the case where the entries are still big enough, but some of the entries are periodic on one side. Then we consider the following formula $\Psi_{(\bar{a},\bar{b}^{+p})|\bar{c}}(\bar{x}_0, \bar{x}_1, \bar{y})$:

$$\exists z \quad (z \neq \infty) \ \wedge \ \big(\bar{a} \cdot \bar{x}_0 + \bar{b} \cdot \bar{x}_1 + pz \ = \ \bar{c} \cdot \bar{y}\big). \tag{5}$$

Note that if $G = (U, V, E)$ is a $(\bar{a}, \bar{b}^{+p})|\bar{c}$-biregular graph with size $(\bar{M}_0, \bar{M}_1)|\bar{N}$, then the number of edges $|E|$ should equal the sum of the degrees of the vertices in U, which is $\bar{a} \cdot \bar{M}_0 + \bar{b} \cdot \bar{M}_1 + zp$, for some integer $z \geqslant 0$. Since this quantity must equal the sum of the degrees of the vertices in V, which is $\bar{c} \cdot \bar{N}$, we again conclude that this formula is a necessary condition – regardless of whether the entries are big enough. We again show the converse.

▶ **Lemma 9.** *For $(\bar{M}_0, \bar{M}_1)|\bar{N}$ big enough for $(\bar{a}, \bar{b}^{+p})|\bar{c}$ the following holds. There is a $(\bar{a}, \bar{b}^{+p})|\bar{c}$-biregular graph with size $(\bar{M}_0, \bar{M}_1)|\bar{N}$ if and only if $\Psi_{(\bar{a},\bar{b}^{+p})|\bar{c}}(\bar{M}_0, \bar{M}_1, \bar{N})$ holds.*

Proof. Assume that $\Psi_{(\bar{a},\bar{b}^{+p})|\bar{c}}(\bar{M}_0, \bar{M}_1, \bar{N})$ holds. As before, abusing notation, we denote the value assigned to variable z by z itself. Suppose $\bar{a} \cdot \bar{M}_0 + \bar{b} \cdot \bar{M}_1 + pz = \bar{N} \cdot \bar{c}$. Since $(\bar{M}_0, \bar{M}_1)|\bar{N}$ is big enough for $(\bar{a}, \bar{b}^{+p})|\bar{c}$, it follows immediately that $(\bar{M}_0, \bar{M}_1, z)|\bar{N}$ is big enough for $(\bar{a}, \bar{b}, p)|\bar{c}$. Applying Lemma 8, there is a $(\bar{a}, \bar{b}, p)|\bar{c}$-biregular graph with size $(\bar{M}_0, \bar{M}_1, z)|\bar{N}$. That is, we have a graph that satisfies our requirements, but there is an additional partition class Z on the left of size z where the number of adjacent vertices is p, rather than being $\bar{b}^{+p}$ as we require. Let $G = (U, V, E)$ be such a graph, and let $U = U_0 \cup U_1 \cup Z$, where U_0, U_1, and Z are the sets of vertices whose degrees are from $\bar{a}$, $\bar{b}$, and from p. Note that $|U_0| = \bar{M}_0 \cdot \bar{1}$, $|U_1| = \bar{M}_1 \cdot \bar{1}$ and $|Z| = z$.

We will construct a $(\bar{a}, \bar{b}^{+p})|\bar{c}$-biregular graph with size $(\bar{M}_0, \bar{M}_1)|\bar{N}$. The idea is to merge the vertices in Z with vertices in U_1. Let $z_0 \in Z$. The number of vertices in U_1 reachable from z_0 in distance 2 is at most $\delta^2_{\max}$. Since $(\bar{M}_0, \bar{M}_1)|\bar{N}$ is big enough for $(\bar{a}, \bar{b}^{+p})|\bar{c}$, we have $|U_1| = \bar{M}_1 \cdot \bar{1} \geqslant \delta^2_{\max} + 1$. Thus, there is a vertex $u \in U_1$ not reachable in distance 2. We merge z_0 and u into one vertex. Since the degree of z_0 is p, such merging increases the degree of u by p, which does not break our requirement. We perform such merging for every vertex in Z. ◀

Finally, we turn to the big enough case where there are periodic entries on both sides. There we will deal with the following formula $\Psi_{(\bar{a},\bar{b}^{+p})|(\bar{c},\bar{d}^{+p})}(\bar{x}_0, \bar{x}_1, \bar{y}_0, \bar{y}_1)$:

$$\exists z_1 \exists z_2 \ (z_1 \neq \infty) \ \wedge \ (z_2 \neq \infty) \ \wedge \big(\bar{a} \cdot \bar{x}_0 + \bar{b} \cdot \bar{x}_1 + pz_1 = \bar{c} \cdot \bar{y}_0 + \bar{d} \cdot \bar{y}_1 + pz_2\big). \tag{6}$$

▶ **Lemma 10.** *For $(\bar{M}_0, \bar{M}_1)|(\bar{N}_0, \bar{N}_1)$ big enough for $(\bar{a}, \bar{b}^{+p})|(\bar{c}, \bar{d}^{+p})$ the following holds: there exists a $(\bar{a}, \bar{b}^{+p})|(\bar{c}, \bar{d}^{+p})$-biregular graph with size $(\bar{M}_0, \bar{M}_1)|(\bar{N}_0, \bar{N}_1)$ if and only if $\Psi_{(\bar{a},\bar{b}^{+p})|(\bar{c},\bar{d}^{+p})}(\bar{M}_0, \bar{M}_1, \bar{N}_0, \bar{N}_1)$ holds.*

Proof. As before, the "only if" part is straightforward, so we focus on the "if" part. Suppose $\Psi_{(\bar{a},\bar{b}^{+p})|(\bar{c},\bar{d}^{+p})}(\bar{M}_0,\bar{M}_1,\bar{N}_0,\bar{N}_1)$ holds. Thus, $\bar{a}\cdot\bar{M}_0+\bar{b}\cdot\bar{M}_1+pz_1=\bar{c}\cdot\bar{N}_0+\bar{d}\cdot\bar{N}_1+pz_2$. If $z_1\geqslant z_2$, then the equation can be rewritten as $\bar{a}\cdot\bar{M}_0+\bar{b}\cdot\bar{M}_1+p(z_1-z_2)=\bar{c}\cdot\bar{N}_0+\bar{d}\cdot\bar{N}_1$. By Lemma 9, there is a $(\bar{a},\bar{b}^{+p})|(\bar{c},\bar{d})$-biregular graph with size $(\bar{M}_0,\bar{M}_1)|(\bar{N}_0,\bar{N}_1)$, which of course, is also $(\bar{a},\bar{b}^{+p})|(\bar{c},\bar{d}^{+p})$-biregular. The case when $z_2\geqslant z_1$ is symmetric. ◀

The previous lemmas give formulas that capture the existence of 1-color biregular graphs for big enough sizes. We now turn to sizes that are not big enough – that is, when one of the conditions (a), (b) or (c) is violated. When condition (a) is violated, we have restricted the total size of the graph, and thus we can write a formula that simply enumerate all possible valid sizes. We will consider the case when condition (b) is violated, with the case where condition (c) is violated being symmetric.

If (b) is violated we can fix the value of $\bar{M}_1\cdot\bar{1}$ as some r, and it suffices to find a formula that works for this r. The idea is that a fixed number of vertices in a graph can be "encoded" as formulas. For $\bar{a}=(a_1,\dots,a_k)$, $\bar{b}=(b_1,\dots,b_l)$, $\bar{c}=(c_1,\dots,c_m)$ and $\bar{d}=(d_1,\dots,d_n)$, and for integer $r\geqslant 0$, define the formula $\Phi^r_{(\bar{a},\bar{b}^{+p})|(\bar{c},\bar{d}^{+p})}(\bar{x}_0,\bar{x}_1,\bar{y}_0,\bar{y}_1)$ as follows:

1. when $r=0$, let
$$\Phi^r_{(\bar{a},\bar{b}^{+p})|(\bar{c},\bar{d}^{+p})}(\bar{x}_0,\bar{x}_1,\bar{y}_0,\bar{y}_1) := \ \bar{x}_1\cdot\bar{1}=0 \ \wedge \ \Psi_{\bar{a}|(\bar{c},\bar{d}^{+p})}(\bar{x}_0,\bar{y}_0,\bar{y}_1),$$
where $\Psi_{\bar{a}|(\bar{c},\bar{d}^{+p})}(\bar{x}_0,\bar{y}_0,\bar{y}_1)$ is as defined in equation (5);
2. when $r\geqslant 1$, let $\bar{x}_1=(x_{1,1},\dots,x_{1,l})$ and
$$\Phi^r_{(\bar{a},\bar{b}^{+p})|(\bar{c},\bar{d}^{+p})}(\bar{x}_0,\bar{x}_1,\bar{y}_0,\bar{y}_1) \ :=$$
$$\exists s\exists\bar{z}_0\exists\bar{z}_1\exists\bar{z}_2\exists\bar{z}_3\bigvee_{i=1}^{l}\left(\begin{array}{l} \quad (x_{1,i}\neq 0) \ \wedge \ (b_i+ps \ = \ \bar{z}_1\cdot\bar{1}+\bar{z}_3\cdot\bar{1}) \ \wedge \ (s\neq\infty) \\ \wedge\,(\bar{z}_0+\bar{z}_1=\bar{y}_0) \ \wedge \ (\bar{z}_2+\bar{z}_3=\bar{y}_1) \\ \wedge\,\Phi^{r-1}_{(\bar{a},\bar{b}^{+p})|(\bar{c},\bar{c}-\bar{1},\bar{d}^{+p},(\bar{d}-\bar{1})^{+p})}(\bar{x}_0,\bar{x}_1-\mathbf{e}_i,\bar{z}_0,\bar{z}_1,\bar{z}_2,\bar{z}_3)\end{array}\right),$$
where $\mathbf{e}_i$ denotes the unit vector (with length k) where the i-th component is 1, and the lengths of $\bar{z}_0$ and $\bar{z}_1$ are the same as $\bar{y}_0$, and the lengths of $\bar{z}_2$ and $\bar{z}_3$ are the same as $\bar{y}_1$.

The motivation for these formulas will be explained in the proof of the following lemma.

▶ **Lemma 11.** *For every $\bar{a},\bar{b},\bar{c},\bar{d}$, every integer $r\geqslant 0$ and every $\bar{M}_0,\bar{M}_1,\bar{N}_0,\bar{N}_1$ such that*
1. $\bar{M}_0\cdot\bar{1}+\bar{N}_0\cdot\bar{1}+\bar{N}_1\cdot\bar{1}\geqslant 2\delta^2_{\max}+3$,
2. $\bar{N}_1\cdot\bar{1}\geqslant\delta^2_{\max}+1$,
3. $\bar{M}_1\cdot\bar{1}=r$,

where $\delta_{\max}=\max(p,\bar{a},\bar{c},\bar{d})$, the following holds: there is a $(\bar{a},\bar{b}^{+p})|(\bar{c},\bar{d}^{+p})$-biregular graph with size $(\bar{M}_0,\bar{M}_1)|(\bar{N}_0,\bar{N}_1)$ if and only if $\Phi^r_{(\bar{a},\bar{b}^{+p})|(\bar{c},\bar{d}^{+p})}(\bar{M}_0,\bar{M}_1,\bar{N}_0,\bar{N}_1)$ holds.

Proof. The proof is by induction on r. The base case $r=0$ follows from Lemma 9, so we focus on the induction step.

We begin with the "only if" direction, which provides the intuition for these formulas. Suppose $G=(U,V,E)$ is a $(\bar{a},\bar{b}^{+p})|(\bar{c},\bar{d}^{+p})$-biregular with size $(\bar{M}_0,\bar{M}_1)|(\bar{N}_0,\bar{N}_1)$. We let $U=U_{0,1}\cup\cdots\cup U_{0,k}\cup U_{1,1}\cup\cdots\cup U_{1,l}$, where $\bar{M}_0=(|U_{0,1}|,\dots,|U_{0,k}|)$ and $\bar{M}_1=(|U_{1,1}|,\dots,|U_{1,l}|)$. Likewise, we let $V=V_{0,1}\cup\cdots\cup V_{0,m}\cup V_{1,1}\cup\cdots\cup V_{1,n}$, where $\bar{N}_0=(|V_{0,1}|,\dots,|V_{0,m}|)$ and $\bar{N}_1=(|V_{1,1}|,\dots,|V_{1,n}|)$.

Since we are not in the base case, we can assume $\bar{M}_1\cdot\bar{1}=\sum_{i=1}^{l}|U_{1,i}|=r\neq 0$. Thus we can fix some i with $1\leqslant i\leqslant l$ such that $U_{1,i}\neq\emptyset$, and fix also some $u\in U_{1,i}$. Based on this u, we define, for each $1\leqslant j\leqslant m$, $Z_{0,j}$ to be the set of vertices in $V_{0,j}$ adjacent to u. For each $1\leqslant j\leqslant n$ we let $Z_{1,j}$ be the set of vertices in $V_{1,j}$ adjacent to u. Figure 1 illustrates the situation.

If we omit the vertex u and all its adjacent edges, we have the following:

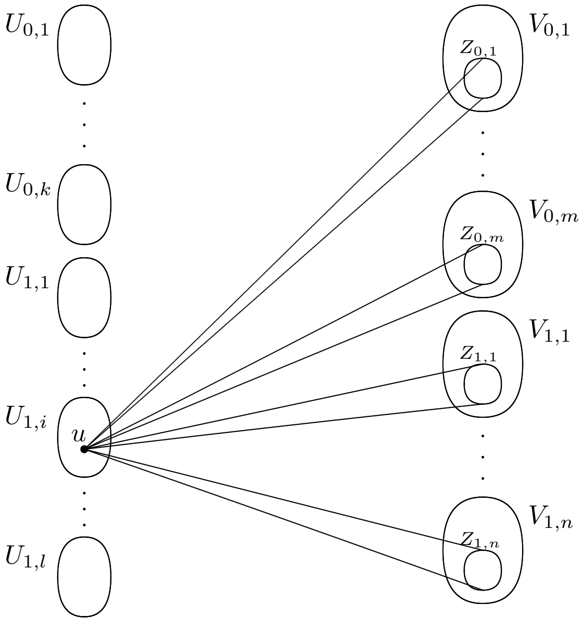

Figure 1 Inductive construction for the "not big enough" case.

1. for every $1 \leqslant j \leqslant m$, every vertex in $Z_{0,j}$ has degree $c_j - 1$,
2. for every $1 \leqslant j \leqslant n$, every vertex in $Z_{1,j}$ has degree $(d_j - 1)^{+p}$.

Thus, we have a $(\bar{a}, \bar{b}^{+p})|(\bar{c}, \bar{c} - \bar{1}, \bar{d}^{+p}, (\bar{d} - \bar{1})^{+p})$-biregular graph with size $(\bar{M}_0, \bar{M}_1 - \mathbf{e}_i)|(\bar{K}_{0,0}, \bar{K}_{0,1}, \bar{K}_{1,0}, \bar{K}_{1,1})$, where

$$\bar{K}_0 = (|V_{0,1}| - |Z_{0,1}|, \ldots, |V_{0,m}| - |Z_{0,m}|), \qquad \bar{K}_1 = (|Z_{0,1}|, \ldots, |Z_{0,m}|),$$
$$\bar{K}_2 = (|V_{1,1}| - |Z_{1,1}|, \ldots, |V_{1,n}| - |Z_{1,n}|), \qquad \bar{K}_3 = (|Z_{1,1}|, \ldots, |Z_{1,n}|).$$

We can check that the sizes allow us to apply the induction hypothesis to this graph, keeping in mind that the sizes on the left have now decreased by one. We conclude that $\Phi^{r-1}_{(\bar{a},\bar{b}^{+p})|(\bar{c},\bar{c}-\bar{1},\bar{d}^{+p},(\bar{d}-\bar{1})^{+p})}(\bar{M}_0, \bar{M}_1 - \mathbf{e}_i)|(\bar{K}_{0,0}, \bar{K}_{0,1}, \bar{K}_{1,0}, \bar{K}_{1,1})$ holds. Moreover, since $u \in U_{1,i}$, and hence the degree of u is b_i^{+p}, we have $\bar{K}_1 \cdot \bar{1} + \bar{K}_3 \cdot \bar{1} = b_i + ps$, for some integer $s \geqslant 0$. Note also that $\bar{K}_0 + \bar{K}_1 = \bar{N}_0$ and $\bar{K}_2 + \bar{K}_3 = \bar{N}_1$. Thus, $\Phi^{r}_{(\bar{a},\bar{b}^{+p})|(\bar{c},\bar{d}^{+p})}(\bar{M}_0, \bar{M}_1)|(\bar{N}_0, \bar{N}_1)$ holds where the variables $\bar{z}_0, \bar{z}_1, \bar{z}_2, \bar{z}_3$ are assigned with $\bar{K}_0, \bar{K}_1, \bar{K}_2, \bar{K}_3$, respectively.

For the "if" direction, suppose $\Phi^{r}_{(\bar{a},\bar{b}^{+p})|(\bar{c},\bar{d}^{+p})}(\bar{M}_0, \bar{M}_1, \bar{N}_0, \bar{N}_1)$ holds. Then we can fix some $s, \bar{z}_0, \bar{z}_1, \bar{z}_2, \bar{z}_3$, and i such that (a) $x_{1,i} \neq 0$, (b) $b_i + ps = \bar{z}_1 \cdot \bar{1} + \bar{z}_3 \cdot \bar{1}$, (c) $\bar{z}_0 + \bar{z}_1 = \bar{N}_0$, (d) $\bar{z}_2 + \bar{z}_3 = \bar{N}_1$, and (e) $\Phi^{r-1}_{(\bar{a},\bar{b}^{+p})|(\bar{c},\bar{c}-\bar{1},\bar{d}^{+p},(\bar{d}-\bar{1})^{+p})}(\bar{M}_0, \bar{M}_1 - \mathbf{e}_i, \bar{z}_0, \bar{z}_1, \bar{z}_2, \bar{z}_3)$ holds.

We prove from this that a biregular graph of the appropriate size exists. Note that the hypothesis requires that $\bar{M}_0 \cdot \bar{1} + \bar{N}_0 \cdot \bar{1} + \bar{N}_1 \cdot \bar{1} \geqslant 2\delta^2_{\max} + 3$, where $\delta_{\max}$ is as defined in the statement of the lemma. Since $\max(p, \bar{a}, \bar{b}, \bar{c}, \bar{c} - \bar{1}, \bar{d}, \bar{d} - \bar{1}) = \delta_{\max}$, the equalities in (c) and (d) imply that $\bar{M}_0 \cdot \bar{1} + \bar{z}_0 \cdot \bar{1} + \bar{z}_1 \cdot \bar{1} + \bar{z}_2 \cdot \bar{1} + \bar{z}_3 \cdot \bar{1}$ is bigger than $2\delta^2_{\max} + 3$.

Note that $(\bar{M}_1 - \mathbf{e}_i) \cdot \bar{1} = r - 1$. Thus we can apply the induction hypothesis and obtain a $(\bar{a}, \bar{b}^{+p})|(\bar{c}, \bar{c} - \bar{1}, \bar{d}^{+p}, (\bar{d} - \bar{1})^{+p})$-biregular graph $G = (U, V, E)$ with size $(\bar{M}_0, \bar{M}_1 - \mathbf{e}_i)|(\bar{z}_0, \bar{z}_1, \bar{z}_2, \bar{z}_3)$. Let $V = V_0 \cup V_1 \cup V_2 \cup V_3$ be the partition of V, where

$$V_0 = V_{0,1} \cup \cdots \cup V_{0,m}, \qquad V_1 = V_{1,1} \cup \cdots \cup V_{1,m},$$
$$V_2 = V_{2,1} \cup \cdots \cup V_{2,n}, \qquad V_3 = V_{3,1} \cup \cdots \cup V_{3,n},$$

and such that

1. for every $1 \leqslant i \leqslant m$, the degree of vertices in $V_{0,j}$ and $V_{1,j}$ are c_j and $c_j - 1$, respectively;
2. for every $1 \leqslant i \leqslant n$, the degree of vertices in $V_{2,j}$ and $V_{3,j}$ are d_j^{+p} and $(d_j - 1)^{+p}$, respectively.

Note also that $\bar{z}_0 = (|V_{0,1}|, \ldots, |V_{0,m}|)$, $\bar{z}_1 = (|V_{1,1}|, \ldots, |V_{1,m}|)$, $\bar{z}_2 = (|V_{2,1}|, \ldots, |V_{2,m}|)$, and $\bar{z}_3 = (|V_{3,1}|, \ldots, |V_{3,m}|)$.

Let u be a fresh vertex. We can construct a $(\bar{a}, \bar{b}^{+p})|(\bar{c}, \bar{d}^{+p})$-biregular graph $G' = (U \cup \{u\}, V, E')$, by connecting the vertex u with every vertex in $V_1 \cup V_3$. Note that the formula states that $\bar{z}_1 \cdot \bar{1} + \bar{z}_3 \cdot \bar{1} = b_i + ps$, which equals to $|V_1| + |V_3|$, thus, the degree of u is $b_i + ps$, which satisfies our requirement for a vertex to be in U_i. Since prior to the connection, the degrees of $V_{1,j}$ and $V_{3,j}$ are $c_j - 1$ and $(d_j - 1)^{+p}$, after connecting u with each vertex in $V_1 \cup V_3$, their degrees become c_j and d_j^{+p}. That is, the right side vertices now have the desired degrees, i.e., G' is $(\bar{a}, \bar{b}^{+p})|(\bar{c}, \bar{d}^{+p})$-biregular. Moreover, $\bar{z}_0 + \bar{z}_1 = \bar{N}_0$ and $\bar{z}_2 + \bar{z}_3 = \bar{N}_1$. Thus, the resulting graph G' has size $(\bar{M}_0, \bar{M}_1)|(\bar{N}_0, \bar{N}_1)$. ◀

The formula $\mathsf{bireg}_{(\bar{a},\bar{b}^{+p})|(\bar{c},\bar{d}^{+p})}(\bar{x}_0, \bar{x}_1, \bar{y}_0, \bar{y}_1)$ characterizing the sizes of $(\bar{a}, \bar{b}^{+p})|(\bar{c}, \bar{d}^{+p})$-biregular graphs can be defined by combining all the cases described above.

4.2 Proof of Lemma 2 for 1-color graphs (the complete case)

We now turn to bootstrapping the biregular case to add the completeness requirement imposed in Lemma 2. Let $\bar{a} = (a_1, \ldots, a_k)$, $\bar{b} = (b_1, \ldots, b_l)$, $\bar{c} = (c_1, \ldots, c_m)$ and $\bar{d} = (d_1, \ldots, d_n)$. Let $\bar{x}_0 = (x_{0,1}, \ldots, x_{0,k})$, $\bar{x}_1 = (x_{1,1}, \ldots, x_{1,l})$, $\bar{y}_0 = (y_{0,1}, \ldots, y_{0,m})$, and $\bar{y}_1 = (y_{1,1}, \ldots, y_{1,n})$.

The formula $\mathsf{c\text{-}bireg}_{(\bar{a},\bar{b}^{+p})|(\bar{c},\bar{d}^{+p})}(\bar{x}_0, \bar{x}_1, \bar{y}_0, \bar{y}_1)$ for the sizes of complete $(\bar{a}, \bar{b}^{+p})|(\bar{c}, \bar{d}^{+p})$-biregular graphs is the conjunction of $\mathsf{bireg}_{(\bar{a},\bar{b}^{+p})|(\bar{c},\bar{d}^{+p})}(\bar{x}_0, \bar{x}_1, \bar{y}_0, \bar{y}_1)$ such that

1. for every $1 \leqslant i \leqslant k$, if $x_{0,i} \neq 0$, then $\bar{y}_0 \cdot \bar{1} + \bar{y}_1 \cdot \bar{1} = a_i$;
2. for every $1 \leqslant i \leqslant l$, if $x_{1,i} \neq 0$, then $\bar{y}_0 \cdot \bar{1} + \bar{y}_1 \cdot \bar{1} = b_i + pz_i$, for some z_i;
3. for every $1 \leqslant i \leqslant m$, if $y_{0,i} \neq 0$, then $\bar{x}_0 \cdot \bar{1} + \bar{x}_1 \cdot \bar{1} = c_i$;
4. for every $1 \leqslant i \leqslant n$, if $y_{1,i} \neq 0$, then $\bar{x}_0 \cdot \bar{1} + \bar{x}_1 \cdot \bar{1} = d_i + pz_i$, for some z_i.

To understand these additional conditions, consider a complete biregular graph meeting the cardinality specification. The completeness criterion for 1-color graphs implies that each element on the left is connected to every element on the right. Thus if the size of a partition required to have fixed outdegree a_i is non-empty, we must have that a_i is exactly the cardinality of the number of elements on the right. This is what is captured in the first item. If we have non-empty size for a partition whose outdegree is constrained to be b_i plus a multiple of p, then the total number of elements on the right must be b_i plus a multiple of p. This is what the second item specifies. Considering elements on the left motivates the third and fourth item. Thus we see that these conditions are necessary.

Suppose $\mathsf{c\text{-}bireg}_{(\bar{a},\bar{b}^{+p})|(\bar{c},\bar{d}^{+p})}(\bar{M}_0, \bar{M}_1, \bar{M}_0, \bar{M}_1)$ holds. Then, there is a $(\bar{a}, \bar{b}^{+p})|(\bar{c}, \bar{d}^{+p})$-biregular graph $G = (U, V, E)$ with size $(\bar{M}_0, \bar{M}_1)|(\bar{N}_0, \bar{N}_1)$, which are not necessarily complete. Note that $\bar{N}_0 \cdot \bar{1} + \bar{N}_1 \cdot \bar{1}$ is precisely the number of vertices in V. The first item states that the existence of a vertex u with degree a_i implies u is adjacent to every vertex in V. Now, suppose there is a vertex $u \in U$ with degree b_i^{+p}. If u is not adjacent to every vertex in V, then we can add additional edges so that u is adjacent to every vertex in V. The second item states that $|V| = b_i^{+p}$. Thus, adding such edges is legal, since the degree of u stays b_i^{+p}. We can make vertices in V adjacent to every vertex in U using the same argument.

4.3 The proof for regular digraphs

Recall that in the prior argument we consider only digraphs without any self-loop. Thus, a digraph can be viewed as a bipartite graph by splitting every vertex u into two vertices, where one is adjacent to all the incoming edges, and the other to all the outgoing edges. Thus, $A|B$-regular digraphs with size $\bar{M}$ can be characterized as $A|B$-biregular graphs with size $\bar{M}|\bar{M}$. For more details, see [13, Section 8].

5 Extensions and applications

A *type/behavior profile* for a model M is the vector of cardinalities of the sets $A_{\pi,g}$ computed in M, where π ranges of 1-types and g over behavior functions (for a fixed ϕ). Recall that in the proof Theorem 4 we actually showed, in Lemma 6, that we can obtain existential Presburger formulas which define exactly the vectors of integers that arise as the type/behavior profiles of models of ϕ. The domain of the model can be broken up as a disjoint union of sets $A_{\pi,g}$, and thus its cardinality is a sum of numbers in this vector. We can thus add one additional integer variable x_{total} in PRES_ϕ, which will be free, with an additional equation stating that x_{total} is the sum of all $X_{\pi,g}$'s. This allows us to conclude definability of the spectrum.

▶ **Theorem 12.** *From an FO^2_{Pres} sentence ϕ, we can effectively construct a Presburger formula $\psi(n)$ such that $\mathcal{N} \models \psi(n)$ exactly when n is the size of a finite structure that satisfies ϕ, and similarly a formulas $\psi_\infty(n)$ such that $\mathcal{N}_\infty \models \psi_\infty(n)$ exactly when n is the size of a finite or countably infinite model of ϕ.*

We say that ϕ has *NP data complexity of (finite) satisfiability* if there is a non-deterministic algorithm that takes as input a set of ground atoms A and determines whether $\phi \wedge \bigwedge A$ is satisfiable, running in time polynomial in the size of A. Pratt-Hartmann [20] showed that C^2 formulas have NP data complexity of both satisfiability and finite satisfiability. Following the general approach to data complexity from [20], while plugging in our Presburger characterization of $\mathsf{FO}^2_{\mathrm{Pres}}$, we can show that the same data complexity bound holds for $\mathsf{FO}^2_{\mathrm{Pres}}$.

▶ **Theorem 13.** *FO^2_{Pres} formulas have NP data complexity of satisfiability and finite satisfiability.*

Proof. We give only the proof for finite satisfiability. We will follow closely the approach used for C^2 in Section 4 of [20], and the terminology we use below comes from that work.

Given a set of facts D, our algorithm guesses a set of facts (including equalities) on elements of D, giving us a finite set of facts D^+ extending D, but with the same domain as D. We check that our guess is consistent with the universal part α and such that equality satisfies the usual transitivity and congruence rules.

Now consider 1-types and 2-types with an additional predicate Observable. Based on this extended language, we consider good functions as before, and define the formulas $\mathsf{consistent}_1$ and $\mathsf{consistent}_2$ based on them. 1-types with that contain the predicate Observable will be referred to as observable 1-types. The restriction of a behavior function to observable 1-types will be called an *observable behavior*. Given a structure M, an observable one-type π, and an observable behavior function g_0, we let M_{π,g_0} be the elements of M having 1-type π and observable behavior g_0, and we analogously let D_{π,g_0} be the elements of D whose 1-type and behavior in D^+ match π and g_0.

We declare that all elements in A are in the predicate Observable. Add to the formulas $\mathsf{consistent}_1$ and $\mathsf{consistent}_2$ additional conjuncts stating that for each observable 1-type π and for each observable behavior function g_0, the total sum of the number of elements with 1-type π and a behavior function g extending g_0 (i.e., the cardinality of M_{π,g_0}) is the same as $|D_{\pi,g_0}|$. with the cardinality being counted modulo equalities of D^+.

At this point our algorithm returns true exactly when the sentence obtained by existentially quantifying this extended set of conjuncts is satisfiable in the integers. The solving procedure is certainly in NP. In fact, since the number of variables is fixed, with only the constants varying, it is in PTIME [17].

We argue for correctness, focusing on the proof that when the algorithm returns true we have the desired model. Assuming the constraints above are satisfied, we get a graph, and from the graph we get a model M. M will clearly satisfy ϕ, but its domain does not contain the domain of D. Letting O be the elements of M satisfying Observable, we know, from the additional constraints imposed, that the cardinality of O matches the cardinality of the domain of D modulo the equalities in D^+, and for each observable 1-type π_o and observable behavior g_0, $|M_{\pi,g_0}| = |D_{\pi,g_0}$.

Fix an isomorphism λ taking each M_{π,g_0} to (equality classes of) D_{π,g_0}. Create M' by redefining M on O by connecting pairs (o_1, o_2) via E exactly when $\lambda(o_1), \lambda(o_2)$ ise connected via E in D^+. We can thus identify O with D^+ modulo equalities in M'.

Clearly M' now satisfies D. To see that M' satisfies ϕ, we simply note that since all of the observable behaviors are unchanged in moving from an element e in M to the corresponding element $\lambda(e)$ in M', and every such e modified has an observable type, it follows that the behavior of every element in M is unchanged in moving from M to M'. Since the 1-types are also unchanged, M' satisfies ϕ. ◀

Note that the data complexity result here is best possible, since even for FO^2 the data complexity can be NP-hard [20].

6 Conclusion

We have shown that we can extend the powerful language two-variable logic with counting to include ultimately periodic counting quantifiers without sacrificing decidability, and without losing the effective definability of the spectrum of formulas within Presburger arithmetic. We believe that by refining our proof we can obtain a 2NEXPTIME bound on complexity. However the only lower bound we know of is NEXPTIME, inherited from FO^2. We leave the analysis of the exact complexity for future work.

Abstract

Our starting point are register automata for data words, in the style of Kaminski and Francez. We study the effects of the single-use restriction, which says that a register is emptied immediately after being used. We show that under the single-use restriction, the theory of automata for data words becomes much more robust. The main results are: (a) five different machine models are equivalent as language acceptors, including one-way and two-way single-use register automata; (b) one can recover some of the algebraic theory of languages over finite alphabets, including a version of the Krohn-Rhodes Theorem; (c) there is also a robust theory of transducers, with four equivalent models, including two-way single use transducers and a variant of streaming string transducers for data words. These results are in contrast with automata for data words without the single-use restriction, where essentially all models are pairwise non-equivalent.

1 Introduction

One of the appealing features of regular languages for finite alphabets is the robustness of the notion: it can be characterised by many equivalent models of automata (one-way, two-way, deterministic, nondeterministic, alternating, etc.), regular expressions, finite semigroups, or monadic second-order logic. A similar robustness appears for transducers, see [11] for a survey; particularly for the class of regular string-to-string functions, which can be characterised using deterministic two-way transducers, streaming string transducers, or MSO transductions.

This robustness vanishes for infinite alphabets. We consider infinite alphabets that are constructed using an infinite set $\mathbb{A}$ of atoms, also called data values. Atoms can only be compared for equality. The literature for infinite alphabets is full of depressing diagrams like [15, Figure 1] or [6, p. 24], which describe countless models that satisfy only trivial relationships such as deterministic ⊆ nondeterministic, one-way ⊆ two-way, etc.

This lack of robustness has caused several authors to ask if there is a notion of "regular language" for infinite alphabets; see [3, p. 703] or [4, p. 2]. This question was probably rhetorical, with the assumed answer being "no". In this paper, we postulate a "yes" answer. The main theme is register automata, as introduced by Kaminski and Francez [13], but with

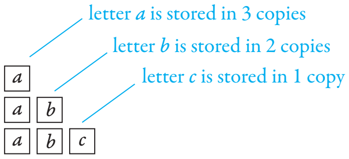
the single-use restriction, which says that immediately after a register is used, its value is destroyed. As we show in this paper, many automata constructions, which fail for unrestricted register automata, start to work again in the presence of the single-use restriction.

Before describing the results in the paper, we illustrate the single-use restriction.

▶ **Example 1.** Consider the language "there are at most three distinct letters in the input word, not counting repetitions", over alphabet $\mathbb{A}$. There is a natural register automaton which recognises this language: use three registers to store the distinct atoms that have been seen so far, and if a fourth atom comes up, then reject. This automaton, however, violates the single-use restriction, because each new input letter is compared to all the registers.



letter *a* is stored in 3 copies
letter *b* is stored in 2 copies
letter *c* is stored in 1 copy
a
a *b*
a *b* *c*

Here is a solution that respects the single-use restriction. The idea is that once the automaton has seen three distinct letters a, b, c, it stores them in six registers as explained in the picture on the right. Assume that a new input letter d is read. The behaviour of the automaton (when it already has three atoms in its registers) is explained in the flowchart in Figure 1.

A similar flowchart is used for the corner cases when the automaton has seen less than three letters so far.

Our first main result, Theorem 6 (in Section 3), says that the following models recognise the same languages over infinite alphabets:

1. deterministic one-way single-use automata;
2. deterministic two-way single-use automata;
3. orbit-finite monoids [5];
4. rigidly guarded MSO$^{\sim}$ [9];
5. string-to-boolean regular list functions with atoms.

The equivalence of the models in items 3 and 4 was shown in [9]; the remaining models and their equivalences are new (item 5 is an extension of the regular list functions from [7]).

Just like their classical versions, one-way and two-way single-use automata are equivalent as language acceptors, but they are no longer equivalent as transducers. For example, a two-way single-use transducer can reverse the input string, which is impossible for a one-way single-use transducer. In Sections 4 and 5 we develop the theory of single-use transducers:

In Section 4, we investigate single-use one-way transducers. For finite alphabets, one of the most important results about one-way transducers is the Krohn-Rhodes Theorem [14], which says that every Mealy machine (which is a length preserving one-way transducer) can be decomposed into certain "prime" Mealy machines. We show that the same can be done for infinite alphabets, using a single-use extension of Mealy machines. The underlying prime machines are the all the machines from the original Krohn-Rhodes theorem, plus one additional register machine which moves atoms to later positions.

In Section 5, we investigate single-use two-way transducers, and show that the corresponding class of string-to-string functions enjoys similar robustness properties as the languages discussed in Theorem 6, with four models being equivalent:

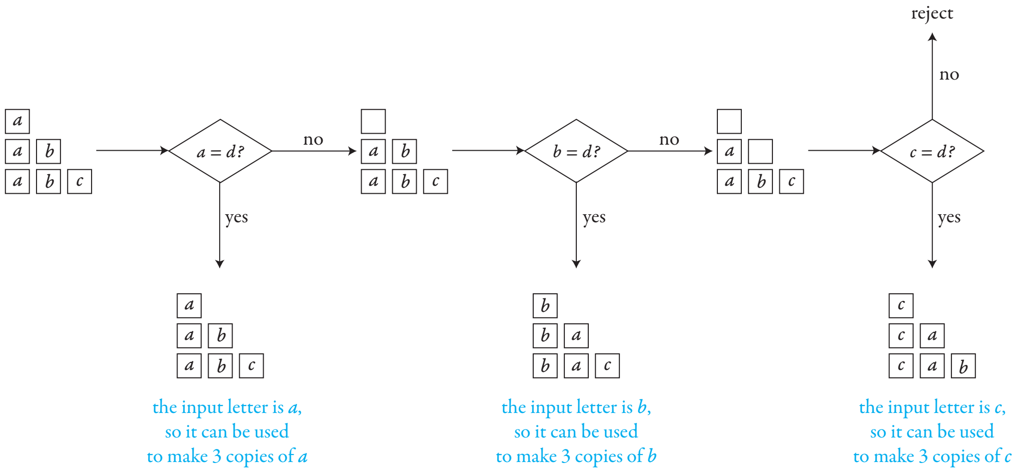


Figure 1 Updating the six registers.

1. single-use two-way transducers;
2. an atom extension of streaming string transducers [2];
3. string-to-string regular list functions with atoms;
4. compositions of certain "prime two-way machines" (Krohn & Rhodes style).

We also show other good properties of the string-to-string functions in the above items, including closure under composition (which follows from item 4) and decidable equivalence.

Summing up, the single-use restriction allows us to identify languages and string-to-string functions with infinite alphabets, which share the robustness and good mathematical theory usually associated with regularity for finite alphabets.

Due to space constraints, and a large number of results, virtually all of the proofs are in an appendix. We use the available space to explain and justify the many new models that are introduced.

2 Automata and transducers with atoms

For the rest of the paper, fix an infinite set $\mathbb{A}$, whose elements are called *atoms*. Atoms will be used to construct infinite alphabets. Intuitively speaking, atoms can only be compared for equality. It would be interesting enough to consider alphabets of the form $\mathbb{A} \times \Sigma$, for some finite Σ, as is typically done in the literature on data words [4, p. 1]. However, in the proofs, we use more complicated sets, such as the set $\mathbb{A}^2$ of pairs of atoms, the set $\mathbb{A} + \{\vdash, \dashv\}$ obtained by adding two endmarkers to the atoms, or the co-product (i.e. disjoint union) $\mathbb{A}^2 + \mathbb{A}^3$. This motivates the following definition.

▶ **Definition 2.** *A* polynomial orbit-finite set[1] *is any set that can be obtained from* $\mathbb{A}$ *and singleton sets by means of finite products and co-products (i.e. disjoint unions).*

We only care about properties of such sets that are stable under atom automorphisms, as described below. Define an *atom automorphism* to be any bijection $\mathbb{A} \to \mathbb{A}$. (This notion of automorphism formalises the intuition that atoms can only be compared for equality). Atom automorphisms form a group. There is a natural action of this group on polynomial

[1] The name "orbit-finite" is used because the above definition is a special case of orbit-finite sets discussed later in the paper, and the name "polynomial" is used to underline that the sets are closed under products and co-products.

orbit-finite sets: for elements of $\mathbb{A}$ we apply the atom automorphism, for singleton sets the action is trivial, and for other polynomial orbit-finite sets the action is lifted inductively along $+$ and $\times$ in the natural way. Let Σ and Γ be sets equipped with an action of the group of atom automorphisms – in particular, these could be polynomial orbit-finite sets. A function $f : \Sigma \to \Gamma$ is called *equivariant* if $f(\pi(x)) = \pi(f(x))$ holds for every $x \in \Sigma$ and every atom automorphism π. The general idea is that equivariant functions can only talk about equality of atoms. In the case of polynomial orbit-finite sets, equivariant functions can also be finitely represented using quantifier-free formulas [6, Lemma 1.3].

The model. We now describe the single-use machine models discussed in this paper. There are four variants: machines can be one-way or two-way, and they can recognise languages or compute string-to-string functions. We begin with the most general form – two-way string-to-string functions – and define the other models as special cases.

The machine reads the input string, extended with left and right endmarkers $\vdash, \dashv$. It uses registers to store atoms that appear in the input string. A register can store either an atom, or the undefined value $\perp$. The single-use restriction, which is highlighted in bold below, says that a register is set to $\perp$ immediately after being used.

▶ **Definition 3.** *The syntax of a* two-way single-use transducer[2] *consists of*

- *input and output alphabets Σ and Γ, both polynomial orbit-finite sets;*
- *a finite set of states Q, with a distinguished initial state $q_0 \in Q$;*
- *a finite set R of register names;*
- *a* transition function *which maps each state $q \in Q$ to an element of:*

$$\underbrace{\textit{questions}}_{\textit{question that is asked}} \times \underbrace{(Q \times \textit{actions})}_{\substack{\textit{what to do if the}\\ \textit{question has a yes answer}}} \times \underbrace{(Q \times \textit{actions})}_{\substack{\textit{what to do if the}\\ \textit{question has a no answer}}}$$

where the allowed questions and actions are taken from the following toolkit:

1. Questions.
   - **a.** *Apply an equivariant function $f : \Sigma + \{\vdash, \dashv\} \to \{yes, no\}$ to the letter under the head, and return the answer.*
   - **b.** *Are the atoms stored in registers r_1, r_2 equal and defined? If any of these registers is undefined, then the run immediately stops and rejects[3].* ***This question has the side effect of setting the values of r_1 and r_2 to $\perp$.***
2. Actions.
   - **a.** *Apply an equivariant function $f : \Sigma + \{\vdash, \dashv\} \to \mathbb{A} + \perp$ to the letter under the head, and store the result in register $r \in R$.*
   - **b.** *Apply an equivariant function $f : \mathbb{A}^k \to \Gamma$ to the contents of distinct registers $r_1, \ldots, r_k \in R$, and append the result to the output string. If any of the registers is undefined, stop and reject.* ***This action has the side effect of setting the values of $r_1, r_2, \ldots, r_k$ to $\perp$.***
   - **c.** *Move the head to the previous/next input position.*
   - **d.** *Accept/reject and finish the run.*

[2] Unless otherwise noted, all transducers and automata considered in this paper are deterministic. The theory of nondeterministic single-use models seems to be less appealing.

[3] By remembering in the state which registers are defined, one can modify an automaton so that this never happens.

The semantics of the transducer is a partial function from strings over the input alphabet to strings over the output alphabet. Consider a string of the form $\vdash w \dashv$ where $w \in \Sigma^*$. A *configuration* over such a string consists of (a) a position in the string; (b) a state; (c) a register valuation, which is a function of type $R \to \mathbb{A} + \bot$; (d) an output string, which is a string over the output alphabet. A *run* of the transducer is defined to be a sequence of configurations, where consecutive configurations are related by applying the transition function in the natural way. The *output* of a run is defined to be the contents of the output string in the last configuration. An *accepting configuration* is one which executes the accept action from item 2d – accepting configurations have no successors. The *initial configuration* is a configuration where the head is over the left endmarker $\vdash$, the state is the initial state, the register valuation maps all registers to the undefined value, and the output string is empty. An *accepting run* is a run that begins in the initial configuration and ends in an accepting one. By determinism, there is at most one accepting run. The semantics of the transducer is defined to be the partial function $\Sigma^* \to \Gamma^*$, which inputs $w \in \Sigma^*$ and returns the output of the accepting run over $\vdash w \dashv$. If there is no accepting run, $f(w)$ has no value.

Special cases. A *one-way single-use transducer* is the special case of Definition 3 which does not use the "previous" action from item 2c. A *two-way single-use automaton* is the special case which does not use the output actions from item 2b. The *language* recognised by such an automaton is defined to be the set of words which admit an accepting run. A *one-way single-use automaton* is the special case of a two-way single-use automaton, which does not use the "previous" action from item 2c.

3 Languages recognised by single-use automata

In this section we discuss languages recognised by single-use automata. The main result is that one-way and two-way single-use automata recognise the same languages, and furthermore these are the same languages that are recognised by orbit-finite monoids [5], the logic rigidly guarded MSO$^\sim$ [9], and a new model called regular list functions with atoms, that will be defined in Section 5.

Orbit-finite monoids. We begin by defining orbit-finite sets and orbit-finite monoids, which play an important technical role in this paper. For more on orbit-finite sets, see the lecture notes [6]. For a tuple $\bar{a} \in \mathbb{A}^*$, an $\bar{a}$-automorphism is defined to be any atom automorphism that maps $\bar{a}$ to itself. Consider set X equipped with an action of the group of atom automorphisms. We say that $x \in X$ is *supported* by a tuple of atoms $\bar{a} \in \mathbb{A}^*$ if $\pi(x) = x$ holds for every $\bar{a}$-automorphism π. We say that a subset of X is $\bar{a}$-supported if it is an $\bar{a}$-supported element of the powerset of X; similarly we define supports of relations and functions. We say that x is finitely supported if it is supported by some tuple $\bar{a} \in \mathbb{A}^*$. Define the *$\bar{a}$-orbit of* x to be its orbit under the action of the group of $\bar{a}$-automorphisms.

▶ **Definition 4** (Orbit-finite sets). *Let X be a set equipped with an action of atom automorphisms. A subset $Y \subseteq X$ is called* orbit-finite *if (a) every element of Y is finitely supported; and (b) there exists some $\bar{a} \in \mathbb{A}^*$ such that Y is a union of finitely many $\bar{a}$-orbits.*

An equivariant orbit-finite set is the special case where the tuple $\bar{a}$ in item (b) is empty. The polynomial orbit-finite sets from Section 2 are a special case of equivariant orbit-finite sets[4]. The following notion was introduced in [5, Section 3].

▶ **Definition 5** (Orbit-finite monoid). *An* orbit-finite monoid *is a monoid where the underlying set is orbit-finite, and the monoid operation is finitely supported. If Σ is an orbit-finite set, then we say that a language $L \subseteq \Sigma^*$ is* recognised *by an orbit-finite monoid M if there is a finitely supported monoid morphism $h : \Sigma^* \to M$ and a finitely supported accepting set $F \subseteq M$ such that L contains exactly the words whose image under h belongs to F.*

In this paper, we are mainly interested in the case where both the morphism and the accepting set are equivariant. In this case, it follows that the alphabet Σ, the image of the morphism, and the recognised language all also have to be equivariant.

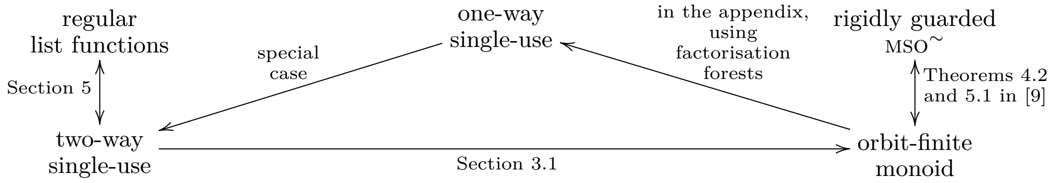
The structural theory of orbit-finite monoids was first developed in [5], where it was shown how the classical results about Green's relations for finite monoids extend to the orbit-finite setting. This theory was further investigated in [9], including a lemma stating that every orbit-finite group is necessarily finite. In the full version of this paper we build on these results, to prove an orbit-finite version of the Factorisation Forest Theorem of Simon [17, Theorem 6.1], which is used in proofs of Theorems 6 and 12.

Main theorem about languages. We are now ready to state Theorem 6, which is our main result about languages.

▶ **Theorem 6.** *Let Σ be a polynomial orbit-finite set. The following conditions are equivalent for every language $L \subseteq \Sigma^*$:*

1. *L is recognised by a single-use one-way automaton;*
2. *L is recognised by a single-use two-way automaton;*
3. *L is recognised by an orbit-finite monoid, with an equivariant morphism and an equivariant accepting set;*
4. *L can be defined in the rigidly guarded $\text{MSO}^\sim$ logic;*
5. *L's characteristic function $\Sigma^* \to \{yes, no\}$ is an orbit-finite regular list function.*

The equivalence of items 4 and 3 has been proved in [9, Theorems 4.2 and 5.1], and since we do not use rigidly guarded $\text{MSO}^\sim$ outside of the this theorem, we do not give a definition here (see [9, Section 3]). The orbit-finite regular list functions from item 5 will be defined in Section 5. The proof outline for Theorem 6 is given in the following diagram



All equivalences in the theorem are effective, i.e. there are algorithms implementing the conversions between any of the models.

The single-use restriction is crucial in the theorem. Automata without the single-use restriction – call them multiple-use – only satisfy the trivial inclusions:

[4] The converse does not hold – there exist sets that are equivariant orbit finite but not polynomial orbit finite e. g. the set of unordered pairs of atoms: $\{\{a, b\} \mid a, b \in \mathbb{A},\ a \neq b\}$.

$$\text{single-use} \overset{\substack{\text{first letter appears again}\\ \text{[6, Exercise 91]}}}{\subsetneq} \text{one-way multiple-use} \overset{\substack{\text{some letter appears twice}\\ \text{[13, Example 11]}}}{\subsetneq} \text{two-way multiple-use.}$$

Two-way multiple-use automata have an undecidable emptiness problem [15, Theorem 5.3]. For one-way (even multiple-use) automata, emptiness is decidable and even tractable in a suitable parametrised understanding [6, Corollary 9.12]. We leave open the following question: given a one-way multiple-use automaton, can one decide if there is an equivalent automaton that is single-use (by Theorem 6, it does not matter whether one-way or two-way)?

3.1 From two-way automata to orbit-finite monoids

In this section, we show the implication 2 ⇒ 3 of Theorem 6. (This is the only proof presented in the conference version of the paper – we chose it, because it illustrates the importance of the single-use restriction). The implication states that the language of every single-use two-way automaton can also be recognised by an equivariant homomorphism into an orbit-finite monoid. In the proof, we use the Shepherdson construction for two-way automata [16] and show that, thanks to the single-use restriction, it produces monoids which are orbit-finite.

Consider a two-way single-use automaton, with k registers and let Q be the set of its states. For a string over the input alphabet (extended with endmarkers), define its *Shepherdson profile* to be the function of the type

$$\overbrace{Q \times (\mathbb{A}+\bot)^k}^{\substack{\text{state and register}\\ \text{valuation at the}\\ \text{start of the run}}} \times \overbrace{\{\leftarrow,\rightarrow\}}^{\substack{\text{does the run}\\ \text{enter from the}\\ \text{left or right}}} \quad \to \quad \{\text{accept}, \text{loop}\} + (\overbrace{Q \times (\mathbb{A}+\bot)^k}^{\substack{\text{state and register}\\ \text{valuation at the}\\ \text{end of the run}}} \times \overbrace{\{\leftarrow,\rightarrow\}}^{\substack{\text{does the run}\\ \text{exit from the}\\ \text{left or right}}} \;)$$

that describes runs of the automaton in the natural way (see [16, Proof of Theorem 2]). The run is taken until the automaton either exits the string from either side, accepts, or enters an infinite loop. By the same reasoning as in Shepherdson's proof, one can equip the set of Shepherdson profiles with a monoid structure so that the function which maps a word to its Shepherdson profile becomes a monoid homomorphism. We use the name Shepherdson monoid for the resulting monoid (it only contains the "achievable" profiles – the image of Σ^*). It is easy to see that whether a word is accepted depends only on an equivariant property of its Shepherdson profile, and therefore the language recognised by the automaton is also recognised by the Shepherdson monoid.

It remains to show that the Shepherdson monoid is orbit-finite, which is the main part of the proof. Unlike the arguments so far, this part of the proof relies on the single-use restriction. To illustrate this, we give an example of a one-way automaton that is not single-use and whose Shepherdson monoid is not orbit-finite.

▶ **Example 7.** Consider the language over $\mathbb{A}$ of words whose first letter appears again. This language is not recognised by any orbit-finite monoid [6, Exercise 91], but it is recognised by a multiple-use one-way automaton, which stores the first letter in a register, and then compares this register with all remaining letters of the input word. For this automaton, the Shepherdson profile needs to remember all of the distinct letters that appear in the word. In particular, if two words have different numbers of distinct letters, then their Shepherdson profiles cannot be in the same orbit. Since input strings can contain arbitrarily many distinct letters, the Shepherdson monoid of this automaton is not orbit-finite.

▶ **Lemma 8.** *For every single-use two-way automaton there is some $N \in \mathbb{N}$ such that every Shepherdson profile is supported by at most N atoms.*

Before proving the lemma, we use it to show that the Shepherdson monoid is orbit-finite. In the full version of the paper, we show that if an equivariant set consists of functions from one orbit-finite set to another orbit-finite set (as is the case for the underling set in the Shepherdson monoid) and all functions in the set have supports of bounded size (as is the case thanks to Lemma 8), then the set is orbit-finite. This leaves us with proving Lemma 8.

Proof. Define a *transition* in a run to be a pair of consecutive configurations. Each transition has a corresponding question and action. A transition in a run is called *important* if its question or action involves a register that has not appeared in any action or question of the run. The number of important transitions is bounded by k – the number of registers. The crucial observation, which relies on the single-use restriction, is that if the input word, head position, and state are fixed (but not the register valuation), then the sequence of actions in the corresponding run depends only on the answers to the questions in the important transitions. This is described in more detail below.

Fix a choice of the following parameters: (a) a string over the input alphabet that might contain endmarkers; (b) an entry point of the automaton – either the left or the right end of the word; (c) a state of the automaton. We do not fix the register valuation. For a register valuation η, define $\rho(\eta)$ to be the run which begins in the configuration described by the parameters (abc) together with η, and which is maximal, i.e. it ends when the automaton either accepts, rejects, or tries to leave the fixed string. For $i \in \{0, 1, \dots, k\}$ define $\alpha_i(\eta)$ to be the sequence of actions that are performed in the maximal prefix of the run $\rho(\eta)$ which uses at most i important transitions. The crucial observation that was stated at the beginning of this proof is that once the parameters (abc) are fixed, then the sequence of actions $\alpha_i(\eta)$ depends only on the answers to the questions asked in the first i important transitions. In particular, the function α_i has at most 2^i possible values. Furthermore, by a simple induction on i, one can show the following claim.

▷ Claim 9. The function α_i is supported by at most 2^{i+1} atoms.

Since there are at most k important transitions in a run, the above claim implies that, for every fixed choice of parameters (abc), at most 2^{k+1} atoms are needed to support the function which maps η to the sequence of actions in the run $\rho(\eta)$. In the arguments for the Shepherdson profile for a fixed word w, parameter (b) can have two values (first or last position) and parameter (c) can have at most $|Q|$ values. Therefore, at most $2|Q|2^{k+1}$ atoms are needed to support the function which takes an argument as in the Shepherdson profile, and returns the sequence of actions in the corresponding run. The lemma follows. ◀

4 A Krohn-Rhodes decomposition of one-way transducers with atoms

In this section, we present a decomposition result for single-use one-way transducers, which is a version of the celebrated Krohn-Rhodes Theorem [14, p. 454]. We think that this result gives further evidence for the good structure of single-use models. In the next section, we give a similar decomposition result for two-way single-use transducers which will be used to prove the equivalence of several other characterisations of the two-way model.

We begin by describing the classical Krohn-Rhodes Theorem. A *Mealy machine* is a deterministic one-way length-preserving transducer, which is obtained from a deterministic finite automaton by labelling transitions with output letters and ignoring accepting states.

The Krohn-Rhodes Theorem says that every function computed by a Mealy machine is a composition of functions computed by certain prime Mealy machines (which are called *reversible* and *reset* in [1, Chapter 6]). In this section, we prove a version of this theorem for orbit-finite alphabets; this version relies crucially on the single-use restriction. To distinguish the original model of Mealy machines from the single-use model described below, we will use the name *classical Mealy machine* for the Mealy machines in the original Krohn-Rhodes Theorem, i.e. the alphabets and state spaces are finite.

Define a *single-use Mealy machine* to have the same syntax as in Definition 3, with the following differences: there are no "next/previous" actions from item 2c, but the output action from item 2b has the side effect of moving the head to the next position. A consequence is that a Mealy machine is length-preserving, i.e. it outputs exactly one letter for each input position. Furthermore, there are no endmarkers and no "accept" or "reject" actions from item 2d; the automaton begins in the first input position and accepts immediately once its head leaves the input word from the right.

▶ **Example 10.** Define *atom propagation* to be the following length-preserving function. The input alphabet is $\mathbb{A} + \{\epsilon, \downarrow\}$ and the output alphabet is $\mathbb{A} + \perp$. If a position i in the input string has label $\downarrow$ and there is some (necessarily unique) position $j < i$ with an atom label such that all positions strictly between j and i have label ϵ, then the output label of position i is the atom in input position j. For all other input positions, the output label is $\perp$. Here is an example of atom propagation:

input	1	2	ϵ	ϵ	$\downarrow$	$\downarrow$	3	ϵ	ϵ	$\downarrow$	ϵ	$\downarrow$
output	$\perp$	$\perp$	$\perp$	$\perp$	2	$\perp$	$\perp$	$\perp$	$\perp$	3	$\perp$	$\perp$

Atom propagation is computed by a single-use Mealy machine, which stores the most recently seen atom in a register, and outputs the register at the nearest appearance of $\downarrow$.

The following example illustrates some of the technical difficulties with single-use Mealy machines: It is often useful to consider a Mealy machine that computes the run of another Mealy machine i. e. decorate every input position with the state and the register valuation that the Mealy machine will have after reading the input up to (but not including) that position. As shown in the following example the single-use restriction makes this construction impossible.

▶ **Example 11.** Consider the single-use Mealy machine that implements the atom propagation function from Example 10. This machine has only one register. Every time it sees an atom value, it stores the value in the register and every time it sees $\downarrow$, and the register is non-empty, the machine outputs the register's content. We claim that the run of this machine cannot be computed by a Mealy machine. If it could, we would be able to use it to construct a Mealy machine that given a word over $\mathbb{A}$, equips every position with the atom from the first position. This would easily lead to a construction of a single-use automaton for the language "the first letter appears again" (from Example 7) which, as we already know, is impossible.

The Krohn-Rhodes Theorem, both in its original version and in our orbit-finite version below, says that every Mealy machine can be decomposed using two types of composition:

$$\frac{\Sigma^* \xrightarrow{f} \Gamma^* \quad \Gamma^* \xrightarrow{g} \Delta^*}{\Sigma^* \xrightarrow{g \circ f} \Delta^*} \text{ sequential} \qquad \frac{\Sigma_1^* \xrightarrow{f_1} \Gamma_1^* \quad \Sigma_2^* \xrightarrow{f_2} \Gamma_2^*}{(\Sigma_1 \times \Sigma_2)^* \xrightarrow{f_1 | f_2} (\Gamma_1 \times \Gamma_2)^*} \text{ parallel}$$

The sequential composition is simply function composition. The parallel composition – which only makes sense for length preserving functions – applies the function f_i to the i-th projection of the input string.

▶ **Theorem 12.** *Every total function computed by a single-use Mealy machine can be obtained, using sequential and parallel composition, from the following* prime functions*:*

1. Length-preserving homomorphisms. *Any function of type $\Sigma^* \to \Gamma^*$, where Σ and Γ are polynomial orbit-finite, obtained by lifting to strings an equivariant function of type $\Sigma \to \Gamma$.*
2. Classic Mealy machines. *Any function computed by a classical Mealy machine.*
3. Atom propagation. *The atom propagation function from Example 10.*

By the original Krohn-Rhodes theorem, classical Mealy machines can be further decomposed.

Define a *composition of primes* to be any function that can be obtained from the prime functions by using a parallel and sequential composition. In this terminology, Theorem 12 says that every function computed by a single-use Mealy machine is a composition of primes. In the full version of the paper we show that the converse is also true: every prime function is computed by a single-use Mealy machine, and single-use Mealy machines are closed under both kinds of composition.

Decomposition of single-use one-way transducers. A Mealy machine is the special case of a single-use one-way transducer which is length preserving, and does not see an endmarker. A corollary of Theorem 12 is that, in order to generate all total functions computed by single-use one-way transducers, it is enough to add two items to the list of prime functions from Theorem 12: (a) a function $w \mapsto w\dashv$ which appends an endmarker[5], and (b) equivariant homomorphisms over polynomial orbit-finite alphabets that are not necessarily length-preserving.

5 Two-way single-use transducers

In this section, we turn to two-way single-use transducers. For them, we show three other equivalent models: (a) compositions of certain two-way prime functions; (b) an atom variant of the streaming string transducer (SST) model of Alur and Černý from [2]; and (c) an atom variant of the regular string functions from [7]. We believe that the atom variants of items (b) and (c), as described in this section, are the natural atom extensions of the original models; and the fact that these extensions are all equivalent to single-use two-way transducers is a further validation of the single-use restriction.

We illustrate the transducer models using the functions from the following example.

▶ **Example 13.** Consider some polynomial orbit-finite alphabet Σ. The input and output alphabets are the same, namely Σ extended with a separator symbol $|$. Define *map reverse* (respectively, *map duplicate*) to be the function which reverses (respectively, duplicates) every string between consecutive separators, as in the following examples:

$$\underbrace{12||345|678|9 \;\mapsto\; 21||543|876|9}_{\text{map reverse}} \qquad \underbrace{12||345|678|9 \;\mapsto\; 1212||345345|678678|99}_{\text{map duplicate}}$$

Both functions can be computed by single-use two-way transducers. These functions will be included in the prime functions for two-way single-use transducers, as discussed in item (a) at the beginning of this section.

[5] This function accounts for the fact that a one-way transducer (contrary to a Mealy machine) may perform some computation and produce some output at the end of the input word.

Streaming string transducers with atoms. A streaming string transducer with atoms has two types of registers: atom registers $r, s, \ldots$ which are the same as in Definition 3, and string registers $A, B, C, \ldots$ which are used to store strings over the output alphabet. Both kinds of registers are subject to the single-use restriction, which is highlighted in bold in the following definition.

▶ **Definition 14** (Streaming string transducer with atoms). *Define the syntax of a* streaming string transducer (SST) with atoms *in the same way as a one-way single-use transducer (variant of Definition 3), except that the model is additionally equipped with a finite set of* string registers*, with a designated* output string register*. The actions are the same as for one-way single-use transducers except that the output action is replaced by two kinds of actions:*

1. *Apply an equivariant function $f : \mathbb{A}^k \to \Gamma$ to the contents of distinct registers $r_1, \ldots, r_k \in R$, and put the result into string register A (overwriting its previous contents). If any of these registers is undefined, then the run immediately stops and rejects.* ***This action has the side effect of setting the values of $r_1, r_2, \ldots, r_{k_j}$ to $\perp$.***
2. *Concatenate string registers A and B, and put the result into string register C.* ***This action has the side effect of setting A and B to the empty string.***

The output of a streaming string transducer is defined to be the contents of the designated output register when the "accept" action is performed. In the atomless case, when no atom registers are allowed and the input and output alphabets are finite, the above definition is equivalent to the original definition of streaming string transducers from [2].

▶ **Example 15.** Consider the map reverse function from Example 13, with alphabet $\mathbb{A}$. To compute it, we use two string registers A and B, with the output register being B. When reading an atom $a \in \mathbb{A}$, the transducer executes an action $A := aA$. (This action needs to be broken into simpler actions as in Definition 14 and requires auxiliary registers). When reading a separator symbol, the automaton executes action $B := B|A$, which erases the content of register A. Similar idea works for map duplicate – it uses two copies of register A.

Regular list functions with atoms. Our last model is based on the regular list functions from [7]. Originally, the regular list functions were introduced to characterise two-way transducers (over finite alphabets), in terms of simple prime functions and combinators [7, Theorem 6.1]. The following definition extends the original definition[6] in only two ways: we add an extra datatype $\mathbb{A}$ and an equality test `eq` : $\mathbb{A}^2 \to$ {yes,no}.

▶ **Definition 16** (Regular list functions with atoms). *Define the* datatypes *to be sets which can be obtained from $\mathbb{A}$ and singleton sets, by applying constructors for products $\tau \times \sigma$, co-products $\tau + \sigma$ and lists τ^*. The class of* regular list functions with atoms *is the least class which:*

1. *contains all equivariant constant functions;*
2. *contains all functions from Figure 2, and an equality test* `eq` $: \mathbb{A}^2 \to$ *{yes,no};*
3. *is closed under applying the following combinators:*
   a. *`comp` function composition $(f, g) \mapsto f \circ g$;*
   b. *`pair` function pairing $(f_0, f_1) \mapsto (x \mapsto (f_0(x), f_1(x)))$;*
   c. *`cases` function co-pairing $(f_0, f_1) \mapsto ((i, a) \mapsto f_i(a))$;*
   d. *`map` lifting functions to lists $f \mapsto ([a_1, \ldots, a_n] \mapsto [f(a_1), \ldots, f(a_n)])$.*

[6] In [7], the group product operation has output type G^*, while this paper uses $(G \times \sigma)^*$. This difference is due to an error in [7].

`project`$_i$	:	$(\sigma_0 \times \sigma_1) \to \sigma_i$ projection $(a_0, a_1) \mapsto a_i$
`coproject`$_i$	:	$\sigma_i \to (\sigma_0 + \sigma_1)$ coprojection $a_i \mapsto (i, a_i)$
`distr`	:	$(\sigma_1 + \sigma_2) \times \tau \to (\sigma_1 \times \tau) + (\sigma_2 \times \tau)$ distribution $((i, a), b) \mapsto (i, (a, b))$
`reverse`	:	$\sigma^* \to \sigma^*$ list reverse $[a_1, \ldots, a_n] \mapsto [a_n, \ldots, a_1]$
`concat`	:	$(\sigma^*)^* \to \sigma^*$ list concatenation, defined by $[] \mapsto []$ and $[a] \cdot l \mapsto a \cdot concat(l)$
`append`	:	$(\sigma \times \sigma^*) \to \sigma^*$ append, defined by $(a, l) \mapsto [a] \cdot l$
`coappend`	:	$\sigma \to (\sigma \times \sigma^*) + \bot$ the opposite of append, defined by $[] \mapsto (1, \bot)$ and $[a] \cdot l \mapsto (0, (a, l))$
`block`	:	$(\sigma + \tau)^* \to (\sigma^* + \tau^*)^*$ group the list into maximal connected blocks from σ^* or τ^*
`group`	:	$(G \times \sigma)^* \to (G \times \sigma)^*$ $[(g_1, a_1), \ldots, (g_n, a_n)] \mapsto [(1, a_1), (g_1, a_2), (g_1 g_2, a_3), \ldots, (g_1 \cdots g_{n-1}, a_n)]$

Figure 2 For every datatypes $\tau, \tau_0, \tau_1, \sigma$, every finite group G, and every $i \in \{0, 1\}$ the above functions are regular list functions with atoms.

Every polynomial orbit-finite set is a datatype (actually, polynomial orbit-finite sets are exactly the datatypes that do not use lists), and therefore it makes sense to talk about regular list functions with atoms that describe string-to-string functions with input and output alphabets that are polynomial orbit-finite sets. Also, one can consider string-to-boolean functions – they describe languages, and are the model mentioned in item 5 of Theorem 6.

▶ **Example 17.** We show that map reverse from Example 13 is a regular list function with atoms. Consider an input string, say

$$[1, 2, |, |, 3, 4, 5, |, 6, 7, 8, |, 9] \in (\mathbb{A} + |)^*.$$

Apply the prime `block` function, yielding

$$[[1, 2], [|, |], [3, 4, 5], [|], [6, 7, 8], [|], [9]] \in (\mathbb{A}^* + |^*)^*.$$

Using the `cases` and `map` combinators, apply `reverse` to all list items, yielding

$$[[2, 1], [|, |], [5, 4, 3], [|], [8, 7, 6], [|], [9]] \in (\mathbb{A}^* + |^*)^*.$$

To get the final output, apply `concat`. A similar idea works for map duplicate, except we need to derive the string duplication function:

$$w \overset{\texttt{pair}(\ldots)}{\mapsto} (w, [w]) \overset{\texttt{append}}{\mapsto} [w, w] \overset{\texttt{concat}}{\mapsto} ww$$

Equivalence of the models. The main result of this section is that all models described above are equivalent, and furthermore admit a decomposition into prime functions in the spirit of the Krohn-Rhodes theorem. Since the functions discussed in this section are no longer length-preserving, the Krohn-Rhodes decomposition uses only sequential composition.

▶ **Theorem 18.** *The following conditions are equivalent for every total function $f : \Sigma^* \to \Gamma^*$, where Σ and Γ are polynomial orbit-finite sets:*

1. *f is computed by a two-way single-use transducer;*
2. *f is computed by a streaming string transducer with atoms;*
3. *f is a regular list function with atoms;*
4. *f is a sequential composition of functions of the following kinds:*
   - **a.** *single-use Mealy machines;*
   - **b.** *equivariant homomorphisms that are not necessarily length-preserving;*
   - **c.** *map reverse and map duplicate functions from Example 13.*

In the future, we plan to extend the above theorem with one more item, namely a variant of MSO transductions based on rigidly guarded MSO$^\sim$. The models in items 3 and 4 are closed under sequential composition, and therefore the same is true for the models in items 1 and 2; we do not know any direct proof of composition closure for items 1 and 2, which contrasts the classical case without atoms [8, Theorem 2]. The Krohn-Rhodes decomposition from item 4, in the case without atoms, was present implicitly in [7]; in this paper we make the decomposition explicit, extend it to atoms, and leverage it to get a relatively simple proof of Theorem 18. Even for the reader interested in transducers but not atoms, our Krohn-Rhodes-based proof of Theorem 18 might be of some independent interest.

Here are some immediate corollaries of Theorem 18:

1. Every function in item 4 is computed by a two-way single-use transducer which is reversible in the sense of [10, p. 2]; hence two-way single-use transducers can be translated into reversible ones.
2. Since the equivalence in Theorem 18 also works for functions with yes/no outputs, it follows that items 2 and 5 in Theorem 6 are equivalent.
3. If f is a transducer from the class described in Theorem 18, then the language class described in Theorem 6 is preserved under inverse images of f.

All conversions between the models in Theorem 18 are effective. Our last result concerns the equivalence problem for these models, which is checking if two transducers compute the same function. Using a reduction to the equivalence problem for *copyful* streaming string transducers without atoms [12, p. 81], we prove the following result:

▶ **Theorem 19.** *Equivalence is decidable for streaming string transducers with atoms (and therefore also for every other of the equivalent models from Theorem 18).*

Abstract

We investigate the connection between properties of formal languages and properties of their generating series, with a focus on the class of *holonomic* power series. We first prove a strong version of a conjecture by Castiglione and Massazza: weakly-unambiguous Parikh automata are equivalent to unambiguous two-way reversal bounded counter machines, and their multivariate generating series are holonomic. We then show that the converse is not true: we construct a language whose generating series is algebraic (thus holonomic), but which is inherently weakly-ambiguous as a Parikh automata language. Finally, we prove an effective decidability result for the inclusion problem for weakly-unambiguous Parikh automata, and provide an upper-bound on its complexity.

1 Introduction

This article investigates the link between *holonomic* (or *D-finite*) power series and formal languages. We consider the classical setting in which this connection is established via the generating series $L(x) = \sum_{n\geq 0} \ell_n x^n$ counting the number ℓ_n of words of length n in a given language $\mathcal{L}$.

On the languages side, the Chomsky–Schützenberger hierarchy [10] regroups languages in classes of increasing complexity: regular, context-free, context-sensitive and recursively enumerable. For power series, a similar hierarchy exists, consisting of the rational, algebraic and holonomic series. The first two levels of each hierarchy share a strong connection, as the generating series of a regular (resp. unambiguous context-free) language is a rational (resp. algebraic) power series.

This connection has borne fruits both in formal language theory and in combinatorics. In combinatorics, finite automata and unambiguous grammars are routinely used to establish rationality and algebraicity of particular power series. In formal languages, this connection was (implicitly) used to give polynomial-time algorithms for the inclusion and universality

tests for unambiguous finite automata [35]. In [15], Flajolet uses the connection between unambiguous context-free grammars and algebraic series to prove the inherent ambiguity of certain context-free languages, solving several conjectures with this tool. Using analytic criteria on the series (for instance, the existence of infinitely many singularities), he establishes that the series of these context-free languages is not algebraic. Hence these languages cannot be described by unambiguous context-free grammars and are therefore inherently ambiguous.

In this article we propose to extend the connection to holonomic series. Holonomic series enjoy non-trivial closure properties whose algorithmic counterparts are actively studied in computer algebra. Our aim is to show that these advances can be leveraged to obtain non-trivial results in the formal languages and verification worlds. These results are particularly noteworthy as the notion of unambiguity in automata theory is not fully understood [11]. The work of extending the connection was already initiated by Massazza in [27], where he introduces two families of languages, named RCM[1] and linearly constrained languages (LCL), whose generating series are holonomic. These classes are, however, not captured by well-known models of automata, and this limits their appeal. Recently, Castiglione and Massazza addressed this issue and conjectured that RCM contains the languages accepted by deterministic one-way reversal bounded machines (RBCM for short) [8]; Massazza proved the result for RBCM for two subclasses of one-way deterministic RBCM [28, 29]. This conjecture hints that the class RCM is related to models of automata such as RBCM, which are used in program verification.

Our first contribution is to prove a stronger version of this conjecture. We show that RCM and LCL respectively correspond to the languages accepted by weakly-unambiguous[2] version of Parikh automata (PA, for short) [24] and pushdown Parikh automata. Intuitively, Parikh automata are[3] finite non-deterministic word automata enriched with the ability to test semilinear constraints between the number of occurrences of each transition in the run. In terms of RBCM, these classes correspond to unambiguous two-way RBCM and unambiguous one-way RBCM enriched with a stack. Parikh automata are also commonly used in program verification. In view of the literature, these results might seem expected but they still require a careful adaptation of the standard techniques in the absence of a stack and become even more involved when a stack is added.

After having established the relevance of the classes of languages under study, we provide two consequences of the holonomicity of their associated generating series.

The first consequence follows Flajolet's approach mentioned previously and gives criteria to establish the inherent weak-ambiguity for languages accepted by PA or pushdown PA, by proving that their generating series are not holonomic. These criteria are sufficient but not necessary; this is not surprising as the inherent weak-ambiguity is undecidable for languages accepted by PA. Yet, the resulting method captures non-trivial examples with quite short and elegant proofs. In contrast, we give an example of inherently weakly-ambiguous PA language having a holonomic series (and therefore not amenable to the analytic method) for which we prove inherent weak-ambiguity *by hand*. The proof is quite involved but shows the inherent ambiguity of this language for a much larger class of automata (i.e., PA whose semi-linear sets are replaced by arbitrary recursive sets).

[1] The name RCM comes from the fact that these languages are defined using a Regular language, a semilinear Constraint and a Morphism.

[2] We use the term weakly-unambiguous here to avoid a possible confusion with the class of unambiguous PA defined in [7] which is strictly contained in our class. Our notion of non-ambiguity is the standard one: every word has at most one accepting computation (this is detailed in Remark 11).

[3] In this article, we use an equivalent definition where the transitions of the automaton are additionally labeled by vectors of natural numbers. A run is accepting if the sum of all the vectors encountered in the run satisfies a semilinear constraint.

The second consequence is of an algorithmic nature. We focus on the inclusion problem for weakly-unambiguous PA, whose decidability can be deduced from Castiglione and Massazza's work [8]. Here our contribution is an effective decidability result: we derive a concrete bound B, depending on the size of the representation of the two PAs, such that the inclusion holds if and only if the languages are included when considering words up to the length B. This bound B is obtained by a careful analysis of the proofs establishing the closure properties of holonomic series (in several variables), notably under Hadamard product and specialization. We do this by controlling various parameters (order, size of the polynomial coefficients, …) of the resulting partial differential equations.

2 Primer on holonomic power series in several variables

In this section, we introduce power series in several variables and the classes of rational, algebraic and holonomic power series. We recall the connection with regular and context-free languages via the notions of generating series in one or several variables.

Let $\mathbb{Q}[x_1, \dots, x_k]$ be the ring of polynomials in the variables $x_1, \dots, x_k$ with coefficients in $\mathbb{Q}$ and let $\mathbb{Q}(x_1, \dots, x_k)$ be the associated field of rational functions.

The *generating series of a sequence* $(f_n)_{n\in\mathbb{N}}$ is the (formal) power series in the variable x defined by $F(x) = \sum_{n\in\mathbb{N}} f_n x^n$. More generally, the generating series of a sequence $a(n_1, \dots, n_k)$ is a multivariate (formal) power series in the variables $x_1, \dots, x_k$ defined by $A(x_1, \dots, x_k) = \sum_{(n_1,\dots,n_k)\in\mathbb{N}^k} a(n_1, \dots, n_k) x_1^{n_1} \dots x_k^{n_k}$. In this article, we only consider power series whose coefficients belong to the field $\mathbb{Q}$. The set of such k-variate power series is denoted $\mathbb{Q}[[x_1, \dots, x_k]]$. Power series are naturally equipped with a sum and a product which generalize those of polynomials, for which $\mathbb{Q}[[x_1, \dots, x_k]]$ is a ring. We use the bracket notation for the coefficient extraction: $[x_1^{n_1} \dots x_k^{n_k}]A(x_1, \dots, x_k) = a(n_1, \dots, n_k)$. The *support* of $A \in \mathbb{Q}[[x_1, \dots, x_k]]$ is the set of $(n_1, \dots, n_k)$ such that $[x_1^{n_1} \dots x_k^{n_k}]A \neq 0$. The inverse $1/A$ of a series $A \in \mathbb{Q}[[x_1, \dots, x_k]]$ is well-defined when its constant term $[x_1^0 \dots x_k^0]A$ is not zero. For instance, the inverse of $A(x_1, x_2) = 1 - x_1 x_2^2$ is $\frac{1}{1-x_1x_2^2} = \sum_{n\geq 0} x_1^n x_2^{2n}$.

The *generating series of a language* $\mathcal{L}$ over the alphabet $\Sigma = \{a_1, \dots, a_k\}$ is the univariate power series $L(x) = \sum_{w\in\mathcal{L}} x^{|w|} = \sum_{n\in\mathbb{N}} \ell_n x^n$, where ℓ_n counts the number of words of length n in $\mathcal{L}$. Similarly the *multivariate generating series* of $\mathcal{L}$ defined by $L(x_{a_1}, \dots, x_{a_k}) = \sum_{(n_1,\dots,n_k)\in\mathbb{N}^k} \ell(n_1, \dots, n_k) x_{a_1}^{n_1} \dots x_{a_k}^{n_k}$ where $\ell(n_1, \dots, n_k)$ denotes the number of words w in $\mathcal{L}$ such that $|w|_{a_1} = n_1$, $|w|_{a_2} = n_2$, …, and $|w|_{a_k} = n_k$, and $|w|_a$ denotes the number of occurrences of $a \in \Sigma$ in w. This way, we create one dimension per letter, so that each letter $a \in \Sigma$ has a corresponding variable x_a.

Observe that the univariate generating series of a language is exactly $L(x, \dots, x)$, obtained by setting each variable to x in its multivariate generating series.

▶ **Example 1.** The generating series of the language $\mathcal{P}$ of well-nested parentheses defined by the grammar $S \to aSbS + \varepsilon$ is $P(x_a, x_b) = \frac{1-\sqrt{1-4x_ax_b}}{2x_ax_b}$ and its counting series is[4] $P(x) = \frac{1-\sqrt{1-4x^2}}{2x^2}$. Indeed the production of the grammar translates to the equation $P(x_a, x_b) = x_a x_b P(x_a, x_b)^2 + 1$. This equation admits only one power series solution, namely $\frac{1-\sqrt{1-4x_ax_b}}{2x_ax_b}$.

[4] As for the inverse, the square root of a power series with nonzero constant term can be defined using the usual Taylor formula $\sqrt{1-x} = \sum_{n\geq 0} \frac{1}{(1-2\,n)\,4^n} \binom{2\,n}{n} x^n$.

A power series $A(x_1,\ldots,x_k) = \sum_{n_1,\ldots,n_k} a(n_1,\ldots,n_k)x_1^{n_1}\ldots x_k^{n_k}$ is *rational* if it satisfies an equation of the form: $P(x_1,\ldots,x_k)A(x_1,\ldots,x_k) = Q(x_1,\ldots,x_k)$, with $P,Q \in \mathbb{Q}[x_1,\ldots,x_k]$ and $P \neq 0$. The generating series (both univariate and multivariate) of regular languages (i.e., languages accepted by a finite state automaton) are rational power series [4]. It is well-known that the generating series can be effectively computed from a deterministic automaton accepting the language (see for instance [17, §I.4.2] for a detailed proof). For example, the multivariate generating series of the regular language $(abc)^*$ is $\frac{1}{1-x_ax_bx_c} = \sum_{n\geq 0} x_a^n x_b^n x_c^n$. Its univariate generating series is $\frac{1}{1-x^3}$.

The connection between rational languages and rational power series is not tight. For instance, the generating series of the non-regular context-free language $\{a^nb^n : n \geq 0\}$ is $\frac{1}{1-x_ax_b}$, which is rational. In fact, it has the same generating series as the regular language $(ab)^*$. Also there exist rational power series with coefficients in $\mathbb{N}$ which are not the generating series of any rational language. This is the case for $\frac{x+5x^2}{1+x-5x^2-125x^3}$ as shown in [4].

A power series $A(x_1,\ldots,x_k)$ is *algebraic* if there exists a non-zero polynomial $P \in \mathbb{Q}[x_1,\ldots,x_k,Y]$ such that $P(x_1,\ldots,x_k,A(x_1,\ldots,x_k)) = 0$. All rational series are algebraic.

▶ **Example 2.** The series $\frac{1}{1-x_1x_2} = \sum_{n\geq 0} x_1^n x_2^n$ is rational, as it satisfies the equation $(1-x_1x_2)A(x_1,x_2) = 1$. The series $A(x_1,x_2) = \sqrt{1-x_1x_2}$ is algebraic but not rational, since $A(x_1,x_2)^2 + (x_1x_2 - 1) = 0$ and there is no similar algebraic equation of degree 1.

The reader is referred to [34, 17] for a detailed account on rational and algebraic series.

In the same manner that rational series satisfy linear equations and algebraic series satisfy polynomial equations, holonomic series satisfy linear differential equations with polynomial coefficients. To give a precise definition, we need to introduce the formal partial differentiation of power series. The differential operator ∂_{x_i} with respect to the variable x_i is defined by

$$\partial_{x_i}A(x_1,\ldots,x_k) = \sum_{n_1,\ldots,n_k} n_i\, a(n_1,\ldots,n_k)x_1^{n_1}\ldots x_{i-1}^{n_{i-1}}x_i^{n_i-1}x_{i+1}^{n_{i+1}}\ldots x_k^{n_k}.$$

The composed operator $\partial_{x_i}^j$ is inductively defined for $j \geq 1$ by $\partial_{x_i}^1 = \partial_{x_i}$ and $\partial_{x_i}^{j+1} = \partial_{x_i} \circ \partial_{x_i}^j$.

▶ **Definition 3** (see [33, 26])**.** *A power series $A(x_1,\ldots,x_k)$ is* holonomic *or* D-finite[5] *if the $\mathbb{Q}(x_1,\ldots,x_k)$-vector space spanned by the family $\{\partial_{x_1}^{i_1}\ldots\partial_{x_k}^{i_k}A(x_1,\ldots,x_k) : (i_1,\ldots,i_k) \in \mathbb{N}^k\}$ has a finite dimension. Equivalently, for every variable $z \in \{x_1,\ldots,x_k\}$, $A(x_1,\ldots,x_k)$ satisfies a linear differential equation of the form $P_r(x_1,\ldots,x_k)\partial_z^r A(x_1,\ldots,x_k) + \ldots + P_0(x_1,\ldots,x_k)A(x_1,\ldots,x_k) = 0$, where the P_i's are polynomials of $\mathbb{Q}[x_1,\ldots,x_k]$ with $P_r \neq 0$.*

In the sequel, except for Section 5, we rely on the closure properties of the holonomic series and will not need to go back to Definition 3.

▶ **Example 4.** A simple example of holonomic series is $A(x) = e^{x^2} = \sum_{n\geq 0} \frac{x^{2n}}{n!}$. It is holonomic (in one variable) since it satisfies $\partial_x A(x) - 2xA(x) = 0$.

For a more involved example, consider the language $\mathcal{L}_3 = \{w \in \{a,b,c\}^* : |w|_a = |w|_b = |w|_c\}$, containing the words having the same number of occurrences of a's, b's and c's. This language is classically not context-free. Moreover there are $\binom{3n}{n,n,n}$ words of length $3n$ in $\mathcal{L}_3$

[5] A priori, these notions differ: a function $A(x_1,\ldots,x_k)$ is called *D-finite* if all its partial derivatives $\partial_{x_1}^{n_1}\cdots\partial_{x_k}^{n_k}\cdot A$ generate a finite dimensional space over $\mathbb{Q}(x_1,\ldots,x_k)$, and *holonomic* if the functions $x_1^{\alpha_1}\cdots x_k^{\alpha_k}\partial_{x_1}^{\beta_1}\cdots\partial_{x_k}^{\beta_k}\cdot A$ subject to the constraint $\alpha_1+\cdots+\alpha_k+\beta_1+\cdots+\beta_k \leq N$ span a vector space whose dimension over $\mathbb{Q}$ grows like $O(N^k)$. The equivalence of these notions is proved by deep results of Bernšteĭn [2] and Kashiwara [21, 36].

and the power series $\sum_{n\geq 0}\binom{3n}{n,n,n}x^n$ is transcendental [15, §7]. Its multivariate generating series $L_3(x_a,x_b,x_c)$ is equal to $\sum_{n\geq 0}\frac{(3\,n)!\,(x_a x_b x_c)^n}{(n!)^3}$ and satisfies the partial differential equation:

$$(27x_a^2 x_b x_c - x_a)\partial^2_{x_a} f(x_a,x_b,x_c) + (54x_a x_b x_c - 1)\partial_{x_a} f(x_a,x_b,x_c) + 6x_b x_c f(x_a,x_b,x_c) = 0,$$

and the symmetric ones for the other variables x_b and x_c.

Holonomic series are an extension of the hierarchy we presented, as stated in the following proposition (see [12] for a proof, and [3] for bounds, algorithms and historical remarks).

▶ **Proposition 5.** *Multivariate algebraic power series are holonomic.*

In the univariate case[6], a power series $A(x)=\sum_n a_n x^n$ is holonomic if and only if its coefficients satisfy a linear recurrence of the form $p_r(n)a_{n+r}+\ldots+p_0(n)a_n=0$, where every p_i is a polynomial with rational coefficients [33, Th. 1.2].

We now focus on these closure properties.

▶ **Proposition 6** ([33])**.** *Multivariate holonomic series are closed under sum and product.*

Holonomic series are also closed under substitution by algebraic series as long as the resulting series is well-defined[7].

▶ **Proposition 7** ([26, Prop. 2.3])**.** *Let $A(x_1,\ldots,x_k)$ be a power series and let $G_i(y_1,\ldots,y_\ell)$ be algebraic power series such that $B(y_1,\ldots,y_\ell)=A(G_1(y_1,\ldots,y_\ell),\ldots,G_k(y_1,\ldots,y_\ell))$ is well-defined as a power series. If A is holonomic, then B is also holonomic.*

A sufficient condition for the substitution to be valid is that $G_i(0,\ldots,0)=0$ for all i (see [33, Th. 2.7]). For the case $G_1=\cdots=G_k=1$, called the *specialization to 1*, a sufficient condition is that for every index $(i_1,\ldots,i_k)$, $[x_1^{i_1}\ldots x_k^{i_k}]A$ is a polynomial in $y_1,\ldots,y_\ell$.

The Hadamard product is the coefficient-wise multiplication of power series. If the series $A(x_1,\ldots,x_k)$ and $B(x_1,\ldots,x_k)$ are the generating series of the sequences $a(n_1,\ldots,n_k)$ and $b(n_1,\ldots,n_k)$, the *Hadamard product* $A\odot B$ of A and B is the power series defined by

$$A\odot B(x_1,\ldots,x_k)=\sum_{(n_1,\ldots,n_k)\in\mathbb{N}^k} a(n_1,\ldots,n_k)b(n_1,\ldots,n_k)x_1^{n_1}\ldots x_k^{n_k}.$$

Observe that the support of $F\odot G$ is the intersection of the supports of F and G.

▶ **Theorem 8** ([25])**.** *Multivariate holonomic series are closed under Hadamard product.*

▶ **Example 9.** The generating series of the language $\mathcal{L}_3$ of Example 4, which is not context-free, can be expressed using the Hadamard product: since $\frac{1}{1-x_a x_b x_c}$ is the support series of the subset $\{(n,n,n) : n\in\mathbb{N}\}$, and since $\frac{1}{1-(x_a+x_b+x_c)}$ is the multivariate series of all the words on $\{a,b,c\}$, we have $L_3(x_a,x_b,x_c)=\frac{1}{1-(x_a+x_b+x_c)}\odot\frac{1}{1-x_a x_b x_c}$, which is not algebraic.

One of our main technical contributions is to provide bounds on the sizes of the polynomials in the differential equations of the holonomic representation of the Hadamard product of two rational series $\frac{P_1}{Q_1}$ and $\frac{P_2}{Q_2}$: we prove that their maxdegree is at most $(kM)^{\mathcal{O}(k)}$ and that the logarithm of their largest coefficient is at most $(kM)^{\mathcal{O}(k^2)}(1+\log S_\infty)$, where M (resp. S_∞) is the maxdegree plus one (resp. largest coefficient) in P_1, Q_1, P_2 and Q_2.

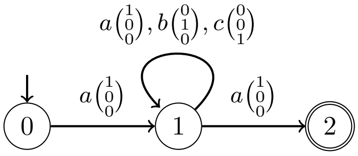
[6] The generalization of this equivalence to the multivariate case is not straightforward (see [26] for more details) and will not be used in this article.

[7] Note that the substitution of a power series into another power series might not yield a power series: for instance substituting x by $1+y$ in $\sum_{n\geq 0}x^n$ does not result in a power series as the constant term would be infinite.

3 Weakly-unambiguous Parikh automata

In this section, we introduce weakly-unambiguous Parikh automata and show that their multivariate generating series are holonomic. We establish that they accept the same languages as unambiguous two-way reversal bounded counter machines [19]. Finally, we prove that the class of accepted languages coincides with Massazza's RCM class [27, 8].

Parikh automata (PA for short) were introduced in [23, 24]. Informally, a PA is a finite automaton whose transitions are labeled by pairs $(a, \boldsymbol{v})$ where a is a letter of the input alphabet and $\boldsymbol{v}$ is a vector in $\mathbb{N}^d$. A run $q_0 \xrightarrow{a_1,\boldsymbol{v_1}} q_1 \xrightarrow{a_2,\boldsymbol{v_2}} q_2 \cdots q_{n-1} \xrightarrow{a_n,\boldsymbol{v_n}} q_n$ computes the word $a_1 \cdots a_n$ and the vector $\boldsymbol{v_1} + \cdots + \boldsymbol{v_n}$ where the sum is done component-wise. The acceptance condition is given by a set of final states and a semilinear set of vectors. A run is accepting if it reaches a final state and if its vector belongs to the semilinear set.



$a\binom{1}{0}{}_{0}, b\binom{0}{1}{}_{0}, c\binom{0}{0}{}_{1}$
$a\binom{1}{0}{}_{0}$
$a\binom{1}{0}{}_{0}$
0
1
2

The PA depicted above, equipped with the semilinear constraint $\{(n_1, n_2, n_1 + n_2) : n_1, n_2 \geq 0\}$, accepts the set of words w over $\{a, b, c\}$ that start and end with a and that are such that $|w|_a + |w|_b = |w|_c$.

3.1 Semilinear sets and their characteristic series

A set $L \subseteq \mathbb{N}^d$ is *linear* if it is of the form $\boldsymbol{c} + P^* := \{\boldsymbol{c} + \lambda_1 \boldsymbol{p_1} + \cdots + \lambda_k \boldsymbol{p_k} : \lambda_1, \dots, \lambda_k \in \mathbb{N}\}$, where $\boldsymbol{c} \in \mathbb{N}^d$ is the *constant* of the set and $P = \{\boldsymbol{p_1}, \dots, \boldsymbol{p_k}\} \subset \mathbb{N}$ its set of *periods.* A set $C \subseteq \mathbb{N}^d$ is *semilinear* if it is a finite union of linear sets. For example, the semilinear set $\{(n_1, n_2, n_1 + n_2) : n_1, n_2 \geq 0\}$ is in fact a linear set $(0, 0, 0) + \{(1, 0, 1), (0, 1, 1)\}^*$.

In [13, 20], it is shown that every semilinear set admits an unambiguous presentation. A presentation $\boldsymbol{c} + P^*$ with $P = \{\boldsymbol{p_1}, \dots, \boldsymbol{p_k}\}$ of a linear set L is unambiguous if for all $\boldsymbol{x} \in L$, the λ_i's such that $\boldsymbol{x} = \boldsymbol{c} + \lambda_1 \boldsymbol{p_1} + \cdots + \lambda_k \boldsymbol{p_k}$ are unique. An *unambiguous presentation of a semilinear set* is given by a disjoint union of unambiguous linear sets. A bound on the size of the equivalent unambiguous presentation is given in [9].

Semilinear sets are ubiquitous in theoretical computer science and admit numerous characterizations. They are the rational subsets of the commutative monoid $(\mathbb{N}^d, +)$, the unambiguous rational subset of $(\mathbb{N}^d, +)$ [13, 20], the Parikh images of context-free languages [30], the sets definable in Presburger arithmetic [31], the sets defined by boolean combinations of linear inequalities, equalities and equalities modulo constants.

For example, the semilinear set $\{(2n, 3n, 5n) : n \geq 0\}$ is equal to $(0, 0, 0) + \{(2, 3, 5)\}^*$. It is also the Parikh image of the regular (hence context-free) language $(aabbbccccc)^*$. In $(\mathbb{N}, +)$, it is defined by the Presburger formula $\phi(x, y, z) = \exists w, x = w + w \wedge y = w + w + w \wedge z = w + w + w + w + w$. Finally it is characterized in $\mathbb{N}^3$ by the equalities $3x = 2y$ and $5x = 2z$.

For a semilinear set $C \subseteq \mathbb{N}^d$, we consider its *characteristic generating series* $C(x_1, \dots, x_d)$ defined by $\sum_{(i_1,\dots,i_d) \in C} x_1^{i_1} \cdots x_d^{i_d}$. It is well-known [13, 20] that this power series is rational[8].

[8] The characteristic series of an unambiguous linear set $\boldsymbol{c} + P^* \subseteq \mathbb{N}$ with $P = \{\boldsymbol{p_1}, \dots, \boldsymbol{p_k}\}$ is $x_1^{\boldsymbol{c}(1)} \dots x_d^{\boldsymbol{c(d)}} \prod_{i=1}^k \left(1 - x_1^{\boldsymbol{p}_i(1)} \cdots x_d^{\boldsymbol{p}_i(d)}\right)^{-1}$ and hence is rational. As an unambiguous semilinear set is the disjoint union of unambiguous linear sets, its characteristic series is the sum of their series and it is therefore rational.

3.2 Weakly-unambiguous PAs and their generating series

We now introduce PA and their weakly-unambiguous variant. We discuss the relationship with the class of unambiguous PA introduced by Cadilhac et al. in [7] and the closure properties of this class.

A *Parikh automaton* of dimension $d \geq 1$ is a tuple $\mathcal{A} = (\Sigma, Q, q_I, F, C, \Delta)$ where Σ is the alphabet, Q is the set of states, $q_I \in Q$ is the initial state, $F \subseteq Q$ is the set of final states, $C \subseteq \mathbb{N}^d$ is the semilinear constraint and $\Delta \subseteq Q \times (\Sigma \times \mathbb{N}^d) \times Q$ is the transition relation.

A run of the automaton is a sequence $q_0 \xrightarrow{a_1,\boldsymbol{v_1}} q_1 \xrightarrow{a_2,\boldsymbol{v_2}} q_2 \cdots q_{n-1} \xrightarrow{a_n,\boldsymbol{v_n}} q_n$ where for all $i \in [1,n]$, $(q_{i-1}, (a_i, \boldsymbol{v_i}), q_i)$ is a transition in Δ. The run is labeled by the pair $(a_1 \cdots a_n, \boldsymbol{v_1} + \cdots + \boldsymbol{v_n}) \in \Sigma^* \times \mathbb{N}^d$. It is accepting if $q_0 = q_I$, the state q_n is final and if the vector $\boldsymbol{v_1} + \cdots + \boldsymbol{v_n}$ belongs to C. The word w is then said to be accepted by $\mathcal{A}$. The language accepted by $\mathcal{A}$ is denoted by $\mathcal{L}(\mathcal{A})$.

To define a notion of size for a PA, we assume that the constraint set is given by an unambiguous presentation $\uplus_{i=1}^{p} \boldsymbol{c_i} + P_i^*$. We denote by $|\mathcal{A}| := |Q| + |\Delta| + p + \sum_i |P_i|$ and by $\|\mathcal{A}\|_\infty$ the maximum coordinate of a vector appearing in Δ, the $\boldsymbol{c_i}$'s and the P_i's.

▶ **Definition 10.** *A Parikh automaton is said to be* weakly-unambiguous *if for every word there is at most one accepting run.*

A language is *inherently weakly-ambiguous* if it cannot be accepted by any weakly-unambiguous PA. The language $\mathcal{S}$ (defined in Section 4.1) is an example[9] of a language accepted by a non-deterministic PA which is inherently weakly-ambiguous.

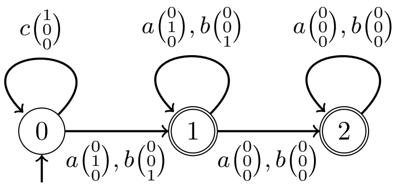
▶ Remark 11. We consider here the standard notion of unambiguity for finite state machines. However we decided to use the name *weakly-unambiguous* to avoid the confusion with the class of unambiguous PA which appears in the literature. This class was introduced by Cadilhac et al. in [7] for constraint automata, a model equivalent to PA and was latter defined directly on PAs. This notion of unambiguity is more restrictive than ours: they call a Parikh automaton *unambiguous* if the underlying automaton on letters, where the vectors have been erased, is unambiguous. Clearly such automata are weakly-unambiguous. However the converse is not true. Consider the language $\mathcal{L} = \{c^n w \ : \ w = x_1 x_2 \cdots x_m \in \{a,b\}^* \ \wedge \ m \geq n > 0 \wedge \ |x_1 x_2 \cdots x_n|_a < |x_1 x_2 \cdots x_n|_b\}$ over the alphabet $\{a,b,c\}$. Using results from [7], one can show that it is not recognized by any unambiguous Parikh automata. However, it is accepted by the weakly-unambiguous automaton depicted in Fig. 1 below with the semilinear $\{(n_1, n_2, n_3) \ : \ n_1 = n_2 + n_3 \text{ and } n_2 < n_3\}$.

The lack of expressivity of unambiguous PAs is counter-balanced by their closure under boolean operations, which is explained by their link with a class of deterministic PA [7, 14]. It was pointed out to us by a reviewer that the class of weakly-unambiguous PA is briefly considered, under the name OneCA, in Cadilhac's PhD thesis [5, p. 117], where only basic properties are established, in particular the strict inclusion of unambiguous PA in this class.

Using a standard product construction when the vectors are concatenated and using the concatenation of the constraints, it is easy to show that weakly-unambiguous PA are closed under intersection. In [8], the authors claim that the class[10] is closed under union. However their construction has an irrecoverable flaw and we do not know if weakly-unambiguous PA are closed under union or under complementation.

[9] Using the equivalences between weakly-unambiguous PA and RCM established in Proposition 13 and PA and RBCM [23, 6], it also gives an example of a language accepted by a RBCM with a non-holonomic generating series (strengthening Theorem 12 of [8]) and a witness for the strict inclusion of RCM in RBCM announced in Theorem 11 of [8]. Remark that their proof of this theorem only shows that there exists no recursive translation from RBCM to RCM.

[10] Actually, their claim is for the class RCM, which we will show to be equivalent in Section 3.4.



$c\binom{1}{0}{0}$ → $c\left(\begin{smallmatrix}1\\0\\0\end{smallmatrix}\right)$
$a\left(\begin{smallmatrix}0\\1\\0\end{smallmatrix}\right), b\left(\begin{smallmatrix}0\\0\\1\end{smallmatrix}\right)$
$a\left(\begin{smallmatrix}0\\0\\0\end{smallmatrix}\right), b\left(\begin{smallmatrix}0\\0\\0\end{smallmatrix}\right)$
0
1

$a\left(\begin{smallmatrix}0\\1\\0\end{smallmatrix}\right), b\left(\begin{smallmatrix}0\\0\\1\end{smallmatrix}\right)$
$a\left(\begin{smallmatrix}0\\0\\0\end{smallmatrix}\right), b\left(\begin{smallmatrix}0\\0\\0\end{smallmatrix}\right)$

Figure 1 A weakly-unambiguous Parikh automaton accepting the language $\mathcal{L} = \{c^n w \ : \ w = x_1 x_2 \cdots x_m \in \{a,b\}^* \ \wedge \ m \geq n > 0 \wedge \ |x_1 x_2 \cdots x_n|_a < |x_1 x_2 \cdots x_n|_b\}$ over the alphabet $\{a,b,c\}$ with the semilinear constraint $\{(n_1,n_2,n_3) \ : \ n_1 = n_2 + n_3$ and $n_2 < n_3\}$.

We now give a very short proof of the fact that weakly-unambiguous languages in PA have holonomic generating series. The idea of the proof can be traced back to [25]. A similar proof was given in [27] for languages in the class RCM but using the closure under algebraic substitutions instead of specialization (see Remark 25).

Our approach puts into light a different multivariate power series associated with a weakly-unambiguous PA $\mathcal{A}$ of dimension d. The multivariate *weighted generating series* $G(x, y_1, \ldots, y_d)$ of $\mathcal{A}$ is such that for all indices $(n, i_1, \ldots, i_d)$, $[x^n y_1^{i_1} \ldots y_d^{i_d}]G$ counts the number of words of length n accepted by $\mathcal{A}$ with a run labeled by the vector $(i_1, \ldots, i_d)$.

▶ **Proposition 12.** *The generating series of the language recognized by a weakly-unambiguous Parikh automaton is holonomic.*

Proof. Let $\mathcal{A}$ be a weakly-unambiguous PA with a constraint set $C \subseteq \mathbb{N}^d$. We first prove that its weighted series $G(x, y_1, \ldots, y_d)$ is holonomic. As holonomic series are closed under Hadamard product (see Theorem 8), it suffices to express G as the Hadamard product of two rational series $\overline{A}$ and $\overline{C}$ in the variables $x, y_1, \ldots, y_d$.

The first series $\overline{A}(x, y_1, \ldots, y_d)$ is such that for all $n, i_1, \ldots, i_d \geq 0$, $[x^n y_1^{i_1} \ldots y_d^{i_d}]\overline{A}$ counts the number of runs of $\mathcal{A}$ starting in q_I, ending in a final state and labeled with a word of length n and the vector $(i_1, \ldots, i_d)$. Note that we do not require that $(i_1, \ldots, i_d)$ belongs to C. As this series simply counts the number of runs in an automaton, its rationality is proved via the standard translation of the automaton into a linear system of equations.

For the second series, we take $\overline{C}(x, y_1, \ldots, y_d) := \frac{1}{1-x}\widetilde{C}(y_1, \ldots, y_d)$ where $\widetilde{C}$ is the support series of C, which is rational (see [13, 20]). A direct computation yields that for all $n, i_1, \ldots, i_d \geq 0$, $[x^n y_1^{i_1} \ldots y_d^{i_d}]\overline{C}$ is equal to 1 if $(i_1, \ldots, i_d)$ belongs to C and 0 otherwise.

The Hadamard product of $\overline{A}$ and $\overline{C}$ counts the number of runs accepting a word of length n with the vector $(i_1, \ldots, i_d)$. As $\mathcal{A}$ is weakly-unambiguous, this quantity is equal to the number of words of length n accepted with this vector. Hence $G = \bar{A} \odot \bar{C}$.

The univariate series $A(x)$ of $\mathcal{A}$ is equal to $G(x, 1, \ldots, 1)$. Indeed, for all $n \geq 0$, $[x^n]G(x, 1, \ldots, 1) = \sum_{\boldsymbol{i}=(i_1,\ldots,i_d)} [x^n y_1^{i_1} \cdots y_d^{i_d}]G(x, y_1, \ldots, y_d)$ is the sum over all vectors $\boldsymbol{i} \in \mathbb{N}^d$ of the number of words of length n accepted with the vector $\boldsymbol{i}$. As $\mathcal{A}$ is weakly-unambiguous, each word is accepted with at most one vector and this sum is therefore equal to the total number of accepted words of length n. Thanks to Proposition 7, $A(x) = G(x, 1, \ldots, 1)$ is holonomic. ◀

3.3 Equivalence with unambiguous reversal bounded counter machines

A *k-counter machine* [19] is informally a Turing machine with one read-only tape that contains the input word, and k counters. Reading a letter a on the input tape, in a state q, the machine can check which of its counters are zero, increment or decrement its counters, change its state, and move its read head one step to the left or right, or stay on its current position. Note that the machine does not have access to the exact value of its counters. A k-counter machine is said (m,n)-*reversal bounded* if its reading head can change direction between left and right at most m times, and if every counter can alternate between incrementing and decrementing at most n times each. Finally, a *reversal bounded counter machine* (RBCM) is a k-counter machine which is (m,n)-reversal bounded for some m and n. A RBCM is *unambiguous* if for every word there is at most one accepting computation.

RBCM are known[11] to recognize the same languages as Parikh automata (see [24, 23, 6]). This equality does not hold anymore for their deterministic versions [6, Prop. 3.14]. However, the proof of the equivalence for the general case can be slightly modified to preserve unambiguity.

▶ **Proposition 13.** *The class of languages accepted by unambiguous* RBCM *and weakly-unambiguous* PA *coincide.*

Proof sketch. Unambiguous RBCMs are shown to be equivalent to one-way unambiguous RBCMs. In turn these are shown to be equivalent to weakly-unambiguous PA with ε-transitions, which in turn are equivalent to weakly-unambiguous PA. This ε-removal step needs to be adapted to preserve weak-unambiguity. ◀

3.4 Equivalence with RCM

If we fix an alphabet $\Gamma = \{a_1, \dots, a_d\}$ with the ordering $a_1 < \dots < a_d$ on the letters, we can associate with every semilinear set C of dimension d, the language $[C] = \{w \in \Gamma^* : (|w|_{a_1}, \dots, |w|_{a_d}) \in C\}$ of words whose numbers of occurrences of each letter satisfy the constraint expressed by C. For instance, if we take the semilinear set $C_0 = \{(n,m,n,m) : n, m \geq 0\}$ and the alphabet $\{a,b,c,d\}$ ordered by $a < b < c < d$, $[C_0]$ consists of all words having as many a's as c's and as many b's as d's.

A language $\mathcal{L}$ over Σ belongs to RCM if there exist a regular language $\mathcal{R}$ over $\Gamma = \{a_1, \dots, a_d\}$, a semilinear set[12] $C \subseteq \mathbb{N}^d$ and a length preserving morphism $\mu\colon \Gamma^* \longrightarrow \Sigma^*$, that is injective over $\mathcal{R} \cap [C]$, so that $\mathcal{L} = \mu(\mathcal{R} \cap [C])$. For example, $\mathcal{L}_{abab} = \{a^n b^m a^n b^m : n, m \in \mathbb{N}\}$ can be shown to be in RCM by taking $\Gamma = \{a,b,c,d\}, \Sigma = \{a,b\}$, $\mu(a) = \mu(c) = a, \mu(b) = \mu(d) = b$, $\mathcal{R} = a^*b^*c^*d^*$ and the semilinear set C_0 defined in the previous paragraph.

▶ **Theorem 14.** $\mathcal{L} \in$ RCM *iff* $\mathcal{L}$ *is recognized by a weakly-unambiguous Parikh automaton.*

Proof sketch. Every language in RCM can be accepted by a weakly-unambiguous PA that guesses the underlying word over Γ: the weak-unambiguity is guaranteed by the injectivity of the morphism. Conversely a language accepted by a weakly-unambiguous PA is in RCM by taking for $\mathcal{R}$ the set of runs of the PA and translating the constraint: the injectivity of the morphism is guaranteed by the weak-unambiguity of the PA. ◀

In [8], the authors conjectured that the class RCM contains the one-way deterministic RBCM. From Theorem 14 and Proposition 13 we get a stronger result:

▶ **Corollary 15.** *The languages in RCM are the languages accepted by unambiguous RBCM.*

[11] The proof in [23] contains a patchable error, that was corrected in [6].

[12] Our definition may seem a little more general than Massazza's, which only uses semilinear defined without modulo constraints, but it can be shown that the classes are equivalent.

3.5 Weakly-unambiguous pushdown Parikh automata

A *pushdown Parikh automaton* ($\mathbb{P}$PA for short) is a PA where the finite automaton is replaced by a pushdown automaton. A *weakly-unambiguous* $\mathbb{P}$PA has at most one accepting run for each word. Most results obtained previously can be adapted for weakly-unambiguous $\mathbb{P}$PA. However, unsurprisingly, the class of languages accepted by weakly-unambiguous $\mathbb{P}$PA is not closed under union and intersection. This can be shown using the inherent weak-ambiguity of the language $\mathcal{D}$ proved in Section 4.1. The closure under complementation is left open.

▶ **Proposition 16.** *The generating series of a weakly-unambiguous* $\mathbb{P}$PA *is holonomic.*

Proof. The proof is almost identical to the proof of Proposition 12. The only difference is that the series $\overline{A}$ is algebraic and not rational. Indeed it counts the number of runs in a pushdown automaton and the language of runs is a deterministic context-free language even if the pushdown automaton is not deterministic. ◀

Remark that using the same techniques, we can prove that the generating series of weakly-unambiguous Parikh tree automata are holonomic. As we proved that all these series are also generating series of $\mathbb{P}$As, we do not elaborate on this model in this extended abstract.

RBCMs can be extended with a pushdown storage to obtain a *RBCM with a stack* [19].

▶ **Theorem 17.** *Weakly-unambiguous* $\mathbb{P}$PA *are equivalent to unambiguous one-way RBCM with a stack.*

Proof sketch. We first establish that unambiguous one-way RBCM with a stack are equivalent to weakly-unambiguous $\mathbb{P}$PA with ε-transitions. Contrarily to the PA case, the removal of ε-transitions is quite involved and uses weighted context-free grammars. ◀

The class LCL of [27] is defined[13] as RCM is, except that the regular language is replaced by an unambiguous context-free[14] language. Similarly to the PA case, one can prove:

▶ **Proposition 18.** *LCL is the set of languages accepted by weakly-unambiguous* $\mathbb{P}$PA.

4 Examples of inherently weakly-ambiguous languages

There is a polynomial-time algorithm to decide whether a given PA is weakly-unambiguous. But inherent weak-unambiguity is undecidable, as a direct application of a general theorem from [18]. This emphasizes that inherent weak-ambiguity is a difficult problem in general.

4.1 Two examples using an analytic criterion

Following an idea from Flajolet [15] for context-free languages, the link between weakly-unambiguous PA and holonomic series yields sufficient criteria to establish inherent weak-ambiguity, of analytic flavor: the contraposition of Proposition 12 indicates that if $\mathcal{L}$ is recognized by a PA but its generating series is not holonomic, then $\mathcal{L}$ is inherently weakly-ambiguous. Hence, any criterion of non-holonomicity can be used to establish the inherent weak-ambiguity. Many such criteria can be obtained when considering the generating series as analytic functions (of complex variables). See [15, 16] for several examples. For the presentation of this method in this extended abstract, we only rely on the following property:

[13] In [27], LCL is defined without the injective morphism but we adapt it following [8].

[14] Using deterministic context-free languages instead of unambiguous ones in the definition of LCL would result in the same class.

▶ **Proposition 19** ([33]). *A holonomic function in one variable has finitely many singularities.*

Our first example is the language $\mathcal{D}$, defined over the alphabet $\{a,b\}$ as follows:

$$\mathcal{D} = \{\underline{n_1}\ \underline{n_2} \dots \underline{n_k}\ :\ k > 0,\ n_1 = 1 \text{ and } \exists j < k, n_{j+1} \neq 2n_j\},\ \text{where } \underline{n} = a^n b.$$

This language is recognized by a weakly-ambiguous Parikh automaton, which guesses the correct j, and then verifies that $n_{j+1} \neq 2n_j$. Let $\overline{\mathcal{D}} = ab(a^*b)^* \setminus \mathcal{D}$, and suppose by contradiction that $\mathcal{D}$ can be recognized by a weakly-unambiguous PA. Then its generating series should be holonomic by Proposition 12. Since the generating series of $\overline{\mathcal{D}}$ is $\overline{D}(x_a, x_b) = \frac{x_a x_b}{1-\frac{x_b}{1-x_a}} - D(x_a, x_b)$, it should be holonomic too. Looking closely at the form of the words of $\overline{\mathcal{D}}$, we get that its generating series is $\sum_{k\geq 1} x_a^{2^k-1} x_b^k$. It is not holonomic as $x\overline{D}(x,1) + x$ has infinitely many singularities, see [15, p. 296–297].

Our second example is Shamir's language $\mathcal{S} = \{a^n b v_1 a^n v_2 : n \geq 1, v_1, v_2 \in \{a,b\}^*\}$. One can easily design a PA recognizing $\mathcal{S}$, where one coordinate stands for the length of the first run of a's and the other one for the second run of a's, the automaton guessing when the second run starts. Flajolet proved that $\mathcal{S}$ is inherently ambiguous as a context-free language, since its generating series $S(z) = \frac{z(1-z)}{1-2z} \sum_{n\geqslant 1} \frac{z^{2n}}{1-2z+z^{n+1}}$ has an infinite number of singularities [15, p. 296–297]. This also yields its inherent weak-ambiguity as a PA language.

4.2 Limit of the method: an example using pumping techniques

As already mentioned, the analytic method presented is not always sufficient to prove inherent ambiguity. In this section, we develop an example where it does not apply. We consider the following language $\mathcal{L}_{even}$, which is accepted both by a deterministic pushdown automaton and a non-deterministic PA (where $\underline{n} = a^n b$ as in Section 4.1):

$$\mathcal{L}_{even} = \left\{\underline{n_1}\ \underline{n_2} \dots \underline{n_{2k}}\ :\ k \in \mathbb{N},\ \forall i \leq 2k, n_i > 0,\ \text{and } \exists j \leq k, n_{2j} = n_{2j-1}\right\}.$$

In other words, $\mathcal{L}_{even}$ is the language of sequences of encoded numbers having two consecutive equal values, the first one being at an odd position. This language is accepted by a non-deterministic PA but is also deterministic context-free. This means that its generating series is algebraic and hence holonomic. This puts it out of the reach of our analytic method.

In this section we establish the following result:

▶ **Theorem 20.** *The language $\mathcal{L}_{even}$ is inherently weakly-ambiguous as a PA language.*

The remainder of this section is devoted to sketch the proof of this proposition. By contradiction, we suppose that $\mathcal{L}_{even}$ is recognized by a weakly-unambiguous PA $\mathcal{A}$.

An *a-piece* ω of $\mathcal{A}$ is a non-empty simple path of a-edges in $\mathcal{A}$, starting and ending at the same state: the states of the path are pairwise distinct, except for its extremities. The *origin* of w is its starting (and ending) state. Let $\Pi(\mathcal{A})$ be the (finite) set of a-pieces in $\mathcal{A}$.

We see a run in $\mathcal{A}$ as a sequence of transitions forming a path in $\mathcal{A}$. An *a-subpath* of a run R in $\mathcal{A}$ is a maximal consecutive subsequence of R whose transitions are all labeled by a's, that is, it cannot be extended further to the left nor to the right in R using a's.

Let R be an accepting run in $\mathcal{A}$. One can show that every a-subpath S of R can be decomposed as $S = w_1 \sigma_1^{s_1} w_2 \sigma_2^{s_2} \cdots w_f \sigma_f^{s_f} w_{f+1}$, where the σ_i's are a-pieces of $\Pi(\mathcal{A})$, the s_i's are positive integers, and the w_i's are paths not using twice the same state. Moreover, this decomposition is unique if we add the condition that if $w_i = \varepsilon$, then $\sigma_i \neq \sigma_{i-1}$ and the only state in common in w_i and σ_i is the origin of σ_i. This is done by repeatedly following the path until a state q is met twice, factorizing this segment of the form $w\sigma$, where σ is an a-piece of origin q. We call this decomposition the *canonical form* of S, and the *signature* of S is the tuple $(w_1, \sigma_1, w_2, \dots, w_f, \sigma_f, w_{f+1})$, i.e., we dropped the s_i's of the canonical form.

From the weak-unambiguity of $\mathcal{A}$ we can prove that there are at most c distinct possible signatures, where c only depends on $\mathcal{A}$, and that f is always at most $|Q_{\mathcal{A}}|$.

Ramsey's Theorem [32] guarantees that there exists an integer r such that any complete undirected graph with at least r vertices, whose edges are colored using c^2 different colors, admits a monochromatic triangle. We fix two positive integers n and k sufficiently large, which will be chosen later on, depending on $\mathcal{A}$ only. For $\ell \in \{1, \ldots, r\}$, let w_ℓ be the word $w_\ell = \underline{n_1}\,\underline{n_2} \ldots \underline{n_{2r}}$, where $n_i = n$ for odd i and $n_{2i} = n + k$ if $i \neq \ell$ and $n_{2\ell} = n$. Each w_ℓ is in $\mathcal{L}_{even}$, with a match at position 2ℓ only. By weak-unambiguity, each w_ℓ has a unique accepting run $\mathcal{R}_\ell$ in $\mathcal{A}$, each such run having $2r$ a-subpaths by construction. For $i \neq j$ in $\{1, \ldots, r\}$, let λ_{ij} be the signature of the $2j$-th a-subpath of $\mathcal{R}_i$, which is a path of length $n + k$ by definition. The complete undirected graph of vertex set $\{1, \ldots, r\}$ where each edge ij, with $i < j$, is colored by the pair $(\lambda_{ij}, \lambda_{ji})$ admits a monochromatic triangle of vertices $\alpha < \beta < \gamma$. In particular, $\lambda_{\alpha\beta} = \lambda_{\alpha\gamma}$ and $\lambda_{\gamma\alpha} = \lambda_{\gamma\beta}$.

We choose $k = \operatorname{lcm}(\{|\sigma| : \sigma \in \Pi(\mathcal{A})\})$, and n sufficiently large so that any a-subpath of an accepting run contains an a-piece σ repeated at least $k + 1$ times. This is possible as the w_i's have bounded length, and there are at most $|Q_{\mathcal{A}}| + 1$ of them. Hence, the 2γ-th a-subpath of w_α contains a a-piece σ that is repeated more than s times, where $s = k/|\sigma|$. As $\lambda_{\alpha\beta} = \lambda_{\alpha\gamma}$, the piece σ is also in the 2β-th a-subpath of w_α. If we alter the accepting path $\mathcal{R}_\alpha$ into $\mathcal{R}'_\alpha$ by looping s more times in σ in the a-subpath at position 2β and s less times in σ at position 2γ, we obtain a run for the word $w = \cdots \underline{n}\,\underset{2\alpha}{\underline{n}} \cdots \underline{n}\,\underset{2\beta}{\underline{n + 2k}} \cdots \underline{n}\,\underset{2\gamma}{\underline{n}} \cdots$. This run is accepting as the PA computes the same vector as for w_α, by commutativity of vectors addition. And the signatures remain unchanged, as there are sufficiently many repetitions of σ at position 2γ in w_α. Similarly, as $\lambda_{\gamma\alpha} = \lambda_{\gamma\beta}$, we can alter the accepting path $\mathcal{R}_\gamma$ into an accepting path $\mathcal{R}'_\gamma$ of same signatures as $\mathcal{R}_\gamma$ for the same word w, by removing $s' = k/|\sigma'|$ iterations of an a-piece σ' at position 2α and adding them at position 2β.

We have built two paths $\mathcal{R}'_\alpha$ and $\mathcal{R}'_\gamma$ that both accept the same word w. Therefore, as $\mathcal{A}$ is weakly-unambiguous, they are equal. As the signatures have not changed, this implies that the signature at position 2α in $\mathcal{R}'_\alpha$ is $\lambda_{\gamma\alpha}$, which is equal to $\lambda_{\gamma\beta}$ (monochromaticity), which is equal to $\lambda_{\alpha\beta}$ ($\mathcal{R}'_\alpha$ and $\mathcal{R}'_\gamma$ have same signatures). This is a contradiction as we could remove one a-piece at position 2α in w_α and add it at position 2β, while computing the same vector with the same starting and ending states: but this word is not in $\mathcal{L}_{even}$.

▶ Remark 21. The proof relies on manipulations of paths in the automaton, and we only use the commutativity of the addition for the vector part. Thus, it still holds if we consider automata where we use a recursively enumerable set instead of a semilinear set for acceptance.

5 Algorithmic consequence of holonomicity

Generating series of languages have already been used to obtain efficient algorithms on unambiguous models of automata. For instance, they were used by Stearns and Hunt as a basic tool to obtain bounds on the length of a word witnessing the non-inclusion between two unambiguous word automata [35]. More precisely, the proof in [35] relies on the recurrence equation satisfied by the coefficients of the generating series (which is guaranteed to exist by holonomicity in one variable). In the rational case, this recurrence relation can be derived from the automaton and does not require advanced results on holonomic series. In this section, our aim is to obtain a similar bound for the inclusion problem for weakly-unambiguous Parikh automata. The inclusion problem for RCM (and hence for weakly-unambiguous PA) is shown to be decidable in [8] but no complexity bound is provided. Note that this problem is known to be undecidable for non-deterministic PA [19]. We follow the same approach as for the rational case [35] and for RCM [8]. In stark contrast with the rational case, it is necessary to closely inspect holonomic closure properties in order to give concrete bounds.

Fix $\mathcal{A}$ and $\mathcal{B}$ two weakly-unambiguous PA. We can construct a weakly-unambiguous PA $\mathcal{C}$ accepting $L(\mathcal{A}) \cap L(\mathcal{B})$. We rely on the key fact that the series $D(x) = A(x) - C(x)$ counts the number of words of length n in $L(\mathcal{A}) \setminus L(\mathcal{B})$. In particular, $L(\mathcal{A}) \subseteq L(\mathcal{B})$ if and only if $D(x) = 0$.

As $D(x)$ is the difference of two holonomic series, it is holonomic. As equality between holonomic series is decidable, [8] concludes that the problem is decidable. But without further analysis, no complexity upper-bound can be derived. The coefficients of $D(x) = \sum_{n \geq 0} d_n x^n$ satisfy a recurrence equation of the form $p_0(n)d_n = \sum_{k=1}^{r} p_k(n)d_{n-k}$ for $n \geq r$ with $p_0(x) \neq 0$. This equation fully determines d_n in terms of its r previous values $d_{n-1}, \dots, d_{n-r}$, *provided that* $p_0(n) \neq 0$. In particular, if the r previous values are all equal to 0, then $d_n = 0$. Consequently, if d_n is equal to 0 for all $n \leq r + R$ where R denotes the largest positive root of p_0 (which is bounded from above by its ∞-norm, as a polynomial on $\mathbb{Z}$) then[15] $D(x) = 0$.

Taking $W := r + R$, we have that if $L(\mathcal{A}) \not\subseteq L(\mathcal{B})$ then there exists a word witnessing this non-inclusion of length at most W. We now aim at computing an upper-bound on W on the size of the inputs $\mathcal{A}$ and $\mathcal{B}$.

For this, we first bound the order of the linear recurrence satisfied by $A(x)$ and $C(x)$, as well as the degrees and norm of the polynomials involved. This is stated in Proposition 22, whose proof follows the one of Proposition 12, while establishing such bounds for the multivariate Hadamard product and the specialization to 1.

▶ **Proposition 22.** *The generating series $A(x)$ of a weakly-unambiguous PA $\mathcal{A}$ of dimension $d \geq 1$ satisfies a non-trivial linear differential equation $q_s(x)\partial_x^s A(x) + \cdots + q_0(x)A(x) = 0$, with $s \leq ((d+1)|\mathcal{A}|\,\|\mathcal{A}\|_\infty)^{O(d)}$ and for all $i \in [0,s]$, $\deg(q_i) \leq ((d+1)|\mathcal{A}|\,\|\mathcal{A}\|_\infty)^{O(d)}$ and $\log \|q_i\|_\infty \leq ((d+1)|\mathcal{A}|\,\|\mathcal{A}\|_\infty)^{O(d^2)}$ using the notations of Section 3.2.*

Finally, we transfer these bounds to the series $D(x)$ of $L(\mathcal{A}) \setminus L(\mathcal{B})$ using the analysis of [22] for the sum of holonomic series in one variable.

▶ **Theorem 23.** *Given two weakly-unambiguous PA $\mathcal{A}$ and $\mathcal{B}$ of respective dimensions $d_\mathcal{A}$ and $d_\mathcal{B}$, if $L(\mathcal{A})$ is not included in $L(\mathcal{B})$ then there exists a word in $L(\mathcal{A}) \setminus L(\mathcal{B})$ of length at most $2^{2^{O(d^2 \log(dM))}}$ where $d = d_\mathcal{A} + d_\mathcal{B}$ and $M = |\mathcal{A}|\,|\mathcal{B}|\,\|\mathcal{A}\|_\infty\,\|\mathcal{B}\|_\infty$.*

Using the bound of Theorem 23, the inclusion problem can be solved in triply exponential time by a naive counting of all words up to the bound. Using dynamic programming to compute the number of accepted words, we can decide inclusion in doubly exponential time.

▶ **Corollary 24.** *Given two weakly-unambiguous PA $\mathcal{A}$ and $\mathcal{B}$ of dimensions $d_\mathcal{A}$ and $d_\mathcal{B}$, we can decide if $L(\mathcal{A})$ is included in $L(\mathcal{B})$ in time $2^{2^{O(d^2 \log(dM))}}$ where $d = d_\mathcal{A} + d_\mathcal{B}$ and $M = |\mathcal{A}|\,|\mathcal{B}|\,\|\mathcal{A}\|_\infty\,\|\mathcal{B}\|_\infty$.*

▶ Remark 25. In [8], the authors propose a different construction to prove the holonomicity of the generating series of languages in RCM. This proof uses the closure of holonomic series under Hadamard product and algebraic substitution $x_1 = x_2 = \cdots = x_n = x$. It is natural to wonder if this approach would lead to better bounds in Proposition 22 (using the

[15] The proof of Theorem 7 in [8] wrongly suggests that we can take the order of the differential equation for D as a bound on the length of a witness for non-inclusion. In general, this is not the case. For instance consider $D(x) = x^{1000}$ which satisfies the first-order differential equation $1000D(x) - x\partial_x D(x) = 0$. It is clear that the coefficients $D_0 = 0$ and $D_1 = 0$ are not enough to decide that D is not zero.

equivalence between weakly-unambiguous PA and RCM). It turns out that the operation $x_1 = x_2 = \cdots = x_n = x$ is more complicated than it seems at a first glance. Indeed, to our knowledge, no proof of the closure under algebraic substitution explains what happens if, during the substitution process, the equations become trivial. This issue can be overcome by doing the substitution step by step: $x_2 = x_1$, then $x_3 = x_1$, etc. However, this naive approach would produce worse bounds.

6 Perspectives

The bounds obtained in Section 5 are derived directly from constructions given in the proofs of the closure properties. In particular, we did not use any information on the special form of our series. The bounds are certainly perfectible using more advanced tools from computer algebra. Also it seems that the complexity of the closure under the algebraic substitution deserves more investigation, as discussed in Remark 25.

A more ambitious perspective is to find larger classes of automata whose generating series are holonomic. This would certainly require new ideas, as for instance any holonomic power series with coefficients in $\{0, 1\}$ is known to be the characteristic series of some semilinear set [1].

Abstract

Let n be a positive integer and $\mathcal{M}$ a set of rational $n \times n$-matrices such that $\mathcal{M}$ generates a finite multiplicative semigroup. We show that any matrix in the semigroup is a product of matrices in $\mathcal{M}$ whose length is at most $2^{n(2n+3)}g(n)^{n+1} \in 2^{O(n^2 \log n)}$, where $g(n)$ is the maximum order of finite groups over rational $n \times n$-matrices. This result implies algorithms with an elementary running time for deciding finiteness of weighted automata over the rationals and for deciding reachability in affine integer vector addition systems with states with the finite monoid property.

1 Introduction

The Burnside Problem

An element g of a semigroup G is called *torsion* if $g^i = g^j$ holds for some naturals $i < j$, and G *torsion* if all its elements are torsion. Burnside [6] asked in 1902 a question which became known as the *Burnside problem* for groups: is every finitely generated torsion group finite? Schur [28] showed in 1911 that this holds true for groups of invertible complex matrices, i.e., any finitely generated torsion subgroup of $GL(n, \mathbb{C})$ is finite. This was generalised by

47th International Colloquium on Automata, Languages, and Programming (ICALP 2020).

Kaplansky [21, p. 105] to matrices over arbitrary fields. The Burnside problem for groups has a negative answer in general: in 1964 Golod and Shafarevich exhibited a finitely generated infinite torsion group [13, 14].

The Maximal Order of Finite Matrix Groups

Schur's result [28] assures that finitely generated torsion matrix groups are finite, but does not bound the group order. Indeed, it is easy to see that any finite cyclic group is isomorphic to a group generated by a matrix in $GL(2, \mathbb{R})$. The same is not true for $GL(n, \mathbb{Q})$: An elementary proof, see e.g. [23], shows that any finite subgroup of $GL(n, \mathbb{Q})$ is conjugate to a finite subgroup of $GL(n, \mathbb{Z})$. Another elementary proof shows that the order of any finite subgroup of $GL(n, \mathbb{Z})$ divides $(2n)!$; see, e.g., [27, Chapter IX]. Thus, denoting the order of the largest finite subgroup of $GL(n, \mathbb{Q})$ by $g(n)$, we have $g(n) \leq (2n)!$. It is shown in a paper by Friedland [12] that $g(n) = 2^n n!$ holds for all sufficiently large n. This bound is attained by the group of signed permutation matrices. Friedland's proof rests on an article by Weisfeiler [34] which in turn is based on the classification of finite simple groups. Feit showed in an unpublished manuscript [9] that $g(n) = 2^n n!$ holds if and only if $n \in \mathbb{N} \setminus \{2, 4, 6, 7, 8, 9, 10\}$.[1] Feit's proof relies on an unpublished manuscript [33], also based on the classification of finite simple groups, which Weisfeiler left behind before his tragic disappearance.

Deciding Finiteness of Matrix Groups

Bounds on group orders give a straightforward, albeit inefficient, way of deciding whether a given set of matrices generates a finite group: starting from the set of generators, enlarge it with products of matrices in the set, until either it is closed under product or the bound on the order has been exceeded. One can do substantially better: it is shown in [2] that, using computations on quadratic forms, one can decide in polynomial time if a given finite set of rational matrices generates a finite group.

Deciding Finiteness of Matrix Semigroups

The Burnside problem has a natural analogue for semigroups. In 1975, McNaughton and Zalcstein [26] positively solved the Burnside problem for matrix semigroups, i.e., they showed, for any field $\mathbb{F}$, that any finitely generated torsion subsemigroup of $\mathbb{F}^{n \times n}$ is finite, using the result for groups by Schur and Kaplansky as a building block. From a computational point of view, McNaughton and Zalcstein's result suggests an approach for deciding finiteness of the semigroup generated by a given set of rational matrices: finiteness is recursively enumerable, by closing the set of generators under product, as described above for groups. On the other hand, infiniteness is recursively enumerable by enumerating elements in the generated semigroup and checking each element whether it is torsion. By the contrapositive of McNaughton and Zalcstein's result, if the generated matrix semigroup is infinite, it has a non-torsion element, witnessing infiniteness. However, deciding whether a given matrix has finite order is nontrivial. Only in 1980 did Kannan and Lipton [19, 20] show that the so-called *orbit problem* is decidable (in polynomial time), implying an algorithm for checking whether a matrix has finite order.

[1] A list of the maximal-order finite subgroups of $GL(n, \mathbb{Q})$ for $n \in \{2, 4, 6, 7, 8, 9, 10\}$ can be found in [3, Table 1].

Avoiding this problem, Mandel and Simon [25] showed in 1977 that there exists a function $f : \mathbb{N}^3 \to \mathbb{N}$ such that if S is a finite subsemigroup of $\mathbb{F}^{n\times n}$, generated by m of its elements, and the subgroups of S have order at most g, then S has size (cardinality) at most $f(n, m, g)$. For rational matrices, one may use the function $g(n)$ from above for g. By making, in a sense, McNaughton and Zalcstein's proof quantitative, Mandel and Simon explicitly construct such a function f, which implies an algorithm, with bounded runtime, for deciding finiteness of a finitely generated rational matrix semigroup. A similar result about the decidability of this problem was obtained independently and concurrently by Jacob [18].

Size Bounds

Unlike the function g for rational matrix groups, Mandel and Simon's function $f(n, m, g)$ depends on m, the number of generators. This is unavoidable: the semigroup generated by the set $\mathcal{M}_m := \left\{\begin{pmatrix} 0 & i \\ 0 & 0 \end{pmatrix} : i \in \{0, \ldots, m-1\}\}\right\}$ is the set $\mathcal{M}_m$ itself, with $|\mathcal{M}_m| = m$ for any $m \in \mathbb{N}$. Further, the growth in n of Mandel and Simon's f is, roughly, a tower of exponentials of height n. They write in [25, Section 3]: "However, it is likely that our upper bound $[f(n, m, g)]$ can be significantly improved."

In [4, Chapter VI], Berstel and Reutenauer also show, for the rational case, the existence of a function in n and m that bounds the semigroup size. They write: "As we shall see, the function [...] grows extremely rapidly." An analysis of their proof shows that the growth of their function is comparable with the growth of Mandel and Simon's function. A related approach is taken in [31]. Further proofs of McNaughton and Zalcstein's result can be found, e.g., in [24, 11, 8, 30], but they do not lead to better size bounds.

Length Bounds

In 1991, Weber and Seidl [32] considered semigroups over *nonnegative* integer matrices. Using combinatorial and automata-theoretic techniques, they showed that if a finite set $\mathcal{M} \subseteq \mathbb{N}^{n\times n}$ generates a finite monoid, then for any matrix M of that monoid there are $M_1, \ldots, M_\ell \in \mathcal{M}$ with $\ell \leq \lceil e^2 n! \rceil - 2$ such that $M = M_1 \cdots M_\ell$; i.e., any matrix in the monoid is a product of matrices in $\mathcal{M}$ whose *length* is at most $\lceil e^2 n! \rceil - 2$. Note that this bound does not depend on the number of generators. Weber and Seidl also give an example that shows that such a length bound cannot be smaller than 2^{n-2}.

Almeida and Steinberg [1] proved in 2009 a length bound for rational matrices and expressing the zero matrix: if a finite set $\mathcal{M} \subseteq \mathbb{Q}^{n\times n}$ (with $n > 1$) generates a *finite* semigroup that includes the zero matrix 0, then there are $M_1, \ldots, M_\ell \in \mathcal{M}$ with $\ell \leq (2n-1)^{n^2} - 1$ such that $0 = M_1 \cdots M_\ell$. A length bound of n^5 for expressing the zero matrix was recently given in the nonnegative integer case [22]. It is open whether there is a polynomial length bound for expressing the zero matrix in the rational case.

Our Contribution

We prove a $2^{O(n^2 \log n)}$ length bound for the rational case:

▶ **Theorem 1.** *Let $\mathcal{M} \subseteq \mathbb{Q}^{n\times n}$ be a finite set of rational matrices such that $\mathcal{M}$ generates a finite semigroup $\overline{\mathcal{M}}$. Then for any $M \in \overline{\mathcal{M}}$ there are $M_1, \ldots, M_\ell \in \mathcal{M}$ with $\ell \leq 2^{n(2n+3)} g(n)^{n+1} \in 2^{O(n^2 \log n)}$ such that $M = M_1 \cdots M_\ell$. (Here $g(n) \leq (2n)!$ denotes the order of the largest finite subgroup of $GL(n, \mathbb{Q})$.)*

The example by Weber and Seidl mentioned above shows that any such length bound must be at least 2^{n-2}. A length bound trivially implies a size bound, and Theorem 1 allows us to obtain the first significant improvement over the fast-growing function of Mandel and Simon.

▶ **Corollary 2.** *Let $\mathcal{M} \subseteq \mathbb{Q}^{n\times n}$ be a finite set of m rational matrices that generate a finite semigroup $\overline{\mathcal{M}}$. Then $|\overline{\mathcal{M}}| \le m^{2^{O(n^2 \log n)}}$.*

The proof of Theorem 1 is largely based on linear-algebra arguments, specifically on the structure of a certain graph of vector spaces obtained from $\mathcal{M}$. This graph was introduced and analysed by Hrushovski et al. [17] for the computation of the *Zariski closure* of the generated matrix semigroup.

After the preliminaries (section 2) and the proof of Theorem 1 (section 3), we discuss applications in automata theory (section 4). In particular we show that our result implies the first elementary-time algorithm for deciding finiteness of weighted automata over the rationals.

2 Preliminaries

We write $\mathbb{N} = \{0, 1, 2, \ldots\}$. For a finite alphabet Σ, we write $\Sigma^* = \{a_1 \cdots a_k : k \ge 0,\ a_i \in \Sigma\}$ and $\Sigma^+ = \{a_1 \cdots a_k : k \ge 1,\ a_i \in \Sigma\}$ for the free monoid and the free semigroup generated by Σ. The elements of Σ^* are called *words*. For a word $w = a_1 \cdots a_k$, its *length* $|w|$ is k. We denote by ε the empty word, i.e., the word of length 0. For $L \subseteq \Sigma^*$, we also write $L^* = \{w_1 \cdots w_k : k \ge 0,\ w_i \in L\} \subseteq \Sigma^*$ and $L^+ = \{w_1 \cdots w_k : k \ge 1,\ w_i \in L\} \subseteq \Sigma^*$.

We denote by I_n the $n\times n$-identity matrix, and by $\vec{0}$ the zero vector. For vectors $v_1, \ldots, v_k$ from a vector space, we denote their span by $\langle v_1, \ldots, v_k\rangle$. In this article, we view elements of $\mathbb{Q}^n$ as *row* vectors.

For some $n \in \mathbb{N} \setminus \{0\}$, let $\mathcal{M} \subseteq \mathbb{Q}^{n\times n}$ be a finite set of rational matrices, generating a finite semigroup $\overline{\mathcal{M}}$. For notational convenience, throughout the paper, we associate to $\mathcal{M}$ an alphabet Σ with $|\mathcal{M}| = |\Sigma|$, and a bijection $M : \Sigma \to \mathcal{M}$ which we extend to the monoid morphism $M : \Sigma^* \to \overline{\mathcal{M}} \cup \{I_n\}$. Thus we may write $M(\Sigma)$ and $M(\Sigma^*)$ for $\mathcal{M}$ and $\overline{\mathcal{M}} \cup \{I_n\}$, respectively.

We often identify a matrix $A \in \mathbb{Q}^{n\times n}$ with its linear transformation $A : \mathbb{Q}^n \to \mathbb{Q}^n$ such that $x \mapsto xA$ for row vectors $x \in \mathbb{Q}^n$. To avoid clutter, we extend linear-algebra notions from matrices to words, i.e., we may write $\operatorname{im} w$, $\ker w$, $\operatorname{rk} w$ for the image $\operatorname{im}(M(w)) = \mathbb{Q}^n M(w)$, the kernel $\ker(M(w)) = \{x \in \mathbb{Q}^n : xM(w) = \vec{0}\}$, and the rank of $M(w)$.

If all matrices in $M(\Sigma)$ are invertible and $M(\Sigma^*)$ is finite, then $M(\Sigma^*)$ is a finite subgroup of $GL(n, \mathbb{Q})$. For $n \in \mathbb{N}$, let us write $g(n)$ for the size of the largest finite subgroup of $GL(n, \mathbb{Q})$. As discussed in the introduction, a non-trivial but elementary proof shows $g(n) \le (2n)!$, and it is known that $g(n) = 2^n n!$ holds for sufficiently large n.

Exterior Algebra

This brief introduction is borrowed and slightly extended from [17, Section 3]. Let V be an n-dimensional vector space over a field $\mathbb{F}$. (We will only consider $V = \mathbb{Q}^n$.) For any $r \in \mathbb{N}$, let $\mathcal{A}_r$ denote the set of maps $B : V^r \to \mathbb{F}$ so that B is linear in each argument and further $B(v_1, \ldots, v_r) = 0$ holds whenever $v_i = v_{i+1}$ holds for some $i \in \{1, \ldots, r-1\}$. These conditions imply that swapping two adjacent arguments changes the sign, i.e.,

$$B(v_1, \ldots, v_{i-2}, v_{i-1}, v_{i+1}, v_i, v_{i+2}, v_{i+3}, \ldots, v_r) \ = \ -B(v_1, \ldots, v_r)\,.$$

These properties of $\mathcal{A}_r$ imply that, given an arbitrary basis $\{e_1, \ldots, e_n\}$ of V, any $B \in \mathcal{A}_r$ is uniquely determined by all $B(e_{i_1}, \ldots, e_{i_r})$ where $1 \leq i_1 < i_2 < \ldots < i_r \leq n$. For any $v_1, \ldots, v_r \in V$, define the *wedge product*

$$v_1 \wedge \cdots \wedge v_r : \mathcal{A}_r \to \mathbb{F} \quad \text{by} \quad (v_1 \wedge \cdots \wedge v_r)(B) = B(v_1, \ldots, v_r)\,.$$

It follows from the properties of $\mathcal{A}_r$ above that the wedge product is linear in each argument: if $v_i = \lambda u + \lambda' u'$ then

$$\Big(\bigwedge_{1\leq i\leq k} v_i\Big)(B) = \lambda\Big(\bigwedge_{1\leq j<i} v_j \wedge u \wedge \bigwedge_{i<j\leq k} v_j\Big)(B) + \lambda'\Big(\bigwedge_{1\leq j<i} v_j \wedge u' \wedge \bigwedge_{i<j\leq k} v_j\Big)(B)$$

Moreover, $(v_1 \wedge \cdots \wedge v_r)(B) = 0$ if $v_i = v_j$ holds for some i, j with $i \neq j$.

For $r \in \mathbb{N}$ define $\Lambda^r V$ as the vector space generated by the length-r wedge products $v_1 \wedge \cdots \wedge v_r$ with $v_1, \ldots, v_r \in V$. For any basis $\{e_1, \ldots, e_n\}$ of V, the set $\{e_{i_1} \wedge \cdots \wedge e_{i_r} : 1 \leq i_1 < \ldots < i_r \leq n\}$ is a basis of $\Lambda^r V$; hence $\dim \Lambda^r V = \binom{n}{r}$. Note that $\Lambda^1 V = V$ and $\binom{n}{r} = 0$ for $r > n$. One can view the wedge product as an associative operation $\wedge : \Lambda^r V \times \Lambda^\ell V \to \Lambda^{r+\ell} V$. Define the *exterior algebra of* V as the direct sum $\Lambda V = \Lambda^0 V \oplus \Lambda^1 V \oplus \cdots$. Then also $\wedge : \Lambda V \times \Lambda V \to \Lambda V$.

It follows that for $u_1, \ldots, u_r \in V$, we have $u_1 \wedge \cdots \wedge u_r \neq \vec{0}$ if and only if $\{u_1, \ldots, u_r\}$ is linearly independent. Furthermore, for $u_1, \ldots, u_r, v_1, \ldots, v_r \in V$ and $u = u_1 \wedge \cdots \wedge u_r \neq \vec{0}$ and $v = v_1 \wedge \cdots \wedge v_r \neq \vec{0}$, we have that u, v are scalar multiples if and only if $\langle u_1, \ldots, u_r \rangle = \langle v_1, \ldots, v_r \rangle$.

The Grassmannian $\mathrm{Gr}(n)$ is the set of subspaces of $\mathbb{Q}^n$. By the above-stated properties of the wedge product there is an injective function

$$\iota : \mathrm{Gr}(n) \to \Lambda\, \mathbb{Q}^n$$

such that, for all $W \in \mathrm{Gr}(n)$, we have $\iota(W) = v_1 \wedge \cdots \wedge v_r$ where $\{v_1, \ldots, v_r\}$ is an arbitrarily chosen basis of W. Note that the particular choice of a basis for W only changes the value of $\iota(W)$ up to a constant. Given subspaces $W_1, W_2 \in \mathrm{Gr}(n)$, we moreover have $W_1 \cap W_2 = \{\vec{0}\}$ if and only if $\iota(W_1) \wedge \iota(W_2) \neq \vec{0}$.

3 Proof of Theorem 1

It is convenient to state and prove our main result in terms of monoids rather than semigroups:

▶ **Theorem 3.** *Let $M : \Sigma^* \to \mathbb{Q}^{n\times n}$ be a monoid morphism whose image $M(\Sigma^*)$ is finite. Then for any $w \in \Sigma^*$ there is $u \in \Sigma^*$ with $M(w) = M(u)$ and*

$$|u| \;\leq\; 2^{n(2n+3)} g(n)^{n+1} \in 2^{O(n^2 \log n)}\,.$$

With this theorem at hand, Theorem 1 follows immediately:

Proof of Theorem 1. Let $M \in \overline{\mathcal{M}}$ be an element of the semigroup generated by $\mathcal{M}$. If $M \neq I_n$, by Theorem 3, M can be written as a short product. Otherwise, $M = I_n \in G$, where $G = \overline{\mathcal{M}} \cap GL(n, \mathbb{Q})$ is a finite group of order at most $g(n)$. For any product $M_1 \cdots M_\ell$ with $\ell > g(n)$, there are $1 \leq i < j \leq \ell$ such that $M_1 \cdots M_i = M_1 \cdots M_j$, and so $M_1 \cdots M_\ell = M_1 \cdots M_i M_{j+1} \cdots M_\ell$. Hence, there are $\ell \in \{1, \ldots, g(n)\}$ and $M_1, \ldots, M_\ell \in \mathcal{M}$ such that $M = I_n = M_1 \cdots M_\ell$. ◀

▶ **Remark 4.** *The same argument as in the proof above shows that in a finite* monoid $(H, \cdot)$, *generated by* $G \subseteq H$, *for any* $h \in H$ *there are* $\ell \in \{0, \ldots, |H|-1\}$ *and* $g_1, \ldots, g_\ell \in G$ *with* $h = g_1 \cdots g_\ell$.

In the remainder of this section, we prove Theorem 3. We assume that $M : \Sigma^* \to \mathbb{Q}^{n\times n}$ is a monoid morphism with finite image $M(\Sigma^*)$.

3.1 The Maximum-Rank Case

In this subsection we prove:

▶ **Proposition 5.** *Suppose that there is* $r \le n$ *with* $\operatorname{rk} a = r$ *for all* $a \in \Sigma$. *Let* $w \in \Sigma^*$ *with* $\operatorname{rk} w = r$. *Then there is* $u \in \Sigma^*$ *with* $M(w) = M(u)$ *and*

$$|u| \ \le\ 2^{2n+3} g(n) - 1 \ \in\ 2^{O(n \log n)} .$$

In this subsection we assume that $\operatorname{rk} a = r$ holds for all $a \in \Sigma$. For the proof of Proposition 5, we define a directed labelled graph G whose vertices are the vector spaces $\operatorname{im} w$ for $w \in \Sigma^*$ such that $\operatorname{rk} w = r$, and whose edges are triples (V_1, a, V_2) such that $a \in \Sigma$ and $V_1 M(a) = V_2$. Let (V_1, a, V_2) be an edge; then $V_2 \subseteq \operatorname{im} a$, but $\dim V_2 = r = \operatorname{rk} a = \dim \operatorname{im} a$, hence $V_2 = \operatorname{im} a$, i.e., the edge label determines the edge target. We will implicitly use the fact that any path in G is determined by its start vertex and the sequence of its edge labels. Note that if V_1 is a vertex and $a \in \Sigma$, the edge $(V_1, a, \operatorname{im} a)$ is present in G if and only if $\operatorname{rk} V_1 M(a) = r$ if and only if $V_1 \cap \ker a = \{\vec{0}\}$.

The following two lemmas, which are variants of lemmas in [17, Section 6], are statements about the structure of G in terms of its strongly connected components (SCCs).

▶ **Lemma 6.** *Let* $w = w_1 \cdots w_k$ *for* $w_1, \ldots, w_k \in \Sigma^+$ *with* $\operatorname{rk} w = r$ *such that the* k *vertices* $\operatorname{im} w_1, \ldots, \operatorname{im} w_k$ *are all in different SCCs of* G. *Then* $k \le 2\binom{n}{r}$.

Proof. Let $i \in \{2, \ldots, k-1\}$. Since $\operatorname{rk} w_i = r = \operatorname{rk}(w_i w_{i+1})$, we have $\operatorname{im} w_i \cap \ker w_{i+1} = \{\vec{0}\}$, thus $\iota(\operatorname{im} w_i) \wedge \iota(\ker w_{i+1}) \ne \vec{0}$. On the other hand, for any $j < i$, since $\operatorname{im} w_i, \operatorname{im} w_j$ are in different SCCs and $\operatorname{im} w_i$ is reachable from $\operatorname{im} w_j$, the vertex $\operatorname{im} w_j$ is not reachable from $\operatorname{im} w_i$; therefore we have $\operatorname{im} w_i \cap \ker w_j \ne \{\vec{0}\}$, thus $\iota(\operatorname{im} w_i) \wedge \iota(\ker w_j) = \vec{0}$. It follows that $\iota(\ker w_{i+1}) \notin \langle \iota(\ker w_j) : j < i\rangle$. Indeed, if $\iota(\ker w_{i+1}) = \sum_{j<i} \lambda_j \iota(\ker w_j)$ for some $\lambda_1, \ldots, \lambda_{i-1}$ then, by linearity of the wedge product, $\iota(\operatorname{im} w_i) \wedge \iota(\ker w_{i+1}) = \sum_{j<i} \lambda_j (\iota(\operatorname{im} w_i) \wedge \iota(\ker w_j)) = \vec{0}$, a contradiction.

We show by induction on i that $\dim \langle \iota(\ker w_j) : j \in \{1, \ldots, i\}\rangle \ge i/2$ for all $i \in \{1, \ldots, k\}$. This is clear for $i = 1, 2$. For the induction step, we have $\dim \langle \iota(\ker w_j) : j \in \{1, \ldots, i+1\}\rangle \ge \dim \langle \iota(\ker w_{i+1}), \iota(\ker w_j) : j \in \{1, \ldots, i-1\}\rangle \ge 1 + (i-1)/2 = (i+1)/2$. Hence $k/2 \le \dim \langle \iota(\ker w_j) : j \in \{1, \ldots, k\}\rangle \le \dim \Lambda^{n-r}\mathbb{Q}^n = \binom{n}{r}$. ◀

▶ **Lemma 7.** *Let* $a_1 \cdots a_k \in \Sigma^*$ *be (the edge labels of) a shortest path in* G *from a vertex* $\operatorname{im} a_0$ *to* $\operatorname{im} a_k$. *Then* $k \le \binom{n}{r}$.

Proof. Let $i \in \{0, \ldots, k-2\}$. We have $\operatorname{im} a_i \cap \ker a_{i+1} = \{\vec{0}\}$, thus $\iota(\operatorname{im} a_i) \wedge \iota(\ker a_{i+1}) \ne \vec{0}$. On the other hand, for any $j > i+1$, since $a_{i+1} \cdots a_j$ is a shortest path from $\operatorname{im} a_i$ to $\operatorname{im} a_j$, there is no edge from $\operatorname{im} a_i$ to $\operatorname{im} a_j$; therefore we have $\operatorname{im} a_i \cap \ker a_j \ne \{\vec{0}\}$, thus $\iota(\operatorname{im} a_i) \wedge \iota(\ker a_j) = \vec{0}$. It follows that $\iota(\ker a_{i+1}) \notin \langle \iota(\ker a_j) : j > i+1\rangle$.

By induction it follows that $\dim \langle \iota(\ker a_j) : j \in \{i+1, \ldots, k\}\rangle \ge k - i$ holds for all $i \in \{0, \ldots, k-1\}$. Hence $k \le \dim \langle \iota(\ker a_j) : j \in \{1, \ldots, k\}\rangle \le \dim \Lambda^{n-r}\mathbb{Q}^n = \binom{n}{r}$. ◀

The next lemmas discuss *cycles* $w \in \Sigma^+$ in G, i.e., (the edge labels of) paths in G such that $\operatorname{im} w \cap \ker w = \{\vec{0}\}$. A cycle w is said to be *around* $\operatorname{im} w_0$ if $\operatorname{im} w = \operatorname{im} w_0$. The following lemma says, loosely speaking, that cycles around a single vertex "generate a group".

▶ **Lemma 8.** *Let $w_0 \in \Sigma^+$ with $\operatorname{rk} w_0 = r$, and let $P \in \mathbb{Q}^{r \times n}$ be a matrix with $\operatorname{im} P = \operatorname{im} w_0$. Then for every cycle $w \in \Sigma^+$ around $\operatorname{im} w_0$ there exists a unique invertible matrix $M'(w) \in GL(r, \mathbb{Q})$ such that $PM(w) = M'(w)P$. Moreover, for any nonempty set $C \subseteq \Sigma^+$ of cycles around $\operatorname{im} w_0$, $M'(C^+)$ is a finite subgroup of $GL(r, \mathbb{Q})$.*

Proof. Let $w \in \Sigma^+$ be a cycle around $\operatorname{im} w_0$. Since $\operatorname{im} P \cap \ker(M(w)) = \{\vec{0}\}$, it follows that $\operatorname{im}(PM(w)) = \operatorname{im} w = \operatorname{im} P$. So the rows of $PM(w)$ are linear combinations of rows of P, and vice versa, hence there is a unique $M'(w) \in GL(r, \mathbb{Q})$ with $PM(w) = M'(w)P$.

Let $C \subseteq \Sigma^+$ be a nonempty set of cycles around $\operatorname{im} w_0$. For any $w_1, w_2 \in C$ we have $M'(w_1 w_2)P = PM(w_1 w_2) = PM(w_1)M(w_2) = M'(w_1)PM(w_2) = M'(w_1)M'(w_2)P$, and since the rows of P are linearly independent, it follows that $M'(w_1 w_2) = M'(w_1)M'(w_2)$. Thus, $M'(C^+)$ is a semigroup.

Towards a contradiction, suppose $M'(C^+)$ were infinite. Since the rows of P are linearly independent, it follows that $M'(C^+)P$ is infinite, thus $PM(C^+)$ is infinite. Since $\operatorname{im} w_0 = \operatorname{im} P$, there is a matrix $B \in \mathbb{Q}^{n \times r}$ with $M(w_0) = BP$. Since the columns of B are linearly independent, the set $BPM(C^+)$ is infinite. But this set equals $M(w_0 C^+)$, contradicting the finiteness of $M(\Sigma^*)$. Thus the semigroup $M'(C^+)$ is finite. As $M'(C^+) \subseteq GL(r, \mathbb{Q})$, it follows that $M'(C^+)$ is a finite group. ◀

The following lemma allows us, loosely speaking, to limit the number of cycles in a word.

▶ **Lemma 9.** *Let $w_0, w_1, \ldots, w_k \in \Sigma^+$ such that $w_1, \ldots, w_k$ are cycles around $\operatorname{im} w_0$. Then there exist $\ell \leq g(n) - 1$ and $\{u_1, \ldots, u_\ell\} \subseteq \{w_1, \ldots, w_k\}$ such that $M(w_0 w_1 \cdots w_k) = M(w_0 u_1 \cdots u_\ell)$.*

Proof. We can assume $k \geq 1$. Let $C = \{w_1, \ldots, w_k\}$. Let P and $M'(w)$ for $w \in C$ as in Lemma 8. By Lemma 8, the set $M'(C^+)$ is a finite subgroup of $GL(r, \mathbb{Q})$, so we have $|M'(C^+)| \leq g(r) \leq g(n)$. By Remark 4, there are $\ell \leq g(n) - 1$ and $u_1, \ldots, u_\ell \in C$ such that $M'(w_1) \cdots M'(w_k) = M'(u_1) \cdots M'(u_\ell)$. Since $\operatorname{im} w_0 = \operatorname{im} P$, there is a matrix $B \in \mathbb{Q}^{n \times r}$ with $M(w_0) = BP$. Hence we have $M(w_0 w_1 \cdots w_k) = BPM(w_1) \cdots M(w_k) = BM'(w_1) \cdots M'(w_k)P = BM'(u_1) \cdots M'(u_\ell)P = BPM(u_1) \cdots M(u_\ell) = M(w_0 u_1 \cdots u_\ell)$. ◀

The following lemma allows us to add cycles to a word.

▶ **Lemma 10.** *Let $w \in \Sigma^+$ be a cycle in G. Then there exists $\rho(w) \in \mathbb{N} \setminus \{0\}$ such that $M(w_0) = M(w_0 w^{\rho(w)})$ holds for all $w_0 \in \Sigma^+$ with $\operatorname{im} w_0 = \operatorname{im} w$.*

Proof. Let $P \in \mathbb{Q}^{r \times n}$ be a matrix with $\operatorname{im} P = \operatorname{im} w$. By Lemma 8, there exists $M'(w) \in GL(r, \mathbb{Q})$ such that $PM(w) = M'(w)P$ and $\{M'(w)^i : i \in \mathbb{N}\}$ is a finite group. Define $\rho(w)$ to be the order of this group, i.e., $M'(w)^{\rho(w)} = I_r$. Let $w_0 \in \Sigma^+$ with $\operatorname{im} w_0 = \operatorname{im} w$. Since $\operatorname{im} w_0 = \operatorname{im} P$, there is a matrix $B \in \mathbb{Q}^{n \times r}$ with $M(w_0) = BP$. Hence $M(w_0) = BP = BI_r P = BM'(w)^{\rho(w)}P = BPM(w)^{\rho(w)} = M(w_0)M(w)^{\rho(w)} = M(w_0 w^{\rho(w)})$. ◀

The following lemma allows us to limit the length of paths within an SCC.

▶ **Lemma 11.** *Let $a \in \Sigma$, and let $w \in \Sigma^*$ be a path in G from $\operatorname{im} a$ such that $\operatorname{im} a$ and $\operatorname{im} w$ are in the same SCC. Then there exists $u \in \Sigma^*$ with $M(aw) = M(au)$ and*

$$|u| \;\leq\; 2^{n+2} g(n) - 2 \;\in\; 2^{O(n \log n)}\,.$$

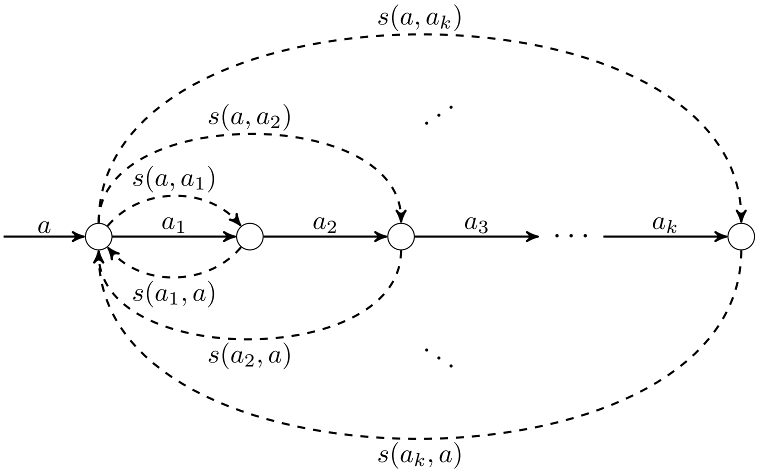

Figure 1 Illustration of the paths w and w' in Lemma 11. Edges are depicted as solid arrows, paths as dashed arrows.

Proof. For any $b_1, b_2 \in \Sigma$ such that $\operatorname{im} b_1, \operatorname{im} b_2$ are in the SCC of $\operatorname{im} a$, let $s(b_1, b_2) \in \Sigma^*$ be a shortest path from $\operatorname{im} b_1$ to $\operatorname{im} b_2$. By Lemma 7, we have $|s(b_1, b_2)| \leq \binom{n}{r}$.

Suppose $w = a_1 \cdots a_k$ for $a_i \in \Sigma$. For $i \in \{1, \ldots, k\}$ define the cycle $w_i := s(a_i, a)s(a, a_i)$ around $\operatorname{im} a_i$. By Lemma 10, we have $M(aw) = M(aw')$ for

$$w' := a_1 w_1^{\rho(w_1)} a_2 w_2^{\rho(w_2)} \cdots a_k w_k^{\rho(w_k)} .$$

For $i \in \{1, \ldots, k\}$ also define the cycle $v_i := s(a, a_i)s(a_i, a)$ around $\operatorname{im} a$. Then we have:

$$w' = a_1 s(a_1, a) v_1^{\rho(w_1)-1} s(a, a_1) a_2 s(a_2, a) v_2^{\rho(w_2)-1} s(a, a_2) \cdots a_k s(a_k, a) v_k^{\rho(w_k)-1} s(a, a_k)$$

Figure 1 illustrates the paths w and w'. Define a set of cycles $C \subseteq \Sigma^*$ around $\operatorname{im} a$ by

$$C := \{a_1 s(a_1, a), v_1, s(a, a_1) a_2 s(a_2, a), v_2, \ldots, s(a, a_{k-1}) a_k s(a_k, a), v_k\} .$$

Since $w' \in C^* s(a, a_k)$, by Lemma 9, there exist $\ell \leq g(n) - 1$ and $u_1, \ldots, u_\ell \in C$ such that $M(aw) = M(aw') = M(au_1 u_2 \cdots u_\ell s(a, a_k))$. For all $v \in C$ we have $|v| \leq 2\binom{n}{r} + 1 \leq 2^{n+2}$, and $|s(a, a_k)| \leq \binom{n}{r} \leq 2^n$. Hence the lemma holds for $u := u_1 u_2 \cdots u_\ell s(a, a_k)$, as $|u| \leq 2^{n+2}(g(n) - 1) + 2^n \leq 2^{n+2} g(n) - 2$. ◀

We are ready to prove Proposition 5.

Proof of Proposition 5. Decompose the word w into $w = a_1 w_1 a_2 w_2 \cdots a_k w_k$ for $a_i \in \Sigma$ so that for all $i \in \{1, \ldots, k\}$ the vertices $\operatorname{im} a_i, \operatorname{im} w_i$ are in the same SCC, and for all $i \in \{1, \ldots, k-1\}$ the vertices $\operatorname{im} w_i, \operatorname{im} a_{i+1}$ are in different SCCs. By Lemma 6, we have $k \leq 2\binom{n}{r} \leq 2^{n+1}$. For all $i \in \{1, \ldots, k\}$, by Lemma 11, there is $u_i \in \Sigma^*$ with $|u_i| \leq 2^{n+2} g(n) - 2$ such that $M(a_i w_i) = M(a_i u_i)$. Hence the proposition holds for $u := a_1 u_1 a_2 u_2 \cdots a_k u_k$, as $|u| \leq 2^{n+1}(2^{n+2} g(n) - 2 + 1) \leq 2^{2n+3} - 1$. ◀

3.2 The General Case

In this subsection we prove Theorem 3. For $r \in \{0, \ldots, n\}$ let $d_r \in \mathbb{N}$ be the smallest number such that for any $w \in \Sigma^*$ with $\operatorname{rk} w \geq r$ there is $u \in \Sigma^*$ with $M(w) = M(u)$ and $|u| \leq d_r$. Also write h for the bound from Proposition 5.

▶ **Proposition 12.** *For any $r \in \{0, \ldots, n-1\}$ we have $d_r \leq d_{r+1} + (d_{r+1} + 1)h$.*

Proof. Let $w \in \Sigma^*$ with $\operatorname{rk} w \geq r$. We need to show that there is $u \in \Sigma^*$ with $M(w) = M(u)$ and $|u| \leq d_{r+1} + (d_{r+1} + 1)h$. Decompose w into $w = w_0 a_1 w_1 a_2 w_2 \cdots a_k w_k$ for $a_i \in \Sigma$ such that $\operatorname{rk} w_0 > r$ and for all $i \in \{1, \ldots, k\}$ we have $\operatorname{rk}(a_i w_i) = r$ and $\operatorname{rk} w_i > r$. (This decomposition is unique; in particular, $a_k w_k$ is the shortest suffix of w with rank r.) By the definition of d_{r+1}, for all $i \in \{0, \ldots, k\}$ there exists $u_i \in \Sigma^*$ with $M(w_i) = M(u_i)$ and $|u_i| \leq d_{r+1}$. Then $M(w) = M(u_0 a_1 u_1 a_2 u_2 \cdots a_k u_k)$.

Define a new alphabet Σ_r and a monoid morphism $M_r : \Sigma_r^* \to \mathbb{Q}^{n \times n}$ with $M_r(\Sigma_r) = \{M(a_i u_i) : i \in \{1, \ldots, k\}\}$, and note that $\operatorname{rk} M_r(b) = r$ for all $b \in \Sigma_r$. Then there is a word $y \in \Sigma_r^*$ such that $M_r(y) = M(a_1 u_1 \cdots a_k u_k)$. By Proposition 5, there is $x \in \Sigma_r^*$ with $M_r(y) = M_r(x)$ and $|x| \leq h$. Obtain the word $v \in \Sigma^*$ from x by replacing each letter $b \in \Sigma_r$ in x by $a_i u_i$ for $i \in \{1, \ldots, k\}$ such that $M_r(b) = M(a_i u_i)$. Then $M_r(x) = M(v)$, and thus $M(w) = M(u_0 a_1 u_1 \cdots a_k u_k) = M(u_0) M_r(y) = M(u_0) M_r(x) = M(u_0) M(v) = M(u_0 v)$, where $|u_0 v| = |u_0| + |v| \leq d_{r+1} + (d_{r+1} + 1)|x| \leq d_{r+1} + (d_{r+1} + 1)h$. ◀

We can now prove our main result.

Proof of Theorem 3. We prove by induction that for all $r \in \{0, \ldots, n\}$ we have $d_r \leq (h+1)^{n-r} d_n + (h+1)^{n-r} - 1$. For the base case, $r = n$, this is trivial. For the step, let $r < n$. We have:

$$\begin{aligned} d_r &\leq h + (h+1) d_{r+1} && \text{(Proposition 12)} \\ &\leq h + (h+1)\big((h+1)^{n-r-1} d_n + (h+1)^{n-r-1} - 1\big) && \text{(induction hypothesis)} \\ &= h + (h+1)^{n-r} d_n + (h+1)^{n-r} - h - 1 \end{aligned}$$

This completes the induction proof. Hence $d_0 \leq (h+1)^n (d_n + 1) = 2^{n(2n+3)} g(n)^n (d_n + 1)$. The rank-$n$ matrices in $M(\Sigma)$ generate a finite subgroup of $GL(n, \mathbb{Q})$. So it follows by Remark 4 that $d_n + 1 \leq g(n)$. Thus $d_0 \leq 2^{n(2n+3)} g(n)^{n+1}$. ◀

4 Algorithmic Applications

Theorem 1 gives an exponential-space algorithm for deciding finiteness of a finitely generated rational matrix semigroup. In fact, the following theorem shows that deciding finiteness is in the second level of the weak EXP hierarchy (see e.g. [16] for a definition).

▶ **Theorem 13.** *Given be a finite set $\mathcal{M} \subseteq \mathbb{Q}^{n \times n}$ of rational matrices, the problem of deciding finiteness of the generated semigroup $\overline{\mathcal{M}}$ is in* coNEXP$^{\text{NP}}$.

Proof. For a NEXP$^{\text{NP}}$ algorithm deciding infiniteness, non-deterministically guess in exponential time some $M = M_1 \cdots M_\ell$, $M_i \in \mathcal{M}$, with $\ell = 2^{n(2n+3)} g(n)^{n+1} + 1$ as a witness for infiniteness. Then, using a call to an NP oracle, check whether there are $M_1', \ldots, M_r' \in \mathcal{M}$ such that $M = M_1' \cdots M_r'$ for some $0 \leq r < \ell$. If the call is successful then reject, otherwise accept.

Correctness of the algorithm immediately follows from Theorem 1: if $\overline{\mathcal{M}}$ is finite, then the $M_1', \ldots, M_r' \in \mathcal{M}$ such that $M = M_1' \cdots M_r'$ are guaranteed to exist. ◀

This is the first improvement of the non-elementary algorithm of Mandel and Simon [25].

Another immediate consequence of Theorem 1 is an upper bound on the complexity of the membership problem for finite matrix semigroups:

▶ **Theorem 14.** *Given a finite set of rational matrices $\mathcal{M} \subseteq \mathbb{Q}^{n\times n}$ such that $\overline{\mathcal{M}}$ is finite and $A \in \mathbb{Q}^{n\times n}$, the problem of deciding whether $A \in \overline{\mathcal{M}}$ is in* NEXP*.*

In the remainder of this section, we discuss implications of Theorem 13 to decision problems in automata theory.

4.1 Weighted Automata

The motivation for Mandel and Simon to study the finiteness problem originated from investigating the decidability of the finiteness problem (originally called boundedness problem in [25]) for weighted automata. A *weighted automaton over* $\mathbb{Q}$ is a quintuple $\mathcal{A} = (n, \Sigma, M, \alpha, \eta)$ where $n \in \mathbb{N}$ is the number of states, Σ is the finite alphabet, $M : \Sigma \to \mathbb{Q}^{n\times n}$ maps letters to transition matrices, $\alpha \in \mathbb{Q}^n$ is the initial state vector, and $\eta \in \mathbb{Q}^n$ is the final state vector. We extend M to the monoid morphism $M : \Sigma^* \to \mathbb{Q}^{n\times n}$ as before. Such an automaton defines a function $|\mathcal{A}| : \Sigma^* \to \mathbb{Q}$ by defining $|\mathcal{A}|(w) = \alpha M(w)\eta^T$, where the superscript T denotes transpose. We say, $\mathcal{A}$ is *finite* if the image of $|\mathcal{A}|$ is finite, i.e., if $|\mathcal{A}|(\Sigma^*) \subseteq \mathbb{Q}$ is a finite set. The *finiteness problem* asks whether a given automaton is finite.

It is clear that if $M(\Sigma^*)$ is finite then $\mathcal{A}$ is finite. The converse is not generally true: e.g., any automaton $\mathcal{A}$ whose initial state vector is the zero vector satisfies $|\mathcal{A}|(\Sigma^*) = \{0\}$, hence is finite, regardless of $M(\Sigma^*)$. However, it is argued in the proof of Corollary 5.4 in [25] that, given an automaton $\mathcal{A}$, one can compute, in exponential time, a polynomial-size automaton $\mathcal{B}$ with monoid morphism $M_{\mathcal{B}}$ such that (i) $|\mathcal{A}| = |\mathcal{B}|$, and (ii) $\mathcal{A}$ (and hence $\mathcal{B}$) is finite if and only if $M_{\mathcal{B}}(\Sigma^*)$ is finite.[2] Mandel and Simon use this argument to show that the finiteness problem for weighted automata over $\mathbb{Q}$ is decidable. Theorem 13 then immediately gives:

▶ **Corollary 15.** *The finiteness problem for weighted automata over* $\mathbb{Q}$ *can be decided in* coNEXP$^{\mathrm{NP}}$.

4.2 Affine Integer Vector Addition Systems with States

We show that Theorem 1 together with Corollary 2 imply an upper bound for the reachability problem in affine integer vector addition systems with states with the finite monoid property (afmp-$\mathbb{Z}$-VASS) studied in [5]. An affine $\mathbb{Z}$-VASS in dimension $d \in \mathbb{N}$ is a tuple $\mathcal{V} = (d, Q, T)$ such that Q is a finite set of states and $T \subseteq Q \times \mathbb{Z}^{d\times d} \times \mathbb{Z}^d \times Q$ is a finite transition relation. Setting $\mathcal{M} := \{A \in \mathbb{Z}^{d\times d} : (q, A, \vec{b}, r) \in T\}$, in afmp-$\mathbb{Z}$-VASS we additionally require that $\overline{\mathcal{M}}$ is finite. A configuration of $\mathcal{V}$ is a tuple $(q, \vec{v}) \in Q \times \mathbb{Z}^d$ which we write as $q(\vec{v})$. We define the step relation $\to \subseteq (Q \times \mathbb{Z}^d)^2$ such that $q(\vec{v}) \to r(\vec{w})$ if and only if there is a transition $(q, A, \vec{b}, r) \in T$ such that $\vec{w} = A \cdot \vec{v} + \vec{b}$. Moreover, we denote by $\to^*$ the reflexive transitive closure of $\to$. For a configuration $q(\vec{v})$, we define the reachability set of $q(\vec{v})$ as $\mathcal{R}(q(\vec{v})) := \{r(\vec{w}) : q(\vec{v}) \to^* r(\vec{w})\}$. Given configurations $q(\vec{v})$ and $r(\vec{w})$, reachability is the problem of deciding whether $r(\vec{w}) \in \mathcal{R}(q(\vec{v}))$. Note that $\mathcal{R}(q(\vec{v}))$ is in general infinite despite $\overline{\mathcal{M}}$ being finite.

[2] We remark that this automaton $\mathcal{B}$ has the minimal number of states among the automata defining the function $|\mathcal{A}|$. This minimal automaton goes back to [29] and has been further studied in, e.g., [7, 10].

The reachability problem for afmp-$\mathbb{Z}$-VASS was shown decidable in [5] by a reduction to reachability in $\mathbb{Z}$-VASS. A $\mathbb{Z}$-VASS is an afmp-$\mathbb{Z}$-VASS in which every transition is of the form $(q, I_d, \vec{b}, r)$. The reachability problem for $\mathbb{Z}$-VASS is known to be NP-complete, see e.g. [15]. The size of the $\mathbb{Z}$-VASS obtained in the reduction given in [5] grows in $|\overline{\mathcal{M}}|$ and hence leads to a non-elementary upper bound for reachability in afmp-$\mathbb{Z}$-VASS assuming Mandel and Simon's bound. The results of this paper enable us to significantly improve this upper bound.

▶ **Corollary 16.** *The reachability problem for afmp-$\mathbb{Z}$-VASS can be decided in* EXPSPACE.

Proof. Let $\mathcal{V} = (d, Q, T)$ be an afmp-$\mathbb{Z}$-VASS and let $\mathcal{M}$ be defined as above. Set $||\mathcal{M}|| := |\overline{\mathcal{M}}| \cdot d^2 \cdot \max\{\log(||A|| + 1) : A \in \overline{\mathcal{M}}\}$, where $||A||$ is the largest absolute value of all entries of A. Since $||A_1 \cdots A_n|| \le d^n \cdot ||A_1|| \cdots ||A_n||$ for all $A_1, \ldots, A_n \in \mathbb{Z}^{d\times d}$ and $n \in \mathbb{N}$, by Theorem 1 and Corollary 2 we have

$$||\mathcal{M}|| \le |T|^{2^{O(d^2\cdot\log d)}} \cdot d^2 \cdot 2^{d(2d+3)} g(d)^{d+1} \cdot (\log d + ||T||) \le ||T||^{2^{O(d^2\cdot\log d)}},$$

where $||T|| := \sum_{(q,A,\vec{b},r)\in T} d^2 \cdot \lceil \log ||A|| + \log ||\vec{b}|| + 1 \rceil$. It can be deduced from the proof of [5, Thm. 7] that reachability in $\mathcal{V}$ can be decided in non-deterministic space that is polynomially bounded in the encoding of $\mathcal{V}$ and poly-logarithmically in $||\mathcal{M}||$, from which the desired exponential space upper bound follows. ◀

5 Conclusion

The main result of this paper has been to show that any element in the finite multiplicative semigroup $\overline{\mathcal{M}}$ generated by a finite set $\mathcal{M}$ of m rational $n \times n$ matrices can be obtained as a product of generators of length at most $2^{O(n^2 \log n)}$. This length bound immediately gives that $|\overline{\mathcal{M}}|$ is bounded by $m^{2^{O(n^2 \log n)}}$.

There remain two immediate questions that we did not answer in this article. The first is whether the order of growth of $|\overline{\mathcal{M}}|$ we obtained is tight. If $\overline{\mathcal{M}}$ is a group its order can be bounded by $2^n n!$ for almost all n, and this bound is attained by the group of signed permutation matrices. In contrast, in the semigroup case $|\overline{\mathcal{M}}|$ also depends on m. We conjecture that our doubly exponential upper bound is not optimal and that it is possible to establish an exponential upper bound of $|\overline{\mathcal{M}}|$ in terms of m and n. The second open question concerns the precise complexity of deciding finiteness of matrix semigroups. We have been unable to establish any non-trivial lower bounds on this problem and conjecture that our coNEXP$^{\text{NP}}$ upper bound can significantly be improved, possibly by adapting techniques of Babai et al. [2].

Abstract

We consider the rational subset membership problem for Baumslag-Solitar groups. These groups form a prominent class in the area of algorithmic group theory, and they were recently identified as an obstacle for understanding the rational subsets of $\mathrm{GL}(2,\mathbb{Q})$.

We show that rational subset membership for Baumslag-Solitar groups $\mathrm{BS}(1,q)$ with $q \geq 2$ is decidable and PSPACE-complete. To this end, we introduce a word representation of the elements of $\mathrm{BS}(1,q)$: their pointed expansion (PE), an annotated q-ary expansion. Seeing subsets of $\mathrm{BS}(1,q)$ as word languages, this leads to a natural notion of PE-regular subsets of $\mathrm{BS}(1,q)$: these are the subsets of $\mathrm{BS}(1,q)$ whose sets of PE are regular languages. Our proof shows that every rational subset of $\mathrm{BS}(1,q)$ is PE-regular.

Since the class of PE-regular subsets of $\mathrm{BS}(1,q)$ is well-equipped with closure properties, we obtain further applications of these results. Our results imply that (i) emptiness of Boolean combinations of rational subsets is decidable, (ii) membership to each fixed rational subset of $\mathrm{BS}(1,q)$ is decidable in logarithmic space, and (iii) it is decidable whether a given rational subset is recognizable. In particular, it is decidable whether a given finitely generated subgroup of $\mathrm{BS}(1,q)$ has finite index.

Acknowledgements The research for this work was carried out in part at the Autobóz Research Camp in 2019 in Firbush, Scotland. The authors are very grateful to Piotr Hofman for comments that led to important insights and to Michael Blondin as well as to all other participants for discussions.

1 Introduction

Subsets of groups. Regular languages are an extremely versatile tool in algorithmics on sets of finite words. This is mainly due to two reasons. First, they are robust in terms of representations and closure properties: They can be described by finite automata, by recognizing morphisms, and by monadic second-order logic and they are closed under Boolean and an abundance of other operations. Second, many properties (such as emptiness) are easily decidable using finite automata.

Given this success, there have been several attempts to develop an analogous notion for subsets of (infinite, finitely generated) groups. Adapting the notion of recognizing morphism yields *recognizable subsets* of a group G. They are closed under Boolean operations, and problems such as membership or emptiness are decidable. However, since they are merely unions of cosets of finite-index normal subgroups, their expressiveness is severely limited.

Another notion is that of *rational subsets*, which transfer (non-deterministic) finite automata to groups. Starting with pioneering work by Benois [6] in 1969, they have matured into an important tool in group theory. Rational subsets are quite expressive: They include finitely generated submonoids and are closed under (finite) union, pointwise product, and Kleene star. Moreover, they have been applied successfully to solving equations in groups [11, 9], as well as in other settings [2, 34].

The high expressiveness of rational subsets comes at the cost of undecidability of decision problems for many groups. The most fundamental one is the *membership problem* for rational subsets: Given a rational subset R of a group G and an element $g \in G$, does g belong to R? Understanding for which groups this problem is decidable received significant attention over the last two decades, see [24] for a survey. Unfortunately, the rational subsets do not quite reach the level of robustness of regular languages. In general, the class of rational subsets of a group is not closed under Boolean operations, and the papers [25, 4] study for which groups the rational subsets form a Boolean algebra.

Baumslag-Solitar groups. A prominent class of groups is that of *Baumslag-Solitar groups* $\mathrm{BS}(p,q)$. For each $p, q \in \mathbb{N}$, the group is defined as $\mathrm{BS}(p,q) = \langle a, t \mid ta^pt^{-1} = a^q\rangle$. They were introduced in 1962 by Baumslag and Solitar to provide an example of a two-generator one-relator group that is non-Hopfian. They recently came into focus from the algorithmic perspective in a paper by Kharlampovich, López, and Miasnikov [22], which shows that solvability of equations is decidable in $\mathrm{BS}(1,q)$. They have also been studied from several other perspectives, such as the decidability and complexity of the word problem [28, 14, 35], the conjugacy problem [14, 35], tiling problems [1], and computing normal forms [13, 18, 17].

More specifically to our setting, the Baumslag-Solitar groups have recently been identified by Diekert, Potapov, and Semukhin [15] as a stumbling block in solving rational subset membership in the group $\mathrm{GL}(2,\mathbb{Q})$, that is, the group of invertible 2×2 matrices over $\mathbb{Q}$. They show that any subgroup of $\mathrm{GL}(2,\mathbb{Q})$ containing $\mathrm{GL}(2,\mathbb{Z})$ is either of the form $\mathrm{GL}(2,\mathbb{Z}) \times \mathbb{Z}^k$ for $k \geq 1$ or contains $\mathrm{BS}(1,q)$ as a subgroup for some $q \geq 2$. Rational subset membership for $\mathrm{GL}(2,\mathbb{Z}) \times \mathbb{Z}^k$ is today a matter of standard arguments [24], because $\mathrm{GL}(2,\mathbb{Z})$ is virtually free. Therefore, making significant progress towards decidability in larger subgroups requires understanding rational subsets of $\mathrm{BS}(1,q)$.

One can represent the elements of $\mathrm{BS}(1,q)$ as pairs (r,m), where r is a number in $\mathbb{Z}[\frac{1}{q}]$, say $r = \pm\sum_{i=-n}^{n} a_iq^i$ for $a_{-n}, a_{-n+1}, \ldots, a_n \in \{0,\ldots,q-1\}$,[1] and $m \in \mathbb{Z}$. Here, one can think of m as a *cursor* pointing to a position in the q-ary expansion $a_nq^n + \cdots + a_{-n}q^{-n}$. Then the action of the generators of $\mathrm{BS}(1,q)$ is as follows. Multiplication by t or t^{-1} moves the cursor to the left or the right, respectively. Multiplication by a adds q^m; likewise, multiplication by a^{-1} subtracts q^m. Thus, from an automata-theoretic perspective, one can view the rational subset membership problem as the reachability problem for an extended version of one-counter automata. Instead of storing a natural number, such an automaton stores a number $r \in \mathbb{Z}[\frac{1}{q}]$. Moreover, instead of instructions "increment by 1" and "decrement

[1] $\mathbb{Z}[\frac{1}{q}]$ denotes (the additive group of) the smallest subring of $(\mathbb{Q},+,\cdot)$ containing $\mathbb{Z}$ and $1/q$; as a set, it consists of all rational numbers of the form $n \cdot q^j$, $n, j \in \mathbb{Z}$.

by 1”, it has an additional $\mathbb{Z}$-counter m that determines the value to be added in the next update. Then, performing “increment” on r will add q^m and “decrement” on r will subtract q^m. The $\mathbb{Z}$-counter m supports the classical “increment” and “decrement” instructions.

Contribution. Our *first main contribution* is to show is that for each group $\mathrm{BS}(1, q)$, the rational subset membership problem is decidable and PSPACE-complete. To this end, we show that each rational subset can be represented by a regular language of finite words that encode elements of $\mathrm{BS}(1, q)$ in the natural way: For (r, m) as above, we encode each digit a_i by a letter; and we decorate the digits at position 0 and at position m. We call this encoding the *pointed expansion* (PE) of (r, m). This leads to a natural notion of subsets of $\mathrm{BS}(1, q)$, which we call *PE-regular*. We regard the introduction of this notion as the *second main contribution* of this work.

The class of PE-regular subsets of $\mathrm{BS}(1, q)$ has several properties that make them a promising tool for decision procedures for $\mathrm{BS}(1, q)$: First, our proof shows that it effectively includes the large class of rational subsets, in particular any finitely generated submonoid. Second, they form an effective Boolean algebra. Third, due to them being regular languages of words, they inherit many algorithmic tools from the setting of free monoids. We apply these properties to obtain *three applications of our main results.*

1. Membership in each fixed rational subset can be decided in logarithmic space.
2. We show that it is decidable whether a given PE-regular subset (and thus a given rational subset) is recognizable. Recognizability of rational subsets is rarely known to be decidable for groups: The only examples known to the authors are free groups, for which decidability was shown by Sénizergues [31] (and simplified by Silva [33]) and free abelian groups (this follows from [19, Theorem 3.1]). Since (i) finitely generated subgroups are rational subsets and (ii) a subgroup of any group G is recognizable if and only if it has finite index in G, our result implies that it is decidable whether a given finitely generated subgroup of $\mathrm{BS}(1, q)$ has finite index. Studying decidability of this finite index problem in groups was recently proposed by Kapovich [12, Section 4.3].
3. Our results imply that emptiness of Boolean combinations (hence inclusion, equality, etc.) of rational subsets is decidable. (We also show that the rational subsets of $\mathrm{BS}(1, q)$ are not closed under intersection.) This is a strong decidability property that already fails for groups as simple as $F_2 \times \mathbb{Z}$ (this follows from [20, Theorem 6.3]), where F_2 is the free group over two generators, and hence for $\mathrm{GL}(2, \mathbb{Z}) \times \mathbb{Z}^k$, $k \geq 1$.

Finally, we remark that since $\mathrm{BS}(1, q)$ is isomorphic to the group of all matrices $\left(\begin{smallmatrix} q^m & r \\ 0 & 1 \end{smallmatrix}\right)$ for $m \in \mathbb{Z}$ and $r \in \mathbb{Z}[\frac{1}{q}]$, our results can be interpreted as solving the rational subset membership problem for this subgroup of $\mathrm{GL}(2, \mathbb{Q})$.

Related work. It is well-known that membership in a given finitely generated subgroup, called the *generalized word problem* of $\mathrm{BS}(1, q)$, is decidable. This is due to a general result of Romanovskiĭ, who showed in [29] and [30] that solvable groups of derived length two have a decidable generalized word problem (it is an easy exercise to show that $\mathrm{BS}(1, q)$ is solvable of derived length two for each $q \in \mathbb{N}$).

Another restricted version of rational subset membership is the *knapsack problem*, which was introduced by Myasnikov, Nikolaev, and Ushakov [27]. Here, one is given group elements $g_1, \ldots, g_k, g$ and is asked whether there exist $x_1, \ldots, x_k \in \mathbb{N}$ with $g_1^{x_1} \cdots g_k^{x_k} = g$. A recent paper on the knapsack problem in Baumslag-Solitar groups by Dudkin and Treyer [16] left open whether the knapsack problem is decidable in $\mathrm{BS}(1, q)$ for $q \geq 2$. This was settled very recently in [26], where one expresses solvability of $g_1^{x_1} \cdots g_k^{x_k} = g$ in a variant of Büchi arithmetic. A slight extension of that proof yields a regular language as above for the set $S = \{g_1^{x_1} \cdots g_k^{x_k} \mid x_1, \ldots, x_k \in \mathbb{N}\}$. Note that each element g_i moves the cursor either to the left (i.e. increases m), to the right (i.e. decreases m), or not at all. Thus, in a product $g_1^{x_1} \cdots g_k^{x_k}$, the cursor direction is reversed at most $k-1$ times. The challenge of our translation from rational subsets to PE-regular subsets is to capture products where the cursor changes direction an unbounded number of times.

Finally, closely related to rational subsets, there is another approach to group-theoretic problems via automata: One can represent finitely generated subgroups of free groups using *Stallings graphs*. Due to the special setting of free groups, they behave in many ways similar to automata over words and are thus useful for decision procedures [21]. Stallings graphs have recently been extended to semidirect products of free groups and free abelian groups by Delgado [10]. However, this does not include products $\mathbb{Z}[\frac{1}{q}] \rtimes \mathbb{Z}$ and is restricted to subgroups.

2 Basic notions

Automata, rational subsets, and regular languages. Since we work with automata over finite words and over groups, we define automata over a general monoid M. A subset $S \subseteq M$ is *recognizable* if there is a finite monoid F and a morphism $\varphi\colon M \to F$ such that $S = \varphi^{-1}(\varphi(S))$. If M is a group, one can equivalently require F to be a finite group.

For a subset $S \subseteq M$, we write $\langle S \rangle$ or S^* for the submonoid *generated by* S, i.e. the set of elements that can be written as a (possibly empty) product of elements of S. In particular, the neutral element $1 \in M$ always belongs to $\langle S \rangle = S^*$. A *generating set* is a subset $\Sigma \subseteq M$ such that $M = \langle \Sigma \rangle$. We say that M is *finitely generated (f.g.)* if it has a finite generating set. Suppose M is finitely generated and fix a finite generating set Σ. An *automaton over* M is a tuple $\mathcal{A} = (Q, \Sigma, E, q_0, q_f)$, where Q is a finite set of *states*, $E \subseteq Q \times \Sigma \times Q$ is a finite set of *edges*, $q_0 \in Q$ is its *initial state*, and $q_f \in Q$ is its *final state*. A *run (in $\mathcal{A}$)* is a sequence $\rho = (p_0, a_1, p_1) \cdots (p_{m-1}, a_m, p_m)$, where $(p_{i-1}, a_i, p_i) \in E$ for $i \in [1, m]$. It is *accepting* if $p_0 = q_0$ and $p_m = q_f$. By $[\rho]$, we denote the *production* of ρ, that is, the element $a_1 \cdots a_m \in M$. Two runs are *equivalent* if they start in the same state, end in the same state, and have the same production. For a set of runs P, we denote $[P] = \{[\rho] \mid \rho \in P\}$.

The subset *accepted by* $\mathcal{A}$ is $\mathsf{L}(\mathcal{A}) = \{[\rho] \mid \rho \text{ is an accepting run in } \mathcal{A}\}$. A subset $R \subseteq M$ is called *rational* if it is accepted by some automaton over M. It is a standard fact that the family of rational subsets of M does not depend on the chosen generating set Σ. Rational subsets of a free monoid Γ^* for some alphabet Γ are also called *regular languages*. If $M = \Gamma^* \times \Delta^*$ for alphabets Γ, Δ, then rational subsets of M are also called *rational transductions*. If $T \subseteq \Gamma^* \times \Delta^*$ and $L \subseteq \Gamma^*$, then we set $TL = \{v \in \Delta^* \mid \exists u \in L\colon (u, v) \in T\}$. It is well-known that if $L \subseteq \Gamma^*$ is regular and $T \subseteq \Gamma^* \times \Delta^*$ is rational, then TL is regular as well [7].

Baumslag-Solitar groups. The *Baumslag-Solitar groups* are the groups $\mathrm{BS}(p, q)$ for $p, q \in \mathbb{N}$, where $\mathrm{BS}(p, q) = \langle a, t \mid ta^pt^{-1} = a^q \rangle$. They were introduced in 1962 by Baumslag and Solitar [3] to provide an example of a non-Hopfian group with two generators and one defining relation. In this paper, we focus on the case $p = 1$. In this case, there is a well-known isomorphism $\mathrm{BS}(1, q) \cong \mathbb{Z}[\frac{1}{q}] \rtimes \mathbb{Z}$ and we will identify the two groups. Here, $\mathbb{Z}[\frac{1}{q}]$ is the additive group of number nq^i with $n, i \in \mathbb{Z}$, and $\rtimes$ denotes semidirect product. Building this semidirect product requires us to specify an automorphism φ_m of $\mathbb{Z}[\frac{1}{q}]$ for each $m \in \mathbb{Z}$, which is given by $\varphi_m(nq^i) = q^m \cdot nq^i$.

For readers not familiar with semidirect products, we give an alternative self-contained definition of $\mathbb{Z}[\frac{1}{q}] \rtimes \mathbb{Z}$. The elements of this group are pairs (r, m), where $r \in \mathbb{Z}[\frac{1}{q}]$ and $m \in \mathbb{Z}$. The multiplication is defined as

$$(r, m)(r', m') = (r + q^m \cdot r', m + m').$$

We think of an element (r, m) as representing a number r in $\mathbb{Z}[\frac{1}{q}]$ together with a cursor m to a position in the q-ary expansion of r. Multiplying an element (r, m) by the pair $(1, 0)$ from the right means adding 1 at the position in r given by m, hence adding q^m to r and leaving the cursor unchanged: we have $(r, m)(1, 0) = (r + q^m, m)$. Multiplying by $(0, 1)$ moves the cursor one position to the left: $(r, m)(0, 1) = (r, m + 1)$. It is easy to see that $\mathbb{Z}[\frac{1}{q}] \rtimes \mathbb{Z}$ is generated by the set $\{(1, 0), (-1, 0), (0, 1), (0, -1)\}$. The isomorphism $\mathrm{BS}(1, q) \xrightarrow{\sim} \mathbb{Z}[\frac{1}{q}] \rtimes \mathbb{Z}$ mentioned above maps a to $(1, 0)$ and t to $(0, 1)$. Since we identify $\mathrm{BS}(1, q)$ and $\mathbb{Z}[\frac{1}{q}] \rtimes \mathbb{Z}$, we will have $a = (1, 0)$ and $t = (0, 1)$. In particular, a can be thought of as "add"/"increment", and t as "move". We regard elements of the subgroup $\mathbb{Z}[\frac{1}{q}] \times \{0\}$ of $\mathrm{BS}(1, q)$ as elements of $\mathbb{Z}[\frac{1}{q}]$, i.e., integers or rational fractions with denominator q^i, $i \geq 1$.

Rational subset membership. Unless specified otherwise, automata over $\mathrm{BS}(1, q)$ will use the generating set $\Sigma = \{a, a^{-1}, t, t^{-1}\} = \{(1, 0), (-1, 0), (0, 1), (0, -1)\}$. The central decision problem of this work is the *rational subset membership problem for* $\mathrm{BS}(1, q)$:
Given An automaton $\mathcal{A}$ over $\mathrm{BS}(1, q)$ and an element $g \in \mathrm{BS}(1, q)$ as a word over Σ.
Question Does g belong to $\mathsf{L}(\mathcal{A})$?

Automata over $\mathbf{BS(1, q)}$. In the following definitions, let $\mathcal{A} = (Q, \Sigma, E, q_0, q_f)$ be an automaton over $\mathrm{BS}(1, q)$. For a run ρ of $\mathcal{A}$, recall that $[\rho] \in \mathbb{Z}[\frac{1}{q}] \rtimes \mathbb{Z}$ is the *production* of ρ. Moreover, if $[\rho] = (r, m)$ with $r \in \mathbb{Z}[\frac{1}{q}]$ and $m \in \mathbb{Z}$, then we define $\mathsf{pos}(\rho) = m$, and call this the *final position* of ρ. More generally, the *position* at a particular point in ρ is the final position of the corresponding prefix of ρ. By $\mathsf{pmax}(\rho)$, we denote the maximal value of $\mathsf{pos}(\pi)$ where π is a prefix of ρ. Analogously, $\mathsf{pmin}(\rho)$ is the minimal value of $\mathsf{pos}(\pi)$ where π is a prefix of ρ. A run ρ is *returning* if $\mathsf{pos}(\rho) = 0$. It is *returning-left* if in addition $\mathsf{pmin}(\rho) = 0$. Note that for a returning run ρ, we have $[\rho] \in \mathbb{Z}[\frac{1}{q}]$ and if ρ is returning-left, we have $[\rho] \in \mathbb{Z}$. Let $|\rho|$ be the length of the run ρ as a word over E. We will often write ρ_i assuming $\rho = \rho_1\rho_2 \ldots \rho_\ell$ where each $\rho_i \in E$ and $\ell = |\rho|$. A run is a *cycle* if it is returning and starts and ends in the same state. The *thickness* of a run ρ is defined as the greatest number of times a position is seen:

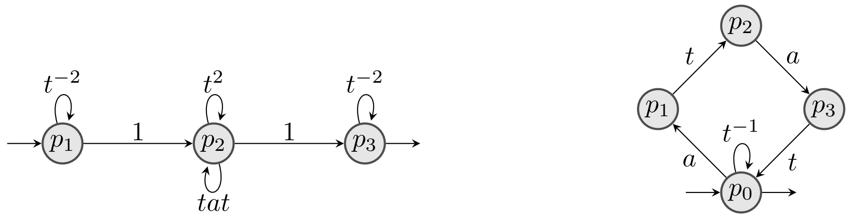
$$\mathsf{thickness}(\rho) = \max_{n \in \mathbb{Z}} |\{i \mid \mathsf{pos}(\rho_1 \cdots \rho_i) = n\}| \ .$$

We call a run *k-thin* if its thickness is at most k.

We let $\mathsf{Runs}(\mathcal{A})$ (resp. $\mathsf{Ret}(\mathcal{A})$, $\mathsf{RetL}(\mathcal{A})$) be the set of all accepting runs (resp. accepting returning runs, accepting returning-left runs) of $\mathcal{A}$. We add k in subscript to restrict the set to k-thin runs; for instance, $\mathsf{Ret}_k(\mathcal{A})$ is the set of k-thin returning runs. Further, we write $\mathsf{Runs}_k^{p \to p'}(\mathcal{A})$ for k-thin runs that start in p and end in p', and use the similar notations $\mathsf{Ret}_k^{p \to p'}(\mathcal{A})$ and $\mathsf{RetL}_k^{p \to p'}(\mathcal{A})$.

Seeing $\{0, \ldots, q-1\}$ as an alphabet, write Φ_q for letters from this alphabet with possibly a $\bullet$ subscript (e.g., $0_\bullet$), a $\triangleleft$ superscript (e.g., $0^\triangleleft$), or both (e.g., $0_\bullet^\triangleleft$). For $v = (r, n) \in \mathrm{BS}(1, q)$, we write $\mathsf{pe}(v)$ for its base-q *pointed expansion* (or just *expansion*) as a word in $\pm\Phi_q^*$, where the subscript $\bullet$ and the superscript $\triangleleft$ appear only once, the former representing the radix point, the latter indicating the value of n. That is, if $r = \sum_{i=-k_2}^{k_1} a_i q^i$, with $k_1, k_2 \geq 0$, $\mathsf{pe}(v)$ is the following word:

$$\pm a_{k_1} \cdots a_1 (a_0)_\bullet a_{-1} \cdots a_{-k_2} \ ,$$



(a) Automaton over $\mathrm{BS}(1,q)$ from Example 3.7.

(b) Automaton over $\mathrm{BS}(1,2)$ from Example 4.1.

Figure 1 Example automata over $\mathrm{BS}(1,q)$.

where $\triangleleft$ is added to a_n. We tacitly assume a uniqueness condition: the expansion $\mathsf{pe}(v)$ of an element $v \in \mathrm{BS}(1,q)$ is the shortest that abides by the definition. Expansions are read by automata in the left to right direction, i.e., from most to least significant digit.

▶ **Definition 2.1.** *We say that a subset of $R \subseteq \mathrm{BS}(1,q)$ is* PE-regular*, where PE stands for pointed expansion, if the word language $\{\mathsf{pe}(v) \mid v \in R\}$ is regular.*

We remark that basic properties of regular languages support the transformation of noncanonical expansions of elements $\mathrm{BS}(1,q)$, i.e., those with zeros on the left or right, into canonical ones, $\mathsf{pe}(v)$. Finally, recall that we identify each $r \in \mathbb{Z}[\frac{1}{q}]$ with $(r,0) \in \mathbb{Z}[\frac{1}{q}] \rtimes \mathbb{Z}$. Hence, for $r \in \mathbb{Z}[\frac{1}{q}]$, $\mathsf{pe}(r)$ is the q-ary expansion of r (with $\triangleleft$ as an additional decoration at the radix point).

3 Main results

Our first main result is that one can translate rational subsets into PE-regular subsets.

▶ **Theorem 3.1.** *Every rational subset of $\mathrm{BS}(1,q)$ is effectively PE-regular.*

This will be shown in Section 4. Since membership is decidable for regular languages and given $g \in \mathrm{BS}(1,q)$ as a word over $\{a, a^{-1}, t, t^{-1}\}$, one can compute $\mathsf{pe}(g)$, Theorem 3.1 implies that rational subset membership is decidable. Our next main result is that the problem is PSPACE-complete.

▶ **Theorem 3.2.** *The rational subset membership problem for $\mathrm{BS}(1,q)$ is* PSPACE*-complete.*

This is shown in Section 5. We shall also conclude that membership to each fixed rational subset is decidable in logspace.

▶ **Theorem 3.3.** *For each fixed rational subset of $\mathrm{BS}(1,q)$, membership is decidable in logarithmic space.*

The proof can also be found in Section 5. Note that, in particular, membership to each fixed subgroup of $\mathrm{BS}(1,q)$ is decidable in logarithmic space. Another application of Theorem 3.1 is that one can decide whether a given rational subset of $\mathrm{BS}(1,q)$ is recognizable.

▶ **Theorem 3.4.** *Given a PE-regular subset R of $\mathrm{BS}(1,q)$, it is decidable whether R is recognizable.*

This is shown in Section 6. Since a subgroup of any group H is recognizable if and only if it has finite index in H (see, e.g. [2, Prop. 3.2]), we obtain:

▶ **Corollary 3.5.** *Given a f.g. subgroup of* $\mathrm{BS}(1,q)$*, it is decidable whether it has finite index.*

We close this section by showing that regular subsets of $\mathrm{BS}(1,q)$ are robust in terms of closure properties.

▶ **Proposition 3.6.** *The PE-regular subsets of* $\mathrm{BS}(1,q)$ *form an effective Boolean algebra. Moreover, for PE-regular subsets* $R, S \subseteq \mathrm{BS}(1,q)$*, the sets* $RS = \{rs \mid r \in R,\ s \in S\}$ *and* $R^{-1} = \{r^{-1} \mid r \in R\}$ *are PE-regular as well.*

The proof is straightforward. Together with Theorem 3.1, this implies that emptiness of Boolean combinations (hence inclusion, equality) is decidable for rational subsets. To further highlight the advantages of PE-regular subsets, we also show that the rational subsets of $\mathrm{BS}(1,q)$ are not closed under intersection.

▶ **Example 3.7** (Intersection of rational subsets)**.** Let R be the set accepted by the automaton in Figure 1a. The automaton first moves an even number of positions to the right (p_1) and then an even number of positions to the left while adding 1 in a subset of the odd positions (p_2). Finally, it goes an even number of positions to the left again. Note that $(r,m) \in R$ if and only if $r = \sum_{i \in A} q^{2i+1}$ for some finite $A \subseteq \mathbb{Z}$ and $m \in 2\mathbb{Z}$. Now consider the rational sets aR and Ra and their intersection $I = aR \cap Ra$. Note that $(r,m) \in aR$ if and only if $r = 1 + \sum_{i \in A} q^{2i+1}$ and $m \in 2\mathbb{Z}$ for some finite $A \subseteq \mathbb{Z}$. Moreover, $(r,m) \in Ra$ if and only if $r = q^m + \sum_{i \in A} q^{2i+1}$ and $m \in 2\mathbb{Z}$ for some finite $A \subseteq \mathbb{Z}$. Therefore, we have $(r,m) \in I$ if and only if $r = 1 + \sum_{i \in A} q^{2i+1}$ and $m = 0$ for some finite $A \subseteq \mathbb{Z}$. Since I only contains elements with cursor 0, but carries non-zero digits in positions that are arbitrarily far to the right, it follows that I is not rational.

However, the PE-regular subsets of $\mathrm{BS}(1,q)$ are not closed under iteration.

▶ **Example 3.8** (Iteration of PE-regular subsets)**.** The subset $A = \{(1 + 2^{-i}, 0) \mid i \geq 1\}$ of $\mathrm{BS}(1,2)$ is PE-regular, because $\mathsf{pe}(A) = 1\overset{\triangleleft}{\bullet}0^*1$ is a regular language. However, the set A^* is not PE-regular: one can show that for each $n \geq 1$, we have $n = \min\{m \in \mathbb{N} \mid (m + 2^{-1} + \cdots + 2^{-n}, 0) \in A^*\}$.[2] Therefore, for each $n \geq 1$, a word in $\mathsf{pe}(A^*)$ with 1^n to the right of the radix point can have an integer part of n and cannot have a smaller integer part. This implies that $\mathsf{pe}(A^*)$ is not regular.

4 Every rational subset of BS(1, q) is effectively PE-regular

In this section, we prove Theorem 3.1. We first illustrate our approach on an example.

▶ **Example 4.1.** Consider the automaton over $\mathrm{BS}(1,2)$ in Figure 1b. In its only initial and final state p_0, it has a choice of two operations: (i) move the cursor one position to the right (i.e. multiplication by t^{-1}) or (ii) perform the increment on two neighbouring cells and stop one position left of them (i.e. multiplication by $atat$). The automaton can perform these operations arbitrarily many times in any order.

We shall prove that the automaton accepts

$$R = \{(3n \cdot 2^{m-2k}, m) \mid n \in \mathbb{N},\ k \in \mathbb{N},\ m \in \mathbb{Z},\ 0 \geq m - 2k,\ 3n \cdot 2^{m-2k} \geq f(m,k)\}\ ,$$

where

$$f(m,k) = \sum_{i=1}^{k} 3 \cdot 2^{m-2i} = \sum_{j=m-2k}^{m-1} 2^j = 2^m - 2^{m-2k}\ .$$

[2] We denote $\mathbb{N} = \{0, 1, 2, \ldots\}$.

The language $\mathsf{pe}(R)$ is regular. Indeed, note that the number $f(m,k)$ has a particularly simple binary representation. A pointed expansion of (r,m) belongs to $\mathsf{pe}(R)$ if there is a position $m-2k \le 0$ such that reading the digits left of position $m-2k$ yields a number (namely $3n$) that (a) is divisible by 3 and (b) lies above a bound with a simple binary expansion.

Let us now prove that the automaton accepts R. Let ρ be an accepting run producing (r,m). Choose $k \in \mathbb{N}$ so that $\mathsf{pmin}(\rho) = m-2k$ or $\mathsf{pmin}(\rho) = m-2k+1$ (depending on whether $m - \mathsf{pmin}(\rho)$ is even or odd). Then $0 \ge \mathsf{pmin}(\rho) \ge m-2k$. Each time operation (ii) is performed from position $\ell \in \mathbb{Z}$, the update is $(r,m) \to (r + 3 \cdot 2^{\ell}, m+2)$.

Now, once ρ visits position $\mathsf{pmin}(\rho)$, in order to eventually reach a position $\ell > \mathsf{pmin}(\rho)$, the operation (ii) must be performed on some position $\ge \ell - 2$. In particular, to reach position m, it must be performed at some position $m_1 \ge m-2$. If $m_1 > \mathsf{pmin}(\rho)$, to reach m_1, it must also be performed at some position $m_2 \ge m-4$, etc. Therefore, ρ has to perform (ii) at positions $m_i \ge m-2i$ for each i with $m > m-2i \ge \mathsf{pmin}(\rho)-1$. In other words, it has to do this for each $i = 1, \ldots, k$. Each time ρ performs (ii) at m_i, it adds $3 \cdot 2^{m_i}$. Moreover, each extra time ρ performs (ii), it adds a multiple of $3 \cdot 2^{m-2k}$, because $\mathsf{pmin}(\rho) \ge m-2k$. Thus, the number produced in total is some $3n \cdot 2^{m-2k}$ where

$$3n \cdot 2^{m-2k} \ge \sum_{i=1}^{k} 3 \cdot 2^{m_i} \ge \sum_{i=1}^{k} 3 \cdot 2^{m-2i} = f(m,k) \ .$$

Conversely, suppose $n \in \mathbb{N}$ and $k \in \mathbb{N}$, $m \in \mathbb{Z}$, $0 \ge m-2k$, and $3n \cdot 2^{m-2k} \ge f(m,k)$. The automaton first moves to position $m-2k$ using operation (i). Then, it performs operations (ii), (i), and (i) again, ℓ times in a loop (we specify ℓ later). That way, it adds $3\ell \cdot 2^{m-2k}$. Then, it moves to position m by applying operation (ii) exactly k times. Hence, it applies (ii) at positions $m-2i$ for $i = 1, \ldots, k$ and each time, it adds $3 \cdot 2^{m-2i}$. In total, the effect is

$$3\ell \cdot 2^{m-2k} + \sum_{i=1}^{k} 3 \cdot 2^{m-2i} = 3\ell \cdot 2^{m-2k} + f(m,k) \ .$$

Since $3n \cdot 2^{m-2k} \ge f(m,k)$ and $f(m,k)$ is an integer multiple of $3 \cdot 2^{m-2k}$, we can choose $\ell \in \mathbb{N}$ so as to produce $3n \cdot 2^{m-2k}$.

Following this example, we first show that any run has the same production as a thin (i.e. bounded thickness) run in which thin returning-left cycles are inserted (p. 9); in the example, such a cycle applies operations (ii), (i), and (i). We then prove that the productions of thin runs form a PE-regular set (p. 10); in the example, the thin run moves to the right to position $\mathsf{pmin}(\rho)$ using operation (i) and then left to $m \ge \mathsf{pmin}(\rho)$ using operations (i) and (ii). Finally, we show that iterating returning-left thin cycles also leads to a PE-regular set (p. 11); in the example, this is how we get all numbers divisible by 3 above a particular bound. We combine these three statements to prove Theorem 3.1.

In combining the thin run with cycles, we will need to ensure that the cycles are anchored on the correct state. To this end, we introduce an annotated version of $\mathsf{pe}([\rho])$ as follows. Let $\mathcal{A}$ be an automaton over $\mathrm{BS}(1,q)$ with state set Q. Let ρ be a run in $\mathcal{A}$ starting and ending in arbitrary states and with $[\rho] = (r,m)$. Letting $\bar{Q} = \{\bar{p} \mid p \in Q\}$ be a copy of Q, we define $\mathsf{sv}(\rho)$, the *state view* of ρ, to be the word over the alphabet $\Phi_q \cup Q \cup \bar{Q} \cup \{\pm\}$ built as follows. First, write: $\mathsf{pe}([\rho]) = \pm a_{k_1} \cdots a_1 a_0 a_{-1} \cdots a_{-k_2}$,where a_0 has subscript $\bullet$. Second, let $P_i \in (Q \cup \bar{Q})^{|Q|}$, for $i \in \{-k_2, \ldots, k_1\}$, be a word that contains all the states of Q once in a fixed ordering of Q, either with a bar or not; the states without a bar are exactly those that visit position i in ρ. That is, p appears in P_i iff there is a prefix of ρ ending in p whose final position is i. The state view of ρ is then:

$$\mathsf{sv}(\rho) = \pm a_{k_1} \cdot P_{k_1} \cdots a_0 \cdot P_0 \cdot a_{-1} \cdot P_{-1} \cdots a_{-k_2} \cdot P_{-k_2} \enspace .$$

We naturally extend sv to sets of runs.

Any run is equivalent to a thin run augmented with thin returning-left cycles. We now focus on two properties of runs: the states they visit in the automaton and the final position of their prefixes. To that end, we introduce the following notions. For Q a finite set, a *position path* is a word $\pi \in (Q \times \mathbb{Z})^*$. We extend the analogy with graphs calling elements of $Q \times \mathbb{Z}$ *vertices*, talking of the vertices *visited* by a position path, and using the notion of (position) *subpaths* and *cycles*. The *thickness* of a position path π is defined as:

$$\mathsf{thickness}(\pi) = \max_{n \in \mathbb{Z}} |\{i \mid \pi_i = (q, n) \text{ for some } q\}| \enspace .$$

▶ **Lemma 4.2.** *Let Q be a finite set and $\pi \in (Q \times \mathbb{Z})^*$ be a position path. For any subset V' of the vertices visited by π, there exists a subpath π' of π such that:*

1. *π' starts and ends with the same vertices as π,*
2. *π' visits all the vertices in V',*
3. $\mathsf{thickness}(\pi') \leq |Q| \cdot (1 + 2|V'|)$,
4. *$\pi - \pi'$ consists only of cycles.*

Proof (sketch). We first consider a shortest subpath π' of π from the initial to the final vertices of π – this implies that π' has thickness at most $|Q|$. We then treat each missing vertex from V' in turn, and add to π' a subpath from π that is a cycle and includes that vertex. Each of these iterations can augment the thickness of π' by at most $2|Q|$. ◀

▶ **Corollary 4.3.** *Let $\mathcal{A}$ be an automaton over $\mathrm{BS}(1, q)$ with state set Q, and let $k = |Q| + 2|Q|^2$. Any run of $\mathcal{A}$ is equivalent to a run in $\mathsf{Runs}_k(\mathcal{A})$ on which, for each state p appearing in the run, cycles from $\mathsf{RetL}_k^{p \to p}(\mathcal{A})$ are inserted at an occurrence of p with smallest position.*

Conversely, any run built by taking a run in $\mathsf{Runs}_k(\mathcal{A})$ and inserting cycles from $\mathsf{RetL}_k^{p \to p}(\mathcal{A})$ at an occurrence of p is a run of $\mathcal{A}$.

Proof. The converse is clear, we thus focus on the first direction.

(Step 1: Decomposing a run into a thin run and cycles.) Let $\rho \in \mathsf{Runs}(\mathcal{A})$, and extract from it a position path $\pi = \pi_0 \cdots \pi_{|\rho|}$ as follows. We let, $\pi_0 = (q_0, 0)$ and for all $i \geq 1$:

$$\pi_i = (p, n) \text{ where } \rho_i = (\cdot, \cdot, p) \text{ and } n = \mathsf{pos}(\rho_1 \cdots \rho_i) \enspace .$$

For each state p visited by ρ, let $n_p = \min\{n \mid \text{there exists } i \text{ such that } \pi_i = (p, n)\}$; in words, n_p is the smallest final position of a prefix of ρ ending in p. Using $V' = \{(p, n_p) \mid \rho \text{ visits } p\}$, Lemma 4.2 provides a position path π' of thickness $\leq k = |Q| + 2|Q|^2$ visiting all of V'.

From π', we can obtain the corresponding subpath ρ' of ρ that has the same starting and ending state and positions as ρ, and such that ρ is made of ρ' onto which cycles are added. The thickness of ρ' is bounded by k, but the cycles can be of any thickness.

(Step 2: Thinning the cycles.) Consider a cycle β that gets added to ρ' to form ρ, say at position i (after initial i moves, $\rho'_1 \cdots \rho'_i$), and assume that $\mathsf{thickness}(\beta) > k$. Since a position is repeated more than $k > |Q|$ times, there is a cycle β' *within* β with $\mathsf{thickness}(\beta') \leq k$;

write then $\beta = \alpha \cdot \beta' \cdot \alpha'$. Let p be the state in β' that has the smallest position, that is, p is the ending state of the prefix γ of β' with final position $\mathsf{pmin}(\beta')$; write $\beta' = \gamma \cdot \gamma'$. By definition, we have $\mathsf{pos}(\rho'_1 \cdots \rho'_i \alpha\gamma) \geq n_p$. Note that $\gamma' \cdot \gamma$ is in $\mathsf{RetL}_k^{p\to p}(\mathcal{A})$. We now remove β' from β and then insert $\gamma' \cdot \gamma$ at the position j in ρ' that is such that $\rho'_1 \cdots \rho'_j$ ends in p with final position n_p. For the contribution of $\gamma' \cdot \gamma$ to be the same as that of β' in the original path, we insert it q^d times, where $d = \mathsf{pos}(\rho'_1 \cdots \rho'_i \alpha\gamma) - n_p$.

This shows that if any cycle added to ρ' is of thickness $> k$, then a subcycle of it can be moved to another position of ρ' as a returning-left cycle. Iterating this process, all the cycles added to ρ' will thus be of thickness $\leq k$. Moreover, if an added cycle β is not returning-left after these operations, or if it does not sit at an occurrence of its initial state with *smallest* position, this means that we can decompose it just as above as $\gamma \cdot \gamma'$, with γ reaching $\mathsf{pmin}(\beta)$, and move $\gamma' \cdot \gamma$, a returning-left cycle, to an appropriate position in ρ' as before. ◀

Intermezzo: reflecting on Corollary 4.3. Before we continue with the proof, we want to illustrate how crucial the previous corollary is. Lemma 4.2 tells us that we can obtain every run from a thin run by then adding cycles. This already simplifies the structure of $\mathsf{Runs}(\mathcal{A})$: indeed, inserting cycles at a certain position in a run $\rho \in \mathsf{Runs}(\mathcal{A})$ corresponds (in algebraic terms) to adding to $[\rho]$ a subset of $\mathbb{Z}[\frac{1}{q}]$ closed under addition, i.e., a submonoid. (Closure under addition follows from the observation that any two returning cycles from each $\mathsf{Ret}_k^{p\to p}(\mathcal{A})$ can be concatenated.)

Sometimes one can conclude that every submonoid of a monoid has a simple structure. For example, every submonoid M of $\mathbb{Z}$ is semilinear and hence a PE-regular subset of $\mathbb{Z}[\frac{1}{q}]$. Unfortunately, the situation in $\mathbb{Z}[\frac{1}{q}]$ is not as simple as in $\mathbb{Z}$: One can show that $\mathbb{Z}[\frac{1}{q}]$ has uncountably many submonoids. Thus, $\mathbb{Z}[\frac{1}{q}]$ has submonoids with undecidable membership problem; moreover, there is no hope for a finite description for every submonoid as in $\mathbb{Z}$. Thus, we need to look at our specific submonoids. A simple observation similar to Lemma 4.2 allows us to obtain every run from a thin part by adding *thin* cycles. Hence, the submonoids that we add are of the form $[\mathsf{Ret}_k^{p\to p}(\mathcal{A})]^*$. It is not hard to show (see Lemma 4.4) that $[\mathsf{Ret}_k^{p\to p}(\mathcal{A})]$ is always a PE-regular set. Thus, one may hope to prove that the regularity of $[\mathsf{Ret}_k^{p\to p}(\mathcal{A})]$ implies regularity of $[\mathsf{Ret}_k^{p\to p}(\mathcal{A})]^*$. (This was an approach to rational subset membership proposed by the third author of this work in [12, Section 4.7].) However, Example 3.8 tells us that even for PE-regular $R \subseteq \mathrm{BS}(1,q)$, the set R^* may not be PE-regular.

Therefore, Corollary 4.3 is the key insight of our proof. It says that a run can be decomposed into a thin part and thin *returning-left* cycles. Since returning-left cycles produce integers, this will lead us to submonoids of $\mathbb{Z}$.

Sets of thin runs are PE-regular.

▶ **Lemma 4.4.** *Let $\mathcal{A}$ be an automaton over* $\mathrm{BS}(1,q)$*, p, p' be states of $\mathcal{A}$, and $k > 0$. The sets* $\mathsf{sv}(\mathsf{Runs}_k^{p\to p'}(\mathcal{A})), \mathsf{sv}(\mathsf{Ret}_k^{p\to p'}(\mathcal{A}))$*, and* $\mathsf{sv}(\mathsf{RetL}_k^{p\to p'}(\mathcal{A}))$ *are effectively regular.*

Proof (sketch). We see $\mathcal{A}$ as a two-way automaton, and apply a construction similar to the classical proof that two-way automata are no more expressive than one-way automata [32]. This transforms $\mathcal{A}$ into a one-way automaton over the alphabet $\{-1, 0, 1\}^k$, where each component tracks a 1-thin partial run. It is a classical exercise to show that automata can compute the addition of numbers in a given base; this can be extended to *signed-digit* expansions, in which negative digits can be used [8, Section 2.2.2.2]. We thus rely on this to compute the sum, componentwise, of these partial runs. Adding state information to that construction is straightforward, so that we obtain automata for state views. ◀

Iterations of returning-left thin cycles are PE-regular. It is well-known that for every set $S \subseteq \mathbb{N}$ the generated monoid $S^* = \{s_1 + \cdots + s_m \mid s_1, \ldots, s_m \in S, m \geq 0\}$ is eventually identical with $\gcd(S) \cdot \mathbb{N}$. In other words, the set $(\gcd(S) \cdot \mathbb{N}) \setminus S^*$ is finite and we may define $F(S) = \max((\gcd(S) \cdot \mathbb{N}) \setminus S^*)$. The number $F(S)$ is called the *Frobenius number* of S. With this, we have $S^* = \{n \in S^* \mid n \leq F(S)\} \cup \{n \in \gcd(S) \cdot \mathbb{N} \mid n > F(S)\}$. If $S \subseteq -\mathbb{N}$, then we set $F(S) := F(-S)$. Now consider an arbitrary set $S \subseteq \mathbb{Z}$. If S contains both a positive and a negative number, then $S^* = \gcd(S) \cdot \mathbb{Z}$ and we set $F(S) := 0$. We shall use the following well-known fact [36].

▶ **Lemma 4.5.** *If $S = \{n_1, \ldots, n_k\}$ with $0 < n_1 < \cdots < n_k$, then $F(S) \leq n_k^2$.*

▶ **Lemma 4.6.** *For every automaton $\mathcal{A}$ over $\mathrm{BS}(1, q)$, the language $\mathsf{pe}([\mathsf{RetL}_k^{p \to p}(\mathcal{A})]^*)$ is effectively regular.*

Proof. Recall that we identify each $r \in \mathbb{Z}[\frac{1}{q}]$ with $(r, 0) \in \mathbb{Z}[\frac{1}{q}]$. In particular, for $n \in \mathbb{Z}$, $\mathsf{pe}(n)$ is the same as $\mathsf{pe}((n, 0))$.

Denote $S = [\mathsf{RetL}_k^{p \to p}(\mathcal{A})]$. We first consider the case $S \subseteq \mathbb{N}$ and $S \neq \emptyset$. Suppose we can compute $\gcd(S)$ and a bound $B \in \mathbb{N}$ with $B \geq F(S)$. Then we have

$$S^* = \underbrace{\{n \in S^* \mid n \leq B\}}_{=:X} \cup \underbrace{\{n \in \gcd(S) \cdot \mathbb{N} \mid n > B\}}_{=:Y} \tag{1}$$

and it suffices to show that $\mathsf{pe}(X)$ and $\mathsf{pe}(Y)$ are effectively regular. Note that X is finite and can be computed by finding all $n \leq B$ with $n \in S$ (recall that membership in S is decidable because $\mathsf{sv}(\mathsf{RetL}_k^{p \to p}(\mathcal{A}))$ is effectively regular by Lemma 4.4) and building sums. Moreover, $\mathsf{pe}(Y)$ is regular because the set $L_0 = \mathsf{pe}(\gcd(S) \cdot \mathbb{N})$ is effectively regular and so is $L_1 = \{\mathsf{pe}(n) \mid n \in \mathbb{N},\ n > B\}$, and hence $\mathsf{pe}(Y) = L_0 \cap L_1$.

Thus, it remains to compute $\gcd(S)$ and some $B \geq F(S)$. For the former, find any $r \in S$ and consider its decomposition $r = p_1^{e_1} \cdots p_m^{e_m}$ into prime powers. For each $i \in [1, m]$, we compute $d_i \in [0, e_i]$ and $n_i \in S$ such that (i) $S \subseteq p_i^{d_i} \cdot \mathbb{N}$, and (ii) $n_i \in S \setminus p_i^{d_i+1} \cdot \mathbb{N}$. Since for $d \in \mathbb{N}$, we can construct an automaton for $\mathsf{pe}(S \cap d \cdot \mathbb{N})$, these d_i and n_i can be computed. Observe that $\gcd(S) = p_1^{d_1} \cdots p_m^{d_m}$. Let $T = \{r, n_1, \ldots, n_k\}$. Observe that $\gcd(T) = \gcd(S)$, and hence T^* and S^* are ultimately identical. Since $T \subseteq S$, this means $F(S) \leq F(T)$. By Lemma 4.5, we have $F(T) \leq (\max\{r, n_1, \ldots, n_k\})^2$, which yields our bound B.

The case $S \subseteq -\mathbb{N}$ is analogous to $S \subseteq \mathbb{N}$. If S contains a positive and a negative number, then $S^* = \gcd(S) \cdot \mathbb{Z}$, so it suffices to just compute $\gcd(S)$. This is done as above. Finally, deciding between these three cases is easy. This completes the proof. ◀

Wrapping up: Proof of Theorem 3.1. Let $\mathcal{A}$ be an automaton over $\mathrm{BS}(1, q)$ with state set Q. Corollary 4.3 indicates that the set of productions of accepting runs is the same as the set of productions of k-thin runs in which thin cycles are introduced.

By Lemma 4.4, $\mathsf{sv}(\mathsf{Runs}_k(\mathcal{A}))$ is a regular language L. For any state p of $\mathcal{A}$, let $L_p = \mathsf{pe}\big([\mathsf{RetL}_k^{p \to p}(\mathcal{A})]^*\big)$, a regular language by Lemma 4.6. For padding purposes, let $s \in Q$ be some state, and let h be the morphism from $(\Phi_q \cup \{\pm\})^*$ to $(\Phi_q \cup Q \cup \{\pm\})^*$ defined, for any $a \in \Phi_q$, by $h(a) = as^{|Q|}$, and $h(+) = +$, $h(-) = -$. Define now L'_p to be the image by h of the version of L_p where arbitrary 0's are added after the sign, and at the end of the number (these 0's do not change the value represented).

Consider now the language R over the alphabet $(\Phi_q \cup Q \cup \bar{Q} \cup \{\pm\})^{|Q|+1}$ whose projection on the first component is the language L, and the other components correspond to the languages L'_p, for each $p \in Q$. The first component indicates in particular the states of $\mathcal{A}$

that visited that location; to synchronize the different components of R, we ensure that the letter annotated with $\bullet$ in L'_p is aligned with a letter from L that is followed by p – that is, the starting position of L'_p is at a position in L that is seen while being in the state p.

Finally, an automaton can do the componentwise addition in base q, collapsing the $|Q|+1$ components into a single one. The radix point is given by the digit with $\bullet$ of L, i.e., in the first component; and similarly for $\lhd$. The resulting language, thanks to Corollary 4.3, is the language of the pointed expansions of all runs in $\mathsf{Runs}(\mathcal{A})$. ◀

5 Complexity

Computing pointed expansions. In this section, we prove Theorems 3.2 and 3.3. For the upper bounds in Theorems 3.2 and 3.3, we shall rely on the fact that, given an element $g \in \mathbb{Z}[\frac{1}{q}] \rtimes \mathbb{Z}$ as a word over $\Sigma = \{a, a^{-1}, t, t^{-1}\}$, one can compute the pointed expansion $\mathsf{pe}(g)$ in logarithmic space. This is a direct consequence of a result of Elder, Elston, and Ostheimer [18, Proposition 32]. They show that given a word w over Σ, one can compute in logarithmic space an equivalent word of one of the forms (i) t^i, (ii) $(a^{\eta_0})^{t^{\alpha_0}}(a^{\eta_1})^{t^{\alpha_1}}\cdots(a^{\eta_k})^{t^{\alpha_k}}t^i$ or (iii) $(a^{-\eta_0})^{t^{\alpha_0}}(a^{-\eta_1})^{t^{\alpha_1}}\cdots(a^{-\eta_k})^{t^{\alpha_k}}t^i$, where $i \in \mathbb{Z}$, $k \in \mathbb{N}$, $0 < \eta_j < q$ for $j \in [0,k]$, and $\alpha_0 > \cdots > \alpha_k$. Here, x^y stands for $y^{-1}xy$ in the group. Since these normal forms denote the elements (i) $(0,i)$, (ii) $(\sum_{j=0}^{k}\eta_j q^{-\alpha_j}, i)$ and (iii) $(-\sum_{j=0}^{k}\eta_j q^{-\alpha_j}, i)$, respectively, it is easy to turn these normal forms into $\mathsf{pe}(w)$ using logarithmic space.

This allows us to prove Theorem 3.3: For every rational subset $R \subseteq \mathrm{BS}(1,q)$, the language $\mathsf{pe}(R)$ is a regular language. In particular, there exists a deterministic automaton $\mathcal{B}$ for $\mathsf{pe}(R)$. Therefore, given $g \in \mathrm{BS}(1,q)$ as a word over $\{a, a^{-1}, t, t^{-1}\}$, we compute $\mathsf{pe}(g)$ in logspace and then check membership of $\mathsf{pe}(g)$ in $\mathsf{L}(\mathcal{B})$, which is decidable in logarithmic space.

PSPACE-completeness. The PSPACE lower bound in Theorem 3.2 is a reduction from the intersection nonemptiness of finite-state automata, a well-known PSPACE-complete problem [23]. For the PSPACE upper bound, we strengthen Theorem 3.1 by constructing a polynomial-size representation of an exponential size automaton for the resulting regular language. A *succinct finite automaton* is a tuple $\mathcal{S} = (n, \Gamma, (\varphi_x)_{x\in\Gamma\cup\{\varepsilon\}}, p_0, p_f\})$, where $n \in \mathbb{N}$ is its *bit length*, Γ is its *input alphabet*, $\varphi_x(\mathsf{v}_1, \ldots, \mathsf{v}_n, \mathsf{v}'_1, \ldots, \mathsf{v}'_n)$ is a formula from propositional logic with free variables $\mathsf{v}_1, \ldots, \mathsf{v}_n, \mathsf{v}'_1, \ldots, \mathsf{v}'_n$ for each $x \in \Gamma \cup \{\varepsilon\}$, $p_0 \in \{0,1\}^n$ is its *initial state*, and $p_f \in \{0,1\}^n$ is its *final state*. The *size* of $\mathcal{S}$ is defined as $|\mathcal{S}| = n + \sum_{x\in\Gamma\cup\{\varepsilon\}} |\varphi_x|$, where $|\varphi|$ denotes the length of the formula φ.

Moreover, $\mathcal{S}$ *represents* the automaton $\mathcal{A}(\mathcal{S})$, which is defined as follows. It has the state set $\{0,1\}^n$, initial state p_0, and final state p_f. For states $p = (b_1, \ldots, b_n), p' = (b'_1, \ldots, b'_n) \in \{0,1\}^n$ and $x \in \Gamma \cup \{\varepsilon\}$, there is an edge (p, x, q) in $\mathcal{A}(\mathcal{S})$ if and only if $\varphi_x(b_1, \ldots, b_n, b'_1, \ldots, b'_n)$ holds. We define the *language accepted by* $\mathcal{S}$ as $\mathsf{L}(\mathcal{S}) = \mathsf{L}(\mathcal{A}(\mathcal{S}))$.

We allow ε-edges in succinct automata, and with Boolean formulas, one can encode steps in a Turing machine. Thus, a succinct automaton of polynomial size can simulate a polynomial space Turing machine with a one-way read-only input tape. Our descriptions of succinct automata will therefore be in the style of polynomial space algorithms. We show:

▶ **Theorem 5.1.** *Given a rational subset* $R \subseteq \mathrm{BS}(1,q)$*, one can construct in polynomial space a polynomial-size succinct automaton accepting* $\mathsf{pe}(R)$*.*

This allows us to decide rational subset membership in PSPACE: Given an automaton $\mathcal{A}$ over $\mathrm{BS}(1,q)$ and an element g as a word over $\{a, a^{-1}, t, t^{-1}\}$, we construct a succinct automaton $\mathcal{B}$ for $\mathsf{pe}(\mathsf{L}(\mathcal{A}))$ and the pointed expansion $\mathsf{pe}(g)$ in logarithmic space. Since membership in succinct automata is well-known to be in PSPACE, we can check whether $\mathsf{pe}(g) \in \mathsf{L}(\mathcal{B})$.

Constructing succinct automata. It remains to prove Theorem 5.1. The construction of a succinct automaton for $\mathsf{pe}(R)$ proceeds with the same steps as in Section 4. For most of these steps, our constructions already yield small succinct automata (e.g., one for $\mathsf{pe}([\mathsf{RetL}_k^{p\to p'}(\mathcal{A})])$ in Lemma 4.4). The exception is Lemma 4.6 – in which case the key ingredient is as follows.

▶ **Proposition 5.2.** *Given an automaton $\mathcal{A}$ over $\mathrm{BS}(1,q)$, a state p of $\mathcal{A}$, and $k \in \mathbb{N}$ in unary, one can compute in polynomial space the number $\gcd([\mathsf{RetL}_k^{p\to p}(\mathcal{A})])$ and a bound $B \geq F([\mathsf{RetL}_k^{p\to p}(\mathcal{A})])$. Both are at most exponential in k and the size of $\mathcal{A}$.*

Our bound on F extends the bound for automatic sets in $\mathbb{N}$ [5, Lemma 4.5] to thin two-way computations. Before proving Proposition 5.2, let us show how it implies Theorem 5.1.

Proof of Theorem 5.1. The constructions in Lemma 4.4 and Theorem 3.1, immediately yield a polynomial-size succinct automaton for $\mathsf{pe}(R)$ once a succinct automaton for each $\mathsf{pe}([\mathsf{RetL}_k^{p\to p}(\mathcal{A})]^*)$ is found. For the latter, we proceed as in Lemma 4.6. Let $S = [\mathsf{RetL}_k^{p\to p}(\mathcal{A})]$ and compute $\gcd(S)$ and a bound $B \geq F(S)$ using Proposition 5.2. Then, by Equation (1) on page 11, it suffices to construct a succinct automaton for $\mathsf{pe}(X)$ and one for $\mathsf{pe}(Y)$. For $\mathsf{pe}(X)$, we use the fact that we can construct a succinct automaton $\mathcal{B}$ for $\mathsf{pe}(S)$. Our automaton for $\mathsf{pe}(X)$ proceeds as follows. With ε-transitions, it runs $\mathcal{B}$ to successively guess numbers $\leq B$ from S and stores each of them temporarily in its state. Such a number requires $O(\log(B))$ bits. In another $O(\log(B))$ bits, it stores the sum of the numbers guessed so far. This continues as long as the sum is at most B. Then, our automaton reads the resulting sum from the input. This automaton clearly accepts $\mathsf{pe}(X)$.

For $\mathsf{pe}(Y)$, we have to construct a succinct automaton that accepts any number $> B$ that is divisible by $\gcd(S)$. Since $\gcd(S)$ is available as a number with polynomially many digits, we can construct a succinct automaton accepting $\mathsf{pe}(\gcd(S)\cdot\mathbb{N})$: It keeps the remainder modulo $\gcd(S)$ of the currently read prefix. This requires $O(\log(\gcd(S))$ many bits. Since B also has polynomially many digits, we can construct a succinct automaton for $\{n \in \mathbb{N} \mid n > B\}$. An automaton for the intersection then accepts $\mathsf{pe}(Y)$. ◀

It is easy to see that the number produced by a returning-left run is at most exponential in the length of the run. The exact bound will not be important.

▶ **Lemma 5.3.** *If ρ is a run in $\mathsf{RetL}_k(\mathcal{A})$ of length ℓ, then $|[\rho]| \leq q^{2\ell}$.*

The main ingredient for Proposition 5.2 will be Lemma 5.4. We write $\rho \ll \rho'$ if $|\rho| < |\rho'|$. Moreover, for $d \in \mathbb{Z}$, we write $\rho \ll_d \rho'$ if $\rho \ll \rho'$ and for some $\ell \in \mathbb{Z}$, we have $[\rho'] = \ell \cdot [\rho] + d$.

▶ **Lemma 5.4.** *There is a polynomial f such that the following holds. Let $\mathcal{A}$ be an n-state automaton over $\mathrm{BS}(1,q)$ and let p, p' be two states of $\mathcal{A}$. Let $\rho_{11} \in \mathsf{RetL}_k^{p\to p'}(\mathcal{A})$ with $|\rho_{11}| > f(n,k)$. There exist runs $\rho_{00}, \rho_{10}, \rho_{01} \in \mathsf{RetL}_k^{p\to p'}(\mathcal{A})$ and $d \in \mathbb{Z}$ so that:*

$$\begin{tikzcd}
\rho_{01} \arrow[r, phantom, "\ll_d"] \arrow[d, phantom, "\rotatebox{90}{$\ll$}"] & \rho_{11} \arrow[d, phantom, "\rotatebox{90}{$\ll$}"] \\
\rho_{00} \arrow[r, phantom, "\ll_d"] & \rho_{10}
\end{tikzcd} \tag{2}$$

Here, one shows that a long run can be shortened independently in two ways: Going left in the diagram (2), and going down. Shortening the run by "going left" changes the production of the run by the same difference, up to a factor ℓ that may differ in the two rows. Lemma 5.5 applies Lemma 5.4 to construct small numbers in $[\mathsf{RetL}_k(\mathcal{A})]$ that are not divisible by a given m. Later, these numbers allow us to compute $\gcd([\mathsf{RetL}_k^{p\to p}(\mathcal{A})])$ and bound $F([\mathsf{RetL}_k^{p\to p}(\mathcal{A})])$.

▶ **Lemma 5.5.** *There is a polynomial f such that the following holds. Let $m \in \mathbb{Z}$. Let $\mathcal{A}$ be an n-state automaton over $\mathrm{BS}(1,q)$ and let p, p' be two states of $\mathcal{A}$. Suppose there is a number in $[\mathsf{RetL}_k^{p\to p'}(\mathcal{A})]$ not divisible by m; then there is also an $s \in [\mathsf{RetL}_k^{p\to p'}(\mathcal{A})]$ not divisible by m such that $|s| \le q^{f(n,k)}$.*

Proof. Let f be the polynomial from Lemma 5.4. Let $\rho \in \mathsf{RetL}_k^{p\to p'}(\mathcal{A})$ be of minimal length such that m does not divide $[\rho]$. Suppose $|\rho| > f(n,k)$. Write $\rho_{11} = \rho$ and apply Lemma 5.4. By minimality of ρ_{11}, we get $[\rho_{00}] \equiv [\rho_{10}] \equiv [\rho_{01}] \equiv 0 \bmod m$. In particular, $\rho_{00} \ll_d \rho_{10}$ implies $d \equiv 0 \bmod m$. However, since $\rho_{01} \ll_d \rho_{11}$ and $[\rho_{11}] \not\equiv 0 \bmod m$, we get $d \not\equiv 0 \bmod m$, a contradiction. Hence, $|\rho| \le f(n,k)$ and thus $|[\rho]| \le q^{2f(n,k)}$ by Lemma 5.3. ◀

With Lemma 5.5 in hand, one can show Proposition 5.2 similarly to Lemma 4.6.

6 Recognizability

In this section, we prove Theorem 3.4. We first present a characterization of recognizability that is easily checkable for PE-regular subsets. It is well-known that a subset S of $\mathbb{Z}$ is recognizable if and only if there is a $k \in \mathbb{Z} \setminus \{0\}$ such that for every $s \in \mathbb{Z}$, we have $s \in S$ if and only if $s + k \in S$. Our characterization is an analog for Baumslag-Solitar groups.

A subset $S \subseteq \mathbb{Z}[\frac{1}{q}] \rtimes \mathbb{Z}$ is called *k-periodic* if for every $s \in \mathbb{Z}[\frac{1}{q}] \rtimes \mathbb{Z}$, we have (i) $s \in S$ if and only if $s(0,k) \in S$ and (ii) for every $\ell \in \mathbb{Z}$, we have $s \in S$ if and only if $s(q^\ell - q^{\ell+k}, 0) \in S$. In other words, membership in S is insensitive to (i) moving the cursor k positions and (ii) replacing a power of q by another power of q whose exponent differs by k. The set S is *periodic* if it is k-periodic for some $k \ge 1$. We show the following:

▶ **Proposition 6.1.** *A subset $S \subseteq \mathbb{Z}[\frac{1}{q}] \rtimes \mathbb{Z}$ is recognizable if and only if S is periodic.*

The fact that recognizable sets are periodic is an easy exercise. For the converse, we show that the subgroup H of $G = \mathbb{Z}[\frac{1}{q}] \rtimes \mathbb{Z}$ generated by $(0,k)$ and all $(q^\ell - q^{\ell+k}, 0)$ for $\ell \in \mathbb{Z}$ is normal and the quotient G/H is finite. Then, S is recognized by the projection $G \to G/H$.

To decide whether a PE-regular $R \subseteq \mathrm{BS}(1,q)$ is recognizable, we show effective regularity of the set $N \subseteq \{\mathtt{a}\}^*$ of all words $\mathtt{a}^k$ such that R is *not* k-periodic. Then, we just have to check whether N contains all words $\mathtt{a}^k$ with $k \ge 1$, which is clearly decidable. Since R is PE-regular, the set $D = R(G \setminus R)^{-1} \cup (G \setminus R)R^{-1}$ is effectively PE-regular (Proposition 3.6). Then R is not k-periodic if and only if $(0,k) \in D$ or $(q^\ell - q^{\ell+k}, 0) \in D$ for some $\ell \in \mathbb{Z}$. The element $(0,k)$ has the pointed expansion $0^{\triangleleft}0^{k-1}0_{\bullet}$. The pointed expansions of $(q^\ell - q^{\ell+k}, 0)$ for $\ell \in \mathbb{Z}$ are exactly those words obtained from words $-0^r(q-1)^{k-1}0^s$ for $r, s \in \mathbb{N}$ by decorating one of the digits with $^{\triangleleft}$ and with $_{\bullet}$, and removing leading or trailing 0's. Therefore, it is easy to see that $T_1 = \{(0^{\triangleleft}0^{k-1}0_{\bullet}, \mathtt{a}^k) \mid k \ge 1\}$ and $T_2 = \{(\mathsf{pe}((q^\ell - q^{\ell+k}, 0)), \mathtt{a}^k) \mid \ell \in \mathbb{Z},\ k \ge 1\}$ are rational transductions. This implies that $N = T_1(\mathsf{pe}(D)) \cup T_2(\mathsf{pe}(D)) \subseteq \mathtt{a}^*$ is effectively regular. Then clearly, R is not k-periodic if and only if $\mathtt{a}^k \in N$.

Abstract

We study the expressive power of *polynomial recursive sequences*, a nonlinear extension of the well-known class of linear recursive sequences. These sequences arise naturally in the study of nonlinear extensions of weighted automata, where (non)expressiveness results translate to class separations. A typical example of a polynomial recursive sequence is $b_n = n!$. Our main result is that the sequence $u_n = n^n$ is not polynomial recursive.

Acknowledgements We thank Maria Donten-Bury for suggesting the proof of Theorem 11 presented here. This proof replaced our previous more elaborate and less transparent argument. We also thank James Worrell, David Purser and Markus Whiteland for helpful comments. The research for this work was carried out in part at the Autobóz Research Camp in 2019 in Firbush, Scotland. Finally, we thank the participants of the automata seminar at the University of Warsaw for an insightful discussion on the class of rational recursive sequences (considered in Section 7).

1 Introduction

Sequences defined recursively arise naturally in many areas, particularly in mathematics and computer science. One of the most studied classes is that of *linear recursive sequences*. Such sequences are defined by fixing the values of the first k elements, while every subsequent

element can be obtained as a linear combination of the k elements preceding it. The most famous example is the Fibonacci sequence, defined by setting $f_0 = 0$, $f_1 = 1$, and the recurrence relation $f_{n+2} = f_{n+1} + f_n$.

It is well known that every linear recursive sequence can be defined by a system of k jointly recursive sequences, where for every sequence we fix the initial value and provide a recurrence relation expressing the $(n+1)$st element as a linear combination of the nth elements of all the sequences [15]. For example, to define the Fibonacci sequence f_n in this way, one needs one auxiliary sequence: we set $f_0 = 0$, $g_0 = 1$, and postulate

$$\begin{cases} f_{n+1} = g_n, \\ g_{n+1} = f_n + g_n. \end{cases} \tag{1}$$

In this paper we study *polynomial recursive sequences* over rational numbers that generalise linear recursive sequences. They are defined by systems of sequences like (1), but on the right hand side we allow arbitrary polynomial expressions, rather than just linear combinations. For example, the sequence $b_n = n!$ can be defined in this way using one auxiliary sequence: we may set $b_0 = c_0 = 1$ and write

$$\begin{cases} b_{n+1} = b_n \cdot c_n, \\ c_{n+1} = c_n + 1. \end{cases} \tag{2}$$

Thus, the recurrence relation uses two polynomials: $P_1(x_1, x_2) = x_1 x_2$ and $P_2(x_1, x_2) = x_2 + 1$.

The two classes of linear and polynomial recursive sequences appear naturally in automata theory, and in particular in connection with weighted automata and higher-order pushdown automata. *Weighted automata* over the rational semiring are a quantitative variant of finite automata that assign rational numbers to words [10]. In the special case of a 1-letter alphabet, each word can be identified with its length. Then a weighted automaton defines a mapping from natural numbers (possible lengths) to rationals, and this can be seen as a sequence. It is known that sequences definable in this way by weighted automata are exactly the linear recursive sequences [6]. *Pushdown automata of order k* can be used for defining mappings from words to words [21]; in particular, for $k = 2$ and 1-letter alphabets, such automata compute exactly the linear recursive sequences of natural integers [11].

Thus, nonlinear extensions of linear recursive sequences may correspond to nonlinear extensions of weighted automata. For the latter, consider three examples:

- *polynomial recurrent relations* that generalise pushdown automata of order 3 [12, 21];
- *cost-register automata* which arose as a variant of streaming transducers [3, 4];
- *polynomial automata*, connected to reachability problems for vector addition systems [7].

Surprisingly, these three models, although introduced in different contexts, are all equivalent.[1] Moreover, over unary alphabets they define exactly polynomial recursive sequences, in the same fashion as weighted automata (respectively order 2 pushdown automata) over unary alphabets define linear recursive sequences.

The goal of this paper is to study the expressive power of polynomial recursive sequences. Clearly, this expressive power extends that of linear recursive sequences: it is easy to see that every linear recursive sequence has growth bounded by $2^{\mathcal{O}(n)}$, while already the sequence $b_n = n!$ grows faster. In fact, already the recurrence relation $a_0 = 2$, $a_{n+1} = (a_n)^2$ defines

[1] This is a simple but technical observation as the three models are essentially syntactically equivalent. Throughout the paper we will use the name *cost-register automata* to refer to all three models.

the sequence 2^{2^n}, whose growth is doubly-exponential. However, there are well-known integer sequences related to these examples for which definability as a polynomial recursive sequence seems much less clear. The first example is the sequence $u_n = n^n$. The second example is the sequence of Catalan numbers $C_n = \frac{1}{n+1}\binom{2n}{n}$. Note that by Stirling's approximation, n^n is asymptotically very close to $n!$, while C_n is, up to factors polynomial in n, roughly equal to 4^n. For these reasons, simple asymptotic considerations cannot prove the sequences $u_n = n^n$ and C_n to be not polynomial recursive. Recall that the Catalan numbers admit multiple combinatorial interpretations, which can be used to derive the recurrence formulas $C_{n+1} = \sum_{i=0}^{n} C_i C_{n-i}$ and $(n+2)C_{n+1} = (4n+2)C_n$. Note that these formulas are *not* of the form of recurrence formulas considered in this work. Additionally, it is known that Catalan numbers C_n are *not* linear recursive (see e.g. [8]), despite having growth $2^{\mathcal{O}(n)}$.

Our results. We show that both the sequence of Catalan numbers C_n and the sequence $u_n = n^n$ are not polynomial recursive. For this, we present two techniques for proving that a sequence is *not* polynomial recursive. The first technique for Catalan numbers is number-theoretical: we show that a polynomial recursive sequence of integers is ultimately periodic modulo any large enough prime. The second technique for n^n is more algebraic in nature: we show that for every polynomial recursive sequence there exists $k \in \mathbb{N}$ such that every k consecutive elements of the sequence satisfy a nontrivial polynomial equation. The fact that $u_n = n^n$ is not polynomial recursive is our main result. These inexpressibility results were announced without proofs by the fifth coauthor in an invited talk in 2007 [21]. The present paper contains proofs and extensions of these results.

Applications. The discussed models of cost-register automata [12, 4, 7] are not the only nonlinear extensions of weighted automata that appear in the literature. We are aware of at least two more extensions: weighted context-free grammars [5, 8] and weighted MSO logic [9, 17]. As it happens, over the 1-letter alphabet, weighted context-free grammars can define Catalan numbers, and weighted MSO logic can define n^n. Therefore, as a corollary of our results we show that functions expressible in pushdown-automata of level 4, weighted context-free grammars and weighted MSO logic are not always expressible in the class of cost-register automata.

The class of holonomic sequences is another extension of linear recursive sequences [16]. These sequences are defined recursively with one sequence, but the coefficients in the recursion are polynomials of the element's index. For example, $b_n = 1$ and $b_{n+1} = (n+1)b_n$ defines $b_n = n!$. The expressiveness of this class has also been studied and in particular the sequence n^n is known to be not in the class of holonomic sequences [14]. As a corollary of our results one can show that there are no inclusions between the classes of holonomic sequences and polynomial recursive sequences. On the one hand every holonomic sequence is asymptotically bounded by $2^{p(n)}$ for some polynomial p [16], and the sequence $a_n = 2^{2^n}$ is polynomial recursive. On the other hand, Catalan numbers admit a definition as a holonomic sequence: $C_0 = 1$ and $(n+2)C_{n+1} = (4n+2)C_n$. In Section 7 we discuss the class of *rational recurrence sequences* that generalises both holonomic and polynomial recursive sequences.

Organisation. In Section 2 we give basic definitions and examples of linear and polynomial recursive sequences. In Section 3 we show that the definition of polynomial recursive sequences requires a system of sequences and, unlike linear recursive sequences, cannot be equivalently defined using only one sequence. Then in Sections 4 and 5 we show that the sequence of Catalan numbers C_n and the sequence $u_n = n^n$ are not polynomial recursive. In Section 6 we explain in details our corollaries for weighted automata. We conclude in Section 7.

2 Preliminaries

By $\mathbb{N}$ we denote the set of nonnegative integers. A *sequence* over a set $\mathbb{D}$ is a function $u\colon \mathbb{N} \to \mathbb{D}$; all the sequences considered in this work are over the field of rationals $\mathbb{Q}$. We use the notation $\langle u_n \rangle_{n\in\mathbb{N}}$ for elements of sequences, where $u_n = u(n)$. Also, we use bold-face letters as a short-hand for sequences, e.g., $\mathbf{u} = \langle u_n \rangle_{n\in\mathbb{N}}$.

We now introduce the two main formalisms for describing sequences: linear recursive sequences and polynomial recursive sequences.

Linear recursive sequences. A *k-variate linear form* (or *linear form* if k is irrelevant) over $\mathbb{Q}$ is a function $L\colon \mathbb{Q}^k \to \mathbb{Q}$ of the form

$$L(x_1, \dots, x_k) = a_1x_1 + \dots + a_kx_k$$

for some $a_1, \dots, a_k \in \mathbb{Q}$. A sequence of rationals $\mathbf{u}$ is a *linear recursive sequence* if there exist $k \in \mathbb{N}$ and a k-variate linear form L such that $\mathbf{u}$ satisfies the recurrence relation

$$u_{n+k} = L(u_n, \dots, u_{n+k-1}) \qquad \text{for all } n \in \mathbb{N}. \tag{3}$$

Observe that such a sequence is uniquely determined by the form L and its first k elements: $u_0, \dots, u_{k-1} \in \mathbb{Q}$. The minimal k for which a description of $\mathbf{u}$ as in (3) can be given is called the *order* of $\mathbf{u}$. For example, Fibonacci numbers are uniquely defined by the recurrence relation $f_{n+2} = f_{n+1} + f_n$ and starting elements $f_0 = 0$, $f_1 = 1$. Note that this recurrence relation corresponds to the linear form $L(x_1, x_2) = x_1 + x_2$.

We now present a second definition of linear recursive sequences which, as we will explain, is equivalent to the first definition. Suppose $\mathbf{u}^1, \mathbf{u}^2, \dots, \mathbf{u}^k$ are sequences of rationals. We say that these sequences *satisfy a system of linear recurrence equations* if there are k-variate linear forms $L_1, \dots, L_k$ such that:

$$\begin{cases} u^1_{n+1} = L_1(u^1_n, \dots, u^k_n), \\ \vdots \\ u^k_{n+1} = L_k(u^1_n, \dots, u^k_n). \end{cases} \tag{4}$$

for all $n \in \mathbb{N}$. Note that such a system can be equivalently rewritten in the matrix form

$$\vec{u}_{n+1} = M\vec{u}_n$$

where $\vec{u}_n = (u^1_n, \dots, u^k_n)^\mathsf{T}$ and M is the $k \times k$ matrix over $\mathbb{Q}$ such that $M\vec{x} = (L_1(\vec{x}), \dots, L_k(\vec{x}))^\mathsf{T}$ for all $\vec{x} \in \mathbb{Q}^k$. Note that then $\vec{u}_n = M^n\vec{u}_0$ for all $n \in \mathbb{N}$.

It is well known that systems of linear recurrence equations can be equivalently used to define linear recursive sequences, as explained in the following result.

▶ **Proposition 1** ([15]). *A sequence $\mathbf{u}$ is a linear recursive sequence if and only if there exists $k \in \mathbb{N}$ and sequences $\mathbf{u}^1, \dots, \mathbf{u}^k$ that satisfy a system of linear recurrence equations, where $\mathbf{u}^1 = \mathbf{u}$. Moreover, the smallest k for which this holds is the order of $\mathbf{u}$.*

To get more accustomed with this equivalent definition, let us consider the sequence $a_n = n^2$. Since $(n+1)^2 = n^2 + 2n + 1$, we consider two auxiliary sequences $b_n = n$ and $c_n = 1$. The initial values of these sequences are $a_0 = b_0 = 0$ and $c_0 = 1$. Thus, a_n can be defined by providing these initial values together with a system of linear equations

$$\begin{cases} a_{n+1} = a_n + 2b_n + c_n, \\ b_{n+1} = b_n + c_n, \\ c_{n+1} = c_n. \end{cases} \tag{5}$$

In the matrix form, we could equivalently write that $(a_n, b_n, c_n)^\intercal = M^n\vec{e}$, where

$$M = \begin{pmatrix} 1 & 2 & 1 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{pmatrix}, \; \vec{e} = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}.$$

It can be readily verified that a_n is also defined by the recurrence $a_{n+3} = 3a_{n+2} - 3a_{n+1} + a_n$.

The difference between the two definitions is that in (3) we have only one sequence, but the depth of the recursion can be any k. Conversely, in (4) we are allowed to have k sequences, but the depth of recursion is 1. The equivalence provided by Proposition 1 is quite convenient and is often used in the literature, see e.g. [20].

We give a short proof of Proposition 1, different from the proof in [15]. The reason is that this proof provides us with intuition that will turn out to be useful later on.

Proof of Proposition 1. For the left-to-right implication, suppose $\mathbf{u}$ is a linear recursive sequence of order k; say it is defined by the recursive formula $u_{n+k} = L(u_n, \ldots, u_{n+k-1})$, where L is a k-variate linear form. Define the sequences $\mathbf{u}^1, \ldots, \mathbf{u}^k$ by setting

$$u^i_n := u_{n+i-1} \qquad \text{for all } i \in \{1, \ldots, k\} \text{ and } n \in \mathbb{N}.$$

Then $\mathbf{u}^1 = \mathbf{u}$ and the sequences $\mathbf{u}^1, \ldots, \mathbf{u}^k$ satisfy the system of equations as in (4), where $L_k = L$ and $L_i(x_1, \ldots, x_k) = x_{i+1}$ for $i \in \{1, \ldots, k-1\}$.

For the right-to-left implication, suppose that there exist $k \in \mathbb{N}$ and sequences $\mathbf{u}^1, \ldots, \mathbf{u}^k$ that satisfy the system of equations (4) for some linear forms $L_1, \ldots, L_k$, such that $\mathbf{u} = \mathbf{u}^1$. Let M be a $k \times k$ matrix over $\mathbb{Q}$ that encodes the linear forms $L_1, \ldots, L_k$; that is, $\vec{u}_n = M^n\vec{u}_0$, where $\vec{u}_n = (u^1_n, \ldots, u^k_n)^\intercal \in \mathbb{Q}^k$. Consider the linear map $R\colon \mathbb{Q}^k \to \mathbb{Q}^{k+1}$ defined as

$$R(\vec{x}) = (\ \vec{e}M^0\vec{x}\,,\ \vec{e}M^1\vec{x}\,,\ \ldots\ ,\ \vec{e}M^k\vec{x}\ )^\intercal,$$

where $\vec{e} = (1, 0, \ldots, 0) \in \mathbb{Q}^k$. Note that

$$R(\vec{u}_n) = (u^1_n, u^1_{n+1}, \ldots, u^1_{n+k}) = (u_n, u_{n+1}, \ldots, u_{n+k}) \qquad \text{for all } n \in \mathbb{N}. \tag{6}$$

Observe that R is a linear map from $\mathbb{Q}^k$ to $\mathbb{Q}^{k+1}$, hence the image of R is a linear subspace of $\mathbb{Q}^{k+1}$ of co-dimension at least 1. Hence, there exists a nonzero linear form $K\colon \mathbb{Q}^{k+1} \to \mathbb{Q}$ such that $\operatorname{im} R \subseteq \ker K$, or equivalently $K(R(\vec{x})) = 0$ for all $\vec{x} \in \mathbb{Q}^k$. By (6), we have

$$K(u_n, u_{n+1}, \ldots, u_{n+k}) = 0 \qquad \text{for all } n \in \mathbb{N}. \tag{7}$$

Let $a_0, a_1, \ldots, a_k \in \mathbb{Q}$ be such that

$$K(x_0, \ldots, x_k) = a_0x_0 + \ldots + a_kx_k.$$

Since K is nonzero there exists the largest index t such that $a_t \neq 0$. From (7) we infer that

$$u_{n+t} = -\frac{a_{t-1}}{a_t} \cdot u_{n+t-1} - \frac{a_{t-2}}{a_t} \cdot u_{n+t-2} - \ldots - \frac{a_0}{a_t} \cdot u_n \qquad \text{for all } n \in \mathbb{N},$$

so $\mathbf{u}$ is a linear recursive sequence of order at most t. ◀

▶ Remark 2. One could imagine setting up all the definitions presented above using *affine forms* instead of linear forms, that is, functions $A\colon \mathbb{Q}^k \to \mathbb{Q}$ of the form

$$A(x_1, \ldots, x_k) = a_1x_1 + \ldots + a_kx_2 + c,$$

where $a_1, \ldots, a_k, c \in \mathbb{Q}$. However, as we may always add constant sequences to the system of recurrence equations defining a sequence, considering affine forms does not increase the expressive power. In fact, from Proposition 1 it can be easily derived that we obtain exactly the same class of linear recursive sequences, regardless of whether we use linear or affine forms in both definitions.

Poly-recursive sequences. We now generalise the concept of linear recursive sequences by allowing polynomial functions instead of only linear forms. The starting point of the generalisation is the definition via a system of recurrence equations, as in (4).

▶ **Definition 3.** *A sequence of rationals* $\mathbf{u}$ *is* polynomial recursive *(or* poly-recursive *for short) if there exist* $k \in \mathbb{N}$*, sequences of rationals* $\mathbf{u}^1, \ldots, \mathbf{u}^k$ *satisfying* $\mathbf{u} = \mathbf{u}^1$*, and polynomials* $P_1, \ldots, P_k \in \mathbb{Q}[x_1, \ldots, x_k]$ *such that for all* $n \in \mathbb{N}$*, we have*

$$\begin{cases} u^1_{n+1} = P_1(u^1_n, \ldots, u^k_n), \\ \vdots \\ u^k_{n+1} = P_k(u^1_n, \ldots, u^k_n). \end{cases} \tag{8}$$

Again, notice that polynomials $P_1, \ldots, P_k$ and the initial values $u^1_0, \ldots u^k_0$ uniquely determine the sequences $\mathbf{u}^1, \ldots, \mathbf{u}^k$, hence in particular the sequence $\mathbf{u} = \mathbf{u}^1$.

Let us examine a few examples. First, recall the sequences $a_n = 2^{2^n}$ and $b_n = n!$ defined in Section 1. Another example is the sequence $d_n = 2^{n^2}$. Since $2^{(n+1)^2} = 2^{n^2+2n+1}$, we define $d_0 = e_0 = 1$ and let

$$\begin{cases} d_{n+1} = d_n \cdot (e_n)^2 \cdot 2, \\ e_{n+1} = e_n \cdot 2. \end{cases}$$

The polynomials used in the last definition are $P_1(x_1, x_2) = 2x_1(x_2)^2$ and $P_2(x_1, x_2) = 2x_2$. Notice that this idea can be easily generalised to define any sequence of the form $r^{Q(n)}$, where r is a rational number and Q is a polynomial with rational coefficients. We remark that all three sequences $a_n = 2^{2^n}$, $b_n = n!$, $d_n = 2^{n^2}$ are not linear recursive for simple asymptotic reasons (from the discussion in Section 1).

3 Simple poly-recursive sequences

The following notion is a natural generalisation of the definition (3) of linear recursive sequences to the setting of recurrences defined using polynomials.

▶ **Definition 4.** *A sequence of rationals* $\mathbf{u}$ *is* simple poly-recursive *if there exists* $k \in \mathbb{N}$ *and a polynomial* $P \in \mathbb{Q}[x_1, x_2, \ldots, x_k]$ *such that*

$$u_{n+k} = P(u_n, u_{n+1}, \ldots, u_{n+k-1}) \qquad \textit{for all } n \in \mathbb{N}. \tag{9}$$

Again, note that if $\mathbf{u}$ is simple poly-recursive as above, then the polynomial P and the first k values $u_0, \ldots, u_{k-1}$ uniquely determine the sequence $\mathbf{u}$.

Clearly, every linear recursive sequence is a simple poly-recursive sequence. In fact, by Proposition 1 and Remark 2, the two notions would coincide if we required that the polynomial P in the definition above has degree at most 1. On the other hand, observe that the same construction as in the first paragraph of the proof of Proposition 1 shows that every simple poly-recursive sequence is poly-recursive. We now prove that this inclusion is strict.

▶ **Theorem 5.** *The sequence* $b_n = n!$ *is not simple poly-recursive.*

Proof. Towards a contradiction, suppose there is $k \in \mathbb{N}$ and a polynomial $P \in \mathbb{Q}[x_1, \ldots, x_k]$ such that

$$b_{n+k} = P(b_n, b_{n+1}, \ldots, b_{n+k-1}) \qquad \text{for all } n \in \mathbb{N}. \tag{10}$$

Let us write

$$P = Q + A,$$

where $Q, A \in \mathbb{Q}[x_1, \ldots, x_k]$ are such that A is the sum of all the monomials in the expansion of P that have degree at most 1, while Q is the sum of all the remaining monomials in the expansion of P. Thus, A is an affine form, while every monomial in the expansion of Q has total degree at least 2.

Since A is an affine form, there exists a number $c \in \mathbb{N}$ such that

$$|A(q_1, \ldots, q_k)| < c + c \cdot \max_{1 \leqslant i \leqslant k} |q_i| \qquad \text{for all } q_1, \ldots, q_k \in \mathbb{Q}.$$

Thus, for all $n > 2c$ we have

$$|A(b_n, b_{n+1}, \ldots, b_{n+k-1})| \leqslant c + c \cdot (n + k - 1)! < (n + k)! = b_{n+k}. \tag{11}$$

Since by (10) it follows that

$$Q(b_n, b_{n+1}, \ldots, b_{n+k-1}) = b_{n+k} - A(b_n, b_{n+1}, \ldots, b_{n+k-1}),$$

using (11) we may conclude that for all $n > 2c$ the following inequality holds:

$$0 < Q(b_n, b_{n+1}, \ldots, b_{n+k-1}) < 2b_{n+k}. \tag{12}$$

Let m be the product of all denominators of all the coefficients appearing in the expansion of P into a sum of monomials. Note that for all $n > m$, the number $\tilde{b}_n := \frac{b_n}{m} = \frac{n!}{m}$ is an integer. Furthermore, we have that $\tilde{b}_n$ divides $\tilde{b}_{n'}$ for all $n' \geqslant n$. Since every monomial in the expansion of Q has total degree at least 2, we infer that for all $n > m$, we have

$$\left(\tilde{b}_n\right)^2 \mid Q(b_n, b_{n+1}, \ldots, b_{n+k-1}). \tag{13}$$

By combining (13) with the left inequality of (12), we conclude that for all $n > \max(2c, m)$,

$$Q(b_n, b_{n+1}, \ldots, b_{n+k-1}) \geqslant \left(\tilde{b}_n\right)^2.$$

This bound together with the right inequality of (12) implies that

$$\left(\frac{n!}{m}\right)^2 = \left(\tilde{b}_n\right)^2 < 2b_{n+k} = 2 \cdot (n + k)!.$$

This inequality, however, is not true for every sufficiently large n, a contradiction. ◀

4 Modular periodicity

Recall that a sequence of numbers $\mathbf{r}$ is *ultimately periodic* if there exist $N, k \in \mathbb{N}$ such that for all $n \geqslant N$, we have $r_n = r_{n+k}$. In this section we prove the following periodicity property of poly-recursive sequences, which, by means of contradiction, provides a basic technique for proving that a given sequence is not poly-recursive.

▶ **Theorem 6.** *Suppose $\mathbf{u}$ is a poly-recursive sequence of integers. Then there exists $a \in \mathbb{N}$ such that for every prime $p > a$, the sequence $r_n := u_n \bmod p$ is ultimately periodic.*

Proof. Let $\mathbf{u}$ be defined by the system of recursive equations

$$\begin{cases} u^1_{n+1} = P_1(u^1_n, \ldots, u^k_n), \\ \vdots \\ u^k_{n+1} = P_k(u^1_n, \ldots, u^k_n), \end{cases} \tag{14}$$

where $\mathbf{u}^1, \ldots, \mathbf{u}^k$ are sequences such that $\mathbf{u}^1 = \mathbf{u}$ and $P_1, \ldots, P_k \in \mathbb{Q}[x_1, \ldots, x_k]$.

Without loss of generality we may assume that the initial values $u_0^1, \ldots, u_0^k$ are integers. Indeed, this is certainly the case for $u_0^1 = u_0$, while for every $i > 1$, we may rewrite the system so that it uses the sequence $\widetilde{\mathbf{u}}^i = q_i \cdot \mathbf{u}^i$ instead of $\mathbf{u}^i$, where q_i is the denominator of u_0^i. For this, the starting condition for $\widetilde{\mathbf{u}}^i$ can be set as $\widetilde{u}_0^i = q_i \cdot u_0^i$, which is an integer, in all polynomials $P_1, \ldots, P_k$ we may substitute x_i with x_i/q_i, and the polynomial P_i can be replaced with $q_i \cdot P_i$.

Further, without loss of generality we may assume that all the monomials present in the expansions of all the polynomials $P_1, \ldots, P_k$ have the same total degree $d > 1$. Such polynomials are called homogeneous of degree d and they have the property that $P_i(ax_1, \ldots, ax_k) = a^d P_i(x_1, \ldots, x_k)$ for all $a \in \mathbb{Q}$. Indeed, let $d > 1$ be any integer that is not smaller than the degrees of all the polynomials $P_1, \ldots, P_k$. To the system (14) we add a new sequence $\mathbf{u}^{k+1}$, defined by setting

$$u_0^{k+1} = 1 \qquad \text{and} \qquad u_{n+1}^{k+1} = \left(u_n^{k+1}\right)^d \text{ for } n \in \mathbb{N}.$$

Thus $\mathbf{u}^{k+1}$ is constantly equal to 1. Then each monomial $M(x_1, \ldots, x_k)$ appearing in the expansion of any of the polynomials $P_i(x_1, \ldots, x_k)$ can be replaced by the monomial $M(x_1, \ldots, x_k) \cdot x_{k+1}^{d-t} \in \mathbb{Q}[x_1, \ldots, x_k, x_{k+1}]$, where t is the total degree of M. It is straightforward to see that the modified system of recursive equations still defines $\mathbf{u} = \mathbf{u}^1$, while all monomials appearing in all the polynomials used in it have the same degree d.

After establishing these two assumptions, we proceed to the main proof. Let $a \in \mathbb{N}$ be a positive integer such that the polynomials

$$\tilde{P}_i \coloneqq a \cdot P_i$$

all belong to $\mathbb{Z}[x_1, \ldots, x_k]$, that is, have integer coefficients. For instance, one can take a to be product of all the denominators of all the rational coefficients appearing in the polynomials $P_1, \ldots, P_k$. For all $i \in \{1, \ldots, k\}$ and $n \in \mathbb{N}$, let us define

$$\tilde{u}_n^i \coloneqq a^{\frac{d^n-1}{d-1}} \cdot u_n^i.$$

By a straightforward induction we show that the sequences $\tilde{\mathbf{u}}^1, \ldots, \tilde{\mathbf{u}}^k$ satisfy the system of recursive equations

$$\begin{cases} \tilde{u}_{n+1}^1 = \tilde{P}_1(\tilde{u}_n^1, \ldots, \tilde{u}_n^k), \\ \vdots \\ \tilde{u}_{n+1}^k = \tilde{P}_k(\tilde{u}_n^1, \ldots, \tilde{u}_n^k). \end{cases} \tag{15}$$

Indeed, the induction base is trivial and for the induction step recall that all monomials have the same degree d, hence

$$\tilde{P}_i(\tilde{u}_n^1, \ldots, \tilde{u}_n^k) = a \cdot P_i(a^{\frac{d^n-1}{d-1}} \cdot u_n^1, \ldots, a^{\frac{d^n-1}{d-1}} \cdot u_n^k) = a \cdot a^{\frac{d^{n+1}-d}{d-1}} \cdot u_{n+1}^i = a^{\frac{d^{n+1}-1}{d-1}} \cdot u_{n+1}^i = \tilde{u}_{n+1}^i.$$

Observe that since the initial values $\tilde{u}_0^i = u_0^i$ are integers, and the polynomials $\tilde{P}_i$ have integer coefficients, we can infer that all entries of the sequences $\tilde{\mathbf{u}}^1, \ldots, \tilde{\mathbf{u}}^k$ are integers.

We now show that for every prime $p > a$, the sequence $\mathbf{r}$ defined as $r_n = u_n \bmod p$ is ultimately periodic; this will conclude the proof. For every $i \in \{1, \ldots, k\}$ and $n \in \mathbb{N}$, let

$$\tilde{r}_n^i \coloneqq \tilde{u}_n^i \bmod p.$$

By (15) and the fact that the polynomials $\tilde{P}_i$ have integer coefficients, for every $n \in \mathbb{N}$ the vector of entries $(\tilde{r}^1_{n+1}, \ldots, \tilde{r}^k_{n+1})$ is uniquely determined by the vector $(\tilde{r}^1_n, \ldots, \tilde{r}^k_n)$. Since this vector may take only at most p^k different values, it follows that the sequences $\tilde{\mathbf{r}}^1, \ldots, \tilde{\mathbf{r}}^k$ are ultimately periodic.

Now note that for every $n \in \mathbb{N}$, we have

$$a^{\frac{d^n-1}{d-1}} \cdot r_n \equiv a^{\frac{d^n-1}{d-1}} \cdot u_n = \tilde{u}^1_n \equiv \tilde{r}^1_n \mod p.$$

Since $p > a$ and p is a prime, we have that a and p are coprime. Therefore, there exists an integer b such that $ab \equiv 1 \bmod p$. By multiplying the above congruence by $b^{\frac{d^n-1}{d-1}}$, we have

$$r_n \equiv b^{\frac{d^n-1}{d-1}} \cdot \tilde{r}^1_n \mod p. \tag{16}$$

Observe that the sequence $b_n = b^{\frac{d^n-1}{d-1}}$ satisfies the recursive equation $b_{n+1} = b \cdot (b_n)^d$, hence the sequence $(b_n \bmod p)$ is ultimately periodic. Since $\tilde{\mathbf{r}}^1$ is ultimately periodic as well, from (16) we conclude that the sequence $\mathbf{r}$ is ultimately periodic. ◀

We use Theorem 6 to prove that the Catalan numbers are not poly-recursive. Recall that the nth Catalan number C_n is given by the formula $C_n = \frac{1}{n+1}\binom{2n}{n}$.

Alter and Kubota [2] studied the behaviour of the Catalan numbers modulo primes. It is easy to see (and proved in [2]) that for every prime p, the sequence C_n contains infinitely many numbers divisible by p, and infinitely many numbers not divisible by p. Let a *p-block* be a maximal contiguous subsequence of the sequence C_n consisting of entries divisible by p. The p-blocks can be naturally ordered along the sequence C_n, so let L^p_k be the length of the kth p-block. Then Alter and Kubota proved the following.

▶ **Theorem 7** ([2]). *For every prime $p > 3$ and $k \geqslant 1$, we have*

$$L^p_k = \frac{p^{m+1} - 3}{2},$$

where m is the largest integer such that $\left(\frac{p+1}{2}\right)^m$ divides k.

Note that Theorem 7 in particular implies that for every prime $p > 3$, the sequence C_n contains arbitrary long p-blocks. This means that C_n taken modulo p cannot be ultimately periodic. By combining this with Theorem 6, we conclude the following.

▶ **Corollary 8.** *Catalan numbers are not poly-recursive.*

5 Cancelling polynomials

Consider the following definition, which can be seen as a variation of the definition of simple poly-recursive sequences, which we discussed in Section 3.

▶ **Definition 9.** *A sequence of rationals* $\mathbf{u}$ *admits a* cancelling polynomial *if there exist $k \in \mathbb{N}$ and a nonzero polynomial $P \in \mathbb{Q}[x_0, \ldots, x_k]$ such that*

$$P(u_n, u_{n+1}, \ldots, u_{n+k}) = 0 \qquad \textit{for all } n \in \mathbb{N}.$$

▶ Remark 10. A cancelling polynomial P can be always assumed to have integer coefficients, i.e. to belong to $\mathbb{Z}[x_0, \ldots, x_k]$, because one may multiply P by the product of all denominators that occur in its coefficients.

Observe that the notion of a cancelling polynomial extends the definition of simple poly-recursive sequences (Definition 4) in the following sense: a sequence is simple poly-recursive if and only if it admits a cancelling polynomial $P(x_0, \ldots, x_k)$ whose expansion into a sum of monomials involves only one term containing x_k, namely the monomial x_k itself. This particular form of the considered algebraic constraint was vitally used in the proof of Proposition 5, where we showed that the sequence $b_n = n!$ is not simple poly-recursive. In fact, if one drops this restriction, then it is easy to see that the sequence $b_n = n!$ actually admits a cancelling polynomial: for instance $P(x_0, x_1, x_2) = x_0x_2 - (x_1)^2 - x_0x_1$.

We now prove that the above example is not a coincidence.

▶ **Theorem 11.** *Every poly-recursive sequence admits a cancelling polynomial.*

Proof. The proof follows the same basic idea as the proof of Proposition 1 that we gave in Section 2. The difference is that instead of linear maps we work with maps defined by polynomial functions, hence instead of linear independence we shall work with the notion of algebraic independence.

Recall that if $\mathbb{K} \subseteq \mathbb{L}$ is a field extension, then elements $a_1, \ldots, a_k \in \mathbb{L}$ are *algebraically dependent* over $\mathbb{K}$ if there is a nonzero polynomial $P \in \mathbb{K}[x_1, \ldots, x_k]$ such that $P(a_1, \ldots, a_k) = 0$ in $\mathbb{L}$. We will use the following well-known fact; see e.g. [18, Chapter VIII, Theorem 1.1].

▷ Claim 12. If $\mathbb{K}$ is a field and $k \in \mathbb{N}$, then in the field of rational expressions $\mathbb{K}(x_1, \ldots, x_k)$ every $k + 1$ elements are algebraically dependent over $\mathbb{K}$.

We proceed to the proof of the theorem. Let $\mathbf{u}$ be the poly-recursive sequence in question. By definition, for some $k \in \mathbb{N}$ there are sequences $\mathbf{u}^1, \ldots, \mathbf{u}^k$ and polynomials $P_1, \ldots, P_k \in \mathbb{Q}[x_1, \ldots, x_k]$ such that for all $n \in \mathbb{N}$,

$$\begin{cases} u^1_{n+1} = P_1(u^1_n, \ldots, u^k_n), \\ \vdots \\ u^k_{n+1} = P_k(u^1_n, \ldots, u^k_n). \end{cases}$$

We inductively define polynomials $P^{(t)}_1, \ldots, P^{(t)}_k \in \mathbb{Q}[x_1, \ldots, x_k]$ as follows. For $t = 0$, set

$$P^{(0)}_i(x_1, \ldots, x_k) = x_i \qquad \text{for all } i \in \{1, \ldots, k\},$$

and for $t \geqslant 1$, set

$$P^{(t)}_i(x_1, \ldots, x_k) = P_i(P^{(t-1)}_1(x_1, \ldots, x_k), \ldots, P^{(t-1)}_k(x_1, \ldots, x_k)) \quad \text{for all } i \in \{1, \ldots, k\}.$$

The following claim follows from the construction by a straightforward induction.

▷ Claim 13. For all $n, t \in \mathbb{N}$ and $i \in \{1, \ldots, k\}$, we have $P^{(t)}_i(u^1_n, \ldots, u^k_n) = u^i_{n+t}$.

Consider the polynomials

$$P^{(0)}_1, P^{(1)}_1, \ldots, P^{(k)}_1 \in \mathbb{Q}[x_1, \ldots, x_k].$$

By Claim 12, these polynomials (treated as elements of $\mathbb{Q}(x_1, \ldots, x_k)$) are algebraically dependent over $\mathbb{Q}$, so there exists a nonzero polynomial $Q \in \mathbb{Q}[y_0, y_1, \ldots, y_k]$ such that the polynomial

$$R(x_1,\dots,x_k) = Q(P_1^{(0)}(x_1,\dots,x_k), P_1^{(1)}(x_1,\dots,x_k),\dots,P_1^{(k)}(x_1,\dots,x_k))$$

is identically zero. It now remains to observe that by Claim 13, for every $n \in \mathbb{N}$ we have

$$0 = R(u_n^1,\dots,u_n^k) = Q(u_n^1, u_{n+1}^1,\dots,u_{n+k}^1) = Q(u_n, u_{n+1},\dots,u_{n+k}),$$

hence Q is a cancelling polynomial for $\mathbf{u}$. ◀

▶ Remark 14. Notice that a given polynomial can be the cancelling polynomial of many different sequences. For example, the polynomial $(x_0)^2 - 1$ is a cancelling polynomial of any sequence over $\{-1, 1\}$. In particular, some of those sequences are not ultimately periodic modulo p, for any prime numbers p, and thus are not poly-recursive by Theorem 6. Hence, the converse direction of Theorem 11 does not hold.

We now present an application of Theorem 11 by showing that the sequence $u_n = n^n$ is not poly-recursive. By Theorem 11, it suffices to show that there is no cancelling polynomial for this sequence. Contrary to the reasoning presented in Section 4, where we used off-the-shelf results about modular (non)periodicity of Catalan numbers, proving the nonexistence of a cancelling polynomial for the n^n sequence turns out to be a somewhat challenging task.

We first observe that when we apply a multivariate polynomial to consecutive entries of u_n, we can rewrite the result in another form:

▶ **Lemma 15.** *Let $Z \in \mathbb{Z}[x_0, x_1,\dots,x_k]$ be a nonzero polynomial. Then there exist nonzero polynomials $P_1,\dots,P_m, Q_1,\dots,Q_m \in \mathbb{Z}[x]$ such that the polynomials $P_1,\dots,P_m$ are pairwise different and for every $n \in \mathbb{N}$,*

$$Z\left(n^n, (n+1)^{n+1},\dots,(n+k)^{n+k}\right) = \sum_{i=1}^{m} P_i(n)^n \cdot Q_i(n).$$

Proof. By expanding Z as a sum of monomials, we may write

$$Z(x_0,\dots,x_k) = \sum_{i=1}^{m} c_i \cdot M_i(x_0,\dots,x_j), \tag{17}$$

where for all $i \in \{1,\dots,m\}$, $c_i \neq 0$ and

$$M_i(x_0,\dots,x_k) = \prod_{j=0}^{k} x_j^{d_{i,j}}$$

are pairwise different monomials. Now observe that for every $n \in \mathbb{N}$, we have

$$\begin{aligned} M_i\left(n^n, (n+1)^{n+1},\dots,(n+k)^{n+k}\right) &= \prod_{j=0}^{k} (n+j)^{d_{i,j}\cdot(n+j)} \\ &= \left(\prod_{j=0}^{k} (n+j)^{d_{i,j}}\right)^n \cdot \prod_{j=0}^{k} (n+j)^{d_{i,j}\cdot j}. \end{aligned} \tag{18}$$

Hence, if we define

$$P_i(x) = \prod_{j=0}^{k} (x+j)^{d_{i,j}} \qquad \text{and} \qquad Q_i(x) = c_i \cdot \prod_{j=0}^{k} (x+j)^{d_{i,j}\cdot j},$$

then, by (17) and (18), we conclude that

$$Z\left(n^n,(n+1)^{n+1},\ldots,(n+k)^{n+k}\right)=\sum_{i=1}^{m}P_i(n)^n\cdot Q_i(n)\qquad\text{for all } n\in\mathbb{N},$$

as required. It now suffices to observe that (1) all polynomials P_i and Q_i are nonzero, because $c_i \neq 0$ and the monomial M_i is nonzero, and (2) the polynomials P_i are pairwise different, because they have pairwise different multisets of roots. ◀

With Lemma 15 established, we move to the main result of this section.

▶ **Theorem 16.** *The sequence $u_n = n^n$ is not poly-recursive.*

Proof. Suppose, for the sake of contradiction, that the sequence $u_n = n^n$ is poly-recursive. By Theorem 11 and Remark 10, there exists a nonzero polynomial $Z \in \mathbb{Z}[x_0, x_1, \ldots, x_k]$ that is cancelling for u_n. By Lemma 15, we can find nonzero polynomials $P_1, \ldots, P_m, Q_1, \ldots, Q_m \in \mathbb{Z}[x]$, where $P_1, \ldots, P_m$ are pairwise different, such that

$$\sum_{i=1}^{m}P_i(n)^n\cdot Q_i(n)=0\qquad\text{for all } n\in\mathbb{N}. \tag{19}$$

This system of equations seems somewhat unwieldy due to the presence of the term $P_i(n)^n$, where n is involved both in the base and in the exponent. The following claim formulates the key idea of the proof: if we consider the equations (19) modulo any prime, then the bases and the exponents of these terms can be made independent.

▷ Claim 17. For every prime p and all $a, b \in \mathbb{Z}$ where $b > 0$, it holds that

$$\sum_{i=1}^{m}P_i(a)^b\cdot Q_i(a)\equiv 0 \mod p\ .$$

Proof. Since p and $p-1$ are coprime, there is an $n \in \mathbb{N}$ such that $n > b$, $n \equiv a \bmod p$ and $n \equiv b \bmod p-1$. Thus for any $1 \leqslant i \leqslant m$:

$$Q_i(n)\equiv Q_i(a) \mod p \qquad\text{and}\qquad P_i(n)^n\equiv P_i(a)^n\equiv P_i(a)^b \mod p\ ,$$

the second part holding by Fermat's Little Theorem. The claim now follows by considering equality (19) modulo p. ◁

Let $a \in \mathbb{N}$ and let $D_a = [d_{ij}]_{1\leqslant i,j\leqslant m}$ be the $m \times m$ matrix defined by $d_{ij} = P_j(a)^i$. Since this is essentially a Vandermonde matrix, its determinant has a simple expression, as expressed in the following claim.

▷ Claim 18. Let $S \in \mathbb{Z}[x]$ be defined as

$$S(x)=\prod_{i=1}^{m}P_i(x)\cdot\prod_{1\leqslant i<j\leqslant m}(P_i(x)-P_j(x))\ .$$

Then S is nonzero and $\det(D_a) = S(a)$.

Proof. That S is nonzero follows from the fact that the polynomials P_i are all nonzero and pairwise different.

Now observe that D_a is a Vandermonde matrix with columns consisting of consecutive powers of $P_j(a)$, for $1 \leqslant j \leqslant m$ with columns consisting of consecutive powers of $P_j(a)$, starting with $P_j(a)^1$ (whereas the Vandermonde matrix starts with $P_j(a)^0$). It is well known that the determinant of the Vandermonde matrix $[P_j(a)^{i-1}]_{1\leqslant i,j\leqslant m}$ is

$$\prod_{1\leqslant i<j\leqslant m} (P_i(a) - P_j(a)) \ .$$

Further, multiplying the jth column by $P_j(a)$, for all j, results in the determinant being multiplied by $\prod_{i=1}^{m} P_i(a)$. This proves the claim. ◁

We will need the following classical definition.

▶ **Definition 19.** *Let R be a ring and M be a $m \times m$ matrix over R. The* adjugate matrix *$\widehat{M}$ of M is an $m \times m$ matrix over R that satisfies $\widehat{M}M = \det(M) \cdot I$, where I is the $m \times m$ identity matrix.*

It is well known that the adjugate matrix always exists. Now let $u_a = (Q_1(a), \dots, Q_m(a))^\intercal$. Claim 17 implies that for every prime p,

$$D_a u_a \equiv \vec{0} \mod p,$$

where $\vec{0}$ is the m-dimensional zero vector. By multiplying both sides of this equation by the adjugate matrix of D_a taken over $\mathbb{Z}_p$, we conclude that for every prime p, we have

$$\det(D_a) \cdot u_a \equiv \vec{0} \mod p \qquad \text{for all } a \in \mathbb{N}.$$

This is equivalent to

$$S(a) \cdot Q_i(a) \equiv 0 \mod p \qquad \text{for all } a \in \mathbb{N} \text{ and } 1 \leqslant i \leqslant m. \tag{20}$$

This means that for every prime p and every $1 \leqslant i \leqslant m$, the following assertion holds: every $a \in \mathbb{F}_p$ is a zero of the polynomial $S \cdot Q_i$ considered as a polynomial over $\mathbb{F}_p$.

Recall that the polynomials $S, Q_1, \dots, Q_m \in \mathbb{Z}[x]$ are nonzero. Consider a prime p that is larger than every coefficient occurring in the expansion of the polynomials S, $Q_1, \dots, Q_m$ into sums of monomials, and that is further larger than $\deg(S) + \max_{j\in\{1,\dots,m\}} \deg(Q_j)$. Then the polynomials $S, Q_1, \dots, Q_m$ are nonzero even when regarded as polynomials over $\mathbb{F}_p$, hence the same can be said also about the polynomials $S \cdot Q_i$, for all $1 \leqslant i \leqslant m$. However, by (20), for every $1 \leqslant i \leqslant m$ the polynomial $S \cdot Q_i$ has at least $p > \deg(S) + \deg(Q_i)$ roots over $\mathbb{F}_p$. This is a contradiction. ◀

6 Applications in weighted automata

In this section we discuss the implications of the results we presented in the previous sections for various questions regarding the expressive power of extensions of weighted automata. We will briefly describe the model of weighted automata and focus only on its expressive power. We refer an interested reader to e.g. [1, 10] for an introduction to the area.

Given a semiring $\mathbb{S}$, a *weighted automaton* $\mathcal{A}$ is a tuple $(d, \Sigma, \{M_a\}_{a\in\Sigma}, I, F)$, where:

- $d \in \mathbb{N}$ is the dimension;
- Σ is a finite alphabet;
- every M_a is a $d \times d$ matrix over $\mathbb{S}$; and
- I and F are the initial and the final vector in $\mathbb{S}^d$, respectively.

In this paper we only consider the semiring $\mathbb{S} = \mathbb{Q}$. A weighted automaton defines a function $[\![\mathcal{A}]\!] : \Sigma^* \to \mathbb{S}$ as follows: if $w = a_1 \dots a_n \in \Sigma^*$, then

$$[\![\mathcal{A}]\!](w) \;=\; I^{\mathsf{T}} \cdot M_{a_1} M_{a_2} \dots M_{a_n} \cdot F. \tag{21}$$

Note that when $|\Sigma| = 1$, this definition coincides with (the matrix form of) the definition (4) of linear recursive sequences. Assuming $|\Sigma| = 1$, one can identify each word with its length, which means that a weighted automaton defines a sequence $[\![\mathcal{A}]\!] : \mathbb{N} \to \mathbb{S}$. Therefore, weighted automata recognise exactly linear recursive sequences. See [6] for a broader discussion of the connection between linear recursive sequences and weighted automata.

We now discuss three nonlinear extensions of weighted automata that can be found in the literature. These extensions are studied in different areas and, as far as we are aware, they have never been compared in terms of expressive power before. We show that the results we presented in Sections 4 and 5 can be used to prove separation results, in terms of the expressive power, for some of these classes.

Like in the case of weighted automata, any automaton within the considered classes defines a function $f \colon \Sigma^* \to \mathbb{Q}$, where Σ is the working alphabet. For our purposes, we restrict attention to the case of unary alphabets, that is, $|\Sigma| = 1$. Thus, the three considered classes of extended weighted automata correspond to three separate classes of sequences $f \colon \mathbb{N} \to \mathbb{Q}$, similarly as standard weighted automata correspond to the class of linear recursive sequences.

Cost-register automata (CRA). Cost-register automata (CRA) were introduced in at least three contexts [21, 4, 7]. To avoid technical details, we simply observe that CRAs over unary alphabets recognize exactly poly-recursive sequences, as defined in Definition 3. Since [21, 4, 7] discuss several variants of CRAs, to avoid ambiguity we refer to the definition of a CRA that can be found in [19][2].

Weighted context-free grammars (WCFG). Weighted automata can be equivalently defined as an extension of finite automata, where each translation is labelled by an element of the semiring $\mathbb{S}$ (see e.g. [1]). In short, each run is assigned a value: the semiring product of the labels of all the transitions used in the run. Given a word w, the automaton outputs the semiring sum of the values assigned to all runs accepting w.

Weighted context-free grammars are an extension of context-free grammars in the same way weighted automata are an extension of finite automata. Every grammar rule is assigned a label from $\mathbb{S}$. Then every derivation tree is assigned the semiring product of the labels of all the rules used in the tree. The output for a word w is defined as the semiring sum of all values assigned to derivation trees of w. See e.g. [13] for more details. Here we present only one example from [13] over the semiring $\mathbb{Q}$.

Consider the grammar with one nonterminal X (which is also the starting nonterminal) and one terminal a with the following rules: $X \to a$, $X \to XX$. Both rules are assigned weight 1. Therefore, for every word a^n the output is the number of derivation trees. It is easy to see that if we denote the output on the word a^n by D_n, then D_n is the number of full binary trees with n leaves, which is the sequence of Catalan numbers shifted by one, i.e. $D_0 = 0$ and $D_{n+1} = C_n$. By Corollary 8 and since it is easy to see that poly-recursive sequences are closed under shifts, we conclude the following.

▶ **Corollary 20.** *The class of sequences definable by unary-alphabet WCFGs over $\mathbb{Q}$ is not contained in the class of sequences recognizable by unary-alphabet CRAs over $\mathbb{Q}$.*

[2] The equivalence of CRAs and poly-recursive sequences over a unary alphabet is basically a syntactic translation, if one assumes that CRAs have only one state. Proving that every CRA can be defined by a one state CRA is a simple encoding of states into the registers.

Weighted MSO (WMSO). Weighted MSO logic [9, 17] was introduced as a logic involving weights that intended to capture the expressive power of weighted automata, similarly as finite automata are characterized by MSO. In general, WMSO turns out to be strictly more expressive than weighted automata. We will not define the whole syntax of WMSO, only a simple fragment that does not even use variables. See [9, 17] for the full definition.

Fix the semiring $\mathbb{S} = \mathbb{Q}$. Similarly as for weighted automata, every WMSO formula φ over $\mathbb{Q}$ defines a function $[\![\varphi]\!] : \Sigma^* \to \mathbb{Q}$. As for atomic formulas, every $c \in \mathbb{Q}$ is an atomic formula that defines the constant function $[\![c]\!](w) = c$. Instead of the boolean connectives $\vee$ and $\wedge$, WMSO formulas can be added using $+$ and multiplied using $\cdot$, with the obvious semantics. Instead of having the existential quantifier $\exists_x$ and the universal quantifier $\forall_x$, we have the sum quantifier $\sum_x$ and the product quantifier $\prod_x$. Then

$$\left[\!\!\left[\sum_x \varphi\right]\!\!\right](w) = \sum_{i=1}^{n} [\![\varphi[x \to a_i]]\!](w) \qquad \text{for all } w = a_1 \dots a_n \in \Sigma^*,$$

and similarly for $[\![\prod_x \varphi]\!](w)$. For example, $[\![\sum_x 1]\!](a^n) = n$. It follows that

$$\left[\!\!\left[\prod_x \sum_y 1\right]\!\!\right](a^n) = n^n.$$

This proves that the sequence n^n can be defined in unary-alphabet WMSO over $\mathbb{Q}$, so by Theorem 16 we may conclude the following.

▶ **Corollary 21.** *The class of sequences definable in unary-alphabet WMSO over $\mathbb{Q}$ is not contained in the class of sequences recognizable by unary-alphabet CRAs over $\mathbb{Q}$.*

7 Conclusion

We proved that two sequences, the Catalan numbers C_n and $u_n = n^n$, are not polynomial recursive. For this, we exhibited two properties that poly-recursive sequences always satisfy: ultimate periodicity modulo large prime numbers and admitting a cancelling polynomial.

Going further than poly-recursive sequences, one can consider the class of *rational recursive sequences*. These are specified like polynomial recursive sequences (Definition 3) but on the right hand side of the system of equations (8) we allow the P_i's to be taken from the field of fractions of the polynomial ring. That is, each P_i is of the form $P_i(x_1, \dots, x_k) = \frac{Q_i(x_1,\dots,x_k)}{R_i(x_1,\dots,x_k)}$, where $Q_i, R_i \in \mathbb{Q}[x_1, \dots, x_k]$ and $R_i \neq 0$.

This class extends both poly-recursive sequences and holonomic sequences (see Section 1). For example one can express the sequence of Catalan numbers, since $C_{n+1} = \frac{4n+2}{n+2} \cdot C_n$ and an ancillary sequence can hold the value n. On the other hand, the proof of the existence of cancelling polynomials for poly-recursive sequences (Theorem 11) carries over to rational recursive sequences. In particular, $u_n = n^n$ is not even rational recursive.

This discussion points to the notion of rational recursive sequences as a natural object for future research.

Abstract

Different graphical calculi have been proposed to represent quantum computation. First the ZX-calculus [4], followed by the ZW-calculus [12] and then the ZH-calculus [1]. We can wonder if new ZX-like calculi will continue to be proposed forever. This article answers negatively. All those language share a common core structure we call Z^*-algebras. We classify Z^*-algebras up to isomorphism in two dimensional Hilbert spaces and show that they are all variations of the aforementioned calculi. We do the same for linear relations and show that the calculus of [2] is essentially the unique one.

1 Introduction

The most common formalization of quantum computing is the circuit model, a diagrammatical language representing unitary matrices in a two dimensional Hilbert space, see [20] for an introduction. Verification of quantum processes requires a sound and complete equational theory for quantum circuits, i.e. a complete presentation of unitaries by generators and relations. This is known to be a difficult open problem.

By relaxing the unitarity condition and allowing all linear maps, at least three different complete equational theories were found. The *ZX-calculus* was introduced in [4] and was designed as a part of the categorical quantum mechanics program. It relies on the interaction between two complementary observables. The ZX-calculus has proven to be a good language to reason about quantum processes [7, 11]. However, finding a set of rules to make it complete has been open for a long time, and part of the solution [15] involved a secondary graphical language: the ZW-calculus [12, 5]. This calculus is built on two tripartite entanglement classes (GHZ and W-states) unraveling new structures. Yet another complete graphical language was later introduced, the ZH-calculus [1], inspired by hyper-graph states.

Compared to quantum circuits, these three languages share an important advantage. Processes and matrices are not represented merely by diagrams, but by *graphs* (hence the term *graph*ical language). Isomorphic graphs represent the same quantum evolution. This peculiarity is embedded in the *only topology matters* paradigm. This is a subtle feature: a usual diagrammatic language (like quantum circuits) starts with a given set of primitives (usually quantum gates) for which the notion of inputs and outputs is significant. When *only topology matters*, one can readily switch an input into an output, and conversely.

This property follows from some specificities of the building blocks of those languages. One goal of this article is to give a formal definition of these specificities.

Then, we will be able to prove that the three existing graphical calculi for quantum computing, ZX, ZH and ZW, are *essentially* the only possible graphical calculi of their kind.

To do this, we identify in this paper a common structure underlying the already defined calculi, that we call a Z^*-algebra. Formally, the structure consists of two Frobenius algebras interacting *via* a bialgebra rule. To this, we add one additional property, called *compatibility*, to ensure the *only topology matters* paradigm. We then describe all the Z^*-algebras in two dimensional Hilbert spaces and show that they all happen to be phase-shifted versions of four structures we call ZX, ZH, ZW and ZZ. The first three appear respectively in the ZX, ZH and ZW-calculus. The last one corresponds to a degenerate calculus arising from only one self-interacting special Frobenius algebra.

It is important to note that languages for quantum computing are not the only known to enjoy these nice properties. In particular Bonchi and his coauthors [2] gave in 2017 a graphical language for linear relations, with striking similarities to the ZX, ZH and ZW calculi. In fact, we will prove that their language is the only Z^*-algebra for linear relations.

There exist some other formalisms trying to unify ZX-like languages, in particular in the context of interacting Frobenius algebras [10] or Hopf-Frobenius algebras [6]. However, these formalisms usually require too much structures, and fail to capture all three examples simultaneously. Typically they do not capture the ZW-calculus.

Some of our work indirectly has to do with the classification of finite dimensional algebras, bialgebras and Frobenius algebras. In the general case, an exact classification of algebras is not known, even in the commutative case. It is known that there is an infinite number of algebras up to isomorphism of dimension d for any $d > 6$. All of them are known for $d \leq 6$ [22]. We find a classification of low dimension bialgebras in [8]. We can find some constructions related to Z^*-algebras in [17] and [9].

This paper starts by introducing the *prop formalism* for graphical languages. The second section introduces various algebraic structures culminating in the definition of Z^*-algebras. The third section provides a classification of Z^*-algebras up to isomorphism for qubits. The last section gives some hint towards classification in higher dimension and provides a classification of Z^*-algebras in the context of linear relations. All the proofs are in the complete version of the paper.

2 Diagrammatical quantum computing

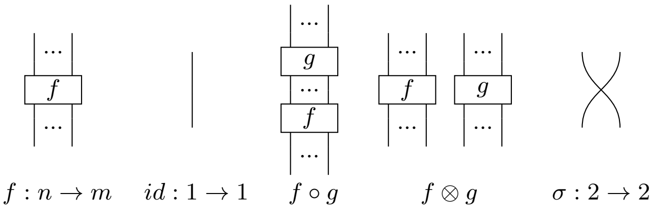
In this paper all processes are represented by a combinatorial structure called a prop [26].

▶ **Definition 1** (prop). *A* ***prop*** $\boldsymbol{P}$ *is a collection of sets* $\boldsymbol{P}[n,m]$*, indexed by* $\mathbb{N}^2$*. An element* $f \in \boldsymbol{P}[n,m]$ *is called a morphism and is usually written* $f : n \to m$*. These sets are linked by the following operators:*

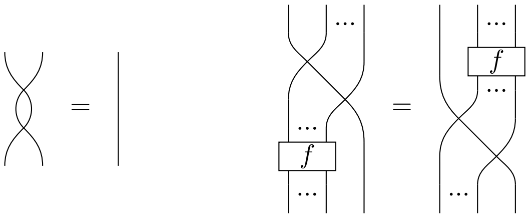
- *A* ***composition*** $\circ : \boldsymbol{P}[b,c] \times \boldsymbol{P}[a,b] \to \boldsymbol{P}[a,c]$ *satisfying:* $(f \circ g) \circ h = f \circ (g \circ h)$*.*
- *A* ***tensor product*** $\otimes : \boldsymbol{P}[a,b] \times \boldsymbol{P}[c,d] \to \boldsymbol{P}[a+c, b+d]$*, satisfying:* $(f \otimes g) \otimes h = f \otimes (g \otimes h)$ *and* $(f \circ g) \otimes (h \circ k) = (f \otimes h) \circ (g \otimes k)$*.*
- *An* ***empty morphism*** $1 : 0 \to 0$ *such that* $f \otimes 1 = 1 \otimes f = f$ *for all* $f : a \to b$*.*
- *An* ***identity*** $id : 1 \to 1$ *such that* $f \circ id^{\otimes a} = id^{\otimes b} \circ f = f$ *for all* $f : a \to b$*. With the convention* $id^{\otimes 0} = 1$*.*
- *A* ***symmetry*** $\sigma : 2 \to 2$ *satisfying:* $\sigma^2 = id^{\otimes 2}$ *and such that,* $\sigma_a \circ (f \otimes id) = (id \otimes f) \circ \sigma_b$*, for all* $f : a \to b$*, where* $\sigma_{n+1} = (1^{\otimes n} \otimes \sigma) \circ (1 \otimes \sigma_n)$*, with* $\sigma_0 = id$*.*

In the language of categories [18], a prop is a small strict symmetric monoidal category whose monoid of object is spanned by a unique object. They can be seen as resource sensitive Lawvere theories where multiple outputs are allowed [3].

Props admit a nice diagrammatical representation that gives a topological interpretation to the axioms [23]. A morphism $f : n \to m$ is represented as a box with n inputs and m outputs. Composition is represented by plugging the boxes. The tensor product by drawing the boxes side by side. The identity is represented by a single wire, the empty morphism by an empty diagram and the symmetry by wire crossing.



That choice of notation fits nicely with the axioms of props. The corresponding equations are natural in the diagrammatic notation. In particular the symmetry axioms express that the boxes can move through wires:



This diagrammatical language is sound [16]. So we can equivalently work with equations or diagrams.

▶ **Example 2** (sets and functions). Let X be a set. In the prop $\mathbf{Fun}_X$, the set $\mathbf{Fun}_X[n, m]$ is exactly the set of functions from X^n to X^m, with composition being the usual composition, and tensor product being the cartesian product.

▶ **Example 3** (matrices). For an integer d and a field $\mathbb{K}$, the prop $\mathbf{Mat}_{\mathbb{K}^d}$ is defined by $\mathbf{Mat}_{\mathbb{K}^d}[n, m] := \mathcal{M}_{d^m \times d^n}(\mathbb{K})$, the matrices of size d^m by d^n over the field $\mathbb{K}$. The composition is the matrix product and the tensor is the Kronecker product. Keeping with quantum computing traditions, we will denote by $(|e_i\rangle)_{1 \leq i \leq d}$ a basis of $\mathbb{K}^d$.

The main prop of interest for quantum computing is $\mathbf{Qubits} := \mathbf{Mat}_{\mathbb{C}^2}$. The quantum analog of bits, the qubits, are described by vectors in $\mathbb{C}^2$. A register of n qubits is then a vector in the tensor product $\mathbb{C}^{2^n}$.

3 Graphical structures

While the diagrammatical languages presented in the previous section make reasoning about props easier, it is still somewhat strict: inputs come to the top of the box representing f, outputs goes out at the bottom. *Graphical languages* do not have this restriction, and we will explain here what additional properties should be satisfied to obtain a better framework.

3.1 Half a spider

We start by studying elementary associative binary operations with units: monoids.

▶ **Definition 4.** *A monoid is a morphism $\mu : 2 \to 1$ (the product) and a morphism $\eta : 0 \to 1$ (the unit) that satisfy the equations: $\mu \circ (\eta \otimes \mathrm{id}) = \mu \circ (\mathrm{id} \otimes \eta) = \mathrm{id}$ and $\mu \circ (\mu \otimes \mathrm{id}) = \mu \circ (\mathrm{id} \otimes \mu)$. If we depict the product*  *and the unit*  *, the equations becomes:* 
and  *The monoid is commutative if $\mu \circ \sigma = \mu$. In pictures,*  *.*

All the monoids in this paper are supposed to be commutative.

Once we have a monoid (μ, η), we can define an n-ary product inductively by $\mu_0 = \eta$, $\mu_1 = id$ and $\mu_{n+1} = \mu \circ (\mu_n \otimes id)$. As an example, here is μ_4:  .

Using the equations, we have more generally $\mu_{n+p} = \mu \circ (\mu_n \otimes \mu_p)$, so how to transform the operator μ_n into compositions of μ and η doesn't matter.

▶ **Example 5.** A monoid in $\mathbf{Fun}_X$ is exactly what is usually called a monoid on X. Monoid in $\mathbf{Mat}_{\mathbb{K}^d}$ are exactly the d-dimensional $\mathbb{K}$-algebras.

In the following we will be mainly interested in the two following examples:

▶ **Example 6** (co-copy)**.** Given a basis $(|i\rangle)_{1 \le i \le d}$ of $\mathbb{K}^d$, the **co-copy** monoid is define in $\mathbf{Mat}_{\mathbb{K}^d}$ by $\eta : 1 \mapsto \sum_{i=1}^{d} |i\rangle$ and $\mu : |i\rangle|j\rangle \mapsto \begin{cases} |i\rangle \text{ if } i = j \\ \text{else } 0 \end{cases}$

▶ **Example 7** (monoid algebra [21])**.** Given a monoid $M = (X, *, e)$ in $\mathbf{Fun}_X$ with X of cardinality d, we can define a monoid $\mathbb{K}[M]$ in $\mathbf{Mat}_{\mathbb{K}^d}$ by indexing each element of a basis by the elements of M. We then take: $\eta : 1 \mapsto |e\rangle$ and $\mu : |a\rangle|b\rangle \mapsto |a * b\rangle$. If M is a group, we will speak of a *group algebra.*

Starting from a monoid M in $\mathbf{Fun}_X$ with X of cardinality $d + 1$ that contains a zero element (that we note $\perp$), we can build a *contracted algebra* $\mathbb{K}M$ in $\mathbf{Mat}_{\mathbb{K}^d}$ by essentially the same construction, but identifying the element $\perp$ with the matrix 0. One can see that the previous example of the co-copy actually fits in this framework: it is exactly $\mathbb{K}M$ for the monoid in $\mathbf{Fun}_{\{\perp,1,\ldots,n\}}$ defined by $i * j = i$ if $i = j$ and $\perp$ otherwise.

Any commutative monoid defines a group of phases:

▶ **Definition 8** (phase)**.** *Given a commutative monoid (μ, η), a **phase** is an invertible morphism $\alpha : 1 \to 1$ such that: $\alpha \circ \mu = \mu \circ (\mathrm{id} \otimes \alpha)$. Pictorially:*  .

The phases form an abelian group. In general we will write this group multiplicatively and write $\alpha\beta$ instead of $\alpha \circ \beta$. *In the following, the notations α and β will be reserved for elements of the phase group.*

▶ **Discussion 9.** *An invertible scalar (a* $0 \to 0$ *morphism) is obviously a phase. Therefore the group of invertible scalars* S *is always a subgroup of the phase group* G*. If it is a direct summand, i.e. if* $G = S \times H$ *for some group* H*, then one can simplify the presentation by "dropping out" the scalars and only consider nontrivial phases. This will be the case later on for the Qubit prop, but there are examples for which such a simplification cannot be made.*

Once we have phases, we can introduce a new sequence of operators $\mu_n(\alpha)$ and $\eta(\alpha)$ defined by $\mu_n(\alpha) = \alpha \circ \mu_n$ and $\eta(\alpha) = \alpha \circ \eta$. Pictorially 
and 
.

These operators satisfy the following equation: 
It is interesting to note that $\mu(\alpha)$ itself defines a monoid, by taking as unit $\eta(\alpha^{-1})$. We will call it a **phase-shifted** monoid of the original monoid.

Monoids dualize to co-monoids:

▶ **Definition 10.** *A co-monoid in a prop is a morphism* $\Delta : 1 \to 2$ *(the co-product) and a morphism* $\epsilon : 1 \to 0$ *(the co-unit) that satisfies the equations:* $(\Delta \otimes \mathrm{id}) \circ \Delta = (\mathrm{id} \otimes \Delta) \circ \Delta$ *and* $(\epsilon \otimes \mathrm{id}) \circ \Delta = (\mathrm{id} \otimes \epsilon) \circ \Delta = \mathrm{id}$*. If we depict the co-product*  *and the co-unit*  *, the equations become:* 
and 
. A co-monoid is co-commutative if it satisfies: $\sigma \circ \Delta = \Delta$*. In pictures,* 
.

All the co-monoids in this paper are supposed to be cocommutative.

Again we can inductively define Δ_n by $\Delta_0 = \epsilon, \Delta_1 = id$ and $\Delta_{n+1} = (\Delta_n \otimes id) \circ \Delta$.

We define phases for co-commutative co-monoids in the same way as phases for commutative monoids, they are the invertible morphisms satisfying: 
.

We can also define the morphisms $\Delta(\alpha)$ and $\epsilon(\alpha)$ as well as the phase-shifted co-monoid $(\Delta(\alpha), \epsilon(1/\alpha))$.

▶ **Example 11** (copy in $\mathbf{Fin}_X$)**.** The functions $\Delta : x \mapsto (x, x)$, with ϵ the only function from X to X^0, defines a co-monoid in $\mathbf{Fin}_X$. This is the only co-monoid in this prop.

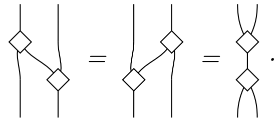
▶ **Example 12** (copy in $\mathbf{Mat}_{\mathbb{K}^d}$)**.** Given a basis of $(|i\rangle)_{1 \leq i \leq d}$, the **copy** co-monoid is defined in $\mathbf{Mat}_{\mathbb{K}^d}$ by $\epsilon : |i\rangle \mapsto 1$ and $\Delta : |i\rangle \mapsto |i\rangle|i\rangle$.

▶ **Example 13** (group co-algebra)**.** Given a finite group G of size d we can define a co-monoid in $\mathbf{Mat}_{\mathbb{K}^d}$ by $|x\rangle \mapsto \frac{1}{d} \sum_{a*b=x} |a\rangle|b\rangle$, the co-unit is $|x\rangle \mapsto \begin{cases} 1 \text{ if } x = e \\ \text{else } 0 \end{cases}$.

3.2 One spider

A monoid and a co-monoid can interact forming a Frobenius algebra.

▶ **Definition 14.** *A monoid* (μ, η) *and a co-monoid* (Δ, ϵ) *form a Frobenius algebra iff they satisfy:* $(\mathrm{id} \otimes \mu) \circ (\Delta \otimes \mathrm{id}) = (\mu \otimes \mathrm{id}) \circ (\mathrm{id} \otimes \Delta) = \Delta \circ \mu$. *Pictorially:*



A Frobenius algebra is commutative if the monoid is commutative and the co-monoid is cocommutative. ***All the Frobenius algebras in this paper are commutative.***

In a Frobenius algebra the phases of the monoid coincide with the phases of the co-monoid. Thus we can speak without ambiguity of the phases of a Frobenius algebra.

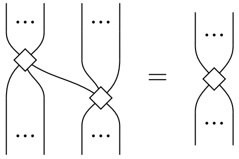
▶ **Example 15** (In $\mathbf{Fin}_X$). There are no Frobenius algebras in $\mathbf{Fin}_X$ (unless $|X| = 1$).

▶ **Example 16** (copy and cocopy). Given a basis $(|i\rangle)_{1 \leq i \leq d}$ of $\mathbb{K}^d$, the co-copy monoid and copy co-monoid form a Frobenius algebra in $\mathbf{Mat}_{\mathbb{K}^d}$.

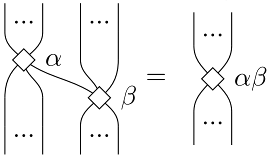
▶ **Example 17** (group Frobenius algebra). Given a group G of size d, the group algebra and the group co-algebra form a Frobenius algebra in $\mathbf{Mat}_{\mathbb{K}^d}$.

When we have a Frobenius algebra $(\mu, \eta, \Delta, \epsilon)$ we can define a family of morphisms $S_{n,m} : n \to m$ by $S_{n,m} := \mu_n \circ \Delta_m$. We call them *spiders* and depict them

. They satisfy the following equation:



. As we have done for monoids and co-monoids, provided a phase α, we define decorated spiders $S_{n,m}(\alpha)$ by $S_n = m_n \circ \alpha \circ \Delta_p$. These new morphisms satisfy the equation:



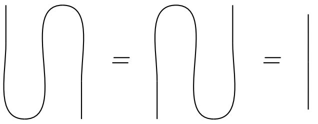
3.2.1 Compact structure

The symmetry in a prop allows various topological moves involving the wires. We can go further by providing a way to bend them. This is done by compact structures.

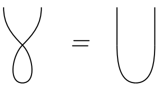
▶ **Definition 18** (compact structure). *A compact structure is given by two morphisms* $\delta : 0 \to 2$ *and* $\nu : 2 \to 0$ *depicted as*

and

satisfying the snake equation $(\nu \otimes \mathrm{id}) \circ (\mathrm{id} \otimes \delta) = (\mathrm{id} \otimes \nu) \circ (\delta \otimes \mathrm{id}) = \mathrm{id}$. *Pictorially:*



. *A compact structure is* symmetric *if* $\nu \circ \sigma = \nu \circ (\mathrm{id} \otimes \mathrm{id})$*: pictorially,*



. *(This implies a similar statement on* δ*).* **All compact structures in this paper are symmetric.**

A compact structure allows to bend the wire leading to new topological properties. This extends the diagrammatical language [23]. Any Frobenius algebra directly provides a compact structure given by $\delta = \Delta \circ \eta$ and $\nu = \epsilon \circ \mu$, pictorially:  =  and  =  .

If the Frobenius algebra is commutative then this compact structure is symmetric.

This compact structure behaves well with the Frobenius algebra, we have: $(\mathrm{id} \otimes \mu) \circ (\delta \otimes \mathrm{id}) = \Delta$, pictorially:  = 
This equation is interesting from a topological point of view. Bending the wires of a diagram gives a diagram representing the same morphism. This has been referred to as the *only topology matters* paradigm [4]. **For us, the only topology matter paradigm is the key property of a graphical language**.

In particular, we can by abuse of notation write:  which may represent any of the following diagrams : 
In general, we can give an unambiguous meaning to any multi-graph with input and outputs. We emphasize that this property plays a central role in the elegance of the Z^* calculi.

3.3 Two spiders

The ZX, ZW and ZH-calculii all have two Frobenius algebras. The next step is therefore to have two of them.

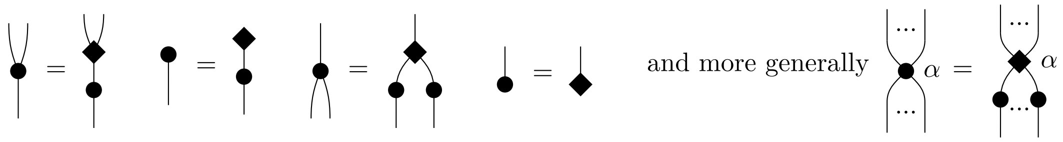
In this setting, the *only topology matters* paradigm doesn't apply anymore. Indeed, coloring the two algebras in white and black, we have:  =  and  =  using the two compact structures corresponding to the two algebras, but in general ≠ .

So we cannot hope for the two compact structures to be equal, but we can hope for some sort of *compatibility*:

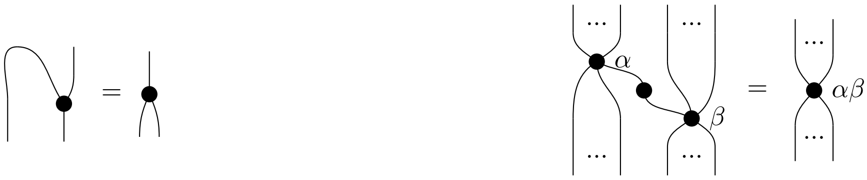
▶ **Definition 19** (compatibility). *Two Frobenius algebras are* ***compatible*** *if their compact structure satisfy:*  =  *. We call the left hand side the* ***dualizer***.

Note that the snake equation(s) implies that the left hand side is always the inverse of the right hand side. In compatible case the dualizer is an involution.

When the two Frobenius algebras are compatible, we can adjust the language so that we can bend wires on both structures. This is done at the price of a slight modification of the second algebra. We introduce now a new generator (represented by a black node) that represents the dualizer, and introduce four new generators in place of the original structures:



With the new generators, we succeed in obtaining a new language: Indeed: we can now bend the wires of the new generator, and we keep a form of the spider rule:

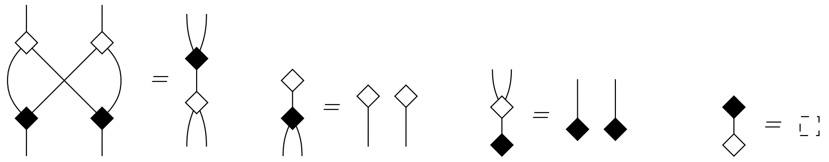


▶ **Discussion 20.** *One could decide similarly to change the first Frobenius algebra rather than the second one. In fact, if there is a preexisting compact structure, it also make sense to search for a compatibility between the preexisting compact structure and the two algebras. This is somehow what has been done in [12].*

3.4 Two spiders interacting

We now require the two spiders to interact in a precise way.

▶ **Definition 21** (Bialgebra)**.** *A co-monoid and a monoid form a bialgebra iff they satisfy the three following equations:*



Bigebra (B) *Copy (C1)* *Cocopy (C2)* *Identity (Id)*

The four bialgebra laws enforces some kind of commutation property between the co-monoid and the monoid. There are conflicting definitions in the literature on which properties one should impose on a bialgebra. The one we take is from Sweedler[25].

We now come to our main definition:

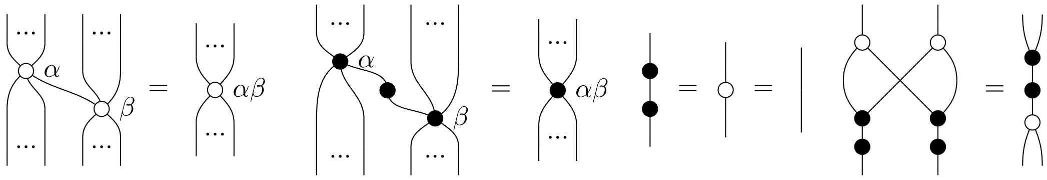
▶ **Definition 22** (Z^*-algebra)**.** *A* ***Z^*-algebra*** *is formed by two compatible Frobenius algebras such that the co-monoid of the first one satisfies the bigebra rule (B) with the monoid of the second one.*

A Z^*-algebra formed by two Frobenius algebras F and G will be denoted FG.

▶ **Discussion 23.** *One could give a different definition of a Z^*-algebra, by imposing all four conditions of the bialgebra law, or even impose it to both monoid/co-monoid pairs. However it turns out that the most important examples (esp. the ZW-calculus) do not satisfy all equations. We isolate the bigebra law as being central.*

Using the notations from the previous section, we see that a Z^*-algebra leads to a *graphical*-calculus, formed by two spiders that are subject to the following rules[1]:

[1] The white node is the same as the white lozenge, but represented differently to emphasize that the whole calculus is different



Together with the *only topology matters* paradigm, which means we can bend the wires of any node, changing an input into an output.

The rules we obtain are a common subset of the rules of the Z^*-calculi [2, 4, 12, 1].

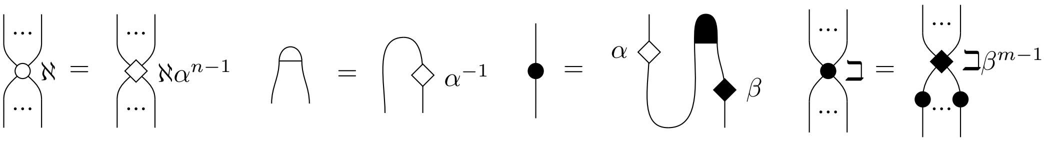
4 Classification of Z^*-algebras in Qubits and LinRel

Now that we have defined what we think is a ZX-like calculus, we can proceed to the main theorem: there are essentially only four possible such calculi for quantum computing up to isomorphism: the ZX-calculus, the ZW-calculus, the ZW-calculus, and the (trivial) ZZ-calculus. Before we can give a formal statement of the theorem, we need to explain what we mean by "essentially".

Consider a Z^*-algebra formed of two Frobenius algebras named A and B. Suppose that λ is a invertible scalar (i.e. a $0 \to 0$ morphism). If we multiply, say, the generators of the monoid of A by λ and the generators of the co-monoid of B by $1/\lambda$, then we obtain a new Z^*-algebra. This new algebra is usually not isomorphic to the first one, but for all practical purposes, they behave the same.

More generally, suppose we add a phase α to the monoid of A (replacing μ, η by $\mu(\alpha)$ and $\eta(\alpha)$) and we add similarly a phase β to the co-monoid of B. Then we obtain two new Frobenius algebras that we will call A^α and B_β which satisfies all axioms of a Z^*-algebra, *except possibly the compatibility relations.* We call this a *phase-shifted* versions of the original Z^*-algebra. We will show that all possible Z^*-algebra for quantum computing are phase-shifted version of four basic ones.

Phase-shifted algebras are a bit subtle. To ease the understanding, we provide here the graphical calculus that corresponds to $A^\alpha B_\beta$ in terms of the original generators, with the caveat that it is a graphical calculus only if the compatibility relation is satisfied (equivalently, the black node below is an involution). n and m denote respectively the number of inputs and outputs and we represent the compact structure of the white algebra differently in both calculi to avoid confusion:



4.1 Z^*-algebras in Qubits

We now investigate the particular case of graphical calculi for quantum computing. This corresponds to the special case **Qubits** = $\mathbf{Mat}_{\mathbb{C}^2}$.

A monoid in Qubit is exactly the same as a $\mathbb{C}$-algebra of dimension 2. Algebras in dimension 2 have been classified [24]: there are only two algebras up to isomorphism.

For our purpose however, we will introduce four algebras (the first three being isomorphic), that we call Z, X, H and W. Working in the basis $(|0\rangle, |1\rangle)$. They correspond to contracted algebras $\mathbb{C}M$, see 7.

Z	$\|0\rangle$	$\|1\rangle$
$\|0\rangle$	$\|0\rangle$	0
$\|1\rangle$	0	$\|1\rangle$

X	$\|0\rangle$	$\|1\rangle$
$\|0\rangle$	$\|0\rangle$	$\|1\rangle$
$\|1\rangle$	$\|1\rangle$	$\|0\rangle$

H	$\|0\rangle$	$\|1\rangle$
$\|0\rangle$	$\|0\rangle$	$\|0\rangle$
$\|1\rangle$	$\|0\rangle$	$\|1\rangle$

W	$\|0\rangle$	$\|1\rangle$
$\|0\rangle$	$\|0\rangle$	$\|1\rangle$
$\|1\rangle$	$\|1\rangle$	0

Those multiplication tables describe the behavior of the algebras on $|0\rangle$ and $|1\rangle$.

We see that Z behaves like a Kronecker delta ensuring equality, X is the XOR gate, H the AND gate and W is the effect algebra on two elements.

The matricial representation in the computational basis are:

 :=

Z	
μ_Z	η_Z
$\begin{pmatrix}1&0&0&0\\0&0&0&1\end{pmatrix}$	$\begin{pmatrix}1\\1\end{pmatrix}$

X	
μ_X	η_X
$\begin{pmatrix}1&0&0&1\\0&1&1&0\end{pmatrix}$	$\begin{pmatrix}1\\0\end{pmatrix}$

H	
μ_H	η_H
$\begin{pmatrix}1&1&1&0\\0&0&0&1\end{pmatrix}$	$\begin{pmatrix}0\\1\end{pmatrix}$

W	
μ_W	η_W
$\begin{pmatrix}1&0&0&0\\0&1&1&0\end{pmatrix}$	$\begin{pmatrix}1\\0\end{pmatrix}$

The phase group of Z is ${\mathbb{C}^*_\times}^2$. The phase group of W is $\mathbb{C}^*_\times \times \mathbb{C}_+$.

If we write the phases for our four favorite monoids, they read:

(a,b) :=

Z
$a,b \in \mathbb{C}^*$
$a\begin{pmatrix}1&0\\0&b\end{pmatrix}$

X
$a,b \in \mathbb{C}^*$
$\frac{a}{2}\begin{pmatrix}1+b&1-b\\1-b&1+b\end{pmatrix}$

H
$a,b \in \mathbb{C}^*$
$a\begin{pmatrix}1&1-b\\0&b\end{pmatrix}$

W
$a \in \mathbb{C}^*\ b \in \mathbb{C}$
$a\begin{pmatrix}1&0\\b&1\end{pmatrix}$

As explained in Discussion 9, in the case of Qubit, we can write[2] the phase group $G = \mathbb{C}^\star \times H$ where the first component $\mathbb{C}^\star$ corresponds to the invertible scalars, and H is some commutative group ($H = \mathbb{C}^\star_\times$ in the first three cases, and $H = \mathbb{C}_+$ in the last case). One could then index the phases only by this subgroup H (i.e. always take $a = 1$), introducing scalars when necessary. This is what has been done in the literature.

All four monoids form Frobenius algebras, with the following co-monoids[3], co-units, and compact structures:

 :=

Z	
Δ_Z	ϵ_Z
$\begin{pmatrix}1&0\\0&0\\0&0\\0&1\end{pmatrix}$	$\begin{pmatrix}1&1\end{pmatrix}$

X	
Δ_X	ϵ_X
$\frac{1}{2}\begin{pmatrix}1&0\\0&1\\0&1\\1&0\end{pmatrix}$	$\begin{pmatrix}2&0\end{pmatrix}$

H	
Δ_H	ϵ_H
$\begin{pmatrix}1&2\\0&-1\\0&-1\\0&1\end{pmatrix}$	$\begin{pmatrix}1&2\end{pmatrix}$

W	
Δ_W	ϵ_W
$\begin{pmatrix}0&0\\1&0\\1&0\\0&1\end{pmatrix}$	$\begin{pmatrix}0&1\end{pmatrix}$

 :=

Z	
δ_Z	ν_Z
$\begin{pmatrix}1\\0\\0\\1\end{pmatrix}$	$\begin{pmatrix}1&0&0&1\end{pmatrix}$

X	
δ_X	ν_X
$\frac{1}{2}\begin{pmatrix}1\\0\\0\\1\end{pmatrix}$	$\begin{pmatrix}2&0&0&2\end{pmatrix}$

H	
δ_H	ν_H
$\begin{pmatrix}2\\-1\\-1\\1\end{pmatrix}$	$\begin{pmatrix}1&1&1&2\end{pmatrix}$

W	
δ_W	ν_W
$\begin{pmatrix}0\\1\\1\\0\end{pmatrix}$	$\begin{pmatrix}0&1&1&0\end{pmatrix}$

We can now state our main theorem:

▶ **Theorem 24.** *The only Z^*-algebras up to isomorphism in **Qubits** are, with $a, b \in \mathbb{C}^*$: $Z^{(a,\frac{b}{a})}Z_{(\frac{1}{a},\frac{a}{b})}$, $Z^{(a,\frac{b}{a})}Z_{(-\frac{1}{a},\frac{a}{b})}$, $Z^{(a,\frac{b}{a})}Z_{(\frac{1}{a},-\frac{a}{b})}$, $Z^{(a,\frac{b}{a})}Z_{(-\frac{1}{a},-\frac{a}{b})}$, $Z^{(a,1)}X_{(\frac{2}{a},1)}$, $Z^{(a,1)}X_{(-\frac{2}{a},1)}$, $Z^{(a,-1)}X_{(\frac{2}{a},1)}$, $Z^{(a,-1)}X_{(-\frac{2}{a},1)}$, $Z^{(\frac{a}{b},b^2)}X_{(\frac{2}{a},-1)}$, $Z^{(a,-1)}X_{(\frac{2b}{a},\frac{1}{b^2})}$, $Z^{(a,\frac{1}{b^2-1})}H_{(\frac{b}{a},\frac{1-b^2}{b^2})}$ with $b^2 \neq 1$, $Z^{(a,\frac{1}{b^2})}W_{(\frac{b}{a},0)}$ and $W^{(a,0)}Z_{(\frac{b}{a},\frac{1}{b^2})}$.*

[2] This can be done more generally in any prop if the group of scalars is divisible.

[3] The co-monoids have been choosen such that the three first Frobenius algebras are isomorphic, hence the weird $\frac{1}{2}$ factor in X.

The idea is to show that, up to isomorphism, there are only five possible monoids/comonoid pairs satisfying the bigebra rule, and then show how they can possibly extend to Z^*-algebras.

We will now compare the calculi we obtain with the literature.

- The ZZ-calculus never has been really considered, as having two spiders that are identical is not useful. However, its existence is not happenstance: in general a Frobenius algebra would not make a bigebra with itself. In this case, it works as Z is a *special* Frobenius algebra.
- The ZX-calculus [4] corresponds to what we call $ZX_{(2,2)}$. This is a particular calculus as the dualizer is trivial: both algebras have the same compact structure (up to scalars). We say that the two algebras are *coflexible*. There are a few substantial differences between our calculus and the ZX-calculus. Instead of using all possibles phases in $\mathbb{C}^\star$, the authors use phases in the unit circle. Subsequent work [19] introduced so-called lambda-boxes to restore all phases. Second, the $ZX_{(2,2)}$-calculus is a bit awkward as the two Frobenius algebras Z and $X_{(2,2)}$ are not isomorphic, but only isomorphic up to a scalar. By rescaling the X algebra, we can obtain a calculus where both algebras are dual, at the price of a slightly different bigebra rule. The isomorphism corresponds to the Hadamard matrix; as this matrix is symmetric, we can add it to our language without changing the *only topology matters* paradigm, and we obtain this way the ZX-calculus defined in [4].
- The fact that other calculi of the form $Z^\alpha X_\beta$ exist corresponds to some commutation properties between phases of the two algebras. In fact, they correspond to what is called *the π-commutation rule*: $(1,\lambda)_Z \circ (1,-1)_X = \lambda(1,-1)_X \circ (1,\frac{1}{\lambda})_Z$ where $(a,b)_Z$ is a phase of Z and $(a,b)_X$ is a phase of X.
- The original rules [4] of the ZX-calculus correspond exactly to:
  - The *only topology matters* paradigm (rule T)
  - The rules above valid on any graphical calculi (rules S1, S2, B2), including in this case the copy rule (B1) and some form of the identity rule (rule D1)
  - one rule relative to the π-commutation (rule K2)
  - one rule relative to Hadamard, the isomorphism between Z and X (rule C)
  - one rule stating that Z is a special Frobenius algebra (hidden in rule S1)
  - one rule called π-copying (K1), and one rule related to the scalars (rules D2). The second rule is anecdotal. The first one relates to what are the automorphisms of Z.

  Therefore, with one omission, all original rules of the ZX-calculus could be rediscovered again in a systematic way using our definition.
- The ZW-calculus as discussed in [13, 14] is exactly what we call ZW. The calculus however do not use phases on the black nodes. The original ZW-calculus introduced in [12] by the same author is slightly different. Intuitively it corresponds to a different kind of graphical languages where the two Frobenius algebras have been made compatible with a third compact structure. The fact that other calculi of the form $Z^\alpha W_\beta$ exist essentially amounts to the same π-commutation rule as before.
- The ZH-calculus as discussed in [1] is exactly what we call $ZH_{(\sqrt{2},-\frac{1}{2})}$. However the authors do not use phases on the white node, and use a different parametrizations of the phases on the black node. The phase they call x is what we would call the phase $(1,1-2x)_H$. This makes the spider rule more awkward in their calculus. The fact that other calculi of the form $Z^\alpha H_\beta$ exist is linked to the following rule: $2\frac{\lambda+1}{\lambda}(1,\lambda)_Z \circ H \circ (1,\frac{1}{2}\frac{1}{\lambda+1})_H = (1,2(\lambda+1))_H \circ H \circ (1,\frac{1}{\lambda})_Z$ where $(a,b)_Z$ is a phase of Z, $(a,b)_H$ is a phase of H and H is the Hadamard gate.

4.2 Generalization for qudits

A similar classification could be theoretically done for other dimensions, i.e. for the prop $\mathbf{Mat}_{\mathbb{C}^d}$. However difficulties arise. Indeed, all possible algebras have been classified only in dimension $d \leq 6$ [22] (in fact there are an infinite number of non isomorphic commutative algebras of dimension 7), and the work is even more terse on bigebras (some work [8] has been done for bi*algebras* in dimension 2 and 3) or Frobenius algebras (although a theoretical characterization exist).

We will therefore focus here on generalizations of the existing structures of dimension 2 to higher dimension.

The ZX-structure corresponds to an interaction between the two algebras $\mathbb{C}^2$ and $\mathbb{C}[\mathbb{Z}/2\mathbb{Z}]$. One could readily generalize this to higher dimensions replacing $\mathbb{Z}/2\mathbb{Z}$ by $\mathbb{Z}/d\mathbb{Z}$, or actually any other commutative group of size d. In higher dimension, the dualizer actually becomes non trivial: it corresponds to the morphism $x \mapsto -x$ in $\mathbb{Z}/d\mathbb{Z}$, which is trivial only if $d = 2$.

The ZW-structure can also be generalized easily. We again replace the algebra $\mathbb{C}^2$ by $\mathbb{C}^d$. and we can generalize the W algebra in dimension 2 to the algebra $\mathbb{C}[X] \big/ \left(X^d\right)$.

We did not find any generalization of ZH that work in arbitrary dimension. The obvious d-dimensional generalization of H would be as a contracted monoid algebra $\mathbb{C}M$ where M is the monoid $(\mathcal{F}, \cap)$ for a family of subsets $\mathcal{F}$ closed under intersection (the 2-dimensional version corresponding to $\mathcal{F} = \{\{1\}, \emptyset\}$). This generalization gives indeed two Frobenius algebra that satisfy a bigebra law, but they usually are not compatible (unless $\mathcal{F} = 2^X$ for some set X).

4.3 In $\mathbf{LinRel}_{\mathbb{K}}$

Quantum computing is not the only place where ZX-like calculi appear: another Z^*-algebra that occurs in the literature is *Graphical linear algebra* [2] in the prop $\mathbf{LinRel}_{\mathbb{K}}$. In $\mathbf{LinRel}_{\mathbb{K}}$ a map $n \to m$ is a linear subspace of $\mathbb{K}^{n+m}$.

It turns out that there are only two monoids in $\mathbf{LinRel}_{\mathbb{K}}$, and they are not isomorphic: the monoid given by the subspace $\{(x, x, x), x \in \mathbb{K}\}$ and the monoid given by $\{(x, y, x+y), x, y \in \mathbb{K}\}$. Their respective phase groups are both trivial. Both these monoids, that we call B and N, actually happen to have Frobenius algebra structures.

▶ **Proposition 25.** *There are only four Z^*-algebras in $\mathbf{LinRel}_{\mathbb{K}}$: BB, NN, BN and NB.*

As these are the only potential candidates, we just have to check that they indeed give Z^*-algebras. BB and NN are trivial, and BN is just a dual version of NB, therefore the graphical calculi of [2] is THE only possible ZX-like calculus for this prop.

5 Future works

We have classified Z^*-algebras in $\mathbf{Mat}_{\mathbb{C}^2}$ and $\mathbf{LinRel}_{\mathbb{K}}$. Further investigations will concern other categories. In the case of $\mathbf{Mat}_{\mathbf{R}}$ for a semiring $\mathbf{R}$, generalizations of ZW and ZX exist. A natural question is which other Z^*-algebras exist in this setting. All the monoids and co-monoids we considered were commutative, the non commutative case is also of interest, leading to a more general notion of graphical language involving *port graphs* or *rotation systems*. An other direction would be to drop the unit and the compact structure and find what defines a graphical language in this case. This is necessary in infinite dimensional Hilbert spaces for example.

6 All graphical calculi for quantum computing

In this last section we provide a complete description of the Z^*-algebras in **Qubits**.

6.1 The ZZ-calculis

6.1.1 $Z^{(a,b/a)}Z_{(1/a,a/b)}$

This is the first calculus presented in the Theorem, up to a re-parametrization that makes it slightly better looking:

 $= \begin{pmatrix} a & 0 & 0 & 0 \\ 0 & 0 & 0 & b \end{pmatrix}$  $= \begin{pmatrix} \frac{1}{a} \\ \frac{1}{b} \end{pmatrix}$  $= \begin{pmatrix} 1 & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & 1 \end{pmatrix}$  $= \begin{pmatrix} 1 & 1 \end{pmatrix}$ 
$= x \begin{pmatrix} 1 & 0 \\ 0 & y \end{pmatrix}$

$= \begin{pmatrix} a & 0 & 0 & b \end{pmatrix}$ $= \begin{pmatrix} \frac{1}{a} \\ 0 \\ 0 \\ \frac{1}{b} \end{pmatrix}$  $= \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$

 $= \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$  $= \begin{pmatrix} 1 \\ 1 \end{pmatrix}$  $= \begin{pmatrix} \frac{1}{a} & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & \frac{1}{b} \end{pmatrix}$  $= \begin{pmatrix} a & b \end{pmatrix}$ 
$= x \begin{pmatrix} 1 & 0 \\ 0 & y \end{pmatrix}$

6.1.2 $Z^{(a,b/a)}Z_{(1/a,-a/b)}$

The only difference with the previous calculus is in the following generators:

 $= \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$  $= \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}$  $= \begin{pmatrix} 1 \\ -1 \end{pmatrix}$

 $= \begin{pmatrix} \frac{1}{a} & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & -\frac{1}{b} \end{pmatrix}$  $= \begin{pmatrix} a & -b \end{pmatrix}$ 
$= x \begin{pmatrix} 1 & 0 \\ 0 & -y \end{pmatrix}$

6.1.3 $Z^{(a,b/a)}Z_{(-1/a,a/b)}$ and $Z^{(a,b/a)}Z_{(-1/a,-a/b)}$

These calculi differ from the previous ones only by the presence of a global scalar “-1” in all matrices corresponding to the black nodes.

6.2 The ZX-calculi

6.2.1 $Z^{(a,1)}X_{(2/a,1)}$

In the case $a = 1$, this is almost the ZX-calculus of [4]:

 $= a \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$  $= \frac{1}{a} \begin{pmatrix} 1 \\ 1 \end{pmatrix}$  $= \begin{pmatrix} 1 & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & 1 \end{pmatrix}$  $= \begin{pmatrix} 1 & 1 \end{pmatrix}$ 
$= x \begin{pmatrix} 1 & 0 \\ 0 & y \end{pmatrix}$

 $= a\begin{pmatrix}1 & 0 & 0 & 1\end{pmatrix}$ $= \frac{1}{a}\begin{pmatrix}1\\0\\0\\1\end{pmatrix}$  $= \begin{pmatrix}1 & 0\\0 & 1\end{pmatrix}$

 $= \begin{pmatrix}1 & 0 & 0 & 1\\0 & 1 & 1 & 0\end{pmatrix}$  $= \begin{pmatrix}1\\0\end{pmatrix}$  $= \frac{1}{a}\begin{pmatrix}1 & 0\\0 & 1\\0 & 1\\1 & 0\end{pmatrix}$  $= a\begin{pmatrix}1 & 0\end{pmatrix}$

 $(x,y) \;= \frac{1}{2}\,x\begin{pmatrix}y+1 & -y+1\\-y+1 & y+1\end{pmatrix}$

6.2.2 $Z^{(a,1)}X_{(2/a,-1)}$

The only difference with the previous calculus is in the following generators:

 $= \begin{pmatrix}0 & 1\\1 & 0\end{pmatrix}$  $= \begin{pmatrix}0 & 1 & 1 & 0\\1 & 0 & 0 & 1\end{pmatrix}$  $= \begin{pmatrix}0\\1\end{pmatrix}$

 $= \frac{1}{a}\begin{pmatrix}0 & 1\\1 & 0\\1 & 0\\0 & 1\end{pmatrix}$  $= a\begin{pmatrix}0 & 1\end{pmatrix}$  $(x,y) \;= \frac{1}{2}\,x\begin{pmatrix}-y+1 & y+1\\y+1 & -y+1\end{pmatrix}$

6.2.3 $Z^{(a,1)}X_{(-2/a,-1)}$ and $Z^{(a,1)}X_{(-2/a,1)}$

These calculi differ from the previous ones only by the presence of a global scalar "-1" in all matrices corresponding to the black nodes.

6.2.4 $Z^{(a/b,b^2)}X_{(2/a,-1)}$

This is a quite different calculus:

 $= a\begin{pmatrix}\frac{1}{b} & 0 & 0 & 0\\0 & 0 & 0 & b\end{pmatrix}$  $= \frac{1}{a}\begin{pmatrix}b\\\frac{1}{b}\end{pmatrix}$  $= \begin{pmatrix}1 & 0\\0 & 0\\0 & 0\\0 & 1\end{pmatrix}$  $= \begin{pmatrix}1 & 1\end{pmatrix}$  $(x,y) \;= x\begin{pmatrix}1 & 0\\0 & y\end{pmatrix}$

$= a\begin{pmatrix}\frac{1}{b} & 0 & 0 & b\end{pmatrix}$ $= \frac{1}{a}\begin{pmatrix}b\\0\\0\\\frac{1}{b}\end{pmatrix}$  $= \begin{pmatrix}0 & b\\\frac{1}{b} & 0\end{pmatrix}$

 $= \begin{pmatrix}0 & b & b & 0\\\frac{1}{b} & 0 & 0 & \frac{1}{b}\end{pmatrix}$  $= \begin{pmatrix}0\\\frac{1}{b}\end{pmatrix}$  $= \frac{1}{a}\begin{pmatrix}0 & b^2\\1 & 0\\1 & 0\\0 & \frac{1}{b^2}\end{pmatrix}$  $= a\begin{pmatrix}0 & 1\end{pmatrix}$

 $(x,y) \;= \frac{1}{2}\,x\begin{pmatrix}-by+b & by+b\\\frac{y+1}{b} & -\frac{y-1}{b}\end{pmatrix}$

6.2.5 $Z^{(a,-1)}X_{(2b/a,1/b^2)}$

This is a calculus dual to the previous one, but the equations look more intricate:

 $= a\begin{pmatrix}1&0&0&0\\0&0&0&-1\end{pmatrix}$  $= \frac{1}{a}\begin{pmatrix}1\\-1\end{pmatrix}$  $= \begin{pmatrix}1&0\\0&0\\0&0\\0&1\end{pmatrix}$  $= \begin{pmatrix}1&1\end{pmatrix}$  $(x,y) \quad = x\begin{pmatrix}1&0\\0&y\end{pmatrix}$

$= a\begin{pmatrix}1&0&0&-1\end{pmatrix}$ $= \frac{1}{a}\begin{pmatrix}1\\0\\0\\-1\end{pmatrix}$  $= \frac{1}{2b}\begin{pmatrix}b^2+1&1-b^2\\b^2-1&-1-b^2\end{pmatrix}$

 $= \frac{1}{2b}\begin{pmatrix}b^2+1&1-b^2&1-b^2&b^2+1\\b^2-1&-1-b^2&-1-b^2&b^2-1\end{pmatrix}$  $= \frac{1}{2b}\begin{pmatrix}b^2+1\\b^2-1\end{pmatrix}$

 $= \frac{1}{2ab}\begin{pmatrix}b^2+1&1-b^2\\b^2-1&-1-b^2\\b^2-1&-1-b^2\\b^2+1&1-b^2\end{pmatrix}$  $= \frac{a}{2b}\begin{pmatrix}b^2+1&1-b^2\end{pmatrix}$

 $(x,y) \quad = \frac{x}{2b}\begin{pmatrix}b^2y+1&1-b^2y\\b^2y-1&-1-b^2y\end{pmatrix}$

6.3 The ZH-calculi

6.3.1 The $Z^{(a,1/(b^2-1))}H_{(b/a,(1-b^2)/b^2)}$ calculus

 $= a\begin{pmatrix}1&0&0&0\\0&0&0&\frac{1}{b^2-1}\end{pmatrix}$  $= \frac{1}{a}\begin{pmatrix}1\\b^2-1\end{pmatrix}$  $= \begin{pmatrix}1&0\\0&0\\0&0\\0&1\end{pmatrix}$  $= \begin{pmatrix}1&1\end{pmatrix}$  $(x,y) \quad = x\begin{pmatrix}1&0\\0&y\end{pmatrix}$

$= a\begin{pmatrix}1&0&0&\frac{1}{b^2-1}\end{pmatrix}$ $= \frac{1}{a}\begin{pmatrix}1\\0\\0\\b^2-1\end{pmatrix}$  $= \frac{1}{b}\begin{pmatrix}1&1\\b^2-1&-1\end{pmatrix}$

 $= \frac{1}{b}\begin{pmatrix}1&1&1&1\\b^2-1&b^2-1&b^2-1&-1\end{pmatrix}$  $= \frac{1}{b}\begin{pmatrix}1\\-1\end{pmatrix}$  $= \frac{1}{ab}\begin{pmatrix}1&1\\b^2-1&b^2-1\\b^2-1&b^2-1\\(b^2-1)^2&1-b^2\end{pmatrix}$

 $= \frac{a}{b}\begin{pmatrix}1&\frac{1}{1-b^2}\end{pmatrix}$  $(x,y) \quad = \frac{x}{b}\begin{pmatrix}1&1\\b^2-1&b^2-1-b^2y\end{pmatrix}$

6.4 The ZW-calculi

6.4.1 The $Z^{(a,1/c^2)}W_{(c/a,0)}$

 $= a\begin{pmatrix}1&0&0&0\\0&0&0&\frac{1}{c^2}\end{pmatrix}$  $= \frac{1}{a}\begin{pmatrix}1\\c^2\end{pmatrix}$  $= \begin{pmatrix}1&0\\0&0\\0&0\\0&1\end{pmatrix}$  $= \begin{pmatrix}1&1\end{pmatrix}$  $(x,y) \quad = x\begin{pmatrix}1&0\\0&y\end{pmatrix}$

$= a\begin{pmatrix}1&0&0&\frac{1}{c^2}\end{pmatrix}$ $= \frac{1}{a}\begin{pmatrix}1\\0\\0\\c^2\end{pmatrix}$  $= \begin{pmatrix}0&\frac{1}{c}\\c&0\end{pmatrix}$

 $= \begin{pmatrix} 0 & \frac{1}{c} & \frac{1}{c} & 0 \\ c & 0 & 0 & 0 \end{pmatrix}$  $= \begin{pmatrix} 0 \\ c \end{pmatrix}$  $= \frac{1}{a} \begin{pmatrix} 0 & \frac{1}{c} \\ c & 0 \\ c & 0 \\ 0 & 0 \end{pmatrix}$  $= a \begin{pmatrix} 0 & \frac{1}{c} \end{pmatrix}$  $(x, y) \quad = x \begin{pmatrix} cy & \frac{1}{c} \\ c & 0 \end{pmatrix}$

6.4.2 The $W^{(a,0)}Z_{(b/a,1/b^2)}$ calculus

This is very similar to the previous calculus, except that W is now chosen as the white node, meaning that the black node is actually Z, up to the dualizer.

 $= a \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 \end{pmatrix}$  $= \frac{1}{a} \begin{pmatrix} 1 \\ 0 \end{pmatrix}$  $= \begin{pmatrix} 0 & 0 \\ 1 & 0 \\ 1 & 0 \\ 0 & 1 \end{pmatrix}$  $= \begin{pmatrix} 0 & 1 \end{pmatrix}$  $(x, y) \quad = x \begin{pmatrix} 1 & 0 \\ y & 1 \end{pmatrix}$

$= a \begin{pmatrix} 0 & 1 & 1 & 0 \end{pmatrix}$  $= \frac{1}{a} \begin{pmatrix} 0 \\ 1 \\ 1 \\ 0 \end{pmatrix}$  $= \begin{pmatrix} 0 & b \\ \frac{1}{b} & 0 \end{pmatrix}$

 $= \begin{pmatrix} 0 & 0 & 0 & b \\ \frac{1}{b} & 0 & 0 & 0 \end{pmatrix}$  $= \begin{pmatrix} b \\ \frac{1}{b} \end{pmatrix}$  $= \frac{1}{a} \begin{pmatrix} 0 & b \\ 0 & 0 \\ 0 & 0 \\ \frac{1}{b} & 0 \end{pmatrix}$  $= a \begin{pmatrix} \frac{1}{b} & b \end{pmatrix}$  $(x, y) \quad = x \begin{pmatrix} 0 & by \\ \frac{1}{b} & 0 \end{pmatrix}$

Abstract

We study the problems of deciding whether a relation definable by a first-order formula in linear rational or linear integer arithmetic with an order relation is definable in absence of the order relation. Over the integers, this problem was shown decidable by Choffrut and Frigeri [*Discret. Math. Theor. C.*, 12(1), pp. 21–38, 2010], albeit with non-elementary time complexity. Our contribution is to establish a full geometric characterisation of those sets definable without order which in turn enables us to prove coNP-completeness of this problem over the rationals and to establish an elementary upper bound over the integers. We also provide a complementary Π_2^{P} lower bound for the integer case that holds even in a fixed dimension. This lower bound is obtained by showing that universality for ultimately periodic sets, i.e., semilinear sets in dimension one, is Π_2^{P}-hard, which resolves an open problem of Huynh [*Elektron. Inf.verarb. Kybern.*, 18(6), pp. 291–338, 1982].

1 Introduction

A central topic in mathematical and computational logic is to investigate the expressive power of first-order formulas in a given structure. Notable results in this context include Robinson's seminal work showing that the integers are first-order definable in the structure $\langle \mathbb{Q}, +, \cdot \rangle$, thus rendering its first-order theory undecidable [13]. Another example is the celebrated theorem of Muchnik [10] showing decidability of the problem of determining whether a relation first-order definable in the structure $\langle \mathbb{Z}, +, V_k, < \rangle$ (whose first-order theory is known as *Büchi arithmetic*) is definable in the weaker substructure $\langle \mathbb{Z}, +, < \rangle$ (known as *linear integer arithmetic* or *Presburger arithmetic*). Here, V_k is the function mapping an integer to the highest power of k dividing it without remainder. Muchnik's approach yields a quadruply exponential time algorithm for this problem when the relation is given as a deterministic finite-state automaton; a polynomial-time algorithm was later claimed by Leroux [9]. It has recently been shown that this problem can be solved in quasi-linear time for unary relations [1].

In this paper, we investigate the computational complexity of the *weak definability problem*, which is the problem of deciding whether a relation first-order definable in the structures $\langle \mathbb{Q}, +, < \rangle$ or $\langle \mathbb{Z}, +, < \rangle$ is definable in its weak counterpart, which is obtained from replacing the order relation with the equality relation. It follows from elementary model-theoretic arguments that such *weak linear arithmetic theories* are strictly less expressive compared to their counterparts that include the order relation, since $h(x) := -x$ is an automorphism in structures without order but fails to be one in the presence of the order relation. For Presburger arithmetic, the weak definability problem was shown decidable by Choffrut and Frigeri, albeit with non-elementary time complexity [5]. To the best of the authors' knowledge, no decidability results on weak definability for the structure $\langle \mathbb{Q}, +, < \rangle$ are known. Following [5], *weak Presburger arithmetic* (alternatively *weak linear integer arithmetic)* refers to the first-order theory of $\langle \mathbb{Z}, +, = \rangle$ whereas *weak linear rational arithmetic* refers to the theory of $\langle \mathbb{Q}, +, = \rangle$.

The main contribution of this paper is to significantly improve existing algorithmic upper bounds for the weak definability problem by establishing elementary upper bounds over both $\mathbb{Q}$ and $\mathbb{Z}$: we show that weak definability is in coNP for rational linear arithmetic, and decidable in elementary time for Presburger arithmetic. To this end, we develop geometric criteria that precisely characterize when a relation is definable without order. We also establish complementary lower bounds. While a matching coNP lower bound in the rational case is easy to obtain, we furthermore establish a Π_2^{P} lower bound for the weak definability problem for Presburger arithmetic that holds even in a fixed dimension. This lower bound is obtained by establishing Π_2^{P}-completeness of the universality problem for ultimately periodic sets, i.e., semi-linear sets in dimension one. This positively answers one of the longest-standing open problems in the theory of semi-linear sets posed by Huynh in 1982 [8], who asked whether the universality problem for semi-linear sets in dimension one is Π_2^{P}-complete. Our lower bound moreover strengthens previously known Π_2^{P} lower bounds for the inclusion problems for linear sets which have only been obtained in recent years, see [4, Thm. 12] and [16].

2 The weak definability problem

Everywhere in this paper, we denote by $\mathbb{Q}$, $\mathbb{Z}$, $\mathbb{N}$ and $\mathbb{N}_+$ the rational numbers, integers, natural numbers including zero and the positive integers, respectively. Given $a, b \in \mathbb{Z}$, we write $[a, b]$ for $\{a, a+1, \ldots, b\}$ and $[a]$ as a shortcut for $[1, a]$. Throughout this paper, numbers are assumed to be encoded in binary.

Linear arithmetic theories. Quantifier-free formulas ψ of the linear arithmetic theories we consider in this paper are obtained as Boolean combinations of linear constraints of the form $a_1 \cdot x_1 + \cdots + a_n \cdot x_n \sim b$, where all a_i and b are integer constants, the x_i are first-order variables, and $\sim$ is a relation symbol $<$ or $=$. If ψ only contains equality symbols it is a formula of a weak linear arithmetic theory, in which case we call ψ *weak*. We can always without loss of generality assume that ψ is in negation normal form, and if ψ is not weak, we can furthermore assume that ψ is negation-free. Formulas Φ of linear arithmetic theories additionally allow for quantification over first-order variables and are of the form $Q_1 x_1 \cdots Q_n x_n\, \psi$, where each Q_i is $\exists$ or $\forall$, and ψ is a quantifier-free formula. We write $\|\Phi\|$ to denote the maximum of two and the maximum of the absolute values of all constants occurring in Φ, and $|\Phi|$ to denote the length of Φ which is the number of symbols required to write down Φ.

The semantics of such formulas is given with respect to the structures of linear rational arithmetic $\langle \mathbb{Q}, +, < \rangle$ and linear integer arithmetic $\langle \mathbb{Z}, +, < \rangle$. We call Φ weak whenever ψ is weak. Let $x_1, \ldots, x_n$ be the free variables of Φ, and let $\mathbb{D} \subseteq \mathbb{Q}$; often $\mathbb{D}$ will be $\mathbb{Q}$ or $\mathbb{Z}$. We write $[\![\Phi]\!]_{\mathbb{D}} \subseteq \mathbb{D}^n$ for the set of all variable assignments making Φ a true sentence in the structure $\langle \mathbb{D}, +, < \rangle$. We may drop the subscript $\mathbb{D}$ when $\mathbb{D}$ is clear from the context.

Definable relations and weak definability. Fix $\mathbb{D}$ to be either $\mathbb{Q}$ or $\mathbb{Z}$. A relation $R \subseteq \mathbb{D}^n$ is called $\mathbb{D}$-definable whenever there is a linear arithmetic formula $\Phi(x_1, \ldots, x_n)$ such that $(m_1, \ldots, m_n) \in R$ if and only if $(m_1, \ldots, m_n) \in [\![\Phi]\!]_{\mathbb{D}}$. In particular, we call R *weakly* $\mathbb{D}$*-definable* if the witnessing formula Φ is weak. The weak definability problem, the main decision problem considered in this paper, asks whether a relation definable by an arbitrary linear arithmetic formula is definable without order: *Given a linear arithmetic formula* Φ*, is the set* $[\![\Phi]\!]_{\mathbb{D}}$ *weakly* $\mathbb{D}$*-definable?*

Obviously, for a relation to be definable without order, it has to also be definable with order. In other words, weak definability, somewhat ironically, is a stronger property than definability.

▶ **Example 1.** Consider $\Phi(x) := x < 0 \vee x \geq 1$. It is not difficult to check that $[\![\Phi]\!]_{\mathbb{Q}}$ is not weakly $\mathbb{Q}$-definable. However, $[\![\Phi]\!]_{\mathbb{Z}}$ is weakly $\mathbb{Z}$-definable by $\Phi'(x) := \neg(x = 0)$, demonstrating that weak $\mathbb{Z}$-definability does not imply weak $\mathbb{Q}$-definability. Conversely, weak $\mathbb{Q}$-definability does not imply weak $\mathbb{Z}$-definability either. Let $\Phi(x) := \exists y\,(x > 0 \wedge x = 2 \cdot y) \vee (x < 0 \wedge x = 3 \cdot y)$. Then $[\![\Phi]\!]_{\mathbb{Z}}$ is not weakly $\mathbb{Z}$-definable, but $[\![\Phi]\!]_{\mathbb{Q}}$ is weakly $\mathbb{Q}$-definable via the same $\Phi'(x)$ as above.

When studying the complexity of weak definability problems, it makes sense to restrict the input formulas we consider. On the one hand, due to quantifier elimination (Fourier-Motzkin and Presburger's quantifier elimination procedures, respectively), quantifier-free formulas of linear rational arithmetic can define all sets definable in linear rational arithmetic, and existential formulas those in linear integer arithmetic. On the other hand, satisfiability can be reduced to deciding weak definability, meaning that if we allow arbitrary formulas as input, deciding weak definability is at least as hard as deciding linear rational and integer arithmetic, respectively. This does, however, blur the inherent complexity of deciding weak definability. For these reasons, we restrict formulas in instances of the weak definability problem to the most restricted fragments that are still expressively complete:

Weak $\mathbb{Q}$-definability: Given a *quantifier-free* formula Φ of linear arithmetic, decide whether $[\![\Phi]\!]_{\mathbb{Q}}$ is weakly $\mathbb{Q}$-definable.

Weak $\mathbb{Z}$-definability: Given an *existential* quantifier-free formula Φ of linear arithmetic, decide whether $[\![\Phi]\!]_{\mathbb{Z}}$ is weakly $\mathbb{Z}$-definable.[1]

By establishing an analogue of semilinear sets characterizing sets definable in weak integer arithmetic, Choffrut and Frigeri [5] have shown that weak $\mathbb{Z}$-definability is decidable. As the main result of the present paper, we show that deciding weak $\mathbb{Q}$-definability is coNP-complete, and deciding weak $\mathbb{Z}$-definability is elementary and Π_2^{P}-hard.

[1] One could alternatively take quantifier-free formulas with additional divisibility predicates $c \,|\, \cdot$ for every $c \in \mathbb{N}_+$.

3 Preliminaries

Linear algebra. We denote by $\boldsymbol{e}_i$ the i-th unit vector in any dimension. For $\boldsymbol{v} = (v_1,\dots,v_d) \in \mathbb{Z}^d$, we denote $\|\boldsymbol{v}\| := \max\{2, \max_{1\leq i\leq d}|v_i|\}$, and for $V \subseteq \mathbb{Q}^d$ we set $\|V\| := \max_{\boldsymbol{v}\in V}\|\boldsymbol{v}\|$. Likewise, for a matrix $\boldsymbol{A}$, $\|\boldsymbol{A}\|$ is defined as the maximum over $\|\boldsymbol{v}\|$ for every column vector $\boldsymbol{v}$ of $\boldsymbol{A}$. We sometimes treat finite sets $V \subseteq \mathbb{Q}^m$ with n elements as $m \times n$ matrices (e.g., by ordering the vectors in V lexicographically), which we denote by $\boldsymbol{V}$. Given $A, B \subseteq \mathbb{Q}^d$, the Minkowski sum of A and B is defined as $A + B := \{a + b : a \in A,\ b \in B\}$. If A or B is a singletons, we omit set brackets and write, e.g., $a + B$ instead of $\{a\} + B$. Analogously, we define $A \cdot B := \{a \cdot b : a \in A,\ b \in B\}$. We write $A \triangle B$ for the symmetric difference of A and B, i.e., $A \triangle B := (A \setminus B) \cup (B \setminus A)$.

A set $A \subseteq \mathbb{Q}^d$ is an *affine subspace* if $A = \boldsymbol{a} + V$ for some $\boldsymbol{a} \in \mathbb{Q}^d$ and a linear subspace $V \subseteq \mathbb{Q}^d$. Affine subspaces are sometimes called flats. The affine hull of any set $V \subseteq \mathbb{Q}^d$ is the smallest affine subspace containing V and is equal to

$$\operatorname{aff} V := \left\{\sum_{i=1}^{n} \lambda_i \cdot \boldsymbol{v}_i : n \in \mathbb{N},\ \boldsymbol{v}_i \in V,\ \lambda_i \in \mathbb{Q},\ i \in [n],\ \sum_{i=1}^{n} \lambda_i = 1\right\}.$$

The *dimension* of an affine subspace A, denoted $\dim A$, is defined as the dimension of the associated linear space A_0 such that $A = \boldsymbol{v} + A_0$ for some $\boldsymbol{v} \in \mathbb{Q}^d$. It is standard that this is well-defined. If affine subspaces A_1, A_2 are such that $A_1 \subseteq A_2$, then $\dim A_1 \leq \dim A_2$ (and moreover $A_1 = A_2$ iff $\dim A_1 = \dim A_2$).

A set S in $\mathbb{Q}^d$ (resp. $\mathbb{Z}^d$) *is vanishing (is zero, has measure zero) with respect to an affine subspace* $A \subseteq \mathbb{Q}^d$ if the set S is contained in a finite union of affine subpaces of A of dimension strictly less than A. Note that $S \subseteq A$ for any such S. For example, all finite subsets of $\mathbb{Q}^d$ have measure zero with respect to $\mathbb{Q}^d$ unless $d = 0$. If we do not specify the affine subspace A explicitly, $A = \mathbb{Q}^d$ is implicitly assumed.

The geometry of linear arithmetic. We recall some definitions and results from the literature on the geometry of solutions to systems of linear constraints.

It is well known that the set of solutions of a system of linear equations $\boldsymbol{B} \cdot \boldsymbol{x} = \boldsymbol{c}$ over the rationals is an affine subspace. Conversely, every affine subspace of $\mathbb{Q}^d$ is the set of solutions to a system of (linearly independent) equations with integer coefficients. For a representation $A = \{\boldsymbol{x} \in \mathbb{Q}^d : \boldsymbol{B} \cdot \boldsymbol{x} = \boldsymbol{c}\}$, we write $\|A\|$ to denote $\max\{\|\boldsymbol{B}\|, \|\boldsymbol{c}\|\}$, when $\boldsymbol{B}$ and $\boldsymbol{c}$ are determined by the context.

The Minkowski–Weyl theorem states that the set of points in a rational polyhedron $\boldsymbol{A} \cdot \boldsymbol{x} \geq \boldsymbol{b}$ can be represented as the sum of a bounded polytope and a convex cone, and vice versa. Given a finite set of vectors $V = \{\boldsymbol{v}_1, \dots, \boldsymbol{v}_n\} \subseteq \mathbb{Q}^d$, we define

$$\operatorname{conv} V := \left\{\sum_{i=1}^{n} \lambda_i \cdot \boldsymbol{v}_i : \sum_{i=1}^{n} \lambda_i = 1,\ \lambda_i \in \mathbb{Q}_{\geq 0},\ i \in [n]\right\} \quad \text{and}$$

$$\operatorname{cone} V := \left\{\sum_{i=1}^{n} \lambda_i \cdot \boldsymbol{v}_i : \lambda_i \in \mathbb{Q}_{\geq 0},\ i \in [n]\right\},$$

the *convex hull* of V and the *convex cone* generated by V, respectively. It follows that sets in $\mathbb{Q}^d$ definable in linear rational arithmetic can be obtained as finite unions of sets of the form $(\operatorname{conv} B + \operatorname{cone} P) \setminus A$, where A is a finite union of affine subspaces of $\mathbb{Q}^d$.

An effective version of the Minkowski–Weyl theorem over $\mathbb{Q}$ states that the two representations (as the intersection of half-spaces and as $\operatorname{conv} F + \operatorname{cone} G$ for finite sets F, G of generators) can be translated from one to another with a single exponential blowup (see, e.g., [15, Chapter 10]).

In the discrete setting, semilinear sets [11] characterize the sets of integer vectors definable in linear integer arithmetic [6]. For technical purposes, we give a slightly more generic definition. Let $\boldsymbol{b} \in \mathbb{Z}^d$ and $P = \{\boldsymbol{p}_1, \ldots, \boldsymbol{p}_n\} \subseteq \mathbb{Z}^d$, we call $(\boldsymbol{b}, P)$ a *generator tuple* with *base* $\boldsymbol{b}$ and *periods* P. Fix $\mathbb{D}$ to be some subset of $\mathbb{Q}^d$, then the $\mathbb{D}$-*linear set* $L_{\mathbb{D}}(\boldsymbol{b}, P)$ generated by the tuple $(\boldsymbol{b}, P)$ is defined as

$$L_{\mathbb{D}}(\boldsymbol{b}, P) = \boldsymbol{b} + \mathbb{D} \cdot \boldsymbol{p}_1 + \cdots + \mathbb{D} \cdot \boldsymbol{p}_n \,.$$

Thus, $\mathbb{N}$-linear sets recover standard linear sets [11] as defined in the literature. Given a set $M \subseteq \mathbb{Z}^d$, we say that M is $\mathbb{D}$-*linear* if there is a generator tuple $(\boldsymbol{b}, P)$ such that $M = L_{\mathbb{D}}(\boldsymbol{b}, P)$. Clearly, $\mathbb{N}$-linear sets contain all $\mathbb{Z}$-linear sets, since $L_{\mathbb{Z}}(\boldsymbol{b}, P) = L_{\mathbb{N}}(\boldsymbol{b}, P \cup -P)$, but the converse does not hold: it is easy to prove that $\mathbb{N}$ is $\mathbb{N}$-linear but not $\mathbb{Z}$-linear.

We say that M is a *hybrid* $\mathbb{D}$-*linear set* if it is a union of the form

$$L_{\mathbb{D}}(B, P) = \bigcup_{\boldsymbol{b} \in B} L_{\mathbb{D}}(\boldsymbol{b}, P)$$

where both sets $B, P \subseteq \mathbb{Z}^d$ are finite. A $\mathbb{D}$-linear or hybrid $\mathbb{D}$-linear set, as defined above, is k-*dimensional* if the linear span of the set P has dimension k; it is *full-dimensional* if $k = d$. One may think of k-dimensional $\mathbb{Z}$-linear sets as of shifted lattices (or cosets of lattices) inside k-dimensional affine subspaces.

We say that M is $\mathbb{D}$-*semilinear* if it is a finite union of $\mathbb{D}$-linear sets. We call a semilinear set *proper* if all sets of period vectors of those linear sets are linearly independent.

Hybrid $\mathbb{N}$-linear sets (often just *hybrid linear sets* for short) are discrete analogues of convex polyhedra; they are exactly sets of integer solutions to systems of linear inequalities $\boldsymbol{A} \cdot \boldsymbol{x} \geq \boldsymbol{c}$ [17, 2], which implies that sets definable in linear integer arithmetic are $\mathbb{N}$-semilinear [6]. Similarly, integer solutions of systems of linear equations are $\mathbb{Z}$-linear:

▶ **Proposition 2.** *Suppose $\boldsymbol{A} \cdot \boldsymbol{x} = \boldsymbol{c}$ has a solution in $\mathbb{Z}^d$. Then its set of solutions in $\mathbb{Z}^d$ is a proper $\mathbb{Z}$-linear set $L_{\mathbb{Z}}(\boldsymbol{b}, P)$, with $\|\boldsymbol{b}\| \leq 2^{O(d^4 \log d)} \cdot \|\boldsymbol{A}\|^{O(d^4)} \cdot \|\boldsymbol{c}\|$ and $\|P\| \leq 2^{O(d^4 \log d)} \cdot \|\boldsymbol{A}\|^{O(d^4)}$. Moreover, $|P| = d - \operatorname{rank} \boldsymbol{A}$ and the vectors in P are fully determined by $\boldsymbol{A}$ (i.e., independent of $\boldsymbol{c}$).*

It should be noted, however, that $\mathbb{Z}$-semilinear sets do not fully characterize sets definable in weak linear integer arithmetic. Choffrut and Frigeri [5] have shown that $M \subseteq \mathbb{Z}^d$ is definable in weak linear arithmetic if and only if $M = \bigcup_{i \in I} S_i \setminus T_i$, where the S_i are proper $\mathbb{Z}$-linear sets, T_i proper $\mathbb{Z}$-semilinear sets, and $T_i \subseteq S_i$ for all $i \in I$.

Descriptional complexity. The complexity upper bounds we obtain in this paper rely on bounds on the constants in the generator representation of sets definable in linear arithmetic theories. Given a $\mathbb{D}$-semilinear set $S \subseteq \mathbb{Z}^d$ in generator representation, $S = \bigcup_{i \in I} L(B_i, P_i)$, we define $\|S\| := \max_{i \in I} \max \|B_i \cup P_i\|$.

▶ **Proposition 3.** *Let Φ be an existential formula of linear integer arithmetic and $S = [\![\Phi]\!]_{\mathbb{Z}}$. Then $S = \bigcup_{i \in I} L(B_i, P_i)$ such that $\log\|S\|, \log|I| \leq \operatorname{poly}(|\Phi|)$.*

Proof. For a system of linear inequalities $\boldsymbol{A} \cdot \boldsymbol{x} \geq \boldsymbol{c}$, the statement follows, e.g., from [17]. Moreover, the disjunctive normal form of Φ consists of at most $2^{|\Phi|}$ conjunctions, each of which is a system of linear inequalities, from which the statement follows. ◀

4 A characterisation of weak $\mathbb{Q}$- and $\mathbb{Z}$-definability

We now establish properties that fully characterize when a subset of $\mathbb{Q}^d$ is weakly $\mathbb{Q}$- and weakly $\mathbb{Z}$-definable, respectively.

▶ **Definition 4.** *Suppose $X \subseteq \mathbb{Q}^d$. We say that X:*

- *has* 0–1 property *with respect to an affine subspace A if either $X \cap A$ or $A \setminus X$ is contained in a finite union of affine subspaces of dimension* $\dim A - 1$*,*
- *has* hierarchical 0–1 property *with respect to an affine subspace A if it has 0–1 property with respect to A, where the subspaces of lower dimension are some $H_1, \ldots, H_m$, and, if* $\dim A > 1$*, it has hierarchical 0–1 property with respect to each H_i, $1 \leq i \leq m$,*
- *has* (hierarchical) 0–1 property *if it has (hierarchical) 0–1 property with respect to $\mathbb{Q}^d$,*
- *has* global 0–1 property *if, for every affine subspace $A \subseteq \mathbb{Q}^d$, it has 0–1 property with respect to A,*
- *has* ℓ-bounded 0–1 property *if, for every affine subspace $A = \{\boldsymbol{x} \in \mathbb{Q}^d : \boldsymbol{B} \cdot \boldsymbol{x} = \boldsymbol{c}\}$ with $\|\boldsymbol{B}\|, \|\boldsymbol{c}\| \leq \ell$, it has 0–1 property with respect to A.*

The term “0–1 property” refers to the intuition that a (weakly $\mathbb{Q}$-definable) set must either vanish (“zero”) or fill almost all the space (“one”). The hierarchical version of the property basically says, “and the same holds recursively for these subspaces of lower dimension.”

The following theorem, whose proof is deferred to the full version of the paper, shows how these properties relate to weak $\mathbb{Q}$-definability.

▶ **Theorem 5.** *For all sets $X \subseteq \mathbb{Q}^d$ the following statements are equivalent:*

- *X is weakly $\mathbb{Q}$-definable,*
- *X has hierarchical 0–1 property,*
- *X has global 0–1 property, and*
- *X has $\|\Phi\|$-bounded 0–1 property, where Φ is a quantifier-free formula of linear rational arithmetic such that $X = [\![\Phi]\!]$.*

▶ **Example 6.** To illustrate the global version of the property, we demonstrate how from Theorem 5 we can derive that $\Phi(x, y) := x \geq 0 \wedge y = 0$ is not weakly $\mathbb{Q}$-definable. Observe that although $[\![\Phi]\!]$ satisfies the 0–1 property, it fails the global 0–1 property with $A = \{(x, 0) : x \in \mathbb{Q}\}$. Indeed, both $[\![\Phi]\!] \cap A$ and $A \setminus [\![\Phi]\!]$ are infinite sets, whereas every affine subspace of A of dimension lower than A, i.e., of dimension zero, is a single point. As a consequence, $[\![\Phi]\!] \cap A$ is not contained in a finite union of such subspaces, and neither is $A \setminus [\![\Phi]\!]$.

In comparison, $\Psi(x, y) := y = 0$ satisfies the global 0–1 property. We observe, for example, that for $A = \{(x, 0) : x \in \mathbb{Q}\}$ the set $A \setminus [\![\Psi]\!]$ is empty and thus contained in a finite union of subspaces of A of dimension $0 < \dim A$.

Note that the ℓ-bounded version of the property will later give a decision procedure for weak $\mathbb{Q}$-definability.

Weakly $\mathbb{Z}$-definable sets do not have to satisfy an immediate analogue of the 0–1 property: $2 \cdot \mathbb{Z} \subseteq \mathbb{Q}$ is an example of a weakly $\mathbb{Z}$-definable set failing the property. The following definition bridges this gap and requires instead that almost all the space is “tiled” by the set X in a periodic manner. Empty tiling (almost all space is empty, i.e., X vanishes) and full tiling ($\mathbb{Z}^d \setminus X$ vanishes in $\mathbb{Q}^d$) are special cases of this.

▶ **Definition 7.** *Suppose $X \subseteq \mathbb{Z}^d$. We say that X:*

- *has* mosaic property *with respect to an affine subspace A if there exists a hybrid $\mathbb{Z}$-linear set $F \subseteq A$ of dimension* $\dim A$ *such that $(X \cap A) \bigtriangleup F$ is contained in a finite union of affine subspaces inside A of dimension* $\dim A - 1$*,*

- *has* hierarchical mosaic property with respect to an affine subspace A *if it has mosaic property with respect to A, where the subspaces of lower dimension are some $H_1, \dots, H_m$, and, if* $\dim A > 1$*, it has hierarchical mosaic property with respect to each H_i, $1 \le i \le m$,*
- *has* (hierarchical) mosaic property *if it has (hierarchical) mosaic property with respect to $\mathbb{Q}^d$,*
- *has* global mosaic property *if, for every affine subspace $A \subseteq \mathbb{Q}^d$, it has mosaic property with respect to A,*
- *has* ℓ-bounded mosaic property *if, for every affine subspace $A = \{\boldsymbol{x} \in \mathbb{Q}^d : \boldsymbol{B} \cdot \boldsymbol{x} = \boldsymbol{c}\}$ with $\|\boldsymbol{B}\|, \|\boldsymbol{c}\| \le \ell$, it has mosaic property with respect to A.*

The intuition behind the variants of the mosaic property is the same as for the 0–1 property.

▶ **Example 8.** We show how the sets defined by the following logical formulae over the integers satisfy the hierarchical mosaic property.

1. $\Phi_1(x, y) := \exists u \exists v.(x = 3u \lor x = 3u + 1) \land y = 2v$. The mosaic property w.r.t. $\mathbb{Q}^2$ holds with $F = L_{\mathbb{Z}}(\{(0, 0), (1, 0)\}, \{(3, 0), (0, 2)\})$, because $[\![\Phi_1]\!]_{\mathbb{Z}} = F$. So the hierarchical mosaic property (w.r.t. $\mathbb{Q}^2$) holds too, with $m = 0$.
2. $\Phi_2(x, y) := (x = 0) \lor (y > 0) \lor (y < 0)$. The mosaic property w.r.t. $\mathbb{Q}^2$ holds with $F = \mathbb{Z}^2 = L_{\mathbb{Z}}(\mathbf{0}, \{\boldsymbol{e}_1, \boldsymbol{e}_2\})$, because we can pick an "exceptional" subspace $H_1 = \{(x, y) \in \mathbb{Q}^2 : y = 0\}$. Going inside H_1, we notice that $[\![\Phi_2]\!]_{\mathbb{Z}}$ also has the mosaic property w.r.t. H_1, because its intersection with H_1 is the singleton $\{\mathbf{0}\}$, so we can pick $F' = \emptyset$ and zero-dimensional subspace $H_{1,1} = \{\mathbf{0}\}$. Therefore, $[\![\Phi_2]\!]_{\mathbb{Z}}$ satisfies the hierarchical mosaic property (w.r.t. $\mathbb{Q}^2$).
3. $\Phi_3(x, y, z) := (y = 0 \land z = 0) \lor (x = 0 \land (\exists t. y = 2t) \land z = 0) \lor (x = 0 \land y = 0 \land (\exists t. z = 3t + 1))$. For the mosaic property w.r.t. $\mathbb{Q}^3$, we can pick $F = \emptyset$ with $H_1 = [\![x = 0]\!]_{\mathbb{Q}}$ and $H_2 = [\![y = 0]\!]_{\mathbb{Q}}$. The mosaic property w.r.t. H_1 holds with $F_1 = \emptyset$ and $H_{1,1} = [\![x = 0 \land z = 0]\!]_{\mathbb{Q}}$, $H_{1,2} = [\![x = 0 \land y = 0]\!]_{\mathbb{Q}}$. Similarly, the mosaic property w.r.t. H_2 holds with $F_2 = \emptyset$ and $H_{2,1} = [\![y = 0 \land z = 0]\!]_{\mathbb{Q}}$, $H_{2,2} = H_{1,2}$. We leave it as an exercise to the reader to check that $[\![\Phi_3]\!]_{\mathbb{Z}}$ has the mosaic property with respect to each of $H_{1,1}$, $H_{1,2}$, and $H_{2,1}$. In conclusion, $[\![\Phi_3]\!]_{\mathbb{Z}}$ has the hierarchical mosaic property (w.r.t. $\mathbb{Q}^3$).

The proof of the following theorem is deferred to the full version of this paper:

▶ **Theorem 9.** *There exists a function $f(s, d) \colon \mathbb{N} \times \mathbb{N} \to \mathbb{N}$, $f(n, d) = s^{d^{O(d)}}$, such that for all sets $X \subseteq \mathbb{Z}^d$ the following statements are equivalent:*

- *X is weakly $\mathbb{Z}$-definable,*
- *X has hierarchical mosaic property,*
- *X has global mosaic property, and*
- *X has $f(\|\Phi\|, d)$-bounded mosaic property, where Φ is an existential formula of linear integer arithmetic such that $X = [\![\Phi]\!]$.*

The function f gives an upper bound on the magnitude of coefficients in systems of linear equations that specify relevant affine subspaces. We can see from the theorem that, for fixed dimension d, the function f is at most polynomial; and in arbitrary dimension, the bit size of required coefficients is at most $d^{O(d)} \cdot \log\|\Phi\|$, a single exponential in d.

4.1 More on mosaic property

We introduce the following problem.

<u>Piece of Mosaic</u>

INPUT: Semilinear set $S \subseteq \mathbb{Z}^d$ in generator representation, system of equations $\boldsymbol{B}\cdot\boldsymbol{x} = \boldsymbol{c}$ with integer coefficients defining an affine subspace $A \subseteq \mathbb{Q}^d$.

OUTPUT: Hybrid $\mathbb{Z}$-linear set F represented as $F = \bigcup_{j\in J} L_{\mathbb{Z}}(C_j, Q_j)$ and such that, if S has mosaic property w.r.t. A, then $(S \triangle F) \cap A$ vanishes w.r.t. A.

Note that this is a promise problem: if S does *not* satisfy the mosaic property w.r.t. A, then no restriction is imposed on F.

The intuition for the name of this problem is that an algorithm for it "finds a piece of mosaic", F, in the set S: if S as a whole satisfies the mosaic property (w.r.t. A), then $S \cap A$ should really look like F everywhere in A (except for maybe lower-dimensional exceptions). But it is also possible that some parts of S are unlike F, and then S does not satisfy the mosaic property (in which case the algorithm may output any hybrid $\mathbb{Z}$-linear set).

Also note that, in the case that S satisfies the mosaic property, although the set F must be hybrid $\mathbb{Z}$-linear, the algorithm is permitted to output a $\mathbb{Z}$-semilinear representation of it. This is because the bit size and the norm can grow significantly if a hybrid $\mathbb{Z}$-linear representation is required. (For example, in dimension one, the set $\bigcup_{i=1}^{n} L_{\mathbb{Z}}(0, i)$ is hybrid $\mathbb{Z}$-linear, but all its representations as $L_{\mathbb{Z}}(C, Q)$ have bit size superpolynomial in n.)

▶ **Lemma 10.** *Let $t := (\|S\| + \|A\|)^{\mathrm{poly}(d)}$. The following statements hold:*

1. *If a semilinear set S satisfies the mosaic property with respect to an affine subspace A, then*
   - (a) *the set F in the definition of the property is determined uniquely and*
   - (b) *$(S \cap A) \triangle F$ is contained in a finite collection of affine subspaces of A of dimension $\dim A - 1$ each, defined by linear equations with integer coefficients of absolute value at most t.*
2. *There is a t-time algorithm that solves the Piece of Mosaic problem, which always produces an $F = \bigcup_{j\in J} L_{\mathbb{Z}}(C_j, Q_j)$ such that $\|C_j\|, \|Q_j\| \le t$.*

The proof is given in the full version of this paper.

▶ **Lemma 11.** *There is an algorithm with running time $2^{(\|A\|+\|S\|)^{\mathrm{poly}(d)}}$ that, given a semilinear set $S = \bigcup_{i\in I} L(B_i, P_i)$ and a system of equations $\boldsymbol{B}\cdot\boldsymbol{x} = \boldsymbol{c}$ with integer coefficients defining an affine subspace $A \subseteq \mathbb{Q}^d$, decides whether S has the mosaic property with respect to A.*

Proof. Run the algorithm from Lemma 10(2) to obtain a hybrid $\mathbb{Z}$-linear set F such that $\|F\| \le t$ with t defined as in the lemma. To check whether S has mosaic property, we determine whether $(S \cap A) \triangle F$ is vanishing. By Proposition 2, $A \cap \mathbb{Z}^d = L(C, Q)$ such that $\|C\|, \|Q\| \le \|A\|^{\mathrm{poly}(d)}$. Then from [2, Thm. 6], we get that $S \cap A = \bigcup_{k\in K} L(D_k, E_k)$ such that $\|D_k\|, \|E_k\| \le (\|S\| + \|A\|)^{\mathrm{poly}(d)}$. We compute the semilinear representation M of $((S \cap A) \setminus F) \cup (F \setminus (S \cap A))$. It follows the bounds on the description size of (each) set difference [2, Cor. 22] that $\log\|M\| \le (\|A\| + \|S\|)^{\mathrm{poly}(d)}$. In order to check whether $(S \cap A) \triangle F$ vanishes w.r.t. to A, it remains to iterate over all hybrid linear sets defining M and to check whether the dimension of the affine hull of the period vectors in each set is strictly less than $\dim A$. We remark that the upper bound on the running time holds, because $\|A\|$ and $\|S\|$ are at most exponential in the bit size of the encoding. ◀

▶ **Lemma 12.** *There is a doubly exponential algorithm that, given $\Phi \subseteq \mathbb{Z}^d$, decides whether $[\![\Phi]\!]$ has the $f(\|\Phi\|, d)$-bounded mosaic property, where f is defined as in Theorem 9.*

Proof. It follows from Proposition 3 that we can compute in time $2^{\text{poly}(|\Phi|)}$ the semilinear representation of $[\![\Phi]\!]$. The lemma then follows by an application of Lemma 11; note that the running time of the algorithm of that lemma has only a single exponential dependency on $\|S\| + \|A\|$. ◀

5 Computational complexity of weak $\mathbb{Q}$- and $\mathbb{Z}$-definability

Building upon the results in the previous sections, we now prove the main theorem of this paper.

▶ **Theorem 13.** *The weak $\mathbb{Q}$-definability problem is coNP-complete, and the weak $\mathbb{Z}$-definability problem is Π_2^{P}-hard and can be decided by an algorithm with elementary running time.*

We first outline the upper bounds of this theorem and then the lower bounds. The lower bound for weak $\mathbb{Z}$-definability already holds in a fixed dimension and is obtained from showing that the universality problem for one-dimensional semi-linear sets is Π_2^{P}-hard. We give the proof of Π_2^{P}-hardness of this universality problem in a separate Section 6.

5.1 Upper bounds for deciding weak $\mathbb{Q}$- and $\mathbb{Z}$-definability

By Theorem 5, a set $X \subseteq \mathbb{Q}^d$ given by a quantifier-free formula Φ of linear rational arithmetic is weakly $\mathbb{Q}$-definable if and only if for every affine subspace A, given by a system of linear equations $\boldsymbol{A} \cdot \boldsymbol{x} = \boldsymbol{c}$ such that $\|\boldsymbol{A}\|, \|\boldsymbol{c}\| \leq \|\Phi\|$, either $X \cap A$ or $A \setminus X = A \cap \overline{X}$ is contained in a finite union of affine subspaces of dimension $\dim A - 1$. To prove that Φ is not weakly $\mathbb{Q}$-definable, we attempt to find an affine subspace A such that neither $X \cap A$ nor $A \setminus X$ is contained in a finite union of affine subspaces of dimension $\dim A - 1$. Note that due to Φ being quantifier-free, $\neg\Phi$ is also a quantifier-free formula of linear rational arithmetic. Hence it will suffice to only discuss the case $X \cap A$; and, in this case, we can also assume without loss of generality that Φ is negation-free. Let Ψ be the disjunctive normal form of Φ. We clearly have $[\![\Psi]\!] = X$, and $[\![\Psi]\!] \cap A$ is not contained in a finite union of hyperplanes of dimension $\dim A - 1$ if and only if for some polyhedron P, defined by a conjunction of Ψ, the polyhedron $P \cap A$ has dimension $\dim A$. We now outline how to decide in polynomial time whether $\dim(P \cap A)$ equals $\dim A$.

Both P and A are given as systems of linear constraints, and hence we immediately obtain $P \cap A$ as a system of linear constraints. The dimension $\dim(P \cap A)$ is, by definition, equal to $\dim \operatorname{aff}(P \cap A)$. When $P \cap A$ is given by a system of non-strict linear inequalities, one can obtain in polynomial time a representation of $\operatorname{aff}(P \cap A)$ as the intersection of at most d implicit equalities of $P \cap A$, each obtained from a row of the system defining $P \cap A$ [15, p. 100]. One can then compute $\dim \operatorname{aff}(P \cap A)$, by (a variant of) Gaussian elimination [15, Section 3.3]. In general, the system of constraints defining P may contain strict inequalities though. However, this does not cause any problems, since for a polyhedron P, $\dim(P) = \dim(\operatorname{cl} P)$, where $\operatorname{cl} P$ is the closure of P. If $P \neq \emptyset$ and given as a system of linear constraints, $\operatorname{cl} P$ can be obtained by making all strict inequalities in the defining system of P non-strict.

From this line of reasoning, we obtain a coNP upper bound for deciding weak $\mathbb{Q}$-definability as follows. We guess $\boldsymbol{A}$ and $\boldsymbol{c}$ above in non-deterministic polynomial time. While the disjunctive normal forms of Φ and $\neg\Phi$ (both assumed negation-free, with no loss of generality) can be exponentially long, we can – given the formulas Φ and $\neg\Phi$ – guess a single conjunction of their disjunctive normal forms in non-deterministic polynomial time, by inspecting the structure of Φ and $\neg\Phi$. These two conjunctions induce polyhedra P and P'. We then decide in polynomial time whether the dimension of the polyhedra $P \cap A$ and $P' \cap A$ equals $\dim A$. We reject if and only if this is the case for both conjunctions.

We now turn towards a sketch of the upper bound for weak $\mathbb{Z}$-definability. To this end, let $X \subseteq \mathbb{Z}^d$ be defined by an existential formula $\Phi(\boldsymbol{x})$ of linear integer arithmetic. For an elementary upper bound, following Theorem 9 we iterate over all affine subspaces A given by systems of equations $\boldsymbol{B} \cdot \boldsymbol{x} = \boldsymbol{c}$ such that $\|\boldsymbol{B}\|, \|\boldsymbol{c}\|$ are at most $f(\|\Phi\|, d)$ and check whether Φ has mosaic property with respect to A. By Lemma 12, there is a doubly exponential algorithm that achieves this.

5.2 Lower bounds for deciding weak $\mathbb{Q}$-definability and $\mathbb{Z}$-definability

Lower bound for weak $\mathbb{Q}$-definability. We show a matching coNP-lower bound for deciding weak $\mathbb{Q}$-definability by a reduction from the problem of deciding whether a Boolean 3-DNF formula is a tautology. Let $\psi = \psi_1 \vee \cdots \vee \psi_k$ be in 3-DNF over Boolean variables $X_1, \ldots, X_d$. Let ϕ_1 be the formula of rational arithmetic obtained from ψ by applying the function h to every literal, with h defined as $h(X_i) := x_i = 1$ and $h(\neg X_i) := x_i = 0$. In addition, define

$$\phi_2 := \bigvee_{1 \le i \le d} x_i > 1 \vee x_i < 0 \vee (0 < x_i < 1)$$

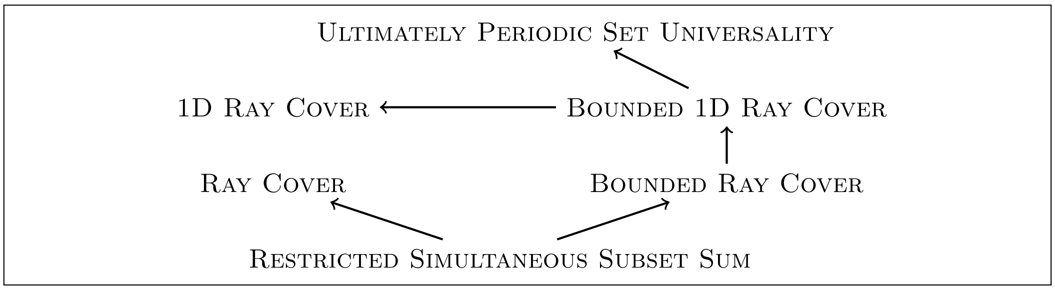
Observe that $[\![\phi_1 \vee \phi_2]\!]$ is the whole of $\mathbb{Q}^d$ except possibly a finite set of points corresponding to those truth assignments that do not make ψ evaluate to true, i.e., $[\![\phi_1 \vee \phi_2]\!] = \mathbb{Q}^d$ if and only if ψ is a tautology. Now define $\Phi := \phi_1 \vee \phi_2 \vee u > 0$, where u is a fresh variable. Note that $[\![\Phi]\!]$ is the whole of $\mathbb{Q}^{d+1}$ except possibly several half-lines that correspond to assignments falsifying ψ. If a half-line is missing then $[\![\Phi]\!]$ does not satisfy the global 0–1 property and is therefore not weakly $\mathbb{Q}$-definable, by Theorem 5. Otherwise no half-line is missing, ψ is a tautology, $[\![\Phi]\!]$ is equal to $\mathbb{Q}^d$ and is weakly $\mathbb{Q}$-definable.

Lower bound for weak $\mathbb{Z}$-definability. We show a Π_2^{P}-lower bound for weak $\mathbb{Z}$-definability via a reduction from the universality problem for semilinear sets. Given a semilinear set $M \subseteq \mathbb{N}^d$ in the generator representation, the *universality problem* is to decide whether $M = \mathbb{N}^d$. It was asked by Huynh [8] whether this problem is Π_2^{P}-hard when he established a Π_2^{P}-upper bound for this problem. We show in the next section that this is the case, even in dimension one, and assume hardness for now to show our lower bound for weak $\mathbb{Z}$-definability.

To this end, let $M = \bigcup_{i \in I} L(\boldsymbol{b}_i, P_i) \subseteq \mathbb{N}^d$. One easily constructs an existential formula $\psi(x_1, \ldots, x_d)$ of linear integer arithmetic such that $M = [\![\psi]\!]$. Now consider $\Phi(u, x_1, \ldots, x_d) := \psi \vee u > 0 \vee \bigvee_{i \in [d]} x_i < 0$, where u is a fresh variable. Analogously to what we showed above, $[\![\Phi]\!]$ is the whole of $\mathbb{Z}^{d+1}$ except possibly several "discrete half-lines" corresponding to elements $\boldsymbol{v} \in \mathbb{N}^d \setminus M$. By the global mosaic property (Theorem 9), $[\![\Phi]\!]$ is weakly $\mathbb{Z}$-definable if and only if no half-line is missing.

6 A lower bound for deciding universality of semilinear sets

We exclusively deal with $\mathbb{N}$-semilinear sets in this section and so, when presenting such semilinear sets in generator presentation, for readability, instead of writing, e.g., $L_{\mathbb{N}}(\boldsymbol{b}, P)$ we subsequently drop the subscript $\mathbb{N}$ and simply write $L(\boldsymbol{b}, P)$. The main result of this section is a Π_2^{P} lower bound for the universality problem for ultimately periodic sets, which are semilinear sets in dimension one:



Ultimately Periodic Set Universality
1D Ray Cover
Bounded 1D Ray Cover
Ray Cover
Bounded Ray Cover
Restricted Simultaneous Subset Sum

Figure 1 Reductions in the proof of Theorem 14. $X \to Y$ denotes a logarithmic-space reduction from X to Y.

Ultimately Periodic Set Universality

INPUT: Finite set I and, for each $i \in I$, a number $b_i \in \mathbb{N}$ and a finite set $P_i \subseteq \mathbb{N}$.
QUESTION: Is $\bigcup_{i \in I} L(b_i, P_i) = \mathbb{N}$?

Since a set $M \subseteq \mathbb{N}^d$ is universal if and only if $L(\mathbf{0}, \{\boldsymbol{e}_1, \ldots, \boldsymbol{e}_d\}) \subseteq M$, this universality problem is a special case of *inclusion* for semilinear sets, which asks to decide if $N \subseteq M$ for semilinear sets M, N. While inclusion for semilinear sets has been known to be Π_2^{P}-complete since the 1980s [8], the lower bound has only been strengthened to hold for inclusion of *linear* sets as recently as 2018 [4, Thm. 12], and then also to linear sets in dimension one [16]. It has also recently been shown that universality for linear sets is decidable in polynomial time, even for hybrid linear sets of the form $L(B, P) := \bigcup_{\boldsymbol{b} \in B} L(\boldsymbol{b}, P)$ [3].

Our new Π_2^{P} lower bound is based on a chain of reductions between intermediate problems that we now introduce. The overall reduction chain is displayed in Figure 1. Our starting point is the Simultaneous Subset Sum problem introduced in [4] from which we derive a slightly restricted version. Both problems are defined in Figure 2 and are variants of the classical subset sum problem. They ask whether all elements in a finite arithmetic progression can be obtained as sums of subsets of a given set $W \subseteq \mathbb{N}$.

Via a reduction from Restricted Simultaneous Subset Sum, we prove Π_2^{P}-hardness of two special cases of the semilinear set inclusion problem, Bounded Ray Cover and Ray Cover, which are defined in Figure 3. The problem Ray Cover asks whether a discrete ray in $\mathbb{N}^d$ (basically an arithmetic progression) is contained in an integer cone (linear set) – this is a restricted variant of linear set inclusion. The problem Bounded Ray Cover is the same but only concerns a finite segment of the ray. The Π_2^{P}-hardness of Ray Cover follows from that of Bounded Ray Cover.

Next, by a reduction from Bounded Ray Cover, we show Π_2^{P}-hardness of the one-dimensional versions of the ray cover problems, formally defined in Figure 4. A reduction from Bounded 1D Ray Cover will then give the desired Π_2^{P}-lower bound of Ultimately Periodic Set Universality.

▶ **Theorem 14.** *All six problems in Figure 1 are* Π_2^{P}*-complete.*

All upper bounds in Theorem 14 are easily obtained from the observation that the respective problems either reduce to semi-linear set inclusion, which is in Π_2^{P} [8], or involve sets of numbers of polynomial bit size.

To prove the lower bounds, once the intermediate problems have been identified, one of the key insights is in the reduction from Bounded Ray Cover to Bounded 1D Ray Cover, which maps a problem from $\mathbb{N}^d$ into $\mathbb{N}$. In the remainder of this section, we focus on the techniques that enable us to overcome this challenge.

SIMULTANEOUS SUBSET SUM

INPUT: Finite set $W \subseteq \mathbb{N}$, and $t, h, 2^m \in \mathbb{N}$ such that $t < h$.

QUESTION: For every $i \in [0, 2^m - 1]$, does there exist a $W' \subseteq W$ such that $\sum W' = t + i \cdot h$?

RESTRICTED SIMULTANEOUS SUBSET SUM

INPUT: Finite set $W \subseteq \mathbb{N}$ and $t, 2^k, 2^m \in \mathbb{N}$ such that $t < 2^k$.

QUESTION: For every $i \in [0, 2^m - 1]$, does there exist a $W' \subseteq W$ such that $\sum W' = t + i \cdot 2^k$?

Figure 2 The simultaneous subset sum problem introduced in [4] and its restricted version.

RAY COVER

INPUT: Finite set $P \subseteq \mathbb{N}^d$ and $a, 2^k \in \mathbb{N}$ such that $a < 2^k$.

QUESTION: Does $L(\mathbf{0}, P) \supseteq L(\boldsymbol{a}, \boldsymbol{b})$, where $\boldsymbol{a} = (a, \mathbf{1})$ and $\boldsymbol{b} = (2^k, \mathbf{0})$?

BOUNDED RAY COVER

INPUT: Finite set $P \subseteq \mathbb{N}^d$ and $a, 2^k, 2^m \in \mathbb{N}$ such that $a < 2^k$.

QUESTION: Does $L(\mathbf{0}, P) \supseteq L(\boldsymbol{a}, \boldsymbol{b}) \cap [0, B]^d$, where $\boldsymbol{a} = (a, \mathbf{1})$, $\boldsymbol{b} = (2^k, \mathbf{0})$, and $B = a + (2^m - 1) \cdot 2^k$?

Figure 3 Ray cover problems in arbitrary dimensions.

1D RAY COVER

INPUT: Finite set $P \subseteq \mathbb{N}$ and $a, 2^k \in \mathbb{N}$ such that $a < 2^k$.

QUESTION: Does $L(0, P) \supseteq L(a, b)$, where $b = 2^k$?

BOUNDED 1D RAY COVER

INPUT: Finite set $P \subseteq \mathbb{N}$ and $a, 2^k, 2^m \in \mathbb{N}$ such that $a < 2^k$.

QUESTION: Does $L(0, P) \supseteq L(a, b) \cap [0, B]$, where $b = 2^k$ and $B = a + (2^m - 1) \cdot b$?

Figure 4 Ray cover problems in dimension one.

6.1 Aggregation of several dimensions into one

Aggregation is an important technique in the theory of integer programming (see, e.g., Schrijver's book [15, Sections 16.6 and 18.2]). It has been used by Huynh [8] and Simon [16] for showing lower bounds for the inclusion problem for (semi)linear sets in dimension one. Aggregation can be achieved in the setting of linear Diophantine equations over nonnegative (integer) variables, following a classic result of Glover and Woolsey [7], which we extend.

As we already mentioned, we apply aggregation in order to reduce BOUNDED RAY COVER to BOUNDED 1D RAY COVER. In the former problem, think of vectors $\boldsymbol{v} \in L(\boldsymbol{a}, \boldsymbol{b}) \cap [0, B]^d$ as targets to hit. Each of them is hit if and only if $L(\mathbf{0}, P)$ contains it, i.e., if the system of equations $\boldsymbol{P} \cdot \boldsymbol{x} = \boldsymbol{v}$ has a solution in $\mathbb{N}^d$. The instance is a yes-instance if and only if all 2^m targets are hit. While Glover and Woolsey's result would allow us to aggregate *one* system of equations like this (for a single target) into a single equation, the key technical challenge in our setting is that – in contrast to [7, Thm. 3] – we need to aggregate *several* such systems, for 2^m different targets (each into its own one equation). That is, these systems have identical coefficients, but different constant terms.

For the following lemma, we will explain the rationale behind the constraints “α is a power of two” and “$\alpha/\beta > \max B$” subsequently.

▶ **Lemma 15.** *Let A, B be finite subsets of $\mathbb{N}_+$. Then there exist $\alpha, \beta \in \mathbb{N}$ such that α is a power of two, $\alpha/\beta > \max B$, and, for each pair $(a, b) \in A \times B$, every system of equations*

$$\begin{cases} \boldsymbol{c} \cdot \boldsymbol{x} = a \\ \boldsymbol{d} \cdot \boldsymbol{x} = b \end{cases}$$

with $\boldsymbol{c}, \boldsymbol{d} \in \mathbb{N}^d$ and $(a, b) \in A \times B$ has the same set of solutions in $\mathbb{N}^d$ as the single equation

$$(\alpha \boldsymbol{c} + \beta \boldsymbol{d}) \cdot \boldsymbol{x} = \alpha a + \beta b\,.$$

Moreover, α and β are polynomial-time computable from $\max A$ and $\max B$ and are independent of $\boldsymbol{c}$ and $\boldsymbol{d}$.

Proof. It follows from [7, Thm. 3] of Glover and Woolsey that when A and B are singletons $A = \{a\}$ and $B = \{b\}$ the statement holds if

$$\alpha > b, \qquad \beta > a, \quad \text{and} \quad \gcd(\alpha, \beta) = 1\,. \tag{1}$$

We show how to find a *single pair* of coefficients $\alpha, \beta \in \mathbb{N}$ that make Glover and Woolsey’s result applicable to the system in question for *all* pairs $(a, b) \in A \times B$. Indeed, choose r as the smallest power of two such that $r - 1$ strictly exceeds both $\max A$ and $\max B$. Pick $\beta = r - 1 > \max A$ and $\alpha = r^2$. We now check that α and β satisfy conditions (1). Observe that

$$\begin{aligned} \alpha &= r^2 > r - 1 > b, && \text{for all } b \in B, \\ \beta &= r - 1 > a, && \text{for all } a \in A, \end{aligned}$$

and $\gcd(\alpha, \beta) = \gcd\left((r - 1)(r + 1) + 1, r - 1\right) = 1$. It remains to note that $\alpha/\beta \geq r > \max B$. ◀

Note that Lemma 15 aggregates several systems using *the same* α and β. It guarantees that the numbers α and β stay small (have polynomial size) and satisfy additional constraints, to make the subsequent reduction from Bounded 1D Ray Cover to Ultimately Periodic Set Universality possible. We now discuss how these constraints arise.

6.2 Additional constraints and the final reduction

Let us take a step forward in the chain of reductions in Figure 1. We illustrate the significance of the additional requirements on the input of Bounded 1D Ray Cover using the following simple observation on the representation of the complement of a segment of a linear progression.

▶ **Lemma 16.** *Let $a, 2^k, 2^m \in \mathbb{N}$. Denote $b = 2^k$ and $B = a + (2^m - 1) \cdot b$, as in the input of Bounded 1D Ray Cover. Then the set $\mathbb{N} \setminus (L(a, b) \cap [0, B])$ is semilinear with a generator representation of size $O(\lfloor a/b \rfloor \log a + k^2 + m)$.*

Proof. Observe that $\mathbb{N} \setminus (L(a, b) \cap [0, B]) = \{n \in \mathbb{N} : n < a,\ n \equiv a \mod b\} \cup \{n \in \mathbb{N} : n \not\equiv a \mod b\} \cup \{n \in \mathbb{N} : n > B\}$. The third set on the right-hand side is $L(B + 1, 1)$, and the first set is a finite set with $\lfloor a/b \rfloor$ elements, i.e., a union of $\lfloor a/b \rfloor$ linear sets of the form $L(x, 0)$, $x < a$. For the second set, we will rely on the assumption that $b = 2^k$. Suppose that in binary we have $a \bmod b = a_{k-1} \cdot 2^{k-1} + \cdots + a_1 \cdot 2^1 + a_0 \cdot 2^0$, $a_i \in \{0, 1\}$. Notice that an arbitrary $n \in \mathbb{N}$ is not congruent to a modulo 2^k if and only if, for some $j \in \{0, \dots, k-1\}$, it is congruent to $c_j := \overline{a}_j \cdot 2^j + a_{j-1} \cdot 2^{j-1} \cdots a_1 \cdot 2^1 + a_0 \cdot 2^0$ modulo 2^{j+1}, where $\overline{a}_j = 1 - a_j$. Therefore, the second set in the equation above is equal to $\bigcup_{j=0}^{k-1} L(c_j, 2^{j+1})$. ◀

Given Lemma 16, the final reduction from Bounded 1D Ray Cover to Ultimately Periodic Set Universality is simple. Indeed, $L(0, P) \supseteq L(a, b) \cap [0, B]$ if and only if $L(0, P) \cup (\mathbb{N} \setminus (L(a, b) \cap [0, B])) = \mathbb{N}$, where the second set in the union is described by a semilinear set in generator representation of polynomial size. The bound on the size holds, because k and m cannot exceed the bit size of the input instance and $\lfloor a/b \rfloor = \lfloor a/2^k \rfloor = 0$ by the promise that $a < 2^k$ in the definition of Bounded 1D Ray Cover.

Note that the proof of Lemma 16 would work just as well if we had b equal to a power of 3, or a power of any other fixed number (other forms are also possible). For the input of Bounded 1D Ray Cover, any of these constraints is not difficult to satisfy on its own. In comparison, the dependence on $\lfloor a/b \rfloor$ in Lemma 16 is more important and more difficult to handle. We ensure in our chain of reductions from Restricted Simultaneous Subset Sum that $a/b < 1$; in particular, in our aggregation procedure (Lemma 15) we require that the coefficients α and β satisfy $\alpha/\beta > b$ The condition that α is a power of two comes from our preference to use an arithmetic progression with a difference of the form 2^v, $v \in \mathbb{N}$, in Lemma 16: $L(a, b)$, $b = 2^k$.

Detailed Π_2^{P}-hardness proofs for the lower bounds in Theorem 14 can be found in the full version of this paper.

7 Conclusion

Choffrut and Frigeri left open the question whether there is an algorithm with an elementary running time deciding weak $\mathbb{Z}$-definability [5]. We have shown in this article that this is the case. There still remains a significant gap between our Π_2^{P} lower bound and the rather crude upper bound that we obtained. Our algorithm is based on a geometric characterisation of sets definable in weak Presburger arithmetic that complements the generator characterisation obtained by Choffrut and Frigeri [5].

While weak definability is an interesting problem in its own right, another motivation for our work stems from the fact it is an open problem whether deciding weak Presburger arithmetic is computationally easier than deciding full Presburger arithmetic. In fact, in his original article [12], Presburger only showed decidability of weak Presburger arithmetic and remarked that his proof could be adapted to also work for Presburger arithmetic. We are unable to give an answer to this open problem at the present stage, but we believe that the geometric insights that enable us to show the elementary upper bounds of the weak definability problems may eventually help settling the computational complexity of weak Presburger arithmetic. Note that deciding weak linear rational arithmetic has essentially the same complexity as linear rational arithmetic [14].

Abstract

A marked free monoid morphism is a morphism for which the image of each generator starts with a different letter, and immersions are the analogous maps in free groups. We show that the (simultaneous) PCP is decidable for immersions of free groups, and provide an algorithm to compute bases for the sets, called equalisers, on which the immersions take the same values. We also answer a question of Stallings about the rank of the equaliser.

Analogous results are proven for marked morphisms of free monoids.

1 Introduction

In this paper we prove results about the classical Post Correspondence Problem ($\mathrm{PCP}_{\mathrm{FM}}$), which we state in terms of equalisers of free monoid morphisms, and the analogue problem $\mathrm{PCP}_{\mathrm{FG}}$ for free groups ([5], [19]), and we describe the solutions to $\mathrm{PCP}_{\mathrm{FM}}$ and $\mathrm{PCP}_{\mathrm{FG}}$ for certain classes of morphisms. While the classical $\mathrm{PCP}_{\mathrm{FM}}$ is famously undecidable for arbitrary maps of free monoids [21] (see also the survey [12] and the recent result of Neary [20]), $\mathrm{PCP}_{\mathrm{FG}}$ for free groups is an important open question [8, Problem 5.1.4]. Additionally, for both free monoids and free groups there are only few results describing algebraically the solutions to classes of instances known to have decidable $\mathrm{PCP}_{\mathrm{FM}}$ or $\mathrm{PCP}_{\mathrm{FG}}$. Our results apply to *marked* morphisms in the monoid case, and to their counterparts in free groups, called *immersions*. Marked morphisms are the key tool used in resolving the $\mathrm{PCP}_{\mathrm{FM}}$ for the free monoid of rank two [9], and therefore understanding the solutions to the $\mathrm{PCP}_{\mathrm{FG}}$ for immersions is an important step towards resolving the $\mathrm{PCP}_{\mathrm{FG}}$ for the free group of rank two. The density of marked morphisms and immersions among all the free monoid or group maps is strictly positive (Section 10), so our results concern a significant proportion of instances.

An *instance* of the $\mathrm{PCP}_{\mathrm{FM}}$ is a tuple $I = (\Sigma, \Delta, g, h)$, where Σ, Δ are finite alphabets, Σ^*, Δ^* are the respective free monoids, and $g, h : \Sigma^* \to \Delta^*$ are morphisms. The *equaliser* of g, h is $\mathrm{Eq}(g, h) = \{x \in \Sigma^* \mid g(x) = h(x)\}$. The $\mathrm{PCP}_{\mathrm{FM}}$ is the decision problem:

$\mathrm{PCP}_{\mathbf{FM}}$: Given $I = (\Sigma, \Delta, g, h)$, is the equaliser $\mathrm{Eq}(g, h)$ trivial?

Analogously, an instance of the $\mathrm{PCP}_{\mathrm{FG}}$ is a four-tuple $I = (\Sigma, \Delta, g, h)$ with $g, h : F(\Sigma) \to F(\Delta)$ morphisms between the free groups $F(\Sigma)$ and $F(\Delta)$, and $\mathrm{PCP}_{\mathrm{FG}}$ is the decision problem pertaining to the similarly defined $\mathrm{Eq}(g, h)$ in free groups.

Beyond $\mathrm{PCP}_{\mathrm{FM}}$, in this paper we also consider the *Algorithmic Equaliser Problem*, denoted $\mathrm{AEP}_{\mathrm{FM}}$ (or $\mathrm{AEP}_{\mathrm{FG}}$ in the group case), which for an instance $I = (\Sigma, \Delta, g, h)$ with g, h free monoid morphisms (or free group morphisms for $\mathrm{AEP}_{\mathrm{FG}}$), says:

$\mathrm{AEP}_{\mathbf{FM}}$: Given $I = (\Sigma, \Delta, g, h)$, output

(a) a finite basis for $\mathrm{Eq}(g, h)$, or

(b) a finite automaton recognising the set $\mathrm{Eq}(g, h)$.

If a finite basis or finite automaton for $\mathrm{Eq}(g, h)$ does not exist then Part (a) or (b), respectively, of the problem is insoluble. Note that (a) and (b) are connected: for free groups these two problems are in fact the same when $\mathrm{Eq}(g, h)$ is finitely generated, while for free monoids (a) implies (b). Part (a) of the $\mathrm{AEP}_{\mathrm{FM}}$ is known to be soluble when $|\Sigma| = 2$ and one of g or h is non-periodic, and insoluble otherwise [13] [12, Corollary 6].

Sets of morphisms. We are particularly interested in sets S of morphisms (not just two morphisms f, g) and their equalisers $\mathrm{Eq}(S) = \bigcap_{g,h\in S} \mathrm{Eq}(g, h)$, and we prove structural results for arbitrary sets and algorithmic results for finite sets. Our results resolve the *simultaneous* $\mathrm{PCP}_{\mathrm{FG}}$ *and* $\mathrm{PCP}_{\mathrm{FM}}$ for immersions and marked morphisms; these problems take as input a finite set S of maps and ask the same questions about equalisers as in the classical setting. Analogously, one could further define the "simultaneous $\mathrm{AEP}_{\mathrm{FG}}$ and $\mathrm{AEP}_{\mathrm{FM}}$". However, the simultaneous $\mathrm{AEP}_{\mathrm{FG}}$ is equivalent to the $\mathrm{AEP}_{\mathrm{FG}}$, and Part (b) of the simultaneous $\mathrm{AEP}_{\mathrm{FM}}$ is equivalent to Part (b) of the $\mathrm{AEP}_{\mathrm{FM}}$, as follows. As bases of intersections of finitely generated subgroups of free groups are computable (and as Parts (a) and (b) of the $\mathrm{AEP}_{\mathrm{FG}}$ are equivalent), if the $\mathrm{AEP}_{\mathrm{FG}}$ is soluble for a class $\mathcal{C}$ of maps then there exists an algorithm with input a finite set S of morphisms from $F(\Sigma)$ to $F(\Delta)$, $S \subseteq \mathcal{C}$, and output a basis for $\mathrm{Eq}(S)$. Similarly, automata accepting intersections of regular languages are computable, and so if Part (b) of the $\mathrm{AEP}_{\mathrm{FM}}$ is soluble for a class $\mathcal{C}$ of maps then there exists an algorithm with input a finite set S of morphisms from Σ^* to Δ^*, $S \subseteq \mathcal{C}$, and output a finite automaton whose language is $\mathrm{Eq}(S) = \bigcap_{g,h\in S} \mathrm{Eq}(g, h)$.

Main results. A set of words $\mathbf{s} \subseteq \Delta^*$ is *marked* if any two distinct $u, v \in \mathbf{s}$ start with a different letter of Δ, which implies $|\mathbf{s}| \leqslant |\Delta|$. A free monoid morphism $f : \Sigma^* \to \Delta^*$ is *marked* if the set $f(\Sigma)$ is marked. An *immersion of free groups* is a morphism $f : F(\Sigma) \to F(\Delta)$ where the set $f(\Sigma \cup \Sigma^{-1})$ is marked (see Section 3 for equivalent formulations). Halava, Hirvensalo and de Wolf [11] showed that $\mathrm{PCP}_{\mathrm{FM}}$ is decidable for marked morphisms; inspired by their methods we were able to obtain stronger results (Theorem A) for this kind of map, as well as expand to the world of free groups (Theorem C), where we employ "finite state automata"-like objects called *Stallings graphs.*

▶ **Theorem A.** *If S is a set of marked morphisms from Σ^* to Δ^*, then there exists a finite alphabet Σ_S and a marked morphism $\psi_S : \Sigma_S^* \to \Sigma^*$ such that* $\mathrm{Image}(\psi_S) = \mathrm{Eq}(S)$*. Moreover, for S finite, there exists an algorithm with input S and output the marked morphism ψ_S.*

▶ **Corollary B.** *The simultaneous* $\mathrm{PCP}_{\mathrm{FM}}$ *is decidable for marked morphisms of free monoids.*

▶ **Theorem C.** *If S is a set of immersions from $F(\Sigma)$ to $F(\Delta)$, then there exists a finite alphabet Σ_S and an immersion $\psi_S : F(\Sigma_S) \to F(\Sigma)$ such that* $\mathrm{Image}(\psi_S) = \mathrm{Eq}(S)$*. Moreover, when S is finite, there exists an algorithm with input S and output the immersion ψ_S.*

▶ **Corollary D.** *The simultaneous* $\mathrm{PCP}_{\mathrm{FG}}$ *is decidable for immersions of free groups.*

The Equaliser Conjecture. Our work was partially motivated by Stallings' Equaliser Conjecture for free groups, which dates from 1984 [22, Problems P1 & 5] (also [7, Problem 6] [24, Conjecture 8.3] [1, Problem F31]). Here $\mathrm{rk}(H)$ stands for the *rank*, or minimum number of generators, of a subgroup H:

▶ **Conjecture 1** (The Equalizer Conjecture, 1984)**.** *If $g, h : F(\Sigma) \to F(\Delta)$ are injective morphisms then* $\mathrm{rk}(\mathrm{Eq}(g, h)) \leqslant |\Sigma|$.

This conjecture has its roots in "fixed subgroups" $\mathrm{Fix}(\phi)$ of free group endomorphisms $\phi : F(\Sigma) \to F(\Sigma)$ (if $\Sigma = \Delta$ then $\mathrm{Fix}(\phi) = \mathrm{Eq}(\phi, \mathrm{id})$), where Bestvina and Handel proved that $\mathrm{rk}(\mathrm{Fix}(\phi)) \leqslant |\Sigma|$ for ϕ an automorphism [3], and Imrich and Turner extended this bound to all endomorphisms [14]. Bergman further extended this bound to all sets of endomorphisms [2]. Like Bergman's result, our first corollary of Theorem C considers sets of immersions, which are injective, and answers Conjecture 1 for immersions.

▶ **Corollary E.** *If S is a set of immersions from $F(\Sigma)$ to $F(\Delta)$ then* $\mathrm{rk}(\mathrm{Eq}(S)) \leqslant |\Sigma|$.

In free monoids, equalisers of injections are free [12, Corollary 4] but they are not necessarily regular languages (and hence not necessarily finitely generated) [12, Example 6]. In order to understand equalisers $\mathrm{Eq}(S)$ of sets of maps we need to understand intersections in free monoids. Recall that the intersection $A^* \cap B^*$ of two finitely generated free submonoids of a free monoid Σ^* is free [23] and one can find a regular expression that represents a basis of $A^* \cap B^*$ [4]. However, the intersection is not necessarily finitely generated [17]. The following result is surprising because we have finite generation, even for the intersection $\mathrm{Eq}(S) = \bigcap_{g,h \in S} \mathrm{Eq}(g, h)$.

▶ **Corollary F.** *If S is a set of marked morphisms from Σ^* to Δ^* then* $\mathrm{Eq}(S)$ *is a free monoid with* $\mathrm{rk}(\mathrm{Eq}(S)) \leqslant |\Sigma|$.

The Algorithmic Equaliser Problem. The $\mathrm{AEP}_{\mathrm{FG}}$ is insoluble in general, as equalisers in free groups are not necessarily finitely generated [24, Section 3], and is an open problem of Stallings' if both maps are injective [22, Problems P3 & 5]. Our next corollary of Theorem C resolves this open problem for immersions.

▶ **Corollary G.** *The* $\mathrm{AEP}_{\mathrm{FG}}$ *is soluble for immersions of free groups.*

The $\mathrm{AEP}_{\mathrm{FM}}$ is insoluble in general, primarily as equalisers are not necessarily regular languages [10, Example 4.6]. Even for maps whose equalisers form regular languages, the problem remains insoluble [18]. Another corollary of Theorem A is the following.

▶ **Corollary H.** *The* $\mathrm{AEP}_{\mathrm{FM}}$ *is soluble for marked morphisms of free monoids.*

Outline of the article. In Section 2 we prove Theorem A and its corollaries about free monoids. The remainder of the paper focuses on free groups, where the central result is Theorem 18, which is Theorem C for $|S| = 2$. In Section 3 we reformulate immersions in terms of Stallings' graphs, and in Section 4 define the "reduction" $I' = (\Sigma', \Delta', g', h')$ of an instance $I = (\Sigma, \Delta, g, h)$ of the $\mathrm{AEP}_{\mathrm{FG}}$ for immersions. Repeatedly computing reductions is the key process in our algorithm. In Section 5 we prove the process of reduction decreases the "prefix complexity" of an instance (so the word "reduction" makes sense), and in Section 6 we prove Theorem 18, mentioned above. In Section 7 we prove Theorem C and its corollaries. In Section 9 we give a complexity analysis for both our free monoid and free group algorithms, and in Section 10 we show that the density of marked morphisms and immersions among all the free monoid or group maps is strictly positive.

2 Marked morphisms in free monoids

In this section we prove Theorem A and its corollaries. We use the following immediate fact.

▶ **Lemma 2.** *Marked morphisms of free monoids are injective.*

Proof. Let $f : \Sigma^* \to \Delta^*$ be marked and let $x \neq y$ be nontrivial. One can write $x = zax'$ and $y = zby'$, where $a, b \in \Sigma$ are the first letter where x and y differ. As f is marked, $f(a) \neq f(b)$, hence $f(x) = f(z)f(a)f(x') \neq f(z)f(b)f(y') = f(y)$, so f is injective. ◀

We may assume $\Sigma \subseteq \Delta$, as $|\Sigma| \leqslant |\Delta|$ holds whenever $f : \Sigma^* \to \Delta^*$ is marked.

Consider morphisms $g : \Sigma_1^* \to \Delta^*$ and $h : \Sigma_2^* \to \Delta^*$. The set of non-empty words over an alphabet Σ is denoted Σ^+. For $a \in \Delta$, a pair $(u, v) \in \Sigma_1^+ \times \Sigma_2^+$ is an *a-block* if (i) $g(u) = h(v)$ starts with a, and (ii) u and v are minimal, that is, the length $|g(u)| = |h(v)|$ is minimal among all such pairs. If the pair (g, h) has blocks $a_i = (u_i, v_i)$, $1 \leqslant i \leqslant m$, then let Σ' be the alphabet consisting of these blocks and define $g' : (\Sigma')^* \mapsto \Sigma_1^*$ by $g'(a_i) = u_i$ and $h' : (\Sigma')^* \mapsto \Sigma_2^*$ by $h'(a_i) = v_i$. These maps are computable and, by an identical logic to [11, Section 2], are seen to be marked. Then $gg' = hh'$, and we let $k = gg' = hh'$ (so $k : (\Sigma')^* \to \Delta^*$). Since k is the composition of marked morphisms, it is itself marked. We therefore have the following.

▶ **Lemma 3.** *If $g : \Sigma_1^* \to \Delta^*$ and $h : \Sigma_2^* \to \Delta^*$ are marked morphisms then the corresponding maps $g' : \Sigma'^* \to \Sigma_1^*$, $h' : \Sigma'^* \to \Sigma_2^*$ and $k : \Sigma'^* \to \Delta^*$, $k = gg' = hh'$, are marked and are computable.*

The *reduction* of an instance $I = (\Sigma, \Delta, g, h)$ of the marked $\mathrm{PCP}_{\mathrm{FM}}$, as defined in [11], is the instance $I' := (\Sigma', \Delta, g', h')$ where Σ' is defined as above, and where g' and h' are as above, but with codomain Δ (which we may do as $\Sigma \subseteq \Delta$). We additionally assume that $\Sigma' \subseteq \Sigma$; we can do this as $|\Sigma'| \leqslant |\Sigma|$ by Lemma 3.

The following relies on [11, Lemma 1], which we strengthen by replacing the notion of "equivalence" with that of "strong equivalence": Two instances I_1 and I_2 of the $\mathrm{PCP}_{\mathrm{FM}}$ are *strongly equivalent* if their equalisers are isomorphic, which we write as $\mathrm{Eq}(I_1) \cong \mathrm{Eq}(I_2)$.

▶ **Lemma 4.** *Let $I' = (\Sigma', \Delta', g', h')$ be the reduction of $I = (\Sigma, \Delta, g, h)$ where g and h are marked. Then I and I' are strongly equivalent, and $g'(\mathrm{Eq}(I')) = \mathrm{Eq}(I) = h'(\mathrm{Eq}(I'))$.*

Proof. Firstly, note that $g'(\mathrm{Eq}(I')) \leqslant \mathrm{Eq}(I)$ [11, Lemma 1, paragraph 2]. From [11, Lemma 1, paragraph 1] it follows that $g'(\mathrm{Eq}(I')) \geqslant \mathrm{Eq}(I)$, so $g'(\mathrm{Eq}(I')) = \mathrm{Eq}(I)$. As g' is injective, the map $g'|_{\mathrm{Eq}(I')}$ is an isomorphism. Hence, I and I' are strongly equivalent, and, by symmetry for the h' map, $g'(\mathrm{Eq}(I')) = \mathrm{Eq}(I) = h'(\mathrm{Eq}(I'))$ as required. ◀

We can now improve the existing result on the marked $\mathrm{PCP}_{\mathrm{FM}}$. We store a morphism $f : \Sigma^* \to \Delta^*$ as a list $(f(a))_{a \in \Sigma}$.

▶ **Theorem 5.** *If $I = (\Sigma, \Delta, g, h)$ is an instance of the marked* $\mathrm{PCP}_{\mathrm{FM}}$ *then there exists an alphabet $\Sigma_{g,h}$ and a marked morphism $\psi_{g,h} : \Sigma^*_{g,h} \to \Sigma^*$ such that* $\mathrm{Image}(\psi_{g,h}) = \mathrm{Eq}(I)$. *Moreover, there exists an algorithm with input I and output the marked morphism $\psi_{g,h}$.*

Proof. We explain the algorithm, and note at the end that the output is a marked morphism $\psi_{g,h} : F(\Sigma_{g,h}) \to F(\Sigma)$ with the required properties, and so the result follows.

Begin by making reductions $I_0, I_1, I_2, \ldots$, starting with $I_0 = I = (\Sigma, \Delta, g, h)$, the input instance. Then by [11, Section 5, paragraph 1] we will obtain an instance $I_j = (\Sigma_j, \Delta, g_j, h_j)$ such that one of the following will occur:

1. $|\Sigma_j| = 1$.
2. $|g_j(a)| = 1 = |h_j(a)|$ for all $a \in \Sigma_j$.
3. There exists some $i < j$ with $I_i = I_j$ (sequence starts cycling).

Keeping in mind the fact that reductions preserve equalisers (Lemma 4), we obtain in each case a subset $\Sigma_{g,h}$ (possibly empty) which forms a basis for $\mathrm{Eq}(I_j)$: For Case (1), writing $\Sigma_j = \{a\}$, the result holds as if $g(a^i) = h(a^i)$ then $g(a)^i = h(a)^i$ and so $g(a) = h(a)$ as roots are unique in a free monoid. For Case (2), suppose $g_j(x) = h_j(x)$. Then g_j and h_j agree on the first letter of $x \in \Sigma^*_j$ because the image of each letter has length one, and inductively we see that they agree on every letter of x. Hence, a subset $\Sigma_{g,h}$ of Σ_j forms a basis for $\mathrm{Eq}(I_j)$.

For Case (3), suppose there is a sequence of reductions beginning and ending at I_j:

$$I_j \to I_{j+1} \to \cdots \to I_{j+(i-1)} \to I_{j+i} = I_j$$

and write $r := j + i$. By Lemma 4, $\mathrm{Eq}(I_j) = g_{j+1}g_{j+2}\ldots g_r(\mathrm{Eq}(I_r)) = \mathrm{Eq}(I_r)$; thus $\overline{g_r} := g_{j+1}g_{j+2}\ldots g_r$ restricts to an automorphism of $\mathrm{Eq}(I_j)$, so $\overline{g_r}|_{\mathrm{Eq}(I_j)} \in \mathrm{Aut}(\mathrm{Eq}(I_j))$. The automorphism $\overline{g_r}$ is necessarily length-preserving ($|\overline{g_r}(w)| = |w|$ for all $w \in \mathrm{Eq}(I_j)$). Consider $x \in \mathrm{Eq}(I_j) = \mathrm{Eq}(I_r)$. Then $\overline{g_r}$ maps the letters occurring in x_r to letters and so $g_j(= g_r)$ and $h_j(= h_r)$ map the letters occuring in x to letters, and it follows that every letter occuring in x is a solution to $I_r = I_j$. Hence, a subset $\Sigma_{g,h}$ of Σ_j forms a basis for $\mathrm{Eq}(I_j)$ as required.

Therefore, in all three cases a subset $\Sigma_{g,h}$ of Σ_j forms a basis for $\mathrm{Eq}(I_j)$, and since Σ_j is computable, this basis is as well. In order to prove the theorem, it is sufficient to prove that there is a computable immersion $\psi_{g,h} : \Sigma^*_{g,h} \to \Sigma^*$. Consider the map $\tilde{g} = g_1g_2\cdots g_j : \Sigma^*_j \to \Sigma^*$ (and the analogous $\tilde{h}$). Now, each g_i is marked, by Lemma 3, and so $\tilde{g}$ is the composition of marked morphisms and hence is marked itself. Define $\psi_{g,h} := \tilde{g}|_{\Sigma^*_{g,h}}$. This map is computable from $\tilde{g}$, and as $\Sigma_{g,h} \subseteq \Sigma_j$, the map $\psi_{g,h}$ is marked. As $\mathrm{Image}(\psi_{g,h}) = g_1g_2\ldots g_j(\mathrm{Eq}(I_j)) = \mathrm{Eq}(I)$, by Lemma 4 and the above, the result follows. ◀

Theorem 5 together with Lemma 6 give the non-algorithmic part of Theorem A. A subsemigroup M of a free monoid Σ^* is *marked* if it is the image of a marked morphism.

▶ **Lemma 6.** *If $\{M_j\}_{j\in J}$ is a set of marked subsemigroups of Σ^* then the intersection $\bigcap_{j\in J} M_j$ is marked.*

Proof. Firstly, suppose $x, y \in M_j$ for some $j \in J$. Then there exist two words $x_0 \ldots x_l$ and $y_0 \ldots y_k$, with $x_i, y_i \in \Sigma$, such that $\phi(x_0 \ldots x_l) = x$ and $\phi(y_0 \ldots y_k) = y$, where ϕ is a marked morphism. If x and y have a nontrivial common prefix, then because ϕ is marked we get $x_0 = y_0$, and $\phi(x_0)$ is a prefix of both x and y, and in particular $\phi(x_0) \in M_j$. By continuing this argument, if z is a maximal common prefix of x and y, then $z \in M_j$.

Now, suppose $x, y \in \bigcap_{j\in J} M_j$, and suppose they both begin with some letter $a \in \Sigma \cup \Sigma^{-1}$. By the above, their maximal common prefix z_a is contained in each M_j and so is contained in $\bigcap_{j\in J} M_j$. Therefore, z_a is a prefix of every element of $\bigcap_{j\in J} M_j$ beginning with an a. It follows that $\bigcap_{j\in J} M_j$ is immersed, as required. ◀

We now prove the algorithmic part of Theorem A (this is independent of Lemma 6).

▶ **Lemma 7.** *There exists an algorithm with input a finite set of marked morphisms S from Σ^* to Δ^* and output a marked morphism $\psi_S : \Sigma_S^* \to \Sigma^*$ such that* $\mathrm{Image}(\psi_S) = \mathrm{Eq}(S)$*.*

Proof. We use induction on $|S|$. By Theorem 5, the result holds if $|S| = 2$. Suppose the result holds for all sets of n marked morphisms, $n \geqslant 2$, and let S be a set of $n+1$ marked morphisms. Take elements $g, h \in S$, and write $S_g = S \setminus \{g\}$. By hypothesis, we can algorithmically obtain marked morphisms $\psi_{S_g} : \Sigma_{S_g}^* \to \Sigma^*$ and $\psi_{g,h} : \Sigma_{g,h}^* \to \Sigma^*$ such that $\mathrm{Image}(\psi_{S_g}) = \mathrm{Eq}(S_g)$ and $\mathrm{Image}(\psi_{g,h}) = \mathrm{Eq}(g, h)$.

By Lemma 3, there exists a (computable) marked morphism $\psi_S : \Sigma_S^* \to \Sigma^*$ such that $\mathrm{Image}(\psi_S) = \mathrm{Image}(\psi_{S_g}) \cap \mathrm{Image}(\psi_{g,h})$ (the map ψ_S corresponds to the map k in Lemma 3, and Σ_S to Σ'). Then, as required: $\mathrm{Image}(\psi_S) = \mathrm{Image}(\psi_{S_g}) \cap \mathrm{Image}(\psi_{g,h}) = \mathrm{Eq}(S_g) \cap \mathrm{Eq}(g, h) = \mathrm{Eq}(S)$. ◀

We now prove Theorem A, which states that the equaliser is the image of a marked map.

Proof of Theorem A. By applying Lemma 6 to Theorem 5, there exists an alphabet Σ_S and a marked morphism $\psi_S : \Sigma_S^* \to \Sigma^*$ such that $\mathrm{Image}(\psi_S) = \mathrm{Eq}(S)$, while by Lemma 7 if S is finite then such a marked morphism can be algorithmically found. ◀

We now prove Corollary F, which says that $\mathrm{Eq}(S)$ is free of rank $\leqslant |\Sigma|$.

Proof of Corollary F. Consider the marked morphism $\psi_S : \Sigma_S^* \to \Sigma^*$ given by Theorem A. By Lemma 2, ψ_S is injective so $\mathrm{Image}(\psi_S)$ is free. As ψ_S is marked the map $\Sigma_S \to \Sigma$ taking each $a \in \Sigma_S$ to the initial letter of $\psi_S(a)$ is an injection, so $|\Sigma_S| \leqslant |\Sigma|$ as required. ◀

We now prove a strong form of the $\mathrm{AEP}_{\mathrm{FM}}$ for marked morphisms.

▶ **Corollary 8.** *There exists an algorithm with input a finite set S of marked morphisms from Σ^* to Δ^* and output a basis for* $\mathrm{Eq}(S)$*.*

Proof. To algorithmically obtain a basis for $\mathrm{Eq}\,(S)$, first use the algorithm of Theorem A to obtain the marked morphism $\overline{\psi}_S : \Sigma_S^* \to \Sigma^*$ such that $\mathrm{Image}(\psi_S) = \mathrm{Eq}(S)$. Then, recalling that we store ψ_S as a list $(\psi_S(a))_{a \in \Sigma}$, the required basis is the set of elements in this list, so the set $\{\psi_S(a)\}_{a \in \Sigma}$. ◀

Corollary H, the $\mathrm{AEP}_{\mathrm{FM}}$ for marked morphisms, follows from Corollary 8 by taking $|S| = 2$, while Corollary B, the simultaneous $\mathrm{PCP}_{\mathrm{FM}}$, also follows as $\mathrm{Eq}\,(S)$ is trivial if and only if its basis is empty.

3 Immersions of free groups

We denote the free group with finite generating set Σ by $F(\Sigma)$, and view it as the set of all *freely reduced words* over $\Sigma^{\pm 1} = \Sigma \cup \Sigma^{-1}$, that is, words not containing xx^{-1} as subwords, $x \in \Sigma^{\pm 1}$, together with the operations of concatenation and free reduction (that is, the removal of any xx^{-1} that might occur when concatenating two words).

We now begin our study of immersions of free groups, as defined in the introduction. We first state the characterising lemma, then explain the terms involved before giving the proof.

▶ **Lemma 9.** *Let $g : F(\Sigma) \to F(\Delta)$ be a free group morphism. The following are equivalent.*

1. *The map g is an immersion of free groups.*
2. *Every word in the language $L(\Gamma_g, v_g)$ is freely reduced.*
3. *For all $x, y \in \Sigma \cup \Sigma^{-1}$ such that $xy \neq 1$, the length identity $|g(xy)| = |g(x)| + |g(y)|$ holds.*

Characterisation (3) is the established definition of Kapovich [15]. Characterisation (2) is the one we shall work with in this article. It uses "Stallings graphs", which are essentially finite state automata that recognise the elements of finitely generated subgroups of free groups. We define these now, and refer the reader to [16] for background on Stallings graphs.

The *(unfolded) Stallings graph* Γ_g of the free group morphism g is the directed graph formed by taking a bouquet with $|\Sigma|$ petals attached at a central vertex we call v_g, where each petal consists of a path labeled by $g(x) \in (\Delta \cup \Delta^{-1})^*$; the elements of Δ^{-1} occur as edges traversed backwards and we denote by e^{-1} the edge e in opposite direction, and by $E\Gamma_g^{\pm 1}$ the sets of edges in both directions. A path $q = (e_1, \dots, e_n)$, $e_i \in E\Gamma_g^{\pm 1}$ edges, is *reduced* if it has no backtracking, that is, $e_i^{-1} \neq e_{i+1}$ for all $1 \leqslant i < n$. We denote by $\iota(p)$ the initial vertex of a path p and $\tau(p)$ for the terminal vertex, and call a reduced path p with $\iota(p) = u = \tau(p)$ a *closed reduced circuit.*

We shall view Γ_g as a finite state automaton (Γ_g, v_g) with start and accept states both equal to v_g. Then the *extended language accepted by* (Γ_g, v_g) is the set of words labelling reduced closed circuits at v_g in Γ_g:

$$L(\Gamma_g, v_g) = \{label(p) \mid p \text{ is a reduced path with } \iota(p) = u = \tau(p)\}.$$

Immersions are precisely those maps g such that every element of $L(\Gamma_g, v_g)$ is freely reduced; this corresponds to the automaton (Γ_g, v_g) and the "reversed" automaton $(\Gamma_g, v_g)^{-1}$, where edge directions are reversed, both being deterministic (map g in Figure 1 is not an immersion; although the automaton (Γ_g, v_g) is deterministic, $(\Gamma_g, v_g)^{-1}$ is not). For such maps, $L(\Gamma_g, v_g)$ is precisely the image of the map g [16, Proposition 3.8].

Proof of Lemma 9. (1) $\Leftrightarrow$ (2). Every element of $L(\Gamma_g, v_g)$ is freely reduced if and only if the graph Γ_g, with base vertex v_g, is such that for all $e_1, e_2 \in (E\Gamma_g)^{\pm 1}$ such that both edes start at v_g or both edges end at v_g, then e_1 and e_2 have different labels (so $\gamma_g(e_1) \neq \gamma_g(e_2)$). This condition on labels is equivalent to $g(\Sigma \cup \Sigma^{-1})$ being marked, as required.

(1) $\Leftrightarrow$ (3). Condition (3) is equivalent to the condition that for all $x, y \in \Sigma \cup \Sigma^{-1}$ such that $xy \neq 1$, free cancellation does not happen between $g(x)$ and $g(y)$, which in turn is equivalent to the condition that for all such x, y the elements $g(x^{-1})$ and $g(y)$ start with different letters of $\Delta \cup \Delta^{-1}$. This is equivalent to $g(\Sigma \cup \Sigma^{-1})$ being marked, as required. ◀

▶ **Example 10.** Let $g : F(a, b) \to F(x, y)$ be the map defined by $g(a) = x^{-2}y$ and $g(b) = y^2x$. Then the graph Γ_g, where the double arrow represents x and the single arrow y, is depicted in Figure 1. The map g is not an immersion since there are two edges labeled x entering v_g (violating Characterisation (2)). Similarly, $g(a)$ and $g(b^{-1})$ both start with x^{-1} (violating Characterisation (1)) and $|g(ba)| = 4 < 6 = |g(a)| + |g(b)|$ (violating Characterisation (3)).

Using Characterisation (2), we see that immersions are injective [16, Proposition 3.8]:

▶ **Lemma 11.** *If $g : F(\Sigma) \to F(\Delta)$ is an immersion then it is injective.*

4 The reduction of an instance in free groups

By an *immersed* instance of the PCP$_{\mathrm{FG}}$ we mean an instance $I = (\Sigma, \Delta, g, h)$ where both g and h are immersions. In this section we define the "reduction" of an immersed instance of the PCP$_{\mathrm{FG}}$, which is similar to the reduction in the free monoid case.

Let Γ be a directed, labeled graph and $u \in V\Gamma$ a vertex of Γ. The *core graph of* Γ *at* u, written $\mathrm{Core}_u(\Gamma)$, is the maximal subgraph of Γ containing u but no vertices of degree 1, except possibly u itself. Note that $L(\mathrm{Core}_u(\Gamma), u) = L(\Gamma, u)$. For Γ_1, Γ_2 directed, labeled

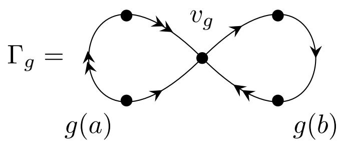

Figure 1 The graph Γ_g for the map $g : F(a,b) \to F(x,y)$ defined by $g(a) = x^{-2}y$, $g(b) = y^2x^{-1}$.

graphs, the *product graph of* Γ_1 *and* Γ_2, denoted $\Gamma_1 \otimes \Gamma_2$, is the subgraph of $\Gamma_1 \times \Gamma_2$ with vertex set $V\Gamma_1 \times V\Gamma_2$ and edge set $\{(e_1, e_2) \mid e_i \in E\Gamma_i^{\pm 1}, label(e_1) = label(e_2)\}$. One may think of the standard construction of an automaton recognising the intersection of two regular languages, each given by a finite state automaton Γ_i with start state s_i, where the core of $\Gamma_1 \otimes \Gamma_2$ at (s_1, s_2) is the automaton recognising this intersection.

Core graph of a pair of morphisms. Let $g : F(\Sigma_1) \to F(\Delta)$, $h : F(\Sigma_2) \to F(\Delta)$ be morphisms. The *core graph of the pair* (g,h), denoted $\mathrm{Core}(g,h)$, is the core graph of $\Gamma_g \otimes \Gamma_h$ at the vertex $v_{g,h} = (v_g, v_h)$, so $\mathrm{Core}(g,h) = \mathrm{Core}_{v_{g,h}}(\Gamma_g \otimes \Gamma_h)$. We shall refer to $v_{g,h}$ as the *central vertex of* $\mathrm{Core}(g,h)$. Note that $\mathrm{Core}(g,h)$ represents the intersection of the two images [16, Lemma 9.3], in the sense that

$$L(\mathrm{Core}(g,h), v_{g,h}) = \mathrm{Image}(g) \cap \mathrm{Image}(h).$$

Write $\delta_g : \mathrm{Core}(g,h) \to \Gamma_g$ and $\delta_h : \mathrm{Core}(g,h) \to \Gamma_h$ for the restriction of $\mathrm{Core}(g,h)$ to the g and h components, respectively, so $\delta_g(e_1, e_2) = e_1$, etc.

Now, let g, h be immersions. The graph $\mathrm{Core}(g,h)$ is a bouquet and every element of $L(\mathrm{Core}(g,h), v_{g,h})$ is freely reduced [16, Lemma 9.2]. We therefore have free group morphisms $g' : L(\mathrm{Core}(g,h), v_{g,h}) \to L(\Gamma_g, v_g)$ and $h' : L(\mathrm{Core}(g,h), v_{g,h}) \to L(\Gamma_h, v_h)$ induced by the maps δ_g, δ_h, where $L(\Gamma_g, v_g) = F(\Sigma_1)$ and $L(\Gamma_h, v_h) = F(\Sigma_2)$. These maps are computable [16, Corollary 9.5]. Let Σ' be the alphabet whose elements consist of the petals of $\mathrm{Core}(g,h)$. Then Σ' generates the free group $L(\mathrm{Core}(g,h), v_{g,h})$, so $F(\Sigma') = L(\mathrm{Core}(g,h), v_{g,h})$, and we see that both g' and h' are immersions with $g' : F(\Sigma') \to F(\Sigma_1)$, $h' : F(\Sigma') \to F(\Sigma_2)$. The map $gg' = hh'$, which we shall call k (so $k : F(\Sigma') \to F(\Delta)$) is the composition of immersions and hence is itself an immersion. We therefore have the following.

▶ **Lemma 12.** *If $g : F(\Sigma_1) \to F(\Delta)$ and $h : F(\Sigma_2) \to F(\Delta)$ are immersions then the corresponding maps $g' : F(\Sigma') \to F(\Sigma_1)$, $h' : F(\Sigma') \to F(\Sigma_2)$ and $k : F(\Sigma') \to F(\Delta)$, where $k = gg' = hh'$, are immersions and are computable.*

Reduction. The *reduction* of an immersed instance $I = (\Sigma, \Delta, g, h)$ of the $\mathrm{PCP}_{\mathrm{FG}}$ is the instance $I' = (\Sigma', \Delta, g', h')$ where g' and h' are as above, but with codomain Δ (which we may do as $\Sigma \subseteq \Delta$). We additionally assume that $\Sigma' \subseteq \Sigma$; we can do this as $|\Sigma'| \leqslant |\Sigma|$ by Lemma 12. As I is immersed, I' is also immersed by Lemma 12. In the next section we show that the name “reduction” makes sense, as it reduces the “prefix complexity” of instances.

▶ **Example 13.** Consider the maps $g, h : F(a,b,c) \to F(x,y,z)$ given by $g(x) = aba^2, g(b) = y^{-1}, g(c) = zxz$ and $h(a) = x, h(b) = yx^2y, h(c) = z$.

Then the graph $\operatorname{Core}(g,h)$ is a bouquet with two petals labelled xyx^2y and zxz, and $\operatorname{Image}(g)\cap\operatorname{Image}(h)=\langle xyx^2y,zxz\rangle$. Moreover, $g(ab^{-1})=h(ab)=xyx^2y$ and $g(z)=h(zxz)=zxz$. Then we can take $\Sigma'=\{a',b'\}$, and the maps given by $g'(a')=ab^{-1},g(b')=c$ and $h'(a')=ab,h'(b')=cac$ are the reduction of (g,h).

We now prove that reduction preserves equalisers. Two instances I_1 and I_2 of the $\mathrm{PCP}_{\mathrm{FG}}$ are *strongly equivalent* if the equalisers are isomorphic, which we write as $\operatorname{Eq}(I_1)\cong\operatorname{Eq}(I_2)$.

▶ **Lemma 14.** *Let $I'=(\Sigma',\Delta',g',h')$ be the reduction of $I=(\Sigma,\Delta,g,h)$ where g and h are immersions. Then I and I' are strongly equivalent, and $g'(\operatorname{Eq}(I'))=\operatorname{Eq}(I)=h'(\operatorname{Eq}(I'))$.*

Proof. It is sufficient to prove that $g'|_{\operatorname{Eq}(I')}$ is injective and $g'(\operatorname{Eq}(I'))=\operatorname{Eq}(I)$; that $h'(\operatorname{Eq}(I'))=\operatorname{Eq}(I)$ follows as $g'|_{\operatorname{Eq}(I')}=h'|_{\operatorname{Eq}(I')}$.

As g' is an immersion it is injective, by Lemma 11. Therefore, $g'|_{\operatorname{Eq}(I')}$ is injective. To see that $\operatorname{Image}(g'|_{\operatorname{Eq}(I')})\leqslant\operatorname{Eq}(I)$, suppose $x'\in\operatorname{Eq}(I')$. Writing $x=g'(x')=h'(x')$, we have $g(x)=gg'(x')=hh'(x')=h(x)$ and so $x=g'(x')\in\operatorname{Eq}(I)$, as required.

To see that $\operatorname{Image}(g'|_{\operatorname{Eq}(I')})\geqslant\operatorname{Eq}(I)$, suppose $x\in\operatorname{Eq}(I)$. Then there exists a path $p_x\in\operatorname{Core}(g,h)$, $\iota(p_x)=v_{g,h}=\tau(p_x)$, such that $\gamma_g\delta_g(p_x)=g(x)=h(x)=\gamma_h\delta_h(p_x)$ [16, Proposition 9.4], where $\gamma_g:\Gamma_g\to\Gamma_\Delta$ is the canonical morphism of directed, labeled graphs from Γ_g to the bouquet Γ_Δ with Δ petals. Hence, writing x' for the element of $F(\Sigma')$ corresponding to $p_x\in L(\operatorname{Core}(g,h),v_{g,h})$, we have that $gg'(x')=g(x)=h(x)=hh'(x)$. As h and g are injective, by Lemma 11, we have that $g'(x')=x=h'(x')$ as required. ◀

5 Prefix complexity of immersions in free groups

In this section we associate to an instance I of the $\mathrm{PCP}_{\mathrm{FG}}$ a certain complexity, called the "prefix complexity". We prove that the process of reduction does not increase this complexity, and that for all $n\in\mathbb{N}$ there are only finitely many instances with complexity $\leqslant n$.

Let $I=(\Sigma,\Delta,g,h)$ be an immersive instance of the $\mathrm{PCP}_{\mathrm{FG}}$. We define, analogously to [11, Section 4] (see also [9]), the *prefix complexity* $\sigma(I)$ as:

$$\begin{aligned}\sigma(I)=&\left|\cup_{a\in\Sigma^{\pm1}}\{x\in F(\Delta)\mid x\text{ is a proper prefix of }g(a)\}\right|\\&+\left|\cup_{a\in\Sigma^{\pm1}}\{x\in F(\Delta)\mid x\text{ is a proper prefix of }h(a)\}\right|.\end{aligned}$$

In the maps in Example 13, $\sigma(I)=10+6=16$, and $\sigma(I')=2+4=6$.

The process of reduction does not increase the prefix complexity, and we prove this by using the fact that, for any $a\in\Sigma^{\pm1}$, the proper prefixes of $g(a)$ and $h(a)$ are in bijection with the proper initial subpaths of the petals of Γ_g and Γ_h, respectively.

▶ **Lemma 15.** *Let $I=(\Sigma,\Delta,g,h)$ be an instance of the $\mathrm{PCP}_{\mathrm{FG}}$ with g and h immersions, and let I' be the reduction of I. Then $\sigma(I')\leqslant\sigma(I)$.*

Proof. We write $V_g\operatorname{Core}(g,h)=\{(v_g,v)\in V\operatorname{Core}(g,h)\mid v\in\Gamma_h\}=\delta_g^{-1}(v_g)$ for the set of vertices in the $\operatorname{Core}(g,h)$ whose first component is the central vertex v_g of Γ_g, and similarly for $V_h\operatorname{Core}(g,h)$. Note that $V_g\operatorname{Core}(g,h)\cap V_h\operatorname{Core}(g,h)=\{v_{g,h}\}$.

By construction, each petal of Γ_g and Γ_h corresponds to a letter $a\in\Sigma^{\pm1}$, and we shall denote the petal also by a. Write $P\Gamma$ for the set of reduced paths in a graph Γ. Similarly to $a\in P\Gamma_g$ and $a\in P\Gamma_h$, we map write $a\in P\operatorname{Core}(g,h)$ for the petal in $\operatorname{Core}(g,h)$ corresponding to $a\in(\Sigma')^{\pm1}$. From now on, all paths are assumed to be reduced. Define

$$\begin{aligned}G &= \cup_{a\in\Sigma^{\pm 1}}\{p \in \Gamma_g \mid p \text{ is a proper initial subpath of petal } a \in \Gamma_g\},\\ G' &= \cup_{a\in(\Sigma')^{\pm 1}}\{p \in \operatorname{Core}(g,h) \mid p \text{ is a proper initial subpath}\\ &\qquad\qquad \text{of } a \in \operatorname{Core}(g,h) \text{ s.t. its end vertex } \tau(p) \in V_g \operatorname{Core}(g,h)\},\end{aligned}$$

and define H and H' analogously. Hence, $\sigma(I) = |G|+|H|$ and analogously $\sigma(I') = |G'|+|H'|$.

For $a \in (\Sigma')^{\pm 1}$ let $q \in G'$ be a subpath of $a \in P\operatorname{Core}(g,h)$. Denote by r_q the shortest subpath of a intersecting q at only one point, their common end vertex (that is, $\tau(q) = \tau(r_q) = q \cap r_q$), such that $\iota(r_q) \in V_h \operatorname{Core}(g,h)$; the paths q and r_q can be seen as "facing" one another on a. As $V_g \operatorname{Core}(g,h) \cap V_h \operatorname{Core}(g,h) = \{v_{g,h}\}$, and as q is a proper initial subpath of a, the projection $\delta_h(r_q)$ is a non-trivial path in Γ_h. Note also that $\iota(\delta_h(r_q)) = v_h$, as $\iota(r_q) \in V_h \operatorname{Core}(g,h)$, hence there exists some $b \in \Sigma^{\pm 1}$ such that $\delta_h(r_q)$ is a proper initial subpath of the petal $b \in \Gamma_h$. Therefore, $\delta_h(r_q) \in H$. Let $\xi_H : G' \to H$ be the map given by $\xi_H(q) = \delta_h(r_q)$.

We now prove that ξ_H is injective. Suppose $p, q \in G'$ are such that $\xi_H(p) = \xi_H(q)$, and let r_p and r_q be the paths obtained from p and q, respectively, such that $\xi_H(p) = \delta_h(r_p)$ and $\xi_H(q) = \delta_h(r_q)$. Write e_p for the terminal edge of r_p, and e_q for the terminal edge of r_q, and note that these two edges have the same label and direction as $\delta_h(e_p) = \delta_h(e_q)$. Now, $\delta_g(\tau(e_p)) = v_g = \delta_g(\tau(e_q))$ as $\tau(r_p), \tau(r_q) \in V_g \operatorname{Core}(g,h)$, and as e_p and e_q have the same label and direction we have that $\delta_g(e_p) = \delta_g(e_q)$. Therefore, both δ_g and δ_h agree on e_p and e_q, and so as $\operatorname{Core}(g,h)$ is a subgraph of $\Gamma_g \times \Gamma_h$ we have that $e_p = e_q$. As $\operatorname{Core}(g,h)$ is a bouquet, there exists a unique shortest reduced path s such that $\iota(s) = v_{g,h}$ and $\tau(s) = s \cap e_p = \tau(e_p)$. Hence, $p = s = q$ as required.

Thus ξ_H is injective, and so $|G'| \leqslant |H|$. The same will hold for an analogously defined function ξ_H from H' to G, so $|H'| \leqslant |G|$. Therefore, $\sigma(I') = |G'|+|H'| \leqslant |G|+|H| = \sigma(I)$. ◀

For a fixed number $n \geqslant 1$ there are obviously only finitely many words which have $\leqslant n$ proper prefixes, and so the following is clear:

▶ **Lemma 16.** *There exist only finitely many distinct instances $I = (\Sigma, \Delta, g, h)$ of the* $\mathrm{PCP}_{\mathrm{FG}}$ *that satisfy $\sigma(I) \leqslant n$.*

As the reduction I' of an instance I gives $\sigma(I') \leqslant \sigma(I)$, and as $|\Sigma'| \subseteq |\Sigma|$, this means that the process of iteratively computing reductions will eventually cycle.

6 Solving the Algorithmic Equaliser Problem in free groups ($\mathrm{AEP}_{\mathrm{FG}}$)

The algorithm for solving the $\mathrm{AEP}_{\mathrm{FG}}$ for immersions is analogous to the algorithm for marked free monoid morphisms in Section 2. Our algorithm starts by making reductions $I_0, I_1, I_2, \ldots$, beginning with $I_0 = I$, the input instance. By Lemma 16, we will obtain an instance $I_j = (\Sigma_j, \Delta, g_j, h_j)$ such that one of the following will occur:

1. $|\Sigma_j| = 1$.
2. $\sigma(I_j) = 0$.
3. there exists some $i < j$ with $I_i = I_j$ (sequence starts cycling).

Keeping in mind the fact that reductions preserve equalisers (Lemma 14), we obtain in each case a subset $\Sigma_{g,h}$ (possibly empty) which forms a basis for $\operatorname{Eq}(I_j)$: For Case (1), writing $\Sigma_j = \{a\}$, the result holds as if $g(a^i) = h(a^i)$ then $g(a)^i = h(a)^i$ and so $g(a) = h(a)$ as roots are unique in a free group. For Case (2), $\sigma(I_j) = 0$ is equivalent to $|g(a)| = |h(a)| = 1$ for all $a \in \Sigma$. Suppose there exists some non-trivial reduced word $x = a_{i_1}^{\epsilon_1} \cdots a_{i_n}^{\epsilon_n}$ such that $g(x) = h(x)$.

Then as g and h are injective, the words $g(a_{i_1})^{\epsilon_1} \cdots g(a_{i_n})^{\epsilon_n}$ and $h(a_{i_1})^{\epsilon_1} \cdots h(a_{i_n})^{\epsilon_n}$ are freely reduced and hence are the same word, and so $g(a_{i_j}) = h(a_{i_j})$. The result then follows for Case (2). Case (3) has a more involved proof.

▶ **Lemma 17.** *Let $I = (\Sigma, \Delta, g, h)$ be an immersive instance of the* $\mathrm{PCP_{FG}}$ *that starts a cycle (i.e. starting the reduction process with I eventually gives I again). If* $\mathrm{Eq}(I)$ *is non-trivial then a subset of Σ forms a basis for* $\mathrm{Eq}(I)$*.*

Proof. There is a sequence of reductions beginning and ending at I:

$$I = I_0 \to I_1 \to \cdots \to I_{r-1} \to I_r = I$$

where $I_i = (\Sigma_i, \Delta, g_i, h_i)$. By Lemma 14, $\mathrm{Eq}(I_0) = g_1 g_2 \dots g_r(\mathrm{Eq}(I_r)) = \mathrm{Eq}(I_r)$ and so $\overline{g_r} = g_1 g_2 \dots g_r$ restricts to an automorphism of $\mathrm{Eq}(I_0)$, that is, $\overline{g_r}|_{\mathrm{Eq}(I_0)} \in \mathrm{Aut}(\mathrm{Eq}(I_0))$. For $\overline{h_r}$ defined analogously, $\overline{h_r}|_{\mathrm{Eq}(I_0)} \in \mathrm{Aut}(\mathrm{Eq}(I_0))$. Write $\mathrm{Eq}(I_k)^{(n)}$ for the set of words in $\mathrm{Eq}(I_k)$ of length precisely n, and $\mathrm{Eq}(I_k)^{(\leqslant n)}$ for the set of words in $\mathrm{Eq}(I_k)$ of length at most n. Consider some $x_0 \in \mathrm{Eq}(I_0)$ and write $x_r = \overline{g_r}^{-1}(x_0)$. Then

$$x_0 = g_1 g_2 \dots g_r(x_r) = \overline{g_r}(x_r),$$
$$x_0 = h_1 h_2 \dots h_r(x_r) = \overline{h_r}(x_r).$$

By Lemma 12, both g_i and h_i are immersions for each i, and so by Characterisation (3) of Lemma 9 we see that $|g_i(w)| \geqslant |w|$ for all $w \in F(\Sigma_i)$. Hence, $|x_0| \geqslant |x_r|$. Therefore, for all $m \geqslant 1$ the map $\overline{g_r}$ induces a map $\overline{g_r}^{(m)} : \mathrm{Eq}(I_r)^{(m)} \to \mathrm{Eq}(I_r)^{(\leqslant m)}$. Clearly $\overline{g_r}^{(1)}$ is a bijection, and so we inductively see that $\overline{g_r}^{(m)}$ has image $\mathrm{Eq}(I_r)^{(m)}$. Therefore, the automorphism $\overline{g_r}$ of $\mathrm{Eq}(I_0)$ is length-preserving ($|\overline{g_r}(w)| = |w|$ for all $w \in \mathrm{Eq}(I)$), and so maps the letters occurring in x_r to letters. Hence, $g_0 (= g_r)$ and $h_0 (= h_r)$ map the letters occuring in x_r to letters, and it follows that every letter occuring in x_r is a solution to I_0. Hence, a subset $\Sigma_{g,h}$ of Σ_r forms a basis for $\mathrm{Eq}(I_r)$. ◀

We now prove the central theorem of this article, which gives an algorithm to describe $\mathrm{Eq}(I)$ as the image of an immersion. Note that not every subgroup of a free group is the image of an immersion: for example, if $|\Sigma| = n$, then no subgroup of $F(\Sigma)$ of rank $> n$ is the image of an immersion. We store a morphism $f : F(\Sigma) \to F(\Delta)$ as a list $(f(a))_{a \in \Sigma}$.

▶ **Theorem 18.** *There exist an algorithm with input an immersive instance $I = (\Sigma, \Delta, g, h)$ of the* $\mathrm{PCP_{FG}}$ *and output an immersion $\psi_{g,h} : F(\Sigma_{g,h}) \to F(\Sigma)$ such that* $\mathrm{Image}(\psi_{g,h}) = \mathrm{Eq}(I)$*.*

Proof. Start by making reductions $I = I_0 \to I_1 \to \cdots$. By Lemma 16 we will obtain an instance $I_j = (\Sigma_j, \Delta, g_j, h_j)$ satisfying one of the Cases (1)–(3) above, and in each case a subset $\Sigma_{g,h}$ of Σ_j forms a basis for $\mathrm{Eq}(I_j)$. Since Σ_j is computable, this basis is as well.

In order to prove the theorem, it is sufficient to prove that there is a computable immersion $\psi_{g,h} : F(\Sigma_{g,h}) \to F(\Sigma)$. Consider the map $\tilde{g} = g_1 g_2 \cdots g_j : F(\Sigma_j) \to F(\Sigma)$ (and the analogous $\tilde{h}$). Now, each g_i is an immersion, so $\tilde{g}$ is the composition of immersions and hence is an immersion. Define $\psi_{g,h} = \tilde{g}|_{F(\Sigma_{g,h})}$. This map is computable from $\tilde{g}$, and as $\Sigma_{g,h} \subseteq \Sigma_j$, the map $\psi_{g,h}$ is an immersion. As $\mathrm{Image}(\psi_{g,h}) = g_1 g_2 \dots g_j(\mathrm{Eq}(I_j)) = \mathrm{Eq}(I)$, by Lemma 14 and the above, the result follows. ◀

We now prove Corollary G, which solves the $\mathrm{AEP_{FG}}$ for immersions of free groups.

Proof of Corollary G. To algorithmically obtain a basis for $\mathrm{Eq}(I)$, first obtain the immersion $\psi_{g,h} : F(\Sigma_{g,h}) \to F(\Sigma)$ given by Theorem 18. Then, recalling that we store $\psi_{g,h}$ as a list $(\psi_{g,h}(a))_{a \in \Sigma}$, the required basis is the set of elements in this list, so the set $\{\psi_{g,h}(a)\}_{a \in \Sigma}$. ◀

7 Sets of immersions

We now prove Theorem C and its corollaries. We first give a general result, from which the non-algorithmic part of Theorem C follows quickly. An *immersed subgroup* H of a free group $F(\Sigma)$ is a subgroup which is the image of an immersion. The proof of Lemma 19 is fundamentally identical to the proof of Lemma 6, via Characterisation 1 of Lemma 9.

▶ **Lemma 19.** *If $\{H_j\}_{j\in J}$ is a set of immersed subgroups of $F(\Sigma)$ then the intersection $\bigcap_{j\in J} H_j$ is immersed.*

Proof. Firstly, suppose $x, y \in H_j$ for some $j \in J$, and let z be their maximal common prefix. Then z decomposes uniquely as $z_1 z_2 \cdots z_n z'_{n+1}$ such that each $z_k \in H_j$. As H_j is immersed, and as z is a maximal common prefix of x and y, we have that $z \in H_j$.

Now, suppose $x, y \in \bigcap_{j\in J} H_j$, and suppose they both begin with some letter $a \in \Sigma \cup \Sigma^{-1}$. By the above, their maximal common prefix z_a is contained in each H_j and so is contained in $\bigcap_{j\in J} H_j$. Therefore, z_a is a prefix of every element of $\bigcap_{j\in J} H_j$ beginning with an a. It follows that $\bigcap_{j\in J} H_j$ is immersed, as required. ◀

The following lemma corresponds to the algorithmic part of Theorem C. Similar to the above, the proof of the lemma is fundamentally identical to the proof of Lemma 7.

▶ **Lemma 20.** *There exists an algorithm with input a finite set of immersions S from $F(\Sigma)$ to $F(\Delta)$ and output an immersion $\psi_S : F(\Sigma_S) \to F(\Sigma)$ such that* $\mathrm{Image}(\psi_S) = \mathrm{Eq}(S)$.

Proof. We proceed by inducting on $|S|$. By Theorem 18, the result holds if $|S| = 2$. Suppose the result holds for all sets of n immersions, $n \geqslant 2$, and let S be a set of $n+1$ immersions. Take elements $g, h \in S$, and write $S_g = S \setminus \{g\}$. By hypothesis, we can algorithmically obtain immersions $\psi_{S_g} : F(\Sigma_{S_g}) \to F(\Sigma)$ and $\psi_{g,h} : F(\Sigma_{g,h}) \to F(\Sigma)$ such that $\mathrm{Image}(\psi_{S_g}) = \mathrm{Eq}(S_g)$ and $\mathrm{Image}(\psi_{g,h}) = \mathrm{Eq}(g, h)$.

By Lemma 12, there exists a (computable) immersion $\psi_S : F(\Sigma_S) \to F(\Sigma)$ such that $\mathrm{Image}(\psi_S) = \mathrm{Image}(\psi_{S_g}) \cap \mathrm{Image}(\psi_{g,h})$ (the map ψ_S corresponds to the map k in the lemma, and Σ_S to Σ'). Then we have the required equality:

$$\begin{aligned}\mathrm{Image}(\psi_S) &= \mathrm{Image}(\psi_{S_g}) \cap \mathrm{Image}(\psi_{g,h})\\ &= \mathrm{Eq}(S_g) \cap \mathrm{Eq}(g,h)\\ &= \mathrm{Eq}(S).\end{aligned}$$ ◀

We now prove Theorem C, which states that the equaliser is the image of a computable immersion.

Proof of Theorem C. By Lemma 19, there exists an alphabet Σ_S and an immersion $\psi_S : F(\Sigma_S) \to F(\Sigma)$ such that $\mathrm{Image}(\psi_S) = \mathrm{Eq}(S)$, while by Lemma 20 if S is finite then such an immersion can be algorithmically found. ◀

We now prove Corollary D, which solves the simultaneous $\mathrm{PCP}_{\mathrm{FG}}$ for immersions.

Proof of Corollary D. First find a basis for $\mathrm{Eq}(I)$: obtain the immersion $\psi_{g,h} : F(\Sigma_{g,h}) \to F(\Sigma)$ given by Theorem C. Then, recalling that we store $\psi_{g,h}$ as a list $(\psi_{g,h}(a))_{a\in\Sigma}$, the required basis is the set of elements in this list, so the set $\{\psi_{g,h}(a)\}_{a\in\Sigma}$. Then $\mathrm{Eq}(S)$ is trivial if and only if this basis is empty. ◀

Finally, we prove Corollary E, which says that $\mathrm{Eq}(S)$ is of rank $\leqslant |\Sigma|$.

Proof of Corollary E. Consider the immersion $\psi_{g,h} : F(\Sigma_{g,h}) \to F(\Sigma)$ given by Theorem C. As $\mathrm{Image}(\psi_{g,h}) = \mathrm{Eq}(S)$ we have that $\mathrm{rk}(\mathrm{Eq}(S)) \leqslant |\Sigma_{g,h}|$, while as $\psi_{g,h}$ is an immersion we have that $|\Sigma_{g,h}| \leqslant |\Sigma|$, and the result follows. ◀

8 Algorithm to compute the equaliser

Theorems A and C produce the equaliser of a set S of morphisms as the image of a computable map ψ_S. For $S = \{g, h\}$, the structure of the algorithm that gives ψ_S (as a list of elements representing the images of the generators) is given below. The values for M in step 3 correspond to the number of instances of complexity $\leqslant \sigma(I)$, as explained in Section 9.

Algorithm 1 Structure of the algorithm that gives ψ_S.

```
1. Input $I = (\Sigma, \Delta, g, h)$.
2. Set $c =; 0$, $i := 0$, $I_0 := I$
3. Set $M := (|\Delta| + 1)^{2|\Sigma|(\sigma(I)+1)}$ (monoids) or $M := (2|\Delta|)^{2|\Sigma|(\sigma(I)+1)}$ (groups)
4. $i := i + 1$
5. Reduce instance $I_{i-1}$ to $I_i$ (as in Sections 2 and 4); store $I_i$ in memory
6. If $I_i$ has source alphabet of size 1 or $\sigma = 0$ then:
   a. Compute a basis $B$ for $\mathrm{Eq}(I_i)$
   b. Print composition($B$, $i$) (see below) and terminate.
7. If $I_i$ is simpler than $I_{i-1}$ (smaller source alphabet or $\sigma$) then set $c = 0$ and goto (4)
8. If $c > M$ then there exists a cycle which starts with $I_i$.
   a. Compute a basis $B$ for $\mathrm{Eq}(I_i)$
   b. Print composition($B$, $i$) and terminate.
```

Procedure `composition(`B`, `i`)` computes the composition of a map, stored as a list B, with the maps obtained in the reduction process, indexed from i downwards.

Algorithm 2 `composition(`B`, `i`)`.

```
1. Set $B := g_i(B)$, where $g_i$ is loaded from memory
2. $i := i - 1$
3. If $i \geqslant 0$, goto (1); else, output $B$.
```

9 Complexity analysis

The size of an instance $I = (\Sigma, \Delta, S)$, S a set of morphisms, is $|\Sigma| + |\Delta| + \sum_{g \in S} \sum_{a \in \Sigma^{\pm 1}} |g(a)|$. The algorithm underlying Theorem A can be run with $O(2^n)$ space, where n is the size of the input instance I, which gives a time bound of $O(2^{2^n})$. The space grows exponentially, unlike in [11], because the algorithm computes instances that must each be stored (as the immersion $\psi_{g,h}$ is their composition; this corresponds to the function `composition(`B`, `i`)`, above). To obtain this space complexity, first suppose $|S| = 2$ (so consider the function `pairs(`g`, `h`)`, above). There are at most $(|\Delta| + 1)^{2|\Sigma|(\sigma(I)+1)}$ instances I_j with $\sigma(I_j) \leqslant \sigma(I)$ [11, Proof of Lemma 3], which is $O(2^n)$. Every other procedure requires asymptotically less space, and hence if $|S| = 2$ we require $O(2^n)$ space. For $S = \{g_1, \dots, g_k\}$, note that we only need to compute the immersions corresponding to $\mathrm{Eq}(g_i, g_{i+1})$ for $1 \leqslant i < k$ (as these intersect to give $\mathrm{Eq}(S)$), and these can all be stored in $(k-1)\times O(2^n)=O(2^n)$ space. Intersection corresponds to reduction, and reduction can be done in PSPACE [11, Section 6]. Hence, the algorithm can be run in $O(2^n)$ space.

Similarly, the algorithm underlying Theorem C runs in $O(2^n)$ space, where n is the input size. The main difference to the above is that there are $O(2^n)$ instances I_j with $\sigma(I_j)\leqslant\sigma(I)$. To see this, write $m:=\sigma(I)$ and $d:=|\Delta|$. If $I_j=(\Sigma_j,\Delta_j,g_j,h_j)$ is such that $\sigma(I_j)\leqslant m$ then $|g(a)|\leqslant m+1$ for all $a\in\Sigma_j^{\pm 1}$, as $g(a)$ has at most m proper prefixes, and similarly $|h(a)|\leqslant m+1$. There are $2d(2d-1)^m$ freely reduced words of length $m+1$ in $F(\Sigma_j)$, and so (by using the empty word) we see that there are at most $(2d)^{m+1}$ freely reduced words of length *at most* $m+1$. As each list of $2|\Sigma_j|$ words defines an instance, there are at most $(2d)^{2|\Sigma_j|(m+1)}\leqslant(2d)^{2|\Sigma|(m+1)}$ instances that satisfy $\sigma(I)\leqslant m$. This is $O(2^n)$ as required.

10 The density of marked morphisms and immersions

Here we show that immersions and marked morphisms are not a negligible (i.e. density zero) subset of the entire set of free group and free monoid morphisms, respectively, but represent a strictly positive proportion of those.

Suppose $\Sigma=\{a_1,\ldots,a_k\}$, and $k=|\Sigma|\geqslant|\Delta|=m$. A morphism in a free monoid or free group, $\phi:\Sigma^*\to\Delta^*$ or $\phi:F(\Sigma)\to F(\Delta)$, is uniquely determined by $(\phi(a_1),\ldots,\phi(a_k))$.

We start with the monoid case. There are m^n words of length n in Δ^*, and $\sum_{1\leqslant i\leqslant n}m^i\sim cm^n$ words of length $\leqslant n$, where $c=\frac{m}{m-1}$ and we write $a_n\sim b_n$ for $\lim_{n\to\infty}\frac{a_n}{b_n}=1$. If α_n is the number of morphisms from Σ^* to Δ^* with images of length at most n, then $\alpha_n\sim(cm^n)^k$. Now let β_n be the number of marked morphisms from Σ^* to Δ^* with images of length at most n. For a marked morphism ϕ, each word in the list $(\phi(a_1),\ldots,\phi(a_k))$ must start with a different letter, followed by any word of length $\leqslant n-1$. Since there are $\binom{m}{k}k!$ options for the first letters, $\beta_n\sim\binom{m}{k}k!(cm^{n-1})^k$ and we get:

▶ **Proposition 21.** *If α_n and β_n are the numbers of morphisms and marked morphisms, respectively, from Σ^* to Δ^*, with images of length at most n, then the density of the marked morphisms among all morphisms is a positive constant:*

$$\lim_{n\to\infty}\frac{\beta_n}{\alpha_n}=\lim_{n\to\infty}\frac{\binom{m}{k}k!(cm^{n-1})^k}{(cm^n)^k}=\frac{m!}{m^k(m-k)!}.$$

In the free group case the counting is similar, but there are more restrictions on the images of an immersion: first, all images need to be reduced words, and second, not just their first letters are constrained, but also their last letters. For some ϕ, let the set of first letters of $(\phi(a_1),\ldots,\phi(a_k))$ be $F\subset\Delta^{\pm 1}$, and the set of inverses of the last letters be $L\subset\Delta^{\pm 1}$. Then $\phi:F(\Sigma)\mapsto F(\Delta)$ is an immersion if all letters in F are distinct, all the letters in L are distinct, which implies $|F|=|L|=k$, and furthermore $F\cap L=\emptyset$. An image $\phi(a_i)$ of length n has the form $\phi(a_i)=\alpha x_1x_2\ldots x_{n-2}\beta$, where $\alpha\in F$, $\beta^{-1}\in L$, $x_i\in\Delta^{\pm 1}$, and $\phi(a_i)$ is reduced, so $x_1\neq\alpha^{-1}$ and $x_{n-2}\neq\beta^{-1}$. Counting such words is more delicate than in the monoid case, but the asymptotics are similar, due to the following result ([6, Proposition 1]).

▶ **Proposition 22.** *Let A and B be subsets of $\Delta^{\pm 1}$. The number of elements of length n in $F(\Delta)$ that do not start with a letter in A and do not end with a letter in B is equal to*

$$f_{A,B}(n)=\frac{(2m-|A|)(2m-|B|)(2m-1)^{n-1}+xm+(-1)^n(|A||B|-ym)}{2m},$$

where $x=|A\cap B|-|A^{-1}\cap B|, y=|A\cap B|+|A^{-1}\cap B|$, and $m=|\Delta|$.

Let $A = \{\alpha^{-1}\}$ and $B = \{\beta^{-1}\}$; then since the number of possible $\phi(a_i)$ of length $\leqslant n$ is equal to the number of reduced words of length $\leqslant n-2$ starting with a letter different from α^{-1} and ending with a letter different from β^{-1}, this number is $\sum_{1 \leqslant j \leqslant n-2} f_{A,B}(j)$. Since $|A| = |B| = 1$, $f_{A,B}(j)$ is asymptotically $(2m-1)^j$, and the number of possible $\phi(a_i)$ is $\sim c_1(2m-1)^{n-2}$, where c_1 is a constant depending on m. Thus for fixed sets F and L the number of immersions ϕ with images in the ball of radius n is $\sim (c_1(2m-1)^{n-2})^k$. Since there are only finitely many choices for sets F and L of first and last letters, respectively, and the number of k-tuples of elements in $F(\Delta)$ of length $\leqslant n$ is $\sim (c_2(2m-1)^n)^k$ for some constant c_2, the number of immersions over the total number of maps $F(\Sigma) \mapsto F(\Delta)$ is $\sim \frac{(c_1(2m-1)^{n-2})^k}{(c_2(2m-1)^n)^k}$; so as $n \mapsto \infty$, this ratio is a positive constant depending on k and m.

Abstract

We study a generalisation of Büchi-Landweber games to the timed setting. The winning condition is specified by a non-deterministic timed automaton with epsilon transitions and only Player I can elapse time. We show that for fixed number of clocks and maximal numerical constant available to Player II, it is decidable whether she has a winning timed controller using these resources. More interestingly, we also show that the problem remains decidable even when the maximal numerical constant is not specified in advance, which is an important technical novelty not present in previous literature on timed games. We complement these two decidability result by showing undecidability when the number of clocks available to Player II is not fixed.

As an application of timed games, and our main motivation to study them, we show that they can be used to solve the deterministic separability problem for nondeterministic timed automata with epsilon transitions. This is a novel decision problem about timed automata which has not been studied before. We show that separability is decidable when the number of clocks of the separating automaton is fixed and the maximal constant is not. The problem whether separability is decidable without bounding the number of clocks of the separator remains an interesting open problem.

1 Introduction

Separability. Separability is a classical problem in theoretical computer science and mathematics. A set S *separates* two sets L, M if $L \subseteq S$ and $S \cap M = \emptyset$. Intuitively, a separator S provides a certificate of disjointness, yielding information on the structure of L, M up to some granularity. There are many elegant results in computer science and mathematics showing that separators with certain properties always exist, such as Lusin's separation theorem in topology (two disjoint analytic sets are separable by a Borel set), Craig's inter-

polation theorem in logic (two contradictory first-order formulas can be separated by one containing only symbols in the shared vocabulary), in model theory (two disjoint projective classes of models are separable by an elementary class), in formal languages (two disjoint Büchi languages of infinite trees are separable by a weak language, generalising Rabin's theorem [44]), in computability (two disjoint co-recursively enumerable sets are separable by a recursive set), in the analysis of infinite-state systems (two disjoint languages recognisable by well-structured transition systems are regular separable [17]), etc.

When separability is not trivial, one may ask whether the problem is decidable. Let $\mathcal{C}$ and $\mathcal{S}$ be two classes of sets. The *$\mathcal{S}$-separability* problem for $\mathcal{C}$ amounts to decide whether, for every input sets $L, M \in \mathcal{C}$ there is a set $S \in \mathcal{S}$ separating L, M. Many results of this kind exist when $\mathcal{C}$ is the class of regular languages of finite words over finite alphabets, and $\mathcal{S}$ ranges over piecewise-testable languages [40, 18] (later generalised to context-free languages [19] and finite trees [28]), locally and locally threshold testable languages [41], first-order logic definable languages [43] (generalised to some fixed levels of the first-order hierarchy [42]). For classes of languages $\mathcal{C}$ beyond the regular ones, decidability results are more rare. For example, regular separability of context-free languages is undecidable [45, 32, 34]. Nonetheless, there are positive decidability results for separability problems on several infinite-state models, such as Petri nets [12], Parikh automata [11], one-counter automata [16], higher-order and collapsible pushdown automata [30, 14], and others.

In this paper, we go beyond languages over finite alphabets, and we study the separability problem for timed languages, which we introduce next.

Timed automata. Nondeterministic timed automata are one of the most widespread model of real-time reactive systems. They consist of finite automata extended with real-valued clocks which can be reset and compared by inequality constraints. Alur and Dill's seminal result showed PSPACE-completeness of the reachability problem [3], for which they received the 2016 Church Award [1]. This paved the way to the automatic verification of timed systems, eventually leading to mature tools such as UPPAAL [6], UPPAAL Tiga (timed games) [10], and PRISM (probabilistic timed automata) [36]. The reachability problem is still a very active research area to these days [23, 31, 2, 26, 27, 29], as well as expressive generalisations thereof, such as the binary reachability problem [15, 21, 35, 25].

Deterministic timed automata form a strict subclass of nondeterministic timed automata where the next configuration is uniquely determined from the current one and the timed input symbol. This class enjoys stronger properties, such as decidable universality/inclusion problems and complementability [3], and it is used in several applications, such as test generation [39], fault diagnosis [7], learning [49, 46]; defining winning conditions in timed games [4, 33, 8], and in a notion of recognisability of timed languages [37].

The *k, m-deterministic separability* problem asks, given two nondeterministic timed automata $\mathcal{A}$ and $\mathcal{B}$ with epsilon transitions, whether there exists a deterministic timed automaton $\mathcal{S}$ with k clocks and maximal constant bounded by m s.t. $L(\mathcal{S})$ separates $L(\mathcal{A}), L(\mathcal{B})$. Likewise one defines *$k$-deterministic separability*, where only k is fixed but not m. We can see $\mathcal{A}$ as recognising a set of good behaviours which we want to preserve and $\mathcal{B}$ recognising a set of bad behaviours which we want to exclude; a deterministic separator, when it exists, provides a compromise between these two conflicting requirements. To the best of our knowledge, separability problems for timed automata have not been investigated before. Our first main result is decidability of k, m and k-deterministic separability.

▶ **Theorem 1.1.** *The k, m and k-deterministic separability problems are decidable.*

Decidability of deterministic separability should be contrasted with undecidability of the corresponding membership problem [24, 48]. This is a rare circumstance, which is shared with languages recognised by one-counter nets [16], and conjectured to be the case for the full class of Petri net languages[1]. We solve the separability problem by reducing to an appropriate timed game (cf. Theorems 1.2 and 1.3 below). This forms the basis of our interest in defining and studying a non-trivial class of timed games, which we introduce next.

Timed games. We consider the following timed generalisation of Büchi-Landweber games [9]. There are two players, called Player I and Player II, which play taking turns in a strictly alternating fashion. At the i-th round, Player I selects a letter a_i from a finite alphabet and a nonnegative timestamp t_i from $\mathbb{R}_{\geq 0}$, and Player II replies with a letter b_i from a finite alphabet. At doomsday, the two players have built an infinite play $\pi = (a_1, b_1, t_1)\,(a_2, b_2, t_2) \cdots$, and Player I wins if, and only if, π belongs to her winning set, which is a timed langauge recognised by a nondeterministic timed automaton with ε-steps. For a fixed number of clocks $k \in \mathbb{N}$ and maximal constant $m \in \mathbb{N}$, the *k, m-timed synthesis problem* asks whether there is a finite-memory timed controller for Player II using at most k clocks and guards with maximal constant bounded by m in absolute value, ensuring that every play π conform to the controller is winning for Player II. Our second contribution is decidability of this problem.

▶ **Theorem 1.2.** *For every fixed $k, m \in \mathbb{N}$, the k, m-timed synthesis problem is decidable.*

We reduce to an untimed finite-state game with an ω-regular winning condition [9]. This should be contrasted with undecidability of the same problem when the set of winning plays for Player II is a nondeterministic timed language (cf. [22] for a similar observation). The *k-timed synthesis problem* asks whether there exists a bound $m \in \mathbb{N}$ s.t. the k, m-timed synthesis problem has a positive answer for Player II, which we also show decidable.

▶ **Theorem 1.3.** *For every fixed $k \in \mathbb{N}$, the k-timed synthesis problem is decidable.*

This requires the synthesis of the maximal constant m, which is a very interesting a technical novelty not shared with the current literature on timed games. We design a protocol whereby Player II demands Player I to be informed when clocks elapse one time unit. We require that the number of such consecutive requests be finite, yielding a bound on m (when such a value exists).

Finally, we complement the two decidability results above by showing that the synthesis problem is undecidable when the number of clocks k available to Player II is not specified in advance (cf. Theorem 6.1).

There are many variants of timed games in the literature, depending whether the players must enforce a nonzeno play, who controls the elapse of time, concurrent actions, etc. [50, 38, 5, 22, 20]. In this terminology, our timed games are asymmetric (only Player I can elapse time) and turn-based (the two players strictly alternate).

2 Preliminaries

Let $\mathbb{R}$ be the set of real numbers and $\mathbb{R}_{\geq 0}$ the set of nonnegative real numbers. For two sets A and B, let their Cartesian product be $A \cdot B$. Let $A^0 = \{\varepsilon\}$, and, for every $n \geq 0$, $A^{n+1} = A \cdot A^n$. The set of finite sequences over A is $A^* = \bigcup_{n \geq 0} A^n$, A^ω is the set of infinite

[1] All these classes of languages have a decidable disjointness problem, however regular separability is not always decidable in this case [47].

sequences, and $A^\infty = A^* \cup A^\omega$. A *(monotonic) timed word* over a finite alphabet Σ is a sequence $w = (a_1, t_1)\,(a_2, t_2) \cdots \in (\Sigma \cdot \mathbb{R}_{\geq 0})^\infty$ s.t. $0 \leq t_1 \leq t_2 \leq \cdots$, and it is *strictly monotonic* if $0 \leq t_1 < t_2 < \cdots$. A *timed language* over Σ is a set $L \subseteq (\Sigma \cdot \mathbb{R}_{\geq 0})^\infty$ of monotonic timed words; it is *strictly monotonic* if it contains only strictly monotonic timed words. The *untiming* $\mathsf{untime}(w)$ of a timed word w as above is the word $a_0 a_1 \cdots \in \Sigma^\infty$ obtained from w by removing the timestamps, which is extended to timed languages L pointwise as $\mathsf{untime}(L) = \{\mathsf{untime}(w) \mid w \in L\}$.

Clocks, constraints, and regions. Let $\mathtt{X} = \{\mathtt{x}_1, \ldots, \mathtt{x}_k\}$ be a finite set of clocks. A *clock valuation* is a function $\mu \in \mathbb{R}_{\geq 0}^{\mathtt{X}}$ assigning a nonnegative real number $\mu(\mathtt{x})$ to every clock $\mathtt{x} \in \mathtt{X}$. For a nonnegative time elapse $\delta \in \mathbb{R}_{\geq 0}$, we denote by $\mu + \delta$ the valuation assigning $\mu(\mathtt{x}) + \delta$ to every clock $\mathtt{x}$; for a set of clocks $\mathtt{Y} \subseteq \mathtt{X}$, let $\mu[\mathtt{Y} \mapsto 0]$ be the valuation which is 0 on $\mathtt{Y}$ and agrees with μ on $\mathtt{X} \setminus \mathtt{Y}$. We write μ_0 for the clock valuation mapping every clock $\mathtt{x} \in \mathtt{X}$ to $\mu_0(\mathtt{x}) = 0$. A *clock constraint* is a quantifier-free formula of the form

$$\varphi, \psi \ ::\equiv \ \mathbf{true} \mid \mathbf{false} \mid \mathtt{x}_i - \mathtt{x}_j \sim z \mid \mathtt{x}_i \sim z \mid \neg\varphi \mid \varphi \wedge \psi \mid \varphi \vee \psi,$$

where $\sim \in \{=, <, \leq, >, \geq\}$ and $z \in \mathbb{Z}$. A clock valuation μ satisfies a constraint φ, written $\mu \models \varphi$, if interpreting each clock $\mathtt{x}_i$ by $\mu(\mathtt{x}_i)$ makes φ true. A constraint φ defines the set $[\![\varphi]\!] = \left\{\mu \in \mathbb{R}_{\geq 0}^{\mathtt{X}} \mid \mu \models \varphi\right\}$ of all clock valuation it satisfies. When the set of clocks is fixed to $\mathtt{X}$ and the absolute value of constants is bounded by $m \in \mathbb{N}$, we speak of $\mathtt{X}, m$-constraints.Two valuations $\mu, \nu \in \mathbb{R}_{\geq 0}^{\mathtt{X}}$ are $\mathtt{X}, m$*-region equivalent*, written $\mu \sim_{\mathtt{X},m} \nu$, if they satisfy the same $\mathtt{X}, m$-constraints. An $\mathtt{X}, m$-region $[\mu]_{\mathtt{X},m} \subseteq \mathbb{R}_{\geq 0}^{\mathtt{X}}$ is an equivalence class of clock valuations w.r.t. $\sim_{\mathtt{X},m}$. For fixed finite $\mathtt{X}$ and $m \in \mathbb{N}$ there are finitely many $\mathtt{X}, m$-regions; let $\mathsf{Reg}(\mathtt{X}, m)$ denote this set. Let $\mu_0 = \lambda \mathtt{x}.0$ and $\mathtt{r}_0 = [\mu_0]_{\mathtt{X},m}$ be its region. We write $\mathtt{r} \models \varphi$ for a region $\mathtt{r} \in \mathsf{Reg}(\mathtt{X}, m)$ whenever $\mu \models \varphi$ for some $\mu \in \mathtt{r}$ (equivalently, for all such μ's). The *characteristic clock constraint* $\varphi_{\mathtt{r}}$ of a region $\mathtt{r} \in \mathsf{Reg}(\mathtt{X}, m)$ is the unique constraint (up to logical equivalence) s.t. $[\![\varphi_{\mathtt{r}}]\!] = \mathtt{r}$. When convenient, we deliberately confuse regions with their characteristic constraints. For two regions $\mathtt{r}, \mathtt{r}' \in \mathsf{Reg}(\mathtt{X}, m)$ we write $\mathtt{r} \prec \mathtt{r}'$ whenever $\mathtt{r} = [\mu]_{\mathtt{X},m}$, $\mathtt{r}' = [\mu + \delta]_{\mathtt{X},m}$ for some $\delta > 0$, and $\mathtt{r} \neq \mathtt{r}'$.

Timed automata. A (nondeterministic) *timed automaton* is a tuple $\mathcal{A} = (\Sigma, \mathtt{L}, \mathtt{X}, \mathtt{I}, \mathtt{F}, \Delta)$, where Σ is a finite input alphabet, $\mathtt{L}$ is a finite set of control locations, $\mathtt{X}$ is a finite set of clocks, $\mathtt{I}, \mathtt{F} \subseteq \mathtt{L}$ are the subsets of initial, resp., final, control locations, and Δ is a finite set of transition rules of the form $\mathsf{tr} = (p, a, \varphi, \mathtt{Y}, q) \in \Delta$, with $p, q \in \mathtt{L}$ control locations, $a \in \Sigma_\varepsilon := \Sigma \cup \{\varepsilon\}$, φ a clock constraint to be tested and $\mathtt{Y} \subseteq \mathtt{X}$ the set of clocks to be reset to 0. A *configuration* of a timed automaton $\mathcal{A}$ is a pair (p, μ) consisting of a control location $p \in \mathtt{L}$ and a clock valuation $\mu \in \mathbb{R}_{\geq 0}^{\mathtt{X}}$. It is *initial* if p is so and $\mu = \mu_0$. It is *final* if p is so. Every transition rule tr induces a discrete transition between configurations $(p, \mu) \xrightarrow{\mathsf{tr}} (q, \nu)$ when $\mu \models \varphi$ and $\nu = \mu[\mathtt{Y} \mapsto 0]$. Intuitively, a discrete transition consists of a test of the clock constraint φ, reset of clocks $\mathtt{Y}$, and step to the location q. Moreover, for every nonnegative $\delta \in \mathbb{R}_{\geq 0}$ and every configuration (p, μ) there is a time-elapse transition $(p, \mu) \xrightarrow{\delta} (p, \mu + \delta)$. The timed language ε*-recognised* by $\mathcal{A}$, denoted $L_\varepsilon(\mathcal{A})$, is the set of finite timed words $w = (a_1, t_1) \cdots (a_n, t_n) \in (\Sigma_\varepsilon \cdot \mathbb{R}_{\geq 0})^*$ s.t. there is a sequence of transitions $(p_0, \mu_0) \xrightarrow{\mathsf{tr}_1, \delta_1} \cdots \xrightarrow{\mathsf{tr}_n, \delta_n} (p_n, \mu_n)$ where $p_0 \in I$ is initial, $\mu_0(\mathtt{x}) = 0$ for every clock $\mathtt{x} \in \mathtt{X}$, $p_n \in F$ is final, and, for every $1 \leq i \leq n$, $\delta_i = t_i - t_{i-1}$ (where $t_0 = 0$) and tr_i is of the form $(p_{i-1}, a_i, \_, \_, p_i)$. The timed ω-language $L_\varepsilon^\omega(\mathcal{A}) \subseteq (\Sigma_\varepsilon \cdot \mathbb{R}_{\geq 0})^\omega$ is defined in terms of sequences as above with the condition that $p_i \in F$ infinitely often. We obtain the timed language $L(\mathcal{A}) = \pi(L_\varepsilon(\mathcal{A})) \subseteq (\Sigma \cdot \mathbb{R}_{\geq 0})^*$, resp., ω-language $L^\omega(\mathcal{A}) = \pi(L_\varepsilon^\omega(\mathcal{A})) \cap (\Sigma \cdot \mathbb{R}_{\geq 0})^\omega \subseteq (\Sigma \cdot \mathbb{R}_{\geq 0})^\omega$ *recognised* by $\mathcal{A}$, where π is the mapping that removes letters of the form $(\varepsilon, \_)$.

A timed automaton (without ε-transitions) is *deterministic* if it has exactly one initial location and, for every two rules $(p, a, \varphi, \mathtt{Y}, q)$, $(p, a, \varphi', \mathtt{Y}', q')$ with $[\![\varphi \wedge \varphi']\!] \neq \emptyset$, we have $\mathtt{Y} = \mathtt{Y}'$ and $q = q'$. We write NTA, DTA for the classes of nondeterministic, resp., deterministic timed automata without epsilon transitions. When the number of clocks in $\mathtt{X}$ is bounded by k we write k-NTA, resp., k-DTA. When the absolute value of the maximal constant is additionally bounded by $m \in \mathbb{N}$ we write k, m-NTA, resp., k, m-DTA. When epsilon transitions are allowed, we write NTA$^\varepsilon$. A timed language is called NTA language, DTA language, and so on, if it is recognized by a timed automaton in the respective class. A k, m-DTA with clocks $\mathtt{X}$ is *regionised* if each constraint is a characteristic constraint $\varphi_{\mathtt{r}}$ of some region $\mathtt{r} \in \mathsf{Reg}(\mathtt{X}, m)$ and for each location p, input $a \in \Sigma$, and $r \in \mathsf{Reg}(\mathtt{X}, m)$ there is a (necessarily unique) transition rule of the form $(p, a, \varphi_{\mathtt{r}}, \mathtt{Y}, q)$. It is well-known that a k, m-DTA can be transformed into an equivalent regionised one by adding exponentially many transitions.

▶ **Example 2.1** (NTA language which is not a DTA language)**.** Let $\Sigma = \{a\}$ be a unary alphabet and let L be the set of timed words of the form $(a, t_1) \cdots (a, t_n)$ s.t. $t_n - t_i = 1$ for some $1 \leq i < n$. $L = L(A)$ for the timed automaton $\mathcal{A} = (\Sigma, \mathtt{L}, \mathtt{X}, \mathtt{I}, \mathtt{F}, \Delta)$ with a single clock $\mathtt{X} = \{\mathtt{x}\}$ three locations $\mathtt{L} = \{p, q, r\}$, of which $\mathtt{I} = \{p\}$ is initial and $\mathtt{F} = \{r\}$ is final, and transitions rules $(p, a, \mathbf{true}, \emptyset, p)$, $(p, a, \mathbf{true}, \{\mathtt{x}\}, q)$, $(q, a, \mathtt{x} < 1, \emptyset, q)$, $(q, a, \mathtt{x} = 1, \emptyset, r) \in \Delta$. Intuitively, in p the automaton waits until it guesses that the next input will be (a, t_i), at which point it moves to q by resetting the clock (and subsequently reading a). From q, the automaton can accept by going to r only if exactly one time unit elapsed since (a, t_i). There is no DTA recognising L, since in order to recognise L deterministically one must store all timestamps in the last unit interval, and thus no bounded number of clocks suffices.

▶ **Example 2.2.** The complement of L from Example 2.1 can be recognised by an NTA with two clocks. Indeed, a timed word $(a, t_1) \cdots (a, t_n)$ is not in L if either of the following conditions hold:

1) its length n is at most 1, or

2) the total time elapsed between the first and the last letter is less than one time unit $t_n - t_1 < 1$, or

3) there is a position $1 \leq i < n$ s.t. $t_n - t_i > 1$ and $t_n - t_{i+1} < 1$.

It is easy to see that two clocks suffice to nondeterministically check the conditions above.

Since checking whether an NTA recognises a deterministic language is undecidable [24, 48], there is no recursive bound on the number of clocks sufficient to deterministically recognise an NTA language (whenever possible). Thus NTA can be non-recursively more succinct than DTA w.r.t. number of clocks. However, in general such NTA recognise timed languages whose complement is not an NTA language. The next example shows a timed language which is both NTA and co-NTA recognisable, however the number of clocks of an equivalent DTA is at least exponential in the number of clocks of the NTA.

▶ **Example 2.3.** For $k \in \mathbb{N}$, let L_k be the set of strictly monotonic timed words $(a, t_1) \cdots (a, t_n)$ s.t. $t_n - t_i = 1$ where $i = n - 2^k$. The language L_k can be recognised by a $(2 \cdot k + 2)$-clock NTA $\mathcal{A}_k$ of polynomial size. There are clocks $\mathtt{x}_0, \mathtt{x}_1, \ldots, \mathtt{x}_k$ and $\mathtt{y}_0, \mathtt{y}_1, \ldots, \mathtt{y}_k$. Clock $\mathtt{x}_0$ is used to check strict monotonicity. Clock $\mathtt{y}_0$ is reset when the automaton guesses (a, t_i). The automaton additionally keeps track of the length of the remaining input. This is achieved by implementing a k-bit binary counter, where $\mathtt{x}_j = \mathtt{y}_j$ represents that the j-th bit is one. In order to set the j-th bit to one, the automaton resets $\mathtt{x}_j, \mathtt{y}_j$; to set it to zero, it resets only $\mathtt{x}_j$. This is correct thanks to strict monotonicity. At the end the automaton checks $\mathtt{y}_0 = 1$ and that the binary counter has value 2^k. Any deterministic automaton recognising

L_k requires exponentially many clocks to store the last 2^k timestamps. The complement of L_k can be recognised by a $(2 \cdot k + 2)$-clock NTA of polynomial size. Indeed, a timed word is not in L_k if any of the following conditions hold:
1) its length n is $\leq 2^k$, or
2) $t_n - t_i < 1$ with $i = n - 2^k$, or
3) $t_n - t_i > 1$ with $i = n - 2^k$.
The automaton guesses which condition holds and uses a k-bit binary counter as above to check that position i has been guessed correctly.

3 Timed synthesis games

Let A and B be two finite alphabets of actions and let $W \subseteq (A \cdot B \cdot \mathbb{R}_{\geq 0})^\omega$ be a language of timed ω-words over the alphabet $A \cdot B$. The *timed synthesis game* $G_{A,B}(W)$ is played by Player I and Player II in rounds. At round $i \geq 0$, Player I chooses a timed action $a_i \cdot t_i \in A \cdot \mathbb{R}_{\geq 0}$ and Player II replies immediately with an untimed action $b_i \in B$. The game is played for ω rounds, and at doomsday the two players have produced an infinite play

$$\pi = a_1 b_1 t_1 a_2 b_2 t_2 \cdots \in (A \cdot B \cdot \mathbb{R}_{\geq 0})^\omega. \tag{1}$$

Player I wins the game if, and only if, $\pi \in W$.

Let $k \in \mathbb{N}$ be a bound on the number of available clocks $\mathtt{X} = \{\mathtt{x}_1, \ldots, \mathtt{x}_k\}$, and let $m \in \mathbb{N}$ be a bound on the maximal constant. A *k, m-controller* for Player II in $G_{A,B}(W)$ is a regionised k, m-DTA $\mathcal{M} = (A, B, \mathtt{L}, \ell_0, \delta)$ with input alphabet A and output alphabet B, where $\mathtt{L}$ is a set of memory locations, $\ell_0 \in \mathtt{L}$ is the initial memory location, and $\delta : \mathtt{L} \cdot A \cdot \mathsf{Reg}(k, m) \to \mathtt{L} \cdot B \cdot 2^{\mathtt{X}}$ is the update function mapping the current memory $\ell \in \mathtt{L}$, input $a \in A$, and region $\varphi \in \mathsf{Reg}(k, m)$ to $\delta(\ell, a, \varphi) = (\ell', b, \mathtt{Y})$, where $\ell' \in \mathtt{L}$ is the next memory location, $b \in B$ is an output symbol, and $\mathtt{Y} \subseteq \mathtt{X}$ is the set of clocks to be reset.

We define by mutual induction the notion of *$\mathcal{M}$-conform partial runs* $\mathsf{Run}(\mathcal{M}) \subseteq \mathtt{L} \cdot \mathbb{R}^{\mathtt{X}}_{\geq 0} \cdot (A \cdot B \cdot \mathbb{R}_{\geq 0} \cdot \mathtt{L} \cdot \mathbb{R}^{\mathtt{X}}_{\geq 0})^*$, and the strategy $[\![\mathcal{M}]\!] : \mathsf{Run}(\mathcal{M}) \cdot A \cdot \mathbb{R}_{\geq 0} \to \mathtt{L} \cdot \mathbb{R}^{\mathtt{X}}_{\geq 0} \cdot B$ induced by the controller on conform runs as follows: Initially, $(\ell_0, \mu_0) \in \mathsf{Run}(\mathcal{M})$, where $\mu_0(\mathtt{x}) = 0$ for every clock $\mathtt{x} \in \mathtt{X}$. Inductively, for every $n \geq 0$ and every $\mathcal{M}$-conform partial run

$$\rho = (\ell_0, \mu_0)\,(a_1, b_1, t_1, \ell_1, \mu_1) \cdots (a_n, b_n, t_n, \ell_n, \mu_n) \in \mathsf{Run}(\mathcal{M}), \tag{2}$$

and for every $(a_{n+1}, t_{n+1}) \in A \cdot \mathbb{R}_{\geq 0}$, we define $[\![\mathcal{M}]\!]\,(\rho \cdot a_{n+1} \cdot t_{n+1}) = (\ell_{n+1}, \mu_{n+1}, b_{n+1})$ for the unique $(\ell_{n+1}, \mu_{n+1}, b_{n+1}) \in \mathtt{L} \cdot \mathbb{R}^{\mathtt{X}}_{\geq 0} \cdot B$ s.t. $\delta(\ell_n, a_{n+1}, \varphi_{\mu_n + \delta_{n+1}}) = (\ell_{n+1}, b_{n+1}, \mathtt{Y})$ and $\mu_{n+1} = (\mu_n + \delta_{n+1})[\mathtt{Y} \mapsto 0]$, where $\delta_{n+1} = t_{n+1} - t_n$ (with $t_0 = 0$). Moreover, $\rho \cdot a_{n+1} \cdot b_{n+1} \cdot t_{n+1} \cdot \ell_{n+1} \cdot \mu_{n+1} \in \mathsf{Run}(\mathcal{M})$. An infinite $\mathcal{M}$-conform run is any sequence $\rho \in \mathtt{L} \cdot \mathbb{R}^{\mathtt{X}}_{\geq 0} \cdot (A \cdot B \cdot \mathbb{R}_{\geq 0} \cdot \mathtt{L} \cdot \mathbb{R}^{\mathtt{X}}_{\geq 0})^\omega$ such that every finite prefix thereof is $\mathcal{M}$-conform; let $\mathsf{Run}_\omega(\mathcal{M})$ be the set of such ρ's. Let $\mathsf{r2p}(\rho) \in (A \cdot B \cdot \mathbb{R}_{\geq 0})^\omega$ be the corresponding play $\pi = \mathsf{r2p}(\rho)$ as in (1) obtained by dropping locations and clocks valuations. The controller $\mathcal{M}$ is *winning* if every infinite $\mathcal{M}$-conform run ρ satisfies $\mathsf{r2p}(\rho) \notin W$. A *$k$-controller* is k, m-controller for some $m \in \mathbb{N}$. For fixed $k, m \in \mathbb{N}$, the *k, m-timed synthesis problem* asks, given A, B and an NTA$^\varepsilon$ timed language $W \subseteq (A \cdot B \cdot \mathbb{R}_{\geq 0})^\omega$, whether Player II has a winning k, m-controller in $G_{A,B}(W)$; the *k-timed synthesis problem* asks instead for a k-controller; finally, the *timed synthesis problem* asks whether there exists a controller. The $0, 0$-timed synthesis problem is equivalent to untimed synthesis problem, which is decidable by the Büchi-Landweber Theorem [9, Theorem 1′]:

▶ **Lemma 3.1** (cf. [13, Appendix A]). *The $0, 0$-synthesis problem is decidable.*

4 Deterministic separability

In this section we prove our first main result Theorem 1.1: we show that the k, m and k-deterministic separability problems are decidable. We begin with a motivating example of nonseparable languages.

▶ **Example 4.1.** Consider the NTA language L from Example 2.1. Thanks to Example 2.2 its complement is also a NTA language. Since neither L nor its complement are deterministic, they cannot be deterministically separable.

Moreover, a deterministic separator, when it exists, may need exponentially many clocks.

▶ **Example 4.2.** We have seen in Example 2.3 an $O(k)$-clock NTA language s.t. 1) its complement is also an $O(k)$-clock NTA language, and 2) any DTA recognising it requires 2^k clocks. Thus, a deterministic separator may need exponentially many clocks in the size of the input NTA.

In the rest of the section we show how to decide the separability problems. We reduce the k, m-deterministic separability to k, m-timed synthesis, and k-deterministic separability to k-timed synthesis, for every fixed $k, m \in \mathbb{N}$. Let $\mathcal{A}, \mathcal{B}$ be two NTA$^\varepsilon$ over alphabet Σ, and let $\mathtt{X}$ be a set of k clocks. We build a timed synthesis game where the two sets of actions are

$$A = \Sigma \quad \text{(Player I)}, \qquad B = \{\mathsf{acc}, \mathsf{rej}\} \quad \text{(Player II)}.$$

We define a projection function $\mathsf{proj}(a, b, t) = (a, t)$, which is extended pointwise to finite and infinite timed words $\mathsf{proj}((a_0, b_0, t_0)\,(a_1, b_1, t_1) \cdots) = (a_0, t_0)\,(a_1, t_1) \cdots$ and timed languages $\mathsf{proj}(L) = \{\mathsf{proj}(w) \mid w \in L \subseteq (A \cdot B \cdot \mathbb{R}_{\geq 0})^\omega\}$. Let $\mathsf{Acc}, \mathsf{Rej} \subseteq (A \cdot B \cdot \mathbb{R}_{\geq 0})^*$ be sets of those timed words ending in a timed letter of the form $(\_, \mathsf{acc}, \_)$, resp., $(\_, \mathsf{rej}, \_)$. The winning condition for Player I is

$$W_0 = \big(\mathsf{proj}^{-1}(L(\mathcal{A})) \cap \mathsf{Rej} \;\cup\; \mathsf{proj}^{-1}(L(\mathcal{B})) \cap \mathsf{Acc}\big) \cdot (A \cdot B \cdot \mathbb{R}_{\geq 0})^\omega. \tag{3}$$

Crucially, we observe that W_0 is a NTA$^\varepsilon$ language since $L(\mathcal{A}), L(\mathcal{B}), \mathsf{Rej}, \mathsf{Acc}$ are so, and this class is closed under inverse homomorphic images, intersections, and unions. The following lemma states the correctness of the reduction.

▶ **Lemma 4.3.** *There is a k, m-controller for Player I in $G_{A,B}(W_0)$ if, and only if, $L(\mathcal{A}), L(\mathcal{B})$ are k, m-deterministically separable.*

Proof. Let $\mathcal{M} = (A, B, \mathtt{L}, \ell_0, \delta)$ be a winning k, m-controller for Player II in $G = G_{A,B}(W_0)$. Let $\mathtt{X} = \{\mathtt{x}_1, \ldots, \mathtt{x}_k\}$ be clocks of $\mathcal{M}$. We construct a separator $\mathcal{S} = (\Sigma, \mathtt{L} \times B, \mathtt{X}, \mathtt{I}, \mathtt{F}, \Delta) \in k, m$-DTA, where $\mathtt{I} = \{(\ell_0, \mathsf{acc})\}$ if $\varepsilon \in L(\mathcal{A})$ and $\mathtt{I} = \{(\ell_0, \mathsf{rej})\}$ otherwise, $\mathtt{F} = \mathtt{L} \times \{\mathsf{acc}\}$, and

$$((\ell, b)\,, a, \varphi, \mathtt{Y}, (\ell', b')) \in \Delta \quad \text{if, and only if,} \quad \delta(\ell, a, \varphi) = (\ell', b', \mathtt{Y})\,. \tag{4}$$

We show that $L(\mathcal{S})$ separates $L(\mathcal{A}), L(\mathcal{B})$ using the fact that $\mathcal{S}$ is deterministic. In order to show $L(\mathcal{A}) \subseteq L(\mathcal{S})$, let $w = (a_1, t_1) \cdots (a_n, t_n) \in L(\mathcal{A})$ and let Player I play this timed word in G. Let the corresponding $\mathcal{M}$-conform partial play be $\pi = (a_1, b_1, t_1) \cdots (a_n, b_n, t_n)$. Since $\mathcal{M}$ is winning, π does not extend to an infinite word in W_0, and in particular $\pi \notin \mathsf{proj}^{-1}(L(\mathcal{A})) \cap \mathsf{Rej}$. But $\mathsf{proj}(\pi) = w \in L(\mathcal{A})$ by assumption, and thus $b_n = \mathsf{acc}$. The unique run of $\mathcal{S}$ on w ends up in an accepting control location of the form $(\_, b_n)$, and thus $w \in L(\mathcal{S})$, as required. The argument showing that $L(\mathcal{S}) \cap L(\mathcal{B}) = \emptyset$ is similar, using the fact that $\mathcal{S}$ is deterministic and must reach $b_n = \mathsf{rej}$ and thus reject all words $(a_1, t_1) \cdots (a_n, t_n) \in L(\mathcal{B})$.

For the other direction, let $\mathcal{S} = (\Sigma, \mathtt{L}, \mathtt{X}, \{\ell_0\}, \mathtt{F}, \Delta) \in k,m\text{-DTA}$ be a deterministic separator. We construct a winning k,m-controller for Player II in G of the form $\mathcal{M} = (A, B, \mathtt{L}, \ell_0, \delta)$ where $\delta(\ell, a, \varphi) = (\ell', b, \mathtt{Y})$ for the unique $\mathtt{Y}, \ell', b$ s.t. $(\ell, a, \varphi, \mathtt{Y}, \ell') \in \Delta$ and $b = \mathsf{acc}$ iff $\ell' \in \mathtt{F}$. In order to argue that $\mathcal{M}$ is winning in G, let $\pi = (a_1, b_1, t_1)\,(a_2, b_2, t_2) \cdots \in (A \cdot B \cdot \mathbb{R}_{\geq 0})^\omega$ be an $\mathcal{M}$-conform play. By construction of $\mathcal{M}$ we have:

▷ Claim 4.4. For every finite nonempty prefix $\pi' = (a_1, b_1, t_1) \cdots (a_n, b_n, t_n)$ of π, $\mathsf{proj}(\pi') \in L(\mathcal{S})$ if, and only if $b_n = \mathsf{acc}$.

Knowing that $L(\mathcal{A}) \subseteq \mathcal{S}$, we deduce that no prefix of π belongs to $\mathsf{proj}^{-1}(L(\mathcal{A})) \cap \mathsf{Rej}$. Similarly, knowing that $L(\mathcal{S}) \cap L(\mathcal{B}) = \emptyset$, we deduce that no prefix of π belongs to $\mathsf{proj}^{-1}(L(\mathcal{B})) \cap \mathsf{Acc}$. Thus $\pi \notin W_0$ and therefore $\mathcal{M}$ is winning. ◀

Proof of Theorem 1.1. Lemma 4.3 provides a reduction from the k,m-deterministic separability problem to the k,m-timed synthesis problem. The latter problem is decidable by Theorem 1.2. Since the construction in Lemma 4.3 is independent of m, it provides also a reduction from the k-deterministic separability problem to the k-timed synthesis problem. The latter problem is decidable by Theorem 1.3. ◀

5 Solving the timed synthesis problems

The second main result of this paper is decidability of the k,m-timed synthesis problem and of the k-synthesis problem, i.e., when the maximal constant m is not specified in advance (Theorems 1.2 and 1.3). This will be achieved in four steps. In the first two steps (see [13, Appendices B.1 and B.2]) we make certain easy simplifying assumptions that winning conditions W are strictly monotonic, and *zero-starting*: all words $(a_1, t_1)\,(a_2, t_2) \cdots \in W$ satisfy $t_1 = 0$. The main technical construction is in Section 5.1, where we prove Theorem 1.2 in such a way that we will easily obtain Theorem 1.3 as a corollary thereof in Section 5.2.

The decidability results of this section are tight, since timed synthesis is undecidable when k is not fixed (cf. Theorem 6.1).

5.1 Solving the k,m-timed synthesis problem

In this section we prove Theorem 1.2 by reducing the k,m-timed synthesis problem to a $0,0$-timed synthesis problem, which is decidable by Lemma 3.1. This is the most technically involved section. The structure of the reduction will be useful in Section 5.2 to show decidability of the k-timed synthesis problem.

Let $\mathtt{X}$ be a fixed set of clocks of size $|\mathtt{X}| = k$ and let $m \in \mathbb{N}$ be a fixed bound on constants. We reduce the k,m-synthesis problem to the $0,0$-synthesis problem by designing a protocol in which Player II, to compensate his inability to measure time elapse, can *request* certain clocks to be *tracked*. In addition, we design the Player I's winning condition that obliges her to remind whenever the value of any tracked clock is an integer, by submitting *expiry* information one time unit after a corresponding request.

Let $\mathsf{fract}(\mathtt{x})$ stand for the fractional part of the value of a clock $\mathtt{x}$. For $\mathtt{Y}_1, \mathtt{Y}_2 \subseteq \mathtt{X}$, two (partial) clock valuations $\mu \in \mathbb{R}_{\geq 0}^{\mathtt{Y}_1}, \nu \in \mathbb{R}_{\geq 0}^{\mathtt{Y}_2}$ are *fractional region equivalent* if $\mathtt{Y}_1 = \mathtt{Y}_2$ and they exhibit the same relations between fractional parts of clocks: $\mu \models \mathsf{fract}(\mathtt{x}) < \mathsf{fract}(\mathtt{x}')$ iff $\nu \models \mathsf{fract}(\mathtt{x}) < \mathsf{fract}(\mathtt{x}')$ and $\mu \models \mathsf{fract}(\mathtt{x}) = 0$ iff $\nu \models \mathsf{fract}(\mathtt{x}) = 0$, for all $\mathtt{x}, \mathtt{x}' \in \mathtt{Y}_1$. By a (partial) fractional $\mathtt{X}$-region $\mathtt{f}$ we mean an equivalence class of this equivalence relation. All elements $\mu \in \mathbb{R}_{\geq 0}^{\mathtt{Y}}$ in $\mathtt{f}$ have the same domain $\mathtt{Y}$, which we denote by $\mathsf{dom}(\mathtt{f}) = \mathtt{Y}$. Let

$\mathbf{0}(\mathtt{f}) = \{\mathtt{x} \in \mathsf{dom}(\mathtt{f}) \mid \mathtt{f} \models \mathsf{fract}(\mathtt{x}) = 0\}$. Let $\mathsf{FReg}(\mathtt{X})$ be the set of all fractional $\mathtt{X}$-regions, including the empty one $\mathtt{f}_0$ with $\mathsf{dom}(\mathtt{f}_0) = \emptyset$. For $\mathtt{r} \in \mathsf{Reg}(\mathtt{X}, m)$ and $\mathtt{f} \in \mathsf{FReg}(\mathtt{X})$, we say that $\mathtt{f}$ *agrees* with $\mathtt{r}$ if they give the same answer for clocks $\mathtt{x}, \mathtt{y} \in \mathsf{dom}(\mathtt{f})$:

- $\mathtt{f} \models \mathsf{fract}(\mathtt{x}) < \mathsf{fract}(\mathtt{y})$ if, and only if, $\mathtt{r} \models \mathsf{fract}(\mathtt{x}) < \mathsf{fract}(\mathtt{y}) \vee \mathtt{x} > m \vee \mathtt{y} > m$;
- $\mathtt{f} \models \mathsf{fract}(\mathtt{x}) = 0$ if, and only if, $\mathtt{r} \models \mathsf{fract}(\mathtt{x}) = 0 \vee \mathtt{x} > m$.

The successor relation between regions induces a corresponding relation between fractional regions: $\mathtt{f} \preceq \mathtt{f}'$ whenever $\mathsf{dom}(\mathtt{f}) = \mathsf{dom}(\mathtt{f}')$, $\mathtt{f}$ agrees with some $\mathtt{r}$, $\mathtt{f}'$ agrees with some $\mathtt{r}'$, and $\mathtt{r} \preceq \mathtt{r}'$. The immediate successor is the minimal $\mathtt{f}'$ with $\mathtt{f} \prec \mathtt{f}'$. Finally, the *successor region of* $\mathtt{r}$ *agreeing with* $\mathtt{f}$ is $\textsc{succ}_{\mathtt{X},m}(\mathtt{r}, \mathtt{f}) = \min_{\preceq} \{\mathtt{r}' \succeq \mathtt{r} \mid \mathtt{f} \text{ agrees with } \mathtt{r}'\}$. In the sequel we apply clock resets also to regions $\mathtt{r}[\mathtt{Y} \mapsto 0]$ and fractional regions.

Let the original game $G = G_{A,B}(W)$ have action alphabets A, B and Player I's winning condition $W \subseteq (A \cdot B \cdot \mathbb{R}_{\geq 0})^\omega$. Thanks to [13, Appendices B.1 and B.2] we assume that W is both strictly monotonic and zero starting. We design a new game $G' = G_{A',B'}(W'_{k,m})$ as follows. We take as the new action alphabets the sets

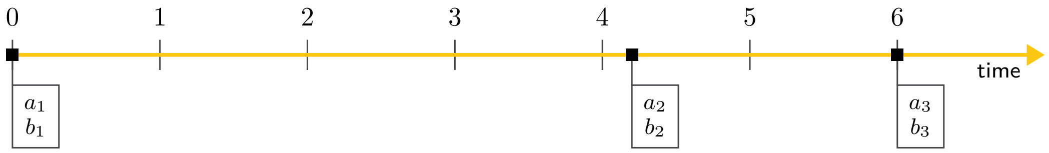
$$A' = (A \cup \{\square\}) \cdot \mathsf{FReg}(\mathtt{X}) \quad \text{and} \quad B' = (B \cup \{\square\}) \cdot 2^{\mathtt{X}}. \tag{5}$$

The players' action sets A', B' depend only on the set of clocks $\mathtt{X}$ and do not depend on the maximal constant m. Moves of the form $(\square, \_)$ are *improper* and the other ones (i.e., those involving an A or B component) are *proper*. Let an infinite play be of the form

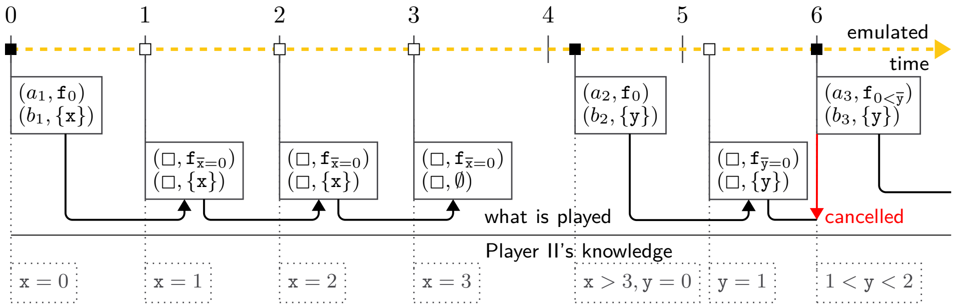
$$\pi = (a'_1, b'_1, t_1)\,(a'_2, b'_2, t_2) \cdots \in (A' \cdot B' \cdot \mathbb{R}_{\geq 0})^\omega, \text{ with } a'_i = (a_i, \mathtt{f}_i) \text{ and } b'_i = (b_i, \mathtt{Y}_i)\,. \tag{6}$$

The domain $\mathtt{T}_i = \mathsf{dom}(\mathtt{f}_i)$ of a fractional region denotes the clocks *tracked* at time t_i, i.e., those for which Player I needs to provide expiry information. Sets $\mathtt{Y}_i$'s denote clocks which Player II wants to be continued to be tracked: by an $\mathtt{x}$-*request at time* t_i we mean a Player II's move b'_i with $\mathtt{x} \in \mathtt{Y}_i$. An $\mathtt{x}$-request at time t_i is *cancelled* if there is another $\mathtt{x}$-request for the same clock at some time $t_i < u < t_i + 1$. An *improper* $\mathtt{x}$-*request chain* starting at time t_i of length $l \geq 1$ is a sequence of improper non-cancelled $\mathtt{x}$-requests at times t_i, $t_i + 1$, $\ldots$, $t_i + l - 2$, followed by an improper (but possibly cancelled) $\mathtt{x}$-request at time $t_i + l - 1$. Likewise one defines an infinite improper $\mathtt{x}$-request chain starting at time t_i.

▶ **Example 5.1.** Before defining the winning set $W'_{k,m}$ formally, we illustrate the underlying idea. Consider the following partial play $(a_1, b_1, 0)\,(a_2, b_2, 4.2)\,(a_3, b_3, 6) \in (A \cdot B \cdot \mathbb{R}_{\geq 0})^*$ in G:



In G', Player II demands Player I to provide clock expiry information. Let $\mathtt{X} = \{\mathtt{x}, \mathtt{y}\}$ and $m = 3$. Suppose Player II wants to make sure that a_2 comes at time > 3. To this end, she makes an $\mathtt{x}$-request chain of length 3 (we write $\overline{\mathtt{x}}$ instead of $\mathsf{fract}(\mathtt{x})$; $\mathtt{f}_\phi$ denotes the fractional $\mathtt{X}$-region agreeing with ϕ):



The length of an $\mathtt{x}$-chain at any given moment corresponds to the integral part of $\mathtt{x}$; the expiry information for $\mathtt{x}$ is provided by Player I precisely when the fractional part of $\mathtt{x}$ is 0.

In order to define $W'_{k,m}$ it will be convenient to have the following additional data extracted from π. Let $\delta_i = t_i - t_{i-1} \geq 0$ be the time elapsed by Player I at round i (with $t_0 = 0$). Furthermore, let $\nu_0 = \lambda \mathtt{x} \cdot 0$ be the initial clock valuation, and, for $i \geq 0$, let

$$\nu_{i+1} = (\nu_i + \delta_{i+1})[\mathtt{Y}_{i+1} \mapsto 0]. \tag{7}$$

In words, every $\mathtt{x}$-request is interpreted as reset of clock $\mathtt{x}$. The winning condition $W'_{k,m}$ in the new game will impose, in addition to W, the following further conditions to be satisfied by Player I in order to win. Let $W^{\mathrm{I}}_k \subseteq (A' \cdot B' \cdot \mathbb{R}_{\geq 0})^\omega$ be the set of plays π as in (6) which are zero-starting ($t_1 = 0$), strictly monotonic and, for every $i \geq 1$:

1. For every $\mathtt{x} \in \mathtt{X}$, $\mathtt{x}$ is expired at time t_i if, and only if, $t_i \geq 1$ and there is a non-cancelled $\mathtt{x}$-request at an earlier time $t_j = t_i - 1$.
2. Tracked clocks are consistent with requests: for every clock $\mathtt{x} \in \mathtt{X}$, $\mathtt{x}$ is tracked $\mathtt{x} \in \mathtt{T}_i$ at time t_i if, and only if, there is an $\mathtt{x}$-request at an earlier t_j with $t_i - 1 \leq t_j < t_i$.
3. The fractional regions are correct: $\mathtt{f}_i$ agrees with $[(\nu_{i-1} + \delta_i)]_{\mathtt{X},m}$.

Thus the conditions above assure that Player I provides exactly all expiry information requested by Player II in a timely manner, and the fractional regions $\mathtt{f}_i$ are consistent with the requests and time elapse. Note that any play in W^{I}_k satisfies $0 < \nu_i(\mathtt{x}) \leq 1$ for every $i \geq 1$ and $\mathtt{x} \in \mathtt{T}_i$. Indeed, positivity is due to strict monotonicity, and the upper bound due to the conditions 1–3. Provided Player I satisfies W^{I}_k, she wins whenever Player II violates any of the conditions below: Let $W^{\mathrm{II}}_{k,m} \subseteq (A' \cdot B' \cdot \mathbb{R}_{\geq 0})^\omega$ be the set of plays π as in (6) s.t.

4. Player II plays a proper move iff Player I does so.
5. Every improper Player II's $\mathtt{x}$-request b'_i is a response to Player I's expiry information for $\mathtt{x}$: $\mathtt{Y}_i \subseteq \mathbf{0}(\mathtt{f}_i)$. (Proper $\mathtt{x}$-requests are allowed unconditionally.)
6. For every clock $\mathtt{x} \in \mathtt{X}$, the length Player II's improper $\mathtt{x}$-request chains is $< m$. This is the only component in the winning condition which depends on m.

Consider the projection function $\phi : (A' \cdot B' \cdot \mathbb{R}_{\geq 0}) \to (A \cdot B \cdot \mathbb{R}_{\geq 0}) \cup \{\varepsilon\}$ s.t. $\phi((a, \_), (b, \_), t) = \varepsilon$ if $a = \Box$ or $b = \Box$, and $\phi((a, \_), (b, \_), t) = (a, b, t)$ if $a \in A$ and $b \in B$, which is extended homomorphically on finite and infinite plays. The winning condition for Player I in G' is

$$W'_{k,m} \ = \ W^{\mathrm{I}}_k \cap \left(\phi^{-1}(W) \cup (A' \cdot B' \cdot \mathbb{R}_{\geq 0})^\omega \setminus W^{\mathrm{II}}_{k,m}\right). \tag{8}$$

Since W, W^{I}_k, are NTA^ε languages, and W^{I}_k and $W^{\mathrm{II}}_{k,m}$ are k-DTA languages over $A' \cdot B'$, thanks to the closure properties DTA and NTA^ε languages the winning condition $W'_{k,m}$ is an NTA^ε language. In what follows, an *untimed controller* is a $0, 0$-controller. Then next two lemmas state the correctness of the reduction. Our assumption on strict monotonicity facilitates the correctness proof since we need not deal with simultaneous events.

▶ **Lemma 5.2.** *If there is a winning k, m-controller $\mathcal{M}$ for G, then there is a winning untimed controller $\mathcal{M}'$ for G'.*

Proof. Let $\mathcal{M} = (A, B, \mathtt{L}, \ell_0, \delta)$ be a winning k, m-controller $\mathcal{M}$ for G with clocks $\mathtt{X} = \{\mathtt{x}_1, \ldots, \mathtt{x}_k\}$ and update function $\delta : \mathtt{L} \cdot A \cdot \mathsf{Reg}(\mathtt{X}, m) \to \mathtt{L} \cdot B \cdot 2^{\mathtt{X}}$. We define a winning untimed controller $\mathcal{M}' = (A', B', \mathtt{L}', \rhd, \delta')$ for G' with memory locations $\mathtt{L}' = \{\rhd\} \cup \mathtt{L} \cdot \mathsf{Reg}(\mathtt{X}, m)$, where $\rhd$ is the initial memory location, and remaing memory locations are of the form $(\ell, \mathtt{r})$, where $\ell \in \mathtt{L}$ is the current memory location of $\mathcal{M}$ and $\mathtt{r} \in \mathsf{Reg}(\mathtt{X}, m)$ is the current region of $\mathcal{M}$'s clocks. The update function $\delta' : \mathtt{L}' \cdot A' \to \mathtt{L}' \cdot B'$ (we omit regions and clock resets because $\mathcal{M}'$ has no clocks) is defined as follows. As long as the play is in W^{I}_k, we can assume that Player I starts with $((a, \mathtt{f}_0), t)$ and $t = 0$, due to the zero-starting restriction, which allows Player II to submit requests at time 0. Consequently, let $\delta'(\rhd, (a, \mathtt{f})) = ((\ell', \mathtt{r}_0), (b, \mathtt{X}))$, where the next location ℓ' and the response b are determined by $\delta(\ell_0, a, \mathtt{r}_0) = (\ell', b)$, and the set $\mathtt{X}$ denotes a request to track all clocks. Then, for every $\ell, \mathtt{r}, a, \mathtt{f}$, let

$$\delta'((\ell, \mathtt{r}), (a, \mathtt{f})) = ((\ell', \mathtt{r}'), (b, \mathtt{Y})), \tag{9}$$

where the r.h.s. is defined as follows. Let $\mathtt{T} = \mathsf{dom}(\mathtt{f})$ be the currently tracked clocks, and $\mathtt{T}_0 = \mathbf{0}(\mathtt{f}) \subseteq \mathtt{T}$ the currently expired ones. If $\mathtt{f}$ agrees with no successor region of $\mathtt{r}$ then Player II wins immediately because Player I is violating condition 3. Therefore, assume such a successor region $\hat{\mathtt{r}} = \textsc{succ}_{\mathtt{X},m}(\mathtt{r}, \mathtt{f})$ exists. We do a case analysis based on whether Player I plays a proper or an improper move.

- Case $a \in A$ (proper move): Let $\delta(\ell, a, \hat{\mathtt{r}}) = (\ell', b, \mathtt{Y})$ thus defining ℓ' and $(b, \mathtt{Y})$ in (9). Take as the new region $\mathtt{r}' = \hat{\mathtt{r}}[\mathtt{Y} \mapsto 0]$.
- Case $a = \square$ (improper move): Let the response be also improper $b = \square$, the control location does not change $\ell' = \ell$, the new clocks to be tracked are the expired clocks with a short improper chain $\mathtt{Y} = \{\mathtt{x} \in \mathtt{T}_0 \mid \hat{\mathtt{r}} \models \mathtt{x} = 1 \vee \cdots \vee \mathtt{x} = m - 1\}$, and $\mathtt{r}' = \hat{\mathtt{r}}$.

Consider an infinite $\mathcal{M}'$-conform run in G' (omitting clock valuations since $\mathcal{M}'$ has no clocks)

$$\rho' \;=\; \rhd (a'_1, b'_1, t_1, (\ell_1, \mathtt{r}_1))\, (a'_2, b'_2, t_2, (\ell_2, \mathtt{r}_2)) \cdots \in \mathsf{Run}_\omega(\mathcal{M}'), a'_i = (a_i, \mathtt{f}_i), b'_i = (b_i, \mathtt{Y}_i).$$

If the induced play $\pi' = \mathsf{r2p}(\rho') = (a'_1, b'_1, t_1)\,(a'_2, b'_2, t_2) \cdots \in (A' \cdot B' \cdot \mathbb{R}_{\geq 0})^\omega$ is not in W^{I}_k, then Player II wins and we are done. Assume $\pi' \in W^{\mathrm{I}}_k$, and thus conditions 1–3 are satisfied. We argue that $\pi' \in W^{\mathrm{II}}_{k,m}$. The conditions 4 and 5 hold by construction. Aiming at demonstrating that 6 holds too, let $\mu_0 = \lambda \mathtt{x} \cdot 0$, and, for $i \geq 0$, let

$$\mu_{i+1} = \begin{cases} \mu_i + \delta_{i+1} & a_i = \square \quad \text{(improper round)} \\ (\mu_i + \delta_{i+1})[\mathtt{Y}_i \mapsto 0] & a_i \in A \quad \text{(proper round).} \end{cases} \tag{10}$$

Thus clock valuations μ_i are defined exactly as ν_i in (7) except that only proper requests are interpreted as clock resets. We claim that the region information $\mathtt{r}_i$ is consistent with μ_i: $\mathtt{r}_i = [\mu_i]_{\mathtt{X},m}$ (*). Indeed, this is due to $\pi' \in W^{\mathrm{I}}_k$, and the fact that $\mathcal{M}'$ updates its stored region consistently with time elapse: at every round $\mathcal{M}'$ uses the successor region agreeing with the current fractional region submitted by Player I, and resets a set of clocks $\mathtt{Y}$ exactly when she plays a proper move of the form $(a, \mathtt{Y}) \in A \cdot 2^{\mathtt{X}}$. Since an $\mathtt{x}$-request is submitted by $\mathcal{M}'$ only when $\hat{r} \models x \leq m{-}1$, condition 6 holds.

In order to show that Player II is winning, consider an $\mathcal{M}'$-conform run ρ'. It suffices to show $\pi' = \mathsf{r2p}(\rho') \notin \phi^{-1}(W)$. Let the proper moves in ρ' be at indices $1 = i_1 < i_2 < \cdots$ ($i_1 = 1$ due to zero-starting). In particular, $\ell_{i_l} = \ell_i$ for $i_l \leq i < i_{l+1}$. Consider the run $\rho = (\ell_0, \mu_0)\,(a_{i_1}, b_{i_1}, t_{i_1}, (\ell_{i_1}, \mu_{i_1}))\,(a_{i_2}, b_{i_2}, t_{i_2}, (\ell_{i_2}, \mu_{i_2})) \cdots$. Using (*) and the definition of

$\mathcal{M}'$, one can prove by induction that ρ is an $\mathcal{M}$-conform run in G. Since $\mathcal{M}$ is winning, the induced play $\pi = \mathsf{r2p}(\rho) = (a_{i_1}, b_{i_1}, t_{i_1})\,(a_{i_2}, b_{i_2}, t_{i_2}) \cdots \in (A \cdot B \cdot \mathbb{R}_{\geq 0})^\omega$, satisfies $\pi \notin W$. Again by induction one can prove that $\pi = \phi(\pi')$. Hence $\phi(\pi') \notin W$ as required. ◀

▶ **Lemma 5.3** (cf. [13, Appendix B.3]). *If there is a winning untimed controller $\mathcal{M}'$ in G', then there is a winning k, m-controller $\mathcal{M}$ in G.*

5.2 Solving the k-timed synthesis problem

In this section we prove Theorem 1.3, stating that the k-timed synthesis problem is decidable, by reducing it to the $0, 0$-synthesis problem, which is decidable by Lemma 5.2. We build on the game defined in Section 5.1. Starting from a timed game $G = G_{A,B}(W)$ we define the timed game $G'' = G_{A',B'}(W''_k)$, where the sets of actions A' and B' are as in (5), and the winning condition W''_k is defined as follows. Let $W^{\mathrm{II}}_k \subseteq (A' \cdot B' \cdot \mathbb{R}_{\geq 0})^\omega$ be the set of plays where, for every clock $\mathtt{x} \in \mathtt{X}$, improper $\mathtt{x}$-request chains have finite lengths: $W^{\mathrm{II}}_k = \bigcup_{m \in \mathbb{N}} W^{\mathrm{II}}_{k,m}$. (In other words, $(A' \cdot B' \cdot \mathbb{R}_{\geq 0})^\omega \setminus W^{\mathrm{II}}_k$ contains plays with an infinite improper $\mathtt{x}$-request chain, for some clock $\mathtt{x} \in \mathtt{X}$.) Then, W''_k is defined as $W'_{k,m}$ from (8), except that $W^{\mathrm{II}}_{k,m}$ is replaced by the weaker condition W^{II}_k (notice W''_k does not depend on m):

$$W''_k \;=\; W^{\mathrm{I}}_k \cap \left(\phi^{-1}(W) \cup (A' \cdot B' \cdot \mathbb{R}_{\geq 0})^\omega \setminus W^{\mathrm{II}}_k\right). \tag{11}$$

▶ **Lemma 5.4.** *There is a winning untimed controller for G'' if, and only if, there is some $m \in \mathbb{N}$ and a winning untimed controller for $G' = G_{A',B'}(W'_{k,m})$.*

Proof. For the "if" direction, we observe that $W''_k \subseteq W'_{k,m}$, for every $m \in \mathbb{N}$. Hence every winning untimed controller for G' is also winning for G''. For the "only if" direction, let $\mathcal{M}'' = (A', B', \mathtt{L}, \ell_0, \delta)$ be an untimed winning controller in G''. Let $m = |A'| \cdot |\mathtt{L}| + 1$. We claim that $\mathcal{M}''$ is also winning in $G' = G_{A',B'}(W'_{k,m})$ for this choice of m. Towards reaching a contradiction, suppose $\mathcal{M}''$ is losing in G'. An $\mathcal{M}''$-conform run ρ in G' (or in G'') and its associated play π are of the form

$$\begin{aligned}\rho &= \ell_0\,(a'_1, b'_1, t_1, \ell_1)\,(a'_2, b'_2, t_2, \ell_2) \cdots \in \mathsf{Run}_\omega(\mathcal{M}''), \text{ with } a'_i = (a_i, \mathtt{f}_i) \text{ and } b'_i = (b_i, \mathtt{Y}_i),\\ \pi &= \mathsf{r2p}(\rho) = (a'_1, b'_1, t_1)\,(a'_2, b'_2, t_2) \cdots \in \mathsf{Play}(\mathcal{M}'').\end{aligned}$$

Let $\rho_i \in \mathsf{Run}(\mathcal{M}'')$ be the finite prefix of ρ ending at $(a'_i, b'_i, t_i, \ell_i)$. Since $\mathcal{M}''$ is losing in G', some $\mathcal{M}''$-conform play π above is in $W'_{k,m}$. Since $\mathcal{M}''$ is winning in G'', $\pi \notin \phi^{-1}(W)$, and thus $\pi \in W^{\mathrm{I}}_k \setminus W^{\mathrm{II}}_{k,m}$. This means that π contains an improper $\mathtt{x}$-request chain C of length m, for some clock $\mathtt{x} \in \mathtt{X}$. By the definition of m, there are indices $i < j$ s.t. the the same controller memory repeats together with Player I's action $(a'_i, \ell_i) = \left(a'_j, \ell_j\right)$. In particular $\mathtt{f}_i = \mathtt{f}_j$. Since $\mathcal{M}''$ is deterministic and its action depends only on Player I's action a'_i and control location ℓ_i, a posteriori we have $b'_i = b'_j$ as well. Moreover, as consecutive timestamps in C are equal to the first one plus consecutive nonnegative integers, $\Delta = t_i - t_j \in \{1, \ldots, m-1\}$. Consider the corresponding infix $\sigma = \left(a'_{i+1}, b'_{i+1}, t_{i+1}, \ell_{i+1}\right) \cdots \left(a'_j, b'_j, t_j, \ell_j\right)$ of the run ρ. Since $\pi \in W'_{k,m}$, thanks to conditions 2 and 3 the fractional regions $\mathtt{f}_i = \mathtt{f}_j$ contain all tracked clocks, and they agree with the clock valuations ν_i and ν_j, respectively, as defined in (7). Let $\{t_i - 1 \leq t_{i_1} < t_{i_2} < \cdots < t_{i_l} < t_i\} = \{t_i - \nu_i(\mathtt{x}) \mid \mathtt{x} \in \mathsf{dom}(\mathtt{f}_i)\}$ be the timestamps corresponding to the last request of the clocks tracked at time t_i, and likewise let $\left\{t_j - 1 \leq t_{j_1} < t_{j_2} < \cdots < t_{j_{l'}} < t_j\right\} = \{t_j - \nu_j(\mathtt{x}) \mid \mathtt{x} \in \mathsf{dom}(\mathtt{f}_j)\}$. By assumption, $\mathtt{f}_i = \mathtt{f}_j$, and hence $l = l'$ and for $\mathtt{x} \in \mathsf{dom}(\mathtt{f}_i) = \mathsf{dom}(\mathtt{f}_j)$ and $1 \leq h \leq l$, $t_{i_h} = t_i - \nu_i(\mathtt{x})$ if, and only if, $t_{j_h} = t_j - \nu_j(\mathtt{x})$ (*). Moreover, since $\mathbf{0}(\mathtt{f}_i) = \mathbf{0}(\mathtt{f}_j)$, we have $t_{i_1} = t_i - 1$ if, and only if, $t_{j_1} = t_j - 1$ (**). Player I will win in G' by forcing a repetition of the infix σ *ad libitum*. In order to do so, we need to modify its timestamps. An *automorphism* of the structure $(\mathbb{R}, \leq, +1)$ is a monotonic bijection preserving integer differences, in the sense that $f(x+1) = f(x) + 1$ for every $x \in \mathbb{R}$. Note that such an automorphism is uniquely defined by its action on any unit-length interval. We claim that there exists such an automorphism $f : \mathbb{R} \to \mathbb{R}$ mapping $t_i - 1$ to $t_j - 1$ (and hence forcedly also t_i to t_j), and each t_{i_h} with $1 \leq h \leq l$ to $f(t_{i_h}) = t_{j_h}$. This is indeed the case, by (*) and (**) all timestamps t_{i_h}'s belong to the unit half-open interval $[t_i - 1, t_i)$ and likewise all timestamps t_{j_h}'s belong to $[t_j - 1, t_j)$. We apply f to a timed word $\sigma \mapsto f(\sigma)$ by acting pointwise on timestamps. Consider the infinite run $\rho' = \rho_i \cdot \sigma \cdot f(\sigma) \cdot f(f(\sigma)) \cdots$; it is $\mathcal{M}''$-conform since the controller $\mathcal{M}''$ is deterministic. By construction, ρ' contains an infinite $\mathtt{x}$-request chain, and thus $\rho' \notin W_k^{\mathrm{II}}$. It remains to argue that $\rho \in W_k^{\mathrm{I}}$ implies $\rho' \in W_k^{\mathrm{I}}$ as well. Let there be a non-cancelled $\mathtt{x}$-request at time t_s in ρ'. If $t_s < t_j - 1$, then this request must be satisfied at time $t_{s'} = t_s + 1 < t_j$, and thus already in $\rho_i \cdot \sigma$, which is the case since the latter is a prefix of $\rho \in W_k^{\mathrm{I}}$. Now assume $t_j - 1 \leq t_s < t_j$. Thus $t_s = t_{j_h}$ for some $1 \leq h \leq l$. By the definition of f, $f^{-1}(t_s) = t_{i_h} < t_j - 1$ and, thanks to the previous case, the request at t_{i_h} is satisfied at $t_{i_h} + 1$ due to (*).By applying f we obtain $f(t_{i_h} + 1) = f(t_{i_h}) + 1 = t_s + 1$, and thus the request at time t_s is satisfied at time $t_s + 1$ in $f(\sigma)$, as required. The general argument for $t_j + n\Delta + d - 1 \leq t_s < t_j + n\Delta + d$, where $n \geq 0$ and $0 \leq d < \Delta$, is similar, using induction on n. ◀

Proof of Theorem 1.3. Due to Lemmas 5.2 to 5.4, there is a winning untimed controller $\mathcal{M}''$ for G'' if, and only if there is some $m \in \mathbb{N}$ and a winning k, m-controller $\mathcal{M}$ for G. Thus the k-synthesis problem reduces to the $0, 0$-synthesis problem, and the latter is decidable thanks to Lemma 3.1. ◀

6 Future work

While deterministic separators may need exponentially many clocks (cf. Example 4.2), we do not have a computable upper bound on the number of clocks of the separating automaton (if one exists). We leave the DTA separability problem when the number of clocks is not fixed in advance as a challenging open problem. In this case, we cannot reduce the separability problem to a timed synthesis problem, since the latter is undecidable (cf. [13, Appendix C]).

▶ **Theorem 6.1.** *The timed synthesis problem is undecidable, and this holds already when Player I's winning condition is a* 1-NTA *language.*

We leave the computational complexity of separability as future work.

Deterministic separability can be considered also over infinite timed words. We chose to present the case of finite words because it allows us to focus on the essential ingredients of this problem. When going to infinite words, new phenomena appear already in the untimed setting; for instance, deterministic Büchi automata are less expressive than deterministic parity automata, and thus one should additionally specify in the input which priorities can be used by the separator; or leave them unspecified and solve a more difficult problem.

Analogous results about separability of register automata can be obtained with techniques similar to the one presented in this paper. We leave such developments for further work.

Abstract

In 2015, it was shown that reachability for arbitrary directed graphs can be updated by first-order formulas after inserting or deleting single edges. Later, in 2018, this was extended for changes of size $\frac{\log n}{\log \log n}$, where n is the size of the graph. Changes of polylogarithmic size can be handled when also majority quantifiers may be used.

In this paper we extend these results by showing that, for changes of polylogarithmic size, first-order update formulas suffice for maintaining (1) undirected reachability, and (2) directed reachability under insertions. For classes of directed graphs for which efficient parallel algorithms can compute non-zero circulation weights, reachability can be maintained with update formulas that may use "modulo 2" quantifiers under changes of polylogarithmic size. Examples for these classes include the class of planar graphs and graphs with bounded treewidth. The latter is shown here.

As the logics we consider cannot maintain reachability under changes of larger sizes, our results are optimal with respect to the size of the changes.

1 Introduction

Suppose we are given a graph G whose edge relation is subjected to insertions and deletions of edges. Which resources are required to update the reachability relation of the graph?

Recently it was shown that if one is allowed to store auxiliary relations, then the reachability relation can be updated after single edge insertions and deletions using first-order logic formulas with access to the graph, the stored relations, and the changed edges [4]. In other words, the reachability query is contained in the dynamic complexity class DynFO [19]. From a database perspective, this means that it can be updated with core-SQL queries; from the perspective of circuit complexity, this means that reachability can be updated by circuits of polynomial size in constant-time due to the correspondence of first-order logic and AC^0 established by Barrington, Immerman, and Straubing [1].

Understanding single edge insertions and deletions is an important first step. Yet in applications, changes to a graph G often come as bulk set ΔE of changed edges. It is natural to ask, how large the set ΔE of edges can be such that reachability can be maintained with the same resources as for single edge changes – that is with first-order formulas or, respectively, AC^0 circuits. Using existing lower bounds for circuits [21], it is easy to see that DynFO (or DynAC^0, respectively) cannot handle changes of size larger than polylogarithmic for many queries, including the reachability query (see Section 3 for a more detailed discussion).

The best one can hope for is to maintain reachability with first-order formulas for changes of polylogarithmic size with respect to the size of the graph. In a first step, a subset of the authors showed that reachability can be maintained in $\mathsf{DynFO}(\leq, +, \times)$ under changes of size $O(\frac{\log n}{\log \log n})$ [7]. Here, the class $\mathsf{DynFO}(\leq, +, \times)$ extends DynFO by access to built-in arithmetic, which for technical reasons is more natural for bulk changes. Unfortunately, the techniques used in [7] seem only be able to handle changes of polylogarithmic size in the extension of DynFO by majority quantifiers, that is, in the class $\mathsf{DynFO{+}Maj}(\leq, +, \times)$.

In this paper we make progress on handling changes of polylogarithmic size in DynFO by attacking the challenge from two directions. First, we establish two restrictions for which reachability can be maintained under these changes.

▶ **Main Theorem 1.** *Reachability can be maintained in* $\mathsf{DynFO}(\leq, +, \times)$ *under*

- *insertions of polylogarithmically many edges; and*
- *insertions and deletions of polylogarithmically many edges if the graph remains undirected.*

As second contribution of this paper, we provide a meta-theorem for establishing classes of graphs for which reachability can be maintained under polylogarithmic-size changes with a slight extension of first-order logic. In this extension, $\mathsf{DynFO{+}Mod\,2}(\leq, +, \times)$, formulas used for updating the reachability information and the auxiliary relations may use parity quantifiers in addition to the traditional universal and existential quantifiers.

▶ **Main Theorem 2.** *Reachability can be maintained in* $\mathsf{DynFO{+}Mod\,2}(\leq, +, \times)$ *under insertions and deletions of polylogarithmically many edges on classes of graphs for which polynomially bounded non-zero circulation weights can be computed in* AC.

Here a weighting function for the edges of a graph has *non-zero circulation*, if the weight of every directed cycle is non-zero (see Section 6 for details). The class AC contains queries computable by circuits of polynomial size and polylogarithmic depth. Examples for graph classes for which non-zero circulation weights can be computed in AC include the class of planar graphs and graphs with bounded treewidth. The latter is shown here. We note that isolating weights, a concept closely related to non-zero circulation weights, have been used previously in dynamic complexity for establishing that reachability is in non-uniform DynFO+Mod $2(\leq, +, \times)$ under single edge changes [3], a precursor result to reachability in DynFO.

For our results, we employ two techniques of independent interest. The first technique relies on the power of first-order logic on structures of polylogarithmic size. It is well-known that reachability can be computed by a uniform circuit family of size $N^{\mathcal{O}(N^{1/d})}$ and depth $2d$. An immediate consequence is that all NL-queries can be expressed by first-order formulas for graphs with n nodes but only polylogarithmically many edges. Thus, for maintaining a query under changes ΔE of polylogarithmic size, a dynamic program can (1) do an arbitrary NL-computation on ΔE, and (2) update the auxiliary data by combining the computed information with the previous auxiliary data using a first-order formula.

The second technique we rely on is a slight generalization of the "Muddling Lemma" from [6]. The Muddling Lemma reduces the requirements for proving that a query is in DynFO: a query is in DynFO if, essentially, one can update the query for polylog many steps starting from auxiliary data precomputed in AC. Here we observe that this can be strengthened for changes of polylogarithmic size: a query is in DynFO if, essentially, one can update the query under one polylogarithmic-size change from auxiliary data precomputed in AC.

Parts of the results presented here have been included in the PhD thesis of Nils Vortmeier [24].

Outline. After recalling the dynamic complexity framework in Section 2, we shortly outline barriers for the size of bulk changes in Section 3 and recall useful techniques in Section 4. Afterwards we present our results for DynFO in Section 5 and for DynFO+Mod $2(\leq, +, \times)$ in Section 6.

2 The dynamic setting

We briefly repeat the essentials of dynamic complexity, closely following [7] which in turn builds on [20]. The goal of a *dynamic program* is to answer a given query on a relational *input structure* subjected to changes that insert tuples into the input relations or delete tuples from them. The program may use auxiliary information represented by an *auxiliary structure* over the same domain as the input structure. Initially, both input and auxiliary structure are empty; and the domain is fixed during each run of the program. Whenever a change to the input structure occurs, the auxiliary structure is updated by means of first-order formulas.

Changes. For a (relational) structure $\mathcal{I}$ over domain D and schema σ, a change $\Delta\mathcal{I}$ consists of sets R^+ and R^- of tuples for each relation symbol $R \in \sigma$. The result $\mathcal{I} + \Delta\mathcal{I}$ of an application of the change $\Delta\mathcal{I}$ to $\mathcal{I}$ is the input structure where $R^{\mathcal{I}}$ is changed to $(R^{\mathcal{I}} \cup R^+) \setminus R^-$. The *size* of $\Delta\mathcal{I}$ is the total number of tuples in relations R^+ and R^- and the set of *affected elements* is the (active) domain of tuples in $\Delta\mathcal{I}$.

Dynamic Programs and Maintenance of Queries. A dynamic program consists of a set of update rules that specify how auxiliary relations are updated after changing the input structure. Let $\mathcal{I}$ be the current input structure over schema σ and let $\mathcal{A}$ be the auxiliary structure over some schema σ_{aux}. An *update rule* for updating an ℓ-ary auxiliary relation T after a change is a first-order formula φ over schema $\sigma \cup \sigma_{\text{aux}}$ with ℓ free variables. After a change $\Delta\mathcal{I}$, the new version of T is $T \stackrel{\text{def}}{=} \{\bar{a} \mid (\mathcal{I} + \Delta\mathcal{I}, \mathcal{A}) \models \varphi(\bar{a})\}$, so, the updated auxiliary relation includes all tuples $\bar{a}$ such that $\varphi(\bar{a})$ is satisfied when it is evaluated on the changed input structure and the old auxiliary structure. Note that a dynamic program can choose to have access also to the old input structure by storing it in its auxiliary relations.

For a state $\mathcal{S} = (\mathcal{I}, \mathcal{A})$ of the dynamic program $\mathcal{P}$ with input structure $\mathcal{I}$ and auxiliary structure $\mathcal{A}$ we denote the state of the program after applying a change sequence α and updating the auxiliary relations accordingly by $\mathcal{P}_\alpha(\mathcal{S})$.

The dynamic program *maintains* a q-ary query Q under changes of size k if it has a q-ary auxiliary relation $\textsc{Ans}$ that at any time stores the result of Q applied to the current input structure. More precisely, for each non-empty sequence α of changes of size k, the relation $\textsc{Ans}$ in $\mathcal{P}_\alpha(\mathcal{S}_\emptyset)$ and $Q(\alpha(\mathcal{I}_\emptyset))$ coincide, where the state $\mathcal{S}_\emptyset \stackrel{\text{def}}{=} (\mathcal{I}_\emptyset, \mathcal{A}_\emptyset)$ consists of an input structure $\mathcal{I}_\emptyset$ and an auxiliary structure $\mathcal{A}_\emptyset$ over some common domain that both have empty relations, and $\alpha(\mathcal{I}_\emptyset)$ is the input structure after applying α.

If a dynamic program maintains a query, we say that the query is in DynFO. Similarly to DynFO one can define variants with built-in auxiliary relations and with more powerful update formulas. For instance, the class $\mathsf{DynFO}(\leq, +, \times)$ contains queries that can be maintained by first-order update formulas with access to three particular auxiliary relations $<, +$, and $\times$ which are initialized as a linear order and the corresponding addition and multiplication relations; in the class $\mathsf{DynFO{+}Mod\ p}$, update formulas may use modulo-p-quantifiers in addition to existential and universal quantifiers.

We state our results for dynamic classes with access to the arithmetic relations $\leq, +$ and $\times$. Handling bulk changes without access to arithmetic leads to technical issues which distract from the fundamental dynamic properties. See [7, 24] for further discussions on this topic and how our results can be stated for DynFO in an adapted setting which takes these technical issues into account.

For the construction of dynamic programs in this paper we assume that changes either only insert edges or only delete edges. This is no restriction, as corresponding update formulas can be combined to process a change that inserts and deletes edges at the same time, by first processing the inserted edges and then processing the deleted edges.

3 Barriers for the size of bulk changes

In the following we outline why it is not possible to maintain reachability under changes of larger than polylogarithmic size with first-order formulas, even in the presence of parity quantifiers.

The idea is simple. A classical result by Smolensky states that for computing the number of ones modulo a prime q occurring in a bit string of length n, an $\mathsf{AC}[p]$ circuit of depth d requires $2^{\Omega(n^{1/2d})}$ many gates, for each prime p distinct from q (see [21] or, for a modern exposition, [17, Theorem 12.27]). A simple, well-known reduction yields that deciding reachability for graphs with n edges which are disjoint unions of paths also requires $\mathsf{AC}[p]$ circuits of size $2^{\Omega(n^{1/2d})}$. Indeed, computing the number of ones in $w = a_1 \cdots a_n$ modulo q can be reduced to reachability as follows. Consider the graph with nodes $\{(i,k) \mid 1 \leq i \leq n+1 \text{ and } 0 \leq k < q\}$ and edges $\{((i,k),(i+1,k)) \mid a_i = 0\} \cup \{((i,k),(i+1,k+1 \bmod q)) \mid a_i = 1\}$. It is easy to see that (i) the graph has $\mathcal{O}(n)$ edges and is a disjoint union of q paths, and (ii) there is a path from $(1,0)$ to $(n+1,0)$ if and only if the number of ones in w is 0 modulo q.

These lower bounds for circuit sizes immediately translate into lower bounds for first-order formulas with modulo p quantifiers via the correspondence due to Barrington, Immerman, and Straubing [1].

▶ **Theorem 1.** *Let $f(n) \in \log^{\omega(1)} n$ be a function from $\mathbb{N}$ to $\mathbb{N}$ and let p be a prime. There is no* FO+Mod p *formula with access to built-in relations that defines*

1. *whether the size of a unary relation U with $|U| \leq f(n)$ is divisible by q, for primes q distinct from p;*
2. *reachability in graphs with at most $f(n)$ edges, even for disjoint unions of paths.*

Proof sketch.

(a) Let $f(n)$ be some function from $\log^{\omega(1)} n$. Suppose, towards a contradiction, that there is an FO+Mod p formula with access to built-in relations that defines whether the size of a unary relation U with $|U| \leq f(n)$ is divisible by q, for some primes $p \neq q$. Then, by [1], for every n there is an AC$[p]$ circuit of some fixed depth d that decides that question for inputs if size n, and the size of this circuit is polynomial in n. That is a contradiction, as by Smolensky's lower bound every such circuit needs to have size $2^{\Omega(f(n)^{1/2d})} = 2^{\log(n)^{\omega(1)}} = n^{\omega(1)}$.

(b) This part can be proven analogously to Part (a), using the circuit lower bound for graph reachability. ◀

Those lower bounds have the immediate consequence that DynFO cannot deal with bulk changes of larger than polylogarithmic size. Indeed, from any formula that updates the result of a query after an insertion of $f(n)$ tuples into an initially empty input relation one can construct a formula that defines the query for inputs of size $f(n)$.

▶ **Corollary 2.** *Let $f(n) \in \log^{\omega(1)} n$ be a function from $\mathbb{N}$ to $\mathbb{N}$ and let p be a prime. Then the following queries cannot be maintained in* DynFO+Mod p *for bulk changes of size $\leq f(n)$, even if the auxiliary relations may be initialized arbitrarily:*

1. *divisibility of the size of a unary relation by a prime $q \neq p$, and*
2. *reachability in graphs, even if restricted to disjoint unions of paths.*

4 Techniques and Tools

In the previous section we recalled that FO$(\leq, +, \times)$, even if equipped with modulo p quantifiers, is not very expressive in general. That changes when we are only interested in small substructures of our input: FO$(\leq, +, \times)$ can express every NL-computable query on subgraphs of polylogarithmic size.

▶ **Theorem 3.** *Let k and c be arbitrary natural numbers, and let Q be a k-ary,* NL*-computable graph query. There is an* FO$(\leq, +, \times)$ *formula φ over schema $\{E, D\}$ such that for any graph G with n nodes, any subset D of its nodes of size at most $\log^c n$ and any k-tuple $\bar{a} \in D^k$: $\bar{a} \in Q(G[D])$ if and only if $(G, D) \models \varphi(\bar{a})$. Here, $G[D]$ denotes the subgraph of G induced by D.*

Proof. We prove the result for the reachability query. As reachability is NL-complete under FO$(\leq, +, \times)$-reductions [16], and every FO$(\leq, +, \times)$-reduction maps an instance of size $\log^c n$ to an instance of size $\log^{cd} n$ for a fixed $d \in \mathbb{N}$, the full result follows.

It is well-known (see for example [2, p. 613]), that for every $d \in \mathbb{N}$ there is a uniform circuit family for reachability where the circuit for inputs of size N has depth $2d$ and size $N^{\mathcal{O}(N^{1/d})}$. Suppose the input size N is only $\log^c n$, for some $c \in \mathbb{N}$ and pick $d \overset{\text{def}}{=} 2c$. Then the circuit size

$$\begin{aligned}N^{\mathcal{O}(N^{1/d})} =&(\log^c n)^{\mathcal{O}((\log^c n)^{1/d})}\\ =&(\log n)^{c\mathcal{O}((\log n)^{c/d})} = (\log n)^{\mathcal{O}((\log n)^{c/2c})} = (\log n)^{\mathcal{O}(\sqrt{\log n})}\\ =&2^{\mathcal{O}(\log\log n\sqrt{\log n})} \subseteq 2^{\mathcal{O}(\sqrt{\log n}\sqrt{\log n})} = 2^{\mathcal{O}(\log n)} = n^{\mathcal{O}(1)}\end{aligned}$$

is polynomial in n, so, the circuit is a uniform AC^0 circuit for reachability for graphs of size $\log^c n$. The existence of φ follows by the equivalence of uniform AC^0 and $\mathsf{FO}(\leq, +, \times)$ [1]. ◀

The Muddling Lemma simplifies the maintenance of queries under single edge changes [6]. It states that for many natural queries Q, in order to show that Q can be maintained, it is enough to show that the query can be maintained for a bounded number of steps. In the following we recall the necessary notions and extend the lemma to bulk changes.

A query Q is *almost domain-independent* if there is a $c \in \mathbb{N}$ such that $Q(\mathcal{A})[(\text{adom}(\mathcal{A}) \cup B)] = Q(\mathcal{A}[(\text{adom}(\mathcal{A}) \cup B)])$ for all structures $\mathcal{A}$ and sets $B \subseteq A \setminus \text{adom}(\mathcal{A})$ with $|B| \geq c$. Here, $\text{adom}(\mathcal{A})$ denotes the *active domain*, i.e. the set of domain elements that are used in some tuple of $\mathcal{A}$. A query Q is *$(\mathcal{C}, f)$-maintainable*, for some complexity class $\mathcal{C}$ and some function $f : \mathbb{N} \to \mathbb{R}$, if there is a dynamic program $\mathcal{P}$ and a $\mathcal{C}$-algorithm $\mathbb{A}$ such that for each input structure $\mathcal{I}$ over a domain of size n, each linear order $\leq$ on the domain, and each change sequence α of length $|\alpha| \leq f(n)$, the relation Q in $\mathcal{P}_\alpha(\mathcal{S})$ and $Q(\alpha(\mathcal{I}))$ coincide, where $\mathcal{S} = (\mathcal{I}, \mathbb{A}(\mathcal{I}, \leq))$.

The Muddling Lemma from [6] has been formulated for bulk changes in [7, 24][1].

▶ **Theorem 4** ([7, 24]). *Let Q be an NL-computable, almost domain independent query, and let $c \in \mathbb{N}$ be arbitrary. If the query Q is $(\mathsf{AC}^d, \log^d n)$-maintainable under changes of size $\log^c n$ for some $d \in \mathbb{N}$, then Q is in $\mathsf{DynFO}(\leq, +, \times)$ under changes of size $\log^c n$.*

The previous theorem can be strengthened as follows.

▶ **Theorem 5.** *Let Q be an NL-computable, almost domain independent query, and let $c \in \mathbb{N}$ be arbitrary. If the query Q is $(\mathsf{AC}^d, 1)$-maintainable under changes of size $\log^{c+d} n$ for some $d \in \mathbb{N}$, then Q is in $\mathsf{DynFO}(\leq, +, \times)$ under changes of size $\log^c n$.*

Proof. Let Q and d be as in the theorem statement, and let $\mathbb{A}$ be an AC^d algorithm and $\mathcal{P}$ a dynamic program that witness that Q is $(\mathsf{AC}^d, 1)$-maintainable under changes of size $\log^{c+d} n$. By Theorem 4 it suffices to show that there is an AC^d algorithm $\mathbb{A}'$ and a dynamic program $\mathcal{P}'$ that witness that Q is $(\mathsf{AC}^d, \log^d n)$-maintainable under changes of size $\log^c n$.

We choose $\mathbb{A}'$ as $\mathbb{A}$. The program $\mathcal{P}'$ just stores the at most $\log^{c+d} n$ changes that accumulate during the $\log^d n$ steps, and in each step uses $\mathcal{P}$ to answer Q, using the initial auxiliary relations computed by $\mathbb{A}$. ◀

5 Handling Polylog Changes with DynFO

So far we do not know how to maintain directed reachability under polylogarithmically many changes in $\mathsf{DynFO}(\leq, +, \times)$. In this section we show that reachability can be maintained in $\mathsf{DynFO}(\leq, +, \times)$ under insertions of polylogarithmically many edges for arbitrary graphs (disallowing any deletions), and under insertions *and* deletions of polylogarithmic size for undirected graphs.

[1] The statement and proof in [7] is slightly flawed and has been corrected in [24].

The general idea is similar in both cases. After changing polylogarithmically many edges with an effect on nodes V_{aff}, the dynamic program (1) computes a structure of polylogarithmic size on V_{aff}, (2) uses Theorem 3 to compute helpful information for this structure, and (3) updates the auxiliary relations by combining this information with the previous auxiliary data. Both (1) and (3) are performed by first-order formulas, and (2) uses an NL-computation.

▶ **Theorem 6.** *Reachability is in* $\mathsf{DynFO}(\leq, +, \times)$ *under insertions of size* $\log^c n$*, for every* $c \in \mathbb{N}$.

Proof. Let $c \in \mathbb{N}$ be fixed. We construct a dynamic program with a single auxiliary relation $\textsc{Ans}$ which stores the transitive closure of the current graph.

Whenever a set E^+ of edges is inserted into the current graph $G = (V, E)$, the dynamic program updates $\textsc{Ans}$ with the help of the transitive closure relation of a graph H defined as follows. The nodes of H are the nodes V_{aff} affected by the change, that is, the nodes incident to edges in E^+. The edge set E_H of H contains the newly inserted edges E^+, and additionally edges (u, v) for all pairs (u, v) of nodes from V_{aff} that are connected by a path in G. Observe that H is of size $O(\log^c n)$ and first-order definable from G, E^+ and $\textsc{Ans}$. Hence, by Theorem 3, the transitive closure of H can be defined by a first-order formula.

The transitive closure relation of $G' \overset{\text{def}}{=} (V, E \cup E^+)$ can now be constructed from the transitive closures of G and H. To this end observe that the transitive closure of H equals the transitive closure relation of G' restricted to V_{aff}: it accounts for all paths from a node $u \in V_{\text{aff}}$ to another node $v \in V_{\text{aff}}$ that may use both newly inserted edges and edges that are already present in G. For this reason, every path ρ in G' consists of three consecutive subpaths $\rho_1\rho_2\rho_3 = \rho$, where ρ_1 and ρ_3 are defined as the maximal subpaths of ρ that do not rely on edges from E^+. These subpaths already exist in G and are represented in $\textsc{Ans}$. The subgraph ρ_2 by definition starts and ends at nodes from V_{aff}, so its existence is given by the transitive closure relation of H.

Hence, the transitive closure of G' can be defined by the formula $\varphi(s, t) \overset{\text{def}}{=} \textsc{Ans}(s, t) \vee \exists x_1 \exists x_2 \big(\textsc{Ans}(s, x_1) \wedge \text{TC}_H(x_1, x_2) \wedge \textsc{Ans}(x_2, t)\big)$. ◀

▶ **Theorem 7.** *Reachability on undirected graphs can be maintained in* $\mathsf{DynFO}(\leq, +, \times)$ *under changes of size* $\log^c n$*, for every* $c \in \mathbb{N}$.

Proof. The dynamic program from [9] that maintains undirected reachability in DynFO under single-edge changes uses, in addition to the transitive closure relation of the input graph, two binary auxiliary relations that represent a directed spanning forest of the input graph and its transitive closure, respectively. We show that these relations can still be maintained in $\mathsf{DynFO}(\leq, +, \times)$ under changes of $\log^c n$ many edges, for fixed $c \in \mathbb{N}$.

Recall that it suffices to treat insertions and deletions independently, as they can be handled subsequently by a dynamic program.

For edge insertions, the construction idea is very similar to the proof of Theorem 6. We define a graph H, where nodes correspond to connected components of the input graph that include an affected node, and edges indicate that some inserted edge connects the respective connected components. As this graph is of polylogarithmic size, thanks to Theorem 3 we can express a spanning forest for H and its transitive closure in $\mathsf{FO}(\leq, +, \times)$, which is sufficient to update the respective relations for the whole input graph.

In the case of edge deletions, the update formulas need to replace deleted spanning tree edges, whenever this is possible. Our approach is very similar to the case of edge insertions. The spanning tree decomposes into polylogarithmically many connected components when edges are deleted. These components can be merged again if non-tree edges exist that connect them, and these edges become tree edges of the spanning forest. For a correspondingly defined graph of polylogarithmic size we can again define a spanning forest and its transitive closure, and from this information select the new tree edges.

We explain both cases in more detail. Let $G = (V, E)$ be the undirected input graph of size n with transitive closure $\textsc{Ans}$, and let S and TC_S be a directed spanning forest for G and its transitive closure, respectively. Suppose that a set E^+ of size at most $\log^c n$ is inserted. We define a graph H as follows. It contains a node $v \in V$ if (1) v is affected, that is, if E^+ contains an edge of v, and (2) v is the smallest affected node in its connected component of G with respect to $\leq$. It contains an edge (u, v) if $(u', v') \in E^+$ for some nodes u', v' with $(u, u') \in \textsc{Ans}$ and $(v, v') \in \textsc{Ans}$, so, if the connected components of u and v are connected by an inserted edge. The graph H is easily seen to be FO-definable using $\textsc{Ans}$. Because H is of polylogarithmic size with respect to n and a spanning forest of a graph can be computed[2] in NL, we can define a spanning tree S_H as well as its transitive closure TC_{S_H} in $\mathsf{FO}(\leq, +, \times)$, thanks to Theorem 3.

The update formulas define updated auxiliary relations for the graph $G' = (V, E \cup E^+)$ as follows. Intuitively, an edge $(u, v) \in S_H$ means that the connected components of u and v in G shall be connected in G' directly by a new tree edge. There might be several edges in E^+ that may serve this purpose, and we need to choose one of them. So, an edge $(u', v') \in E^+$ becomes part the updated spanning forest if there is an edge $(u, v) \in S_H$ such that u' and u as well as v' and v are in the same connected component of G, respectively, and (u', v') is the lexicographically minimal edge with these properties. This is clearly $\mathsf{FO}(\leq, +, \times)$-expressible using the old auxiliary relations. The old tree edges from S are taken over to the updated version, although some directions need to be inverted, if for a newly chosen tree edge (u', v') the node v' was not the root of the directed spanning tree of its connected component. First-order formulas that determine which edges need to be reversed and that provide the adjusted transitive closure for the components of the spanning forest are given in [9]. The relation TC_S is updated by combining this information with TC_{S_H}.

We note that $\textsc{Ans}$ is first-order expressible from TC_S. In conclusion, all auxiliary relations can be updated in $\mathsf{FO}(\leq, +, \times)$.

Now suppose that a set E^- of at most $\log^c n$ edges is deleted. Let S' be the spanning forest that results from S after all tree edges from E^- are removed, and let $\text{TC}_{S'}$ be its transitive closure, which is easily FO-expressible from TC_S. Similarly as above we define a graph H, with nodes being the minimal affected nodes in a weakly connected component of S', which are connected by an edge if the respective weakly connected components of S' are connected by some edge from $E \setminus E^-$. The same way as above, $\mathsf{FO}(\leq, +, \times)$ formulas can define a spanning forest and its transitive closure for H and then use this information to define a spanning forest and its transitive closure for the changed graph $G' = (V, E \setminus E^-)$. ◀

6 Handling Polylog Changes with DynFO+Mod 2

While we have seen, in the last section, that reachability for directed graphs can be maintained under edge insertions of polylogarithmic size, a matching result for edge deletions is still missing. Two intermediate results were shown in [7], building on the work of [13]: reachability can be maintained in $\mathsf{DynFO}(\leq, +, \times)$ under insertions and deletions that affect $\frac{\log n}{\log \log n}$ nodes, and in $\mathsf{DynFO{+}Maj}$ under insertions and deletions of polylogarithmically many edges.

[2] For example the breadth-first spanning forest with the minimal nodes of each component, with respect to $\leq$, as roots can be computed with the inductive counting technique due to Immerman and Szelepcsényi [15, 22].

In this section, we adapt the proof of the latter result, also using ideas that appear in [3], and show that reachability can be maintained in DynFO+Mod $2(\leq, +, \times)$ under edge insertions and deletions of polylogarithmic size for classes of directed graphs for which non-vanishing weight assignments can be computed in AC, that is, by polynomial-size circuits of polylogarithmic depth. This is possible for example for planar graphs [23], as well as for graphs with bounded treewidth, as we show towards the end of this section.

We start by giving the necessary definitions regarding isolating and non-vanishing weight assignments.

6.1 Isolating and non-vanishing weights

A *weighted* directed graph (G, w) consists of a graph $G = (V, E)$ and a *weight assignment* $w \colon E \to \mathbb{Z}$ that assigns an integer weight $w(e)$ to each edge $e \in E$. The weight assignment w is *bounded* by a function $f(|V|)$ if w assigns only weights from the interval $[-f(|V|), f(|V|)]$.

The weighted graph (G, w) is *min-unique* if (1) w only gives positive weights to the edges E, and (2) if some path from s to t exists, for some pair s, t of nodes, then there is a unique path from s to t with minimum weight under w. Here, the weight of a path (and in general every sequence of edges) is the sum of the weights of its edges. If (G, w) is min-unique, we say that w *isolates* (minimal paths in) G.

Define $\overleftrightarrow{G} = (V, \overleftrightarrow{E})$ to be the *bidirected extension* of G, where $\overleftrightarrow{E} \overset{\text{def}}{=} \{(u, v), (v, u) \mid (u, v) \in E\}$. A weight assignment w is *skew-symmetric* if $w(u, v) = -w(v, u)$ for all $(u, v) \in \overleftrightarrow{E}$. It has *non-zero circulation* if the weight of every simple directed cycle in $\overleftrightarrow{G}$ is non-zero (here, a cycle is *simple* if no node occurs twice).

From polynomially bounded non-zero circulation weights for $\overleftrightarrow{G}$ we can easily compute isolating weights for G.

▶ **Lemma 8.** *Let $G = (V, E)$ be a graph with n nodes, and let w be skew-symmetric non-zero circulation weight assignment for $\overleftrightarrow{G}$, which is bounded by n^k for some $k \in \mathbb{N}$. Then w' with $w'(e) = w(e) + n^{k+2}$ for every $e \in E$ isolates G.*

Proof. All weights in w' are clearly positive. It remains to show that w' isolates minimal paths in G. Assume, towards a contradiction, that there are two different s-t-paths ρ_1, ρ_2 with the same minimal weight under w' in G, for some nodes s and t. Without loss of generality, they are both simple paths, as otherwise they cannot be minimal. Let u be the last node visited by both paths before they differ for the first time, and let v be the first node after u that is visited by both paths. Let ρ_1^{uv}, ρ_2^{uv} be the subpaths in ρ_1, ρ_2 from u to v, respectively. If these subpaths have different weights, say, $w'(\rho_1^{uv}) < w'(\rho_2^{uv})$, then we can replace ρ_2^{uv} by ρ_1^{uv} in ρ_2 and get a lighter path, contradicting the assumption that both ρ_1 and ρ_2 are paths with minimal weight. So, $w'(\rho_1^{uv}) = w'(\rho_2^{uv})$ needs to hold. Then also $w(\rho_1^{uv}) = w(\rho_2^{uv})$ holds, because $w(\rho)$ and $w'(\rho)$ differ by a multiple of n^{k+2} for any path ρ, and the difference between $w(\rho)$ and $w(\rho')$ is at most n^{k+1}, for simple paths ρ and ρ'. So, w' cannot compensate weight differences under w. But then the concatenation of ρ_1^{uv} and the reverse of ρ_2^{uv} is a simple cycle in $\overleftrightarrow{G}$ with weight $w(\rho_1^{uv}) - w(\rho_2^{uv}) = 0$, contradiction the assumption that w has non-zero circulation. ◀

We explain how (families of) polynomially bounded weight assignments for graphs are represented in relational structures. Let V be the node set of a weighted graph of size n. We identify V with the set $\{0, \ldots, n-1\}$ of numbers according to the given linear order $\leq$. A tuple $(a_1, \ldots, a_k)$ of nodes then represents the number $\sum_{i=1}^{k} a_i n^{i-1}$. A (partial) function $f \colon V^k \to V^\ell$ is represented as a $(k+\ell)$-ary relation F over V, such that for each $\bar{a} \in V^k$ there is at most one $\bar{b} \in V^\ell$ with $(\bar{a}, \bar{b}) \in F$. We say that f is $\mathsf{FO}(\leq, +, \times)$-definable if F is defined by an $\mathsf{FO}(\leq, +, \times)$ formula $\psi(\bar{x}, \bar{y})$, where $\bar{x} = x_1, \ldots, x_k$ and $\bar{y} = y_1, \ldots, y_\ell$. An $\mathsf{FO}(\leq, +, \times)$ formula $\psi(\bar{z}, \bar{x}, \bar{y})$, with $\bar{z} = z_1, \ldots, z_m$, defines a family $\{f(\bar{c})\colon V^k \to V^\ell \mid \bar{c} \in V^m\}$ of functions.

6.2 Maintaining Reachability in weighted graphs

We now state and prove the main result of this section.

▶ **Theorem 9.** *Let $\mathcal{G}$ be a class of graphs for which polynomially bounded skew-symmetric non-zero circulation weights can be computed in* AC. *Then, reachability for graphs in $\mathcal{G}$ is in* $\mathsf{DynFO{+}Mod}\,2(\leq, +, \times)$ *under changes of size $\log^c n$, for every $c \in \mathbb{N}$.*

Although this result leaves open whether reachability can be maintained in $\mathsf{DynFO}(\leq, +, \times)$ under polylogarithmically many edge changes, note that, in light of Corollary 2, it gives a tight upper bound for the size of changes that can be handled in $\mathsf{DynFO{+}Mod}\,2(\leq, +, \times)$.

We outline the proof strategy, which closely follows the strategy from [7]. Suppose, we are given a weighted directed graph (G, w) where $G = (V, E)$ is a graph with n nodes and w is an isolating weight assignment. We represent this weighted graph by an $n \times n$ matrix $A_{(G,w)}(x)$ as follows: if $(u, v) \in E$, then the u-v-entry of $A_{(G,w)}(x)$ is $x^{w(u,v)}$, where x is a formal variable, otherwise the u-v-entry is 0.

The matrix $D \stackrel{\text{def}}{=} \sum_{i=0}^{\infty}(A_{G_w}(x))^i$ is a matrix of formal power series in the formal variable x, and from an s-t-entry $\sum_{i=0}^{\infty} c_i x^i$ of this matrix we can read the number c_i of paths from s to t with weight i. Our goal is to determine the coefficients c_i modulo 2, for all i up to some polynomial bound. From this information we can deduce whether there is a path from s to t in G: as w isolates minimal paths in G, if there is some path from s to t, then there is a unique path with minimal weight, which means that for the weight ℓ of this path we have $c_\ell \equiv 1 \pmod 2$. Otherwise, if no path from s to t exists, $c_\ell \equiv 0 \pmod 2$ for all i.

We use the following insights to actually compute and update the coefficients c_i. Notice that the matrix D is invertible over the ring of formal power series (see [7] and its full version [8]) and can be written as $D = (I - A_{(G,w)}(x))^{-1}$, where I is the identity matrix.

So, we need to compute and update the inverse of a matrix. This cannot be done effectively for matrices of inherently infinite formal power series. For this reason we compute D only approximately. A *b-approximation* C of D, for some $b \in \mathbb{N}$, is a matrix of formal polynomials that agrees with the entries of D on the low-degree coefficients c_i for all $i \leq b$. This precision is preserved by the matrix operations we use, see [7, Proposition 14]. Note that it is sufficient to maintain an approximation of D, as for a weighted graph with polynomially bounded weights the maximal possible weight $w_{\max}$ of a minimal path is bounded by a polynomial, and thus only the coefficients c_i with $i \leq w_{\max}$ are relevant.

To update the matrix inverse, we employ the Sherman-Morrison-Woodbury identity (cf. [12]). This identity states that when updating a matrix A to a matrix $A + \Delta A$, with ΔA writeable as matrix product UBV, the inverse of A can be updated as follows:

$$(A + \Delta A)^{-1} = (A + UBV)^{-1} = A^{-1} - A^{-1}U(I + BVA^{-1}U)^{-1}BVA^{-1}.$$

When ΔA has only k non-zero rows and columns, there is a decomposition UBV where B is a $k \times k$ matrix.

The right-hand side can be computed in $\mathsf{FO{+}Mod}\,2(\leq, +, \times)$ for $k \stackrel{\text{def}}{=} \log^c n$. To see this, we observe that also $I + BVA^{-1}U$ is a $k \times k$ matrix. Computing the right-hand side now requires multiplication and iterated addition of polynomials over $\mathbb{Z}$ as well as the computation of the inverse of a $k \times k$ matrix. As all computations are done modulo 2, this is indeed possible in FO+Mod $2(\leq, +, \times)$ for (matrices of) polynomials with polynomial degree using results of [11]. We provide more details later.

As we work with isolating weight assignments, our update routines also need to assign weights to changed edges such that the resulting weight assignment is again isolating. We show that this can be done if we start with (slightly adjusted) non-zero circulation weights. Using Theorem 5 we can assume that such an assignment is given, and that we only need to update the weights once.

Proof sketch (of Theorem 9). Let c be arbitrary. Thanks to Theorem 5 it suffices to show that there is a $d \in \mathbb{N}$ such that reachability is $(\mathsf{AC}^d, 1)$-maintainable by a dynamic program $\mathcal{P}$ under changes of size $\log^{c+d} n$. Let $d' \in \mathbb{N}$ be such that polynomially bounded skew-symmetric non-zero circulation weights for graphs from $\mathcal{G}$ can be computed in $\mathsf{AC}^{d'}$, and set $d \overset{\text{def}}{=} \max(2, d')$.

Let $G = (V, E)$ be a graph with n nodes. Let u be skew-symmetric non-zero circulation weights for G and let n^k be the polynomial bound on the weights. Further, let w be the weight assignment that gives weight $n^{k+2} + u(e)$ to each edge $e \in E$. Notice that w is polynomially bounded by n^{k+3} and isolates G according to Lemma 8.

The AC^d initialization computes, as auxiliary information, the weightings u and w and an n^b-approximation C of $(I - A_{(G,w)}(x))^{-1} \bmod 2$, that is, a matrix of formal polynomials in x that agree with the formal power series in $(I - A_{(G,w)}(x))^{-1} \bmod 2$ on the coefficients up to degree n^b. Here, $b \in \mathbb{N}$ is a constant to be determined later.

When changing G via a change ΔE with deletions E^- and insertions E^+, the dynamic program $\mathcal{P}$ handles deletions and insertions subsequently:

(1) Handling of deletions:
 - **(a)** Define isolating weights w^- for $G^- \overset{\text{def}}{=} (V, E \setminus E^-)$. The weights w^- will differ from w only for the at most $\log^{c+d} n$ edges in E^-.
 - **(b)** Compute an n^b-approximation of $(I - A_{(G^-,w^-)}(x))^{-1} \bmod 2$ using the existing n^b-approximation of $(I - A_{(G,w)}(x))^{-1} \bmod 2$.

(2) Handling of insertions:
 - **(a)** Define a family $W^{-/+}$ of weightings such that one member of the family is isolating for $G^{-/+} \overset{\text{def}}{=} (V, (E \setminus E^-) \cup E^+)$. All weightings of the family will differ from w^- only for the at most $\log^{c+d} n$ edges in E^+.
 - **(b)** Compute an n^b-approximation of $(I - A_{(G^{-/+},w^{-/+})}(x))^{-1} \bmod 2$ using the existing n^b-approximation of $(I - A_{(G^-,w^-)}(x))^{-1} \bmod 2$ for all members $w^{-/+}$ of $W^{-/+}$.

We first explain Steps (1a) and (2a) in more detail. For computing the isolating weights w^-, the program proceeds as follows. Skew-symmetric non-zero circulation weights u^- for G^- are obtained from the non-zero circulation weights u for G by setting the weight of deleted edges $e \in E^-$ to 0. As u^- gives the same weight to all simple cycles in G^- as u gives to these cycles in G, it has non-zero circulation. Now, the weight assignment w^- defined by $n^{k+2} + u^-(e)$ is isolating for G^- due to Lemma 8, and differs from w only for edges in E^-.

Computing the isolation weights for insertions is more challenging. In Lemma 11 below we show that from G^-, its transitive closure, and a set E^+ of edges of polylogarithmic size one can $\mathsf{FO}(\leq, +, \times)$-define a family $W^{-/+}$ of weight assignments such that one of these assignments is isolating for $G^{-/+}$.

For both Steps (1b) and (2b), the inverse of a matrix of polynomials over $\mathbb{Z}_2$ of polynomial degree needs to be updated after changing polylogarithmically many entries (i.e. entries corresponding to E^- and E^+, respectively). Inverses can be updated under such changes in

$\mathsf{FO{+}Mod}\,2(\leq,+,\times)$ due to Lemma 10 (see below) and the observation that changes ΔA of size $\log^{c+d} n$ to such a matrix can be decomposed into UBV as required by Lemma 10, see Lemma 7 in [7]. For Step (2b) this is done in parallel for all members of $W^{-/+}$.

For checking whether there is a path from s to t after the change ΔE to G, the dynamic program checks whether there is a member of $W^{-/+}$ such that the s-t-entry of $(I - A_{(G^{-/+},w^{-/+})}(x))^{-1} \bmod 2$ is non-zero. Since one member of $W^{-/+}$ is isolating, a path will be discovered this way. ◀

In the remainder of this subsection we show how inverses for matrices of polynomials can be updated under changes of polylogarithmic size, and how weights for inserted edges can be found.

The following lemma is obtained using the same techniques as in [7]. Here, $\mathbb{Z}_2[[x]]$ denotes the ring of formal power series with coefficients from $\mathbb{Z}_2$, and $\mathbb{Z}_2[x]$ denotes its subring that consists of all finite polynomials.

▶ **Lemma 10.** *Suppose $A \in \mathbb{Z}_2[[x]]^{n\times n}$ is invertible over $\mathbb{Z}_2[[x]]$, and $C \in \mathbb{Z}_2[x]^{n\times n}$ is an m-approximation of A^{-1}. If $A + \Delta A$ is invertible over $\mathbb{Z}_2[[x]]$ and ΔA can be written as UBV with $U \in \mathbb{Z}_2[x]^{n\times k}, B \in \mathbb{Z}_2[x]^{k\times k}$, and $V \in \mathbb{Z}_2[x]^{k\times n}$, then*

$$(A + \Delta A)^{-1} \approx_m C - CU(I + BVCU)^{-1}BVC$$

Furthermore, if $k \leq \log^c n$ for some fixed c and all involved polynomials have polynomial degree in n, then the right-hand side can be defined in $\mathsf{FO{+}Mod}\,2(\leq,+,\times)$ from C and ΔA.

Proof sketch. The correctness of the equation can be proved exactly as in Proposition 14 in [7] (there, this is proved for $\mathbb{Z}[[x]]$ instead of $\mathbb{Z}_2[[x]]$).

We argue that the right-hand side can be defined in $\mathsf{FO{+}Mod}\,2(\leq,+,\times)$. The involved matrix additions and multiplications modulo 2 can easily be expressed in $\mathsf{FO{+}Mod}\,2(\leq,+,\times)$, see [11]. It remains to explain how the inverse of the $\log^c n \times \log^c n$ matrix $I + BVCU$ can be found.

To this end, recall that the i-j-entry of the inverse of a matrix D is equal to $(-1)^{i+j}\frac{\det D_{ji}}{\det D}$, where D_{ji} is obtained from D by removing the j-th row and the i-th column.

So, it is sufficient to show that the determinant of a $\log^c n \times \log^c n$ matrix of polynomials with polynomial degree can be expressed modulo 2. In [7, Lemma 15] it was shown that such a determinant can be expressed in $\mathsf{FO{+}Maj}(\leq,+,\times)$, by observing that one only needs to be able to express the sum of polynomially many polynomials and the product of $\log^c n$ many polynomials. This observation is still valid for computing the determinant modulo 2 in $\mathsf{FO{+}Mod}\,2(\leq,+,\times)$. Both kind of computations are possible modulo 2 in $\mathsf{FO{+}Mod}\,2(\leq,+,\times)$ as well [11]. ◀

▶ **Lemma 11.** *Let $G = (V,E)$ be a graph and let $n = |V|$. Further, let w be a polynomially bounded isolating weight assignment for G, and let E^+ be a set of $\mathcal{O}(\log^c n)$ edges that is disjoint from E, for some $c \in \mathbb{N}$. Then there is a family W' of polynomially many polynomially bounded weight assignments such that*

1. *W' is $\mathsf{FO}(\leq,+,\times)$-definable from G, $\textsc{Reach}(G)$, E^+ and w,*
2. *all $w' \in W'$ agree with w on E,*
3. *at least one $w' \in W'$ is isolating for $(V, E \cup E^+)$.*

The proof works along the following lines. We use the approach from [18] to obtain weights for the inserted edges with the following idea: if there is an s-t-path that uses at least one inserted edge from E^+, then there is a unique minimal path under all s-t-paths that use at least one such edge, where we ignore the weight of the paths that is contributed by edges from E. We multiply these constructed weights for the edges from E^+ by a large polynomial to ensure that the combined weight assignment with the existing weights for edges in E is isolating for the graph $(V, E \cup E^+)$.

The approach from [18] does not lead to polynomially bounded weights in the size of the graph it is used for. We construct them for a graph with $N = \mathcal{O}(\log^c n)$ many nodes, and although they are not polynomially bounded in N, they are in n.

We now get to the details of the construction. In the following, we consider graphs with two sets of edges. An *adorned* graph $G = (V, E, F)$ has, besides the set E of *real* edges, a further set F of *fictitious* edges, which is not necessarily disjoint from E. For each pair s, t of nodes, let $\mathcal{P}'_{s,t}$ be the set of s-t-paths in G that use at least one real edge $e \in E$ and arbitrarily many fictitious edges $e' \in F$. Let $\mathcal{P}_{s,t}$ be the set of edge sequences that result from $\mathcal{P}'_{s,t}$ by removing the fictitious edges from the paths.

We say that a weight assignment w *real-isolates* G, if (1) it maps each real edge $e \in E$ to a positive integer, and (2) each non-empty $\mathcal{P}_{s,t}$ has a unique minimal element under w. In the following, we will need a stronger property. We say that w *strongly* real-isolates G, if in addition for each pair $\mathcal{P}_{s,t}$ and $\mathcal{P}_{s',t'}$ of non-empty sets with $(s,t) \neq (s',t')$ the unique minimal elements of $\mathcal{P}_{s,t}$ and $\mathcal{P}_{s',t'}$ have different weights under w.

The following lemma can be proved along the lines of [18], see the full version for details.

▶ **Lemma 12.** *There is a constant $\beta \in \mathbb{N}$ such that for every natural number N and every adorned graph $G = (V, E, F)$ with $V = \{1, \dots, N\}$ there is a sequence $\bar{p} = p_1, p_2, \dots, p_{\log N}$ of primes, each consisting of at most $(\beta - 2)\log N$ bits, such that the weight assignment*

$$w_{\bar{p}}(e) = \begin{cases} \sum_{j=1}^{\log N} N^{\beta(\log N - j)}(w_0(e) \bmod p_j) & e \in E \\ 0 & e \in F \end{cases}$$

strongly real-isolates G. Here, $w_0(u,v) \overset{def}{=} 2^{(N+1)u+v}$.

Using this lemma, we can prove Lemma 11.

Proof of Lemma 11. Let $V_{\text{aff}} \subseteq V$ be the set of nodes with edges in E^+. We construct an adorned graph $H = (V_H, E_H, F_H)$ with node set $V_H \overset{\text{def}}{=} V_{\text{aff}}$ as follows. The set E_H of real edges is $E_H \overset{\text{def}}{=} E^+$, and the set F_H of fictitious edges is $F_H \overset{\text{def}}{=} \{(u,v) \mid u, v \in V_H, (u,v) \in \textsc{Reach}(G)\}$. So, a fictitious edge (u,v) of H represents the existence of a u-v-path in G.

Let $\beta, \bar{p}$ and $w_{\bar{p}}$ be as promised to exist for H by Lemma 12. Further, let n^k be the upper bound on the weights of w. We define the weight assignment w' for $G' \overset{\text{def}}{=} (V, E \cup E^+)$ as follows.

- $w'(e) = w(e)$ for all $e \in E$,
- $w'(e) = n^{k+2} \cdot w_{\bar{p}}(e)$ for all $e \in E^+ = E_H$.

We show that w' isolates G' first, afterwards we show that w' is a member of an $\mathsf{FO}(\leq, +, \times)$-definable family of weightings.

For showing that w' isolates G' suppose, towards a contradiction, that there are two lightest simple s-t-paths π, ρ in G' with respect to w', for some nodes s and t. Let $\pi_1\pi_2\pi_3 = \pi$ and $\rho_1\rho_2\rho_3 = \rho$ be the subpaths of π and ρ such that edges from E^+ are only used in π_2 and ρ_2 and those subpaths are minimal with that property. Notice that both π_2 and ρ_2 are non-empty, as otherwise ρ and π are also lightest paths in G with respect to w, contradicting the assumption that w isolates G. Let π' and ρ' be the paths in H that correspond to π_2 and ρ_2, where subpaths of π_2 and ρ_2 are replaced by fictitious edges. We consider two cases.

If $w_{\bar{p}}(\pi') \neq w_{\bar{p}}(\rho')$, then the total weight of π and ρ contributed by the edges from E^+ differs by at least n^{k+2}. As the total weight contributed by the remaining edges is upper-bounded by n^{k+1}, we have that $w'(\pi) \neq w'(\rho)$, the desired contradiction.

Thus assume, without loss of generality, that $w_{\bar{p}}(\pi') = w_{\bar{p}}(\rho')$. We can assume that both paths π' and ρ' are lightest paths in H: if, say, π' is not a lightest path, then we can replace π_2 in π by a path that uses lighter edges from E^+, leading to an overall lighter path by the argument of the previous case. Then, because $w_{\bar{p}}$ strongly isolates H, the edges from $E_H = E^+$ used in π' and ρ' must be equal, and the same is true for π_2 and ρ_2. These edges must also be used in the same order, as otherwise a path with fewer edges from E^+ exists, which by the argument of previous case is lighter than both π and ρ. Because π and ρ are different paths, there must be subpaths π^* and ρ^* that consist only of edges from E and are both simple u-v-paths, for some nodes u and v. As w is isolating for G, not both subpaths can be lightest u-v-paths in G. Say, ρ^* is not such a lightest path. If we replace ρ^* in ρ by the lightest u-v-path in G, we obtain a path that is lighter than ρ, as w' agrees with w on E. So, ρ is not a lightest s-t-path in G' with respect to w', the desired contradiction. It follows that w' is isolating for G'.

The weight assignment $w_{\bar{p}}$ is clearly $\mathsf{FO}(\leq, +, \times)$-definable from $G, \textsc{Reach}(G), E^+, w$ and $\bar{p}$, as H is $\mathsf{FO}(\leq, +, \times)$-definable, the involved numbers consist of at most polylogarithmically many bits, and $\mathsf{FO}(\leq, +, \times)$ can express the necessary arithmetic on numbers of that magnitude (see [14, Theorem 5.1]). The sequence $\bar{p}$ consists of $\mathcal{O}(\log\log n)$ many primes (as H is of size polylog) which in turn are represented by $\mathcal{O}(\log\log n)$ many bits, because H has only polylogarithmic size in n. So, $\bar{p}$ can be represented by a tuple of nodes from V, and it follows that a family W' of weight assignments with $w' \in W'$ is $\mathsf{FO}(\leq, +, \times)$-definable from $G, \textsc{Reach}(G), E^+$ and w. ◀

6.3 Computing weights for bounded-treewidth graphs

In this section, we show that isolating weights for graphs of bounded treewidth can be computed in LOGSPACE. As an immediate consequence, reachability can be maintained for such graphs under changes of polylogarithmic size.

A *tree decomposition* $\mathcal{T} = (T, \mathcal{B})$ of a graph $G = (V, E)$ consists of a (rooted, directed) tree $T = (I, F, r)$, with (tree) nodes I, (tree) edges F, a distinguished root node $r \in I$, and a function $\mathcal{B}\colon I \to 2^V$ such that

(1) the set $\{i \in I \mid v \in \mathcal{B}(i)\}$ is non-empty for each node $v \in V$,
(2) there is an $i \in I$ with $\{u, v\} \subseteq \mathcal{B}(i)$ for each edge $(u, v) \in E$, and
(3) the subgraph $T[\{i \in I \mid v \in \mathcal{B}(i)\}]$ is connected for each node $v \in V$.

We refer to the number of children of a node i of T as its *degree*, and to the set $\mathcal{B}(i)$ as its *bag*. We denote the parent node of i by parent(i). The *width* of a tree decomposition is defined as the maximal size of a bag minus 1. The *treewidth* of a graph G is the minimal width among all tree decompositions of G. A tree decomposition is binary, if all tree nodes have degree at most 2. Its depth is the length of a longest path from the root r to a leaf of T. We inductively define the *height* $h(i)$ of i to be 1 if i is a leaf, and $h(i') + 1$ if i is an inner tree node and i' is a child of i with maximal height. For a node $v \in V$ we denote by $B(v)$ the highest bag that contains u, and let $h(u) \overset{\text{def}}{=} h(B(u))$. This bag $B(v)$ is well-defined for each node v thanks to condition (3) of the definition of a tree decomposition.

We usually identify tree nodes i and their bag $\mathcal{B}(i)$, and use the above notions and measures directly for bags. We also abuse notation and write $B \in \mathcal{B}$ if $B = \mathcal{B}(i)$ for some tree node i.

As a first step we construct isolation weights for bounded treewidth graphs that additionally have bounded degree. Isolation weights for all graphs of bounded treewidth are provided afterwards.

▶ **Proposition 13.** *Let $c, d, k \in \mathbb{N}$ be fixed. Let $G = (V, E)$ be a graph with maximal degree d, and let n be the number of its nodes. Let $\mathcal{T}$ be a binary tree decomposition of G with width k and depth at most $c \log n$. A polynomially bounded skew-symmetric weight assignment with non-zero circulation for G can be computed in* LOGSPACE.

Proof. The idea for assigning weights is the following. We associate each edge with one bag of the tree decomposition, namely the highest bag that contains one endpoint of the edge. For each bag B, we denote the set of all edges that are associated with B by $S(B)$. As the width of $\mathcal{T}$ and the degree of G are bounded by a constant, so is $|S(B)|$. An edge e is assigned a weight that depends exponentially on the height of the bag B it is associated with, and also exponentially on its position in some linear order on $S(B)$. For each cycle C there is a unique highest bag B_C that some of the cycle's edges is associated with. The idea for establishing non-zero circulation of C is that its weight is dominated by the weight of the unique edge which (1) is associated with B_C and (2) has largest index in the linear order on $S(B)$ among all edges of the cycle. As the height of a bag is logarithmic in n and $|S(B)|$ is bounded by a constant, the weight of every edge is polynomial in n.

We now proceed to the details. For each $e \in \vec{E}$, let B_e be the (unique) highest bag that contains one of the end points of e. For a bag B, define the set $S(B)$ of its associated edges as $S(B) \overset{\text{def}}{=} \{e \in \vec{E} \mid B = B_e\}$. Observe that the sets $S(B)$ partition the set $\vec{E}$ of edges and that the size of $S(B)$ is bounded by a constant $\beta \overset{\text{def}}{=} 2d(k+1)$, as each bag B contains at most $k+1$ nodes and each node has degree at most d in G and therefore degree at most $2d$ in $\vec{G}$. For each $S(B)$ we fix an enumeration of its elements[3]. Now, for each edge e, we set $h(e) = h(B_e)$ and $\ell(e) = i$, if e is the i-th element in the enumeration of $S(B_e)$.

We set the weight $w(e)$ of an edge $e = (u, v)$ with $u \leq v$ to be $w(e) \overset{\text{def}}{=} (4\beta \cdot 3^\beta + 2)^{h(e)} \cdot 3^{\ell(e)}$. The weight of an edge (u, v) with $u > v$ is $w(u, v) = -w(v, u)$. Notice that this weight assignment is polynomially bounded and skew-symmetric and can be computed in LOGSPACE. We now show that it has non-zero circulation.

Let $\mathcal{C}$ be any simple cycle in $\vec{G}$, and let $e_1, \ldots, e_m$ be an enumeration of its edges. Without loss of generality we assume that e_1 is the edge with the maximal weight among all edges in $\mathcal{C}$. This edge is well-defined, as there is a unique highest bag B such that $S(B)$ contains an edge of $\mathcal{C}$, and the term $4\beta \cdot 3^\beta + 2$ is strictly greater than $3^{\ell(e)}$ for any value of $\ell(e)$.

We show $|w(e_1)| > |w(e_2) + \cdots + w(e_m)|$, which implies the claim. Actually, we show that the weight of $w(e_1)$ exceeds the combined weight of all other edges e that are either in $S(B)$ and have $\ell(e) < \ell(e_1)$ or are in $S(B')$ for some bag B' below B in the tree decomposition. Note that there are $\sum_{h=1}^{h(e_1)-1} 2^{h(e_1)-h}$ many of those bags B', each $S(B')$ contains at most β edges, and the weight of each edge is upper bounded by $(4\beta \cdot 3^\beta + 2)^{h(B')} \cdot 3^\beta$.

$$\begin{aligned}
&|w(e_2) + \cdots + w(e_m)| \\
&\quad < \sum_{i=1}^{l(e_1)-1} (4\beta \cdot 3^\beta + 2)^{h(e_1)} \cdot 3^i + \sum_{h=1}^{h(e_1)-1} 2^{h(e_1)-h} \cdot \beta \cdot (4\beta \cdot 3^\beta + 2)^h \cdot 3^\beta \\
&\quad = \sum_{i=1}^{l(e_1)-1} (4\beta \cdot 3^\beta + 2)^{h(e_1)} \cdot 3^i + \sum_{h=1}^{h(e_1)-1} 2^{h(e_1)} \cdot \beta \cdot (2\beta \cdot 3^\beta + 1)^h \cdot 3^\beta
\end{aligned}$$

[3] As we devise an LOGSPACE algorithm, we can assume the existence of a linear order on the input.

$$
\begin{aligned}
&= (4\beta \cdot 3^{\beta} + 2)^{h(e_1)} \cdot \sum_{i=1}^{l(e_1)-1} 3^i + 2^{h(e_1)} \cdot \beta \cdot 3^{\beta} \cdot \sum_{h=1}^{h(e_1)-1} (2\beta \cdot 3^{\beta} + 1)^h \\
&= (4\beta \cdot 3^{\beta} + 2)^{h(e_1)} \cdot \frac{3^{l(e_1)} - 3}{2} + 2^{h(e_1)} \cdot \beta \cdot 3^{\beta} \cdot \frac{(2\beta \cdot 3^{\beta} + 1)^{h(e_1)} - (2\beta \cdot 3^{\beta} + 1)}{2\beta \cdot 3^{\beta}} \\
&< (4\beta \cdot 3^{\beta} + 2)^{h(e_1)} \cdot 3^{\ell(e_1)} = |w(e_1)|
\end{aligned}
$$
◀

Non-zero circulation weights cannot only be computed in LOGSPACE for bounded-treewidth graphs with bounded degree, as given by Proposition 13, but also for all graphs with bounded treewidth. Also, using a result of Elberfeld, Jakoby and Tantau [10], no tree decomposition needs to be given as input.

▶ **Theorem 14.** *Let $k \in \mathbb{N}$ be fixed and let $G = (V, E)$ be a graph with treewidth at most k. A polynomially bounded skew-symmetric weight assignment with non-zero circulation for G can be computed in* LOGSPACE.

The idea for proving Theorem 14 is as follows. From a given graph G with treewidth at most k we construct a graph G' with treewidth and degree $\mathcal{O}(k)$ as well as a tree decomposition. The graph G' basically results from a tree decomposition $\mathcal{T}$ of G by making a copy of a node v for every bag of $\mathcal{T}$ that contains v. These copies are connected by an edge if the corresponding bags in $\mathcal{T}$ are. Using Proposition 13, we obtain non-zero circulation weights for G', and we show that they can be translated to non-zero circulation weights for G.

Proof. Fix $k \in \mathbb{N}$ and let $G = (V, E)$ be a graph with treewidth at most k. Let n be the size of V. There are constants $c_1, c_2 \in \mathbb{N}$ that only depend on k such that a binary tree decomposition $\mathcal{T} = (T, \mathcal{B})$ of G of width at most $c_1 k$ and depth at most $c_2 \log n$ can be computed in LOGSPACE [10]. From G and $\mathcal{T}$ we construct a graph $G' = (V', E')$ as follows. Let V' be the set $V' \overset{\text{def}}{=} \{v_B \mid B \in \mathcal{B}, v \in B\}$ and let $E' \overset{\text{def}}{=} \{(v_B, v_{B'}) \mid B' = \text{parent}(B)\} \cup \{(u_B, v_B) \mid (u, v) \in E, u \notin \text{parent}(B) \text{ or } v \notin \text{parent}(B)\}$. So, we have one copy v_B of a node $v \in V$ for each bag B such that v is contained in B. Two copies of a node are connected by an edge if they originate from adjacent bags in the tree decomposition, and there is an edge between two copies u_B and v_B, originating from the same bag B, if B is the highest bag of $\mathcal{T}$ that contains both endpoints u and v.

The degree of G' is bounded by $c_1 k + 3$. The tree decomposition $\mathcal{T}' = (T, \mathcal{B}')$ that replaces each bag B of $\mathcal{T}$ by $\{v_B \mid v \in B\} \cup \{v_{\text{parent}(B)} \mid v \in \text{parent}(B)\}$ is a tree decomposition of G' and has width at most $2c_1 k + 1$. Furthermore, it is binary and has depth at most $c_2 \log n$. So, by Proposition 13, one can compute in LOGSPACE polynomially bounded, skew-symmetric non-zero circulation weights w' for G'.

We construct a weight function w for $\overleftrightarrow{G}$ as follows. For that, we associate with each edge $(u, v) \in \overleftrightarrow{E}$ a sequence $P(u, v)$ of edges in $\overleftrightarrow{G'}$. Recall that for each edge (u, v) there is a highest bag in which both u and v appear. The bag above that bag contains either (a) none of the two vertices, or (b) v but not u, or (c) u but not v. The definition of $P(u, v)$ distinguishes these three cases:

1. Suppose $B(u) = B(v)$. We set $P(u, v) = (u_{B(u)}, v_{B(v)})$.
2. Suppose $B(u)$ is a proper descendant of $B(v)$. Let $B = B(u)$ and $B' = B(v)$. We set $P(u, v) = (u_B, v_B), (v_B, v_{\text{parent}(B)}), \ldots, (v_{\text{parent}(\cdots(\text{parent}(B)))}, v_{B'})$.
3. Suppose $B(v)$ is a proper descendant of $B(u)$. Let $B = B(u)$ and $B' = B(v)$. We set $P(u, v) = (u_B, u_{\text{parent}(\cdots(\text{parent}(B')))}), \ldots, (u_{\text{parent}(B')}, u_{B'}), (u_{B'}, v_{B'})$.

Now, let $w(u, v)$ be the sum $\sum_{e \in P(u,v)} w'(e)$ of the weights of the edges e in $P(u, v)$. Because w' is a polynomially bounded skew-symmetric weight assignment, so is w.

It remains to show that w has non-zero circulation. Let $\mathcal{C}$ be an arbitrary simple cycle in $\overleftrightarrow{G}$. We need to show that w assigns a non-zero weight to $\mathcal{C}$. Let $e_1, \dots, e_m$ be the sequence of edges that constitutes $\mathcal{C}$, and let $\mathcal{W}'$ be the sequence $P(e_1), \dots, P(e_m)$ of edges. By definition, the weight of $\mathcal{C}$ under w is the same as the weight of $\mathcal{W}'$ under w'.

Note that $\mathcal{W}'$ constitutes a cycle in $\overleftrightarrow{G}'$ which is not necessarily simple: some nodes might be visited more than once. We show that we can construct from $\mathcal{W}'$ a simple cycle $\mathcal{C}'$ by removing parts of $\mathcal{W}'$ with total weight 0. As a result, $\mathcal{C}'$ has the same weight as $\mathcal{W}'$ under w'. Because w' has non-zero circulation, the weight of $\mathcal{C}'$ and $\mathcal{W}'$ is non-zero, and so is the weight of $\mathcal{C}$ under w.

Suppose that some node u_B is visited twice by $\mathcal{W}'$. Then $\mathcal{W}'$ has the subsequence $P(v,u)P(u,v')$ for some nodes v and v', because u is visited only once in $\mathcal{C}$ and no node appears twice in a single sequence $P(u,u')$. Moreover, it most be that $h(u)$ is greater than both $h(v)$ and $h(v')$, or smaller than both $h(v)$ and $h(v')$, and either $B(v)$ is a descendent of $B(v')$ or $B(v')$ is a descendant of $B(v)$. We consider the case that $h(u)$ is greater than both $h(v)$ and $h(v')$, and $B(v')$ is a descendant of $B(v)$. The other cases are analogous. Then $P(v,u)P(u,v')$ visits the nodes $v_{B(v)}, u_{B(v)}, u_{\text{parent}(B(v))}, \dots, u_{B(u)}, \dots u_{\text{parent}(B(v))}, u_{B(v)}, \dots, u_{B(v')}, v'_{B(v')}$ in that order. The closed walk from $u_{B(v)}$ to $u_{B(u)}$ and back to $u_{B(v)}$ has, because of skew-symmetry, a total weight of 0 under w'. So, the corresponding edges can be removed from $\mathcal{W}'$ without changing the weight. Repeating this step results in a simple cycle $\mathcal{C}'$ with the same weight under w' as $\mathcal{C}$ under w. As w' has non-zero circulation, the weight of $\mathcal{C}'$ is non-zero, and so is the weight of $\mathcal{C}$. ◀

7 Conclusion

The complexity of maintaining (variants of) the reachability query is the dominant research question in dynamic complexity theory. With this paper we basically settle this question for reachability in undirected graphs, at least with respect to the size of a change: reachability in undirected graphs is in DynFO$(\leq, +, \times)$ if and only if the changes have at most polylogarithmic size. For reachability in directed graphs, we can only show this for insertions of polylogarithmic size, and the main open problem is whether this can be extended to also allow for deletions of single edges, non-constantly many edges, or even polylogarithmically many edges.

We give preliminary results for classes of graphs for which non-zero circulation weights can be computed in AC: reachability for these graphs is in DynFO+Mod 2$(\leq, +, \times)$ under insertions and deletions of polylogarithmic size. We show that one can compute such weight assignments for graphs with bounded treewidth. Other graph classes for which this is possible include the class of planar graphs [23], and in general all graphs with bounded genus, which one can show using results from [5].

A question for further research is whether reachability for classes of directed graphs can be maintained in DynFO$(\leq, +, \times)$ under insertions and deletions of polylogarithmic size. Candidate classes are graphs with bounded treewidth, and directed acyclic graphs.

Abstract

The Strahler number of a rooted tree is the largest height of a perfect binary tree that is its minor. The Strahler number of a parity game is proposed to be defined as the smallest Strahler number of the tree of any of its attractor decompositions. It is proved that parity games can be solved in quasi-linear space and in time that is polynomial in the number of vertices n and linear in $(d/2k)^k$, where d is the number of priorities and k is the Strahler number. This complexity is quasi-polynomial because the Strahler number is at most logarithmic in the number of vertices. The proof is based on a new construction of small Strahler-universal trees.

It is shown that the Strahler number of a parity game is a robust, and hence arguably natural, parameter: it coincides with its alternative version based on trees of progress measures and – remarkably – with the register number defined by Lehtinen (2018). It follows that parity games can be solved in quasi-linear space and in time that is polynomial in the number of vertices and linear in $(d/2k)^k$, where k is the register number. This significantly improves the running times and space achieved for parity games of bounded register number by Lehtinen (2018) and by Parys (2020).

The running time of the algorithm based on small Strahler-universal trees yields a novel trade-off $k \cdot \lg(d/k) = O(\log n)$ between the two natural parameters that measure the structural complexity of a parity game, which allows solving parity games in polynomial time. This includes as special cases the asymptotic settings of those parameters covered by the results of Calude, Jain Khoussainov, Li, and Stephan (2017), of Jurdziński and Lazić (2017), and of Lehtinen (2018), and it significantly extends the range of such settings, for example to $d = 2^{O\left(\sqrt{\lg n}\right)}$ and $k = O\left(\sqrt{\lg n}\right)$.

1 Context

Parity Games. Parity games are a fundamental model in automata theory and logic [8, 32, 17, 2], and their applications to verification, program analysis, and synthesis. In particular, they are intimately linked to the problems of emptiness and complementation of non-deterministic automata on trees [8, 32], model checking and satisfiability of fixpoint logics [9, 2], and evaluation of nested fixpoint expressions [1, 18]. It is a long-standing open problem whether parity games can be solved in polynomial time [9].

The impact of parity games goes well beyond their home turf of automata theory, logic, and formal methods. For example, an answer [14] of a question posed originally for parity games [31] has strongly inspired major breakthroughs on the computational complexity of fundamental algorithms in stochastic planning [12] and linear optimization [15, 16].

Strahler Number. The Strahler number has been proposed by Horton (1945) and made rigorous by Strahler (1952), in their morphological study of river networks in hydrogeology. It has been also studied in other sciences, such as botany, anatomy, neurophysiology, physics, and molecular biology, where branching patterns appear. The Strahler number has been identified in computer science by Ershov [10] as the smallest number of registers needed to evaluate an arithmetic expression. It has since been rediscovered many times in various areas of computer science; see the surveys of Knuth [23], Viennot [30], and Esparza, Luttenberger, and Schlund [11].

Related Work. A major breakthrough in the quest for a polynomial-time algorithm for parity games was achieved by Calude, Jain, Khoussainov, Li, and Stephan [3], who have given the first quasi-polynomial algorithm. Other quasi-polynomial algorithms have been developed soon after by Jurdziński and Lazić [20], and Lehtinen [24]. Czerwiński, Daviaud, Fijalkow, Jurdziński, Lazić, and Parys [4] have introduced the concepts of *universal trees* and *separating automata*, and argued that all the aforementioned quasi-polynomial algorithms were intimately linked to them.

By establishing a quasi-polynomial lower bound on the size of universal trees, Czerwiński et al. have highlighted the fundamental limitations of the above approaches, motivating further the study of the attractor decomposition algorithm due to McNaughton [27] and Zielonka [32]. Parys [28] has proposed an ingenious quasi-polynomial version of McNaughton-Zielonka algorithm, but Lehtinen, Schewe, and Wojtczak [26], and Jurdziński and Morvan [21] have again strongly linked all quasi-polynomial variants of the attractor decomposition algorithm to universal trees.

Among several prominent quasi-polynomial algorithms for parity games, Lehtinen's approach [24] has relatively least attractive worst-case running time bounds. Parys [29] has offered some running-time improvements to Lehtinen's algorithm, but it remains significantly worse than state-of-the-art bounds of Jurdziński and Lazić [20], and Fearnley, Jain, de Keijzer, Schewe, Stephan, and Wojtczak [13], in particular because it always requires at least quasi-polynomial working space.

Our Contributions. We propose the Strahler number as a parameter that measures the structural complexity of dominia in a parity game and that governs the computational complexity of the most efficient algorithms currently known for solving parity games. We establish that the Strahler number is a robust, and hence natural, parameter by proving that it coincides with its version based on trees of progress measures and with the register number defined by Lehtinen [24].

We give a construction of small Strahler-universal trees that, when used with the progress measure lifting algorithm [19, 20] or with the universal attractor decomposition algorithm [21], yield algorithms that work in quasi-linear space and quasi-polynomial time. Moreover, usage of our small Strahler-universal trees allows to solve parity games in polynomial time for a wider range of asymptotic settings of the two natural structural complexity parameters (number of priorities d and the Strahler/register number k) than previously known, and that covers as special cases the $k = O(1)$ criterion of Lehtinen [24] and the $d < \lg n$ and $d = O(\log n)$ criteria of of Calude et al. [3], and of Jurdziński and Lazić [20], respectively.

Proofs. Proofs of some of our technical results can be found in the long version of this extended abstract available on arXiv [7].

2 Dominions, Attractor Decompositions, and Their Trees

Strategies, Traps, and Dominions. A *parity game* [8] $\mathcal{G}$ consists of a finite directed graph (V, E), a partition $(V_{\text{Even}}, V_{\text{Odd}})$ of the set of vertices V, and a function $\pi : V \to \{0, 1, \ldots, d\}$ that labels every vertex $v \in V$ with a non-negative integer $\pi(v)$ called its *priority*. We say that a cycle is *even* if the highest vertex priority on the cycle is even; otherwise the cycle is *odd*. We say that a parity game is (n, d)*-small* if it has at most n vertices and all vertex priorities are at most d.

For a set S of vertices, we write $\mathcal{G} \cap S$ for the substructure of $\mathcal{G}$ whose graph is the subgraph of (V, E) induced by the sets of vertices S. Sometimes, we also write $\mathcal{G} \setminus S$ to denote $\mathcal{G} \cap (V \setminus S)$. We assume throughout that every vertex has at least one outgoing edge, and we reserve the term *subgame* to substructures $\mathcal{G} \cap S$, such that every vertex in the subgraph of (V, E) induced by S has at least one outgoing edge.

A (positional) *Steven strategy* is a set $\sigma \subseteq E$ of edges such that:

- for every $v \in V_{\text{Even}}$, there is an edge $(v, u) \in \sigma$,
- for every $v \in V_{\text{Odd}}$, if $(v, u) \in E$ then $(v, u) \in \sigma$.

For a non-empty set of vertices R, we say that a Steven strategy σ *traps Audrey in* R if $w \in R$ and $(w, u) \in \sigma$ imply $u \in R$. We say that a set of vertices R is a *trap for Audrey* [32] if there is a Steven strategy that traps Audrey in R. Observe that if R is a trap in a game $\mathcal{G}$ then $\mathcal{G} \cap R$ is a subgame of $\mathcal{G}$. For a set of vertices $D \subseteq V$, we say that a Steven strategy σ is a *Steven dominion strategy on* D if σ traps Audrey in D and every cycle in the subgraph (D, σ) is even. Finally, we say that a set D of vertices is a *Steven dominion* [22] if there is a Steven dominion strategy on it.

Audrey strategies, trapping Steven, and Audrey dominions are defined in an analogous way by swapping the roles of the two players. We note that the sets of Steven dominions and of Audrey dominions are each closed under union, and hence the largest Steven and Audrey dominions exist, and they are the unions of all Steven and Audrey dominions, respectively. Moreover, every Steven dominion is disjoint from every Audrey dominion.

Attractor Decompositions. In a parity game $\mathcal{G}$, for a target set of vertices B ("bullseye") and a set of vertices A such that $B \subseteq A$, we say that a Steven strategy σ is a *Steven reachability strategy to B from A* if every infinite path in the subgraph (V, σ) that starts from a vertex in A contains at least one vertex in B.

For every target set B, there is the largest (with respect to set inclusion) set from which there is a Steven reachability strategy to B in $\mathcal{G}$; we call this set the *Steven attractor to B in $\mathcal{G}$* [32]. *Audrey reachability strategies* and *Audrey attractors* are defined analogously. We highlight the simple fact that if A is an attractor for a player in $\mathcal{G}$ then its complement $V \setminus A$ is a trap for them.

If $\mathcal{G}$ is a parity game in which all priorities do not exceed a non-negative even number d then we say that $\mathcal{H} = \langle A, (S_1, \mathcal{H}_1, A_1), \ldots, (S_\ell, \mathcal{H}_\ell, A_\ell)\rangle$ is a *Steven d-attractor decomposition* [5, 6, 21] of $\mathcal{G}$ if:

- A is the Steven attractor to the (possibly empty) set of vertices of priority d in $\mathcal{G}$;

and setting $\mathcal{G}_1 = \mathcal{G} \setminus A$, for all $i = 1, 2, \ldots, \ell$, we have:

- S_i is a non-empty trap for Audrey in $\mathcal{G}_i$ in which every vertex priority is at most $d - 2$;
- $\mathcal{H}_i$ is a Steven $(d-2)$-attractor decomposition of subgame $\mathcal{G} \cap S_i$;
- A_i is the Steven attractor to S_i in $\mathcal{G}_i$;
- $\mathcal{G}_{i+1} = \mathcal{G}_i \setminus A_i$;

and the game $\mathcal{G}_{\ell+1}$ is empty. If $d = 0$ then we require that $\ell = 0$.

The following proposition states that if a subgame induced by a trap for Audrey has a Steven attractor decomposition then the trap is a Steven dominion. Indeed, a routine proof argues that the union of all the Steven reachability strategies, implicit in the attractors listed in the decomposition, is a Steven dominion strategy.

▶ **Proposition 1** ([32, 5, 21]). *If d is even, R is a trap for Audrey in $\mathcal{G}$, and there is a Steven d-attractor decomposition of $\mathcal{G} \cap R$, then R is a Steven dominion in $\mathcal{G}$.*

Attractor decompositions for Audrey can be defined in the analogous way by swapping the roles of players as expected, and then a dual version of the proposition holds routinely.

The following theorem implies that every vertex in a parity game is either in the largest Steven dominion or in the largest Audrey dominion – it is often referred to as the *positional determinacy theorem* for parity games.

▶ **Theorem 2** ([8, 27, 32, 21]). *For every parity game $\mathcal{G}$, there is a partition of the set of vertices into a trap for Audrey W_{Even} and a trap for Steven W_{Odd}, such that there is a Steven attractor decomposition of $\mathcal{G} \cap W_{\text{Even}}$ and an Audrey attractor decomposition of $\mathcal{G} \cap W_{\text{Odd}}$.*

Ordered Trees and Their Strahler Numbers. Ordered trees are defined inductively; the trivial tree $\langle\rangle$ is an ordered tree and so is a sequence $\langle T_1, T_2, \ldots, T_\ell\rangle$, where T_i is an ordered tree for every $i = 1, 2, \ldots, \ell$. The trivial tree has only one node called the root, which is a leaf; and a tree of the form $\langle T_1, T_2, \ldots, T_\ell\rangle$ has the root with k children, the root is not a leaf, and the i-th child of the root is the root of ordered tree T_i.

Because the trivial tree $\langle\rangle$ has just one node, we sometimes write $\circ$ to denote it. If T is an ordered tree and i is a positive integer, then we use the notation T^i to denote the sequence $T, T, \ldots, T$ consisting of i copies of tree T. Then the expression $\left\langle T^i \right\rangle = \langle T, \ldots, T\rangle$ denotes the tree whose root has i children, each of which is the root of a copy of T. We also use the $\cdot$ symbol to denote concatenation of sequences, which in the context of ordered trees can be interpreted as sequential composition of trees by merging their roots; for example, $\langle\langle\circ^3\rangle\rangle \cdot \left\langle \circ^4, \langle\langle\circ\rangle\rangle^2 \right\rangle = \left\langle \langle\circ^3\rangle, \circ^4, \langle\langle\circ\rangle\rangle^2 \right\rangle = \langle\langle\circ, \circ, \circ\rangle, \circ, \circ, \circ, \circ, \langle\langle\circ\rangle\rangle, \langle\langle\circ\rangle\rangle\rangle$.

For an ordered tree T, we write $\operatorname{height}(T)$ for its *height* and $\operatorname{leaves}(T)$ for its *number of leaves*, which are defined by the following routine induction: the trivial tree $\langle\rangle = \circ$ has 1 leaf and its height is 1; the number of leaves of tree $\langle T_1, T_2, \ldots, T_\ell\rangle$ is the sum of the numbers of leaves of trees T_1, T_2, ..., T_ℓ; and its height is 1 plus the maximum height of trees T_1, T_2, ..., T_ℓ. For example, the tree $\left\langle\left\langle\circ^3\right\rangle, \circ^4, \langle\langle\circ\rangle\rangle^2\right\rangle$ has 9 leaves and height 4 We say that an ordered tree is (n, h)*-small* if it has at most n leaves and its height is at most h.

The *Strahler number* $\operatorname{Str}(T)$ of a tree T is defined to be the largest height of a perfect binary tree that is a minor of T. Alternatively, it can be defined by the following structural induction: the Strahler number of the trivial tree $\langle\rangle = \circ$ is 1; and if $T = \langle T_1, \ldots, T_\ell\rangle$ and m is the largest Strahler number of trees $T_1, \ldots, T_\ell$, then $\operatorname{Str}(T) = m$ if there is a unique i such that $\operatorname{Str}(T_i) = m$, and $\operatorname{Str}(T) = m+1$ otherwise. For example, we have $\operatorname{Str}\left(\left\langle\left\langle\circ^3\right\rangle, \circ^4, \langle\langle\circ\rangle\rangle^2\right\rangle\right) = 2$ because $\operatorname{Str}(\circ) = \operatorname{Str}(\langle\langle\circ\rangle\rangle) = 1$ and $\operatorname{Str}\left(\left\langle\circ^3\right\rangle\right) = 2$.

▶ **Proposition 3.** *For every (n, h)-small tree T, we have* $\operatorname{Str}(T) \leq h$ *and* $\operatorname{Str}(T) \leq \lfloor\lg n\rfloor + 1$.

Trees of Attractor Decompositions. The definition of an attractor decomposition is inductive and we define an ordered tree that reflects the hierarchical structure of an attractor decomposition. If d is even and $\mathcal{H} = \langle A, (S_1, \mathcal{H}_1, A_1), \ldots, (S_\ell, \mathcal{H}_\ell, A_\ell)\rangle$ is a Steven d-attractor decomposition then we define the *tree of attractor decomposition* $\mathcal{H}$ [6, 21], denoted by $T_{\mathcal{H}}$, to be the trivial ordered tree $\langle\rangle$ if $\ell = 0$, and otherwise, to be the ordered tree $\langle T_{\mathcal{H}_1}, T_{\mathcal{H}_2}, \ldots, T_{\mathcal{H}_\ell}\rangle$, where for every $i = 1, 2, \ldots, \ell$, tree $T_{\mathcal{H}_i}$ is the tree of attractor decomposition $\mathcal{H}_i$. Trees of Audrey attractor decompositions are defined analogously.

Observe that the sets $S_1, S_2, \ldots, S_\ell$ in an attractor decomposition as above are non-empty and pairwise disjoint, which implies that trees of attractor decompositions are small relative to the number of vertices and the number of distinct priorities in a parity game. The following proposition can be proved by routine structural induction.

▶ **Proposition 4** ([6, 21])**.** *If $\mathcal{H}$ is an attractor decomposition of an (n, d)-small parity game then its tree $T_{\mathcal{H}}$ is $(n, \lceil d/2\rceil + 1)$-small.*

We define the *Strahler number of an attractor decomposition* $\mathcal{H}$, denoted by $\operatorname{Str}(\mathcal{H})$, to be the Strahler number $\operatorname{Str}(T_{\mathcal{H}})$ of its tree $T_{\mathcal{H}}$. We define the *Strahler number of a parity game* to be the maximum of the smallest Strahler numbers of attractor decompositions of the largest Steven and Audrey dominions, respectively.

3 Strahler Strategies in Register Games

This section establishes a connection between the register number of a parity game defined by Lehtinen [24] and the Strahler number. More specifically, we argue that from every Steven attractor decomposition of Strahler number k, we can derive a dominion strategy for Steven in the k-register game. Once we establish the Strahler number upper bound on the register number, we are faced with the following two natural questions:

▶ Question 5. Do the Strahler and the register numbers coincide?

▶ Question 6. Can the relationship between Strahler and register numbers be exploited algorithmically, in particular, to improve the running time and space complexity of solving register games studied by Lehtinen [24] and Parys [29]?

This work has been motivated by those two questions and it answers them both positively (Lemma 7 and Theorem 8, and Theorem 26, respectively).

For every positive number k, a Steven *k-register game* on a parity game $\mathcal{G}$ is another parity game $\mathcal{R}^k(\mathcal{G})$ whose vertices, edges, and priorities will be referred to as *states*, *moves*, and *ranks*, respectively, for disambiguation. The states of the Steven k-register game on $\mathcal{G}$ are either pairs $(v, \langle r_k, r_{k-1}, \ldots, r_1\rangle)$ or triples $(v, \langle r_k, r_{k-1}, \ldots, r_1\rangle, p)$, where v is a vertex in $\mathcal{G}$, $d \geq r_k \geq r_{k-1} \geq \cdots \geq r_1 \geq 0$, and $1 \leq p \leq 2k+1$. The former states have rank 1 and the latter have rank p. Each number r_i, for $i = k, k-1, \ldots, 1$, is referred to as the value of the i-th register in the state. Steven owns all states $(v, \langle r_k, r_{k-1}, \ldots, r_1\rangle)$ and the owner of vertex v in $\mathcal{G}$ is the owner of states $(v, \langle r_k, r_{k-1}, \ldots, r_1\rangle, p)$ for every p. How the game is played by Steven and Audrey is determined by the available moves:

- at every state $(v, \langle r_k, r_{k-1}, \ldots, r_1\rangle)$, Steven picks i, such that $0 \leq i \leq k$, and *resets* registers $i, i-1, i-2, \ldots, 1$, leading to state $\left(v, \left\langle r'_k, \ldots, r'_{i+1}, r'_i, 0, \ldots, 0\right\rangle, p\right)$ of rank p and with updated register values, where:

$$p = \begin{cases} 2i & \text{if } i \geq 1 \text{ and } \max\left(r_i, \pi(v)\right) \text{ is even,} \\ 2i+1 & \text{if } i = 0, \text{ or if } i \geq 1 \text{ and } \max\left(r_i, \pi(v)\right) \text{ is odd;} \end{cases}$$

  $r'_j = \max(r_j, \pi(v))$ for $j \geq i+1$, and $r'_i = \pi(v)$;
- at every state $(v, \langle r_k, r_{k-1}, \ldots, r_1\rangle, p)$, the owner of vertex v in $\mathcal{G}$ picks an edge (v, u) in $\mathcal{G}$, leading to state $(u, \langle r_k, r_{k-1}, \ldots, r_1\rangle)$ of rank 1 and with unchanged register values.

For example, at state $(v, \langle 9, 6, 4, 4, 3\rangle)$ of rank 1, if the priority $\pi(v)$ of vertex v is 5 and Steven picks $i = 3$, this leads to state $(v, \langle 9, 6, 5, 0, 0\rangle, 7)$ of rank $2i+1 = 7$ because $\max(r_3, \pi(v)) = \max(4, 5) = 5$ is odd, $r'_4 = \max(r_4, \pi(v)) = \max(6, 5) = 6$, and $r'_3 = \pi(v) = 5$.

Observe that the first components of states on every cycle in game $\mathcal{R}^k(\mathcal{G})$ form a (not necessarily simple) cycle in parity game $\mathcal{G}$; we call it the cycle in $\mathcal{G}$ *induced* by the cycle in $\mathcal{R}^k(\mathcal{G})$. If a cycle in $\mathcal{R}^k(\mathcal{G})$ is even (that is, the highest state rank on it is even) then the induced cycle in $\mathcal{G}$ is also even. Lehtinen [24, Lemmas 3.3 and 3.4] has shown that a vertex v is in the largest Steven dominion in $\mathcal{G}$ if and only if there is a positive integer k such that a state $(v, \overline{r})$, for some register values $\overline{r}$ is in the largest Steven dominion in $\mathcal{R}^k(\mathcal{G})$. Lehtinen and Boker [25, a comment after Definition 3.1] have further clarified that for every k, if a player has a dominion strategy in $\mathcal{R}^k(\mathcal{G})$ from a state whose first component is a vertex v in $\mathcal{G}$, then they also have a dominion strategy in $\mathcal{R}^k(\mathcal{G})$ from every state whose first component is v. This allows us to say without loss of rigour that a vertex v in $\mathcal{G}$ is in a dominion in $\mathcal{R}^k(\mathcal{G})$.

By defining the *(Steven) register number* [24, Definition 3.5] of a parity game $\mathcal{G}$ to be the smallest number k such that all vertices v in the largest Steven dominion in $\mathcal{G}$ are in a Steven dominion in $\mathcal{R}^k(\mathcal{G})$, and by proving the $1 + \lg n$ upper bound on the register number of every (n, d)-small parity game [24, Theorem 4.7], Lehtinen has contributed a novel quasi-polynomial algorithm for solving parity games, adding to those by Calude et al. [3] and Jurdziński and Lazić [20].

Lehtinen [24, Definition 4.8] has also considered the concept of a Steven *defensive dominion strategy* in a k-register game (for brevity, we call it a k-defensive strategy): it is a Steven dominion strategy on a set of states in $\mathcal{R}^k(\mathcal{G})$ in which there is no state of rank $2k+1$. Alternatively, the same concept can be formalized by defining the *defensive k-register game* $\mathcal{D}^k(\mathcal{G})$, which is played exactly like the k-register game $\mathcal{R}^k(\mathcal{G})$, but in which Audrey can also win just by reaching a state of rank $2k+1$. Note that the game $\mathcal{D}^k(\mathcal{G})$ can be thought of as having the winning criterion for Steven as being a conjunction of a parity and a safety criteria, and the winning criterion for Audrey as a disjunction of a parity and a reachability criteria. Routine arguements allow to extend positional determinacy from parity games to such games with combinations of parity, and safety or reachability winning criteria.

We follow Lehtinen [24, Definition 4.9] by defining the *(Steven) defensive register number* of a Steven dominion D in $\mathcal{G}$ as the smallest number k such that Steven has a defensive dominion strategy in $\mathcal{R}^k(\mathcal{G})$ on a set of states that includes all $(v, \langle r_k, \ldots, r_1 \rangle)$ for $v \in D$, and such that r_k is an even number at least as large as every vertex priority in D. We propose to call it the *Lehtinen number* of a Steven dominion in $\mathcal{G}$ to honour Lehtinen's insight that led to this – as we argue in this work – fundamental concept. We also define the Lehtinen number of a vertex in $\mathcal{G}$ to be the smallest Lehtinen number of a Steven dominion in $\mathcal{G}$ that includes the vertex, and the Lehtinen number of a parity game to be the Lehtinen number of its largest Steven dominion. We also note that the register and the Lehtinen numbers of a parity game nearly coincide (they differ by at most one), and hence the conclusions of our analysis of the latter also apply to the former.

▶ **Lemma 7.** *The Lehtinen number of a parity game is no larger than its Strahler number.*

The arguments used in our proof of this lemma are similar to those used in the proof of the main result of Lehtinen [24, Theorem 4.7]. Our contribution here is to pinpoint the Strahler number of an attractor decomposition as the structural parameter of a dominion that naturally bounds the number of registers used in Lehtinen's construction of a defensive dominion strategy.

Proof of Lemma 7. Consider a parity game $\mathcal{G}$ and let d be the least even integer no smaller than any of the priority in $\mathcal{G}$. Consider a Steven d-attractor decomposition $\mathcal{H}$ of $\mathcal{G}$ of Strahler number k. We construct a defensive k-register strategy for Steven on $\mathcal{R}^k(\mathcal{G})$. The strategy is defined inductively on the height of $\mathcal{T}_{\mathcal{H}}$, and has the additional property of being *$\mathcal{G}$-positional* in the following sense: if $((v, \langle r_k, \ldots, r_1 \rangle), (v, \langle r'_k, \ldots, r'_1 \rangle, p))$ is a move then the register reset by Steven only depends on v, not on the values in the registers. Similarly, if $((v, \langle r_k, \ldots, r_1 \rangle, p), (u, \langle r_k, \ldots, r_1 \rangle))$ is a move and v is owned by Steven, u only depends on v and not on the values of the registers or p.

Strategy for Steven. If $\mathcal{H} = \langle A, \emptyset \rangle$, then $\mathcal{G}$ consists of the set of vertices of priority d and of its Steven attractor. In this case, Steven follows the strategy induced by the reachability strategy in A to the set of vertices of priority d, only resetting register r_1 immediately after visiting a state with first component a vertex of priority d in $\mathcal{G}$. More precisely, the Steven defensive strategy is defined with the following moves:

- $((v, \langle r_1 \rangle), (v, \langle r_1 \rangle, 1))$ if v is not a vertex of priority d in $\mathcal{G}$;
- $((v, \langle r_1 \rangle), (v, \langle r'_1 \rangle, 2))$ if v is a vertex of priority d in $\mathcal{G}$ and $r'_1 = \max(r_1, d)$ is even;
- $((v, \langle r_1 \rangle), (v, \langle r'_1 \rangle, 3))$ if v is a vertex of priority d in $\mathcal{G}$ and $r'_1 = \max(r_1, d)$ is odd (we state this case for completeness but this will never occur);
- $((v, \langle r_1 \rangle, p), (u, \langle r_1 \rangle))$ where (v, u) belongs to the Steven reachability strategy from A to the set of vertices of priority d in $\mathcal{G}$.

Note that this strategy is $\mathcal{G}$-positional.

Suppose now that $\mathcal{H} = \langle A, (S_1, \mathcal{H}_1, A_1), \ldots, (S_\ell, \mathcal{H}_\ell, A_\ell) \rangle$ and that it has Strahler number k. For all $i = 1, 2, \ldots, \ell$, let k_i be the Strahler number of $\mathcal{H}_i$. By induction, for all i, we have a Steven defensive k_i-register strategy σ_i, which is $(\mathcal{G} \cap S_i)$-positional, on a set of states Ω_i in $\mathcal{R}^{k_i}(\mathcal{G} \cap S_i)$ including all the states $(v, \langle r_{k_i}, \ldots, r_1 \rangle)$ for $v \in S_i$ and r_{k_i} an even number at least as large as every vertex priority in S_i. Let Γ_i be the set of states in $\mathcal{R}^k(\mathcal{G} \cap S_i)$ defined as all the states $(v, \langle d, r_{k-1}, \ldots, r_1 \rangle)$ for $v \in S_i$ if $k_i \neq k$ and as the union of the states $(v, \langle d, r_{k-1}, \ldots, r_1 \rangle)$ for $v \in S_i$ and Ω_i, otherwise.

The strategy σ_i induces a strategy on Γ_i in $\mathcal{R}^k(\mathcal{G} \cap S_i)$ by simply ignoring registers $r_{k_i+1}, \ldots, r_k$, and using $(\mathcal{G} \cap S_i)$-positionality to define moves from the states not in Ω_i. More precisely, in a state $(v, \langle r_k, \ldots, r_1 \rangle)$, Steven resets register j if and only if register j is reset in a state $\left(v, \left\langle r'_{k_i}, \ldots, r'_1 \right\rangle\right)$ of Ω_i according to σ_i. This is well defined by $(\mathcal{G} \cap S_i)$-positionality. Similarly, we add moves $((v, \langle r_k, \ldots, r_1 \rangle, p), (u, \langle r_k, \ldots, r_1 \rangle))$ to the strategy if and only if there is a move $\left(\left(v, \left\langle r'_{k_i}, \ldots, r'_1 \right\rangle, p'\right), \left(u, \left\langle r'_{k_i}, \ldots, r'_1 \right\rangle\right)\right)$ in σ_i. This is again well-defined by $(\mathcal{G} \cap S_i)$-positionality.

This strategy is denoted by τ_i. Note that τ_i is a defensive k-register strategy on Γ_i, which is $\mathcal{G}$-positional.

The Steven defensive strategy in $\mathcal{R}^k(\mathcal{G})$ is defined by the following moves, where S denotes the set of vertices of priority d in $\mathcal{G}$:

- On the set of states with first component a vertex of $A_i \setminus S_i$, the moves are given by τ_i.
- On the set of states with first component a vertex of $A \setminus S$, Steven uses the strategy induced by the reachability strategy from A_i to S_i, without resetting any registers.
- On $\mathcal{R}^k(\mathcal{G} \cap (A \setminus S))$, Steven uses the strategy induced by the reachability strategy from A to S, without resetting any registers.
- On the set of states with first component a vertex of S,
  - $((v, \langle r_k, \ldots, r_1 \rangle), (v, \langle d, 0, \ldots, 0 \rangle, p))$ where v is a vertex in S and $p = 2k$ if $\max(r_k, d)$ is even and $p = 2k + 1$ otherwise.
  - $((v, \langle r_k, \ldots, r_1 \rangle, p), (u, \langle r_k, \ldots, r_1 \rangle))$ for some uniquely chosen u such that (v, u) in E if v is owned by Steven and for all u such that (v, u) in E if v is owned by Audrey.

Observe that this strategy is $\mathcal{G}$-positional.

Correctness of the Strategy. We prove now that the strategy defined above is indeed a defensive k-register strategy. We proceed by induction on the height of $\mathcal{T}_{\mathcal{H}}$ and define a set of states Γ, including all the states $(v, \langle d, r_{k-1}, \ldots, r_1 \rangle)$ such that v is a vertex of $\mathcal{G}$.

Base Case: If the height of $\mathcal{T}_{\mathcal{H}}$ is 0 and $\mathcal{H} = \langle A, \emptyset \rangle$, let Γ be the set of states $(v, \langle r_1 \rangle)$ and $(v, \langle r_1 \rangle, p)$ with v a vertex of $\mathcal{G}$, $1 \leq r_1 \leq d$ and p being either 1 or 2. It is easy to see that the strategy defined above is a defensive dominion strategy on this set.

Inductive step: If $\mathcal{H} = \langle A, (S_1, \mathcal{H}_1, A_1), \ldots, (S_\ell, \mathcal{H}_\ell, A_\ell) \rangle$ with Strahler number k and k_i being the Strahler number of $\mathcal{H}_i$ for all i (note that $k_i \leq k$ for all i, and by definition of Strahler number, there is at most one m such that $k_m = k$), we define Γ to be the set comprising the union of the Γ_i and all the states of the form $(v, \langle r_k, \ldots, r_1 \rangle)$ and $(v, \langle r_k, \ldots, r_1 \rangle, p)$ with v a vertex of $(A_i \setminus S_i) \cup A$ and $1 \leq p \leq 2k$.

Case 1: For each i, $k_i < k$. We first show that Γ is a trap for Audrey for the strategy defined above, showing that rank $2k+1$ can never be reached (implying that the strategy is defensive). This comes from the fact that the register of rank k is only reset in a state $(v, \langle r_k, \ldots, r_1 \rangle)$ with v in S. Since $\max(r_k, d) = d$ is even then this leads to a state $(v, \langle d, 0, \ldots, 0 \rangle, 2k)$. Otherwise, register k is never reset, so a state with rank $2k + 1$ cannot be reached.

Consider now any cycle in $\mathcal{R}^k(\mathcal{G})$ with moves restricted to the strategy constructed above. If this cycle contains a state whose first component is a vertex of S, then as explained above, the highest rank in the cycle is $2k$. Otherwise, the cycle is necessarily in $\mathcal{R}^k(\mathcal{G} \cap S_i)$ for some i. By induction, τ_i is winning and so the cycle is even.

Case 2: There is a unique m such that $k_m = k$. We first show that a state of rank $2k+1$ is never reached. Observe that register k is reset in two places: (1) immediately after a state with first component a vertex of S is visited, (2) if register k is reset by τ_m. In the first case, similarly as shown above, a state of rank $2k$ is reached. In the second case, register k is either reset in a state $(v, \langle d, r_{k-1}, \ldots, r_1\rangle)$, and similarly as above, a state of rank $2k$ is reached, or in a state of Ω_i. In this case, as τ_i is defensive on Ω_i by induction, a state of rank $2k+1$ cannot be reached, and the highest rank that can be reached is $2k$. Proving that every cycle is even is similar to the previous case. ◀

4 Strahler-Optimal Attractor Decompositions

In this section we prove that every parity game whose Lehtinen number is k has an attractor decomposition of Strahler number at most k. In other words, we establish the Lehtinen number upper bound on the Strahler number, which together with Lemma 7 provides a positive answer to Question 5.

▶ **Theorem 8.** *The Strahler number of a parity game is no larger than its Lehtinen number.*

When talking about strategies in parity games in Section 2, we only considered positional strategies, for which it was sufficient to verify the parity criterion on (simple) cycles. Instead, we explicitly consider the parity criterion on infinite paths here, which we find more convenient to establish properties of Audrey strategies in the proof of Theorem 8.

First, we introduce the concepts of *tight* and *offensively optimal* attractor decompositions.

▶ **Definition 9.** *A Steven d-attractor decomposition $\mathcal{H}$ of $\mathcal{G}$ is* tight *if Audrey has a winning strategy from at least one state in $\mathcal{D}^{\mathrm{Str}(\mathcal{H})-1}(\mathcal{G})$ in which the value of register* $\mathrm{Str}(\mathcal{H})-1$ *is d.*

By definition, the existence of a tight Steven d-attractor decomposition on a parity game implies that the Lehtinen number of the game is at least its Strahler number, from which Theorem 8 follows. Offensive optimality of an attractor decomposition, the concept we define next, may seem less natural and more technical than tightness, but it facilitates our proof that every game has a tight attractor decomposition.

▶ **Definition 10.** *Let $\mathcal{H} = \langle A, (S_1, \mathcal{H}_1, A_1), \ldots, (S_\ell, \mathcal{H}_\ell, A_\ell)\rangle$ be a Steven d-attractor decomposition, let games $\mathcal{G}_i$ for $i = 1, 2, \ldots, \ell$ be as in the definition of an attractor decomposition, let A'_i be the Audrey attractor of the set of vertices of priority $d-1$ in $\mathcal{G}_i$, and let $\mathcal{G}'_i = \mathcal{G}_i \setminus A'_i$. We say that $\mathcal{H}$ is* offensively optimal *if for every $i = 1, 2, \ldots, \ell$, we have:*

- *Audrey has a dominion strategy on $\mathcal{R}^{\mathrm{Str}(\mathcal{H}_i)-1}(\mathcal{G}'_i)$;*
- *Audrey has a dominion strategy on $\mathcal{D}^{\mathrm{Str}(\mathcal{H}_i)}(\mathcal{G}'_i \setminus S_i)$.*

Proving that every offensively optimal Steven attractor decomposition is tight (Lemma 11), and that every Steven dominion in a parity game has an offensively optimal Steven attractor decomposition (Lemma 12), will complete the proof of Theorem 8.

▶ **Lemma 11.** *Every offensively optimal Steven attractor decomposition is tight.*

Proof. Let $\mathcal{H} = \langle A, (S_1, \mathcal{H}_1, A_1), \ldots, (S_\ell, \mathcal{H}_\ell, A_\ell)\rangle$ be an offensively optimal d-attractor decomposition of a parity game and let $k = \mathrm{Str}(\mathcal{H})$. We construct a strategy for Audrey in $\mathcal{D}^{k-1}(\mathcal{G})$ that is winning for her from at least one state in which the value of register $k-1$ is d. We define $\mathcal{G}'_i$ and A'_i as in Definition 10.

Case 1: $\mathrm{Str}(\mathcal{H}_i) = k$ for some unique i in $\{1, \ldots, \ell\}$. In this case, we show that Audrey has a dominion strategy on $\mathcal{D}^{k-1}(\mathcal{G}_i)$. Since $\mathcal{G}_i$ is a trap for Steven in $\mathcal{G}$, this gives the desired result. Consider the following strategy in $\mathcal{D}^{k-1}(\mathcal{G}_i)$:

- On the set of states whose vertex components are in A'_i, Audrey follows a strategy induced by the reachability strategy in A'_i to a vertex of priority $d-1$ (picking any move if v is of priority $d-1$);

- In states whose vertex component is in $\mathcal{G}'_i$, Audrey plays a $(k-1)$-register dominion strategy on $\mathcal{R}^{k-1}(\mathcal{G}'_i)$. Such a strategy exists by the definition of offensive optimality and by the assumption that $\mathrm{Str}\,(\mathcal{H}_i) = k$.

This strategy is indeed an Audrey dominion strategy on $\mathcal{D}^{k-1}(\mathcal{G}_i)$, because any play either visits a state whose first component is a vertex in A'_i infinitely often, or it eventually remains in $\mathcal{R}^{k-1}(\mathcal{G}'_i)$. In the former case, the play visits a state whose first component is a vertex of priority $d-1$ infinitely often. In the latter case, the state parity criterion holds. Note that this even defines an Audrey dominion strategy on $\mathcal{R}^{k-1}(\mathcal{G}_i)$.

Case 2: There are $1 \leq i < j \leq \ell$ such that $\mathrm{Str}\,(\mathcal{H}_i) = \mathrm{Str}\,(\mathcal{H}_j) = k-1$. We construct a strategy for Audrey in $\mathcal{D}^{k-1}(\mathcal{G})$ that is winning for her from all states in $\mathcal{G}_j$ whose register $k-1$ has value d. Firstly, since $\mathcal{H}$ is offensively optimal, Audrey has a dominion strategy on $\mathcal{D}^{k-1}(\mathcal{G}'_i \setminus S_i)$, denoted by τ_i, and a dominion strategy on $\mathcal{R}^{k-2}(\mathcal{G}'_i)$, denoted by τ'_i. Moreover, since $\langle \emptyset, (S_j, \mathcal{H}_j, A_j), \ldots, (S_\ell, \mathcal{H}_\ell, A_\ell) \rangle$ is an offensively optimal attractor decomposition of $\mathcal{G}_j$, an argument similar to the one in Case 1. yields that Audrey has a dominion strategy, denoted by τ_j, on $\mathcal{R}^{k-2}(\mathcal{G}_j)$ (note that $\mathcal{G}_j$ is a trap for Steven in $\mathcal{G}$). Consider the following strategy for Audrey in $\mathcal{D}^{k-1}(\mathcal{G})$, starting from a state whose vertex component is in $\mathcal{G}_j$ and register $k-1$ has value d:

- As long as the value of register $k-1$ is larger than $d-1$, Audrey follows the strategy induced by τ_j, while ignoring the value of register $k-1$, as long as this value is larger than $d-1$.
- If the value in register $k-1$ is at most $d-1$:
  - In states whose vertex component is in A'_i, Audrey follows a strategy induced by the reachability strategy from A'_i to a vertex of priority $d-1$ (picking any move if the vertex has priority $d-1$);
  - In states whose vertex component is in $\mathcal{G}'_i \setminus S_i$ and whose register $k-2$ has value at most $d-2$, Audrey follows τ_i;
  - In states whose vertex component is in $\mathcal{G}'_i$ and whose register $k-1$ has value $d-1$, Audrey follows the strategy induced by τ'_i, while ignoring the value of regiser $k-1$.

Audrey plays any move if none of the above applies.

We argue that this strategy is winning for Audrey in $\mathcal{D}^{k-1}(\mathcal{G})$ from states whose vertex component is in $\mathcal{G}_j$ and register $k-1$ has value d. Consider an infinite path that starts in such a state. As long as register $k-1$ has value d, Audrey follows τ_j. If Steven never resets register $k-1$ then Audrey wins. Otherwise, once register $k-1$ has been reset, its value is at most $d-1$. Note that $\mathcal{G}_j$ is included in $A'_i \cup (\mathcal{G}'_i \setminus S_i)$. If register $k-1$ has a value smaller than $d-1$, and the play never visits a state whose vertex component is in A'_i, then Audrey has followed τ_i along the play (she has never left $\mathcal{G}'_i \setminus S_i$ as the only way for Steven to go out $\mathcal{G}'_i \setminus S_i$ is to go to A'_i) and wins. Otherwise, the play visits a state whose vertex component is in A'_i, and so it visits a state whose vertex component has priority $d-1$, leading to a state in which register $k-1$ has value $d-1$. Finally, if a state whose vertex component is in A'_i is visited infinitely many times then Audrey wins. Otherwise, Audrey eventually plays according to τ'_i. If Steven never resets register $k-1$ then Audrey wins. Otherwise, if Steven resets register $k-1$, which at this point has value $d-1$, a state of rank $2k-1$ is visited and Audrey wins. ◀

▶ **Lemma 12.** *Every Steven dominion in a parity game has an offensively optimal Steven attractor decomposition.*

Proof. Consider a parity game $\mathcal{G}$ which is a Steven dominion. Let k be the Lehtinen number of $\mathcal{G}$ and let d be the largest even value such that $\pi^{-1}(\{d, d-1\}) \neq \emptyset$. We construct an offensively optimal Steven attractor decomposition by induction.

If $d = 0$, it is enough to consider $\langle A, \emptyset \rangle$, where A is the set of all vertices in $\mathcal{G}$.

If $d > 1$, let A be the Steven attractor of the set of vertices of priority d in $\mathcal{G}$. Let $\mathcal{G}_0 = \mathcal{G} \setminus A$. If $\mathcal{G}_0 = \emptyset$ then $\langle A, \emptyset \rangle$ is an offensively optimal Steven attractor decomposition for $\mathcal{G}$. Otherwise, $\mathcal{G}_0$ is a non-empty trap for Steven in $\mathcal{G}$ and therefore $\mathcal{G}_0$ has a Lehtinen number at most k. Let A' be the Audrey attractor of all the vertices of priority $d-1$ in the sub-game $\mathcal{G}_0$ and let $\mathcal{G}'_0 = \mathcal{G}_0 \setminus A'$.

Given a positive integer b, let L^b be the largest dominion in $\mathcal{G}'_0$ such that Steven has a dominion strategy on $\mathcal{D}^b(\mathcal{G}'_0)$. We define m to be the smallest number such that $L^m \neq \emptyset$ and let $S_0 = L^m$. We show that $m \leq k$. To prove this, we construct an Audrey dominion strategy on $\mathcal{D}^b(\mathcal{G}_0)$ for all b such that $L^b = \emptyset$. Since the Lehtinen number of $\mathcal{G}_0$ is at most k, this implies that $m \leq k$. The Audrey dominion strategy on $\mathcal{D}^b(\mathcal{G}_0)$, assuming $L^b = \emptyset$, is as follows:

- If the vertex component of a state is in A' then Audrey uses the strategy in A' induced by the reachability strategy to vertices of priority $d-1$;
- If the vertex component of a state is in $\mathcal{G}'_0$ then Audrey uses her dominion strategy on $\mathcal{D}^b(\mathcal{G}'_0)$, which exists because the Steven dominion L^b in $\mathcal{D}^b(\mathcal{G}'_0)$ is empty.

Any play following the above strategy and visiting infinitely often a state of $\mathcal{D}^b(\mathcal{G}_0 \cap A')$ is winning for Audrey. A play following the above strategy and remaining eventually in $\mathcal{D}^b(\mathcal{G}'_0)$ is also winning for Audrey.

Let $\mathcal{H}_0$ be the $(d-2)$-attractor decomposition of S_0 obtained by induction. In particular, $\mathcal{H}_0$ is offensively optimal.

Let A_0 be the Steven attractor to S_0 in $\mathcal{G}_0$ and let $\mathcal{G}_1 = \mathcal{G}_0 \setminus A_0$. Subgame $\mathcal{G}_1$ is a trap for Steven and therefore it is a Steven dominion. Let $\mathcal{H}' = \langle \emptyset, (S_1, \mathcal{H}_1, A_1), \ldots, (S_\ell, \mathcal{H}_\ell, A_\ell) \rangle$ be an offensively optimal Steven d-attractor decomposition of $\mathcal{G}_1$ obtained by induction.

We claim that $\mathcal{H} = \langle A, (S_0, \mathcal{H}_0, A_0), (S_1, \mathcal{H}_1, A_1), \ldots, (S_\ell, \mathcal{H}_\ell, A_\ell) \rangle$ is an offensively optimal Steven d-attractor decomposition of $\mathcal{G}$. Since $\mathcal{H}'$ is offensively optimal, it is enough to show that:

- Audrey has a dominion strategy on $\mathcal{R}^{\mathrm{Str}(\mathcal{H}_0)-1}(\mathcal{G}'_0)$,
- Audrey has a dominion strategy on $\mathcal{D}^{\mathrm{Str}(\mathcal{H}_0)}(\mathcal{G}'_0 \setminus S_0)$.

Since $\mathcal{H}_0$ is offensively optimal, Audrey has a dominion strategy in $\mathcal{R}^{\mathrm{Str}(\mathcal{H}_0)-1}(S_0)$, by Lemma 11, and hence $m \geq \mathrm{Str}\,(\mathcal{H}_0)$. Moreover, by construction of S_0, Audrey has a dominion strategy on $\mathcal{D}^m(\mathcal{G}'_0 \setminus S_0)$. This implies that Audrey has a dominion strategy on $\mathcal{D}^{\mathrm{Str}(\mathcal{H}_0)}(\mathcal{G}'_0 \setminus S_0)$.

By choice of m, Steven does not have a defensive dominion strategy on $\mathcal{D}^{\mathrm{Str}(\mathcal{H}_0)-1}(\mathcal{G}'_0)$ from any state. This means that for all states s, Audrey has a winning strategy τ_s on $\mathcal{D}^{\mathrm{Str}(\mathcal{H}_0)-1}(\mathcal{G}'_0)$ starting in s. We construct a dominion strategy for her on $\mathcal{R}^{\mathrm{Str}(\mathcal{H}_0)-1}(\mathcal{G}'_0)$: after every visit to a state of rank $2\mathrm{Str}\,(\mathcal{H}_0) - 1$, Audrey follows τ_s, where s is the first state that follows on the path and whose rank is smaller than $2\mathrm{Str}\,(\mathcal{H}_0) - 1$. This defines a dominion strategy on $\mathcal{R}^{\mathrm{Str}(\mathcal{H}_0)-1}(\mathcal{G}'_0)$. ◀

5 Strahler-Universal Trees

Our attention now shifts to tackling Question 6. The approach is to develop constructions of small ordered trees into which trees of attractor decompositions or of progress measures can be embedded. Such trees can be seen as natural search spaces for dominion strategies, and existing meta-algorithms such as the universal attractor decomposition algorithm [21] and progress measure lifting algorithm [19, 20] can use them to guide their search, performed in time proportional to the size of the trees in the worst case.

An ordered tree is *universal* for a class of trees if all trees from the class can be embedded into it. The innovation offered in this work is to develop optimized constructions of trees that are universal for classes of trees whose complex structural parameter, such as the Strahler number, is bounded. This is in contrast to less restrictive universal trees introduced by Czerwiński et al. [4] and implicitly constructed by Jurdziński and Lazić [20], whose sizes therefore grow faster with size parameters, leading to slower algorithms.

Firstly, we give an inductive construction of Strahler-universal trees and an upper bound on their numbers of leaves. Then we introduce labelled ordered trees, provide a succinct bit-string labelling of the Strahler-universal trees, and give an alternative and more explicit characterization of the succinctly-labelled Strahler-universal trees. Finally, we argue how the succinct bit-string labelling of Strahler-universal trees facilitates efficient computation of the so-called "level-p successors" in them, which is the key computational primitive that allows using ordered trees to solve parity games. The constructions and techniques we develop here are inspired by and significantly refine those introduced by Jurdziński and Lazić [20].

Strahler-Universal Trees and Their Sizes. Intuitively, an ordered tree *can be embedded in* another if the former can be obtained from the latter by pruning some subtrees. More formally, the trivial tree $\langle\rangle$ can be embedded in every ordered tree, and $\langle T_1, T_2, \ldots, T_k\rangle$ can be embedded in $\langle T'_1, T'_2, \ldots, T'_\ell\rangle$ if there are indices $i_1, i_2, \ldots, i_k$ such that $1 \le i_1 < i_2 < \cdots < i_k \le \ell$ and for every $j = 1, 2, \ldots, k$, we have that T_j can be embedded in T'_{i_j}.

An ordered tree is (n, h)*-universal* [4] if every (n, h)-small ordered tree can be embedded in it. We define an ordered tree to be k*-Strahler* (n, h)*-universal* if every (n, h)-small ordered tree whose Strahler number is at most k can be embedded in it, and we give a construction of small Strahler-universal trees.

▶ **Definition 13** (Trees $U^k_{t,h}$ and $V^k_{t,h}$). *For all $t \ge 0$, we define trees $U^k_{t,h}$ (for all h and k such that $h \ge k \ge 1$) and $V^k_{t,h}$ (for all h and k such that $h \ge k \ge 2$) by mutual induction:*

1. *if $h = k = 1$ then $U^k_{t,h} = \langle\rangle$;*
2. *if $h > 1$ and $k = 1$ then $U^k_{t,h} = \left\langle U^k_{t,h-1}\right\rangle$;*
3. *if $h \ge k \ge 2$ and $t = 0$ then $U^k_{t,h} = V^k_{t,h} = \left\langle U^{k-1}_{t,h-1}\right\rangle$;*
4. *if $h \ge k \ge 2$ and $t \ge 1$ then $V^k_{t,h} = V^k_{t-1,h} \cdot \left\langle U^{k-1}_{t,h-1}\right\rangle \cdot V^k_{t-1,h}$;*
5. *if $h = k \ge 2$ and $t \ge 2$ then $U^k_{t,h} = V^k_{t,h}$;*
6. *if $h > k \ge 2$ and $t \ge 2$ then $U^k_{t,h} = V^k_{t,h} \cdot \left\langle U^k_{t,h-1}\right\rangle \cdot V^k_{t,h}$.*

For $g \ge 0$, let I_g be the trivial tree, that is the tree with exactly one leaf, of height g. For example, $I_1 = \langle\rangle$ and $I_3 = \langle\langle\langle\rangle\rangle\rangle = \langle\langle\circ\rangle\rangle$. It is routine to verify that if $h \ge k = 1$ or $t = 0$ then $U^k_{t,h} = I_h$, and if $h \ge k \ge 2$ and $t = 0$ then $V^k_{t,h} = I_h$.

▶ **Lemma 14.** *For all $n \ge 1$ and $h \ge k \ge 1$, the ordered tree $U^k_{\lfloor \lg n\rfloor,h}$ is k-Strahler (n, h)-universal.*

Proof. We say that a tree has *weak Strahler number* at most k if every subtree rooted in a child of the root has Strahler number at most $k - 1$. A tree is then *weakly k-Strahler (n, h)-universal* if every (n, h)-small ordered tree whose weak Strahler number is at most k can be embedded in it. We proceed by induction on the number of leaves in an ordered tree and its height, using the following strengthened inductive hypothesis:

- for all $n \ge 1$ and $h \ge k \ge 1$, ordered tree $U^k_{\lfloor \lg n\rfloor,h}$ is k-Strahler (n, h)-universal;
- for all $n \ge 1$ and $h \ge k \ge 2$, ordered tree $V^k_{\lfloor \lg n\rfloor,h}$ is weakly k-Strahler (n, h)-universal.

Let T be an (n,h)-small ordered tree of Strahler number at most k. If $n=1$, $h=1$, or $k=1$, then T is the trivial tree (with just one leaf) of height at most h, and hence it can be embedded in $U^k_{\lfloor \lg n \rfloor, h} = I_h$, the trivial tree of height h. Likewise, if $h \geq k \geq 2$ and $n=1$, then T is the trivial tree of height at most h, and hence it can be embedded in $V^k_{\lfloor \lg n \rfloor, h} = I_h$, the trivial tree of height h.

Otherwise, we have that $T = \langle T_1, \dots, T_j \rangle$ for some $j \geq 1$. We consider two cases: either $\operatorname{Str}(T_i) \leq k-1$ for all $i = 1, \dots, j$, or there is q such that $\operatorname{Str}(T_q) = k$. Note that by Proposition 3, the latter case can only occur if $h > k$.

If $\operatorname{Str}(T_i) \leq k-1$ for all $i = 1, \dots, j$, then we argue that T can be embedded in $V^k_{\lfloor \lg n \rfloor, h}$, and hence also in $U^k_{\lfloor \lg n \rfloor, h}$, because $V^k_{\lfloor \lg n \rfloor, h}$ can be embedded in $U^k_{\lfloor \lg n \rfloor, h}$ by definition (see items 3., 5., and 6. of Definition 13). Let p (a pivot) be an integer such that both trees $T' = \langle T_1, \dots, T_{p-1} \rangle$ and $T'' = \langle T_{p+1}, \dots, T_j \rangle$ are $(\lfloor n/2 \rfloor, h)$-small. Then by the strengthened inductive hypothesis, each of the two trees T' and T'' can be embedded in tree $V^k_{\lfloor \lg \lfloor n/2 \rfloor \rfloor, h} = V^k_{\lfloor \lg n \rfloor - 1, h}$ and tree T_p can be embedded in $U^{k-1}_{\lfloor \lg n \rfloor, h-1}$. It then follows that tree $T = T' \cdot \langle T_p \rangle \cdot T''$ can be embedded in $V^k_{\lfloor \lg n \rfloor, h} = V^k_{\lfloor \lg n \rfloor - 1, h} \cdot \left\langle U^{k-1}_{\lfloor \lg n \rfloor, h-1} \right\rangle \cdot V^k_{\lfloor \lg n \rfloor - 1, h}$.

If $\operatorname{Str}(T_q) = k$ for some q (the pivot), then we argue that T can be embedded in $U^k_{\lfloor \lg n \rfloor, h}$. Note that each of the two trees $T' = \langle T_1, \dots, T_{q-1} \rangle$ and $T'' = \langle T_{q+1}, \dots, T_j \rangle$ is (n,h)-small and all trees $T_1, \dots, T_{q-1}$ and $T_{q+1}, \dots, T_j$ have Strahler numbers at most $k-1$. By the previous paragraph, it follows that each of the two trees T' and T'' can be embedded in $V^k_{\lfloor \lg n \rfloor, h}$. Moreover, tree T_q is $(n, h-1)$-small and hence, by the inductive hypothesis, it can be embedded in $U^k_{\lfloor \lg n \rfloor, h-1}$. It follows that tree $T = T' \cdot \langle T_q \rangle \cdot T''$ can be embedded in $U^k_{\lfloor \lg n \rfloor, h} = V^k_{\lfloor \lg n \rfloor, h} \cdot \left\langle U^k_{\lfloor \lg n \rfloor, h-1} \right\rangle \cdot V^k_{\lfloor \lg n \rfloor, h}$. ◀

▶ **Lemma 15.** *For all $t \geq 0$, we have:*

- *if $h \geq k = 1$ then* $\operatorname{leaves}\left(U^k_{t,h}\right) = 1$;
- *if $h \geq k \geq 2$ then* $\operatorname{leaves}\left(U^k_{t,h}\right) \leq 2^{t+k} \binom{t+k-2}{k-2} \binom{h-1}{k-1}$.

▶ **Theorem 16.** *For $k \leq \lg n$, the number of leaves of the k-Strahler (n,h)-universal ordered trees $U^k_{\lfloor \lg n \rfloor, h}$ is $n^{O(1)} \cdot (h/k)^k = n^{k \lg(h/k)/\lg n + O(1)}$, which is polynomial in n if $k \cdot \lg(h/k) = O(\log n)$. In more detail, the number is at most $n^{c(n)} \cdot (h/k)^k$, where $c(n) = 5.45$ if $k \leq \lg n$, $c(n) = 3 + o(1)$ if $k = o(\log n)$, and $c(n) = 1 + o(1)$ if $k = O(1)$.*

▶ Remark 17. By Proposition 3 and Lemma 14, for all positive integers n and h, the tree $U^{\lfloor \lg n \rfloor + 1}_{\lfloor \lg n \rfloor, h}$ is (n,h)-universal. Theorem 16 implies that the number of leaves of $U^{\lfloor \lg n \rfloor + 1}_{\lfloor \lg n \rfloor, h}$ is $n^{\lg(h/\lg n) + O(1)}$, which matches the asymptotic number of leaves of (n,h)-universal trees of Jurdziński and Lazić [20, Lemma 6]. In particular, if $h = O(\log n)$ then $\lg(h/\lg n) = O(1)$, and hence the number of leaves of $U^{\lfloor \lg n \rfloor + 1}_{\lfloor \lg n \rfloor, h}$ is polynomial in n.

Labelled Strahler-Universal Trees. *Labelled ordered tree* are similar to ordered trees: the trivial tree $\langle \rangle$ is an *A-labelled ordered tree* and so is a sequence $\langle (a_1, \mathcal{L}_1), (a_2, \mathcal{L}_2), \dots, (a_k, \mathcal{L}_k) \rangle$, where $\mathcal{L}_1$, $\mathcal{L}_2$, …, $\mathcal{L}_k$ are A-labelled ordered trees, and a_1, a_2, …, a_k are distinct elements of a linearly ordered set $(A, \leq)$ and $a_1 < a_2 < \cdots < a_k$ in that linear order. We define the *unlabelling* of a labelled ordered tree $\langle (a_1, \mathcal{L}_1), (a_2, \mathcal{L}_2), \dots, (a_k, \mathcal{L}_k) \rangle$, by straightforward induction, to be the ordered tree $\langle T_1, T_2, \dots, T_k \rangle$, where T_i is the unlabelling of $\mathcal{L}_i$ for every $i = 1, 2, \dots, k$. An *A-labelling* of an ordered tree T is an A-labelled tree $\mathcal{L}$ whose unlabelling is T. We define the *natural labelling* of an ordered tree $T = \langle T_1, \dots, T_k \rangle$, again by a straightfoward induction, to be the $\mathbb{N}$-labelled tree $\langle (1, \mathcal{L}_1), \dots, (k, \mathcal{L}_k) \rangle$, where $\mathcal{L}_1$, …, $\mathcal{L}_k$ are the natural labellings of trees T_1, …, T_k.

For an A-labelled tree $\langle (a_1, \mathcal{L}_1), \ldots, (a_k, \mathcal{L}_k) \rangle$, its set of *nodes* is defined inductively to consist of the root $\langle\rangle$ and all the sequences in A^* of the form $\langle a_i \rangle \cdot v$, where $v \in A^*$ is a node in $\mathcal{L}_i$ for some $i = 1, \ldots, k$, and where the symbol $\cdot$ denotes concatenation of sequences. For example, the natural labelling of tree $\left\langle \langle \circ^3 \rangle, \circ^4, \langle\langle \circ \rangle\rangle^2 \right\rangle$ has the set of nodes that consists of the following set of leaves $\langle 1,1 \rangle$, $\langle 1,2 \rangle$, $\langle 1,3 \rangle$, $\langle 2 \rangle$, $\langle 3 \rangle$, $\langle 4 \rangle$, $\langle 5 \rangle$, $\langle 6,1,1 \rangle$, $\langle 7,1,1 \rangle$, and all of their prefixes. Indeed, the set of nodes of a labelled ordered tree is always prefix-closed. Moreover, if $L \subseteq A^*$ then its closure under prefixes uniquely identifies a labelled ordered tree that we call the labelled ordered tree *generated* by L, and its unlabelling is the ordered tree generated by L. For example, the set $\{ \langle 1 \rangle, \langle 3,1 \rangle, \langle 3,4,1 \rangle, \langle 6,1 \rangle \}$ generates ordered tree $\langle \circ, \langle \circ, \langle \circ \rangle \rangle, \langle \circ \rangle \rangle$.

Consider the following linear order on the set $\{0,1\}^*$ of bit strings: for each bit $b \in \{0,1\}$, and for all bit strings $\beta, \beta' \in \{0,1\}^*$, if ε is the empty string, then we have $0\beta < \varepsilon$, $\varepsilon < 1\beta$, and $b\beta < b\beta'$ iff $\beta < \beta'$.

For a bit string $\beta \in \{0,1\}^*$, we write $|\beta|$ for the number of bits used in the string. For example, we have $|\varepsilon| = 0$ and $|010| = 3$, and $|11| = 2$. Suppose that $\langle \beta_i, \beta_{i-1}, \ldots, \beta_1 \rangle$ is a node in a $\{0,1\}^*$-labelled ordered tree. Then if $\beta_j = b\beta$ for some $j = 1, 2, \ldots, i$, $b \in \{0,1\}$, and $\beta \in \{0,1\}^*$, then we refer to the first bit b as the *leading bit* in β_j, and we refer to all the following bits in β as *non-leading bits* in β_j. For example, node $\langle \varepsilon, 010, \varepsilon, \varepsilon, 11 \rangle$ has two non-empty strings and hence two leading bits, and it uses three non-leading bits overall, because $|010| + |11| - 2 = 3$.

For a bit $b \in \{0,1\}$ and a $\{0,1\}^*$-labelled ordered tree $\mathcal{L} = \langle (\beta_1, \mathcal{L}_1), \ldots, (\beta_\ell, \mathcal{L}_\ell) \rangle$, we define the $\{0,1\}^*$-labelled ordered tree $[\mathcal{L}]^b$ to be equal to $\mathcal{L} = \langle (b\beta_1, \mathcal{L}_1), \ldots, (b\beta_\ell, \mathcal{L}_\ell) \rangle$. In other words, $[\mathcal{L}]^b$ is the labelled ordered tree that is obtained from $\mathcal{L}$ by adding an extra copy of bit b as the leading bit in the labels of all children of the root of $\mathcal{L}$.

The inductive structure of the next definition is identical to that of Definition 13, and hence labelled ordered trees $\mathcal{U}^k_{t,h}$ and $\mathcal{V}^k_{t,h}$ defined here are labellings of the ordered trees $U^k_{t,h}$ and $V^k_{t,h}$, respectively.

▶ **Definition 18** (Trees $\mathcal{U}^k_{t,h}$ and $\mathcal{V}^k_{t,h}$). *For all $t \geq 0$, we define $\{0,1\}^*$-labelled ordered trees $\mathcal{U}^k_{t,h}$ (for all h and k such that $h \geq k \geq 1$) and $\mathcal{V}^k_{t,h}$ (for all h and k such that $h \geq k \geq 2$) by mutual induction:*

1. *if $h = k = 1$ then $\mathcal{U}^k_{t,h} = \langle\rangle$;*
2. *if $h > 1$ and $k = 1$ then $\mathcal{U}^k_{t,h} = \left\langle \left(\varepsilon, \mathcal{U}^k_{t,h-1} \right) \right\rangle$;*
3. *if $h \geq k \geq 2$ and $t = 0$ then $\mathcal{V}^k_{t,h} = \left\langle \left(\varepsilon, \mathcal{U}^{k-1}_{t,h-1} \right) \right\rangle$ and $\mathcal{U}^k_{t,h} = \left[\mathcal{V}^k_{t,h} \right]^0 = \left\langle \left(0, \mathcal{U}^{k-1}_{t,h-1} \right) \right\rangle$;*
4. *if $h \geq k \geq 2$ and $t \geq 1$ then $\mathcal{V}^k_{t,h} = \left[\mathcal{V}^k_{t-1,h} \right]^0 \cdot \left\langle \left(\varepsilon, \mathcal{U}^{k-1}_{t,h-1} \right) \right\rangle \cdot \left[\mathcal{V}^k_{t-1,h} \right]^1$;*
5. *if $h = k \geq 2$ and $t \geq 1$ then $\mathcal{U}^k_{t,h} = \left[\mathcal{V}^k_{t,h} \right]^0$;*
6. *if $h > k \geq 2$ and $t \geq 1$ then $\mathcal{U}^k_{t,h} = \left[\mathcal{V}^k_{t,h} \right]^0 \cdot \left\langle \left(\varepsilon, \mathcal{U}^k_{t,h-1} \right) \right\rangle \cdot \left[\mathcal{V}^k_{t,h} \right]^1$.*

The inductive definition of labelled ordered trees $\mathcal{U}^k_{t,h}$ and $\mathcal{V}^k_{t,h}$ makes it straightforward to argue that their unlabellings are equal to trees $U^k_{t,h}$ and $V^k_{t,h}$, respectively, and hence to transfer to them Strahler-universality established in Lemma 14 and upper bounds on the numbers of leaves established in Lemma 15 and Theorem 16. We now give an alternative and more explicit characterization of those trees, which will be more suitable for algorithmic purposes. To that end, we define $\{0,1\}^*$-labelled trees $\mathcal{B}^k_{t,h}$ and $\mathcal{C}^k_{t,h}$ and then we argue that they are equal to trees $\mathcal{U}^k_{t,h}$ and $\mathcal{V}^k_{t,h}$, respectively, by showing that they satisfy all the recurrences in Definition 18.

▶ **Definition 19** (Trees $\mathcal{B}^k_{t,h}$ and $\mathcal{C}^k_{t,h}$). *For all $t \geq 0$ and $h \geq k \geq 1$, we define $\{0, 1\}^*$-labelled ordered trees $\mathcal{B}^k_{t,h}$ as the tree generated by sequences $\langle \beta_{h-1}, \ldots, \beta_1 \rangle$ such that:*

1. *the number of non-empty bit strings among β_{h-1}, ..., β_1 is $k-1$;*
2. *the number of bits used in bit strings β_{h-1}, ..., β_1 overall is at most $(k-1)+t$;*

and for every $i = 1, \ldots, h-1$, we have the following:

3. *if there are less than $k-1$ non-empty bit strings among β_{h-1}, ..., β_{i+1}, but there are t non-leading bits used in them, then $\beta_i = 0$;*
4. *if all bit strings β_i, ..., β_1 are non-empty, then each of them has 0 as its leading bit.*

For all $t \geq 0$ and $h \geq k \geq 2$, we define $\{0, 1\}^*$-labelled ordered trees $\mathcal{C}^k_{t,h}$ as the tree generated by sequences $\langle \beta_{h-1}, \ldots, \beta_1 \rangle$ such that:

1. *the number of non-empty bit strings among β_{h-2}, ..., β_1 is $k-2$;*
2. *the number of bits used in bit strings β_{h-1}, ..., β_1 overall is at most $(k-2)+t$;*

and for every $i = 1, \ldots, h-1$, we have the following:

3. *if there are less than $k-2$ non-empty bit strings among β_{h-2}, ..., β_{i+1}, but there are $t - |\beta_{h-1}|$ non-leading bits used in them, then $\beta_i = 0$;*
4. *if all bit strings β_i, ..., β_1 are non-empty, then each of them has 0 as its leading bit.*

▶ **Lemma 20.** *For all $t \geq 0$ and $h \geq k \geq 1$, we have $\mathcal{U}^k_{t,h} = \mathcal{B}^k_{t,h}$.*

The following corollary follows from Lemma 20, and from the identical inductive structures of Definitions 13 and 18.

▶ **Corollary 21.** *For all $t \geq 0$ and $h \geq k \geq 1$, the unlabelling of $\mathcal{B}^k_{t,h}$ is equal to $U^k_{t,h}$.*

Efficiently Navigating Labelled Strahler-Universal Trees. The computation of the *level-p successor* of a leaf in a labelled ordered tree of height h is the following problem: given a leaf $\langle \beta_h, \beta_{h-1}, \ldots, \beta_1 \rangle$ in the tree and given a number p, such that $1 \leq p \leq h$, compute the $<_{\text{lex}}$-smallest leaf $\langle \beta'_h, \beta'_{h-1}, \ldots, \beta'_1 \rangle$ in the tree, such that $\langle \beta_h, \ldots, \beta_p \rangle <_{\text{lex}} \langle \beta'_h, \ldots, \beta'_p \rangle$. As (implicitly) explained by Jurdziński and Lazić [20, Proof of Theorem 7], the level-p successor computation is the key primitive used extensively in an implementation of a progress measure lifting algorithm.

▶ **Lemma 22.** *Every leaf in tree $\mathcal{B}^k_{t,h}$ can be represented using $O\left((k+t)\log h\right)$ bits and for every $p = 1, 2, \ldots, h$, the level-p successor of a leaf in tree $\mathcal{B}^k_{t,h}$ can be computed in time $O\left((k+t)\log h\right)$.*

6 Progress-Measure Strahler Numbers

Consider a parity game $\mathcal{G}$ in which all vertex priorities are at most an even number d. If $(A, \leq)$ is a well-founded linear order then we write sequences in $A^{d/2}$ in the following form $\langle m_{d-1}, m_{d-3}, \ldots, m_1 \rangle$, and for every priority $p \in \{0, 1, \ldots, d\}$, we define the *$p$-truncation* of $\langle m_{d-1}, m_{d-3}, \ldots, m_1 \rangle$, denoted by $\langle m_{d-1}, m_{d-3}, \ldots, m_1 \rangle|_p$, to be the sequence $\langle m_{d-1}, \ldots, m_{p+2}, m_p \rangle$ if p is odd and $\langle m_{d-1}, \ldots, m_{p+3}, m_{p+1} \rangle$ if p is even. We use the lexicographic order $\leq_{\text{lex}}$ to linearly order the set $A^* = \bigcup_{i=0}^{\infty} A^i$.

A *Steven progress measure* [8, 19, 20] on a parity game $\mathcal{G}$ is a map $\mu : V \to A^{d/2}$ such that for every vertex $v \in V$:

- if $v \in V_{\text{Even}}$ then there is a μ-progressive edge $(v, u) \in E$;
- if $v \in V_{\text{Odd}}$ then every edge $(v, u) \in E$ is μ-progressive;

where we say that an edge $(v, u) \in E$ is *μ-progressive* if:

- if $\pi(v)$ is even then $\mu(v)|_{\pi(v)} \geq_{\text{lex}} \mu(u)|_{\pi(v)}$;
- if $\pi(v)$ is odd then $\mu(v)|_{\pi(v)} >_{\text{lex}} \mu(u)|_{\pi(v)}$.

We define *the tree of a progress measure* μ to be the ordered tree generated by the image of V under μ.

▶ **Theorem 23** ([8, 19, 20])**.** *There is a Steven progress measure on a parity game $\mathcal{G}$ if and only if every vertex in $\mathcal{G}$ is in its largest Steven dominion. If game $\mathcal{G}$ is (n, d)-small then the tree of a progress measure on $\mathcal{G}$ is $(n, d/2 + 1)$-small.*

We define the *Steven progress-measure Strahler number* of a parity game $\mathcal{G}$ to be the smallest Strahler number of a tree of a progress measure on $\mathcal{G}$. The following theorem refines and strengthens Theorems 2 and 23 by establishing that the Steven Strahler number and the Steven progress-measure Strahler number of a parity game nearly coincide.

▶ **Theorem 24.** *The Steven Strahler number and the Steven progress-measure Strahler number of a parity game differ by at most* 1*.*

The translations between progress measures and attractor decompositions are as given by Daviaud, Jurdziński, and Lazić [5]; here we point out that they do not increase the Strahler number of the underlying trees by more than 1. This coincidence of the two complexity measures, one based on attractor decompositions and the other based on progress measures, allows us in Section 7 to use a progress measure lifting algorithm to solve games with bounded Strahler number.

7 Strahler-Universal Progress Measure Lifting Algorithm

Jurdziński and Lazić [20, Section IV] have implicitly suggested that the progress-measure lifting algorithm [19] can be run on any ordered tree and they have established the correctness of such an algorithm if their *succinct multi-counters trees* were used. This has been further clarified by Czerwiński et al. [4, Section 2.3], who have explicitly argued that any $(n, d/2)$-universal ordered tree is sufficient to solve an (n, d)-small parity game in this way. We make explicit a more detailed observation that follows using the same standard arguments (see, for example, Jurdziński and Lazić [20, Theorem 5]).

▶ **Proposition 25.** *Suppose the progress measure-lifting algorithm is run on a parity game $\mathcal{G}$ and on an ordered tree T. Let D be the largest Steven dominion in $\mathcal{G}$ on which there is a Steven progress measure whose tree can be embedded in T. Then the algorithm returns a Steven dominion strategy on D.*

An elementary corollary of this observation is that if the progress-measure lifting algorithm is run on the tree of a progress measure on some Steven dominion in a parity game, then the algorithm produces a Steven dominion strategy on a superset of that dominion. Note that this is achieved in polynomial time because the tree of a progress measure on an (n, d)-small parity game is $(n, d/2)$-small and the running time of the algorithm is dominated by the size of the tree [20, Section IV.B].

▶ **Theorem 26.** *There is an algorithm for solving (n, d)-small parity games of Strahler number k in quasi-linear space and time $n^{O(1)} \cdot (d/2k)^k = n^{k \lg(d/k)/\lg n + O(1)}$, which is polynomial in n if $k \cdot \lg(d/k) = O(\log n)$.*

Proof. By Proposition 3, we may assume that $k \leq 1 + \lg n$. In order to solve an (n, d)-small parity game of Steven Strahler number k, run the progress-measure lifting algorithm for Steven on tree $\mathcal{B}^{k+1}_{\lfloor \lg n \rfloor, d/2+1}$, which is $(k + 1)$-Strahler $(n, d/2 + 1)$-universal by Lemma 14 and Corollary 21. By Theorem 24 and by Proposition 25, the algorithm will then return a Steven dominion strategy on the largest Steven dominion. The running time and space upper bounds follow from Theorem 16, by the standard analysis of progress-measure lifting as in [20, Theorem 7], and by Lemma 22. ◀

▶ Remark 27. We highlight the $k \cdot \lg(d/k) = O(\log n)$ criterion from Theorem 26 as offering a novel trade-off between two natural structural complexity parameters of parity games (number of of priorities d and the Strahler/Lehtinen number k) that enables solving them in time that is polynomial in the number of vertices n. It includes as special cases both the $d < \lg n$ criterion of Calude et al. [3, Theorem 2.8] and the $d = O(\log n)$ criterion of Jurdziński and Lazić [20, Theorem 7] (set $k = \lfloor \lg n \rfloor + 1$ and use Propositions 4 and 3 to justify it), and the $k = O(1)$ criterion of Lehtinen [24, Theorem 3.6] (by Theorem 8).

We argue that the new $k \cdot \lg(d/k) = O(\log n)$ criterion (Theorem 26) enabled by our results (coincidence of the Strahler and the Lehtinen numbers: Theorem 8) and techniques (small and efficiently navigable Strahler-universal trees: Theorem 16, Corollary 21, and Lemma 22) considerably expands the asymptotic ranges of the natural structural complexity parameters in which parity games can be solved in polynomial time. We illustrate it by considering the scenario in which the rates of growth of both k and $\lg d$ as functions of n are $O\big(\sqrt{\log n}\big)$, i.e., d is $2^{O\left(\sqrt{\log n}\right)}$. Note that the number of priorities d in this scenario is allowed to grow as fast as $2^{b \cdot \sqrt{\lg n}}$ for an arbitrary positive constant b, which is significantly larger than what is allowed by the $d = O(\log n)$ criterion of Jurdziński and Lazić [20, Theorem 7]. Indeed, its rate of growth is much larger than any poly-logarithmic function of n, because for every positive constant c, we have $(\lg n)^c = 2^{c \cdot \lg \lg n}$, and $c \cdot \lg \lg n$ is exponentially smaller than $b \cdot \sqrt{\lg n}$. At the same time, the $O\big(\sqrt{\log n}\big)$ rate of growth allowed in this scenario for the Strahler number k substantially exceeds $k = O(1)$ required by Lehtinen [24, Theorem 3.6].

Abstract

For quadratic word equations, there exists an algorithm based on rewriting rules which generates a directed graph describing all solutions to the equation. For regular word equations – those for which each variable occurs at most once on each side of the equation – we investigate the properties of this graph, such as bounds on its diameter, size, and DAG-width, as well as providing some insights into symmetries in its structure. As a consequence, we obtain a combinatorial proof that the problem of deciding whether a regular word equation has a solution is in NP.

1 Introduction

A *word equation* is a tuple (α, β), usually written $\alpha \doteq \beta$, such that α and β are words comprised of letters from a *terminal alphabet* $\Sigma = \{\mathtt{a}, \mathtt{b}, \ldots\}$ and *variables* from a set $X = \{x, y, z, \ldots\}$. Solutions are substitutions of the variables for words in Σ^* making both sides identical. For example, one solution to the word equation $x\mathtt{aby} \doteq y\mathtt{ba}x$ is given by $x \to \mathtt{b}$ and $y \to \mathtt{bab}$. A system of equations is a set of equations, and a solution to the system is a substitution for the variables which is a solution to all the equations in the system.

One of the most fundamental questions concerning word equations is the satisfiability problem: determining whether or not a word equation has a solution. Makanin [22] famously showed in 1977 that the satisfiability problem for word equations is decidable by giving a general algorithm. Since then, several further algorithms have been presented. Most notable among these are the algorithm given by Plandowski [25] which demonstrated that the satisfiability problem is in PSPACE, the algorithm based on Lempel-Ziv encodings by Plandowksi and Rytter [26], and the method of recompression by Jeż, which has since been shown to require only non-deterministic linear space [15, 16]. On the other hand, it is easily seen that solving word equations is NP-hard due to fact that the subcase when one side of the equation consists only of terminals is exactly the pattern matching problem which is NP-complete [3, 12]. It remains a long-standing open problem whether or not the satisfiability problem for word equations is contained in NP.

Recently, there has been elevated interest in solving more general versions of the satisfiability problem, originating from practical applications in e.g. software verification where several *string solving* tools capable of solving word equations are being developed [1, 4, 6, 18, 2] and database theory [14, 13], where one asks whether a given (system of) word equation(s) has a solution which satisfies some additional constraints. Prominent examples include requiring that the substitution for a variable x belongs to some regular language $\mathcal{L}_x$ (regular constraints), or that the lengths of the substitutions of the variables satisfy a set of given linear diophantine equations. Adding regular constraints makes the problem PSPACE complete (see [10, 25, 27], while it is another long standing open problem whether the satisfiability problem with length constraints is decidable. There are also many other kinds of constraints, however many lead to undecidable variants of the satisfiability problem [7, 19]. The main difficulty in dealing with additional constraints is that the solution-sets to word equations are often infinite sets with complex structures. For example, they are not parametrizable [24], and the set of lengths of solutions is generally not definable in Presburger arithmetic [20]. Thus, a better understanding of the solution-sets and their structures is a key aspect of improving our ability to solve problems relating to word equations both in theory and practice.

Quadratic word equations (QWEs) are equations in which each variable occurs at most twice. For QWEs, a conceptually simple and easily implemented algorithm exists which produces a representation of the set of all solutions as a graph. Despite this, however, the satisfiability problem for quadratic equations remains NP-hard, even for severely restricted subclasses [8, 11], while inclusion in NP, and whether the satisfiability problem with length constraints is decidable, have remained open for a long time, just as for the general case.

The algorithm solving QWEs is based on iteratively rewriting the equation(s) according to some simple rules called *Nielsen transformations.* If there exists a sequence of transformations from the original equation to the trivial equation $\varepsilon \doteq \varepsilon$, then the equation has a solution. Otherwise, there is no solution. Hence the satisfiability problem becomes a reachability problem for the underlying rewriting transformation relation, which we denote $\Rightarrow_{NT}$. It is natural to represent this relation as a directed graph $\mathcal{G}^{\Rightarrow_{NT}}$ in which the vertices are word equations and the edges are the rewriting transformations. This has the advantage that the set of all solutions to an equation E corresponds exactly to the set of walks in the graph starting at E and finishing at the trivial equation $\varepsilon \doteq \varepsilon$.[2] Consequently, the properties of the subgraph of $\mathcal{G}^{\Rightarrow_{NT}}$ containing all vertices reachable from E (denoted $\mathcal{G}^{\Rightarrow_{NT}}_{[E]}$) are also informative about the set of solutions to the equation. For example, in [24] a connection is made between the non-parameterisability of the solution set of E and the occurrence of combinations of cycles in the graph. Since equations with a parametrisable solution set are much easier to work with when dealing with additional constraints, this also establishes a connection between the structure of $\mathcal{G}^{\Rightarrow_{NT}}_{[E]}$ and the potential (un)decidability of variants of the satisfiability problem. Moreover, new insights into the structure and symmetries of these graphs are necessary for better understanding and optimising the practical performance of the algorithm.

[2] Each choice of edge in a walk can be seen as a decision about the corresponding solution. It is not necessarily true that different walks will result in different solutions. However, all possible decisions are accounted for, so it is guaranteed that for every solution there is a walk from E to $\varepsilon \doteq \varepsilon$ which corresponds to that solution.

Our Contribution

We consider a subclass of QWEs called regular equations (RWEs) introduced in [23]. A word equation is *regular* if each variable occurs at most once on each side of the equation. Thus, for example, $x\mathtt{ab}y \doteq y\mathtt{ba}x$ is regular while $x\mathtt{ab}x \doteq y\mathtt{ba}y$ is not. Understanding RWEs is a vital step towards understanding the quadratic case, not only because they constitute a significant and general subclass, but also because many non-regular quadratic equations can exhibit the same behaviour as regular ones (consider, e.g. $zz \doteq x\mathtt{ab}yy\mathtt{ba}x$ for which all solutions must satisfy $z = x\mathtt{ab}y = y\mathtt{ba}x$). The satisfiability problem was shown in [8] to be NP-hard for RWEs, and shown to be NP-complete in [9] for some restricted subclasses of RWEs including the classes of regular-reversed and regular-ordered equations.

For RWEs E, we investigate the structure of the graphs $\mathcal{G}^{\Rightarrow_{NT}}_{[E]}$, and as a consequence, are able to describe some of their most important properties. We achieve this by first noting that $\mathcal{G}^{\Rightarrow_{NT}}_{[E]}$ can be divided into strongly connected components $\mathcal{G}^{\Rightarrow}_{[E']}$ for which all the vertices are equations of the same length ($\Rightarrow$ shall be used to denote the restriction of $\Rightarrow_{NT}$ to length preserving transformations only). The “full” graph $\mathcal{G}^{\Rightarrow_{NT}}_{[E]}$ is comprised of these individual components $\mathcal{G}^{\Rightarrow}_{[E']}$ arranged in a DAG-like structure of linear depth (see Section 3) and therefore many properties and parameters of the “full” graph $\mathcal{G}^{\Rightarrow_{NT}}_{[E]}$ are determined by the equivalent properties and parameters of the individual components $\mathcal{G}^{\Rightarrow}_{[E']}$. We then focus on the structure of the subgraphs $\mathcal{G}^{\Rightarrow}_{[E']}$, and as a result are able to give bounds on certain parameters such as diameter, size, and DAG-width.

Our structural results come in two stages, based on whether the equation belongs to a the class of “jumbled” equations introduced in Section 4.3. In the first stage, we consider equations which are not jumbled, and we show that for all such equations E, there exists a jumbled equation $\hat{E}$ such that $\mathcal{G}^{\Rightarrow}_{[E]}$ is comprised mainly of several well-connected near-copies of $\mathcal{G}^{\Rightarrow}_{[\hat{E}]}$. For jumbled equations $\hat{E}$, we show in Section 4.4 that every vertex in $\mathcal{G}^{\Rightarrow}_{[\hat{E}]}$ is close to a vertex in a certain normal form. We show that the vertices in this normal form are determined to a large extent by a property invariant under $\Rightarrow$ introduced in Section 4.2.

With regards to the diameter of $\mathcal{G}^{\Rightarrow}_{[E']}$, we give upper bounds which are polynomial in the length of the equation. It follows that the diameter of the full graph $\mathcal{G}^{\Rightarrow_{NT}}_{[E]}$ is also polynomial, and consequently, that the satisfiability problem for RWEs is NP-complete. This can be generalised to systems of equations satisfying a natural extension of the regularity property (see Section 4.7). We also give exact upper and lower bounds on the number of vertices[3] in $\mathcal{G}^{\Rightarrow}_{[E']}$ for a subclass of RWEs called *basic* RWEs (see Section 4.1), as well as describing exactly for which equations these bounds are achieved. For RWEs which are not basic, we can infer similar bounds, at the cost of a small (linear in the length of the equation) degree of imprecision. Since in the worst case (e.g. for equations without a solution), running the algorithm will perform a full “search” of the graph, the number of vertices is integral to the running time of the algorithm, and is potentially a better indicator of difficult instances than the complexity class alone. An example of this, comes from comparing two subclasses of RWEs called regular-ordered and regular rotated equations. It follows from our results that while both classes have an NP-complete satisfiability problem, if E' is regular-ordered, then $\mathcal{G}^{\Rightarrow}_{[E']}$ will contain at most n vertices, where n is the length of the equation, while if E' is regular rotated, but not regular-ordered, then $\mathcal{G}^{\Rightarrow}_{[E']}$ will contain $\frac{n!}{2}$ vertices, indicating a vast difference in the number of vertices the algorithm would have to visit.

[3] We consider the number of vertices, rather than edges, because it is the number of vertices which is relevant to the performance of the algorithm, and by definition of $\Rightarrow_{NT}$, the out-degree of the graph is bounded by a constant so the the number of edges is linear in the number of vertices.

Motivated by generalisations of the satisfiability problem permitting additional constraints, we also consider the connectivity of the graphs $\mathcal{G}^{\Rightarrow_{NT}}_{[E]}$. To do this, we use DAG-width, a measure for directed graphs which is in several ways analogous to treewidth for undirected graphs. Intuitively, equations for which $\mathcal{G}^{\Rightarrow_{NT}}_{[E]}$ has low DAG-width are likely to be more amenable when considering additional constraints such as length constraints (see Section 3.3). We give an example class of equations for which the DAG-width is unbounded, as well as a class for which the DAG-width is at most two. The latter includes the class of regular-ordered equations which is the most general subclass of QWEs for which it is known that the satisfiability problem with length constraints is decidable [20], and we expect that both cases will be interesting classes to consider in the context of this problem.

2 Preliminaries

For a set S, we denote the cardinality of S by $\text{Card}(S)$. Let Σ be an alphabet. By Σ^*, we denote the set of all words over Σ, and by ε the empty word. By Σ^+, we denote the free semigroup $\Sigma^*\backslash\{\varepsilon\}$. A word u is a prefix (resp. suffix) of a word w if there exists v such that $w = uv$ (resp. $w = vu$). Similarly, u is a factor of w if there exist v, v' such that $w = vuv'$. A prefix/suffix/factor is *proper* if is neither the whole word w, nor ε. The length of a word w is denoted $|w|$, while for $\mathtt{a} \in \Sigma$, $|w|_\mathtt{a}$ denotes the number of occurrences of $\mathtt{a}$ in w. For a word $w = \mathtt{a}_1\mathtt{a}_2 \dots \mathtt{a}_n$ with $\mathtt{a}_i \in \Sigma$ for $1 \leq i \leq n$, the notation $w[i]$ refers to the letter $\mathtt{a}_i$ in the i^{th} position. By w^R, we denote the reversal $\mathtt{a}_n\mathtt{a}_{n-1} \dots \mathtt{a}_1$ of the word w. Two words w_1, w_2 are conjugate (written $w_1 \sim w_2$) if there exist u, v such that $w_1 = uv$ and $w_2 = vu$.

We shall generally distinguish between two types of alphabet: an infinite set $X = \{x_1, x_2, \dots\}$ of variables, and a set $\Sigma = \{\mathtt{a}, \mathtt{b}, \dots\}$ of terminal symbols. We shall assume that $\text{Card}(\Sigma) \geq 2$, and that there exists an order on X leading to a lexicographic order on X^*. For a word $\alpha \in (X \cup \Sigma)^*$, we shall denote by $\text{var}(\alpha)$ the set $\{x \in X \mid x \text{ is a factor of } \alpha\}$. We shall denote by $\text{qv}(\alpha)$ the set $\{x \in \text{var}(\alpha) \mid |\alpha|_x = 2\}$. A word equation is a tuple $(\alpha, \beta) \in (X \cup \Sigma)^* \times (X \cup \Sigma)^*$, usually written $\alpha \doteq \beta$. Solutions are morphisms $h : (X \cup \Sigma)^* \to \Sigma^*$ with $h(\mathtt{a}) = \mathtt{a}$ for all $\mathtt{a} \in \Sigma$ such that $h(\alpha) = h(\beta)$. The satisfiability problem is the problem of deciding algorithmically whether a given word equation has a solution. For equations E given by $\alpha \doteq \beta$, we shall often extend notations regarding words in $(X \cup \Sigma)^*$ to E for convenience, so that, e.g. $|E| = |\alpha\beta|$, $\text{var}(E) = \text{var}(\alpha\beta)$ and $\text{qv}(E) = \text{qv}(\alpha\beta)$. An equation $\alpha \doteq \beta$ is quadratic if $|\alpha\beta|_x \leq 2$ for all $x \in X$. It is regular if $|\alpha|_x \leq 1$ and $|\beta|_x \leq 1$ hold for all $x \in X$. Thus all regular equations are quadratic, but not all quadratic equations are regular. We shall usually abbreviate regular (resp. quadratic) word equation to RWE (resp. QWE). For $Y \subseteq X$, let $\pi_Y : (X \cup \Sigma^*) \to Y^*$ be the morphism such that $\pi_Y(x) = x$ if $x \in Y$ and $\pi_Y(x) = \varepsilon$ otherwise; i.e. π_Y is a projection from $(X \cup \Sigma)^*$ onto Y^*. A regular equation E given by $\alpha \doteq \beta$ is regular-ordered if $\pi_{\text{qv}(E)}(\alpha) = \pi_{\text{qv}(E)}(\beta)$, it is regular rotated if $\pi_{\text{qv}(E)}(\alpha) \sim \pi_{\text{qv}(E)}(\beta)$ and it is regular reversed if $\pi_{\text{qv}(E)}(\alpha) = \pi_{\text{qv}(E)}(\beta)^R$.

Given a set S and binary relation $\mathcal{R} \subseteq S \times S$, we denote the reflexive-transitive closure of $\mathcal{R}$ as $\mathcal{R}^*$. For each $s \in S$, we denote by $[s]_\mathcal{R}$ the set $\{s' \mid s\mathcal{R}^*s'\}$. The relation $\mathcal{R}$ may be represented as a directed graph, which we denote $\mathcal{G}^\mathcal{R}$, with vertices from S and edges from $\mathcal{R}$. Usually, we will be interested in the subgraph of $\mathcal{G}^\mathcal{R}$ containing vertices belonging to $[s]$ for some $s \in S$. Thus, for a subset T of S we shall denote by $\mathcal{G}^\mathcal{R}_T$ the subgraph of $\mathcal{G}^\mathcal{R}$ containing vertices from T. Given a (directed) graph $\mathcal{G}$, with vertices $V(\mathcal{G})$ and edges $E(\mathcal{G})$, a root vertex is some $v \in V(\mathcal{G})$ such that there does not exist $(u, v) \in E(\mathcal{G})$. We denote by $\text{diam}(\mathcal{G})$ the diameter: the maximum length of a shortest (directed) path between two vertices. For $W, V' \subseteq V(\mathcal{G})$, we say that W *guards* V' if for all $(u, v) \in E(\mathcal{G})$ with $u \in V'$, we have $v \in V' \cup W$. If $\mathcal{G}$ is acyclic, we write $v_1 \leq_{\mathcal{G}} v_2$ if there is a directed path from v_1 to v_2 in $\mathcal{G}$ or $v_1 = v_2$. Following [5], A DAG-decomposition of $\mathcal{G}$ is a pair (D, χ) such that D is a directed acyclic graph (DAG) with vertices $V(D)$, and $\chi = \{X_d \mid d \in V(D)\}$ is a family of subsets of $V(\mathcal{G})$ satisfying:

(D1) $V(\mathcal{G}) = \bigcup\limits_{d \in V(D)} X_d$,

(D2) if $d, d', d'' \in V(D)$ such that $d \leq_D d' \leq_D d''$, then $X_d \cap X_{d''} \subseteq X_{d'}$,

(D3) For all edges (d, d') of D, $X_d \cap X_{d'}$ guards $X_{\geq d'} \backslash X_d$, where $X_{\geq d'} = \bigcup\limits_{d'' \geq_D d'} X_{d''}$, and for all root vertices d, $X_{\geq d}$ is guarded by $\emptyset$.

The width of the DAG-decomposition is $\max\{\text{Card}(X_d) \mid d \in V(D)\}$. The DAG-width of $\mathcal{G}$ is the minimum width of any possible DAG-decomposition of $\mathcal{G}$ and is denoted $\text{dgw}(\mathcal{G})$.

3 Solving regular word equations

In this section we present the algorithm for solving QWEs discussed in the introduction as a rewriting system given by a relation $\Rightarrow_{NT}$. The rewriting transformations are derived from morphisms called Nielsen transformations, and we shall abuse this terminology slightly and generally also refer to the rewriting transformations themselves as Nielsen transformations. The Nielsen transformations never introduce new variables or terminal symbols, and never increase the length of the equation. They also preserve the properties of being quadratic (resp. regular). Thus, given a quadratic (resp. regular) word equation, the possible space of all equations reachable via Nielsen transformations is finite. Moreover, given an equation which has a solution h, there is always at least one Nielsen transformation which produces an equation which has a solution, such that the new equation or the new solution is shorter than the previous one. It follows that, given an equation which possesses a solution, it is possible to reach the equation $\varepsilon \doteq \varepsilon$ after finitely many rewriting steps. For a more detailed description of the algorithm, we refer the reader to e.g. Chapter 12 of [21].

3.1 Nielsen transformations

The Nielsen transformations are defined as follows: for $x \in X \cup \Sigma$ and $y \in X$, let $\psi_{x<y} : (X \cup \Sigma)^* \to (X \cup \Sigma)^*$ be the morphism given by $\psi_{x<y}(y) = xy$ and $\psi_{x<y}(z) = z$ if $z \neq y$. We define the rewriting transformations via the relations $\Rightarrow_L, \Rightarrow_R, \Rightarrow_>$ as follows. Suppose we have a QWE E of the form $x\alpha \doteq y\beta$ where $x, y \in X \cup \Sigma$ and $\alpha, \beta \in (X \cup \Sigma)^*$. Then:

1. if $x \in \text{qv}(E)$ and $x \neq y$, then $x\alpha \doteq y\beta \Rightarrow_L x\psi_{y<x}(\alpha) \doteq \psi_{y<x}(\beta)$, and
2. if $y \in \text{qv}(E)$ and $x \neq y$, then $x\alpha \doteq y\beta \Rightarrow_R \psi_{x<y}(\alpha) \doteq y\psi_{x<y}(\beta)$, and
3. if $x \in X \backslash \text{qv}(E)$, then $x\alpha \doteq y\beta \Rightarrow_> x\alpha \doteq \beta$, and
4. if $y \in X \backslash \text{qv}(E)$, then $x\alpha \doteq y\beta \Rightarrow_> \alpha \doteq y\beta$, and
5. if $x = y$, then $x\alpha \doteq y\beta \Rightarrow_> \alpha \doteq \beta$.

Moreover, for a QWE E of the form $\alpha \doteq \beta$ with $\alpha, \beta \in (X \cup \Sigma)^*$, and for each $Y \subseteq \text{var}(E)$, we have the additional transformations $\alpha \doteq \beta \Rightarrow_> \pi_{X \backslash \{Y\}}(\alpha) \doteq \pi_{X \backslash \{Y\}}(\beta)$. Now, our full rewriting relation, $\Rightarrow_{NT}$, is given by $\Rightarrow_L \cup \Rightarrow_R \cup \Rightarrow_>$. For convenience, we shall define $\Rightarrow$ to be $\Rightarrow_L \cup \Rightarrow_R$. We shall call the rewriting transformations in $\Rightarrow$ *length-preserving*, since they are exactly those for which the resulting equation has the same length as the original.

▶ Remark 1. Let E, E' be QWEs such that $E \Rightarrow_{NT} E'$. If E is regular, then E' is regular. Moreover, if $E \Rightarrow E'$, then $\text{var}(E) = \text{var}(E')$, $\text{qv}(E) = \text{qv}(E')$, and $|E| = |E'|$.

If E_1, E_2 are RWEs such that $E_1 \Rightarrow_L E_2$, then it follows from the definitions that there exist $x, y \in X$ and $\alpha_1, \alpha_2, \beta_1, \beta_2, \in (X \backslash \{x, y\})^*$ such that E_1 is given by $x\alpha_1 y\alpha_2 \doteq y\beta_1 x\beta_2$ and E_2 is given by $x\alpha_1 y\alpha_2 \doteq \beta_1 yx\beta_2$. Extending this observation to multiple applications of

$\Rightarrow_L$, we may conclude that the set $\{E_2 \mid E_1 \Rightarrow_L^* E_2'\}$ is exactly the set $\{x\alpha_1 y\alpha_2 \doteq \beta_3 x\beta_2 \mid \beta_3 \sim y\beta_1\}$. A similar statement can be made for $\Rightarrow_R^*$. Consequently, $\Rightarrow_L^*$ and $\Rightarrow_R^*$ are symmetric. Since they are reflexive and transitive by definition, we get the following.

▶ Remark 2. Let E be a RWE and $Z \in \{L, R\}$. Then $\mathrm{Card}(\{E' \mid E \Rightarrow_Z^* E'\}) < |E|$ and $\Rightarrow_Z^*$ is an equivalence relation. It follows that $\Rightarrow^*$ is also an equivalence relation.

The following well-known result forms the basis for the algorithm for solving QWEs.

▶ **Theorem 3** ([21]). *Let E be a QWE. Then E has a solution if and only if $E \Rightarrow_{NT}^* \varepsilon \doteq \varepsilon$.*

3.2 The graph of all solutions

Theorem 3 provides the basis for treating the satisfiability of QWEs as a reachability problem for the rewriting relation $\Rightarrow_{NT}$. Since any relation R is naturally represented as a (directed) graph $\mathcal{G}^R$, it is also natural to interpret the resulting algorithm as a search in the graph $\mathcal{G}_{[E]}^{\Rightarrow_{NT}}$, in order to determine whether a path exists in the graph from the original equation E to the trivial equation $\varepsilon \doteq \varepsilon$. In fact, the graph $\mathcal{G}_{[E]}^{\Rightarrow_{NT}}$ can tell us significantly more than simply whether a solution to E exists: every walk from E to $\varepsilon \doteq \varepsilon$ in $\mathcal{G}_{[E]}^{\Rightarrow_{NT}}$ corresponds to a solution to E and likewise, every solution to E is represented by a walk in $\mathcal{G}_{[E]}^{\Rightarrow_{NT}}$ from E to $\varepsilon \doteq \varepsilon$. Thus the graphs $\mathcal{G}_{[E]}^{\Rightarrow}$ contain a full description of all solutions to E, and as such, their properties and structure are of inherent interest to the study of QWEs and their solutions. An immediate example of this is the diameter, which is strongly related to the complexity of the satisfiability problem, as demonstrated in the following proposition.

▶ **Proposition 4.** *Let $\mathcal{C}$ be a class of QWEs. Suppose there exists $k \in \mathbb{N}$ such that for each $E \in \mathcal{C}$, we have $\mathrm{diam}(\mathcal{G}_{[E]}^{\Rightarrow_{NT}}) \in O(|E|^k)$. Then the satisfiability problem for $\mathcal{C}$ is in NP.*

Many properties will be determined mostly (i.e. up to some small imprecision) on the subgraphs obtained by restricting our rewriting relation to length-preserving transformations only (i.e. to $\Rightarrow$). Since the rewriting relation $\Rightarrow_{NT}$ allows us to preserve or decrease the length, but never increase it again, any walk in the graph will visit a subgraph containing equations of each length only once, and in order of decreasing length.

The following proposition is an example of how we may infer a global property of $\mathcal{G}_{[E]}^{\Rightarrow_{NT}}$ from its "local" values in the individual subgraphs $\mathcal{G}_{[E']}^{\Rightarrow}$.

▶ **Proposition 5.** *Let E be a QWE. Then*

1. $\mathrm{diam}(\mathcal{G}_{[E]}^{\Rightarrow_{NT}}) \leq 1 + (|E| + 1) \max\{\mathrm{diam}(\mathcal{G}_{[E']}^{\Rightarrow}) \mid E \Rightarrow_{NT}^* E'\}$, *and*
2. $\mathrm{dgw}(\mathcal{G}_{[E]}^{\Rightarrow_{NT}}) = \max\{\mathrm{dgw}(\mathcal{G}_{[E']}^{\Rightarrow}) \mid E \Rightarrow_{NT}^* E'\}$.

In what follows, we shall focus predominantly on the structure of the (sub)graphs $\mathcal{G}_{[E']}^{\Rightarrow}$ corresponding to the length-preserving transformations given by $\Rightarrow$. This has the advantage of allowing us to apply further restrictions, including a reduction to the case of basic equations introduced in Section 4.1, without significantly altering the structure of the graph.

3.3 Solving equations modulo constraints

For many kinds of additional constraint, it is possible to adapt the algorithm by finding, for each Nielsen transformation, an appropriate corresponding transformation of the constraints. For example, if $x, y, z \in X$ and we have the length constraint $|x| = |z|$, when we apply the Nielsen transformation associated with $\psi_{y<x}$ to our equation, we replace each occurrence of x with yx. Thus, the updated constraint would be $|x| + |y| = |z|$. However, in some cases, including length constraints, the resulting space of possible combinations of equations and

constraints becomes infinite, meaning the algorithm is no longer guaranteed to terminate. A possible solution to this is to find finite descriptions of the potentially infinite sets of constraints which may occur alongside each equation. The task of finding such descriptions, and consequently the decidability of the corresponding extended satisfiability problems, is dependent on the structural properties of the graph, as can be seen e.g. in [20, 24].

4 Properties of the graphs $\mathcal{G}^{\Rightarrow NT}_{[E]}$ for regular equations E

The remainder of the paper concentrates on describing the structure of the graphs $\mathcal{G}_{[E]}$ for RWEs E. Our general description of $\mathcal{G}_{[E]}$ is comprised of several steps, with each one accounting for a particular aspect. The first step (Section 4.1) describes the effect of terminal symbols, single-occurrence variables, and 'decomposability' on the structure of $\mathcal{G}_{[E]}$, essentially reducing the structure of $\mathcal{G}_{[E]}$ to $\mathcal{G}_{[E']}$ for a "basic" equation E' which does not contain any of these features. The second step (Section 4.3) describes a particular symmetric structure which arises from the same factor(s) occurring on both sides of the equation once we have simplified the equations by eliminating the aforementioned features. This allows for a description of $\mathcal{G}_{[E']}$ as a combination of (near) copies of some smaller graph $\mathcal{G}_{[E'']}$ where E'' is a "jumbled equation" obtained by deleting the appropriate variables from E'. Finally, we are able to show (Section 4.4) that for jumbled equations E'', all vertices in $\mathcal{G}_{[E'']}$ are "close" to a vertex from a small subset conforming to a very particular structure called Lex Normal Form, allowing us to draw conclusions in Sections 4.5 and 4.6 about the diameter, number of vertices and connectivity (DAG-width) of $\mathcal{G}_{[E]}$. Finally, in Section 4.7 we note a generalisation of our results to systems of equations.

4.1 Basic equations: a convenient abstraction

The current section is devoted to reducing the study of the graphs $\mathcal{G}^{\Rightarrow}_{[E]}$ to the case of basic equations. This has several advantages, including a significant reduction in the size of the graphs which is useful for working with examples, as well as allowing for the simpler formulation of precise results, e.g. regarding the size of the graphs in Section 4.6, as well as avoiding unnecessary repetition in the formal statements and their proofs..

▶ **Definition 6** (Basic Equations). *Let E be a QWE given by $\alpha \doteq \beta$. Then E is* decomposable *if there exist proper prefixes α', β' of α and β such that* $\mathrm{var}(\alpha') \cap \mathrm{qv}(E) = \mathrm{var}(\beta') \cap \mathrm{qv}(E)$. *Otherwise, E is* indecomposable. *E is* basic *if it is indecomposable and $\alpha, \beta \in \mathrm{qv}(E)^*$.*

A RWE is basic only if both sides of the equation are permutations of the same set of variables, for example $x_1x_2x_3 \doteq x_3x_1x_2$ and $xywz \doteq wzxy$ are both basic and regular while $xyzw \doteq yxzw$ and $xy \doteq yz$ are not. It is easily verified that the property of being basic is preserved under $\Rightarrow^*$. In order to formally present our reduction from arbitrary RWEs to basic RWEs, we need the following notion for graphs which are structurally similar.

▶ **Definition 7** (Isolated path compression). *Let G_1, G_2 be (directed) graphs. We say that G_1 is an* isolated path compression *of order n of G_2 if G_2 may be obtained from G_1 by replacing each edge (e, e') in G_1 by a path $(e, e_1), (e_1, e_2), \ldots (e_{k-1}, e_k), (e_k, e')$ such that $k \leq n$ and $e_1, e_2, e_3, \ldots, e_k$ are new vertices unique to the edge (e, e').*

Informally, an isolated path compression of a graph is obtained simply by replacing "isolated paths" (paths whose internal vertices are not adjacent to to any vertices outside the path) of a bounded length with single edges. It is easy to see that many structural properties are thus preserved.

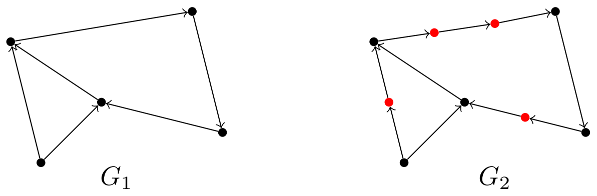

Figure 1 The graph G_1 is an isolated path compression of order two of the graph G_2.

▶ Remark 8. Consider graphs G_1, G_2 such that G_1 is an isolated path compression of order n of G_2. If $\mathrm{dgw}(G_1) = 1$, then $\mathrm{dgw}(G_2) \in \{1, 2\}$. If $\mathrm{dgw}(G_1) \geq 2$, then the $\mathrm{dgw}(G_1) = \mathrm{dgw}(G_2)$. Moreover, $\mathrm{diam}(G_2) \leq (n + 1)\,\mathrm{diam}(G_1)$, and the number of vertices (resp. edges) in G_2 is at most the number of vertices in G_1 plus n times the number of edges of G_1.

Using isolated path compressions, it is possible to describe the structure of the graph $\mathcal{G}^{\Rightarrow}_{[E]}$ for any RWE E in terms of the graph $\mathcal{G}^{\Rightarrow}_{[E']}$ for a basic RWE E'.

▶ **Theorem 9.** *Let E be a RWE given by $\alpha \doteq \beta$. Let α', β' be the shortest non-empty prefixes of α, β respectively such that $\mathrm{var}(\alpha') \cap \mathrm{qv}(E) = \mathrm{var}(\beta') \cap \mathrm{qv}(E)$. Let E' be the equation given by $\pi_{\mathrm{qv}(E)}(\alpha') \doteq \pi_{\mathrm{qv}(E)}(\beta')$. Then E' is basic, and $\mathcal{G}^{\Rightarrow}_{[E']}$ is isomorphic to an isolated path compression of order $|E|$ of $\mathcal{G}^{\Rightarrow}_{[E]}$.*

4.2 A useful invariant

When reasoning about the graphs $\mathcal{G}^{\Rightarrow}_{[E]}$, we need a way to help determine whether, for two equations E_1, E_2, we have $E_1 \Rightarrow^* E_2$. Usually, showing that $E_1 \Rightarrow^* E_2$ is not a problem, since it is sufficient to simply find a sequence of length-preserving Nielsen transformations from E_1 to E_2. However, showing that $E_1 \not\Rightarrow^* E_2$ presents more of a challenge. The naive way would be to enumerate all vertices in $\mathcal{G}^{\Rightarrow}_{[E_1]}$ and show that E_2 is not among them. However, this is not suitable for generic reasoning, and, even in concrete cases, is inelegant and time-consuming. The following is a property of basic RWEs which is preserved under $\Rightarrow$ and thus provides a concise and more general means for showing that $E_1 \not\Rightarrow^* E_2$. It is an indispensable component of the proofs of our main results.

▶ **Definition 10** (The invariant Υ_E)**.** *Let $\#$ be a new symbol not in X. Let E be a basic RWE such that $\mathrm{Card}(\mathrm{var}(E)) > 1$. Then we may write E as $x\alpha_1 y\alpha_2 \doteq y\beta_1 x\beta_2$ with $x, y \in X$ and $\alpha_1, \alpha_2, \beta_1, \beta_2 \in (X \backslash \{x, y\})^*$. Let $\mathcal{Z}_E = \mathrm{var}(\alpha_1\alpha_2\beta_1\beta_2) \cup \{\#\}$. Let the function $Q_E : \mathcal{Z}_E \to X^2$ be defined as follows: for each $z \in \mathcal{Z}_E \backslash \{\#\}$, let $Q_E(z) = (u, v)$ where uz is a factor of $x\alpha_1 y\alpha_2$ and vz is a factor of $y\beta_1 x\beta_2$. Let $Q_E(\#) = (u, v)$ where uy is a factor of $x\alpha_1 y\alpha_2$ and vx is a factor of $y\beta_1 x\beta_2$. Let $\Upsilon_E = \{Q_E(z) \mid z \in \mathcal{Z}_E\}$.*

▶ **Theorem 11.** *Let E_1, E_2 be basic RWEs such that $E_1 \Rightarrow^* E_2$. Then $\Upsilon_{E_1} = \Upsilon_{E_2}$.*

As an example, let E_1 be the basic RWE given by $xuzwy \doteq ywuxz$. Then $\mathcal{Z}_{E_1} = \{u, z, w, \#\}$ and Q_{E_1} is the function such that $Q_{E_1}(u) = (x, w)$, $Q_{E_1}(z) = (u, x)$, $Q_{E_1}(w) = (z, y)$ and $Q_{E_1}(\#) = (w, u)$. Thus, $\Upsilon_{E_1} = \{(w, u), (x, w), (u, x), (z, y)\}$. Similarly, if E_2 is the basic RWE given by $xuwzy \doteq yuxwz$, then $\Upsilon_{E_2} = \{(x, y), (u, x), (w, w), (z, u)\}$. Consequently, we may conclude that $E_1 \not\Rightarrow^* E_2$ (and symmetrically $E_2 \not\Rightarrow^* E_1$).

Since the invariant Υ_E provides a necessary condition on when two basic RWEs belong to the same equivalence class under $\Rightarrow^*$, we might also ask whether it is also sufficient, and hence characteristic. However, this is not the case. For instance, if E_1 is given by $xuvwy \doteq ywvux$ and E_2 is given by $xwvuy \doteq yuvwx$, then $\Upsilon_{E_1} = \Upsilon_{E_2} = \{(x, v), (u, w), (v, y), (w, u)\}$ but it can be verified by enumerating $[E_1]_{\Rightarrow}$ and $[E_2]_{\Rightarrow}$ that $E_1 \not\Rightarrow^* E_2$.

4.3 A special case of symmetry

The invariant property Υ_E introduced in the previous section is a set of pairs of variables. The case that $(x, x) \in \Upsilon_E$ for some $x \in \text{var}(E)$ is special in the sense that it leads to a particular symmetrical structure in $\mathcal{G}^{\Rightarrow}_{[E]}$. Intuitively, $(x, x) \in \Upsilon_E$ when there exists $y \in X$ and $\alpha \doteq \beta \in [E]_{\Rightarrow}$ such that xy is a factor of both α and β. Hence the number of variables x such that $(x, x) \in \Upsilon_E$ is, in a sense, a measure of the "jumbledness" of E.

▶ **Definition 12** (Jumbled Equations and $\Delta(E)$)**.** *Let E be a basic RWE. Let $\Delta(E) = \{x \in \text{var}(E) \mid (x, x) \in \Upsilon_E\}$. If $\text{Card}(\Delta(E)) = 0$, then E is* jumbled.

Note that since Υ_E is invariant under $\Rightarrow^*$, so is the property of being (not) jumbled. Any basic RWE E can be turned into a jumbled equation by simply erasing each $x \in \Delta(E)$.

▶ **Lemma 13.** *Let E be a basic RWE given by $\alpha \doteq \beta$ and let $Y = \text{var}(E)\backslash\Delta(E)$. Then the equation E_Y given by $\pi_Y(\alpha) \doteq \pi_Y(\beta)$ is jumbled.*

The following theorem describes the structure of $\mathcal{G}^{\Rightarrow}_{[E]}$ for a RWE E which is not jumbled in terms of $\mathcal{G}^{\Rightarrow}_{[E_Y]}$ where E_Y is obtained from E by deleting the variables in $\Delta(E)$.

▶ **Theorem 14.** *Let E be a basic RWE given by $\alpha \doteq \beta$. Let $Y = \text{var}(E)\backslash\Delta(E)$. Let E_Y be the equation $\pi_Y(\alpha) \doteq \pi_Y(\beta)$. Let $V = [E_Y]_{\Rightarrow}$. Let Φ be the set of morphisms $\varphi : Y^* \to \text{var}(E)^*$ satisfying $\varphi(y) \in \Delta(E)^*y$ for all $y \in Y$, and $\sum_{y \in Y} |\varphi(y)|_x = 1$ for all $x \in \Delta(E)$. For each $\varphi \in \Phi$, let $\varphi(V)$ denote the set $\{\varphi(\alpha') \doteq \varphi(\beta') \mid \alpha' \doteq \beta' \in V\}$. Then:*

1. *$\bigcup_{\varphi \in \Phi} \varphi(V) \subseteq [E]_{\Rightarrow}$,*
2. *for each $E' \in [E]_{\Rightarrow}$ and $Z \in \{L, R\}$, there exists $E'' \in \bigcup_{\varphi \in \Phi} \varphi(V)$ such that $E' \Rightarrow^*_Z E''$,*
3. *for each $\varphi \in \Phi$, there exists a subgraph $\mathcal{H}_\varphi$ of $\mathcal{G}^{\Rightarrow}_{[E]}$ containing $\varphi(V)$ such that $\mathcal{G}^{\Rightarrow}_{[E_Y]}$ is isomorphic to a structure-preserving contraction of order $\text{Card}(\Delta(E))$ of $\mathcal{H}_\varphi$.*
4. *if $d = \text{diam}(\mathcal{G}^{\Rightarrow}_{[E_Y]})$, then $\text{diam}(\mathcal{G}^{\Rightarrow}_{[E]}) \in O(d|E|^2)$.*

Theorem 14 deserves a few remarks. Firstly, we note that, recalling Remark 2, it follows from statements 1. and 2. of the theorem that $\bigcup_{\varphi \in \Phi} \varphi(V)$ is a dense subset of the vertices of $\mathcal{G}^{\Rightarrow}_{[E]}$ in the sense that every vertex is at most distance $|E|$ away from one contained in $\bigcup_{\varphi \in \Phi} \varphi(V)$. Moreover, since each morphism $\varphi \in \Phi$ is injective, the sets $\varphi(V)$ are pairwise disjoint. Consequently, $\mathcal{G}^{\Rightarrow}_{[E]}$ is made up of many (one for each $\varphi \in \Phi$) slightly modified copies of the graph $\mathcal{G}^{\Rightarrow}_{[\alpha \doteq \beta]}$, with the remaining vertices creating short paths between the different copies. Due to the bound on the diameter, we see that these copies are well connected. Finally, it is worth noting that $\text{Card}(\Phi)$ grows exponentially w.r.t. $\text{Card}(\Delta(E))$.

4.4 Normal forms and block decompositions

Having described the structure $\mathcal{G}^{\Rightarrow}_{[E]}$ for equations E which are not jumbled in the previous section, it remains to consider equations which are jumbled. In this case, the structure of $\mathcal{G}^{\Rightarrow}_{[E]}$ is more intricate and a different approach is required. Our main insight for jumbled equations is the existence of certain normal forms, from which every vertex is polynomial distance away. By constructing these normal forms in a specific way based on reversals, we are able to take full advantage of the invariant Υ_E from Section 4.2 when reasoning about which of these normal forms may occur. The first normal form is defined as follows.

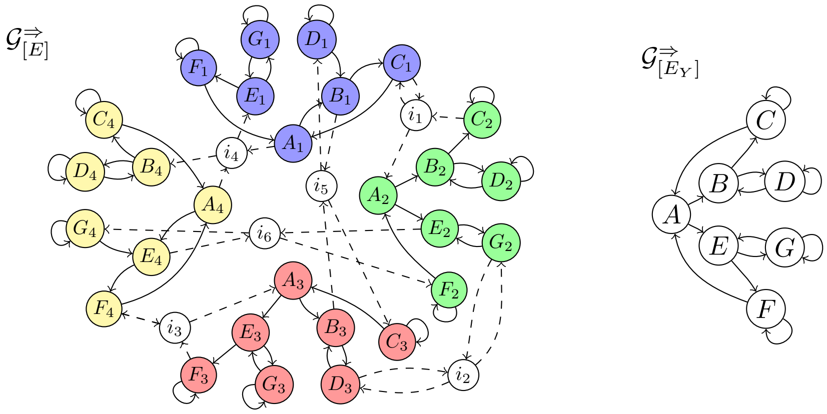

Figure 2 Example illustrating Theorem 14. On the left is $\mathcal{G}^{\Rightarrow}_{[E]}$ for the equation E given by $x_1yx_2x_3x_4 \doteq x_4x_3yx_2x_1$. Note that $\Delta(E) = \{y\}$, so $Y = \{x_1, x_2, x_3, x_4\}$ and E_Y is $x_1x_2x_3x_4 \doteq x_4x_3x_2x_1$. The graph $\mathcal{G}^{\Rightarrow}_{[E_Y]}$ is shown on the right, where the equations in $[E_Y]_{\Rightarrow}$ have been labelled A, B, C, D, E, F, G. The set Φ contains four morphisms φ_i, $1 \leq i \leq 4$, such that $\varphi_i(x_i) = yx_i$ and $\varphi_i(x_j) = x_j$ for $j \neq i$. For each $Z \in \{A, B, C, D, E, F, G\}$ given by $\alpha_Z \doteq \beta_Z$, Z_i denotes the equation $\varphi_i(\alpha_Z) \doteq \varphi_i(\beta_Z)$. The graph $\mathcal{G}^{\Rightarrow}_{[E]}$ contains a "near-copy" of $\mathcal{G}^{\Rightarrow}_{[E_Y]}$ corresponding to each of the morphisms φ_i. Each copy can be made exact by contracting length-two paths (dashed) passing through the intermediate vertices $i_1, i_2, \ldots, i_6$. For example, the subgraph containing the vertices $A_1, B_1, C_1, D_1, E_1, F_1, G_1$ can be made isomorphic to $\mathcal{G}^{\Rightarrow}_{[E_Y]}$ by contracting the paths $(A_1, i_4, E_1), (B_1, i_5, D_1)$, and (C_1, i_1, C_1) into single edges $(A_1, E_1), (B_1, D_1)$ and (C_1, C_1).

▶ **Definition 15** (Normal Form). *Let E be a basic RWE. Then E is in* normal form *if it can be written as $x\alpha_1\alpha_2, \ldots \alpha_k y \doteq y\alpha_1^R\alpha_2^R \ldots \alpha_k^R x$ where $x, y \in X$, $\alpha_i \in X^+$ for $1 \leq i \leq k$, and $|\alpha_i| \leq 3$ for $1 \leq i < k$.*

We can obtain an equation in normal form from any basic RWE by applying a polynomial number of rewriting operations.

▶ **Theorem 16.** *Let E be a jumbled basic RWE. Then there exists $\overline{E}$ which is in normal form and such that $E \Rightarrow^{n_1} \overline{E}$ and $\overline{E} \Rightarrow^{n_2} E$ for some $n_1, n_2 \in O(|E|^3)$.*

The idea behind the first normal form is to divide the RWE into pairs (α_i, α_i^R) which are regular-reversed word equations (although solutions to the full equation E are not necessarily solutions to these smaller equations), and for which all but one belong to a finite number of cases (i.e. three cases depending on the length of α_i). Forcing the sub-equations to be regular-reversed gives us the most control when working with the invariant Υ_E. Some intuition behind this fact can be derived from the observation that if we know that a (complete) basic RWE E is regular-reversed, we can uniquely reconstruct it from the leftmost two variables on the LHS and Υ_E. Indeed, any regular-reversed basic RWE E can be written in the form $x_1x_2 \ldots x_n \doteq x_nx_{n-1} \ldots x_1$, meaning that $\Upsilon_E = \{(x_{i-1}, x_{i+1} \mid 2 \leq i \leq n\} \cup \{(x_{n-1}, x_2)\}$, and if we know x_1, then we may infer from Υ_E all the odd-index variables $(x_3, x_5, \ldots)$ and if we know x_2 then we may infer all the even-index variables $(x_4, x_6, \ldots)$.

Rather than looking at the pairs (α_i, α_i^R) in isolation, in order to take full advantage of the invariant Υ_E, we actually need to consider pairs of the form $(\alpha_i\alpha_{i+1} \ldots \alpha_j, \alpha_i^R\alpha_{i+1}^R \ldots \alpha_j^R)$. We shall call such pairs *blocks*, which we define formally below. Our second normal form will be a restriction of the first, and is based on the notion of blocks.

Figure 3 A depiction of the equation E given by $xz_1z_2z_3z_4z_5z_6z_7z_8z_9z_{10}z_{11}z_{12}z_{13}z_{14}z_{15}y \doteq yz_2z_1z_5z_4z_3z_7z_6z_8z_{10}z_9z_{11}z_{15}z_{14}z_{13}z_{12}x$ where x, y and z_i for $1 \leq i \leq 15$ are variables. The LHS and RHS of the equation are aligned vertically. The block decomposition $\mathfrak{B} = (B_0, B_1, B_2, B_3)$ of E is shown with solid rectangles and with the variety and type of the block written beneath. The additional divisions into the factors α_i, α_i^R required by the definition of normal form are indicated by dashed lines (so that, i.e. $\alpha_1 = z_1z_2$, $\alpha_2 = z_3z_4z_5$, $\alpha_3 = z_6z_7$, $\alpha_4 = z_8, z_5$, $\alpha_5 = z_9z_{10}$, $\alpha_6 = z_{11}$ and $\alpha_7 = z_{12}z_{13}z_{14}z_{15}$). In order for the equation to satisfy the definition of Lex Normal Form, the variables highlighted in bold must be lexicographically minimal with respect to the appropriate sets Γ_i. Note that $\Gamma_1 = \{z_i \mid 3 \leq i \leq 15\} \backslash \{z_4\}$. In particular, Γ_1 consists of the first variable in the block B_1 (x_3) along with (nearly) all variables on the LHS of the equation occurring to the right of z_3, excluding the rightmost variable (y), and since B_1 is Type B, also excluding the second variable in the block B_1 (namely z_4). On the other hand, since B_2 is Type A, in this case we do not need to exclude the second variable in the block B_2, so $\Gamma_2 = \{z_i \mid 8 \leq i \leq 15\}$. Assuming an underlying lexicographic order for which z_{i+1} is greater than z_i, we can conclude that E is in Lex Normal Form.

▶ **Definition 17** (Blocks). *We define 3 variations of blocks which may each have up to two types.*

1. *A* standard block *is a pair* $(\alpha_1\alpha_2 \ldots \alpha_j, \alpha_1^R\alpha_2^R \ldots \alpha_j^R)$ *such that* $j \geq 1$, $\alpha_i \in X^*$ *for* $1 \leq i \leq j$, $|\alpha_1| \in \{1, 3\}$, *and for each* $i, 1 < i \leq j$, $|\alpha_i| = 2$. *It is* Type A *if* $|\alpha_1| = 1$ *and* Type B *if* $|\alpha_1| = 3$.
2. *An* initial block *is a pair* $(x\alpha_1 \ldots \alpha_j, y\alpha_1^R \ldots \alpha_j^R)$ *with* $j \geq 0$, $x, y \in X$ *with* $x \neq y$, *and* $\alpha_i \in (X \backslash \{x, y\})^*$ *for* $1 \leq i \leq j$ *such that* $|\alpha_i| = 2$ *for* $1 \leq i \leq j$. *All initial blocks are* Type A.
3. *An* end block *is a pair* $(\gamma_1\delta y, \gamma_2\delta^R x)$ *where* $x, y \in X$ *with* $x \neq y$, *and* $\gamma_1, \gamma_2, \delta \in (X \backslash \{x, y\})^*$ *with* $|\delta| \geq 1$ *such that* (γ_1, γ_2) *is a block (initial or standard). It is Type A if* (γ_1, γ_2) *is Type A, and Type B otherwise.*

Given an equation which is in normal form, we may decompose it uniquely into blocks in the following manner. The intuition behind this decomposition is that if we fix the invariant property Υ_E, then each block (with the exception of the final block) is determined entirely by the block preceding it and its first (leftmost in the first element) variable. This gives us a crucial degree of control when considering which equations in normal form may appear in $\mathcal{G}^{\Rightarrow}_{[E]}$.

▶ **Definition 18** (Block Decomposition). *Let E be a basic RWE in normal form. Then E may be written as* $x\alpha_1\alpha_2 \ldots \alpha_n y \doteq y\alpha_1^R\alpha_2^R \ldots \alpha_n^R x$ *where* $x, y \in X$, $\alpha_i \in X^+$ *for* $1 \leq i \leq n$, *and* $|\alpha_i| \leq 3$ *for* $1 \leq i < n$. *Let* $I = \{i_1, i_2, \ldots, i_k\} = \{i \mid 1 \leq i < n \text{ and } |\alpha_i| \neq 2\}$ *with* $1 \leq i_1 < i_2 < \ldots < i_k < n$. *If* $I = \emptyset$, *let* $\mathfrak{B} = (E)$. *Otherwise, let* $\mathfrak{B} = (B_0, B_1, \ldots, B_k)$ *where for* $0 \leq j \leq k$, *the* B_j *are blocks such that:*

1. $B_0 = (x\alpha_1 \ldots \alpha_{i_1-1}, y\alpha_1^R \ldots \alpha_{i_1-1}^R)$,
2. $B_k = (\alpha_{i_k} \ldots \alpha_n y, \alpha_{i_k}^R \ldots \alpha_n^R x)$, *and*
3. *for* $1 \leq j < k$, $B_j = (\alpha_{i_j} \ldots \alpha_{i_{j+1}-1}, \alpha_{i_j}^R \ldots \alpha_{i_{j+1}-1}^R)$.

Then $\mathfrak{B}$ is the block decomposition *of E.*

An example illustrating a block decomposition of an equation in normal form is given in Figure 3. Since the blocks are fixed by their first variable, it is natural to ask for which variables we can find an equation in our graph $\mathcal{G}^{\Rightarrow}_{[E]}$ such that the block begins with that variable. In particular, can we find an equation in normal form in $\mathcal{G}^{\Rightarrow}_{[E]}$ for which the first variable of each block is lexicographically minimal when going from left to right? The answer to the question is "nearly". In other words, if we relax the notion slightly to account for some specific cases in which we cannot guarantee minimality, then we can always guarantee the existence of such an equation. This leads to the notion of Lex Normal Form defined below.

▶ **Definition 19** (Lex Normal Form). *Let E be a basic RWE in normal form. Then there exist $x, y \in X$ and $\alpha, \beta \in (X \backslash \{x, y\})^*$ such that E has the form $x\alpha y \doteq y\beta x$. Let $(B_0, B_1, \ldots, B_n)$ be the block decomposition of E. For each i, $0 \leq i \leq n$, let $\gamma_i, \gamma_i' \in X^*$ such that $B_i = (\gamma_i, \gamma_i')$, let $S_i = \{\gamma_i[2], y\}$ whenever B_i is Type B and $S_i = \{y\}$ otherwise, and let $\Gamma_i = \left(\bigcup\limits_{i \leq j \leq n} \text{var}(\gamma_j) \right) \backslash S_i$. A block B_i is* lex-minimal *if $\gamma_i[1]$ is lexicographically minimal in Γ_i. The equation E is in Lex Normal Form (LNF) if, for each i, $0 < i < n$, B_i is lex-minimal.*

Lex Normal Form (see also Fig. 3 for an example) describes the class of equations for which the first variable of each blocks is lexicographically minimal *whenever possible*. We can, in general, guarantee the existence of an equation E' in $\mathcal{G}^{\Rightarrow}_{[E]}$ such that the first variable of each block is lexicographically minimal with the following exceptions. Firstly, we must exclude the first and last blocks (the first block is fixed completely by Υ_E). Secondly, we must only compare the first variable to other variables occurring further right in the LHS of the equation, and excluding the rightmost variable on the LHS of the equation (y in the definition above) and, for blocks of Type B, the second variable in the block. The sets Γ_i in the definition account for these exclusions. It turns out that every vertex in $\mathcal{G}^{\Rightarrow}_{[E]}$ is never more than a polynomial distance away from a vertex corresponding to an equation in LNF.

▶ **Theorem 20.** *Let E be a jumbled basic RWE. Then there exists E' such that E' is in Lex Normal Form, and such that $E \Rightarrow^{n_1} E'$ and $E \ \Rightarrow^{n_2} E$ for some $n_1, n_2 \in O(|E|^4)$.*

4.5 Diameter

It was mentioned in the previous section that the choices for the blocks in a block decomposition of an equation in normal form are restricted by the invariant Υ_E. We shall now make full use of that fact to show that the number of equations in LNF in a single graph $\mathcal{G}^{\Rightarrow}_{[E]}$ is polynomial in $|E|$, and as a consequence that the diameter of $\mathcal{G}^{\Rightarrow}_{[E]}$ is also polynomial. Since each equation in LNF has a unique block decomposition, it is sufficient to count the possible block decompositions for a given value of Υ_E for which the conditions for LNF hold. The restrictions imposed on the blocks by Υ_E are given formally in the following lemmata.

▶ **Lemma 21.** *Let E_1, E_2 be basic RWEs in normal form such that $\Upsilon_{E_1} = \Upsilon_{E_2}$. Let $(B_0, B_1, \ldots, B_k)$ and $(C_0, C_1, \ldots, C_\ell)$ be their respective block decompositions and let $k, \ell > 0$. Then $B_0 = C_0$. Moreover, suppose that $B_i = C_j$, for some $i < k - 1$, $j < \ell - 1$. Let $B_{i+1} = (\gamma_1, \gamma_2)$ and $C_{j+1} = (\delta_1, \delta_2)$ with $\gamma_1, \gamma_2, \delta_1, \delta_2 \in X^*$. If $\gamma_1[1] = \delta_1[1]$, then $B_{i+1} = C_{j+1}$.*

Lemma 21 tells us that the equations in LNF belonging to a single graph $\mathcal{G}^{\Rightarrow}_{[E]}$ are remarkably similar in that they are identical up to the last block of the shorter decomposition.

▶ **Corollary 22.** *Let E_1, E_2 be basic RWEs in LNF such that $\Upsilon_{E_1} = \Upsilon_{E_2}$. Let $(B_0, B_1, \ldots, B_k)$ and $(C_0, C_1, \ldots, C_\ell)$ be their respective block decompositions and suppose that $k, \ell > 0$. Then $B_i = C_i$ for $0 \leq i < \min(k, \ell)$.*

Consequently, two equations in LNF in the graph $\mathcal{G}^{\Rightarrow}_{[E]}$ with block decompositions containing the same number of blocks may differ only in the final block. Clearly, the number of blocks is at most Card(var(E)). Thus, in order to show that there are only polynomially many equations in LNF in $\mathcal{G}^{\Rightarrow}_{[E]}$, it remains to consider the possibilities for the final block.

▶ **Lemma 23.** *Let E_1, E_2 be basic RWEs in normal form such that $\Upsilon_{E_1} = \Upsilon_{E_2}$. Let $(B_0, B_1, \ldots, B_k)$ and $(C_0, C_1, \ldots, C_\ell)$ be their respective block decompositions and suppose that $k, \ell > 0$. Suppose moreover that $B_{k-1} = C_{\ell-1}$. Let $B_k = (\alpha_1\alpha_2\ldots\alpha_n y, \alpha_1^R\alpha_2^R\ldots\alpha_n^R x)$ and $C_\ell = (\beta_1\beta_2\ldots\beta_m y, \beta_1^R\beta_2^R\ldots, \beta_m^R x)$, where $x, y \in X$, $\alpha_1, \alpha_2, \ldots, \alpha_n$, $\beta_1, \beta_2, \ldots, \beta_m \in X^+$, $|\alpha_1| = |\beta_1| \in \{1, 3\}$ and $|\alpha_i|, |\beta_j| = 2$ for $2 \leq i < n$ and $2 \leq j < m$. Then if $\alpha_1[1] = \beta_1[1]$, $n = m$, and $\alpha_n[1] = \beta_m[1]$, we have $B_k = C_\ell$.*

Lemma 23 reveals that the options for last block are dependent only on the choices of three parameters: $\alpha_1[1], \alpha_n[1]$, and n. Since each of these can take at most $|E|$ possible values, there are $|E|^3$ possibilities altogether. Thus for each possible number of blocks, there are at most $|E|^3$ possible block decompositions, and therefore only $|E|^4$ possible block decompositions respecting the invariant Υ_E in total. Since every equation in LNF permits a unique block decomposition, this gives us our desired polynomial bound.

▶ **Theorem 24.** *Let E be a basic RWE. Let S be the set of basic regular equations E' in Lex Normal Form for which $\Upsilon_E = \Upsilon_{E'}$. Then* $\mathrm{Card}(S) \leq |E|^4$.

Since every vertex in $\mathcal{G}^{\Rightarrow}_{[E]}$ is at polynomial distance from a vertex in LNF, and since there are only polynomially many such vertices, it is straightforward to show that the diameter of $\mathcal{G}^{\Rightarrow}_{[E]}$ must also be polynomial: indeed if we have a sufficiently long path between two vertices, then we must have a long path between two vertices which are close to the same vertex in LNF. Since they are close to the same vertex, we can find a shortcut between them, and the initial long path is not minimal. Since the diameter of $\mathcal{G}^{\Rightarrow}_{[E]}$ is polynomial, it follows from Theorem 9 (see also Remark 8) and Proposition 5 that the diameter of $\mathcal{G}^{\Rightarrow NT}_{[E]}$ is polynomial whenever E is regular, even in the case that E is not basic.

▶ **Theorem 25.** *Let E be a basic RWE. Then* $\mathrm{diam}(\mathcal{G}^{\Rightarrow}_{[E]}) \in O(|E|^{10})$. *Consequently, for any RWE E,* $\mathrm{diam}(\mathcal{G}^{\Rightarrow NT}_{[E]}) \in O(|E|^{12})$.

Thus, by Proposition 4, we may infer that the satisfiability problem for RWEs is in NP. It was already shown in [8] that the satisfiability problem for RWEs is NP-hard, and thus we obtain matching upper and lower bounds for its complexity.

▶ **Theorem 26.** *The satisfiability problem for RWEs is NP-complete.*

4.6 Size and DAG-width

While the diameter of $\mathcal{G}^{\Rightarrow}_{[E]}$ is one important parameter, being directly related to the complexity of the satisfiability problem, it is by no means the only interesting one. The overall size of the graphs will also play a central role in the practical performance of the algorithm described in Section 3. For basic RWEs, we have the following tight upper and lower bounds on the number of vertices in the graphs $\mathcal{G}^{\Rightarrow}_{[E]}$.

▶ **Theorem 27.** *Let E be a basic RWE and let $n = \mathrm{Card}(\mathrm{var}(E))$. Suppose that $n > 1$. Let V be the number of vertices in $\mathcal{G}^{\Rightarrow}_{[E]}$. $2^{n-1} - 1 \leq V \leq \frac{n!}{2}$.*

It is worth noting that the lower bound given by Theorem 27 is already exponential in the number of variables. The interpretation of the theorem in the more general (i.e. not basic) setting therefore tells us that the number of vertices in $\mathcal{G}^{\Rightarrow}_{[E]}$ is exponential in the number of variables occurring twice in the appropriate (indecomposable) parts of the LHS and RHS. In other words, we see the rather intuitive fact here that decomposable equations are somehow easier to deal with than indecomposable equations of the same length. The following demonstrates that the bounds given by Theorem 27 are tight.

▶ **Theorem 28.** *Let E be a basic RWE and let $n = \mathrm{Card}(\mathrm{var}(\alpha))$. Suppose that $n > 1$. Let V be the number of vertices in $\mathcal{G}^{\Rightarrow}_{[E]}$. Then:*

1. *$V = 2^{n-1} - 1$ if and only if there exists $E' \in [E]_{\Rightarrow}$ such that E' is regular reversed,*
2. *$V = \frac{n!}{2}$ if and only if there exists $E' \in [E]_{\Rightarrow}$ such that E' is regular rotated.*

In addition to the size we are also able to give some insights about the connectedness of the graphs, which, as discussed in Section 3.3, are of interest when solving RWEs modulo additional constraints. We show firstly that there exist classes of equations E for which $\mathrm{dgw}(\mathcal{G}^{\Rightarrow_{NT}}_{[E]})$ may be arbitrarily large.

▶ **Theorem 29.** *Let $x, y, z_0, z_1, z_2, \ldots, z_n \in X$. Let E be the RWE given by $xz_0z_1z_2 \ldots z_ny \doteq yz_0z_nz_{n-1} \ldots z_1x$. Then $\mathrm{dgw}(\mathcal{G}^{\Rightarrow_{NT}}_{[E]}) > n$.*

Since high connectivity can be seen as an obstacle to deciding the satisfiability problem with additional constraints, it is also worth noting classes for which the DAG-width is bounded by a small constant, such as with those described in the next theorem.

▶ **Theorem 30.** *Let $\alpha_1, \alpha_2, \ldots, \alpha_n, \beta_1, \beta_2, \ldots, \beta_n \in X^*$ such that $\mathrm{var}(\alpha_i) = \mathrm{var}(\beta_i)$ for $1 \leq i \leq n$ and $\mathrm{var}(\alpha_i) \cap \mathrm{var}(\alpha_j) = \emptyset$ for $1 \leq i, j \leq n$ with $i \neq j$. Let E be the RWE $\alpha_1\alpha_2 \ldots \alpha_n \doteq \beta_1\beta_2 \ldots \beta_n$. Then $\mathrm{dgw}(\mathcal{G}^{\Rightarrow_{NT}}_{[E]}) = 2$.*

4.7 Extension to systems of equations

So far, we have considered individual equations. However, it is often the case in practice that there is not just one equation to be solved, but a system of several concurrent equations. However, while constructions exist which transform a system of equations into a single equation (see e.g. [17]), the resulting equation will generally not be quadratic/regular. We extend the definition of regular equations to regular systems as follows.

▶ **Definition 31** (Regular systems). *Let $\Theta = \{\alpha_1 \doteq \beta_1, \alpha_2 \doteq \beta_2, \ldots, \alpha_n \doteq \beta_n\}$ be a system of word equations. An* orientation *of Θ is any element of $\{\alpha_1 \doteq \beta_1, \beta_1 \doteq \alpha_1\} \times \{\alpha_2 \doteq \beta_2, \beta_2 \doteq \alpha_2\} \times \ldots \times \{\alpha_n \doteq \beta_n, \beta_n \doteq \alpha_n\}$. We say that Θ is regular if it has an orientation for which each variable occurs at most once across all LHSs and at most once across all RHSs.*

▶ **Theorem 32.** *The satisfiability problem for regular systems of equations is NP-complete. Moreover, whether a system of word equations is regular can be decided in polynomial time.*

5 Conclusions

A famous algorithm for solving quadratic word equations can be used to produce a (directed) graph containing all solutions to the equation. In the case of regular equations, we have described some underlying structures of these graphs with the intention of better understanding their solution sets. We give bounds on their diameter and number of vertices, as well as provide classes with bounded (resp. unbounded) DAG-width. Probably the most significant result arising from our analysis is that the satisfiability problem for regular word equations is in NP (and thus NP-complete), which we also extend to regular systems of equations.

We leave open many interesting problems, the most obvious of which is to generalise our results to the (full) quadratic case. We also believe that our analysis and techniques open up the possibility to investigate in far more detail the graphs $\mathcal{G}^{\Rightarrow}_{[E]}$, even in the case of regular equations. For example, in light of our results, it seems reasonable to suggest that determining whether $E_1 \Rightarrow^* E_2$ for two regular equations E_1 and E_2 may be done in polynomial time. A particularly nice characterisation of E_1 and E_2 such that $E_1 \Rightarrow^* E_2$ might yield a much quicker algorithm than the one resulting from our bound on the diameter of $\mathcal{G}_{[E]}^{\Rightarrow NT}$ by significantly reducing the degree of the polynomial. We also expect that a detailed analysis of the length-reducing transformations and symmetries which may be found there would be particularly helpful in understanding further the structure of solution sets and the performance of algorithms solving regular equations in practice.

Finally, we mention the task of investigating the decidability of the satisfiability problem for regular equations with additional constraints, in particular length constraints, with the hope that having identified cases where the DAG-width is particularly high/low, along with improved means to describe precisely the structure of the solution-graphs, might provide some useful hints with how to proceed in this direction.

Abstract

This paper proves the decidability of several important properties of additive cellular automata over finite abelian groups. First of all, we prove that equicontinuity and sensitivity to initial conditions are decidable for a nontrivial subclass of additive cellular automata, namely, the linear cellular automata over $\mathbb{K}^n$, where $\mathbb{K}$ is the ring $\mathbb{Z}/m\mathbb{Z}$. The proof of this last result has required to prove a general result on the powers of matrices over a commutative ring which is of interest in its own.

Then, we extend the decidability result concerning sensitivity and equicontinuity to the whole class of additive cellular automata over a finite abelian group and for such a class we also prove the decidability of topological transitivity and all the properties (as, for instance, ergodicity) that are equivalent to it. Finally, a decidable characterization of injectivity and surjectivity for additive cellular automata over a finite abelian group is provided in terms of injectivity and surjectivity of an associated linear cellular automata over $\mathbb{K}^n$.

1 Introduction

Cellular automata (CA) are widely known formal models for studying and simulating complex systems (for recent results, an up-to date bibliography on CA, and simulations of complex systems, see for instance [18, 1, 8, 9, 22, 5]). They are used in many disciplines ranging from physics to biology, stepping through sociology, ecology and many others. In computer science they are used for designing security schemes, random number generation, image processing, etc. This extensive use is essentially due to three main ingredients: the huge variety of distinct dynamical behaviors; the emergence of complex behaviors from local interactions; the ease of implementation (even at a hardware level). In practical applications one needs to know if the CA used for modelling a system has or not some specific property and this can be an issue. Indeed, Jarkko Kari proved a strong result stating (roughly speaking) that all non-trivial dynamical behaviors are undecidable [27]. From this seminal result, a long sequence followed (see [2, 21, 25], just to cite some of them).

The undecidability issue can be tackled by adding more constraints on the model. These constraints may consist of conservation laws over the evolutions [24, 20, 23, 3, 34] or superposition principles induced by imposing a rich algebraic structure over the CA alphabet [26, 31, 30, 28, 7, 6, 19] (in both cases the literature is huge and only a very small excerpt is cited here).

In this paper we follow the latter trend: the alphabet of the CA is a finite abelian group G and its global update map is an additive function, i.e., an endomorphism of $G^{\mathbb{Z}}$. This pretty broad requirement provides a class of CA generalizing those with linear local rule defined by $n \times n$ matrices (see the previous citations for $n = 1$ and [28, 4] for $n > 1$).

Even if the superposition principle still allows us to prove deep and interesting results on the asymptotic behavior of linear CA over $(\mathbb{Z}/m\mathbb{Z})^n$ (for some integers $m, n > 1$), their dynamics is definitely more interesting and expressive than that of linear CA over $\mathbb{Z}/m\mathbb{Z}$ (the classical linear CA setting) and exhibits much more complex features.

In [13, 10], we proved that ergodicity coincides with topological transitivity (and many other properties) for additive CA over finite abelian groups and in [12] we proved the decidability of those properties for the restricted case of linear CA over $(\mathbb{Z}/m\mathbb{Z})^n$.

The present paper adds the following important results to the panorama of the existing ones for additive CA over finite abelian groups:

- a lifting of the decidability of topological transitivity, ergodicity, and all the related properties from linear CA to the general case of additive CA over finite abelian groups;
- a decidable characterization of sensitivity to initial conditions for linear CA over $(\mathbb{Z}/m\mathbb{Z})^n$ which is then lifted to additive CA over finite abelian groups;
- a dichotomy property of sensitivity to initial conditions vs. equicontinuity;
- a characterization of surjectivity and injectivity properties extending the known results for linear CA given in [28, 4].

The above results are important features of the dynamics of additive CA over finite abelian groups which are involved in the most complex CA behaviors. Two main tools were used in the proofs:

- an embedding of an additive CA over a finite abelian group into a linear CA over a commutative ring;
- a deep result about commutative algebras defined over a commutative ring which is of interest in its own;

The paper is structured as follows. The next section introduces all the necessary background and formal definitions. Section 3 recalls the known results about linear CA over $(\mathbb{Z}/m\mathbb{Z})^n$ and proves the new ones, including the non trivial algebra result about powers of matrix over commutative rings. Section 4 explains the embedding allowing to lift results from linear CA over $(\mathbb{Z}/m\mathbb{Z})^n$ to generic additive CA over abelian groups. It also contains all the main results. In the last section we draw our conclusion and provide some perspectives.

2 Background on DTDS and Cellular Automata

We begin by reviewing some general notions about discrete time dynamical systems and cellular automata.

A *discrete time dynamical system* (DTDS) is a pair $(\mathcal{X}, \mathcal{F})$, where $\mathcal{X}$ is any set equipped with a distance function d (i.e., $(\mathcal{X}, d)$ is a metric space) and $\mathcal{F} : \mathcal{X} \to \mathcal{X}$ is a map that is continuous on $\mathcal{X}$ according to the topology induced by d.

Let $(\mathcal{X}, \mathcal{F})$ be a DTDS. We say that it is *surjective*, resp., *injective*, if $\mathcal{F}$ is *surjective*, resp., *injective*. The DTDS $(\mathcal{X}, \mathcal{F})$ is *sensitive to the initial conditions* (or simply *sensitive*) if there exists $\varepsilon > 0$ such that for any $x \in \mathcal{X}$ and any $\delta > 0$ there is an element $y \in \mathcal{X}$ such that $0 < d(y, x) < \delta$ and $d(\mathcal{F}^k(y), \mathcal{F}^k(x)) > \varepsilon$ for some $k \in \mathbb{N}$. The system $(\mathcal{X}, \mathcal{F})$ is said to be *equicontinuous* if $\forall \varepsilon > 0$ there exists $\delta > 0$ such that for all $x, y \in \mathcal{X}$, $d(x, y) < \delta$ implies that $\forall k \in \mathbb{N}$, $d(\mathcal{F}^k(x), \mathcal{F}^k(y)) < \varepsilon$. As dynamical properties, sensitivity and equicontinuity represent the main features of unstable and stable dynamical systems, respectively. The former is the well-known basic component and essence of the chaotic behavior of discrete time dynamical systems, while the latter is a strong form of stability.

The DTDS $(\mathcal{X}, \mathcal{F})$ is *topologically transitive* (or, simply, *transitive*) if for all nonempty open subsets U and V of $\mathcal{X}$ there exists a natural number h such that $\mathcal{F}^h(U) \cap V \neq \emptyset$, while it is said to be *topologically mixing* if for all nonempty open subsets U and V of $\mathcal{X}$ there exists a natural number h_0 such that the previous intersection condition holds for every $h \geq h_0$. Clearly, topological mixing is a stronger condition than transitivity. Moreover, $(\mathcal{X}, \mathcal{F})$ is *topologically weakly mixing* if the DTDS $(\mathcal{X} \times \mathcal{X}, \mathcal{F} \times \mathcal{F})$ is topologically transitive, while it is *totally transitive* if $(\mathcal{X}, \mathcal{F}^h)$ is topologically transitive for all $h \in \mathbb{N}$.

Let $(\mathcal{X}, \mathcal{M}, \mu)$ be a probability space and let $(\mathcal{X}, \mathcal{F})$ be a DTDS where $\mathcal{F}$ is a measurable map which preserves μ, i.e., $\mu(E) = \mu(\mathcal{F}^{-1}(E))$ for every $E \in \mathcal{M}$. The DTDS $(\mathcal{X}, \mathcal{F})$, or, the map $\mathcal{F}$, is *ergodic* with respect to μ if for every $E \in \mathcal{M}$

$$\big(E = \mathcal{F}^{-1}(E)\big) \Rightarrow \mu(E)(1 - \mu(E)) = 0$$

It is well known that $\mathcal{F}$ is ergodic iff for any pair of sets $A, B \in \mathcal{M}$ it holds that

$$\lim_{h \to \infty} \frac{1}{h} \sum_{i=0}^{h-1} \mu(\mathcal{F}^{-i}(A) \cap B) = \mu(A)\mu(B)$$

The DTDS $(\mathcal{X}, \mathcal{F})$ is *(ergodic) mixing*, if for any pair of sets $A, B \in \mathcal{M}$ it holds that

$$\lim_{h \to \infty} \mu(\mathcal{F}^{-h}(A) \cap B) = \mu(A)\mu(B) \ ,$$

while it is *(ergodic) weak mixing*, if for any pair of sets $A, B \in \mathcal{M}$ it holds that

$$\lim_{h \to \infty} \frac{1}{h} \sum_{i=0}^{h-1} |\mu(\mathcal{F}^{-i}(A) \cap B) - \mu(A)\mu(B)| = 0$$

We now recall some general notions about cellular automata.

Let S be a finite set. A configuration over S is a map from $\mathbb{Z}$ to S. We consider the following *space of configurations* $S^{\mathbb{Z}} = \{\boldsymbol{c} | \ \boldsymbol{c} \colon \mathbb{Z} \to S\}$. Each element $\boldsymbol{c} \in S^{\mathbb{Z}}$ can be visualized as an infinite one-dimensional cell lattice in which each cell $i \in \mathbb{Z}$ contains the element $\boldsymbol{c}_i \in S$.

Let $r \in \mathbb{N}$ and $\delta \colon S^{2r+1} \to S$ be any map. We say that r is the radius of δ.

▶ **Definition 1** (Cellular Automaton). *A one-dimensional CA based on a radius r local rule δ is a pair $(S^{\mathbb{Z}}, F)$, where $F \colon S^{\mathbb{Z}} \to S^{\mathbb{Z}}$ is the* global transition map *defined as follows:*

$$\forall \boldsymbol{c} \in S^{\mathbb{Z}}, \forall i \in \mathbb{Z}, \quad F(\boldsymbol{c})_i = \delta\left(\boldsymbol{c}_{i-r}, \ldots, \boldsymbol{c}_{i+r}\right). \tag{1}$$

We stress that the local rule δ completely determines the global rule F of a CA.

In order to study the dynamical properties of one-dimensional CA, we introduce a distance over the space of the configurations. Namely, $S^{\mathbb{Z}}$ is equipped with the Tychonoff distance d defined as follows

$$\forall \boldsymbol{c}, \boldsymbol{c}' \in S^{\mathbb{Z}}, \quad d(\boldsymbol{c}, \boldsymbol{c}') = \begin{cases} 0, & \text{if} \quad \boldsymbol{c} = \boldsymbol{c}', \\ 2^{-\min\{i \in \mathbb{N} \,:\, \boldsymbol{c}_i \neq \boldsymbol{c}'_i \text{ or } \boldsymbol{c}_{-i} \neq \boldsymbol{c}'_{-i}\}} & \text{otherwise} \end{cases} .$$

It is easy to verify that metric topology induced by d coincides with the product topology induced by the discrete topology on $S^{\mathbb{Z}}$. With this topology, $S^{\mathbb{Z}}$ is a compact and totally disconnected space and the global transition map F of any CA $(S^{\mathbb{Z}}, F)$ turns out to be (uniformly) continuous. Therefore, any CA itself is also a discrete time dynamical system. Moreover, any map $F : S^{\mathbb{Z}} \to S^{\mathbb{Z}}$ is the global transition rule of a CA if and only if F is (uniformly) continuous and $F \circ \sigma = \sigma \circ F$, where $\sigma : S^{\mathbb{Z}} \to S^{\mathbb{Z}}$ is the *shift map* defined as $\forall \boldsymbol{c} \in S^{\mathbb{Z}}$, $\forall i \in \mathbb{Z}$, $\sigma(\boldsymbol{c})_i = \boldsymbol{c}_{i+1}$. From now, when no misunderstanding is possible, we identify a CA with its global rule. Moreover, whenever an ergodic property is considered for CA, μ is the well-known Haar measure over the collection $\mathcal{M}$ of measurable subsets of $S^{\mathbb{Z}}$, i.e., the one defined as the product measure induced by the uniform probability distribution over S.

2.1 Additive and Linear Cellular Automata

Let us introduce the background of additive CA. The alphabet S will be a finite abelian group G, with group operation $+$, neutral element 0, and inverse operation $-$. In this way, the configuration space $G^{\mathbb{Z}}$ turns out to be a finite abelian group, too, where the group operation of $G^{\mathbb{Z}}$ is the componentwise extension of $+$ to $G^{\mathbb{Z}}$. With an abuse of notation, we denote by the same symbols $+$, 0, and $-$ the group operation, the neutral element, and the inverse operation, respectively, both of G and $G^{\mathbb{Z}}$. Observe that $+$ and $-$ are continuous functions in the topology induced by the metric d. A configuration $\boldsymbol{c} \in G^{\mathbb{Z}}$ is said to be *finite* if the number of positions $i \in \mathbb{Z}$ with $\boldsymbol{c}_i \neq 0$ is finite.

▶ **Definition 2** (Additive Cellular Automata). *An* additive CA *over a abelian finite group G is a CA $(G^{\mathbb{Z}}, F)$ where the global transition map $F : G^{\mathbb{Z}} \to G^{\mathbb{Z}}$ is an endomorphism of $G^{\mathbb{Z}}$.*

The *sum of two additive CA* F_1 and F_2 over G is naturally defined as the map on $G^{\mathbb{Z}}$ denoted by $F_1 + F_2$ and such that

$$\forall \boldsymbol{c} \in G^{\mathbb{Z}}, \quad (F_1 + F_2)(\boldsymbol{c}) = F_1(\boldsymbol{c}) + F_2(\boldsymbol{c})$$

Clearly, $F_1 + F_2$ is an additive CA over G.

We now recall the notion of linear CA, an important subclass of additive CA. We stress that, whenever the term *linear* is involved, the alphabet S is $\mathbb{K}^n$, where $\mathbb{K} = \mathbb{Z}/m\mathbb{Z}$ for some positive integer m. Both $\mathbb{K}^n$ and $(\mathbb{K}^n)^{\mathbb{Z}}$ become $\mathbb{K}$-modules in the obvious (i.e., entrywise) way.

A local rule $\delta \colon (\mathbb{K}^n)^{2r+1} \to \mathbb{K}^n$ of radius r is said to be linear if it is defined by $2r + 1$ matrices $A_{-r}, \ldots, A_0, \ldots, A_r \in \mathbb{K}^{n \times n}$ as follows:

$$\forall (x_{-r}, \ldots, x_0, \ldots, x_r) \in (\mathbb{K}^n)^{2r+1}, \quad \delta(x_{-r}, \ldots, x_0, \ldots, x_r) = \sum_{i=-r}^{r} A_i \cdot x_i \ .$$

▶ **Definition 3** (Linear Cellular Automata (LCA)). *A* linear CA (LCA) *over $\mathbb{K}^n$ is a CA based on a linear local rule.*

Let $\mathbb{K}^n[X, X^{-1}]$ and $\mathbb{K}^n[[X, X^{-1}]]$ denote the set of *Laurent polynomials* and the set of *Laurent series*, respectively, with coefficients in $\mathbb{K}^n$. Before proceeding, let us recall that such formalisms have been successfully used to study the dynamical behaviour of LCA in the case $n = 1$ [26, 31]. Indeed, global rules and configurations are represented by Laurent polynomials and Laurent series, respectively, and the application of a global rule turns into a polynomial-series multiplication. In the more general case of LCA over $\mathbb{K}^n$, a configuration $\boldsymbol{c} \in (\mathbb{K}^n)^{\mathbb{Z}}$ can be associated with the Laurent series

$$\boldsymbol{P_c}(X) = \sum_{i\in\mathbb{Z}} \boldsymbol{c}_i X^i = \begin{bmatrix} c^1(X) \\ \vdots \\ c^n(X) \end{bmatrix} = \begin{bmatrix} \sum_{i\in\mathbb{Z}} c^1_i X^i \\ \vdots \\ \sum_{i\in\mathbb{Z}} c^n_i X^i \end{bmatrix} \in \left(\mathbb{K}[[X, X^{-1}]]\right)^n \cong \mathbb{K}^n[[X, X^{-1}]] \ .$$

Then, if F is the global rule of a LCA defined by $A_{-r}, \ldots, A_0, \ldots, A_r$, one finds

$$\boldsymbol{P}_{F(\boldsymbol{c})}(X) = A \cdot \boldsymbol{P_c}(X)$$

where

$$A = \sum_{i=-r}^{r} A_i X^{-i} \in \mathbb{K}[X, X^{-1}]^{n\times n}$$

is the *the matrix associated with the LCA F*. In this way, for any integer $k > 0$ the matrix associated with F^k is A^k, and then $\boldsymbol{P}_{F^k(\boldsymbol{c})}(X) = A^k \cdot \boldsymbol{P_c}(X)$.

A matrix $A \in \mathbb{K}[X, X^{-1}]^{n\times n}$ is in *Frobenius normal form* if

$$A = \begin{bmatrix} 0 & 1 & 0 & \ldots & 0 & 0 \\ 0 & 0 & 1 & \ddots & 0 & 0 \\ 0 & 0 & 0 & \ddots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & 0 & \ldots & 0 & 1 \\ \mathbb{a}_0 & \mathbb{a}_1 & \mathbb{a}_2 & \ldots & \mathbb{a}_{n-2} & \mathbb{a}_{n-1} \end{bmatrix} \tag{2}$$

where each $\mathbb{a}_i \in \mathbb{K}[X, X^{-1}]$. Recall that the coefficients of the characteristic polynomial of A are just the elements $\mathbb{a}_i$ of the n-th row of A (up to sign).

▶ **Definition 4** (Frobenius LCA). *A LCA $((\mathbb{K}^n)^{\mathbb{Z}}, F)$ is said to be a* Frobenius LCA *if the matrix $A \in \mathbb{K}[X, X^{-1}]^{n\times n}$ associated with F is in Frobenius normal form.*

3 Decidability Results about Linear CA

We now deal with sensitivity and equicontinuity for LCA over $\mathbb{K}^n$. First of all, we remind that a dichotomy between sensitivity and equicontinuity holds for LCA. Moreover, these properties are characterized by the behavior of the powers of the matrix associated with a LCA.

▶ **Proposition 5** ([14]). *Let $\left((\mathbb{K}^n)^{\mathbb{Z}}, F\right)$ be a LCA over $\mathbb{K}^n$ and let A be the matrix associated with F. The following statements are equivalent:*

1. *F is sensitive to the initial conditions;*
2. *F is not equicontinuous;*
3. $\left|\{A^1, A^2, A^3, \ldots\}\right| = \infty$.

An immediate consequence of Proposition 5 is that any decidable characterization of sensitivity to the initial conditions in terms of the matrices defining LCA over $\mathbb{K}^n$ would also provide a characterization of equicontinuity. In the sequel, we are going to show that such a characterization actually exists. First of all, we remind that a decidable characterization of sensitivity and equicontinuity was provided for the class of Frobenius LCA in [14]. In particular, the following result holds.

▶ **Theorem 6** (Theorem 31 in [14]). *Sensitivity and equicontinuity are decidable for Frobenius LCA over $\mathbb{K}^n$.*

In order to prove that equicontinuity and sensitivity are decidable for the whole class of LCA over $\mathbb{K}^n$, we need to prove the following result whose proof is strongly far from trivial and, for a lack of space, is omitted (the proof can be found in [11]).

Notation. Let $\mathbb{K}$ be a commutative ring. Let $n \in \mathbb{N}$. Let A be an $n \times n$-matrix over $\mathbb{K}$. We denote by χ_A the *characteristic polynomial* of A which is as usual defined as the polynomial $\det(tI_n - A) \in \mathbb{K}[t]$, where I_n stands for the $n \times n$ identity matrix and $tI_n - A$ is considered as an $n \times n$-matrix over the polynomial ring $\mathbb{K}[t]$.

▶ **Theorem 7.** *Let $\mathbb{K}$ be a finite commutative ring. Let $\mathbb{L}$ be a commutative $\mathbb{K}$-algebra. Let $n \in \mathbb{N}$. Let A and B be two $n \times n$-matrices over $\mathbb{L}$ such that $\chi_A = \chi_B$. Then, the set $\{A^0, A^1, A^2, \ldots\}$ is finite if and only if the set $\{B^0, B^1, B^2, \ldots\}$ is finite.*

We are now able to prove the following

▶ **Theorem 8.** *Sensitivity and equicontinuity are decidable for LCA over $\mathbb{K}^n$.*

Proof. Let $\left((\mathbb{K}^n)^{\mathbb{Z}}, G\right)$ be any LCA over $\mathbb{K}^n$ and let A be the matrix associated with G. Consider the Frobenius LCA $\left((\mathbb{K}^n)^{\mathbb{Z}}, F\right)$ such that $\chi_A = \chi_B$, where B is the matrix (in Frobenius normal form) associated with F. By Theorem 7 and Proposition 5 the former LCA is equicontinuous if and only if the latter is. Theorem 6 concludes the proof. ◀

For a sake of completeness, we recall that injectivity and surjectivity are decidable for LCA over $\mathbb{K}^n$. This result follows from a characterization of these properties in terms of the determinant of the matrix associated with a LCA and from the fact that injectivity and surjectivity are decidable for LCA over $\mathbb{K}$ (for the latter, see [26]).

▶ **Theorem 9** ([4, 28]). *Injectivity and surjectivity are decidable for LCA over $\mathbb{K}^n$. In particular, a LCA over $\mathbb{K}^n$ is injective (resp., surjective) if and only if the determinant of the matrix associated with it is the Laurent series associated with an injective (resp., surjective) LCA over $\mathbb{K}$.*

The decidability of topologically transitivity, ergodicity, and other mixing and ergodic properties for LCA over $\mathbb{K}^n$ has been recently proved in [13]. In particular, authors showed the equivalence of all the mixing and ergodic properties for additive CA over a finite abelian group and the decidability for LCA over $\mathbb{K}^n$ (see also [10]).

▶ **Theorem 10** ([13, 10]). *Let F be any additive CA over a finite abelian group. The following statements are equivalent: (1) F is topologically transitive; (2) F is ergodic; (3) F is surjective and for every $k \in \mathbb{N}$ it holds that $F^k - I$ is surjective; (4) F is topologically mixing; (5) F is weak topologically transitive; (6) F is totally transitive; (7) F is weakly ergodic mixing; (8) F is ergodic mixing. Moreover, all the previously mentioned properties are decidable for LCA over $\mathbb{K}^n$.*

4 From Linear to Additive CA

In this section we are going to prove that sensitivity, equicontinuity, topological transitivity, and all the properties equivalent to the latter are decidable also for additive CA over a finite abelian group. For each of them we will reach the decidability result by extending the analogous one obtained for LCA to the wide class of additive CA over a finite abelian group. In a similar way, we provide a decidable characterization of injectivity and surjectivity for additive CA over a finite abelian group.

We recall that the local rule $\delta : G^{2r+1} \to G$ of an additive CA of radius r over a finite abelian group G can be written as

$$\forall (x_{-r}, \dots, x_r) \in G^{2r+1}, \qquad \delta(x_{-r}, \dots, x_r) = \sum_{i=-r}^{r} \delta_i(x_i) \tag{3}$$

where the functions δ_i are endomorphisms of G.

The fundamental theorem of finite abelian groups states that every finite abelian group G is isomorphic to $\bigoplus_{i=1}^{h} \mathbb{Z}/k_i\mathbb{Z}$ where the numbers $k_1, \dots, k_h$ are powers of (not necessarily distinct) primes and $\oplus$ is the direct sum operation. Hence, the global rule F of an additive CA over G splits into the direct sum of a suitable number h' of additive CA over subgroups $G_1, \dots, G_{h'}$ with $h' \le h$ and such that $\gcd(|G_i|, |G_j|) = 1$ for each pair of distinct $i, j \in \{1, \dots, h'\}$. Each of them can be studied separately and then the analysis of the dynamical behavior of F can be carried out by combining together the results obtained for each component.

In order to make things clearer, consider the following example. If F is an additive CA over $G \cong \mathbb{Z}/4\mathbb{Z} \times \mathbb{Z}/8\mathbb{Z} \times \mathbb{Z}/3\mathbb{Z} \times \mathbb{Z}/3\mathbb{Z} \times \mathbb{Z}/25\mathbb{Z}$ then F splits into the direct sum of 3 additive CA F_1, F_2, and F_3 over $\mathbb{Z}/4\mathbb{Z} \times \mathbb{Z}/8\mathbb{Z}$, $\mathbb{Z}/3\mathbb{Z} \times \mathbb{Z}/3\mathbb{Z}$ and $\mathbb{Z}/25\mathbb{Z}$, respectively. Therefore, F will be sensitive to initial conditions iff at least one F_i is sensitive to the initial conditions, while F will be topological transitive iff every F_i is topological transitive.

The above considerations lead us to three distinct scenarios:

1) $\boldsymbol{G \cong \mathbb{Z}/p^k\mathbb{Z}}$**.** Then, G is cyclic and we can define each δ_i simply assigning the value of δ_i applied to the unique generator of G. Moreover, every pair δ_i, δ_j commutes, i.e., $\delta_i \circ \delta_j = \delta_j \circ \delta_i$, and this makes it possible a detailed analysis of the global behavior of F. Indeed, additive cellular automata over $\mathbb{Z}/p^k\mathbb{Z}$ are nothing but LCA over $\mathbb{Z}/p^k\mathbb{Z}$ and almost all dynamical properties, including sensitivity to the initial conditions, equicontinutity, injectivity, surjectivity, topological transitivity and so on are well understood and characterized (see [31]).

2) $\boldsymbol{G \cong (\mathbb{Z}/p^k\mathbb{Z})^n}$**.** In this case, G is not cyclic anymore and has n generators. We can define each δ_i assigning the value of δ_i for each generator of G. This gives rise to the class of linear CA over $(\mathbb{Z}/p^k\mathbb{Z})^n$. Now, δ_i and δ_j do not commute in general and this makes the analysis of the dynamical behavior much harder. Nevertheless, in Section 3 we have proved that sensitivity and equicontinuity are decidable by exploiting Theorem 7. As pointed out in [14], we also recall that linear CA over $(\mathbb{Z}/p^k\mathbb{Z})^n$ allow the investigation of some classes of non-uniform CA over $\mathbb{Z}/p^k\mathbb{Z}$ ((for these latter see [15, 16, 17]).

3) $\boldsymbol{G \cong \bigoplus_{i=1}^{n} \mathbb{Z}/p^{k_i}\mathbb{Z}}$**.** In this case ($\mathbb{Z}/4\mathbb{Z} \times \mathbb{Z}/8\mathbb{Z}$ in the example), G is again not cyclic and F turns out to be a subsystem of a suitable LCA. Then, the analysis of the dynamical behavior of F is even more complex than in **2)**. We do not even know easy checkable characterizations of basic properties like surjectivity or injectivity so far. We will provide them in the sequel as we stated at the beginning of this section.

Therefore, without loss of generality, in the sequel we can assume that $G = \mathbb{Z}/p^{k_1}\mathbb{Z} \times \ldots \times \mathbb{Z}/p^{k_n}\mathbb{Z}$ with $k_1 \ge k_2 \ge \ldots \ge k_n$ in order to reach our goal.

For any $i \in \{1, \dots, n\}$ let us denote by $\boldsymbol{e}^{(i)} \in G^{\mathbb{Z}}$ the bi-infinite configuration such that $\boldsymbol{e}^{(i)}_0 = e_i$ and $\boldsymbol{e}^{(i)}_j = 0$ for every integer $j \neq 0$.

▶ **Definition 11.** *Let $(G^{\mathbb{Z}}, F)$ be an additive CA over G. We say that $\boldsymbol{e}^{(i)} \in G^{\mathbb{Z}}$* spreads under F *if for every $\ell \in \mathbb{N}$ there exists $k \in \mathbb{N}$ such that $F^k(\boldsymbol{e}^{(i)})_j \neq 0$ for some integer j with $|j| > \ell$.*

▶ Remark 12. Whenever we consider $\boldsymbol{P}_{\boldsymbol{e}^{(i)}}(X) \in G[X, X^{-1}]$, we will say that $\boldsymbol{P}_{\boldsymbol{e}^{(i)}}(X)$ spreads under F if for every $\ell \in \mathbb{N}$ there exists $k \in \mathbb{N}$ such that $\boldsymbol{P}_{F^k(\boldsymbol{e}^{(i)})}(X)$ has at least one component with a non null monomial of degree which is greater than ℓ in absolute value. Clearly, $\boldsymbol{P}_{\boldsymbol{e}^{(i)}}(X)$ spreads under F if and only if $\boldsymbol{e}^{(i)}$ spreads under F.

Let $\hat{G} = (\mathbb{Z}/p^{k_1}\mathbb{Z})^n$. Define the map $\psi : G \to \hat{G}$ as follows

$$\forall h \in G, \quad \forall i = 1, \dots, n, \quad \psi(h)^i = h^i \, p^{k_1 - k_i} \ ,$$

where, for a sake of clarity, we stress that h^i denotes the i-th component of h, while $p^{k_1-k_i}$ is just the $(k_1 - k_i)$-th power of p.

▶ **Definition 13.** *We define the function $\Psi : G^{\mathbb{Z}} \to \hat{G}^{\mathbb{Z}}$ as the componentwise extension of ψ, i.e.,*

$$\forall \boldsymbol{c} \in G^{\mathbb{Z}}, \quad \forall j \in \mathbb{Z}, \quad \Psi(\boldsymbol{c})_j = \psi(\boldsymbol{c}_j) \ .$$

It is easy to check that Ψ is continuous and injective. Since every configuration $\boldsymbol{c} \in G^{\mathbb{Z}}$ (or $\hat{G}^{\mathbb{Z}}$) is associated with the Laurent series $\boldsymbol{P}_{\boldsymbol{c}}(X) \in G[[X, X^{-1}]]$ (or $\hat{G}[[X, X^{-1}]]$), with an abuse of notation we will sometimes consider Ψ as map from $G[[X, X^{-1}]]$ to $\hat{G}[[X, X^{-1}]]$ with the obvious meaning.

For any additive CA over G, we are now going to define a LCA over $(\mathbb{Z}/p^{k_1}\mathbb{Z})^n$ associated to it. With a further abuse of notation, in the sequel we will write p^{-m} with $m \in \mathbb{N}$ even if this quantity might not exist in $\mathbb{Z}/p^k\mathbb{Z}$. However, we will use it only when it multiplies $p^{m'}$ for some integer $m' > m$. In such a way $p^{m'-m}$ is well-defined in $\mathbb{Z}/p^k\mathbb{Z}$ and we will note it as product $p^{-m} \cdot p^{m'}$.

▶ **Definition 14.** *Let $(G^{\mathbb{Z}}, F)$ be any additive CA and let $\delta : G^{2r+1} \to G$ be its local rule defined, according to* (3)*, by $2r+1$ endomorphisms $\delta_{-r}, \dots, \delta_r$ of G . For each $z \in \{-r, \dots, r\}$, we define the matrix $A_z = (a^{(z)}_{i,j})_{1 \le i \le n, 1 \le j \le n} \in (\mathbb{Z}/p^{k_1}\mathbb{Z})^{n \times n}$ as*

$$\forall i, j \in \{1, \dots, n\}, \qquad a^{(z)}_{i,j} = p^{k_j - k_i} \cdot \delta_z(e_j)^i$$

The LCA *associated with the additive* CA *$(G^{\mathbb{Z}}, F)$ is $(\hat{G}^{\mathbb{Z}}, L)$, where L is defined by $A_{-r}, \dots, A_r$ or, equivalently, by $A = \sum_{z=-r}^{r} A_z X^{-z} \in \hat{G}[X, X^{-1}]^{n \times n}$.*

▶ Remark 15. Since every δ_z is an endomorphism of G, by construction A turns out to be well-defined.

▶ Remark 16. The following diagram commutes

$$\begin{tikzcd}
G^{\mathbb{Z}} \arrow[r, "F"] \arrow[d, "\Psi"'] & G^{\mathbb{Z}} \arrow[d, "\Psi"] \\
\hat{G}^{\mathbb{Z}} \arrow[r, "L"'] & \hat{G}^{\mathbb{Z}}
\end{tikzcd} ,$$

i.e., $L \circ \Psi = \Psi \circ F$. Therefore we say that $(\hat{G}^{\mathbb{Z}}, L)$ is the LCA associated with $(G^{\mathbb{Z}}, F)$ *via the embedding* Ψ.

4.1 Sensitivity and Equicontinuity for Additive Cellular Automata

Let us start with the decidability of sensitivity and equicontinuity.

▶ **Lemma 17.** *Let $(G^{\mathbb{Z}}, F)$ be any additive CA. If for some $i \in \{1, \ldots, n\}$ the configuration $\boldsymbol{e}^{(i)} \in G^{\mathbb{Z}}$ spreads under F then $(G^{\mathbb{Z}}, F)$ is sensitive to the initial conditions.*

Proof. We prove that F is sensitive with constant $\varepsilon = 1$. Let $\boldsymbol{e}^{(i)} \in G^{\mathbb{Z}}$ be the configuration spreading under F. Choose arbitrarily an integer $\ell \in \mathbb{N}$ and a configuration $\boldsymbol{c} \in G^{\mathbb{Z}}$. Let $t \in \mathbb{N}$ and $j \notin \{-\ell, \ldots, \ell\}$ be the integers such that $F^t(\boldsymbol{e}^{(i)})_j \neq 0$. Consider the configuration $\boldsymbol{c}' = \boldsymbol{c} + \sigma^j(\boldsymbol{e}^{(i)})$. Clearly, it holds that $d(\boldsymbol{c}, \boldsymbol{c}') < 2^{-\ell}$ and $F^t(\boldsymbol{c}') = F^t(\boldsymbol{c}) + F^t(\sigma^j(\boldsymbol{e}^{(i)})) = F^t(\boldsymbol{c}) + \sigma^j(F^t(\boldsymbol{e}^{(i)}))$. So, we get $d(F^t(\boldsymbol{c}'), F^t(\boldsymbol{c})) = 1$ and this concludes the proof. ◀

In order to prove the decidability of sensitivity, we need to deal with the following notions about Laurent polynomials.

▶ **Definition 18.** *Given any polynomial $\mathbb{p}(X) \in \mathbb{Z}/p^{k_1}\mathbb{Z}\left[X, X^{-1}\right]$, the* positive *(resp.,* negative*)* degree *of $\mathbb{p}(X)$, denoted by $deg^+[\mathbb{p}(X)]$ (resp., $deg^-[\mathbb{p}(X)]$) is the maximum (resp., minimum) degree among those of the monomials having both positive (resp., negative) degree and coefficient which is not multiple of p. If there is no monomial satisfying both the required conditions, then $deg^+[\mathbb{p}(X)] = 0$ (resp., $deg^-[\mathbb{p}(X)]$=0).*

▶ **Lemma 19.** *Let $(\hat{G}^{\mathbb{Z}}, L)$ be a LCA and let $A \in \mathbb{Z}/p^{k_1}\mathbb{Z}\left[X, X^{-1}\right]^{n \times n}$ be the matrix associated to it. If $(\hat{G}^{\mathbb{Z}}, L)$ is sensitive then for every integer $m \geq 1$ there exists an integer $k \geq 1$ such that at least one entry of A^k has either positive or negative degree with absolute value which is greater than m.*

Proof. We can write $A = B + p \cdot C$ for some $B, C \in \mathbb{Z}/p^{k_1}\mathbb{Z}\left[X, X^{-1}\right]^{n \times n}$, where the monomials of all entries of B have coefficient which is not multiple of p. Assume that there exists a bound $b \geq 1$ such that for every $k \geq 1$ all entries of A^k have degree less than b in absolute value. Therefore, it holds that $\left|\{A^k, k \geq 1\}\right| < \infty$ and so, by Proposition 5, $(\hat{G}^{\mathbb{Z}}, L)$ is not sensitive. ◀

We are now able to prove the following important result.

▶ **Theorem 20.** *Let $(G^{\mathbb{Z}}, F)$ be any additive CA over G and let $(\hat{G}^{\mathbb{Z}}, L)$ be the LCA associated to it via the embedding Ψ. Then, the CA $(G^{\mathbb{Z}}, F)$ is sensitive to the initial conditions if and only if $(\hat{G}^{\mathbb{Z}}, L)$ is. Moreover, the CA $(G^{\mathbb{Z}}, F)$ is equicontinuous if and only if $(\hat{G}^{\mathbb{Z}}, L)$ is.*

Proof. Let us start with the equivalence between sensitivity of $(G^{\mathbb{Z}}, F)$ and sensitivity of $(\hat{G}^{\mathbb{Z}}, L)$.

$\Longrightarrow$: Assume that $(\hat{G}^{\mathbb{Z}}, L)$ is not sensitive. Then, by Proposition 5, there exist two integers $k \in \mathbb{N}$ and $m > 0$ such that $L^{k+m} = L^k$. Therefore, we get $\Psi \circ F^{k+m} = L^{k+m} \circ \Psi = L^k \circ \Psi = \Psi \circ F^k$. Since Ψ is injective, it holds that $F^{k+m} = F^k$ and so $(G^{\mathbb{Z}}, F)$ is not sensitive.

$\Longleftarrow$: Assume that $(\hat{G}^{\mathbb{Z}}, L)$ is sensitive and for any natural k let $A^k = (a^{(k)}_{i,j})_{1 \leq i \leq n, 1 \leq j \leq n}$ be the k-th power of $A \in \mathbb{Z}/p^{k_1}\mathbb{Z}\left[X, X^{-1}\right]^{n \times n}$, where A is the matrix associated to $(\hat{G}^{\mathbb{Z}}, L)$. We are going to show that at least one configuration among $\boldsymbol{e}^{(1)}, \ldots, \boldsymbol{e}^{(n)}$ spreads under F. Choose arbitrarily $\ell \in \mathbb{N}$. By Lemma 19, there exist an integer $m \geq 1$ and one entry (i, j) such that either $deg^-[a^{(m)}_{i,j}] < -\ell$ or $deg^+[a^{(m)}_{i,j}] > \ell$. Without loss of generality suppose that $deg^+[a^{(m)}_{i,j}] > \ell$. The i–th component of $\boldsymbol{P}_{F^m(\boldsymbol{e}^{(j)})}(X)$ is the well defined polynomial $p^{k_i - k_1} \cdot p^{k_1 - k_j} \cdot a^{(m)}_{i,j}$. Since $deg^+[a^{(m)}_{i,j}] > \ell$, we can state that $\boldsymbol{e}^{(j)}$ spreads under F. By Lemma 17, it follows that $(G^{\mathbb{Z}}, F)$ is sensitive.

As to the equicontinuity equivalence, the above first implication also proves that if $(\hat{G}^{\mathbb{Z}}, L)$ is equicontinuous (i.e., by Proposition 5, it is not sensitive) then $F^{k+m} = F^k$, i.e., by [29], $(G^{\mathbb{Z}}, F)$ is equicontinuous. Conversely, if $(G^{\mathbb{Z}}, F)$ is equicontinuous then it trivially follows that it is not sensitive, i.e., by the above second implication, $(\hat{G}^{\mathbb{Z}}, L)$ is not sensitive, i.e., by Proposition 5, $(\hat{G}^{\mathbb{Z}}, L)$ is equicontinuous. ◀

As immediate consequence of Theorem 20 we can state that the dichotomy between sensitivity and equicontinuity also holds for additive CA.

▶ **Corollary 21.** *Any additive CA over a finite abelian group is sensitive to the initial conditions if and only if it is not equicontinuous.*

The following decidability result follows from Theorem 20 and the decidability of sensitivity for LCA.

▶ **Corollary 22.** *Equicontinuity and sensitivity to the initial conditions are decidable for additive CA over a finite abelian group.*

Proof. Use Theorem 8 and 20. ◀

4.2 Surjectivity and Injectivity for Additive Cellular Automata

We now study injectivity and surjectivity for additive CA.

▶ **Lemma 23.** *Let $(\hat{G}^{\mathbb{Z}}, L)$ be any LCA over $\hat{G}$. If there exists a configuration $\boldsymbol{b} \in \hat{G}^{\mathbb{Z}}$ with $\boldsymbol{b} \neq 0$ and $L(\boldsymbol{b}) = 0$, then there exists a configuration $\boldsymbol{b}' \in \Psi(G^{\mathbb{Z}})$ such that $\boldsymbol{b}' \neq 0$ and $L(\boldsymbol{b}') = 0$. In particular, if $\boldsymbol{b}$ is finite then $\boldsymbol{b}'$ is finite too.*

Proof. Let $\boldsymbol{b} \in \hat{G}^{\mathbb{Z}}$ any configuration with $\boldsymbol{b} \neq 0$ and $L(\boldsymbol{b}) = 0$. Set $\boldsymbol{b}^{(1)} = p \cdot \boldsymbol{b}$. If $\boldsymbol{b}^{(1)} = 0$ then for every $i \in \mathbb{Z}$ each component of $\boldsymbol{b}_i$ has $p^{k_1 - 1}$ as factor. So, $\boldsymbol{b} \in \Psi(G^{\mathbb{Z}})$ and $\boldsymbol{b}' = \boldsymbol{b}$ is just one possible configuration the thesis requires to exhibit. Otherwise, by repeating the same argument, set $\boldsymbol{b}^{(2)} = p \cdot \boldsymbol{b}^{(1)}$. If $\boldsymbol{b}^{(2)} = 0$ then, for every $i \in \mathbb{Z}$, each component of $\boldsymbol{b}_i^{(1)}$ has p^{k_1-1} as factor and so $\boldsymbol{b}^{(1)} \in \Psi(G^{\mathbb{Z}})$. Since $L(\boldsymbol{b}^{(1)}) = 0$, a configuration we are looking for is $\boldsymbol{b}' = \boldsymbol{b}^{(1)}$. After $k_1 - 1$ iterations, i.e., once we get $\boldsymbol{b}^{(k_1-1)} = p \cdot \boldsymbol{b}^{(k-2)}$ (with $\boldsymbol{b}^{(k-2)} \neq 0$), if $\boldsymbol{b}^{(k_1-1)} = 0$ holds we conclude that $\boldsymbol{b}' = \boldsymbol{b}^{(k_1-2)}$ by using the same argument of the previous steps. Otherwise, by definition, for every $i \in \mathbb{Z}$ each component of $\boldsymbol{b}_i^{(k_1-1)}$ itself certainly contains p^{k_1-1} as factor. Therefore, $\boldsymbol{b}^{(k_1-1)} \in \Psi(G^{\mathbb{Z}})$. Moreover, $L(\boldsymbol{b}^{(k_1-1)}) = 0$. Hence, we can set $\boldsymbol{b}' = \boldsymbol{b}^{(k_1-1)}$ and this concludes the proof. ◀

The following lemma will be useful for studying both surjectivity and other properties.

▶ **Lemma 24.** *Let $(G^{\mathbb{Z}}, F)$ and $(\hat{G}^{\mathbb{Z}}, L)$ be any additive CA over G and any LCA over $\hat{G}$, respectively, such that $L \circ \Psi = \Psi \circ F$. Then, the CA $(G^{\mathbb{Z}}, F)$ is surjective if and only if $(\hat{G}^{\mathbb{Z}}, L)$ is.*

Proof. $\Longleftarrow$: Assume that F is not surjective. Then, by the Garden of Eden theorem [32, 33], F is not injective on the finite configurations, i.e., there exist two distinct and finite configurations $\boldsymbol{c}', \boldsymbol{c}'' \in G^{\mathbb{Z}}$ with $F(\boldsymbol{c}') = F(\boldsymbol{c}'')$. Therefore, the element $\boldsymbol{c} = \boldsymbol{c}' - \boldsymbol{c}'' \in G^{\mathbb{Z}}$ is a finite configuration such that $\boldsymbol{c} \neq 0$ and $F(\boldsymbol{c}) = 0$. So, we get both $\Psi(\boldsymbol{c}) \neq 0$ and $L(\Psi(\boldsymbol{c})) = \Psi(F(\boldsymbol{c})) = 0$. Since $\Psi(\boldsymbol{c}) \neq 0$, it follows that L is not surjective.
$\Longrightarrow$: Assume that L is not surjective. Then it is not injective on the finite configurations. Thus, there exist a finite configuration $\boldsymbol{b} \neq 0$ with $L(\boldsymbol{b}) = 0$. By Lemma 23, there exists a finite configuration $\boldsymbol{b}' \in \Psi(G^{\mathbb{Z}})$ such that $\boldsymbol{b}' \neq 0$ and $L(\boldsymbol{b}') = 0$. Let $\boldsymbol{c} \in G^{\mathbb{Z}}$ be the finite

configuration such that $\Psi(\boldsymbol{c}) = \boldsymbol{b}'$. Clearly, it holds that $\boldsymbol{c} \neq 0$. We get $\Psi(F(\boldsymbol{c})) = L(\Psi(\boldsymbol{c})) = 0$. Since Ψ is injective, it follows that $F(\boldsymbol{c}) = 0$. Therefore, we conclude that F is not surjective. ◀

Next two theorems state that surjectivity and injectivity behave as sensitivity when looking at an additive CA over G and the associated LCA via the embedding Ψ.

▶ **Theorem 25.** *Let $(G^{\mathbb{Z}}, F)$ be any additive CA over G and let $(\hat{G}^{\mathbb{Z}}, L)$ be the LCA associated with it via the embedding Ψ. Then, the CA $(G^{\mathbb{Z}}, F)$ is surjective if and only if $(\hat{G}^{\mathbb{Z}}, L)$ is.*

Proof. Use Lemma 24. ◀

▶ **Theorem 26.** *Let $(G^{\mathbb{Z}}, F)$ be any additive CA and let $(\hat{G}^{\mathbb{Z}}, L)$ be the LCA associated with it via the embedding Ψ. Then, the CA $(G^{\mathbb{Z}}, F)$ is injective if and only if $(\hat{G}^{\mathbb{Z}}, L)$ is.*

Proof. $\Longleftarrow$: Assume that F is not injective. Then, there exist two distinct configurations $\boldsymbol{c}, \boldsymbol{c}' \in G^{\mathbb{Z}}$ with $F(\boldsymbol{c}) = F(\boldsymbol{c}')$. We get $L(\Psi(\boldsymbol{c})) = \Psi(F(\boldsymbol{c})) = \Psi(F(\boldsymbol{c}')) = L(\Psi(\boldsymbol{c}'))$ and, since Ψ is injective, it follows that L is not injective.
$\Longrightarrow$: Assume that L is not injective. Then, there exists a configuration $\boldsymbol{b} \in \hat{G}^{\mathbb{Z}}$ such that $\boldsymbol{b} \neq 0$ and $L(\boldsymbol{b}) = 0$. By Lemma 23, there exists a configuration $\boldsymbol{b}' \in \Psi(G^{\mathbb{Z}})$ such that $\boldsymbol{b}' \neq 0$ and $L(\boldsymbol{b}') = 0$. Let $\boldsymbol{c} \in G^{\mathbb{Z}}$ be the configuration such that $\Psi(\boldsymbol{c}) = \boldsymbol{b}'$. Clearly, it holds that $\boldsymbol{c} \neq 0$. We get $\Psi(F(\boldsymbol{c})) = L(\Psi(\boldsymbol{c})) = 0$. Since Ψ is injective, it follows that $F(\boldsymbol{c}) = 0$. Since $F(0) = 0$, we conclude that F is not injective. ◀

4.3 Topological transitivity and ergodicity

We start by proving that the embedding Ψ also preserves topological transitivity between an additive CA over G and the associated LCA.

▶ **Theorem 27.** *Let $(G^{\mathbb{Z}}, F)$ be any additive CA over G and let $(\hat{G}^{\mathbb{Z}}, L)$ be the LCA associated with it via the embedding Ψ. Then, the CA $(G^{\mathbb{Z}}, F)$ is topologically transitive if and only if $(\hat{G}^{\mathbb{Z}}, L)$ is.*

Proof. Since $\Psi \circ F = L \circ \Psi$, for every $k \in \mathbb{N}$ it holds that $\Psi \circ (F^k - I) = \Psi \circ F^k - \Psi = L^k \circ \Psi - \Psi = (L^k - I) \circ \Psi$. By Lemma 24 , $F^k - I$ is surjective iff $L^k - I$ is. Theorem 25 and 10 conclude the proof. ◀

As a final result, we get the decidability of many mixing and ergodic properties for additive CA over any finite abelian group, including topological transitivity and ergodicity.

▶ **Corollary 28.** *All the following properties are decidable for additive CA over any finite abelian group: (1) topological transitivity; (2) ergodicity; (3) topological mixing; (4) weak topological transitivity; (5) total transitivity; (6) weak ergodic mixing; (7) ergodic mixing.*

Proof. It is an immediate consequence of Theorem 10 and 27. ◀

5 Conclusions

In this paper we have provided many decidability and characterization results about the dynamical behavior of additive CA over finite abelian groups. These results were obtained using an embedding of linear CA over $(\mathbb{Z}/m\mathbb{Z})^n$ to additive CA over finite abelian groups and a deep algebra result about powers of matrices over commutative rings.

The are at least three main research directions that are worth investigating. First, one might ask which results and characterizations are still true when considering non-abelian groups. Second, it would be very interesting to find characterizations or decidability results about positive expansivity and strong transitivity for the case of additive CA over finite abelian groups. Finally, an important research direction consists in generalizing our results to higher dimensions (see [18] for recent results about D-dimensional CA).

Abstract

We prove new complexity results for computational problems in certain wreath products of groups and (as an application) for free solvable groups. For a finitely generated group we study the so-called power word problem (does a given expression $u_1^{k_1} \dots u_d^{k_d}$, where $u_1, \dots, u_d$ are words over the group generators and $k_1, \dots, k_d$ are binary encoded integers, evaluate to the group identity?) and knapsack problem (does a given equation $u_1^{x_1} \dots u_d^{x_d} = v$, where $u_1, \dots, u_d, v$ are words over the group generators and $x_1, \dots, x_d$ are variables, have a solution in the natural numbers). We prove that the power word problem for wreath products of the form $G \wr \mathbb{Z}$ with G nilpotent and iterated wreath products of free abelian groups belongs to TC^0. As an application of the latter, the power word problem for free solvable groups is in TC^0. On the other hand we show that for wreath products $G \wr \mathbb{Z}$, where G is a so called uniformly strongly efficiently non-solvable group (which form a large subclass of non-solvable groups), the power word problem is coNP-hard. For the knapsack problem we show NP-completeness for iterated wreath products of free abelian groups and hence free solvable groups. Moreover, the knapsack problem for every wreath product $G \wr \mathbb{Z}$, where G is uniformly efficiently non-solvable, is Σ_2^p-hard.

1 Introduction

Since the seminal work of Dehn [7] on the word and conjugacy problem in surface groups, the area of combinatorial group theory [31] is tightly connected to algorithmic questions. The famous Novikov-Boone result [4, 40] on the existence of finitely presented groups with undecidable word problem was one of the first undecidability results that touched real mathematics. Since this pioneering work, the area of algorithmic group theory has been extended in many different directions. More general algorithmic problems have been studied and also the computational complexity of group theoretic problems has been investigated. In this paper, we focus on the decidability/complexity of two specific problems in group theory that have received considerable attention in recent years: the knapsack problem and the power word problem.

Knapsack problems. There exist several variants of the classical knapsack problem over the integers [21]. In the variant that is particularly relevant for this paper, it is asked whether a linear equation $x_1 \cdot a_1 + \cdots + x_d \cdot a_d = b$, with $a_1, \ldots, a_d, b \in \mathbb{Z}$, has a solution $(x_1, \ldots, x_d) \in \mathbb{N}^d$. A proof for the NP-completeness of this problem for binary encoded integers $a_1, \ldots, a_d, b$ can be found in [15]. In contrast, if the numbers a_i, b are given in unary notation then the problem falls down into the circuit complexity class TC^0 [8]. In the course of a systematic investigation of classical commutative discrete optimization problems in non-commutative group theory, Myasnikov, Nikolaev, and Ushakov [33] generalized the above definition of knapsack to any f.g. group G: The input for the knapsack problem for G (KP(G) for short) is an equation of the form $g_1^{x_1} \cdots g_d^{x_d} = h$ for group elements $g_1, \ldots, g_d, h \in G$ (specified by finite words over the generators of G) and pairwise different variables $x_1, \ldots, x_d$ that take values in $\mathbb{N}$ and it is asked whether this equation has a solution (in Section 3.2, we formulate this problem in a slightly more general but equivalent way). In this form, KP($\mathbb{Z}$) is exactly the above knapsack problem for unary encoded integers studied in [8] (a unary encoded integer can be viewed as a word over a generating set $\{t, t^{-1}\}$ of $\mathbb{Z}$). For the case where $g_1, \ldots, g_d, h$ are commuting matrices over an algebraic number field, the knapsack problem has been studied in [1]. Let us emphasize that we are looking for solutions of knapsack equations in the natural numbers. One might also consider the variant, where the variables $x_1, \ldots, x_d$ take values in $\mathbb{Z}$. This latter version can be easily reduced to our knapsack version (with solutions in $\mathbb{N}$), but we are not aware of a reduction in the opposite direction.[1] Let us also mention that the knapsack problem is a special case of the more general rational subset membership problem [26].

We also consider a generalization of KP(G): An exponent equation is an equation of the form $g_1^{x_1} \cdots g_d^{x_d} = h$ as in the specification of KP(G), except that the variables $x_1, \ldots, x_d$ are not required to be pairwise different. *Solvability of exponent equations* for G (ExpEq(G) for short) is the problem where the input is a conjunction of exponent equations (possibly with shared variables) and the question is whether there is a joint solution for these equations in the natural numbers.

Let us briefly survey the results about knapsack obtained in [33] and subsequent papers:

- Knapsack can be solved in polynomial time for every hyperbolic group [33]. Some extensions of this result can be found in [11, 25].
- There are nilpotent groups of class 2 for which knapsack is undecidable. Examples are direct products of sufficiently many copies of the discrete Heisenberg group $H_3(\mathbb{Z})$ [22], and free nilpotent groups of class 2 and sufficiently high rank [37]. In contrast, knapsack for $H_3(\mathbb{Z})$ is decidable [22]. Thus, direct products to not preserve decidability of knapsack.
- Knapsack is decidable for every co-context-free group [22], i.e., groups where the set of all words over the generators that do not represent the identity is a context-free language. Lehnert and Schweitzer [23] have shown that the Higman-Thompson groups are co-context-free.
- Knapsack belongs to NP for all virtually special groups (finite extensions of subgroups of graph groups) [28]. The class of virtually special groups is very rich. It contains all Coxeter groups, one-relator groups with torsion, fully residually free groups, and fundamental groups of hyperbolic 3-manifolds. For graph groups (a.k.a. right-angled Artin groups) a

[1] Note that the problem whether a given system of linear equations has a solution in $\mathbb{N}$ is NP-complete, whereas the problem can be solved in polynomial time (using the Smith normal form) if we ask for a solution in $\mathbb{Z}$. In other words, if we consider the knapsack problem for $\mathbb{Z}^n$ with n part of the input, then looking for solutions in $\mathbb{N}$ seems to be more difficult than looking for solutions in $\mathbb{Z}$.

complete classification of the complexity was obtained in [29]: If the underlying graph contains an induced path or cycle on 4 nodes, then knapsack is NP-complete; in all other cases knapsack can be solved in polynomial time (even in LogCFL).

- Knapsack is NP-complete for every wreath product $A \wr \mathbb{Z}$ with $A \neq 1$ f.g. abelian [12] (wreath products are formally defined in Section 3.1).
- Decidability of knapsack is preserved under finite extensions, HNN-extensions over finite associated subgroups and amalgamated free products over finite subgroups [28].

For a knapsack equation $g_1^{x_1} \cdots g_d^{x_d} = h$ we may consider the set of all solutions $\{(n_1, \ldots, n_d) \in \mathbb{N}^d \mid g_1^{n_1} \cdots g_d^{n_d} = g \text{ in } G\}$. In the papers [25, 22, 29] it turned out that in many groups the solution set of every knapsack equation is a *semilinear set* (see Section 2 for a definition). We say that a group is *knapsack-semilinear* if for every knapsack equation the set of all solutions is semilinear and a semilinear representation can be computed effectively (the same holds then also for exponent equations). Note that in any group G the set of solutions on an equation $g^x = h$ is periodic and hence semilinear. This result generalizes to solution sets of knapsack instances of the for $g_1^x g_2^y = h$ (see Lemma 9), but there are examples of knapsack instances with three variables where solutions sets (in certain groups) are not semilinear. Examples of knapsack-semilinear groups are graph groups [29] (which include free groups and free abelian groups), hyperbolic groups [25], and co-context free groups [22].[2] Moreover, the class of knapsack-semilinear groups is closed under finite extensions, graph products, amalgamated free products with finite amalgamated subgroups, HNN-extensions with finite associated subgroups (see [10] for these closure properties) and wreath products [12].

Power word problems. In the power word problem for a f.g. group G (PowerWP(G) for short) the input consists of an expression $u_1^{n_1} u_2^{n_2} \cdots u_d^{n_d}$, where $u_1, \ldots, u_d$ are words over the group generators and $n_1, \ldots, n_d$ are binary encoded integers. The problem is then to decide whether the expression $u_1^{n_1} u_2^{n_2} \cdots u_d^{n_d}$ evaluates to the identity in G. The power word problem arises very naturally in the context of the knapsack problem: it allows us to verify a proposed solution for a knapsack equation with binary encoded numbers. The power word problem has been first studied in [27], where it was shown that the power word problem for f.g. free groups has the same complexity as the word problem and hence can be solved in logarithmic space. Other groups with easy power word problems are f.g. nilpotent groups and wreath products $A \wr \mathbb{Z}$ with A f.g. abelian [27]. In contrast it is shown in [27] that the power word problem for wreath products $G \wr \mathbb{Z}$, where G is either finite non-solvable or f.g. free, is coNP-complete. Implicitly, the power word problem appeared also in the work of Ge [13], where it was shown that one can verify in polynomial time an identity $\alpha_1^{n_1} \alpha_2^{n_2} \cdots \alpha_d^{n_d} = 1$, where the α_i are elements of an algebraic number field and the n_i are binary encoded integers. The power word problem is a special case of the compressed word problem [24], which asks whether a grammar-compressed word over the group generators evaluates to the group identity.

Main results. Our main focus is on the problems PowerWP(G), KP(G) and ExpEq(G) for the case where G is a wreath product. We start with the following result:

▶ **Theorem 1.** *PowerWP($G \wr \mathbb{Z}$) is in TC^0 for every f.g. nilpotent group G.*

[2] Knapsack-semilinearity of co-context free groups is not stated in [22] but follows immediately from the proof for the decidability of knapsack.

Theorem 1 generalizes the above mentioned result from [27] (for G abelian) in a nontrivial way. Our proof analyzes periodic infinite words over a nilpotent group G. Roughly speaking, we show that one can check in TC^0, whether a given list of such periodic infinite words pointwise multiplies to the identity of G. We believe that this is a result of independent interest. We use this result also in the proof of the following theorem:

▶ **Theorem 2.** *KP*$(G \wr \mathbb{Z})$ *is* NP*-complete for every finite nilpotent group* $G \neq 1$*.*

Next, we consider iterated wreath products. Fix $r \geq 1$ and define the iterated wreath products $W_{0,r} = \mathbb{Z}^r$ and $W_{m+1,r} = \mathbb{Z}^r \wr W_{m,r}$. By a famous result of Magnus [32] the free solvable group $S_{m,r}$ of derived length r and rank m embeds into $W_{m,r}$. Our main results for these groups are:

▶ **Theorem 3.** *PowerWP*$(W_{m,r})$ *and hence PowerWP*$(S_{m,r})$ *is in* TC^0 *for* $m \geq 0$*,* $r \geq 1$*.*

It was only recently shown in [35] that the word problem (and the conjugacy problem) for every free solvable group belongs to TC^0. Theorem 3 generalizes TC^0 membership of the word problem.

▶ **Theorem 4.** *ExpEq*$(W_{m,r})$ *and hence ExpEq*$(S_{m,r})$ *is* NP*-complete for* $m \geq 0$*,* $r \geq 1$*.*

For the proof of Theorem 4 we show that if a given knapsack equation over $W_{m,r}$ has a solution then it has a solution where all numbers are exponentially bounded in the length of the knapsack instance. Theorem 4 then follows easily from Theorem 3. For some other algorithmic results for free solvable groups see [34].

Finally, we show new hardness results for the power word problem and knapsack problem. For this we make use so-called *uniformly strongly efficiently non-solvable* groups (uniformly SENS groups) that were recently defined in [3]. Roughly speaking, a group G is uniformly SENS if there exists nontrivial nested commutators of arbitrary depth that moreover, are efficiently computable in a certain sense (see Section 6 for the precise definition). The essence of these groups is that they allow to carry out Barrington's argument showing the NC^1-hardness of the word problem for a finite solvable group [2]. We prove the following:

▶ **Theorem 5.** *PowerWP*$(G \wr \mathbb{Z})$ *is* coNP*-hard for every f.g. uniformly SENS group* G*.*

This result generalizes a result from [27] saying that PowerWP$(G \wr \mathbb{Z})$ is coNP-hard for the case that G is f.g. free or finite non-solvable.

▶ **Theorem 6.** *KP*$(G \wr \mathbb{Z})$ *is* Σ_2^p*-hard for every f.g. uniformly SENS group* G*.*

Recall that for every nontrivial group G, KP$(G \wr \mathbb{Z})$ is NP-hard [12]. We also show several corollaries of Theorems 5 and 6. For instance, we show that for the famous Thompson's group F, PowerWP(F) is coNP-complete and KP(F) is Σ_2^p-hard.

2 Preliminaries

Complexity theory. We assume some knowledge in complexity theory; in particular the reader should be familiar with the classes P, NP, and coNP. The class Σ_2^p (second existential level of the polynomial time hierarchy) contains all languages $L \subseteq \Sigma^*$ for which there exists a polynomial p and a language $K \subseteq \Sigma^*\#\{0,1\}^*\#\{0,1\}^*$ in P (for a symbol $\# \notin \Sigma \cup \{0,1\}$) such that $x \in L$ if and only if $\exists y \in \{0,1\}^{\leq p(|x|)} \forall z \in \{0,1\}^{\leq p(|x|)} : x\#y\#z \in K$.

The class TC^0 contains all problems that can be solved by a family of threshold circuits of polynomial size and constant depth. In this paper, TC^0 will always refer to the $\mathsf{DLOGTIME}$-uniform version of TC^0. A precise definition is not needed for our work; see [42] for details.

All we need is that the following arithmetic operations on binary encoded integers belong to TC^0: iterated addition and multiplication (i.e., addition and multiplication of n many n-bit numbers) and division with remainder.

For languages (or computational problems) $A, B_1, \ldots, B_k \subseteq \{0,1\}^*$ we write $A \in \mathsf{TC}^0(B_1, \ldots, B_k)$ (A is TC^0-Turing-reducible to $B_1, \ldots, B_k$) if A can be solved by a family of threshold circuits of polynomial size and constant depth that in addition may also use oracle gates for the languages $B_1, \ldots, B_k$ (an oracle gate for B_i yields the output 1 if and only if the string of input bits belongs to B_i).

Semilinear sets. Fix a dimension $d \geq 1$. All vectors will be column vectors. For a vector $\boldsymbol{v} = (v_1, \ldots, v_d)^\mathsf{T} \in \mathbb{Z}^d$ we define its norm $\|\boldsymbol{v}\| := \max\{|v_i| \mid 1 \leq i \leq d\}$ and for a matrix $M \in \mathbb{Z}^{c \times d}$ with entries $m_{i,j}$ ($1 \leq i \leq c$, $1 \leq j \leq d$) we define the norm $\|M\| = \max\{|m_{i,j}| \mid 1 \leq i \leq c, 1 \leq j \leq d\}$. Finally, for a finite set of vectors $A \subseteq \mathbb{N}^d$ let $\|A\| = \max\{\|\boldsymbol{a}\| \mid \boldsymbol{a} \in A\}$. We extend the operations of vector addition and multiplication of a vector by a matrix to sets of vectors in the obvious way. A *linear subset* of $\mathbb{N}^d$ is a set of the form $L = L(\boldsymbol{b}, P) := \boldsymbol{b} + P \cdot \mathbb{N}^k$, where $\boldsymbol{b} \in \mathbb{N}^d$ and $P \in \mathbb{N}^{d \times k}$. A set $S \subseteq \mathbb{N}^d$ is called *semilinear* if it is a finite union of linear sets. Semilinear sets play an important role in automata theory, logic, and other areas. They are precisely the sets definable in Presburger arithmetic, i.e. first-order logic over the structure $(\mathbb{N}, +)$, and thus form a Boolean algebra.

For a semilinear set $S = \bigcup_{i=1}^k L(\boldsymbol{b}_i, P_i)$, we call the tuple $(\boldsymbol{b}_1, P_1, \ldots, \boldsymbol{b}_k, P_k)$ a *semilinear representation* of S. The magnitude of the semilinear representation $(\boldsymbol{b}_1, P_1, \ldots, \boldsymbol{b}_k, P_k)$ is $\max\{\|\boldsymbol{b}_1\|, \|P_1\| \ldots, \|\boldsymbol{b}_k\|, \|P_k\|\}$. The *magnitude* $\|S\|$ of a semilinear set S is the minimal magnitude of all semilinear representations for S.

It is often convenient to treat mappings $\nu\colon \{x_1, \ldots, x_d\} \to \mathbb{N}$, where $X = \{x_1, \ldots, x_d\}$ is a finite set of variables, as vectors. To this end, we identify ν with the vector $(\nu(x_1), \ldots, \nu(x_d))^\mathsf{T}$. This way, vector operations (e.g. addition and scalar multiplication) and the notion of semilinearity carry over to the set $\mathbb{N}^X$ of all mappings from X to $\mathbb{N}$.

3 Groups

We assume that the reader is familiar with the basics of group theory. Let G be a group. We always write 1 for the group identity element. For $g, h \in G$ we write $[g, h] := g^{-1}h^{-1}gh$ for the commutator of g and h and g^h for $h^{-1}gh$. For subgroups A, B of G we write $[A, B]$ for the subgroup generated by all commutators $[a, b]$ with $a \in A$ and $b \in B$. The order of an element $g \in G$ is the smallest number $z > 0$ with $g^z = 1$ and ∞ if such a z does not exist. The group G is torsion-free, if every $g \in G \setminus \{1\}$ has infinite order.

We say that G is *finitely generated (f.g.)* if there is a finite subset $\Sigma \subseteq G$ such that every element of G can be written as a product of elements from Σ; such a Σ is called a *finite generating set* for G. We also write $G = \langle \Sigma \rangle$. We then have a canonical morphism $h\colon \Sigma^* \to G$ that maps a word over Σ to its product in G. If $h(w) = 1$ we also say that $w = 1$ in G. For $g \in G$ we write $|g|$ for the length of a shortest word $w \in \Sigma^*$ such that $h(w) = g$. This notation depends on the generating set Σ. We always assume that the generating set Σ is symmetric in the sense that $a \in \Sigma$ implies $a^{-1} \in \Sigma$. Then, we can define on Σ^* a natural involution $\cdot^{-1}$ by $(a_1 a_2 \cdots a_n)^{-1} = a_n^{-1} \cdots a_2^{-1} a_1^{-1}$ for $a_1, a_2, \ldots, a_n \in \Sigma$. This allows to use the notations $[g, h] = g^{-1}h^{-1}gh$ and $g^h = h^{-1}gh$ in the case $g, h \in \Sigma^*$. By *computing a homomorphism* $h\colon G_1 = \langle \Sigma_1 \rangle \to G_2 = \langle \Sigma_2 \rangle$, we mean computing the images $h(a)$ for $a \in \Sigma_1$.

A group G is called *orderable* if there exists a linear order $\leq$ on G such that $g \leq h$ implies $xgy \leq xhy$ for all $g, h, x, y \in G$ [39, 38]. Every orderable group is torsion-free (this follows directly from the definition) and has the unique roots property [41], i.e., $g^n = h^n$ implies $g = h$. The are numerous examples of orderable groups: for instance, torsion-free nilpotent groups, right-angled Artin groups, and diagram groups are all orderable.

Two elements $g, h \in G$ in a group G are called *commensurable* if $g^x = h^y$ for some $x, y \in \mathbb{Z} \setminus \{0\}$. This defines an equivalence relation on G, in which the elements with finite order form an equivalence class. By [39, Corollary 1.2] commensurable elements in an orderable group commute.

3.1 Wreath products

Let G and H be groups. Consider the direct sum $K = \bigoplus_{h \in H} G_h$, where G_h is a copy of G. We view K as the set $G^{(H)}$ of all mappings $f \colon H \to G$ such that $\mathrm{supp}(f) := \{h \in H \mid f(h) \neq 1\}$ is finite, together with pointwise multiplication as the group operation. The set $\mathrm{supp}(f) \subseteq H$ is called the *support* of f. The group H has a natural left action on $G^{(H)}$ given by $hf(a) = f(h^{-1}a)$, where $f \in G^{(H)}$ and $h, a \in H$. The corresponding semidirect product $G^{(H)} \rtimes H$ is the (restricted) *wreath product* $G \wr H$. In other words:

- Elements of $G \wr H$ are pairs (f, h), where $h \in H$ and $f \in G^{(H)}$.
- The multiplication in $G \wr H$ is defined as follows: Let $(f_1, h_1), (f_2, h_2) \in G \wr H$. Then $(f_1, h_1)(f_2, h_2) = (f, h_1h_2)$, where $f(a) = f_1(a)f_2(h_1^{-1}a)$.

There are canonical mappings

- $\sigma \colon G \wr H \to H$ with $\sigma(f, h) = h$ and
- $\tau \colon G \wr H \to G^{(H)}$ with $\tau(f, h) = f$

In other words: $g = (\tau(g), \sigma(g))$ for $g \in G \wr H$. Note that σ is a homomorphism whereas τ is in general not a homomorphism. Throughout this paper, the letters σ and τ will have the above meaning, which of course depends on the underlying wreath product $G \wr H$, but the latter will be always clear from the context.

The following intuition might be helpful: An element $(f, h) \in G \wr H$ can be thought of as a finite multiset of elements of $G \setminus \{1_G\}$ that are sitting at certain elements of H (the mapping f) together with the distinguished element $h \in H$, which can be thought of as a cursor moving in H. If we want to compute the product $(f_1, h_1)(f_2, h_2)$, we do this as follows: First, we shift the finite collection of G-elements that corresponds to the mapping f_2 by h_1: If the element $g \in G \setminus \{1_G\}$ is sitting at $a \in H$ (i.e., $f_2(a) = g$), then we remove g from a and put it to the new location $h_1a \in H$. This new collection corresponds to the mapping $f_2' \colon a \mapsto f_2(h_1^{-1}a)$. After this shift, we multiply the two collections of G-elements pointwise: If in $a \in H$ the elements g_1 and g_2 are sitting (i.e., $f_1(a) = g_1$ and $f_2'(a) = g_2$), then we put the product g_1g_2 into the location a. Finally, the new distinguished H-element (the new cursor position) becomes h_1h_2.

Clearly, H is a subgroup of $G \wr H$. We also regard G as a subgroup of $G \wr H$ by identifying G with the set of all $f \in G^{(H)}$ with $\mathrm{supp}(f) \subseteq \{1\}$. This copy of G together with H generates $G \wr H$. In particular, if $G = \langle \Sigma \rangle$ and $H = \langle \Gamma \rangle$ with $\Sigma \cap \Gamma = \emptyset$ then $G \wr H$ is generated by $\Sigma \cup \Gamma$. In this situation, we will also apply the above mappings σ and τ to words over $\Sigma \cup \Gamma$.

In [34] it was shown that the word problem of a wreath product $G \wr H$ is TC^0-reducible to the word problems for G and H. Let us briefly sketch the argument. Assume that $G = \langle \Sigma \rangle$ and $H = \langle \Gamma \rangle$. Given a word $w \in (\Sigma \cup \Gamma)^*$ one has to check whether $\sigma(w) = 1$ in H and $\tau(w)(h) = 1$ in H for all h in the support of $\tau(w)$. One can compute in TC^0 the word $\sigma(w)$ by projecting w onto the alphabet Γ. Moreover, one can enumerate the support of $\tau(w)$ by going over all prefixes of w and checking which σ-values are the same. Similarly, one produces for a given $h \in \mathrm{supp}(\tau(w))$ a word over Σ that represents $\tau(w)(h)$.

We will need the following result from [30] (which holds only for the so-called restricted wreath product that we consider in this paper):

▶ **Theorem 7** ([30]). *If G and H are orderable then also $G \wr H$ is orderable.*

3.2 Knapsack problem

Let $G = \langle \Sigma \rangle$ be a f.g. group. An *exponent expression* over G is an expression of the form $E = v_0 u_1^{x_1} v_1 u_2^{x_2} v_2 \cdots u_d^{x_d} v_d$ with $d \geq 1$, words $v_0, \ldots, v_d \in \Sigma^*$, non-empty words $u_1, \ldots, u_d \in \Sigma^*$, and variables $x_1, \ldots, x_d$. Here, we allow $x_i = x_j$ for $i \neq j$. If every variable x_i occurs at most once, then E is called a *knapsack expression*. Let $X = \{x_1, \ldots, x_d\}$ be the set of variables that occur in E. For a homomorphism $h \colon G \to G' = \langle \Sigma' \rangle$ (that is specified by a mapping from Σ to $(\Sigma' \cup \Sigma'^{-1})^*$), we denote with $h(E)$ the exponent expression $h(v_0)h(u_1)^{x_1}h(v_1)h(u_2)^{x_2}h(v_2) \cdots h(u_d)^{x_d}h(v_d)$. For a mapping $\nu \in \mathbb{N}^X$, we define $\nu(E) = v_0 u_1^{\nu(x_1)} v_1 u_2^{\nu(x_2)} v_2 \cdots u_d^{\nu(x_d)} v_d \in \Sigma^*$. We say that ν is a *G-solution* for E if $\nu(E) = 1$ in G. With $\mathrm{sol}_G(E)$ we denote the set of all G-solutions of E. The *length* of E is defined as $|E| = \sum_{i=1}^{d} |u_i| + |v_i|$. We define *solvability of exponent equations over G*, $\textsc{ExpEq}(G)$ for short, as the following decision problem:

Input A finite list of exponent expressions $E_1, \ldots, E_n$ over G.

Question Is $\bigcap_{i=1}^{n} \mathrm{sol}_G(E_i)$ non-empty?

The *knapsack problem for G*, $\mathrm{KP}(G)$ for short, is the following decision problem:

Input A single knapsack expression E over G.

Question Is $\mathrm{sol}_G(E)$ non-empty?

It is an easy observation that the choice of the generating set Σ has no influence on the decidability or complexity of these problems. For the knapsack problem in wreath products the following result has been shown in [12]:

▶ **Theorem 8** ([12]). *For every nontrivial group G, $KP(G \wr \mathbb{Z})$ is* NP*-hard.*

3.3 Knapsack-semilinear groups

The group G is called *knapsack-semilinear* if for every knapsack expression E over Σ, the set $\mathrm{sol}_G(E)$ is a semilinear set of vectors and a semilinear representation can be effectively computed from E. Since semilinear sets are effectively closed under intersection, it follows that for every exponent expression E over Σ, the set $\mathrm{sol}_G(E)$ is semilinear and a semilinear representation can be effectively computed from E. Moreover, solvability of exponent equations is decidable for every knapsack-semilinear group. As mentioned above, the class of knapsack-semilinear groups is very rich. An example of a group G, where knapsack is decidable but solvability of exponent equations is undecidable is the Heisenberg group $H_3(\mathbb{Z})$ (which consists of all upper triangular (3×3)-matrices over the integers, where all diagonal entries are 1), see [22]. In particular, $H_3(\mathbb{Z})$ is not knapsack-semilinear. A non-semilinear solution set can be achieved with a three-variable knapsack instance over $H_3(\mathbb{Z})$. For two variables, the solutions sets are semilinear for any group. In fact, they have a particularly simple structure:

▶ **Lemma 9.** *Let G be a group and $g_1, g_2, h \in G$ be elements.*

(i) *The solution set $S_1 = \{(x, y) \in \mathbb{Z}^2 \mid g_1^x g_2^y = 1\}$ is a subgroup of $\mathbb{Z}^2$. If G is torsion-free and $\{g_1, g_2\} \neq \{1\}$ then S_1 is cyclic.*

(ii) *The solution set $S = \{(x, y) \in \mathbb{Z}^2 \mid g_1^x g_2^y = h\}$ is either empty or a coset $(a, b) + S_1$ of S_1 where $(a, b) \in S$ is any solution.*

For a knapsack-semilinear group G and a finite generating set Σ for G we define a growth function. For $n \in \mathbb{N}$ let $\mathsf{Knap}(n)$ (resp., $\mathsf{Exp}(n)$) be the finite set of all knapsack expressions (resp., exponent expression) E over Σ such that $\mathrm{sol}_G(E) \neq \emptyset$ and $|E| \leq n$. We define the mapping $\mathsf{K}_{G,\Sigma} \colon \mathbb{N} \to \mathbb{N}$ and $\mathsf{E}_{G,\Sigma} \colon \mathbb{N} \to \mathbb{N}$ as follows:

$$\mathsf{K}_{G,\Sigma}(n) = \max\{\|\mathrm{sol}_G(E)\| \mid E \in \mathsf{Knap}(n)\}, \quad (1)$$

$$\mathsf{E}_{G,\Sigma}(n) = \max\{\|\mathrm{sol}_G(E)\| \mid E \in \mathsf{Exp}(n)\}. \quad (2)$$

Clearly, if $\mathrm{sol}_G(E) \neq \emptyset$ and $\|\mathrm{sol}_G(E)\| \leq N$ then E has a G-solution ν such that $\nu(x) \leq N$ for all variables x that occur in E. Thus, if G has a decidable word problem and a computable bound on the function $\mathsf{K}_{G,\Sigma}$, then we can solve $\mathrm{KP}(G)$ non-deterministically: given a knapsack expression E with variables from X, we guess $\nu \colon X \to \mathbb{N}$ with $\sigma(x) \leq N$ for all variables x and then check (using an algorithm for the word problem) whether ν is a solution.

Let Σ and Σ' be two generating sets for the group G. Then there is a constant c such that $\mathsf{K}_{G,\Sigma}(n) \leq \mathsf{K}_{G,\Sigma'}(cn)$, and similarly for $\mathsf{E}_{G,\Sigma}(n)$. To see this, note that for every $a \in \Sigma'$ there is a word $w_a \in \Sigma^*$ such that a and w_a represent the same element in G. Then we can choose $c = \max\{|w_a| \mid a \in \Sigma'\}$. Due to this fact, we do not have to specify the generating set Σ when we say that $\mathsf{K}_{G,\Sigma}$ (resp., $\mathsf{E}_{G,\Sigma}$) is polynomially/exponentially bounded.

Important for us is also the following result from [12]:

▶ **Theorem 10** ([12]). *If G and H are knapsack-semilinear then so is $G \wr H$.*

The proof of this result in [12] does not yield a good bound of $\mathsf{K}_{G\wr H}(n)$ in terms of $\mathsf{K}_G(n)$ and $\mathsf{K}_H(n)$ (and similarly for the E-function). One of our main achievements is such a bound for the case that the left factor G is f.g. abelian. For $\mathsf{E}_G(n)$ we then have the following bound, which follows from well-known bounds on solutions of linear Diophantine equations [43]:

▶ **Lemma 11.** *If G is a f.g. abelian group then $\mathsf{E}_G(n) \leq 2^{n^{\mathcal{O}(1)}}$.*

3.4 Power word problem

A *power word* (over Σ) is a tuple $(u_1, k_1, u_2, k_2, \ldots, u_d, k_d)$ where $u_1, \ldots, u_d \in \Sigma^*$ are words over the group generators (called the periods of the power word) and $k_1, \ldots, k_d \in \mathbb{Z}$ are integers that are given in binary notation. Such a power word represents the word $u_1^{k_1} u_2^{k_2} \cdots u_d^{k_d}$. We will often identify the power word $(u_1, k_1, u_2, k_2, \ldots, u_d, k_d)$ with the word $u_1^{k_1} u_2^{k_2} \cdots u_d^{k_d}$. Moreover, if $k_i = 1$, then we usually omit the exponent 1 in a power word. The *power word problem* for the f.g. group G, PowerWP(G) for short, is the following:

Input A power word $(u_1, k_1, u_2, k_2, \ldots, u_d, k_d)$.

Question Does $u_1^{k_1} u_2^{k_2} \cdots u_d^{k_d} = 1$ hold in G?

Due to the binary encoded exponents, a power word can be seen as a succinct description of an ordinary word. We have the following simple lemma.

▶ **Lemma 12.** *If the f.g. group G is knapsack-semilinear, $\mathsf{E}_G(n)$ is exponentially bounded, and* PowerWP(G) *belongs to* NP *then* ExpEq(G) *belongs to* NP.

4 Wreath products of nilpotent groups and the integers

Nilpotent groups. The *lower central series* of a group G is the sequence of groups $(G_i)_{i\geq 0}$ with $G_0 = G$ and $G_{i+1} = [G_i, G]$. The group G is *nilpotent* if there is a $c \geq 0$ with $G_c = 1$; in this case the minimal c with $G_c = 1$ is called the *nilpotency class* of G. In this section we prove Theorems 1 and 2. Our main tool are periodic words over G as introduced in [12].

Periodic words over groups. Let $G = \langle \Sigma \rangle$ be a f.g. group. Let G^ω be the set of all functions $f\colon \mathbb{N} \to G$, which forms a group by pointwise multiplication $(fg)(t) = f(t) \cdot g(t)$. A function $f \in G^\omega$ is *periodic* if there exists a number $d \geq 1$ such that $f(t) = f(t+d)$ for all $t \geq 0$. The smallest such d is called the *period* of f. If $f \in G^\omega$ has period d and $g \in G^\omega$ has period e then fg has period at most $\mathrm{lcm}(d,e)$. A periodic function $f \in G^\omega$ with period d can be specified by its initial d elements $f(0), \dots, f(d-1)$ where each element $f(t)$ is given as a word over the generating set Σ. The *periodic words problem* PERIODIC(G) over G is the following:

Input Periodic functions $f_1, \dots, f_m \in G^\omega$ and a binary encoded number T.

Question Does the product $f = \prod_{i=1}^m f_i$ satisfy $f(t) = 1$ for all $t \leq T$?

We shall derive Theorems 1 and 2 from the following result:

▶ **Theorem 13.** *If G is a f.g. nilpotent group then* PERIODIC(G) *belongs to* TC^0.

Previously it was proven that PERIODIC(G) belongs to TC^0 if G is abelian [12]. As an introduction let us reprove this result.

Let $\rho\colon G^\omega \to G^\omega$ be the *shift*-operator, i.e. $(\rho(f))(t) = f(t+1)$, which is a group homomorphism. For a subgroup H of G^ω, we denote by $H^{(n)}$ the smallest subgroup of G^ω that contains $\rho^0(H), \rho^1(H), \dots, \rho^n(H)$. Note that $(H^{(m)})^{(n)} = H^{(m+n)}$ for any $m, n \in \mathbb{N}$. A function $f \in G^\omega$ *satisfies a recurrence of order* $d \geq 1$ if $\rho^d(f)$ is contained in the subgroup $\langle f \rangle^{(d-1)}$ of G^ω. If f has period d then f clearly satisfies a recurrence of order d.

Let us now consider the case that G is abelian. Then, also G^ω is abelian and we use the additive notation for G^ω. The following lemma is folklore:

▶ **Lemma 14** (cf. [17]). *Let G be a f.g. abelian group. If $f_1, \dots, f_m \in G^\omega$ satisfy recurrences of order $d_1, \dots, d_m \geq 1$ respectively, then $\sum_{i=1}^m f_i$ satisfies a recurrence of order $\sum_{i=1}^m d_i$.*

Proof. Observe that G^ω is a $\mathbb{Z}[x]$-module with scalar multiplication

$$\sum_{i=0}^{d} a_i x^i \cdot f \mapsto \sum_{i=0}^{d} a_i \rho^i(f). \tag{3}$$

Then $f \in G^\omega$ satisfies a recurrence of order $d \geq 1$ if and only if there exists a monic polynomial $p \in \mathbb{Z}[x]$ of degree d (where monic means that the leading coefficient is one) such that $pf = 0$. Therefore, if $p_1, \dots, p_m \in \mathbb{Z}[x]$ such that $\deg(p_i) = d_i \geq 1$ and $p_i f_i = 0$ then $\prod_{i=1}^m p_i \sum_{j=1}^m f_j = \sum_{j=1}^m (\prod_{i=1}^m p_i) f_j = 0$. Since $\prod_{i=1}^m p_i$ is a monic polynomial of degree $d := \sum_{i=1}^m d_i$, $\sum_{i=1}^m f_i$ satisfies a recurrence of order d. ◀

The above lemma implies that $\sum_{i=1}^m f_i = 0$ if and only if $\sum_{i=1}^m f_i(t) = 0$ for all $0 \leq t \leq d-1$, where d is the sum of the periods of the f_i.

Let us now turn to the nilpotent case. For $n \in \mathbb{N}$, let $G^{\omega,n}$ be the subgroup of G^ω generated by all elements with period at most n. Then $G^{\omega,n}$ is closed under shift. The key fact for showing Theorem 13 is the following.

▶ **Proposition 15.** *If G is a f.g. nilpotent group, then there is a polynomial p such that every element of $G^{\omega,n}$ satisfies a recurrence of order $p(n)$.*

Let $H \leq G^\omega$ be a subgroup which is closed under shifting, i.e. $\rho(H) \subseteq H$. Since the shift is a homomorphism, the commutator subgroup $[H,H]$ is closed under shifting as well. We will work in the abelianization $H' = H/[H,H]$ where we write $\bar{f}$ for the coset $f[H,H]$. We also define $\rho\colon H' \to H'$ by $\rho(\bar{f}) = \overline{\rho(f)}$. This is well-defined since $fg^{-1} \in [H,H]$ implies $\rho(f)\rho(g)^{-1} = \rho(fg^{-1}) \in [H,H]$ and hence $\overline{\rho(f)} = \overline{\rho(g)}$. As an abelian group H' is a $\mathbb{Z}$-module and, in fact, H' forms a $\mathbb{Z}[x]$-module using the shift-operator. By the above remark (see (3)) we have the following (where we use the multiplicative notation for H'):

▶ **Lemma 16.** *H' is a $\mathbb{Z}[x]$-module with the scalar multiplication $\sum_{i=0}^{d} a_i x^i \cdot \bar{f} \mapsto \prod_{i=0}^{d} \rho^i(\bar{f})^{a_i}$.*

Our first step for proving Proposition 15 is to show that every element of $G^{\omega,n}$ satisfies a polynomial-order recurrence, modulo some element in $[G^{\omega,n}, G^{\omega,n}]$.

▶ **Lemma 17.** *For every $f \in G^{\omega,n}$, we have $\rho^d(f) \in \langle f\rangle^{(d-1)}[G^{\omega,n}, G^{\omega,n}]$ for $d = n(n+1)/2$.*

Proof. Suppose $f = f_1 \cdots f_m$ such that $f_1, \dots, f_m \in G^{\omega}$ are elements of period $\leq n$. According to Lemma 16, we consider $G^{\omega,n}/[G^{\omega,n}, G^{\omega,n}]$ as a $\mathbb{Z}[x]$-module.

If $g \in G^{\omega}$ has period q then $\rho^q(g)g^{-1} = 1$ and thus $(x^q - 1)\bar{g} = \rho^q(\bar{g})\bar{g}^{-1} = 1$. Define the polynomial $p(x) = \prod_{i=1}^{n}(x^i - 1) = \sum_{i=0}^{d} a_i x^i$ of degree $d = n(n+1)/2$ satisfying $a_d = 1$. Since all functions $f_1, \dots, f_m$ have period at most n, we have $p\bar{f} = 1$. Explicitly, this means $1 = p\bar{f} = \rho^0(\bar{f})^{a_0} \cdot \rho^1(\bar{f})^{a_1} \cdots \rho^d(\bar{f})^{a_d} = \overline{\rho^0(f)^{a_0} \cdots \rho^d(f)^{a_d}}$. Noticing that $a_d = 1$, we can write $\rho^d(f) = gh$ for some $g \in \langle f\rangle^{(d-1)}$ and $h \in [G^{\omega,n}, G^{\omega,n}]$, which has the desired form. ◀

The following lemma gives us control over the remaining factor from $[G^{\omega,n}, G^{\omega,n}]$.

▶ **Lemma 18.** *Let G be a group with nilpotency class c. Then $[G^{\omega,n}, G^{\omega,n}] \subseteq [G,G]^{\omega,n^{2c}}$.*

Proof. We need the fact that the commutator subgroup $[F,F]$ of a group F with generating set Γ is generated by all left-normed commutators $[g_1, \dots, g_k] := [[\dots[[g_1, g_2], g_3], \dots], g_k]$, where $g_1, \dots, g_k \in \Gamma \cup \Gamma^{-1}$ and $k \geq 2$, cf. [6, Lemma 2.6]. Therefore $[G^{\omega,n}, G^{\omega,n}]$ is generated by all left-normed commutators $[g_1, \dots, g_k]$ where $k \geq 2$ and $g_1, \dots, g_k \in G^{\omega}$ have period at most n. Furthermore, we can bound k by c since any left-normed commutator $[g_1, \dots, g_{c+1}]$ is trivial (recall that G is nilpotent of class c). A left-normed commutator $[g_1, \dots, g_k]$ with $2 \leq k \leq c$ and $g_1, \dots, g_k$ periodic with period at most n is a product containing at most $2k \leq 2c$ distinct functions of period at most n (namely, the $g_1, \dots, g_k$ and their inverses). Hence $[G^{\omega,n}, G^{\omega,n}]$ is generated by functions $g \in [G,G]^{\omega}$ of period at most n^{2c}. ◀

Proof of Proposition 15. We proceed by induction on the nilpotency class of G. If G has nilpotency class 0, then G is trivial and the claim is vacuous. Now suppose that G has nilpotency class $c \geq 1$. According to Lemma 17, we have $\rho^d(f) \in \langle f\rangle^{(d-1)}h$ for some $h \in [G^{\omega,n}, G^{\omega,n}]$. By Lemma 18, we have $[G^{\omega,n}, G^{\omega,n}] \subseteq [G,G]^{\omega,n^{2c}}$. Since the group $[G,G]$ has nilpotency class at most $c-1$ (we included a proof for this in the full version [9]), we may apply induction. Thus, we know that $\rho^e(h) \in \langle h\rangle^{(e-1)}$ for some $e = e(n^{2c})$. We claim that then $\rho^{d+e}(f) \in \langle f\rangle^{(d+e-1)}$. Note that $\rho^{d+e}(f) \in \rho^e(\langle f\rangle^{(d-1)}h) \subseteq \rho^e(\langle f\rangle^{(d-1)})\rho^e(h) \subseteq \langle f\rangle^{(d+e-1)} \cdot \rho^e(h)$. Therefore, it suffices to show that $\rho^e(h) \in \langle f\rangle^{(d+e-1)}$. Since $\rho^d(f) \in \langle f\rangle^{(d-1)}h$ we have $h \in \langle f\rangle^{(d)}$ and thus $\rho^e(h) \in \langle h\rangle^{(e-1)} \subseteq (\langle f\rangle^{(d)})^{(e-1)} = \langle f\rangle^{(d+e-1)}$. ◀

Proof of Theorem 13. Given periodic functions $f_1, \dots, f_m \in G^{\omega}$ with maximum period n, and a number $T \in \mathbb{N}$. By Proposition 15 the product $f = f_1 \cdots f_m$ satisfies a recurrence of order d, where d is bounded polynomially in n. Notice that $f = 1$ if and only if $f(t) = 1$ for all $t \leq d-1$. Hence, it suffices to verify that $f_1(t) \cdots f_m(t) = 1$ for all $t \leq \min\{d, T\}$. This can be accomplished by solving in parallel a polynomial number of instances of the word problem over G, which is contained in TC^0 by [36]. ◀

Proof of Theorem 1. In [27] it is shown that for every f.g. group G, PowerWP($G \wr \mathbb{Z}$) belongs to TC^0(Periodic(G), PowerWP(G)). By [27] the power word problem for a f.g. nilpotent group belongs to TC^0 and by Theorem 13, Periodic(G) belongs to TC^0. ◀

Proof of Theorem 2. By Theorem 8, KP($G \wr \mathbb{Z}$) is NP-hard. For the upper bound we use the following result from [12] that holds for every f.g. group G: There is a non-deterministic polynomial time Turing machine M that takes as input a knapsack expression E over $G \wr \mathbb{Z}$ and outputs in each leaf of the computation tree the following data: (i) an instance of $\textsc{ExpEq}(G)$ and (ii) a finite list of instances of $\textsc{Periodic}(G)$. Moreover, the input expression E has a $(G \wr \mathbb{Z})$-solution if and only if the computation tree has a leaf in which all $\textsc{Periodic}(G)$ instances are positive. If G is finite and nilpotent, then $\textsc{Periodic}(G)$ belongs to TC^0 and $\textsc{ExpEq}(G)$ belongs to NP (this holds for every finite group). The theorem follows. ◀

5 Wreath products with abelian left factors

In this section we consider wreath products $A \wr H$ where A is f.g. abelian and H is a f.g. torsion-free group. We study for which groups H, the complexity of the power word/knapsack problem in H is passed on to $A \wr H$. As applications, we obtain Theorems 3 and 4.

Power word problem over $A \wr H$. As a first step, we *normalize* a given power word $u_1^{k_1} \dots u_d^{k_d}$, i.e. ensure that $u_1, \dots, u_d \in AH$, say $u_i = a_i h_i$ for some $a_i \in A$ and $h_i \in H$ for $1 \le i \le d$. Intuitively, the computation of the power word can be described by finite progressions in the Cayley graph of H, which are labelled with elements a_i from A. The goal is to determine whether the labels on each point cancel out in the abelian group A. Here, a *progression* in H is a sequence $\boldsymbol{p} = (gh^k)_{0 \le k \le \ell}$ with *offset* $g \in H$ and *period* $h \in H$. If $h \neq 1$ then $\boldsymbol{p}$ is a *ray*. For all $1 \le i \le d$ the power word writes the element a_i into the Cayley graph of H along the progression $\boldsymbol{p}_i = (h_1^{k_1} \dots h_{i-1}^{k_{i-1}} h_i^k)_{0 \le k \le k_i}$. Notice that the offset of $\boldsymbol{p}_i$ is given as a power word for $h_1^{k_1} \dots h_{i-1}^{k_{i-1}}$ and the period is given explicitly as a word for the group element h; we call such a progression *power-compressed*.

To solve the power word problem over $A \wr H$ it seems inevitable to compute the intersection set $\{(i,j) \in [0,k] \times [0,\ell] \mid ab^i = gh^j\}$ of two given power-compressed progressions $\boldsymbol{p} = (ab^i)_{0 \le i \le k}, \boldsymbol{q} = (gh^j)_{0 \le j \le \ell}$, for any pair of progressions appearing in the power word. Such a intersection set is always a finite progression in $\mathbb{N}^2$ (c.f. Lemma 9).

However, the key insight of Theorem 3 is that it essentially suffices to compute the intersection of *parallel* rays, i.e. rays with commensurable periods. This is because two non-parallel rays can intersect at most once. Therefore, the number of points in H that cancel to zero with the help of intersections between non-parallel rays can be at most polynomial.

Therefore, roughly speaking, we proceed as follows. Consider a class C of parallel rays from the progressions $\boldsymbol{p}_1, \dots, \boldsymbol{p}_d$. First, we compute the intersection sets of all rays in C. Second, we decide whether the number of points in the support of C which do not cancel to 0 in A exceeds a polynomial bound. In order to count such non-cancelling points, we use Lemma 14 to limit the search to (polynomially many) polynomial-length rays. If our bound on such non-cancelling points is exceeded, then we can reject the entire power word: As mentioned above, non-parallel rays $\boldsymbol{p}_i$ can only intersect at a polynomial number of points in C. If, however, our bound is obeyed, we can explicitly compute the non-cancelling points (as power compressed words) for each parallelity class C and verify that they do evaluate to 0 in the entire set of progressions $\boldsymbol{p}_i$.

In order to (i) compute the intersection set of two parallel power-compressed rays and (ii) count non-cancelling points, we need to solve a generalization of the power word problem in the group H, which we explain next. For a f.g. group $G = \langle \Sigma \rangle$ we define the *power compressed power problem* $\textsc{PowerPP}(G)$:

Input A word $u \in \Sigma^*$ and a power word $(v_1, k_1, \dots, v_d, k_d)$ over Σ.

Output A binary encoded number $z \in \mathbb{Z}$ with $u^z = v$ where $v = v_1^{k_1} \dots v_d^{k_d}$, or **no** if $u^z = v$ has no solution.

Note that the word u in the input of PowerPP is uncompressed. In order to guarantee that we have small uncompressed inputs to PowerPP, we need to show another property of our groups. Specifically, we prove that the intersection set of parallel rays has a small period: A group $G = \langle \Sigma \rangle$ is *tame with respect to commensurability*, or short *c-tame*, if there exists a number $d \in \mathbb{N}$ such that for all commensurable elements $g, h \in G$ having infinite order there exist numbers $s, t \in \mathbb{Z} \setminus \{0\}$ such that $g^s = h^t$ and $|s|, |t| \leq \mathcal{O}((|g| + |h|)^d)$.

Our algorithm for the power word problem sketched above yields the following:

▶ **Proposition 19.** *If the group H is c-tame and torsion-free then PowerWP$(A \wr H)$ is TC^0-reducible to PowerPP(H).*

This means, in order to solve the power word problem for groups $W_{m,r}$ and $S_{m,r}$ in TC^0, we also need to solve the power compressed power problem in TC^0. To this end, we first establish TC^0 membership of PowerPP in groups $W_{m,r}$ in the following transfer result.

▶ **Theorem 20.** *Let H and A be f.g. groups where A is abelian and H is c-tame and torsion-free. Then PowerPP$(A \wr H)$ is TC^0-reducible to PowerPP(H).*

To show Theorem 20, we provide an elementary (but still somewhat involved) TC^0-reduction from PowerPP$(A \wr H)$ to PowerWP$(A \wr H)$ and PowerPP(H) and apply Proposition 19.

Finally, we need to show that all the groups $W_{m,r}$ and $S_{m,r}$ are c-tame.

▶ **Proposition 21.** *For all $r \geq 1$, $m \geq 0$ the groups $W_{m,r}$ and $S_{m,r}$ are c-tame.*

For Proposition 21, we use elementary arguments and the unique roots property of $W_{m,r}$. The preceding ingredients now yield Theorem 3.

Proof of Theorem 3. We will prove by induction on $m \in \mathbb{N}$ that PowerPP$(W_{m,r})$ and hence also PowerWP$(W_{m,r})$ belongs to TC^0. If $m = 0$ then PowerPP$(W_{0,r})$ is the problem of solving a system of r linear equations $a_i x = b_i$ where a_i is given in unary encoding and b_i is given in binary encoding for $1 \leq i \leq r$. Since integer division belongs to TC^0 (here, we only have to divide by the unary encoded integers a_i) this problem can be solved in TC^0. The inductive step follows from Theorem 20 and the fact that all groups $W_{m,r}$ are c-tame (Proposition 21) and torsion-free. ◀

Knapsack problem over $A \wr H$. For the knapsack problem we prove the following transfer theorem (recall the definition of an orderable group from Section 3 and the definition of the function $\mathsf{E}_G(n)$ from (2) in Section 3.3):

▶ **Theorem 22.** *Let H and A be f.g. groups where A is abelian and H is orderable and knapsack-semilinear. If $\mathsf{E}_H(n)$ is exponentially bounded then so is $\mathsf{E}_{A \wr H}(n)$.*

The proof of Theorem 22 follows a similar pattern as Theorem 20. The condition that H is orderable ensures that parallel rays in H are contained in cosets of a common cyclic subgroup. We describe the solution set of an exponent equation over $A \wr H$ as a disjunction of polynomially large existential Presburger formulas, which use exponent equations over H and inequalities as atomic formulas. Here, we do not need to algorithmically construct the formula: Its mere existence yields an exponential bound on the size of a solution.

Using Theorem 3 and 22 we can prove Theorem 4: let us fix an iterated wreath product $W = W_{m,r}$ for some $m \geq 0$, $r \geq 1$ (recall that $W_{0,r} = \mathbb{Z}^r$ and $W_{m+1,r} = \mathbb{Z}^r \wr W_{m,r}$). Since $\mathbb{Z}^m$ is orderable, Theorem 7 implies that W is orderable. Moreover, by Theorem 10, W is also knapsack-semilinear. Since by Lemma 11, $\mathsf{E}_A(n)$ is exponentially bounded for every f.g. abelian group A, it follows from Theorem 22 that $\mathsf{E}_W(n)$ is exponentially bounded as well. By Theorem 3 and Lemma 12, $\textsc{ExpEq}(W)$ belongs to NP. Finally, NP-hardness of $\textsc{ExpEq}(W)$ follows from the fact that the question whether a given system of linear Diophantine equations with unary encoded numbers has a solution in $\mathbb{N}$ is NP-hard.

6 Wreath products with difficult knapsack and power word problems

In this section we provide additional details concerning Theorems 5 and 6. We start with a formal definition of uniformly SENS groups [3].

Strongly efficiently non-solvable groups. Let us fix a f.g. group $G = \langle \Sigma \rangle$. Following [3] we need the additional assumption that the generating set Σ contains the group identity 1. This allows to pad words over Σ to any larger length without changing the group element represented by the word. One also says that Σ is a *standard generating set* for G. The group G is called *strongly efficiently non-solvable (SENS)* if there is a constant $\mu \in \mathbb{N}$ such that for every $d \in \mathbb{N}$ and $v \in \{0,1\}^{\leq d}$ there is a word $w_{d,v} \in \Sigma^*$ with the following properties:

- $|w_{d,v}| = 2^{\mu d}$ for all $v \in \{0,1\}^d$,
- $w_{d,v} = [w_{d,v0}, w_{d,v1}]$ for all $v \in \{0,1\}^{<d}$ (here we take the commutator of words),
- $w_{d,\varepsilon} \neq 1$ in G.

The group G is called *uniformly strongly efficiently non-solvable* if, moreover,

- given $v \in \{0,1\}^d$, a binary number i with μd bits, and $a \in \Sigma$ one can decide in linear time on a random access Turing-machine whether the i-th letter of $w_{d,v}$ is a.

In [3] the authors defines also the weaker condition of being (uniformly) efficiently non-solvable. The definition is more technical and it is not clear whether it really leads to a larger class of groups. Examples for uniformly SENS groups are: finite non-solvable groups (more generally, every f.g. group that has a finite non-solvable quotient), f.g. non-abelian free groups, Thompson's group F, and weakly branched self-similar groups with a f.g. branching subgroup (this includes several famous self-similar groups like the Grigorchuk group, the Gupta-Sidki groups and the Tower of Hanoi groups); see [3] for details.

Wreath products with difficult knapsack problems. Recall that Theorem 6 states that $\mathrm{KP}(G \wr \mathbb{Z})$ is Σ_2^p-hard for every uniformly SENS group G. For the proof we consider G-programs. A *G-program* is a sequence of instructions (X, a, b) where X is a boolean variable and a, b are generators of G. Given an assignment for the boolean variables, one can evaluate the G-program in the natural way: If X is set to 1 (resp., 0) then the instruction (X, a, b) evaluates to a (resp. b). The resulting sequence of group generators evaluates to an element of G and this is the evaluation of the G-program under the given assignment. We consider now the following computational problem $\exists\forall\text{-}\textsc{Sat}(G)$: Given a G-program P, whose variables are split into two sets $\overline{X}$ and $\overline{Y}$, does there exist an assignment $\alpha : \overline{X} \to \{0,1\}$ such that for every assignment $\beta : \overline{Y} \to \{0,1\}$ the program P evaluates to the group identity under the combined assignment $\alpha \cup \beta$?

We prove Theorem 6 in two steps. The first is Σ_2^p-hardness of $\exists\forall\text{-}\textsc{Sat}(G)$.

▶ **Lemma 23.** *Let the f.g. group $G = \langle \Sigma \rangle$ be uniformly SENS. Then, $\exists\forall\text{-}\textsc{Sat}(G)$ is Σ_2^p-hard.*

Proof. We prove the lemma by a reduction from the following Σ_2^p-complete problem: given a boolean formula $F = F(\overline{X}, \overline{Y})$ in disjunctive normal form, where $\overline{X}$ and $\overline{Y}$ are disjoint tuples of boolean variables, does the quantified boolean formula $\exists \overline{X} \forall \overline{Y} : F$ hold? Let us fix such a formula $F(\overline{X}, \overline{Y})$. We can write F as a fan-in two boolean circuit of depth $\mathcal{O}(\log |F|)$.

By [3, Remark 34] we can compute in logspace from F a G-program P over the variables $\overline{X} \cup \overline{Y}$ of length polynomial in $|F|$ such that for every assignment $\gamma : \overline{X} \cup \overline{Y} \to \{0,1\}$ the following two statements are equivalent:

- $F(\gamma(\overline{X}), \gamma(\overline{Y}))$ holds.
- $P(\gamma) = 1$ in G.

Hence, $\exists\overline{X}\forall\overline{Y} : F$ holds if and only if $\exists\overline{X}\forall\overline{Y} : P = 1$ holds. ◀

The second step is to reduce $\exists\forall$-SAT(G) to KP($G \wr \mathbb{Z}$). In fact, this reduction works for any f.g. group G.

▶ **Lemma 24.** *For every f.g. nontrivial group G, $\exists\forall$-SAT(G) is logspace many-one reducible to KP($G \wr \mathbb{Z}$).*

Proof sketch. Let us fix a G-program

$$P = (Z_1, a_1, b_1)(Z_2, a_2, b_2) \cdots (Z_\ell, a_\ell, b_\ell) \in ((\overline{X} \cup \overline{Y}) \times \Sigma \times \Sigma)^*$$

where $\overline{X}$ and $\overline{Y}$ are disjoint sets of variables. Let $m = |\overline{X}|$ and $n = |\overline{Y}|$. We want to construct a knapsack expression E over $G \wr \mathbb{Z}$ which has a solution if and only if there is an assignment $\alpha : \overline{X} \to \{0,1\}$ such that $P(\alpha \cup \beta) = 1$ for every assignment $\beta : \overline{Y} \to \{0,1\}$. Let us choose a generator t for $\mathbb{Z}$. Then $\Sigma \cup \{t, t^{-1}\}$ generates the wreath product $G \wr \mathbb{Z}$. First, we compute in logspace the $m+n$ first primes $p_1, \ldots, p_{m+n}$ and fix a bijection $p : \overline{X} \cup \overline{Y} \to \{p_1, \ldots, p_{m+n}\}$. Moreover, let $M = \prod_{i=1}^{m+n} p_i$.

Roughly speaking, the idea is as follows. Each assignment $\alpha : \overline{X} \to \{0,1\}$ will correspond to a valuation ν for our expression E. The resulting element $\nu(E) \in G \wr \mathbb{Z}$ then encodes the value $P(\alpha \cup \beta)$ for each $\beta \colon \overline{Y} \to \{0,1\}$ in some position $s \in [0, M-1]$. To be precise, to each $s \in [0, M-1]$, we associate the assignment $\beta_s \colon \overline{Y} \to \{0,1\}$ where $\beta_s(Y) = 1$ if and only if $s \equiv 0 \bmod p(Y)$. Then, $\tau(\nu(E))(s)$ will be $P(\alpha \cup \beta_s)$. This means, $\nu(E) = 1$ implies that $P(\alpha \cup \beta) = 1$ for all assignments $\beta \colon \overline{Y} \to \{0,1\}$.

Our expression implements this as follows. For each $i = 1, \ldots, \ell$, it walks to the right to some position $M' \geq M$ and then walks back to the origin. On the way to the right, the behavior depends on whether Z_i is an existential or a universal variable. If Z_i is existential, we either place a_i at every position (if $\alpha(Z_i) = 1$) or b_i at every position (if $\alpha(Z_i) = 0$). If Z_i is universal, we place a_i in the positions divisible by $p(Z_i)$; and we place b_i in the others. That way, in position $s \in [0, M-1]$, the accumulated element will be $P(\alpha \cup \beta_s)$. The complete proof can be found in the full version [9]. ◀

Let us now show some applications of Theorem 6:

▶ **Corollary 25.** *KP($G \wr \mathbb{Z}$) is Σ_2^p-complete for G finite non-solvable or f.g.non-abelian free.*

Proof. Finite non-solvable groups and f.g. non-abelian free groups are uniformly SENS [3]. By Theorem 6, KP($G \wr \mathbb{Z}$) is Σ_2^p-hard. It remains to show that KP($G \wr \mathbb{Z}$) belongs to Σ_2^p. According to [12] (see also the proof of Theorem 2) it suffices to show that PERIODIC(G) and EXPEQ(G) both belong to Σ_2^p. The problem PERIODIC(G) belongs to coNP (since the word problem for G can be solved in polynomial time) and EXPEQ(G) belongs to NP. For a finite group this is clear and for a free group one can use [29]. ◀

Theorem 6 can be also applied to Thompson's group F. This is one of the most well studied groups in (infinite) group theory due to its unusual properties, see e.g. [5]. It can be defined in several ways; let us just mention the following finite presentation: $F = \langle x_0, x_1 \mid [x_0x_1^{-1}, x_0^{-1}x_1x_0], [x_0x_1^{-1}, x_0^{-2}x_1x_0^2] \rangle$. Thompson's group F is uniformly SENS [3] and contains a copy of $F \wr \mathbb{Z}$ [14]. Theorem 6 yields:

▶ **Corollary 26.** *The knapsack problem for Thompson's group F is Σ_2^p-hard.*

We conjecture Σ_2^p-completeness. Since F is co-context-free [23], KP(F) is decidable [22].

Wreath product with difficult power word problems. In [27] it was shown that the problem PowerWP($G \wr \mathbb{Z}$) is coNP-complete in case G is a finite non-solvable group or a f.g. free group. The proof in [27] immediately generalizes to the case were G is uniformly SENS. This yields Theorem 5. Alternatively, one can prove Theorem 5 by showing that

- $\forall$-Sat(G) (the question whether a given G-program P evaluates to the group identity for all assignment) is coNP-hard if G is uniformly SENS, and
- $\forall$-Sat(G) is logspace many-one reducible to PowerWP($G \wr \mathbb{Z}$).

This can be shown with the same reductions as in Lemmas 23 and 24.

Fix a f.g. group $G = \langle \Sigma \rangle$. With WP$(G, \Sigma)$ we denote the set of all words $w \in \Sigma^*$ such that $w = 1$ in G (the word problem for G with respect to Σ). We say that G is *co-context-free* if $\Sigma^* \setminus \mathrm{WP}(G, \Sigma)$ is context-free (the choice of Σ is not relevant for this) [18, Section 14.2].

▶ **Theorem 27.** *The power word problem for a co-context-free group G belongs to* coNP*.*

Proof. The following argument is similar to the decidability proof for knapsack in co-context-free groups in [22]. Let $G = \langle \Sigma \rangle$ and let $(u_1, k_1, u_2, k_2, \dots, u_d, k_d)$ be the input power word, where $u_i \in \Sigma^*$. We can assume that all k_i are positive. We have to check whether $u_1^{k_1} u_2^{k_2} \cdots u_d^{k_d}$ is trivial in G. Let L be the complement of WP(G, Σ), which is context-free. Take the alphabet $\{a_1, \dots, a_d\}$ and define the morphism $h : \{a_1, \dots, a_d\}^* \to \Sigma^*$ by $h(a_i) = u_i$. Consider the language $K = h^{-1}(L) \cap a_1^* a_2^* \cdots a_d^*$. Since the context-free languages are closed under inverse morphisms and intersections with regular languages, K is context-free too. Moreover, from the tuple $(u_1, u_2, \dots, u_d)$ we can compute in polynomial time a context-free grammar for K: Start with a push-down automaton M for L (since L is a fixed language, this is an object of constant size). From M one can compute in polynomial time a push-down automaton M' for $h^{-1}(L)$: when reading the symbol a_i, M' has to simulate (using ε-transitions) M on $h(a_i)$. Next, we construct in polynomial time a push-down automaton M'' for $h^{-1}(L) \cap a_1^* a_2^* \cdots a_d^*$ using a product construction. Finally, we transform M'' back into a context-free grammar. This is again possible in polynomial time using the standard triple construction. It remains to check whether $a_1^{k_1} a_2^{k_2} \cdots a_d^{k_d} \notin L(G)$. This is equivalent to $(k_1, k_2, \dots, k_d) \notin \Psi(L(G))$, where $\Psi(L(G))$ denotes the Parikh image of $L(G)$. Checking $(k_1, k_2, \dots, k_d) \in \Psi(L(G))$ is an instance of the uniform membership problem for commutative context-free languages, which can be solved in NP according to [19]. This implies that the power word problem for G belongs to coNP. ◀

▶ **Theorem 28.** *For Thompson's group F, the power word problem is* coNP*-complete.*

Proof. Since F is co-context-free [23], Theorem 27 yields the upper bound. The lower bound follows from Theorem 5 and the facts that F is uniformly SENS and that $F \wr \mathbb{Z} \leq F$. ◀

7 Open problems

Our results naturally lead to several open research problems:

- Theorems 1 and 5 leave some room for further improvements. In this context, a particularly interesting problem is the power word problem for a wreath product $G \wr \mathbb{Z}$, where G is finite solvable but not nilpotent. Recall that for Theorem 5 we reduced $\forall$-Sat(G) to PowerWP($G \wr \mathbb{Z}$). This reduction works for every non-trivial f.g. group. Moreover, the problem whether a given equation $u = v$ with variables holds in G for all assignments of the variables to elements of G (called EqnId(G) in [44]) can be easily reduced to ∀-Sat(G). This allows us to apply recent results from [44], where the author constructs finite solvable groups G for which EqnId(G) cannot be solved in polynomial time assuming the exponential time hypothesis (this holds for instance for all finite solvable groups of Fitting length at least 4). Hence, there is no hope to find a polynomial time algorithm for the power word problem for $G \wr \mathbb{Z}$ for every finite solvable group G, but one can still look at restricted classes of solvable groups.

- We believe that in Theorem 22, the assumption that H is orderable is not needed. In other words, we conjecture the following: Let H and A be f.g. groups where A is abelian and H is knapsack-semilinear. If $\mathsf{E}_H(n)$ is exponentially bounded then so is $\mathsf{E}_{A \wr H}(n)$.
- Recall the we proved that knapsack for Thompson's group F is Σ_2^p-hard. Decidability of knapsack for Thompson's group F follows from [22] and the fact that F is co-context-free. It is shown in [22] that for every co-context-free group the knapsack problem reduces to checking non-universality of the Parikh image of a bounded context-free language. The latter problem belongs to $\mathsf{NEXPTIME}$ [20, Theorem 2.10] (see also [16, Corollary 1]). It would be interesting to find better complexity bounds for this problem.

Abstract

In this paper, we study the notion of adversarial Stackelberg value for two-player non-zero sum games played on bi-weighted graphs with the mean-payoff and the discounted sum functions. The adversarial Stackelberg value of Player 0 is the largest value that Player 0 can obtain when announcing her strategy to Player 1 which in turn responds with any of his best response. For the mean-payoff function, we show that the adversarial Stackelberg value is not always achievable but ϵ-optimal strategies exist. We show how to compute this value and prove that the associated threshold problem is in NP. For the discounted sum payoff function, we draw a link with the target discounted sum problem which explains why the problem is difficult to solve for this payoff function. We also provide solutions to related gap problems.

Acknowledgements We thank anonymous reviewers, Dr. Shibashis Guha and Ms. Mrudula Balachander for useful comments on a preliminary version of this paper.

1 Introduction

In this paper, we study two-player non-zero sum infinite duration quantitative games played on graph games. In non-zero sum games, the notion of worst-case value is not rich enough to reason about the (rational) behavior of players. More elaborate solution concepts have been proposed in game theory to reason about non-zero sum games: Nash equilibria, subgames perfect equilibria, admissibility, and Stackelberg equilibria are important examples of such solution concepts, see e.g. [18] and [19].

Let us first recall the abstract setting underlying the notion of Stackelberg equilibria and explain the variant that is the focus of this paper. Stackelberg games are strategic games played by two players. We note Σ_0 the set of strategies of Player 0, also called

47th International Colloquium on Automata, Languages, and Programming (ICALP 2020).

the *leader*, and Σ_1 the set of strategies of Player 1, also called the *follower*. Additionally, the game comes with two (usually $\mathbb{R}$-valued) payoff functions, Payoff_0 and Payoff_1, that determine the payoff each player receives: if $\sigma_0 \in \Sigma_0$ and $\sigma_1 \in \Sigma_1$ are chosen then Player 0 receives the payoff $\mathsf{Payoff}_0(\sigma_0, \sigma_1)$ while Player 1 receives the payoff $\mathsf{Payoff}_1(\sigma_0, \sigma_1)$. Both players aim at maximizing their respective payoffs, and in a Stackelberg game, players play sequentially as follows. ① Player 0, the leader, announces her choice of strategy $\sigma_0 \in \Sigma_0$. ② Player 1, the follower, announces his choice of strategy $\sigma_1 \in \Sigma_1$. ③ Both players receive their respective payoffs: $\mathsf{Payoff}_0(\sigma_0, \sigma_1)$ and $\mathsf{Payoff}_1(\sigma_0, \sigma_1)$. Due to the sequential nature of the game, Player 1 knows the strategy σ_0, and so to act rationally (s)he should choose a strategy σ_1 that maximizes the payoff $\mathsf{Payoff}_1(\sigma_0, \sigma_1)$. If such a strategy σ_1 exists, it is called a *best-response* [1] to the strategy $\sigma_0 \in \Sigma_0$. In turn, if the leader assumes a rational response of the follower to her strategy, this should guide the leader when choosing $\sigma_0 \in \Sigma_0$. Indeed, the leader should choose a strategy $\sigma_0 \in \Sigma_0$ such that the value $\mathsf{Payoff}_0(\sigma_0, \sigma_1)$ is as large as possible when σ_1 is a best-response of the follower.

Two different scenarios can be considered in this setting: either the best-response $\sigma_1 \in \Sigma_1$ is imposed by the leader (or equivalently chosen *cooperatively* by the two players), or the best-response is chosen *adversarially* by Player 1. In classical results from game theory and most of the close related works on games played on graphs [13, 15], with the exception of [17], only the cooperative scenario has been investigated. But, the adversarial case is interesting because it allows us to model the situation in which the leader chooses $\sigma_0 \in \Sigma_0$ only and must be prepared to face any rational response of Player 1, i.e. if Player 1 has several possible best responses then σ_0 should be designed to face all of them. In this paper, our main contribution is to investigate the second route. As already noted in [17], this route is particularly interesting for applications in *automatic synthesis*. Indeed, when designing a program, and this is especially true for reactive programs [20, 2], we aim for robust solutions that works for multiple rational usages, e.g. all the usages that respect some specification or that maximize some measure for the user.

To reflect the two scenarios above, there are two notions of *Stackelberg values*. First, the *cooperative Stackelberg value* is the largest value that Player 0 can secure by proposing a strategy σ_0 and a strategy σ_1 to the follower with the constraint that σ_1 is a best-response for the follower to σ_0. Second, the *adversarial Stackelberg value* is the largest value that Player 0 can secure by proposing a strategy σ_0 and facing any best response σ_1 of the follower to the strategy σ_0. In this paper, we mostly concentrate on the *adversarial* Stackelberg value, for infinite duration games played on bi-weighted game graphs for the mean-payoff function and the discounted sum function. The cooperative case has been studied in [13, 15] and we only provide some additional results when relevant for that case (see also related works below).

Main contributions. First, we consider the mean-payoff function. For this payoff function, best responses of Player 1 to a strategy $\sigma_0 \in \Sigma_0$ not always exist (Lemma 3). As a consequence, the *cooperative* (CSV) and *adversarial* (ASV) Stackelberg values are defined using ϵ-best responses. While strategies of Player 0 to achieve CSV always exist as shown in [13], we show that it is not the case for ASV (Theorem 4). The ASV can only be approached in general and memory may be necessary to play optimally or ϵ-optimally in adversarial Stackelberg games for the mean-payoff function (Theorem 4). We also provide results for related algorithmic

[1] As we will see later in the paper, sometimes, best-responses are not guaranteed to exist. In such cases, we need to resort to weaker notions such as ϵ-best-responses. We leave those technical details for later in the paper.

problems. We provide a notion of witness for proving that the ASV is (strictly) above some threshold (Theorem 5), and it is the basis for an NP algorithm to solve the threshold problem (Theorem 7). Finally, we show how the ASV can be computed effectively (Theorem 12).

Second, we consider the discounted sum function. In that case, best responses of Player 1 to strategies $\sigma_0 \in \Sigma_0$ of Player 0 always exist (Lemma 13). The CSV and ASV are directly based on best-responses in that case. Then we draw a link between the *target discounted sum problem* and the CSV threshold problem (Lemma 15). The target discounted sum problem has been studied recently in [1], left open there for the general case and shown to be related to other open problems in piecewise affine maps and the representation of numbers in nonintegral bases. As a consequence, we introduce a relaxation of the threshold problems for both CSV and ASV in the form of gap problems (or promised problems as defined in [12]). We provide algorithms to solve those gap problems (Theorem 17) both for CSV and ASV. Finally, we prove NP-hardness for the gap problems both for CSV and ASV (Theorem 18).

Closely related work. The notions of cooperative and adversarial synthesis have been introduced in [11, 17], and further studied in [7, 10]. Those two notions are closely related to our notion of cooperative and adversarial Stackelberg value respectively. The games that are considered in those papers are infinite duration games played on graphs but they consider Boolean ω-regular payoff functions or finite range ω-regular payoff functions. Neither the mean-payoff function nor the discounted sum payoff function are ω-regular, and thus they are not considered in [11, 17]. The ω-regularity of the payoff functions that they consider is central to their techniques: they show how to reduce their problems to problems on tree automata and strategy logic. Those reductions cannot be used for payoff functions that are *not* ω-regular functions and we need specific new techniques to solve our problems.

In [13, 15], the cooperative scenario for Stackelberg game is studied for mean-payoff and discounted sum respectively. Their results are sufficient to solve most of the relevant questions on the CSV but not for ASV. Indeed, the techniques that are used for CSV are closely related to the techniques that are used to reason on Nash equilibria and build on previous works [4] which in turn reduce to algorithmic solutions for zero-sum one dimensional mean-payoff (or discounted sum games). For the ASV in the context of the mean-payoff function, we have to use more elaborate multi-dim. mean-payoff games and a notion of Pareto curve adapted from [3]. Additionally, we provide new results on the CSV for the discounted sum function. First, our reduction that relates the target discounted sum problem to the CSV is new and gives additional explanations why the CSV is difficult to solve and not solved in the general case in [15]. Second, while we also leave the general problem open here, we show how to solve the gap problems related to both CSV and ASV. Finally, the authors of [14] study *incentive equilibria* for multi-player mean-payoff games. This work is an extension of their previous work [13] and again concentrates on CSV and does not consider ASV.

Structure of the paper. In Sect. 2, we introduce the necessary preliminaries for our definitions and developments. In Sect. 3, we consider the adversarial Stackelberg value for the mean-payoff function. In Sect. 4, we present our results for the discounted sum function.

2 Preliminaries and notations

Arenas. A (bi-weighted) *arena* $\mathcal{A} = (V, E, \langle V_0, V_1 \rangle, w_0, w_1)$ consists of a finite set V of vertices, a set $E \subseteq V \times V$ of edges such that for all $v \in V$ there exists $v' \in V$ such that $(v, v') \in E$, a partition $\langle V_0, V_1 \rangle$ of V, where V_0 (resp. V_1) is the set of vertices for Player 0 (resp. Player 1), and two edge weight functions $w_0 : E \mapsto \mathbb{Z}, w_1 : E \mapsto \mathbb{Z}$. In the sequel, we denote the maximum absolute value of a weight in $\mathcal{A}$ by W. As arenas are directed weighted graphs, we use, sometimes without recalling the details, the classical vocabulary for directed graphs. E.g., a set of vertices $S \subseteq V$ is a strongly connected component of the arena (SCC for short), if for all $s_1, s_2 \in S$, there exists a path from s_1 to s_2 and a path from s_2 to s_1.

Plays and histories. A *play* in $\mathcal{A}$ is an infinite sequence of vertices $\pi = \pi_0\pi_1 \cdots \in V^\omega$ such that for all $k \in \mathbb{N}, (\pi_k, \pi_{k+1}) \in E$. We denote by $\mathsf{Plays}_\mathcal{A}$ the set of plays in $\mathcal{A}$, omitting the subscript $\mathcal{A}$ when the underlying arena is clear from the context. Given $\pi = \pi_0\pi_1 \cdots \in \mathsf{Plays}_\mathcal{A}$ and $k \in \mathbb{N}$, the prefix $\pi_0\pi_1 \dots \pi_k$ of π (resp. suffix $\pi_k\pi_{k+1} \dots$ of π) is denoted by $\pi_{\leq k}$ (resp. $\pi_{\geq k}$). An *history* in $\mathcal{A}$ is a (non-empty) prefix of a play in $\mathcal{A}$. The length $|h|$ of an history $h = \pi_{\leq k}$ is the number $|h| = k$ of its edges. We denote by $\mathsf{Hist}_\mathcal{A}$ the set of histories in $\mathcal{A}$, $\mathcal{A}$ is omitted when clear from the context. Given $i \in \{0, 1\}$, the set $\mathsf{Hist}^i_\mathcal{A}$ denotes the set of histories such that their last vertex belongs to V_i. We denote the last vertex of a history h by $\mathsf{last}(h)$. We write $h \leq \pi$ whenever h is a prefix of π. A play π is called a lasso if it is obtained as the concatenation of a history h concatenated with the infinite repetition of another history l, i.e. $\pi = h \cdot l^\omega$ with $h, l \in \mathsf{Hist}_\mathcal{A}$ (notice that l is not necessary a simple cycle). The *size* of a lasso $h \cdot l^\omega$ is defined as $|h \cdot l|$. Given a vertex $v \in V$ in the arena $\mathcal{A}$, we denote by $Succ(v) = \{v'|(v, v') \in E\}$ the set of successors of v and by $Succ^*$ its transitive closure.

Games. A *game* $\mathcal{G} = (\mathcal{A}, \langle \mathsf{Val}_0, \mathsf{Val}_1 \rangle)$ consists of a bi-weighted arena $\mathcal{A}$, a value function $\mathsf{Val}_0 : \mathsf{Plays}_\mathcal{A} \mapsto \mathbb{R}$ for Player 0 and a value function $\mathsf{Val}_1 : \mathsf{Plays}_\mathcal{A} \mapsto \mathbb{R}$ for Player 1. In this paper, we consider the classical *mean-payoff* and *discounted-sum* value functions. Both are played in bi-weighted arenas.

In a *mean-payoff* game $\mathcal{G} = (\mathcal{A}, \langle \mathsf{MP}_0, \mathsf{MP}_1 \rangle)$ the payoff functions $\mathsf{MP}_0, \mathsf{MP}_1$ are defined as follows. Given a play $\pi \in \mathsf{Plays}_\mathcal{A}$ and $i \in \{0, 1\}$, the payoff $\underline{\mathsf{MP}}_i(\pi)$ is given by $\underline{\mathsf{MP}}_i(\pi) = \liminf_{k\to\infty} \frac{1}{k} w_i(\pi_{\leq k})$, where the weight $w_i(h)$ of an history $h \in \mathsf{Hist}$ is the sum of the weights assigned by w_i to its edges. In our definition of the mean-payoff, we have used $\liminf$, we will also need the $\limsup$ case for technical reasons. Here is the formal definition together with its notation: $\overline{\mathsf{MP}}_i(\pi) = \limsup_{k\to\infty} \frac{1}{k} w_i(\pi_{\leq k})$

For a given discount factor $0 < \lambda < 1$, a *discounted sum* game is a game $\mathcal{G} = (\mathcal{A}, \langle \mathsf{DS}^\lambda_0, \mathsf{DS}^\lambda_1 \rangle)$ where the payoff functions $\mathsf{DS}^\lambda_0, \mathsf{DS}^\lambda_1$ are defined as follows. Given a play $\pi \in \mathsf{Plays}_\mathcal{A}$ and $i \in \{0, 1\}$, the payoff $\mathsf{DS}^\lambda_\mathsf{i}(\pi)$ is defined as $\mathsf{DS}^\lambda_i(\pi) = \sum_{k=0}^{\infty} \lambda^k w_i(\pi_k, \pi_{k+1})$.

Strategies and payoffs. A strategy for Player $i \in \{0, 1\}$ in a game $\mathcal{G} = (\mathcal{A}, \langle \mathsf{Val}_0, \mathsf{Val}_1 \rangle)$ is a function $\sigma : \mathsf{Hist}^i_\mathcal{A} \mapsto V$ that maps histories ending with a vertex $v \in V_i$ to a successor of v. The set of all strategies of Player $i \in \{0, 1\}$ in the game $\mathcal{G}$ is denoted $\Sigma_i(\mathcal{G})$, or Σ_i when $\mathcal{G}$ is clear from the context.

A strategy has memory M if it can be realized as the output of a finite state machine with M states. A memoryless (or positional) strategy is a strategy with memory 1, that is, a function that only depends on the last element of the given partial play. We note Σ^{ML}_i the set of memoryless strategies of Player i, and Σ^{FM}_i its set of finite memory strategies. A *profile* is a pair of strategies $\bar{\sigma} = (\sigma_0, \sigma_1)$, where $\sigma_0 \in \Sigma_0(\mathcal{G})$ and $\sigma_1 \in \Sigma_1(\mathcal{G})$. As we consider games with perfect information and deterministic transitions, any profile $\bar{\sigma}$ yields, from any history h, a unique *play* or *outcome*, denoted $\mathsf{Out}_h(\mathcal{G}, \bar{\sigma})$. Formally, $\mathsf{Out}_h(\mathcal{G}, \bar{\sigma})$ is the play π such that $\pi_{\leq |h|-1} = h$ and $\forall k \geq |h| - 1$ it holds that $\pi_{k+1} = \sigma_i(\pi_{\leq k})$ if $\pi_k \in V_i$. The set of outcomes (resp. histories) compatible with a strategy $\sigma \in \Sigma_{i\in\{0,1\}}(\mathcal{G})$ after a history h is $\mathsf{Out}_h(\mathcal{G}, \sigma) = \{\pi \mid \exists \sigma' \in \Sigma_{1-i}(\mathcal{G})$ such that $\pi = \mathsf{Out}_h(\mathcal{G}, (\sigma, \sigma'))\}$ (resp. $\mathsf{Hist}_h(\sigma) = \{h' \in \mathsf{Hist}(\mathcal{G}) \mid \exists \pi \in \mathsf{Out}_h(\mathcal{G}, \sigma), n \in \mathbb{N} : h' = \pi_{\leq n}\}$.

Each outcome π in $\mathcal{G} = (\mathcal{A}, \langle \mathsf{Val}_0, \mathsf{Val}_1\rangle)$ yields a payoff $\mathsf{Val}(\pi) = (\mathsf{Val}_0(\pi), \mathsf{Val}_1(\pi))$, where $\mathsf{Val}_0(\pi)$ is the payoff for Player 0 and $\mathsf{Val}_1(\pi)$ is the payoff for Player 1. We denote by $\mathsf{Val}(h, \bar{\sigma}) = \mathsf{Val}(\mathsf{Out}_h(\mathcal{G}, \bar{\sigma}))$ the payoff of a profile of strategies $\bar{\sigma}$ after a history h.

Usually, we consider game instances such that players start to play at a fixed vertex v_0. Thus, we call an initialized game a pair $(\mathcal{G}, v_0)$, where $\mathcal{G}$ is a game and $v_0 \in V$ is the initial vertex. When the initial vertex v_0 is clear from context, we speak directly of $\mathcal{G}, \mathsf{Out}(\mathcal{G}, \bar{\sigma}), \mathsf{Out}(\mathcal{G}, \sigma)$, $\mathsf{Val}(\bar{\sigma})$ instead of $(\mathcal{G}, v_0)$, $\mathsf{Out}_{v_0}(\mathcal{G}, \bar{\sigma})$, $\mathsf{Out}_{v_0}(\mathcal{G}, \sigma)$,$\mathsf{Val}(v_0, \bar{\sigma})$. We sometimes simplify further the notation omitting also $\mathcal{G}$, when the latter is clear from the context.

Best-responses and adversarial value in zero-sum games. Let $\mathcal{G} = (\mathcal{A}, \langle \mathsf{Val}_0, \mathsf{Val}_1\rangle)$ be a $(\mathsf{Val}_0, \mathsf{Val}_1)$-game on the bi-weighted arena $\mathcal{A}$. Given a strategy σ_0 for Player 0, we define two sets of strategies for Player 1. His *best-responses* to σ_0, noted $\mathsf{BR}_1(\sigma_0)$, and defined as:

$$\{\sigma_1 \in \Sigma_1 \mid \forall v \in V \cdot \forall \sigma_1' \in \Sigma_1 : \mathsf{Val}_1(\mathsf{Out}_v(\sigma_0, \sigma_1)) \geq \mathsf{Val}_1(\mathsf{Out}_v(\sigma_0, \sigma_1'))\}\,.$$

And his *ϵ-best-responses* to σ_0, for $\epsilon > 0$, noted $\mathsf{BR}_1^{\epsilon}(\sigma_0)$, and defined as:

$$\{\sigma_1 \in \Sigma_1 \mid \forall v \in V \cdot \forall \sigma_1' \in \Sigma_1 : \mathsf{Val}_1(\mathsf{Out}_v(\sigma_0, \sigma_1) \geq \mathsf{Val}_1(\mathsf{Out}_v(\sigma_0, \sigma_1')) - \epsilon\}\,.$$

We also introduce notations for zero-sum games (that are needed as intermediary steps in our algorithms). The adversarial value that Player 1 can enforce in the game $\mathcal{G}$ from vertex v as: $\mathsf{WCV}\ _1(v) = \sup_{\sigma_1 \in \Sigma_1} \inf_{\sigma_0 \in \Sigma_0} \mathsf{Val}_1(\mathsf{Out}_v(\sigma_0, \sigma_1))$. Let $\mathcal{A}$ be an arena, $v \in V$ one of its states, and $\mathcal{O} \subseteq \mathsf{Plays}_{\mathcal{A}}$ be a set of plays (called objective), then we write $\mathcal{A}, v \models \ll i \gg \mathcal{O}$, if $\exists \sigma_i \in \Sigma_i \cdot \forall \sigma_{1-i} \in \Sigma_{1-i} : \mathsf{Out}_v(\mathcal{A}, (\sigma, \sigma')) \in \mathcal{O}$, for $i \in \{0, 1\}$. Here the underlying interpretation is zero-sum: Player i wants to force an outcome in $\mathcal{O}$ and Player $1 - i$ has the opposite goal. All the zero-sum games we consider in this paper are *determined* meaning that for all $\mathcal{A}$, for all objectives $\mathcal{O} \subseteq \mathsf{Plays}_{\mathcal{A}}$ we have that: $\mathcal{A}, v \models \ll i \gg \mathcal{O}$ iff $\mathcal{A}, v \not\models \ll 1 - i \gg \mathsf{Plays}_{\mathcal{A}} \setminus \mathcal{O}$.

Convex hull and F_{min}. First, we need som e additional notations and vocabulary related to linear algebra. Given a finite set of d-dim. vectors $X \subset \mathbb{R}^d$, we note the set of all their convex combinations as $\mathsf{CH}(X) = \{v \mid v = \sum_{x \in X} \alpha_x \cdot x \wedge \forall x \in X : \alpha_x \in [0, 1] \wedge \sum_{x \in X} \alpha_x = 1\}$, this set is called the *convex hull* of X. We also need the following additional, and less standard notions, introduced in [5]. Given a finite set of d-dim. vectors $X \subset \mathbb{R}^d$, let $f_{\mathsf{min}}(X)$ be the vector $v = (v_1, v_2, \ldots, v_d)$ where $v_i = \min\ \{c \mid \exists x \in X : x_i = c\}$, i.e. the vector v is the pointwise minimum of the vectors in X. Let $S \subseteq \mathbb{R}^d$, then $F_{\mathsf{min}}(S) = \{f_{\mathsf{min}}(P) \mid P$ is a finite subset of $S\}$. The following proposition expresses properties of the $F_{\mathsf{min}}(S)$ operator that are useful for us in the sequel. The interested reader will find more results about the F_{min} operator in [5].

▶ **Proposition 1.** *For all sets $S \subseteq \mathbb{R}^d$, for all $x \in F_{min}(S)$, there exists $y \in S$ such that $x \leq y$. If S is a closed bounded set then $F_{min}(S)$ is also a closed bounded set.*

In the sequel, we also use formulas of the theory of the reals with addition and order, noted $\langle \mathbb{R}, +, \leq \rangle$, in order to define subsets of $\mathbb{R}^n$. This theory is decidable and admits effective quantifier elimination [8].

3 Adversarial Stackelberg value for mean-payoff games

Mean-payoffs induced by simple cycles. Given a play $\pi \in \mathsf{Plays}_{\mathcal{A}}$, we note $\mathsf{inf}(\pi)$ the set of vertices v that appear infinitely many times along π, i.e. $\mathsf{inf}(\pi) = \{v \mid \forall i \in \mathbb{N} \cdot \exists j \geq i : v = \pi_j\}$. It is easy to see that $\mathsf{inf}(\pi)$ is an SCC in the underlying graph of the arena $\mathcal{A}$. A *cycle* c is a sequence of edges that starts and stops in a given vertex v, it is *simple* if it does not contain any other repetition of vertices. Given an SCC S, we write $\mathbb{C}(S)$ for the set of simple cycles inside S. Given a simple cycle c, for $i \in \{0,1\}$, let $\mathsf{MP}_i(c) = \frac{w_i(c)}{|c|}$ be the mean of w_i weights along edges in the simple cycle c, and we call the pair $(\mathsf{MP}_0(c), \mathsf{MP}_1(c))$ the *mean-payoff coordinate* of the cycle c. We write $\mathsf{CH}(\mathbb{C}(S))$ for the convex-hull of the set of mean-payoff coordinates of simple cycles of S. The following theorem relates the d-dim. mean-payoff values of infinite plays and the d-dim. mean-payoff of simple cycles in the arena.

▶ **Theorem 2** ([5]). *Let S be an SCC in the arena $\mathcal{A}$, the following two properties hold: (i) for all $\pi \in \mathsf{Plays}_{\mathcal{A}}$, if $\mathit{inf}(\pi) \subseteq S$ then $(\underline{\mathit{MP}}_0(\pi), \underline{\mathit{MP}}_1(\pi)) \in F_{\mathit{min}}(\mathit{CH}(\mathbb{C}(S)))$ (ii) for all $(x,y) \in F_{\mathit{min}}(\mathit{CH}(\mathbb{C}(S)))$, there exists $\pi \in \mathsf{Plays}_{\mathcal{A}}$ such that $\mathit{inf}(\pi) = S$ and $(\underline{\mathit{MP}}_0(\pi), \underline{\mathit{MP}}_1(\pi)) = (x,y)$. Furthermore, the set $F_{\mathit{min}}(\mathit{CH}(\mathbb{C}(S)))$ is effectively expressible in $\langle \mathbb{R}, +, \leq \rangle$.*

In the sequel, we denote by $\Phi_S(x,y)$ the formula with two free variables in $\langle \mathbb{R}, +, \leq \rangle$ such that for all $(u,v) \in \mathbb{R}^2$, $(u,v) \in F_{\mathsf{min}}(\mathsf{CH}(\mathbb{C}(S)))$ if and only if $\Phi_S(x,y)[x/u, y/v]$ is true.

On the existence of best-responses for MP. We start the study of mean-payoff games with some considerations about the existence of best-responses and ϵ-best-responses for Player 1 to strategies of Player 0.

▶ **Lemma 3.** *There is a mean-payoff game $\mathcal{G}$ and a strategy $\sigma_0 \in \Sigma_0(\mathcal{G})$ such that $\mathit{BR}_1(\sigma_0) = \varnothing$. For all mean-payoff games $\mathcal{G}$ and finite memory strategies $\sigma_0 \in \Sigma_0^{\mathit{FM}}(\mathcal{G})$, $\mathit{BR}_1(\sigma_0) \neq \varnothing$. For all mean-payoff games $\mathcal{G}$, for all strategies $\sigma_0 \in \Sigma_0(\mathcal{G})$, for all $\epsilon > 0$, $\mathit{BR}_1^{\epsilon}(\sigma_0) \neq \varnothing$.*

Proof sketch - full proof in the full version [9]. First, in the arena of Fig. 1, we consider the strategy of Player 0 that plays the actions c and d with a frequency that is equal to $1 - \frac{1}{k}$ for c and $\frac{1}{k}$ for d where k is the number of times that Player 1 has played a in state 1 before sending the game to state 2. We claim that there is no best response of Player 1 to this strategy of Player 0. Indeed, taking a one more time before going to state 2 is better for Player 1.

Second, if Player 0 plays a finite memory strategy, then a best response for Player 1 is an optimal path for the mean-payoff of Player 1 in the finite graph obtained as the product of the original game arena with the finite state strategy of Player 0. Optimal mean-payoff paths are guaranteed to exist [16].

Finally, the existence of ϵ-best responses for $\epsilon > 0$, is guaranteed by an analysis of the infinite tree obtained as the unfolding of the game arena with the (potentially infinite memory) strategy of Player 1. Branches of this tree witness responses of Player 1 to the strategy of Player 0. The supremum of the values of those branches for Player 1 is always approachable to any $\epsilon > 0$. ◀

According to Lemma 3, the set of best-responses of Player 1 to a strategy of Player 0 can be empty. As a consequence, we need to use the notion of ϵ-best-responses (which are always guaranteed to exist) when we define the adversarial Stackelberg value:

$$\mathsf{ASV}(\sigma_0)(v) = \sup_{\epsilon \geq 0 \ \mid \ \mathsf{BR}_1^{\epsilon}(\sigma_0) \neq \varnothing} \ \inf_{\sigma_1 \in \mathsf{BR}_1^{\epsilon}(\sigma_0)} \underline{\mathsf{MP}}_0(\mathsf{Out}_v(\sigma_0, \sigma_1)) \text{ and } \mathsf{ASV}(v) = \sup_{\sigma_0 \in \Sigma_0} \mathsf{ASV}(\sigma_0)(v)$$

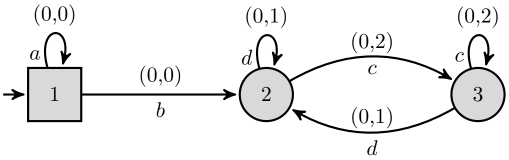

Figure 1 A mean-payoff game in which there exists a Player 0's strategy σ_0 such that $\mathsf{BR}_1(\sigma_0) = \varnothing$.

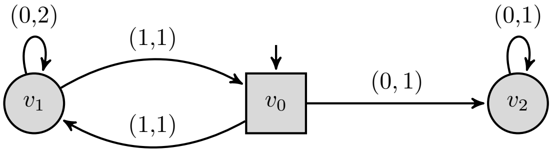

Figure 2 In this game, $\mathsf{ASV}(v_0) = 1$ but there is no Player 0 strategy to achieve this value.

We note that when best-responses to a strategy σ_0 exist, then as expected the following equality holds, because $\mathsf{BR}_1(\sigma_0) = \mathsf{BR}_1^0(\sigma_0)$ and $\mathsf{BR}_1^{\epsilon_1}(\sigma_0) \subseteq \mathsf{BR}_1^{\epsilon_2}(\sigma_0)$ for all $\epsilon_1 \leq \epsilon_2$, ϵ should be taken equal to 0:

$$\mathsf{ASV}(\sigma_0)(v) = \sup_{\epsilon \geq 0 \ \mid \ \mathsf{BR}_1^{\epsilon}(\sigma_0) \neq \varnothing} \ \inf_{\sigma_1 \in \mathsf{BR}_1^{\epsilon}(\sigma_0)} \underline{\mathsf{MP}}_0(\mathsf{Out}_v(\sigma_0, \sigma_1)) = \inf_{\sigma_1 \in \mathsf{BR}_1(\sigma_0)} \underline{\mathsf{MP}}_0(\mathsf{Out}_v(\sigma_0, \sigma_1))$$

Finally, we note that changing the sup over ϵ into an inf in our definition, we get the classical notion of worst-case value in which the rationality of Player 1 and his payoff are ignored. We also recall the definition of CSV, the cooperative Stackelberg value:

$$\mathsf{CSV}(\sigma_0)(v) = \sup_{\epsilon \geq 0 \ \mid \ \mathsf{BR}_1^{\epsilon}(\sigma_0) \neq \varnothing} \ \sup_{\sigma_1 \in \mathsf{BR}_1^{\epsilon}(\sigma_0)} \underline{\mathsf{MP}}_0(\mathsf{Out}_v(\sigma_0, \sigma_1)) \text{ and } \mathsf{CSV}(v) = \sup_{\sigma_0 \in \Sigma_0} \mathsf{CSV}(\sigma_0)(v)$$

The interest reader is referred to [13] for an in-depth treatment of this value.

The adversarial Stackelberg value may not be achievable. In contrast with results in [13] that show that CSV can always be achieved, the following statement expresses the fact that the adversarial Stackelberg value may not be achievable but it can always be approximated by a strategy of Player 0.

▶ **Theorem 4.** *There exists a mean-payoff game $\mathcal{G}$ in which Player 0 has no strategy which enforces the adversarial Stackelberg value. Furthermore, for all mean-payoff games $\mathcal{G}$, for all vertices $v \in V$, for all $\epsilon > 0$, there exists a strategy $\sigma_0 \in \Sigma_0$ such that $\mathsf{ASV}(\sigma_0)(v) > \mathsf{ASV}(v) - \epsilon$. Memory is needed to achieve high ASV.*

Proof sketch - full proof in the full version [9]. First, consider the game depicted in Fig 2. In this game, $\mathsf{ASV}(v_0) = 1$ and it is not achievable. Player 0 needs to ensure that Player 1 does not take the transition from v_0 to v_2 otherwise she gets a payoff of 0. To ensure this, Player 0 needs to choose a strategy (that cycles within $\{v_0, v_1\}$) and that gives to Player 1 at least $1 + \epsilon$ with $\epsilon > 0$. Such strategies gives $1 - \epsilon$ to Player 0, and the value 1 cannot be reached.

Second, by definition of the ASV, the value is obtained as the sup over all strategies of Player 0. As a consequence, ϵ-optimal strategies (for $\epsilon > 0$) exist. ◀

Witnesses for the ASV. Given a mean-payoff game $\mathcal{G}$, we associate with each vertex v, the following set of pairs of real numbers: $\Lambda(v) = \{(c,d) \in \mathbb{R}^2 \mid v \models \ll 1 \gg \underline{\mathsf{MP}}_0 \leq c \wedge \underline{\mathsf{MP}}_1 \geq d\}$. We say that v is (c,d)-bad if $(c,d) \in \Lambda(v)$. Let $c' \in \mathbb{R}$. A play π in $\mathcal{G}$ is called a (c',d)-witness of $\mathsf{ASV}(v) > c$ if it starts from v, $(\underline{\mathsf{MP}}_0(\pi), \underline{\mathsf{MP}}_1(\pi)) = (c', d)$, $c' > c$ and π does not contain any (c,d)-bad vertex. A play π is called a witness of $\mathsf{ASV}(v) > c$ if it is a (c',d)-witness of $\mathsf{ASV}(v) > c$ for some c', d. The following theorem justifies the name witness.

▶ **Theorem 5.** *Let $\mathcal{G}$ be a mean-payoff game and v be one of its vertices. $\mathsf{ASV}(v) > c$ iff there exists a play π in $\mathcal{G}$ such that π is a witness of $\mathsf{ASV}(v) > c$.*

Proof. *From right to left.* Assume the existence of a (c',d)-witness π and let us show that there exists a strategy σ_0 which forces $\mathsf{ASV}(\sigma_0)(v) > c$. We define σ_0 as follows:

1. for all histories $h \leq \pi$ such that *last* (h) belongs to Player 0, $\sigma_0(h)$ follows π.
2. for all histories $h \not\leq \pi$ where there has been a deviation from π by Player 1, we assume that Player 0 switches to a strategy that we call *punishing*. This strategy is defined as follows. In the subgame after history h' where h' is a first deviation by Player 1 from π, we know that Player 0 has a strategy to enforce the objective: $\underline{\mathsf{MP}}_0 > c \vee \underline{\mathsf{MP}}_1 < d$. This is true because π does not cross any (c,d)-bad vertex. So, we know that $h' \not\models \ll 1 \gg \underline{\mathsf{MP}}_0 \leq c \wedge \underline{\mathsf{MP}}_1 \geq d$ which entails the previous statement by determinacy of n-dimension mean-payoff games [21] (here $n = 2$).
3. for all other histories h, Player 0 can behave arbitrarily as those histories are never reached when Player 0 plays as defined in point 1 and 2 above.

Let us now establish that the strategy σ_0 satisfies $\mathsf{ASV}(\sigma_0)(v) > c$. We have to show the existence of some $\epsilon \geq 0$ such that $\mathsf{BR}_1^{\epsilon}(\sigma_0) \neq \varnothing$ and for all $\sigma_1 \in \mathsf{BR}_1^{\epsilon}(\sigma_0)$, $\underline{\mathsf{MP}}_0(\mathsf{Out}_v(\sigma_0,\sigma_1)) > c$ holds. For that, we consider two subcases:

1. $\sup_{\sigma_1} \underline{\mathsf{MP}}_1(\mathsf{Out}_v(\sigma_0,\sigma_1)) = d = \underline{\mathsf{MP}}_1(\pi)$. This means that any strategy σ_1 of Player 1 that follows π is for $\epsilon = 0$ a best-response to σ_0. Now let us consider any strategy $\sigma_1 \in \mathsf{BR}_1^0(\sigma_0)$. Clearly, $\pi' = \mathsf{Out}_v(\sigma_0,\sigma_1)$ is such that $\underline{\mathsf{MP}}_1(\pi') \geq d$. If $\pi' = \pi$, we have that $\underline{\mathsf{MP}}_0(\pi') = c' > c$. If $\pi' \neq \pi$, then when π' deviates from π, we know that σ_0 behaves as the punishing strategy and so we have that $\underline{\mathsf{MP}}_0(\pi') > c \vee \underline{\mathsf{MP}}_1(\pi') < d$. But as $\sigma_1 \in \mathsf{BR}_1^0(\sigma_0)$, we conclude that $\underline{\mathsf{MP}}_1(\pi') \geq d$, and so in turn, we obtain that $\underline{\mathsf{MP}}_0(\pi') > c$.
2. $\sup_{\sigma_1} \underline{\mathsf{MP}}_1(\mathsf{Out}_v(\sigma_0,\sigma_1)) = d' > d$. Let $\epsilon > 0$ be such that $d' - \epsilon > d$. By Lemma 3, $\mathsf{BR}_1^{\epsilon}(\sigma_0) \neq \varnothing$. Let us now characterize the value that Player 0 receives against any strategy $\sigma_1 \in \mathsf{BR}_1^{\epsilon}(\sigma_0)$. First, if σ_1 follows π then Player 0 receives $c' > c$. Second, if σ_1 deviates from π, Player 1 receives at least $d' - \epsilon > d$. But by definition of σ_0, we know that if the play deviates from π then Player 0 applies her punishing strategy. Then we know that the outcome satisfies $\underline{\mathsf{MP}}_0 > c \vee \underline{\mathsf{MP}}_1 < d$. But as $d' - \epsilon > d$, we must conclude that the outcome π' is such that $\underline{\mathsf{MP}}_0(\pi') > c$.

From left to right. Let σ_0 such that $\mathsf{ASV}(\sigma_0)(v) > c$. Then by the equivalence shown in the proof of Theorem 4, we know that

$$\exists \epsilon \geq 0 : \mathsf{BR}_1^{\epsilon}(\sigma_0) \neq \varnothing \wedge \forall \sigma_1 \in \mathsf{BR}_1^{\epsilon}(\sigma_0) : \mathsf{Out}_v(\sigma_0,\sigma_1) > c \tag{1}$$

Let ϵ^* be a value for ϵ that makes eq. (1) true. Take any $\sigma_1 \in \mathsf{BR}_1^{\epsilon^*}(\sigma_0)$ and consider $\pi = \mathsf{Out}_v(\sigma_0,\sigma_1)$. We will show that π is a witness for $\mathsf{ASV}(v) > c$.

We have that $\underline{\mathsf{MP}}_0(\pi) > c$. Let $d_1 = \underline{\mathsf{MP}}_1(\pi)$ and consider any $\pi' \in \mathsf{Out}_v(\sigma_0)$. Clearly if $\underline{\mathsf{MP}}_1(\pi') \geq d_1$ then there exists $\sigma_1' \in \mathsf{BR}_1^{\epsilon^*}(\sigma_0)$ such that $\pi' = \mathsf{Out}_{v_0}(\sigma_0,\sigma_1')$ and we conclude that $\underline{\mathsf{MP}}_0(\pi') > c$. So all deviations of Player 1 w.r.t. π against σ_0 are either giving him a $\underline{\mathsf{MP}}_1$ which is less than d_1 or it gives to Player 0 a $\underline{\mathsf{MP}}_0$ which is larger than c. So π is a $(\underline{\mathsf{MP}}_0(\pi), \underline{\mathsf{MP}}_1(\pi))$-witness for $\mathsf{ASV}(v) > c$ as we have shown that π never crosses an $(c, \underline{\mathsf{MP}}_1(\pi))$-bad vertex, and we are done. ◀

The following statement is a direct consequence of the proof of the previous theorem.

▶ **Corollary 6.** *If π is a witness for $\mathsf{ASV}(v) > c$ then all π' such that: $\pi'(0) = v$, the set of vertices visited along π and π' are the same, and $\underline{\mathsf{MP}}_0(\pi') \geq \underline{\mathsf{MP}}_0(\pi)$ and $\underline{\mathsf{MP}}_1(\pi') \geq \underline{\mathsf{MP}}_1(\pi)$, are also witnesses for $\mathsf{ASV}(v) > c$.*

Small witnesses and NP membership. Here, we refine Theorem 5 to establish membership of the threshold problem to NP.

▶ **Theorem 7.** *Given a mean-payoff game $\mathcal{G}$, a vertex v and a rational value $c \in \mathbb{Q}$, it can be decided in nondeterministic polynomial time if $\mathsf{ASV}(v) > c$.*

Proof of Thm. 7 relies on the existence of small witnesses established in the following lemma:

▶ **Lemma 8.** *Given a mean-payoff game $\mathcal{G}$, a vertex v and $c \in \mathbb{Q}$, $\mathsf{ASV}(v) > c$ if and only if there exists an SCC reachable from v that contains two simple cycles ℓ_1, ℓ_2 such that: (i) there exist $\alpha, \beta \in \mathbb{Q}$ such that $\alpha \cdot w_0(\ell_1) + \beta \cdot w_0(\ell_2) = c' > c$, and $\alpha \cdot w_1(\ell_1) + \beta \cdot w_1(\ell_2) = d$ (ii) there is no (c, d)-bad vertex v' along the path from v to ℓ_1, the path from ℓ_1 to ℓ_2, and the path from ℓ_2 to ℓ_1.*

Proof sketch - full proof in the full version [9]. Theorem 5 establishes the existence of a witness π for $\mathsf{ASV}(v) > c$. In turn, we show here that the existence of such a π can be established by a polynomially checkable witness composed of the following elements. First, a simple path from v to the SCC in which π gets trapped in the long run, (ii) two simple cycles (that can produce the value (c', d) of π) by looping at the right frequencies along the two cycles. Indeed, $(\underline{\mathsf{MP}}_0(\pi), \underline{\mathsf{MP}}_1(\pi))$ only depends on the suffix in the SCC in which it gets trapped. Furthermore, by Theorem 2, Proposition 1 and Corollary 6, we know that the mean-payoff of witnesses can be obtained as the convex combination of the mean-payoff coordinates of simple cycles, and 3 such simple cycles are sufficient by the Carathéodory baricenter theorem. A finer analysis of the geometry of the sets allows us to go to 2 cycles only (see the full proof in [9]). ◀

Proof of Theorem 7. According to Lemma 8, the nondeterministic algorithm that establishes the membership to NP guesses a reachable SCC together with the two simple cycles ℓ_1 and ℓ_2, and parameters α and β. Additionally, for each vertex v' that appears along the paths to reach the SCC, on the simple cycles ℓ_1 and ℓ_2, and to connect those simple cycles, the algorithm guesses a memoryless strategy $\sigma_0^{v'}$ for Player 0 that establishes $v' \not\models \ll 1 \gg \underline{\mathsf{MP}}_0 \leq c \wedge \underline{\mathsf{MP}}_1 \geq d$ which means by determinacy of multi-dimensional mean-payoff games, that $v' \models \ll 0 \gg \underline{\mathsf{MP}}_0 > c \vee \underline{\mathsf{MP}}_1 < d$. The existence of those memoryless strategy is established in Propositions 20 and 21 in the full version [9] (in turn those propositions rely on results from [21]). Those memoryless strategies are checkable in PTime [16]. ◀

Computing the ASV in mean-payoff games. The previous theorems establish the existence of a notion of witness for the adversarial Stackelberg value in non zero-sum two-player mean-payoff games. This notion of witness can be used to decide the threshold problem in NPTIME. We now show how to use this notion to effectively compute the ASV. This algorithm is also based on the computation of an effective representation, for each vertex v of the game graph, of the infinite set of pairs $\Lambda(v)$. The following lemma expresses that a symbolic representation of this set of pairs can be constructed effectively. This result is using techniques that have been introduced in [3].

▶ **Lemma 9.** *Given a bi-weighted game graph $\mathcal{G}$ and a vertex $v \in V$, we can effectively construct a formula $\Psi_v(x,y)$ of $\langle \mathbb{R}, +, \leq \rangle$ with two free variables such that $(c,d) \in \Lambda(v)$ if and only if the formula $\Psi_v(x,y)[x/c, y/d]$ is true.*

Extended graph game. From the graph game $\mathcal{G} = (V, E, w_0, w_1)$, we construct the extended graph game $\mathcal{G}^{\mathsf{ext}} = (V^{\mathsf{ext}}, E^{\mathsf{ext}}, w_0^{\mathsf{ext}}, w_1^{\mathsf{ext}})$, whose vertices and edges are defined as follows. The set of vertices is $V^{\mathsf{ext}} = V \times 2^V$. With an history h in $\mathcal{G}$, we associate a vertex in $\mathcal{G}^{\mathsf{ext}}$ which is a pair (v, P), where $v = \mathit{last}\,(h)$ and P is the set of the vertices traversed along h. Accordingly the set of edges and the weight functions are defined as $E^{\mathsf{ext}} = \{((v,P),(v',P')) \mid (v,v') \in E \wedge P' = P \cup \{v'\}\}$ and $w_i^{\mathsf{ext}}((v,P),(v',P')) = w_i((v,v'))$, for $i \in \{0,1\}$. Clearly, there exists a bijection between the plays π in $\mathcal{G}$ and the plays π^{ext} in $\mathcal{G}^{\mathsf{ext}}$ which start in vertices of the form $(v,\{v\})$, i.e. π^{ext} is mapped to the play π in $\mathcal{G}$ that is obtained by erasing the second dimension of its vertices.

▶ **Proposition 10.** *For all game graph $\mathcal{G}$, the following holds:*

1. *Let π^{ext} be an infinite play in the extended graph and π be its projection into the original graph $\mathcal{G}$ (over the first component of each vertex) , the following properties hold: (i) For all $i < j$: if $\pi^{\mathsf{ext}}(i) = (v_i, P_i)$ and $\pi^{\mathsf{ext}}(j) = (v_j, P_j)$ then $P_i \subseteq P_j$. (ii) $\underline{\mathsf{MP}}_i(\pi^{\mathsf{ext}}) = \underline{\mathsf{MP}}_i(\pi)$, for $i \in \{0,1\}$.*
2. *The unfolding of $\mathcal{G}$ from v and the unfolding of $\mathcal{G}^{\mathsf{ext}}$ from $(v,\{v\})$ are isomorphic, and so $\mathsf{ASV}(v) = \mathsf{ASV}(v,\{v\})$.*

By the first point of the latter proposition and since the set of vertices of the graph is finite, the second component of any play π^{ext} stabilises into a set of vertices of $\mathcal{G}$ which we denote by $V^*(\pi^{\mathsf{ext}})$.

We now show how to characterize $\mathsf{ASV}(v)$ with the notion of witness introduced above and the decomposition of G^{ext} into SCC. This is formalized in the following lemma:

▶ **Lemma 11.** *For all mean-payoff games $\mathcal{G}$, for all vertices $v \in V$, let $\mathsf{SCC}^{\mathsf{ext}}(v)$ be the set of strongly-connected components in $\mathcal{G}^{\mathsf{ext}}$ which are reachable from $(v,\{v\})$, then we have*

$$\mathsf{ASV}(v) = \max_{S \in \mathsf{SCC}^{\mathsf{ext}}(v)} \sup\{c \in \mathbb{R} \mid \exists \pi^{\mathsf{ext}} : \pi^{\mathsf{ext}} \textit{ is a witness for } \mathsf{ASV}(v,\{v\}) > c \textit{ and } V^*(\pi^{\mathsf{ext}}) = S\}$$

Proof. First, we note the following sequence of equalities:

$$\begin{aligned}
&\mathsf{ASV}(v)\\
&= \sup\{c \in \mathbb{R} \mid \mathsf{ASV}(v) \geq c\}\\
&= \sup\{c \in \mathbb{R} \mid \mathsf{ASV}(v) > c\}\\
&= \sup\{c \in \mathbb{R} \mid \exists \pi : \pi \text{ is a witness for } \mathsf{ASV}(v) > c\}\\
&= \sup\{c \in \mathbb{R} \mid \exists \pi^{\mathsf{ext}} : \pi^{\mathsf{ext}} \text{ is a witness for } \mathsf{ASV}(v,\{v\}) > c\}\\
&= \max\nolimits_{S \in \mathsf{SCC}^{\mathsf{ext}}(v)} \sup\{c \in \mathbb{R} \mid \exists \pi^{\mathsf{ext}} : \pi^{\mathsf{ext}} \text{ is a witness for } \mathsf{ASV}(v,\{v\}) > c \text{ and } V^*(\pi^{\mathsf{ext}}) = S\}
\end{aligned}$$

The first two equalities are direct consequences of the definition of the supremum and that $\mathsf{ASV}(v) \in \mathbb{R}$. The third is a consequence of Theorem 5 that guarantees the existence of witnesses for strict inequalities. The fourth equality is a consequence of point 2 in Proposition 10. The last equality is the consequence of point 1 in Proposition 10. ◀

By definition of $\mathcal{G}^{\mathsf{ext}}$, for all SCC S of $\mathcal{G}^{\mathsf{ext}}$, there exists a set of vertices of $\mathcal{G}$ which we also denote by $V^*(S)$ such that any vertex of S is of the form $(v, V^*(S))$. The set of bad thresholds for S is then defined as $\Lambda^{\mathsf{ext}}(S) = \bigcup_{v \in V^*(S)} \Lambda(v)$. Applying Lemma 9, we can construct a formula $\Psi_S(x,y)$ which symbolic encodes the set $\Lambda^{\mathsf{ext}}(S)$.

Now, we are equipped to prove that $\mathsf{ASV}(v)$ is effectively computable. This is expressed by the following theorem and established in its proof.

▶ **Theorem 12.** *For all mean-payoff games $\mathcal{G}$, for all vertices $v \in V$, the value $\mathit{ASV}(v)$ can be effectively expressed by a formula ρ_v in $\langle \mathbb{R}, +, \leq \rangle$ and explicitly computed from this formula.*

Proof. To establish this theorem, we show how to build the formula $\rho_v(z)$ that is true iff $\mathsf{ASV}(v) = z$. We use Lemma 11, to reduce this to the construction of a formula that expresses the existence of witnesses for $\mathsf{ASV}(v)$ from $(v, \{v\})$:

$$\mathsf{ASV}(v) = \max_{S \in \mathsf{SCC}^{\mathsf{ext}}(v)} \sup\{c \in \mathbb{R} \mid \exists \pi^{\mathsf{ext}} : \pi^{\mathsf{ext}} \text{ is a witness for } \mathsf{ASV}(v, \{v\}) > c \text{ and } V^*(\pi^{\mathsf{ext}}) = S\}$$

As $\max_{S \in \mathsf{SCC}^{\mathsf{ext}}(v)}$ is easily expressed in $\langle \mathbb{R}, +, \leq \rangle$, we concentrate on one SCC S reachable from $(v, \{v\})$ and we show how to express

$$\sup\{c \in \mathbb{R} \mid \exists \pi^{\mathsf{ext}} : \pi^{\mathsf{ext}} \text{ is a witness for } \mathsf{ASV}(v, \{v\}) > c \text{ and } V^*(\pi^{\mathsf{ext}}) = S\}$$

First, we define a formula that express the existence of a witness for $\mathsf{ASV}(v) > c$. This is done by the following formula:

$$\rho_{v_0}^S(c) \equiv \exists x, y \cdot x > c \wedge \Phi_S(x, y) \wedge \neg \Psi_S(c, y)$$

Where $\Phi_S(x, y)$ is the symbolic encoding of $F_{\mathsf{min}}(\mathsf{CH}(\mathbb{C}(S)))$ as defined in Theorem 2. This ensures that the values (x, y) are the mean-payoff values realizable by some path in S. By Lemma 9, $\neg \Psi_S(c, y)$ expresses that the path does not cross a (c, y)-bad vertex. So the conjunction $\exists x, y \cdot x > c \wedge \Phi_S(x, y) \wedge \neg \Psi_S(c, y)$ establishes the existence of a witness with mean-payoff values (x, y) for the threshold c. From this formula, we can compute the ASV by quantifier elimination in:

$$\exists z \cdot \forall e > 0 \cdot (\rho_{v_0}^S(z - e) \wedge (\forall y \cdot \rho_{v_0}^S(y) \implies y \leq z))$$

and obtain the unique value of z that makes the formula true. ◀

4 Stackelberg values for discounted-sum games

In this section, we study the notion of Stackelberg value in the case of discounted sum measures. Beside the adversarial setting considered so far, we also refer to a *cooperative* framework for discounted sum-games, since we add some results to [15], where the cooperative Stackelberg value for discounted-sum measures has been previously introduced and studied.

On the existence of best-responses for DS. First, we show that the set of best-responses for Player 1 to strategies of Player 0 is guaranteed to be nonempty for discounted sum games, while this was not the case in mean-payoff games.

▶ **Lemma 13.** *For all discounted sum games $\mathcal{G}$ and strategies $\sigma_0 \in \Sigma_0(\mathcal{G})$, $\mathit{BR}_1(\sigma_0) \neq \varnothing$.*

Proof. Given $\sigma \in \Sigma_0(\mathcal{G})$, consider $S = \{\mathsf{DS}_1(\mathsf{Out}(\sigma, \tau)) \mid \tau \in \Sigma_1(\mathcal{G})\}$. S is a non empty limited subset of $\mathbb{R}$, since for each $\tau \in \Sigma_1(\mathcal{G})$ it holds $\mathsf{DS}_1(\mathsf{Out}(\sigma, \tau)) \leq \dfrac{W}{1 - \lambda}$, where W is the maximum absolute value of a weight in $\mathcal{G}$. Hence, S admits a unique superior extreme $s = \mathit{sup}(S)$. By definition of superior extreme, for each $\epsilon > 0$, there exists $v_\epsilon \in S$ such that $s \geq v_\epsilon > s - \epsilon$. Therefore, for each $\epsilon > 0$ there exists $\tau_\epsilon \in \Sigma_1(\mathcal{G})$ such that $s \geq \mathsf{DS}_1(\mathsf{Out}(\sigma, \tau_\epsilon)) > \mathsf{s} - \epsilon$, i.e.:

$$0 \leq s - \mathsf{DS}_1(\mathsf{Out}(\sigma, \tau_\epsilon)) < \epsilon \qquad (2)$$

We show that this implies that $\mathsf{Out}(\sigma)$ contains a play π^* such that $\mathsf{DS}_1(\pi^*) = s$, which leads to $BR_1(\sigma) \neq \varnothing$, since Player 1 has a strategy to achieve $s = sup(\{\mathsf{DS}_1(\mathsf{Out}(\sigma, \tau)) \mid \tau \in \Sigma_1(\mathcal{G})\})$. By contradiction, suppose that $\mathsf{Out}(\sigma)$ does not contain any play π such that $\mathsf{DS}_1(\pi) = s$. Hence, for each $\pi \in \mathsf{Out}(\sigma)$, it holds that $\mathsf{DS}_1(\pi) < s$ and π admits a prefix $\pi_{\leq k}$ such that:

$$\mathsf{DS}_1(\pi_{\leq k}) + W\frac{\lambda^k}{1-\lambda} < s \tag{3}$$

Hence, we can cut each play in $\mathsf{Out}(\sigma)$ as soon as Equation 3 is accomplished, leading to a finite tree T (by Konig lemma, since $\mathsf{Out}(\sigma)$ is finitely branching). Let $\pi^*_T = \pi_0 \dots \pi_k$ be a branch in the finite tree T such that the value $v(\pi^*_T) = s - (\mathsf{DS}_1(\pi^*_T) + W\frac{\lambda^k}{1-\lambda})$ is minimal. Note that, by Equation 3, $v(\pi^*_T) > 0$ since $v(\pi^*_T) = s - (\mathsf{DS}_1(\pi^*_T) + W\frac{\lambda^k}{1-\lambda}) > s - s = 0$.

Then, for each play π, let $\pi_{\leq p}$ be the longest prefix of π which is also a branch in the finite tree T. By definition of π^*_T, we have:

$$s - \mathsf{DS}_1(\pi) \geq s - (\mathsf{DS}_1(\pi_{\leq p}) + W\frac{\lambda^p}{1-\lambda}) \geq v(\pi^*_T) > 0 \tag{4}$$

This leads to a contradiction to the fact that for all $\epsilon > 0$ there exists $\tau \in \Sigma_1(\mathcal{G})$ such that $s - \mathsf{DS}_1(\mathsf{Out}(\sigma, \tau_\epsilon)) < \epsilon$, established within Equation 2. ◀

Stackelberg values for DS in the adversarial and cooperative settings. The existence of best-responses allows us to simplify the notion of Stackelberg value for discounted sum measures, avoiding the parameter ϵ used for mean-payoff games. In particular, the adversarial Stackelberg value $\mathsf{ASV}(v)$ for discounted sum games is defined for all $\sigma_0 \in \Sigma_0(\mathcal{G})$ as:

$$\mathsf{ASV}(\sigma_0)(v) = \inf_{\sigma_1 \in \mathsf{BR}_1(\sigma_0)} \mathsf{DS}^\lambda_0(\mathsf{Out}_v(\sigma_0, \sigma_1)) \text{ and } \mathsf{ASV}(v) = \sup_{\sigma_0 \in \Sigma_0} \mathsf{ASV}(\sigma_0)(v)$$

As previously announced, we also consider the notion of Stackelberg value for discounted sum measures in the cooperative setting, where Player 0 suggests a profile of strategies (σ_0, σ_1) and Player 1 agrees to play σ_1 if the latter strategy is a best response to σ_0. Formally, the cooperative Stackelberg value $\mathsf{CSV}(v)$ for discounted sum games is defined as:

$$\mathsf{CSV}(\sigma_0)(v) = \sup_{\sigma_1 \in \mathsf{BR}_1(\sigma_0)} \mathsf{DS}^\lambda_0(\mathsf{Out}_v(\sigma_0, \sigma_1)) \text{ and } \mathsf{CSV}(v) = \sup_{\sigma_0 \in \Sigma_0} \mathsf{CSV}(\sigma_0)(v)$$

Lemma 15 below links the cooperative Stackelberg value for discounted-sum measures to the *target discounted-sum problem* [1] (cfr. Definition 14), whose decidability is notoriously hard to solve and relates to several open questions in mathematics and computer science [1].

▶ **Definition 14** (Target Discount Sum Problem [1] (TDS)). *Given a rational discount factor $0 < \lambda < 1$ and three rationals a, b, t does there exist an infinite sequence $w \in \{a, b\}^\omega$ such that $\sum_{i=0}^{\infty} w(i)\lambda^i = t$?*

In particular, given an instance $I = (a, b, t, \lambda)$ of the TDS problem, Figure 3 depicts a discounted sum game $\mathcal{G}^I$ such that I admits a solution iff $\mathsf{CSV}(v) \geq \lambda \cdot t$.

▶ **Lemma 15.** *The target discounted-sum problem reduces to the problem of deciding if $\mathsf{CSV}(v) \geq c$ in discounted-sum games.*

Proof. Let $I = (a, b, t, \lambda)$ be an instance of the target discounted sum problem and consider the game $\mathcal{G}^I$ depicted in Figure 3. We prove that I admits a solution iff $\mathsf{CSV}(v) \geq \lambda \cdot t$.

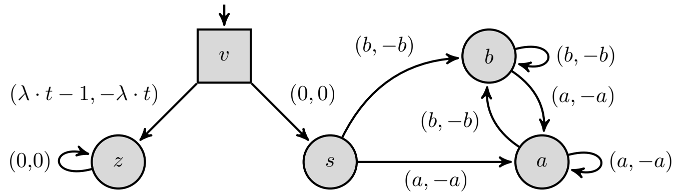

Figure 3 The instance of TDS $I = (a, b, \lambda, t)$ admits a solution iff $\mathsf{CSV}(v) \geq \lambda \cdot t$.

Suppose that I admits a solution and let $w \in \{a,b\}^\omega$ such that $\sum_{i=0}^{\infty} w(i)\lambda^i = t$. Consider the following strategy σ for Player 0: for all $\alpha \in \{a,b\}^*$, $\sigma(vs\alpha) = x$ if $w(|\alpha|) = x$, where $x \in \{a,b\}$. We prove that if τ is a best response to σ, then $\mathsf{DS}_0(\mathsf{Out}(\sigma,\tau)) = \lambda \cdot t$. In fact, Player 1 has two choices from v. Let us denote τ_s (resp. τ_z) the strategy that prescribes to Player 1 to proceed to vertex s (resp. z) out from v. We have that $\mathsf{DS}_1(\mathsf{Out}(\sigma,\tau_\mathsf{s})) = \mathsf{DS}_1(\mathsf{Out}(\sigma,\tau_\mathsf{z})) = -\lambda \cdot t$, by definition of σ and $\mathcal{G}^I$. Hence, τ_s is a best response to σ which guarantees to Player 0 a payoff $\mathsf{DS}_0(\mathsf{Out}(\sigma,\tau_\mathsf{s})) = \lambda \cdot t$.

In the other direction, suppose that I does not admit any solution, i.e. there does not exist an infinite sequence $w \in \{a,b\}^\omega$ such that $\sum_{i=0}^{\infty} w(i)\lambda^i = t$. We prove that for any strategy σ for Player 0, if τ is a best response of Player 1 to σ then $\mathsf{DS}_0(\mathsf{Out}(\sigma,\tau)) < \lambda \cdot t$. Let σ be an arbitrary strategy for Player 0 and consider the strategy τ_z for Player 1.

We have two cases to consider depending on wether τ_z is a best response to σ or not. In the first case, we have that $\mathsf{DS}(\mathsf{Out}(\sigma,\tau_\mathsf{z})) = (\lambda \cdot t - 1, -\lambda \cdot t)$ and, since τ_z is a best response to σ, we need to have $\mathsf{DS}_1(\mathsf{Out}(\sigma,\tau_\mathsf{s})) \leq -\lambda \cdot t$. We can not have that $\mathsf{DS}_1(\mathsf{Out}(\sigma,\tau_\mathsf{s})) = -\lambda \cdot t$, since this would imply $\mathsf{DS}_0(\mathsf{Out}(\sigma,\tau_\mathsf{i})) = -\mathsf{DS}_1(\mathsf{Out}(\sigma,\tau_\mathsf{s})) = \lambda \cdot t$ contradicting our hypothesis that I does not admit any solution. Therefore, $\mathsf{DS}_1(\mathsf{Out}(\sigma,\tau_\mathsf{s})) < -\lambda \cdot t$, meaning that τ_s is not a best response to σ and $\mathsf{CSV}(v) = \lambda \cdot t - 1 < \lambda \cdot t$.

In the second case, where σ_z is not a best response to σ, we have that $\mathsf{DS}_1(\mathsf{Out}(\sigma,\tau_\mathsf{s})) > -\lambda \cdot t$ which implies that $\mathsf{CSV}(v) = \mathsf{DS}_0(\mathsf{Out}(\sigma,\tau_\mathsf{s})) = -\mathsf{DS}_1(\mathsf{Out}(\sigma,\tau_\mathsf{s})) < \lambda \cdot t$. ◀

The construction used to link the cooperative Stackelberg value to the target discounted sum problem can be properly modified[2] to prove that infinite memory may be necessary to allow Player 0 to achieve her CSV, recovering a result originally proved in [15]. In the same paper, the authors show that in 3-player discounted sum games the cooperative Stackelberg value cannot be approximated by considering strategies with bounded memory only. In the next section, we show that this is not the case for 2-player discounted sum games.

Gap problems and their algorithmic solutions. We consider a gap approximation of the Stackelberg value problem in both the cooperative and the adversarial settings. Given $\epsilon > 0$ and $c \in \mathbb{Q}$, and $\mathsf{VAL} \in \{\mathsf{CSV}, \mathsf{ASV}\}$, let us define the sets of games:

- $\mathsf{Yes}^{\epsilon,c}_{\mathsf{VAL}} = \{(\mathcal{G}, v) \mid \mathcal{G} \text{ is a game with } \mathsf{VAL}(v) > c + \epsilon\}$
- $\mathsf{No}^{\epsilon,c}_{\mathsf{VAL}} = \{(\mathcal{G}, v) \mid \mathcal{G} \text{ is a game with } \mathsf{VAL}(v) < c - \epsilon\}$

The (ϵ, c)-CSV-gap (resp. (ϵ, c)-ASV-gap) problem (also referred to as (ϵ, c)-gap problems or just gap problems when ϵ and c are clear from the context) consists in determining if a given game $\mathcal{G}$ and an initial vertex v belong to $\mathsf{Yes}^{\epsilon,c}_{\mathsf{CSV}}$ or $\mathsf{No}^{\epsilon,c}_{\mathsf{CSV}}$ (resp. $\mathsf{Yes}^{\epsilon,c}_{\mathsf{ASV}}$ or $\mathsf{No}^{\epsilon,c}_{\mathsf{ASV}}$). More

[2] Consider the game $\mathcal{G}^I$ depicted in Figure 3 for $a = 0, b = 1, \lambda = \frac{2}{3}, t = \frac{3}{2}$. By Proposition 1 in [6], Player 0 can achieve $\frac{3}{2}$ from s – and therefore CSV(v)=1 – only with infinite memory.

precisely, solving the Stackelberg value gap problem in e.g. the cooperative setting amounts to answer Yes if the instance of the game belongs to $\mathsf{Yes}^{\epsilon,c}_{\mathsf{CSV}}$, answer No if the instance belongs to $\mathsf{No}^{\epsilon,c}_{\mathsf{CSV}}$, never answer or answer arbitrarily otherwise.

Theorem 17 below uses the results in Lemma 16 to provide an algorithm that solves the Stackelberg value gap problem in the cooperative and adversarial settings, for games with discounted sum objectives. In particular, Lemma 16, shows that finite memory strategies are sufficient to witness Stackelberg values strictly greater than a threshold $c \in \mathbb{Q}$.

▶ **Lemma 16.** *Let $\mathcal{G}$ be a discounted-sum game and consider $c \in \mathbb{Q}$ and $\epsilon > 0$. If Player 0 has a strategy σ_0 such that $\mathit{CSV}(\sigma_0)(v) > c + \epsilon$ (resp. $\mathit{ASV}(\sigma_0)(v) > c + \epsilon$), then Player 0 has a strategy σ_0^* with finite memory $M(\epsilon)$ such that $\mathit{CSV}(\sigma_0^*)(v) > c$ (resp. $\mathit{ASV}(\sigma_0^*)(v) > c$). Moreover, $M(\epsilon)$ is computable given ϵ.*

Proof. Let $\sigma^{\mathsf{DS}_1}_{min} \in \Sigma_0$ a memoryless strategy for Player 0 minimizing $sup_{\tau \in \Sigma_1} \mathsf{DS}_1(\mathsf{Out}(\sigma, \tau))$. Let $\sigma^{\mathsf{DS}_1}_{max} \in \Sigma_0$ be a memoryless strategy for Player 0 that maximizes $sup_{\tau \in \Sigma_1} \mathsf{DS}_1(\mathsf{Out}(\sigma, \tau))$. Such memoryless strategies exist since 2-player (single-valued) discounted-sum games are memoryless determined. In particular, $\sigma^{\mathsf{DS}_1}_{min} \in \Sigma_0$ can be obtained by using standard algorithms for two players (single-valued) discounted-sum games. In turn, $\sigma^{\mathsf{DS}_1}_{max} \in \Sigma_0$ can be computed by solving a single player (single valued) discounted-sum game, in which all the nodes are controlled by the maximizer who aims at maximizing DS_1.

Cooperative Setting: Let $\sigma^* \in \Sigma_0(\mathcal{G})$ be a strategy for Player 0 s.t. $\mathsf{DS}_0(\mathsf{Out}(\sigma^*, \tau)) > \mathsf{c} + \epsilon$ for some strategy $\tau \in BR_1(\sigma^*)$. Denote by π^* the play $\pi^* = \mathsf{Out}(\sigma^*, \tau)$ and let N such that $\lambda^N \dfrac{W}{1-\lambda} < \dfrac{\epsilon}{2}$. Given the above premises, consider the finite memory strategy $\sigma' \in \Sigma_0$ for Player 0 that follows σ^* for the first N steps and then either apply the memoryless strategy $\sigma^{\mathsf{DS}_1}_{min} \in \Sigma_0$ or the memoryless strategy $\sigma^{\mathsf{DS}_1}_{max} \in \Sigma_0$, depending on the history h followed up to N. In particular, if $h = \pi^*_{\leq N}$, then the strategy σ' prescribes to Player 0 to follow $\sigma^{\mathsf{DS}_1}_{max} \in \Sigma_0$, cooperating with Player 1 at maximizing DS_1. Otherwise ($h \neq \pi^*_{\leq N}$), the strategy σ' prescribes to Player 0 to follow $\sigma^{\mathsf{DS}_1}_{min} \in \Sigma_0$, minimizing the payoff of the adversary. We show that a best response τ' for Player 1 to σ' consists in following π^* up to N and then applying the memoryless strategy $\tau^{\mathsf{DS}_1}_{max} \in \Sigma_1$, i.e. maximizing $sup_{\sigma \in \Sigma_0} \mathsf{DS}_1(\mathsf{Out}(\sigma, \tau))$. In fact, by definition of σ' and τ' we have that:

- $\mathsf{DS}_1(\mathsf{Out}(\sigma', \tau')) \geq \mathsf{DS}_1(\pi^*)$
- for any other strategy $\tau'' \neq \tau'$ for Player 1:
  - if $\mathsf{Out}(\sigma', \tau'')_{\leq N} = x \neq \pi^*_{\leq N}$, then:

$$\mathsf{DS}_1(\mathsf{Out}(\sigma', \tau'')) = \mathsf{DS}_1(x) + \lambda^N \mathsf{DS}_1(\mathsf{Out}_x(\sigma^{\mathsf{DS}_1}_{min}, \tau'')) \leq$$
$$\leq \mathsf{DS}_1(x) + \lambda^N (sup_{\tau \in \Sigma_1}(\mathsf{DS}_1(\mathsf{Out}_x(\sigma^{\mathsf{DS}_1}_{min}, \tau))) \leq$$
$$\leq \mathsf{DS}_1(x) + \lambda^N (sup_{\tau \in \Sigma_1}(\mathsf{DS}_1(\mathsf{Out}_x(\sigma^*, \tau))) = \mathsf{DS}_1(\pi^*) \leq \mathsf{DS}_1(\mathsf{Out}(\sigma', \tau'))$$

  since $\mathsf{DS}_1(\pi^*)$ is the payoff (for player 1) of a best response of Player 1 to σ^*.
  - if $\mathsf{Out}(\sigma', \tau'')_{\leq N} = x = \pi^*_{\leq N}$, then:

$$\mathsf{DS}_1(\mathsf{Out}(\sigma', \tau'')) \leq \mathsf{DS}_1(x) + \lambda^N \cdot sup\{\mathsf{DS}_1(\pi) \mid \pi \in \mathsf{Plays}(\mathcal{G}) \wedge \pi \text{ starts at } last(x)\} =$$
$$= \mathsf{DS}_1(x) + \lambda^N \cdot \mathsf{DS}_1(\mathsf{Out}_x(\sigma^{\mathsf{DS}_1}_{max}, \tau^{\mathsf{DS}_1}_{max})) = \mathsf{DS}_1(\mathsf{Out}(\sigma', \tau'))$$

Finally, we show that the best response π' of Player 1 to σ' guarantees to Player 0 a payoff greater than c. In fact, $\mathsf{DS}_0(\mathsf{Out}(\sigma', \tau')) > \mathsf{DS}_0(\pi^*_{\leq N}) - \dfrac{\epsilon}{2} > c + \dfrac{\epsilon}{2} - \dfrac{\epsilon}{2} = c$, since $\mathsf{DS}_0(\pi^*_{\leq N}) > c + \dfrac{\epsilon}{2}$. Due to the choice of N, having $\mathsf{DS}_0(\pi^*_{\leq N}) \leq c + \dfrac{\epsilon}{2}$ would lead in fact to the following contradiction: $\mathsf{DS}_0(\pi^*) \leq \mathsf{DS}_0(\pi^*_{\leq N}) + \lambda^N \dfrac{W}{1-\lambda} < \mathsf{DS}_0(\pi^*_{\leq N}) + \dfrac{\epsilon}{2} \leq c + \dfrac{\epsilon}{2} + \dfrac{\epsilon}{2} = c + \epsilon$, i.e. $\mathsf{DS}_0(\pi^*) \leq c + \epsilon$.

Adversarial Setting: Let $\sigma \in \Sigma_0$ be a strategy for Player 0 such that for all $\tau \in BR_1(\sigma)$ it holds $\mathsf{DS}_0(\mathsf{Out}(\sigma, \tau)) > \mathsf{c} + \epsilon$. Let N such that $\lambda^N \dfrac{W}{1-\lambda} < \dfrac{\epsilon}{2}$ and consider the unfolding T of $\mathsf{Out}(\sigma)$ up to N. For each maximal root-to-leaf branch b of T, color its leaf $last(b)$ green if b is the prefix $\pi_{\leq N}$ of some play $\pi = \mathsf{Out}(\sigma, \tau)$ such that $\tau \in BR_1(\sigma)$. Otherwise, let the leaf $last(b)$ of b be colored by red. We show that the finite memory strategy $\sigma^* \in \Sigma_0$ that prescribes to Player 0 to follow σ up to N and then:

- from each green node apply the memoryless strategy $\sigma^{\mathsf{DS}_1}_{max} \in \Sigma_0$ (i.e. cooperate with Player 1 to maximize the payoff DS_1)
- from each red node apply the memoryless strategy $\sigma^{\mathsf{DS}_1}_{min} \in \Sigma_0$ (i.e. minimize the payoff DS_1 of the adversary)

is such that $ASV(\sigma^*) > c$. Let $d = sup\{\mathsf{DS}_1(\mathsf{Out}(\sigma, \tau)) | \tau \in \mathsf{\Sigma}_1(\mathcal{G})\}$ and consider $\pi \in \mathsf{Out}(\sigma^*)$.

First, we show that if π contains a green node then $\mathsf{DS}_0(\pi_{\leq \mathsf{N}}) > \mathsf{c}$. In fact, $\mathsf{DS}_0(\pi_{\leq N}) > \mathsf{DS}_0(\pi_{\leq N}) - \lambda^N \dfrac{W}{1-\lambda} > c + \dfrac{\epsilon}{2} - \dfrac{\epsilon}{2} = c$, since $\lambda^N \dfrac{W}{1-\lambda} < \dfrac{\epsilon}{2}$ by definition of N and since $\mathsf{DS}_0(\pi_{\leq N}) > c + \dfrac{\epsilon}{2}$ being $last(\pi_{\leq N})$ a green node (witnessing that $\pi_{\leq N}$ is the prefix of a play π' compatible with a best response of Player 1 to σ^*, for which $\mathsf{DS}_0(\pi') > \mathsf{c} + \epsilon$).

Moreover, there is a play $\pi \in \mathsf{Out}(\sigma^*)$ containing a green node for which $\mathsf{DS}_1(\pi) \geq d$. This is because of two reasons. First, a play in $\mathsf{Out}(\sigma)$ compatible with a best response to σ by Player 1 is of the form $hv\pi'$, where hv is a maximal root-to-leaf branch b of T with $last(b) = v$ green (by definition of green nodes). Second, for each hystory hv such that hv is a maximal root-to-leaf branch b of T with $last(b) = v$ green, $\mathsf{Out}(\sigma^*)$ contains a play $hv\bar{\pi}$, where $\bar{\pi}$ is a play starting in v maximizing DS_1. Therefore $\mathsf{DS}_1(hv\bar{\pi}) = \mathsf{DS}_1(hv) + \lambda^N \mathsf{DS}_1(\bar{\pi}) \geq \mathsf{DS}_1(hv) + \lambda^N \mathsf{DS}_1(\pi')) = d$, where $hv\pi'$ is a play compatible with a best response of Player 1 to σ. To conclude our proof, we need just to show that each play $\pi \in \mathsf{Out}(\sigma^*)$ containing a red node is such that $\mathsf{DS}_1(\pi) < d$. In fact, being $last(\pi_{\leq N})$ red, the history $\pi_{\leq N}$ can not be a prefix of any play in $\mathsf{Out}(\sigma)$ compatible with a best response of Player 1 to σ. In other words, by playing σ Player 0 allows the adversary to gain a payoff that is at most $r < d$ on each play $\pi = hv\pi'$ with v red. Therefore, switching her strategy from σ to σ^* (i.e. playing σ for the first N turns and then switching to the memoryless strategy $\sigma^{\mathsf{DS}_1}_{min} \in \Sigma_0$) Player 0 is sure to let Player 1 gain a payoff that is at most $r' \leq r < d$ on each play $\pi = hv\pi'$ with v red.

As a conclusion, against σ^* Player 1 can achieve at least a value d. Hence, each best response to σ^* visits a green node (if it does not, then $\mathsf{DS}_1 < d$ which is a contradiction). This guarantees that $\mathsf{DS}_0 > c$. ◀

The approximation algorithm for solving the Stackelberg values gap problems introduced in Theorem 17 roughly works as follows. Given a discounted sum game $\mathcal{G}$, a rational threshold $c \in \mathbb{Q}$ and a tolerance rational value $\epsilon > 0$, the procedure checks whether there exists a strategy $\sigma_0 \in \Sigma_0(\mathcal{G})$ with finite memory $M(\epsilon)$ such that $\mathsf{ASV}(\sigma_0) > c$ (resp. $\mathsf{CSV}(\sigma_0) > c$). If such a strategy exists, the procedure answers Yes, otherwise it answers No. The correctness of the outlined procedure follows directly from Lemma 16.

▶ **Theorem 17.** *The (ϵ, c)-gap problems for both the CSV and ASV are decidable for games with discounted-sum objectives.*

We conclude this subsection by providing a reduction from the partition problem to our gap problems (for both CSV and ASV), showing NP-hardness for the corresponding problems.

▶ **Theorem 18.** *The (ϵ, c)-gap problems for both the CSV and ASV are* NP*-hard for games with discounted-sum objectives, where ϵ and c are given as input.*

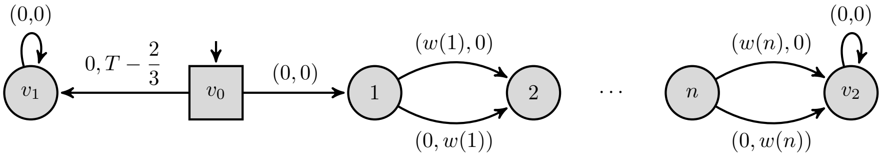

Figure 4 Arena for hardness proof of the gap problem.

Proof. We do a reduction from the Partition problem to our gap problems, working for both CSV and ASV. Let us consider an instance of the partition problem defined by a set $A = \{1, 2, \dots n\}$, a function $w : A \to \mathbb{N}_0$. The partition problem asks if there exists $B \subset A$ such that $\sum_{a \in B} w(a) = \sum_{a \in A \setminus B} w(a)$. W.l.o.g., we assume $\sum_{a \in A} w(a) = 2 \cdot T$ for some T.

To define our reduction, we first fix c to $T - \frac{1}{2}$, and the two parameters $\lambda \in (0,1)$ and $\epsilon > 0$ by choosing values that respect the following two constraints:

$$T \cdot \lambda^{n+1} > T - \frac{1}{2} + \epsilon \qquad\qquad (T-1) \cdot \lambda^{n+1} < T - \frac{1}{2} - \epsilon \tag{5}$$

It is not difficult to see that such values always exist and they can be computed in polynomial time from the description of the partition problem. Then, we construct the bi-weighted arena $\mathcal{A}$ depicted in Fig. 4. In this arena, Player 1 has only two choices in the starting state of the game v_0. There, he can either send the game to the state v_1, and get a payoff of $T - \frac{2}{3}$, or he can go to state 1.

From state 1, Player 0 can simulate a partition of the elements of A by choosing edges: left edges simulate the choice of putting the object corresponding to the state in the left class and right edges simulate the choice of putting the corresponding object in the right class. Let D_0 and D_1 be the discounted sum obtained by Player 0 and Player 1 when arriving in v_2. Because λ and ϵ have been chosen according to eq. (5) , we have that: $D_0 > T - \frac{1}{2} + \epsilon \wedge D_1 > T - \frac{1}{2} + \epsilon$ if and only if the choices of edges of Player 0 correspond to a valid partition of A.

Indeed, assume that $B \subseteq A$ is a solution to the partition problem. Assume that Player 0 follows the choices defined by B. Then when the game reaches state v_2, the discounted sum of rewards for both players is larger than $T \cdot \lambda^{n+1}$. This is because along the way to v_2, the discounted factor applied on the rewards obtained by both players has always been smaller than λ^{n+1} as they were equal to λ^{i+1} for all $i \leq n$. Additionally, we know that sum of (non-discounted) rewards for both players is equal to T as B is a correct partition. Now, it should be clear that both $\mathsf{ASV}(v_0)$ and $\mathsf{CSV}(v_0)$ are greater than $T - \frac{1}{2} + \epsilon$ as in the two cases, Player 1 has no incentive to deviate from the play that goes to v_1 as Player 1 would only get $T - \frac{2}{3}$ which is strictly smaller than D_1.

Now, assume that there is no solution to the partition problem. In that case, Player 0 cannot avoid to give less than $T - 1$ to herself or to Player 1 when going from v_0 to v_2. In the first case, its reward is less than $T - 1$ and in the second case, the reward of Player 1 is less than $T - 1$ and Player 1 has an incentive to deviate to state v_1. In the two cases, we have that both $\mathsf{ASV}(v_0)$ and $\mathsf{CSV}(v_0)$ are less than $T - \frac{1}{2} - \epsilon$. So, we have established that the answer to the gap problem is yes if the partition instance is positive, and the answer is no if the partition instance is negative. ◀

The Topology of Local Computing in Networks

Abstract

Modeling distributed computing in a way enabling the use of formal methods is a challenge that has been approached from different angles, among which two techniques emerged at the turn of the century: protocol complexes, and directed algebraic topology. In both cases, the considered computational model generally assumes communication via shared objects (typically a shared memory consisting of a collection of read-write registers), or message-passing enabling direct communication between any pair of processes. Our paper is concerned with network computing, where the processes are located at the nodes of a network, and communicate by exchanging messages along the edges of that network (only neighboring processes can communicate directly).

Applying the topological approach for verification in network computing is a considerable challenge, mainly because the presence of identifiers assigned to the nodes yields protocol complexes whose size grows exponentially with the size of the underlying network. However, many of the problems studied in this context are of local nature, and their definitions do not depend on the identifiers or on the size of the network. We leverage this independence in order to meet the above challenge, and present *local* protocol complexes, whose sizes do not depend on the size of the network. As an application of the design of "compacted" protocol complexes, we reformulate the celebrated lower bound of $\Omega(\log^* n)$ rounds for 3-coloring the n-node ring, in the algebraic topology framework.

1 Context and Objective

Several techniques for formalizing distributed computing based on algebraic topology have emerged in the last decades, including the study of complexes capturing all possible global states of the systems at a given time [11], and the study of the (di)homotopy classes of directed paths representing the execution traces of concurrent programs [7]. We refer to [10] for a recent attempt to reconcile the two approaches. This paper is focusing on the approach based on the study of complexes.

A generic methodology for studying distributed computing through the lens of topology has been set by Herlihy and Shavit [12]. This methodology has played an important role in distributed computing, mostly for establishing lower bounds and impossibility results [5,12,18],

but also for the design of algorithms [6]. It is based on viewing distributed computation as a topological deformation of an input space. More specifically, recall that a *simplicial complex* $\mathcal{K}$ is a collection of non-empty subsets of a finite set V, downward closed under inclusion, i.e., for every $\sigma \in \mathcal{K}$, and every non-empty $\sigma' \subset \sigma$, it holds that $\sigma' \in \mathcal{K}$. Every $\sigma \in \mathcal{K}$ is called a *simplex*, and every $v \in V$ is called a *vertex*. For instance, a graph $G = (V, E)$ with $E \subseteq \binom{V}{2}$, can be viewed as the complex $\mathcal{K} = \{\{v\} : v \in V\} \cup E$ on the set V of vertices. A *sub-complex* of a complex $\mathcal{K}$ is a subset of simplices of $\mathcal{K}$ forming a complex. The dimension of a simplex is one less than the number of its elements. A *facet* of a complex $\mathcal{K}$ is a maximal simplex of $\mathcal{K}$, that is, a simplex not contained in any other simplex. E.g., the facets of a graph with no isolated nodes are its edges. We note that a set of facets uniquely defines a complex.

The set of all possible input (resp., output) configurations of a distributed system can be viewed as a simplicial complex, called *input complex* (resp., *output complex*), and denoted by $\mathcal{I}$ (resp., $\mathcal{O}$). A vertex of $\mathcal{I}$ (resp., $\mathcal{O}$) is a pair (p, x) where p is a process name, and x is an input (resp., output) value. For instance, the input complex of binary consensus in an n-process system with process names $p_1, \dots, p_n$ is:

$$\mathcal{I}_{\|} = \Big\{ \big\{ (p_i, x_i) : i \in I, x_i \in \{0,1\} \text{ for every } i \in I \big\} : I \subseteq [n], I \neq \varnothing \Big\},$$

with $[n] = \{1, \dots, n\}$, and the output complex is:

$$\mathcal{O}_{\|} = \Big\{ \big\{ (p_i, y) : i \in I \big\}, I \subseteq [n], I \neq \varnothing, y \in \{0,1\} \Big\}.$$

One can check that $\mathcal{I}_{\|}$ and $\mathcal{O}_{\|}$ are indeed collections of non-empty subsets of a finite set, downward closed under inclusion. A distributed computing *task* is then specified as a *carrier map* $\Delta : \mathcal{I} \to 2^{\mathcal{O}}$, i.e., a function Δ that maps every input simplex $\sigma \in \mathcal{I}$ to a sub-complex $\Delta(\sigma)$ of the output complex, satisfying that, for every $\sigma, \sigma' \in \mathcal{I}$, if $\sigma \subseteq \sigma'$ then $\Delta(\sigma)$ is a sub-complex of $\Delta(\sigma')$. The carrier map Δ is describing the output configurations that are legal with respect to the input configuration σ. For instance, the specification of consensus is, for every $\sigma = \{(p_i, x_i) : i \in I, x_i \in \{0,1\}\} \in \mathcal{I}_{\|}$,

$$\Delta_{\|}(\sigma) = \begin{cases} \{\{(p_i, 0) : i \in I\}, \{(p_i, 1) : i \in I\}\} & \text{if } \exists\, i, j \in I,\ x_i \neq x_j; \\ \{\{(p_i, y) : i \in I\}\} & \text{if } \forall\, i \in I,\ x_i = y. \end{cases}$$

Note that the specification of consensus given here is very general, i.e., Δ is specified for every simplex $\sigma \in \mathcal{I}_{\|}$. This enables, e.g., to handle crash failures. In absence of failures, the specification of a task can be done just by specifying Δ for the facets in the input complex.

In the topological framework, computation is modeled by a *protocol complex* that evolves with time, where the notion of "time" depends on the computational model at hand. The protocol complex at time t, denoted by $\mathcal{P}^{(t)}$, captures all possible states of the system at time t. Typically, a vertex of $\mathcal{P}^{(t)}$ is a pair (p, s) where p is a process name, and s is a possible state of p at time t. A set $\{(p_i, s_i) : i \in I\}$ of such vertices, for $\emptyset \neq I \subseteq [n]$, forms a simplex of $\mathcal{P}^{(t)}$ if the states s_i, $i \in I$, are mutually compatible, that is, if $\{s_i : i \in I\}$ forms a possible global state for the processes in the set $\{p_i : i \in I\}$ at time t.

A crucial point is that an algorithm that outputs in time t induces a mapping $\delta : \mathcal{P}^{(t)} \to \mathcal{O}$. Specifically, if the process p_i with state s_i at time t outputs y_i, then δ maps the vertex $(p_i, s_i) \in \mathcal{P}^{(t)}$ to the vertex $\delta(p_i, s_i) = (p_i, y_i)$ in $\mathcal{O}$. For the task to be correctly solved, the mapping δ must preserve the simplices of $\mathcal{P}^{(t)}$, and must agree with the specification Δ of the task. That is, δ must map simplices to simplices, and if the configuration $\{(p_i, s_i), i \in I\}$ of a distributed system is reachable at time t starting from the input configuration $\{(p_i, x_i), i \in I\}$, then it must be the case that $\{\delta(p_i, s_i), i \in I\} \in \Delta(\{(p_i, x_i), i \in I\})$. The set of configurations reachable in time t stating from an input configuration $\sigma \in \mathcal{I}$ is denoted by $\Xi_t(\sigma)$. In particular, $\Xi_t : \mathcal{I} \to 2^{\mathcal{P}^{(t)}}$ is a carrier map.

Fundamental Lemma. The framework defined by Herlihy and Shavit [12] enables to characterize the power and limitation of distributed computing, thanks to the following generic result, which can be viewed as the basis of distributed computing within the topological framework. Let us consider some (deterministic) distributed computing model, assumed to be *full information*, that is, every process communicates its entire history at each of its communication step. The following result connects solvability of a task by an algorithm in a given model with the existence of a mapping of a specific form between the topological complexes corresponding to this task and this model (see [4, 11, 12] for instantiations of this result for different computational models).

▶ **Lemma 1.** *A task $(\mathcal{I}, \mathcal{O}, \Delta)$ is solvable in time t if and only if there exists a simplicial map $\delta : \mathcal{P}^{(t)} \to \mathcal{O}$ such that, for every $\sigma \in \mathcal{I}$, $\delta(\Xi_t(\sigma)) \subseteq \Delta(\sigma)$.*

Again, beware that the notion of *time* in the above lemma depends on the computational model. The topology of the protocol complex $\mathcal{P}^{(t)}$, and the nature of the carrier map Ξ_t, depend on the input complex $\mathcal{I}$, and on the computing model at hand. For instance, wait-free computing in asynchronous shared memory systems induces protocol complexes by a deformation of the input complex, called *chromatic subdivisions* [11]. Similarly, t-resilient computing may introduce *holes* in the protocol complex, in addition to chromatic subdivisions. More generally, the topological deformation Ξ_t of the input complex caused by the execution of a full information protocol in the considered computing model entirely determines the existence of a decision map $\delta : \mathcal{P}^{(t)} \to \mathcal{O}$, which makes the task $(\mathcal{I}, \mathcal{O}, \Delta)$ solvable or not in that model.

Topological Invariants. The typical approach for determining whether a task (e.g., consensus) is solvable in t rounds consists of identifying topological *invariants*, i.e., properties of complexes that are preserved by simplicial maps. Specifically, the approach consists in:

1. Identifying a topological invariant, i.e., a property satisfied by the input complex $\mathcal{I}$, and preserved by Ξ_t;
2. Checking whether this invariant, which must be satisfied by the sub-complex $\delta(\mathcal{P}^{(t)})$ of the output complex $\mathcal{O}$, does not contradict the specification Δ of the task.

For instance, in the case of binary consensus, the input complex $\mathcal{I}_{||}$ is a *sphere*. One basic property of spheres is being *path-connected* (i.e., there is a path in $\mathcal{I}_{||}$ between any two vertices). As mentioned earlier, shared-memory wait-free computing corresponds to subdividing the input complex [11]. Therefore, independently from the length t of the execution, the protocol complex $\mathcal{P}^{(t)}$ is a chromatic subdivision of the sphere $\mathcal{I}_{||}$, and thus it remains path-connected. On the other hand, the output complex $\mathcal{O}_{||}$ of binary consensus is the disjoint union of two complexes $\mathcal{O}_0$ and $\mathcal{O}_1$, where $\mathcal{O}_y = \big\{\{(i, y) : i \in I\}, I \subseteq [n], I \neq \varnothing\big\}$ for $y \in \{0, 1\}$. Since simplicial maps preserve connectivity, it follows that $\delta(\mathcal{P}^{(t)}) \subseteq \mathcal{O}_0$ or $\delta(\mathcal{P}^{(t)}) \subseteq \mathcal{O}_1$. As a consequence, δ cannot agree with $\Delta_{||}$, as the latter maps the simplex $\{(i, 0), i \in [n]\}$ to $\mathcal{O}_0$, and the simplex $\{(i, 1), i \in [n]\}$ to $\mathcal{O}_1$. Therefore, consensus cannot be achieved wait-free, regardless of the number t of rounds.

The fact that connectivity plays a significant role in the inability to solve consensus in the presence of asynchrony and crash failures is known since the original proof of the FLP theorem [8] in the early 1980s. However, the relation between k-set agreement and higher dimensional forms of connectivity (i.e., the ability to contract high dimensional spheres) was only established ten years later [12, 18]. We refer to [11] for numerous applications of Lemma 1 to various models of distributed computing, including asynchronous crash-prone shared-memory or fully-connected message passing models. In particular, for tasks such as renaming, identifying the minimal number t of rounds enabling a simplicial map δ to exist is currently the only known technique for upper bounding their time complexities [1].

Network Computing. Recently, Castañeda et al. [4] applied Lemma 1 to synchronous fault-free computing in networks, that is, to the framework in which processes are located at the vertices of a simple (no multiple edges, no loops) n-node undirected graph G, and can exchange messages only along the edges of that graph. They mostly focus on *input-output tasks* such as consensus and set-agreement, in a simplified computing model, called KNOW-ALL, specifying that every process is initially aware of the name and the location of all the other processes in the network. As observed in [4], synchronous fault-free computing in the KNOW-ALL model preserves the *facets* of the input complex, and does not subdivide them. However, *scissor cuts* may occur between adjacent facets during the course of the computation, that is, the protocol complex $\mathcal{P}^{(t)}$ is obtained from the input complex $\mathcal{I}$ by partially separating facets that initially shared a simplex. Figure 1 illustrates two types of scissor cuts applied to the sphere, corresponding to two different communication networks. The positions of the cuts depend on the structure of the graph G in which the computation takes place, and determining the precise impact of the structure of G on the topology of the protocol complex is a nontrivial challenge, even in the KNOW-ALL model.

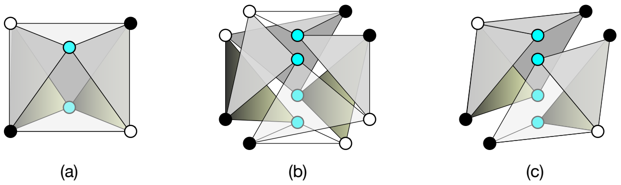

Figure 1 (a) The input complex of binary consensus for three processes; (b) The scissor cuts for the consistently directed 3-process cycle C_3 after one round; (c) The scissor cuts for the directed 3-process star S_3, where edges are directed from the center to the leaves, after one round.

Instead, we aim at analyzing classical *graph problems* (e.g., coloring, independent set, etc.) in the standard LOCAL model [17] of network computing, which is weaker than the KNOW-ALL model, and thus allows for more complicated topological deformations. In the LOCAL model, every node is initially aware of solely its identifier (which is unique in the network), and its input (e.g., for minimum weight vertex cover or for list-coloring), all nodes wake up synchronously, and compute in locksteps. The LOCAL model is an ideal model for studying *locality* in the context of network computing [17].

In addition to the fact that the topological deformations of the protocol complexes strongly depend on the structure of the network, another obstacle that makes applying the topological approach to the LOCAL model even more challenging is the presence of process *identifiers*. Indeed, the model typically assumes that the node IDs are taken in a range $[N]$ where $N = \text{poly}(n)$. As a consequence, independently from the potential presence of other input values, the size of the complexes (i.e., their number of vertices) may become as large as $\binom{N}{n}n!$, since there are $\binom{N}{n}$ ways of choosing n IDs, and $n!$ ways of assigning the n chosen IDs to the n nodes of G (unless G presents symmetries). For instance, Figure 1 assumes the KNOW-ALL model, hence fixed IDs. Redrawing these complexes assuming that the three processes can pick arbitrary distinct IDs as in the LOCAL model, even in the small domain $\{1,2,3,4\}$, would yield a cumbersome figure with 24 nodes. Note that the presence of IDs also results in input complexes that may be topologically more complicated than pseudospheres, even for tasks such as consensus.

Importantly, the fact that the IDs are not fixed a priori, and may even be taken in a range exceeding $[n]$, is inherent to distributed network computing. Indeed, this framework aims at understanding the power and limitation of computing in large networks, from LANs to the whole Internet, where the processing nodes are assigned arbitrary IDs taken from a range of values which may significantly exceed the number of nodes in the network.

Objective. To sum up, while the study of protocol complexes has found numerous applications in the context of fault-tolerant message-passing or shared-memory computing, extending this theory to network computing faces a difficulty caused by the presence of arbitrary IDs, which are often the only inputs to the processes [17]. The objective of this paper is to show how the combinatorial blowup caused by the presence of IDs in network computing can be bypassed, at least as far as local computing is concerned.

2 Our Results

We show how to bypass the aforementioned exponential blowup in the size of the complexes, that would result from a straightforward application of Lemma 1 for analyzing the complexity of tasks in networks. Our result holds for a variety of problems, including classical graph problems such as vertex and edge-coloring, maximal independent set (MIS), maximal matching, etc. More specifically, it holds for the large class of *locally checkable labeling* (LCL) tasks [16] on bounded-degree graphs. These are tasks for which it is possible to verify locally the correctness of a solution, and thus they are sometimes viewed as the analog of NP in the context of computing in networks. An LCL task is described by a finite set of labels, and a local description of how these labels can be legally assigned to the nodes of a network. Our local characterization theorem is strongly based on a seminal result by Naor and Stockmeyer [16] who showed that the *values* of the IDs do not actually matter much for solving LCL tasks in networks, but only their *relative order* matters.

We prove an analog of Lemma 1, but where the size of the complexes involved in the statement is independent of the size of the networks. Specifically, the size of the complexes in our characterization theorem depends solely on the maximum degree d of the network, the number of labels used for the description of the task, and the number of rounds of the considered algorithm for solving that task. In particular, the identifiers are taken from a bounded-size set, even if the theorem applies to tasks defined on n-node networks with arbitrarily large n, and for identifiers taken in an arbitrarily large range $[N]$. We denote by $\mathcal{K}_{x,[y]}$ the fact that the facets of $\mathcal{K}$ have dimension x, and that the IDs are taken in the set $\{1,\dots,y\}$, and we let $\mathcal{K}_x = \mathcal{K}_{x,\varnothing}$. Also $\pi : \mathcal{K}_{x,[y]} \to \mathcal{K}_x$ denotes the mapping that removes the IDs of the vertices. Every LCL task in networks with maximum degree d can be expressed topologically as a task $(\mathcal{I}_d, \mathcal{O}_d, \Delta)$ where $\mathcal{I}_d$ and $\mathcal{O}_d$ are complexes of dimension d. Our main result is the following.

▶ **Theorem 2** (A simplified version of Theorem 3). *For every LCL task $T = (\mathcal{I}_d, \mathcal{O}_d, \Delta)$ on graphs of maximum degree d, and for every $t \geq 0$, there exists $R \in \mathbb{N}$ such that the following holds. The task T is solvable in t rounds in the LOCAL model if and only if there is a simplicial map $\delta : \mathcal{P}^{(t)}_{d,[R]} \to \mathcal{O}_d$ such that, for every facet $\sigma \in \mathcal{I}_{d,[R]}$, $\delta(\Xi_t(\sigma)) \subseteq \Delta(\pi(\sigma))$.*

Figure 2 provides a rough description of the commutative diagram corresponding to the brute force application of Lemma 1 to LCL tasks, and of the commutative diagram corresponding to Theorem 2. Note that Lemma 1, which corresponds to the left diagram in Figure 2, involves *global* complexes with $(n-1)$-dimensional facets, whose vertices are labeled by IDs in an arbitrarily large set $[N]$. In contrast, the complexes corresponding to Theorem 2, which correspond to the right diagram, are *local* complexes, with facets of constant dimension, and vertices labeled with IDs in a finite set whose size is constant w.r.t. the number of nodes n in the network.

$$\begin{tikzcd}
\mathcal{I}_{n-1,[N]} \arrow[r, "\Xi_t"] \arrow[dr, "\Delta"'] & \mathcal{P}^{(t)}_{n-1,[N]} \arrow[d, "\delta"] \\
 & \mathcal{O}_{n-1,[N]}
\end{tikzcd}
\qquad\qquad
\begin{tikzcd}
\mathcal{I}_{d,[R]} \arrow[r, "\Xi_t"] \arrow[d, "\pi"'] & \mathcal{P}^{(t)}_{d,[R]} \arrow[d, "\delta"] \\
\mathcal{I}_d \arrow[r, "\Delta"] & \mathcal{O}_d
\end{tikzcd}$$

Figure 2 The commutative diagrams of Lemma 1 (left), and Theorem 2 (right).

As an application of Theorem 2, we reformulate the celebrated lower bound $\Omega(\log^* n)$ rounds for 3-coloring the n-node ring by Linial [15], in the algebraic topology framework (see Corollary 4).

3 Models and Definitions

The LOCAL model. The LOCAL model was introduced more than a quarter of a century ago (see, e.g., [15, 16]) for studying which tasks can be solved *locally* in networks, that is, which tasks can be solved when every node is bounded to collect information only from nodes in its vicinity. Specifically, the LOCAL model [17] states that the processors are located at the nodes of a simple connected graph $G = (V, E)$ modeling a network. All nodes are fault-free, they wake up simultaneously, and they execute the same algorithm. Computation proceeds in synchronous rounds, where a round consists of the following three steps performed by every node: (1) sending a message to each neighbor in G, (2) receiving the messages sent by the neighbors, and (3) performing local computation. There are no bounds on the size of the messages exchanged at every round between neighbors, and there are no limits on the individual computational power or memory of the nodes. These assumptions enable the design of unconditional lower bounds on the number of rounds required for performing some task (e.g., for providing the nodes with a proper coloring), while the vast majority of the algorithms solving these tasks do not abuse of these assumptions [19], that is, they exchange small (i.e., polylogarithmic size) messages, and perform efficient (i.e., poly-time) individual computations.

Every node in the network has an identifier (ID) which is supposed to be unique in the network. In n-node networks, the IDs are supposed to be in a range $1, \dots, N$ where $N \gg n$ typically holds (most often, $N = \text{poly}(n)$). The absence of limits on the amount of communication and computation that can be performed at every round implies that the LOCAL model enables *full-information* protocols, that is, protocols in which, at every round, every node sends all the information it acquired during the previous rounds to its neighbors. Therefore, for every $t \geq 0$, and every graph G, a t-round algorithm allows every node in G to acquires a local *view* of G, which is a ball in G centered at that node, and of radius t. A view includes the inputs and the IDs of the nodes in the corresponding ball. It follows that a t-round algorithm in the LOCAL model can be considered as a function from the set of views of radius t to the set of output values.

Locally Checkable Labelings (LCL). Let $d \geq 2$, and let $\mathcal{G}_d$ be the class of connected simple undirected d-regular graphs (all nodes have degree d). Recall that, for a positive integer c, c-coloring is the task consisting in providing each node with a color in $\{1, \dots, c\}$ in such a way that no two adjacent nodes are given the same color. Maximal independent set (MIS) is the closely related task consisting in providing each node with a boolean value (0 or 1) such that no two adjacent nodes are given the value 1, and every node with value 0 is adjacent to at least one node with value 1. Proper c-coloring in $\mathcal{G}_d$ can actually be described by the collection of *good stars* of degree d, and with nodes colored by labels in $\{1, \dots, c\}$, such that the center node has a color different from the color of each leaf. Similarly, maximal independent set (MIS) in $\mathcal{G}_d$ can be described by the collection of stars with degree d, and with each node colored by a label in $\{0, 1\}$, such that if the center node is labeled 1 then all the leaves are colored 0, and if the center node is labeled 0 then at least one leaf is colored 1. Other tasks such as variants of coloring, or $(2, 1)$-ruling set[1] can be described similarly, by a finite number of legal labeled stars.

More generally, given a finite set $\mathcal{L}$ of labels, we denote by $\mathbf{S}_d^{\mathcal{L}}$ the set of all labeled stars resulting from labeling each node of the $(d + 1)$-node star by some label in $\mathcal{L}$. A *locally checkable labeling* (LCL) [16] is then defined by a finite set $\mathcal{L}$ of labels, and a set $\mathcal{S} \subseteq \mathbf{S}_d^{\mathcal{L}}$. Every star in $\mathcal{S}$ is called a *good* star, and those in $\mathbf{S}_d^{\mathcal{L}} \setminus \mathcal{S}$ are *bad*. The computing task defined by an LCL $(\mathcal{L}, \mathcal{S})$ consists, for every node of every graph $G \in \mathcal{G}_d$, of computing a label in $\mathcal{L}$ such that every resulting labeled radius-1 star in G is isomorphic to a star in $\mathcal{S}$. In other words, the objective of every node is to compute a label in $\mathcal{L}$ such that every resulting labeled radius-1 star in G is good. It is undecidable, in general, whether a given LCL task has an algorithm performing in $O(1)$ rounds in the LOCAL model [16].

In their full generality, LCL tasks include tasks in which nodes have inputs, potentially of some restricted format. For instance, this is the case of the task consisting of reducing c-coloring to MIS in the n-node cycle C_n, studied in the next section. Hence, in its full generality, an LCL task is described by a quadruple $(\mathcal{L}_{in}, \mathcal{S}_{in}, \mathcal{L}_{out}, \mathcal{S}_{out})$ where $\mathcal{L}_{in}$ and $\mathcal{L}_{out}$ are the input and output labels, respectively. The set of stars $\mathcal{S}_{in}$ can often be simply viewed as a promise stating that every radius-1 star of the input graph G belongs to $\mathcal{S}_{in}$, and the set $\mathcal{S}_{out}$ is the target set of good radius-1 stars. LCL tasks also capture settings in which the legality of the output stars depends on the inputs. A typical example of such a setting is list-coloring where the output color of each node must belong to a list of colors given to this node as input. The framework of LCL tasks can be extended to balls of radius $r > 1$, and assuming radius 1 is not restrictive, up to increasing the size of the set of labels [3].

4 Warm Up: Coloring and MIS in the Ring

In this section, we exemplify our technique, in a way that resembles the proof of Theorem 2. We consider an LCL task on a ring, where the legal input stars define a proper 3-coloring, and the output stars define a maximal independent set (MIS). That is, we study the time complexity of reducing a 3-coloring to a MIS on a ring. It is known [15] that there is a 2-round algorithm for the problem in the LOCAL model, and we show that this is optimal using topological arguments. This toy example provides the basic concepts and arguments that we use later, when considering general LCL tasks and proving Theorem 2.

[1] Recall that an (α, β)-ruling set in a graph $G = (V, E)$ is a set $R \subseteq V$ such that, for any node $v \in V$ there is a node $u \in R$ in distance at most β from v, and any two nodes in R are at distance at least α from each other.

4.1 Reduction from 3-coloring to MIS

Let us consider three consecutive nodes of the n-node ring C_n, denoted by p_{-1}, p_0, and p_1, as displayed on Figure 3.

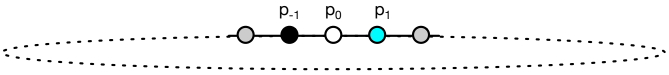

Figure 3 Three consecutive nodes in the n-node ring.

By the independence property, if p_0 is in the MIS, then neither p_{-1} nor p_1 can be in the MIS, and, by the maximality property, if p_0 is not in the MIS, then p_{-1} or p_1, or both, must be in the MIS. These constraints are captured by the complex $\mathcal{M}_2$ displayed on Figure 4, including six vertices (p_i, x), with $i \in \{-1, 0, 1\}$, and $x \in \{0, 1\}$, where $x = 1$ (resp., $x = 0$) indicates that p_i is in the MIS (resp., not in the MIS).

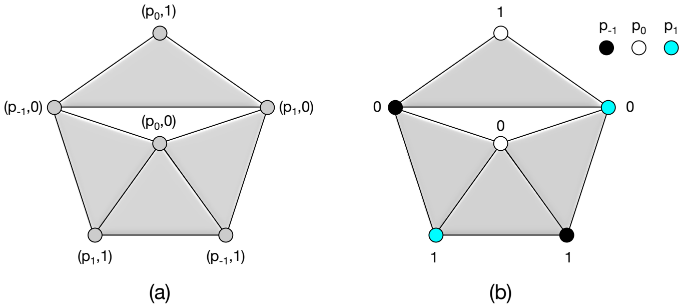

Figure 4 The local complex $\mathcal{M}_2$ of MIS in the ring. (a) the vertices are labeled with the index of the processes and the values; (b) the indexes of the processes are replaced by colors.

The complex $\mathcal{M}_2$ of Figure 4 has four facets of dimension 2: they are triangles. Some triangles intersect along an edge, while some others intersect only at a node. The complex $\mathcal{M}_2$ is called the *local* complex of MIS in the ring (the index 2 refers to the fact that rings have degree 2). Note that the sets $\{(p_{-1}, 0), (p_0, 0), (p_1, 0)\}$ and $\{(p_{-1}, 1), (p_0, 1), (p_1, 1)\}$ do not form simplices of $\mathcal{M}_2$. We call these two sets monochromatic. In the objective of reducing 3-coloring to MIS, $\mathcal{M}_2$ will be the output complex, corresponding to $\mathcal{O}_d$ with $d = 2$ in Figure 2 and in Theorem 2.

Similarly, let us focus on 3-coloring, with the same three processes p_{-1}, p_0, and p_1. The neighborhood of p_0 cannot include the same color as its own color, and thus there are twelve possible colorings of the nodes in the star centered at p_0. Each of these stars corresponds to a 2-dimensional simplex, forming the facets of the local complex $\mathcal{C}_2$ of 3-coloring in the ring, depicted in Figure 5. This complex contains nine vertices of the form (p_i, c), with $i \in \{-1, 0, 1\}$, and $c \in \{1, 2, 3\}$, and twelve facets. Note that the vertices $(p_{-1}, 3)$ and $(p_1, 3)$ appear twice in the figure, since the leftmost and rightmost edges are identified, but in opposite direction, forming a Möbius strip. $\mathcal{C}_2$ is a manifold (with boundary). When reducing 3-coloring to MIS, $\mathcal{C}_2$ will be the input complex, corresponding to $\mathcal{I}_d$ with $d = 2$ in Figure 2.

Remark. It is crucial to note that the complexes displayed in Figures 4 and 5 are not the ones used in the standard settings (e.g., [4, 11]), for which Lemma 1 would use vertices of the form (p, x) for $p \in [n]$, or even $p \in [N]$ assuming IDs in a range of N values. As

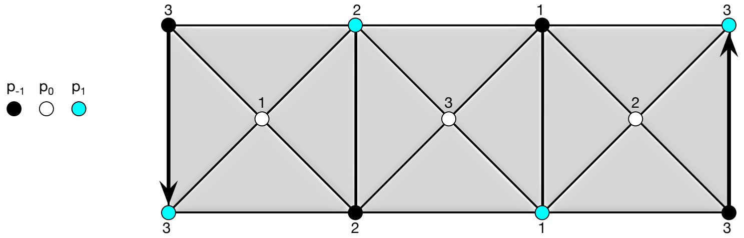

Figure 5 Local complex $\mathcal{C}_2$ of 3-coloring in the ring.

a consequence, these complexes have 6 vertices instead of $2n!\binom{N}{n}$ for MIS, and 9 vertices instead of $3n!\binom{N}{n}$ for coloring, where n can be arbitrarily large. Even if the IDs would have been fixed, the approach of Lemma 1 would yield complexes with a number of vertices linear in n, while the complexes of Figs. 4 and 5 are of constant size.

As it is well know since the early work by Linial [15], a properly 3-colored ring can be "recolored" into a MIS in just two rounds. First, the nodes colored 3 recolor themselves 1 if they have no neighbors originally colored 1. Then, the nodes colored 2 do the same, i.e., they recolor themselves 1 if they have no neighbors colored 1 (whether it be neighbors originally colored 1, or nodes that recolored themselves 1 during the first round). The nodes colored 1 output 1, and the other nodes output 0. The set of nodes colored 1 forms a MIS. Note that this algorithm is *ID-oblivious*, i.e., it can run in an anonymous network.

Task specification. The specification of reducing 3-coloring to MIS can be given by the trivial carrier map $\Delta : \mathcal{C}_2 \to 2^{\mathcal{M}_2}$ defined by $\Delta(F) = \{F' : F' \text{ is a facet of } \mathcal{M}_2\}$ for every facet F of $\mathcal{C}_2$. (As the LOCAL model is failure-free, it is enough to describe all maps at the level of facets.) Note that the initial coloring of a facet in $\mathcal{C}_2$ does not induce constraints on the facet of $\mathcal{M}_2$ to which it should be mapped. Figure 6 displays some of the various commutative diagrams that will be considered in this section. In all of them, Δ is the carrier map specifying reduction from 3-coloring to MIS in the ring, and none of the simplicial maps δ exist. Also recall that π is the map removing IDs.

\end{tikzcd}$$

Figure 6 Complexes corresponding to reduction from 3-coloring to MIS in the n-node ring. From left to right: 0 rounds without IDs, 1-round without IDs, 0 rounds with ID, and 1-round with IDs.

4.2 ID-Oblivious Algorithms

Impossibility in Zero Rounds. Let us consider an alleged ID-oblivious algorithm ALG which reduces 3-coloring to MIS in zero rounds. Such an algorithm sees only the node's color $c \in \{1, 2, 3\}$, and must map it to some $x \in \{0, 1\}$. This mapping can be extended to a mapping δ that maps every pair (p_i, c) with $i \in \{-1, 0, 1\}$ and $c \in \{1, 2, 3\}$ to a pair $\delta(p_i, c) = (p_j, x)$, $j \in \{-1, 0, 1\}$ and $x \in \{0, 1\}$, with the following properties.

- *Name-preservation.* The mapping δ must satisfy that $p_j = p_i$, i.e., δ is *name-preserving*. By the name-preserving property, the algorithm maps the vertices in Figure 5 to the vertices in Figure 4(b) while preserving the names p_{-1}, p_0, p_1 of these vertices. Therefore, the algorithm induces a *chromatic* simplicial map $\delta : \mathcal{C}_2 \to \mathcal{M}_2$. (The "color" of p, i.e., p's name, is preserved).
- *Name-independence.* In addition to name-preservation, the mapping δ must satisfy that, for every $i \neq j$, (p_i, c) and (p_j, c) are mapped to (p_i, x_i) and (p_j, x_j), respectively, with $x_i = x_j$, i.e., δ is *name-independent*. Indeed, the names p_{-1}, p_0, and p_1 given to the nodes are "external", i.e., they are not part of the input to the algorithm ALG.

We are therefore questioning the existence of a name-preserving name-independent simplicial map $\delta : \mathcal{C}_2 \to \mathcal{M}_2$. This is in correspondence to Figure 2 and Theorem 2, in the degenerated case where $t = 0$ and $[R] = \varnothing$, for which $\mathcal{C}_2 = \mathcal{I}_2$, and $\mathcal{C}_{2,\varnothing} = \mathcal{I}_{2,\varnothing} = \mathcal{P}^{(0)}_{2,\varnothing} = \mathcal{C}_2$ – see the leftmost diagram in Figure 6. There cannot exist a name-preserving name-independent simplicial map δ from the manifold $\mathcal{C}_2$ to $\mathcal{M}_2$ (from Figure 5 to Figure 4(b)), which we formally prove in the full version of the paper [9]. The intuition is that if some triangle of $\mathcal{C}_2$ is mapped to the triangle $\{(p_0, 1), (p_{-1}, 0), (p_1, 0)\}$ of $\mathcal{M}_2$ then *all* triangles of $\mathcal{C}_2$ must be mapped to that triangle of $\mathcal{M}_2$, from which it follows by name-independence that all processes output 1, or all processes output 0, which leads to contraction in both cases. The absence of a name-independent name-preserving simplicial map $\delta : \mathcal{C}_2 \to \mathcal{M}_2$ is a witness of the impossibility to construct a MIS from a 3-coloring of the ring in zero rounds, when using an ID-oblivious algorithm.

Impossibility in One Round. For analyzing 1-round algorithms, let us consider the local protocol complex $\mathcal{P}^{(1)}_{2,\varnothing}$, including the views of the three nodes p_{-1}, p_0, and p_1 after one round. The vertices of $\mathcal{P}^{(1)}_{2,\varnothing}$ are of the form (p_i, xyz) with $i \in \{-1, 0, 1\}$, and $x, y, z \in \{1, 2, 3\}$, $x \neq y$, and $y \neq z$. The vertex (p_i, xyz) is representing a process p_i starting with color y, and receiving the input colors x and z from its left and right neighbors, respectively. The facets of $\mathcal{P}^{(1)}_{2,\varnothing}$ are of the form $\{(p_{-1}, x'xy), (p_0, xyz), (p_1, yzz')\}$. Figure 7 displays that complex, which consists of three connected components $\mathcal{K}_1, \mathcal{K}_2$, and $\mathcal{K}_3$ where, for $y = 1, 2, 3$, $\mathcal{K}_y$ includes the four vertices (p_0, xyz) for $x, z \in \{1, 2, 3\} \smallsetminus \{y\}$, and all triangles that include these vertices. Each set of four triangles sharing a vertex (p_0, xyz) forms a cone (see Figure 8). These cones are displayed twisted on Figure 7 to emphasis the "circular structure" of the three components.

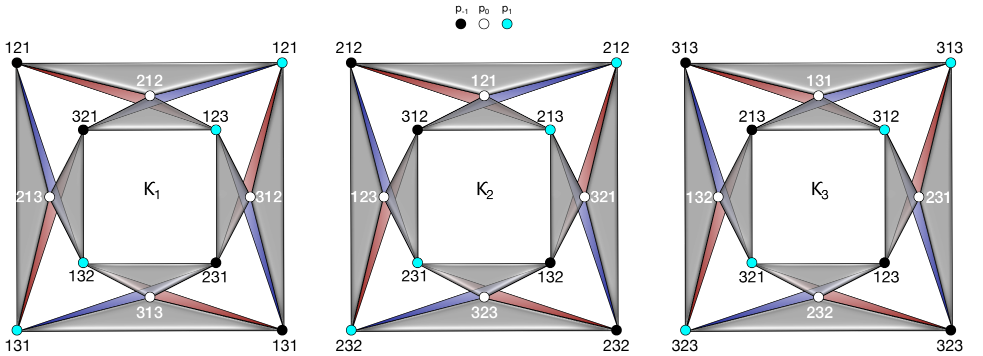

Figure 7 Local protocol complex $\mathcal{P}^{(1)}_{2,\varnothing}$ after 1 round starting from a 3-coloring of the ring.

Following the same reasoning as for 0-round algorithms, a 1-round algorithm ALG induces a chromatic (i.e., name-preserving) simplicial map $\delta : \mathcal{P}^{(1)}_{2,\varnothing} \to \mathcal{M}_2$, as in the second to left diagram in Figure 6. In the full version, we show that such a mapping cannot exist [9].

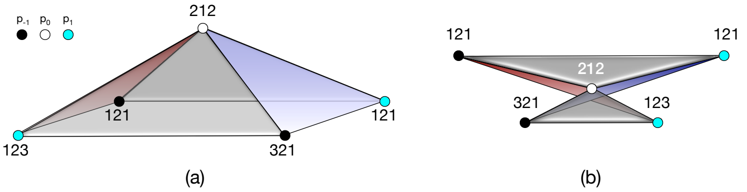

Figure 8 (a) A cone composed of four triangles; (b) The same cone "twisted".

The 2-Round Algorithm. The local protocol complex $\mathcal{P}^{(2)}_{2,\varnothing}$ includes the views of the three nodes p_{-1}, p_0, and p_1 after two rounds. The vertices of $\mathcal{P}^{(2)}_{2,\varnothing}$ are of the form $(p_i, c_1c_2c_3c_4c_5)$ with $i \in \{-1, 0, 1\}$, $c_j \in \{1, 2, 3\}$ for $1 \le j \le 5$, and $c_j \neq c_{j+1}$ for $1 \le j < 5$. Figure 9(a) displays one of the connected components of $\mathcal{P}^{(2)}_{2,\varnothing}$, denoted $\mathcal{K}_{323}$,which includes the four vertices $(p_0, c_1 323 c_5)$, $c_1, c_5 \in \{1, 2\}$. There are 12 disjoint isomorphic copies of this connected component in $\mathcal{P}^{(2)}_{2,\varnothing}$, one for each triplet $c_2, c_3, c_4 \in \{1, 2, 3\}$, $c_2 \neq c_3$, and $c_3 \neq c_4$.

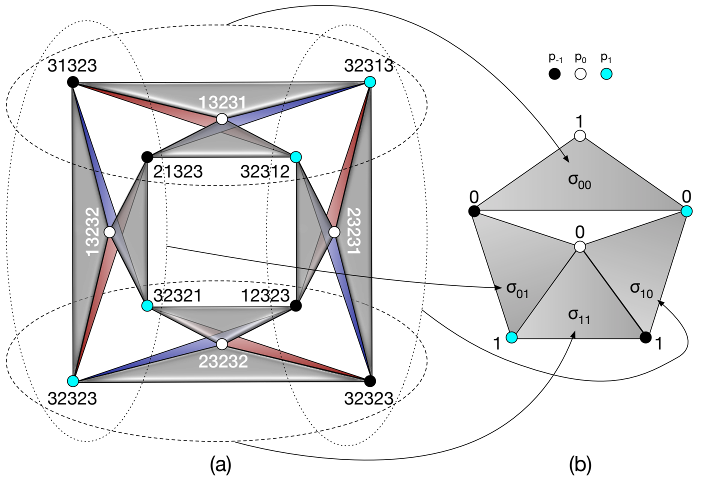

Figure 9 (a) The sub-complex $\mathcal{K}_{323}$ of the local protocol complex $\mathcal{P}^{(2)}_{2,\varnothing}$. (b) The facets of $\mathcal{M}_2$.

Interestingly, each connected component of $\mathcal{P}^{(2)}_{2,\varnothing}$ is isomorphic to each connected component of $\mathcal{P}^{(1)}_{2,\varnothing}$, while there are more connected components in $\mathcal{P}^{(2)}_{2,\varnothing}$ than in $\mathcal{P}^{(1)}_{2,\varnothing}$. However, the larger views of the processes provides more flexibility for the mapping from $\mathcal{P}^{(2)}_{2,\varnothing}$ to $\mathcal{M}_2$ than for the mapping from $\mathcal{P}^{(1)}_{2,\varnothing}$ to $\mathcal{M}_2$. And indeed, the 2-round anonymous algorithm presented at the end of Section 4.1 does induce a chromatic simplicial map $\delta : \mathcal{P}^{(2)}_{2,\varnothing} \to \mathcal{M}_2$. Specifically, the four sub-complexes $\mathcal{K}_{x1y}$, as well as the simplex $\mathcal{K}_{232}$ are entirely mapped to the simplex σ_{00} (see Figure 9(b) for the labeling of the four facets of $\mathcal{M}_2$). The two sub-complexes $\mathcal{K}_{1x1}$ are entirely mapped to the simplex σ_{11}. The two sub-complexes $\mathcal{K}_{321}$ and $\mathcal{K}_{231}$ are entirely mapped to the sub-complex $\sigma_{01} \cup \sigma_{11}$, and the two sub-complexes $\mathcal{K}_{123}$ and $\mathcal{K}_{132}$ are entirely mapped to the sub-complex $\sigma_{10} \cup \sigma_{11}$. The mapping of the remaining sub-complex $\mathcal{K}_{323}$ is more sophisticated, and illustrates that the simple algorithm showing reduction from 3-coloring to MIS in [15] is actually topologically non-trivial. Indeed, $\mathcal{K}_{323}$ is mapped by the algorithm so that it wraps around the hole in $\mathcal{M}_2$, as depicted in Figure 9.

4.3 General Case with IDs

The presence of IDs given to the nodes adds power to the distributed algorithms, as the output of a process is not only a function of the observed colors in its neighborhood, but also of the observed IDs. In particular, after one round, a process p is not only aware of a triplet of colors $(c_1c_2c_3)$, but also of a triplet of distinct IDs $(x_1x_2x_3)$.

Impossibility in Zero Rounds with IDs. Since the simplicial maps δ induced by the potential algorithms are name-preserving, they actually act on pairs (x, c) where x is an ID and c is a color, i.e., $\delta(p,(x,c)) = (p, \hat{\delta}(x,c))$ for some $\hat{\delta}$. For brevity, we identify $\hat{\delta}$ with δ. Let us assume that the IDs are from $\{1,\dots,R\}$, for some $R \geq 4$. That is, we consider now $\mathcal{C}_{2,[R]}$ for $R \geq 4$. By the pigeon-hole principle, there exists a set $I_1 \subseteq \{1,\dots,R\}$ with $|I_1| \geq R/2$ such that, for every $x, x' \in I_1$, $\delta(x,1) = \delta(x',1)$. Therefore, again by the pigeon-hole principle, there exists a set $I_2 \subseteq I_1$ with $|I_2| \geq |I_1|/2$ such that, for every $x, x' \in I_2$, $\delta(x,2) = \delta(x',2)$. Finally, there exists a set $I_3 \subseteq I_2$ with $|I_3| \geq |I_2|/2$ such that, for every $x, x' \in I_3$, $\delta(x,3) = \delta(x',3)$. Therefore, there exists a set $I \subseteq \{1,\dots,R\}$ with $|I| \geq R/8$ such that, for every $x, x' \in I$, $\delta(x,1) = \delta(x',1)$, $\delta(x,2) = \delta(x',2)$, and $\delta(x,3) = \delta(x',3)$. Therefore, whenever $R \geq 24$, the set I has size at least 3. Consider the sub-complex $\mathcal{C}'_{2,[R]}$ of $\mathcal{C}_{2,[R]}$ induced by the three smallest IDs in I – this sub-complex is isomorphic to $\mathcal{C}_{2,\varnothing}$ (Figure 5). More importantly, the mapping from $\mathcal{C}'_{2,[R]}$ to $\mathcal{M}_2$ depends only on the colors and not on the IDs, by the choice of I. Hence, if there was a mapping from $\mathcal{C}'_{2,[R]}$ to $\mathcal{M}_2$, then there would exist a mapping from $\mathcal{C}_{2,\varnothing}$ to $\mathcal{M}_2$, which we know does not exist.

It follows that there are no mappings from $\mathcal{C}_{2,[24]} = \mathcal{P}^{(0)}_{2,[24]}$ to $\mathcal{M}_2$ – see the second to right diagram in Figure 6. In other words, if the IDs are picked from a set of at least 24 values, then 3-coloring cannot be reduced to MIS in zero rounds.

Impossibility in One Rounds with IDs. We reduce the case with IDs to the case without IDs following the guideline introduced in [16]. We consider the 1-round protocol complex with IDs in a finite set X with at least 5 elements, denoted by $\mathcal{P}^{(1)}_{2,X}$. That is, $\mathcal{P}^{(1)}_{2,X} = \mathcal{P}^{(1)}_{2,[k]}$ with $k = |X|$. The vertices of this complex are of the form $(p_i,(xyz,abc))$ where $i \in \{-1,0,1\}$, $\{x,y,z\} \in \binom{X}{3}$, and $a,b,c \in \{1,2,3\}$ with $a \neq b$ and $b \neq c$. The facets of $\mathcal{P}^{(1)}_{2,X}$ are of the form $F = \{(p_{-1},(x'xy,a'ab)),(p_0,(xyz,abc)),(p_1,(yzz',bcc'))\}$. Let us assume the existence of a name-preserving name-independent simplicial map $\delta : \mathcal{P}^{(1)}_{2,X} \to \mathcal{M}_2$ (see the rightmost diagram in Figure 6). This map induces a labeling of the pairs (xyz,abc) with labels in $\{0,1\}$, where xyz is an ordered triplet of distinct IDs, and abc is an ordered triplet of colors in $\{1,2,3\}$. It follows that δ induces a labeling of the ordered triplets xyz of distinct IDs by labels in $\{0,1\}^{12}$, by applying δ to the 12 possible choices of color triplets. By Ramsey's Theorem [14], by taking the IDs in the set $X = \{1,\dots,R\}$ with R large enough, there exists a set Y of five IDs such that, for every two sets $\{x,y,z\}$ and $\{x,'y',z'\}$ of IDs in Y, with $x<y<z$ and $x'<y'<z'$, and for every ordered sequence abc of colors, $\delta(p_0,(xyz,abc)) = \delta(p_0,(x'y'z',abc))$. Let $\mathcal{P}^{(1)}_{2,Y}$ be the sub-complex of the 1-round protocol complex $\mathcal{P}^{(1)}_{2,X}$ induced by the vertices with IDs in Y ordered in increasing order. By construction of Y, δ is ID-oblivious on $\mathcal{P}^{(1)}_{2,Y}$. Now, let $\mathcal{P}^{(1)}_{2,\varnothing}$ as displayed on Figure 7. Let us define the map $\delta' : \mathcal{P}^{(1)}_{2,\varnothing} \to \mathcal{M}_2$ by $\delta'(p_i,abc) = \delta(p_i,(xyz,abc))$ where $\{x,y,z\} \subset Y$ and $x<y<z$. Note that δ' is well defined as δ is ID-oblivious on Y. Assuming $\delta : \mathcal{P}^{(1)}_{2,X} \to \mathcal{M}_2$ is simplicial yields that $\delta' : \mathcal{P}^{(1)}_{2,\varnothing} \to \mathcal{M}_2$ is simplicial as well. We have seen in Section 4.2 that such a simplicial mapping does not exist. It follows that there are no name-preserving name-independent simplicial maps $\delta : \mathcal{P}^{(1)}_{2,[R]} \to \mathcal{M}_2$ whenever R is large enough (see Figure 6).

5 Topology of LCL Tasks

Let S_d be the star of $d+1$ nodes, whose center node is named p_0, and the leaves are named p_i, for $i=1,\dots,d$. We consider algorithms for classes $\mathcal{G}\subseteq\mathcal{G}_d$ of graphs. Let $T=(\mathcal{L}_{in},\mathcal{S}_{in},\mathcal{L}_{out},\mathcal{S}_{out})$ be an LCL task for $\mathcal{G}\subseteq\mathcal{G}_d$. The input complex $\mathcal{I}_d$ (resp., output complex $\mathcal{O}_d$) associated with T is the complex where $\{(p_i,x_i):i\in\{0,\dots,d\}\}$ is a facet of $\mathcal{I}_d$ (resp., a facet of $\mathcal{O}_d$) if $x_i\in\mathcal{L}_{in}$ (resp., $\mathcal{L}_{out}$) for every $i\in\{0,\dots,d\}$, and the labeled star resulting from assigning label x_i to the node p_i of S_d for every $i\in\{0,\dots,d\}$ is in $\mathcal{S}_{in}$ (resp., $\mathcal{S}_{out}$). If the considered LCL task T imposes constraints on the correctness of the outputs as a function of the inputs, as in list-coloring, then the carrier map $\Delta:\mathcal{I}_d\to 2^{\mathcal{O}_d}$ specifies, for each facet $F\in\mathcal{I}_d$, the facets $\Delta(F)$ which are legal with respect to F. Otherwise, $\Delta(F)=\{\text{all facets of } \mathcal{O}_d\}$, for every facet F of $\mathcal{I}_d$.

Let $t\geq 0$, and let us fix a graph $G=(V,E)$ in $\mathcal{G}\subseteq\mathcal{G}_d$. In t rounds, every node in G acquires a *view* w, whose structure is isomorphic to a radius-t ball in G centered at that node, including the input labels and the IDs of the nodes in the ball. An ordered collection $w_0,\dots,w_d$ of views at distance t forms a collection of *mutually compatible* views for $\mathcal{G}$ if there exists a graph $G\in\mathcal{G}$, an assignment of input labels and IDs to the nodes of G, and a star S in G, with nodes $v_0,\dots,v_d$, centered at v_0, such that w_i is the view of v_i in G after t rounds, for $i=0,\dots,d$.

Let T be an LCL task for $\mathcal{G}\subseteq\mathcal{G}_d$, and let $t\geq 0$. The t-round protocol complex associated with T for a finite set X of IDs, is the complex $\mathcal{P}^{(t)}_{d,X}$ where $F=\{(p_i,w_i):i\in\{0,\dots,d\}\}$ is a facet of $\mathcal{P}^{(t)}_{d,X}$ if $w_0,\dots,w_d$ is an ordered collection of mutually compatible views at distance t for $\mathcal{G}$. The special case $t=0$ corresponds to $\mathcal{P}^{(0)}_{d,X}=\mathcal{I}_{d,X}$ where $\mathcal{I}_{d,X}$ in the input complex $\mathcal{I}_d$ extended with IDs in X. The set X must be large enough for all the nodes in the views w_i, $i=0,\dots,d$, to be provided with distinct IDs. Namely, $|X|\geq N(d,t+1)$, where $N(d,t+1)$ denotes the maximum number of nodes in the ball of radius t in a graph in $\mathcal{G}$.

Two mappings from $\mathcal{I}_{d,X}$ play a crucial role. The first is the simplicial map $\pi:\mathcal{I}_{d,X}\to\mathcal{I}_d$ defined by $\pi(p_i,(\mathsf{id},x))=(p_i,x)$ for every $i=0,\dots,d$, every $\mathsf{id}\in X$, and every $x\in\mathcal{L}_{in}$. The second is the carrier map $\Xi_t:\mathcal{I}_{d,X}\to 2^{\mathcal{P}^{(t)}_{d,X}}$ that specifies, for each facet $F\in\mathcal{I}_{d,X}$, the set $\Xi_t(F)$ of facets which may result from F after t rounds of computation in graphs in $\mathcal{G}$. Specifically, they are merely the facets of $\mathcal{P}^{(t)}_{d,X}$ for which the views $w_0,\dots,w_d$ are compatible with the IDs and inputs of $p_0,\dots,p_d$ in F.

Our main result is an analog of the generic lemma (see Lemma 1), but involving local complexes, even for tasks defined on arbitrarily large networks, and for arbitrarily large sets of IDs.

▶ **Theorem 3.** *Let $T=(\mathcal{I}_d,\mathcal{O}_d,\Delta)$ be an LCL task for $\mathcal{G}\subseteq\mathcal{G}_d$, and let $t\geq 0$.*

- *If there exists a distributed algorithm solving T in t rounds in the LOCAL model then, for every $R\geq N(d,t+1)$, there is a name-independent and name-preserving simplicial map $\delta:\mathcal{P}^{(t)}_{d,[R]}\to\mathcal{O}_d$ such that, for every facet $F\in\mathcal{I}_{d,[R]}$, $\delta(\Xi_t(F))\subseteq\Delta(\pi(F))$.*
- *There exists $R\geq N(d,t+1)$ satisfying that, if there is a name-independent and name-preserving simplicial map $\delta:\mathcal{P}^{(t)}_{d,[R]}\to\mathcal{O}_d$ such that, for every facet $F\in\mathcal{I}_{d,[R]}$, $\delta(\Xi_t(F))\subseteq\Delta(\pi(F))$, then there is a distributed algorithm solving T in t rounds in the LOCAL model.*

Proof. Let us fix an LCL task $T=(\mathcal{L}_{in},\mathcal{S}_{in},\mathcal{L}_{out},\mathcal{S}_{out})=(\mathcal{I}_d,\mathcal{O}_d,\Delta)$ for $\mathcal{G}$, and $t\geq 0$. Let ALG be a t-round algorithm for T. For any finite set X of IDs, let $\delta_X:\mathcal{P}^{(t)}_{d,X}\to\mathcal{O}_d$ defined by $\delta_X(p_i,w_i)=(p_i,\textsc{alg}(w_i))$, for every $i=0,\dots,d$. By construction, δ_X is name-independent, and name-preserving. To show that δ_X is simplicial, let $F'=\{(p_i,w_i):i\in\{0,\dots,d\}\}$ be a facet of the protocol complex $\mathcal{P}^{(t)}_{d,X}$. This facet is mapped to $\delta_X(F')=\{(p_i,\textsc{alg}(w_i)):$

$i \in \{0, \dots, d\}\}$. Since ALG solves T, every output $\text{ALG}(w_i)$ is in $\mathcal{L}_{out}$, and the labeled star resulting from assigning label $\text{ALG}(w_i)$ to the node p_i of the star S_d, for every $i \in \{0, \dots, d\}$, is in $\mathcal{S}_{out}$. It follows that $\delta_X(F')$ is a facet of $\mathcal{O}_d$, and thus δ_X is simplicial. Moreover, if the facet F' belongs to the image $\Xi_t(F)$ of a facet F of $\mathcal{I}_{d,X}$, since ALG solves T, it follows that $\delta_X(F') \in \Delta(\pi(F))$ as desired. So, the existence of an algorithm ALG guarantees the existence of a simplicial map δ_X satisfying the requirements of the theorem for *every* large enough set X of IDs.

We now show that, to guarantee the existence of an algorithm, it is sufficient to guarantee the existence of a simplicial map δ_X just for *one* specific set $X = [R]$. In order to identify R, we follow the same guideline as the specific impossibility proof in Section 4.3, using Ramsey's theorem. Note that the number of possible balls of radius t in graphs of $\mathcal{G}$ is finite, and depends only on t and d. Given such a ball B, there are finitely many ways of assigning input labels to the vertices of B. The number of assignments depends only on the structure of B, and on $|\mathcal{L}_{in}|$. (It may also depend on $\mathcal{S}_{in}$, but in the worst case, all assignments are possible.) Let us enumerate all the labeled balls in $\mathcal{G}$ as $B^{(1)}, \dots, B^{(k)}$. The number k of such labeled balls depends only on d, t, and $|\mathcal{L}_{in}|$. (It may also depend on $\mathcal{G}$, but it is upper bounded by a function of d, t, and $|\mathcal{L}_{in}|$.)

For every labeled ball $B^{(i)}$, $i = 1, \dots, k$, let $\nu_i = |B^{(i)}|$. Let us rank the vertices of $B^{(i)}$ arbitrarily from 1 to ν_i, and let Σ_i be the set of all permutations of $\{1, \dots, \nu_i\}$. To every $\pi \in \Sigma_i$ corresponds a labeled ball $B^{(i)}_\pi$ in which the rank of the vertices is determined by π. Now, let X be a finite set of IDs with $|X| \geq N(d, t+1)$. We consider all possible identity-assignments with IDs in X to the nodes of the labeled balls with ranked vertices, $B^{(i)}_\pi$, $i = 1, \dots, k$, $\pi \in \Sigma_i$, as follows. For every $S \subseteq X$ with $|S| = N(d, t)$, let us order the IDs in S in increasing order. Given a ranked labeled ball $B^{(i)}_\pi$, i.e., a labeled ball $B^{(i)}$ whose vertices are ranked by some permutation $\pi \in \Sigma_i$, the IDs in S are assigned to the nodes of $B^{(i)}_\pi$ by assigning the jth smallest ID in S to the node ranked $\pi(j)$ in $B^{(i)}_\pi$, for $j = 1, \dots, \nu_i$. By picking all $i = 1, \dots, k$, all $\pi \in \Sigma_i$, and all $S \subseteq X$, we obtain all possible views resulting from performing a t-round algorithm in $\mathcal{G}$ with IDs taken from X. Let us order these views as $w^{(1)}, \dots, w^{(h)}$, where the views induced by $B^{(1)}$ are listed first, then the views induced by $B^{(2)}$, etc., until the views induced by $B^{(k)}$. Moreover, for a given $i \in \{1, \dots, k\}$, the views corresponding to the labeled ball $B^{(i)}$ are listed according to the lexicographic order of the permutations in Σ_i. Note that the number h of views depends only on d, t, $|\mathcal{L}_{in}|$, and $|X|$. Each set S is then "colored" by

$$c(S) = (\delta_X(p_0, w^{(1)}), \dots, \delta_X(p_0, w^{(h)})) \in \{1, \dots, |\mathcal{L}_{out}|\}^h.$$

In this way, the set $\binom{X}{N(d,t)}$ is partitioned into $|\mathcal{L}_{out}|^h$ classes. Thanks to Ramsey's Theorem, by taking set

$$X = [R] \text{ with } R = R(a, b, c) \text{ for } a = |\mathcal{L}_{out}|^h, \text{ and } b = c = N(d, t+1),$$

we are guaranteed that there exists a set Y of at least $N(d, t+1)$ IDs such that every two sets S and S' of $N(d, t)$ IDs in Y are given the same color $c(S) = c(S')$. In other words, for any ball B of radius t in a graph from $\mathcal{G}$, and for every valid assignment of inputs values to the nodes of B, if one assigns the IDs in S and S' in the same manner (i.e., the ith smallest ID of S is assigned to the same node as the ith smallest ID of S'), then $\delta_X(p_0, w) = \delta_X(p_0, w')$, where w and w' are the views resulting from assigning IDs from S and S' to the nodes, respectively.

Now, let us define the following t-round algorithm ALG for T. Actually, this is precisely the order-invariant algorithm constructed in [16]. Every node v collects the data available in its centered ball $B = B_G(v,t)$ of radius t in the actual graph $G \in \mathcal{G}$. Note that B contains IDs, and input values. Node v reassigns the IDs to the nodes of B by using the $|B|$ smallest IDs in Y, and assigning these IDs to the nodes of B in the order respecting the order of the actual IDs assigned to the nodes of B. Then node v considers the view w after reassignment of the IDs, and outputs $\text{ALG}(w) = \delta_X(p_0, w)$. Note that δ_X returns values in $\mathcal{L}_{out}$, and thus ALG is well defined.

To show correctness, let us consider a star $v_0, \dots, v_d$ centered at v_0 in some graph $G \in \mathcal{G}$. Performing ALG in G, each of these $d+1$ nodes acquires a view of radius t. These views are mutually compatible. Let us reassign the IDs in the ball of radius $t+1$ centered at v_0 in G, using the at most $N(d, t+1)$ smallest IDs in Y, and assigning these IDs to the nodes of the ball B of radius $t+1$ centered at v_0, in the order respecting the order of the actual IDs assigned to the nodes of B. The resulting views $w_0, \dots, w_d$ of the $d+1$ nodes $v_0, \dots, v_d$ remain mutually compatible. It follows that if these $d+1$ nodes would output $\delta_X(p_0, w_0), \dots, \delta_X(p_d, w_d)$, respectively, then the resulting star would be good. We claim that this is exactly what occurs with ALG. Indeed, first, δ_X is name-independent, and thus $\delta_X(p_0, w) = \delta_X(p_i, w)$ for every $i = 1, \dots, d$. Second, and more importantly, by the construction of Y, the actual *values* of the IDs do not matter, but solely their *relative order*. The reassignment of IDs performed at each of the nodes $v_0, \dots, v_d$ is different from the reassignment of IDs in the ball B of radius $t+1$ around v_0, but the relative order of these IDs is preserved as it is governed by the relative order of the original IDs in B. As a consequence, the nodes of S_d correctly output $\delta_X(p_0, w_0), \dots, \delta_X(p_d, w_d)$ in ALG, as desired. ◀

To illustrate Theorem 3, we reprove the celebrated result by Linial [15] regarding 3-coloring the n-node ring in at least $\frac{1}{2}\log^* n - 1$ rounds (see also [2, 3, 13]), which can be obtained by iterating Corollary 4.

▶ **Corollary 4.** *Let $t \geq 1$, $k \geq 2$, $n \geq 1$, and $N \geq n$. If there is a t-round algorithm for k-coloring $C_n = (v_1, \dots, v_n)$ whenever the IDs in $[N]$ are assigned to consecutive nodes v_i, v_{i+1}, $i \in \{1, \dots, n-1\}$, in increasing order of their indices, then there is a $(t-1)$-round algorithm for 2^{2^k}-coloring C_n under the same constraints of the identity assignment.*

Proof. Our aim is to find $\delta_{t-1} : \mathcal{P}^{(t-1)}_{[R]} \to \mathcal{O}_{2^{2^k}}$ where $\mathcal{O}_{2^{2^k}}$ is the output complex for 2^{2^k}-coloring C_n. For this purpose, we follows the approach illustrated on Figure 10. That is, first, we identify a functor Φ on a category corresponding to a subclass of simplicial complexes. From the simplicial map $\delta_t : \mathcal{P}^{(t)}_{[R]} \to \mathcal{O}_k$, we derive the simplicial map $\Phi(\delta_t) : \Phi(\mathcal{P}^{(t)}_{[R]}) \to \Phi(\mathcal{O}_k)$. Then we show that $\Phi(\mathcal{O}_k) \subseteq \mathcal{O}_{2^{2^k}}$, and therefore $\Phi(\delta_t)$ maps $\Phi(\mathcal{P}^{(t)}_{[R]})$ to $\mathcal{O}_{2^{2^k}}$. Finally, we identify a simplicial map $f : \mathcal{P}^{(t-1)}_{[R]} \to \Phi(\mathcal{P}^{(t)}_{[R]})$ enabling to conclude that $\delta_{t-1} : \mathcal{P}^{(t-1)}_{[R]} \to \mathcal{O}_{2^{2^k}}$ defined by $\delta_{t-1} = \Phi(\delta_t) \circ f$ satisfies the hypotheses of Theorem 3, showing the existence of a $(t-1)$-round algorithm for 2^{2^k}-coloring C_n.

More specifically, given any complex $\mathcal{K}$ with vertices (p_i, v) with $i \in \{-1, 0, 1\}$, and $v \in V$ where V is a finite set of values, we define the functor Φ as follows. The complex $\Phi(\mathcal{K})$ is on the set of vertices $(p_i, \mathbf{S})$ where $\mathbf{S} = \{S_1, \dots, S_\ell\}$ for some $\ell \geq 0$, and $S_i \subseteq V$ for every $i = 1, \dots, \ell$. A set $\{(p_{-1}, \mathbf{S}_{-1}), (p_0, \mathbf{S}_0), (p_1, \mathbf{S}_1)\}$ forms a facet of $\Phi(\mathcal{K})$ if for every $i \in \{0, 1\}$,

$$\exists S \in \mathbf{S}_{i-1} \;\; \forall S' \in \mathbf{S}_i \;\; \exists v' \in S' \;\; \forall v \in S \;:\; \{(p_{i-1}, v), (p_i, s')\} \in \mathcal{K}. \qquad (1)$$

$$\begin{tikzcd}
\mathcal{P}^{(t)}_{[R]} \arrow[r, "\Phi"] \arrow[d, "\delta_t"'] & \Phi(\mathcal{P}^{(t)}_{[R]}) \arrow[d, "\Phi(\delta_t)"'] & \mathcal{P}^{(t-1)}_{[R]} \arrow[l, "f"'] \arrow[dl, "\delta_{t-1}"'] \\
\mathcal{O}_k \arrow[r, "\Phi"] & \Phi(\mathcal{O}_k) \subseteq \mathcal{O}_{2^{2^k}} &
\end{tikzcd}$$

Figure 10 Commutative diagrams in the proof of Corollary 4.

Given a simplicial map $\psi : \mathcal{A} \to \mathcal{B}$ the map $\Phi(\psi)$ is defined as

$$\Phi(\psi)(p_i, \mathbf{S}) = \Big(p_i, \Big\{\{\pi_2\circ\psi(p_i, v_{1,1}), \dots, \pi_2\circ\psi(v_{1,s_1})\}, \dots, \{\pi_2\circ\psi(v_{\ell,1}), \dots, \pi_2\circ\psi(v_{\ell,s_\ell})\}\Big\}\Big)$$

for every $i = \{-1, 0, 1\}$, and every $\mathbf{S} = \{S_1, \dots, S_\ell\}$ with $S_j = \{v_{j,1}, \dots, v_{j,s_j}\}$ and $s_j \geq 0$, where $\pi_2 : \mathcal{B} \to V$ is the mere projection $\pi_2(p_i, v) = v$ for every value v. By construction, $\Phi(\psi) : \Phi(\mathcal{A}) \to \Phi(\mathcal{B})$ is simplicial. Note that if ψ is name-invariant and name-preserving, then $\Phi(\psi)$ as well.

Next, we observe that $\Phi(\mathcal{O}_k)$ is a sub-complex of $\mathcal{O}_{2^{2^k}}$. To see why, note first that Φ maps vertices of $\mathcal{O}_k$ to vertices of $\mathcal{O}_{2^{2^k}}$. Moreover, a facet $F = \{(p_{-1}, \mathbf{S}_{-1}), (p_0, \mathbf{S}_0), (p_1, \mathbf{S}_1)\}$ of $\Phi(\mathcal{O}_k)$ is a facet of $\mathcal{O}_{2^{2^k}}$. Indeed, Eq. (1) guarantees that there exists a set S in $\mathbf{S}_{-1}$ such that for every set S' in $\mathbf{S}_0$, there exists a color v' in S' that is different from all the colors in S. It follows that $S \notin \mathbf{S}_0$, and therefore $\mathbf{S}_{-1} \neq \mathbf{S}_0$. By the same argument, $\mathbf{S}_0 \neq \mathbf{S}_1$, and thus F is a facet of $\mathcal{O}_{2^{2^k}}$, as claimed. Finally, we define the simplicial map $f : \mathcal{P}^{(t-1)}_{[R]} \to \Phi(\mathcal{P}^{(t)}_{[R]})$ as follows. Let us consider a vertex $(p_i, w) \in \mathcal{P}^{(t-1)}_{[R]}$, with $w = (z_{-(t-1)}, \dots, z_{-1}, z_0, z_1, \dots, z_{t-1}) \in [R]^{2t-1}$ with $z_{-(t-1)} < \cdots < z_{t-1}$. For every $b \in [R]$ with $b > z_{t-1}$, let $W_i^b = \{awb : a \in [R], a < z_{-(t-1)}\}$, and let $\mathbf{W}_i = \{W_i^b : b \in [R], b > z_{t-1}\}$. We set $f(p_i, w) = (p_i, \mathbf{W}_i)$. This mapping maps every vertex of $\mathcal{P}^{(t-1)}_{[R]}$ to a vertex of $\Phi(\mathcal{P}^{(t)}_{[R]})$. Let us show that f is simplicial. For this purpose, let us consider a facet

$$F = \{(p_{-1}, x'xw), (p_0, xwy), (p_1, wyy')\}$$

of $\mathcal{P}^{(t-1)}_{[R]}$. Here $w = (z_{-(t-2)}, \dots, z_{-1}, z_0, z_1, \dots, z_{t-2}) \in [R]^{2t-3}$ with $x' < x < z_{-(t-2)} < \cdots < z_{t-2} < y < y'$. Let us consider the two sets $W_{-1}^y \in \mathbf{W}_{-1}$ and $W_0^{y'} \in \mathbf{W}_0$. We claim that these are the two sets witnessing the validity of Eq. (1) for establishing the fact that $f(F)$ is a facet of $\Phi(\mathcal{P}^{(t)}_{[R]})$. To see why, let $W_0^b \in \mathbf{W}_0$, and let $x'xwyb \in W_0^b$. The view $ax'xwy$ for p_{-1} is compatible with the view $x'xwyb$ for p_0, for every $a < x'$. Therefore, for every set $W_0^b \in \mathbf{W}_0$, there exists a view $x'xwyb \in W_0^b$ such that, for every view $ax'xwy \in W_{-1}^y$,

$$\{(p_{-1}, ax'xwy), (p_0, x'xwyb)\} \in \mathcal{P}^{(t)}_{[R]}.$$

Hence Eq. (1) is satisfied for p_{-1} and p_0. By the same arguments, using $W_0^{y'}$ instead of W_{-1}^y, Eq. (1) is satisfied for p_{-1} and p_0, from which it follows that $f(F)$ is a facet of $\Phi(\mathcal{P}^{(t)}_{[R]})$. We conclude that f is simplicial. Since both f and $\Phi(\delta)$ are simplicial, the map $\delta' = \Phi(\delta) \circ f$ is simplicial too, which completes the proof by application of Theorem 3. ◀

6 Conclusion and Further Work

This paper shows that the study of algorithms for solving LCL tasks in the LOCAL model can be achieved by considering simplicial complexes whose sizes are independent of the number of nodes, and independent of the number of possible IDs that could be assigned to these nodes.

Two main directions for further work can be identified. A first direction is understanding topological properties of the carrier map $\Xi_t : \mathcal{I}_{d,X} \to \mathcal{P}^{(t)}_{d,X}$ occurring in the LOCAL model depending on the network. Another direction is understanding what governs the existence of the simplicial map $\delta : \mathcal{P}^{(t)}_{d,X} \to \mathcal{O}$ depending on the considered task.

Abstract

We study the problem of verifying differential privacy for loop-free programs with probabilistic choice. Programs in this class can be seen as randomized Boolean circuits, which we will use as a formal model to answer two different questions: first, deciding whether a program satisfies a prescribed level of privacy; second, approximating the privacy parameters a program realizes. We show that the problem of deciding whether a program satisfies ε-differential privacy is $\mathbf{coNP}^{\#\mathbf{P}}$-complete. In fact, this is the case when either the input domain or the output range of the program is large. Further, we show that deciding whether a program is (ε, δ)-differentially private is $\mathbf{coNP}^{\#\mathbf{P}}$-hard, and in $\mathbf{coNP}^{\#\mathbf{P}}$ for small output domains, but always in $\mathbf{coNP}^{\#\mathbf{P}^{\#\mathbf{P}}}$. Finally, we show that the problem of approximating the level of differential privacy is both **NP**-hard and **coNP**-hard. These results complement previous results by Murtagh and Vadhan [35] showing that deciding the optimal composition of differentially private components is #**P**-complete, and that approximating the optimal composition of differentially private components is in **P**.

1 Introduction

Differential privacy [22] is currently making significant strides towards being used in large scale applications. Prominent real-world examples include the use of differentially private computations by the US Census' OnTheMap project[1], applications by companies such as Google and Apple [24, 36, 4, 18], and the US Census' plan to deploy differentially private releases in the upcoming 2020 Decennial [1].

More often than not, algorithms and their implementations are analyzed "on paper" to show that they provide differential privacy. This analysis – a proof that the outcome distribution of the algorithm is stable under the change in any single individual's information – is often intricate and may contain errors (see [32] for an illuminating discussion about several wrong versions of the sparse vector algorithm which appeared in the literature). Moreover, even if it is actually differentially private, an algorithm may be incorrectly implemented when used in practice, e.g., due to coding errors, or because the analysis makes assumptions which do not hold in finite computers, such as the ability to sample from continuous distributions (see [34] for a discussion about privacy attacks on naive implementations of continuous distributions). Verification tools may help validate, given the code of an implementation, that it would indeed provide the privacy guarantees it is intended to provide. However, despite the many verification efforts that have targeted differential privacy based on automated or interactive techniques (see, e.g.,[37, 9, 40, 25, 7, 44, 6, 2, 14, 15]), little is known about the complexity of some of the basic problems in this area. Our aim is to clarify the complexity of some of these problems.

In this paper, we consider the computational complexity of determining whether programs satisfy (ε, δ)-differential privacy. The problem is generally undecidable, and we hence restrict our attention to probabilistic loop-free programs, which are part of any reasonable programming language supporting random computations. To approach this question formally, we consider probabilistic circuits. The latter are Boolean circuits with input nodes corresponding both to input bits and to uniformly random bits ("coin flips") where the latter allow the circuit to behave probabilistically (see Figure 1). We consider both decision and approximation versions of the problem, where in the case of decision the input consists of a randomized circuit and parameters ε, δ and in the case of approximation the input is a randomized circuit, the desired approximation precision, and one of the two parameters ε, δ. In both cases, complexity is measured as function of the total input length in bits (circuit and parameters).

Previous works have studied the complexity of composing differentially private components. For any k differentially private algorithms with privacy parameters $(\varepsilon_1, \delta_1), \ldots, (\varepsilon_k, \delta_k)$, it is known that their composition is also differentially private [22, 23, 35], making composition a powerful design tool for differentially private programs. However, not all interesting differentially private programs are obtained by composing differentially private components, and a goal of our work is to understand what is the complexity of verifying that full programs are differentially private, and how this complexity differs from the one for programs which result of composing differentially private components.

Regarding the resulting parameters, the result of composing the k differentially private algorithms above results in $(\varepsilon_g, \delta_g)$-differentially private for a multitude of possible $(\varepsilon_g, \delta_g)$ pairs. Murtagh and Vadhan showed that determining the minimal ε_g given δ_g is $\#\mathbf{P}$-complete [35]. They also gave a polynomial time approximation algorithm that computes ε_g to arbitrary accuracy, giving hope that for "simple" programs deciding differential privacy or approximating of privacy parameters may be tractable. Unfortunately, our results show that this is not the case.

1.1 Contributions

Following the literature, we refer to the variant of differential privacy where $\delta = 0$ as *pure* differential privacy and to the variant where $\delta > 0$ as *approximate* differential privacy. We contribute in three directions.

- **Bounding pure differential privacy.** We show that determining whether a randomized circuit is ε-differentially private is $\mathbf{coNP}^{\#\mathbf{P}}$-complete.[2] To show hardness in $\mathbf{coNP}^{\#\mathbf{P}}$ we consider a complement to the problem E-Maj-Sat [31], which is complete for $\mathbf{NP}^{\#\mathbf{P}}$ [13]. In the complementary problem, All-Min-Sat, given a formula ϕ over $n+m$ variables the task is to determine if for all allocations $\boldsymbol{x} \in \{0,1\}^n$, $\phi(\boldsymbol{x}, \boldsymbol{y})$ evaluates to true on no more than $\frac{1}{2}$ of allocations to $\boldsymbol{y} \in \{0,1\}^m$.
- **Bounding approximate differential privacy.** Turning to the case where $\delta > 0$, we show that determining whether a randomized circuit is (ε, δ)-differentially private is $\mathbf{coNP}^{\#\mathbf{P}}$-complete when the number of output bits is small relative to the total size of the circuit and otherwise between $\mathbf{coNP}^{\#\mathbf{P}}$ and $\mathbf{coNP}^{\#\mathbf{P}^{\#\mathbf{P}}}$.
- **Approximating the parameters ε and δ.** Efficient approximation algorithms exist for optimal composition [35], and one might expect the existence of polynomial time algorithms to approximate ε or δ in randomized circuits. We show this is $\mathbf{NP}$-hard and $\mathbf{coNP}$-hard, and therefore an efficient algorithm does not exist (unless $\mathbf{P} = \mathbf{NP}$).

Our results show that for loop-free programs with probabilistic choice directly verifying whether a program is differentially private is intractable. These results apply to programs in any reasonable programming language supporting randomized computations. Hence, they set the limits on where to search for automated techniques for these tasks.

The relation to quantitative information flow

Differential privacy shares similarities with quantitative information flow [17, 27], which is an entropy-based theory measuring how secure a program is. Alvim et al. [3] showed that a bound on pure differential privacy implies a bound on quantitative information flow. So, one could hope that bounding differential privacy could be easier than bounding quantitative information flow. Yasuoka and Terauchi [42] have shown that bounding quantitative information flow for loop free boolean programs with probabilistic choice is $\mathbf{PP}$-hard (but in $\mathbf{PSPACE}$). In contrast, our results show that bounding pure differential privacy is $\mathbf{coNP}^{\#\mathbf{P}}$-complete. Chadha et al. [11] showed the problem to be $\mathbf{PSPACE}$-complete for boolean programs with loops and probabilistic choice (notice that this would be not true for programs with integers). We leave the analogous question for future works.

2 Preliminaries

Numbers

By a *number given as a rational* we mean a number of the form $\frac{x}{y}$ where x, y are given as binary integers.

2.1 Loop-free probabilistic programs

We consider a simple loop-free imperative programming language built over Booleans, and including probabilistic choice.

$$
\begin{array}{lcll}
x & ::= & [\mathrm{a{-}z}]^+ & \text{(variable identifiers)}\\
b & ::= & \texttt{true} \mid \texttt{false} \mid \texttt{random} \mid x \mid b \wedge b \mid b \vee b \mid \neg b & \text{(boolean expressions)}\\
c & ::= & \texttt{SKIP} \mid x := b \mid c;\ c \mid \texttt{if } b \texttt{ then } c \texttt{ else } c & \text{(commands)}\\
t & ::= & x \mid t, x & \text{(list of variables)}\\
p & ::= & \texttt{input}(t);\ c;\ \texttt{return}(t) & \text{(programs)}
\end{array}
$$

[2] The class $\mathbf{coNP}^{\#\mathbf{P}}$ is contained in $\mathbf{PSPACE}$ and contains the polynomial hierarchy (as, per Toda's Theorem, $\mathbf{PH} \subseteq \mathbf{P}^{\#\mathbf{P}}$).

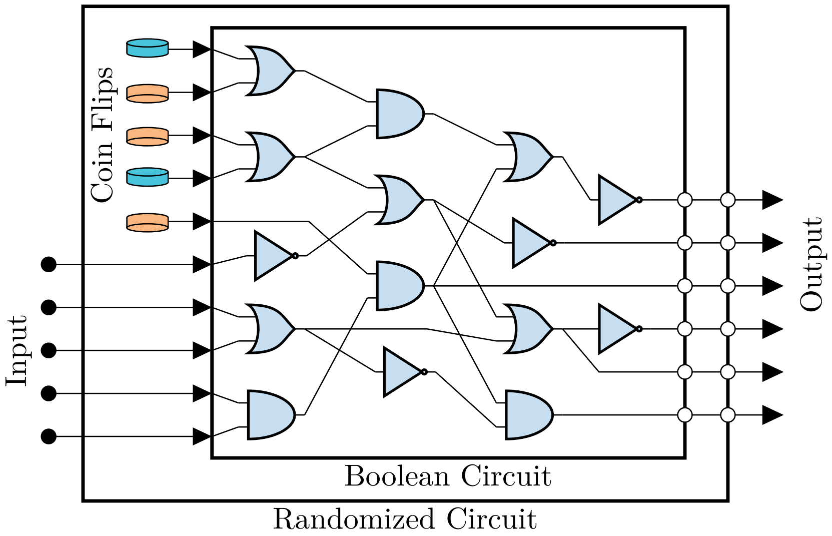

Figure 1 Example randomized circuit.

Probabilistic programs [30] extend standard programs with the addition of coin tosses; this is achieved by the probabilistic operation `random`, which returns either `true` or `false` with equal probability. A standard operation, sometimes denoted by $c \oplus c$, which computes one of the two expressions with probability $\frac{1}{2}$ each is achieved with `if random then` c `else` c. The notation $c \oplus c$ is avoided as $\oplus$ refers to *exclusive or* in this paper.

The semantics of the programming language are standard and straight forward. Without loss of generality, each variable assignment is final, that is, each assignment must go to a fresh variable. Looping behaviour is not permitted, although bounded looping can be encoded by unrolling the loop.

▶ Remark 1. Our results also hold when the language additionally supports integers and the associated operations (e.g. $+, \times, -, \geq, =$ etc.), providing the integers are of a bounded size. Such a language is equally expressive as the language presented here. Further details are given in the full version of the paper.

2.2 Probabilistic circuits

▶ **Definition 2.** *A Boolean circuit ψ with n inputs and ℓ outputs is a directed acyclic graph $\psi = (V, E)$ containing n input vertices with zero in-degree, labeled $X_1, \ldots, X_n$ and ℓ output vertices with zero out-degree, labeled $O_1, \ldots, O_\ell$. Other nodes are assigned a label in $\{\wedge, \vee, \neg\}$, with vertices labeled $\neg$ having in-degree one and all others having in-degree two. The size of ψ, denoted $|\psi|$, is defined to be $|V|$. A* randomized circuit *has m additional random input vertices labeled $R_1, \ldots, R_m$.*

Given an input string $\boldsymbol{x} = (x_1, \ldots, x_n) \in \{0,1\}^n$, the circuit is evaluated as follows. First, the values $x_1, \ldots, x_n$ are assigned to the nodes labeled $X_1, \ldots, X_n$. Then, m bits $\boldsymbol{r} = (r_1, \ldots, r_m)$ are sampled uniformly at random from $\{0,1\}^m$ and assigned to the nodes labeled $R_1, \ldots, R_m$. Then, the circuit is evaluated in topological order in the natural way. E.g., let v be a node labeled $\wedge$ with incoming edges $(u_1, v), (u_2, v)$ where u_1, u_2 were assigned values z_1, z_2 then v is assigned the value $z_1 \wedge z_2$. The outcome of ψ is $(o_1, \ldots, o_\ell)$, the concatenation of values assigned to the ℓ output vertices $O_1, \ldots, O_\ell$.

For input $\boldsymbol{x} \in \{0,1\}^n$ and event $E \subseteq \{0,1\}^\ell$ we have

$$\Pr[\psi(\boldsymbol{x}) \in E] = \frac{|\{\boldsymbol{r} \in \{0,1\}^m \ : \ \psi(\boldsymbol{x}, \boldsymbol{r}) \in E\}|}{2^m}.$$

▶ Remark 3. The operators, $\wedge, \vee$ and $\neg$ are functionally complete. However, we will also use $\oplus$ (exclusive or), such that $p \oplus q \iff (p \vee q) \wedge \neg(p \wedge q)$.

2.3 Equivalence of programs and circuits

▶ **Lemma 4.** *A loop-free probabilistic program can be converted into an equivalent probabilistic boolean circuit in linear time in the size of the program (and vice-versa).*

Proof sketch. It is clear that a probabilistic circuit can be expressed as a probabilistic program using just boolean operations by expressing a variable for each vertex after sorting the vertices in topological order.

To convert a probabilistic Boolean program into a probabilistic circuit, each of the commands can be handled using a fixed size sub-circuit, each of which can be composed together appropriately. ◀

Given the equivalence between loop-free probabilistic programs and probabilistic circuits, the remainder of the paper will use probabilistic circuits.

2.4 Differential privacy in probabilistic circuits

Let X be any input domain. An input to a differentially private analysis would generally be an array of elements from a data domain X, each corresponding to the information of an individual, i.e., $\boldsymbol{x} = (x_1, \ldots, x_n) \in X^n$.

The definition of differential privacy depends on adjacency between inputs, we define *neighboring* inputs.

▶ **Definition 5.** *Inputs $\boldsymbol{x} = (x_1, \ldots, x_n)$ and $\boldsymbol{x}' = (x'_1, \ldots, x'_n) \in X^n$ are called* neighboring *if there exist $i \in [n]$ s.t. if $j \neq i$ then $x_j = x'_j$.*

In this work, we will consider input domains with finite representation. Without loss of generality we set $X = \{0,1\}^k$ and hence an array $x = (x_1, \ldots, x_n)$ can be written as a sequence of nk bits, and given as input to a (randomized) circuit with nk inputs. Our lower bounds work already for for $k = 1$ and our upper bounds are presented using $k = 1$ but generalise to all k.

▶ **Definition 6** (Differential Privacy [22, 21])**.** *A probabilistic circuit ψ is (ε, δ)-differentially private if for all neighboring $\boldsymbol{x}, \boldsymbol{x}' \in X^n$ and for all $E \subseteq \{0,1\}^\ell$,*

$$\Pr[\psi(\boldsymbol{x}) \in E] \leq e^\varepsilon \cdot \Pr[\psi(\boldsymbol{x}') \in E] + \delta.$$

Following common use, we refer to the case where $\delta = 0$ as *pure* differential privacy and to the case where $\delta > 0$ as *approximate* differential privacy. When omitted, δ is understood to be zero.

2.5 Problems of deciding and approximating differential privacy

We formally define our three problems of interest.

▶ **Definition 7.** *The problem* Decide-ε-DP *asks, given ε and ψ, if ψ is ε-differentially private. We assume ε is given by the input e^ε as a rational number.*

▶ **Definition 8.** *The problem* Decide-ε,δ-DP *asks, given ε, δ and ψ, if ψ is (ε,δ)-differentially private. We assume ε is given by the input e^ε as a rational number.*

▶ **Definition 9.** *Given an approximation error $\gamma > 0$, the* Approximate-δ *problem and the* Approximate-ε *problem, respectively, ask:*

- *Given ε, find $\hat{\delta} \in [0,1]$, such that $0 \leq \hat{\delta} - \delta \leq \gamma$, where δ is the minimal value such that ψ is (ε,δ)-differentially private.*
- *Given δ, find $\hat{\varepsilon} \geq 0$, such that $0 \leq \hat{\varepsilon} - \varepsilon \leq \gamma$, where ε is the minimal value such that ψ is (ε,δ)-differentially private.*

2.6 The class $\mathbf{coNP}^{\#\mathbf{P}}$

The complexity class $\#\mathbf{P}$ is the counting analogue of **NP** problems. In particular #Sat, the problem of counting the number of satisfying assignments of a given a boolean formula ϕ on n variables, is complete for $\#\mathbf{P}$. Similarly #CircuitSat, the problem of counting the satisfying assignments of a circuit with a single output, is complete for $\#\mathbf{P}$.

A language L is in $\mathbf{coNP}^{\#\mathbf{P}}$ if membership in L can be refuted using a polynomial time non-deterministic Turing machine with access to a $\#\mathbf{P}$ oracle. It is easy to see that $\mathbf{coNP}^{\#\mathbf{P}} = \mathbf{coNP}^{\mathbf{PP}}$, and $\mathbf{PH} \subseteq \mathbf{coNP}^{\#\mathbf{P}} \subseteq \mathbf{PSPACE}$, where $\mathbf{PH} \subseteq \mathbf{coNP}^{\#\mathbf{P}}$ follows by Toda's theorem ($\mathbf{PH} \subseteq \mathbf{P}^{\#\mathbf{P}}$) [39].

The following decision problem is complete for $\mathbf{NP}^{\#\mathbf{P}}$ [13]:

▶ **Definition 10.** *E-Maj-Sat asks, given ϕ a quantifier free formula over $n+m$ variables if there exist an allocation $\boldsymbol{x} \in \{0,1\}^n$ such that there are strictly greater than $\frac{1}{2}$ of allocations to $\boldsymbol{y} \in \{0,1\}^m$ where $\phi(\boldsymbol{x},\boldsymbol{y})$ evaluates to true.*

The complementary problem All-Min-Sat, is complete for $\mathbf{coNP}^{\#\mathbf{P}}$: a formula ϕ is All-Min-Sat, if ϕ is not E-Maj-Sat. That is, ϕ a quantifier free formula over $n+m$ variables is All-Min-Sat if for all allocations $\boldsymbol{x} \in \{0,1\}^n$ there are no more than $\frac{1}{2}$ of allocations to $\boldsymbol{y} \in \{0,1\}^m$ where $\phi(\boldsymbol{x},\boldsymbol{y})$ evaluates to true.

3 The complexity of deciding pure differential privacy

In this section we classify the complexity of deciding ε-differential privacy, for which we show the following theorem:

▶ **Theorem 11.** Decide-ε-DP *is* $\mathbf{coNP}^{\#\mathbf{P}}$*-complete.*

It will be convenient to consider the well-known simpler reformulation of the definition of pure differential privacy in finite ranges to consider specific outcomes $\boldsymbol{o} \in \{0,1\}^\ell$ rather than events $E \subseteq \{0,1\}^\ell$.

▶ **Reformulation 12** (Pure differential privacy)**.** A probabilistic circuit ψ is ε-differentially private if and only if for all neighboring $\boldsymbol{x},\boldsymbol{x'} \in X^n$ and for all $\boldsymbol{o} \in \{0,1\}^\ell$,

$$\Pr[\psi(\boldsymbol{x}) = \boldsymbol{o}] \leq e^\varepsilon \cdot \Pr[\psi(\boldsymbol{x'}) = \boldsymbol{o}].$$

3.1 Decide-ε-DP is in $\mathbf{coNP}^{\#\mathbf{P}}$

We show a non-deterministic Turing machine which can "refute" ψ being ε-differentially private in (non-deterministic) polynomial time with a $\#\mathbf{P}$ oracle. A circuit ψ is shown not to be ε-differentially private by exhibiting a combination $\boldsymbol{x}, \boldsymbol{x'}, \boldsymbol{o}$ such that $\Pr[\psi(\boldsymbol{x}) = \boldsymbol{o}] > e^{\varepsilon} \cdot \Pr[\psi(\boldsymbol{x'}) = \boldsymbol{o}]$. The witness to the non-deterministic Turing machine would be a sequence of $2n$ bits parsed as neighboring inputs $\boldsymbol{x}, \boldsymbol{x'} \in \{0,1\}^n$ and ℓ bits describing an output $\boldsymbol{o} \in \{0,1\}^{\ell}$. The constraint can then be checked in polynomial time, using the $\#\mathbf{P}$ oracle to compute $\Pr[\psi(\boldsymbol{x}) = \boldsymbol{o}]$ and $\Pr[\psi(\boldsymbol{x'}) = \boldsymbol{o}]$.

To compute $\Pr[\psi(\boldsymbol{x}) = \boldsymbol{o}]$ in $\#\mathbf{P}$ we create an instance to #CircuitSat, which will count the number of allocations to the m probabilistic bits consistent with this output. We do this by extending ψ with additional gates reducing to a single output which is true only when the input is fixed to $\boldsymbol{x}$ and the output of ψ was $\boldsymbol{o}$.

3.2 $\mathbf{coNP}^{\#\mathbf{P}}$-hardness of Decide-$\varepsilon$-DP

To show $\mathbf{coNP}^{\#\mathbf{P}}$-hardness of Decide-$\varepsilon$-DP we show a reduction from All-Min-Sat in Lemma 14; together with the inclusion result above, this entails that Decide-ε-DP is $\mathbf{coNP}^{\#\mathbf{P}}$-complete (Theorem 11).

Randomized response [41] is a technique for answering sensitive Yes/No questions by flipping the answer with probability $p \leq 0.5$. Setting $p = \frac{1}{1+e^{\varepsilon}}$ gives ε-differential privacy. Thus $p = 0$ gives no privacy and $p = 0.5$ gives total privacy (albeit no utility).

▶ **Definition 13** (Randomized Response).

$$RR_{\varepsilon}(x) = \begin{cases} x & w.p. \quad \frac{e^{\varepsilon}}{1+e^{\varepsilon}} \\ \neg x & w.p. \quad \frac{1}{1+e^{\varepsilon}} \end{cases}$$

▶ **Lemma 14.** All-Min-Sat *reduces in polynomial time to* Decide-ε-DP.

Proof. We will reduce from All-Min-Sat to Decide-ε-DP using randomized response. We will take a boolean formula ϕ and create a probabilistic circuit that is ε-differentially private if and only if ϕ is All-Min-Sat.

Consider the circuit ψ which takes as input the value $z \in \{0,1\}$. It probabilistically chooses a value of $\boldsymbol{x} \in \{0,1\}^n$ and $\boldsymbol{y} \in \{0,1\}^m$ and one further random bit p_1 and computes $b = z \oplus \neg(p_1 \vee \phi(\boldsymbol{x}, \boldsymbol{y}))$. The circuit outputs $(\boldsymbol{x}, b)$.

▷ Claim 15. ψ is $\ln(3)$-differentially private if and only if ϕ is All-Min-Sat.

Suppose $\phi \in$ All-Min-Sat then, no matter the choice of $\boldsymbol{x}$,

$$0 \leq \Pr_{y}[\phi(\boldsymbol{x}, \boldsymbol{y}) = 1] \leq \frac{1}{2},$$

and hence

$$\frac{1}{4} \leq \Pr_{y,p_1}[\neg(p_1 \vee \phi(\boldsymbol{x}, \boldsymbol{y})) = 1] \leq \frac{1}{2}.$$

We conclude the true answer z is flipped between $\frac{1}{4}$ and $\frac{1}{2}$ of the time, observe this is exactly the region in which randomized response gives us the most privacy. In the worst case $p = \frac{1}{4} = \frac{1}{1+e^{\varepsilon}}$, gives $e^{\varepsilon} = 3$, so $\ln(3)$-differential privacy.

In the converse, suppose $\phi \in$ E-MAJ-SAT, then for some $\boldsymbol{x}$

$$\frac{1}{2} < \Pr_{y}[\phi(\boldsymbol{x}, \boldsymbol{y}) = 1] \leq 1,$$

and then

$$\Pr_{y,p_1}[\neg(p_1 \vee \phi(\boldsymbol{x}, \boldsymbol{y})) = 1] < \frac{1}{4},$$

in which case the randomized response does not provide $\ln(3)$-differential privacy. ◀

▶ Remark 16. We skew the result so that in the positive case (when $\phi \in$ ALL-MIN-SAT) the proportion of accepting allocations is between $\frac{1}{4}$ and $\frac{1}{2}$, resulting in the choice of $\ln(3)$-differentially privacy. Alternative skews, using more bits akin to p_1, shows hardness for other choices of ε.

Hardness by circuit shape

In our proof of the upper-bound we use **coNP** to resolve the non-deterministic choice of both input and output. We show this is necessary in the sense **coNP** is still required for either large input or large output. The hardness proof used in Lemma 14 shows that when $|\psi| = n$ the problem is hard for $\Omega(1)$-bit input and $\Omega(n)$-bit output.

We can also prove this is hard for $\Omega(n)$-bit input and $\Omega(1)$-bit output. Intuitively a counter example to differential privacy has two choices: a pair of adjacent input and a given output upon which the relevant inequality will hold. So to “refute” ALL-MIN-SAT the counterexample of the ALL choice (i.e. $\boldsymbol{x}$) can be selected in the input, rather than the output as in our case. Since the input is now non-trivial we must take care of what happens when the adjacent bit is in the choice of $\boldsymbol{x}$. Details are given in the full version.

Further the problem is in $\mathbf{P}^{\#\mathbf{P}}$ for $O(\log(n))$-bit input and $O(\log(n))$-bit output, as in this case, the choices made by **coNP** can instead be checked deterministically in polynomial time. In this case we show **PP**-hardness, which applies even when there is 1-bit input and 1-bit output.

4 On the complexity of deciding approximate differential privacy

It is less clear whether deciding (ε, δ)-differential privacy can be done in $\mathbf{coNP}^{\#\mathbf{P}}$. First we consider restrictions to the shape of the circuit so that $\mathbf{coNP}^{\#\mathbf{P}}$ can be recovered, and then show that in general the problem is in $\mathbf{coNP}^{\#\mathbf{P}^{\#\mathbf{P}}}$.

Recall that in the case of ε-differential privacy it was enough to consider singleton events $\{\boldsymbol{o}\}$ where $\boldsymbol{o} \in \{0,1\}^{\ell}$, however in the definition of (ε, δ)-differential privacy we must quantify over output events $E \subseteq \{0,1\}^{\ell}$. If we consider circuits with one output bit ($\ell = 1$), then the event space essentially reduces to $E \in \{\emptyset, \{0\}, \{1\}, \{0,1\}\}$ and we can apply the same technique.

We expand this to the case when the number of outputs bits is logarithmic $\ell \leq \log(|\psi|)$. To cater to this, rather than guessing a violating $E \in \{0,1\}^{\ell}$, we consider a violating subset of events $E \subseteq \{0,1\}^{\ell}$. Given such an event E we create a circuit ψ_E on ℓ inputs and a single output which indicates whether the input is in the event E. The size of this circuit is exponential in ℓ, thus polynomial in $|\psi|$. Composing $\psi_E \circ \psi$, we check the conditions hold for this event E, with just one bit of output.

▷ Claim 17. DECIDE-ε, δ-DP, restricted to circuits ψ with ℓ bit outputs where $\ell \leq \log(|\psi|)$, is in $\mathbf{coNP}^{\#\mathbf{P}}$ (and hence $\mathbf{coNP}^{\#\mathbf{P}}$-complete).

The claim trivially extends to $\ell \leq c \cdot \log(|\psi|)$ for any *fixed* $c > 0$.

4.1 Decide-$\boldsymbol{\varepsilon}$, $\boldsymbol{\delta}$-DP is in $\mathbf{coNP}^{\#\mathbf{P}^{\#\mathbf{P}}}$

We now show that Decide-ε,δ-DP in the most general case can be solved in $\mathbf{coNP}^{\#\mathbf{P}^{\#\mathbf{P}}}$. We will assume $e^\varepsilon = \alpha$ is given as a rational, with $\alpha = \frac{u}{v}$ for some integers u and v. Recall we use n, ℓ and m to refer to the number of input, output and random bits of a circuit respectively. While we will use non-determinism to choose inputs leading to a violating event, unlike in Section 3 it would not be used for finding a violating event E, as an (explicit) description of such an event may be of super-polynomial length. It would be useful for us to use a reformulation of approximate differential privacy, using a sum over potential individual outcomes.

▶ **Reformulation 18** (Pointwise differential privacy [7]). A probabilistic circuit ψ is (ε,δ)-differentially private if and only if for all neighboring $\boldsymbol{x}, \boldsymbol{x}' \in X^n$ and for all $\boldsymbol{o} \in \{0,1\}^\ell$,

$$\sum_{\boldsymbol{o}\in\{0,1\}^\ell} \delta_{\boldsymbol{x},\boldsymbol{x}'}(\boldsymbol{o}) \le \delta,$$

where $\delta_{\boldsymbol{x},\boldsymbol{x}'}(\boldsymbol{o}) = \max\left(\Pr[\psi(\boldsymbol{x}) = \boldsymbol{o}] - e^\varepsilon \cdot \Pr[\psi(\boldsymbol{x}') = \boldsymbol{o}], 0\right).$

We define $\mathcal{M}$, a non-deterministic Turing Machine with access to a $\#\mathbf{P}$-oracle, and where each execution branch runs in polynomial time. On inputs a probabilistic circuit ψ and neighboring $\boldsymbol{x}, \boldsymbol{x}' \in X^n$ the number of accepting executions of $\mathcal{M}$ would be proportional to $\sum_{\boldsymbol{o}\in\{0,1\}^\ell} \delta_{\boldsymbol{x},\boldsymbol{x}'}(\boldsymbol{o})$.

In more detail, on inputs ψ, $\boldsymbol{x}$ and $\boldsymbol{x}'$, $\mathcal{M}$ chooses $\boldsymbol{o} \in \{0,1\}^\ell$ and an integer $C \in \{1, 2, \dots, 2^{m+\lceil\log(v)\rceil}\}$ (this requires choosing $\ell + m + \lceil\log(v)\rceil$ bits). Through a call to the $\#\mathbf{P}$ oracle, $\mathcal{M}$ computes

$$a = |\{\boldsymbol{r} \in \{0,1\}^m : \psi(\boldsymbol{x}, \boldsymbol{r}) = \boldsymbol{o}\}|$$

and

$$b = |\{\boldsymbol{r} \in \{0,1\}^m : \psi(\boldsymbol{x}', \boldsymbol{r}) = \boldsymbol{o}\}|.$$

Finally, $\mathcal{M}$ accepts if $v \cdot a - u \cdot b \ge C$ and otherwise rejects.

▶ **Lemma 19.** *Given two inputs $\boldsymbol{x}, \boldsymbol{x}' \in X^n$, $\mathcal{M}(\psi, \boldsymbol{x}, \boldsymbol{x}')$ has exactly $v \cdot 2^m \sum_{\boldsymbol{o}\in\{0,1\}^\ell} \delta_{\boldsymbol{x},\boldsymbol{x}'}(\boldsymbol{o})$ accepting executions.*

Proof. Let $\mathbb{1}\{X\}$ be the indicator function, which is one if the predicate X holds and zero otherwise.

$$v \cdot 2^m \sum_{\boldsymbol{o}\in\{0,1\}^\ell} \delta_{\boldsymbol{x},\boldsymbol{x}'}(\boldsymbol{o}) = \sum_{\boldsymbol{o}\in\{0,1\}^\ell} v \cdot 2^m \max\Big(\Pr[\psi(\boldsymbol{x}) = \boldsymbol{o}] - \alpha \Pr[\psi(\boldsymbol{x}') = \boldsymbol{o}], 0\Big)$$

$$= \sum_{\boldsymbol{o}\in\{0,1\}^\ell} v2^m \max\left(\frac{1}{2^m} \sum_{\boldsymbol{r}\in\{0,1\}^m} \mathbb{1}\{\psi(\boldsymbol{x},\boldsymbol{r}) = \boldsymbol{o}\} - \alpha\frac{1}{2^m} \sum_{\boldsymbol{r}\in\{0,1\}^m} \mathbb{1}\big\{\psi(\boldsymbol{x}',\boldsymbol{r}) = \boldsymbol{o}\big\}, 0\right)$$

$$= \sum_{\boldsymbol{o}\in\{0,1\}^\ell} \max\left(v \sum_{\boldsymbol{r}\in\{0,1\}^m} \mathbb{1}\{\psi(\boldsymbol{x},\boldsymbol{r}) = \boldsymbol{o}\} - v\alpha \sum_{\boldsymbol{r}\in\{0,1\}^m} \mathbb{1}\big\{\psi(\boldsymbol{x}',\boldsymbol{r}) = \boldsymbol{o}\big\}, 0\right)$$

$$
\begin{aligned}
\dots &= \sum_{\boldsymbol{o}\in\{0,1\}^\ell} \max\left(v \sum_{\boldsymbol{r}\in\{0,1\}^m} \mathbb{1}\{\psi(\boldsymbol{x},\boldsymbol{r})=\boldsymbol{o}\} - u \sum_{\boldsymbol{r}\in\{0,1\}^m} \mathbb{1}\big\{\psi(\boldsymbol{x}',\boldsymbol{r})=\boldsymbol{o}\big\}, 0 \right)\\
&= \sum_{\boldsymbol{o}\in\{0,1\}^\ell} \sum_{C=1}^{2^{\lceil\log(v)\rceil+m}} \mathbb{1}\left\{ \max\left(v \sum_{\boldsymbol{r}\in\{0,1\}^m} \mathbb{1}\{\psi(\boldsymbol{x},\boldsymbol{r})=\boldsymbol{o}\} - u \sum_{\boldsymbol{r}\in\{0,1\}^m} \mathbb{1}\big\{\psi(\boldsymbol{x}',\boldsymbol{r})=\boldsymbol{o}\big\}, 0 \right) \geq C \right\}\\
&= \text{number of accepting executions in } \widehat{\mathcal{M}}
\end{aligned}
$$
◀

We can now describe our $\mathbf{coNP}^{\#\mathbf{P}^{\#\mathbf{P}}}$ procedure for Decide-ε,δ-DP. The procedure takes as input a probabilistic circuit ψ.

1. Non-deterministically choose neighboring $\boldsymbol{x}$ and $\boldsymbol{x}' \in \{0,1\}^n$ (i.e., $2n$ bits).
2. Let $\mathcal{M}$ be the non-deterministic Turing Machine with access to a $\#\mathbf{P}$-oracle as described above. Create a machine $\widehat{\mathcal{M}}$ with no input that executes $\mathcal{M}$ on $\psi, \boldsymbol{x}, \boldsymbol{x}'$.
3. Make an $\#\mathbf{P}^{\#\mathbf{P}}$ oracle call for the number of accepting executions $\widehat{\mathcal{M}}$ has.
4. Reject if the number of accepting executions is greater than $v \cdot 2^m \cdot \delta$ and otherwise accept.

By Lemma 19, there is a choice $\boldsymbol{x}, \boldsymbol{x}'$ on which the procedure rejects if and only if ψ is not (ε,δ)-differentially private.

4.2 Hardness

Theorem 11 shows that Decide-ε-DP is $\mathbf{coNP}^{\#\mathbf{P}}$-complete, in particular $\mathbf{coNP}^{\#\mathbf{P}}$-hard and since Decide-$\varepsilon$-DP is a special case of Decide-ε,δ-DP, this is also $\mathbf{coNP}^{\#\mathbf{P}}$-hard. Nevertheless the proof is based on particular values of ε and in the full version we provide an alternative proof of hardness based on δ. This proof result will apply for any ε (even for $\varepsilon = 0$) and for a large range of δ (but not $\delta = 0$).

The proof proceeds by first considering the generalisation of All-Min-Sat to the version where *minority*, i.e. less than $\frac{1}{2}$ of the assignments, is replaced with another threshold. This problem is also $\mathbf{coNP}^{\#\mathbf{P}}$-hard for a range of thresholds. Note however, if this threshold is exactly 1 the problem is true for all formulae, and if the threshold is 0 the problem is simply asks if the formula is unsatisfiable (a **coNP** problem).

This generalised problem can then be reduced to deciding Decide-ε,δ-DP, where the threshold corresponds exactly to δ. It will turn out in the resulting circuit ε does not change the status of differential privacy, i.e. it is (ε,δ)-differentially private for all ε, or not.

The proof shows hardness for $\Omega(n)$-input bits and 1-output bit; the case in which there also exists a $\mathbf{coNP}^{\#\mathbf{P}}$ upper-bound. Hence, showing hardness in a higher complexity class, e.g., $\mathbf{coNP}^{\#\mathbf{P}^{\#\mathbf{P}}}$, would require a reduction to a circuit with more output bits.

5 Inapproximability of the privacy parameters ε, δ

Given the difficulty of deciding if a circuit is differentially private, one might naturally consider whether approximating ε or δ could be efficient. We show that these tasks are both **NP**-hard and **coNP**-hard.

We show that distinguishing between (ε,δ), and (ε',δ')-differential privacy is **NP**-hard, by reduction from a problem we call Not-Constant which we also show is **NP**-hard. A boolean formula is in Not-Constant if it is satisfiable and not also a tautology.

▶ **Lemma 20.** *Not-Constant is* **NP**-*complete. (hence Constant is* **coNP**-*complete).*

Proof. Clearly, Not-Constant $\in$ **NP**, the witness being a pair of satisfying and non-satisfying assignments. We reduce 3-SAT to Not-Constant. Given a Boolean formula ϕ over variables $x_1, \ldots, x_n$ let $\phi'(x_1, \ldots, x_n, x_{n+1}) = \phi(x_1, \ldots, x_n) \wedge x_{n+1}$. Note that ϕ' is never a tautology as $\phi'(x_1, \ldots, x_n, 0) = 0$. Furthermore, ϕ' is satisfiable iff ϕ is. ◀

In Definition 13 we used randomized response in the pure differential privacy setting. We now consider the approximate differential privacy variant $RR_{\varepsilon,\delta} : \{0,1\} \to \{\top, \bot\} \times \{0,1\}$ defined as follows:

$$RR_{\varepsilon,\delta}(x) = \begin{cases} (\top, x) & \text{w.p. } \delta \\ (\bot, x) & \text{w.p. } (1-\delta)\frac{\alpha}{1+\alpha} \\ (\bot, \neg x) & \text{w.p. } (1-\delta)\frac{1}{1+\alpha} \end{cases} \quad \text{where} \quad \alpha = e^{\varepsilon}$$

I.e., with probability δ, $RR_{\varepsilon,\delta}(x)$ reveals x and otherwise it executes $RR_{\varepsilon}(x)$. The former is marked with "$\top$" and the latter with "$\bot$". This mechanism is equivalent to the one described in [35] and is (ε, δ)-differentially private.

▶ **Definition 21.** *Let $0 \leq \varepsilon \leq \varepsilon'$, $0 \leq \delta \leq \delta' \leq 1$, with either $\varepsilon < \varepsilon'$ or $\delta < \delta'$. The problem* Distinguish-$(\varepsilon, \delta), (\varepsilon', \delta')$-DP *takes as input a circuit ψ, guaranteed to be either (ε, δ)-differentially private, or (ε', δ')-differentially private. The problem asks whether ψ is (ε, δ)-differentially private or (ε', δ')-differentially private.*

▶ **Lemma 22.** *Distinguish-$(\varepsilon, \delta), (\varepsilon', \delta')$-DP is* **NP***-hard (and* **coNP***-hard).*

Proof. We reduce Not-Constant to Distinguish-$(\varepsilon, \delta), (\varepsilon', \delta')$-DP. Given the boolean formula $\phi(\boldsymbol{x})$ on n bits, we create a probabilistic circuit ψ. The input to ψ consists of the n bits $\boldsymbol{x}$ plus a single bit y. The circuit ψ has four output bits (o_1, o_2, o_3, o_4) such that $(o_1, o_2) = RR_{\varepsilon,\delta}(y)$ and $(o_3, o_4) = RR_{\varepsilon',\delta'}(\phi(\boldsymbol{x}))$.

Observe that $(o_1, o_2) = RR_{\varepsilon,\delta}(y)$ is always (ε, δ) differentially private. As for $(o_3, o_4) = RR_{\varepsilon',\delta'}(\phi(\boldsymbol{x}))$, if $\phi \in$ Not-Constant then there are adjacent $\boldsymbol{x}, \boldsymbol{x}'$ such that $\phi(\boldsymbol{x}) \neq \phi(\boldsymbol{x}')$. In this case, $(o_3, o_4) = RR_{\varepsilon',\delta'}(\phi(\boldsymbol{x}))$ is (ε', δ')-differentially private, and, because $(\varepsilon, \delta) < (\varepsilon', \delta')$, so is ψ . On the other hand, if $\phi \notin$ Not-Constant then $\phi(\boldsymbol{x})$ does not depend on $\boldsymbol{x}$ and hence (o_3, o_4) does not affect privacy, in which case we get that ψ is (ε, δ) differentially private.

The same argument also gives **coNP**-hardness. ◀

Notice that the above theorem holds when $\delta = \delta'$ and $\varepsilon < \varepsilon'$ (similarly, $\varepsilon = \varepsilon'$ and $\delta < \delta'$), which entails the following theorem:

▶ **Theorem 23.** *Assuming* **P** $\neq$ **NP***, for any approximation error $\gamma > 0$, there does not exist a polynomial time approximation algorithm that given a probabilistic circuit ψ and δ computes some $\hat{\varepsilon}$, where $|\hat{\varepsilon} - \varepsilon| \leq \gamma$ and ε is the minimal such that ψ is (ε, δ)-differentially private within error γ. Similarly, given ε, no such $\hat{\delta}$ can be computed polynomial time where $|\hat{\delta} - \delta| \leq \gamma$ and δ is minimal.*

▶ Remark 24. The result also applies when approximating within a given ratio $\rho > 1$ (e.g. in the case of approximating ε, to find $\hat{\varepsilon}$ such that $\frac{\hat{\varepsilon}}{\varepsilon} \leq \rho$). Moreover, the result also holds when approximating pure differential privacy, that is when $\delta = 0$.

6 Related work

Differential privacy was introduced in [22]. It is a definition of privacy in the context of data analysis capturing the intuition that information specific to an individuals is protected if every single user's input has a bounded influence on the computation's outcome distribution, where the bound is specified by two parameters, usually denoted by ε, δ. Intuitively, these parameters set an upperbound on privacy loss, where the parameter ε limits the loss and the parameter δ limits the probability in which the loss may exceed ε.

Extensive work has occurred in the computer-assisted or automated of verification of differential privacy. Early work includes, PINQ [33] and Airavat [38] which are systems that keep track of the privacy budgets (ε and δ) using trusted privacy primitives in SQL-like and MapReduce-like paradigms respectively. In other work, programming languages were developed, that use the type system to keep track of the sensitivity and ensure the correct level of noise is added [37, 9, 16, 8]. Another line of work uses proof assistants to help prove that an algorithm is differentially private [7]; although much of this work is not automated, recent work has gone in this direction [2, 44].

These techniques focuses on "soundness", rather than "completeness" thus are not amenable to complexity analysis. In the constrained case of verifying differential privacy on probabilistic automata and Markov chains there are bisimulation based techniques [40, 12]. Towards complexity analysis; [15] shows that computing the optimal value of δ for a finite labelled Markov chain is undecidable. Further [14] and [15] provides distances, which are (necessarily) not tight, but can be computed in polynomial time with an **NP** oracle and a weaker bound in polynomial time. Recent works have focused on developing techniques for finding violations of differential privacy [19, 10]. The methods proposed so far have been based on some form of testing. Our result limits also the tractability of these approaches. Finally, [5] proposes an automated technique for proving differential privacy or finding counterexamples. This paper studies a constrained class of programs extending the language we presented here, and provides a "complete" procedure for deciding differential privacy for them. The paper does not provide any complexity guarantee for the proposed method and we expect our results to apply also in their setting.

As we already discussed, Murtagh and Vadhan [35] showed that finding the optimal values for the privacy parameters when composing different algorithms in a black-box way is #**P**-complete, but also that approximating the optimal values can be done efficiently. In contrast, our results show that when one wants to consider programs as white-box, as often needed to achieve better privacy guarantees (e.g. in the case of the sparse vector technique), the complexity is higher.

Several works have explored different property testing related to differential privacy [20, 29, 26], including verification [26]. In the standard model used in property testing, a user has only black-box access to the function and the observable outputs are the ones provided by a privacy mechanism. In contrast, our work is based on the program description and aim to provide computational limits to the design of techniques for program analyses for differential privacy.

We already discussed some works on quantitative information flow. In addition to those, it was shown that comparing the quantitative information flow of two programs on inputs coming from the uniform distribution is #**P**-hard [43]. However, when quantifying over all distributions the question is **coNP**-complete [43].

As we remarked earlier, our language is equally expressive when integers of a fixed size are added. Recently Jacomme, Kremer and Barthe [28] show deciding equivalence of two such programs, operating over a fixed finite field, is $\mathbf{coNP}^{\mathbf{C_=P}}$-complete and the majority problem, which is similar to pure differential privacy, is $\mathbf{coNP}^{\mathbf{PP}}$-complete – matching the class we show for deciding ε-differential privacy. Further the universal equivalence problem, which shows the programs are equivalent over all field extensions, is decidable in 2-**EXP**; the universal majority problem is not know to be decidable.

7 Conclusions and future work

Verifying differential privacy of loop-free probabilistic boolean programs

We have shown the difficulty of verifying differential privacy in loop-free probabilistic boolean programs through their correspondence with probabilistic circuits. Deciding ε-differential privacy is $\mathbf{coNP}^{\#\mathbf{P}}$-complete and (ε, δ)-differential privacy is $\mathbf{coNP}^{\#\mathbf{P}}$-hard and in $\mathbf{coNP}^{\#\mathbf{P}^{\#\mathbf{P}}}$ (a gap that we leave for future work). Both problems are positioned in the counting hierarchy, in between the polynomial hierarchy **PH** and **PSPACE**.

Verifying differential privacy of probabilistic boolean programs

One interesting question that our work leaves open is the characterization of the complexity of deciding differential privacy problems for probabilistic boolean programs, including loops. Similarly to the works on quantitative information flow [11], we expect these problems to be decidable and we expect them to be in **PSPACE**. However, this question requires some further investigation that we leave for future work.

Solvers mixing non-determinism and counting

Returning to our motivation for this work – developing practical tools for verifying differential privacy – our results seem to point to a deficiency in available tools for model checking. The model checking toolkit includes well established SAT solvers for **NP** (and **coNP**) problems, solvers for further quantification in **PH**, solvers for #SAT (and hence for #**P** problems[3]). However to the best of our knowledge, there are currently no solvers that are specialized for mixing the polynomial hierarchy **PH** and counting problems #**P**, in particular $\mathbf{coNP}^{\#\mathbf{P}}$ and $\mathbf{coNP}^{\#\mathbf{P}^{\#\mathbf{P}}}$.

Approximating the differential privacy parameters

We show that distinguishing (ε, δ)-differential privacy from (ε', δ') differential privacy where $(\varepsilon, \delta) < (\varepsilon', \delta')$ is both **NP**- and **coNP**-hard. We leave refining the classification of this problem as an open problem.

Logical Characterisation of Hybrid Conformance

Maciej Gazda

Abstract

Logical characterisation of a behavioural equivalence relation precisely specifies the set of formulae that are preserved and reflected by the relation. Such characterisations have been studied extensively for exact semantics on discrete models such as bisimulations for labelled transition systems and Kripke structures, but to a much lesser extent for approximate relations, in particular in the context of hybrid systems. We present what is to our knowledge the first characterisation result for approximate notions of hybrid refinement and hybrid conformance involving tolerance thresholds in both time and value. Since the notion of conformance in this setting is approximate, any characterisation will unavoidably involve a notion of relaxation, denoting how the specification formulae should be relaxed in order to hold for the implementation. We also show that an existing relaxation scheme on Metric Temporal Logic used for preservation results in this setting is not tight enough for providing a characterisation of neither hybrid conformance nor refinement. The characterisation result, while interesting in its own right, paves the way to more applied research, as our notion of hybrid conformance underlies a formal model-based technique for the verification of cyber-physical systems.

1 Introduction

Cyber-physical systems integrate discrete aspects of computation, with continuous aspects of physical phenomena, and asynchronous aspects of communication protocols. To test cyber-physical systems against their discrete abstractions (also called discrete-event systems), several notions of conformance have been proposed [13, 28, 31]; we refer to the tutorial volume edited by Broy et al. [8] for an overview. Logical characterisations of conformance [21, 3] are of particular importance in this context, because they precisely specify the set of logical formulae that are preserved and reflected under conformance (we refer to [4] for an accessible introduction). Such logical characterisations provide a rigorous basis for design trajectories that involves subsequent conformance test at different layers of abstraction. Moreover, logical characterisations are stepping stones towards devising the notion of characterising formulae, which have been used in tools and algorithms for checking conformance [4, 10].

In the context of hybrid systems, i.e., abstractions of CPSs integrating both discrete and continuous aspects, some notions of conformance have been proposed in the recent literature [2, 1, 11, 16] (see [22] for an overview). However, not much is known about logical

characterisation of such notions; to our knowledge, the closest known results to a logical characterisation of hybrid conformance are the logical preservation results [16, 1] and the characterisation of metric bisimulation [12] and stochastic bisimulation for systems with rewards [17] (see the related work section for an in-depth discussion). This paper aims at bridging this gap and comes up with, to the best of our knowledge, the first logical characterisation of approximate conformance for hybrid systems [2, 1] in terms of Metric Temporal Logic [23, 5].

To this end, we study the hybrid conformance notion due to Abbas, Mittelmann and Fainekos [2, 1], as well as its its associated preorder which we call hybrid refinement (for both notions, we also study their extensions to non-deterministic hybrid-systems). We provide logical characterisations for each of theses notions in terms of Metric Temporal Logic (MTL) and suitable notions of relaxation. We also show that the notions of relaxation proposed in the preservation result by Abbas, Mittelmann and Fainekos [1] is insufficiently precise to lead to a logical characterisation. We formulate our results in a general semantic domain, called generalised timed traces, which encompasses both discretised hybrid systems (as studied by Abbas, Mittelmann, and Fainekos [1]) and their continuous variants that have not been given a logical characterisation so far, to the best of our knowledge. Moreover, we study a generalisation of these results for both bounded and unbounded nondeterministic systems.

The contributions of this paper have both theoretical and practical motivation and relevance. The theoretical motivation for logical characterisation is that it not only provides an idea about the logic that is preserved under conformance (subject to relaxation) such as – in our case – MTL, but also it specifies precise bounds on the relaxation required for such formulae to hold. The practical motivation is that firstly, it provides designers with a precisely specified set of properties that carry over from specification to implementation (while preservations results only provide a rough approximation of such properties) and moreover, logical characterisation sets the scene for developing algorithms for finding distinguishing formulae, and hence, provide an alternative means for checking hybrid conformance. Logical characterisations have also proven to be a versatile auxiliary tool in e.g. developing congruence formats for operational semantics [7], as well as providing approximations of hybrid systems [26].

The rest of this paper is organised as follows. In Section 2, we review the related work and position our contributions with respect to the state of the art. In Section 3, we define some preliminary notions, including our semantic domain, the notions of hybrid refinement and conformance [1] and Metric Temporal Logic [6]. Subsequently in Section 4, we define appropriate notions of relaxations to characterise these notions using Metric Temporal Logic. We compare our results to the past preservation results in Section 5, where we show that the existing relaxation scheme for Metric Temporal Logic are too lax to serve for a logical characterisation of hybrid refinement and conformance. Namely, we prove there is a class of non-conforming implementations that do satisfy all relaxed MTL formulae satisfied by the specification. In Section 6, we conclude the paper, and present the directions of our ongoing research in this domain.

2 Related work

Logical characterisations of conformance relations allow for identifying conforming systems by means of the logical formulae satisfied by them. They also facilitate the converse operation, important from a practical perspective, namely, distinguishing non-conforming systems with a formula that forms a succinct counterexample.

Characterisations using modal logic have been studied extensively in the setting of exact behavioural semantics on discrete models such as labelled transition systems [21, 30]. In this context, characterisations use direct comparison i.e. inclusion of sets of formulae satisfied by systems in question; distinguishing formulae are those belonging to a set difference of such sets. Our work differs from this line of work in that it deals with approximate behavioural semantics and hence, cannot use standard inclusion check between sets of satisfied formulae.

To our knowledge, the first notion of characterisation for approximate behavioural semantics has been offered in the context of Metric Transition Systems [12] for linear and branching distances based on Metric Bisimulation [20, 19].

On a general level, our semantic model and conformance relation are different from those in [12, 20] in that they involve separate time and value dimensions, both of which can be subject to perturbations. Our choices for the semantic model and the notion of conformance are motivated by the practical applications of hybrid conformance [2, 1] in testing cyber-physical systems, e.g., in the automotive- [29] and healthcare domain [27]. Moreover, from a technical perspective, we base our characterisation on a logic with a qualitative (binary) satisfaction relation, but with quantities embedded in its syntax, namely, the Metric Temporal Logic (MTL). However, our approach can be easily translated to a quantitative setting of [12], by defining an evaluation of a formulae as the least degree of relaxation after applying which the formula is satisfied by a system. Also in this case, the choice of Metric Temporal Logic [23, 5] (and its concrete instantiation with signal values for propositions: Signal Temporal Logic [24]) is motivated by its wide-spread use in the hybrid systems literature and in practice [1, 18, 15].

Prabhakar, Vladimerou, Viswanathan, and Dullerud [26] provide a characterisation theorem for approximate simulation [19]; the characterisation serves as an auxiliary tool for developing approximations of hybrid systems with polynomial flows. In terms of semantic domain and relation under consideration, their characterisation result is strongly related to [12]. One technical feature which makes that paper somewhat closer in style to ours than [12] is the use of a relaxation operator (called a shrink of a formula in [26]).

Desharnais, Gupta, Jagadeesan and Panangaden [14] provide an approximate characterisation of probabilistic bisimulation for labelled Markov processes. They do so using a quantitative extension of Hennessy-Milner logic. This work has led to several follow-up applications, e.g., to a logical characterisation of differential privacy by Castiglioni, Chatzikokolakis, and Palamidessi [9]. Gburek and Baier [17] have recently investigated characterisation of bisimulation for stochastic systems with actions and rewards with two probabilistic logics: a very expressive APCTL*, and simpler APCTL$_\circ$, that can provide succinct distinguishing formulae. Unlike their approach [17], our work is set in the context of standard hybrid systems.

The results that appear closest to ours in terms of underlying models, and conformance relations that allow for disturbances in both time and space values, are logical preservation results for hybrid conformance [1] and Skorokhod conformance [16]. Both papers define syntactical transformations on temporal logics yielding more relaxed formulae; they differ on the conformance relations and temporal logics investigated. We improve upon them by providing different relaxation schemes that are proven to be tight, i.e., are precisely sufficient for a characterisation. Moreover, we generalise their results to semantic models that can encompass both discrete and continuous behaviour and non-determinism. Our framework of generalised timed traces subsumes both discrete timed state sequences (TSSs) and continuous trajectories, e.g., allowing for a comparison of behaviours of different types (such as sampled discretised behaviour against continuous trajectories).

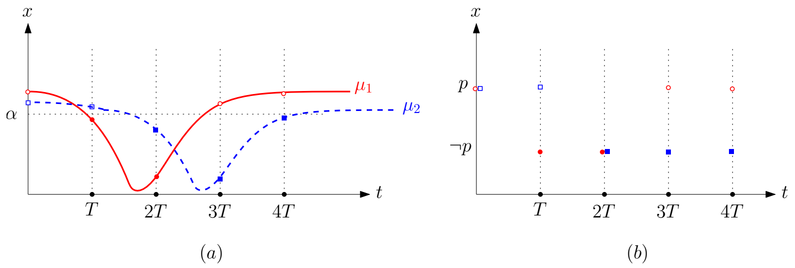

Figure 1 Examples of (a) continuous and (b) discretised GTTs.

3 Preliminaries

In this section, we define some preliminaries regarding our semantic domain, Metric Temporal Logic and notions of hybrid conformance and refinement.

Generalised timed traces and hybrid systems. In order for our theory to remain as general as possible, we define generalised timed traces, a notion that generalises both discrete semantic models, such as timed state sequences (TSSs) [1], and continuous-time trajectories [16]. A generalised timed trace is essentially a mapping from a discrete or continuous time domain to a set of values within some metric space.

▶ **Definition 1.** *Let $(\mathcal{Y}, d_{\mathcal{Y}})$ be a metric space. A $\mathcal{Y}$-valued generalised timed trace is a function $\mu : \mathcal{T} \to \mathcal{Y}$ such that $\mathcal{T} \subseteq \mathbb{R}_{\geq 0}$ is the time domain, and in addition $0 \in \mathcal{T}$ is the least element in $\mathcal{T}$. The set of all $\mathcal{Y}$-valued generalised timed traces is denoted by $GTT(\mathcal{Y})$.*

Observe that a timed state sequence (TSS) is simply a generalised timed trace with $\mathcal{T}$ being a finite subset of $\mathbb{R}_{\geq 0}$; moreover, in case $\mathcal{T}$ is an interval within $\mathbb{R}_{\geq 0}$, we obtain a standard continuous-time trajectory. We could generalise the domain of μ to any totally-ordered metric space, but we dispense with this generalisation here for the sake of simplicity. Likewise, the assumption that 0 is the least element of the time domain could be also dispensed with.

▶ **Example 2.** Consider trajectories μ_1 and μ_2 depicted in Figure 1.(a), where μ_1 represents the specification of a system and μ_2 its implementation. The mappings from the subset of reals in the domain of each trajectory to the value of x at the corresponding point form real-valued GTTs.

Consider the discretisation of these two trajectories where we sample the trajectories with a period T and we record whether the value of x at the sampling point is higher than α (denoted by $p \doteq x > \alpha$) or at most α (denoted by $\neg p \doteq x \leq \alpha$). The corresponding mappings from $\{0, T, 2T, 3T, 4T\}$ to $P = \{p, \neg p\}$ are discretised GTTs depicted in Figure 1.(b) are P-valued GTTs.

A hybrid system, defined below, is a mapping from initial conditions and inputs to sets of generalised (output) traces. We use the notation $\mathcal{P}(S)$ and $\mathcal{P}_{FIN}(S)$ denote, respectively, a powerset of S, and the powerset of S restricted to the finite subsets.

▶ **Definition 3.** *Given sets $\mathcal{C}$ and $\mathcal{I}$ of initial conditions and input space, the set of $\mathcal{Y}$-valued hybrid systems, denoted by $\mathcal{H}(\mathcal{C}, \mathcal{I}, \mathcal{Y})$ is the set of all functions of the type $\mathcal{C} \times \mathcal{I} \to \mathcal{P}(GTT(\mathcal{Y}))$. In addition, we distinguish the following two classes of hybrid systems: the class of* finitely branching hybrid systems *is defined as $\mathcal{H}_{FIN}(\mathcal{C}, \mathcal{I}, \mathcal{Y}) := \{H : \mathcal{C} \times \mathcal{I} \to \mathcal{P}_{FIN}(GTT(\mathcal{Y}))\}$; similarly, the class of* deterministic hybrid systems *is defined as $\mathcal{H}_{DET}(\mathcal{C}, \mathcal{I}, \mathcal{Y}) := \{H : \mathcal{C} \times \mathcal{I} \to \mathcal{P}(GTT(\mathcal{Y})) \,|\, \forall_{c \in \mathcal{C}, i \in \mathcal{I}} |H(c, i)| = 1\}$.*

Note that we intentionally left the nature of the initial conditions and input space implicit, as they play no role in the development of this paper. In reality, input conditions are typically constraints on input signals and the input space is typically a generalised timed trace with the same domain as the generalised timed trace for output. Also note that we focus mainly on finitely branching hybrid systems. When the parameters $\mathcal{I}, \mathcal{C}, \mathcal{Y}$ are not relevant or are clear from the context, we leave them out and refer to the set of hybrid systems with fixed parameters as $\mathcal{H}$.

3.1 Metric Temporal Logic

Metric Temporal Logic (MTL) [23, 5] is an extension of Linear Temporal Logic [25] with intervals; the introduction of intervals allows for reasoning about the real-time behaviour of dynamic systems once the propositions of the logic are interpreted over real-valued signals [24] (this interpretation of MTL is also called Signal Temporal Logic, or STL in the literature). MTL serves as an intuitive formalism for reasoning about hybrid systems [24, 1, 18, 15].

We work with the following language MTL^+ of MTL formulas in the negation-normal form

$$\phi ::= \mathsf{T} \mid \mathsf{F} \mid p \mid \neg p \mid \phi \wedge \phi \mid \phi \vee \phi \mid \phi \, \mathcal{U}_I \, \phi \mid \phi \, \mathcal{R}_I \, \phi$$

where p ranges over a collection of atomic propositions AP, and I ranges over intervals, $\mathcal{U}_I$ denotes the until operator and $\mathcal{R}_I$ denotes the release operator (both annotated with interval I).

For the purpose of relaxation, we shall also use the slightly extended language MTL^+_{ext} that in addition includes $p^+(\epsilon)$ and $p^-(\epsilon)$ constructs. Intuitively, they denote, respectively, the expansion- and contraction of the domain of validity of proposition p by ϵ.

$$\phi ::= \quad \mathsf{T} \mid \mathsf{F} \mid p \mid \neg p \mid \phi \wedge \phi \mid \phi \vee \phi \mid \phi \, \mathcal{U}_I \, \phi \mid \phi \, \mathcal{R}_I \, \phi \mid p^+(\epsilon) \mid p^-(\epsilon) \qquad (\epsilon \in \mathbb{R}_{\geq 0})$$

▶ **Example 4.** To illustrate the intuitive meaning of $p^+(\epsilon)$ and $p^-(\epsilon)$ consider the predicate $p := x > \alpha$ in Example 2. $p^+(\epsilon)$ relaxes p into $x > \alpha - \epsilon$; in other words $p^+(\epsilon)$ allows for an error margin of ϵ when checking p, while $p^-(\epsilon)$ shrinks p into $x > \alpha + \epsilon$. The latter is helpful for defining the relaxation of negated propositions.

In order to provide the formal semantics for MTL^+, we need two auxiliary definitions of δ-expansion and δ-contraction. Below, we assume the context of some metric space $(\mathcal{Y}, d_\mathcal{Y})$, and S ranges over subsets of $\mathcal{Y}$.

- $E(S, \delta) := \{x \in \mathcal{Y} \mid \exists y \in S : d_\mathcal{Y}(x, y) \leq \delta\}$ (δ-expansion)
- $C(S, \delta) := \mathcal{Y} \setminus E(\mathcal{Y} \setminus S, \delta)$ (δ-contraction)

Note that our definitions slightly differ from [1]. In particular, for any $y_0 \in \mathcal{Y}$, and the set $\overline{B_\epsilon}(y_0) = \{y \in \mathcal{Y} |, d_\mathcal{Y}(y, y_0) > \epsilon\}$ (complement of an ϵ-ball of point y_0), we have $E(\overline{B_\epsilon}(y_0), \epsilon) = \{y_0\}$ (rather than $\emptyset$ which the expansion of [1] would yield).

We also remark that the semantics of MTL^+_{ext} is provided in the context of an interpretation function $\mathcal{O} : AP \to \mathcal{P}(\mathcal{Y})$. This is a standard approach, similar to e.g. [1], but also to Signal Temporal Logic [24]. Note that the nature of the interpretation function restricts the expressive power of the logic, as the propositions are interpreted over the domain of values only (excluding time domain), which precludes expressing more powerful properties such as signal tracking (which is possible in Freeze LTL [16]).

▶ **Definition 5.** *Let $\mu : \mathcal{T} \to \mathcal{Y}$ be a generalised timed trace, $t \in \mathbb{R}$, and $\mathcal{O} : AP \to \mathcal{P}(\mathcal{Y})$ be an interpretation mapping for atomic propositions. The semantics of MTL^+_{ext} formulas is defined as follows:*
$(\mu, t) \models \mathsf{T} \quad (\mu, t) \not\models \mathsf{F}$
$(\mu, t) \models p$ *iff* $t \in \mathcal{T}$ *and* $\mu(t) \in \mathcal{O}(p)$
$(\mu, t) \models \neg p$ *iff* $t \in \mathcal{T}$ *and* $\mu(t) \notin \mathcal{O}(p)$
$(\mu, t) \models p^+(\epsilon)$ *iff* $t \in \mathcal{T}$ *and* $\mu(t) \in E(\mathcal{O}(p), \epsilon)$
$(\mu, t) \models p^-(\epsilon)$ *iff* $t \in \mathcal{T}$ *and* $\mu(t) \notin C(\mathcal{O}(p), \epsilon)$
$(\mu, t) \models \phi \wedge \psi$ *iff* $(\mu, t) \models \phi$ *and* $(\mu, t) \models \psi$
$(\mu, t) \models \phi \vee \psi$ *iff* $(\mu, t) \models \phi$ *or* $(\mu, t) \models \psi$
$(\mu, t) \models \phi \mathcal{U}_I \psi$ *iff* $\exists t' \in \mathcal{T}.\ t' - t \in I. (\mu, t') \models \psi$
$\wedge \forall t'' \in \mathcal{T}. t'' \in [t, t') \implies ((\mu, t'') \models \phi \vee (t'' - t \in I \wedge (\mu, t'') \models \psi))$
$(\mu, t) \models \psi \mathcal{R}_I \phi$ *iff* $\forall t' \in \mathcal{T}. (t' - t \in I \ \wedge\ (\mu, t') \not\models \phi) \implies (\exists t_1 \in \mathcal{T}. t_1 \in [t, t') \ \wedge\ (\mu, t_1) \models \psi)$

We say that a generalised timed trace $\mu : \mathcal{T} \to \mathcal{Y}$ satisfies an MTL^+ formula ϕ, notation $\mu \models \phi$ iff $(\mu, 0) \models \phi$. The satisfaction relation is lifted to hybrid systems in the standard manner, i.e., $H(c, i) \models \phi \iff \forall \mu \in H(c, i). \mu \models \phi$.

In the remainder of this paper, we use the common shorthand notation for eventually and always, defined as: $\Diamond_I \phi := \mathsf{T} \mathcal{U}_I \phi \quad \Box_I \phi := \mathsf{F} \mathcal{R}_I \phi$.

We remark that the semantics of the until operator slightly differs from the standard one used e.g. for MTL over discrete-time models. There, one simply requires the safety formula ϕ to hold in every time point before the “ultimate” formula ψ holds. In order to cater for dense-time domains where there may be no “earliest” time point satisfying ψ, we require that in all the preceding time points either ϕ, *or* ψ holds. A similar kind of semantics can be found in [16].

We also remark that the semantics of until operator makes it possible for the “ultimate” formula ψ to hold *before* the current state (time point); this is because we allow formulae to be annotated with arbitrary intervals, in particular those with negative endpoints.

Furthermore, note that the semantics allows for certain “ambiguous” cases where neither a formula nor its negation (which can be syntactically obtained by an appropriate transformation) is satisfied by a given state. This happens in case of (negated) propositions, and tuples of the form (μ, t), where t does not belong to the time domain $\mathcal{T}$. For instance, in case of a generalised timed trace $\mu : \{0, 1, 2, 3\} \to \mathbb{R}$ corresponding to a small sampling of a real-valued signal, and proposition pos such that $\mathcal{O}(\mathsf{pos}) = \mathbb{R}_{>0}$ we have $(\mu, \sqrt{2}) \not\models \mathsf{pos}$, and $(\mu, \sqrt{2}) \not\models \neg\,\mathsf{pos}$, regardless of the actual values of μ for the sampling points in the time domain.

However, if all occurrences of propositions in a formula are guarded by an until or release operator, the satisfaction status of a formula is never ambiguous – this is because semantics of those operators refer only to time points within the time domain. Throughout the rest of the paper, we work with propositions that are guarded with until or release and hence, in our context, the ambiguity is never an issue in the context of our theory.

3.2 Hybrid Conformance

Next, we provide the definition of hybrid conformance, due to Abbas and Fainekos [2, 1], in the context of our generalised semantic domain. Intuitively, hybrid conformance allows for conforming signal to differ up to τ in time and up to ϵ in the value. In addition to the “standard” hybrid conformance, which is a symmetric relation on traces, we also define its one-directional variant which we call hybrid refinement.

▶ **Definition 6.** *Let $\mu_1 : \mathcal{T}_1 \to \mathcal{Y}$ and $\mu_2 : \mathcal{T}_2 \to \mathcal{Y}$ be $\mathcal{Y}$-valued generalised timed traces. A trace μ_1 is a (τ, ϵ)-refinement of μ_2, notation $\mu_1 \sqsubseteq_{\tau,\epsilon} \mu_2$, iff:*

$$\forall t_1 \in dom(\mu_1).\ \exists t_2 \in dom(\mu_2).\ |t_2 - t_1| \leq \tau \wedge d_{\mathcal{Y}}(\mu_2(t_2), \mu_1(t_1)) \leq \epsilon$$

In the above definition, μ_2 can match any value in μ_1 within a sufficiently small time interval, but can potentially contain some other signal values that cannot be matched by μ_1. We know at least that the "behaviour"of μ_1 in terms of signal values does not go beyond those of μ_2 (up to the (τ, ϵ)-window).

By requiring two traces to be mutually conforming, we obtain the standard notion of hybrid conformance [2, 1] for individual traces:

▶ **Definition 7.** *Let $\mu_1 : \mathcal{T}_1 \to \mathcal{Y}$ and $\mu_2 : \mathcal{T}_2 \to \mathcal{Y}$ be $\mathcal{Y}$-valued generalised timed traces. μ_1 and μ_2 are (τ, ϵ)-close, denoted by $\mu_1 \sim_{\tau,\epsilon} \mu_2$, whenever $\mu_1 \sqsubseteq_{\tau,\epsilon} \mu_2$ and $\mu_2 \sqsubseteq_{\tau,\epsilon} \mu_1$.*

When the precise value of τ and ϵ is not relevant, we refer to (τ, ϵ)-refinement, and (τ, ϵ)-closeness, as respectively, hybrid refinement, and hybrid conformance. The two notions can be lifted to hybrid systems in the following manner:

▶ **Definition 8.**

1. *A system H_1 is a (τ, ϵ)-refinement of H_2, notation $H_1 \sqsubseteq_{\tau,\epsilon} H_2$, if for all $c \in \mathcal{C}$ and $i \in \mathcal{I}$, it holds that:*

$$\forall \mu_1 \in H_1(c, i).\ \exists \mu_2 \in H_2(c, i).\ \mu_1 \sqsubseteq_{\tau,\epsilon} \mu_2$$

2. *Two hybrid systems H_1, H_2 are (τ, ϵ)-close, denoted by $H_1 \sim_{\tau,\epsilon} H_2$, if and only if for all $c \in \mathcal{C}$ and $i \in \mathcal{I}$, it holds that*

$$\forall \mu_1 \in H_1(c, i).\ \exists \mu_2 \in H_2(c, i). \mu_1 \sim_{\tau,\epsilon} \mu_2$$

$$\forall \mu_2 \in H_2(c, i).\ \exists \mu_1 \in H_1(c, i). \mu_1 \sim_{\tau,\epsilon} \mu_2$$

4 Logical Characterisation of Hybrid Refinement and Hybrid Conformance

4.1 Logical Characterisation via Relaxation

Logical characterisation of a relation provides means to uniquely identify classes of related systems by sets of formulae in a certain logic. In case of non-exact relations involving some tolerance thresholds for disturbances, such as hybrid conformance or refinement, one cannot directly compare sets of formulae satisfied by systems in question.

Our approach to characterisation involves the notion of relaxation of logical formulae, that has been used in the context of hybrid systems [1, 16, 26]. It involves a syntactical transformation of a formula to a weaker one, which is supposed to be also satisfied by at least one trace of a conforming system.

For the purpose of logical characterisation, we introduce the following relation.

▶ **Definition 9.** *We say that a system potentially* exhibits property ϕ, *notation $H(c, i) \models_{\exists} \phi$, whenever* there exists $\mu \in H(c, i)$ *such that $\mu \models \phi$.*

The relation $\models_{\exists}$ can be seen as a variant of satisfaction relation for nondeterministic systems that has existential, rather than universal interpretation, the latter being the traditional interpretation in LTL literature. This alternative view on satisfaction is similar to one that is used in the context of Hennessy-Milner logic and its variations for behavioural models [21, 30], where a logical formula represents a (potentially) observable behaviour of a system. This approach is more suitable for the purpose of logical chracterisation.

Assume a logic (a collection of formulae) $\mathcal{L}$ and a notion of relaxation $\mathsf{rlx} : \mathcal{L} \to \mathcal{L}$. Our notion of characterisation can now be defined as follows

▶ **Definition 10.** *A logic $\mathcal{L}$ and a notion of relaxation $\mathit{rlx} : \mathcal{L} \to \mathcal{L}$ characterise a relation $R \subseteq \mathcal{H} \times \mathcal{H}$ if and only if, for any two systems H and H' we have:*

$$H\,R\,H' \iff \forall \phi \in \mathcal{L}.\ H \models_\exists \phi \implies H' \models_\exists \mathit{rlx}(\phi)$$

The implication from left to right is called preservation; in our context, there already exist some preservation results in the literature [1, 16]; the implication from right to left (called reflection) has not been studied for hybrid conformance and MTL to the best of our knowledge.

We remark that for certain classes of “well-behaved” relations, the implication under the existential interpretation in definition 10, namely $H \models_\exists \phi \implies H' \models_\exists \mathsf{rlx}(\phi)$, is equivalent to a dual one under the more common universal interpretation, i.e. $H' \models \phi \implies H \models \mathsf{rlx}(\phi)$. Regarding the two relations considered in our work, only hybrid conformance has this property on all systems, while hybrid refinement does not. This is because the underlying relation on individual traces is not symmetric, and moreover allows the presence of considerably different values on the side of the “larger” trace (as long as it also matches all the required values on other timepoints within the relevant time interval).

In this section, we define two novel (and in our view, very natural) relaxation operators on MTL which, as we subsequently show, precisely serve this purpose.

4.2 Characterisation of hybrid refinement

Relaxation operator $\mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}$. We shall now introduce the first relaxation operator on MTL, which (as we subsequently prove) gives rise to the characterisation of hybrid refinement. Syntactically, it has a very simple structure: the actual relaxation is performed on the level of propositions only.

▶ **Definition 11.** *Let $\tau, \epsilon \geq 0$. The relaxation operator $\mathit{rlx}^{\sqsubseteq}_{\tau,\epsilon} : \mathit{MTL}^{+} \to \mathit{MTL}^{+}_{ext}$ is defined as follows:*

$$\begin{array}{lcl}
\mathit{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\mathit{T}) = \mathit{T} & , & \mathit{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\mathit{F}) = \mathit{F} \\
\mathit{rlx}^{\sqsubseteq}_{\tau,\epsilon}(p) = \Diamond_{[-\tau,\tau]}\, p^{+}(\epsilon) & , & \mathit{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\neg p) = \Diamond_{[-\tau,\tau]}\, p^{-}(\epsilon) \\
\mathit{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi_1 \wedge \phi_2) & = & \mathit{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi_1) \wedge \mathit{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi_2) \\
\mathit{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi_1 \vee \phi_2) & = & \mathit{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi_1) \vee \mathit{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi_2) \\
\mathit{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi\, \mathcal{U}_I\, \psi) & = & \mathit{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi)\, \mathcal{U}_I\, \mathit{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\psi) \\
\mathit{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi\, \mathcal{R}_I\, \psi) & = & \mathit{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi)\, \mathcal{R}_I\, \mathit{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\psi)
\end{array}$$

Note that each relaxation of a formula different than T and F is guarded by either release or until formulae, and hence its satisfaction status is always unambiguous.

4.2.1 Characterisation of traces

We proceed to show that the introduced relaxation operator can be used to characterise the (τ, ϵ)-refinement, starting with the individual timed traces. Note that since the results below concern arbitrary generalised timed traces, they apply also to the setting with two traces of different kind, e.g., a discrete TSS against a continuous trajectory.

4.2.1.1 Preservation modulo relaxation

We start by proving that the satisfaction of MTL^+ formulae is preserved by the refinement relation $\sqsubseteq_{\tau,\epsilon}$ on timed traces modulo $\mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}$ relaxation.

▶ **Proposition 12.** *Let $\mu_1 : \mathcal{T}_1 \to \mathcal{Y}$, $\mu_2 : \mathcal{T}_2 \to \mathcal{Y}$ be two $\mathcal{Y}$-valued generalised timed traces, and ϕ be an MTL formula. If $\mu_1 \sqsubseteq_{\tau,\epsilon} \mu_2$, then, for any $t \in \mathbb{R}$:*

$$(\mu_1, t) \models \phi \implies (\mu_2, t) \models \mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi)$$

Proof. The proof proceeds by structural induction on the formula ϕ.

- $\phi = p$: since $(\mu_1, t) \models p$, we have $t \in \mathcal{T}_1$ and $\mu_1(t) \in \mathcal{O}(p)$. Furthermore, since $\mu_1 \sqsubseteq_{\tau,\epsilon} \mu_2$, we know that there is some t' such that $|t' - t| \le \tau$ and $d(\mu_1(t), \mu_2(t')) \le \epsilon$. We have thus $\mu_2(t') \in \mathcal{O}(p^+(\epsilon))$, and hence $(\mu_2, t') \models p^+(\epsilon)$. Moreover, since $|t' - t| \le \tau$, we obtain $(\mu_2, t) \models \Diamond_{[-\tau,\tau]}\, p^+(\epsilon) = \mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(p)$.
- $\phi = \neg p$: since $(\mu_1, t) \models \neg p$, we have $t \in \mathcal{T}_1$ and $\mu_1(t) \notin \mathcal{O}(p)$. Furthermore, since $\mu_1 \sqsubseteq_{\tau,\epsilon} \mu_2$, we know that there is some t' such that $|t' - t| \le \tau$ and $d(\mu_1(t), \mu_2(t')) \le \epsilon$. From the latter and $\mu_1(t) \in \mathcal{Y} \backslash \mathcal{O}(p)$, we obtain $\mu_2(t') \in E(\mathcal{Y} \backslash \mathcal{O}(p), \epsilon)$, which is equivalent to $\mu_2(t') \notin C(\mathcal{O}(p), \epsilon)$. Hence $(\mu_2, t) \models \Diamond_{[-\tau,\tau]}\, p^-(\epsilon) = \mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\neg p)$
- $\phi = \phi \,\mathcal{U}_I\, \psi$: since $(\mu_1, t) \models \phi \,\mathcal{U}_I\, \psi$, there is some $t_1 \in \mathcal{T}_1$ such that $t_1 - t \in I$ and $(\mu_1, t_1) \models \psi$, and moreover for any $t_0 \in [t, t_1)$ we have $(\mu_1, t_0) \models \phi \vee (\mu_1, t_0) \models \psi$. By applying the inductive hypothesis, we obtain that $(\mu_2, t_1) \models \mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\psi)$, and for any $t_0 \in [t, t_1)$ we have $(\mu_2, t_0) \models \mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi)$ or $(\mu_2, t_0) \models \mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\psi)$. We thus have $(\mu_2, t) \models \mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi)\,\mathcal{U}_I\, \mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\psi)$, and from the definition of relaxation we immediately obtain $(\mu_2, t) \models \mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi \,\mathcal{U}_I\, \psi)$.
- $\phi = \phi \,\mathcal{R}_I\, \psi$: take any $t' \in \mathcal{T}_2$ such that $t' - t \in I$ and $(\mu_2, t') \not\models \mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\psi)$. From the inductive hypothesis, we have $(\mu_1, t') \not\models \psi$, and since $(\mu_1, t) \models \phi \,\mathcal{R}_I\, \psi$, we know that there is some $t_1 \in \mathcal{T}_1$ such that $t_1 \in [t, t')$, and $(\mu_1, t_1) \models \phi$. By applying the inductive hypothesis again, we obtain $(\mu_2, t_1) \models \mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi)$. From the statements obtained above we can now infer that $(\mu_2, t) \models \mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi \,\mathcal{R}_I\, \psi)$. ◀

4.2.1.2 Existence of distinguishing formula

We shall now prove that the converse of the preceding theorem holds as well: whenever a timed trace is not a (τ, ϵ)-refinement of another, we can always find an MTL formula that witnesses this, that is, preservation modulo $\mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}$ relaxation operator does not hold.

▶ **Proposition 13.** *Let $\mu_1 : \mathcal{T}_1 \to \mathcal{Y}$ and $\mu_2 : \mathcal{T}_2 \to \mathcal{Y}$ be two $\mathcal{Y}$-valued timed traces. If $\mu_1 \not\sqsubseteq_{\tau,\epsilon} \mu_2$, then there is a formula $\phi \in \mathsf{MTL}^+$ such that ϕ distinguishes μ_1 from μ_2 modulo relaxation $\mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}$, that is $\mu_1 \models \phi \wedge \mu_2 \not\models \mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi)$*

Proof. Suppose that there is some $t_1 \in \mathcal{T}_1$ for which there is no $t_2 \in \mathcal{T}_2$ such that $|t_2 - t_1| \le \tau$ and $|\mu_2(t_2) - \mu_1(t_1)| \le \epsilon$. Consider an MTL formula $\phi = \Diamond_{[t_1,t_1]} p$, where $\mathcal{O}(p) = \{\mu_1(t_1)\}$. Obviously, we have $\mu_1 \models \phi$, however, the relaxed version of the formula $\mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi) = \Diamond_{[t_1,t_1]}\Diamond_{[-\tau,\tau]} p^+(\epsilon)$ cannot be satisfied by μ_2. ◀

4.2.2 Characterisation of hybrid systems

4.2.2.1 Finitely branching systems

Propositions 12 and 13 provide the characterisation of relation $\sqsubseteq_{\tau,\epsilon}$ by MTL^+ through the relaxation $\mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}$ on individual traces. Based on those results, for hybrid systems that are finitely branching (i.e. have bounded non-determinism, see definition 3), the characterisation result for hybrid refinement can be obtained in a straightforward manner.

▶ **Theorem 14.** *The logic MTL^+, together with the relaxation operator $\mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}$, characterise the conformance relation $\sqsubseteq_{\tau,\epsilon}$ on finitely branching hybrid systems. That is, for arbitrary finitely branching hybrid systems H and H', the following statements hold:*

$$H \sqsubseteq_{\tau,\epsilon} H' \iff (\forall \phi \in \mathsf{MTL}^+.\ H \models_\exists \phi \implies H' \models_\exists \mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi))$$

Proof.

- (preservation): Take any two hybrid systems H_1, H_2 such that $H_1 \sqsubseteq_{\tau,\epsilon} H_2$. Take any $c \in \mathcal{C}, i \in \mathcal{I}$. Suppose w.l.o.g. that $H_1(c,i) \models_\exists \phi$; we need to show that $H_2(c,i) \models_\exists \mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi)$. From $H_1(c,i) \models_\exists \phi$ we know that there is a $\mu_1 \in H_1(c,i)$ such that $\mu_1 \models \phi$. Moreover, since $H_1 \sqsubseteq_{\tau,\epsilon} H_2$, there is some $\mu_2 \in H_2(c,i)$ such that $\mu_1 \sqsubseteq_{\tau,\epsilon} \mu_2$. From Proposition 12 we thus obtain $\mu_2 \models \mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi)$, and hence $H_2(c,i) \models_\exists \mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi)$.
- (reflection/distinguishing formula): Suppose that $H_1 \not\sqsubseteq_{\tau,\epsilon} H_2$. Then for certain $c \in \mathcal{C}, i \in \mathcal{I}$ there is some $\mu_1 \in H_1(c,i)$ such that for all $\mu_2^j \in H_2(c,i)$ we have $\mu_1 \not\sqsubseteq_{\tau,\epsilon} \mu_2^j$. From Proposition 13 we know that for each such $\mu_2^j \in H_2(c,i)$ there is a distinguishing formula ϕ_j such that $\mu_1 \models \phi_j$ and $\mu_2^j \not\models \mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi_j)$. Consider a formula $\Phi = \bigwedge_{j:\mu_2^j \in H_2(c,i)} \phi_j$. Since $H_2(c,i)$ is a finite set, Φ is a well-formed MTL^+formula. We now have $H_1(c,i) \models_\exists \Phi$, but since obviously for any j, $\mu_2^j \not\models \mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\Phi)$, we also have $H_2(c,i) \not\models_\exists \mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\Phi)$. Hence Φ distinguishes $H_1(c,i)$ from $H_2(c,i)$. ◀

4.2.2.2 Systems with unbounded non-determinism

In order to provide characterisation for hybrid refinement on systems with infinite branching, one needs to endow the logic MTL^+ with infinite conjunctions and disjunction; the syntax of such logic, denoted with MTL^+_∞, is given below (*Ind* ranges over arbitrary sets of indices).

$$\phi ::= \mathsf{T} \mid \mathsf{F} \mid p \mid \neg p \mid \bigwedge_{i \in Ind} \phi_i \mid \bigvee_{i \in Ind} \phi_i \mid \phi\, \mathcal{U}_I\, \phi \mid \phi\, \mathcal{R}_I\, \phi$$

▶ **Theorem 15.** *The logic MTL^+_∞, together with the relaxation operator $\mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}$, characterise the conformance relation $\sqsubseteq_{\tau,\epsilon}$ on arbitrary hybrid systems.*

Proof. The proof is nearly the same as the one of Theorem 14, except that while proving the reflection property, the set of distinguishing formulae for individual traces may be infinite. However, a disjunction over such a set is now a well-formed MTL^+_∞ formula, hence the construction is valid. ◀

4.3 Characterisation of hybrid conformance

4.3.1 Relaxation operator $\mathsf{rlx}^{\sim}_{\tau,\epsilon}$

While the relaxation operator $\mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}$ introduced in the previous section allows one to preserve – up to the relevant (τ,ϵ)-window – properties of (signal values at) individual timepoints, it falls short of preserving properties of entire intervals. Therefore, in order to characterise the standard, symmetric notion of (τ,ϵ)-closeness, or hybrid conformance, one needs a finer notion of relaxation.

In what follows, we shall use the following notation: for an interval I, by $I_{<a,b>}$ we denote the modified interval: $I_{<a,b>} := \{x \in \mathbb{R} \mid \exists x_a, x_b \in I : x_a + a \leq x \land x \leq x_b + b\}$.

Below, we define a relaxation operator $\mathsf{rlx}^{\sim}_{\tau,\epsilon}$ where:

- for propositions not in the scope of a temporal operator, the relaxation is done similarly as in the $\mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}$ operator

- for temporal operators, the interval endpoints are modified (i.e. "shrinked" to relax the temporal obligations accordingly)
- for propositions guarded by a temporal operator, only ϵ-relaxation of a signal value is perfomed (the relaxation of timeline has already been handled through interval relaxation)

▶ **Definition 16.** *Let $\tau, \epsilon \geq 0$. The relaxation operator $\mathsf{rlx}^{\sim}_{\tau,\epsilon} : \mathsf{MTL}^{+} \to \mathsf{MTL}^{+}_{ext}$ is defined as follows:*

$$\begin{array}{lcl}
\mathsf{rlx}^{\sim}_{\tau,\epsilon}(\mathsf{T}) = \mathsf{T} & , & \mathsf{rlx}^{\sim}_{\tau,\epsilon}(\mathsf{F}) = \mathsf{F} \\
\mathsf{rlx}^{\sim}_{\tau,\epsilon}(p) = \Diamond_{[-\tau,\tau]} p^{+}(\epsilon) & , & \mathsf{rlx}^{\sim}_{\tau,\epsilon}(\neg p) = \Diamond_{[-\tau,\tau]} p^{-}(\epsilon) \\
\mathsf{rlx}^{\sim}_{\tau,\epsilon}(\phi_1 \wedge \phi_2) & = & \mathsf{rlx}^{\sim}_{\tau,\epsilon}(\phi_1) \wedge \mathsf{rlx}^{\sim}_{\tau,\epsilon}(\phi_2) \\
\mathsf{rlx}^{\sim}_{\tau,\epsilon}(\phi_1 \vee \phi_2) & = & \mathsf{rlx}^{\sim}_{\tau,\epsilon}(\phi_1) \vee \mathsf{rlx}^{\sim}_{\tau,\epsilon}(\phi_2) \\
\mathsf{rlx}^{\sim}_{\tau,\epsilon}(\phi\, \mathcal{U}_I\, \psi) & = & \begin{cases} \Diamond_{[\tau,\tau]} \left(\mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\phi)\, \mathcal{U}_{I_{<0,-2\tau>}}\, (\Diamond_{[0,2\tau]} \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\psi))\right) & if\ \ I_{<0,-2\tau>} \neq \emptyset \\ \Diamond_{I_{<-\tau,\tau>}} \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\psi) & if\ \ I_{<0,-2\tau>} = \emptyset \end{cases} \\
\mathsf{rlx}^{\sim}_{\tau,\epsilon}(\phi\, \mathcal{R}_I\, \psi) & = & (\Diamond_{[-\tau,\tau]} \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\phi))\, \mathcal{R}_{I_{<\tau,-\tau>}}\, \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\psi)
\end{array}$$

where the auxilliary relaxation $\mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}$ for subformulae guarded by a temporal operator is defined as follows:

$$\begin{array}{lcl}
\mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\mathsf{T}) = \mathsf{T} & , & \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\mathsf{F}) = \mathsf{F} \\
\mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(p) = p^{+}(\epsilon) & , & \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\neg p) = p^{-}(\epsilon) \\
\mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\phi_1 \wedge \phi_2) & = & \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\phi_1) \wedge \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\phi_2) \\
\mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\phi_1 \vee \phi_2) & = & \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\phi_1) \vee \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\phi_2) \\
\mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\phi\, \mathcal{U}_I\, \psi) & = & \begin{cases} \Diamond_{[\tau,\tau]} \left(\mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\phi)\, \mathcal{U}_{I_{<0,-2\tau>}}\, (\Diamond_{[0,2\tau]} \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\psi))\right) & if\ \ I_{<0,-2\tau>} \neq \emptyset \\ \Diamond_{I_{<-\tau,\tau>}} \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\psi) & if\ \ I_{<0,-2\tau>} = \emptyset \end{cases} \\
\mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\phi\, \mathcal{R}_I\, \psi) & = & (\Diamond_{[-\tau,\tau]} \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\phi))\, \mathcal{R}_{I_{<\tau,-\tau>}}\, \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\psi)
\end{array}$$

4.3.2 Characterisation of traces

4.3.2.1 Preservation

Before stating the main preservation property, we prove the key lemma which lists certain properties of the auxilliary relaxation operator $\mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}$.

▶ **Lemma 17.** *Suppose $\mu_1 \sim_{\tau,\epsilon} \mu_2$. For any $\phi \in \mathsf{MTL}^{+}$ we have:*

1. $\mu_1, t \models \phi \implies \exists t' \in [t-\tau, t+\tau].\ \mu_2, t' \models \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\phi)$
2. $(\forall t \in I.\, \mu_1, t \models \phi) \implies (\forall t \in I_{<\tau,-\tau>}.\ \mu_2, t \models \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\phi))$
3. *if in addition ϕ is of the form $\chi\, \mathcal{U}_I\, \psi$ or $\psi\, \mathcal{R}_I\, \chi$, then $\mu_1, t \models \phi \implies \mu_2, t \models \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\phi)$*

Proof. We proceed by structural induction on ϕ; for technical reasons, it is convenient to prove all the properties simultaneously. We focus on three key cases: atomic propositions, as well as the until and release operators.

- $\phi = p$:
  1. Suppose $\mu_1, t \models p$; from the semantics of MTL^{+} this means that $\mu_1(t) \in \mathcal{O}(p)$. Since $\mu_1 \sim_{\tau,\epsilon} \mu_2$, there is some $t' \in [t-\tau, t+\tau]$ such that $d_{\mathcal{Y}}(\mu_1(t), \mu_2(t)') \leq \epsilon$. From this and $\mu_1(t) \in \mathcal{O}(p)$ we obtain $\mu_2(t') \in E(\mathcal{O}(p), \epsilon)$, and hence $\mu_2, t' \models p^{+}(\epsilon) = \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(p)$.
  2. Suppose that for all $t \in I$ we have $\mu_1, t \models p$, that is, for all $t \in I$ $\mu_1(t) \in \mathcal{O}(p)$. Take any $t_2 \in I_{<\tau,-\tau>}$. Observe that the "matching" timepoint for μ_2 and t_2 in μ_1 must be in the interval I, i.e. there is some $t_1 \in I$ such that $d_{\mathcal{Y}}(\mu_1(t_1), \mu_2(t_2)) \leq \epsilon$. Since $t_1 \in I$, we have $\mu_1(t_1) \in \mathcal{O}(p)$, and hence $\mu_2(t_2) \in E(\mathcal{O}(p, \epsilon))$, from which $\mu_2, t_2 \models p^{+}(\epsilon) = \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(p)$ follows.

- $\phi = \chi \mathcal{U}_I \psi$: we only need to prove the third statement, as it is stronger than the first two. Moreover, we consider only the more involved case when $I_{<0,-2\tau>} \neq \emptyset$.
  Suppose $\mu_1, t \models \chi \mathcal{U}_I \psi$. Then there is some $t_\psi \in t + I$ such that $\mu_1, t_\psi \models \psi$ (note that since $I_{<0,-2\tau>} \neq \emptyset$, we have $t_\psi - t \geq 2\tau$). From $\mu_1 \sim_{\tau,\epsilon} \mu_2$ and applying the inductive hypothesis on statement 1 of Lemma 17 there is some $t'_\psi \in [t_\psi - \tau, t_\psi + \tau]$ such that $\mu_2, t'_\psi \models \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\psi)$. This in particular implies that
  (*) $\mu_2, t_\psi - \tau \models \Diamond_{[0,2\tau]}\mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\psi)$.
  From $\mu_1, t \models \chi \mathcal{U}_I \psi$ it further follows that for all $t' \in [t, t_\psi)$ we have $\mu_1, t' \models \chi$. From applying the inductive hypothesis on statement 2 of Lemma 17 we therefore have
  (**) for all $t' \in [t + \tau, t_\psi - \tau)$ we have $\mu_2, t' \models \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\chi)$.
  That $\mu_2, t \models \Diamond_{[\tau,\tau]} \left(\mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\chi) \mathcal{U}_{I_{<0,-2\tau>}} (\Diamond_{[0,2\tau]}\mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\psi))\right) = \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\chi \mathcal{U}_I \psi)$ now follows immediately from (*) and (**).
- $\phi = \psi \mathcal{R}_I \chi$: similarly as above, we only prove the third statement. Note that whenever the interval I is strictly shorter than 2τ, we have $I_{<0,-2\tau>} = \emptyset$, and the relaxation yields a formula equivalent to T.
  Take any $t'_{\neg\chi} \in t + I_{<\tau,-\tau>}$ such that $\mu_2, t'_{\neg\chi} \not\models \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\chi)$. Consider the interval $I \cap [t, t'_{\neg\chi} + \tau]$. There must be some $t_{\neg\chi} \in [t'_{\neg\chi} - \tau, t'_{\neg\chi} + \tau] \subseteq t + I$ such that $\mu_1, t_{\neg\chi} \not\models \chi$. Indeed, were it not the case, then from the inductive hypothesis (statement 2), we would have that for all $t' \in [t'_{\neg\chi}, t'_{\neg\chi}]$, $t' \models \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\chi)$, contradicting $\mu_2, t'_{\neg\chi} \not\models \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\chi)$.
  From $\mu_1, t \models \psi \mathcal{R}_I \chi$ and $\mu_1, t_{\neg\chi} \not\models \chi$, one obtains existence of some $t_\psi \in [t, t_{\neg\chi})$ such that $\mu_1, t_\psi \models \psi$. From the inductive hypothesis (1) we know that $\mu_2, t_\psi \models \Diamond_{[-\tau,\tau]}\mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\psi)$.
  We have thus shown that $\mu_2, t \models (\Diamond_{[-\tau,\tau]}\mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\psi)) \mathcal{R}_{I_{<\tau,-\tau>}} \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\chi) = \mathsf{t\text{-}rlx}^{\sim}_{\tau,\epsilon}(\psi \mathcal{R}_I \chi)$ ◀

The preservation property is given in the proposition below.

▶ **Proposition 18.** $\mu_1 \sim_{\tau,\epsilon} \mu_2 \implies \forall \phi, t.\ \mu_1, t \models \phi \implies \mu_2, t \models \mathit{rlx}^{\sim}_{\tau,\epsilon}(\phi)$

Proof. Formally, the proof proceeds by structural induction. However, the key cases of temporal operators are now immediate corollaries of Lemma 17 (point 3); while for the remaining cases including base the proof is very straightforward. ◀

4.3.2.2 Reflection

We proceed to show that for non-conforming traces, one can always find a distinguishing formula, regardless of the "direction" in which the conformance fails. Since $\sim_{\tau,\epsilon}$ is symmetric, this is equivalent to the statement that if $\mu_1 \not\sim_{\tau,\epsilon} \mu_2$, then one can find both a formula distinguishing μ_1 from μ_2, and also one that distinguishes μ_2 from μ_1.

▶ **Proposition 19.** $\mu_1 \not\sim_{\tau,\epsilon} \mu_2 \implies \exists \phi.\ \mu_1 \models \phi \wedge \mu_2 \not\models \mathit{rlx}^{\sim}_{\tau,\epsilon}(\phi)$

Proof. Suppose $\mu_1 \not\sim_{\tau,\epsilon} \mu_2$; we show that there is always a formula that distinguishes μ_1 from μ_2. We distinguish two cases:

- there is some $t_1 \in \mathcal{T}_1$ such that the value $\mu_1(t_1)$ cannot be matched within the (τ, ϵ)-window by μ_2, that is:

  $$(*) \ \ \forall t' \in \mathcal{T}_2.\ |t' - t_1| \leq \tau \implies d_{\mathcal{Y}}(\mu_2(t'), \mu_1(t_1)) > \epsilon$$

  We use a similar construction as for the relaxation $\mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}$, by defining

  $$\Phi_{DIST} := \Diamond_{[t_1,t_1]} p$$

  where $\mathcal{O}(p) = \{\mu_1(t_1)\}$. Then $\mathsf{rlx}^{\sim}_{\tau,\epsilon}(\Phi_{DIST}) = \Diamond_{[t_1-\tau,t_1+\tau]}\, p^+(\epsilon)$. We have $\mu_1 \models \Phi_{DIST}$, but from (*) we clearly have $\mu_2 \not\models \mathsf{rlx}^{\sim}_{\tau,\epsilon}(\Phi_{DIST})$.

- there is some $t_2 \in \mathcal{T}_2$ that cannot be matched by μ_1, that is: that is:

  $$\forall t' \in \mathcal{T}_1.\ |t' - t_2| \leq \tau \implies d_{\mathcal{Y}}(\mu_1(t'), \mu_2(t_2)) > \epsilon$$

  we define

  $$\Phi_{DIST} := \Box_{[t_2-\tau, t_2+\tau]} p$$

  where $\mathcal{O}(p) = \{y \in \mathcal{Y} \mid d_{\mathcal{Y}}(y, \mu_2(t_2)) > \epsilon\}$. Note that $p^+(\epsilon) = \mathcal{Y} \setminus \{\mu_2(t_2)\}$ (at this point using our definition of expansion operator rather than the one from [1] proves essential). We have $\mu_1 \models \Phi_{DIST}$, but on the other hand: $\mathsf{rlx}^{\sim}_{\tau,\epsilon}(\Phi_{DIST}) = (\Diamond_{[-\tau,\tau]} \mathsf{F})\, \mathcal{R}_{[t_2,t_2]}\, p^+(\epsilon) \equiv \Box_{[t_2,t_2]} p^+(\epsilon)$, and since $\mu_2(t_2) \notin \mathcal{Y} \setminus \{\mu_2(t_2)\} = p^+(\epsilon)$, we have $\mu_2 \not\models \mathsf{rlx}^{\sim}_{\tau,\epsilon}(\Phi_{DIST})$. ◀

4.3.3 Characterisation of hybrid systems

Characterisation results for hybrid conformance and their proofs share many similarities with those for hybrid refinement. One fine point worth noting is the proof of reflection property: when, similarly as in the proof of Theorem 14, we arrive at the case when $\mu_1 \not\sim_{\tau,\epsilon} \mu_2^j$, we know from Proposition 19 that for all j there is a formula that distinguishes μ_1 *from* μ_2^j, regardless of the direction in which the (τ, ϵ)-matching fails . We therefore have a family of formulae distinguishing μ_1 from μ_2^j for each j, and hence can construct a distinguishing formula by taking their conjunction.

In addition, since hybrid conformance is based on a symmetric relation on individual traces, the characterisation result holds for the standard (universal) interpretation of satisfaction relation as well.

▶ **Theorem 20.** *The logic MTL^+ [resp. MTL^+_∞], together with the relaxation operator $\mathsf{rlx}^{\sim}_{\tau,\epsilon}$, characterise the conformance relation $\sqsubseteq_{\tau,\epsilon}$ on finitely branching [resp. arbitrary] hybrid systems. That is, for finitely branching [resp. arbitrary] hybrid systems H and H', the following statements hold:*

$$H \sim_{\tau,\epsilon} H' \iff (\forall \phi \in \mathsf{MTL}^+\, [\mathsf{MTL}^+_\infty].\ H \models_\exists \phi \implies H' \models_\exists \mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi))$$

Moreover, the characterisation result holds for the universal interpretation of satisfaction relation as well, that is:

$$H \sim_{\tau,\epsilon} H' \iff (\forall \phi \in \mathsf{MTL}^+\, [\mathsf{MTL}^+_\infty].\ H' \models \phi \implies H \models \mathsf{rlx}^{\sqsubseteq}_{\tau,\epsilon}(\phi))$$

5 Comparison with an existing relaxation

In this section, we discuss the existing relaxation operator for MTL from the literature due to Abbas, Mittelmann, and Fainekos [1], which is known to preserve MTL formulae for discrete samplings (timed-state sequences). We show that their relaxation cannot distinguish between traces not related by hybrid conformance, and hence is too lax for the purpose of logical characterisation for either hybrid conformance, or refinement.

5.1 AMF-Relaxation

We recall the relaxation operator from [1], which we call AMF-relaxation (for Abbas, Mittelmann, and Fainekos). Originally the definition was given on the super-dense time domain (i.e., a time domain that allows for specifying the ordering of simultaneous events).

Since the "super-denseness" of the time domain does not have any influence on our study, we simplify the time domain to a dense time domain (such as non-negative real numbers). We also adapt the presentation to the generalised timed traces framework.

▶ **Definition 21.** *Given $\tau, \epsilon \geq 0$, the relaxation operator $[]^{AMF}_{\tau,\epsilon} : \mathsf{MTL}^+ \to \mathsf{MTL}^+_{ext}$ is defined as follows:*

$$\begin{array}{lcl}
[\mathsf{T}]^{AMF}_{\tau,\epsilon} = \mathsf{T} & , & [\mathsf{F}]^{AMF}_{\tau,\epsilon} = \mathsf{F} \\
[p]^{AMF}_{\tau,\epsilon} = p^+(\epsilon) & , & [\neg p]^{AMF}_{\tau,\epsilon} = p^-(\epsilon) \\
[\phi_1 \wedge \phi_2]^{AMF}_{\tau,\epsilon} & = & [\phi_1]^{AMF}_{\tau,\epsilon} \wedge [\phi_2]^{AMF}_{\tau,\epsilon} \\
[\phi_1 \vee \phi_2]^{AMF}_{\tau,\epsilon} & = & [\phi_1]^{AMF}_{\tau,\epsilon} \vee [\phi_2]^{AMF}_{\tau,\epsilon} \\
[\phi\, \mathcal{U}_I\, \psi]^{AMF}_{\tau,\epsilon} & = & (\Diamond_{(-2\tau,0]} [\phi]^{AMF}_{\tau,\epsilon})\, \mathcal{U}_{I_{\ll -2\tau, 2\tau \gg}}\, (\Diamond_{[0,2\tau)} [\psi]^{AMF}_{\tau,\epsilon}) \\
[\phi\, \mathcal{R}_I\, \psi]^{AMF}_{\tau,\epsilon} & = & (\Diamond_{(-2\tau,0]} [\phi]^{AMF}_{\tau,\epsilon})\, \mathcal{R}_{I_{\ll 2\tau, -2\tau \gg}}\, (\Diamond_{[0,2\tau)} [\psi]^{AMF}_{\tau,\epsilon}),
\end{array}$$

where $I_{\ll a,b \gg}$ is the relaxation of the bounds of interval I with constants a and b, formally defined as follows. For $a, b \in \mathbb{R}$, let $\mathcal{T}(a,b) := \{[a,b], (a,b], [a,b), (a,b)\}$; then for any interval $I \in \mathcal{T}(a,b)$, $I_{\ll c,d \gg} := (a+c, b+d)$.

Note that the interval relaxation $I_{\ll a,b \gg}$ differs from $I_{<a,b>}$ in that the former always yields an open interval, while the latter yields an interval of the same kind as I. For instance $[4,7]_{\ll -1,1 \gg} = (3,8)$, whereas $[4,7]_{<-1,1>} = [3,8]$.

It follows from Definition 21 that the relaxation operator $[]^{\mathrm{AMF}}_{\tau,\epsilon}$ applied to until or release formulae annotated with any interval from $\mathcal{T}(a,b)$ produces the same formulae:

▶ **Observation 22.** *For any $I \in \mathcal{T}(a,b)$, we have:*

$$\begin{array}{lcl}
[\phi\, \mathcal{U}_I\, \psi]^{AMF}_{\tau,\epsilon} & = & (\Diamond_{(-2\tau,0]} [\phi]^{AMF}_{\tau,\epsilon})\, \mathcal{U}_{(a-2\tau, b+2\tau)}\, (\Diamond_{[0,2\tau)} [\psi]^{AMF}_{\tau,\epsilon}) \\
[\phi\, \mathcal{R}_I\, \psi]^{AMF}_{\tau,\epsilon} & = & (\Diamond_{(-2\tau,0]} [\phi]^{AMF}_{\tau,\epsilon})\, \mathcal{R}_{(a+2\tau, b-2\tau)}\, (\Diamond_{[0,2\tau)} [\psi]^{AMF}_{\tau,\epsilon})
\end{array}$$

The following preservation result can be found in [1].

▶ **Theorem 23.** *Let $\phi \in \mathsf{MTL}^+$. Let $\mu_1 : \mathcal{T}_1 \to \mathcal{Y}$ and $\mu_2 : \mathcal{T}_2 \to \mathcal{Y}$ be two discrete GTTs, i.e. $\mathcal{T}_1, \mathcal{T}_2 \subseteq \mathcal{P}_{FIN}(\mathbb{R}_{\geq 0})$. If $\mu_1 \sim_{\tau,\epsilon} \mu_2$, then for any $t_1 \in \mathcal{T}_1$ if $(\mu_1, t_1) \models \phi$, then for all $t_2 \in \mathcal{T}_2$ such that $|t_2 - t_1| \leq \tau$ and $|\mu_2(t_2) - \mu_1(t_1)| \leq \epsilon$, we have $\mu_1, t_1 \models \phi \implies \mu_2, t_2 \models [\phi]^{AMF}_{\tau,\epsilon}$.*

Observe that the above preservation property is very strong: it holds for *any* sampling point in the conforming trace that matches the given point within the (τ, ϵ)-"window". This kind of result comes at a price of having to employ a relaxation operator which yields considerably weaker formulae, which explains the significant relaxation of intervals in $[]^{\mathrm{AMF}}_{\tau,\epsilon}$.

5.2 Laxness of AMF-Relaxation

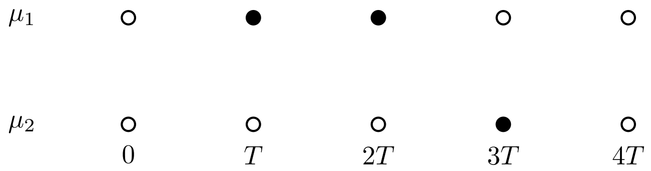
In this section, we prove that the notion of AMF-relaxation is too lax for the purpose of logical characterisation of hybrid conformance, i.e. there is a class of non-conforming implementations which preserve AMF-relaxations of all MTL properties satisfied by their specifications.

Throughout this section, we assume a simple setting where values range over Booleans, i.e. $\mathcal{Y} = \mathbb{B} = \{\mathbf{true}, \mathbf{false}\}$. The associated metric on $\mathcal{P}(\mathbb{B})$ is defined as $d(b_1, b_2) = 0$ if $b_1 = b_2$, and ∞ otherwise.

Recall that we refer to generalised timed traces with a finite time domain as timed state sequences, or TSSs.

We first explain the gist of our proof by showing one instance of the above-mentioned family of non-conforming counter-examples.

▶ **Example 24.** Fix $\tau > 0$ and let T be a value very slightly smaller than τ, i.e. $T = \tau - \delta$, where $\delta \ll \tau$. Consider the discretised GTTs presented in Example 2, which we recall here for the sake of convenience; μ_1 holds value **true** only at T and $2T$ and μ_2 holds value **true** at $3T$ and **false**, otherwise. The two TSSs can be depicted as follows (white/black dots represent states that have value, respectively, **true** / **false**):



μ_1 and μ_2 are not $(\tau, 0)$-close, not even $(t, 0)$-close for any $t < 2T$. To observe this note that for instance $\mu_1(T)$ cannot be matched by μ_2 within $(-T, 3T)$ since no state in μ_2 has value **false** in this interval. On the other hand, as we show next, TSSs μ_2 satisfies the AMF-relaxation of all MTL formulae satisfied by μ_1 (relaxed by parameters $(\tau, 0)$ and vice versa. Intuitively, this is because the intervals in the until and release formulae are respectively expanded and compressed by 2τ, allowing for shifts by 2τ in the states of TSS without affecting the satisfaction of formulae.

In the remainder of this section, we generalise this example and prove this fact for a broader, infinite class of pairs of TSSs which are not $(t, 0)$-equivalent for any $t < 2\tau$.

▶ **Definition 25.** *For a pair of TSSs $\mu_A : \mathcal{T}_A \to \mathbb{B}$ and $\mu_B : \mathcal{T}_B \to \mathbb{B}$, we say that μ_B is* stretched to the right of μ_A by less than t, *if there is some $K \in \mathbb{N}$ and functions $\textsc{chunk}_A : \mathcal{T}_A \to \{1, \ldots, K\}$ and $\textsc{chunk}_B : \mathcal{T}_B \to \{1, \ldots, K\}$ such that the following hold:*

- *$\textsc{chunk}_A$ and $\textsc{chunk}_B$ are surjective and non-decreasing*
- *all states that map to the same chunk number have the same value, i.e. for all $k \in \{1, \ldots, K\}$ and for all $t_A \in \mathcal{T}_A$, $t_B \in \mathcal{T}_A$ such that $\textsc{chunk}_A(t_A) = \textsc{chunk}_B(t_B) = k$, we have $\mu_A(t_A) = \mu_B(t_B)$*
- *for any $t_A \in \mathcal{T}_A$, there is some $t_B \in \mathcal{T}_B$ such that*

  $$(*) \quad 0 \le t_B - t_A < t \quad \wedge \quad \textsc{chunk}_A(t_A) = \textsc{chunk}_B(t_B)$$

  and conversely, for any $t_B \in \mathcal{T}_B$ there is some $t_A \in \mathcal{T}_A$ such that (*) holds. We shall call a pair $(\mu_A, t_A), (\mu_B, t_B)$ satisfying (*) a pair of ***t-corresponding states****.*

Note that in the last condition, the inequality in (*) involves the actual difference between t_B and t_A, not its absolute value – we allow μ_B to be shifted only to the right as compared to μ_A. The following example illustrates this definition.

▶ **Example 26.** Consider the TSSs in Example 24; the TSS μ_2 is stretched to the right of μ_1 by less than 2τ, as witnessed by the following functions $\textsc{chunk}_1$ and $\textsc{chunk}_2$:

$\textsc{chunk}_1(0) = 1$	$\textsc{chunk}_2(t) = 1$ for $t \in \{0, T, 2T\}$
$\textsc{chunk}_1(t) = 2$ for $t \in \{T, 2T\}$	$\textsc{chunk}_2(3T) = 2$
$\textsc{chunk}_1(t) = 3$ for $t \in \{3T, 4T\}$	$\textsc{chunk}_2(4T) = 3$

▶ **Example 27.** Considering Example 24 and propositions $p_{\mathbf{t}}$ and $p_{\mathbf{f}}$ such that $\mathcal{O}(p_{\mathbf{t}}) = \{\mathbf{true}\}$ and $\mathcal{O}(p_{\mathbf{f}}) = \{\mathbf{false}\}$; we have $(\mu_2, 0) \models p_{\mathbf{t}}\, \mathcal{U}_{[3T,3T]}\, p_{\mathbf{f}}$, and the 2τ-corresponding state $(\mu_1, 0)$ satisfies the relaxed formula $[p_{\mathbf{t}}\, \mathcal{U}_{[3T,3T]}\, p_{\mathbf{f}}]^{\mathrm{AMF}}_{\tau,0}$. The latter statement can be deduced from that $(\mu_1, 0)$ satisfies $p_{\mathbf{t}}\, \mathcal{U}_{(3T-2\tau,3T+2\tau)}\, p_{\mathbf{f}}$, a simpler formula that logically entails $[p_{\mathbf{t}}\, \mathcal{U}_{[3T,3T]}\, p_{\mathbf{f}}]^{\mathrm{AMF}}_{\tau,0}$.

The key proposition below states that for 2τ-corresponding states, the satisfaction of all formulae in MTL^+ is preserved modulo relaxation $[]^{\text{AMF}}_{\tau,0}$.

▶ **Proposition 28.** *Suppose μ_B is stretched to the right of μ_A by less than 2τ. Then for any $t_A \in \mathcal{T}_A$, and any $t_B \in \mathcal{T}_B$ satisfying*

$$(*) \quad 0 \leq t_B - t_A < 2\tau \quad \wedge \quad \mathit{CHUNK}_A(t_A) = \mathit{CHUNK}_B(t_B)$$

we have, for all formulae $\phi \in \mathsf{MTL}^+$: $(\mu_A, t_A) \models \phi \implies (\mu_B, t_B) \models [\phi]^{AMF}_{\tau,0}$, and $(\mu_B, t_B) \models \phi \implies (\mu_A, t_A) \models [\phi]^{AMF}_{\tau,0}$.

Proof. The proof by structural induction on ϕ is rather tedious and technical, and omitted in this version of the paper. ◀

6 Conclusions and Future Work

In this paper, we have studied the notion of hybrid conformance from the literature, as well its associated preorder, called hybrid refinement. We have presented a logical characterisation of both relations in Metric Temporal Logic. Since the notions of refinement and conformance allow for some deviations (in time and value), the characterisation is expressed in terms of a relaxation of the set of formulae satisfied by a system. The relaxation operators corresponding to the two relations differ considerably – while for hybrid refinement it suffices to perform relaxation on the level of propositions only, characterising hybrid conformance requires relaxing bounds of intervals in temporal operators. We note that with hybrid conformance we obtain stronger characterisation result; it holds in particular under both existential and universal interpretation of the satisfaction relation.

We have also showed that the existing relaxation scheme proposed by Abbas, Fainekos, and Mittelmann is too lax to serve for a characterisation, i.e., there is a class of non-conforming systems that do satisfy all relaxations of the specification properties. Hence, we proposed a tighter notion of relaxation and showed that it is the appropriate notion to provide a characterisation of hybrid conformance.

Our preservation and characterisation results for hybrid refinement are formulated using the existential interpretation of the satisfaction relation, while our results for hybrid conformance hold both for the existential- and universal interpretation of the satisfaction relation. This is inherent to our notion of hybrid refinement and cannot be remedied in any straightforward manner, as far as we could investigate. We envisage that there could be other definitions of hybrid refinement that are well-behaved in this respect and we would like to study and propose such notions in the future.

As another line of future research, we would also like to investigate the possibility of characterising Skorokhod conformance with Freeze Temporal Logic and the notion of relaxation provided by Deshmukh, Majumdar, and Prabhu [16]. Coming up with the notion of characteristic formulae is another avenue for our future research, which leads to a new technique for checking hybrid conformance.

Abstract

We produce a class of ω-categorical structures with finite signature by applying a model-theoretic construction – a refinement of an encoding due to Hrushosvki – to ω-categorical structures in a possibly infinite signature. We show that the encoded structures retain desirable algebraic properties of the original structures, but that the constraint satisfaction problems (CSPs) associated with these structures can be badly behaved in terms of computational complexity. This method allows us to systematically generate ω-categorical templates whose CSPs are complete for a variety of complexity classes of arbitrarily high complexity, and ω-categorical templates that show that membership in any given complexity class cannot be expressed by a set of identities on the polymorphisms. It moreover enables us to prove that recent results about the relevance of topology on polymorphism clones of ω-categorical structures also apply for CSP templates, i.e., structures in a finite language. Finally, we obtain a concrete algebraic criterion which could constitute a description of the delineation between tractability and NP-hardness in the dichotomy conjecture for first-order reducts of finitely bounded homogeneous structures.

1 Introduction

1.1 Constraint Satisfaction Problems

The *Constraint Satisfaction Problem*, or CSP for short, over a relational structure $\mathbb{A}$ is the computational problem of deciding whether a given finite relational structure $\mathbb{B}$ in the signature of $\mathbb{A}$ can be homomorphically mapped into $\mathbb{A}$. The structure $\mathbb{A}$ is known as the *template* or *constraint language* of the CSP, and the CSP of the particular structure $\mathbb{A}$ is denoted by $\mathrm{CSP}(\mathbb{A})$. A host of interesting computational problems can be modelled using CSPs by choosing an appropriate template. For example, if $\mathbb{A}$ is the structure with domain $\{0,1\}$ and all binary relations on the set $\{0,1\}$, then $\mathrm{CSP}(\mathbb{A})$ is precisely the 2-SAT problem, and if $\mathbb{A}$ is the complete graph on three vertices, then $\mathrm{CSP}(\mathbb{A})$ is the 3-colouring problem. Note that the template $\mathbb{A}$ which defines the problem can also be infinite – only the input structure $\mathbb{B}$ is required to be finite in order to obtain a computational problem. Many well-known computational problems can be modelled, and can in fact only be modelled, using an infinite template. One example is the CSP of the order of the rational numbers $(\mathbb{Q};<)$, which is equivalent to the problem of deciding whether a given finite directed graph is acyclic. The size of the signature of the template $\mathbb{A}$, or in other words the number of its relations, is however generally required to be finite: otherwise, the encoding of its relational symbols might influence the computational complexity of $\mathrm{CSP}(\mathbb{A})$, so that this complexity is not well-defined as per the structure $\mathbb{A}$ itself. To emphasize the importance of this requirement, we shall henceforth only call relational structures in a finite signature *CSP templates*.

The general aim in the study of CSPs is to understand the structural reasons for the hardness or the tractability of such problems. This has been successfully achieved for CSPs of structures over a finite domain. As it turns out, every finite template either has, in a certain precise sense, as little symmetry as the 3-colouring problem above, in which case its CSP is NP-complete; or it has more symmetry and its CSP is polynomial-time solvable, just like the 2-SAT problem. This dichotomy result was conjectured by Feder and Vardi [19, 20], and proved, almost 25 years later, independently by Bulatov [18] and Zhuk [28].

1.2 A dichotomy conjecture and local identities

The algebraic approach behind these proofs does not require the template to be finite, but also works under the assumption of ω-categoricity. And although every computational decision problem is polynomial-time Turing-equivalent to the CSP of some infinite template [9], for a large and natural class of ω-categorical templates, which considerably expands the class of finite templates, a similar conjecture as for finite-domain CSPs has been formulated.

▶ **Conjecture 1** (see [3, 5, 17]). *Let $\mathbb{A}$ be a CSP template which is a first-order reduct of a countable finitely bounded homogeneous structure. Then one of the following holds.*

- *$\mathbb{A}$ satisfies some non-trivial set of h1 identities locally, i.e., on every finite subset of its domain, and $\mathrm{CSP}(\mathbb{A})$ is in P.*
- *There exists a finite subset of its domain on which $\mathbb{A}$ satisfies no non-trivial set of h1 identities, and $\mathrm{CSP}(\mathbb{A})$ is NP-complete.*

The conjectured P/NP-complete dichotomy has been demonstrated for numerous subclasses: for example for all CSPs in the class MMSNP [11], as well as for the CSPs of the first-order reducts of $(\mathbb{Q};<)$ [10], of any countable homogeneous graph [12] (including the random graph [15]), and of the random poset [24].

It is thus the *local h1 identities* which are believed to be the "right" measure of symmetry of a template $\mathbb{A}$ – according to the conjecture, they determine tractability or hardness of its CSP. The distinction between local and global h1 identities is, of course, void in the case of a finite template $\mathbb{A}$, and the above-stated dichotomy is true by the theorem of Bulatov and Zhuk and results from [5]. One of the main challenges towards proving Conjecture 1 is to determine whether this distinction could be void as well for structures within its range. The satisfaction of non-trivial h1 identities in $\mathbb{A}$ is characterised by the non-existence of particular maps called *minion homomorphisms* from the *polymorphism clone* $\mathrm{Pol}(\mathbb{A})$ of $\mathbb{A}$ to the *projection clone* $\mathscr{P}$. The mentioned distinction between local and global h1 identities is then mirrored by the distinction between those maps that are *uniformly continuous* and those that are not. Hence, the question whether non-trivial local h1 identities imply non-trivial global h1 identities in a relational structure $\mathbb{A}$ raises the following question.

▶ **Question 2.** *Does the existence of a minion homomorphism from* $\mathrm{Pol}(\mathbb{A})$ *to* $\mathscr{P}$ *imply the existence of a uniformly continuous minion homomorphism from* $\mathrm{Pol}(\mathbb{A})$ *to* $\mathscr{P}$*?*

2 Results

Among all finite structures, it is known that CSP templates (i.e., those structures with finite signature) have considerably better algebraic properties than other structures [2, 1]. We refine a model-theoretic trick due to Hrushovski [23] to encode ω-categorical structures with an infinite signature into ω-categorical CSP templates whilst preserving certain properties of the original, showing that a similar phenomenon does not seem to appear within the class of ω-categorical structures. Using this method, we produce ω-categorical CSP templates with various “untame” properties of both algebraic and complexity-theoretic nature.

2.1 Local versus global identities

Recently, in [13, 14], an example of an ω-categorical structure answering Question 2 in the negative was given; however, this structure had an infinite language and therefore this result had *a priori* no consequence for the study of CSPs. Using our encoding, we provide a negative answer within the realm of CSP templates.

▶ **Theorem 3.** *There is an ω-categorical CSP template $\mathbb{U}$ with slow orbit growth such that there exists a minion homomorphism from* $\mathrm{Pol}(\mathbb{U})$ *to* $\mathscr{P}$*, but no uniformly continuous one.*

We also encode a counterexample from [17] for *clone homomorphisms*, which are mappings preserving arbitrary (not only h1) identities, into a finite language. Clone homomorphisms appear in the original (and equivalent [3, 4]) formulation of Conjecture 1 from [17] (also see [6, 7]).

▶ **Theorem 4.** *There exists an ω-categorical CSP template $\mathbb{U}$ with a clone homomorphism from* $\mathrm{Pol}(\mathbb{U})$ *to* $\mathscr{P}$ *that is not uniformly continuous.*

2.2 Dissected weak near-unanimity identities

Our proof of the fact that the template $\mathbb{U}$ from Theorem 3 satisfies non-trivial h1 identities locally is constructive: we exhibit a concrete set of such identities which we call *dissected weak near-unanimity*. Moreover, we obtain quite general conditions on the symmetry of a structure which force our identities to be satisfied locally. It follows that the original infinite-language structure from [13, 14] satisfies them; this contrasts the indirect proof in [13, 14] which does not provide any concrete set of h1 identities.

▶ **Theorem 5.** *Let $\mathbb{U}$ be a homogeneous structure. Let F be a finite subset of its domain, and let $k \geq 1$. Suppose that:*

(i) *Only relations of arity smaller than k hold for tuples of elements in F.*

(ii) *There is an embedding from $\mathbb{U}^2$ into $\mathbb{U}$.*

Then $\mathbb{U}$ satisfies (n,k) dissected weak near-unanimity identities on F for all $n > k$.

Dissected weak near-unanimity identities can be viewed as a generalization of *weak near-unanimity* identities. It follows from [26] and [5] that if $\mathbb{U}$ is a finite relational structure satisfying non-trivial h1 identities, then $\mathbb{U}$ satisfies weak near-unanimity identities. The satisfaction of dissected weak near-unanimity identities has been proven for a large number of structures within the range of Conjecture 1 in [4, 3]; since they now reappeared in the rather different context of Theorem 3, the following question emerges naturally.

▶ **Question 6.** *Let $\mathbb{U}$ be an ω-categorical structure with slow orbit growth which satisfies non-trivial h1 identities locally. Does $\mathbb{U}$ satisfy dissected weak near-unanimity identities locally?*

2.3 ω-categorical CSP monsters

The complexity of CSP($\mathbb{A}$) is, for every ω-categorical CSP template $\mathbb{A}$, determined by Pol($\mathbb{A}$) viewed as a topological clone: if there exists a topological clone isomorphism Pol($\mathbb{A}$) $\to$ Pol($\mathbb{B}$) and $\mathbb{A}$ and $\mathbb{B}$ are ω-categorical, then CSP($\mathbb{A}$) and CSP($\mathbb{B}$) are equivalent under log-space reductions [16]. In other words, the local (not necessarily h1) identities satisfied in Pol($\mathbb{A}$) encode the complexity of CSP($\mathbb{A}$). Conjecture 1 even postulates that for every template $\mathbb{A}$ within its scope, membership of CSP($\mathbb{A}$) in P only depends on the local h1 identities of $\mathbb{A}$. The latter is equivalent to the statement that polynomial-time tractability is characterised by the global satisfaction of the single identity $\alpha s(x,y,x,z,y,z) = \beta s(y,x,z,x,z,y)$ [4, 7].

Using our encoding, we prove that global identities do not characterise membership in P – or, in fact, in any other non-trivial class of languages containing AC^0 – for the class of homogeneous CSP templates.

▶ **Theorem 7.** *Let $\mathcal{C}$ be any class of languages that contains AC^0 and that does not intersect every Turing degree. Then there is no countable set Θ of identities such that for all homogeneous CSP templates membership in $\mathcal{C}$ is equivalent to the satisfaction of Θ.*

The proof of Theorem 7 relies on encoding arbitrary languages as CSPs of homogeneous templates. These templates are obtained by applying our encoding to structures which have only empty relations, but a complicated infinite signature. On the way, we obtain a new proof of a result by Bodirsky and Grohe [9].

▶ **Theorem 8.** *Let $\mathcal{C}$ be a complexity class such that there exist* CONP$^{\mathcal{C}}$*-complete problems. Then there exists a homogeneous CSP template that satisfies non-trivial h1 identities and whose CSP is* CONP$^{\mathcal{C}}$*-complete. Moreover, if P $\neq$* CONP*, then there exists a CSP template with these algebraic properties whose CSP has* CONP*-intermediate complexity.*

In particular, Theorem 8 gives complete problems for classes such as Π_n^{P} for every $n \geq 1$, PSPACE, EXPTIME, or even every fast-growing time complexity class $\mathbf{F}_\alpha$ where $\alpha \geq 2$ is an ordinal (such as the classes TOWER or ACKERMANN, see [27]).

3 Outline

The most important definitions, in particular those of notions which appear in the introduction and the results, are given in Section 4. A complete exposition of all notions, as well as most proofs are left to the appendix due to space restrictions; we also refer to the long version of this extended abstract which is available on arXiv [22]. Our variant of Hrushovski's encoding and its most important properties are presented in Section 5. Dissected weak near-unanimity identities, as well as the proof of Theorem 3, are the contents of Section 6. In Section 7, we sketch the proofs of Theorem 7 and of the first statement of Theorem 8. Due to space restrictions, we cannot address the proofs of Theorems 4 and of the second statement of Theorem 8 at all – they can be found in the long version.

4 Preliminaries

If $\mathbb{A}$ is a relational structure in a finite signature, called a *CSP template*, then $\mathrm{CSP}(\mathbb{A})$ is the set of all finite structures $\mathbb{B}$ in the same signature with the property that there exists a homomorphism from $\mathbb{B}$ into $\mathbb{A}$. This set can be viewed as a computational problem where we are given a finite structure $\mathbb{B}$ in that signature, and we have to decide whether $\mathbb{B} \in \mathrm{CSP}(\mathbb{A})$.

We will tacitly assume that all relational structures, as well as their signatures, are at most countably infinite.

4.1 Polymorphisms, identities, and clone and minion homomorphisms

A *polymorphism* of a relational structure $\mathbb{A}$ is a homomorphism from some finite power $\mathbb{A}^n$ of the structure into $\mathbb{A}$. The set of all polymorphisms of $\mathbb{A}$ is called the *polymorphism clone* of $\mathbb{A}$ and is denoted by $\mathrm{Pol}(\mathbb{A})$.

An *identity* is a formal expression $s(x_1, \dots, x_n) = t(y_1, \dots, y_m)$ where s and t are abstract terms of function symbols, and $x_1, \dots, x_n, y_1, \dots, y_m$ are the variables that appear in these terms. The identity is of *height 1*, and called *h1 identity*, if the terms s and t contain precisely one function symbol, i.e., no nesting of function symbols is allowed, and no term may be just a variable.

A set Θ of identities is *satisfied* in $\mathbb{A}$ if the function symbols of Θ can be assigned functions in $\mathrm{Pol}(\mathbb{A})$ in such a way that all identities of Θ become true for all possible values of their variables in $\mathbb{A}$. If F is a finite subset of the domain of $\mathbb{A}$, then Θ *is satisfied locally on* F if the above situation holds where only values within F are considered for the variables.

A set of identities is called *trivial* if it is satisfied in the *projection clone* $\mathscr{P}$ consisting of the projection operations on the set $\{0, 1\}$. Otherwise, the set is called *non-trivial*. We say that $\mathbb{A}$ satisfies non-trivial identities *locally* if on every finite subset of its domain it locally satisfies some non-trivial set of identities. We shall use similar terminology for h1 identities.

A map $\xi\colon \mathrm{Pol}(\mathbb{A}) \to \mathrm{Pol}(\mathbb{B})$ is called a *clone homomorphism* if it preserves arities, maps the i-th n-ary projection in $\mathrm{Pol}(\mathbb{A})$ to the i-th n-ary projection in $\mathrm{Pol}(\mathbb{B})$ for all $1 \leq i \leq n$, and satisfies $\xi(f \circ (g_1, \dots, g_n)) = \xi(f) \circ (\xi(g_1), \dots, \xi(g_n))$ for all $n, m \geq 1$, all n-ary $f \in \mathrm{Pol}(\mathbb{A})$, and all m-ary $g_1, \dots, g_n \in \mathrm{Pol}(\mathbb{A})$. This is the case if and only if the map ξ *preserves identities*, i.e., whenever some functions in $\mathrm{Pol}(\mathbb{A})$ witness the satisfaction of some identity in $\mathrm{Pol}(\mathbb{A})$, then their images under ξ witness the satisfaction of the same identity in $\mathrm{Pol}(\mathbb{B})$.

A map $\xi\colon \mathrm{Pol}(\mathbb{A}) \to \mathrm{Pol}(\mathbb{B})$ is called a *minion homomorphism* if it preserves arities and composition with projections; the latter meaning that for all $n, m \geq 1$, all n-ary $f \in \mathrm{Pol}(\mathbb{A})$, and all m-ary projections $p_1, \dots, p_n \in \mathrm{Pol}(\mathbb{A})$, we have $\xi(f \circ (p_1, \dots, p_n)) = \xi(f) \circ (p'_1, \dots, p'_n)$, where p'_i is the m-ary projection in $\mathrm{Pol}(\mathbb{B})$ onto the same variable as p_i, for all $1 \leq i \leq n$. This is the case if and only if the map ξ preserves h1 identities in the sense above.

The existence of clone and minion homomorphisms $\mathrm{Pol}(\mathbb{A}) \to \mathscr{P}$ is connected to the satisfaction of non-trivial identities in a relational structure $\mathbb{A}$. Namely, there exists a clone homomorphism $\mathrm{Pol}(\mathbb{A}) \to \mathscr{P}$ if and only if every set of identities satisfied in $\mathbb{A}$ is trivial; and there exists a minion homomorphism $\mathrm{Pol}(\mathbb{A}) \to \mathscr{P}$ if and only if every set of h1 identities satisfied in $\mathbb{A}$ is trivial.

Similarly, the *local satisfaction* of identities and h1 identities can be characterised via *uniformly continuous* clone and minion homomorphisms, respectively [16, 21, 5]. However, the reader will not need any knowledge of topology and can only keep in mind that the topology reflects the local/global distinction.

4.2 Homogeneity, boundedness, reducts, ω-categoricity, orbit growth

Let $\mathcal{C}$ be a class of finite structures in a common relational signature which is closed under isomorphisms. We define the following properties the class $\mathcal{C}$ might have.

Hereditary property (HP): if $\mathbb{A} \in \mathcal{C}$ and if $\mathbb{B}$ is a substructure of $\mathbb{A}$, then $\mathbb{B} \in \mathcal{C}$;

Amalgamation property (AP): if $\mathbb{A}, \mathbb{B}, \mathbb{C} \in \mathcal{C}$ and if $f_1 \colon \mathbb{A} \to \mathbb{B}$ and $f_2 \colon \mathbb{A} \to \mathbb{C}$ are embeddings, then there exist $\mathbb{D} \in \mathcal{C}$ and embeddings $g_1 \colon \mathbb{B} \to \mathbb{D}$ and $g_2 \colon \mathbb{C} \to \mathbb{D}$ such that $g_1 \circ f_1 = g_2 \circ f_2$;

Strong amalgamation property (SAP): $\mathcal{C}$ satisfies AP and in addition g_1 and g_2 can be chosen to have disjoint ranges, except for the common values enforced by above equation.

A relational structure $\mathbb{C}$ is *homogeneous* if every isomorphism between finite induced substructures extends to an automorphism of the entire structure $\mathbb{C}$. In that case, $\mathbb{C}$ is uniquely determined, up to isomorphism, by its *age*, i.e., the class of its finite induced substructures up to isomorphism. This is a consequence of the following theorem.

▶ **Theorem 9** (Fraïssé's Theorem, see [23]). *Let σ be a relational signature and let $\mathcal{C}$ be a class of finite σ-structures which is closed under isomorphisms and satisfies HP and AP. Then there exists a σ-structure $\mathbb{A}$ such that $\mathbb{A}$ is countable, homogeneous, and the age of $\mathbb{A}$ equals $\mathcal{C}$. Furthermore $\mathbb{A}$ is unique up to isomorphism.*

The structure $\mathbb{A}$ above is called the *Fraïssé limit* of $\mathcal{C}$, and the class $\mathcal{C}$ a *Fraïssé class.*

A class $\mathcal{C}$ of finite structures in the same finite signature is *finitely bounded* if it is given by a finite set $\mathcal{F}$ of forbidden finite substructures, i.e., $\mathcal{C}$ consists precisely of those finite structures in its signature which do not embed any member of $\mathcal{F}$. A class $\mathcal{C}$ of finite structures in the same signature is *homomorphically bounded* by a (possibly infinite) set $\mathcal{F}$ of finite structures if it is defined by forbidding the structures in $\mathcal{F}$ homomorphically, i.e., $\mathcal{C}$ consists precisely of those finite structures in its signature which do not contain a homomorphic image of any member of $\mathcal{F}$ as a substructure. A structure $\mathbb{A}$ is finitely bounded (homomorphically bounded) if its age is.

A *first-order reduct* of a relational structure $\mathbb{C}$ is a relational structure $\mathbb{A}$ on the same domain which is first-order definable without parameters in $\mathbb{C}$. Every first-order reduct $\mathbb{A}$ of a finitely bounded homogeneous structure is *ω-categorical*, i.e., the automorphism group $\mathrm{Aut}(\mathbb{A})$ has finitely many orbits in its componentwise action on A^n, for all finite $n \geq 1$. In fact, if $\mathbb{A}$ is such a first-order reduct, then the number of orbits in the action of $\mathrm{Aut}(\mathbb{A})$ on A^n grows exponentially in n; in general, we say that ω-categorical structures where this number grows less than double exponentially in n have *slow orbit growth.*

For a relational structure $\mathbb{A}$ in signature $\sigma = (R_i)_{i \in I}$, and $J \subseteq I$, we call the structure $(A; (R_i^{\mathbb{A}})_{i \in J})$ in signature $\rho := (R_i)_{i \in J}$ the *ρ-reduct* of $\mathbb{A}$; conversely $\mathbb{A}$ is called an *expansion* of any of its reducts, and a *first-order expansion* of a reduct if all of its relations have a first-order definition in the reduct. We say that a structure is *homogenizable* if it has a homogeneous first-order expansion. All ω-categorical structures are homogenizable. A homogenizable structure $\mathbb{A}$ has *no algebraicity* if the age of any, or equivalently some, homogeneous first-order expansion of $\mathbb{A}$ has SAP.

A formula is *primitive positive*, in short *pp*, if it contains only existential quantifiers, conjunctions, equalities, and relational symbols. If $\mathbb{A}$ is a relational structure, then a relation is *pp-definable* in $\mathbb{A}$ if it can be defined by a pp-formula in $\mathbb{A}$. A structure $\mathbb{A}$ *pp-interprets* $\mathbb{B}$ if a structure isomorphic to $\mathbb{B}$ can be constructed from $\mathbb{A}$ by pp-defining a subset S of some finite power of its domain, then pp-defining an equivalence relation $\sim$ on S, and then pp-defining relations on the equivalence classes of $\sim$.

5 The encoding

We present the encoding of an arbitrary homogenizable structure with no algebraicity into a CSP template, which will be the basis of our results. The construction is originally due to Hrushovski [23, Section 7.4]; it was designed to capture properties of the first-order theory and consequently the automorphism group of the original structure. We refine his construction in order to also compare the polymorphism clones of the original structure and its encoded counterpart, and to control the complexity of the CSPs of the produced templates.

5.1 Encoding and Decoding

Let Σ be a finite alphabet, and let $\Sigma^{\geq 2}$ denote the set of all finite words over Σ of length at least two. We are going to encode structures with a signature of the form $\rho = (R_w)_{w \in W}$, where $W \subseteq \Sigma^{\geq 2}$ and where the arity of each symbol R_w equals the length $|w|$ of the word w. For the rest of this section we fix Σ and ρ. Our goal is to encode any homogenizable ρ-structure $\mathbb{A}$ with no algebraicity into a structure $\mathbf{E}\,\mathbb{A}$ (where $\mathbf{E}$ stands for *E. Hrushovski*) in a finite signature θ which is disjoint from ρ and only depends on Σ.

Note that by renaming its signature, and possibly artificially inflating the arity of its relations (by adding dummy variables), any arbitrary structure with countably many relations can be given a signature of the above form without changing, for example, its polymorphism clone. However, the encoding will depend on these modifications, and their effect on the algebraic and combinatorial properties of the encoding is beyond the scope of this article. The original encoding [23, Section 7.4] roughly corresponds to the case where $|\Sigma| = 1$, and our generalization allows us to avoid such modifications for the structures we wish to encode, making in particular our complexity-theoretic results possible.

▶ **Definition 10.** *Let θ denote the signature $\{P, \iota, \tau, S\} \cup \{H_s \mid s \in \Sigma\}$, where P, ι, τ are unary relation symbols, H_s is a binary relation symbol for each $s \in \Sigma$, and S is a 4-ary relation symbol. For every signature σ disjoint from θ, define σ^+ to be the union $\sigma \cup \theta$.*

The encoding of a ρ-structure $\mathbb{A}$ will roughly be obtained as follows: first, one takes a homogeneous first-order expansion $\mathbb{B}$ in some signature σ; from its age K, one defines a class K^+ of finite structures in signature σ^+; and the encoding is the θ-reduct of the Fraïssé limit of K^+. In order to define the class K^+, we need the following definitions.

▶ **Definition 11.** *Let σ be a signature disjoint from θ, let $\mathbb{A}$ be a σ^+-structure, and let $w \in \Sigma^{\geq 2}$. A tuple $(a_1, \dots, a_{|w|}, c_1, \dots, c_{|w|})$ of elements of $\mathbb{A}$ is a* valid w-code *in $\mathbb{A}$ if the following hold:*

(a) $a_1, \dots, a_{|w|} \in P^{\mathbb{A}}$;

(b) $H^{\mathbb{A}}_{w_i}(c_i, c_j)$ *for all* $1 \leq i, j \leq |w|$ *such that* $j \equiv i + 1 \pmod{|w|}$;

(c) $\iota^{\mathbb{A}}(c_1)$ *and* $\tau^{\mathbb{A}}(c_{|w|})$;

(d) $S^{\mathbb{A}}(a_i, a_j, c_i, c_j)$ *for all* $1 \leq i, j \leq |w|$ *with* $i \neq j$.

Figure 1 Sources and destinations of the operators related to the encoding and decoding.

▶ **Definition 12.** *Let σ be a signature disjoint from θ, and let $\mathbb{A}$ be a σ^+-structure. Then $\mathbb{A}$ is called* separated *if*

(i) *$H_s^{\mathbb{A}}$ only relates pairs within $A \setminus P^{\mathbb{A}}$ for all $s \in \Sigma$;*
(ii) *$\iota^{\mathbb{A}}, \tau^{\mathbb{A}}$ are contained in $A \setminus P^{\mathbb{A}}$;*
(iii) *If $(a, b, c, d) \in S^{\mathbb{A}}$, then $c, d \in A \setminus P^{\mathbb{A}}$ and $c \neq d$.*

It follows from (iii) above that in a separated structure a valid w-code can only exist if $|w| \geq 2$; this is the reason for the exclusion of unary relation symbols from ρ.

▶ **Definition 13.** *Let $\mathbb{A}$ be a ρ-structure and let $\mathbb{B}$ be a homogeneous first-order expansion of $\mathbb{A}$ with signature σ and age K. Define K^+ to be the class of all finite σ^+-structures $\mathbb{C}$ with the following properties:*

(1) *The σ-reduct of the restriction of $\mathbb{C}$ to $P^{\mathbb{C}}$ is an element of K;*
(2) *$\mathbb{C}$ is separated and for every $R \in \sigma$ the relation $R^{\mathbb{C}}$ only relates tuples which lie entirely within $P^{\mathbb{C}}$;*
(3) *If $R_w \in \rho$ and $(a_1, \dots, a_{|w|}, c_1, \dots, c_{|w|})$ is a valid w-code in $\mathbb{C}$, then $(a_1, \dots, a_{|w|}) \in R_w^{\mathbb{C}}$.*

▶ **Lemma 14.** *Let $\mathbb{A}$ be a ρ-structure and let $\mathbb{B}$ be a homogeneous first-order expansion of $\mathbb{A}$ with age K. If K has the HP and the SAP, then K^+ has the HP and the SAP as well.*

By Lemma 14, if $\mathbb{A}$ has no algebraicity[1], and $\mathbb{B}$ is a homogeneous first-order expansion of $\mathbb{A}$ with age K, then K^+ has a Fraïssé limit, allowing us to define our encoding as follows.

▶ **Definition 15.** *Let $\mathbb{A}$ be a ρ-structure with no algebraicity and let $\mathbb{B}$ be a homogeneous first-order expansion of $\mathbb{A}$ with age K. We define $\overrightarrow{\mathbf{B}}_{\mathbb{B}}\,\mathbb{A}$, the* encoding blow up *of $\mathbb{A}$, to be the Fraïssé limit of K^+. Moreover, we define $\overrightarrow{\mathbf{R}}\,\mathbb{C}$ to be the θ-reduct of any structure $\mathbb{C}$ with signature containing θ. The* Hrushovski-encoding *$\mathbf{E}\,\mathbb{A}$ is defined by $\mathbf{E}\,\mathbb{A} := \overrightarrow{\mathbf{R}}\,\overrightarrow{\mathbf{B}}_{\mathbb{B}}\,\mathbb{A}$.*

▶ Remark 16. All ω-categorical structures have a homogeneous first-order expansion. This expansion is not unique, but the encoding $\mathbf{E}\,\mathbb{A}$ of $\mathbb{A}$ does not depend on it.

[1] Contrary to a claim in [23], AP of K is not a sufficient assumption for AP of K^+ in Lemma 14.

Figure 2 The encoding $\mathbf{E}\,\mathbb{A}$ of a structure $\mathbb{A}$.

It might be of help to the reader if we note that the operators used in the encoding of a structure, i.e., $\overrightarrow{\mathbf{B}}_{\mathbb{B}}$ and $\overrightarrow{\mathbf{R}}$, bear arrows from left to right; the operators used in the decoding of a structure, defined below, bear arrows in the opposite direction. Table 1 contains an informal summary of all operators, and Figure 1 describes on which classes of structures they operate.

Table 1 The meaning of the operators.

Operator	Name	Description
$\overrightarrow{\mathbf{B}}_{\mathbb{B}}$	encoding blow up	The first step in an encoding, extends the domain and defines relations for the signature θ via a homogeneous expansion $\mathbb{B}$ of the input.
$\overrightarrow{\mathbf{R}}$	θ-reduct	Returns the θ-reduct of a structure.
$\mathbf{E}$	encoding	Combines $\overrightarrow{\mathbf{B}}_{\mathbb{B}}$ and $\overrightarrow{\mathbf{R}}$ to obtain a θ-structure from a ρ-structure.
$\overleftarrow{\mathbf{B}}$	decoding blow up	The first step in decoding a θ-structure, it converts valid codes into corresponding relations in ρ.
$\overleftarrow{\mathbf{R}}$	relativised reduct	Restricts a structure to the set named by P and forgets relations not in ρ.
$\mathbf{D}$	decoding	Combines $\overleftarrow{\mathbf{R}}$ and $\overleftarrow{\mathbf{B}}$ to obtain the ρ-structure $\mathbb{A}$ from the encoded θ-structure $\mathbf{E}\,\mathbb{A}$.
$\mathbf{C}$	canonical code	Defines in a canonical way a finite θ-structure from a finite ρ-structure in which every relation which holds in the input is witnessed by a valid code.

Like the encoding of a structure, the decoding of a structure is a composition of two steps; first a *decoding blow up*, and then a *relativised reduct.*

▶ **Definition 17.** *Let $\mathbb{C}$ be a θ-structure. Then the* decoding blow up $\overleftarrow{\mathbf{B}}\,\mathbb{C}$ *of $\mathbb{C}$ is the expansion of $\mathbb{C}$ in signature ρ^+, where for any symbol $R_w \in \rho$ the relation $R_w^{\overleftarrow{\mathbf{B}}\,\mathbb{C}}$ is defined to consist of those tuples $(a_1, \ldots, a_{|w|})$ for which there exist $c_1, \ldots, c_{|w|}$ such that the tuple $(a_1, \ldots, a_{|w|}, c_1, \ldots, c_{|w|})$ is a valid w-code in $\mathbb{C}$.*

For a structure $\mathbb{D}$ in a signature containing ρ^+, the relativised reduct $\overleftarrow{\mathbf{R}}\,\mathbb{D}$ *of $\mathbb{D}$ is defined to be the ρ-reduct of $\mathbb{D}$ restricted to $P^{\mathbb{D}}$.*

Finally, we set $\mathbf{D}\,\mathbb{C} := \overleftarrow{\mathbf{R}}\,\overleftarrow{\mathbf{B}}\,\mathbb{C}$, the decoding of $\mathbb{C}$, *for any θ-structure $\mathbb{C}$.*

The following proposition states that the operator $\mathbf{D}$ indeed decodes $\mathbf{E}\,\mathbb{A}$. It also allows us to identify $\mathbb{A}$ and $\mathbf{D}\,\mathbf{E}\,\mathbb{A}$, an assumption we shall thenceforth make.

▶ **Proposition 18.** *Let $\mathbb{A}$ be a homogenizable ρ-structure with no algebraicity. Then $\mathbb{A}$ and $\mathbf{D}\,\mathbf{E}\,\mathbb{A}$ are isomorphic. Moreover, for any θ-structure $\mathbb{D}$, the structure $\mathbf{D}\,\mathbb{D}$ has a pp-interpretation in $\mathbb{D}$.*

5.2 The relationship between $\mathbb{A}$ and $\mathbf{E}\,\mathbb{A}$

We derive the following main properties of the encoding $\mathbf{E}\,\mathbb{A}$ of a ρ-structure $\mathbb{A}$:

- $\mathbf{E}\,\mathbb{A}$ is ω-categorical if and only if $\mathbb{A}$ is, and has slow orbit growth if and only if $\mathbb{A}$ does (Proposition 19);
- There exists a uniformly continuous clone homomorphism ξ from $\mathrm{Pol}(\mathbf{E}\,\mathbb{A})$ into $\mathrm{Pol}(\mathbb{A})$; conversely, if $\mathbb{A}$ is ω-categorical, then injective polymorphisms of $\mathbb{A}$ essentially extend to polymorphisms of $\mathbf{E}\,\mathbb{A}$ (Proposition 20).

We start by investigating the relationship of the orbits of $\mathrm{Aut}(\mathbb{A})$ with those of $\mathrm{Aut}(\mathbf{E}\,\mathbb{A})$, showing that ω-categoricity and slow orbit growth are preserved by the encoding.

▶ **Proposition 19.** *Let $\mathbb{A}$ be a homogenizable ρ-structure with no algebraicity.*

1. *$\mathbb{A}$ is ω-categorical if and only if $\mathbf{E}\,\mathbb{A}$ is.*
2. *Let $\mathbb{A}$ be ω-categorical. For $n \geq 1$, write $f(n)$ and $g(n)$ for the number of orbits of n-tuples under the action of $\mathrm{Aut}(\mathbb{A})$ and $\mathrm{Aut}(\mathbf{E}\,\mathbb{A})$, respectively. Then $f(n) \leq g(n) \leq 2^{6|\Sigma|n^4} f(n)$ for all $n \geq 1$. In particular, $\mathbb{A}$ has slow orbit growth if and only if $\mathbf{E}\,\mathbb{A}$ does.*

We now turn to the polymorphism clones of $\mathbb{A}$ and $\mathbf{E}\,\mathbb{A}$. An immediate consequence of Proposition 18 is that polymorphisms of $\mathbf{E}\,\mathbb{A}$ can be restricted to polymorphisms of $\mathbb{A}$. Conversely, one can prove that assuming ω-categoricity of $\mathbb{A}$, for every injective $f \in \mathrm{Pol}(\mathbb{A})$ there exists an embedding u of $\mathbb{A}$ such that uf can be extended to a polymorphism of $\mathbf{E}\,\mathbb{A}$.

▶ **Proposition 20.** *Let $\mathbb{A}$ be a structure with no algebraicity, and let $\mathbb{B}$ be a homogeneous first-order expansion of $\mathbb{A}$. Then the following hold:*

(1) *For every $f \in \mathrm{Pol}(\mathbf{E}\,\mathbb{A})$, the restriction $f|_{P^{\mathbf{E}\,\mathbb{A}}}$ of f to $P^{\mathbf{E}\,\mathbb{A}}$ is a polymorphism of $\mathbb{A}$. The map $f \mapsto f|_{P^{\mathbf{E}\,\mathbb{A}}}$ is a uniformly continuous clone homomorphism $\mathrm{Pol}(\mathbf{E}\,\mathbb{A}) \to \mathrm{Pol}(\mathbb{A})$.*

(2) *If $\mathbb{A}$ is ω-categorical, then for every injective $f \in \mathrm{Pol}(\mathbb{A})$ there exists an embedding $u\colon \overrightarrow{\mathbf{B}}_{\mathbb{B}}\,\mathbb{A} \to \overrightarrow{\mathbf{B}}_{\mathbb{B}}\,\mathbb{A}$ such that uf extends to a polymorphism of $\mathbf{E}\,\mathbb{A}$.*

(3) *If $\mathbb{A}$ is ω-categorical, then for all $k \geq 1$, $\mathbb{B}^k$ embeds into $\mathbb{B}$ if and only if $(\overrightarrow{\mathbf{B}}_{\mathbb{B}}\,\mathbb{A})^k$ embeds into $\overrightarrow{\mathbf{B}}_{\mathbb{B}}\,\mathbb{A}$.*

Propositions 19 and 20 are the fundamental results upon which the following sections rely. They allow us to relate $\mathrm{Pol}(\mathbf{E}\,\mathbb{A})$ and $\mathrm{Pol}(\mathbb{A})$ and to transfer the exotic behaviour of the latter (for a well-chosen $\mathbb{A}$ with infinite signature) into the former.

5.3 Homomorphisms and the encoding

We now examine the relationship between the finite structures that homomorphically map into a structure $\mathbb{A}$ with those that homomorphically map into its encoding $\mathbf{E}\,\mathbb{A}$ (which is precisely $\mathrm{CSP}(\mathbf{E}\,\mathbb{A})$). This will be particularly relevant in Section 7 where we investigate the complexity of CSPs of structures encoded with our encoding.

▶ **Proposition 21.** *There exists a log-space computable function $\mathbb{C} \mapsto \mathbf{C}\,\mathbb{C}$ from the set of finite ρ-structures to the set of finite θ-structures satisfying the following properties:*

- *For every finite ρ-structure $\mathbb{C}$, we have $\mathbf{D}\,\mathbf{C}\,\mathbb{C} = \mathbb{C}$.*
- *If $\mathbb{C}$ is a finite ρ-structure, and $\mathbb{D}$ is a θ-structure, then there exists a homomorphism from $\mathbb{C}$ to $\mathbf{D}\,\mathbb{D}$ if and only if there exists a homomorphism from $\mathbf{C}\,\mathbb{C}$ to $\mathbb{D}$.*

The properties from Proposition 21 are enough to give a concrete description of $\mathrm{CSP}(\mathbf{E}\,\mathbb{A})$ when $\mathbb{A}$ is homomorphically bounded.

▶ **Proposition 22.** *Let $\mathbb{A}$ be a homogenizable ρ-structure with no algebraicity which is homomorphically bounded by a set $\mathcal{G}$ of finite ρ-structures. Let $\mathbb{X}$ be a θ-structure. Then the following are equivalent.*

(1) *There exists an embedding of $\mathbb{X}$ into $\mathbf{E}\,\mathbb{A}$;*
(2) *There exists a homomorphism from $\mathbb{X}$ to $\mathbf{E}\,\mathbb{A}$;*
(3) *$\mathbb{X}$ is separated and for all $\mathbb{G} \in \mathcal{G}$ there exists no homomorphism from $\mathbf{C}\,\mathbb{G}$ to $\mathbb{X}$.*

Note that being separated can be characterised by not containing the homomorphic image of any element of a finite set $\mathcal{S}$ of finite θ-structures. As an immediate consequence of Proposition 22 we therefore obtain the following corollary.

▶ **Corollary 23.** *Let $\mathbb{A}$ be a homogenizable ρ-structure with no algebraicity which is homomorphically bounded by a set $\mathcal{G}$ of finite ρ-structures. Then $\mathbf{E}\,\mathbb{A}$ is homomorphically bounded by $\{\mathbf{C}\,\mathbb{G} \mid \mathbb{G} \in \mathcal{G}\} \cup \mathcal{S}$.*

6 Height 1 identities: local without global

Recall that in [13] a negative answer to Question 2 of the introduction was established by an infinite-language example which is ω-categorical and has slow orbit growth. We are now going to prove that the encoding of that structure, or in fact, of a simplification $\mathbb{S}$ thereof, also provides an example. Since $\mathbf{E}\,\mathbb{S}$ is a CSP template, and since both ω-categoricity and slow orbit growth are preserved by the encoding, $\mathbf{E}\,\mathbb{S}$ is a witness for the truth of Theorem 3. While the non-satisfaction of non-trivial global h1 identities lifts from $\mathbb{S}$ to $\mathbf{E}\,\mathbb{S}$ by virtue of Proposition 20 (1), we do not know in general when this is the case for the local satisfaction of non-trivial h1 identities. Our proof thus relies on specific structural properties of $\mathbb{S}$; we show that both $\mathbb{S}$ and $\mathbf{E}\,\mathbb{S}$ locally satisfy *dissected weak near-unanimity identities.*

6.1 Dissected weak near-unanimity identities

▶ **Definition 24.** *Let $n > k > 1$, let $g_1, \ldots, g_n$ be binary function symbols, and for every injective function $\psi\colon \{1, \ldots, k\} \to \{1, \ldots, n\}$ let f_ψ be a k-ary function symbol. Then the set of (n, k)* dissected weak near-unanimity identities *consists of the identities*

$$f_\psi(x, \ldots, x, \overset{\overset{i}{\downarrow}}{y}, x, \ldots, x) = g_{\psi(i)}(x, y)$$

for all injective functions $\psi\colon \{1, \ldots, k\} \to \{1, \ldots, n\}$ and $i \in \{1, \ldots, k\}$.

Note that any polymorphism clone which satisfies identities of the form

$$f(y, x, \ldots, x) = \cdots = f(x, \ldots, x, y),$$

called *k-ary weak near-unanimity identities* when f is k-ary for some $k \geq 3$, must also satisfy the (n, k) dissected weak near-unanimity identities for all $n > k$. This can be seen by setting $f_\psi = f$ for every ψ. Moreover, there exist polymorphism clones which satisfy dissected weak near-unanimity identities, but do not satisfy any weak near-unanimity identities: one example is the polymorphism clone consisting of all injective functions (up to dummy variables) on a countable set, see [4]. Hence, we can regard dissected weak near-unanimity identities as a strict weakening of the weak near-unanimity identities.

Further note that, for all parameters $m \geq n > k > 1$, the (n,k) dissected weak near-unanimity identities form a subset of the (m,k) dissected weak near-unanimity identities. Thus for every fixed $k > 1$ the family of (n,k) dissected weak near-unanimity identities form an infinite chain of h1 identities of increasing strength. In the special case $k = 2$, the satisfaction of any of the $(n,2)$ dissected weak near-unanimity identities is equivalent to the existence of a binary commutative polymorphism (as they imply $g_1(x,y) = g_2(y,x) = g_3(x,y) = g_1(y,x)$).

▶ **Lemma 25.** *For all $n > k > 1$ the (n,k) dissected weak near-unanimity identities are non-trivial.*

Proof. Assume to the contrary that there exist projections $g_1, \ldots, g_n \in \mathscr{P}$ and $f_\psi \in \mathscr{P}$ for every injection $\psi\colon \{1,\ldots,k\} \to \{1,\ldots,n\}$ that satisfy the (n,k) dissected weak near-unanimity identities. First, suppose that there are two distinct $1 \leq i,j \leq k$ such that g_i, g_j are both the projection onto the second coordinate. Then let ψ be an injective function with $\psi(1) = i, \psi(2) = j$. It follows from the identities that $f_\psi(y,x,\ldots,x) = f_\psi(x,y,\ldots,x) = y$ holds for all values of the variables, which contradicts f_ψ being a projection. Therefore at most one operation g_i equals the projection to its second coordinate. Since $n > k$, there is an injective function $\psi\colon \{1,\ldots,k\} \to \{1,\ldots,n\}$ such that $g_{\psi(i)}$ is the first projection for all $i \in \{1,\ldots,k\}$. Then f_ψ satisfies the weak near-unanimity identities, which again contradicts f_ψ being a projection. ◀

▶ **Lemma 26.** *Let $\mathbb{U}$ be a relational structure and let $n \geq 2$. Then there exists an embedding from $\mathbb{U}^2$ into $\mathbb{U}$ if and only if there exists an embedding from $\mathbb{U}^n$ into $\mathbb{U}$.*

Proof. If there is an embedding $f\colon \mathbb{U}^n \to \mathbb{U}$ for some $n \geq 2$, then $g\colon \mathbb{U}^2 \to \mathbb{U}$, defined by $g(x,y) := f(x,y,\ldots,y)$, is also an embedding. On the other hand, if for some $n \geq 2$ there exist embeddings $g\colon \mathbb{U}^2 \to \mathbb{U}$ and $h\colon \mathbb{U}^n \to \mathbb{U}$, then the composition $f(x_1,\ldots,x_{n+1}) := g(h(x_1,\ldots,x_n),x_{n+1})$ is an embedding from $\mathbb{U}^{n+1}$ into $\mathbb{U}$. Hence by induction the existence of an embedding from $\mathbb{U}^2$ into $\mathbb{U}$ implies the existence of an embedding from $\mathbb{U}^n$ into $\mathbb{U}$ for all $n \geq 2$. ◀

Proof of Theorem 5. For all $l \geq 2$, define $X_l \subseteq F^l$ by

$$X_l := \bigcup_{a,b \in F} \{(a,\ldots,a,b),(a,\ldots,a,b,a),\ldots,(b,a,\ldots,a)\},$$

and let $\mathbb{X}_l$ be the substructure which X_l induces in $\mathbb{U}^l$.

The first step of our proof is to show that if $n \geq k$, then there exists an embedding $h\colon \mathbb{X}_k \to \mathbb{X}_n$ such that $\mathbf{x}$ is an initial segment of $h(\mathbf{x})$ for all $\mathbf{x} \in X_k$. Let us first assume that $k \geq 3$. For every tuple $\mathbf{x} \in \mathbb{X}_k$ we denote the unique element of F which occurs more than once among its entries by $s(\mathbf{x})$. Define $h\colon X_k \to X_n$ to be the map that extends the tuple $\mathbf{x}$ by $n-k$ many entries with value $s(\mathbf{x})$. In order to prove that h is an embedding let $\mathbf{x}_1,\ldots,\mathbf{x}_m \in X_k$ be such that $R^{\mathbb{U}^k}(\mathbf{x}_1,\ldots,\mathbf{x}_m)$ holds for some m-ary relation symbol R in the signature of $\mathbb{U}$. By assumption (i) we have $m < k$. Thus there exists $1 \leq j \leq k$ such that the projection of each $\mathbf{x}_i$ to its j-th coordinate equals $s(\mathbf{x}_i)$. Therefore $(s(\mathbf{x}_1),\ldots,s(\mathbf{x}_m)) \in R^{\mathbb{U}}$, and hence h is a homomorphism. Also its inverse – the projection of n-tuples to the first k-coordinates – is a homomorphism, and thus h is an embedding. Now assume the remaining case where $k = 2$. Define a map $h\colon X_2 \to X_n$ by $(x_1, x_2) \mapsto (x_1, x_2, \dots, x_2)$. To check that that h is an embedding, by assumption (i), we only need to check that h is an embedding with respect to unary relations, which however follows from its definition.

Observe that h was defined in such a way that, for each index $1 \le i \le k$, the i-th projection of $h(\mathbf{x})$ is equal to x_i. By permuting the coordinates of its image in a suitable manner, we can obtain embeddings $h_\psi\colon \mathbb{X}_k \to \mathbb{X}_n$ for every injection $\psi\colon \{1, \dots, k\} \to \{1, \dots, n\}$ such that the $\psi(i)$-th projection of $h_\psi(\mathbf{x})$ is equal to x_i for all $1 \le i \le k$.

In order to construct the operations f_ψ on F, let $f\colon \mathbb{U}^k \to \mathbb{U}$ and $g\colon \mathbb{U}^n \to \mathbb{U}$ be embeddings, which exist by (ii) and Lemma 26. For every injection $\psi : \{1, \dots, k\} \to \{1, \dots, n\}$ define the map $u_\psi\colon f(\mathbb{X}_k) \to g(\mathbb{X}_n)$ by

$$u_\psi(f(a, \dots, a, \underset{i^{\text{th}}}{b}, a, \dots, a)) := g(a, \dots, a, \underset{\psi(i)^{\text{th}}}{b}, a, \dots, a). \tag{1}$$

Then u_ψ is equal to $g \circ h_\psi \circ f^{-1}$. Since h_ψ is an embedding, $u_\psi\colon f(\mathbb{X}_k) \to u_\psi(f(\mathbb{X}_k))$ is an isomorphism between finite substructures of $\mathbb{U}$. By the homogeneity of $\mathbb{U}$, it can be extended to an automorphism v_ψ of $\mathbb{U}$. Set $f_\psi := v_\psi \circ f$ and, for all $1 \le i \le n$, define $g_i(x, y) := g(x, \dots, x, y, x, \dots, x)$, where the only y appears at the i-th coordinate of g. It then follows from (1) that these polymorphisms satisfy the (n, k) dissected weak near-unanimity identities on F, concluding the proof. ◀

6.2 Revisiting the infinite-language counterexample

We now investigate the simplification $\mathbb{S}$ of the infinite-language structure from [13]; $\mathbb{S}$ satisfies the same local and global h1 identities as the structure in [13]. Namely, we consider the superposition as in [13, Construction 6.4], but directly of the CSS structures in the proof of [13, Lemma 6.3] rather than of their model-complete cores; we are able to do this due to our constructive, rather than indirect, proof of the local satisfaction of h1 identities. The structure $\mathbb{S}$ has the following properties.

▶ **Proposition 27** (Consequence of the results from [13]). *There exist ω-categorical structures $\mathbb{S}$ and $\mathbb{H}$ with slow orbit growth and without algebraicity, as well as a strictly increasing function $\alpha\colon \mathbb{N} \to \mathbb{N}$ such that the following hold:*

(1) *$\mathbb{H}$ is a homogeneous expansion of $\mathbb{S}$ by pp-definable relations.*

(2) *Every relation of $\mathbb{H}$ has arity $k \cdot \alpha(n)$ for some $k, n \ge 1$, and for every $n \ge 1$ there exist only finitely many relations of arity of the form $k \cdot \alpha(n)$. Moreover, if $(a_1, \dots, a_{k\cdot\alpha(n)}) \in R$ for some relation R of $\mathbb{H}$, then $\{a_1, \dots, a_{k\cdot\alpha(n)}\}$ has size at least $\alpha(n)$.*

(3) *$\mathbb{H}$ is homomorphically bounded.*

(4) *There exists a minion homomorphism from $\mathrm{Pol}(\mathbb{S})$ to $\mathscr{P}$.*

Proof of Theorem 3. Let $\mathbb{S}, \mathbb{H}$ be as in Proposition 27. We can assume that $\mathbb{S}$ has signature ρ as in Section 5 since this change does not affect the properties claimed in Proposition 27; see the remark at the beginning of Section 5.1. Since $\mathbb{S}$ has no algebraicity, it has an ω-categorical finite-language encoding $\mathbb{U} = \mathbf{E}\,\mathbb{S}$. Moreover, since $\mathbb{S}$ has slow orbit growth, so does $\mathbb{U}$ by Proposition 19. There is a minion homomorphism $\mathrm{Pol}(\mathbb{U}) \to \mathrm{Pol}(\mathbb{S})$ by Proposition 20 (1) and a minion homomorphism $\mathrm{Pol}(\mathbb{S}) \to \mathscr{P}$ by Proposition 27, thus we obtain a minion homomorphism $\mathrm{Pol}(\mathbb{U}) \to \mathscr{P}$ by composition.

It remains to prove that there is no uniformly continuous minion homomorphism from $\mathrm{Pol}(\mathbb{U})$ to $\mathscr{P}$. We do so by showing that for every finite subset F of the domain, there exists $k > 1$ such that $\mathrm{Pol}(\mathbb{U})$ satisfies the (n, k) dissected weak near-unanimity identities on F for all

$n > k$. Note that $\mathbb{U} = \mathbf{E}\,\mathbb{S}$ is a reduct of the blowup $\overrightarrow{\mathbf{B}}_{\mathbb{H}}\,\mathbb{S}$, and hence $\mathrm{Pol}(\overrightarrow{\mathbf{B}}_{\mathbb{H}}\,\mathbb{S}) \subseteq \mathrm{Pol}(\mathbf{E}\,\mathbb{S})$. It is therefore sufficient to prove that there exists some $k > 1$ for which $\overrightarrow{\mathbf{B}}_{\mathbb{H}}\,\mathbb{S}$ satisfies the (n,k) dissected weak near-unanimity identities on F for all $n > k$.

In order to prove this statement, we verify that conditions (i) and (ii) of Theorem 5 hold for $\overrightarrow{\mathbf{B}}_{\mathbb{H}}\,\mathbb{S}$, F, and a suitable $k > 1$. Since $\mathbb{H}$ is homomorphically bounded, it is well-known that $\mathbb{H}^2$ embeds into $\mathbb{H}$. By Proposition 20 (3), there exists an embedding of $(\overrightarrow{\mathbf{B}}_{\mathbb{H}}\,\mathbb{S})^2$ into $\overrightarrow{\mathbf{B}}_{\mathbb{H}}\,\mathbb{S}$, and thus condition (ii) holds.

It remains to check (i) which states that there exists an upper bound on the arity of tuples in F that satisfy some relation from $\overrightarrow{\mathbf{B}}_{\mathbb{H}}\,\mathbb{S}$. Denote the signature of $\mathbb{H}$ by σ. Suppose that $R^{\overrightarrow{\mathbf{B}}_{\mathbb{H}}\,\mathbb{S}}$ contains a tuple entirely within F for some $R \in \sigma^+$, the language of $\overrightarrow{\mathbf{B}}_{\mathbb{H}}\,\mathbb{S}$. Since $\sigma^+ = \sigma \cup \theta$, and all relations in θ have arity at most 4, we may assume that $R \in \sigma$. Then any tuple in $R^{\overrightarrow{\mathbf{B}}_{\mathbb{H}}\,\mathbb{S}}$ must lie entirely within $P^{\overrightarrow{\mathbf{B}}_{\mathbb{H}}\,\mathbb{S}}$, and essentially the proof of Proposition 18 shows that this implies that the tuple is an element of $R^{\mathbb{H}}$.

By Proposition 27 (2), R has arity $k \cdot \alpha(n)$ for some $n, k \geq 1$ and at least $\alpha(n)$ many of the values of any tuple in $R^{\mathbb{H}}$ are distinct. Therefore, $\alpha(n)$ must be smaller than $|F|$. Since α is a strictly increasing function, it follows that only finitely many relations of $R^{\overrightarrow{\mathbf{B}}_{\mathbb{H}}\,\mathbb{S}}$ have tuples that lie entirely in F. Let $k > 1$ be a strict upper bound on the arity of those relations. For this choice of k we have that (i) of Theorem 5 holds, and thus $R^{\overrightarrow{\mathbf{B}}_{\mathbb{H}}\,\mathbb{S}}$ satisfies the (n,k) dissected weak near-unanimity identities on F for all $n > k$. ◀

▶ Remark 28. It follows that the original structure $\mathbb{S}$ satisfies dissected weak near-unanimity identities locally as well, since by Proposition 20 (1), there is a uniformly continuous minion homomorphism from $\mathrm{Pol}(\mathbf{E}\,\mathbb{S})$ to $\mathrm{Pol}(\mathbb{S})$. This result is new and no other explicit description of non-trivial local h1 identities of $\mathbb{S}$ was given in [13].

7 Identities and CSPs with Homogeneous Templates

7.1 Encoding arbitrary languages as CSPs

Let Σ be a finite alphabet and $W \subseteq \Sigma^{\geq 2}$. Let ρ_W be the signature consisting of one $|w|$-ary relation symbol R_w for every word $w \in W$. The *trivial structure* $\mathbb{T}_W$ is the countable ρ_W-structure whose relations are all empty. For every word $w \in W$, the *w-edge structure* $\mathbb{F}_w$ is the ρ_W-structure on the set $F_w = \{1, \ldots, |w|\}$ whose only non-empty relation is $R_w^{\mathbb{F}_w} = \{(1, \ldots, |w|)\}$.

The trivial structure $\mathbb{T}_W$ is homomorphically bounded by the set of all edge-structures $\mathbb{F}_w$ with $w \in W$. Moreover, $\mathbb{T}_W$ has no algebraicity. It is not hard to see that $\mathbf{E}\,\mathbb{T}_W$ is homogeneous. Applying Theorem 5 and a compactness argument, one can see that $\mathbf{E}\,\mathbb{T}_W$ satisfies non-trivial h1 identities.

Since $\mathbb{T}_W$ is homomorphically bounded, Corollary 23 can be used to give an explicit description of $\mathrm{CSP}(\mathbf{E}\,\mathbb{T}_W)$, which we use to prove the results of this section. We employ the notion of coNP-many-one reduction first defined in [8]: a language K coNP-many-one reduces to L if there is a non-deterministic polynomial-time Turing machine M such that for all words w, we have $w \in K$ if and only if each computational path of M, on input w, produces a word in L. Note that if K has a coNP-many-one reduction to L, then in particular K is in coNP^L.

▶ **Proposition 29.** *Let $L \subseteq \Sigma^{\geq 2}$ and $W := \Sigma^{\geq 2} \setminus L$ both be nonempty. Then L has a log-space many-one reduction to $\mathrm{CSP}(\mathbf{E}\,\mathbb{T}_W)$, and $\mathrm{CSP}(\mathbf{E}\,\mathbb{T}_W)$ coNP-many-one reduces to L.*

Proof. The function $w \mapsto \mathbf{C}\,\mathbb{F}_w$, for every $w \in \Sigma^{\geq 2}$, is computable in logarithmic space with respect to $|w|$ by Proposition 21. Also note that there is a homomorphism $\mathbf{C}\,\mathbb{F}_u \to \mathbf{C}\,\mathbb{F}_w$ if and only if $w = u$. Moreover, it follows from Proposition 22 that there is a homomorphism $\mathbf{C}\,\mathbb{F}_w \to \mathbf{E}\,\mathbb{T}_W$ if and only if $w \in L$. Thus L has a log-space many-one reduction to $\mathrm{CSP}(\mathbb{T}_W)$.

For the other reduction, let $\mathbb{X}$ be a finite θ-structure, an instance of $\mathrm{CSP}(\mathbf{E}\,\mathbb{T}_W)$. If there is no homomorphism $\mathbb{X} \to \mathbf{E}\,\mathbb{T}_W$, by Proposition 22, either $\mathbb{X}$ is not separated (which can be checked in polynomial time), or there is a word $w \in W$ not longer than the size of the domain of $\mathbb{X}$ and a homomorphism $f\colon\, \mathbf{C}\,\mathbb{F}_w \to \mathbb{X}$. The reduction does the following: if $\mathbb{X}$ is not separated, we map it to a fixed element of W. Otherwise, we guess a word w not longer than the size of the domain of $\mathbb{X}$ and a function $f\colon\, \mathbf{C}\,\mathbb{F}_w \to \mathbb{X}$. If this function is not a homomorphism, we map $\mathbb{X}$ to a fixed word of L. If f is a homomorphism, we map $\mathbb{X}$ to w. Thus, if $\mathbb{X} \in \mathrm{CSP}(\mathbf{E}\,\mathbb{T}_W)$ then all runs of the reduction output a word of L. Moreover, if $\mathbb{X} \notin \mathrm{CSP}(\mathbf{E}\,\mathbb{T}_W)$, then at least one run outputs word in W. ◀

We can now prove the first statement of Theorem 8.

Proof of the first statement of Theorem 8. Let $L \subseteq \Sigma^{\geq 2}$ be a $\mathrm{coNP}^{\mathcal{C}}$-complete language, and let W be its complement. Then L reduces to $\mathrm{CSP}(\mathbf{E}\,\mathbb{T}_W)$ by Proposition 29, so $\mathrm{CSP}(\mathbf{E}\,\mathbb{T}_W)$ is $\mathrm{coNP}^{\mathcal{C}}$-hard. Moreover, it follows from Proposition 29 and the fact that $\mathrm{coNP}^{\mathcal{C}}$ is closed under coNP-many-one reductions that $\mathrm{CSP}(\mathbf{E}\,\mathbb{T}_W)$ belongs to $\mathrm{coNP}^{\mathcal{C}}$. ◀

The second statement of Theorem 8 follows from the following proposition whose proof is inspired by Ladner's proof on the existence of NP-intermediate problems [25].

▶ **Proposition 30.** *Let $L \subseteq \{0,1\}^{\geq 2}$ be a language in coNP $\setminus$ P. Then there is a unary language $I \subseteq \{0\}^{\geq 2}$ such that* $\mathrm{CSP}(\mathbf{E}\,\mathbb{T}_I)$ *is also in coNP $\setminus$ P, but L is not polynomial-time reducible to* $\mathrm{CSP}(\mathbf{E}\,\mathbb{T}_I)$.

Finally, we are ready to prove Theorem 7. In the following, let $\mathcal{L}$ be the extension of existential second-order logic allowing countably many second-order quantifiers, followed by a countable conjunction of first-order formulas. It can be seen that the upward direction of Łoś's theorem and the downward Löwenheim-Skolem theorem hold for this logic.

Proof of Theorem 7. We prove the following: there is no countable set Θ of θ-formulas in $\mathcal{L}$ such that the equivalence $\mathbb{A} \models \Theta \Leftrightarrow \mathrm{CSP}(\mathbb{A}) \in \mathcal{C}$ holds for all homogeneous θ-structures $\mathbb{A}$. This proves the theorem, as the satisfaction of a countable set of identities by polymorphisms can be expressed in $\mathcal{L}$.

Assume that such a Θ exists. Let L be a language over Σ whose Turing-degree is not intersected by $\mathcal{C}$, and let $W = \Sigma^{\geq 2} \setminus L$. For every $n \in \mathbb{N}$, let $W \cap \Sigma^{\leq n}$ be the set of words of length at most n in W. Corollary 23 implies that $\mathrm{CSP}(\mathbf{E}\,\mathbb{T}_{W\cap\Sigma^{\leq n}})$ is finitely bounded, hence $\mathrm{CSP}(\mathbf{E}\,\mathbb{T}_{W\cap\Sigma^{\leq n}})$ is in AC^0. Therefore, since $\mathbf{E}\,\mathbb{T}_{W\cap\Sigma^{\leq n}}$ is homogeneous, our assumption implies that $\mathbf{E}\,\mathbb{T}_{W\cap\Sigma^{\leq n}} \models \Theta$. Let $\mathcal{U}$ be a non-principal ultrafilter on $\mathbb{N}$, and let $\mathbb{X}$ be the ultraproduct $\big(\prod_{n\in\mathbb{N}} \mathbf{E}\,\mathbb{T}_{W\cap\Sigma^{\leq n}}\big)/\mathcal{U}$. Then $\mathbb{X} \models \Theta$ by Łoś's theorem and $\mathbb{X}$ is homogeneous, as all the factors in the ultraproduct are homogeneous. By the Löwenheim-Skolem theorem, $\mathbb{X}$ has a countable elementary substructure $\mathbb{Y}$ that also satisfies Θ. Note that $\mathbb{Y}$ is homogeneous and has the same age as $\mathbb{X}$, as it is an elementary substructure of $\mathbb{X}$.

Finally, we claim that $\mathbb{X}$ and $\mathbf{E}\,\mathbb{T}_W$ have the same age. Every finite substructure of $\mathbf{E}\,\mathbb{T}_W$ embeds into $\mathbf{E}\,\mathbb{T}_{W\cap\Sigma^{\leq n}}$ for all $n \in \mathbb{N}$, by Corollary 23, and therefore into their ultraproduct, which is $\mathbb{X}$. Conversely, assume that a finite structure $\mathbb{C}$ embeds into $\mathbb{X}$. This precisely means that $I := \{n \in \mathbb{N} \mid \mathbb{C} \text{ embeds into } \mathbf{E}\,\mathbb{T}_{W\cap\Sigma^{\leq n}}\}$ is in $\mathcal{U}$. Moreover, since $\mathcal{U}$ is not principal, I is infinite. Let $w \in W$. Since I is infinite there is an $n \geq |w|$ such that $\mathbb{C}$ embeds into

$\mathbf{E}\,\mathbb{T}_{W\cap\Sigma^{\leq n}}$. Since $w \in W \cap \Sigma^{\leq n}$, Corollary 23 gives that $\mathbf{C}\,\mathbb{F}_w$ does not homomorphically map to $\mathbb{C}$, and that $\mathbb{C}$ is separated. Since this holds for all $w \in W$, it follows that $\mathbb{C}$ embeds into $\mathbf{E}\,\mathbb{T}_W$.

By Theorem 9, the two structures $\mathbb{Y}$ and $\mathbf{E}\,\mathbb{T}_W$ are isomorphic. By Proposition 29, L and CSP($\mathbf{E}\,\mathbb{T}_W$) have the same Turing-degree, therefore CSP($\mathbf{E}\,\mathbb{T}_W$) is not in $\mathcal{C}$, a contradiction. ◀

Descriptive Complexity on Non-Polish Spaces II

Mathieu Hoyrup
Université de Lorraine, CNRS, Inria, LORIA, Nancy, France
mathieu.hoyrup@inria.fr

Abstract

This article is a study of descriptive complexity of subsets of represented spaces. Two competing measures of descriptive complexity are available. The first one is topological and measures how complex it is to obtain a set from open sets using boolean operations. The second one measures how complex it is to test membership in the set, and we call it symbolic complexity because it measures the complexity of the symbolic representation of the set. While topological and symbolic complexity are equivalent on countably-based spaces, they differ on more general spaces. Our investigation is aimed at explaining this difference and highly suggests that it is related to the well-known mismatch between topological and sequential aspects of topological spaces.

1 Introduction

This article fits in the line of research extending descriptive set theory, mainly developed on Polish spaces, to other classes of topological spaces relevant to theoretical computer science, such as domains [21], quasi-Polish spaces [2], and represented spaces [13, 4, 1]. We pursue our investigation of descriptive set theory on represented spaces, started in [1].

Theoretical computer science, logic and descriptive set theory closely interact, providing different ways of describing properties, by programs, formulas or boolean operation from basic properties, all intimately related. For instance, a property of real numbers that is decidable in the limit must belong to the class $\undertilde{\mathbf{\Delta}}^0_2$, and every $\undertilde{\mathbf{\Delta}}^0_2$-property is decidable in the limit relative to some oracle.

This correspondence works very well on Polish spaces and more generally countably-based topological spaces. However, little is known for other topological spaces whose points can be represented and processed by a program, and it has been shown in [1] that the correspondence fails, even on natural spaces such as the space of polynomials with real coefficients: there is a property which can be decided with 2 mind-changes, but which is not a difference of two open sets, and is in no level below $\undertilde{\mathbf{\Delta}}^0_2$.

We introduce *symbolic* descriptive complexity, which captures the algorithmic complexity of a set, and compare it to topological descriptive complexity. Our general goal is to understand when and why these two measures of complexity differ, and what topological properties of the underlying space cause this disagreement. Our results suggest that the mismatch between the two measures of complexity reflects the discordance between the sequential and the topological aspects of the space, so that symbolic complexity may be

interpreted as a measure of *sequential* complexity rather than topological complexity, in the same way as many topological notions have a sequential counterpart (sequential continuity, sequential compactness, sequential closure, etc.).

More precisely, we show that among Hausdorff spaces, the spaces that are not Fréchet-Urysohn exhibit a disagreement between symbolic and topological complexity at the lowest level above the open sets, namely the differences of open sets. This result extends a similar result obtained in [1] for the subclass of coPolish spaces.

We focus on the space of open sets of a Polish space, and relate the disagreement between symbolic and topological complexity to the compactness properties of the Polish space, by dividing Polish spaces into 4 classes, ranging from the locally compact to the non σ-compact spaces, and giving a detailed analysis of descriptive complexity of sets in each case.

Along the way, we develop several tools and techniques that are needed to prove our results and are interesting on their own right. In particular we argue that the classical notion of hardness, which makes sense on countably-based spaces, is too restrictive on other spaces and we solve the problem by introducing the weaker notion of hard* set.

We finally observe that the discordance between topological and sequential aspects is already at the core of the theory of admissibly represented topological spaces. These spaces, also characterized as the T_0 quotients of countably-based spaces, are all sequential and form a subclass of topological spaces which behave particularly well from a categorical perspective: for instance, contrary to general topological spaces, they form a cartesian closed category. More concretely, in this category, the space constructions such as product space or subspaces do not coincide with the ones in the category of topological spaces, but with their sequentializations. Our separation results between symbolic and topological complexity heavily rely on the disagreement between sequential and topological space constructions.

1.1 Summary of the main results

We give a quick overview of the main results, stated informally.

In a represented space $\mathbf{X} = (X, \delta_{\mathbf{X}})$, we introduce the *symbolic* complexity of a set $A \subseteq X$. If Γ is a descriptive complexity class, such as $\undertilde{\mathbf{\Sigma}}^0_n$ or $\undertilde{\mathbf{D}}_n$ (difference of n open sets), then we define the corresponding symbolic complexity class $[\Gamma]$ as follows:

$$A \in [\Gamma](\mathbf{X}) \iff \delta_{\mathbf{X}}^{-1}(A) \in \Gamma(\mathrm{dom}(\delta_{\mathbf{X}})).$$

In a topological space with an admissible representation, one usually has $\Gamma(\mathbf{X}) \subseteq [\Gamma](\mathbf{X})$ and our goal is to understand when and why the other inclusion does not hold, i.e. when and why the topological and symbolic measures of complexity differ. It is know from [2] that they coincide when $\mathbf{X}$ is a countably-based space.

We first observe that the classical notion of hardness, which is very useful to identify the complexity of a set, is closely related to symbolic rather than topological complexity. We introduce a weaker version, called hard* set and prove:

▶ **Theorem** (Theorem 3.2)**.** *For a Borel subset A of an analytic space $\mathbf{X}$,*

$$\begin{aligned} A \textit{ is } \Gamma\textit{-hard} &\iff A \notin [\check{\Gamma}](\mathbf{X}), \\ A \textit{ is } \Gamma\textit{-hard*} &\iff A \notin \check{\Gamma}(\mathbf{X}). \end{aligned}$$

A topological subspace of a sequential space is not always sequential, so the subspace constructions differ in the categories of topological and sequential spaces. This difference implies a difference between symbolic and topological complexity.

The sequential spaces whose subspaces are sequential are called the Fréchet-Urysohn spaces. The class $\underset{\sim}{\mathbf{D}}_2$ consists of differences of two open sets.

▶ **Theorem** (Theorem 4.1). *If $\mathbf{X}$ is admissibly represented, Hausdorff and not Fréchet-Urysohn, then*

$$[\underset{\sim}{\mathbf{D}}_2](\mathbf{X}) \not\subseteq \underset{\sim}{\mathbf{D}}_2(\mathbf{X}).$$

The assumption that the space is Hausdorff is needed. Indeed, spaces of open sets behave better at low complexity levels.

▶ **Theorem** (Theorem 5.1). *If $\mathbf{X}$ is admissibly represented then*

$$[\underset{\sim}{\mathbf{D}}_n](\mathcal{O}(\mathbf{X})) = \underset{\sim}{\mathbf{D}}_n(\mathcal{O}(\mathbf{X})).$$

However, the proof is not constructive and we show that the corresponding effective classes disagree. The class D_2 consists of differences of two *effective* open sets. Let $\mathcal{N}_1$ be the space of functions $\mathbb{N} \to \mathbb{N}$ having at most 1 non-zero value.

▶ **Theorem** (Theorem 5.3). *One has $[\mathrm{D}_2](\mathcal{O}(\mathcal{N}_1)) \not\subseteq \mathrm{D}_2(\mathcal{O}(\mathcal{N}_1))$.*

Finally, we give a rather detailed study of descriptive complexity on the spaces $\mathcal{O}(\mathbf{X})$ when $\mathbf{X}$ is Polish. More precisely, we connect the relationship between symbolic and topological complexity classes to the compactness properties of $\mathbf{X}$. Some of the proofs heavily rely on the fact that the product topology is not sequential in general, so product space constructions differ in the categories of topological and sequential spaces.

In particular, symbolic and topological complexity differ at higher levels when $\mathbf{X}$ is Polish and not locally compact.

▶ **Theorem** (Theorem 6.5).

- *There exists $A \in [\underset{\sim}{\mathbf{D}}_\omega](\mathcal{O}(\mathcal{N}_1))$ which is $\underset{\sim}{\mathbf{\Delta}}^0_3$-complete*.*
- *There exists $A \in [\underset{\sim}{\mathbf{\Sigma}}^0_k](\mathcal{O}(\mathbb{N} \times \mathcal{N}_1))$ which is $\underset{\sim}{\mathbf{\Sigma}}^0_{k+1}$-complete*, for each $k \geq 2$.*
- *There exists $A \in [\underset{\sim}{\mathbf{\Sigma}}^0_2](\mathcal{O}(\mathcal{N}))$ which is not Borel.*

The paper is organized as follows. In Section 2, after giving the needed background on represented spaces, we introduce symbolic complexity and provide simple tools for its study. In Section 3 we introduce and study the notion of hard* set, used to capture the topological complexity of sets. In Section 4 we prove that Hausdorff spaces that are not Fréchet-Urysohn exhibit a disagreement between symbolic and topological complexity at the lowest level. In Section 5, we study spaces of open sets. In particular, in Section 6 we focus on open subsets of Polish spaces and locate symbolic complexity classes depending on the compactness properties of the Polish space.

We sometimes include the proof in the body of the article, and sometimes only give the intuition. Complete proofs can be found in [9].

2 Symbolic complexity

2.1 Represented spaces

The Baire space is $\mathcal{N} = \mathbb{N}^{\mathbb{N}}$, whose elements are either viewed as functions or infinite sequences. To finite sequence of natural numbers $\sigma \in \mathbb{N}^*$, we associate the cylinder $[\sigma]$ which is the set of elements of $\mathcal{N}$ extending σ. The Baire space is then endowed with the topology generated by the cylinders. Every subset of $\mathcal{N}$ is endowed with the subspace topology.

A **represented space** is a pair $\mathbf{X} = (X, \delta_{\mathbf{X}})$ where X is a set and $\delta_{\mathbf{X}} :\subseteq \mathcal{N} \to X$ is a partial surjective function called a **representation**. If $\delta_{\mathbf{X}}(p) = x$, then p is a **name** of x. If $\mathbf{X}, \mathbf{Y}$ are represented spaces then a function $F :\subseteq \mathcal{N} \to \mathcal{N}$ is a **realizer** of $f : \mathbf{X} \to \mathbf{Y}$ if $f \circ \delta_{\mathbf{X}} = \delta_{\mathbf{Y}} \circ F$. f is **computable** if it has a computable realizer. We write $\mathbf{X} \cong \mathbf{Y}$ if there exists a bijection between $\mathbf{X}$ and $\mathbf{Y}$ which is computable in both directions.

A representation δ of a topological space (X, τ) is **admissible** if τ is the final topology of δ and every partial continuous function $f :\subseteq \mathcal{N} \to X$ has a continuous realizer, which is a continuous function $F :\subseteq \mathcal{N} \to \mathcal{N}$ satisfying $f = \delta \circ F$.

If $\mathbf{X}, \mathbf{Y}$ are admissibly represented spaces, then a function $f : \mathbf{X} \to \mathbf{Y}$ is continuous if and only if it has a continuous realizer. In particular, f is continuous if and only if it is computable relative to some oracle.

The topological spaces having an admissible representation are exactly the T_0-spaces that are quotients of countably-based spaces, and are also called QCB_0-spaces. These spaces form a cartesian closed category, with very natural representations for products and function spaces. They enjoy the following remarkable but overlooked properties, as proved by Schröder [16]: if X is a QCB_0-space, then

- X is sequential, separable and has a countable network, i.e. a countable family of subsets such that every open set is a union of them,
- X is first-countable if and only if X is countably-based,
- X is hereditarily Lindelöf,
- When identifying the space of open sets $\mathcal{O}(X)$ with the function space $\mathbb{S}^X$ where $\mathbb{S}$ is the Sierpinski space, the topology on $\mathcal{O}(X)$ is the Scott topology.

As far as topology is concerned, admissibly represented spaces and QCB_0-spaces are the same. However, computability can only be expressed in terms of representations, so we will refer to admissibly represented spaces rather than QCB_0-spaces.

Countably-based T_0-spaces have a particular representation, called standard representation, which is admissible. Once a countable basis indexed by $\mathbb{N}$ has been chosen, say $(B_i)_{i\in\mathbb{N}}$, a name of x is any sequence $p \in \mathcal{N}$ such that $\{i \in \mathbb{N} : \exists n, p(n) = i + 1\} = \{i \in \mathbb{N} : x \in B_i\}$, so that x is described by enumerating its basic neighbourhoods in any order.

2.2 Symbolic complexity

Let Γ be a descriptive complexity class, i.e. a family $\Gamma = \{\Gamma(X)\}$ where X ranges over topological spaces and $\Gamma(X)$ is a collection of subsets of X. The simplest class is $\boldsymbol{\Sigma}^0_1 = \{\boldsymbol{\Sigma}^0_1(X)\}$ where $\boldsymbol{\Sigma}^0_1(X)$ is the collection of open subsets of X. The class $\boldsymbol{\Sigma}^0_n$ is inductively defined as the class of countable unions of differences of $\boldsymbol{\Sigma}^0_{n-1}$-sets. The class $\mathbf{D}_n$ is inductively defined as follows: $\mathbf{D}_1 = \boldsymbol{\Sigma}^0_1$ and $\mathbf{D}_{n+1}$ consists of sets $U \setminus A$ where $U \in \boldsymbol{\Sigma}^0_1$ and $A \in \mathbf{D}_n$. For any class Γ, the class $\check{\Gamma}$ consists of the complements of sets in Γ.

Let $\mathbf{X} = (X, \delta_{\mathbf{X}})$ be a represented space, which is also a topological space by taking the final topology of $\delta_{\mathbf{X}}$: $U \subseteq \mathbf{X}$ is open iff $\delta_{\mathbf{X}}^{-1}(U)$ is open in $\mathrm{dom}(\delta_{\mathbf{X}})$.

▶ **Definition 2.1.** *Let $\mathbf{X} = (X, \delta_{\mathbf{X}})$ be a represented space. We define the **symbolic** complexity class $[\Gamma](\mathbf{X})$ as follows: for $A \subseteq X$,*

$$A \in [\Gamma](\mathbf{X}) \iff \delta_{\mathbf{X}}^{-1}(A) \in \Gamma(\mathrm{dom}(\delta_{\mathbf{X}})).$$

By definition of the final topology of $\delta_{\mathbf{X}}$, one always has $[\boldsymbol{\Sigma}^0_1](\mathbf{X}) = \boldsymbol{\Sigma}^0_1(\mathbf{X})$. A descriptive complexity class Γ is often closed under continuous preimages, and in that case one has $\Gamma(\mathbf{X}) \subseteq [\Gamma](\mathbf{X})$ because $\delta_{\mathbf{X}}$ is continuous. Moreover, for such classes Γ, it is not hard to see that the symbolic complexity class $[\Gamma]$ does not depend on the choice of the admissible representation, hence $\Gamma(\mathbf{X})$ is intrinsic to X as a topological space. However, effective complexity classes are sensitive to the choice of an admissible representation (but not to the choice of a computably admissible one, which we do not discuss here).

Our general goal is to understand symbolic complexity classes, relate them to topological complexity classes and understand for which $\mathbf{X}$ and which Γ we have $[\Gamma](\mathbf{X}) = \Gamma(\mathbf{X})$.

An important result due to de Brecht [2] is that symbolic and topological complexity coincide when $\mathbf{X}$ is a countably-based T_0-space with its standard representation.

▶ **Theorem 2.2** ([2])**.** *Let $\mathbf{X}$ be a countably-based T_0-space with its standard representation, and let $\alpha, \beta < \omega_1$. One has*

$$[\underset{\sim}{\mathbf{D}}_\alpha(\underset{\sim}{\mathbf{\Sigma}}^0_\beta)](\mathbf{X}) = \underset{\sim}{\mathbf{D}}_\alpha(\underset{\sim}{\mathbf{\Sigma}}^0_\beta)(\mathbf{X}).$$

It was improved in [1] by observing that the equality is uniform and effective, so it also holds for the effective complexity classes $\mathrm{D}_m(\Sigma^0_n)$, $m, n \in \mathbb{N}$.

2.3 Tools

We give a simple way of locating a symbolic complexity class. A **network** in a topological space X is a family $\mathcal{F}$ of subsets of X such that every open set is a union of elements of $\mathcal{F}$ [5]. Every admissibly represented space has a countable network, given by the images of cylinders under the admissible representation.

▶ **Proposition 2.3.** *Let $\mathbf{X}$ be admissibly represented. Assume that $\mathbf{X}$ has a countable network of sets in $\underset{\sim}{\mathbf{\Sigma}}^0_{i+1}(\mathbf{X})$. For all $n \in \mathbb{N}$, one has*

$$[\underset{\sim}{\mathbf{\Sigma}}^0_n](\mathbf{X}) \subseteq \underset{\sim}{\mathbf{\Sigma}}^0_{n+i}(\mathbf{X}).$$

Proof. Let $\mathbf{Y}$ be the topological space with underlying set X and whose topology is generated by the countable network of $\mathbf{X}$. $\mathbf{Y}$ is countably-based and inherits the T_0-property of $\mathbf{X}$, let $\delta_{\mathbf{Y}}$ be its standard representation. Therefore, one has $[\underset{\sim}{\mathbf{\Sigma}}^0_n](\mathbf{Y}) = \underset{\sim}{\mathbf{\Sigma}}^0_n(\mathbf{Y})$ by Theorem 2.2.

By definition of a network, every open subset of $\mathbf{X}$ is an open subset of $\mathbf{Y}$. In other words, $\mathrm{id} : \mathbf{Y} \to \mathbf{X}$ is continuous hence continuously realizable, which implies that $[\underset{\sim}{\mathbf{\Sigma}}^0_n](\mathbf{X}) \subseteq [\underset{\sim}{\mathbf{\Sigma}}^0_n](\mathbf{Y})$. Conversely, every open subset of $\mathbf{Y}$ belongs to $\underset{\sim}{\mathbf{\Sigma}}^0_{i+1}(\mathbf{X})$ which implies, by induction on n, that $\underset{\sim}{\mathbf{\Sigma}}^0_n(\mathbf{Y}) \subseteq \underset{\sim}{\mathbf{\Sigma}}^0_{n+i}(\mathbf{X})$.

Putting everything together, we obtain $[\underset{\sim}{\mathbf{\Sigma}}^0_n](\mathbf{X}) \subseteq [\underset{\sim}{\mathbf{\Sigma}}^0_n](\mathbf{Y}) = \underset{\sim}{\mathbf{\Sigma}}^0_n(\mathbf{Y}) \subseteq \underset{\sim}{\mathbf{\Sigma}}^0_{n+i}(\mathbf{X})$. ◀

We take the following notion from [19]. An admissibly represented space is **quasi-zero-dimensional** if it is the sequentialization of a zero-dimensional space, i.e. if its open sets are the sequentially open sets of a space having a basis of clopen sets. For instance, the spaces $2^{\mathcal{N}}$ and $\mathbb{N}^{\mathcal{N}}$ are not zero-dimensional, as proved by Schröder [18], but they are quasi-zero-dimensional.

▶ **Corollary 2.4.** *Let $\mathbf{X}$ be quasi-zero-dimensional, for instance $\mathbf{X} = 2^{\mathcal{N}}$ or $\mathbb{N}^{\mathcal{N}}$. One has*

$$[\underset{\sim}{\mathbf{\Sigma}}^0_n](\mathbf{X}) \subseteq \underset{\sim}{\mathbf{\Sigma}}^0_{n+1}(\mathbf{X}).$$

Proof. The images of cylinders under the representation are closed subsets of $\mathbf{X}$ (Proposition 7 in [19]). ◀

A common technique to prove a separation result in a space $\mathbf{Y}$ is to prove it in a simpler space $\mathbf{X}$ and then transfer the result to $\mathbf{Y}$ by including $\mathbf{X}$ into $\mathbf{Y}$.

▶ **Proposition 2.5.** *Let Γ, Γ' be complexity classes that are closed under continuous (resp. computable) preimages.*

Let $\mathbf{X}$ be a continuous (resp. computable) retract of $\mathbf{Y}$. If $[\Gamma](\mathbf{Y}) \subseteq \Gamma'(\mathbf{Y})$, then $[\Gamma](\mathbf{X}) \subseteq \Gamma'(\mathbf{X})$.

Proof. Let $r : \mathbf{Y} \to \mathbf{X}$ and $s : \mathbf{X} \to \mathbf{Y}$ be continuous (resp. computable) functions such that $r \circ s = \mathrm{id}_{\mathbf{X}}$. Let $A \in [\Gamma](\mathbf{X})$ and $B = r^{-1}(A)$. As r is continuous hence continuously realizable (resp. computable), one has $B \in [\Gamma](\mathbf{Y})$ so $B \in \Gamma(\mathbf{Y})$. As s is continuous (resp. computable) and $A = s^{-1}(B)$, we conclude that $A \in \Gamma'(\mathbf{X})$. ◀

If $\mathbf{Y} = (Y, \delta_{\mathbf{Y}})$ is a represented space and $X \subseteq Y$, then $\mathbf{X} := (X, \delta_{\mathbf{X}})$ is a represented space by taking $\delta_{\mathbf{X}}$ as the restriction of $\delta_{\mathbf{Y}}$ to $\delta_{\mathbf{Y}}^{-1}(X)$. Observe that as a topological space, $\mathbf{X}$ is not always a topological subspace of $\mathbf{Y}$, but the sequentialization of the topological subspace [17].

▶ **Proposition 2.6.** *Let Γ be closed under finite intersections and continuous (resp. computable) preimages, and Γ' be closed under continuous (resp. computable) preimages. Let $X \in \Gamma(\mathbf{Y})$. If $[\Gamma](\mathbf{Y}) \subseteq \Gamma'(\mathbf{Y})$, then $[\Gamma](\mathbf{X}) \subseteq \Gamma'(\mathbf{X})$.*

Proof. The representation $\delta_{\mathbf{X}}$ of $\mathbf{X}$ is the restriction of $\delta_{\mathbf{Y}}$ to $\delta_{\mathbf{Y}}^{-1}(X)$.

Let $A \in [\Gamma](\mathbf{X})$. One has $A \in [\Gamma](\mathbf{Y})$. Indeed, $\delta_{\mathbf{Y}}^{-1}(A) = \delta_{\mathbf{X}}^{-1}(A) = S \cap \mathrm{dom}(\delta_{\mathbf{X}})$ for some $S \in \Gamma(\mathcal{N})$, and $\mathrm{dom}(\delta_{\mathbf{X}}) = \delta_{\mathbf{Y}}^{-1}(X) = T \cap \mathrm{dom}(\delta_{\mathbf{Y}})$ for some $T \in \Gamma(\mathcal{N})$. By assumption, $U := S \cap T \in \Gamma(\mathcal{N})$ so $\delta_{\mathbf{Y}}^{-1}(A) = U \cap \mathrm{dom}(\delta_{\mathbf{Y}})$ and $A \in [\Gamma](\mathbf{Y})$.

Threfore, $A \in \Gamma'(\mathbf{Y})$ so by continuity (resp. computability) of the identity from $\mathbf{X}$ to $\mathbf{Y}$, we conclude that $A \in \Gamma'(\mathbf{X})$. ◀

3 Hardness

An important tool to pinpoint the descriptive complexity of a set is provided by the notions of hardness and completeness. If Γ is a descriptive complexity class, then in any topological space X, one can define a set $A \subseteq X$ to be **Γ-hard** if for each $C \in \Gamma(\mathcal{N})$, there is a continuous reduction from C to A, i.e. a continuous function $f : \mathcal{N} \to X$ such that $C = f^{-1}(A)$. Note that the reduction always starts from $\mathcal{N}$. It contrasts with the generalizations of Wadge reducibility between subsets of a topological or represented spaces investigated in [14, 15].

As is well known in descriptive set theory on Polish (and even quasi-Polish) spaces, the hardness of a set is closely related to its complexity: Wadge's Lemma implies that for any class $\Gamma \neq \check{\Gamma}$ of Borel sets and any Borel subset A of a Polish space X,

$$A \text{ is } \Gamma\text{-hard} \iff A \notin \check{\Gamma}(X).$$

However, outside countably-based spaces it turns out that the hardness of a set is related to its symbolic rather than topological complexity, which usually differ as we will see shortly.

Therefore, we need another notion of hardness which reflects the topological complexity of a set.

▶ **Definition 3.1.** *Let (X, τ) be a topological space and Γ a descriptive complexity class. We say that $A \subseteq X$ is Γ-**hard*** if for every countably-based topology $\tau' \subseteq \tau$, A is Γ-hard in (X, τ'). A set is Γ-**complete*** if it belongs to $\Gamma(X)$ and is Γ-hard*.*

Note that when (X, τ) is countably-based, these notions coincide with the standard notions of hardness and completeness.

Now we can state the main result of this section, making clear that hardness is related to symbolic complexity, while hardness* is related to topological complexity. Say that a topological space is analytic if it is a continuous image of $\mathcal{N}$.

▶ **Theorem 3.2.** *Let $\Gamma = \mathbf{D}_\alpha(\boldsymbol{\Sigma}^0_\beta)$ where α, β are countable ordinals. For an analytic admissibly represented space X and $A \subseteq X$ Borel,*

$$\begin{aligned} A \text{ is } \Gamma\text{-hard} &\iff A \notin [\check{\Gamma}](X), \\ A \text{ is } \Gamma\text{-hard*} &\iff A \notin \check{\Gamma}(X). \end{aligned}$$

For $\beta = 1$, the assumptions that the space is analytic and that A is Borel can be dropped. The proof assumes $\boldsymbol{\Sigma}^1_1$-determinacy.

3.1 Hausdorff-Kuratowski Theorem

On Polish and even quasi-Polish spaces, there is no $\boldsymbol{\Delta}^0_n$-complete set because of the Hausdorff-Kuratowski Theorem. Other spaces may admit $\boldsymbol{\Delta}^0_n$-complete* sets, and we show that this possibility is again tightly related to the validity of the Hausdorff-Kuratowski Theorem for $\boldsymbol{\Delta}^0_n$-sets.

▶ **Definition 3.3.** *A topological space X has the **Hausdorff-Kuratowski property at level $\boldsymbol{\Delta}^0_n$** if*

$$\boldsymbol{\Delta}^0_n(X) = \bigcup_{\alpha < \omega_1} \mathbf{D}_\alpha(\boldsymbol{\Sigma}^0_{n-1})(X).$$

▶ **Theorem 3.4.** *Let X be an analytic topological space.*

For each $n \geq 2$, X has the Hausdorff-Kuratowski property at level $\boldsymbol{\Delta}^0_n$ if and only if X has no $\boldsymbol{\Delta}^0_n$-complete set.*

For $n = 2$, the analyticity assumption can be droppped.

Proof. If the HK property is satisfied, then there is no $\boldsymbol{\Delta}^0_n$-complete* set. Indeed, such a set A would be in $\mathbf{D}_\alpha(\boldsymbol{\Sigma}^0_{n-1})$ for some $\alpha < \omega_1$ and some countably-based topology, and $\boldsymbol{\Delta}^0_n$-hard for that topology, which would imply that $\boldsymbol{\Delta}^0_n(\mathcal{N}) \subseteq \mathbf{D}_\alpha(\boldsymbol{\Sigma}^0_{n-1})(\mathcal{N})$, which is known to be false (the difference hierarchies do not collapse on $\mathcal{N}$).

Conversely, if the HK property does not hold, then there exists $A \in \boldsymbol{\Delta}^0_n(X)$ such that $A \notin \mathbf{D}_\alpha(\boldsymbol{\Sigma}^0_{n-1})$ for any $\alpha < \omega_1$. If X is analytic or $n = 2$, then A is $\check{\mathbf{D}}_\alpha(\boldsymbol{\Sigma}^0_{n-1})$-hard* for each $\alpha < \omega_1$ by Theorem 3.2. As a result, A is $\boldsymbol{\Delta}^0_n$-hard*, hence $\boldsymbol{\Delta}^0_n$-complete*. ◀

We now give a criterion for the validity of the Hausdorff-Kuratowski property at a given level.

▶ **Theorem 3.5.** *Let (X, τ) be a topological space. If there exists a Polish topology τ' such that $\tau \subseteq \tau' \subseteq \boldsymbol{\Sigma}^0_n(\tau)$, then (X, τ) has the Hausdorff-Kuratowski property for all levels $\boldsymbol{\Delta}^0_k$ with $k \geq n + 1$.*

Proof. The proof follows the line of the argument in [10], reducing the case of $\boldsymbol{\Delta}^0_n$ to $\boldsymbol{\Delta}^0_2$ by enriching the topology. However, some care is needed because we have to deal with two topologies.

▷ Claim 3.6. For any $k \leq n$ and any countable family $\mathcal{F} \subseteq \boldsymbol{\Sigma}^0_k(X, \tau)$, there exists a Polish topology $\tau'' \subseteq \boldsymbol{\Sigma}^0_n(X, \tau)$ containing $\mathcal{F}$.

Proof of the Claim. We prove it by induction on k. For $k = 1$, the result is immediate by taking $\tau'' = \tau'$, as $\mathcal{F}$ is already contained in τ'. Assume the result for $k < n$ and let $\mathcal{F} \subseteq \boldsymbol{\Sigma}^0_{k+1}(X, \tau)$. There exists a countable family $\mathcal{G} \subseteq \boldsymbol{\Sigma}^0_k(X, \tau)$ such that each element of $\mathcal{F}$ is a countable union of differences of elements of $\mathcal{G}$. By induction, there is a Polish topology $\tau'' \subseteq \boldsymbol{\Sigma}^0_n(X, \tau)$ containing $\mathcal{G}$. Let τ''' be generated by τ'' and the complements of the elements of $\mathcal{G}$. As the latter sets are closed in τ'' which is Polish, τ''' is Polish. Moreover, those sets belong to $\boldsymbol{\Pi}^0_k(X, \tau) \subseteq \boldsymbol{\Sigma}^0_n(X, \tau)$, so $\tau''' \subseteq \boldsymbol{\Sigma}^0_n(X, \tau)$. Finally, each element of $\mathcal{F}$ is open in τ''', and the claim is proved. ◁

We now prove the theorem. Let $A \in \boldsymbol{\Delta}^0_{n+1}(X, \tau)$. There exists a countable family $\mathcal{F} \subseteq \boldsymbol{\Sigma}^0_n(X, \tau)$ such that A and its complement are countable unions of differences of elements of $\mathcal{F}$. Applying the claim, there exists a Polish topology $\tau'' \subseteq \boldsymbol{\Sigma}^0_n(X, \tau)$ containing $\mathcal{F}$. Therefore, $A \in \boldsymbol{\Delta}^0_2(X, \tau'')$ so applying the Hausdorff-Kuratowski theorem for Polish spaces, one has $A \in \mathbf{D}_\alpha(X, \tau'')$ for some $\alpha < \omega_1$. We conclude by observing that $\tau'' \subseteq \boldsymbol{\Sigma}^0_n(X, \tau)$. ◀

We give two simple applications of this result.

The space $\mathbb{R}[X]$ of polynomials with real coefficients is an example of a coPolish space which is not countably-based [3]. A polynomial is represented by giving an upper bound on its degree as well as standard names of its coefficients. On $\mathbb{R}[X]$, hence on $\mathbb{R}[X]^\mathbb{N}$, there is a set in $[\mathrm{D}_\omega]$ which is $\boldsymbol{\Delta}^0_2$-complete* (Theorem 5.8 in [1]). Theorem 3.5 implies that there is no $\boldsymbol{\Delta}^0_k$-complete* set for $k \geq 3$.

▶ **Corollary 3.7.** *The space $\mathbb{R}[X]^\mathbb{N}$ has the Hausdorff-Kuratowski property for all levels $\boldsymbol{\Delta}^0_k$ with $k \geq 3$, therefore that space has no $\boldsymbol{\Delta}^0_k$-complete* set for $k \geq 3$.*

Proof. For each $n, d \in \mathbb{N}$, the set $C_{n,d} := \{(P_i)_{i\in\mathbb{N}} : \deg(P_i) \leq d\}$ is closed. Enriching the topology on $\mathbb{R}[X]^\mathbb{N}$ with these sets results in a Polish topology contained in $\boldsymbol{\Sigma}^0_2(\mathbb{R}[X]^\mathbb{N})$ (the space becomes homeomorphic to $\mathbb{R}^\mathbb{N}$). ◀

We will see later that on $\mathcal{O}(\mathcal{N}_1)$, hence on $\mathcal{O}(\mathbb{N} \times \mathcal{N}_1)$, there is a set in $[\mathrm{D}_\omega]$ which is $\boldsymbol{\Delta}^0_3$-complete* (Theorem 6.5). Theorem 3.5 implies that there is no $\boldsymbol{\Delta}^0_k$-complete* set for $k \geq 4$.

▶ **Corollary 3.8.** *The space $\mathcal{O}(\mathbb{N}\times\mathcal{N}_1)$ has the Hausdorff-Kuratowski property for all levels $\boldsymbol{\Delta}^0_k$ with $k \geq 4$, therefore that space has no $\boldsymbol{\Delta}^0_k$-complete* set for $k \geq 4$.*

Proof. We add the following sets to the topology: for each $(n, f) \in \mathbb{N} \times \mathcal{N}_1$, the closed set $C_{n,f} := \{U : (n, f) \notin U\}$; for each $(n, p) \in \mathbb{N}^2$, the $\boldsymbol{\Pi}^0_2$-set $P_{n,p} := \{U : \{n\} \times [0^p] \subseteq U\}$, where $[0^p]$ is the set of functions $f \in \mathcal{N}_1$ such that $f(i) = 0$ for all $i < p$. We now show that the resulting topological space is homeomorphic to a closed subset of the Baire space, which implies that it is Polish.

We encode $U \in \mathcal{O}(\mathbb{N} \times \mathcal{N}_1)$ into two sequences g_n, h_n of elements of $\mathcal{N}$, which we can encode into a single element of $\mathcal{N}$. We use a one-to-one enumeration $(f_i)_{i\in\mathbb{N}}$ of the elements of $\mathcal{N}_1$, where f_0 is the null function.

Given U, we define its code $(g_n, h_n)_{n\in\mathbb{N}}$ as follows:

- $g_n(i) = 1$ if $(n, f_i) \in U$ and $g_n(i) = 0$ if $(n, f_i) \notin U$.
- $h_n(0) = 0$ if $(n, f_0) \notin U$, and $h_n(0) = p + 1$ if $(n, f_0) \in U$ and p is minimal such that $\{n\} \times [0^p] \subseteq U$.

It is not hard to see that the function sending U to $(g_n, h_n)_{n\in\mathbb{N}}$ is one-to-one and continuous for the enriched topology, as well as its inverse, and that the subset of $\mathcal{N}$ consisting of the codes of elements of $\mathcal{O}(\mathbb{N} \times \mathcal{N}_1)$ is closed. As a result, the enriched topological space is Polish.

Moreover, the enriched topology is contained in $\boldsymbol{\Sigma}^0_3(\mathcal{O}(\mathbb{N} \times \mathcal{N}_1))$. ◀

4 Fréchet-Urysohn property

In [1] we have given a characterization of the coPolish spaces on which the symbolic complexity differs from the topological complexity at the level $\underset{\sim}{\mathbf{D}}_2$: they are exactly the spaces that are not Fréchet-Urysohn.

We can extend part of the argument from coPolish spaces to Hausdorff admissibly represented spaces. We will see later (Theorem 5.1) that the assumption that the space is Hausdorff cannot be dropped.

▶ **Theorem 4.1.** *Let* $\mathbf{X}$ *be admissibly represented and Hausdorff. If* $\mathbf{X}$ *is not Fréchet-Urysohn, then*

$$[\underset{\sim}{\mathbf{D}}_2](\mathbf{X}) \not\subseteq \underset{\sim}{\mathbf{D}}_2(\mathbf{X}).$$

We use the Arens' space $\mathbf{S_2}$, which is the inductive limit of

$$X_N = \{0\} \cup \left\{\frac{1}{n} : n \in \mathbb{N}\right\} \cup \left\{\frac{1}{n} + \frac{1}{k} X^n : n \leq N, k \in \mathbb{N}\right\}.$$

As in [1], one has $[\underset{\sim}{\mathbf{D}}_2](\mathbf{S_2}) \not\subseteq \underset{\sim}{\mathbf{D}}_2(\mathbf{S_2})$ and a witness is the set $A = \{0\} \cup \{\frac{1}{n} + \frac{1}{k}X^n : n, k \in \mathbb{N}\}$. Therefore, Theorem 4.1 is an immediate corollary of the next result together with Proposition 2.6.

▶ **Proposition 4.2.** *Let* $\mathbf{X}$ *be admissibly represented and Hausdorff.* $\mathbf{X}$ *is not Fréchet-Urysohn if and only if* $\mathbf{X}$ *contains a closed copy of* $\mathbf{S_2}$*.*

▶ Remark 4.3 (Historical remark about Proposition 4.2). Franklin [7] proved that when X is a Hausdorff sequential space, X is Fréchet-Urysohn if and only if it does not contain a set which, endowed with the sequentialization of the subspace topology, is homeomorphic to $\mathbf{S_2}$ (Proposition 7.3 in [7]). It implies that if $\mathbf{X}$ is a Hausdorff admissibly represented space, then $\mathbf{X}$ is not Fréchet-Urysohn if and only if $\mathbf{X}$ does not contain $\mathbf{S_2}$ as a represented subspace.

In [22] and [11] it is proved that when X is a Hausdorff sequential space having a point-countable k-network, X is not Fréchet-Urysohn if and only if it does not contain a *closed* set homeomorphic to $\mathbf{S_2}$ (Theorem 2.12 in [11]). Observe that the subspace topology on a closed subset of a sequential space is always sequential, so there is no need to take the sequentialization of the subspace topology as in Franklin's result. This result implies ours, because admissibly represented spaces are sequential and the images of cylinders under the representation give a countable k-network. However we provide a proof in our setting for self-containedness.

The result was also recently proved in [3] for the subclass of coPolish spaces (Proposition 66 in [3], where $\mathbf{S_2}$ is called $\mathbf{S_{min}}$).

5 Spaces of open sets

As already mentioned, the assumption that the space is Hausdorff is important in Theorem 4.1, because some spaces admitting a rich poset structure behave more smoothly. This phenomenon has been already exploited in many ways in the realm of domain theory. We show that even in the absence of a countable basis, some positive results are still valid.

▶ **Theorem 5.1.** *Let $\mathbf{X}$ be admissibly represented. For every $n \geq 2$,*

$$[\underset{\sim}{\mathbf{D}}_n](\mathcal{O}(\mathbf{X})) = \underset{\sim}{\mathbf{D}}_n(\mathcal{O}(\mathbf{X})).$$

We will see that this equality cannot be extended to level ω: if $\mathbf{X}$ is Polish and not locally compact, then $[\underset{\sim}{\mathbf{D}}_\omega](\mathcal{O}(\mathbf{X}))$ contains a $\underset{\sim}{\boldsymbol{\Delta}}^0_3$-complete* set (Theorem 6.5).

Informal proof. The strategy is inspired from the one developed in [8] and [20] where a similar result is proved in the context of numbered sets and algebraic domains. We show that the result can be proved in the context of represented spaces, and without assuming a countable basis.

We first isolate a property of Scott open sets: say that a set $A \subseteq \mathcal{O}(\mathbf{X})$ is *approximable* if for every directed set $\Delta \subseteq \mathcal{O}(\mathbf{X})$ such that $\sup \Delta \in A$, Δ intersects A. A set is Scott open, i.e. in $\underset{\sim}{\boldsymbol{\Sigma}}^0_1(\mathcal{O}(\mathbf{X}))$ if and only if it is upwards closed and approximable.

We prove the following generalization. A set A is in $\underset{\sim}{\mathbf{D}}_n(\mathcal{O}(\mathbf{X}))$ if and only if both A and A^c are approximable and has no $n+1$-chain, i.e. no sequence $U_0 \subseteq U_1 \subseteq \ldots \subseteq U_n$ such that $U_i \in A$ iff i is even (it indeed generalizes the case of open sets for $n = 1$).

The last step is to prove that:

- A subset of $\mathcal{O}(\mathbf{X})$ that is not approximable is necessarily $\underset{\sim}{\boldsymbol{\Pi}}^0_2$-hard,
- A subset of $\mathcal{O}(\mathbf{X})$ having an $n+1$-chain is necessarily $\check{\underset{\sim}{\mathbf{D}}}_n$-hard.

Therefore, if $A \in [\underset{\sim}{\boldsymbol{\Sigma}}^0_2](\mathcal{O}(\mathbf{X}))$ then A is approximable, and if moreover $A \in [\underset{\sim}{\mathbf{D}}_n](\mathcal{O}(\mathbf{X}))$, then A has no $n+1$-chain.

Putting everything together implies that $[\underset{\sim}{\mathbf{D}}_n](\mathcal{O}(\mathbf{X})) \subseteq \underset{\sim}{\mathbf{D}}_n(\mathcal{O}(\mathbf{X}))$. ◀

A consequence of the preceding development is a characterization of the class $[\underset{\sim}{\boldsymbol{\Delta}}^0_2]$ in certain cases.

▶ **Proposition 5.2.** *Let $\mathbf{X}$ be countably-based. The class $[\underset{\sim}{\boldsymbol{\Delta}}^0_2](\mathcal{O}(\mathbf{X}))$ is precisely the class of approximable and co-approximable sets.*

Proof. We know from the proof of Theorem 5.1 that if $A \in [\underset{\sim}{\boldsymbol{\Delta}}^0_2](\mathcal{O}(\mathbf{X}))$ then both A and A^c are approximable.

Conversely, assume that $A \subseteq \mathcal{O}(\mathbf{X})$ and its complement are approximable. Observe that if U_i is a growing sequence of open sets with union U, then $\mathbf{1}_A(U_i)$ converges to $\mathbf{1}_A(U)$ as $i \to \infty$, as both A and A^c are approximable. Let $(B_i)_{i \in \mathbb{N}}$ be a countable basis of $\mathbf{X}$, closed under finite intersections and unions. Let $E = \{i \in \mathbb{N} : B_i \in A\}$. From a name of an open set $U \in \mathcal{O}(\mathbf{X})$, one can continuously derive a sequence $(i_n)_{n \in \mathbb{N}}$ such that $B_{i_n} \subseteq B_{i_{n+1}}$ and $\bigcup_n B_{i_n} = U$. Therefore, whether $U \in A$ can be tested with finitely mind changes, by testing whether $i_n \in E$. ◀

5.1 Effectiveness

The proof of Theorem 5.1 is not effective. We show that there is no effective argument by proving that $[\mathrm{D}_2](\mathcal{O}(\mathbf{X})) \nsubseteq \mathrm{D}_2(\mathcal{O}(\mathbf{X}))$ for some particular $\mathbf{X}$.

▶ **Theorem 5.3.** *One has*

$$[\mathrm{D}_2](\mathcal{O}(\mathcal{N}_1)) \nsubseteq \mathrm{D}_2(\mathcal{O}(\mathcal{N}_1)),$$

and a witness can be taken in $\underset{\sim}{\mathbf{D}}_2(\mathcal{O}(\mathcal{N}_1))$.

Such a set is a difference of two open sets, but computationally speaking, its name set is strictly easier to describe than the set itself.

Informal proof. We prove the separation result for the space $\mathbb{N} \times \mathcal{O}(\mathcal{N}_1)$ and observe that this space embeds as a D_2-subset of $\mathcal{O}(\mathcal{N}_1)$, to which the result immediately transfers by Proposition 2.6. The following discussion is rather general, and $\mathcal{O}(\mathcal{N}_1)$ is a possible instance of $\mathbf{X}$.

In [1] we proved that if $\mathbf{X}$ is not countably-based, then for sets in $\underset{\sim}{\mathbf{D}}_2(\mathbf{X})$, one cannot continuously convert $[\underset{\sim}{\mathbf{D}}_2]$-names into $\underset{\sim}{\mathbf{D}}_2$-names. Another way of formulating this result is expressed by the existence of a function $f : \mathbf{Y} \to \underset{\sim}{\mathbf{D}}_2(\mathbf{X})$ for some represented space $\mathbf{Y}$, such that:

- $f : \mathbf{Y} \to [\underset{\sim}{\mathbf{D}}_2](\mathbf{X})$ is continuously realizable,
- $f : \mathbf{Y} \to \underset{\sim}{\mathbf{D}}_2(\mathbf{X})$ is not continuously realizable.

Equivalently, it means that $\{(y, x) : x \in f(y)\}$ belongs to $[\underset{\sim}{\mathbf{D}}_2](\mathbf{Y} \times \mathbf{X})$ but not $\underset{\sim}{\mathbf{D}}_2(\mathbf{Y} \times \mathbf{X})$.

If $f : \mathbf{Y} \to [\underset{\sim}{\mathbf{D}}_2](\mathbf{X})$ is moreover computable and if there is an effective enumeration $(y_i)_{i \in \mathbb{N}}$ of the computable elements of $\mathbf{Y}$, then we can consider the following set:

$$A = \{(i, x) \in \mathbb{N} \times \mathbf{X} : x \in f(y_i)\}.$$

One immediately has $A \in \underset{\sim}{\mathbf{D}}_2(\mathbb{N} \times \mathbf{X})$, $A \in [\mathrm{D}_2](\mathbb{N} \times \mathbf{X})$ and one has to prove that $A \notin \mathrm{D}_2(\mathbb{N} \times \mathbf{X})$, which depends on the details of Y and f.

For $\mathbf{X} = \mathcal{O}(\mathcal{N}_1)$, one can make $\mathbf{Y}$ and $f : \mathbf{Y} \to \underset{\sim}{\mathbf{D}}_2(\mathbf{X})$ very explicit: let $\mathbf{Y} = \overline{\mathbb{N}} \times \overline{\mathbb{N}}$ and

$$\begin{aligned} f(\infty, y) &= \{U \in \mathcal{O}(\mathcal{N}_1) : f_\infty \in U\}, \\ f(n, \infty) &= \emptyset, \\ f(n, p) &= \{U \in \mathcal{O}(\mathcal{N}_1) : f_{n,p} \notin U\}, \end{aligned}$$

where f_∞ is the null function and $f_{n,p} \in \mathcal{N}_1$ is the only function satisfying $f_{n,p}(n) = p + 1$.

One can take the following effective indexing of $\mathbf{Y} = \overline{\mathbb{N}} \times \overline{\mathbb{N}}$: if $\langle .,. \rangle : \mathbb{N}^2 \to \mathbb{N}$ is a computable bijection, and t_i is the halting time of Turing machine number i, then let $y_{\langle i,j \rangle} = (t_i, t_j)$. The set $A \subseteq \mathbb{N} \times \mathcal{O}(\mathcal{N}_1)$ becomes:

$$A = \{(\langle i, j \rangle, U) : f_\infty \in U \text{ and } M_i \text{ does not halt, or } M_i \text{ and } M_j \text{ halt and } f_{t_i,t_j} \notin U\}. \qquad \blacktriangleleft$$

▶ **Corollary 5.4.** *If $\mathcal{N}_1$ embeds as a D_2-subset of $\mathbf{X}$, then*

$$[\mathrm{D}_2](\mathcal{O}(\mathbf{X})) \nsubseteq \mathrm{D}_2(\mathcal{O}(\mathbf{X})).$$

Proof. $\mathcal{O}(\mathcal{N}_1)$ is a computable retract of $\mathcal{O}(\mathbf{X})$, so the separation result (Theorem 5.3) about $\mathcal{O}(\mathcal{N}_1)$ extends to $\mathcal{O}(\mathbf{X})$ by Proposition 2.5. ◀

We consider the so-called sequential fan $\mathbf{S}(\omega) = \{0\} \cup \{\frac{1}{p}X^n : n, p \in \mathbb{N}\} \subseteq \mathbb{R}[X]$. It is Fréchet-Urysohn but has one point with no countable basis of neighborhoods. The space $\mathbb{N} \times \mathbf{S}(\omega)$ has infinitely many points with no countable basis of neighborhoods.

▶ **Theorem 5.5.** *Let $\mathbf{X} = \mathbb{N} \times \mathbf{S}(\omega)$. One has*

$$[\mathrm{D}_2](\mathbf{X}) \nsubseteq \mathrm{D}_2(\mathbf{X}),$$

and it is witnessed by an open set.

Proof. We follow the same scheme as in the preceding proof. Let

$$A = \{(n, P) : \text{if } M_n \text{ halts then } \deg(P) > t_n\}.$$

First, A is open because it is Σ^0_1 relative the halting set.

We show that $A \in [\mathrm{D}_2](\mathbf{X})$. We are given (n, P), with an upper bound d on $\deg(P)$. We run M_n for d steps. If M_n halts before d steps, then we know the value of t_n so we can test whether $\deg(P) > t_n$ (i.e. we start rejecting (n, P) until this test succeeds, in which case we accept (n, P)). If M_n does not halt before d steps, then we accept (n, P) and eventually reject it if M_n halts (indeed, in that case one has $\deg(P) \leq d \leq t_n$).

We show that $A \notin \mathrm{D}_2(\mathbf{X})$. Observe that for each n, $(n, 0)$ belongs to the closure of A: if M_n does not halt then $(n, 0) \in A$; if M_n halts then $(n, 0)$ is the limit when p grows of $(n, \frac{1}{p}X^{t_n+1}) \in A$.

Assume that $A = U \setminus V$ where U, V are open subsets of $\mathbf{X}$ and U is effectively open. For each n, as $(n, 0)$ belongs to the closure of A then one must have $(n, 0) \notin V$. Therefore, $(n, 0) \in A \iff (n, 0) \in U$. However, $(n, 0) \in A$ iff M_n does not halt, so it cannot be equivalent to $(n, 0) \in U$ which is a c.e. condition. We obtain a contradiction, so $A \notin \mathrm{D}_2(\mathbf{X})$. ◀

Proposition 2.6 immediately implies

▶ **Corollary 5.6.** *If $\mathbb{N} \times \mathbf{S}(\omega)$ computably embeds as a D_2-subset of $\mathbf{X}$, then*

$$[\mathrm{D}_2](\mathbf{X}) \nsubseteq \mathrm{D}_2(\mathbf{X})$$

with a witness in $\underset{\sim}{\mathbf{D}}_2(\mathbf{X})$.

One easily checks that the spaces $\mathbb{R}[X]$, $2^{\mathbb{N}^\mathbb{N}}$ and $\mathbb{N}^{\mathbb{N}^\mathbb{N}}$ are instances of this result:

- $\mathbb{N} \times \mathbf{S}(\omega) \subseteq \mathbb{R}[X]$ by identifying (n, P) with $\frac{1}{n} + XP$,
- $\mathbb{N} \times \mathbf{S}(\omega) \subseteq 2^{\mathbb{N}^\mathbb{N}}$ by identifying $(n, 0)$ with $\{f \in \mathcal{N} : f(0) = n\}$ and $(n, \frac{1}{p}X^q)$ with $\{f \in \mathcal{N} : f(0) = n \text{ and } f(q+1) \leq p\}$.

6 Spaces of open subsets of Polish spaces

We now focus on spaces of open subsets of Polish spaces, for which we can establish a rather precise picture of the relationship between symbolic and topological complexity, depending on the compactness properties of the space. We show how the behavior of symbolic complexity classes on $\mathcal{O}(X)$ is closely related to the compactness properties of X.

6.1 The 4 classes

The first observation is that when X is locally compact, for instance $X = \mathbb{R}$, $\mathcal{O}(X)$ is countably-based so it behaves very well in terms of descriptive complexity: symbolic and topological complexity coincide. We split the whole class of Polish spaces into 4 disjoint classes, ranging from the locally compact spaces to the non σ-compact spaces.

Let $X_{\text{nk}} = \{x \in X : x \text{ has no compact neighborhood}\}$, which is a closed subset of X.

▶ **Definition 6.1.** *Let X be a Polish space.*

1. *$X \in$ Class I if $X_{\text{nk}} = \emptyset$, i.e. X is locally compact,*
2. *$X \in$ Class II if $X_{\text{nk}} \neq \emptyset$ is finite,*
3. *$X \in$ Class III if $X_{\text{nk}} \neq \emptyset$ is infinite and X is σ-compact,*
4. *$X \in$ Class IV if X is not σ-compact.*

Observe that the union of Classes I, II, III is the class of σ-compact spaces.

▶ **Example 6.2.** Let us give one example for each class:

1. $\mathbb{R}$ belongs to Class I,
2. $\mathcal{N}_1 = \{f \in \mathcal{N} : f \text{ takes at most one positive value}\}$ belongs to Class II, with one element having no compact neighborhood, namely the zero function f_0,

3. $\mathbb{N}\times\mathcal{N}_1$ belongs to Class III, where the elements with no compact neighborhood are the pairs (n, f_0),
4. $\mathcal{N}$ belongs to Class IV.

Moreover, the three latter spaces are minimal in their respective classes, i.e. embed into every space of their classes.

▶ **Proposition 6.3.** *Let X be Polish.*

- *$X \notin$ Class I $\iff$ X contains a closed copy of $\mathcal{N}_1$,*
- *$X \notin$ Classes I or II $\iff$ X contains a $\underset{\sim}{\mathbf{D}}_2$ copy of $\mathbb{N}\times\mathcal{N}_1$,*
- *$X \notin$ Classes I, II or III $\iff$ X contains a closed copy of $\mathcal{N}$.*

Proof. The backwards implications are easy, because if C is a closed subset, or even a $\underset{\sim}{\mathbf{D}}_2$-subset of $\mathbf{X}$ and $x \in C$ has no compact neighborhood in the subspace C, then x has no compact neighborhood in $\mathbf{X}$.

Assume that $\mathbf{X}$ is not locally compact and let $x_0 \in \mathbf{X}_{\mathrm{nk}}$. We define a double-sequence $x_{i,n}$ by induction on i. Let B_0 be a basic neighborhood of x_0. As $\overline{B_0}$ is not compact, it contains a sequence $x_{0,n}$ with no converging subsequence. In particular, there exists a neighborhood B_1 of x_0 such that $\overline{B_1}$ does not contain any $x_{0,n}$. Again, $\overline{B_1}$ is not compact so it contains a sequence $x_{i,n}$ with no converging subsequence. We continue, making sure that the radius of B_i converges to 0. One easily checks that the set $\{x_0\}\cup\{x_{i,n} : i,n\in\mathbb{N}\}$ is closed and homeomorphic to $\mathcal{N}_1$, by sending x_0 to the zero function, and $x_{i,n}$ to the function f such that $f(i) = n$.

Assume that $\mathbf{X}_{\mathrm{nk}}$ is infinite. It contains a copy D of $\mathbb{N}$ with $D \in \underset{\sim}{\mathbf{D}}_2(\mathbf{X})$. Each point $x \in D$ is contained in a neighrbohood B_x such that $\overline{B_x}\cap\overline{B_y} = \emptyset$ for $x \neq y$. Around each point x of D and inside B_x we can build a closed copy of $\mathcal{N}_1$ as in the previous case. Their union is a copy of $\mathbb{N}\times\mathcal{N}_1$ and belongs to $\underset{\sim}{\mathbf{D}}_2(\mathbf{X})$.

The third statement is a particular case of Hurewicz theorem (Theorem 7.10 in [10]). ◀

6.2 Classification

We now relate the behavior of symbolic complexity on $\mathcal{O}(X)$ to the class of X. We first locate the symbolic complexity classes.

▶ **Theorem 6.4** (Classification – Positive results)**.** *Let X be Polish.*

1. *If $X \in$ Class I, then $[\underset{\sim}{\mathbf{\Sigma}}^0_k](\mathcal{O}(X)) = \underset{\sim}{\mathbf{\Sigma}}^0_k(\mathcal{O}(X))$ for all k,*
2. *If $X \in$ Class II, then $[\underset{\sim}{\mathbf{\Sigma}}^0_k](\mathcal{O}(X)) = \underset{\sim}{\mathbf{\Sigma}}^0_k(\mathcal{O}(X))$ for $k \geq 3$,*
3. *If $X \in$ Class III, then $[\underset{\sim}{\mathbf{\Sigma}}^0_k](\mathcal{O}(X)) \subseteq \underset{\sim}{\mathbf{\Sigma}}^0_{k+2}(\mathcal{O}(X))$ for $k \geq 2$.*

Informal proof. If $X \in$ Class I, i.e. if X is locally compact, then $\mathcal{O}(\mathbf{X})$ is countably-based [16], so symbolic and topological complexity coincide there (Theorem 2.2).

If $X \in$ Class II, then up to a finite set, X is countably-based, and we show that this finite set do not affect the complexity of sets for levels $k \geq 3$.

If $X \in$ Class III, then X is σ-compact, so its open sets are σ-compact as well. Therefore, for each open set B, the corresponding set $P_B = \{U \in \mathcal{O}(\mathbf{X}) : B \subseteq U\}$ belongs to $\underset{\sim}{\mathbf{\Pi}}^0_2(\mathcal{O}(X))$. The countable family $\mathcal{B}$ of finite unions basic open subsets of X induces a countable network $(P_B)_{B\in\mathcal{B}}$ of $\mathcal{O}(\mathbf{X})$ made of $\underset{\sim}{\mathbf{\Pi}}^0_2$-sets. Therefore, we can apply Proposition 2.3. ◀

We then identify gaps between symbolic and topological complexity.

▶ **Theorem 6.5** (Classification – Negative results)**.** *Let X be Polish.*

1. *If $X \notin$ Class I, then $[\boldsymbol{D}_\omega](\mathcal{O}(X))$ contains a $\boldsymbol{\Delta}^0_3$-complete* set,*
2. *If $X \notin$ Class II, then $[\boldsymbol{\Sigma}^0_k](\mathcal{O}(X))$ contains a $\boldsymbol{\Sigma}^0_{k+1}$-complete*-set for $k \geq 2$,*
3. *If $X \notin$ Class III, then $[\boldsymbol{\Sigma}^0_2](\mathcal{O}(X))$ contains a non-Borel set.*

We observe that two phenomena are possible. For some spaces, the classes $[\boldsymbol{\Sigma}^0_k]$ and $\boldsymbol{\Sigma}^0_k$ differ for low values of k and then coincide after some rank (if X is in Class II, then they coincide for $k \geq 3$). For other spaces, the classes never coincide (if X is in Class III or IV).

It is open whether $\boldsymbol{\Sigma}^0_k(O(X)) \subseteq \boldsymbol{\Sigma}^0_{k+1}(\mathcal{O}(X))$ when X belongs to Class III. A similar study should be done when X is not Polish.

Informal proof. The difference between symbolic and topological complexity is related to the fact that product spaces usually have two different natural topologies: the product topology (which is the structure obtained as the cartesian product in the category of topological spaces), and its sequentialization (obtained from the cartesian product in the category of QCB$_0$-spaces, or admissibly represented spaces). These two different topologies obviously induce different topological complexity classes, already at the first level $\boldsymbol{\Sigma}^0_1$.

For instance, on $\mathcal{N} \times \mathcal{O}(\mathcal{N})$, the set $\{(f, U) : f \in U\}$ is open but is not Borel for the product topology.

The proof shows how to exploit the difference between the product topology and its sequentialization on the space $\mathcal{N} \times \mathcal{O}(\mathbf{X})$ and turn it into a difference between symbolic and topological complexity on $\mathcal{O}(\mathbf{X})$.

When $\mathbf{X} = \mathbb{N} \times \mathcal{N}_1$, one has $\mathbf{X} \cong \mathbb{N} \times \mathbf{X}$ so $\mathcal{O}(\mathbf{X}) \cong \mathcal{O}(\mathbf{X})^{\mathbb{N}}$. This equality enables one to iterate: if $A_k \in [\Sigma^0_k](\mathcal{O}(\mathbf{X}))$ is $\boldsymbol{\Sigma}^0_{k+1}$-complete*, then the set

$$A_{k+1} = \{(U_i)_{i \in \mathbb{N}} \in \mathcal{O}(\mathbf{X})^{\mathbb{N}} : \exists i, U_i \notin A_k\}$$

belongs to $[\boldsymbol{\Sigma}^0_{k+1}](\mathcal{O}(\mathbf{X})^{\mathbb{N}})$ and it $\boldsymbol{\Sigma}^0_{k+2}$-complete*. ◀

The fact that $\mathbf{X}$ is Polish is essential in the proofs. A particular property of Polish and quasi-Polish spaces that is used is the following.

▶ **Proposition 6.6.** *If $\mathbf{X}$ and $\mathbf{Y}$ are quasi-Polish, then the topologies on the admissiby represented spaces $\mathcal{O}(\mathbf{X})^{\mathbb{N}}$ and $\mathcal{O}(\mathbf{X}) \times \mathcal{O}(\mathbf{Y})$ are the product topologies.*

Proof. As represented spaces, one has $\mathcal{O}(\mathbf{X})^{\mathbb{N}} \cong \mathcal{O}(\mathbb{N} \times \mathbf{X})$ and $\mathcal{O}(\mathbf{X}) \times \mathcal{O}(\mathbf{Y}) \cong \mathcal{O}(\mathbf{X} \sqcup \mathbf{Y})$. The topologies on the admissibly represented spaces $\mathcal{O}(\mathbb{N} \times \mathbf{X})$ and $\mathcal{O}(\mathbf{X} \sqcup \mathbf{Y})$ are the Scott topologies.

On the other hand, for any topological spaces X, Y, it is easy to see that the compact-open topology on $\mathcal{O}(\mathbb{N} \times X)$ and $\mathcal{O}(X \sqcup Y)$ is the product topology on $\mathcal{O}(X)^{\mathbb{N}}$ and $\mathcal{O}(X) \times \mathcal{O}(Y)$ respectively, where $\mathcal{O}(X)$ and $\mathcal{O}(Y)$ are endowed with the compact-open topology.

When $\mathbf{X}$ and $\mathbf{Y}$ are quasi-Polish, so are $\mathbb{N} \times \mathbf{X}$ and $\mathbf{X} \sqcup \mathbf{Y}$, so $\mathbf{X}$, $\mathbf{Y}$, $\mathbb{N} \times \mathbf{X}$ and $\mathbf{X} \sqcup \mathbf{Y}$ are consonant, i.e. the Scott topology and the compact-open topology coincide on their spaces of open sets [4]. As a result the topology on the represented spaces $\mathcal{O}(\mathbf{X})^{\mathbb{N}}$ and $\mathcal{O}(\mathbf{X}) \times \mathcal{O}(\mathbf{Y})$ is the product of the topologies on $\mathcal{O}(\mathbf{X})$ and $\mathcal{O}(\mathbf{Y})$. ◀

Open subsets of the Baire space

We now give the complete proof that the class $[\Sigma^0_2](\mathcal{O}(\mathcal{N}))$ contains a set that is not Borel (Theorem 6.5, item 3.).

Proof. We have seen that two represented spaces $\mathbf{X}$ and $\mathbf{Y}$ naturally induce a third represented space $\mathbf{X} \times \mathbf{Y}$. The topology induced by that representation is not in general the product topology, but its sequentialization.

A simple example is given by $\mathbf{X} = \mathcal{N}$ and $\mathbf{Y} = \mathcal{O}(\mathcal{N})$. The evaluation map $\mathcal{N} \times \mathcal{O}(\mathcal{N}) \to \mathbb{S}$ is continuous (and computable), however it is not continuous w.r.t. the product topology, because $\mathcal{N}$ is not locally compact (see [6] for more details on this topic). In other words the set $\{(f, O) \in \mathcal{N} \times \mathcal{O}(\mathcal{N}) : f \in O\}$ is not open for the product topology (but it is sequentially open, or open for the topology induced by the representation). It is even worse.

▶ **Proposition 6.7.** *$E = \{(f, O) \in \mathcal{N} \times \mathcal{O}(\mathcal{N}) : f \in O\}$ is not Borel for the product topology.*

Proof. We prove that for every Borel set A, there exists a dense G_δ-set $G \subseteq \mathcal{N}$ such that for every $f \in G$, $(f, \mathcal{N} \setminus \{f\}) \in A \iff (f, \mathcal{N}) \in A$. It implies the result as it is obviously false for the set E. To prove it, we show that the class of sets satisfying this condition contains the open sets in the product topology and is closed under taking complements and countable unions, which implies that this class contains the Borel sets.

First, consider a basic open set $A = [u] \times \mathcal{U}_K$ where u is a finite sequence of natural numbers, K is a compact subset of $\mathcal{N}$ and $\mathcal{U}_K = \{O \in \mathcal{O}(\mathcal{N}) : K \subseteq O\}$. Define $G = [u]^c \cup [u] \setminus K$, which is a dense open set. For $f \in [u]^c$, no (f, O) belongs to A. For $f \in [u] \setminus K$, both $(f, \mathcal{N} \setminus \{f\})$ and $(f, \mathcal{N})$ belong to A.

If A satisfies the condition with a dense G_δ-set G, then A^c satisfies the condition with the same G. If A_i satisfy the condition with dense G_δ-sets G_i then $\bigcup_i A_i$ satisfies the condition with $G = \bigcap_i G_i$. ◀

We now use the set E to build a set in $[\Sigma^0_2](\mathcal{O}(\mathcal{N}))$ which is not Borel. We show that $\mathcal{N} \times_{\text{prod}} \mathcal{O}(\mathcal{N})$, which is the topological space endowed with the product topology, is a $[\Sigma^0_2]$-retract of $\mathcal{O}(\mathcal{N})$. We build:

- A continuous function $s : \mathcal{N} \times_{\text{prod}} \mathcal{O}(\mathcal{N}) \to \mathcal{O}(\mathcal{N})$,
- A $[\Sigma^0_2]$-measurable function $r : \mathcal{O}(\mathcal{N}) \to \mathcal{N} \times \mathcal{O}(\mathcal{N})$,
- Such that $r \circ s = \text{id}$.

First, these ingredients enable us to derive the result. Indeed, let E be the set from Proposition 6.7 and $F := r^{-1}(E) \subseteq \mathcal{O}(\mathcal{N})$. As E is open in $\mathcal{N} \times \mathcal{O}(\mathcal{N})$, F is Σ^0_2. However F is not Borel, otherwise $E = s^{-1}(F)$ would be Borel in $\mathcal{N} \times_{\text{prod}} \mathcal{O}(\mathcal{N})$.

Let us now build s and r. We identify $\mathcal{O}(\mathcal{N})$ with $\mathcal{O}(\mathcal{N}) \times \mathcal{O}(\mathcal{N})$ and use the fact that the topology on $\mathcal{O}(\mathcal{N}) \times \mathcal{O}(\mathcal{N})$ coincides with the product topology by Proposition 6.6.

▶ **Lemma 6.8.** *$\mathcal{N}$ is a $[\Sigma^0_2]$-retract of $\mathcal{O}(\mathbb{N})$: there exists $r : \mathcal{O}(\mathbb{N}) \to \mathcal{N}$ which is $[\Sigma^0_2]$-measurable, $s : \mathcal{N} \to \mathcal{O}(\mathbb{N})$ which is computable, such that $r \circ s = \text{id}_{\mathcal{N}}$.*

Proof. Let $\langle .,. \rangle : \mathbb{N}^2 \to \mathbb{N}$ be a computable bijection. Let $r(E) = f_E$ be defined by

$$f_E(i) = \begin{cases} \min\{j \in \mathbb{N} : \langle i, j \rangle \in E\} & \text{if that set is non-empty,} \\ 0 & \text{otherwise.} \end{cases}$$

Let $s(f) = \{\langle i, f(i) \rangle : i \in \mathbb{N}, f(i) \geq 1\}$. One easily checks that r and s satisfy the required conditions. ◀

By Lemma 6.8, $\mathcal{N}$ is a $[\Sigma^0_2]$-retract of $\mathcal{O}(\mathbb{N})$, which is a computable retract of $\mathcal{O}(\mathcal{N})$, so $\mathcal{N}$ is a $[\Sigma^0_2]$-retract of $\mathcal{O}(\mathcal{N})$. It is witnessed by two functions $r_0 : \mathcal{O}(\mathcal{N}) \to \mathcal{N}$ and $s_0 : \mathcal{N} \to \mathcal{O}(\mathcal{N})$ such that $r_0 \circ s_0 = \mathrm{id}_{\mathcal{N}}$.

Let us simply pair s_0 and r_0 with the identity on $\mathcal{O}(\mathcal{N})$: let $s(f, O') = (s_0(f), O')$ and $r(O, O') = (r_0(O), O')$. ◀

In particular, that set is not a countable union of differences of open sets, as it should be on Polish or quasi-Polish spaces. More generally, it is not a countable boolean combination of open sets.

In order to overcome the mismatch between the hierarchy inherited from $\mathcal{N}$ via the representation and the class of Borel sets, one may attempt to change the definition of Borel sets. In [12] the Borel sets are redefined as the smallest class containing the open sets and the saturated compact sets, and closed under countable unions and complements. We observe here that this class is too large in the space $\mathcal{O}(\mathcal{N})$. First, if $U \subseteq \mathcal{N}$ is open then the set $\{V \in \mathcal{O}(\mathcal{N}) : U \subseteq V\}$ is compact and saturated in $\mathcal{O}(\mathcal{N})$. From this it is easy to see that the set built above is Borel in this weaker sense. However this notion of Borel sets is too loose, because compact saturated sets do not usually have a Borel pre-image. For instance, the singleton $\{\mathcal{N}\}$ is compact saturated but its pre-image under the representation is a $\utilde{\mathbf{\Pi}}^1_1$-complete set, hence is not Borel.

Abstract

We consider the time-bounded reachability problem for continuous-time Markov decision processes. We show that the problem is decidable subject to Schanuel's conjecture. Our decision procedure relies on the structure of optimal policies and the conditional decidability (under Schanuel's conjecture) of the theory of reals extended with exponential and trigonometric functions over bounded domains. We further show that any unconditional decidability result would imply unconditional decidability of the bounded continuous Skolem problem, or equivalently, the problem of checking if an exponential polynomial has a non-tangential zero in a bounded interval. We note that the latter problems are also decidable subject to Schanuel's conjecture but finding unconditional decision procedures remain longstanding open problems.

1 Introduction

Continuous-time Markov decision processes (CTMDPs) are a widely used model for continuous-time systems which exhibit both stochastic and non-deterministic choice. A CTMDP consists of a finite set of states, a finite set of actions, and for each action, a transition rate matrix that determines the rate (in an exponential distribution in continuous time) to go from one state to the next when the action is chosen. A *policy* for a CTMDP maps a timed execution path to state-dependent actions. Given a fixed policy, a CTMDP determines a stochastic process in continuous time, where the rate matrix determines the distribution of switches.

A fundamental decision problem for CTMDPs is the *time-bounded reachability problem*, which asks, given a CTMDP $\mathcal{M}$ with a designated "**good**" state, a time bound B, and a rational vector r, whether there exists a policy that controls the Markov decision process such that the probability of reaching the good state from state s within time bound B is at least $r(s)$. The time-bounded reachability problem is at the core of model checking CTMDPs with respect to stochastic temporal logics [5] and has been extensively studied [10, 21, 28, 20, 9].

Existing papers either consider *time-abstract* policies [5, 25, 8, 28, 20] or focus on numerical approximation schemes [10, 21, 3, 13, 9, 26]. However, policies that depend on time are strictly more powerful and the *decision problem* has remained open. For the special case of continuous-time Markov chains (CTMCs), where each state has a unique action, the time-bounded reachability problem is decidable [4]. The proof uses tools from transcendental number theory, specifically, the Lindemann-Weierstrass theorem. One might expect that a similar argument might be used to show decidability for CTMDPs as well.

In this paper, we show *conditional* decidability. Our result uses, like several other conditional results on dynamical systems, Schanuel's conjecture from transcendental number theory (see, e.g., [14]). Our proof has the following ingredients. First, we use the fact that the optimal policy for the time-bounded reachability problem is a timed, *piecewise constant* function with a *finite* number of switches [19, 22, 24]. We show that each switch point of an optimal policy corresponds to a non-tangential zero of an associated linear dynamical system. Second, we use the result of Macintyre and Wilkie [16, 17] that Schanuel's conjecture implies the decidability of the real-closed field together with the exponential, sine, and cosine functions over a bounded domain. The existence of non-tangential zeros of linear dynamical systems can be encoded in this theory. Third, for each natural number $k \in \mathbb{N}$, we write a sentence in this theory whose validity implies there is an optimal strategy with exactly k switch points. By enumerating over k, we find the exact number of switches in an optimal strategy. Finally, we write another sentence in the theory that checks if the reachability probability attained by (an encoding of) the optimal policy is greater than the given bound.

We also study the related decision problem whether there is a *stationary* (i.e., time independent) optimal policy. We show that there is a "direct" conditional decision procedure for this problem based on Schanuel's conjecture and recent results on zeros of exponential polynomials [11], which avoids the result of Macintyre and Wilkie.

At the same time, we show that an *unconditional* decidability result is likely to be very difficult. We show that the bounded continuous-time Skolem problem [7, 11] reduces to checking if there is an optimal stationary policy in the time-bounded CTMDP problem. The bounded continuous Skolem problem is a long-standing open problem about linear dynamical systems [11, 7]; it asks if a linear dynamical system in continuous time has a non-tangential zero in a bounded interval. Our reduction, in essence, demonstrates that CTMDPs can "simulate" any linear dynamical system: a non-tangential zero in the dynamics corresponds to a policy switch point in the simulating CTMDP.

Our result is in the same spirit as several recent results providing conditional decision procedures, based on Schanuel's conjecture, or hardness results, based on variants of the Skolem problem, for problems on probabilistic systems. For example, Daviaud et al. [12] showed conditional decidability of subcases of the containment problem for probabilistic automata subject to the conditional decidability of the theory of real closed fields with the exponential function [18, 27]. For lower bounds, Akshay et al. [2] showed a reduction from the (unbounded, discrete) Skolem problem to reachability on discrete time Markov chains and Piribauer and Baier [23] show that the positivity problem in discrete time can be reduced into several decision problems corresponding to optimization tasks over discrete time MDPs.

In summary, we summarize our contribution as the following theorem.

▶ **Theorem 1.** *(1) The time-bounded reachability problem for CTMDPs is decidable assuming Schanuel's conjecture. (2) Whether the time-bounded reachability problem has a stationary optimal policy is decidable assuming Schanuel's conjecture. (3) The bounded continuous Skolem problem reduces to checking if the time-bounded reachability problem has a stationary optimal policy.*

2 Continuous Time Markov Decision Processes

▶ **Definition 2.** *A continuous-time Markov decision process (CTMDP) is a tuple $\mathcal{M} = (S, \mathcal{D}, \mathbf{Q})$ where*

- *$S = \{1, 2, \ldots, \mathfrak{n}\}$ is a finite set of states for some $\mathfrak{n} > 0$;*
- *a set $\mathcal{D} = \prod_{s=1}^{\mathfrak{n}} \mathcal{D}_s$ of* decision vectors*, where $\mathcal{D}_s$ is a finite set of* actions *that can be taken in state $s \in S$;*
- *$\mathbf{Q}$ is a $\mathcal{D}$-indexed family of $\mathfrak{n} \times \mathfrak{n}$* generator matrices*; we write $\mathbf{Q}^{\mathbf{d}}$ for the generator matrix corresponding to the decision vector $\mathbf{d} \in \mathcal{D}$. The entry $\mathbf{Q}^{\mathbf{d}}(s, s') \geq 0$ for $s' \neq s$ gives the* rate of transition *from state s to state s' under action $\mathbf{d}(s)$, and $\mathbf{Q}^{\mathbf{d}}(s, s')$ is independent of elements of $\mathbf{d}$ except $\mathbf{d}(s)$. The entry $\mathbf{Q}^{\mathbf{d}}(s, s) = -\sum_{s' \neq s} \mathbf{Q}^{\mathbf{d}}(s, s')$.*

A CTMDP $\mathcal{M} = (S, \mathcal{D}, \mathbf{Q})$ with $|\mathcal{D}| = 1$, i.e., when only a unique action can be taken in each state, is called a *continuous-time Markov chain* (CTMC) and is simply denoted by the tuple $(S, \mathbf{Q})$, and with abuse of notation, we also write $\mathbf{Q}$ for the unique generator matrix. The CTMDP $\mathcal{M}$ reduces to a CTMC whenever a decision vector $\mathbf{d}$ is fixed for all time on the CTMDP.

Intuitively, $\mathbf{Q}^{\mathbf{d}}(s, s') > 0$ indicates that by fixing a decision vector $\mathbf{d}$, a transition from s to s' is possible and that the timing of the transition is exponentially distributed with rate $\mathbf{Q}^{\mathbf{d}}(s, s')$. If there are several states s' such that $\mathbf{Q}^{\mathbf{d}}(s, s') > 0$, more than one transition will be possible. For each decision vector $\mathbf{d} \in \mathcal{D}$ and any $s \in S$, the total rate of taking an outgoing transition from state s when $\mathbf{d}$ is fixed is given by $E_{\mathbf{d}}(s) = \sum_{s' \neq s} \mathbf{Q}^{\mathbf{d}}(s, s')$, By fixing this decision vector $\mathbf{d}$, a transition from a state s into s' occurs within time t with probability

$$\mathbf{P}(s, s', t) = \frac{\mathbf{Q}^{\mathbf{d}}(s, s')}{E_{\mathbf{d}}(s)} . (1 - e^{-E_{\mathbf{d}}(s)t}), \quad t \geq 0.$$

Intuitively, $1 - e^{-E_{\mathbf{d}}(s)t}$ is the probability of taking an outgoing transition at s within time t (exponentially distributed with rate $E_{\mathbf{d}}(s)$) and $\mathbf{Q}^{\mathbf{d}}(s, s')/E_{\mathbf{d}}(s)$ is the probability of taking transition to s' among possible next states at s. Thus, the total probability of moving from s to s' under the decision $\mathbf{d}$ in one transition, written $\mathbf{P}_{\mathbf{d}}(s, s')$ is $\mathbf{Q}^{\mathbf{d}}(s, s')/E_{\mathbf{d}}(s)$. A state $s \in S$ is called *absorbing* if and only if $\mathbf{Q}^{\mathbf{d}}(s, s') = 0$ for all $s' \in S$ and all decision vectors $\mathbf{d} \in \mathcal{D}$. For an absorbing state, we have $E_{\mathbf{d}}(s) = 0$ for any decision vector $\mathbf{d}$ and no transitions are enabled. The initial state of a CTMDP is either fixed deterministically or selected randomly according to a probability distribution α over the set of states S.

Consider a time interval $[0, B]$ with time bound $B > 0$. Let Ω denote the set of all right-continuous step functions $f : [0, B] \to S$, i.e., there are time points $t_0 = 0 < t_1 < t_2 < \ldots < t_m = B$ such that $f(t') = f(t'')$ for all $t', t'' \in [t_i, t_{i+1})$ for all $i \in \{0, 1, \ldots, m-1\}$. Let $\mathcal{F}$ denote the sigma-algebra of the *cylinder sets*

$$\mathsf{Cyl}(s_0, I_0, \ldots, I_{m-1}, s_m) := \{f \in \Omega \,|\, \forall 0 \leq i \leq m \cdot f(t_i) = s_i \wedge i < m \Rightarrow (t_{i+1} - t_i) \in I_i\}. \quad (1)$$

for all m, $s_i \in S$ and non-empty time intervals $I_0, I_1, \ldots, I_{m-1} \subset [0, B]$.

▶ **Definition 3.** *A* policy π *is a function from* $[0,B]$ *into* $\mathcal{D}$*, which is assumed to be Lebesgue measurable. Any policy gives a decision vector* $\pi_t \in \mathcal{D}$ *at time* t *such that the action* $\pi_t(s)$ *is taken when the CTMDP is at state* s *at time* t*. The set of all such polices is denoted by* Π_B*.*

Any policy π together with an initial distribution α induces the probability space $(\Omega, \mathcal{F}, \mathbf{P}^\pi_\alpha)$. If the initial distribution is chosen deterministically as $s \in S$, we denote the probability measure by $\mathbf{P}^\pi_s$ instead of $\mathbf{P}^\pi_\alpha$.

A policy $\pi : [0,B] \to \mathcal{D}$ is *piecewise constant* if there exist a number $m \in \mathbb{N}$ and time points $t_0 = 0 < t_1 < t_2 < \ldots < t_m = B$ such that $\pi_{t'} = \pi_{t''}$ for all $t', t'' \in (t_i, t_{i+1}]$ and all $i \in \{0, 1, \ldots, m-1\}$. The policy is *stationary* if $m = 1$. We denote the class of stationary policies by $\Pi_{\mathtt{st}}$; observe that a stationary policy is given by a fixed decision vector, so $\Pi_{\mathtt{st}}$ is isomorphic with the set of decision vectors $\mathcal{D}$. In particular, it is a finite set.

▶ Remark 4. The policies in Def. 3 are called *timed positional* policies since the action is selected deterministically as a function of time and the state of the CTMDP at that time. A stationary policy is only positional since the selected action is independent of time.

▶ **Problem 1.** *Consider a CTMDP* $\mathcal{M} = (\{1, \ldots, n\} \uplus \{\mathbf{good}\}, \mathcal{D}, \mathbf{Q})$ *with a distinguished absorbing state named* **good** *and a time bound* $B > 0$*. Define the event*

$$\boldsymbol{reach} := \cup\{f \in \Omega \mid f(t) = \mathbf{good} \text{ for some } t \in [0,B]\}. \tag{2}$$

The time-bounded reachability problem *asks if for a rational vector* $r \in [0,1]^n$*, we have*

$$\sup_{\pi \in \Pi_B} \mathbf{P}^\pi_s(\boldsymbol{reach}) > r(s), \qquad \text{for all } s \in \{1, \ldots, n\}.$$

The event **reach** defined in (2) is written as a union of an uncountable number of functions but it is measurable in the probability space $(\Omega, \mathcal{F}, \mathbf{P}^\pi_\alpha)$ for any α. Since the state space is finite, **reach** can be written as a countable union of cylinder sets in the form of (1) by taking all the time intervals to be $[0,B]$ and enumerating over all possible sequence of states (which is countable) [6].

A policy $\pi^* \in \Pi_B$ is *optimal* if $P^{\pi^*}_s(\mathbf{reach}) = \sup_{\pi \in \Pi_B} \mathbf{P}^\pi_s(\mathbf{reach})$. Note that there are more general classes of policies that may depend also on the history of the states in the previous time points and which map the history to a distribution over $\mathcal{D}$. It is shown that piecewise constant timed positional policies are sufficient for the optimal reachability probability [19, 22, 24]. That is, if there is an optimal policy from the larger class of policies, there is already one from the class of piecewise constant, timed, positional policies.

A closely related problem is the existence of *stationary* optimal policies; here, it is possible that the optimal stationary policy performs strictly worse than an optimal policy.

▶ **Problem 2.** *Consider a CTMDP* $\mathcal{M} = (\{1, \ldots, n\} \uplus \{\mathbf{good}\}, \mathcal{D}, \mathbf{Q})$ *and a time bound* $B > 0$*. Decide whether there is an optimal policy* π^* *that is stationary, namely*

$$\exists \pi^* \in \Pi_{\mathtt{st}} \text{ s.t. } \sup_{\pi \in \Pi_B} \mathbf{P}^\pi_s(\boldsymbol{reach}) = \mathbf{P}^{\pi^*}_s(\boldsymbol{reach}), \qquad \text{for all } s \in \{1, \ldots, n\}.$$

In the following, we shall assume that the CTMDPs and all bounds in the above decision problems are given using rational numbers. That is, rates of transitions in each generator matrix is a rational number, and the time bound B is a rational number.

▶ **Theorem 5** ([10, 19])**.** *A policy* $\pi \in \Pi_B$ *is optimal if* $\mathbf{d}_t$*, the decision vector taken by* π *at time* $B - t$*, maximizes for almost all* $t \in [0,B]$

$$\max_{\mathbf{d}_t}(\mathbf{Q}^{\mathbf{d}_t} W^\pi_t) \text{ with } \frac{d}{dt} W^\pi_t = \mathbf{Q}^{\mathbf{d}_t} W^\pi_t, \tag{3}$$

with the initial condition $W^\pi_0(\mathbf{good}) = 1$ *and* $W^\pi_0(s) = 0$ *for all* $s \in \{1, 2, \ldots, n\}$*. There exists a piecewise constant policy* π *that maximizes the equations.*

The maximization in Equation (3) above is performed element-wise. Equation (3) should be solved forward in time to construct the policy π backward in time due to the definition $\mathbf{d}_t = \pi_{B-t}$. One can alternatively write down (3) directly backward in time based on π_t.

The proof of Theorem 5 is constructive [10, 19] and is based on the following sets for any vector W:

$$\begin{aligned} &\mathcal{F}_1(W) = \{\mathbf{d} \in \mathcal{D} \,|\, \mathbf{d} \text{ maximizes } \mathbf{Q}^{\mathbf{d}} W\},\\ &\mathcal{F}_2(W) = \{\mathbf{d} \in \mathcal{F}_1(W) \,|\, \mathbf{d} \text{ maximizes } [\mathbf{Q}^{\mathbf{d}}]^2 W\},\\ &\dots\\ &\mathcal{F}_j(W) = \{\mathbf{d} \in \mathcal{F}_{j-1}(W) \,|\, \mathbf{d} \text{ maximizes } [\mathbf{Q}^{\mathbf{d}}]^j W\}. \end{aligned} \tag{4}$$

The sets $\mathcal{F}_j(W)$ form a sequence of decreasing sets such that $\mathcal{F}_1(W) \supseteq \mathcal{F}_2(W) \supseteq \ldots \supseteq \mathcal{F}_{n+2}(W) = \mathcal{F}_{n+k}(W)$ for all $k > 2$. An optimal piecewise constant policy is the one that satisfies the condition $\mathbf{d}_t \in \mathcal{F}_{n+2}(W_t^\pi)$ for all $t \in [0, B]$. Note that if $\mathcal{F}_j(W_t^\pi)$ has only one element for some j, $\mathcal{F}_k(W_t^\pi) = \mathcal{F}_j(W_t^\pi)$ for all $k \geq j$ and that element is the optimal decision vector. The next proposition shows that when $\mathcal{F}_{n+2}(W_t^\pi)$ has more than one element, we can pick any one (and in fact, switch between them arbitrarily).

▶ **Proposition 6.** *Let π be an optimal policy satisfying Equation (3). Take any t^* such that $\mathcal{F}_{n+2}(W_{t^*}^\pi) \neq \lim_{t\uparrow t^*} \mathcal{F}_{n+2}(W_t^\pi)$. If $\mathcal{F}_{n+2}(W_{t^*}^\pi) = \{\mathbf{d}^1, \mathbf{d}^2, \ldots, \mathbf{d}^p\}$ for some $p > 1$ and*

$$\Delta_i := \sup\{\delta > 0 \,|\, \mathbf{d}^i \in \mathcal{F}_{n+2}(W_t^\pi) \text{ for all } t \in [t^*, t^* + \delta)\}, \quad \forall i \in \{1, 2, \ldots, p\}$$

Then, $\Delta_1 = \Delta_2 = \cdots = \Delta_p$.
Suppose there are points δ_1, δ_2 such that $t^* \leq \delta_1 < \delta_2 < t^* + \Delta_1$ and for all $t \in [\delta_1, \delta_2)$, we have $\pi_{B-t} = \mathbf{d}$ for some $\mathbf{d} \in \mathcal{F}_{n+1}(W_{t^*}^\pi)$. If π' is a policy that agrees with π on $[0, \delta_1)$ but for all $t \in [\delta_1, \delta_2)$, we have $\pi'_{B-t} = \mathbf{d}'$ for some $\mathbf{d}' \in \mathcal{F}_{n+1}(W_{t^*}^\pi) \setminus \{\mathbf{d}\}$, then π' also satisfies Equation (3) for almost all $t \in [0, \delta_2)$.

Proof. Since $\mathcal{F}_{n+2}(W_{t^*}^\pi) = \mathcal{F}_{n+k}(W_{t^*}^\pi)$ for all $k > 2$, for any $\mathbf{d}^i$ and $\mathbf{d}^j$ belonging to the set $\mathcal{F}_{n+2}(W_{t^*}^\pi)$, we have $[\mathbf{Q}^{\mathbf{d}^i}]^l W_{t^*}^\pi = [\mathbf{Q}^{\mathbf{d}^j}]^l W_{t^*}^\pi$ for all $l \geq 0$. Pick $\delta > 0$ sufficiently small such that $\{\mathbf{d}^1, \mathbf{d}^2, \ldots, \mathbf{d}^p\} \subseteq \mathcal{F}_{n+2}(W_t^\pi)$ for all $t \in [t^*, t^* + \delta)$. If the policy π selects $\mathbf{d}^i$ for all $t \in [t^*, t^* + \delta)$, we can write

$$W_t^\pi = e^{[\mathbf{Q}^{\mathbf{d}^i}](t-t^*)} W_{t^*}^\pi \text{ for } t \in [t^*, t^* + \delta),$$

where $e^\Gamma := \sum_{k=0}^{\infty} \frac{1}{k!}\Gamma^k$ denotes the exponential of a matrix Γ. Therefore, using the fact that $[\mathbf{Q}^{\mathbf{d}^i}]^l W_{t^*}^\pi = [\mathbf{Q}^{\mathbf{d}^j}]^l W_{t^*}^\pi$ for all $l \geq 0$ we have

$$e^{[\mathbf{Q}^{\mathbf{d}^i}](t-t^*)} W_{t^*}^\pi = e^{[\mathbf{Q}^{\mathbf{d}^j}](t-t^*)} W_{t^*}^\pi, \quad \forall\, t \geq t^*. \tag{5}$$

Similarly, we have

$$[\mathbf{Q}^{\mathbf{d}^i}]^l e^{[\mathbf{Q}^{\mathbf{d}^i}]\Delta} W_{t^*}^\pi = [\mathbf{Q}^{\mathbf{d}^j}]^l e^{[\mathbf{Q}^{\mathbf{d}^j}]\Delta} W_{t^*}^\pi, \quad \forall\, l \geq 0 \text{ and } \Delta \geq 0. \tag{6}$$

Now take any $i = \arg\min_j \Delta_j$, thus $\Delta_i \leq \Delta_j$ for all j. Also take $\mathbf{d}' \in \mathcal{F}_{n+2}(W_{t^*+\Delta_i}^\pi)$ and $\mathbf{d}' \neq \mathbf{d}^i$ (this is possible due to the definition of Δ_i). Denote by h the smallest integer for which $1 \leq h \leq n+2$ and

$$[\mathbf{Q}^{\mathbf{d}'}]^h W_{t^*+\Delta_i}^\pi > [\mathbf{Q}^{\mathbf{d}^i}]^h W_{t^*+\Delta_i}^\pi \Rightarrow [\mathbf{Q}^{\mathbf{d}'}]^h e^{[\mathbf{Q}^{\mathbf{d}^i}]\Delta_i} W_{t^*}^\pi > [\mathbf{Q}^{\mathbf{d}^i}]^h e^{[\mathbf{Q}^{\mathbf{d}^i}]\Delta_i} W_{t^*}^\pi.$$

Combining the above expression with Equation (6), we get

$$[\mathbf{Q}^{\mathbf{d}'}]^h e^{[\mathbf{Q}^{\mathbf{d}^i}]\Delta_i} W_{t^*}^\pi > [\mathbf{Q}^{\mathbf{d}^j}]^h e^{[\mathbf{Q}^{\mathbf{d}^j}]\Delta_i} W_{t^*}^\pi \;\Rightarrow\; [\mathbf{Q}^{\mathbf{d}'}]^h W_{t^*+\Delta_i}^\pi > [\mathbf{Q}^{\mathbf{d}^j}]^h W_{t^*+\Delta_i}^\pi,$$

which implies that $\Delta_j \leq \Delta_i$ for any j. The particular selection of i results in $\Delta_j = \Delta_i$ for all i, j. The second part of the proposition is obtained by setting $\Delta = (\delta_2 - \delta_1)$ in Equation (6) and using the definition of the exponential of a matrix. ◀

The above proposition highlights the fact that whenever $\mathcal{F}_{n+2}(W_t^\pi)$ contains more than one decision vector over a time interval, one can construct infinitely many optimal policies by arbitrarily switching between such decision vectors. In the rest of this paper, we restrict our attention to optimal policies that take only mandatory switches: the optimal policy will take an element of $\mathcal{F}_{n+2}(W_t^\pi)$ as long as possible. This does not influence Problems 1 and 2.

The major challenge in the computation of the optimal policy, thus answering the reachability problem, is the computation of the largest time $t \in [0, B)$ such that $\mathcal{F}_{n+2}(W_t^\pi) \neq \mathcal{F}_{n+2}(W_{t^-}^\pi)$, where $W_{t^-}^\pi$ denotes the value of $W_{t-\delta}^\pi$ with δ converging to zero from the right. Suppose a decision vector $\mathbf{d}_0 \in \mathcal{F}_{n+2}(W_0^\pi)$ is selected. The optimal policy will change at the following time point:

$$t'' := \sup\{t \mid \mathbf{d}_0 \in \mathcal{F}_{n+2}(W_{t'}^\pi) \text{ for all } t' \in [0, t)\}.$$

3 Conditional Decidability of Problems 1 and 2

3.1 Schanuel's Conjecture and its Implications

Our decidability results will assume Schanuel's Conjecture for the complex numbers, a unifying conjecture in transcendental number theory (see, e.g., [14]). Recall that a *transcendence basis* of a field extension L/K is a subset $S \subseteq L$ such that S is algebraically independent over K and L is algebraic over $K(S)$. The *transcendence degree* of L/K is the (unique) cardinality of some basis.

▶ **Conjecture 7** (**Schanuel's Conjecture (SC)**). *Let $a_1, \ldots, a_n$ be complex numbers that are linearly independent over rational numbers $\mathbb{Q}$. Then the field $\mathbb{Q}(a_1, \ldots, a_n, e^{a_1}, \ldots, e^{a_n})$ has transcendence degree at least n over $\mathbb{Q}$.*

An important consequence of Schanuel's conjecture is that the theory of reals $(\mathbb{R},0,1,+,\cdot,\leq)$ remains decidable when extended with the exponential and trigonometric functions over bounded domains.[1]

▶ **Theorem 8** (Macintyre and Wilkie (see [16, 17])). *Assume **SC**. For any $n \in \mathbb{N}$, the theory $\mathbb{R}_{\mathsf{MW}} := (\mathbb{R}, \exp \restriction [0, n], \sin \restriction [0, n], \cos \restriction [0, n])$ is decidable.*

Our main result will show that Problems 1 and 2 can be decided based on Theorem 8. In fact, Problem 2 can be decided directly from Schanuel's conjecture and recent results on exponential polynomials [11].

▶ **Theorem 9** (Main Result). *Assume **SC**. Then Problems 1 and 2 are decidable.*

In contrast, solving the time-bounded reachability problem for *stationary* policies is decidable unconditionally. This is because fixing a stationary policy reduces the time-bounded reachability problem to one on CTMCs, and one can use the decision procedure from [4].

[1] We note that while the result is claimed in several papers [16, 17], a complete proof of this result has never been published. Thus, it would be nice to have a "direct" proof of our main theorem (Theorem 1) starting with Schanuel's conjecture. We do not know such a proof.

3.2 Non-tangential Zeros

Recall that the solution to a first-order linear ODE of dimension n:

$$\frac{d}{dt}X_t = AX_t, \quad z_t = CX_t$$

with real matrices A and C and real initial condition $X_0 \in \mathbb{R}^n$, can be written as $z_t = Ce^{At}X_0$ where e^Γ denotes the exponential of a square matrix Γ, and defined as the infinite sum $e^\Gamma := \sum_{k=0}^{\infty} \frac{1}{k!}\Gamma^k$ that is guaranteed to converge for any matrix Γ. The function can be expressed as an exponential polynomial $z_t = \sum_{j=1}^{k} P_t(j)e^{\lambda_j t}$, where $\lambda_1, \ldots, \lambda_k$ are the distinct (real or complex) eigenvalues of A. Each function $P_t(j)$ is a polynomial function of t possibly with complex coefficients and has a degree one less than the multiplicity of the eigenvalue λ_j. Since the eigenvalues come in conjugate pairs, we can write the real-valued function z as

$$z_t = \sum_{j=1}^{k} e^{a_j t} \sum_{l=0}^{m_j-1} c_{j,l}t^l \cos(b_j t + \varphi_{j,l}), \tag{7}$$

where the eigenvalues are $a_j \pm \mathbf{i}b_j$ with multiplicity m_j. If A, X_0, and C are over the rational numbers, then a_j, b_j, $c_{j,l}$ are real algebraic and $\varphi_{j,l}$ is such that $e^{\mathbf{i}\varphi_{j,l}}$ is algebraic for all j and l. We can symbolically compute derivatives of z which also become functions with a similar closed-form as in (7).

▶ **Definition 10.** *The function z_t has a* zero *at $t = t^*$ if $z_{t^*} = 0$. The zero is said to be* non-tangential *if there is an $\varepsilon > 0$ such that $z_{t_1}z_{t_2} < 0$ for all $t_1 \in (t^* - \varepsilon, t^*)$ and all $t_2 \in (t^*, t^* + \varepsilon)$. The zero is called* tangential *if there is an $\varepsilon > 0$ such that $z_{t_1}z_{t_2} > 0$ for all $t_1 \in (t^* - \varepsilon, t^*)$ and all $t_2 \in (t^*, t^* + \varepsilon)$.*

Note that there are functions with zeros that are neither tangential nor non-tangential. Consider the function $z_t = t\sin\left(\frac{1}{t}\right)$ for $t \neq 0$ and $z_0 = 0$. The function does not satisfy the conditions of being tangential or non-tangential. For any $\varepsilon > 0$, there are $t_1 \in (-\varepsilon, 0)$ and $t_2 \in (0, \varepsilon)$, such that $z_{t_1}z_{t_2} = t_1t_2 \sin\left(\frac{1}{t_1}\right)\sin\left(\frac{1}{t_2}\right)$ is positive. There are also t_1 and t_2 in the respective intervals that make $z_{t_1}z_{t_2}$ negative. In this paper, we only work with functions of the form (7) that are analytic thus infinitely differentiable. Therefore, the first non-zero derivative of z_t at t^* will decide if t^* is tangential or not.

▶ **Proposition 11.** *For any function z_t of the form (7) such that $z_{t^*} = 0$ and $z \not\equiv 0$, there is a k_0 such that $\frac{d^k}{dt^k}z_t\big|_{t=t^*} = 0$ for all $k < k_0$ and $\frac{d^{k_0}}{dt^{k_0}}z_t\big|_{t=t^*} \neq 0$. Moreover, t^* is tangential if k_0 is an even number and is non-tangential if k_0 is an odd number.*

Proof. The proof is based on the Taylor series of z_t at $t = t^*$. Take k_0 the order of the first non-zero derivative of z_t at $t = t^*$. This k_0 always exists since otherwise $z \equiv 0$. The Taylor series of z_t will be

$$z_t = \sum_{k=k_0}^{\infty} \frac{(t-t^*)^k}{k!}\frac{d^k}{dt^k}z_t\big|_{t=t^*} = (t-t^*)^{k_0}\frac{d^{k_0}}{dt^{k_0}}z_t\big|_{t=t^*}\sum_{k=0}^{\infty}\alpha_k(t-t^*)^k, \tag{8}$$

for some $\{\alpha_0, \alpha_1, \ldots\}$ with $\alpha_0 = \frac{1}{k_0!}$. Define the function g by $g_t := \frac{z_t}{(t-t^*)^{k_0}}$ for $t \neq t^*$ and $g_{t^*} := \frac{1}{k_0!}\frac{d^{k_0}}{dt^{k_0}}z_t\big|_{t=t^*}$. Using (8), we get that g is continuous at t^* with $g_{t^*} \neq 0$. Therefore, there is an interval $(t^* - \varepsilon, t^* + \varepsilon)$ over which the function has the same sign as g_{t^*}. For all $t_1 \in (t^* - \varepsilon, t^*)$ and $t_2 \in (t^*, t^* + \varepsilon)$

$$
\begin{aligned}
&g_{t_1} g_{t^*} > 0 \Rightarrow \frac{z_{t_1}}{(t_1 - t^*)^{k_0}} g_{t^*} > 0 \Rightarrow (-1)^{k_0} z_{t_1} g_{t^*} > 0 \\
&g_{t_2} g_{t^*} > 0 \Rightarrow \frac{z_{t_2}}{(t_2 - t^*)^{k_0}} g_{t^*} > 0 \Rightarrow z_{t_2} g_{t^*} > 0 \\
&\Rightarrow (-1)^{k_0} z_{t_1} g_{t^*} z_{t_2} g_{t^*} > 0 \Rightarrow (-1)^{k_0} z_{t_1} z_{t_2} > 0.
\end{aligned}
$$

This means $z_{t_1} z_{t_2} > 0$ for even k_0 and t^* becomes tangential, and $z_{t_1} z_{t_2} < 0$ for odd k_0 and t^* becomes non-tangential. ◀

For any function $z_t = Ce^{At}X_0$, the predicate $\mathsf{NonTangentialZero}(z, l, u)$ stating the existence of a non-tangential zero in an interval (l, u) is expressible in $\mathbb{R}_{\mathsf{MW}}$:

$$\exists t^* \,.\, l < t^* < u \wedge z_{t^*} = 0 \wedge [\exists \varepsilon > 0 \,.\, \forall t_1 \in (t^* - \varepsilon, 0), t_2 \in (0, t^* + \varepsilon) \,.\, z_{t_1} z_{t_2} < 0]$$

3.3 Switch Points are Non-Tangential Zeroes

Given a CTMDP $\mathcal{M}$ and a piecewise constant optimal policy $\pi : [0, B] \to \mathcal{D}$ for the time-bounded reachability problem, a *switch point* t^* is a point of discontinuity of π. Consider a switch point t^* such that the optimal policy takes the decision vector $\mathbf{d}$ in the time interval $(t^* - \varepsilon)$ and then switches to another decision vector $\mathbf{d}'$ at time t^* for some $\varepsilon > 0$:

$$
\begin{aligned}
&\mathbf{d} \in \mathcal{F}_{n+2}(W_t^\pi) \text{ and } \mathbf{d}' \notin \mathcal{F}_{n+2}(W_t^\pi) \quad \forall t \in (t^* - \varepsilon, t^*), \\
&\mathbf{d} \notin \mathcal{F}_{n+2}(W_t^\pi) \text{ and } \mathbf{d}' \in \mathcal{F}_{n+2}(W_t^\pi) \quad \forall t \in (t^*, t^* + \varepsilon).
\end{aligned}
$$

Consider a (not necessarily unique) state $s \in S$ with actions $a, b \in \mathcal{D}_s$ such that $a \neq b$ and $\mathbf{d}(s) = a$, $\mathbf{d}'(s) = b$. Define the following set of first-order ODEs

$$\Sigma : \begin{cases} \frac{d}{dt} W_t^\pi = \mathbf{Q^d} W_t^\pi \\ z_t = (q^a - q^b) W_t^\pi \end{cases} \tag{9}$$

for $t \in (t^* - \varepsilon, t^* + \varepsilon)$, where q^a and q^b denote the s^{th} row of the matrices $\mathbf{Q^d}$ and $\mathbf{Q^{d'}}$, respectively. The optimal decision vector on an interval before t^* is $\mathbf{d}$, thus for all $t \in (t^* - \varepsilon, t^*)$,

$$\mathbf{d} \in \mathcal{F}_1(W_t^\pi) \Rightarrow \mathbf{Q^d} W_t^\pi \geq \mathbf{Q^{d'}} W_t^\pi \Rightarrow (\mathbf{Q^d} - \mathbf{Q^{d'}}) W_t^\pi \geq 0 \Rightarrow (q^a - q^b) W_t^\pi \geq 0 \Rightarrow z_t \geq 0.$$

The next lemma states that the switch point t^* corresponds to a non-tangential zero for z_t.

▶ **Lemma 12.** *Let π be an optimal piecewise constant policy for the time-bounded reachability problem with bound B. Suppose $\pi(B - t) = \mathbf{d}_t$ for all $t \in [0, B]$. Suppose that for a time point t^*, $\mathbf{d} \in \mathcal{D}$ is an optimal decision before t^* and $\mathbf{d}' \neq \mathbf{d}$ is optimal right after t^*. There is an ε such that for any $s \in S$ with $\mathbf{d}(s) \neq \mathbf{d}'(s)$, $z_t < 0$ for all $t \in (t^*, t^* + \varepsilon)$ with z_t defined in* (9)*.*

Proof. Take k_0 to be the smallest index $k \leq n$ with $\mathbf{d} \notin \mathcal{F}_{k+1}(W_{t^*}^\pi)$ and $\mathbf{d}' \in \mathcal{F}_{k+1}(W_{t^*}^\pi)$. Since $\mathbf{d}'$ is optimal at t^*, we have $\mathbf{d}, \mathbf{d}' \in \mathcal{F}_{k+1}(W_{t^*}^\pi)$ for all $k < k_0$. We show inductively that

$$[\mathbf{Q^d}]^{k+1} W_{t^*}^\pi = [\mathbf{Q^{d'}}]^{k+1} W_{t^*}^\pi \text{ and } \frac{d^k}{dt^k} z_{t^*} = 0 \text{ for all } 0 \leq k < k_0. \tag{10}$$

The claim is true for $k = 0$:

$$\begin{aligned}
&\mathbf{d}, \mathbf{d}' \in \mathcal{F}_1(W^\pi_{t^*}) \Rightarrow \mathbf{Q}^{\mathbf{d}} W^\pi_{t^*} = \mathbf{Q}^{\mathbf{d}'} W^\pi_{t^*}\\
&\Rightarrow (\mathbf{Q}^{\mathbf{d}} - \mathbf{Q}^{\mathbf{d}'}) W^\pi_{t^*} = \begin{bmatrix} \dots \\ q^a - q^b \\ \dots \end{bmatrix} W^\pi_{t^*} = 0 \Rightarrow (q^a - q^b) W^\pi_{t^*} = 0 \Rightarrow z_{t^*} = 0.
\end{aligned}$$

Now suppose (10) holds for $(k-1)$ with $k < k_0$. Then

$$\begin{aligned}
&\mathbf{d}, \mathbf{d}' \in \mathcal{F}_{k+1}(W^\pi_{t^*}) \Rightarrow [\mathbf{Q}^{\mathbf{d}}]^{k+1} W^\pi_{t^*} = [\mathbf{Q}^{\mathbf{d}'}]^{k+1} W^\pi_{t^*}\\
&\Rightarrow \mathbf{Q}^{\mathbf{d}} [\mathbf{Q}^{\mathbf{d}}]^{k} W^\pi_{t^*} = \mathbf{Q}^{\mathbf{d}'} [\mathbf{Q}^{\mathbf{d}'}]^{k} W^\pi_{t^*} \Rightarrow^{(*)} \mathbf{Q}^{\mathbf{d}} [\mathbf{Q}^{\mathbf{d}}]^{k} W^\pi_{t^*} = \mathbf{Q}^{\mathbf{d}'} [\mathbf{Q}^{\mathbf{d}}]^{k} W^\pi_{t^*}\\
&\Rightarrow [\mathbf{Q}^{\mathbf{d}} - \mathbf{Q}^{\mathbf{d}'}] [\mathbf{Q}^{\mathbf{d}}]^{k} W^\pi_{t^*} = 0 \Rightarrow^{(**)} [\mathbf{Q}^{\mathbf{d}} - \mathbf{Q}^{\mathbf{d}'}] \frac{d^k}{dt^k} X_{t^*} = 0\\
&\Rightarrow (q^a - q^b) \frac{d^k}{dt^k} X_{t^*} = 0 \Rightarrow \frac{d^k}{dt^k} z_{t^*} = 0,
\end{aligned}$$

where $(*)$ holds due to the induction assumption and $(**)$ is true due to the differential equation (9). Finally, we show that $\frac{d^{k_0}}{dt^{k_0}} z_{t^*} < 0$.

$$\begin{aligned}
&\mathbf{d} \notin \mathcal{F}_{k_0+1}(W^\pi_{t^*}) \text{ and } \mathbf{d}' \in \mathcal{F}_{k_0+1}(W^\pi_{t^*}) \Rightarrow [\mathbf{Q}^{\mathbf{d}}]^{k_0+1} W^\pi_{t^*} < [\mathbf{Q}^{\mathbf{d}'}]^{k_0+1} W^\pi_{t^*}\\
&\Rightarrow \mathbf{Q}^{\mathbf{d}} [\mathbf{Q}^{\mathbf{d}}]^{k_0} W^\pi_{t^*} < \mathbf{Q}^{\mathbf{d}'} [\mathbf{Q}^{\mathbf{d}'}]^{k_0} W^\pi_{t^*} \Rightarrow^{(\imath)} \mathbf{Q}^{\mathbf{d}} [\mathbf{Q}^{\mathbf{d}}]^{k_0} W^\pi_{t^*} < \mathbf{Q}^{\mathbf{d}'} [\mathbf{Q}^{\mathbf{d}}]^{k_0} W^\pi_{t^*}\\
&\Rightarrow [\mathbf{Q}^{\mathbf{d}} - \mathbf{Q}^{\mathbf{d}'}] \frac{d^{k_0}}{dt^{k_0}} W^\pi_{t^*} < 0 \Rightarrow (q^a - q^b) \frac{d^{k_0}}{dt^{k_0}} W^\pi_{t^*} < 0 \Rightarrow \frac{d^{k_0}}{dt^{k_0}} z_{t^*} < 0,
\end{aligned}$$

where $(\imath)$ holds due to (10) for $k_0 - 1$.

Since $z_{t^*} = 0$, we can select ε such that $z_t > 0$ for all $t \in (t^* - \varepsilon, t^*)$. Using Taylor expansion (8) and the facts that $\frac{d^{k_0}}{dt^{k_0}} z_{t^*} < 0$ and $z_t > 0$ for $t \in (t^* - \varepsilon, t^*)$, we have that k_0 must be an odd number, which means t^* is non-tangential by Prop. 11. The function z_t changes sign from positive to negative at t^*. ◀

3.4 Conditional Decidability

The decision procedure for Problem 1 is as follows. Fix a CTMDP $\mathcal{M} = (\{1, \dots, n\} \uplus \{\mathbf{good}\}, \mathcal{D}, \mathbf{Q})$ and a bound B. We inductively construct a piecewise constant optimal policy, going forward in time. To begin, we set the initial decision vector to $\mathbf{d}^1$, where $\mathbf{d}^1$ is selected such that $\mathbf{d}^1 \in \mathcal{F}_{n+2}(W^\pi_0)$ (Equation (4)) with W^π_0 set to the indicator vector that is 1 at the **good** state and 0 in other states.

Note that in general $\mathcal{F}_{n+2}(W^\pi_t)$ in (4) may have finitely many elements and the choice of optimal decision at time t, $\mathbf{d}_t \in \mathcal{F}_{n+2}(W^\pi_t)$ is not unique. Based on results of Proposition 6, any arbitrary element of $\mathcal{F}_{n+2}(W^\pi_t)$ can be chosen; but, we do not alter this choice until the picked decision vector does not belong to $\mathcal{F}_{n+2}(W^\pi_t)$ anymore. We know that there is a piecewise constant optimal policy π with finitely many switches obtained from the charactrization in Theorem 5. Denote the (unknown) number of switches by $k \in \mathbb{N}$.

We find k as follows. We inductively check the existence of a sequence of decision vectors $\mathbf{d}^1, \dots, \mathbf{d}^k$ and time points $t_1, \dots, t_{k-1}$ such that the optimal policy (given a lexicographical order on $\mathcal{D}$) switches from $\mathbf{d}^i$ to $\mathbf{d}^{i+1}$ at time t_i but does not have any switch between the time points. Then, we check if the optimal policy makes at least one additional switch point in the interval (t_k, B). The check reduces the question to a number of satisfiability questions in $\mathbb{R}_{\mathsf{MW}}$. If we find an additional switch, we know that the optimal strategy has at least $k+1$ switches and continue to check if there are further switch points. If not, we know that the optimal policy has k switch points.

We need some notation. A *prefix* $\sigma_k = (\mathbf{d}^1, t_1, \mathbf{d}^2, t_2, \ldots, t_{k-1}, \mathbf{d}^k) \in (\mathcal{D} \times (0, B))^* \times \mathcal{D}$ is a finite sequence of decision vectors from $\mathcal{D}$ and strictly increasing time points $0 < t_1 < t_2 < \ldots < t_{k-1} < B$ such that $\mathbf{d}^i \neq \mathbf{d}^{i+1}$ for $i \in \{1, \ldots, k-1\}$. Intuitively, it represents the prefix of a piecewise constant policy with the first $k-1$ switches. For two decision vectors $\mathbf{d}, \mathbf{d}'$, let $\Delta(\mathbf{d}, \mathbf{d}') := \{s \mid \mathbf{d}(s) \neq \mathbf{d}'(s)\}$ be the states at which the actions suggested by the decision vectors differ. For a decision vector $\mathbf{d}$, let $\mathbf{d}[s \mapsto b]$ denote the decision vector that maps state s to action b but agrees with $\mathbf{d}$ otherwise.

For a prefix $\sigma_k = (\mathbf{d}^1, t_1, \mathbf{d}^2, t_2, \ldots, t_{k-1}, \mathbf{d}^k)$, a state $s \in S$, and an action $b \in \mathcal{D}_s$, define

$$y_t^{s,b}(\sigma_k) = \mathbf{u}^T(s)([\mathbf{Q}^{\mathbf{d}^k}] - [\mathbf{Q}^{\mathbf{d}^k[s \mapsto b]}])e^{[\mathbf{Q}^{\mathbf{d}^k}](t-t_{k-1})}e^{[\mathbf{Q}^{\mathbf{d}^{k-1}}](t_{k-1}-t_{k-2})} \ldots e^{[\mathbf{Q}^{\mathbf{d}^1}]t_1}\mathbf{u}(\mathbf{good}),$$

where $\mathbf{u}(s)$ is a vector of dimension $n+1$ that assigns one to s and zero to every other entry. Observe that $y_t^{s,b}(\sigma_k)$ is a solution of a set of linear ODEs similar to z_t in Equation (9):

$$\begin{cases} \frac{d}{dt}W_t = [\mathbf{Q}^{\mathbf{d}^k}]W_t \\ y_t^{s,b}(\sigma_k) = \mathbf{u}^T(s)([\mathbf{Q}^{\mathbf{d}^k}] - [\mathbf{Q}^{\mathbf{d}^k[s \mapsto b]}])W_t, \end{cases} \tag{11}$$

with the condition $W_{t_{k-1}} = e^{[\mathbf{Q}^{\mathbf{d}^{k-1}}](t_{k-1}-t_{k-2})} \ldots e^{[\mathbf{Q}^{\mathbf{d}^1}]t_1}\mathbf{u}(\mathbf{good})$.

We shall use (variants of) the predicate $\mathsf{NonTangentialZero}(y^{\cdot,\cdot}, t_1, t_2)$, but write the predicates informally for readability. We need two additional predicates $\mathsf{Switch}(\sigma_k, t^*, \mathbf{d}')$ and $\mathsf{NoSwitch}(\sigma_{k+1})$. The predicate Switch states that, given a prefix σ_k, the first switch from $\mathbf{d}^k$ to a new decision vector $\mathbf{d}'$ occurs at time point $t^* > t_{k-1}$. This new switch requires three conditions. First, there is a simultaneous non-tangential zero at t^* for all dynamical systems of the form (11) associated with $y_t^{s,\mathbf{d}'(s)}(\sigma_k)$, $s \in \Delta(\mathbf{d}^k, \mathbf{d}')$. Second, t^* is the first time after t_{k-1} that any of the dynamical systems have a non-tangential zero. Finally, none of the states in $S \setminus \Delta(\mathbf{d}^k, \mathbf{d}')$ whose action remains the same before and after the switch, have a non-tangential zero in $(t_{k-1}, t^*]$ (up to and including t^*):

$$\mathsf{Switch}(\underbrace{(\mathbf{d}^1, t_1, \ldots, t_{k-1}, \mathbf{d}^k)}_{\sigma_k}, t^*, \mathbf{d}') \equiv$$

$$0 < t_1 < \ldots < t_{k-1} < B \wedge (B > t^* > t_{k-1}) \wedge (\Delta(\mathbf{d}^k, \mathbf{d}') \neq \emptyset) \wedge$$

$$\bigwedge_{s \in \Delta(\mathbf{d}^k, \mathbf{d}')} \left(\begin{array}{c} \text{“}y_t^{s,\mathbf{d}'(s)}(\sigma_k) \text{ has a non-tangential zero at } t^*\text{”} \wedge \\ \text{“}y_t^{s,\mathbf{d}'(s)}(\sigma_k) \text{ has no non-tangential zero in } (t_{k-1}, t^*)\text{”} \end{array} \right) \wedge$$

$$\bigwedge_{s \in S \setminus \Delta(\mathbf{d}^k, \mathbf{d}')} \text{“}y_t^{s,\mathbf{d}'(s)}(\sigma_k) \text{ has no non-tangential zero in } (t_{k-1}, t^*]\text{”}$$

The predicate $\mathsf{NoSwitch}(\sigma_{k+1})$ states that, given a prefix σ_{k+1}, the last decision vector $\mathbf{d}^{k+1}$ of (σ_{k+1}) stays optimal and does not switch to another decision vector within the interval (t_k, B). This is equivalent to stating that none of the dynamical systems of the from (11) associated with $y_t^{s,b}(\sigma_{k+1})$ for $s \in S, b \in \mathcal{D}_s \setminus \mathbf{d}^{k+1}(s)$ has a non-tangential zero in (t_k, B):

$$\mathsf{NoSwitch}(\sigma_{k+1}) \equiv \bigwedge_{s, b \neq \mathbf{d}^{k+1}(s)} \text{“}y_t^{s,b}(\sigma_{k+1}) \text{ has no non-tangential zero in } (t_k, B)\text{”}$$

We can now check if the optimal strategy has exactly k switches. The first part of the predicate written below sets up a proper σ and the last conjunct states that there is no further switch after the last one.

$$\exists t_1, \ldots, t_k.(0 < t_1 < t_2 \ldots < t_k < B) \wedge \bigwedge_{i=1}^{k} \mathsf{Switch}(\underbrace{\mathbf{d}^1, t_1, \ldots, \mathbf{d}^i, t_i, \mathbf{d}^{i+1}}_{\sigma_{i+1}}) \wedge \mathsf{NoSwitch}(\sigma_{k+1}).$$

We can enumerate these formulas with increasing k over all choices of decision vectors and stop when the above formula is valid. At this point, we know that there is a piecewise constant optimal policy with k switches, which plays the decision vectors $\mathbf{d}^1, \ldots, \mathbf{d}^k$. We can make one more query to check if the probability of reaching **good** when playing this strategy is at least a given rational vector $r \in [0,1]^n$:

$$\exists t_1, \ldots, t_k.(0 < t_1 < \ldots, t_k < B) \wedge \bigwedge_{i=1}^{k} \mathsf{Switch}(\mathbf{d}^1, t_1, \ldots, \mathbf{d}^i, t_i, \mathbf{d}^{i+1}) \wedge \mathsf{NoSwitch}(\sigma_{k+1}) \\ \wedge \bigwedge_{s=1}^{n} \mathbf{u}^T(s) e^{[\mathbf{Q}^{\mathbf{d}^{k+1}}](B-t_k)} e^{[\mathbf{Q}^{\mathbf{d}^k}](t_k - t_{k-1})} \ldots e^{[\mathbf{Q}^{\mathbf{d}^1}]t_1} \mathbf{u}(\mathbf{good}) > r(s) \tag{12}$$

This completes the proof of conditional decidability of Problem 1.

Conditional Decidability for Problem 2. A stationary policy $\mathbf{d}$ is not optimal if there is a switch point. Using the Switch predicate and conditional decidability of $\mathbb{R}_{\mathsf{MW}}$, this shows conditional decidability of Problem 2.

In fact, to check the presence of a single non-tangential zero, one can avoid Theorem 8 and get a direct construction based on Schanuel's conjecture. This construction is similar to [11] and is provided in Section 5. Unfortunately, when there are multiple switch points, we have to existentially quantify over previous switch points. Thus, the techniques of [11] cannot be straightforwardly extended to find a direct conditional decision procedure for Problem 1.

We do not know if there is a numerical procedure that only uses an oracle for non-tangential zeros. The problem is that, while numerical techniques can be used to bound each non-tangential zero with rational intervals with arbitrary precision as well as compute the reachability probability to arbitrary precision, we do not know how to numerically detect whether the reachability probability in (12) is exactly equal to a given r. By the Lindemann-Weierstrass Theorem [15], we already know that for CTMDPs with stationary optimal strategies, the value of reachability probability for any rational time bound $B > 0$ is transcendental and hence $\sup_{\pi \in \Pi_B} \mathbf{P}_s^{\pi}(\mathbf{reach}) \neq r(s)$ for all $s \in S$. However, we cannot prove that the reachability probability remains irrational in the general case.

4 Lower Bound: Continuous Skolem Problem

▶ **Problem 3** (Bounded Continuous-Time Skolem Problem). *Given a linear ordinary differential equation (ODE)*

$$\frac{d^n}{dt^n} z_t + a_{n-1} \frac{d^{n-1}}{dt^{n-1}} z_t + \cdots + a_1 \frac{d}{dt} z_t + a_0 z_t = 0 \tag{13}$$

with rational initial conditions $z_0, \frac{dz_t}{dt}|_{t=0}, \ldots, \frac{d^{n-1}z_t}{dt^{n-1}}|_{t=0} \in \mathbb{Q}$ *and rational coefficients* $a_{n-1}, a_{n-2}, \ldots, a_0 \in \mathbb{Q}$ *and a time bound* $B \in \mathbb{Q}$, *the* bounded continuous Skolem problem *asks whether there exists* $0 < t^* < B$ *such that it is a non-tangential zero for* z_t. *Further, we can assume w.l.o.g. that* $z_0 = 0$ *in the initial condition.*[2]

[2] The assumption is w.l.o.g. because given a linear ODE whose solution is z_t, one can construct another linear ODE whose solution is $y_t = t z_t$. Clearly, $y_0 = 0$ and there is a non-tangential zero of z in $(0, B)$ iff there is a non-tangential zero of y in $(0, B)$.

We note that our definition is slightly different from the usual definition of the problem, e.g., in [7, 11], which simply asks for any zero (i.e., $z_{t^*} = 0$), not necessarily a non-tangential one. Our version of the bounded continuous Skolem problem is also decidable assuming **SC** [11]. However, there is no unconditional decidability result known for this problem, even though we only look for a non-tangential zero.

We can encode any given linear ODE of order n in the form of (13) into a set of n first-order linear ODE on $X : [0, B] \to \mathbb{R}^n$ with

$$\begin{cases} \frac{d}{dt}X_t = AX_t, \quad X_0 = \left[z_0, \frac{dz_t}{dt}\Big|_{t=0}, \ldots, \frac{d^{n-1}z_t}{dt^{n-1}}\Big|_{t=0}\right]^T \\ z_t = CX_t, \end{cases} \tag{14}$$

with the state matrix A and output matrix C are

$$A = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \\ -a_0 & -a_1 & -a_2 & \cdots & -a_{n-1} \end{bmatrix}, \quad C = \begin{bmatrix} 1 & 0 & \cdots & 0 \end{bmatrix}. \tag{15}$$

Using the representation (14), the solution of the linear ODE (13) can be written as $z_t = Ce^{At}X_0$. Therefore, the bounded continuous-time Skolem problem can be restated as whether the expression $Ce^{At}X_0$ has a non-tangential zero in the interval $(0, B)$.

We now reduce the bounded continuous-time Skolem problem to Problem 2. Given an instance (14)-(15) of the Skolem problem of dimension n, we shall construct a CTMDP over states $\{1, \ldots, 2n\} \cup \{\mathbf{good}, \mathbf{bad}\}$ and bound B, and just two decision vectors $\mathbf{d}^a$ and $\mathbf{d}^b$ that only differ in the available actions (a or b) at state 1. Our reduction will ensure that the answer of the Skolem problem has a non-tangential zero iff there is a switch in the optimal policy in the time-bounded reachability problem for bound B, and thus, iff stationary policies are not optimal.

▶ **Theorem 13.** *For every instance of the bounded continuous-time Skolem problem with dynamics $\frac{d}{dt}X_t = AX_t$, $z_t = CX_t$, initial condition X_0, and time bound B, there is a CTMDP $\mathcal{M}$ such that the dynamical system has a non-tangential zero in $(0, B)$ iff the optimal strategy of the CTMDP in the time-bounded reachability problem is not stationary.*

We sketch the main ideas of the proof here. Consider the linear differential equation described by the state space representation in (14) with the initial condition X_0 that has its first element equal to zero $X_0(1) = 0$. Given the time bound $B > 0$, to solve the bounded continuous Skolem problem, we are looking for the existence of a time $0 < t^* < B$ such that $z_{t^*} = 0$ is non-tangential. Equivalently, we want to find a non-tangential zero for the function $Ce^{At}X_0$, where $C = \begin{bmatrix} 1 & 0 & \cdots & 0 \end{bmatrix}$.

There are three obstacles to go from (14) to generator matrices for a CTMDP. Each generator matrix must have non-diagonal entries that are non-negative. The sum of each row of the matrix must be zero. Moreover, the last state of the CTMDP must be absorbing. None of these properties may hold for a general A. We show a series of transformations that take the matrix A to a matrix P that is sub-stochastic. Then we construct the generator matrices of the CTMDP using P that include the required absorbing state. We denote by $\mathbf{0}_\mathsf{m}$ and $\mathbf{1}_\mathsf{m}$ as row vectors of dimension m with all elements equal to zero and one, respectively.

▶ **Theorem 14.** *Suppose $A \in \mathbb{Q}^{n\times n}$, $X_0 \in \mathbb{Q}^n$ and $C = [1, \mathbf{0}_{n-1}]$ are given with $X_0(1) = 0$. There are positive constants γ, λ and a* generator *matrix $P \in \mathbb{Q}^{(2n+1)\times(2n+1)}$ such that*

$$Ce^{At}X_0 = \gamma e^{\lambda t}\left[C'e^{Pt}Y_0\right], \quad C' = [1, -1, \mathbf{0}_{2n-1}], \quad Y_0 = [\mathbf{0}_{2n}, 1]^T. \tag{16}$$

▶ Remark 15. The first equality in (16) ensures that nature of zeros of the two functions $Ce^{At}X_0$ and $C'e^{Pt}Y_0$ are the same. If one of them has a non-tangential zero at t^* the other one will also have a non-tangential zero at t^*. To see this, suppose $Ce^{At^*}X_0 = 0$ and $Ce^{At}X_0$ changes sign at t^*. The same things happen to $C'e^{Pt}Y_0$ due to the fact that the two functions are different with only a positive factor of $\gamma e^{\lambda t}$.

Without loss of generality, we assume the element A_{11} is negative. This assumption is needed when constructing the CTMDP in the sequel. If the assumption does not hold, we can always replace A with $A - \lambda_0\mathbb{I}_n$ for a sufficiently large λ_0 and merge λ_0 with λ in (16). Define the map $\phi_1 : \cup_n\mathbb{Q}^{n\times n} \to \cup_n\mathbb{Q}^{2n\times 2n}_{\geq 0}$ such that $\phi_1(A)$ is obtained by replacing each entry A_{ij} with the matrix $\begin{bmatrix}\alpha_{ij} & \beta_{ij}\\ \beta_{ij} & \alpha_{ij}\end{bmatrix}$, where $\alpha_{ij} = max(A_{ij}, 0)$ and $\beta_{ij} = max(-A_{ij}, 0)$. The map ϕ_1 maps any square matrix to another matrix with non-negative entries ([2]). Also define the map $\phi_2 : \cup_n\mathbb{Q}^n \to \cup_n\mathbb{Q}^{2n}$ such that $\phi_2(X)$ replaces each entry $X(i)$ with two entries $[X(i), 0]^T$.

▶ **Proposition 16.** *We have $C''e^{\phi_1(A)t}Y_2 = Ce^{At}X_0$ with $Y_2 := \phi_2(X_0)$ and $C'' := [1, -1, \mathbf{0}_{2n-2}]$.*

Proof. We can show inductively that for any $k \in \{0, 1, 2, \ldots\}$, $\{\alpha_1, \alpha_2, \ldots, \alpha_n\}$, and $[\beta_1, \beta_2, \ldots, \beta_n] := [\alpha_1, \alpha_2, \ldots, \alpha_n]A^k$, we have

$$[\alpha_1, -\alpha_1, \alpha_2, -\alpha_2, \ldots, \alpha_n, -\alpha_n]\phi_1(A)^k = [\beta_1, -\beta_1, \beta_2, -\beta_2, \ldots, \beta_n, -\beta_n].$$

Substitute $[\alpha_1, \alpha_2, \ldots, \alpha_n]$ by C and $[\beta_1, \beta_2, \ldots, \beta_n] = CA^k$ to get

$$C''\phi_1(A)^kY_2 = C''\phi_1(A)^k\phi_2(X_0) = [\beta_1, -\beta_1, \beta_2, -\beta_2, \ldots, \beta_n, -\beta_n]\phi_2(X_0)$$
$$= [\beta_1, \beta_2, \ldots, \beta_n]X_0 = CA^kX_0$$
$$\Rightarrow C''e^{\phi_1(A)t}Y_2 = \sum_{k=0}^{\infty}\frac{t^k}{k!}C''\phi_1(A)^kY_2 = \sum_{k=0}^{\infty}\frac{t^k}{k!}CA^kX_0 = Ce^{At}X_0.$$ ◀

Next, we define $\lambda := \max_i \sum_{j=1}^n |A_{ij}| + 1$, $P_2 := \phi_1(A) - \lambda\mathbb{I}_n$, and the vector $\boldsymbol{\beta} \in \mathbb{Q}^{2n}$ with

$$\boldsymbol{\beta}(2i-1) = \boldsymbol{\beta}(2i) = \max(0, -P_2Y_2(2i-1), -P_2Y_2(2i)) \quad 1 \leq i \leq n.$$

Note that the row sum of P_2 is at most -1 and $\boldsymbol{\beta} + P_2Y_2$ is element-wise non-negative with the maximum element

$$\gamma := \max_i P_2Y_2(i) + \boldsymbol{\beta}(i).$$

▶ **Proposition 17.** *The above choices of λ, γ and the matrix*

$$P := \begin{bmatrix} P_2 & \vdots & (P_2Y_2 + \boldsymbol{\beta})/\gamma \\ \cdots & \cdots & \cdots \\ \mathbf{0} & \vdots & 0 \end{bmatrix}$$

satisfy (16) *in Theorem 14. Moreover, P is row sub-stochastic.*

Proof. We can easily show by induction that

$$P^k Y_0 = \begin{bmatrix} P_2^{k-1}(P_2 Y_2 + \boldsymbol{\beta})/\gamma \\ 0 \end{bmatrix}, \quad \forall k \in \{1, 2, \ldots\}.$$

$$C' e^{Pt} Y_0 = \sum_{k=0}^{\infty} \frac{t^k}{k!} C' P^k Y_0 = C' Y_0 + C'' \sum_{k=1}^{\infty} \frac{t^k}{k!} P_2^{k-1}(P_2 Y_2 + \boldsymbol{\beta})/\gamma,$$

where $C'' := [1, -1, \mathbf{0}_{2n-2}]$ is the same vector as C' but the last element is eliminated.

$$C' e^{Pt} Y_0 = C' Y_0 + C'' e^{P_2 t} Y_2/\gamma - C'' Y_2/\gamma + \sum_{k=1}^{\infty} \frac{t^k}{k!} C'' P_2^{k-1} \boldsymbol{\beta}/\gamma.$$

The term $C' Y_0$ is zero by simple multiplication of the two vectors. $C'' Y_2 = C'' \phi_2(X_0) = X_0(1)$, which is also assumed to be zero. Finally, we see by induction that for all $k \in \{1, 2, \ldots\}$, the elements $(2i-1)$ and $2i$ of the matrix $P_2^{k-1}\boldsymbol{\beta}$ are equal due to the particular structure of P_2 and $\boldsymbol{\beta}$. Therefore, the last sum in the above is also zero and we get

$$\begin{aligned} C' e^{Pt} Y_0 &= C'' e^{P_2 t} Y_2/\gamma = C'' e^{\phi_1(A)t - \lambda \mathbb{I} t} \phi_2(X_0)/\gamma \\ &= C'' e^{\phi_1(A)t} \phi_2(X_0) e^{-\lambda t}/\gamma = C e^{AtX_0} e^{-\lambda t}/\gamma. \end{aligned}$$

To show that P is a sub-stochastic matrix, we recall that $P_2 Y_2 + \boldsymbol{\beta} \geq 0$ with maximum element γ. Then

$$P_2 \times \mathbf{1}_{2n} + (P_2 Y_2 + \boldsymbol{\beta})/\gamma \leq \phi_1(A)\mathbf{1}_{2n} - \lambda \mathbf{1}_{2n} + \mathbf{1}_{2n} = \phi_1(A)\mathbf{1}_{2n} - \max_i \sum_j |A_{ij}| \leq 0. \quad ◀$$

As the last step, we add an additional row and column to P to make it stochastic:

$$\mathbf{Q}^a := \begin{bmatrix} P_2 & \vdots & \Theta & \vdots & (P_2 Y_2 + \boldsymbol{\beta})/\gamma \\ \cdots & & \cdots & & \cdots \\ \mathbf{0}_{2\times 2n} & \vdots & \mathbf{0}_{2\times 1} & \vdots & \mathbf{0}_{2\times 1} \end{bmatrix}, \bar{C} = \begin{bmatrix} 1 & -1 & \mathbf{0}_{2n} \end{bmatrix}, \bar{Y}_0 = \begin{bmatrix} \mathbf{0}_{2n+1} \\ 1 \end{bmatrix},$$

where Θ has non-negative entries and is such that $\mathbf{Q}^a$ is stochastic (sum of elements of each row is zero). The added row and column correspond to an absorbing state for a CTMDP with no effect on reachability probability: $\bar{C} e^{t\mathbf{Q}^a} \bar{Y}_0 = C' e^{Pt} Y_0$.

Next, we obtain a second generator matrix for the CTMDP. Define $\mathbf{Q}^b := \mathbf{Q}^a + K$ with

$$K := \begin{bmatrix} -r & r & \mathbf{0}_{2n} \\ \mathbf{0}_{(2n+1)\times 1} & \mathbf{0}_{(2n+1)\times 1} & \mathbf{0}_{(2n+1)\times 2n} \end{bmatrix},$$

Note that $\mathbf{Q}^b$ has exactly the same transition rates as in $\mathbf{Q}^a$ except the transition from state 1 to state 2, which is changed by r.

▶ Remark 18. We assumed w.l.o.g. that A_{11} is negative. The construction of $P_2, P, \mathbf{Q}^a$ results in a positive value for $\mathbf{Q}^a_{12}$. Therefore, it is possible to select both negative and positive values for r such that $\mathbf{Q}^b_{12} = \mathbf{Q}^a_{12} + r \geq 0$.

Construction of the CTMDP. The CTMDP $\mathcal{M}$ has $2n+2$ states, corresponding to the rows of $\mathbf{Q}^a$ and $\mathbf{Q}^b$, with the absorbing state $2n+2$ associated with the **good** state and the absorbing state $2n+1$ with reachability probability equal to zero. We shall set the time bound to be B. $\mathcal{D}_s$ the set of actions that can be taken in state $s \in \{2, 3, \ldots, 2n+2\}$

is singleton and $\mathcal{D}_1 = \{a, b\}$. The set of decision vectors has two elements $\mathcal{D} = \{\mathbf{d}^a, \mathbf{d}^b\}$ corresponding to the actions a, b taken at state 1. For simplicity, we denote the generator matrices of these decision vectors by $\mathbf{Q}^a$ and $\mathbf{Q}^b$, respectively. Moreover, the two actions a, b have the same transition rates for jumping from state 1 to other states, except giving different rates r_a, r_b for jumping from 1 to 2 such that $r_b - r_a = r$.

The optimal policy π takes decision vector $\mathbf{d}_t \in \mathcal{D}$ at time $B - t$ such that $\mathbf{d}_t \in \mathcal{F}_{n+2}(W_t^\pi)$ for all $t \in [0, B]$ as defined in (4).

▶ **Proposition 19.** *Let r have the same sign of the first non-zero element of the set $\{\bar{C}\bar{Y}_0, \bar{C}\mathbf{Q}^a\bar{Y}_0, \bar{C}(\mathbf{Q}^a)^2\bar{Y}_0, \ldots\}$ and such that $\mathbf{Q}_{12}^a + r \geq 0$. This particular selection of r results in the optimality of $\mathbf{d}^a$ at $t = 0$.*

Proof. We have $W_0^\pi = \bar{Y}_0$ and $\mathcal{F}_k(W_0^\pi) = \arg\max_{\mathbf{d}}[\mathbf{Q}^{\mathbf{d}}]^k\bar{Y}_0$. Then, we need to compare $[\mathbf{Q}^a]^k\bar{Y}_0$ with $[\mathbf{Q}^b]^k\bar{Y}_0$ for different values of k and see which one gives the first highest value. These two are the same for $k = 1$ and $\mathcal{F}_1(W_0^\pi) = \arg\max_{\mathbf{d}} \mathbf{Q}^{\mathbf{d}}\bar{Y}_0 = \{\mathbf{d}^a, \mathbf{d}^b\}$. Suppose For $k_0 > 1$ is the smallest index such that $\bar{C}[\mathbf{Q}^a]^{k_0}\bar{Y}_0 \neq 0$. It can be shown inductively that $[\mathbf{Q}^b]^k\bar{Y}_0 = [\mathbf{Q}^a]^k\bar{Y}_0$ for all $1 \leq k \leq k_0$:

$$\begin{aligned}[\mathbf{Q}^b]^k\bar{Y}_0 &= \mathbf{Q}^b[\mathbf{Q}^b]^{k-1}\bar{Y}_0 = (\mathbf{Q}^a + K)[\mathbf{Q}^b]^{k-1}\bar{Y}_0 = (\mathbf{Q}^a + K)[\mathbf{Q}^a]^{k-1}\bar{Y}_0 \\ &= [\mathbf{Q}^a]^k\bar{Y}_0 + K[\mathbf{Q}^a]^{k-1}\bar{Y}_0 = [\mathbf{Q}^a]^k\bar{Y}_0 - r\begin{bmatrix}\bar{C}[\mathbf{Q}^a]^{k-1}\bar{Y}_0 \\ \mathbf{0}_{(2n+1)\times 2n}\end{bmatrix} = [\mathbf{Q}^a]^k\bar{Y}_0.\end{aligned}$$

This means $\mathcal{F}_k(W_0^\pi) = \arg\max_{\mathbf{d}}[\mathbf{Q}^{\mathbf{d}}]^k\bar{Y}_0 = \{\mathbf{d}^a, \mathbf{d}^b\}$ for all $1 \leq k \leq k_0$. We have for $k = k_0 + 1$

$$[\mathbf{Q}^b]^{k_0+1}\bar{Y}_0 = [\mathbf{Q}^a]^{k_0+1}\bar{Y}_0 - r\begin{bmatrix}\bar{C}[\mathbf{Q}^a]^{k_0}\bar{Y}_0 \\ \mathbf{0}_{(2n+1)\times 2n}.\end{bmatrix}$$

The first element of $[\mathbf{Q}^b]^{k_0+1}\bar{Y}_0$ is strictly less than the first element of $[\mathbf{Q}^a]^{k_0+1}\bar{Y}_0$ since r has the same sign as $\bar{C}[\mathbf{Q}^a]^{k_0}\bar{Y}_0$. Thus $\mathcal{F}_{k_0+1}(W_0^\pi) = \arg\max_{\mathbf{d}}[\mathbf{Q}^{\mathbf{d}}]^{k_0+1}\bar{Y}_0 = \{\mathbf{d}^a\}$. ◀

Note that the Skolem problem is trivial with the solution $z_t = 0$ for all $t \in [0, B]$ if all the elements of the set $\{\bar{C}\bar{Y}_0, \bar{C}\mathbf{Q}^a\bar{Y}_0, \bar{C}(\mathbf{Q}^a)^2\bar{Y}_0, \ldots\}$ are zero.

Prop. 19 guarantees existence of an $\varepsilon \in (0, B)$ such that W_t^π satisfies

$$\frac{d}{dt}W_t^\pi = \mathbf{Q}^a W_t^\pi \quad \forall t \in (0, \varepsilon),$$

with the initial condition $W_0^\pi(2n+2) = 1$ and $W_0^\pi(s) = 0$ for all $s \in \{1, 2, \ldots, 2n+1\}$.

To check if the optimal policy switches to $\mathbf{d}^b$ at some time point, we should check if there is $t^* < B$ such that $\mathbf{d}^b \in \mathcal{F}_{n+2}(W_{t^*}^\pi)$. This is equivalent to having t^* being non-tangential for the maximization in $\mathcal{F}_1(W_t^\pi)$, which means t^* is non-tangential for the equation

$$\mathbf{Q}^a W_t^\pi = \mathbf{Q}^b W_t^\pi \Leftrightarrow K W_t^\pi = 0 \Leftrightarrow \bar{C} W_t^\pi = 0.$$

Summarizing the above derivations, we have the following set of ODEs

$$\frac{d}{dt}W_t^\pi = \mathbf{Q}^a W_t^\pi \quad , W_0^\pi = \bar{Y}_0, \quad z_t = \bar{C} W_t^\pi. \tag{17}$$

The optimal policy for CTMDP $\mathcal{M}$ switches from $\mathbf{d}^a$ to $\mathbf{d}^b$ at some time point t^* if and only if z_t in (17) has a non-tangential zero in $(0, B)$ if and only if the original dynamics $Ce^{At}X_0$ has a non-tangential zero in $(0, B)$. This completes the proof of Theorem 13.

5 A Direct Algorithm for Problem 2

We now show a "direct" method for decidability of Problem 2 based on Schanuel's conjecture but without relying on the decidability of $\mathbb{R}_{\mathsf{MW}}$. As stated before, a switch point in a strategy corresponds to the existence of a non-tangential zero for the functions $y_t^{s,b}(\mathbf{d}^1)$ for $s \in S$ and $b \in \mathcal{D}_s \setminus \mathbf{d}^1(s)$. We know $y_t^{s,b}(\mathbf{d}^1)$ is an exponential polynomial of the form (7). Thus, deciding Problem 2 reduces to checking if an exponential polynomial of the form (7) in one free variable t has a non-tangential zero in a bounded interval. We use the following result from [11].

▶ **Theorem 20** ([11]). *Assume* ***SC****. It is decidable whether an exponential polynomial of the form* (7) *has a zero in the interval* (t_1, t_2) *with* $t_1, t_2 \in \mathbb{Q}$.

Theorem 20 decides whether a zero, not necessarily a non-tangential one, exists. We shall use the characterization of Proposition 11 to check if a non-tangential zero of $y_t := y_t^{s,b}(\mathbf{d}^1)$ exists in $(0, B)$. Define the functions

$$z_t^k = y_t^2 + \sum_{j=1}^{k} \left(\frac{d^j}{dt^j} y_t \right)^2, \quad k \in \{0, 1, 2, \ldots\}. \tag{18}$$

▶ **Theorem 21.** *Fix rational numbers* $t_1 < t_2$*. Suppose* y_t *has a zero in the interval* (t_1, t_2) *and* y_t *is not identically zero over this interval. There is* k_0 *as the smallest* k *such that* z_t^k *in* (18) *does* not *have any zero in* (t_1, t_2)*. Moreover, the zero of* y_t *in* (t_1, t_2) *is non-tangential if* k_0 *is odd and is tangential if* k_0 *is even.*

Intuitively, the above theorem states that if y_t has at least one zero in (t_1, t_2), we can check for the existence of a tangential or non-tangential zero by a finite number of applications of Theorem 20 to functions z_t^k in (18). Note that y_t may have both tangential and non-tangential zeros; Theorem 21 gives a way of identifying the type of one of the zeros (the one with the largest order).

Proof of Theorem 21. Since y_t is an exponential polynomial, so is z_t^k for all k. Thus, we can use Theorem 20 to check if z_t^k has a zero in (t_1, t_2). Note that z_t^k is the sum of squares of $\frac{d^j}{dt^j} y_t$, which means

$$z_{t^*}^k = 0 \;\Rightarrow\; y_{t^*} = \frac{dy_t}{dt}\Big|_{t=t^*} = \cdots = \frac{d^k y_t}{dt^k}\Big|_{t=t^*} = 0. \tag{19}$$

The first part of the theorem is proved by showing that if for each k, z_t^k has a zero in (t_1, t_2), then y_t is identically zero. Suppose $z_t^k = 0$ for some $t = t_k^*$ in the interval (t_1, t_2), for any $k \in \{0, 1, 2, \ldots\}$. Using (19), we get that $y_t = 0$ for all $t \in \{t_0^*, t_1^*, t_2^*, \ldots\}$. If the set $\{t_0^*, t_1^*, t_2^*, \ldots\}$ is not finite, we get that y_t is identically zero according to the identity theorem [1]. If the set of zeros is finite, there is some t^* that appears infinitely often in the sequence $(t_0^*, t_1^*, t_2^*, \ldots)$. Therefore, $z_{t^*}^k = 0$ for infinitely many indices, which means $\frac{d^k y_t}{dt^k}\big|_{t=t^*} = 0$ for all k. Having y_k as an analytic function, this again implies that y_t is identically zero.

Since y_t is not identically zero, take k_0 such that $z_t^{k_0}$ does not have a zero in (t_1, t_2) but $z_t^{k_0 - 1}$ does. Then, there is $t^* \in (t_1, t_2)$ such that y_t and all its derivatives up to order $k_0 - 1$ are zero at t^* but $\frac{d^{k_0}}{dt^{k_0}} y_t\big|_{t=t^*} \neq 0$. This t^* and k_0 satisfy the conditions of Proposition 11. Thus, t^* is a non-tangential zero for y_t if k_0 is odd and a tangential zero if k_0 is even. ◀

To check if there is a non-tangential zero in an interval $(0, B)$, we apply Theorem 21 to each zero of y_t individually. Suppose y_t has at least one zero. We can localize all zeros of y_t as follows:

1. Set $(t_1, t_2) := (0, B)$;
2. Set k_0 to be the smallest index such that z_t^k in (18) does not have any zero in (t_1, t_2);
3. If $k_0 > 0$, do the next steps:
   - Use bisection to find an interval $(t', t'') \subset (t_1, t_2)$ such that over this interval, $z_t^{k_0-1}$ has a zero and $z_t^{k_0}$ and $\frac{d^{k_0}}{dt^{k_0}} y_t$ do not have any zero;
   - Store (t', t'');
   - Repeat Steps 2-3 with $(t_1, t_2) := (t_1, t')$;
   - Repeat Steps 2-3 with $(t_1, t_2) := (t'', t_2)$.

The bisection used in the above algorithm sequentially splits the interval into two sub-intervals and picks the one that contains the zero of $z_t^{k_0-1}$. It stops when $\frac{d^{k_0}}{dt^{k_0}} y_t$ does not have any zero over the selected sub-interval. The splitting terminates after a finite number of iterations due to the fact that $\frac{d^{k_0}}{dt^{k_0}} y_t$ is a continuous function and non-zero at the zero of y_t. The whole algorithm terminates after a finite number of iterations since y_t has a finite number of zeros in $(0, B)$ (note that if y_t has infinite number of zeros in $(0, B)$, it will be identically zero according to the identity theorem [1]). The output of the algorithm is a set of intervals. Within each interval, y_t has a single zero. Applying Theorem 21 to each such interval will decide whether the zero is tangential or non-tangential.

When Is a Bottom-Up Deterministic Tree Translation Top-Down Deterministic?

Abstract

We consider two natural subclasses of deterministic top-down tree-to-tree transducers, namely, linear and uniform-copying transducers. For both classes we show that it is decidable whether the translation of a transducer *with* look-ahead can be realized by a transducer *without* look-ahead. The transducers constructed in this way, may still make use of *inspection*, i.e., have an additional tree automaton restricting the domain. We provide a second procedure which decides whether inspection can be removed and if so, constructs an equivalent transducer *without* inspection. The construction relies on a fixpoint algorithm that determines inspection requirements and on dedicated earliest normal forms for linear as well as uniform-copying transducers which can be constructed in polynomial time. As a consequence, equivalence of these transducers can be decided in polynomial time. Applying these results to deterministic bottom-up transducers, we obtain that it is decidable whether or not their translations can be realized by deterministic uniform-copying top-down transducers without look-ahead (but with inspection) – or without both look-ahead and inspection.

Category Track B: Automata, Logic, Semantics, and Theory of Programming

1 Introduction

Even though top-down and bottom-up tree transducers are well-studied formalisms that were introduced already in the 1970's (by Rounds [13] and Thatcher [14] independently, and by Thatcher [15], respectively), some fundamental questions have remained open until today. A prominent example of such a question is: can we decide for a given deterministic bottom-up tree transducer whether or not its translation can be realized by a top-down tree transducer? We answer this question affirmatively, however, for a slight restriction on the considered top-down tree transducers: they must be *uniform-copying* (*uc*). This means that all copies of the same input subtree must be processed by the same state.

It is well-known that for every deterministic bottom-up tree transducer an equivalent deterministic top-down tree transducer can be constructed which, however, makes use of regular look-ahead [7]. That transducer indeed is *uc*. The question which we ask therefore is: can regular look-ahead in *uc* transducers be eliminated? In order to answer this question, we provide a canonical earliest normal form for *uc* (as well as for linear) deterministic top-down transducers with and without look-ahead. We prove that if an earliest such transducer A can be realized by such a transducer A' *without* look-ahead (but with input inspection),

then A must be synchronizing, twinning, and erasing. To understand the *synchronizing* property, consider a transducer with look-ahead that translates an input tree of the form $a(f(t_1,t_2)))$ into the tree $\langle a,f\rangle(t_1,t_2)$, where $\langle a,f\rangle$ is a binary output symbol. Clearly this translation *can* be done by a transducer without look-ahead: it outputs nothing at the root node, keeps the node label in its state, and at its child outputs the corresponding binary symbol. Now consider that $a(f(g(t_1),t_2)))$ is translated to $\langle a,g\rangle(f(t_1,t_2))$. Such a translation can*not* be realized by a transducer without look-ahead. The information about the g-node cannot be "synchronized" at the f-node because it comes after the output must be produced (contradicting the order of origins of output nodes [12], see also [10, 11]).

The *twinning* property is similar to the string case [5] (see also [2, 3]), but now for paths. To understand the *erasing* property, consider a transducer with the following rules.

$$\begin{array}{lcllcl} q_0(a(x_1:h_e)) & \to & a(a(e)) & q_{\mathrm{id}}(a(x_1:h_f)) & \to & a(q_{\mathrm{id}}(x_1)) \\ q_0(a(x_1:h_f)) & \to & a(q_{\mathrm{id}}(x_1)) & q_{\mathrm{id}}(f) & \to & f \\ q_0(f) & \to & f & & & \end{array}$$

Here, input trees are of the form $a(\cdots a(e)\cdots)$ or $a(\cdots a(f)\cdots)$. The look-ahead automaton has two states h_e and h_f, indicating that the input tree is of the first form (e-leaf) or the second form (f-leaf). The transducer translates input trees of the first form to the fixed tree $a(a(e))$ and realizes the identity on trees of the second form. This translation can*not* be realized by a transducer without look-ahead. The *erasing* property demands that if an input path depends on two different look-ahead states h_1,h_2, where for h_1 a constant output tree is produced (viz. the tree $a(a(e))$), then for h_2 no output may be produced in any loop.

Given a *uc* transducer A with look-ahead that is synchronizing, twinning, and erasing we construct an equivalent *uc* transducer with *inspection* (if it exists), i.e., a *uc* transducer where the domain is given separately via some top-down deterministic tree automaton.

The *third highlight* of our contribution is a procedure that removes inspection (if possible). The idea here is quite different from what we have discussed until now. Let us consider an example. The domain automaton accepts trees of the form $f(t_1,t_2)$ where t_2 is an arbitrary binary tree (with internal nodes labeled f and leaves labeled a or b) and t_1 is a tree which has a left-most leaf labeled a and a right-most leaf labeled b. The transducer has this rule:

$$q_0(f(x_1,x_2)) \to f(f(b,b),q_{\mathrm{id}}(x_2)),$$

where state q_{id} realizes the identity. Does there exist an equivalent top-down tree transducer *without* inspection? As it turns out, the answer is "yes". The idea is that the output subtree $f(b,b)$ can be used to simulate inspection! These are the rules of an equivalent transducer without inspection:

$$\begin{array}{lll} q_0(f(x_1,x_2)) \to f(q(x_1),q_{\mathrm{id}}(x_2)) & q_a(f(x_1,x_2)) \to q_a(x_1) & q_b(f(x_1,x_2)) \to q_b(x_2) \\ q(f(x_1,x_2)) \to f(q_a(x_1),q_b(x_2)) & q_a(a) \to b & q_b(b) \to b \end{array}$$

We show that it is decidable for a given top-down deterministic tree language, whether or not it can be simulated on a given output tree. The challenge now is that it may be necessary to *delay* outputting certain output subtrees, until rules are encountered which require these output trees for simulating their inspection needs. Similar as before, such delay is only possible along input paths and must stop when two input subtrees of an input node are processed. Using a fixpoint algorithm we are able to determine whether or not sufficiently large output subtrees can be made available in order to satisfy all inspection needs. The approach we have sketched here is quite different from earlier methods for look-ahead removal [9] that rely on *difference bounds*, i.e., the differences in the translation with respect to different look-ahead states. In order to obtain an effective construction, however, so far a variety of technical restrictions had to be introduced – implying that even for *linear* deterministic top-down tree transducers, look-ahead removal remained an open problem. To the best of our knowledge, this paper is the first to present look-ahead removal for natural and known subclasses of top-down tree transducers.

2 Basics

Let Σ denote a ranked alphabet. Then Σ_k is the set of all symbols in Σ of rank k. As usual, we define the set $\mathcal{T}_\Sigma$ of all (finite) *trees* over Σ as the set of all strings $t = f(t_1, \ldots, t_k)$ where $f \in \Sigma_k$ for some $k \geq 0$ and $t_1, \ldots, t_k \in \mathcal{T}_\Sigma$. For convenience, we also write f for $f()$ if f is of rank 0. A subtree of that form is also called *leaf*. Let $X = \{x_i \mid i \in \mathbb{N}\}$ denote an infinite set of distinct *variables* which is disjoint from any other occurring ranked alphabet (be it the input or the output alphabet of a transducer). All elements of the set X are assumed to have rank 0. For a finite set $J \subseteq \mathbb{N}$ we denote by X_J the set of variables $\{x_j \mid j \in J\}$, and we write $\mathcal{T}_\Sigma(X_J)$ for the set of all trees t over $\Sigma \cup X_J$. E.g., $f(h(x_2), a) \in \mathcal{T}_\Sigma(\{x_2\})$ where $f \in \Sigma_2$, $h \in \Sigma_1$, and $a \in \Sigma_0$. Trees in $\mathcal{T}_\Sigma(X_J)$ are also called *patterns*. Of particular importance is the set of *unary* patterns $\mathcal{T}_\Sigma(\{x_1\}) = \mathcal{T}_\Sigma(x_1)$. This set forms a *free monoid* where the monoid operation "$\cdot$" is substitution into the variable x_1. The tree $t = f(h(x_1), g(a, h(x_1)))$, e.g., can be uniquely factored into $f(x_1, g(a, x_1))$ and $h(x_1)$. We thus write $f(h(x_1), g(a, h(x_1))) = f(x_1, g(a, x_1)) \cdot h(x_1)$. We also consider the set $\mathcal{C}_\Sigma \subseteq \mathcal{T}_\Sigma(x_1)$ of *contexts* over Σ which is the subset of unary patterns which contain exactly one occurrence of x_1. Technically, this means that each context t either is equal to x_1, or is of the form $t = f(t_1, \ldots, t_k)$ for some $f \in \Sigma_k$ for some $k \geq 1$ and $1 \leq j, j' \leq k$ so that t_j is a context and $t_{j'} \in \mathcal{T}_\Sigma$ for all $j' \neq j$.

In the following, Σ and Δ denote fixed non-empty ranked alphabets of input and output symbols, respectively. In this paper, we consider deterministic top-down tree transducers with *uniform copying*, or *uc*-transducers for short. Intuitively, *uniform copying* means that each subtree of the input is processed at most once – while the produced output may be copied arbitrarily often. This restriction is trivially met by *linear* deterministic top-down transducers – but also by those that arise from the top-down simulation of deterministic *bottom-up* transducers by means of regular look-ahead. Here, we refrain from introducing transducers with *look-ahead* and *inspection* separately, as this would result in awkward duplication of almost identical definitions. Instead, we find it convenient to introduce yet another model, namely, deterministic transducers with (unambiguous) *advice* – which later can be instantiated either with top-down deterministic inspection (no interference with the computation of the transducer, only restriction to relevant input) or bottom-up deterministic look-ahead (interference with the computation as well as restriction to relevant input).

A *finite tree automaton over* Σ, (for short, *TA*) B consists of

1. a finite set H of states,
2. a subset $F \subseteq H$ of accepting states, and a transition relation $\delta \subseteq \bigcup_{k\geq 0} H \times \Sigma_k \times H^k$.

The computation of B on some input tree t can be represented by a tree in $\mathcal{T}_T$ where the ranked alphabet T consists of all transitions $\tau = \langle h, f, h_1 \ldots h_k\rangle \in \delta$ where the rank of τ equals the rank of the input symbol f. For $h \in H$, an h-computation ϕ for some $t = f(t_1, \ldots, t_k) \in \mathcal{T}_\Sigma$ is a tree $\phi = \tau(\phi_1, \ldots, \phi_k)$ where ϕ_i is a h_i-computation for t_i for all $i = 1, \ldots, k$. We write $h : t$ to indicate that there is an h-computation for t. We write $\mathsf{dom}_B(h) = \{t \in \mathcal{T}_\Sigma \mid h : t\}$ and define the set of trees accepted by B as $\mathcal{L}(B) = \{t \in \mathcal{T}_\Sigma \mid \exists h_0 \in F \text{ such that } h_0 : t\}$. An (h, h')-computation ϕ of B on some context $t \in \mathcal{C}_\Sigma$ is analogously defined as a context in $\mathcal{C}_T$ where h is the state at the root and h' is assumed at the variable leaf. We write $(h, h') : t$ to indicate that a (h, h')-computation for t exists. In particular, $(h, h) : x_1$ for every state h of B. In general, we assume that every occurring TA B is *trim*, i.e., every transition of B occurs in some *accepting* computation, i.e., some h-computation with $h \in F$. We call B

- *bottom-up deterministic*, when for every tuple $(f, h_1 \dots h_k) \in \Sigma_k \times H^k$, there is at most one $h \in H$ so that $\langle h, f, h_1 \dots h_k\rangle \in \delta$;
- *top-down deterministic* when F consists of a single state only, and for every $k \geq 0$ and pair $(h, f) \in H \times \Sigma_k$, there is at most one tuple $(h_1 \dots h_k) \in H^k$ such that $\langle h, f, h_1 \dots h_k\rangle \in \delta$;
- *unambiguous*, if for each $t \in \mathcal{T}_\Sigma$, there is at most one $h \in F$ and at most one h-computation ϕ of B for t.

It is well-known that B is unambiguous whenever B is bottom-up deterministic, or top-down deterministic. In the following definition, we assume that the TA B is trim, unambiguous, and has a single accepting state h_0.

A *deterministic uniform-copying top-down tree transducer with advice over* Σ *and* Δ (for short, a $\mathsf{DT}^{\mathrm{A}}_{\mathrm{uc}}$ *transducer*, or *uc-transducer*, or a $\mathsf{DT}^{\mathrm{A}}_{\mathrm{uc}}$) A is a tuple (B, Q, ι, T_0, R) where

1. B is an unambiguous *advice* TA with a single final state h_0;
2. Q is a finite set of states together with a mapping $\iota : Q \to H$
3. T_0 is an axiom which is either a tree from $\mathcal{T}_\Delta$, or of the form $T_0 = p \cdot q_0(x_1)$ where $p \in \mathcal{T}_\Delta(x_1)$ with $q_0 \in Q$ and $\iota(q_0) = h_0$;
4. R is the set of rules such that for every transition $\langle h, f, h_1 \dots h_k\rangle$ of B and every state $q \in Q$ with $\iota(q) = h$, R contains one rule

$$q(f(x_1 : h_1, \dots, x_k : h_k)) \to T \tag{1}$$

where $f \in \Sigma_k$ for some $k \geq 0$, and $T = p\{x_j \mapsto q_j(x_j) \mid j \in J\}$ where $p \in T_\Delta(X_J)$ for some subset $J \subseteq \{1, \dots, k\}$ and for all $j \in J$, $q_j \in Q$ with $\iota(q_j) = h_j$ (thus $\{x_j \mapsto \dots\}$ is our notation of substituting leaves labeled x_j by the correspoding trees).

A *uc*-transducer is *linear*, if each input variable x_i occurs at most once in the right-hand side of every rule (we also say "$\mathsf{DT}^{\mathrm{A}}_{\mathrm{lin}}$ transducer").

We remark that we view the set Q of states of A as symbols of rank 1 distinct from all symbols in Δ. Given an h-computation ϕ of B on some input tree $t \in \mathcal{T}_\Sigma$, the rule (in R) at each node of t is uniquely determined by the state $q \in Q$ (with $\iota(q) = h$) at the root of t, and the transitions chosen in ϕ. Assume that $t = f(t_1, \dots, t_k)$, and $\phi = \tau(\phi_1, \dots, \phi_k)$ for $\tau = \langle h, f, h_1 \dots h_k\rangle$. A q-computation ψ of A on t with output s is given by $\rho(\sigma_1, \dots, \sigma_k)$ provided the following holds:

1. ρ is a rule of the form (1);
2. if $j \in J$, then σ_j is a q_j-computation for t_j with some output s_j and otherwise, $\sigma_j = \phi_j$;
3. $s = T\{x_j \mapsto s_j \mid j \in J\}$.

If such a q-computation for t exists with output s, we write $q : t \to s$.

As for TAs, we not only require the notion of a q-computation of A for input trees $t \in \mathcal{T}_\Sigma$ with output s, but also the notion of a (q, h)-computation of A on a context $t \in \mathcal{C}_\Sigma$ with output s. Let ϕ denote a $(\iota(q), h)$-computation of B. If $t = x_1$, then x_1 is a (q, h)-computation for x_1 with output $s = q(x_1)$ whenever $\iota(q) = h$. Assume that $t = f(t_1, \dots, t_k)$ and $t_j \in \mathcal{C}_\Sigma$ is a context, and let $\phi = \tau(\phi_1, \dots, \phi_k)$ denote the corresponding $(\iota(q), h)$-computation of B. Assume that the rule ρ is of the form (1). Then $\rho(\psi_1, \dots, \psi_k)$ is a (q, h)-computation for t with output $s = p\{x_j \mapsto s_j \mid j \in J\}$, if the following holds:

1. If $j' \notin J$, then $\psi_{j'} = \phi_{j'}$;
2. If $j' \in J \setminus \{j\}$, then $\psi_{j'}$ is a q_j-computation for $t_{j'}$ with output $s_{j'}$;
3. If $j' = j \in J$, then $\psi_{j'}$ is a (q_j, h)-computation for t_j with output s_j.

We remark that if s is non-ground, i.e., is not contained in $\mathcal{T}_\Delta$, then $s = s' \cdot q'(x_1)$ with $\iota(q') = h$. If such a (q, h)-computation exists, we write $(q, h) : t \to s$.

The *translation* of A is the partial mapping $[\![.]\!]_A : \mathcal{T}_\Sigma \to \mathcal{T}_\Delta$ defined by $[\![t]\!]_A = p_0$ if the axiom of A is the ground tree p_0 and $t \in \mathcal{L}(B)$, and $[\![t]\!]_A = p_0 \cdot s$ if the axiom is of the form $p_0 \cdot q_0(x_1)$ and $q_0 : t \to s$ holds.

Let us briefly list instances of *uc*-transducers with advice that are of interest here.

Transducers with Look-ahead. If the advice automaton B is chosen as bottom-up deterministic, the transducer A is a *uc*-transducer with regular look-ahead (for short, a $\mathsf{DT}^{\mathrm{R}}_{\mathrm{uc}}$ transducer, or a $\mathsf{DT}^{\mathrm{R}}_{\mathrm{uc}}$). We remark that the single axiom does not impose a severe restriction. Consider the generalization of a look-ahead automaton B with a non-singleton set F of accepting states and, accordingly, equip A with one dedicated axiom T_h for each accepting state $h \in F$. Instead, we may introduce a fresh unary input symbol \$ and define a new look-ahead automaton B' with a single fresh accepting state h_0 and a transducer A' with a single axiom such that $\mathcal{L}(B') = \{\$(t) \mid t \in \mathcal{L}(B)\}$ and $[\![\$(t)]\!]_{A'} = s$ holds iff $[\![t]\!]_A = s$ holds. In order to achieve that, we add to the set of transitions of B, all transitions $\langle h_0, \$, h\rangle$, $h \in F$, and likewise introduce a fresh axiom $q_0(x_1)$ for A' together with a fresh state q_0 where $\iota(q_0) = h_0$ and the rules $q_0(\$(x_1 : h)) \to T_h$ whenever $h \in F$ and T_h is the axiom of A for h.

Transducers with Inspection. If the advice automaton B is chosen as top-down deterministic, the transducer A can be considered as a *uc*-transducer with inspection automaton B (for short, a $\mathsf{DT}^{\mathrm{I}}_{\mathrm{uc}}$ transducer, or a $\mathsf{DT}^{\mathrm{I}}_{\mathrm{uc}}$). In this case, the state annotations h_i in the rule (1), can be dropped since these are obtained from $\iota(q)$ (q the current state of the transducer) and the input symbol f. A deterministic *bottom-up* tree transducer in the classical sense, e.g., as in [6] is obtained in our model as a $\mathsf{DT}^{\mathrm{A}}_{\mathrm{uc}}$ transducer where $Q = H$ and ι is the identity. A classical deterministic *top-down* tree transducer with uniform copying, on the other hand, is obtained as a $\mathsf{DT}^{\mathrm{I}}_{\mathrm{uc}}$ transducer where the inspection does not restrict the domain. This can be achieved, e.g., by setting $H = Q \cup \{\top\}$ for a fresh symbol $\top$ and $\iota(q) = q$. Moreover, for each $f \in \Sigma_k$, $\langle \top, f, \top^k\rangle \in \delta$ as well as $\langle q, f, q'_1 \dots q'_k\rangle \in \delta$ whenever there is a rule $q(f(x_1, \dots, x_k)) \to T$ such that for each $i = 1, \dots, k$, $q'_i = q_i$ if $q_i(x_i)$ occurs in T and $q'_i = \top$ otherwise.

We remark that in the same way, deterministic *linear* top-down tree transducers with look-ahead as well as deterministic linear bottom-up transducers and deterministic linear top-down transducers with inspection are instances of *linear* $\mathsf{DT}^{\mathrm{A}}_{\mathrm{uc}}$ transducers.

3 A Dedicated Earliest Normal Form for *uc*-Transducers with Advice

In this section we present the construction of earliest normal-forms for *uc*-transducers with advice. We also indicate how a corresponding construction is obtained for *linear* transducers. In the following, we fix some unambiguous TA B for advice. A construction of *earliest* top-down transducers has already been provided in [8] for top-down deterministic domain automata B and as well as in [4] for bottom-up deterministic B. Here, we are slightly more liberal by allowing *unambiguous* B to generalize both cases. The constructions from [8, 4], on the other hand, neither preserve linearity nor uniform-copying.

▶ **Example 1.** Consider a linear top-down transducer with the rules:

$$\begin{array}{lcllcl} q_0(g(x_1)) & \to & q_1(x_1) & \qquad q_0(a) & \to & a \\ q_1(f(x_1,x_2)) & \to & f(q_0(x_1), q_0(x_2)) & \qquad q_0(b) & \to & b \end{array}$$

and the axiom $q_0(x_1)$. The (canonical) earliest transducer constructed according to the methods in [8] has the same axiom $q_0(x_1)$, but the rules:

$$\begin{array}{lllllll}
q_0(g(x_1)) & \to & f(q_{11}(x_1), q_{12}(x_1)) & & q_0(a) & \to & a \\
q_{11}(f(x_1, x_2)) & \to & q_0(x_1) & & q_0(b) & \to & b \\
q_{12}(f(x_1, x_2)) & \to & q_0(x_2) & & & &
\end{array}$$

where no inspection automaton is required. The non-linearity in the first rule arises inevitably, because the output f-node is already determined at this point and therefore must be output for the transducer to be *earliest*.

We introduce *dedicated* constructions which allow to construct equivalent *canonical* transducers, but retain linearity or uniform-copying. It turns out that these normal forms can be obtained in polynomial time. Our key insight is that *dedicated* notions should be provided for the notion of *maximal common prefix* of a given set S of trees. In [8], a pattern such as $p = a(x_1, g(x_1))$ was used to represent the common part of trees in S (note that they do not use the symbol x_1, but the symbol $\top$ to denote "any tree"). This meant for an element $t \in S$ such as $t = a(b, g(c))$ that different occurrences of the symbol x_1 in p could correspond to not necessarily isomorphic subtrees of t, in the example, b and c, respectively. In that point, we will now be more restrictive and only allow *substitutions*, i.e., equal replacements of the occurrences of the single variable x_1 in patterns. For a distinction, we call such patterns *uniform.* Let us denote by $\mathcal{P}_\Delta$ the set $\mathcal{T}_\Delta \cup \mathcal{T}_\Delta(x_1) \cup \{\bot\}$ of all ground trees and unary patterns, extended with one specific element $\bot$. This set forms a *partial order* where for $t_1, t_2 \in \mathcal{P}_\Delta$, $t_1 \sqsubseteq t_2$ iff $t_1 = \bot$ or $t_1 = t_2\{x_1 \mapsto s\}$ for some $s \in \mathcal{T}_\Delta \cup \mathcal{T}_\Delta(x_1)$. In fact, $\mathcal{P}_\Delta$, partially ordered in this way, forms a *complete lattice* with finite ascending chains. In particular, the top-most element is x_1, and the binary least upper bound operation $\sqcup$ for incomparable elements $t_1, t_2 \neq \bot$, is given by $t_1 \sqcup t_2 = s$ where s is the maximal prefix such that $s\{x_1 \mapsto t'_i\} = t_i$ for suitable trees t'_i $(i = 1, 2)$.

We remark that uniform patterns may contain more than one occurrence of x_1 – all representing, though, isomorphic subtrees. Let $\mathcal{P}^{(1)}_\Delta \subseteq \mathcal{P}_\Delta$ denote the subset $\mathcal{T}_\Delta \cup \mathcal{C}_\Delta \cup \{\bot\}$ of all elements which either equal $\bot$ or contain at most one occurrence of x_1. Patterns in that set are also called *1-patterns.* For the induced partial ordering on $\mathcal{P}^{(1)}_\Delta$, we again obtain a complete lattice with finite ascending chains only. For a distinction, let us denote the least upper bound operation with respect to $\mathcal{P}^{(1)}_\Delta$ with $\sqcup^{(1)}$.

▶ **Example 2.** The difference between the two least upper bound operations becomes apparent when considering trees which differ in more than one subtree:

$$\begin{array}{lll}
f(g(a,a),c) \sqcup f(g(b,b),c) & = & f(g(x_1,x_1),c) \\
f(g(a,a),c) \sqcup^{(1)} f(g(b,b),c) & = & f(x_1,c).
\end{array}$$

On the other hand, $f(g(a,a),c) \sqcup f(g(b,b),d) = f(g(a,a),c) \sqcup^{(1)} f(g(b,b),d) = x_1$. We remark that the earliest construction in [8] would return $f(g(x_1,x_1),x_1)$ in the latter case – implying that the place holder x_1 no longer represents *isomorphic* subtrees.

For $q \in Q$, let

$$\mathsf{pref}_A(q) = \bigsqcup\{s \in \mathcal{T}_\Delta \mid \exists t \in \mathcal{T}_\Sigma.\, q : t \to s\} \text{ and } \mathsf{pref}^{(1)}_A(q) = \bigsqcup{}^{(1)}\{s \in \mathcal{T}_\Delta \mid \exists t \in \mathcal{T}_\Sigma.\, q : t \to s\}$$

In the following, we show that $\mathsf{pref}_A : Q \to \mathcal{P}_\Delta$ as the least solutions of the set $\mathcal{C}_A$ of constraints. The case of $\mathsf{pref}^{(1)}_A$ is analogous. The set $\mathcal{C}_A$ consists of one constraint $c(\rho)$ for each rule ρ of A. Assume that $\tau \equiv q(f(\ldots)) \to T$ of A where $T = p\{x_j \mapsto q_j(x_j) \mid j \in J\}$ for some $p \in \mathcal{T}_\Delta(X_J)$ and suitable $q_j \in Q$. Then the constraint $c(\tau)$ is given by

$$\sigma(q)^\sharp \quad \sqsupseteq \quad [\![T]\!]^\sharp \sigma^\sharp \tag{2}$$

where the value $[\![T]\!]^\sharp\sigma^\sharp$ returns $\bot$ if for any state $q_j, j \in J$, $\sigma^\sharp(q_j) = \bot$. Otherwise, assume that p' is obtained from p and $\sigma^\sharp$ by replacing $q_j(x_j)$ with $\sigma^\sharp(q_j) \cdot x_j$ where $j \in J$ and with $\sigma^\sharp(q_j)$ whenever $\sigma^\sharp(q_j)$ is ground. If p' is ground, we set $[\![T]\!]^\sharp\sigma^\sharp = p'$. If p' contains occurrences of x_j for a single $j \in J$, i.e., is of the form $p' = p'' \cdot x_j$ for some $p'' \in \mathcal{T}_\Delta(x_1)$, then $[\![T]\!]^\sharp\sigma^\sharp = p''$. Otherwise, i.e., if p' contains occurrences of more than one variable, then $[\![T]\!]^\sharp\sigma^\sharp = u$ where $u \in \mathcal{T}_\Delta(x_1)$ is the maximal prefix such that $p' = u \cdot p''$ for some p'' containing all x_j, i.e., u has maximal size with this property and thus is *least* with respect to the ordering on patterns.

▶ **Example 3.** Let $T = f(g(q_2(x_2), a), g(q_2(x_2), q_1(x_1))$, and thus $p = f(g(x_2, a), g(x_2, x_1))$. Then for $\sigma^\sharp = \{q_1 \mapsto a, q_2 \mapsto h(x_1)\}$, we have that $p' = f(g(h(x_2), a), g(h(x_2), a))$, and thus, $[\![T]\!]^\sharp\sigma^\sharp = f(x_1, x_1) \cdot g(x_1, a) \cdot h(x_1) = f(g(h(x_1), a), g(h(x_1), a))$.

We remark that each right-hand side of a constraint in $\mathcal{C}_A$ represents a function which is *distributive* in each argument, i.e., commutes with the binary operator $\sqcup$ in each accessed argument $\sigma^\sharp(q_j)$. Recall that any distributive function is also monotonic. Since the partial ordering on $\mathcal{P}_\Delta$ and likewise on $\mathcal{P}_\Delta^{(1)}$ are complete lattices with finite ascending chains, the constraint system (2) as well as the respective system for linear transducers and 1-patterns, has a least solution. We thus obtain:

▶ **Lemma 4.** *Let $\mathsf{pref}_A(q), q \in Q$, denote the least solution of the set of constraints* (2) *over the complete lattice $\mathcal{P}_\Delta$ ($\mathcal{P}_\Delta^{(1)}$). Then for every $a \in Q$,*

$$\mathsf{pref}_A(q) = \bigsqcup\{s \mid \exists t \in \mathcal{T}_\Sigma.\ q : t \to s\} \tag{3}$$

holds. Moreover, this least solution can be computed in polynomial time.

Proof. Recall that by our assumption, the advice automaton is trim. Therefore, according to our construction, there is a q-computation for every state $q \in Q$, i.e., $\mathsf{pref}_A(q) \neq \bot$ for each $q \in Q$. The equality in equation (3) then is due to the fixpoint transfer lemma [1]. More explicitly, let $X_q^{(i)}$ denote the ith iterate of the fixpoint iteration for the constraint system for $i \geq 0$. By induction on i, it can be verified that $X_q^{(i)}$ equals the maximal common prefix of all s such that $q : t \to s$ for trees $t \in \mathcal{T}_\Sigma$ of depth less than i. Thereby, the prefixes $X_q^{(i+1)}$ can be determined from the preixes $X_q^{(i)}$ in polynomial time. This is obvious for *linear* transducers A. When A is *uniform copying*, and general uniform patterns are used, polynomial time can be obtained when trees are represented as *dags* where isomorphic subtrees are represented only once. Since the number of iterations required for reaching the least fixpoint of the constraint system is bounded by the size of the transducer A, the overall complexity statement follows. ◀

Now let A denote some *uc*-transducer (*linear* transducer) A with advice and a non-empty set of states. In particular, the axiom of A contains an occurrence of some state q_0 (with $\iota(q_0) = h_0$). We call A an earliest *uc*-transducer (*linear* transducer), if $\mathsf{pref}_A(q) = x_1$ ($\mathsf{pref}_A^{(1)}(q) = x_1$) for all states q of A. If this is not yet the case, we construct a transducer A' of the same kind as A as follows where we only present the construction for *uc* transducers (the linear case is analogous). The set Q' of states of A' is obtained from the set Q of states of A by $Q' = \{q \in Q \mid \mathsf{pref}_A(q) \notin \mathcal{T}_\Delta\}$. Assume that the axiom T_0 of A equals $T_0 = p \cdot q_0(x_1)$. If $\mathsf{pref}_A(q_0) = s \in \mathcal{T}_\Delta$, then the axiom T_0' of A' is given by $T_0' = p \cdot s$. Otherwise, the new axiom T_0' is given by $T_0' = p \cdot \mathsf{pref}_A(q_0) \cdot q_0(x_1)$. Now assume that $q \in Q'$, and $\mathsf{pref}_A(q) = u$. Then for each rule $q(f(x_1 : h_1, \ldots, x_k : h_k)) \to p\{x_j \mapsto q_j(x_j) \mid j \in J\}$ of A, A' has a rule $q(f(x_1 : h_1, \ldots, x_k : h_k) \to T'$ where T' is defined as follows. For $j \in J$, let $s_j = \mathsf{pref}_A(q_j)$ if $\mathsf{pref}_A(q_j) \in \mathcal{T}_\Delta$, and $s_j = u_j \cdot q_j(x_j)$ if $\mathsf{pref}_A(q_j) = u_j \in \mathcal{T}_\Delta(x_1)$. Then u must be a prefix of $p\{x_j \mapsto s_j \mid j \in J\}$, and we choose T' such that $p\{x_j \mapsto s_j \mid j \in J\} = u \cdot T'$ holds.

▶ **Lemma 5.** *Assume that A is a DT^A_{uc} and A' the DT^A_{uc} as constructed above. Then,*

1. *For each state q of A' with $u = \mathsf{pref}_A(q)$, it holds that*
   - **a.** *If $q : t \to s$ holds for A, then $q : t \to s'$ holds for A' for some $s' \in \mathcal{T}_\Delta$ so that $s = u \cdot s'$, and vice versa,*
   - **b.** *If $q : t \to s'$ holds for A', then $q : t \to u \cdot s'$ holds for A.*
   - **c.** *A and A' are equivalent where $\mathsf{pref}_{A'}(q) = x_1$ holds for all states q of A'.*
2. *A' can be constructed from A in polynomial time.*

The analogous properties hold for DT^A_{lin} transducers.

Due to this lemma, we obtain that for each *uc*-transducer (*linear* transducer) an equivalent earliest transducer can be constructed in polynomial time. In fact that transducer can further be *minimized*. For that, we define $\equiv$ as the coarsest equivalence relation on states such that $q \equiv q'$ implies that $\iota(q) = \iota(q')$, and for each input symbol $f \in \Sigma$ there is a rule $q(f(x_1 : h_1, \ldots, x_k : h_k)) \to T$ iff there is a rule $q'(f(x_1 : h_1, \ldots, x_k : h_k)) \to T'$ such that $T = p\{x_j \mapsto q_j(x_j) \mid j \in J\}$ and $T' = p\{x_j \mapsto q'_j(x_j) \mid x_j \in X_J\}$ for some common pattern $p \in \mathcal{T}_\Delta(X_J)$ and states $q_j, q'_j \in Q$ such that for all $j \in J$, $q_j \equiv q'_j$ holds.

▶ **Lemma 6.** *Let A be an earliest* uc*-transducer (*linear *transducer) and $\equiv$ the equivalence relation as defined above. Then the following holds:*

1. *$q \equiv q'$ iff for all $[\![q]\!]_A = [\![q']\!]_A$;*
2. *$\equiv$ can be constructed in polynomial time.*

The proof of Lemma 6 follows closely the corresponding proof of Theorem 13 of [8]. Putting Lemmas 5 and 6 together, we obtain:

▶ **Theorem 7.** *For each DT^A_{uc} (DT^A_{lin}) transducer A, a unique canonical earliest DT^A_{uc} (DT^A_{lin}) transducer A' can be constructed such that (1) A' has at most as many states as A, (2) A' is equivalent to A, and (3) A' can be constructed in polynomial time.*

4 How to Remove Look-ahead

In the following, we assume that we are given a deterministic top-down tree transducer A with regular look-ahead. By Theorem 7, we may assume that A is earliest. Our goal is to decide whether the translation of A can be realized by a deterministic top-down tree transducer *without* look-ahead (but with inspection). A necessary condition for the latter is that the domain of the given translation can be accepted by a top-down deterministic automaton. By assumption, the domain of the translation of A is given by the set $\mathcal{L}(B)$ of all trees accepted by B. If the translation can be realized by a *uc*-transducer with inspection only, $\mathcal{L}(B) = \mathcal{L}(B')$ for some top-down deterministic automaton B'. One such B' can be obtained by means of the *powerset* construction. The set H' of states of B' are subsets of states of B where in particular, $\{h_0\} \in H'$ is the accepting state. Moreover, if $S \subseteq H$ is a state in H', then for every input symbol $f \in \Sigma_k$ and every $j \in \{1, \ldots, k\}$,

$$S_j = \{h_j \in H \mid \exists h \in S,\ h_1, \ldots, h_{j-1}, h_{j+1}, \ldots, h_k \in H.\, \langle h, f, h_1 \ldots h_k\rangle \in \delta\} \ \in\ H'$$

and $\langle S, f, S_1 \ldots S_k\rangle$ is in the transition relation of B'. As B is assumed to be trim, the automaton B' constructed in this way, is trim as well. Checking whether or not $\mathcal{L}(B) = \mathcal{L}(B')$ is decidable. In fact, the two automata are equivalent iff for each transition $\langle S, f, S_1 \ldots S_k\rangle$ constructed for B', and every tuple of states $(h_1, \ldots, h_k) \in S_1 \times \ldots \times S_k$ there is some $h \in S$ such that $\langle h, f, h_1 \ldots h_k\rangle$ is a transition of B.

Let us thus assume that B and B' are equivalent. The following construction is given for uniform copying transducers (the construction for linear transducers is analogous). Let us assume that the earliest $\mathsf{DT}^{\mathrm{R}}_{\mathrm{uc}}$ transducer A is canonical and equivalent to a $\mathsf{DT}^{\mathrm{I}}_{\mathrm{uc}}$ transducer. As the case where the axiom T_0 of A is ground, is trivial, we now assume that the axiom is non-ground, i.e., $T_0 = s_0 \cdot q_0(x_1)$ with $\iota(q_0) = h_0$. Then we construct a $\mathsf{DT}^{\mathrm{I}}_{\mathrm{uc}}$ transducer A' as follows. The states of A' are given by $\langle\rho\rangle$ for mappings ρ which assign to the states h in some set $S \in H'$, trees $\rho(h)$ which are either in $\mathcal{T}_\Delta$ or of the form $\rho(h) = s \cdot q(x_1)$ where $s \in \mathcal{T}_\Delta(x_1)$ and $q \in Q$ is a state of A with $\iota(q) = h$. For that mapping ρ, we define $\iota'(\langle\rho\rangle) = S$. The axiom of A' is given by $T'_0 = s_0 \cdot \langle\{h_0 \mapsto q_0(x_1)\}\rangle$.

Assume now that $\langle\rho\rangle$ is a state of A' with domain S. Consider some input symbol $f \in \Sigma$ of rank $k \geq 0$ where $\langle S, f, S_1 \ldots S_k\rangle$ is a transition of B'. Let p' denote a pattern in $\mathcal{T}_\Delta(X_{J'})$ for some $J' \subseteq \{1, \ldots, k\}$. Let ρ_i, $i = 1, \ldots, k$ be mappings with domains S_i such that for $h \in S$ and $\langle h, f, h_1 \ldots h_k\rangle \in \delta$,

1. If $\rho(h) \in \mathcal{T}_\Delta$, then $h_j \in S_j$ for all $j \in \{1, \ldots, k\}$, and $\rho(h) = p'\{x_j \mapsto \rho_j(h_j) \mid j \in J'\}$;
2. If $\rho(h) = s \cdot q(x_1)$, and A has a rule of the form (1), then $J \subseteq J'$ and $s \cdot p = p'\{x_j \mapsto u_j \mid j \in J'\}$ where $u_j = \rho_j(h_j)$ if $\rho_j(h_j)$ is ground, and $u_j = \rho_j(h_j) \cdot x_j$ otherwise.
3. For each $j \in J'$, the mapping ρ_j is (up to states in Q) prefix-free, i.e., the longest common prefix of $\rho_j(h), h \in S_j$, in $\mathcal{T}_\Delta(x_1)$ is x_1.

If A is equivalent to some $\mathsf{DT}_{\mathrm{uc}}$ transducer, p' and ρ_j with these properties must always exist, and then are uniquely defined.

▶ **Example 8.** Assume that $\rho = \{h_1 \mapsto f(a, g(c)), h_2 \mapsto f(b, g(c)), h_3 \mapsto f(a, b), h_4 \mapsto f(b, b), h_5 \mapsto c\}$ and for the binary input symbol f, B has the transitions $\langle h_1, f, h_a h_c\rangle, \langle h_2, f, h_b h_c\rangle, \langle h_3, f, h_a h_b\rangle, \langle h_4, f, h_b h_b\rangle$ while there is no transition for f resulting in state h_5. By comparing the outputs for h_1 and h_2, we identify the subtrees a and b whose outputs cannot be decided depending on the input symbol f alone, but require information about the first child of f. Likewise, by comparing the outputs for h_3 and h_4, we identify the corresponding subtrees $g(a)$ and b whose outputs can be discriminated only depending on the second child of f in the input. Accordingly, the pattern is given by $p' = f(x_1, x_2)$ where $\rho_1 = \{h_a \mapsto a, h_b \mapsto b\}$ and $\rho_2 = \{h_c \mapsto g(c), h_b \mapsto b\}$.

Example 8 illustrates the perhaps most complicated case, namely, when all outputs stored in ρ are ground. Given that J', p' and $\rho_j, j \in J'$, with the given properties exist, we add to A' the states $\langle\rho_j\rangle, j \in J'$, together with the rule

$$\langle\rho\rangle(f(x_1 : S_1, \ldots, x_k : S_k)) \to p'\{x_j \mapsto \langle\rho_j\rangle(x_j) \mid j \in J'\}. \tag{4}$$

The resulting transducer is a $\mathsf{DT}^{\mathrm{I}}_{\mathrm{uc}}$ transducer A' which is equivalent to A. Now assume that the construction successfully terminates. The following two lemmas summarize the properties of the resulting transducer A'.

▶ **Lemma 9.** *Consider a state $\langle\rho\rangle$ of A' for some mapping ρ with domain S, $h \in S$ and $t \in \mathcal{T}_\Sigma$ with $h : t$.*

1. *If $\rho(h) = u$ is ground, then $\langle\rho\rangle : t \to u$;*
2. *If $\rho(h) = u \cdot q(x_1)$ for some $u \in \mathcal{T}_\Delta(x_1)$, and $q : t \to s$, then $\langle\rho\rangle : t \to u \cdot s$.*

▶ **Lemma 10.** *Assume that $t \in \mathcal{C}_\Sigma$ is a context where $(S_0, S) : t$ holds in B' for $S_0 = \{h_0\}$.*

1. *$S = \{h \in H \mid \exists s_h. (q_0, h) : t \to s_h\}$, i.e., S is the set of all h such that there is a (q_0, h)-computation of A for t;*
2. *Assume that for each $h \in S$, $(q_0, h) : t \to s_h$. Then $(\langle\rho_0\rangle, S) : t \to s$ for $\rho_0 = \{h_0 \mapsto q_0(x_1)\}$ so that the following holds:*

- *If s is ground, then s_h is ground for each $h \in S$, and $s = s_h$ holds for each $h \in S$;*
- *If $s = s' \cdot \langle\rho\rangle(x_1)$, then ρ is a mapping with domain S, and for each $h \in S$,*
  - *$\rho(h)$ is ground iff s_h is ground where $s' \cdot \rho(h) = s_h$.*
  - *If $\rho(h) = u_h \cdot q(x_1)$ for some u_h, then $s' \cdot u_h \cdot q(x_1) = s_h$.*

The proof of these two lemmas is by induction on the structure of t, following the definition of A'. We conclude that, upon successful termination, A and A' are equivalent. It thus suffices to prove successful termination whenever A is equivalent to *some* DT_{uc} transducer.

We introduce three properties. The $\mathsf{DT}^{\text{R}}_{\text{uc}}$ transducer A is called *synchronizing*, if for every input tree $t_0 \in \mathcal{C}_\Sigma$, input symbol $f \in \Sigma$ of rank $k \geq 0$ and look-ahead states h'_1, h'_2 so that $(q_0, h_i) : t \to s_i \cdot q_i(x_1)$ for $i = 1, 2$, the following holds. Let $q_i(f(x_1 : h_{i,1}, \ldots, x_k : h_{i,k})) \to T_i$ be rules of A according to (1) where both T_1 and T_2 are non-ground. Then one of the following two cases occurs.

Case 1. There are patterns $p_1, p_2 \in \mathcal{T}_\Delta(X_J)$ which agree in their sets of occurring variables, and factorizations $T_i = p_i\{x_j \mapsto u_{i,j} \mid j \in J\}$ for $i = 1, 2$ such that

- $s_1 \cdot p_1 = s_2 \cdot p_2$,
- for each $j \in J$, each $u_{i,j}$ is either ground, or is of the form $s' \cdot q'(x_j)$ for suitable s', q'.

Case 2. There is some j such that both $T_1 = s'_1 \cdot q'_1(x_j)$ and $T_2 = s'_2 \cdot q'_2(x_j)$ for suitable $s'_1, s'_2 \in \mathcal{T}_\Delta(x_1)$ and states $q'_1, q'_2 \in Q$.

Secondly, the $\mathsf{DT}^{\text{R}}_{\text{uc}}$ transducer A is called *twinning*, if the following holds for all states q_1, q_2 and contexts $t, t' \in \mathcal{C}_\Sigma$ such that $(q_0, \iota(q_i)) : t \to s_i \cdot q_i(x_1)$ and $(q_i, \iota(q_i)) : t' \to s'_i \cdot q_i(x_1)$.

- Either $s'_1 = s'_2 = x_1$,
- or there are trees $u, v \in \mathcal{T}_\Delta(x_1)$ such that $s_1 = s_2 \cdot w$, $s'_1 = v \cdot w$ and $s'_2 = w \cdot v$ or vice versa, $s_2 = s_1 \cdot w$, $s'_2 = v \cdot w$ and $s'_1 = w \cdot v$ for suitable $w, v \in \mathcal{T}_\Delta(x_1)$.

Finally, the $\mathsf{DT}^{\text{R}}_{\text{uc}}$ transducer A is called *erasing*, if the following holds for all input trees $t, t' \in \mathcal{C}_\Sigma$ and states $h_1, h_2 \in H$. Assume that $(q_0, h_i) : t \to s_i$ for $i = 1, 2$ where s_1 is of the form $s'_1 \cdot q(x_1)$ (thus, $\iota(q) = h_1$) and s_2 is ground. Then $(q, h_1) : t' \to u \cdot q(x_1)$ for some $u \in \mathcal{T}_\Delta(x_1)$ and $(h_2, h_2) : t'$ implies that $u = x_1$.

The *variation* $\|t_1, t_2\|$ of $t_1, t_2 \in \mathcal{T}_\Delta(x_1)$ is the minimal depth of u_1, u_2 such that $t_i = t_0 \cdot u_i, i = 1, 2$ for a $t_0 \in \mathcal{T}_\Delta(x_1)$. The $\mathsf{DT}^{\text{R}}_{\text{uc}}$ transducer A has *bounded variation* if $\exists K \geq 0$ such that for every $t \in \mathcal{C}_\Sigma$ and $h_1, h_2 \in H$ with $(q_0, h_i) : t \to s_i$ for $i = 1, 2$, $\|s'_1, s'_2\| \leq K$ holds. – Assume that A is synchronizing, erasing and twinning. Then the outputs of any two computations for the same input tree, cannot not differ much. Intuitively, the variation is synchronized at branching rules, does not increase in monadic loops and may increase only marginally once one of the outputs is ground. Let us define the *size* $|A|$ of some $\mathsf{DT}^{\text{A}}_{\text{uc}}$ A as the sum of the sizes of all rules of A where the size of the rule (1) is $k + 1$ plus the number on nodes in the right-hand side. Altogether, we prove:

▶ **Lemma 11.** *Assume that the domain of A is top-down deterministic where the bottom-up deterministic look-ahead automaton B has $m \geq 1$ states.*

1. *If A is equivalent to some DT^{I}_{uc} A', then A is synchronizing, erasing and twinning.*
2. *If the DT^{R}_{uc} A is synchronizing, erasing and twinning, then A has bounded variation where the bound is given by $|A| \cdot (|A| + m)$.*

Proof. The proof that A then must be twinning follows along the same lines as for word transducers. Here, we only consider synchronization. Assume that A is equivalent to some $\mathsf{DT}^{\text{I}}_{\text{uc}}$ A', and $(\{h_0\}, S) : t$ for some $t \in \mathcal{C}_\Sigma$ and state S of B'. Then $(\bar{q}, S) : t \to s_0 \cdot \bar{q}(x_1)$ holds for the initial state $\bar{q}_0$ of A' and some state $\bar{q}$ of A' where $\iota(\bar{q}_0) = \{h_0\}$ and $\iota(\bar{q}) = S$. Assume that there is a transition $\bar{q}(f(\ldots)) \to T$ of A'. Consider any $h \in S$ so that $\langle h, f, h_1 \ldots h_k\rangle$ is a transition of B, and assume that $(q_0, h) : t_0 \to s \cdot q(x_1)$ for some $s \in \mathcal{T}_\Delta(x_1)$. Since A is assumed to be earliest, we have that $s_0 \cdot u_0 = s$ for some $u_0 \in \mathcal{T}_\Delta(x_1)$. Moreover, there is a rule $q(f(x_1 : h_1, \ldots, x_k : h_k)) \to T'$ of A for f. We consider three cases.

1. T is ground. Then T' is ground with $s_0 \cdot T = s \cdot T' = s_0 \cdot u_0 \cdot T'$. Consequently by top-cancellation, $T = u_0 \cdot T'$ holds.
2. T contains occurrences of a single variable x_j only, i.e., is of the form $p \cdot \bar{q}'(x_j)$ for some state $\bar{q}'$ of A'. If T' is ground, then $s_0 \cdot p \cdot v = s \cdot T' = s_0 \cdot u \cdot T'$ for some $v \in \mathcal{T}_\Delta$, i.e., $p \cdot v = u_0 \cdot T'$. If T' in non-ground, it necessarily is of the form $T' = p' \cdot q'(x_j)$ where (again by top-cancellation) $p \cdot u' = u_0 \cdot p'$ holds for some $u' \in \mathcal{T}_\Delta(x_1)$.
3. T contains occurrences of variables $x_{j_1} \neq x_{j_2}$. Let J denote the set of indices j so that x_j occurs in T. Then $T = u_0 \cdot p\{x_j \mapsto \bar{q}_j(x_j) \mid j \in J\}$ holds for some $p \in \mathcal{T}_\Delta(X_J)$ so that $T' = p\{x_j \mapsto u_j \mid j \in J\}$ for some u_j which are either ground or of the form $s_j \cdot q_j(x_j)$ with $q_j \in Q$.

Now assume that we have $(q_0, h_i) : t_0 \to s_i \cdot q_i(x_1)$, and let $(\bar{q}_0, S) : t \to s_0 \cdot \bar{q}(x_1)$ denote the corresponding computation of the $\mathsf{DT}^{\mathrm{I}}_{\mathrm{uc}}$ A'. In particular, this means that $h_1, h_2 \in S$, and we can apply the observations listed above. Let $q_i(f_i(x_1 : h_{i,1}, \ldots, x_k : h_{i,k}) \to T_i, i = 1, 2$, be rules of A for q_i and f such that T_1, T_2 are both non-ground. Then there also must be a rule $\bar{q}(f(\ldots)) \to T$ of A' where T is not ground as well, i.e., the first of the three cases does not apply. Now, assume that the monadic second case of the synchronization property also does not apply. Then T contains at least two variables, and there are factorizations $T = u_i \cdot p_i$ for $i = 1, 2$ so that $T_i = p_i\tau_i$ for substitutions of τ_i mapping each x_j to some ground tree or expression $s_{i,j} \cdot q_{i,j}(x_j)$ where $s_i = s_0 \cdot u_i$. We conclude that

$$s_1 \cdot p_1 = s_0 \cdot u_1 \cdot p_1 = s_0 \cdot u_2 \cdot p_2 = s_2 \cdot p_2$$

holds. Finally, consider some j where $h_{1,j} = h_{2,j} = h'$ for some h'. Assume for a contradiction that $\tau_1(h') \neq \tau_2(h')$, and consider any input tree t' so that $h' : t'$. Since $h_1 \neq h_2$ holds, some $j' \neq j$ exists so that $h_{1,j'} \neq h_{2,j'}$ holds. In particular, this means that the right-hand side T of ρ for f contains an occurrence of $\bar{q}'(x_j)$ for some state $\bar{q}'$ of A'. Then $\bar{q}' : t' \to s'$ for some ground tree s'. If $\tau_i(h) = v_i \cdot q'_i(x_j)$ for states q'_i of A, then $q'_i : t' \to s'_i$ with $s' = v_i \cdot s'_i$. Now since A is earliest, it follows that $v_1 = v_2$ must hold while q'_1 and q'_2 are equivalent, as their outputs coincide for each input. Since A is canonical, this further means that $q'_1 = q'_2$. Likewise, if $\tau_1(h') = s'_1$ is ground, then necessarily $\tau_2(h')$ also must be ground and coincide. Thus, the synchronization property follows.

It remains to prove the second assertion of lemma, namely, that every $\mathsf{DT}^{\mathrm{R}}_{\mathrm{uc}}$ A which is synchronizing, erasing and twinning, has a variation bounded by $|A| \cdot (|A| + m)$. Let B' denote the top-down deterministic automaton accepting the domain of A, and assume for a contradiction that $t \in \mathcal{C}_\Sigma$ is a context with a minimal number of nodes violating the claim of the lemma. Let S denote the state of B' such that $(\{h_0\}, S) : t$ holds. For $h_1, h_2 \in S$, assume that $(h_f, h_\nu) : t \to s_\nu$, $\nu = 1, 2$, holds for A. Assume that $t = t_1 \cdot \ldots \cdot t_m$ where $t_i = f_i(u_{i,1}, \ldots, u_{i,j_i-1}, x_1, u_{i,j_i+1}, \ldots, u_{i,k_i})$ for some some $1 \leq j_i \leq k_i$, some $f_i \in \Sigma_{k_i}$ and ground trees $u_{i,j'}, j' \neq j_i$. Let $h_{i,0}, \ldots, h_{i,m}$ states of B so that $(h_{i-1}, h_i) : t_i$ holds for $i = 1, \ldots, m$. Clearly, if $m = 0$, $s_1 = s_2 = x_1$ and the assertion holds. First, we consider the case that there is a maximal $m' \leq m$ where $(q_0, h'_m) : t_1 \ldots t_{m'-1} \to s'_i \cdot q_i(x_0)$ holds such that $(q_i, h_{i,m'}) : p_i\tau_i$ for some $p_1, p_2 \in \mathcal{T}_\Delta(X_J)$ and substitutions τ_i, where

- $s'_1 \cdot p_1 = s'_2 \cdot p_2$;
- $\tau_1(x_{j'}) = \tau_2(x_j) \in \mathcal{T}_\Delta$ for $j' \neq j_{m'}$;
- $\tau_i(x_{j_{m'}})$ is of the form $v'_i \cdot q'_i(x_1)$ where $v'_i \cdot q'_i(x_{j_{m'}})$ is a subtree of some right-hand side of A.

If $m' = m$, then obviously, the claim of the lemma holds. Therefore, either there is no such m' or $m' < m$. Assume that u is obtained from p_1 by substituting x_j with $\tau_1(x_j)$ for all $j \neq j_{m'}$. Thus, $s' = s'_1 \cdot u$ is a common prefix of s_1 and s_2. In case that the properties above are never satisfied, we set $m' = 0$, $s' = x_1$, and let $v'_i \cdot q'_i(x_1)$ equal $q_i(x_1)$.

Assume that $m'' \geq m'$ is chosen maximal so that $(q'_i, h_{i,m''}) : t_{m'+1} \dots t_{m''} \to s''_i \cdot q''_i(x_i)$, i.e., both outputs are non-ground. The variation for the context $t_1 \cdot \ldots \cdot t_{m''}$ then is given by $\|v'_1 \cdot s''_1 \cdot q''_1(x_1), v'_2 \cdot s''_2 \cdot q''_2(x_1)\|$. We claim that this variation is bounded by $|A|^2$. Assume for a contradiction that this were not the case. Then due to the synchronization property and the choice of m', this implies that $m'' - m' > n^2$ where n is the number of states of A. Therefore, at least one pair of states occurs at least twice. But then, due to the twinning property, the same variation is attained with a smaller context – contradicting the minimality of t.

To continue with our argument, we conclude that m'' must be less than m. By the definition of m'' this means that one of the right-hand sides chosen for q''_i and $f_{m''+1}$ must be ground. W.l.o.g., assume that this is the right-hand side T_1 for q''_1. But then due to the erasing property, the depth of the output for $t_{m''+1} \cdot \ldots \cdot t_m$ is bounded by $|A| \cdot m$. Altogether therefore, the variation is bounded by $|A|^2 + |A| \cdot m = |A| \cdot (|A| + m)$ – in contradiction to our assumption. This concludes the proof. ◀

In summary, we obtain:

▶ **Theorem 12.** *Let A be a DT^R_{uc}. It is decidable whether or not the translation of A can be realized by a DT^I_{uc}, and if so an equivalent DT^I_{uc} A' can be constructed.*

A corresponding theorem also holds for $\mathsf{DT}^{\mathrm{R}}_{\mathrm{lin}}$ transducers.

5 How to Inspect Top-Down Deterministic Languages

Now consider a $\mathsf{DT}^{\mathrm{I}}_{\mathrm{uc}}$ A with underlying top-down deterministic automaton B which is assumed to be canonical earliest. For the following, we denote the unique state h of B with $\mathsf{dom}_B(h) = \mathcal{T}_\Sigma$ (given that there is such a state), by $\top$. The $\mathsf{DT}^{\mathrm{I}}_{\mathrm{uc}}$ ($\mathsf{DT}^{\mathrm{I}}_{\mathrm{lin}}$) A is *without inspection* (denoted by $\mathsf{DT}_{\mathrm{uc}}$ and $\mathsf{DT}_{\mathrm{lin}}$) if for every rule $q(f(x_1 : h_1, \dots, x_k : h_k) \to T$ of A, $h_j = \top$ whenever x_j does not occur in T. When B does not have a state $\top$, then A is without inspection only if the right-hand side of every rule of A contains all variables x_j occurring in its left-hand side, i.e., A is *non-deleting*. Note that a $\mathsf{DT}_{\mathrm{uc}}$ can easily be changed in such a way that no advice automaton is present at all (and still the same translation is realized).

Consider a fixed output tree $s \in \mathcal{T}_\Delta$. A language $L \subseteq \mathcal{T}_\Sigma$ is called $\mathsf{DT}_{\mathrm{uc}}$ ($\mathsf{DT}_{\mathrm{lin}}$) *output recognizable by* s iff there is a $\mathsf{DT}_{\mathrm{uc}}$ ($\mathsf{DT}_{\mathrm{lin}}$) A such that $[\![t]\!]_A$ is defined iff $t \in L$, where $[\![t]\!]_A = s$ for all $t \in L$. It turns out that a language is output recognizable via some $\mathsf{DT}_{\mathrm{uc}}$ iff it is output recognizable via some $\mathsf{DT}_{\mathrm{lin}}$. Hence, we drop the qualification. The language L is called *output recognizable* (without further mentioning of an output tree) if L is out recognizable by some $s \in \mathcal{T}_\Delta$. Assume that the language L is accepted by the trim top-down deterministic TA B. Then it can be decided in *polynomial time* whether or not L is output recognizable, and if so, whether or not L is output recognizable by a particular given tree s.

▶ **Lemma 13.** *$\mathcal{L}(B)$ is output recognizable iff for every strongly connected component H' of the transition relation of B, every transition $\langle h', f, h_1 \dots h_k\rangle$ of B, and i with $h', h_i \in H'$, it holds that $h_j = \top$ for all $j \neq i$.*

Let s denote any output tree in $\mathcal{T}_\Delta$ and h a state of B. Then $\mathsf{dom}_B(h)$ is output recognizable by s if for every transition $\langle h, f, h_1 \dots h_k\rangle$ with subsequence $h_{i_1} \dots h_{i_r}$ of states different from $\top$, there is a pattern $s' \in \mathcal{T}_\Delta(X_r)$ such that $s = s'\{x_j \mapsto s_j \mid j = 1, \dots, r\}$ and $\mathsf{dom}_B(h_{i_j})$ is output recognizable by s_j for all $j = 1, \ldots, r$. In case that h and one of the h_j are contained in the same strongly connected component of B, then r must equal 1. Accordingly, then s' can be chosen as x_1. We further remark that the pattern s' can be chosen to be *linear*, i.e., each variable x_j occurs exactly once. The constructed transducer thus is in fact, a $\mathsf{DT}_{\rm lin}$. Finally we note that the set of all states h such that $\mathsf{dom}_B(h)$ is output recognizable by s, can be determined by a TA running over s.

▶ **Theorem 14.** *For a given state h of a top-down deterministic TA B,*

1. *it can be decided in polynomial time whether or not $\mathsf{dom}_B(h)$ is output recognizable;*
2. *it can be decided in polynomial time whether or not $\mathsf{dom}_B(h)$ is output recognizable by a particular tree s and if so, a DT_{lin} $A_{B,h,s}$ without inspection can be constructed in polynomial time with domain $\mathsf{dom}_B(h)$ such that $[\![t]\!]_{A_{B,h,s}} = s$ for all $t \in \mathsf{dom}_B(h)$.*

6 How to Satisfy Inspection Needs

In the following, we consider an arbitrary $\mathsf{DT}^{\rm I}_{\rm uc}$ transducer A with underlying top-down deterministic TA B as *inspection* automaton. Consider a rule τ of the form $q(f(x_1 : h_1, \ldots, x_k : h_k)) \to T$ of A. For every x_i not occurring in T, it must be verified that the corresponding subtree of the input is contained in $\mathsf{dom}_B(h_i)$. This verification is trivial if $\mathsf{dom}_B(h_i) = \mathcal{T}_\Sigma$. Such a state h_i (if present) has been denoted by $\top$. Accordingly, let J_τ denote the set of indices j such that x_j does *not* occur in the right-hand side of T while at the same time, $h_j \neq \top$. Let us thus call the *multiset* $\eta_\tau = \{h_j \mid j \in J_\tau\}$ the *inspection need* of the rule τ. Assume that T has disjoint ground subtrees $s_j, j \in J_\tau$, such that $\mathsf{dom}_B(h_j)$ is output recognizable by s_j for $j \in J_\tau$. Then the rule τ can equivalently be replaced by a rule without inspection need. In this case, we say that τ *satisfies* its inspection need.

▶ **Example 15.** Consider the rule $q(f(x_1 : h_1, x_2 : h_2)) \to g(x_1, r(b))$ where $\mathsf{dom}_B(h_2)$ equals the set $L = \{g(a,t) \mid t \in \mathcal{T}_\Sigma\}$. Then $J_\tau = \{2\}$ where the language L is output realizable with respect to $r(b)$. The latter can be seen by means of the rules $q_1(g(x_1, x_2)) \to r(q_2(x_1))$ and $q_2(a) \to b$. Accordingly, the given rule for q and f satisfies its inspection need.

Our goal is to construct for a given $\mathsf{DT}^{\rm I}_{\rm uc}$ transducer A an equivalent $\mathsf{DT}_{\rm uc}$ transducer A' such that each rule of A' satisfies its inspection need. If each rule of A satisfies its inspection need, this need no longer be the case for the *earliest* transducer equivalent to A. The reason is that some ground subtrees of prefixes of right-hand sides may have been moved to the right-hand sides of other rules. Satisfying inspection needs of rules therefore requires to partly *revert* the *earliest* transformation. In the following, we call a state q of the $\mathsf{DT}^{\rm I}_{\rm uc}$ A *constant*, if there is a single output tree s such that $s = s'$ whenever $q : t \to s'$ holds.

▶ **Lemma 16.** *For a partial mapping $\mu : \mathcal{T}_\Sigma \to \mathcal{T}_\Delta$, the following are equivalent: (1) μ is realized by a DT_{uc} without inspection; (2) μ is realized by a DT^{I}_{uc} without constant states, but where all inspection needs are satisfied.*

Assume that A' is a $\mathsf{DT}_{\rm uc}$ and A the corresponding $\mathsf{DT}^{\rm I}_{\rm uc}$ in canonical earliest normal form. This means that for each state q of A and each state $q' \in q$ of A' with $\mathsf{pref}_{A'}(q') = p$, $q' : t \to s'$ holds for A' iff $q : t \to s$ with $s' = p \cdot s$ holds. In particular, the constant outputs for some states of A' may occur as subtrees in p and thus are already produced before A processes t. In order to recover the (yet unknown) $\mathsf{DT}_{\rm uc}$ A' without inspection from A, we determine the minimal suffix p' of p so that all inspections possibly encountered when q processes its input, can be satisfied. Such a *generalized inspection need* of a q-computation is represented by a sequence $(M_1, \emptyset) \ldots (M_{r-1}, \emptyset)(M_r, \phi)$, $r \geq 0$, where $M_1, \ldots, M_r$ are multisets of inspection states and ϕ is a downward-closed subset of sub-multisets of M_r with $M_r \notin \psi$. Intuitively, a generalized inspection need is the *sequence* of future inspections yet to be simulated. The pair (M_r, ϕ) to the right is meant to occur farest in the future. Thereby, the set ϕ describes which sub-multisets of individual inspections of M_r can already be accomplished (the available ground terms might be used in more than one way). If $M_r \in \phi$, then *all* languages $\mathsf{dom}_B(h), h \in M_r$, are simultaneously realizable – implying that the whole pair (M_r, ϕ) can be dropped.

For a finite multiset G of trees in $\mathcal{T}_\Delta$ and a finite multiset M of states in H, define $\langle\langle G, M\rangle\rangle$ as the set of all sub-multisets M' of M so that the multiset of languages $\{\mathsf{dom}_B(h) \mid h \in M'\}$ are simultaneously output recognizable by means of disjoint subtrees of trees in G.

Now assume that $p \in \mathcal{T}_\Delta(x_1)$ where $p = s_1 \cdot \ldots \cdot s_m$ where each of the $s_j \in \mathcal{T}_\Delta(x_1)$ is *irreducible*, i.e., cannot be written as a product of patterns different from x_1. For p, we define the auxiliary transformation $\llbracket p\rrbracket^{\sharp\sharp}$ as the composition $\llbracket s_1\rrbracket^{\sharp\sharp} \circ \ldots \circ \llbracket s_m\rrbracket^{\sharp\sharp}$ where for an irreducible pattern $s \in \mathcal{T}_\Delta(x_1)$, the transformation is defined as follows. First, $\llbracket s\rrbracket^{\sharp\sharp}\epsilon = \epsilon$. For $\alpha = \alpha'\,(M, \phi)$, the pattern s can only be used to satisfy the inspection need of the *last* pair in α. Let G denote the set of maximal distinct ground subtrees of s. Let ϕ' denote the set of multisets of inspection needs which become satisfiable when the ground terms from G are additionally available, i.e., $\phi' = \{R_1 \cup R_2 \mid R_1 \in \phi, R_2 \in \langle\langle G, M \setminus R_1\rangle\rangle\}$. Then $\llbracket s\rrbracket^{\sharp\sharp}\alpha = \alpha'$ if $M \in \phi'$ and $\llbracket s\rrbracket^{\sharp\sharp}\alpha = \alpha'\,(M, \phi')$ otherwise. Let I the set of all possible generalized inspection needs. Let us introduce some notation. For a particular state q and input tree t, let us define the inspection need $\eta_q(t)$ of q for t as follows. Assume that $t = f(t_1, \ldots, t_k)$ and τ is the rule of A of the form $q(f(x_1 : h_1, \ldots, x_k : h_k)) \to p\{x_j \mapsto q_j(x_j) \mid j \in J\}$ such that $p \in \mathcal{T}_\Delta(X_J)$ holds with $h_i : t_i$ for $i = 1, \ldots, k$. For the rule τ, we define the transformation

$$\llbracket\tau\rrbracket^\sharp : (X_J \to I) \to I \quad \text{such that} \quad \eta_q(t) = \llbracket\tau\rrbracket^\sharp\{x_j \mapsto \eta_{q_j}(t_j) \mid j \in J\} \quad \text{holds.}$$

The transformation $\llbracket\tau\rrbracket^\sharp$ is defined by case distinction. If $J = \emptyset$, i.e., p is ground, we check in how far p itself is sufficient for η_τ to be output realizable. Let $\phi = \langle\langle\{p\}, \eta_\tau\rangle\rangle$. Then

$$\llbracket\tau\rrbracket^\sharp\emptyset = \left\{ \begin{array}{ll} \epsilon & \text{if } \eta_\tau \in \phi \\ (\eta_\tau, \phi) & \text{otherwise} \end{array} \right.$$

$$\llbracket\tau\rrbracket^\sharp\{x_j \mapsto \alpha\} = \llbracket p\rrbracket^{\sharp\sharp}((\eta_\tau, \emptyset)\alpha)$$

Finally, assume that J contains more than one index. Let $p = p'\{x_j \mapsto p_j \cdot x_j \mid j \in J\}$ for *maximal* patterns $p_j \in \mathcal{T}_\Delta(x_1)$. For $\alpha_j, j \in J$, assume that $p_j = p'_j \cdot u_j$ for some *minimal* suffix $u_j \in \mathcal{T}_\Delta(x_1)$ with $\llbracket u_j\rrbracket^{\sharp\sharp}\alpha_j = \epsilon$. These suffixes must exist, whenever A is equivalent to some $\mathsf{DT}_{\mathrm{uc}}$ without inspection. Let G denote the set of distinct maximal ground subtrees of $p'\{x_j \mapsto p'_j \cdot x_j \mid j \in J\}$, and $\phi = \langle\langle G, \eta_\tau\rangle\rangle$. Then we define

$$\llbracket\tau\rrbracket^\sharp\{x_j \mapsto \alpha_j \mid x_j \in X_J\} = \left\{ \begin{array}{ll} \epsilon & \text{if } \eta_\tau \in \phi \\ (\eta_\tau, \phi) & \text{otherwise} \end{array} \right.$$

We have:

▶ **Lemma 17.** *Assume that A is the canonical earliest normal form of some DT_{uc} A' without inspection. Let q denote some state of A, i.e., an equivalence class of states of A'. Let $q' \in q$ be state of A', let $p = \mathsf{pref}_{A'}(q')$ the maximal common prefix of outputs of A' for q', and $t \in \mathsf{dom}_B(\iota(q))$. Then (1) $\eta_q(t)$ is defined and (2) $\llbracket p\rrbracket^{\sharp\sharp}(\eta_q(t)) = \epsilon$.*

The proof is by induction on the structure of t where we use that for $q' : t \to s'$ and $q : t \to s$ we have that $s' = p \cdot s$ for $p = \mathsf{pref}_{A'}(q')$.

By computing $\eta_q(t)$, we partly recover information on the (unknown) common prefix p of the (yet to be constructed) $\mathsf{DT}_{\mathrm{uc}}$ A' for q'. By computing the set of *all* these inspection needs for q, we determine the maximal requirement on a suffix of output already produced by A when reaching q, whose delay then is sufficient to satisfy all possible future inspection needs. Therefore, let $S[q] = \{\eta_q(t) \mid t \in \mathsf{dom}_B(\iota(q)\}$. In order to calculate this set, we construct a constraint system $\mathcal{C}_I$ with unknowns X_q, where q is state of A. The system consists of one constraint per rule of A. Assume that τ is the rule $q(f(\ldots)) \to p\{x_j \mapsto q_j(x_j) \mid j \in J\}$ where $p \in \mathcal{T}_\Delta(X_J)$ and $q_j, j \in J$ are states of A. Then the constraint system $\mathcal{C}_I$ has the constraint

$$X_q \supseteq \{[\![\tau]\!]^\sharp\{x_j \mapsto \alpha_j \mid j \in J\} \mid \forall j \in J.\, \alpha_j \in X_{q_j}\}$$

The given constraint system is over subsets of I where all right-hand sides are monotonic w.r.t. subset inclusion. Therefore, it has a *least* solution. Moreover, we have:

▶ **Lemma 18.** *Assume that A is a canonical DT^I_{uc} transducer which is equivalent to some DT_{uc} A' without inspection. Let X_q, q a state of A, denote the least solution of the system of constraints $\mathcal{C}_I$. Then for each state q of A: (1) $X_q = S[q]$ and (2) the length of each $\alpha \in S[q]$ is bounded by $|A|$.*

Proof. In order to verify the first statement, we prove by induction that the ith iterate $X_q^{(i)}$ of the constraint system exactly equals the set of all $\eta_q(t)$ for trees t of depth less than i. For a proof of the second statement, we note that each $\alpha \in S[q]$ is the inspection need of some execution starting in q which must be accomplished by every pattern available at q. More precisely, for every state q of A there is a context $t \in \mathcal{C}_\Sigma$ such that $(q_0, h) : t \to u \cdot q(x_1)$ holds where $\iota(q) = h$. Here, we rely on the minimality of A, implying that each state q can be reached in this way. Let $T'_0 \cdot q_0(x_1)$ denote the axiom of A. Then t can be chosen in such a way that $T_0 \cdot u$ consists of at most $|A|$ factors. Since at least one factor of the pattern is required to realize the inspection at one rule, the upper bound to the lengthes of inspection needs $\alpha \in S[q]$ follows. ◀

As a consequence, the sets $S[q]$, q a state of A, are effectively computable.

For a finite set $S \subseteq I$, let t^S denote the minimal suffix v of t such that $[\![v]\!]^{\sharp\sharp}\alpha = \epsilon$ for all $\alpha \in S$. The states of the new $\mathsf{DT}_{\mathrm{uc}}$ A' are pairs $\langle q, s\rangle$, q a state of A and $s \in \mathcal{T}_\Delta(x_1)$ an output pattern for A, which will also be called the *buffer*. Assume that we are given for each state q of A, the (finite) set $S[q]$ of inspection needs which are to be satisfied by q-computations. Assume that $T'_0 = u \cdot v$ where $v = (T'_0)^{S[q_0]}$. Then the axiom of A' is given by $u \cdot \langle q_0, v\rangle(x_1)$. Assume that state $\langle q, u\rangle$ of A' has already been constructed, and τ is a rule of A of the form $q(f(\ldots)) \to p\{x_j \mapsto q_j(x_j) \mid j \in J\}$ where $p \in \mathcal{T}_\Delta(X_J)$.

If $J = \emptyset$, A' has a rule $\langle q, u\rangle(f(\ldots)) \to u \cdot p$. In case that $\eta_\tau \neq \epsilon$, $u \cdot p$ must be sufficient to satisfy the inspection needs incurred by the rule τ, i.e., $\langle\langle\{u \cdot t\}, \eta_\tau\rangle\rangle$ must contain η_τ.

Next assume that $J = \{j\}$, i.e., $p = p' \cdot x_j$. Then $[\![u \cdot p']\!]^{\sharp\sharp}((\eta_\tau, \emptyset)\,\alpha) = \epsilon$ must hold for all $\alpha \in S[q_j]$. Therefore, there is a factorization such that $u \cdot p' = u' \cdot v$ where $v = (u \cdot p')^{S[q_j]}$; we add the rule $\langle q, u\rangle(f(\ldots)) \to u' \cdot \langle q', v\rangle(x_i)$ to A'. Finally, assume that J contains at least two elements. Then p is of the form $p = p'\{x_j \mapsto p_j \cdot x_j \mid j \in J\}$ for $p' \in \mathcal{T}_\Delta(X_J)$ and maximal patterns $p_j \in \mathcal{T}_\Delta(x_1)$. For each $j \in J$, there must be a factorization $p_j = u_j \cdot v_j$ where $v_j = (p_j)^{S[q_j]}$. Moreover, the subset G of ground subtrees of u, p' and $u_j, j \in J$, must be sufficient to satisfy the inspection need of τ itself, i.e., $\langle\langle G, \eta_\tau\rangle\rangle$ contains η_τ. Then add the rule $\langle q, u\rangle(f(\ldots)) \to u \cdot p'\{x_j \mapsto u_j \cdot \langle q_j, v_j\rangle(x_j) \mid j \in J\}$ to A'. Correctness and termination of the construction follows from the following lemma.

▶ **Lemma 19.** *Assume that A is the canonical earliest DT^{I}_{uc} for a DT_{uc} A'' without inspection. Then the construction in Section 6 terminates with some A' so that the following properties are satisfied:*

1. *A is equivalent to A';*
2. *Each inspection need η_τ of A' is satisfiable;*
3. *For each constructed state $\langle q, u\rangle$ of A', $u \in \mathcal{T}_\Delta(x_1)$ has length at most $|A|^2 \cdot (a-1)$ if a is the maximal rank of an input symbol.*

Proof. Assume that A is equivalent to some A'' without inspection, i.e., is the canonical earliest normal form of A''. This means that for states q_1, q_2 of A, $t_1 \in \mathcal{C}_\Sigma$ and $t_2 \in \mathcal{T}_\Sigma$ with $(q_1, \iota(q_2)) : t_1 \to s_1 \cdot q_2(x_1)$, and $q_2 : t_2 \to s_2$ and all states q'_1, q'_2 of A'' so that $q'_i \in q_i$, $(q'_1, \iota(q'_2)) : t \to s'_1 \cdot q'_2(x_1)$ and $q'_2 : t \to s'_2$, for some s'_1, s'_2, it holds that $v_1 \cdot s_1 = s'_1 \cdot v_2$ and $v_2 \cdot s_2 = s'_2$ for $v_i = \mathsf{pref}_{A'}(q'_i)$.

Consider a pair $\langle q, u\rangle$ returned by the construction and let $q' \in q$ denote a state of A'' contained in q with $v_{q'} = \mathsf{pref}_{A''}(q')$. Then u is a suffix of $v_{q'}$. Consequently, the set of all constructed states $\langle q, u\rangle$ is finite, and all pre-conditions at the construction of rules are met. This means that all inspection needs of the resulting transducer are satisfiable. Moreover, we have that $q : t \to s$ holds for A iff $\langle q, u\rangle : t \to s'$ holds for A' where $u \cdot s = s'$ – implying that A and A' are equivalent.

It remains to prove item (3), i.e., to provide an upper bound for the lengthes of the patterns u occurring in the construction as second components of states $\langle q, u\rangle$ – not in terms of the transducer A'', but in terms of the transducer A, which serves as the input to the construction. According to thr construction, we know that u is a minimal pattern to satisfy all generalized inspection needs in $S[q]$.

First, assume that $(q, \iota(q)) : t \to s \cdot q(x_1)$ holds for A some context $t \in \mathcal{C}_\Sigma$ so that only rules τ are applied whose right-hand sides have occurrences of single variables only. In that case, $t = t_1 \cdot \ldots \cdot t_m$ for irreducible contexts $t_i \in \mathcal{C}_\Sigma$ where each computation for t_i consists in the application of a single rule τ_i. *Case 1*: $s = x_1$. Then η_{τ_i} must be $\emptyset$ for all $i = 1, \ldots, m$. *Case 2*: $s \neq x_1$. Then $u \cdot s = u_1 \cdot v$ so that all inspections to be satisfied by the τ_i together can be satisfied by u_1 while v is sufficient to satisfy all generalized inspection needs in $S[q]$. Accordingly, $[\![s^{|A|\cdot(a-1)}]\!]^{\sharp\sharp}\alpha = \epsilon$ for each $\alpha \in S[q]$. Therefore, s (independently of u) is at least able to satisfy each (M, ϕ) occurring inside some $\alpha \in S[q]$.

Now assume for a contradiction, that a state $\langle q, u\rangle$ is constructed where u is of length exceeding $|A|^2 \cdot (a-1)$. Then there is a minimal context $t \in \mathcal{C}_\Sigma$ of the form $t = t' \cdot t_1 \cdot \ldots \cdot t_N \cdot t''$ for $N = |A|^2 \cdot (a-1) + 1$ such that $(q_1, \iota(q')) : t' \to s' \cdot q'(x_1)$, $(q', \iota(q')) : t_i \to s_i \cdot q'(x_1)$ for $i = 1, \ldots, N$ with $s_i \neq x_1$, and $(q', \iota(q)) : t' \to s'' \cdot q(x_1)$ so that for some $v_0 \in \mathcal{T}_\Delta(x_1)$, one of the following two conditions holds:

- The axiom of A is of the form $s_0 \cdot v_1 \cdot q_1(x_1)$; or
- there is a right-hand side of a rule of A which is of the form $p\{x_j \mapsto v'_j \cdot q'_j(x_j) \mid j \in J\}$ for some J of cardinality exceeding 1, where $v_1 = v'_{j'}$ and $q_1 = q'_{j'}$ for some $j' \in J$.

By construction, all inspection needs along the way, are satisfied by $v_1 \cdot s'$. According to our observation above, though, u must be a suffix of $s_2 \cdot \ldots \cdot s_N \cdot s''$ – contradicting the minimality of the context t. We conclude that the maximal length of the buffer is bounded by $|A|^2 \cdot (a-1)$. ◀

In summary, we have shown:

▶ **Theorem 20.** *(1) For a DT^{I}_{uc} (DT^{I}_{lin}) A it is decidable if is equivalent to a DT_{uc} (DT_{lin}) A', and if so, such A' can be constructed. (2) For a DT^{R}_{uc} (DT^{R}_{lin}) A is decidable if A is equivalent to a DT_{uc} (DT_{lin}) A', and if so, such A' can be constructed.*

In Section 2 we have seen that a bottom-up deterministic transducer (DB) can be seen as a particularly simple $\mathsf{DT}^{\mathrm{R}}_{\mathrm{uc}}$ transducer. Accordingly, we obtain as a corollary:

▶ **Corollary 21.** *Let A be a (linear) DB. It is decidable if an equivalent DT^{I}_{uc} (DT^{I}_{lin}) or an equivalent DT_{uc} (DT_{lin}) exists, and if so, such a transducer can be constructed.*

7 Conclusion

We showed for two natural subclasses of deterministic top-down tree transducers how to remove (bottom-up deterministic) look-ahead and replace it whenever possible, with (top-down deterministic) inspection. We then also showed for the given classes how to remove inspection (if possible). The constructions are technically intricate, but crucially rely on canonical earliest normal forms for the transducers in question. As a corollary we obtain that for a given deterministic bottom-up transducer it is decidable whether or not it can be realized by a deterministic top-down tree transducer that is either *uc* or linear.

One may wonder if our results imply that for a given deterministic bottom-up tree transducer U it is decidable whether or not it can be realized by an *arbitrary* deterministic top-down tree transducer. I.e., if U *can* be realized by top-down transducer can be realized by a *uc* such transducer? Interestingly, this is *not* the case: let h_a, h_b be look-ahead states that indicate that the left-most leaf of the input tree is labeled a and b, respectively and consider a transducer which has these rules (for every $h \in \{h_a, h_b\}$):

$$q_0(f(x_1 : h_a, x_2 : h)) \to g(a, b, q_{\mathrm{id}}(x_2)) \qquad q_0(f(x_1 : h_b, x_2 : h)) \to g(c, d, q_{\mathrm{id}}(x_2))$$

The corresponding translation *can* be realized by a deterministic top-down tree transducer! However, the transducer is *not uc* (viz. the output leaves a and b must be produced by different states, but both on the input variable x_1).

Abstract

We give a characterization of *star-free languages* in a λ-calculus with support for *non-commutative affine types* (in the sense of linear logic), via the algebraic characterization of the former using *aperiodic monoids*. When the type system is made commutative, we show that we get *regular languages* instead. A key ingredient in our approach – that it shares with higher-order model checking – is the use of *Church encodings* for inputs and outputs. Our result is, to our knowledge, the first use of non-commutativity in implicit computational complexity.

Acknowledgements The initial trigger for this line of work was twofold: the serendipitous rediscovery of Hillebrand and Kanellakis's theorem by Damiano Mazza, Thomas Seiller and the first author, and Mikołaj Bojańczyk's suggestion to the second author to look into connections between transducers and linear logic. Célia Borlido proposed looking at star-free languages at the Topology, Algebra and Categories in Logic 2019 summer school.
During its long period of gestation, this work benefited from discussions with many other people: Pierre Clairambault, Amina Doumane, Marie Fortin, Jérémy Ledent, Paolo Pistone, Lorenzo Tortora de Falco, Noam Zeilberger and others that we may have forgotten to mention.
We also thank the anonymous reviewers for their constructive feedback, especially for their highly relevant pointers to the literature.

1 Introduction

A type-theoretic implicit automata theory. This paper explores connections between the languages recognized by automata and those definable in certain typed λ-calculi (minimalistic functional programming languages). It is intended to be the first in a series, whose next installments will investigate the functions computable by transducers (automata with output, see e.g. [15, 36]). Insofar as programming language theory is related to proof theory, via the Curry–Howard correspondence, we are therefore trying to *bridge logic and automata.* That said, our work does not fit in the "logics as specification languages" paradigm, exemplified by the equivalence of recognition by finite-state automata and Monadic Second-Order Logic (MSO). One could sum up the difference by analogy with the two main approaches to machine-free complexity: *implicit computational complexity (ICC)* and *descriptive complexity.*

Both aim to characterize complexity classes without reference to a machine model, but the methods of ICC have a more computational flavor.

programming paradigm	declarative	functional
complexity classes	Descriptive Complexity	Implicit Computational Complexity
automata theory	subsystems of MSO	**this paper** (and planned sequels)

To our knowledge, very few works have looked at this kind of "type-theoretic" or "proof-theoretic" ICC for automata. Let us mention a few recent papers (that we will discuss further in §7) concerning transducers [13, 10] and multi-head automata [46, 28] and, most importantly, a remarkable result from 1996 that provides our starting point:

▶ **Theorem 1.1** (Hillebrand & Kanellakis [24, Theorem 3.4]). *A language $L \subseteq \Sigma^*$ can be defined in the* simply typed λ-calculus *by some* closed λ-term *of type* $\mathtt{Str}_\Sigma[A] \to \mathtt{Bool}$ *for some type A (that may depend on L) if and only if it is a* regular language.

Let us explain this statement. We consider a grammar of simple types with a single base type: $A, B ::= o \mid A \to B$, and use the *Church encodings* of booleans and strings:

$$\mathtt{Bool} = o \to o \to o \qquad\qquad \mathtt{Str}_\Sigma = (o \to o) \to \ldots \to (o \to o) \to o \to o$$

with $|\Sigma|$ arguments of type $(o \to o)$, where Σ is a finite alphabet. Moreover, given any other chosen type A, one can form the type $\mathtt{Str}_\Sigma[A]$ by substituting A for the ground type o:

▶ **Notation 1.2.** For types A and B, we denote by $B[A]$ the substitution $B\{o := A\}$ of every occurrence of o in B by A.

Every closed λ-term t of type $\mathtt{Str}_\Sigma$ can also be seen as a term of type $\mathtt{Str}_\Sigma[A]$. (This is a way to simulate a modicum of parametric polymorphism in a monomorphic type system.) It follows that any closed λ-term of type $\mathtt{Str}_\Gamma[A] \to \mathtt{Bool}$ in the simply typed λ-calculus defines a predicate on strings, i.e. a language $L \subseteq \Sigma^*$.

Although little-known[1], Hillebrand and Kanellakis's theorem should not be surprising in retrospect: there are strong connections between Church encodings and automata (see e.g. [45, 48, 34]), that have been exploited in particular in *higher-order model checking* for the past 15 years [2, 38, 25, 21, 23, 49]. This is not a mere contrivance: these encodings have been a canonical data representation for λ-calculi for much longer[2].

Star-free languages. We would like to extend this result by characterizing strict subclasses of regular languages, the most famous being the *star-free languages.* Recall that the canonicity of the class of regular languages is firmly established by its various definitions: regular expressions, finite automata, definability in MSO and the algebraic characterization.

▶ **Theorem 1.3** (cf. [44, §II.2.]). *A language $L \subseteq \Sigma^*$ is regular if and only if for some* finite monoid M*, some subset $P \subseteq M$ and some* monoid morphism $\varphi \in \mathrm{Hom}(\Sigma^*, M)$*, $L = \varphi^{-1}(P)$.*

Similarly, the seminal work of Schützenberger, Petrone, McNaughton and Papert in the 1960s (see [47] for a historical discussion) has led to many equivalent definitions for star-free languages, with the algebraic notion of *aperiodicity* playing a key role:

[1] See e.g. Damiano Mazza's answer to this MathOverflow question: `https://mathoverflow.net/q/296879`

[2] They were introduced for booleans and integers by Church in the 1930s, and later generalized by Böhm and Berarducci [12], see also `http://okmij.org/ftp/tagless-final/course/Boehm-Berarducci.html`. (Similar ideas appear around the same time in [31].) As for the refined encodings with linear types that we use later, they already appear in Girard's founding paper on linear logic [17, §5.3.3].

▶ **Definition 1.4.** *A monoid M is* aperiodic *when any sequence of iterated powers is eventually constant, i.e. for any $x \in M$ there exists an exponent $n \in \mathbb{N}$ such that $x^n = x^{n+1}$.*

▶ **Theorem 1.5** (cf. [47])**.** *For a language $L \subseteq \Sigma^*$, the following conditions are equivalent:*

- *L is defined by some* star-free regular expression: $E, E' ::= \varnothing \mid \{a\} \mid E \cup E' \mid E \cdot E' \mid E^c$ *where a can be any letter in Σ and E^c denotes the* complement *of E ($[\![E^c]\!] = \Sigma^* \setminus [\![E]\!]$);*
- *$L = \varphi^{-1}(P)$ for some finite and* aperiodic *monoid M, some subset $P \subseteq M$ and some monoid morphism $\varphi \in \mathrm{Hom}(\Sigma^*, M)$;*
- *L is recognized by a deterministic finite automaton whose transition monoid is* aperiodic*;*
- *L is definable in first-order logic.*

Attempting to capture star-free languages in a λ-calculus presents a serious methodological challenge: they form a strict subclass of uniform AC^0, and, as far as we know, type-theoretic ICC has never managed before to characterize complexity classes as small as this.

Non-commutative affine types. Monoids appear in typed λ-calculi when one looks at the functions from a type A to itself, i.e. at the (closed) terms of type $A \to A$. At first glance, it seems difficult indeed to enforce the aperiodicity of such monoids via a type system. For instance, one needs to rule out $\texttt{not} = \lambda b.\, \lambda x.\, \lambda y.\, b\, y\, x : \texttt{Bool} \to \texttt{Bool}$ since it "has period two": its iteration yields the sequence (modulo $\beta\eta$-conversion) $\texttt{not}, \texttt{id}, \texttt{not}, \texttt{id}, \ldots$ (where $\texttt{id} = \lambda b.\, b$) which is not eventually constant. Observe that $\texttt{not}$ essentially *exchanges* the two arguments of b; to exclude it, we are therefore led to require functions to *use their arguments in the same order that they are given in.*

It is well-known that in order to make such a *non-commutative* λ-calculus work – in particular to ensure that non-commutative λ-terms are closed under β-reduction – one needs to make the type system *affine*, that is, to restrict the duplication of data. This is achieved by considering a type system based on Girard's linear[3] logic [17], a system whose "resource-sensitive" nature has been previously exploited in ICC [20, 19]. Not coincidentally, the theme of non-commutativity first appeared in a form of linear logic *ante litteram*, namely the Lambek calculus [29], and resurfaced shortly after the official birth of linear logic: it is already mentioned by Girard in a 1987 colloquium [18].

We shall therefore introduce and use a variant of Polakow and Pfenning's Intuitionistic Non-Commutative Linear Logic [39, 40], making a distinction between two kinds of function arrows: $A \multimap B$ and $A \to B$ are, respectively, the types of affine functions and non-affine functions from A to B. Accordingly:

▶ **Definition 1.6.** *A type is said to be* purely affine *if it does not contain the "$\to$" connective.*

In our system that we call the *$\lambda\wp$-calculus*, the types of Church encodings become

$$\texttt{Bool} = o \multimap o \multimap o \qquad\qquad \texttt{Str}_\Sigma = (o \multimap o) \to \ldots \to (o \multimap o) \to (o \multimap o)$$

where $\texttt{Str}_\Sigma$ has $|\Sigma|$ arguments[4] of type $(o \multimap o)$. Setting $\texttt{true} = \lambda^\circ x.\, \lambda^\circ y.\, x : \texttt{Bool}$ and $\texttt{false} = \lambda^\circ x.\, \lambda^\circ y.\, y : \texttt{Bool}$ for the rest of the paper, we can now state our main result:

▶ **Theorem 1.7.** *A language $L \subseteq \Sigma^*$ is* star-free *if and only if it can be defined by a closed $\lambda\wp$-term of type $\texttt{Str}_\Sigma[A] \multimap \texttt{Bool}$ for some* purely affine *type A (that may depend on L).*

[3] The main difference between so-called linear and affine type systems is that the latter allow *weakening*, that is, to not use some argument. Typically, $\lambda x.\, \lambda y.\, x$ is affine but not linear while $\lambda x.\, x\, x$ is neither linear nor affine. The type system that we use in this paper is affine, not strictly linear.

[4] $o \multimap o$ occurs $|\Sigma| + 1$ times in $\texttt{Str}_\Sigma$: $|\Sigma|$ arguments plus the output.

However, if we use the *commutative* variant of the $\lambda\wp$-calculus instead, then what we get is the class of regular languages (Theorem 5.1), just as in Hillebrand and Kanellakis's theorem.

As far as we know, non-commutative type systems have never been applied to implicit complexity before (but they have been used to control the expressivity of a domain-specific programming language [26]). Previous works indeed tend to see non-commutative λ-terms (or proof nets) as static objects, and to focus on their topological aspects (e.g. [6, 51, 35]), though there is another tradition relating self-dual non-commutativity to process algebras[5] [41, 22].

Proof strategy. As usual in implicit computational complexity, the proof of Theorem 1.7 consists of a *soundness* part – "every $\lambda\wp$-definable language is star-free" – and an *extensional completeness* part – the converse implication. In our case, soundness is a corollary of the following property of the purely affine fragment of the $\lambda\wp$-calculus – what one might call the *planar*[6] *affine λ-calculus* (cf. [1, 51]):

▶ **Theorem 1.8** (proved in §3). *For any* purely affine *type A, the set of closed $\lambda\wp$-terms of type $A \multimap A$, quotiented by $\beta\eta$-convertibility and endowed with function composition ($f \circ g = \lambda^{\circ}x.\, f\,(g\,x)$), is a* finite and aperiodic monoid*.*

Extensional completeness turns out here to be somewhat deeper than the "programming exercise of limited theoretical interest" [33, p. 137] that one generally finds in ICC. Indeed, we have only managed to encode star-free languages in the $\lambda\wp$-calculus by relying on a powerful tool from semigroup theory: the *Krohn–Rhodes decomposition* [27].

Plan of the paper. After having defined the $\lambda\wp$-calculus in §2, we prove Theorem 1.7: soundness is treated in §3 and extensional completeness in §4. Then we discuss the analogous results for the commutative variant of the $\lambda\wp$-calculus and its extension with additives (§5), our plans for the next papers in the series (§6) and finally some related work (§7).

Prerequisites. We assume that the reader is familiar with the basics of λ-calculi and type systems, but require no prior knowledge of automata theory. This choice is motivated by the impression that it is more difficult to introduce the former than the latter in a limited number of pages. Nevertheless, we hope that our results will be of interest to both communities.

2 Preliminaries: the $\lambda\wp$-calculus and Church encodings

The terms and types of the $\lambda\wp$-calculus are defined by the respective grammars

$$A, B ::= o \mid A \to B \mid A \multimap B \qquad t, u ::= x \mid t\,u \mid \lambda^{\to}x.\,t \mid \lambda^{\circ}x.\,t$$

As always, the $\lambda\wp$ terms are identified up to α-equivalence (both $\lambda^{\to}$ and λ° are binders). There are two rules for β-reduction (closed under contexts)

$$(\lambda^{\to}x.\,t)\,u \longrightarrow_{\beta} t\{x := u\} \qquad (\lambda^{\circ}x.\,t)\,u \longrightarrow_{\beta} t\{x := u\}$$

[5] This connection with the sequential composition of processes can be seen as a sort of embodiment of Girard's slogan "time is the contents of non-commutative linear logic" [18, IV.6]. But generally, these works follow a "proof search as computation" paradigm (logic programming) rather than "normalization as computation" (functional programming).

[6] Hence our choice of name: the "Weierstraß P" character "$\wp$" in "$\lambda\wp$" stands for "planar".

$$\frac{}{\Gamma \uplus \{x : A\} \mid \varnothing \vdash x : A} \qquad \frac{\Gamma \mid \Delta \vdash t : A \to B \qquad \Gamma \mid \varnothing \vdash u : A}{\Gamma \mid \Delta \vdash t\,u : B} \qquad \frac{\Gamma \uplus \{x : A\} \mid \Delta \vdash t : B}{\Gamma \mid \Delta \vdash \lambda^{\to} x.\, t : A \to B}$$

$$\frac{}{\Gamma \mid x : A \vdash x : A} \qquad \frac{\Gamma \mid \Delta \vdash t : A \multimap B \qquad \Gamma \mid \Delta' \vdash u : A}{\Gamma \mid \Delta \cdot \Delta' \vdash t\,u : B} \qquad \frac{\Gamma \mid \Delta \cdot (x : A) \vdash t : B}{\Gamma \mid \Delta \vdash \lambda^{\circ} x.\, t : A \multimap B}$$

$$\frac{\Gamma \mid \Delta \vdash t : A}{\Gamma \mid \Delta' \vdash t : A} \text{ when } \Delta \text{ is a subsequence of } \Delta'$$

Figure 1 The typing rules of the $\lambda\wp$-calculus (see Appendix C in [37] for examples of derivations).

and the remaining conversion rules are the expected η-reduction/η-expansion rules.

The typing judgements make use of dual contexts (a common feature originating in [7]): they are of the form $\Gamma \mid \Delta \vdash t : A$ where t is a term, A is a type, Γ is a set of bindings of the form $x : B$ (x being a variable and B a type), and Δ is an *ordered list* of bindings – this order is essential for non-commutativity. The typing rules are given in Figure 1, where $\Delta \cdot \Delta'$ denotes the *concatenation of the ordered lists* Δ *and* Δ'. For both $\Gamma, \Gamma', \ldots$ and $\Delta, \Delta', \ldots$ we require each variable to appear at most once on the left of a colon.

▶ Remark 2.1. Unlike Polakow and Pfenning's system [39, 40], the $\lambda\wp$-calculus:

- contains two function types instead of four[7], with the top two rows of Figure 1 corresponding almost exactly[8] to the rules given for those connectives in [39];
- is affine instead of linear, as expressed by the "ordered weakening" rule at the bottom of Figure 1 – this seems important to get enough expressive power for our purposes[9].

▶ Remark 2.2. Morally, the non-affine variables "commute with everything". More formally, one could translate the $\lambda\wp$-calculus into a non-commutative version of Intuitionistic Affine Logic whose exponential modality "!" incorporates the customary rules (see e.g. [50])

$$\frac{\Gamma, !A, B, \Delta \vdash C}{\Gamma, B, !A, \Delta \vdash C} \qquad\qquad \frac{\Gamma, B, !A, \Delta \vdash C}{\Gamma, !A, B, \Delta \vdash C}$$

▶ **Proposition 2.3.** *The $\lambda\wp$-calculus enjoys subject reduction and admits normal forms (that is, every well-typed $\lambda\wp$-term is convertible to a β-normal η-long one).*

Proof sketch. This is routine: subject reduction follows from a case analysis, while the fact that the simply typed λ-calculus has normal forms entails that the $\lambda\wp$-calculus also does (the obvious translation preserves the β-reduction and η-expansion relations). ◀

We have already seen the type $\mathtt{Str}_\Sigma = (o \multimap o) \to \ldots \to (o \multimap o) \to (o \multimap o)$ of Church-encoded strings in the introduction. Let us now introduce the term-level encodings:

[7] Our "$\to$" and "$\multimap$" are called "intuitionistic functions" and "right ordered functions" in [39]; we have no counterpart for the "linear [commutative] functions" and "left ordered functions" in the $\lambda\wp$-calculus.

[8] The only difference is that we drop the linear commutative context.

[9] Usually, the linear/affine distinction does not matter for implicit computational complexity if we allow collecting the garbage produced during the computation in a designated part of the output, as in e.g. [30]. But non-commutativity obstructs the free movement of garbage.

▶ **Definition 2.4.** *Let Σ be a finite alphabet, $w = w[1] \dots w[n] \in \Sigma^*$ be a string, and for each $c \in \Sigma$, let t_c be a $\lambda\wp$-term (on which the next proposition will add typing assumptions). We abbreviate $(t_c)_{c\in\Sigma}$ as $\vec{t_\Sigma}$, and define the $\lambda\wp$-term $w^\dagger(\vec{t_\Sigma}) = \lambda^\circ x.\, t_{w[1]}\,(\dots\,(t_{w[n]}\,x)\dots)$.*

Given a total order $c_1 < \dots < c_{|\Sigma|}$ on the alphabet $\Sigma = \{c_1, \dots, c_{|\Sigma|}\}$, the Church encoding *of any string $w \in \Sigma^*$ is $\overline{w} = \lambda^{\to} f_{c_1}.\ \dots\ \lambda^{\to} f_{c_{|\Sigma|}}.\, w^\dagger(\vec{f_\Sigma})$.*

This is simpler than the notation might suggest: as an example, for $\Sigma = \{a, b\}$ with $a < b$, $\overline{baa} = \lambda^{\to} f_a.\ \lambda^{\to} f_b.\ \lambda^\circ x.\ f_b\ (f_a\ (f_a\ x))$. Our choice of presentation is meant to stress the role of the *open* subterm $(baa)^\dagger(\vec{f_{\{a,b\}}}) = \lambda^\circ x.\ f_b\ (f_a\ (f_a\ x))$, cf. Remark 2.9.

We now summarize the classical properties of the Church encoding of strings.

▶ **Proposition 2.5.** *We reuse the notations of the above definition.*

- *Assume that there is a type A and a typing context $\Gamma \mid \Delta$ such that for all $c \in \Sigma$, $\Gamma \mid \Delta \vdash t_c : A \multimap A$. Then $\Gamma \mid \Delta \vdash w^\dagger(\vec{t_\Sigma}) : A \multimap A$.*
- *In particular, $\{f_c : o \multimap o \mid c \in \Sigma\} \mid \varnothing \vdash w^\dagger(\vec{f_\Sigma}) : o \multimap o$ for any* variables *$(f_c)_{c\in\Sigma}$.*
- *Furthermore, in the case of variables, $w \in \Sigma^* \mapsto w^\dagger(\vec{f_\Sigma})$ is in fact a* bijection *between the strings over Σ and the $\lambda\wp$-terms u such that $\{f_c : o \multimap o \mid c \in \Sigma\} \mid \varnothing \vdash u : o \multimap o$ and considered up to $\beta\eta$-conversion*[10]*.*
- *It follows from the above that $w \in \Sigma^* \mapsto \overline{w}$ is a bijection from Σ^* to the set of* closed *$\lambda\wp$-terms of type $\texttt{Str}_\Sigma$ modulo $\beta\eta$.*
- *Finally, with the assumptions on t_c of the first item, we have $\overline{w}\,t_{c_1}\ \dots\ t_{c_{|\Sigma|}} \longrightarrow^*_\beta w^\dagger(\vec{t_\Sigma})$.*

▶ **Example 2.6.** Given two closed $\lambda\wp$-terms $t_a, t_b : \texttt{Bool} \multimap \texttt{Bool}$, one can define the term $g = \lambda^\circ s.\ s\ t_a\ t_b\ \texttt{false} : \texttt{Str}_{\{a,b\}}[\texttt{Bool}] \multimap \texttt{Bool}$. Then for any $w = w[1] \dots w[n] \in \{a, b\}^*$, we have $g\ \overline{w} \longrightarrow^*_\beta w^\dagger(\vec{t_{\{a,b\}}})\ \texttt{false} \longrightarrow^*_\beta t_{w[1]}\ (\dots\ (t_{w[n]}\ \texttt{false}))$.

- For $t_a = \lambda^\circ x.\ \texttt{true}$ and $t_b = \lambda^\circ x.\ x$, g decides the language of words in $\{a, b\}^*$ that contain at least one a; this language is indeed star-free as it can be expressed as $\varnothing^c a \varnothing^c$.
- Coming back to a point raised in the introduction, if negation were definable by a $\lambda\wp$-term $\texttt{not} : \texttt{Bool} \multimap \texttt{Bool}$, then for $t_a = t_b = \texttt{not}$, the language decided by g would consist of words of odd length: a standard example of regular language that is not star-free.

▶ Remark 2.7. Actually, the $\lambda\wp$-term $\texttt{not}' : \lambda^\circ b.\ b\ \texttt{false}\ \texttt{true} : \texttt{Bool}[\texttt{Bool}] \multimap \texttt{Bool}$ does "define negation". A point of utmost importance is that because of the heterogeneity of the input and output types, this term does not contradict Theorem 1.8 and *cannot be iterated by a Church-encoded string.* Monomorphism is therefore crucial for us: if our type system had actual polymorphism, one could give $\texttt{not}'$ the type $(\forall\alpha.\ \texttt{Bool}[\alpha]) \multimap (\forall\alpha.\ \texttt{Bool}[\alpha])$, whose input and output types are equal, and then the words of odd length would be $\lambda\wp$-definable.

An analogous phenomenon in the simply typed λ-calculus is that one can define $n \mapsto 2^n$ on the type of Church numerals $\texttt{Nat}$ by a term of type $\texttt{Nat}[o \to o] \to \texttt{Nat}$, but not by a term of type $\texttt{Nat} \to \texttt{Nat}$ (since iterating it would give rise to a tower of exponentials of variable height, which is known to be inexpressible by any $\texttt{Nat}[A] \to \texttt{Nat}$).

Yet our ersatz of polymorphism still allows for some form of compositionality that will prove useful in several places in §4 (the proof may be found in Appendix B in [37]):

▶ **Lemma 2.8.** *If $\vdash t : A[T] \multimap B$ and $\vdash u : B[U] \multimap C$, then $\vdash \lambda^\circ x.\, u\,(t\,x) : A[T[U]] \multimap C$.*

▶ Remark 2.9. One final observation on Church encodings: when the context Γ of non-affine variables contains $f_c : o \multimap o$ for each $c \in \Sigma$, then any string $w \in \Sigma^*$ can be represented as

[10] η-conversion is necessary to identify $\lambda^{\to} f.\, f : \texttt{Str}_{\{a\}}$ with $\overline{a} = \lambda^{\to} f.\ \lambda^\circ x.\ f\ x : \texttt{Str}_{\{a\}}$.

the open $\lambda\wp$-term $\Gamma \mid \ldots \vdash w^\dagger(\vec{f_\Sigma}) : o \multimap o$ in that context, and such strings can even be concatenated by function composition. The point is that this gives us a kind of *purely affine type of strings*, which will allow us in §4.2 to encode sequential transducers as $\lambda\wp$-terms of type $\mathtt{Str}_\Sigma[A] \multimap \mathtt{Str}_\Pi$ for some purely affine type A (compare Theorem 1.7).

3 Proof of soundness

As stated in the introduction, the soundness part of our main Theorem 1.7 will follow from Theorem 1.8, so we start this section by proving the latter. First, the monoid structure on the closed $\lambda\wp$-terms of *any* type $A \multimap A$ can be verified routinely: both $(f \circ g) \circ h$ and $f \circ (g \circ h)$ β-reduce to $\lambda^\circ x.\, f\ (g\ (h\ x))$, and $\lambda^\circ x.\, x$ provides the identity element. The finiteness of this monoid for A *purely affine* comes from a slightly more general statement:

▶ **Proposition 3.1.** *For any purely affine type B, there are finitely many $\beta\eta$-equivalence classes of closed $\lambda\wp$-terms of type B.*

Proof. This is a well-known property of affine type systems: here, non-commutativity plays no role. We provide a proof in Appendix B in [37]. ◀

The substantial part of Theorem 1.8 is the *aperiodicity* of this monoid. It is here that non-commutativity comes into play. Morally, it is a kind of monotonicity condition that $\lambda\wp$-terms obey. A first idea would therefore be to seek to exploit the fact that the monoid of monotone functions on an ordered set is aperiodic. What we end up using is closely related:

▶ **Lemma 3.2.** *For any $k \in \mathbb{N}$, the monoid of* partial non-decreasing *functions from $\{1, \ldots, k\}$ to itself (endowed with usual function composition) is aperiodic.*

Proof. Let $f : \{1, \ldots, k\} \rightharpoonup \{1, \ldots, k\}$ be non-decreasing. For any $i \in \{1, \ldots, k\}$, the sequence $(f^n(i))_{n\in\mathbb{N}}$ is either non-increasing or non-decreasing as long as it is defined (depending on whether $i \geq f(i)$ or $i \leq f(i)$); so at some $n = N_i$, either it becomes undefined or it reaches a fixed point of f. By taking $N = \max_{1\leq i\leq k} N_i$, we have $f^N = f^{N+1}$. ◀

This underlies the proof of the key lemma below, that allows one to reduce the aperiodicity of some $t : A \multimap A$ to the aperiodicity of $\lambda\wp$-terms at smaller types.

▶ **Notation 3.3.** $\Delta \vdash t : A$ is an abbreviation for $\varnothing \mid \Delta \vdash t : A$ (indeed, the context of non-affine variables will be generally empty in our proof).

▶ **Notation 3.4.** Let $u_1, \ldots, u_k$ and $v_1, \ldots, v_l$ be $\lambda\wp$-terms. The notation $\vec{v}[\vec{y} := \vec{u}]$ denotes the componentwise parallel substitution $(v_i[y_1 := u_1, \ldots, y_k := u_k])_{1\leq i\leq l}$.

▶ **Lemma 3.5.** *Let $t = \lambda^\circ x.\, \lambda^\circ y_1. \ldots \lambda^\circ y_m.\, x\, u_1 \ldots u_k$ be a well-typed closed $\lambda\wp$-term of type $A \multimap A$ in η-*long form*, so that $x : A,\ y_1 : B_1,\ \ldots,\ y_k : B_k \vdash x\, u_1 \ldots u_k : o$ with $A = B_1 \multimap \ldots \multimap B_k \multimap o$. Then:*

- *$t^n = t \circ \ldots \circ t$ (n times) is β-convertible to $\lambda^\circ x.\, \lambda^\circ y_1. \ldots \lambda^\circ y_k.\, x\, u_1^{(n)} \ldots u_k^{(n)}$ where $\vec{u}^{(0)} = (y_1, \ldots, y_k)$, $\vec{u}^{(n+1)} = \vec{u}^{(n)}[\vec{y} := \vec{u}]$;*
- *For large enough $n \in \mathbb{N}$, each $u_i^{(n+1)}$ depends only on $u_i^{(n)}$ for the same $i \in \{1, \ldots, k\}$. More precisely, there exists $N \in \mathbb{N}$ such that for all $i \in \{1, \ldots, k\}$ there exists a well-typed closed $\lambda\wp$-term $t'_i : B_i \multimap B_i$ such that for all $n \geq N$, $u_i^{(n+1)} = t'_i\ u_i^{(n)}$.*

Proof. The first item is established by induction: abbreviating $\lambda^{\circ} y_1. \ldots \lambda^{\circ} y_k.$ as $\lambda^{\circ}\vec{y}.$,

$$\begin{aligned} t \circ (\lambda^{\circ} x. \lambda^{\circ}\vec{y}. x\, u_1^{(n)} \ \ldots\ u_k^{(n)}) &=_\beta \lambda^{\circ} x. \lambda^{\circ}\vec{y}. (\lambda^{\circ}\vec{y}. x\, u_1^{(n)} \ \ldots\ u_k^{(n)})\, u_1 \ \ldots\ u_k \\ &=_\beta \lambda^{\circ} x. \lambda^{\circ}\vec{y}. x\, (u_1^{(n)}[\vec{y} := \vec{u}]) \ \ldots\ u_k^{(n)}([\vec{y} := \vec{u}]) \end{aligned}$$

(We invite to reader to reproduce the full computation to check that no spurious capture of free variables happens.)

For the second item, let us define the partial function $\mu_{\vec{u}} : \{1, \ldots, k\} \rightharpoonup \{1, \ldots, k\}$ by $\mu_{\vec{u}}(i) = j \iff y_i \in \mathrm{FV}(u_j)$. ($\mathrm{FV}(u)$ denotes the set of free variables of u.) The relation on the right-hand side of the equivalence is indeed a partial function because of the affineness of $t = \lambda^{\circ} x. \lambda^{\circ} y_1. \ldots \lambda^{\circ} y_k. z\, u_1 \ldots u_k$. One can also show that for all $n \in \mathbb{N}$, $\mathrm{FV}(u_i^{(n)}) = \{y_j \mid (\mu_{\vec{u}})^n(j) = i\}$.

As a consequence of non-commutativity, $\mu_{\vec{u}}$ is non-decreasing. This is because for the typing judgment on $x\, u_1 \ldots u_k$ to hold, there must exist $\Delta_1, \ldots, \Delta_k$ such that:

- for all $j \in \{1, \ldots, k\}$, $\Delta_j \vdash u_j$ and $\forall i,\ y_i \in \mathrm{FV}(u_j) \iff (y_i : B_i) \in \Delta_j$;
- $\Delta_1 \cdot \ldots \cdot \Delta_k$ is an *ordered subsequence* of $(y_1 : B_1) \cdot \ldots \cdot (y_k : B_k)$.

Therefore, by Lemma 3.2, there exists $N \in \mathbb{N}$ such that $(\mu_{\vec{u}})^N = (\mu_{\vec{u}})^{N+1}$.

Next, let $i \in \{1, \ldots, k\}$. We may reformulate our goal as finding $t'_i : B_i \multimap B_i$ such that $t'_i\ u_i^{(N+n)} =_{\beta\eta} u^{(N+n+1)}$ for all $n \in \mathbb{N}$. The simple case is when $i \notin (\mu_{\vec{u}})^N(\{1, \ldots, k\})$: $u_i^{(N)}$ has no free variables, so $u_i^{(N+1)} = u_i^{(N)}[\vec{y} := \vec{u}] = u_i^{(N)}$: we may then take $t'_i = \lambda^{\circ} z.\ z$. For the remainder of the proof we assume otherwise, that is, we take i in the range of $(\mu_{\vec{u}})^N$.

First, $\vec{u}^{(n+1)} = \vec{u}[\vec{y} := \vec{u}^{(n)}]$ because parallel substitution is associative[11]. Thus,

$$\forall n \in \mathbb{N},\ u_i^{(N+n+1)} = u_i \left[y_j := u_j^{(N+n)} \text{ for } j \in \{1, \ldots, k\} \text{ such that } \mu_{\vec{u}}(j) = i \right]$$

Any $j \in \{1, \ldots, k\} \setminus \{i\}$ such that $\mu_{\vec{u}}(j) = i$ is not a fixed point of $\mu_{\vec{u}}$, and therefore is not in the range of $(\mu_{\vec{u}})^N$ since $(\mu_{\vec{u}})^N = (\mu_{\vec{u}})^{N+1} = \mu_{\vec{u}} \circ (\mu_{\vec{u}})^N$. By the simple case already treated, we then have $u_j^{(N+n)} = u_j^{(N)}$. This allows us to write the above equation as

$$u_i^{(N+n+1)} = r_i[y_i := u_i^{(N+n)}] \quad \text{where} \quad r_i = u_i \left[y_j := u_j^{(N)} \text{ for } j \neq i \text{ s.t. } \mu_{\vec{u}}(j) = i \right]$$

Using β-conversion, $u_i^{(N+n+1)} =_\beta (\lambda^{\circ} y_i. r_i)\, u_i^{(N+n)}$. We conclude by setting $t'_i = (\lambda^{\circ} y_i. r_i)$. It is clear that this $\lambda\wp$-term is closed, but one should check that it is well-typed; to do so, one convenient observation is that the $u_j^{(N)}$ are closed (because $j \notin (\mu_{\vec{u}})^N(\{1, \ldots, k\})$) and well-typed (as closed subterms of a reduct of the N-fold composition t^N). ◀

The remainder of the proof of Theorem 1.8 is essentially bureaucratic.

Proof of the aperiodicity part of Theorem 1.8. Let $t : A \multimap A$; our goal is to show that the sequence $t^n = t \circ \ldots \circ t$ is eventually constant modulo $\beta\eta$. We shall do so by *induction on the size of A*. The type A is *purely affine* by assumption, and can therefore be written as $B_1 \multimap \ldots \multimap B_m \multimap o$ where the B_i are also purely affine for $i \in \{1, \ldots, m\}$. The base case $m = 0$ being trivial, we assume $m \geq 1$. In this case, by Proposition 2.3, t has an η-long β-normal form $t = \lambda^{\circ} x. \lambda^{\circ} y_1. \ldots \lambda^{\circ} y_m. z\, u_1 \ldots u_k$ where z is a variable. There are two cases:

- $z = y_i$ for some i. Then $(y_i : B_i) \cdot \Delta \vdash z\, u_1 \ldots u_k$ by application rule (we omit the non-affine context Γ which will always be empty during this proof). The abstraction rule only allows introducing $\lambda^{\circ} y_i$ when $(y_i : B_i)$ is on the right, so by then Δ must have been

[11] More precisely, $(\vec{t_1}[\vec{x} := \vec{t_2}])[\vec{y} := \vec{t_3}] = \vec{t_1}[\vec{x} := \vec{t_2}[\vec{y} := \vec{t_3}]]$ when $\vec{y} \cap (\mathrm{FV}(\vec{t_1}) \setminus \vec{x}) = \varnothing$.

entirely emptied out by previous abstractions. This means that $\lambda^{\circ} y_i. \ldots \lambda^{\circ} y_m. z\, u_1 \ldots u_k$ is a closed term, so in particular it contains no free occurrence of x: t is a constant function from A to A. So the sequence of iterations stabilizes from $n = 1$.

- $z = x$, which entails $k = m$ since the variable x is of type $A = B_1 \multimap \ldots \multimap B_m \multimap o$ and we must have $x : A,\ y_1 : B_1,\ \ldots,\ y_m : B_m \vdash x\, u_1 \ldots u_k : o$. Lemma 3.5 gives us closed $\lambda\wp$-terms $t'_i : B_i \multimap B_i$ $(i \in \{1, \ldots, k\})$ whose iterates eventually determine those of t. Since the type B_i has size strictly smaller than A, the induction hypothesis applies: each $((t'_i)^n)_{n\in\mathbb{N}}$ is eventually constant modulo $\beta\eta$. Therefore, this is also the case for t. ◀

Let us now apply Theorem 1.8 to the $\lambda\wp$-terms defining languages.

▶ **Lemma 3.6.** *Let $\Sigma = \{c_1, \ldots, c_{|\Sigma|}\}$ be a finite alphabet, A be a* purely affine *type and $t : \mathtt{Str}_\Sigma[A] \multimap \mathtt{Bool}$ be a closed $\lambda\wp$-term. Then there exist some closed $\lambda\wp$-terms $g_c : A \multimap A$ for $c \in \Gamma$ and $h : (A \multimap A) \multimap \mathtt{Bool}$ such that $t =_{\beta\eta} \lambda^{\circ} s.\, h\,(s\, g_{c_1} \ldots g_{c_{|\Sigma|}})$.*

Proof. By inspection of the normal form of t, see Appendix B in [37]. ◀

Reusing the notations of this lemma, let us define $\varphi : \Sigma^* \to \{v \mid v : A \multimap A\}/{=_{\beta\eta}}$ to be the monoid morphism such that $\varphi(c) = g_c$ for $c \in \Sigma$. Then for all $w \in \Sigma^*$, $\varphi(w) = w^\dagger(\vec{g}_\Sigma)$ (in the quotient): by a similar computation than for $f \circ (g \circ h) =_{\beta\eta} (f \circ g) \circ h$, we have $g_{w[1]} \circ \ldots \circ g_{w[n]} \longrightarrow^*_\beta w^\dagger(\vec{g}_\Sigma)$. Therefore, by Proposition 2.5, $\varphi^{-1}(\{v \mid h\, v =_{\beta\eta} \mathtt{true}\})$ is none other than the language defined by the $t : \mathtt{Str}_\Sigma[A] \multimap \mathtt{Bool}$ in the lemma. Thus, L fits the second definition of star-free languages given in Theorem 1.5: indeed, the codomain of φ is finite and aperiodic by Theorem 1.8. This proves the soundness part of Theorem 1.7.

4 Expressiveness of the $\lambda\wp$-calculus

We now turn to the *extensional completeness* part in Theorem 1.7: our goal is to construct, for any star-free language, a closed $\lambda\wp$-term of type $\mathtt{Str}_\Sigma[A] \multimap \mathtt{Bool}$ (for some purely affine A) that defines this language. To do so, the most convenient way that we have found is to take a detour through automata that compute an output string instead of a single bit (acceptance/rejection). We will recall the notion of *aperiodic sequential function* (Definition 4.4), and then establish that:

▶ **Theorem 4.1.** *Any* aperiodic sequential function $\Sigma^* \to \Pi^*$ *can be expressed by a $\lambda\wp$-term of type $\mathtt{Str}_\Sigma[A] \multimap \mathtt{Str}_\Pi$ for some* purely affine *type A.*

The advantage of working with this class of functions is that they can be assembled from small "building blocks" by function composition, as the *Krohn–Rhodes decomposition* (Theorem 4.8) tells us. Our proof strategy for the above theorem will consist in encoding these blocks (Lemma 4.10) and composing them together (as a special case of Lemma 2.8).

To deduce the desired result, we rely on two lemmas (proved in Appendix B in [37]):

▶ **Lemma 4.2.** *If a language $L \subseteq \Sigma^*$ is* star-free, *then its* (string-valued) indicator function *$\chi_L : \Sigma^* \to \{1\}^*$, defined by $\chi_L(w) = 1$ if $w \in L$ and $\chi_L(w) = \varepsilon$ otherwise, is aperiodic sequential.*

▶ **Lemma 4.3.** *There exists a $\lambda\wp$-term $\mathtt{nonempty} : \mathtt{Str}_{\{1\}}[\mathtt{Bool}] \multimap \mathtt{Bool}$ that tests whether its input string is non-empty.*

Let L be a star-free language. Combining Lemma 4.2 and Theorem 4.1, χ_L is definable by some $\lambda\wp$-term $\mathtt{indic}_L : \mathtt{Str}_\Sigma[A] \multimap \mathtt{Str}_{\{1\}}$ where A is purely affine. To compose this with the non-emptiness test of Lemma 4.3, we use Lemma 2.8 again: the $\lambda\wp$-term

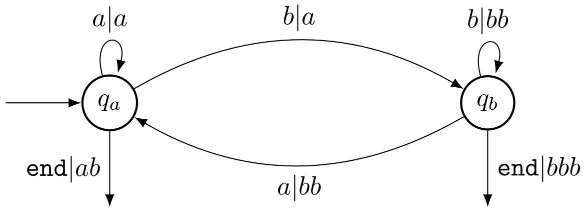

Figure 2 A schematic representation of a sequential transducer whose formal definition is $Q = \{q_a, q_b\}$, $\delta(q, a) = (q_a, a)$ and $\delta(q, b) = (q_b, bb)$ for $q \in Q$, $q_I = q_a$, $F(q_a) = ab$ and $F(q_b) = bbb$.

$t_L = \lambda^\circ x.\ \mathtt{nonempty}\ (\mathtt{indic}_L\ x) : \mathtt{Str}_\Sigma[A[\mathtt{Bool}]] \multimap \mathtt{Bool}$ defines L. Since A and $\mathtt{Bool}$ are purely affine, so is $A[\mathtt{Bool}]$: we just deduced extensional completeness from Theorem 4.1. Proving the latter is the goal of the rest of this section.

4.1 Reminders on automata theory

Sequential transducers are among the simplest models of automata with output. They are deterministic finite automata which can append a word to their output at each transition, and at the end, they can add a suffix to the output depending on the final state. The definition is classical; a possible reference is [44, Chapter V].

▶ **Definition 4.4.** *A* sequential transducer *with input alphabet* Σ *and output alphabet* Π *consists of a set of* states Q, *a* transition function $\delta : Q \times \Sigma \to Q \times \Pi^*$, *an* initial state $q_I \in Q$, *and a* final output function $F : Q \to \Pi^*$. *We abbreviate* $\delta_i = \pi_i \circ \delta$ *for* $i \in \{1, 2\}$, *where* $\pi_1 : Q \times \Pi^* \to Q$ *and* $\pi_2 : Q \times \Pi^* \to \Pi^*$ *are the projections of the product.*

Given an input string $w = w[1] \dots w[n] \in \Sigma^*$, *the* run *of the transducer over* w *is the sequence of states* $q_0 = q_I$, $q_1 = \delta_{\mathrm{st}}(q_0, w[1])$, $\dots$, $q_n = \delta_{\mathrm{st}}(q_{n-1}, w[n])$. *Its* output *is obtained as the concatenation* $\delta_{\mathrm{out}}(q_0, w[1]) \cdot \ldots \cdot \delta_{\mathrm{out}}(q_{n-1}, w[n]) \cdot F(q_n)$.

A sequential function *is a function* $\Sigma^* \to \Pi^*$ *computed as described above by some sequential transducer.*

▶ **Definition 4.5.** *The* transition monoid *of a sequential transducer is the submonoid of* $Q \to Q$ *(endowed with reverse function composition:* $fg = g \circ f$*) generated by the maps* $\{\delta_{\mathrm{st}}(-, c) \mid c \in \Sigma\}$ *(where* $\delta_{\mathrm{st}}(-, c)$ *stands for* $q \mapsto \delta_{\mathrm{st}}(q, c)$*).*

A sequential transducer is said to be aperiodic *when its transition monoid is aperiodic. A function that can be computed by such a transducer is called an* aperiodic sequential function.

▶ **Example 4.6.** The transducer in Figure 2 computes $f : w \in \{a, b\}^* \mapsto a \cdot \psi(w) \cdot b$ where ψ is the monoid morphism that doubles every b: $\psi(a) = a$ and $\psi(b) = bb$. Its transition monoid T is generated by $G = \{(\delta_{\mathrm{st}}(-, a) : q \mapsto q_a), (\delta_{\mathrm{st}}(-, b) : q \mapsto q_b)\}$; one can verify that $T = G \cup \{\mathrm{id}\}$ and therefore $\forall h \in T,\ h \circ h = h$. Thus, f is an aperiodic sequential function.

▶ Remark 4.7. The converse to Lemma 4.2 is also true; more generally, the preimage of a star-free language by an aperiodic sequential function is star-free, and the preimage of a regular language is regular. But we will not need this here.

▶ **Theorem 4.8** (Krohn–Rhodes decomposition, aperiodic case, cf. Appendix A in [37])**.** *Any* aperiodic sequential function $f : \Sigma^* \to \Pi^*$ *can be realized as a composition* $f = f_1 \circ \ldots \circ f_n$ *(with* $f_i : \Xi_i^* \to \Xi_{i-1}^*$, $\Xi_0 = \Pi$ *and* $\Xi_n = \Sigma$*) where each function* f_i *is computed by some aperiodic sequential transducer* with 2 states.

Figure 2 gives an example of aperiodic transducer with two states.

▶ Remark 4.9. This is not the standard way to state this theorem, though one may find it in the literature, usually without proof (e.g. [10, §1.1]); see [8] for a tutorial containing a proof sketch of this version. In Appendix A in [37], we show how Theorem 4.8 follows from the more usual statement on wreath products of monoid actions.

4.2 Encoding aperiodic sequential transducers

Thanks to the Krohn–Rhodes decomposition and to the fact that the string functions definable in the $\lambda\wp$-calculus (as specified by Theorem 4.1) are closed under composition (by Lemma 2.8), the following entails Theorem 4.1, thus concluding our completeness proof.

▶ **Lemma 4.10.** *Any function $\Sigma^* \to \Pi^*$ computed by some aperiodic sequential transducer* with 2 states *can be expressed by some $\lambda\wp$-term of type $\mathtt{Str}_\Sigma[A] \multimap \mathtt{Str}_\Pi$, for a* purely affine *type A depending on the function.*

Let us start by exposing the rough idea of the encoding's trick using set-theoretic maps. We reuse the notations of Definition 4.4 and assume w.l.o.g. that the set of states is $Q = \{1, 2\}$.

Suppose that at some point, after processing a prefix of the input, the transducer has arrived in state 1 (resp. 2) and in the meantime has outputted $w \in \Pi^*$. We can represent this "history" by the pair (κ_w, ζ) (resp. (ζ, κ_w)) where

$$\zeta, \kappa_w : \Pi^* \to \Pi^* \qquad \zeta : x \mapsto \varepsilon \qquad \kappa_w : x \mapsto w \cdot x$$

For instance, in the case of Example 4.6, after reading a string $s = s'b$, the transducer is in the state q_b and has outputted[12] $w = a \cdot \psi(s')$, which we represent as $(\zeta, \kappa_{a\cdot\psi(s')})$ (taking $q_a = 1$ and $q_b = 2$; ψ is described in Example 4.6). In general, some key observations are

$$\zeta \circ \kappa_w = \zeta \qquad \kappa_w \circ \kappa_{w'} = \kappa_{ww'} \qquad \kappa_w(w')\zeta(w'') = \zeta(w'')\kappa_w(w') = ww'$$

Now, consider an input letter $c \in \Sigma$; how to encode the corresponding transition $\delta(-, c)$ as a transformation on the pair encoding the current state and output history? It depends on the state transition $\delta_{\mathrm{st}}(-, c)$; we have thanks to the above identities:

- $(h, g) \mapsto (h \circ \kappa_{\delta_{\mathrm{out}}(1,c)}, g \circ \kappa_{\delta_{\mathrm{out}}(2,c)})$ when $\delta_{\mathrm{st}}(-, c) = \mathrm{id}$;
- $(h, g) \mapsto (\kappa_{h(\delta_{\mathrm{out}}(1,c))g(\delta_{\mathrm{out}}(2,c))}, \zeta)$ when $\delta_{\mathrm{st}}(-, c) : q' \mapsto 1$ (note that $h = \zeta$ xor $g = \zeta$);
- $(h, g) \mapsto (\zeta, \kappa_{h(\delta_{\mathrm{out}}(1,c))g(\delta_{\mathrm{out}}(2,c))})$ when $\delta_{\mathrm{st}}(-, c) : q' \mapsto 2$;
- The remaining case $\delta_{\mathrm{st}}(-, c) : q \mapsto 3 - q$ is *excluded by aperiodicity.* This point is crucial: this case would correspond to $(h, g) \mapsto (g \circ \kappa_{\delta_{\mathrm{out}}(2,c)}, h \circ \kappa_{\delta_{\mathrm{out}}(1,c)})$ which morally "uses its arguments h, g in the wrong order".

Coming back to Example 4.6, let us say that after the transducer has read a prefix $s = s'b$ of its input string as we previously described, the next letter is a. Then the expression $h(\delta_{\mathrm{out}}(1, c))g(\delta_{\mathrm{out}}(2, c))$ above is in this case $\zeta(a)\kappa_{a\cdot\psi(s')}(bb) = \varepsilon \cdot a \cdot \psi(s') \cdot bb = a \cdot \psi(s)$ which is indeed the output that the transducer produces after reading the input prefix $sa = s'ba$.

Next, we must transpose these ideas to the setting of the $\lambda\wp$-calculus.

[12] This is indeed $a \cdot \psi(s')$ and not $a \cdot \psi(s) = a \cdot \psi(s') \cdot bb$. If the input turns out to end there, the final output function will provide the missing suffix $F(q_b) = bbb$ to obtain $f(s) = a \cdot \psi(s) \cdot b = a \cdot \psi(s') \cdot bbb$.

Proof of Lemma 4.10. We define the $\lambda\wp$-term meant to compute our sequential function as

$$\lambda^{\circ} s.\, \lambda^{\to} f_{a_1}. \;\ldots\; \lambda^{\to} f_{a_{|\Pi|}}. \, \mathtt{out}\,(s\,\mathtt{trans}_{c_1}\;\ldots\;\mathtt{trans}_{c_{|\Sigma|}}) : \mathtt{Str}_{\Sigma}[A] \multimap \mathtt{Str}_{\Pi}$$

where $\Sigma = \{c_1, \ldots, c_{|\Sigma|}\}$, $\Pi = \{a_1, \ldots, a_{|\Pi|}\}$ and, writing $\Gamma = \{f_a : o \multimap o \mid a \in \Pi\}$,

$$\Gamma \mid \varnothing \vdash \mathtt{trans}_c : A \multimap A \quad (\text{for all } c \in \Sigma) \qquad\qquad \Gamma \mid \varnothing \vdash \mathtt{out} : (A \multimap A) \multimap (o \multimap o)$$

In the presence of this non-affine context Γ, the type $S = o \multimap o$ morally serves as a purely affine type of strings, as mentioned in Remark 2.9. Moreover this "contextual encoding of strings" supports concatenation (by function composition), leading us to represent the maps ζ and κ_w as open terms of type $T = S \multimap S$ that use non-affinely the variables f_a for $a \in \Pi$.

We shall take the type A, at which the input $\mathtt{Str}_{\Sigma}$ is instantiated, to be $A = T \multimap T \multimap S$, which is indeed purely affine as required by the theorem statement. This can be seen morally as a type of continuations [42] taking pairs of type $T \otimes T$ (although our $\lambda\wp$-calculus has no actual $\otimes$ connective). Without further ado, let us program (the typing derivations for some of the following $\lambda\wp$-terms are given in Appendix C in [37]):

- $\mathtt{cat} = \lambda^{\circ} w.\, \lambda^{\circ} w'.\, \lambda^{\circ} x.\, w\,(w'\,x) : S \multimap S \multimap o \multimap o = S \multimap S \multimap S = S \multimap T$ plays the roles of both the concatenation operator and of $w \mapsto \kappa_w$ (thanks to currying)
- $\mathtt{zeta} = \lambda^{\circ} w'.\, \lambda^{\circ} x.\, x : S \multimap o \multimap o = T$
- $u_q = \delta_{\mathrm{out}}(q,c)^{\dagger}(\vec{f_{\Pi}}) : o \multimap o$ (by Proposition 2.5) represents the output word $\delta_{\mathrm{out}}(q,c)$ that corresponds to a given input letter $c \in \Sigma$ and state $q \in Q = \{1,2\}$
- case $\delta_{\mathrm{st}}(q,c) = q$: $\mathtt{trans}_c = \lambda^{\circ} k.\, \lambda^{\circ} h.\, \lambda^{\circ} g.\, k\,(\lambda^{\circ} y.\, h\,(\mathtt{cat}\,u_1\,y))\,(\lambda^{\circ} z.\, g\,(\mathtt{cat}\,u_2\,z))$ – if we wanted to handle the excluded case $\delta_{\mathrm{st}}(q,c) = 3 - q$, we would write a similar term with the occurrences of h and g exchanged $(\lambda^{\circ} k.\, \lambda^{\circ} h.\, \lambda^{\circ} g.\, k\,(\lambda^{\circ} y.\, g\;\ldots)\,(\lambda^{\circ} z.\, h\;\ldots))$, violating the non-commutativity requirement (contrast with the proof of Theorem 5.4);
- case $\delta_{\mathrm{st}}(q,c) = 1$: $\mathtt{trans}_c = \lambda^{\circ} k.\, \lambda^{\circ} h.\, \lambda^{\circ} g.\, k\,(\mathtt{cat}\,(\mathtt{cat}\,(h\,u_1)\,(g\,u_2)))\,\mathtt{zeta}$
- case $\delta_{\mathrm{st}}(q,c) = 2$: $\mathtt{trans}_c = \lambda^{\circ} k.\, \lambda^{\circ} h.\, \lambda^{\circ} g.\, k\,\mathtt{zeta}\,(\mathtt{cat}\,(\mathtt{cat}\,(h\,u_1)\,(g\,u_2)))$
- $\mathtt{out} = \lambda^{\circ} j.\, j\,(\lambda^{\circ} h.\, \lambda^{\circ} g.\, \mathtt{cat}\,(h\,v_1)\,(g\,v_2))\,(\lambda^{\circ} x.\, x)\,\mathtt{zeta}$, where $v_q = F(q)^{\dagger}(\vec{f_{\Pi}})$ represents the output suffix for state $q \in \{1,2\}$, assuming w.l.o.g. that the initial state is 1 (also, here $\lambda^{\circ} x.\, x$ represents κ_{ε} since the latter is the identity on Π^*)

We leave it to the reader to check that these $\lambda\wp$-terms have the expected computational behavior; again, see Appendix C in [37] for typing derivations. Note that in functional programming terms, the use of continuations turns the "right fold" of the Church-encoded input string into a "left fold", and the latter fits with the left-to-right processing of a sequential transducer. ◀

5 Regular languages in extensions of the $\lambda\wp$-calculus

5.1 The commutative case

The $\lambda\wp$-calculus adds two restrictions to the simply typed λ-calculus, namely affineness and non-commutativity, with the latter depending on the former as already mentioned. One could wonder whether affineness by itself would be enough to characterize star-free languages. We now show that it is not the case.

The *commutative* variant of the $\lambda\wp$-calculus – let us call this variant the *λa-calculus*[13] – has the same grammar of types and terms as the $\lambda\wp$-calculus (cf. §2). The typing rules are also given by Figure 1, but their interpretation differs from the previous one as follows:

[13] *a* standing for "affine".

Δ, Δ' stand for *sets* of bindings $x : A$, $\Delta \cdot \Delta'$ denotes the *disjoint union* of sets, and one must read "subset" instead of "subsequence". In other words, the main difference is that in the λa-calculus, the affine context Δ does not keep track of the *ordering* of variables.

By plugging this commutative system in the statement of our main result (Theorem 1.7), we get *regular languages* instead of star-free languages:

▶ **Theorem 5.1.** *A language $L \subseteq \Sigma^*$ is* regular *if and only if it can be defined by a closed λa-term of type $\mathtt{Str}_\Sigma[A] \multimap \mathtt{Bool}$ for some purely affine type A (that may depend on L).*

Proof. Soundness is a consequence of Hillebrand and Kanellakis's Theorem 1.1, by a simple translation from the λa-calculus to the simply typed λ-calculus which "forgets affineness".

For extensional completeness, consider a regular language $L = \varphi^{-1}(P)$ where P is a subset of a finite monoid M and $\varphi : \Sigma^* \to M$ is a morphism (cf. Theorem 1.3). If we represent an element $m \in M$ by a M-indexed bit vector v_m such that $v_m[i] = 1 \iff i = m$, then a translation $m \mapsto mp$ can be represented by a *purely disjunctive* formula:

$$v_{mp}[i] = v_m[j_1] \vee \ldots \vee v_m[j_k] \text{ where } \{j_1, \ldots, j_k\} = \{j \in M \mid jp = i\}$$

Moreover, this is *linear* in the following sense: given a fixed $p \in M$, each index $j \in M$ is involved in the right-hand side of this formula for exactly one $i \in M$.

Let $\mathtt{ttt} = \lambda^\circ x.\,\mathtt{true} : \mathtt{Bool} \multimap \mathtt{Bool}$ and $\mathtt{fff} = \lambda^\circ x.\,x : \mathtt{Bool} \multimap \mathtt{Bool}$. This makes the type $B = \mathtt{Bool} \multimap \mathtt{Bool}$ into a kind of type of booleans that supports a disjunction of type $B \multimap B \multimap B$ (by function composition) and a type-cast function of type $B \multimap \mathtt{Bool}$ (by applying to $\mathtt{false}$). (Of course B has other closed inhabitants besides $\mathtt{ttt}$ and $\mathtt{fff}$, but we only use those two.) Using this type and the "iteration+continuations" recipe of the proof of Lemma 4.10, one can define a λa-term of type $\mathtt{Str}_\Sigma[A] \multimap \mathtt{Bool}$ that decides the language L with $A = B \multimap \ldots \multimap B \multimap \mathtt{Bool}$ (with $|M|$ arguments of type B). ◀

Let us go further. According to Theorem 4.1, the $\lambda\wp$-calculus can define all aperiodic sequential functions; we show that as one can expect, the aperiodicity condition is lifted when moving to the commutative λa-calculus. However, the trick used in the direct encoding of the above proof does not work, and we have only managed to encode general sequential functions by resorting to the Krohn–Rhodes theorem.

▶ **Theorem 5.2** (Krohn–Rhodes decomposition, non-aperiodic case, cf. Appendix A in [37])**.** *Any* sequential function $f : \Sigma^* \to \Pi^*$ *can be realized as a composition $f = f_1 \circ \ldots \circ f_n$ (with $f_i : \Xi_i^* \to \Xi_{i-1}^*$, $\Xi_0 = \Pi$ and $\Xi_n = \Sigma$) where each function f_i is computed by some sequential transducer whose transition monoid is either* aperiodic *or a* group*.*

▶ Remark 5.3. By Theorem 4.8, the aperiodic transducers among the f_i can be further decomposed into two-state aperiodic transducers.

▶ **Theorem 5.4.** *Any sequential function $\Sigma^* \to \Pi^*$ can be expressed by some λa-term of type $\mathtt{Str}_\Sigma[A] \multimap \mathtt{Str}_\Pi$, for a* purely affine *type A depending on the function.*

Proof sketch. First, by Theorem 4.1, we can already encode aperiodic sequential functions, since every well-typed $\lambda\wp$-term is also a well-typed λa-term. One can also show that Lemma 2.8 applies to the λa-calculus. By the general Krohn–Rhodes theorem, we just need to handle the case of a sequential transducer whose transition monoid is a group.

The idea, in terms of set-theoretic maps as in our explanation of the proof of Lemma 4.10 (whose notations we borrow here), is as follows. The current state $q \in Q$ and output history $w \in \Pi^*$ is represented by a Q-indexed family $(g_{q'})_{q' \in Q}$ of functions such that $g_q = \kappa_w$ and for

$q' \neq q$, $g_{q'} = \zeta$. The transition $\delta(-,c)$ is represented by $(g_q)_{q\in Q} \mapsto (g_{\sigma(q)} \circ \kappa_{\delta_{\mathrm{out}}(\sigma(q),c)})_{q\in Q}$ where $\sigma = (\delta_{\mathrm{st}}(-,c))^{-1}$ – the latter is well-defined because the group assumption means that $\delta_{\mathrm{st}}(-,c)$ is a permutation of Q. The final output is obtained at the end as the concatenation $g_{q_1}(F(q_1)) \dots g_{q_n}(F(q_n))$ where $Q = \{q_1, \dots, q_n\}$ (with an arbitrary enumeration of Q).

The elaboration of the corresponding λa-term is left to the reader. Keep in mind that the reason this term will not be well-typed for the $\lambda\wp$-calculus is that the inversions in the permutation $\delta_{\mathrm{st}}(-,c)$ correspond to violations of non-commutative typing. ◀

5.2 Extension with additive pairs

Let's look at what happens if we add the *additive conjunction* connective of linear logic to the $\lambda\wp$-calculus. The $\lambda\wp^{\&}$*-calculus* is obtained by adding $A, B ::= \dots \mid A \mathbin{\&} B$ to the grammar of types and $t, u ::= \dots \mid \langle t, u\rangle \mid \pi_1\, t \mid \pi_2\, t$ for terms, with the typing rules

$$\frac{\Gamma \mid \Delta \vdash t : A \quad \Gamma \mid \Delta \vdash u : B}{\Gamma \mid \Delta \vdash \langle t, u\rangle : A \mathbin{\&} B} \qquad \frac{\Gamma \mid \Delta \vdash t : A_1 \mathbin{\&} A_2}{\Gamma \mid \Delta \vdash \pi_i\, t : A_i} \qquad \text{(see [39, §4])}$$

the β-reduction rules $\pi_i\,\langle t_1, t_2\rangle \longrightarrow_\beta t_i$, and the corresponding η-conversion rules.

Recall that we discussed both in the introduction and in Remark 2.7 the need to prevent the existence of a $\lambda\wp$-term of type $\texttt{Bool} \multimap \texttt{Bool}$ for negation. However, if we use the additive conjunction to define the type $\texttt{Bool}^{\&} = (o \mathbin{\&} o) \multimap o$, the following are well-typed $\lambda\wp^{\&}$-terms:

$$\texttt{true}^{\&} = \lambda^{\circ} p.\ \pi_1\, p \qquad \texttt{false}^{\&} = \lambda^{\circ} p.\ \pi_2\, p \qquad \texttt{not}^{\&} = \lambda^{\circ} b.\ \lambda^{\circ} p.\ b\ \langle \pi_2\, p, \pi_1\, p\rangle$$

More generally:

▶ **Proposition 5.5.** *Let* $\texttt{Fin}^{\&}(n) = (o \mathbin{\&} \dots \mathbin{\&} o) \multimap o$*. For all* $n \in \mathbb{N}$*, there is a canonical bijection between* $\{1, \dots, n\}$ *and the closed* $\lambda\wp^{\&}$*-terms of type* $\texttt{Fin}^{\&}(n)$*. Furthermore, using this encoding, every map* $\{1, \dots, n_1\} \times \dots \times \{1, \dots, n_k\} \to \{1, \dots, m\}$ *can be defined by a closed* $\lambda\wp^{\&}$*-term of type* $\texttt{Fin}^{\&}(n_1) \multimap \dots \texttt{Fin}^{\&}(n_k) \multimap \texttt{Fin}^{\&}(m)$*.*

▶ **Corollary 5.6.** *Every* regular *language can be defined by a closed* $\lambda\wp^{\&}$*-term of type* $\texttt{Str}_\Sigma[A] \multimap \texttt{Bool}$ *for some purely affine type* A *– we consider "&" as an affine connective and therefore allow it in* A*.*

Proof idea. Take $A = \texttt{Fin}^{\&}(|M|)$ where M is any finite monoid that recognizes the language as specified in Theorem 1.3. (We could also prove the converse by relying on an extension of Hillebrand and Kanellakis's Theorem 1.1 to the simply typed λ-calculus with products.) ◀

Similarly, one could show that the addition of the *additive disjunction* "$\oplus$" of linear logic to the $\lambda\wp$-calculus would be sufficient to encode all regular languages.

5.3 On regular and first-order tree languages: a discussion

There is a rich theory of *tree automata* that extends the notion of regular language to trees over ranked alphabets instead of strings. Such trees admit Church encodings; for instance, for an alphabet with arities $(a : 2, b : 2, x : 0)$ (i.e. for trees with two kind of binary nodes and one kind of leaf) one would have $\texttt{Tree}_{(2,2,0)} = (o \multimap o \multimap o) \to (o \multimap o \multimap o) \to o \to o$.

▶ Remark 5.7. A string over an alphabet $\Sigma = \{c_1, \dots, c_{|\Sigma|}\}$ can be seen as a tree with arities $(c_1 : 1,\ \dots,\ c_{|\Sigma|} : 1, \varepsilon : 0)$. This would lead to defining the type of Church-encoded strings as $\texttt{Str}'_\Sigma = (o \multimap o) \to \dots \to (o \multimap o) \to o \to o$. Our type $\texttt{Str}_\Sigma$, which is the traditional choice in linear logic (see the discussion on Church numerals in [17, §5.3.2]), is a bit more precise since it expresses that such a "unary tree" can only contain one ε node. But as there exist conversion functions $\mathtt{Str}_\Sigma \multimap \mathtt{Str}'_\Sigma$ and $\mathtt{Str}'_\Sigma[o \multimap o] \multimap \mathtt{Str}_\Sigma$, this choice does not make much difference (thanks again to Lemma 2.8).

We shall not go into the details of tree automata here, but the knowledgeable reader may check that Proposition 5.5 can be used to encode all *regular tree languages* over $(a : 2, b : 2, x : 0)$ as closed $\lambda\wp^{\&}$-terms of type $\mathtt{Tree}_{(2,2,0)}[A] \multimap \mathtt{Bool}$ for purely affine A. Predictably, this fails for the $\lambda\wp$-calculus without additive connectives. More noteworthy is the failure of the trick used to prove Theorem 5.1 for the commutative λa-calculus when one replaces strings with trees. Thus, it seems (though this remains conjectural) that *the additives of linear logic might be required to express some regular tree languages.*

We believe that this is no accident and that some fundamental difficulty of automata theory is being manifested here. Indeed, if we had a characterization of regular tree languages in the λa-calculus, we could expect that moving to the $\lambda\wp$-calculus would yield the *first-order tree languages*, which are the commonly accepted counterpart of star-free languages for trees. (Recall from Theorem 1.5 that definability in first-order logic is among the equivalent definitions of star-free languages.) However, while Theorem 1.5 demonstrates that star-free languages are well-understood, the situation is quite different for first-order tree languages: there is no known algebraic characterization, and neither is there any known algorithm to decide whether a tree automaton recognizes a first-order language (see e.g. [9, §3]). Another argument for the necessity of additives, discussed in the next section, comes from transducers.

6 Next episode preview: transducers in typed λ-calculi

We started from Hillebrand and Kanellakis's Theorem 1.1 and obtained an analogous statement for star-free languages instead of regular languages. Another direction that we could have pursued is to replace languages by *functions*, by looking at the type $\mathtt{Str}_\Sigma[A] \to \mathtt{Str}_\Pi$. Indeed, an immediate consequence of this "regular = λ-definable" result is:

▶ **Corollary 6.1.** *If $f : \Sigma^* \to \Pi^*$ is definable by a closed simply typed λ-term of type $\mathtt{Str}_\Sigma[A] \to \mathtt{Str}_\Pi$, then for any regular language $L \subseteq \Pi^*$, $f^{-1}(L) \subseteq \Sigma^*$ is also regular.*

Proof idea. Let $u : \mathtt{Str}_\Pi[B] \to \mathtt{Bool}$ and $t : \mathtt{Str}_\Sigma[A] \to \mathtt{Str}_\Pi$ be simply typed λ-terms defining L and f respectively. Then $f^{-1}(L)$ is defined by $\lambda x.\, u\,(t\,x)$ which is well-typed with type $\mathtt{Str}_\Sigma[A[B]] \to \mathtt{Bool}$ (analogously to Lemma 2.8). ◀

This suggests a connection between these λ-definable string functions and automata theory. But while it is not too hard to define functions of hyperexponential growth in the simply typed λ-calculus, most classes of string functions from automata theory (see [36] for a recent survey) grow much more slowly (polynomially or even linearly in the input size). The challenge then becomes to *restrict the expressiveness via types* to capture such classes. This calls for the recipes that have worked here, namely affine types and non-commutativity.

▷ Claim 6.2 (to be proved in a sequel). *The functions definable by closed terms of type $\mathtt{Str}_\Sigma[A] \multimap \mathtt{Str}_\Pi$, for purely affine A, are the MSO transductions*[14] [14] (a.k.a. *regular functions*[15]) *in the λa-calculus and the FO transductions in the $\lambda\wp$-calculus.*

[14] MSO stands for Monadic Second-Order Logic while FO stands for First-Order Logic, cf. the introduction.

[15] This name is somewhat confusing, since there are multiple classes of string functions that collapse to the single class of regular languages when we consider indicator functions. For example, in-between the sequential functions (Definition 4.4) and the regular (MSO-definable) functions, there is a widely

This goes beyond the encodings of sequential transducers presented in this paper (Theorem 4.1 and Theorem 5.4). But the latter are an important stepping stone, since we do not know how to prove the above claim without using the Krohn–Rhodes decomposition somewhere. To summarize the results of the present paper together with its planned sequel:

calculus	affine	commutative	$\mathtt{Str}_\Sigma[A] \multimap \mathtt{Bool}$	$\mathtt{Str}_\Sigma[A] \multimap \mathtt{Str}_\Pi$
$\lambda\wp$	yes	no	star-free (FO-definable) languages	FO transductions
λa	yes	yes	regular (MSO-definable) languages	MSO transductions

While the connection between non-commutativity and aperiodicity came as a surprise to us, we had more reasons to suspect that affine types should have something to do with transducers. Indeed, the term "linear" itself has been used to describe the *copyless assignment* condition on streaming string transducers (SSTs) [5], a machine model for MSO transductions, e.g. "updates should make a linear use of registers" [15, §5] (in our terminology, the register assignments of SSTs are in fact affine, not strictly linear). Moreover, it seems (informally speaking) that the more sophisticated *single-use-restricted assignments* of streaming *tree* transducers [3] correspond to a form of linearity that incorporates an *additive conjunction*, whereas copyless assignments are purely *multiplicative*; compare with the discussion of §5.3.

7 Related work

We have already mentioned in the introduction several lines of tangentially related research, such as higher-order model checking or the topology of non-commutative proofs. In this section, we discuss a few references that we deemed to be more directly relevant.

Automata as circular proofs. Aside from Hillebrand and Kanellakis's Theorem 1.1, perhaps our most direct precursors in "implicit automata theory" are the works by DeYoung and Pfenning [13] on sequential transducers (their version seems to be equivalent to Definition 4.4) and by Kuperberg, Pinault and Pous [28] characterizing regular languages and deterministic logarithmic space complexity. Both rely on a proofs-as-programs interpretation of *circular*[16] *proof systems* for some variants of linear logic with fixed points.

The Church encoding of strings is obtained by a systematic procedure [12] from the inductive definition $s ::= \varepsilon \mid c_1 \cdot s \mid \ldots \mid c_{|\Sigma|} \cdot s$ ($\Sigma = \{c_1, \ldots, c_{|\Sigma|}\}$). Using fixed points of formulas, one can instead turn it into the recursive type[17] $\mathtt{Str}^\mu_\Sigma = 1 \oplus \mathtt{Str}^\mu_\Sigma \oplus \ldots \oplus \mathtt{Str}^\mu_\Sigma$; this is the definition of the type of strings in [13], and it is also implicitly at work in[18] [28].

So both our approach (following Hillebrand and Kanellakis [24]) and those using fixed point logics morally work because the consumption of strings represented as inductive data types is similar to their traversal by automata. However, while the use of the "right fold" provided by a Church-encoded string involves an "inversion of control" (in programming jargon) that, in the case of the simply typed λ-calculus, has drastic effects on expressive power[19] (contrast Theorem 1.1 with the fact that $\beta\eta$-convertibility of simply typed λ-terms is not elementary recursive [32]), circular proofs seem to give the programmer more degrees of freedom: Kuperberg et al. do not need to add polymorphism to go beyond regular languages.

studied strictly intermediate class called the *rational functions*. (The adjective "rational" is used to refer to regular languages in a French tradition going back to Nivat and Schützenberger.)

[16] These are sometimes called "cyclic" proofs, but in our context, this would create a confusion with an unrelated non-commutative logic, *cyclic linear logic* [50].

[17] Formally, this is expressed as the least fixed point $\mathtt{Str}^\mu_\Sigma = \mu\alpha.\ 1 \oplus \alpha \oplus \ldots \oplus \alpha$.

[18] The left rules given in [28, Figure 1] for A and A^* correspond to $A = 1 \oplus \ldots \oplus 1$ and $A^* = 1 \oplus (A \otimes A^*)$.

[19] To overcome those limits and express any elementary recursive function as a simply typed λ-term, Hillebrand and Kanellakis use an alternative representation of inputs inspired by database theory [24].

Recognizable languages of λ-terms. A modern point of view on Hillebrand and Kanellakis's Theorem 1.1 can be implicitly found in a paper by Terui [48] emphasizing the method of *evaluation in a finite denotational semantics* used to prove it. Along these lines, general notions of recognizable languages of closed λ-terms of a given type (specializing to regular languages for the type of Church-encoded strings) have been proposed, based on finite semantics, in the simply-typed λ-calculus by Salvati [45] and in an infinitary λ-calculus by Melliès [34]. It is plausible that Theorem 1.1 can be extended to give an equivalent syntactic definition for Salvati's recognizable languages: for a simple type B they would be the languages definable by $B[A] \to \texttt{Bool}$. An interesting question would be whether one can give an encoding of *higher-dimensional trees* in the simply typed λ-calculus so that this notion of recognizability coincides with Rogers's automata for those trees [43, 16].

Other implicit automata results. In a recent preprint, Bojańczyk [10] introduces a new class of string-to-string functions that admits several equivalent definitions (see also [11]). One of them uses the simply typed λ-calculus enriched with a ground type of lists and several primitive functions on lists. Strings are represented as lists of characters, which differs from our use of functional encodings in a λ-calculus without any primitive data type.

Using a computational model inspired by denotational semantics of linear logic, Seiller [46] gives a characterization of each level of the k-head two-way non-deterministic automata hierarchy. The lowest level ($k = 1$) corresponds to regular languages, while the union over $k \in \mathbb{N}_{\geq 1}$ gives the complexity class NL (non-deterministic logarithmic space). Something in common with our work is that the representation of strings used by [46] is more or less a semantic version of Church encodings (see [46, §3.2]). There is one main difference with what one usually calls implicit complexity: Seiller's result does not take place inside a syntactically defined programming language (and it is far from obvious how to turn this model into a similarly expressive syntax, because of the previously mentioned inversion of control).

Controlling expressible functions with non-commutativity. The tree-processing programming language of Kodama, Suenaga and Kobayashi [26] uses non-commutative types to force programs to process their input in a depth-first, left-to-right fashion. This allows them to be compiled into a target language that works on a stream of tokens, suggesting a possible connection with nested word automata [4]. The non-commutativity is restricted to arguments of ground type in [26], whereas it is important for our $\lambda\wp$-calculus that it applies at all orders (indeed, since we encode data as functions, higher-order functions are pervasive).

Abstract

This work addresses the problem of computing measures of recognisable sets of infinite trees. An algorithm is provided to compute the probability measure of a tree language recognisable by a weak alternating automaton, or equivalently definable in weak monadic second-order logic. The measure is the uniform coin-flipping measure or more generally it is generated by a branching stochastic process. The class of tree languages in consideration, although smaller than all regular tree languages, comprises in particular the languages definable in the alternation-free μ-calculus or in temporal logic CTL. Thus, the new algorithm may enhance the toolbox of probabilistic model checking.

2012 ACM Subject Classification Theory of computation → Automata over infinite objects; Mathematics of computing → Markov processes

Keywords and phrases infinite trees, weak alternating automata, coin-flipping measure

1 Introduction

The non-emptiness problem asks if an automaton accepts at least one object. From a logical perspective, it is an instance of the consistency question: does a given specification have a model? Sometimes it is also relevant to ask a quantitative version of this question: whether a *non-negligible* set of models satisfy the specification. When taken to the realm of probability theory, this boils down to estimating the probability that a random object is accepted by a given automaton. In this paper, models under consideration are infinite binary trees labelled by a finite alphabet. Our main problem of interest is the following.

▶ **Problem 1.** *Given a regular tree language L, compute the probability that a randomly generated tree belongs to L.*

In other words, we ask for the probability measure of L. Here, the tree language L might be given by a formula of monadic second-order logic, but for complexity reasons it is more suitable to present it by a tree automaton or by a formula of modal μ-calculus, see e.g. [9,13]. By default, the considered measure is the uniform *coin-flipping* measure, where each letter

is chosen independently at random; but also more specific measures are of interest. If the computed probability is rational then it can be represented explicitly, but the measure can be irrational, see e.g. [15], and may require more complex representation. One of the possible choices, exploited in this paper, is a formula over the field of reals $\mathbb{R}$.

Chen et al. [6] addressed Problem 1 in the case where the tree language L is recognised by a deterministic top-down automaton and the measure is induced by a stochastic branching process, which then makes also a part of the input data. Their algorithm compares the probability with any given rational number in polynomial space and with 0 or 1 in polynomial time. The limitations of this result come from the deterministic nature of the considered automata: deterministic top-down tree automata are known to have limited expressive power within all regular tree languages.

Michalewski and Mio [15] stated Problem 1 explicitly and solved it for languages L given by so-called *game automata* and the coin-flipping measure. This class of automata subsumes deterministic ones and captures some important examples including the game languages, cf. [10], but even here the strength of non-determinism is limited; in particular, the class is not closed under finite union. The algorithm from [15] reduces the problem to computing the value of a Markov branching play, and uses Tarski's decision procedure for the theory of reals. These authors also discover that the measure of a regular tree language can be irrational, which stays in contrast with the case of ω-regular languages, i.e. regular languages of infinite words, where the coin-flipping measure is always rational, cf. [5].

Another step towards a solution to Problem 1 was made by the second author of the present article, who proposed an algorithm to compute the coin-flipping measure of tree languages definable in fragments of first-order logic [20]. This work is subsumed in a report [21] (accepted for publication in a journal) co-authored with the third author, where a new class of languages L is also resolved: tree languages recognised by safety automata, i.e. non-deterministic automata with a trivial accepting condition.

An analogue of Problem 1 can be stated for ω-regular languages. As noted by [6], the problem then reduces to a well-known question in verification solved by Courcoubetis and Yannakakis [8] already in the 1990s, namely whether a run of a finite-state Markov chain satisfies an ω-regular property. The algorithm runs in single-exponential time w.r.t. the automaton (and linear w.r.t. the Markov chain). A related question was also studied by Staiger [24], who gave an algorithm to compute Hausdorff dimension and Hausdorff measure of a given ω-regular language.

In general, Problem 1 remains unsolved. At first sight, one may even wonder if it is well-stated, as regular tree languages need not in general be Borel, cf. [18]. However, due to [12, 16], we know that regular languages of trees are always universally measurable.

In the present paper, we solve Problem 1 in the case where the language L is recognised by a weak alternating automaton or, equivalently, defined by a formula of weak monadic second-order logic, cf. [17]. The class of tree languages in consideration is incomparable with the one considered by Michalewski and Mio [15], but subsumes those considered in [20, 21]. Yet another presentation of this class can be given in terms of alternation-free fragment of modal μ-calculus, see [1] for details. This fragment is known to be useful in verification and model checking, in particular, temporal logic CTL embeds into this fragment.

We consider the coin-flipping measure as our primary case, but we also show how to extend our approach to measures generated by stochastic branching processes, as in [6]. The computed probability is presented by a first-order formula in prenex normal form over the field of reals. The provided formula is exponential in the size of the automaton and polynomial in the size of the branching process. Moreover, the quantifier alternation of the computed formula is constant (equal 4). Combined with the known decision procedures for the theory of reals, this gives the following.

▶ **Theorem 2.** *There is an algorithm that inputs a weak alternating parity automaton $\mathcal{A}$, a branching process $\mathcal{P}$, and a rational number q encoded in binary; and decides if the measure generated by $\mathcal{P}$ of the language recognised by $\mathcal{A}$ is equal, smaller, or greater than q. The algorithm works in time polynomial in q, doubly exponential in $\mathcal{A}$, and singly exponential in $\mathcal{P}$.*

Similarly to the approach taken in [21], we reduce the problem to computation of an appropriate probability distribution over the powerset of the automaton's states. To do so, we consider the set of all such distributions $\mathcal{D}\mathsf{P}(Q)$ with a suitable ordering $\preceq$. The structure is in fact a finitary case of a probabilistic powerdomain introduced by Saheb-Djahromi [22] (see also [14]), but we do not exploit category-theoretic concepts in this paper. The key step is an approximation of the target language L by two families of tree languages representing safety and reachability properties, respectively. Then we can apply fixed-point constructions thanks to a kind of synergy between the order and topological properties of $\mathcal{D}\mathsf{P}(Q)$.

2 Trees, topology, and measure

The set of natural numbers $\{0, 1, 2, \ldots\}$ is denoted by $\mathbb{N}$, or by ω whenever we treat it as an ordinal. A finite non-empty set A is called an *alphabet*. By $\mathsf{P}(X)$ we denote the family of all subsets of a set X. The set of *finite words* over an alphabet A (including the *empty word* ε) is denoted by A^*, and the set of ω-words by A^ω. The *length* of a finite word $w \in A^*$ is denoted by $|w|$. A *full infinite binary tree* over an alphabet A (or simply a *tree* if confusion does not arise) is a mapping $t\colon \{\mathtt{L}, \mathtt{R}\}^* \to A$. The set of all such trees, denoted by Tr_A, can be equipped with a topology induced by a metric

$$d(t_1, t_2) = \begin{cases} 0 & \text{if } t_1 = t_2 \\ 2^{-n} \text{ with } n = \min\{|w| \mid t_1(w) \neq t_2(w)\} & \text{otherwise.} \end{cases}$$

It is well-known that this topology coincides with the product topology on A^ω, where A is a discrete topological space. The topology can be generated by a basis consisting of all the sets U_f, where $f\colon \mathrm{dom}(f) \to A$ is a function with a finite domain $\mathrm{dom}(f) \subset \{\mathtt{L}, \mathtt{R}\}^*$, and U_f consists of all trees t that coincide with f on $\mathrm{dom}(f)$. If A has at least 2 elements then this topology is homeomorphic to the Cantor discontinuum $\{0, 1\}^\omega$ (see, e.g. [19]).

The set of trees can be further equipped with a probabilistic measure μ_0, which is the standard Lebesgue measure on the product space defined on the basis by $\mu_0\left(U_f\right) = \left|A\right|^{-|\mathrm{dom}(f)|}$.

We note a useful property of this measure, which intuitively amounts to saying that events happening in incomparable nodes are independent. For $t \in \mathrm{Tr}_A$ and $v \in \{\mathtt{L}, \mathtt{R}\}^*$, the subtree of t induced by v is a tree $t{\restriction_v} \in \mathrm{Tr}_A$ defined by $t{\restriction_v}(w) = t(vw)$, for $w \in \{\mathtt{L}, \mathtt{R}\}^*$.

▶ Remark 3. If $v_1, \ldots, v_k \in \{\mathtt{L}, \mathtt{R}\}^*$ are pairwise incomparable nodes (i.e., none is a prefix of another) and $V_1, \ldots, V_k \subseteq \mathrm{Tr}_A$ are Borel sets then

$$\mu_0\left(\{t \in \mathrm{Tr}_A \mid t{\restriction_{v_i}} \in V_i \text{ for } i = 1, \ldots, k\}\right) \quad = \quad \mu_0(V_1) \cdot \ldots \cdot \mu_0(V_k). \tag{1}$$

We refer to e.g. [12] for more detailed considerations of measures on sets of infinite trees.

3 Tree automata and games

An *alternating parity automaton* over infinite trees can be presented as a tuple $\mathcal{A} = \langle A, Q, q_{\mathrm{I}}, \delta, \Omega\rangle$, where A is a finite alphabet; Q a finite set of *states*; $q_{\mathrm{I}} \in Q$ an *initial state*; $\delta\colon Q \times A \to \mathrm{BC}^+\big(\{\mathtt{L}, \mathtt{R}\} \times Q\big)$ a *transition function* that assigns to a pair $(q, a) \in Q \times A$ a finite positive Boolean combination of pairs $(d, q') \in \{\mathtt{L}, \mathtt{R}\} \times Q$; and finally $\Omega\colon Q \to \mathbb{N}$ is a *priority mapping*.

In this paper, we assume that automata are *weak*, i.e. the priorities $\Omega(q)$ are non-increasing along transitions. More precisely, if (d, q') is an atom that appears in the formula $\delta(q, a)$ then $\Omega(q) \geq \Omega(q')$. Given $n \in \mathbb{N}$, we denote by $Q_{<n}$ and $Q_{\geq n}$ the subsets of Q consisting of those states whose priority is respectively strictly smaller or greater than n.

The semantics of an automaton can be given in a terms of a game played by two players $\exists$ and $\forall$ over a tree t in Tr_A from a state $p \in Q$. Let Γ be the set of all sub-formulae of the formulae in $\delta(q, a)$, for all $(q, a) \in Q \times A$. The set of *positions* of the game is the set $\big(Q \sqcup \Gamma\big) \times \{\mathrm{L}, \mathrm{R}\}^*$ and the *initial position* is $\big(p, \varepsilon\big)$. The positions of the form $\big(q, v\big)$, $\big(\phi_1 \vee \phi_2, v\big)$, and $\big((d, q), v\big)$ are controlled by $\exists$, while the positions of the form $\big(\phi_1 \wedge \phi_2, v\big)$ are controlled by $\forall$. The edges connect the following types of positions:

- $\big(q, v\big)$ and $\big(\delta(q, t(v)), v\big)$,
- $\big(\phi_1 \vee \phi_2, v\big)$ and $\big(\phi_i, v\big)$ for $i = 1, 2$,
- $\big(\phi_1 \wedge \phi_2, v\big)$ and $\big(\phi_i, v\big)$ for $i = 1, 2$,
- $\big((d, q), v\big)$ and $\big(q, v \cdot d\big)$.

We assume that every formula in the image $\delta(Q \times A)$ is non-trivial and, thus, every position is a source of some edge.

The directed graph described above forms the *arena* of our game that we denote by $\mathcal{G}(t, p)$. A *play* in the arena is any infinite path starting from the initial position $\big(p, \varepsilon\big)$. We call the positions of the form (q, v) *state positions*. Given a play π, the *states* of the play denoted states(π) is the sequence of states $(q_0, q_1, \ldots) \in Q^\omega$ such that the successive state positions visited during π are $\big(q_i, v_i\big)$, for $i = 0, 1, \ldots$, and some $(v_i)_{i \in \omega}$.

To complete the definition of the game, we specify a winning criterion for $\exists$. The default is the *parity condition*, but we will also consider other criteria. Let

$$\mathrm{Runs} \overset{\text{def}}{=} \{\rho \in Q^\omega \mid \forall i \in \omega.\ \Omega(\rho(i)) \geq \Omega(\rho(i{+}1))\}$$

be the set that contains all sequences of states that induce non-increasing sequences of priorities. Notice that since $\mathcal{A}$ is weak, only such sequences may arise in the game. In general, a *winning condition* is any set $W \subseteq \mathrm{Runs}$. That is, a play π is *winning* for $\exists$ with respect to W if, and only if, states$(\pi) \in W$. The game with a winning set W is denoted by $\mathcal{G}(t, p, W)$.

The *parity condition* $W_P \subseteq \mathrm{Runs}$ for a weak automaton amounts to: $(q_0, q_1, \ldots) \in W_P$ if $\lim_{i \to \infty} \Omega(q_i) \equiv 0 \mod 2$, i.e. the limit priority of states visited in a play is even. Let $\mathrm{L}(\mathcal{A}, p)$ be the set of trees such that $\exists$ has a winning strategy in $\mathcal{G}(t, p, W_P)$. Then, the language of an automaton $\mathcal{A}$ is the set $\mathrm{L}(\mathcal{A}) \overset{\text{def}}{=} \mathrm{L}(\mathcal{A}, q_{\mathrm{I}})$, where q_{I} is the initial state of $\mathcal{A}$.

As mentioned above, we will consider games with various winning criteria. The following simple observation is useful.

▶ Remark 4. If $W \subseteq W' \subseteq \mathrm{Runs}$ then the following implication holds: if $\exists$ wins $\mathcal{G}(t, p, W)$ then $\exists$ wins also $\mathcal{G}(t, p, W')$.

Since the winning criteria in consideration will always be ω-regular languages of infinite words, we implicitly rely on the following classical fact (cf. [13]).

▶ **Proposition 5.** *Games on graphs with ω-regular winning conditions are finite memory determined.*

We will also use the following fact, cf. e.g. [17, 23].

▶ **Proposition 6.** *For a weak alternating parity automaton $\mathcal{A}$, all tree languages $\mathrm{L}(\mathcal{A}, p)$ are Borel and, consequently, measurable with respect to the uniform measure μ_0 (and also any other Borel measure on Tr_A).*

Note that measurability holds for non-weak automata as well [12].

4 Approximations

For the sake of this section we fix a weak alternating parity automaton $\mathcal{A}$. Our aim is to provide some useful approximations for the tree languages $\mathrm{L}(\mathcal{A}, p)$. The approximations are simply some families of tree languages indexed by states $p \in Q$. Those families, called *Q-indexed families*, or *Q-families* for short, are represented by functions $\mathcal{L}\colon Q \to \mathsf{P}(\mathrm{Tr}_A)$. By the construction, we will guarantee that the tree languages $\mathcal{L}(q)$ will themselves be recognisable by some weak alternating automata. Each Q-family naturally possesses a dual representation by a mapping $\mathrm{Tr}_A \to \mathsf{P}(Q)$ that we denote by the same letter (but with different brackets)

$$\mathcal{L}[t] \stackrel{\text{def}}{=} \{q \in Q \mid t \in \mathcal{L}(q)\} \in \mathsf{P}(Q).$$

If $\rho \in \mathrm{Runs} \subseteq Q^\omega$ is an infinite sequence of states then $\lim_{i\to\infty} \Omega(\rho(i))$ (denoted by $\mathrm{limit}(\rho)$) exists, because by the definition of Runs the priorities are non-increasing and bounded. Recall that $W_P \subseteq \mathrm{Runs}$ is the set of runs satisfying the parity condition, i.e. $W_P = \{\rho \in \mathrm{Runs} \mid \mathrm{limit}(\rho) \equiv 0 \mod 2\}$. For $i, n \in \mathbb{N}$, consider the following subsets of Runs:

$$S_i^n \stackrel{\text{def}}{=} W_P \cup \big\{\rho \in \mathrm{Runs} \mid \Omega(\rho(i)) \geq n\big\},$$
$$S_\infty^n \stackrel{\text{def}}{=} W_P \cup \big\{\rho \in \mathrm{Runs} \mid \mathrm{limit}(\rho) \geq n\big\},$$
$$R_i^n \stackrel{\text{def}}{=} W_P \cap \big\{\rho \in \mathrm{Runs} \mid \Omega(\rho(i)) < n\big\},$$
$$R_\infty^n \stackrel{\text{def}}{=} W_P \cap \big\{\rho \in \mathrm{Runs} \mid \mathrm{limit}(\rho) < n\big\}.$$

Connotatively, the name of the sets S_i^n comes from the condition of *safety*, while the sets R_i^n are named after *reachability*. More precisely, S_i^n is an over-approximation of W_P, that makes $\exists$ win also if she manages to reach a priority $\geq n$ in the ith visited node of a given tree. Analogously, R_i^n is an under-approximation of W_P that makes $\forall$ win in the above case.

Based on the above definitions, we define the respective Q-families. For $p \in Q$, let $\mathcal{S}_i^n(p)$, $\mathcal{S}_\infty^n(p)$, $\mathcal{R}_i^n(p)$, and $\mathcal{R}_\infty^n(p)$ be the sets of trees such that $\exists$ has a winning strategy in the game $\mathcal{G}(t, p, W)$, where W is respectively S_i^n, S_∞^n, R_i^n, and R_∞^n. Figure 1 below depicts the way these Q-families are used in the general construction.

It is easy to see that all the tree languages above can be recognised by weak parity alternating automata.

▶ **Lemma 7.** *For every $n \in \mathbb{N}$ and $i \in \mathbb{N}$, we have*

$$S_i^n \supseteq S_{i+1}^n \supseteq S_\infty^n \text{ and } R_i^n \subseteq R_{i+1}^n \subseteq R_\infty^n.$$

Analogously, for every $p \in Q$,

$$\mathcal{S}_i^n(p) \supseteq \mathcal{S}_{i+1}^n(p) \supseteq \mathcal{S}_\infty^n(p) \text{ and } \mathcal{R}_i^n(p) \subseteq \mathcal{R}_{i+1}^n(p) \subseteq \mathcal{R}_\infty^n(p).$$

Proof. The first property follows directly from the definition of Runs, which guarantees that $\Omega(\rho(0)) \geq \Omega(\rho(1)) \geq \ldots \geq \mathrm{limit}(\rho)$. Then, the second property follows from Remark 4. ◀

It is straightforward to see that $S_\infty^n = \bigcap_{i\in\mathbb{N}} S_i^n$ and $R_\infty^n = \bigcup_{i\in\mathbb{N}} R_i^n$. However, it is not clear that these equalities imply the desired properties for the respective sets of trees. Lemma 9 below implies that it is the case. The proof relies on combinatorics of binary trees, namely on König's Lemma.

▶ **Lemma 8.** *Take $n \in \mathbb{N}$ and $p \in Q$. Let $B^n_\infty = \{\rho \in \mathrm{Runs} \mid \mathrm{limit}(\rho) < n\}$ and, for $i \in \mathbb{N}$, let $B^n_i = \{\rho \in \mathrm{Runs} \mid \Omega(\rho(i)) < n\}$. If σ is a winning strategy of $\exists$ in $\mathcal{G}(t, p, B^n_\infty)$ then there exists a number $J \in \mathbb{N}$, such that σ is actually winning in $\mathcal{G}(t, p, B^n_J)$. An analogous property holds if σ is a winning strategy for $\forall$.*

Proof. Let σ be a winning strategy of $\exists$ in $\mathcal{G}(t, p, B^n_\infty)$ (the case of $\forall$ is completely analogous). Let $T \subseteq \big(Q \times \{\mathtt{L}, \mathtt{R}\}\big)^*$ be the set of sequences $(q_i, d_i)_{i \leq \ell}$, with $q_0 = p$, such that there exists a play consistent with σ that visits all the positions $(q_i, d_0 \cdots d_{i-1})$ for $i = 0, 1, \ldots, \ell$, and additionally $\Omega(q_\ell) \geq n$. Observe that T is prefix-closed. Thus, we can treat T as a tree. Moreover, as $Q \times \{\mathtt{L}, \mathtt{R}\}$ is finite, T is finitely branching. If T is finite then there exists J such that all the sequences in T have length at most J. In that case σ is winning in $\mathcal{G}(t, p, B^n_J)$, and we are done.

For the sake of contradiction, suppose that T is infinite. Apply König's Lemma to obtain an infinite path $(q_i, d_i)_{i \in \omega}$ in T. By the definition of T, it implies that there exists an infinite play consistent with σ such that $(q_i)_{i \in \omega}$ is the sequence of states visited during the play. But this is a contradiction, because $\mathrm{limit}\big((q_i)_{i \in \omega}\big) \geq n$ by the definition of T and, therefore, the considered play is losing for $\exists$. ◀

▶ **Lemma 9.** *Using the above notions, for every state $p \in Q$, we have*

$$\mathcal{S}^n_\infty(p) = \bigcap_{i \in \mathbb{N}} \mathcal{S}^n_i(p) \quad \textit{and} \quad \mathcal{R}^n_\infty(p) = \bigcup_{i \in \mathbb{N}} \mathcal{R}^n_i(p).$$

Proof. Consider the first claim and take a tree $t \in \mathrm{Tr}_A$ such that for every $i \in \mathbb{N}$ we have $t \in \mathcal{S}^n_i(p)$. We need to prove that $t \in \mathcal{S}^n_\infty(p)$. Assume contrarily, that $t \notin \mathcal{S}^n_\infty(p)$. By determinacy, see Proposition 5, it means that there exists a strategy σ' of $\forall$ such that for every play π consistent with σ', we have $\mathrm{limit}(\mathrm{states}\,(\pi)) < n$ and $\mathrm{limit}(\mathrm{states}\,(\pi))$ is odd. Hence, in particular, σ' is winning for $\forall$ in $\mathcal{G}(t, p, B^n_\infty)$. Therefore, by Lemma 8, we know that there exists a number $J \in \mathbb{N}$ such that, for every π consistent with σ' with $\mathrm{states}\,(\pi) = (q_0, q_1, \ldots)$, we have $\Omega(q_J) < n$. Therefore, the strategy σ' witnesses that $t \notin \mathcal{S}^n_J(p)$, a contradiction.

We now prove the second claim. Take a tree $t \in \mathcal{R}^n_\infty(p)$. We need to prove that $t \in \mathcal{R}^n_i(p)$ for some $i \in \mathbb{N}$. Let σ be a strategy of $\exists$ witnessing that $t \in \mathcal{R}^n_\infty(p)$. Again, Lemma 8 guarantees that there exists a number $J \in \mathbb{N}$ such that if π is a play consistent with σ with $\mathrm{states}\,(\pi) = (q_0, q_1, \ldots)$ then $\Omega(q_J) < n$. Thus, $t \in \mathcal{R}^n_J(p)$. ◀

The following lemma provides another characterisation of the above Q-families.

▶ **Lemma 10.** *For each $p \in Q$, we have $\mathcal{S}^0_i(p) = \mathrm{Tr}_A$ and $\mathcal{R}^0_i(p) = \emptyset$. Take $n > 0$. If $\Omega(p) \geq n$ then $\mathcal{S}^n_0(p) = \mathrm{Tr}_A$ and $\mathcal{R}^n_0(p) = \emptyset$. If $\Omega(p) < n$ then*

$$\begin{aligned} &\mathrm{L}(\mathcal{A}, p) = \mathcal{S}^n_0(p), && \mathrm{L}(\mathcal{A}, p) = \mathcal{R}^n_0(p), \\ &\mathrm{L}(\mathcal{A}, p) = \mathcal{S}^{n-1}_\infty(p) \quad \textit{for odd } n, && \mathrm{L}(\mathcal{A}, p) = \mathcal{R}^{n-1}_\infty(p) \quad \textit{for even } n. \end{aligned}$$

Proof. The cases of $n = 0$ are trivial. The first two claims in the case $\Omega(p) \geq n$ follow directly from the definitions. Take p such that $\Omega(p) < n$. Notice that in that case the sequence of states ρ in a play in $\mathcal{G}(t, p)$ satisfies

$$\begin{aligned} &\rho \in W_P \iff \rho \in S^n_0, && \rho \in W_P \iff \rho \in R^n_0, \\ &\rho \in W_P \iff \rho \in S^{n-1}_\infty \quad \text{for odd } n, && \rho \in W_P \iff \rho \in R^{n-1}_\infty \quad \text{for even } n. \end{aligned}$$

where the first two equivalences follow from the fact that $\Omega(\rho(0)) = \Omega(p) < n$. The last two equivalences can be derived from the fact that $\mathrm{limit}(\rho) \leq \Omega(p) < n$. First, we have $\mathrm{limit}(\rho) \geq n{-}1 \Leftrightarrow \mathrm{limit}(\rho) = n{-}1$. Thus, if n is odd and $\mathrm{limit}(\rho) \geq n{-}1$ then we know that $\mathrm{limit}(\rho)$ is even. Analogously, if n is even then $n{-}1$ is odd and the fact that $\mathrm{limit}(\rho)$ is even guarantees that $\mathrm{limit}(\rho) < n{-}1$.

Clearly, the above equivalences imply that, under the assumption of the lemma, a strategy winning for the condition W_P is winning for the respective conditions and vice-versa. ◀

Our aim now is to define a function $\Delta\colon \mathsf{P}(Q) \times A \times \mathsf{P}(Q) \to \mathsf{P}(Q)$ that will allow us to form equations over Q-families. An ordered pair of sets of states $P_{\mathtt{L}}, P_{\mathtt{R}} \in \mathsf{P}(Q)$ induces a *valuation* $v_{P_{\mathtt{L}},P_{\mathtt{R}}}$ to the atoms in $\{\mathtt{L},\mathtt{R}\} \times Q$ defined by: $v_{P_{\mathtt{L}},P_{\mathtt{R}}}(d,p)$ is true if $p \in P_d$. Now, consider additionally a letter $a \in A$ and put

$$\Delta(P_{\mathtt{L}}, a, P_{\mathtt{R}}) = \big\{q \in Q \mid v_{P_{\mathtt{L}},P_{\mathtt{R}}} \models \delta(q,a)\big\}.$$

Equivalently, $q \in \Delta(P_{\mathtt{L}}, a, P_{\mathtt{R}})$ if $\exists$ can play the finite game represented by $\delta(q,a)$ in such a way to reach only such atoms (d,p) that satisfy $p \in P_d$.

▶ **Lemma 11.** *The function $\Delta\colon \mathsf{P}(Q) \times A \times \mathsf{P}(Q) \to \mathsf{P}(Q)$ is monotone, i.e. if $P_{\mathtt{L}} \subseteq P'_{\mathtt{L}}$ and $P_{\mathtt{R}} \subseteq P'_{\mathtt{R}}$ then $\Delta(P_{\mathtt{L}}, a, P_{\mathtt{R}}) \subseteq \Delta(P'_{\mathtt{L}}, a, P'_{\mathtt{R}})$.*

Proof. It follows directly from the fact that the Boolean formulae in $\delta(q,a)$ are positive. ◀

Recall that $t{\restriction}_v \in \mathrm{Tr}_A$ denotes the subtree of t induced by a node v, cf. Section 2. The following lemma shows how to increase the index i of the above Q-families $\mathcal{S}^n_i$ and $\mathcal{R}^n_i$.

▶ **Lemma 12.** *Take $n \in \mathbb{N}$, $i \in \mathbb{N}$, and a tree $t \in \mathrm{Tr}_A$. Then we have:*

$$\mathcal{S}^n_{i+1}[t] = \Delta\big(\mathcal{S}^n_i[t{\restriction}_{\mathtt{L}}], t(\varepsilon), \mathcal{S}^n_i[t{\restriction}_{\mathtt{R}}]\big),$$
$$\mathcal{R}^n_{i+1}[t] = \Delta\big(\mathcal{R}^n_i[t{\restriction}_{\mathtt{L}}], t(\varepsilon), \mathcal{R}^n_i[t{\restriction}_{\mathtt{R}}]\big).$$

The proof of this lemma is based on a standard technique of merging strategies: the game $\mathcal{G}(t,p)$ can be split into a finite game corresponding to the formula $\delta\big(p, t(\varepsilon)\big)$ that leads to the sub-games $\mathcal{G}(t{\restriction}_{\mathtt{L}}, p_{\mathtt{L}})$ and $\mathcal{G}(t{\restriction}_{\mathtt{R}}, p_{\mathtt{R}})$ for some states $p_{\mathtt{L}}, p_{\mathtt{R}} \in Q$.

Proof. Take a play π in the arena $\mathcal{G}(t,p)$ for some state $p \in Q$. Recall that, by the definition of the game, the initial position of the play is (p,ε) and the next state position will have the form (q,d), for some $q \in Q$ and $d \in \{\mathtt{L},\mathtt{R}\}$. Consider the suffix of the play π starting from that position. Clearly, this suffix induces a play, say π', in the arena $\mathcal{G}(t{\restriction}_d, q)$, starting from the position (q,ε) (technically, to satisfy our definition, we need also to replace every position (α, dv) by (α, v) in the original play). Moreover, the sequence of states visited by π', $\mathrm{states}(\pi')$, is a suffix of the sequence $\mathrm{states}(\pi)$ obtained by removing just the first element. By the definition of S^n_i and R^n_i we have therefore

$$\mathrm{states}(\pi) \in S^n_{i+1} \iff \mathrm{states}(\pi') \in S^n_i, \text{ and } \mathrm{states}(\pi) \in R^n_{i+1} \iff \mathrm{states}(\pi') \in R^n_i. \tag{2}$$

We will now provide the proof for $\mathcal{S}^n_{i+1}$, the case of $\mathcal{R}^n_{i+1}$ is analogous. Let $P_{\mathtt{L}}$ and $P_{\mathtt{R}}$ equal respectively $\mathcal{S}^n_i[t{\restriction}_{\mathtt{L}}]$ and $\mathcal{S}^n_i[t{\restriction}_{\mathtt{R}}]$. Put $a = t(\varepsilon)$. Recall that by the duality of the two representations of Q-families, $p \in \mathcal{S}^n_{i+1}[t]$ iff $t \in \mathcal{S}^n_{i+1}(p)$. So we need to prove that for every $p \in Q$ we have $t \in \mathcal{S}^n_{i+1}(p)$ if and only if $p \in \Delta(P_{\mathtt{L}}, a, P_{\mathtt{R}})$.

Assume that $t \in \mathcal{S}^n_{i+1}(p)$. Take a strategy σ witnessing that. Notice that if a position of the form (q,d) can be reached by σ then by (2) we know that $t{\restriction}_d \in \mathcal{S}^n_i(q)$, i.e. $q \in P_d$. Thus, the strategy σ witnesses that $p \in \Delta(P_{\mathtt{L}}, a, P_{\mathtt{R}})$.

$$\begin{tikzcd}
\vec{\mu_0}(\mathcal{S}^0_0) \arrow[d, "\mathcal{F}"'] & \vec{\mu_0}(\mathcal{R}^1_\infty) \arrow[r, mapsto, "\mathcal{Q}_{\geq 2}"'] & \vec{\mu_0}(\mathcal{S}^2_0) \arrow[d, "\mathcal{F}"'] & \vec{\mu_0}(\mathcal{R}^3_\infty) \arrow[r, mapsto, "\mathcal{Q}_{\geq 4}"'] & \vec{\mu_0}(\mathcal{S}^4_0) \arrow[d, "\mathcal{F}"'] & \cdots \\
\vec{\mu_0}(\mathcal{S}^0_1) \arrow[d, "\mathcal{F}"'] & \vec{\mu_0}(\mathcal{R}^1_4) \arrow[u, "\mathcal{F}"] & \vec{\mu_0}(\mathcal{S}^2_1) \arrow[d, "\mathcal{F}"'] & \vec{\mu_0}(\mathcal{R}^3_4) \arrow[u, "\mathcal{F}"] & \vec{\mu_0}(\mathcal{S}^4_1) \arrow[d, "\mathcal{F}"'] & \\
\vec{\mu_0}(\mathcal{S}^0_2) \arrow[d, "\mathcal{F}"'] & \vec{\mu_0}(\mathcal{R}^1_3) \arrow[u, "\mathcal{F}"] & \vec{\mu_0}(\mathcal{S}^2_2) \arrow[d, "\mathcal{F}"'] & \vec{\mu_0}(\mathcal{R}^3_3) \arrow[u, "\mathcal{F}"] & \vec{\mu_0}(\mathcal{S}^4_2) \arrow[d, "\mathcal{F}"'] & \cdots \\
\vec{\mu_0}(\mathcal{S}^0_3) \arrow[d, "\mathcal{F}"'] & \vec{\mu_0}(\mathcal{R}^1_2) \arrow[u, "\mathcal{F}"] & \vec{\mu_0}(\mathcal{S}^2_3) \arrow[d, "\mathcal{F}"'] & \vec{\mu_0}(\mathcal{R}^3_2) \arrow[u, "\mathcal{F}"] & \vec{\mu_0}(\mathcal{S}^4_3) \arrow[d, "\mathcal{F}"'] & \\
\vec{\mu_0}(\mathcal{S}^0_4) \arrow[d, "\mathcal{F}"'] & \vec{\mu_0}(\mathcal{R}^1_1) \arrow[u, "\mathcal{F}"] & \vec{\mu_0}(\mathcal{S}^2_4) \arrow[d, "\mathcal{F}"'] & \vec{\mu_0}(\mathcal{R}^3_1) \arrow[u, "\mathcal{F}"] & \vec{\mu_0}(\mathcal{S}^4_4) \arrow[d, "\mathcal{F}"'] & \\
\vec{\mu_0}(\mathcal{S}^0_\infty) \arrow[r, mapsto, "\mathcal{Q}_{<1}"] & \vec{\mu_0}(\mathcal{R}^1_0) \arrow[u, "\mathcal{F}"] & \vec{\mu_0}(\mathcal{S}^2_\infty) \arrow[r, mapsto, "\mathcal{Q}_{<3}"] & \vec{\mu_0}(\mathcal{R}^3_0) \arrow[u, "\mathcal{F}"] & \vec{\mu_0}(\mathcal{S}^4_\infty) \arrow[r, mapsto, "\mathcal{Q}_{<5}"] & \cdots
\end{tikzcd}$$

Figure 1 A schematic presentation of the relationship between the distributions used in the proof. The vertical axis represents the order $\preceq$, i.e. $\vec{\mu_0}(\mathcal{S}^0_0) \succeq \vec{\mu_0}(\mathcal{S}^0_\infty)$. The edges marked $\mathcal{F}$, $\mathcal{Q}_{<n}$, and $\mathcal{Q}_{\geq n}$ represent applications of the respective operations. The vertical convergence is understood in terms of pointwise limits in $\mathbb{R}^{\mathsf{P}(Q)}$.

For the opposite direction, assume that $p \in \Delta(P_{\mathtt{L}}, a, P_{\mathtt{R}})$. This means that there exists a finite strategy of $\exists$ that allows her to resolve the formula $\delta(p, a)$ in such a way that for every atom (d, q) that can be reached by this strategy, we have $(d, q) \in P_d$. The last means that $\exists$ has a winning strategy in the game $\mathcal{G}(t{\restriction}_d, q, \mathcal{S}^n_i)$. Now we can combine all above strategies in a strategy in the game $\mathcal{G}(t, p, S^n_{i+1})$, which by Equation (2) is again winning for $\exists$. Hence, $t \in \mathcal{S}^n_{i+1}(p)$, as desired. ◀

5 Measures and distributions

Following an approach started in [21], we transfer the problem of computing measures of tree languages $\mathrm{L}(\mathcal{A}, p)$ to computing a suitable probability distribution on the sets of the automaton states. We start with a general construction. For a finite set X, consider the set of probability distributions over X, $\mathcal{D}X \overset{\text{def}}{=} \{\alpha \colon X \to [0,1] \mid \sum_{x \in X} \alpha(x) = 1\}$. Observe that, if X is partially ordered by a relation $\leq$ then $\mathcal{D}X$ is partially ordered by a relation $\preceq$ defined as follows: $\alpha \preceq \beta$ if for every upward-closed[1] set $U \subseteq X$, we have $\sum_{x \in U} \alpha(x) \leq \sum_{x \in U} \beta(x)$. In this article, we are interested in $\langle X, \leq \rangle$ being the powerset $\mathsf{P}(Q)$ ordered by inclusion $\subseteq$.

▶ Remark 13. The relation $\preceq$ is a partial order on $\mathcal{D}X$ (as an intersection of a finite family of partial orders).

Every Q-family $\mathcal{L}$ for a weak alternating automaton $\mathcal{A}$ induces naturally a member of $\mathcal{D}\mathsf{P}(Q)$, which is a distribution $\vec{\mu_0}(\mathcal{L})$ defined by

$$\vec{\mu_0}(\mathcal{L})(P) = \mu_0\{t \in \mathrm{Tr}_A \mid \mathcal{L}[t] = P\}.$$

Here μ_0 is the uniform probability measure on Tr_A. The sets in consideration are measurable thanks to Proposition 6.

Note that if the language family is exactly $\mathcal{L}(q) = \mathrm{L}(\mathcal{A}, q)$ then the probability assigned to a set of states P amounts to the probability that a randomly chosen tree, with respect to μ_0, is accepted precisely from the states in P.

▶ **Lemma 14.** *If for each $q \in Q$ we have $\mathcal{L}(q) \subseteq \mathcal{L}'(q)$ then $\vec{\mu_0}(\mathcal{L}) \preceq \vec{\mu_0}(\mathcal{L}')$ in $\mathcal{D}\mathsf{P}(Q)$.*

[1] That is if $x \leq y$ and $x \in U$ then $y \in U$.

Proof. Take any upward-closed family $U \subseteq \mathsf{P}(Q)$. Then

$$\sum_{P\in U} \vec{\mu_0}\big(\mathcal{L}\big)(P) = \sum_{P\in U} \mu_0\big\{t\in \mathrm{Tr}_A \mid \mathcal{L}[t]=P\big\} = \mu_0\big\{t\in \mathrm{Tr}_A \mid \mathcal{L}[t]\in U\big\} \leq$$
$$\leq \mu_0\big\{t\in \mathrm{Tr}_A \mid \mathcal{L}'[t]\in U\big\} = \sum_{P\in U} \mu_0\big\{t\in \mathrm{Tr}_A \mid \mathcal{L}'[t]=P\big\} = \sum_{P\in U} \vec{\mu_0}\big(\mathcal{L}'\big)(P),$$

where the middle inequality follows from the assumption that $\mathcal{L}(q)\subseteq\mathcal{L}'(q)$ and the fact that the family U is upward-closed. ◀

We now examine the sequences of distributions $\vec{\mu_0}\big(\mathcal{S}^n_i\big)$, $\vec{\mu_0}\big(\mathcal{R}^n_i\big)$, $\vec{\mu_0}\big(\mathcal{S}^n_\infty\big)$, and $\vec{\mu_0}\big(\mathcal{R}^n_\infty\big)$ arising from the Q-families introduced in the previous section. Our aim is to bind them by equations computable within $\mathcal{D}\mathsf{P}(Q)$. As an analogue to the operation Δ, we introduce a function $\mathcal{F}\colon \mathcal{D}\mathsf{P}(Q)\to\mathcal{D}\mathsf{P}(Q)$ defined for $\beta\in\mathcal{D}\mathsf{P}(Q)$ and $P\in\mathsf{P}(Q)$ by

$$\mathcal{F}(\beta)(P) = \frac{1}{|A|}\cdot \sum_{(P_{\mathtt{L}},a,P_{\mathtt{R}})\in\Delta^{-1}(P)} \beta(P_{\mathtt{L}})\cdot\beta(P_{\mathtt{R}}). \tag{3}$$

Note that the formula guarantees that $\mathcal{F}(\beta)$ is indeed a probabilistic distribution in $\mathcal{D}\mathsf{P}(Q)$. The operator $\mathcal{F}$ allows us to lift the inductive definitions of the Q-families $\mathcal{S}^n_{i+1}$ and $\mathcal{R}^n_{i+1}$ given by Lemma 12, to their counterparts in the level of probability distributions.

▶ **Lemma 15.** *For each $n\in\mathbb{N}$ and $i\in\mathbb{N}$ we have*

$$\vec{\mu_0}\big(\mathcal{S}^n_{i+1}\big) = \mathcal{F}\Big(\vec{\mu_0}\big(\mathcal{S}^n_i\big)\Big) \text{ and } \vec{\mu_0}\big(\mathcal{R}^n_{i+1}\big) = \mathcal{F}\Big(\vec{\mu_0}\big(\mathcal{R}^n_i\big)\Big).$$

Proof. Take $P\in\mathsf{P}(Q)$ and observe that

$$\begin{aligned}
\mathcal{F}\Big(\vec{\mu_0}\big(\mathcal{S}^n_i\big)\Big)(P) &\overset{(1)}{=} \frac{1}{|A|}\cdot \sum_{(P_{\mathtt{L}},a,P_{\mathtt{R}})\in\Delta^{-1}(P)} \vec{\mu_0}\big(\mathcal{S}^n_i\big)(P_{\mathtt{L}})\cdot\vec{\mu_0}\big(\mathcal{S}^n_i\big)(P_{\mathtt{R}})\\
&\overset{(2)}{=} \sum_{(P_{\mathtt{L}},a,P_{\mathtt{R}})\in\Delta^{-1}(P)} \mu_0\big\{t_{\mathtt{L}} \mid \mathcal{S}^n_i[t_{\mathtt{L}}]{=}P_{\mathtt{L}}\big\}\cdot\frac{1}{|A|}\cdot\mu_0\big\{t_{\mathtt{R}} \mid \mathcal{S}^n_i[t_{\mathtt{R}}]{=}P_{\mathtt{R}}\big\}\\
&\overset{(3)}{=} \sum_{(P_{\mathtt{L}},a,P_{\mathtt{R}})\in\Delta^{-1}(P)} \mu_0\big\{t \mid \mathcal{S}^n_i[t{\restriction}_{\mathtt{L}}]{=}P_{\mathtt{L}}\wedge t(\varepsilon){=}a\wedge\mathcal{S}^n_i[t{\restriction}_{\mathtt{R}}]{=}P_{\mathtt{R}}\big\}\\
&\overset{(4)}{=} \mu_0\left(\bigcup_{(P_{\mathtt{L}},a,P_{\mathtt{R}})\in\Delta^{-1}(P)} \big\{t \mid \mathcal{S}^n_i[t{\restriction}_{\mathtt{L}}]{=}P_{\mathtt{L}}\wedge t(\varepsilon){=}a\wedge\mathcal{S}^n_i[t{\restriction}_{\mathtt{R}}]{=}P_{\mathtt{R}}\big\}\right)\\
&\overset{(5)}{=} \mu_0\Big\{t\in\mathrm{Tr}_A \mid \Delta\big(\mathcal{S}^n_i[t{\restriction}_{\mathtt{L}}],t(\varepsilon),\mathcal{S}^n_i[t{\restriction}_{\mathtt{R}}]\big){=}P\Big\}\\
&\overset{(6)}{=} \mu_0\Big\{t\in\mathrm{Tr}_A \mid \mathcal{S}^n_{i+1}[t]{=}P\Big\} \overset{(7)}{=} \vec{\mu_0}\big(\mathcal{S}^n_{i+1}\big)(P),
\end{aligned}$$

where: (1) is just the definition of $\mathcal{F}\Big(\vec{\mu_0}\big(\mathcal{S}^n_i\big)\Big)$; (2) follows from the definition of $\vec{\mu_0}\big(\mathcal{S}^n_i\big)$; (3) follows from Remark 3 and the independence of $\{t(\varepsilon)=a\}$ from the other events in consideration; (4) follows from the fact that the measured sets are pairwise disjoint; (5) follows simply from the definition of Δ; (6) follows from Lemma 12; and (7) is just the definition of $\vec{\mu_0}\big(\mathcal{S}^n_{i+1}\big)$.

The proof for $\mathcal{R}^n_{i+1}$ follows the same steps, except it uses the $\mathcal{R}^n_i$ variant of Lemma 12. ◀

Now, recall that $Q_{\geq n}$ and $Q_{<n}$ are sets of states of respective priorities. Let the functions $\mathcal{Q}_{<n}, \mathcal{Q}_{\geq n}\colon \mathcal{D}\mathsf{P}(Q) \to \mathcal{D}\mathsf{P}(Q)$ be defined by

$$\mathcal{Q}_{<n}(\beta)(P) \overset{\text{def}}{=} \textstyle\sum_{P'\colon P'\cap Q_{<n}=P} \beta(P'), \tag{4}$$

$$\mathcal{Q}_{\geq n}(\beta)(P) \overset{\text{def}}{=} \textstyle\sum_{P'\colon P'\cup Q_{\geq n}=P} \beta(P'). \tag{5}$$

Again, the formulae guarantee that $\mathcal{Q}_{<n}(\beta)$ and $\mathcal{Q}_{\geq n}(\beta)$ are both probabilistic distributions in $\mathcal{D}\mathsf{P}(Q)$. The following lemma shows the relation between these functions and the limit distributions $\vec{\mu_0}\big(\mathcal{S}^{n-1}_\infty\big)$ and $\vec{\mu_0}\big(\mathcal{R}^{n-1}_\infty\big)$.

▶ **Lemma 16.** *For each $n \in \mathbb{N}$ we have*

$$\mathcal{Q}_{<n}\Big(\vec{\mu_0}\big(\mathcal{S}^{n-1}_\infty\big)\Big) = \vec{\mu_0}\big(\mathcal{R}^{n}_0\big) \qquad \textit{if } n \textit{ is odd,}$$

$$\mathcal{Q}_{\geq n}\Big(\vec{\mu_0}\big(\mathcal{R}^{n-1}_\infty\big)\Big) = \vec{\mu_0}\big(\mathcal{S}^{n}_0\big) \qquad \textit{if } n \textit{ is even.}$$

This lemma follows from Lemma 10 in a similar way as Lemma 15 follows from Lemma 12.

Proof. Consider the case of even n and a tree $t \in \mathrm{Tr}_A$. We need to show that

$$\mathcal{Q}_{\geq n}\Big(\vec{\mu_0}\big(\mathcal{R}^{n-1}_\infty\big)\Big) = \vec{\mu_0}\big(\mathcal{S}^{n}_0\big).$$

Lemma 10 implies that

$$\mathcal{S}^n_0[t] = \big(\mathcal{R}^{n-1}_\infty[t]\big) \cup Q_{\geq n}. \tag{6}$$

Therefore, for each $P \in \mathsf{P}(Q)$ we have

$$\begin{aligned}
\vec{\mu_0}\big(\mathcal{S}^n_0\big)(P) &= \mu_0\big\{t \in \mathrm{Tr}_A \mid \mathcal{S}^n_0[t] = P\big\}\\
&= \mu_0\big\{t \in \mathrm{Tr}_A \mid \big(\mathcal{R}^{n-1}_\infty[t]\big) \cup Q_{\geq n} = P\big\}\\
&= \mu_0\left(\bigcup_{P'\colon P'\cup Q_{\geq n}=P} \big\{t \in \mathrm{Tr}_A \mid \mathcal{R}^{n-1}_\infty[t] = P'\big\}\right)\\
&= \sum_{P'\colon P'\cup Q_{\geq n}=P} \mu_0\big\{t \in \mathrm{Tr}_A \mid \mathcal{R}^{n-1}_\infty[t] = P'\big\}\\
&= \sum_{P'\colon P'\cup Q_{\geq n}=P} \vec{\mu_0}\big(\mathcal{R}^{n-1}_\infty\big)(P')\\
&= \mathcal{Q}_{\geq n}\big(\vec{\mu_0}\big(\mathcal{R}^{n-1}_\infty\big)\big)(P)
\end{aligned}$$

The case of odd n is entirely analogous. ◀

The two above lemmata express the properties of the operators $\mathcal{F}$, $\mathcal{Q}_{<n}$, and $\mathcal{Q}_{\geq n}$ as depicted on Figure 1.

6 Limit distributions $\vec{\mu_0}\big(\mathcal{S}^n_\infty\big)$ and $\vec{\mu_0}\big(\mathcal{R}^n_\infty\big)$

In this section we show how to represent the distributions $\vec{\mu_0}\big(\mathcal{S}^n_\infty\big)$ and $\vec{\mu_0}\big(\mathcal{R}^n_\infty\big)$ as fixed points. We begin by proving that these distributions are limits in $\mathbb{R}^{\mathsf{P}(Q)}$ of the sequences of vectors $\big(\vec{\mu_0}\big(\mathcal{S}^n_i\big)\big)_{i\in\mathbb{N}}$ and $\big(\vec{\mu_0}\big(\mathcal{R}^n_i\big)\big)_{i\in\mathbb{N}}$ respectively. This is a consequence of Lemmata 7 and 9.

▶ **Lemma 17.** *For each $n \in \mathbb{N}$ and $P \in \mathsf{P}(Q)$ we have*

$$\lim_{i\to\infty} \vec{\mu_0}\big(\mathcal{S}^n_i\big)(P) = \vec{\mu_0}\big(\mathcal{S}^n_\infty\big)(P) \text{ and } \lim_{i\to\infty} \vec{\mu_0}\big(\mathcal{R}^n_i\big)(P) = \vec{\mu_0}\big(\mathcal{R}^n_\infty\big)(P).$$

Proof. We consider case of $\vec{\mu_0}\big(\mathcal{S}^n_\infty\big)$, the case of $\vec{\mu_0}\big(\mathcal{R}^n_\infty\big)(P)$ is entirely dual. First, we show that the respective limits agree when taking sums over any upward closed family $U \subseteq \mathsf{P}(Q)$, see (7) below. For $i \in \mathbb{N}$ let $X_i = \bigcup_{P'\in U}\{t \in \mathrm{Tr}_A \mid \mathcal{S}^n_i[t] = P'\}$ and $X_\infty = \bigcup_{P'\in U}\{t \in \mathrm{Tr}_A \mid \mathcal{S}^n_\infty[t] = P'\}$. Lemma 7 together with the fact that U is upward-closed imply that $X_0 \supseteq X_1 \supseteq \ldots \supseteq X_\infty$. Lemma 9 and finiteness of Q imply that for every tree t there exists an index J such that $\mathcal{S}^n_J[t] \subseteq \mathcal{S}^n_\infty[t]$. Therefore, $\bigcap_{i\in\mathbb{N}} X_i = X_\infty$. By continuity of the measure μ_0 we get that $\lim_{i\to\infty}\mu_0(X_i) = \mu_0(X_\infty)$. This means that

$$\lim_{i\to\infty} \sum_{P'\in U} \vec{\mu_0}\big(\mathcal{S}^n_i\big)(P') = \lim_{i\to\infty} \mu_0(X_i) = \mu_0(X_\infty) = \sum_{P'\in U} \vec{\mu_0}\big(\mathcal{S}^n_\infty\big)(P'). \tag{7}$$

Clearly, $\{P\} = \{P' \in \mathsf{P}(Q) \mid P' \supseteq P\} \setminus \{P' \in \mathsf{P}(Q) \mid P' \supsetneq P\}$ with both these families upward closed. Therefore, we can apply (7) twice and obtain the desired equation. ◀

The monotonicity of Δ, see Lemma 11, implies the following lemma.

▶ **Lemma 18.** *The operator $\mathcal{F}\colon \mathcal{D}\mathsf{P}(Q) \to \mathcal{D}\mathsf{P}(Q)$, see Equation (3), is monotone in $\preceq$.*

Proof. We need to prove that $\mathcal{F}$ is monotone w.r.t. the order $\preceq$. Thus, for every $\alpha \preceq \beta \in \mathcal{D}\mathsf{P}(Q)$ and an upward-closed family $U \subseteq \mathsf{P}(Q)$ we should have $\sum_{P\in U}\mathcal{F}(\alpha)(P) \leq \sum_{P\in U}\mathcal{F}(\beta)(P)$.

After multiplying by $\frac{1}{|A|}$ and splitting the sum over separate letters $a \in A$ (see the definition of $\mathcal{F}$, cf. (3)), it is enough to show that for each $a \in A$ and $O_a \stackrel{\text{def}}{=} \{(P_{\mathtt{L}}, P_{\mathtt{R}}) \mid \Delta(P_{\mathtt{L}}, a, P_{\mathtt{R}}) \in U\}$ we have

$$\sum_{(P_{\mathtt{L}},P_{\mathtt{R}})\in O_a} \alpha(P_{\mathtt{L}})\cdot\alpha(P_{\mathtt{R}}) \leq \sum_{(P_{\mathtt{L}},P_{\mathtt{R}})\in O_a} \beta(P_{\mathtt{L}})\cdot\beta(P_{\mathtt{R}}).$$

Now, by monotonicity of Δ (see Lemma 11) and the fact that U is upward-closed, we know that if $P_{\mathtt{L}} \subseteq P'_{\mathtt{L}}$, $P_{\mathtt{R}} \subseteq P'_{\mathtt{R}}$, and $(P_{\mathtt{L}}, P_{\mathtt{R}}) \in O_a$ then also $(P'_{\mathtt{L}}, P'_{\mathtt{R}}) \in O_a$. By $P_{\mathtt{L}}^{-1}\cdot O_a$ and $O_a \cdot P_{\mathtt{R}}^{-1}$ we will denote the sections $\{P_{\mathtt{R}} \mid (P_{\mathtt{L}}, P_{\mathtt{R}}) \in O_a\}$ and $\{P_{\mathtt{L}} \mid (P_{\mathtt{L}}, P_{\mathtt{R}}) \in O_a\}$ respectively. Notice that both of them are upward-closed. Thus, using the assumption that $\alpha \preceq \beta$ twice, we obtain

$$\begin{aligned}
\sum_{(P_{\mathtt{L}},P_{\mathtt{R}})\in O_a} \alpha(P_{\mathtt{L}})\cdot\alpha(P_{\mathtt{R}}) &= \sum_{P_{\mathtt{L}}\in\mathsf{P}(Q)} \alpha(P_{\mathtt{L}})\cdot\left(\sum_{P_{\mathtt{R}}\in P_{\mathtt{L}}^{-1}\cdot O_a} \alpha(P_{\mathtt{R}})\right)\\
&\leq \sum_{P_{\mathtt{L}}\in\mathsf{P}(Q)} \alpha(P_{\mathtt{L}})\cdot\left(\sum_{P_{\mathtt{R}}\in P_{\mathtt{L}}^{-1}\cdot O_a} \beta(P_{\mathtt{R}})\right)\\
&= \sum_{(P_{\mathtt{L}},P_{\mathtt{R}})\in O_a} \alpha(P_{\mathtt{L}})\cdot\beta(P_{\mathtt{R}}) = \sum_{(P_{\mathtt{L}},P_{\mathtt{R}})\in O_a} \beta(P_{\mathtt{R}})\cdot\alpha(P_{\mathtt{L}})\\
&= \sum_{P_{\mathtt{R}}\in\mathsf{P}(Q)} \beta(P_{\mathtt{R}})\cdot\left(\sum_{P_{\mathtt{L}}\in O_a\cdot P_{\mathtt{R}}^{-1}} \alpha(P_{\mathtt{L}})\right)\\
&\leq \sum_{P_{\mathtt{R}}\in\mathsf{P}(Q)} \beta(P_{\mathtt{R}})\cdot\left(\sum_{P_{\mathtt{L}}\in O_a\cdot P_{\mathtt{R}}^{-1}} \beta(P_{\mathtt{L}})\right)\\
&= \sum_{(P_{\mathtt{L}},P_{\mathtt{R}})\in O_a} \beta(P_{\mathtt{R}})\cdot\beta(P_{\mathtt{L}}) = \sum_{(P_{\mathtt{L}},P_{\mathtt{R}})\in O_a} \beta(P_{\mathtt{L}})\cdot\beta(P_{\mathtt{R}}).
\end{aligned}$$

◀

With the two lemmata above, we are ready to conclude this section: we characterise the distributions $\vec{\mu_0}\big(\mathcal{S}^n_\infty\big)$ and $\vec{\mu_0}\big(\mathcal{R}^n_\infty\big)$, see Figure 1, by a specialised variant of the Knaster-Tarski fixed point theorem.

▶ **Proposition 19.** *For each $n\in\mathbb{N}$ the distribution $\vec{\mu_0}\big(\mathcal{S}^n_\infty\big)$ is the $\preceq$-greatest distribution β satisfying $\beta=\mathcal{F}(\beta)$ and $\beta\preceq\vec{\mu_0}\big(\mathcal{S}^n_0\big)$. Similarly, $\vec{\mu_0}\big(\mathcal{R}^n_\infty\big)$ is the $\preceq$-least distribution β satisfying $\beta=\mathcal{F}(\beta)$ and $\beta\succeq\vec{\mu_0}\big(\mathcal{R}^n_0\big)$.*

Proof. Consider the case of $\vec{\mu_0}\big(\mathcal{S}^n_\infty\big)$. Observe that $\mathcal{F}$ is continuous in $\mathbb{R}^{\mathsf{P}(Q)}$. Indeed, it is given by a vector of quadratic polynomials from $\mathbb{R}^{\mathsf{P}(Q)}$ to $\mathbb{R}^{\mathsf{P}(Q)}$. Now, take $P\in\mathsf{P}(Q)$ and observe that

$$\begin{aligned}
\vec{\mu_0}\big(\mathcal{S}^n_\infty\big)(P) = \lim_{i\to\infty}\vec{\mu_0}\big(\mathcal{S}^n_i\big)(P) = \lim_{i\to\infty}\mathcal{F}\big(\vec{\mu_0}\big(\mathcal{S}^n_i\big)\big)(P) =\\
\mathcal{F}\Big(\lim_{i\to\infty}\vec{\mu_0}\big(\mathcal{S}^n_i\big)(P)\Big) = \mathcal{F}\Big(\vec{\mu_0}\big(\mathcal{S}^n_\infty\big)(P)\Big)
\end{aligned}$$

where the first equality follows from Lemma 17; the second from Lemma 15; the third from continuity of $\mathcal{F}$; and the last from Lemma 17, again. Therefore, $\beta=\vec{\mu_0}\big(\mathcal{S}^n_\infty\big)$ satisfies $\beta=\mathcal{F}(\beta)$. Moreover, Lemmata 7 and 14 imply that $\beta\preceq\vec{\mu_0}\big(\mathcal{S}^n_0\big)$.

Consider now any distribution $\beta\in\mathcal{D}\mathsf{P}(Q)$ such that $\beta=\mathcal{F}(\beta)$ and $\beta\preceq\vec{\mu_0}\big(\mathcal{S}^n_0\big)$. We need to prove that $\beta\preceq\vec{\mu_0}\big(\mathcal{S}^n_\infty\big)$. Lemma 18 states that $\mathcal{F}$ is monotone. Therefore, by inductively applying Lemma 15 for $i=0,\ldots$, we infer that

$$\beta=\mathcal{F}(\beta)\leq\mathcal{F}\Big(\vec{\mu_0}\big(\mathcal{S}^n_i\big)\Big)=\vec{\mu_0}\big(\mathcal{S}^n_{i+1}\big).$$

Take any upward-closed family $U\subseteq\mathsf{P}(Q)$. The above inequality implies that for each $i\in\mathbb{N}$ we have $\sum_{P\in U}\beta(P)\leq\sum_{P\in U}\vec{\mu_0}\big(\mathcal{S}^n_i\big)(P)$. By taking the limit as in Lemma 17 we obtain that $\sum_{P\in U}\beta(P)\leq\sum_{P\in U}\vec{\mu_0}\big(\mathcal{S}^n_\infty\big)(P)$. This implies that $\beta\preceq\vec{\mu_0}\big(\mathcal{S}^n_\infty\big)$.

The case of $\vec{\mu_0}\big(\mathcal{R}^n_\infty\big)$ is similar, we utilise the opposite monotonicity $\beta\succeq\vec{\mu_0}\big(\mathcal{R}^n_{i+1}\big)$. ◀

7 Computing measures

In this section, we conclude our solution to Problem 1 for weak alternating automata. This is achieved by a reduction to the first-order theory of the real numbers $\mathcal{R} = \langle \mathbb{R}, 0, 1, +, \cdot \rangle$. The theory is famously decidable thanks to Tarski-Seidenberg theorem, see e.g. [25].

Throughout this section, we assume that the reader is familiar with the syntax and semantics of first-order logic. We say that a formula $\varphi(x_1, \ldots, x_k)$ *represents* a relation $r \subseteq \mathbb{R}^k$ if it holds in $\mathbb{R}$ according to an evaluation v of the free variables $x_1, \ldots, x_n$, precisely when the tuple $\langle v(x_1), \ldots, v(x_k) \rangle$ belongs to r. For example, the formula $\exists z.\ x + (z \cdot z) = y$ represents the standard ordering $\leq$ on real numbers. A formula represents a number $a \in \mathbb{R}$ if it represents the singleton $\{a\}$; for example the formula $x \cdot x = 1{+}1 \wedge \exists z.\ x = z \cdot z$, represents the number $\sqrt{2}$.

▶ **Theorem 20.** *Given a weak alternating automaton $\mathcal{A}$ one can compute a formula $\psi_{\mathcal{A}}(x)$ that represents the number $\mu_0\big(\mathrm{L}(\mathcal{A})\big)$. Moreover, the formula is in a prenex normal form, its size is exponential in the size of $\mathcal{A}$, and the quantifier alternation of $\psi_{\mathcal{A}}(x)$ is constant.*

Proof. Fix a weak alternating automaton $\mathcal{A} = \langle A, Q, q_{\mathrm{I}}, \delta, \Omega \rangle$. Let $N > \Omega(q_{\mathrm{I}})$ be an even number (either $\Omega(q_{\mathrm{I}}){+}1$ or $\Omega(q_{\mathrm{I}}){+}2$). Fix an enumeration $\{P_1, \ldots, P_K\}$ of $\mathsf{P}(Q)$ with $K = 2^{|Q|}$. We will identify a distribution $\alpha \in \mathcal{D}\mathsf{P}(Q)$ with its representation $\alpha = (a_1, \ldots, a_K) \in \mathbb{R}^K$ as a vector of real numbers. Following this identification, $\alpha(P_k)$ stands for a_k. Clearly the properties that $\mathcal{F}(\alpha) = \beta$, $\mathcal{Q}_{<n}(\alpha) = \beta$, and $\mathcal{Q}_{\geq n}(\alpha) = \beta$ are definable by quantifier free formulae of size polynomial in K.

The following formula defines the fact that $\alpha \in \mathcal{D}\mathsf{P}(Q)$.

$$\mathrm{dist}(\alpha) \equiv \sum_{k=1}^{K} \alpha(P_k) = 1 \ \wedge \ \bigwedge_{k=1}^{K} 0 \leq \alpha(P_k) \leq 1$$

Analogously to our representation of distributions, every subset $U \subseteq \mathsf{P}(Q)$ can be represented by its indicator: a vector of numbers $\iota = (i_1, \ldots, i_K)$ such that $\iota(P)$ is either 0 (if $P \notin U$) or 1 (if $P \in U$). Note that if U is upward closed then whenever $P \subseteq P'$ and $\iota(P) = 1$ then $\iota(P') = 1$. The following formula defines the fact that ι represents an upward-closed set.

$$\mathrm{upward}(\iota) \equiv \bigwedge_{k=1}^{K} \big(\iota(P_k){=}0 \vee \iota(P_k){=}1\big) \wedge \bigwedge_{P \subseteq P'} \iota(P){=}1 \to \iota(P'){=}1.$$

Thus, to check if $\alpha \preceq \beta$ one can use the following formula (see Claim 21 below)

$$\mathrm{minor}(\alpha, \beta, \iota) \equiv \sum_{k=1}^{K} \alpha(P_k) \cdot \iota(P_k) \leq \sum_{k=1}^{K} \beta(P_k) \cdot \iota(P_k).$$

Notice that all the above formulae: $\mathrm{dist}(\alpha)$, $\mathrm{upward}(\iota)$, and $\mathrm{minor}(\alpha, \beta, \iota)$ are quantifier free: the $\bigwedge$ there are just explicitly written as finite conjunctions. Therefore, these formulae can be used to relativise quantifiers in a prenex normal form of a formula: for instance we write $\forall \alpha \colon \mathrm{dist}(\alpha).\ \exists \beta \colon \mathrm{dist}(\beta).\ \psi(\alpha, \beta)$ to denote $\forall \alpha.\ \exists \beta.\ \mathrm{dist}(\alpha) \to \big(\mathrm{dist}(\beta) \wedge \psi(\alpha, \beta)\big)$.

▷ Claim 21. Given two distributions α and β, we have $\alpha \preceq \beta$ if and only if

$$\forall \iota \colon \mathrm{upward}(\iota).\ \mathrm{minor}(\alpha, \beta, \iota).$$

$$\begin{tikzcd}
\alpha_0 = \vec{\mu}_0(\mathcal{S}_0^0) \arrow[dd, "\heartsuit"'] & & \beta_1 = \vec{\mu}_0(\mathcal{R}_\infty^0) \arrow[r, "\mathcal{Q}_{\geq 2}"'] & \alpha_2 = \vec{\mu}_0(\mathcal{S}_0^0) \arrow[dd, "\heartsuit"'] & & \beta_3 = \vec{\mu}_0(\mathcal{R}_\infty^0) \arrow[r, "\mathcal{Q}_{\geq 4}"'] & \cdots \\
 & & & & & & \cdots \\
\beta_0 = \vec{\mu}_0(\mathcal{S}_\infty^0) \arrow[r, "\mathcal{Q}_{<1}"] & \alpha_1 = \vec{\mu}_0(\mathcal{R}_0^0) \arrow[uur, "\spadesuit"] & & \beta_2 = \vec{\mu}_0(\mathcal{S}_\infty^0) \arrow[r, "\mathcal{Q}_{<3}"] & \alpha_3 = \vec{\mu}_0(\mathcal{R}_0^0) \arrow[uur, "\spadesuit"] & & \cdots
\end{tikzcd}$$

Figure 2 A diagram of the distributions α_n and β_n in the formula $\psi_{\mathcal{A}}(x)$, cf. Figure 1. The symbol $\heartsuit$ represents applications of Proposition 19 in the case of $\mathcal{S}_0^n$ and $\mathcal{S}_\infty^n$; while $\spadesuit$ corresponds to the dual case of $\mathcal{R}_0^n$ and $\mathcal{R}_\infty^n$.

The formula $\psi_{\mathcal{A}}(x)$ is indented to specify the distributions $(\alpha_n, \beta_n)_{n=0,\ldots,N}$ in a way depicted on Figure 2. The value $\vec{\mu}_0\big(\mathcal{S}_0^0(P)\big)$ is 1 if $P = Q$ and 0 otherwise, see Lemma 10. Proposition 19 allows us to define $\vec{\mu}_0\big(\mathcal{S}_\infty^n\big)$ (resp. $\vec{\mu}_0(\mathcal{R}_\infty^n)$) using $\vec{\mu}_0\big(\mathcal{S}_0^n\big)$ (resp. $\vec{\mu}_0\big(\mathcal{R}_0^n\big)$) as specific fixed points of the operation $\mathcal{F}$. Finally, Lemma 16 allows us to define $\vec{\mu}_0\big(\mathcal{R}_0^n\big)$ using $\mathcal{Q}_{<n}$, and $\vec{\mu}_0\big(\mathcal{S}_0^n\big)$ using $\mathcal{Q}_{\geq n}$. The value of x is related to those distributions based on Lemma 10 which implies that $\mu_0\big(\mathrm{L}(\mathcal{A})\big) = \sum_{P\colon q_{\mathrm{I}}\in P\in \mathsf{P}(Q)} \vec{\mu}_0\big(\mathcal{S}_0^N\big)(P)$.

The following equation defines the formula $\psi_{\mathcal{A}}(x)$.

$$\psi_{\mathcal{A}}(x) \equiv \exists \alpha_0, \beta_0\colon \mathrm{dist}(\alpha_0), \mathrm{dist}(\beta_0), \beta_0{=}\mathcal{F}(\beta_0).$$

$$\vdots \tag{8}$$

$$\exists \alpha_N, \beta_N\colon \mathrm{dist}(\alpha_N), \mathrm{dist}(\beta_N), \beta_N{=}\mathcal{F}(\beta_N).$$

$$\forall \theta\colon \mathrm{dist}(\theta), \theta{=}\mathcal{F}(\theta). \tag{9}$$

$$\exists \iota_0\colon \mathrm{upward}(\iota_0).$$

$$\vdots \tag{10}$$

$$\exists \iota_N\colon \mathrm{upward}(\iota_N).$$

$$\forall \gamma_0\colon \mathrm{upward}(\gamma_0).$$

$$\vdots \tag{11}$$

$$\forall \gamma_N\colon \mathrm{upward}(\gamma_N).$$

$$\left(\alpha_0(Q) = 1 \wedge \bigwedge_{P\neq Q} \alpha_0(P) = 0\right) \wedge \tag{12}$$

$$\left(\bigwedge_{n=1}^{N} [n \text{ is odd}] \rightarrow \alpha_n = \mathcal{Q}_{<n}(\beta_{n-1})\right) \wedge \tag{13}$$

$$\left(\bigwedge_{n=1}^{N} [n \text{ is even}] \rightarrow \alpha_n = \mathcal{Q}_{\geq n}(\beta_{n-1})\right) \wedge \tag{14}$$

$$\left(\bigwedge_{n=0}^{N} [n \text{ is odd}] \rightarrow \mathrm{minor}(\alpha_n, \beta_n, \gamma_n)\right) \wedge \tag{15}$$

$$\left(\bigwedge_{n=0}^{N} [n \text{ is even}] \rightarrow \mathrm{minor}(\beta_n, \alpha_n, \gamma_n)\right) \wedge \tag{16}$$

$$\left(\bigwedge_{n=0}^{N} [n \text{ is odd}] \rightarrow \Big(\neg\mathrm{minor}(\alpha_n, \theta, \iota_n) \vee \mathrm{minor}(\beta_n, \theta, \gamma_n)\Big)\right) \wedge \tag{17}$$

$$\left(\bigwedge_{n=0}^{N}[n \text{ is even}] \rightarrow \Big(\neg\mathrm{minor}(\theta,\alpha_n,\iota_n) \vee \mathrm{minor}(\theta,\beta_n,\gamma_n)\Big)\right) \quad \wedge \tag{18}$$

$$\left(\sum_{P\ni q_{\mathrm{I}}} \alpha_N(P) = x\right) \tag{19}$$

Observe that the size of this formula is polynomial in K and N (in fact it is $\mathcal{O}(N\cdot K^2)$), i.e. exponential in the size of the automaton $\mathcal{A}$. Moreover, the formula is in prenex normal form and its quantifier alternation is 4 (the sub-formulae that involve $\bigwedge$ are written explicitly as conjunctions).

We begin by proving soundness of the formula: we assume that $\psi_{\mathcal{A}}(x)$ holds and show that $x = \mu_0\big(\mathrm{L}(\mathcal{A})\big)$. Consider a sequence of distributions $(\alpha_n,\beta_n)_{n=0,\ldots,N}$ witnessing (8). The following two lemmata prove inductively that for $n = 0,\ldots,N$ we have

$$\begin{aligned} &\alpha_n = \vec{\mu_0}(\mathcal{S}_0^n) \text{ and } \beta_n = \vec{\mu_0}(\mathcal{S}_\infty^n) && \text{for even } n,\\ &\alpha_n = \vec{\mu_0}(\mathcal{R}_0^n) \text{ and } \beta_n = \vec{\mu_0}(\mathcal{R}_\infty^n) && \text{for odd } n. \end{aligned} \tag{20}$$

▶ **Lemma 22.** *Using the above notations and the assumption that $\psi_{\mathcal{A}}(x)$ holds:*

for even n, if $\alpha_n = \vec{\mu_0}(\mathcal{S}_0^n)$ then $\beta_n = \vec{\mu_0}(\mathcal{S}_\infty^n)$,
for odd n, if $\alpha_n = \vec{\mu_0}(\mathcal{R}_0^n)$ then $\beta_n = \vec{\mu_0}(\mathcal{R}_\infty^n)$.

Proof. Both claims follow from Proposition 19. Take n odd and assume that $\alpha_n = \vec{\mu_0}(\mathcal{R}_0^n)$. We know that $\beta_n = \mathcal{F}(\beta_n)$ by (8). Moreover, by Claim 21, the arbitrary choice of γ_n, and (15) we know that $\alpha_n \preceq \beta_n$. It is enough to prove that if θ is any distribution satisfying $\alpha_n \preceq \theta$ and $\theta = \mathcal{F}(\theta)$ then $\beta_n \preceq \theta$.

Assume contrarily that θ is a distribution such that $\alpha_n \preceq \theta$ and $\theta = \mathcal{F}(\theta)$ but $\beta_n \not\preceq \theta$. We know that θ must satisfy the sub-formula in (9). Take the upward closed sets $(\iota_\ell)_{\ell=0,\ldots,N}$ given by (10). Now let $(\gamma_\ell)_{\ell=0,\ldots,N}$ be any sequence of upward closed sets such that γ_n witnesses the fact that $\beta_n \not\preceq \theta$, i.e. $\neg\mathrm{minor}(\beta_n,\theta,\gamma_n)$ holds. But this is a contradiction with (17) because $\mathrm{minor}(\alpha_n,\theta,\iota_n)$ is true as $\alpha_n \preceq \theta$ and $\mathrm{minor}(\beta_n,\theta,\gamma_n)$ is false.

The case of even n is analogous. ◀

▶ **Lemma 23.** *Using the above notations and the assumption that $\psi_{\mathcal{A}}(x)$ holds:*

$\alpha_n = \vec{\mu_0}(\mathcal{S}_0^n)$ for even n and $\alpha_n = \vec{\mu_0}(\mathcal{R}_0^n)$ for odd n.

Proof. The proof is inductive in n. First, $\alpha_0 = \vec{\mu_0}(\mathcal{S}_0^n)$ because of (12) and the statement for $n = 0$ in Lemma 10 (we can take $\theta = \beta_0$ and $\gamma_\ell = \iota_\ell$ for $\ell = 0,\ldots,N$ to check that Condition (12) holds).

Now assume that the above conditions are true for $n-1$ for some $n \in \{1,\ldots,N\}$. Again, by the symmetry we assume that n is odd, i.e. $\alpha_{n-1} = \vec{\mu_0}(\mathcal{S}_0^{n-1})$. By Lemma 22 we know that $\beta_{n-1} = \vec{\mu_0}(\mathcal{S}_\infty^{n-1})$. Condition (13) says that $\alpha_n = \mathcal{Q}_{<n}(\beta_{n-1}) = \mathcal{Q}_{<n}\big(\vec{\mu_0}(\mathcal{S}_\infty^{n-1})\big)$. Now Lemma 16 implies that $\mathcal{Q}_{<n}\big(\vec{\mu_0}(\mathcal{S}_\infty^{n-1})\big) = \vec{\mu_0}\big(\mathcal{R}_0^n\big)$ and the induction step is complete. ◀

Equation (20) together with Condition (19), imply that $x = \mu_0\{t \in \mathrm{Tr}_A \mid q_{\mathrm{I}} \in \mathcal{S}_0^N[t]\}$. Since $N > \Omega(q_{\mathrm{I}})$ is even, Lemma 10 implies that $\mathcal{S}_0^N(q_{\mathrm{I}}) = \mathrm{L}(\mathcal{A}, q_{\mathrm{I}})$ and therefore, $q_{\mathrm{I}} \in \mathcal{S}_0^N[t]$ if and only if $t \in \mathrm{L}(\mathcal{A})$. This guarantees that $x = \mu_0\big(\mathrm{L}(\mathcal{A})\big)$.

We will now prove completeness of the formula: if $x = \mu_0\big(\mathrm{L}(\mathcal{A})\big)$ then $\psi_{\mathcal{A}}(x)$ holds. Choose the distributions $(\alpha_n,\beta_n)_{n=0,\ldots,N}$ in (8) as in (20). We will show that then the rest of the formula holds. Consider any distribution θ. For each $n = 0,\ldots,N$ let ι_n be an upward-closed set witnessing that $\alpha_n \not\preceq \theta$ for n odd (resp. $\theta \not\preceq \alpha_n$ for n even); or any upward closed set if the respective inequality holds.

Take any $(\gamma_n)_{n=0,\ldots,N}$ that are upward closed. We need to check that the sub-formula starting in (12) holds. Conditions (12) – (16) and (19) hold by the same lemmata as mentioned in the previous section. To check Conditions (17) and (18) one again invokes Proposition 19: either ι_n witnesses that $\alpha_n \not\preceq \theta$ (resp. $\theta \not\preceq \alpha_n$) or, if ι_n was chosen arbitrarily, then Proposition 19 implies that also the respective inequality with β_n holds. ◀

7.1 Branching processes

This section is devoted to the variant of Theorem 20 in the case when instead of the standard measure μ_0 one uses a measure $\mu_{\mathcal{P}}$ generated by a given branching process $\mathcal{P}$. For the sake of simplicity we define only binary branching processes, the case of a fixed higher arity can be solved analogously.

A *branching process* is a tuple $\mathcal{P} = \langle A, \tau, \alpha_{\mathrm{I}} \rangle$ where A is a finite alphabet; $\tau \colon A \to \mathcal{D}A^2$ a *branching function* that assigns a probability distribution over A^2 to every letter in A; and $\alpha_{\mathrm{I}} \in \mathcal{D}A$ an *initial distribution.* We assume that all probabilities occurring in these distributions are rational. By the *size* of $\mathcal{P}$ we understand the size of its binary representation.

A branching process $\mathcal{P}$ can be seen as a generator of random trees: it defines a complete Borel measure $\mu_{\mathcal{P}}$ over the set of infinite trees in the following way. Let $f\colon \mathrm{dom}(f) \to A$ be a complete finite tree of depth $d \geq 0$ i.e. $\mathrm{dom}(f) = \{u \in \{\mathtt{L},\mathtt{R}\}^* \mid |u| \leq d\} = \{\mathtt{L},\mathtt{R}\}^{<d+1}$. Then the measure $\mu_{\mathcal{P}}$ of the basic set U_f, see Section 2, is defined by

$$\mu_{\mathcal{P}}(U_f) \overset{\text{def}}{=} \alpha_{\mathrm{I}}(f(\varepsilon)) \cdot \prod_{u \in \{\mathtt{L},\mathtt{R}\}^{<d}} \tau(f(u))\big(f(u\mathtt{L}), f(u\mathtt{R})\big). \tag{21}$$

Now, $\mu_{\mathcal{P}}$ can be extended in a standard way to a complete Borel measure on the set of all infinite trees Tr_A. Intuitively, a tree $t \in \mathrm{Tr}_A$ that is chosen according to $\mu_{\mathcal{P}}$ is generated in a top-down fashion: the root label $t(\varepsilon)$ is chosen according to the initial distribution α_{I}; and the labels of the children $u\mathtt{L}$ and $u\mathtt{R}$ of a node u are chosen according to the distribution $\tau(t(u)) \in \mathcal{D}A^2$ defined for the label of their parent u.

Observe that the uniform measure μ_0 over trees Tr_A equals the measure $\mu_{\mathcal{P}_0}$ defined by the branching process $\mathcal{P}_0 = \langle A, \tau_0, \alpha_0 \rangle$, where $\alpha_0(a) = |A|^{-1}$ and $\tau_0(a)(a_{\mathtt{L}}, a_{\mathtt{R}}) = |A|^{-2}$ for each $a, a_{\mathtt{L}}, a_{\mathtt{R}} \in A$.

▶ **Theorem 24.** *Given a weak alternating automaton $\mathcal{A}$ and a branching process $\mathcal{P}$ one can compute a formula $\psi_{\mathcal{A},\mathcal{P}}(x)$ that represents the number $\mu_{\mathcal{P}}\big(\mathrm{L}(\mathcal{A})\big)$. Moreover, the formula is in a prenex normal form; its size is exponential in the size of $\mathcal{A}$ and polynomial in the size of $\mathcal{P}$; and the quantifier alternation of $\psi_{\mathcal{A},\mathcal{P}}$ is constant.*

To prove Theorem 24, we construct the formula $\psi_{\mathcal{A},\mathcal{P}}(x)$ directly along the same lines as the formula $\psi_{\mathcal{A}}(x)$ in Theorem 20. The difference is that instead of working in the space $\mathcal{D}\mathsf{P}(Q)$ with the order $\preceq$, our computations are performed in the space $(\mathcal{D}\mathsf{P}(Q))^A$ ordered by the order $\preceq$ considered coordinate-wise. A complete presentation of this more general construction will be given in the full version of this article.

7.2 Representing algebraic numbers

We now use the formulae $\psi_{\mathcal{A}}$ and $\psi_{\mathcal{A},\mathcal{P}}$ constructed above to find the measure of the language $\mathrm{L}(\mathcal{A})$. We use the celebrated result of Tarski [25] and its two algorithmic improvements.

▶ **Theorem 25** ([2, 3])**.** *Given a formula ψ of first-order logic over $\mathbb{R}$, one can decide if ψ holds in deterministic exponential space. Moreover, if ψ is in a prenex normal form and the alternation of quantifiers $\forall$ and $\exists$ in ψ is bounded then the algorithm works in single exponential time in the size of ψ.*

Proof of Theorem 2. Input a weak alternating automaton $\mathcal{A}$, a branching process $\mathcal{P}$, and a rational number q. Consider the formula $\psi \equiv \exists x.\ \psi_{\mathcal{A},\mathcal{P}}(x) \wedge q \bowtie x$, where $\bowtie$ is one of $<$, $=$, or $>$. Notice that ψ is in prenex normal form; its size is exponential in the size of $\mathcal{A}$ and polynomial in the size of $\mathcal{P}$; and its quantifier alternation is constant. Apply the algorithm from Theorem 25 to check whether ψ is true in $\mathbb{R}$. ◀

We can also compute a representation of the measure $\mu_{\mathcal{P}}\big(\mathrm{L}(\mathcal{A})\big)$. The *quantifier elimination* procedure due to Tarski [25] transforms a formula $\psi(x_1,\ldots,x_n)$ into an equivalent quantifier-free formula $\widehat{\psi}(x_1,\ldots,x_n)$, which moreover can be represented by a *semialgebraic* set, see [4, Chapter 2].

▶ **Theorem 26** ([7]). *Given a formula $\psi(x_1,\ldots,x_n)$ of first-order logic over $\mathbb{R}$, one can construct a representation of the set of tuples $(x_1,\ldots,x_n)$ satisfying ψ, as a semialgebraic set. Moreover, this algorithm works in time doubly-exponential in the size of ψ.*

Theorems 20 and 24 together with the above results imply the following claim.

▶ **Corollary 27.** *Given a weak alternating automaton $\mathcal{A}$ of size n, one can compute a representation of the value $\mu_0\big(\mathrm{L}(\mathcal{A})\big)$ as a singleton semialgebraic set in time triply exponential in n. Moreover, given a branching process of size m, one can compute a representation of the value $\mu_{\mathcal{P}}\big(\mathrm{L}(\mathcal{A})\big)$ as a singleton semialgebraic set in time triply exponential in n and doubly exponential in m.*

8 Conclusions

We have shown how to compute the probability measure of a tree language L recognised by a weak alternating automaton. The crucial trait is *continuity* of certain approximations of the measure of L in a properly chosen order $\preceq$, see Lemma 17. This continuity relies on König's lemma, cf. Lemma 9. In terms of μ-calculus, it stems from both the absence of alternation between least and greatest fixed points in formulae and the boundedness of branching in models (for a study of continuity in μ-calculus see [11]).

Whether our techniques can be extended beyond weak automata – hopefully to all tree automata or, equivalently, full MSO logic, or full μ-calculus – remains open. The question is of interest as, e.g. translation of the logic CTL* into μ-calculus requires at least one alternation between least and greatest fixed points (cf. [9], Exercise 10.13). On the other hand, fixed point formulas over binary trees are not continuous in general, and may require ω_1 iterations to reach stabilisation, already on the second level of the fixed-point hierarchy.

This problem has been already successfully tackled in the context of measurability of regular tree languages – Mio [16] uses Martin's axiom to control the behaviour of measure when taking limits of sequences of length ω_1. Such behaviour cannot be directly simulated in $\mathcal{D}X$, because each well-founded chain of distributions has a countable length. However, this need not be an absolute obstacle as it might be the case that the values of the measure of the iterations stabilise before the actual fixed point is reached, possibly in ω steps.

Finite Sequentiality of Finitely Ambiguous Max-Plus Tree Automata

Erik Paul
Institute of Computer Science, Leipzig University, Germany
epaul@informatik.uni-leipzig.de

Abstract

We show that the finite sequentiality problem is decidable for finitely ambiguous max-plus tree automata. A max-plus tree automaton is a weighted tree automaton over the max-plus semiring. A max-plus tree automaton is called finitely ambiguous if the number of accepting runs on every tree is bounded by a global constant. The finite sequentiality problem asks whether for a given max-plus tree automaton, there exist finitely many deterministic max-plus tree automata whose pointwise maximum is equivalent to the given automaton.

1 Introduction

A *max-plus automaton* is a finite automaton whose transitions are weighted by real numbers. A max-plus automaton assigns a weight to each of its runs by adding the weights of the transitions which constitute the run and it assigns a weight to every word by taking the maximum over the weights of all runs on the given word. Max-plus automata are weighted automata [40, 39, 27, 6, 13] over the max-plus semiring. In the form of min-plus automata, they were originally introduced by Imre Simon as a means to show the decidability of the *finite power property* [42, 43] and they enjoy a continuing interest [26, 19, 22, 7, 12, 16, 28]. They have found applications in many different contexts, for example to determine the star height of a language [18], to prove the termination of certain string rewriting systems [44], and to model discrete event systems [23]. They also appear in the context of natural language processing [29], where probabilities are often computed in the min-plus semiring as negative log-likelihoods for reasons of numerical stability.

Like finite automata, max-plus automata are by definition non-deterministic devices. However, while every finite automaton can be determinized [36], the same is in general not true for max-plus automata [22]. Actually, it is a long-standing open question whether given a max-plus automaton, the existence of an equivalent deterministic automaton can be decided. This problem is commonly known as the *sequentiality problem* and is one of the most prominent open questions about max-plus automata. For practical applications, the execution of a deterministic automaton is of course much more efficient than the execution of a non-deterministic one, so being able to decide whether a given automaton can be determinized is very much desirable. While open in general, the sequentiality problem has been shown to be decidable for some important subclasses of max-plus automata, namely for *unambiguous* [29], *finitely ambiguous* [22], and *polynomially ambiguous* [21] max-plus automata. Here, we call a max-plus automaton *unambiguous* if there exists at most one run on every word, *finitely ambiguous* if the number of runs on each word is bounded by a global constant, and *polynomially ambiguous* if the number of runs on each word is bounded polynomially in the length of the word. Note that the classes of deterministic, unambiguous, finitely ambiguous, polynomially ambiguous, and arbitrary max-plus automata form a strictly ascending hierarchy [22, 20, 28]. Also, deciding the degree of ambiguity of a max-plus automaton can easily be reduced to deciding the degree of ambiguity of a finite automaton. It is trivial to decide whether a finite automaton is deterministic. Polynomial time algorithms to decide whether a finite automaton is unambiguous, finitely ambiguous, or polynomially ambiguous can be found in [8, 45, 41].

While a given max-plus automaton may not be equivalent to a single deterministic max-plus automaton, this does not exclude the possibility that it is equivalent to the pointwise maximum of finitely many deterministic automata. The problem of deciding whether a max-plus automaton possesses such a *finitely sequential* representation is known as the *finite sequentiality problem.* The decidability of the finite sequentiality problem was posed as an open question in [19] and has been solved only recently for unambiguous [4] and finitely ambiguous [3] max-plus automata. Note that the class of max-plus automata which possess a finitely sequential representation lies strictly between the classes of deterministic and finitely ambiguous max-plus automata, and it is incomparable to the class of unambiguous max-plus automata [22].

In this paper, we show that the finite sequentiality problem is decidable for finitely ambiguous *max-plus tree automata.* Operating on trees instead of words, max-plus tree automata are a generalization of max-plus word automata and more generally, they are weighted tree automata [1, 5, 14, 17] over the max-plus semiring. Applications of max-plus tree automata include proving the termination of certain term rewriting systems [24] and they are commonly employed in natural language processing [35] in the form of *probabilistic context-free grammars.* Our approach to proving the decidability of the finite sequentiality problem for finitely ambiguous max-plus tree automata employs ideas from Bala's proof of the corresponding result for finitely ambiguous max-plus word automata [3]. However, due to lack of space, formal proofs had to be omitted in [3] and Bala's informal description of his methods does not suffice for reconstruction. Also, no other published version of [3] exists. We provide an honest attempt to compare our approach to his but note that our interpretation might not be accurate.

In his proof for max-plus word automata, Bala first introduces the *A-Fork property* and then proceeds to show that this property is a decidable criterion characterizing the finite sequentiality of a finitely ambiguous max-plus automaton. More precisely, he shows that a finitely ambiguous max-plus automaton possesses a finitely sequential representation if and only if the A-Fork property is not satisfied. To show the decidability of the A-Fork property, he shows its expressibility in a decidable fragment of Presburger arithmetic. To show that an automaton is not finitely sequential if the A-Fork property is satisfied, he uses pumping techniques similar to those employed in [4] for the finite sequentiality problem of unambiguous max-plus word automata. This part of his proof most likely employs Ramsey's Theorem [37] as it involves "colorings of finite hypercubes". His proof for the existence of a finitely sequential representation in case that the A-Fork property is not satisfied employs transducers and the notions of *critical pairs* and *close approximations*, none of which occur in our approach. We are thus unsure about the nature of this particular part of the proof, but it most likely uses a reduction to the decidability of the finite sequentiality problem for unambiguous automata.

Our approach is as follows. First, we introduce the *separation property*, a twofold modification of the A-Fork property. On the one hand, we endow our new property with a criterion accounting for the non-linear structure of trees. This new criterion is inspired by the criterion we added in [34] to the *fork property* [4], the property characterizing finite sequentiality of unambiguous max-plus word automata, in order to obtain the *tree fork property*, the property characterizing finite sequentiality of unambiguous max-plus tree automata. On the other hand, we strengthen the A-Fork property as with only the first modification, our new property would wrongly characterize some finitely sequential automata as not being finitely sequential. We then show that the separation property is decidable by employing Parikh's Theorem [31, 15] for a reduction to the decidability of the satisfiability of systems of linear inequalities over the rational numbers with integer solutions [30, 9]. This means in particular that we show the decidability of the finite sequentiality problem only for automata with weights in the rationals. Then we employ Ramsey's Theorem to show that no finitely sequential representation exists whenever the separation property is satisfied. Due to the criterion accounting for the non-linearity of trees, this is considerably more difficult than in [3] and it is in fact the most technical and the most challenging aspect of our result. Finally, we show that if the separation property is not satisfied for a given max-plus tree automaton, then we can construct finitely many unambiguous max-plus tree automata which all do not satisfy the tree fork property and whose pointwise maximum is equivalent to the automaton. By [34], these unambiguous automata then possess finitely sequential representations. Combining these, we obtain a finitely sequential representation of the original automaton.

2 Preliminaries

For a set X, we denote the power set of X by $\mathcal{P}(X)$ and the cardinality of X by $|X|$. For two sets X and Y and a mapping $f\colon X \to Y$, we call X the *domain* of f, denoted by $\mathrm{dom}(f)$. For a subset $X' \subseteq X$, we call the set $f(X') = \{y \in Y \mid \exists x \in X'\colon f(x) = y\}$ the *image* or *range of* X' *under* f. The *restriction of* f *to* X', denoted by $f{\restriction_{X'}}$, is the mapping $f{\restriction_{X'}}\colon X' \to Y$ defined by $f{\restriction_{X'}}(x) = f(x)$ for every $x \in X'$. For an element $y \in Y$, we call the set $f^{-1}(y) = \{x \in X \mid f(x) = y\}$ the *preimage of* y *under* f. For a second mapping $g\colon X \to Y$, we write $f = g$ if for all $x \in X$ we have $f(x) = g(x)$.

We let $\mathbb{N} = \{0, 1, 2, \ldots\}$. By $\mathbb{N}^*$ we denote the set of all finite words over $\mathbb{N}$. The empty word is denoted by ε, and the length of a word $w \in \mathbb{N}^*$ by $|w|$. The set $\mathbb{N}^*$ is partially ordered by the prefix relation $\leq_{\mathrm{P}}$ and totally ordered with respect to the lexicographic ordering $\leq_{\mathrm{L}}$. Two words from $\mathbb{N}^*$ are called *prefix-dependent* if they are in prefix relation, and otherwise they are called *prefix-independent*.

A *ranked alphabet* is a pair $(\Gamma, \mathrm{rk}_\Gamma)$, often abbreviated by Γ, where Γ is a finite set and $\mathrm{rk}_\Gamma\colon \Gamma \to \mathbb{N}$ a mapping which assigns a *rank* to every symbol. For every $m \geq 0$ we define $\Gamma^{(m)} = \mathrm{rk}_\Gamma^{-1}(m)$ as the set of all symbols of rank m. The rank of Γ is defined as $\mathrm{rk}(\Gamma) = \max\{\mathrm{rk}_\Gamma(a) \mid a \in \Gamma\}$. The set of (*finite, labeled, and ordered*) Γ*-trees*, denoted by T_Γ, is the set of all pairs $t = (\mathrm{pos}(t), \mathrm{label}_t)$, where $\mathrm{pos}(t) \subset \mathbb{N}^*$ is a finite non-empty prefix-closed set of *positions*, $\mathrm{label}_t\colon \mathrm{pos}(t) \to \Gamma$ is a mapping, and for every $w \in \mathrm{pos}(t)$ we have $wi \in \mathrm{pos}(t)$ iff $1 \leq i \leq \mathrm{rk}_\Gamma(\mathrm{label}_t(w))$. We write $t(w)$ for $\mathrm{label}_t(w)$ and $|t|$ for $|\mathrm{pos}(t)|$. We also refer to the elements of $\mathrm{pos}(t)$ as *nodes*, to ε as the *root* of t, and to prefix-maximal nodes as *leaves*. The *height* of t is defined as $\mathrm{height}(t) = \max_{w \in \mathrm{pos}(t)} |w|$. For a leaf $w \in \mathrm{pos}(t)$, the set $\{v \in \mathrm{pos}(t) \mid v \leq_{\mathrm{P}} w\}$ is called a *branch* of t.

Now let $s, t \in T_\Gamma$ and $w \in \mathrm{pos}(t)$. The *subtree of t at w*, denoted by $t{\restriction_w}$, is a Γ-tree defined as follows. We let $\mathrm{pos}(t{\restriction_w}) = \{v \in \mathbb{N}^* \mid wv \in \mathrm{pos}(t)\}$ and for $v \in \mathrm{pos}(t{\restriction_w})$, we let $\mathrm{label}_{t\restriction_w}(v) = t(wv)$. The *substitution of s into w of t*, denoted by $t\langle s \to w\rangle$, is a Γ-tree defined as follows. We let $\mathrm{pos}(t\langle s \to w\rangle) = (\mathrm{pos}(t) \setminus \{v \in \mathrm{pos}(t) \mid w \leq_{\mathrm{P}} v\}) \cup \{wv \mid v \in \mathrm{pos}(s)\}$. For $v \in \mathrm{pos}(t\langle s \to w\rangle)$, we let $\mathrm{label}_{t\langle s\to w\rangle}(v) = s(u)$ if $v = wu$ for some $u \in \mathrm{pos}(s)$, and otherwise $\mathrm{label}_{t\langle s\to w\rangle}(v) = t(v)$. For $a \in \Gamma^{(m)}$ and trees $t_1, \dots, t_m \in T_\Gamma$, we also write $a(t_1, \dots, t_m)$ to denote the tree t with $\mathrm{pos}(t) = \{\varepsilon\} \cup \{iw \mid i \in \{1, \dots, m\}, w \in \mathrm{pos}(t_i)\}$, $\mathrm{label}_t(\varepsilon) = a$, and $\mathrm{label}_t(iw) = t_i(w)$. For $a \in \Gamma^{(0)}$, the tree $a()$ is abbreviated by a.

For a ranked alphabet Γ, a tree over the alphabet $\Gamma_\diamond = (\Gamma \cup \{\diamond\}, \mathrm{rk}_\Gamma \cup \{\diamond \mapsto 0\})$ is called a *Γ-context*. Let $t \in T_{\Gamma_\diamond}$ be a Γ-context and let $w_1, \dots, w_n \in \mathrm{pos}(t)$ be a lexicographically ordered enumeration of all leaves of t labeled $\diamond$. Then we call t an *n-Γ-context* and define $\Diamond_i(t) = w_i$ for $i \in \{1, \dots, n\}$. For an n-Γ-context t and contexts $t_1, \dots, t_n \in T_{\Gamma_\diamond}$, we define $t(t_1, \dots, t_n) = t\langle t_1 \to \Diamond_1(t)\rangle \cdots \langle t_n \to \Diamond_n(t)\rangle$ by substitution of $t_1, \dots, t_n$ into the $\diamond$-leaves of t. A 1-Γ-context is also called a *Γ-word*. For a Γ-word s, we define $s^0 = \diamond$ and $s^{n+1} = s(s^n)$ for $n \geq 0$.

A *commutative semiring* is a tuple $(K, \oplus, \odot, \mathbb{0}, \mathbb{1})$, abbreviated by K, with operations sum $\oplus$ and product $\odot$ and constants $\mathbb{0}$ and $\mathbb{1}$ such that $(K, \oplus, \mathbb{0})$ and $(K, \odot, \mathbb{1})$ are commutative monoids, multiplication distributes over addition, and $\kappa \odot \mathbb{0} = \mathbb{0} \odot \kappa = \mathbb{0}$ for every $\kappa \in K$. In this paper, we mainly consider the following two semirings.

- The *Boolean semiring* $\mathbb{B} = (\{0, 1\}, \vee, \wedge, 0, 1)$ with disjunction $\vee$ and conjunction $\wedge$.
- The *max-plus semiring* $\mathbb{Q}_{\max} = (\mathbb{Q} \cup \{-\infty\}, \max, +, -\infty, 0)$ where the sum and the product operations are max and $+$, respectively, extended to $\mathbb{Q} \cup \{-\infty\}$ in the usual way.

For a commutative semiring $(K, \oplus, \odot, \mathbb{0}, \mathbb{1})$ and an integer $n \geq 1$, the *product semiring* $(K^n, \oplus_n, \odot_n, \mathbb{0}_n, \mathbb{1}_n)$ is defined by componentwise operations and the constants $\mathbb{0}_n = (\mathbb{0}, \dots, \mathbb{0})$ and $\mathbb{1}_n = (\mathbb{1}, \dots, \mathbb{1})$. We will usually denote $\oplus_n$ and $\odot_n$ simply by $\oplus$ and $\odot$.

Let $(K, \oplus, \odot, \mathbb{0}, \mathbb{1})$ be a commutative semiring. A *weighted bottom-up finite state tree automaton (short: WTA) over K and Γ* is a tuple $\mathcal{A} = (Q, \Gamma, \mu, \nu)$ where Q is a finite set (of states), Γ is a ranked alphabet (of input symbols), $\mu\colon \bigcup_{m=0}^{\mathrm{rk}(\Gamma)} Q^m \times \Gamma^{(m)} \times Q \to K$ (the function of transition weights), and $\nu\colon Q \to K$ (the function of final weights). We define $\Delta_{\mathcal{A}} = \mathrm{dom}(\mu)$. A tuple $d \in \Delta_{\mathcal{A}}$ is called a *transition* and d is called *valid* if $\mu(d) \neq \mathbb{0}$. A state $q \in Q$ is called *final* if $\nu(q) \neq \mathbb{0}$.

We call a WTA over the max-plus semiring a *max-plus-WTA* and a WTA over the Boolean semiring a *finite tree automaton* (FTA). We also write a WTA $\mathcal{A} = (Q, \Gamma, \mu, \nu)$ over $\mathbb{B}$ as a tuple $\mathcal{A}' = (Q, \Gamma, \delta, F)$ where $\delta = \{d \in \Delta_{\mathcal{A}} \mid \mu(d) = 1\}$ and $F = \{q \in Q \mid \nu(q) = 1\}$.

For a tree $t \in T_\Gamma$, a mapping $r\colon \mathrm{pos}(t) \to Q$ is called a *quasi-run of $\mathcal{A}$ on t*. For a quasi-run r on t and a position $w \in \mathrm{pos}(t)$ with $t(w) = a \in \Gamma^{(m)}$, the tuple $\mathbb{t}(t, r, w) = (r(w1), \dots, r(wm), a, r(w))$ is called the *transition at w*. The quasi-run r is called a *(valid) run* if for every $w \in \mathrm{pos}(t)$ the transition $\mathbb{t}(t, r, w)$ is valid with respect to $\mathcal{A}$. We call a run r *accepting* if $r(\varepsilon)$ is final. By $\mathrm{Run}_{\mathcal{A}}(t)$ and $\mathrm{Acc}_{\mathcal{A}}(t)$ we denote the sets of all runs and all accepting runs of $\mathcal{A}$ on t, respectively. For a state $q \in Q$, we denote by $\mathrm{Run}_{\mathcal{A}}(t, q)$ the set of all runs $r \in \mathrm{Run}_{\mathcal{A}}(t)$ such that $r(\varepsilon) = q$.

For a run $r \in \mathrm{Run}_{\mathcal{A}}(t)$, the *weight of r* is defined by $\mathrm{wt}_{\mathcal{A}}(t, r) = \bigodot_{w \in \mathrm{pos}(t)} \mu(\mathbb{t}(t, r, w))$. The *behavior of $\mathcal{A}$*, denoted by $[\![\mathcal{A}]\!]$, is the mapping defined for every $t \in T_\Gamma$ by $[\![\mathcal{A}]\!](t) = \bigoplus_{r \in \mathrm{Acc}_{\mathcal{A}}(t)} (\mathrm{wt}_{\mathcal{A}}(t, r) \odot \nu(r(\varepsilon)))$, where the sum over the empty set is $\mathbb{0}$ by convention. The *support* of a WTA $\mathcal{A}$ is the set $\mathrm{supp}(\mathcal{A}) = \{t \in T_\Gamma \mid [\![\mathcal{A}]\!](t) \neq \mathbb{0}\}$. The support of an FTA $\mathcal{A}$ is also called the *language accepted by $\mathcal{A}$* and denoted by $\mathcal{L}(\mathcal{A})$. A subset $L \subseteq T_\Gamma$ is called *recognizable* if there exists an FTA $\mathcal{A}$ with $L = \mathcal{L}(\mathcal{A})$.

For a WTA $\mathcal{A} = (Q, \Gamma, \mu, \nu)$, a run of $\mathcal{A}$ on a Γ-context t is a run of the WTA $\mathcal{A}' = (Q, \Gamma_\diamond, \mu', \nu)$ on t, where $\mu'(\diamond, q) = \mathbb{1}$ for all $q \in Q$ and $\mu'(d) = \mu(d)$ for all $d \in \Delta_{\mathcal{A}}$. We denote $\mathrm{Run}^\diamond_{\mathcal{A}}(t) = \mathrm{Run}_{\mathcal{A}'}(t)$ and for $r \in \mathrm{Run}^\diamond_{\mathcal{A}}(t)$ write $\mathrm{wt}^\diamond_{\mathcal{A}}(t, r) = \mathrm{wt}_{\mathcal{A}'}(t, r)$. For an n-Γ-context $t \in T_{\Gamma_\diamond}$ and states $q_0, \ldots, q_n$, we denote by $\mathrm{Run}^\diamond_{\mathcal{A}}(q_1, \ldots, q_n, t, q_0)$ the set of all runs $r \in \mathrm{Run}^\diamond_{\mathcal{A}}(t)$ such that $r(\varepsilon) = q_0$ and $r(\Diamond_i(t)) = q_i$ for every $i \in \{1, \ldots, n\}$.

We consider the set $\Gamma \times Q$ as an alphabet by defining $\mathrm{rk}_{\Gamma\times Q}(a, q) = \mathrm{rk}_\Gamma(a)$ for every pair $(a, q) \in \Gamma \times Q$ and identify every tree $t' \in T_{\Gamma\times Q}$ with the pair (t, r) given by $t = (\mathrm{pos}(t'), \pi_\Gamma \circ \mathrm{label}_{t'}) \in T_\Gamma$ and $r = \pi_Q \circ \mathrm{label}_{t'}$, where $\pi_\Gamma \colon \Gamma \times Q \to \Gamma$ and $\pi_Q \colon \Gamma \times Q \to Q$ are the projections. For a Γ-word $s \in T_{\Gamma_\diamond}$, a state $q \in Q$, and a run $r_s \in \mathrm{Run}^\diamond_{\mathcal{A}}(q, s, q)$, we define $(s, r_s)^0 = (\diamond, q)$ and $(s, r_s)^{n+1} = (s, r_s)\langle (s, r_s)^n \to \Diamond_1(s)\rangle$ for $n \geq 0$.

We call a WTA $\mathcal{A} = (Q, \Gamma, \mu, \nu)$ over K and Γ *trim* if for every $p \in Q$, there exist $t \in T_\Gamma$, $r \in \mathrm{Acc}_{\mathcal{A}}(t)$, and $w \in \mathrm{pos}(t)$ with $r(w) = p$. The *trim part of* $\mathcal{A}$ is the automaton obtained from $\mathcal{A}$ by removing all states $p \in Q$ for which no such t, r, and w exist. This process obviously has no influence on $[\![\mathcal{A}]\!]$. We call $\mathcal{A}$ *complete* if for every $m \geq 0$, $a \in \Gamma^{(m)}$, and $(q_1, \ldots, q_m) \in Q^m$, there exists at least one $q \in Q$ with $\mu(q_1, \ldots, q_m, a, q) \neq \mathbb{0}$. We call $\mathcal{A}$ *deterministic* or *sequential* if for every $m \geq 0$, $a \in \Gamma^{(m)}$, and $(q_1, \ldots, q_m) \in Q^m$, there exists at most one $q \in Q$ with $\mu(q_1, \ldots, q_m, a, q) \neq \mathbb{0}$. If there exists an integer $M \geq 1$ such that $|\mathrm{Acc}_{\mathcal{A}}(t)| \leq M$ for every $t \in T_\Gamma$, we call $\mathcal{A}$ *M-ambiguous*. We call $\mathcal{A}$ *finitely ambiguous* if it is M-ambiguous for some $M \geq 1$ and *unambiguous* if it is 1-ambiguous. We call the behavior $[\![\mathcal{A}]\!]$ of $\mathcal{A}$ *finitely sequential* if there exist finitely many deterministic WTA $\mathcal{A}_1, \ldots, \mathcal{A}_n$ over K and Γ such that $[\![\mathcal{A}]\!] = \bigoplus_{i=1}^n [\![\mathcal{A}_i]\!]$, where the sum is taken pointwise.

3 The Criterion for Finite Sequentiality

We will show that for a finitely ambiguous max-plus-WTA $\mathcal{A}$, it is decidable whether its behavior $[\![\mathcal{A}]\!]$ is finitely sequential. For this, we first formulate the *separation property*, a generalization of Bala's *A-Fork property* [3]. Then we show that it is decidable whether the separation property is satisfied and that the behavior of a max-plus-WTA is finitely sequential if and only if the separation property is not satisfied. In the following, let Γ be a ranked alphabet. We begin by recalling the tree fork property and the related concepts of *rivals*, *reachers*, *distinguishers*, and *forks*. Intuitively, two states of a finitely ambiguous max-plus-WTA $\mathcal{A}$ are called *rivals* if they can be reached by the same tree u and they can loop in the same Γ-word s but the weights of these loops differ. The tree u is then called a *reacher* of p and q and the Γ-word s a *distinguisher* for p and q. For two rivals p and q, a Γ-word f is called a *p-q-fork* if f can both loop in p and also go from p to q, in a bottom-up sense. We say that $\mathcal{A}$ satisfies the tree fork property if there exist two rivals p and q such that either there exists a p-q-fork or p and q can occur at prefix-independent positions in some run of $\mathcal{A}$. Formally, these definitions are as follows.

▶ **Definition 1.** *Let $\mathcal{A} = (Q, \Gamma, \mu, \nu)$ be a finitely ambiguous max-plus-WTA. Two states $p, q \in Q$ are called* rivals *if there exists a tree $u \in T_\Gamma$ with $\mathrm{Run}_{\mathcal{A}}(u, p) \neq \emptyset$ and $\mathrm{Run}_{\mathcal{A}}(u, q) \neq \emptyset$ and a Γ-word s with runs $r_p \in \mathrm{Run}^\diamond_{\mathcal{A}}(p, s, p)$ and $r_q \in \mathrm{Run}^\diamond_{\mathcal{A}}(q, s, q)$ such that $\mathrm{wt}^\diamond_{\mathcal{A}}(s, r_p) \neq \mathrm{wt}^\diamond_{\mathcal{A}}(s, r_q)$. In this case, we call u a p-q-*reacher *and s a p-q-*distinguisher*. We say that $\mathcal{A}$ satisfies the *tree fork property *if at least one of the following two conditions is satisfied.*

(i) *There exist rivals $p, q \in Q$ and a Γ-word f with $\mathrm{Run}_{\mathcal{A}}(p, f, p) \neq \emptyset$ and $\mathrm{Run}_{\mathcal{A}}(p, f, q) \neq \emptyset$. In this case, we call f a p-q-*fork*.*

(ii) *There exist rivals $p, q \in Q$, a 2-Γ-context $t \in T_{\Gamma_\diamond}$, and a run $r \in \mathrm{Run}^\diamond_{\mathcal{A}}(t)$ with $r(\Diamond_1(t)) = p$ and $r(\Diamond_2(t)) = q$. In this case, we call t a p-q-*split*.*

We have the following theorem relating the tree fork property to finite sequentiality of unambiguous max-plus-WTA.

▶ **Theorem 2** ([34]). *The behavior of a trim unambiguous max-plus-WTA $\mathcal{A}$ is finitely sequential if and only if $\mathcal{A}$ does not satisfy the tree fork property. If $[\![\mathcal{A}]\!]$ is finitely sequential, a finitely sequential representation of $\mathcal{A}$ can be effectively constructed.*

For finitely ambiguous max-plus-WTA, however, the tree fork property does not capture finite sequentiality. To see why, consider an unambiguous max-plus-WTA $\mathcal{A}$ satisfying the tree fork property [34, 4, 22] and let L be the largest weight used in $\mathcal{A}$. Then construct a one-state max-plus-WTA $\mathcal{B}$ whose every transition weight and every final weight is L. Clearly, $\mathcal{B}$ is deterministic and we have $[\![\mathcal{B}]\!] \geq [\![\mathcal{A}]\!]$. By taking the disjoint union $\mathcal{A} \cup \mathcal{B}$ of $\mathcal{A}$ and $\mathcal{B}$, we obtain a 2-ambiguous max-plus-WTA which satisfies the tree fork property but whose behavior coincides with that of the deterministic automaton $\mathcal{B}$. In this particular example, the states relevant for the tree fork property to be satisfied are not relevant at all for the behavior of the automaton.

For the rest of this paper, let $\mathcal{A}$ be a trim finitely ambiguous max-plus-WTA over the ranked alphabet Γ. In order to reduce the finite sequentiality problem of finitely ambiguous max-plus-WTA to that of unambiguous max-plus-WTA, we decompose $\mathcal{A}$ into a maximum of finitely many unambiguous max-plus-WTA $\mathcal{A}_1, \ldots, \mathcal{A}_N$ and then analyze the interplay of these latter automata. We can do so as in fact, every finitely ambiguous WTA can be decomposed into finitely many unambiguous WTA [22, 32]. This is a common approach when dealing with finite ambiguity [22, 25, 33] and is also used by Bala in the corresponding proof for words [3]. In the simplest case, if $\mathcal{A}_1, \ldots, \mathcal{A}_N$ all do not satisfy the tree fork property, we find a finitely sequential representation of $\mathcal{A}$ by constructing such a representation for each $\mathcal{A}_n$ and then combining all of these. However, if some $\mathcal{A}_n$ does satisfy the tree fork property, we have to analyze whether this automaton contributes enough to the behavior of $\mathcal{A}$ for there not to exist a finitely sequential representation of $\mathcal{A}$. For an easier analysis of the automata $\mathcal{A}_1, \ldots, \mathcal{A}_N$, we normalize their final weights and consider their product as follows.

▶ **Lemma 3** ([41, 22, 32, 10]). *We can effectively find an integer $M \in \mathbb{N}$ and construct a trim WTA $\mathcal{U} = (Q, \Gamma, \mu, \nu)$ over $\mathbb{Q}^M_{\max}$ and Γ such that*

- *$\mathcal{U}$ is unambiguous,*
- *$\mu(\Delta_\mathcal{U}) \subseteq \mathbb{Q}^M \cup \{(-\infty, \ldots, -\infty)\}$ and $\nu(Q) \subseteq \{(0, \ldots, 0), (-\infty, \ldots, -\infty)\}$, and*
- *for every $t \in T_\Gamma$ we have $[\![\mathcal{A}]\!](t) = \max_{i=1}^{M} \pi_i([\![\mathcal{U}]\!](t))$,*

where $\pi_i \colon \mathbb{Q}^M_{\max} \to \mathbb{Q}_{\max}$ is the projection to the i-th coordinate for every $i \in \{1, \ldots, M\}$.

Let $\mathcal{U}$ be the automaton we obtain for $\mathcal{A}$ from Lemma 3. For a tree $t \in T_\Gamma$, a Γ-word $s \in T_{\Gamma_\diamond}$, runs $r_t \in \mathrm{Run}_\mathcal{U}(t)$, $r_s \in \mathrm{Run}^\diamond_\mathcal{U}(s)$, states $p, q \in Q$, and a coordinate $i \in \{1, \ldots, M\}$, we let $\mathrm{wt}_i(t, r_t) = \pi_i(\mathrm{wt}_\mathcal{U}(t, r_t))$, $\mathrm{wt}^\diamond_i(s, r_s) = \pi_i(\mathrm{wt}^\diamond_\mathcal{U}(s, r_s))$, and $\mathrm{wt}^\diamond_i(p, s, q) = \mathrm{wt}^\diamond_i(s, r^q_p)$ for the unique run $r^q_p \in \mathrm{Run}^\diamond_\mathcal{U}(p, s, q)$. We define the concepts of rivals, reachers, distinguishers, and forks for $\mathcal{U}$ as follows.

▶ **Definition 4.** *Let $i \in \{1, \ldots, M\}$, $p, q \in Q$, $t \in T_\Gamma$, and $r \in \mathrm{Acc}_\mathcal{U}(t)$.*

- *We call p and q i-*rivals *if there exists a tree $u \in T_\Gamma$ such that $\mathrm{Run}_\mathcal{U}(u, p) \neq \emptyset$ and $\mathrm{Run}_\mathcal{U}(u, q) \neq \emptyset$ and a Γ-word s such that $\mathrm{Run}^\diamond_\mathcal{U}(p, s, p) \neq \emptyset$, $\mathrm{Run}^\diamond_\mathcal{U}(q, s, q) \neq \emptyset$, and $\mathrm{wt}^\diamond_i(p, s, p) \neq \mathrm{wt}^\diamond_i(q, s, q)$. In this case, we also call u a p-q-*reacher *and s an i-p-q-*distinguisher.
- *We call a Γ-word f an i-p-q-*fork *if p and q are i-rivals, $\mathrm{Run}^\diamond_\mathcal{U}(p, f, p) \neq \emptyset$, and $\mathrm{Run}^\diamond_\mathcal{U}(p, f, q) \neq \emptyset$.*

- *We say that (t,r) is i-p-q-*fork-broken *if there exist positions $w_p, w_q \in \operatorname{pos}(t)$ such that $w_q <_P w_p$, $r(w_p) = p$, $r(w_q) = q$, and $(t\langle \diamond \to w_p \rangle)\restriction_{w_q}$ is an i-p-q-fork.*
- *We say that (t,r) is i-p-q-*split-broken *if p and q are i-rivals and there exist two prefix-independent positions $w_p, w_q \in \operatorname{pos}(t)$ with $r(w_p) = p$ and $r(w_q) = q$.*

*When appropriate, we may drop some of the hyphenated modifiers from the terms above; for example, we will refer to (t,r) as i-*fork-broken *if there exist states $p, q \in Q$ such that (t,r) is i-p-q-fork-broken and as i-*split-broken *if there exist states $p, q \in Q$ such that (t,r) is i-p-q-split-broken. We call (t,r) i-*broken *if it is i-fork-broken or i-split-broken.*

Our concept of brokenness, is inspired by Bala's notion of "broken paths" [3]. Of course, as his proof is concerned with words, the concept of split-brokenness does not exist. His notion of brokenness corresponds to our notion of fork-brokenness. Employing the notion of brokenness, Bala characterizes finite sequentiality of finitely ambiguous max-plus word automata using the *A-Fork property*. Translated to tree automata, the A-Fork property is defined as follows. We say that $\mathcal{U}$ satisfies the A-Fork property if for every constant $C > 0$, there exists a tree $t \in T_\Gamma$ and an accepting run $r \in \operatorname{Acc}_{\mathcal{U}}(t)$ such that for some weight-maximal coordinate i, i.e., with $\operatorname{wt}_i(t,r) = \max_{j=1}^{M} \operatorname{wt}_j(t,r)$, we have that (t,r) is i-broken and for every coordinate j such that (t,r) is not j-broken, we have $\operatorname{wt}_j(t,r) < \operatorname{wt}_i(t,r) - C$. In other words, the A-Fork property is satisfied if broken coordinates are able to dominate non-broken coordinates by an arbitrarily large margin. Bala shows that a finitely ambiguous max-plus word automaton is finitely sequential if and only if the corresponding automaton $\mathcal{U}$ does not satisfy the A-Fork property. For tree automata, however, this criterion does not capture finite sequentiality. More precisely, if we know that there do not exist a tree t and a run r on t such that (t,r) is split-broken, then the A-Fork property does capture finite sequentiality also for tree automata. However, if $\mathcal{U}$ satisfies the A-Fork property due to split-broken coordinates dominating non-broken coordinates, the behavior of $\mathcal{A}$ may still be finitely sequential. This is evidenced by the following example.

▶ **Example 5.** Consider the scenario for $\mathcal{U}$ as defined in Figure 1. The support of $\mathcal{U}$ consists of all trees of the form $c(b^k(a_i^m(d_i)), b^l(a_j^n(d_j)))$ with $i, j \in \{1,2\}$, $k, l > 0$, and $m, n \geq 0$. A valid run on such a tree necessarily assigns states from $\{p_1, p_2, p\}$ to the left branch of the tree and states from $\{q_1, q_2, q\}$ to the right branch of the tree. Moreover, if a branch begins with a letter d_i, this branch is assigned states from $\{p_i, q_i, p, q\}$. In particular, we see that $\mathcal{U}$ is unambiguous. The states p and q are 2-rivals as we see from the p-q-reacher $u = b(a_1(d_1))$ and the 2-p-q-distinguisher $s = b(\diamond)$. By considering the trees $t_n = c(b(a_1^n(d_1)), b(a_2^n(d_2)))$, we see that runs exist where p and q occur prefix-independently and the weight of coordinate 2 is arbitrarily larger than the weights of coordinates 1 and 3 since we have $[\![\mathcal{U}]\!](t_n) = (-n, 0, -n)$. However, in t_n the subtrees below p and q are distinct, thus a deterministic automaton can distinguish between them.

In fact, if $\mathcal{U}$ is given this way, we can construct a finitely sequential representation of $[\![\mathcal{A}]\!]$ as follows. All trees of the form $c(b^k(a_1^m(d_1)), b^l(a_1^n(d_1)))$ are assigned the weight $(-m-n+k+l-2, k-l, k+l-2)$, so coordinate 3 is always dominant. Similarly, coordinate 1 is dominant for trees of the form $c(b^k(a_2^m(d_2)), b^l(a_2^n(d_2)))$. These trees can be handled by the deterministic max-plus-WTA obtained from $\mathcal{U}$ by removing the states q_1 and q_2, letting $\mu(p, p, c, \top) = (0,0,0)$, and replacing μ with $\pi_1 \circ \mu$ and $\pi_3 \circ \mu$, respectively. For trees of the form $c(b^k(a_1^m(d_1)), b^l(a_2^n(d_2)))$, we remove the states p_2 and q_1 from $\mathcal{U}$ and then construct three deterministic max-plus-WTA by replacing μ by $\pi_1 \circ \mu, \pi_2 \circ \mu$, and $\pi_3 \circ \mu$, respectively. For the trees $c(b^k(a_2^m(d_2)), b^l(a_1^n(d_1)))$ we can proceed similarly. The pointwise maximum of the automata constructed this way is then equivalent to $[\![\mathcal{A}]\!]$. This example shows in particular that if $\mathcal{U}$ satisfies the A-Fork property, $[\![\mathcal{A}]\!]$ can still be finitely sequential.

$$\nu(\top) = (0,0,0) \qquad \mu(p,b,p) = (1,1,1) \qquad \mu(p_1,a_1,p_1) = \mu(q_1,a_1,q_1) = (-1,0,0)$$

$$\mu(p,q,c,\top) = (0,0,0) \qquad \mu(q,b,q) = (1,-1,1) \qquad \mu(p_2,a_2,p_2) = \mu(q_2,a_2,q_2) = (0,0,-1)$$

$$\mu(p_1,b,p) = \mu(p_2,b,p) = \mu(q_1,b,q) = \mu(q_2,b,q) = (0,0,0)$$

$$\mu(d_1,p_1) = \mu(d_1,q_1) = \mu(d_2,p_2) = \mu(d_2,q_2) = (0,0,0)$$

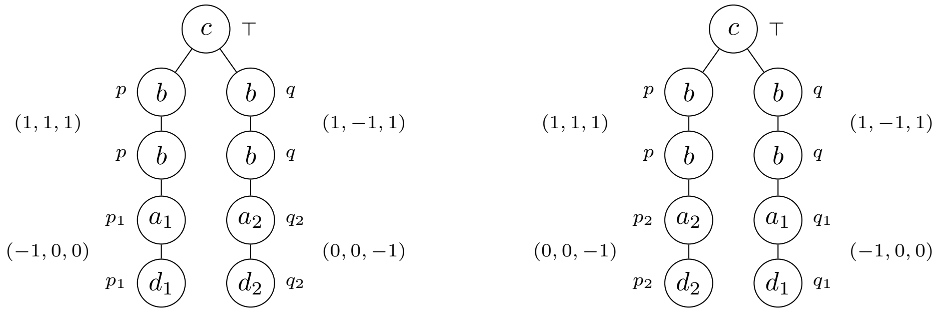

Figure 1 A scenario for the automaton $\mathcal{U}$: The automaton $(\{p_1,p_2,q_1,q_2,p,q,\top\},\Gamma,\mu,\nu)$ over the ranked alphabet $\Gamma = \{a_1,a_2,b,c,d_1,d_2\}$ where $c \in \Gamma^{(2)}$, $a_1,a_2,b \in \Gamma^{(1)}$, and $d_1,d_2 \in \Gamma^{(0)}$. All unspecified weights are assumed to be $-\infty$. The states p and q are 2-rivals.

Our fundamental idea to adapt the A-Fork property to tree automata is to formulate our version not for $\mathcal{U}$ but for a *covering* of $\mathcal{U}$. Oversimplifying, a *covering* of an automaton is a new automaton obtained by enhancing the states of the original automaton with additional capacities to store information. A prominent example of a covering construction is the *Schützenberger covering* of an automaton. The Schützenberger covering in particular has already been employed in a number of decidability results for max-plus automata [22, 4, 3, 33, 34]. For more background on coverings, see [38].

Here, we construct from $\mathcal{U}$ an unambiguous automaton $\boldsymbol{\mathcal{U}}$ with the same behavior as $\mathcal{U}$ and whose states are tuples from $Q \times \mathcal{P}(Q) \times \mathcal{P}(Q^4 \times \mathcal{P}(Q^2))$. Every run $\mathbf{r}$ of $\boldsymbol{\mathcal{U}}$ on a tree $t \in T_\Gamma$ will correspond uniquely to a run of $\mathcal{U}$ on t, given by projecting to the first entry. For a position w, the second entry of $\mathbf{r}(w)$ will be the set of all states $q \in Q$ which can be reached by $t\!\upharpoonright_w$, i.e., for which $\mathrm{Run}_{\mathcal{U}}(t\!\upharpoonright_w, q)$ is non-empty. The third entry of $\mathbf{r}(w)$ will contain a tuple (p,q,p',q',Y) if and only if $t\!\upharpoonright_w$ can reach p and q with two runs r_p and r_q, these runs visited p' and q' simultaneously at some position v in the past, and Y consists of all pairs of states which these runs visited simultaneously up to v. More precisely, the third entry of $\mathbf{r}(w)$ will consist of all tuples (p,q,p',q',Y) such that (1) there exist runs $r_p \in \mathrm{Run}_{\mathcal{U}}(t\!\upharpoonright_w, p)$ and $r_q \in \mathrm{Run}_{\mathcal{U}}(t\!\upharpoonright_w, q)$, (2) for some position below w, i.e., some position $v \in \mathrm{pos}(t\!\upharpoonright_w)$, we have $r_p(v) = p'$ and $r_q(v) = q'$, and (3) Y is the set of all pairs of states $(r_p(vu), r_q(vu))$ with $u \in \mathrm{pos}(t\!\upharpoonright_{wv})$. Our intention of considering the covering $\boldsymbol{\mathcal{U}}$ is to increase the knowledge we have about each pair of rivals. For two rivals of $\mathcal{U}$, all we know is what the definition of rivals specifies. For two rivals of $\boldsymbol{\mathcal{U}}$ on the other hand, we can show that they are necessarily of the form (p,P,V) and (q,P,V) where p and q are rivals of $\mathcal{U}$. This allows us to infer statements about the rivals of $\boldsymbol{\mathcal{U}}$ which are not necessarily true for the rivals of $\mathcal{U}$. The precise construction of $\boldsymbol{\mathcal{U}}$ is as follows.

▶ **Construction 6.** We define $\boldsymbol{\mathcal{U}} = (\mathbf{Q},\Gamma,\boldsymbol{\mu},\boldsymbol{\nu})$ as the trim part of the automaton $\boldsymbol{\mathcal{U}}' = (\mathbf{Q}',\Gamma,\boldsymbol{\mu}',\boldsymbol{\nu}')$ defined as follows. We let $\mathbf{Q}' = Q \times \mathcal{P}(Q) \times \mathcal{P}(Q^4 \times \mathcal{P}(Q^2))$ and for subsets $P_1,\ldots,P_m \subseteq Q$ and a letter $a \in \Gamma$ with $\mathrm{rk}_\Gamma(a) = m$, we let $\mathrm{succ}(P_1,\ldots,P_m,a) = \{q_0 \mid \exists (q_1,\ldots,q_m) \in P_1 \times \ldots \times P_m \text{ with } \mu(q_1,\ldots,q_m,a,q_0) \in \mathbb{Q}^M\}$. For $i \in \{1,\ldots,\mathrm{rk}_\Gamma(a)\}$ and states $(p,q,p',q',Y) \in Q^4 \times \mathcal{P}(Q^2)$, we let $\mathrm{succ}(P_1,\ldots,P_m,(p,q,p',q',Y),i,a) =$

$\mathrm{succ}(P_1, \ldots, P_{i-1}, \{p\}, P_{i+1}, \ldots, P_m, a) \times \mathrm{succ}(P_1, \ldots, P_{i-1}, \{q\}, P_{i+1}, \ldots, P_m, a) \times \{p'\} \times \{q'\} \times \{Y\}$. For $V \subseteq Q^4 \times \mathcal{P}(Q^2)$ and $p, q \in Q$, we let $\mathrm{visited}(p, q, V) = \{(p', q') \mid (p, q, p', q', Y) \in V \text{ for some } Y \subseteq Q^2\}$. Then for $a \in \Gamma$ with $\mathrm{rk}_\Gamma(a) = m$ and $(p_0, P_0, V_0), \ldots, (p_m, P_m, V_m) \in \mathbf{Q}'$, we define $\boldsymbol{\nu}'(p_0, P_0, V_0) = \nu(p_0)$ and $\boldsymbol{\mu}'((p_1, P_1, V_1), \ldots, (p_m, P_m, V_m), a, (p_0, P_0, V_0)) =$

$$\begin{cases} \mu(p_1, \ldots, p_m, a, p_0) & \text{if } P_0 = \mathrm{succ}(P_1, \ldots, P_m, a) \text{ and with} \\ & V = \bigcup_{i=1}^m \bigcup_{(p,q,p',q',Y) \in V_i} \mathrm{succ}(P_1, \ldots, P_m, (p, q, p', q', Y), i, a) \\ & \text{we have } V_0 = V \cup \{(p, q, p, q, Y) \mid p, q \in P_0 \text{ and} \\ & \qquad\qquad Y = \mathrm{visited}(p, q, V) \cup \{(p, q)\}\} \\ (-\infty, \ldots, -\infty) & \text{otherwise.} \end{cases}$$

Then $\boldsymbol{\mathcal{U}}$ satisfies the properties described above. We let $\pi_1 \colon \mathbf{Q} \to Q$, $\pi_2 \colon \mathbf{Q} \to \mathcal{P}(Q)$, and $\pi_3 \colon \mathbf{Q} \to \mathcal{P}(Q^4 \times \mathcal{P}(Q^2))$ be the projections, and let $\mathbf{wt}_i$ and $\mathbf{wt}_i^\diamond$ be defined for $\boldsymbol{\mathcal{U}}$ in the same way we defined wt_i and $\mathrm{wt}_i^\diamond$ for $\mathcal{U}$. Furthermore, we note that the concepts of rivals, reachers, distinguishers, and forks as defined for $\mathcal{U}$ in Definition 4 apply to $\boldsymbol{\mathcal{U}}$ in a similar fashion.

Finally, we introduce our version of the A-Fork property. To allow for easier proofs, we use a different formulation and consequently a different name. But in fact, $\boldsymbol{\mathcal{U}}$ satisfies the separation property if and only if it satisfies the A-Fork property in the way we translated it to trees earlier.

▶ **Definition 7.** *Let $C \in \mathbb{N}$. We call a set $I \subseteq \{1, \ldots, M\}$ C-*separable *if there exists a tree $t \in T_\Gamma$ and a run $\mathbf{r} \in \mathrm{Acc}_{\boldsymbol{\mathcal{U}}}(t)$ such that*

(i) *if $i \in I$, then $(t, \mathbf{r})$ is i-broken and*

(ii) *if $j \in \{1, \ldots, M\} \setminus I$, then $\mathbf{wt}_j(t, \mathbf{r}) \leq \mathbf{wt}_i(t, \mathbf{r}) - C$ for all $i \in I$.*

*In this case, we also say that $(t, \mathbf{r})$ is I-C-*separated. *We call I* separable *if it is C-separable for every $C \in \mathbb{N}$ and define $\mathcal{I}$ as the set of all separable subsets $I \subseteq \{1, \ldots, M\}$. If $\mathcal{I}$ is non-empty, we say that $\boldsymbol{\mathcal{U}}$ satisfies the* separation property *or, for short, that $\boldsymbol{\mathcal{U}}$ is* broken.

Our main result is to prove the following theorem relating the separation property to the finite sequentiality problem of finitely ambiguous max-plus-WTA.

▶ **Theorem 8.** *The behavior $[\![\mathcal{A}]\!]$ of $\mathcal{A}$ is finitely sequential if and only if $\boldsymbol{\mathcal{U}}$ is not broken. Moreover, it is decidable whether $\boldsymbol{\mathcal{U}}$ is broken. In particular, it is decidable whether $[\![\mathcal{A}]\!]$ is finitely sequential.*

We separate the proof of Theorem 8 into three parts. Due to lack of space, we have to restrict ourselves to brief descriptions of our methods. In Section 3.1, we outline that it is decidable whether $\boldsymbol{\mathcal{U}}$ is broken. This part of the proof does not follow any idea from [3] as in his proof, Bala reduces the decidability of the A-Fork property to the decidability of a decidable fragment of Presburger arithmetic. In Section 3.2, we show that if $\boldsymbol{\mathcal{U}}$ is broken, then $[\![\mathcal{A}]\!]$ is not finitely sequential. This part of the proof employs ideas from [4, 3, 34], but extends these non-trivially. This particular proof is the most challenging and technical aspect of our result. Finally, in Section 3.3, we outline how to construct finitely many deterministic max-plus-WTA whose pointwise maximum is equivalent to $[\![\mathcal{A}]\!]$ in case that $\boldsymbol{\mathcal{U}}$ is not broken. Although this part is inspired by an idea in [3], we are not sure whether we employ this idea in the same way.

For all of our proofs, it is crucial that for every two states of $\boldsymbol{\mathcal{U}}$, we can decide whether they are rivals [2, Section 4], [11, Section 5.4]. For two rivals of an unambiguous automaton, it is in fact quite easy to give an upper bound on the size of their smallest distinguisher and smallest reacher. Thus, deciding whether two states are rivals reduces to checking for finitely many trees whether they can reach both states and checking for finitely many Γ-words whether they are a distinguisher for these two states. For Section 3.3, we require an even more precise statement, namely that if s is a distinguisher for two rivals $\mathbf{p}$ and $\mathbf{q}$, then we can obtain a $\mathbf{p}$-$\mathbf{q}$-distinguisher of height at most $4|\mathbf{Q}|^2$ by removing loops from the unique runs looping in $\mathbf{p}$ and $\mathbf{q}$. For this, we employ the notion of a *truncation*. Simply put, for a Γ-word s and a run $\mathbf{r}$ on s, a truncation of $(s, \mathbf{r})$ is any pair $(s', \mathbf{r}')$ of a Γ-word s' and a run $\mathbf{r}'$ on s' which can be obtained by repeatedly cutting loops from $(s, \mathbf{r})$.

▶ **Definition 9.** *Let $s, s' \in T_{\Gamma_\diamond}$ be Γ-words, $\mathbf{r} \in \mathrm{Run}^{\diamond}_{\boldsymbol{\mathcal{U}}}(s)$, and $\mathbf{r}' \in \mathrm{Run}^{\diamond}_{\boldsymbol{\mathcal{U}}}(s')$. We say that $(s', \mathbf{r}')$ is a* truncation *of $(s, \mathbf{r})$, denoted by $(s, \mathbf{r}) \mathrel{\text{✄}} (s', \mathbf{r}')$, if there exists a mapping $g\colon \mathrm{pos}(s') \to \mathrm{pos}(s)$ such that $g(\varepsilon) = \varepsilon$, $g(\Diamond_1(s')) = \Diamond_1(s)$, for all $w \in \mathrm{pos}(s')$ we have $\mathbb{t}(s', \mathbf{r}', w) = \mathbb{t}(s, \mathbf{r}, g(w))$, and for all $w_1, w_2 \in \mathrm{pos}(s')$ we have $g(w_1) \leq_L g(w_2)$ if and only if $w_1 \leq_L w_2$ and $g(w_1) \leq_P g(w_2)$ if and only if $w_1 \leq_P w_2$.*

We can use truncations to bound the size of distinguishers as follows.

▶ **Lemma 10** ([11, Lemma 5.10],[34])**.** *Let $\mathbf{p}, \mathbf{q} \in \mathbf{Q}$ be i-rivals for some $i \in \{1, \ldots, M\}$, let $u \in T_\Gamma$ be a $\mathbf{p}$-$\mathbf{q}$-reacher, let $f \in T_{\Gamma_\diamond}$ be a $\mathbf{p}$-$\mathbf{q}$-fork, let $s \in T_{\Gamma_\diamond}$ be an i-$\mathbf{p}$-$\mathbf{q}$-distinguisher, and let $\mathbf{r_p} \in \mathrm{Run}^{\diamond}_{\boldsymbol{\mathcal{U}}}(\mathbf{p}, s, \mathbf{p})$ and $\mathbf{r_q} \in \mathrm{Run}^{\diamond}_{\boldsymbol{\mathcal{U}}}(\mathbf{q}, s, \mathbf{q})$. Then there exists a $\mathbf{p}$-$\mathbf{q}$-reacher u' with* $\mathrm{height}(u') \leq |\mathbf{Q}|^2$*, a $\mathbf{p}$-$\mathbf{q}$-fork f' with* $\mathrm{height}(f') \leq 2|\mathbf{Q}|^2$*, and an i-$\mathbf{p}$-$\mathbf{q}$-distinguisher s' with* $\mathrm{height}(s') \leq 4|\mathbf{Q}|^2$ *such that for the runs $\mathbf{r}'_\mathbf{p} \in \mathrm{Run}^{\diamond}_{\boldsymbol{\mathcal{U}}}(\mathbf{p}, s', \mathbf{p})$ and $\mathbf{r}'_\mathbf{q} \in \mathrm{Run}^{\diamond}_{\boldsymbol{\mathcal{U}}}(\mathbf{q}, s', \mathbf{q})$, $(s', \mathbf{r}'_\mathbf{p})$ is a truncation of $(s, \mathbf{r_p})$ and $(s', \mathbf{r}'_\mathbf{q})$ is a truncation of $(s, \mathbf{r_q})$. In particular, for every two states $\mathbf{p}, \mathbf{q} \in \mathbf{Q}$, it is decidable whether $\mathbf{p}$ and $\mathbf{q}$ are rivals.*

3.1 Decidability

In order to show that it is decidable whether $\boldsymbol{\mathcal{U}}$ is broken, we construct a covering $\bar{\mathcal{U}}$ of $\boldsymbol{\mathcal{U}}$ with the capability to detect the broken coordinates of a run of $\boldsymbol{\mathcal{U}}$. The covering $\bar{\mathcal{U}}$ possesses the same behavior as $\boldsymbol{\mathcal{U}}$ and each run of $\bar{\mathcal{U}}$ corresponds to exactly one run of $\boldsymbol{\mathcal{U}}$. We construct $\bar{\mathcal{U}}$ by adding to each state of $\mathbf{Q}$ one entry containing all states reachable on the current subtree, one entry containing all states visited on the current run, one entry containing all pairs $(\mathbf{p}, \mathbf{q})$ of states such that $\mathbf{q}$ is reachable by a run which visited $\mathbf{p}$ at a position where our current run also visited $\mathbf{p}$, and one entry containing a record of all broken coordinates. This allows us to infer the brokenness of a run directly from the state at its root. More precisely, we construct $\bar{\mathcal{U}} = (\bar{Q}, \Gamma, \bar{\mu}, \bar{\nu})$ with states from $\bar{Q} = \mathbf{Q} \times \mathcal{P}(\mathbf{Q}) \times \mathcal{P}(\mathbf{Q}) \times \mathcal{P}(\mathbf{Q}^2) \times \{0,1\}^M$ such that if $t \in T_\Gamma$, $\bar{r} \in \mathrm{Run}_{\bar{\mathcal{U}}}(t)$, $w \in \mathrm{pos}(t)$, and $\bar{r}(w) = (\mathbf{q}, P, V, W, \bar{a})$, then the following statements hold. We have (1) the projection $\pi_\mathbf{Q}\colon \bar{Q} \to \mathbf{Q}$ to the first coordinate induces a bijection $\pi_\mathbf{Q}\colon \mathrm{Acc}_{\bar{\mathcal{U}}}(t) \to \mathrm{Acc}_{\boldsymbol{\mathcal{U}}}(t)$ preserving weights of runs, (2) $P = \{\mathbf{p} \in \mathbf{Q} \mid \mathrm{Run}_{\boldsymbol{\mathcal{U}}}(t{\restriction}_w, \mathbf{p}) \neq \emptyset\}$, (3) $V = \{\pi_\mathbf{Q} \circ \bar{r}(wv) \mid v \in \mathrm{pos}(t{\restriction}_w)\}$, (4) $W = \{(\mathbf{p}_1, \mathbf{p}_2) \in \mathbf{Q}^2 \mid \text{for some } v \in \mathrm{pos}(t{\restriction}_w) \text{ we have } \pi_\mathbf{Q} \circ \bar{r}(wv) = \mathbf{p}_1 \text{ and } \mathrm{Run}^{\diamond}_{\boldsymbol{\mathcal{U}}}(\mathbf{p}_1, t\langle \diamond \to wv \rangle{\restriction}_w, \mathbf{p}_2) \neq \emptyset\}$, and (5) $\bar{a}[i] = 1$ if and only if $(t, \pi_\mathbf{Q} \circ \bar{r}){\restriction}_w$ is i-broken.

We let $d_1, \ldots, d_D$ be an enumeration of $\Delta_{\bar{\mathcal{U}}}$ and for a tree $t \in T_\Gamma$ and a run $\bar{r} \in \mathrm{Run}_{\bar{\mathcal{U}}}(t)$, define the *transition Parikh vector* of $(t, \bar{r})$ by $\mathbb{p}(t, \bar{r}) = (|\{w \in \mathrm{pos}(t) \mid \mathbb{t}(t, \bar{r}, w) = d_1\}|, \ldots, |\{w \in \mathrm{pos}(t) \mid \mathbb{t}(t, \bar{r}, w) = d_D\}|)$, i.e., we count the number of occurrences of each transition in $(t, \bar{r})$. We can employ Parikh's Theorem [31, 15] to show that the set $\mathbb{p}(\bar{\mathcal{U}}) = \{\mathbb{p}(t, r) \mid t \in T_\Gamma, r \in \mathrm{Acc}_{\bar{\mathcal{U}}}(t)\}$ is *semilinear*, i.e., that there exist integers $k, k_1, \ldots, k_k$, vectors $\alpha^{(l)} \in \mathbb{N}^D$, and matrices $\beta^{(l)} \in \mathbb{N}^{D \times k_l}$ $(l \in \{1, \ldots, k\})$ with $\mathbb{p}(\bar{\mathcal{U}}) = \bigcup_{l=1}^{k} \{\alpha^{(l)} + \beta^{(l)} \bar{X} \mid \bar{X} = (X_1, \ldots, X_{k_l}) \in \mathbb{N}^{k_l}\}$. We note that Parikh's Theorem is effective, so we can effectively compute all of these integers, vectors, and matrices.

Next, we let $\Omega = (\bar{\mu}(d_1), \ldots, \bar{\mu}(d_D)) \in \mathbb{Q}^{M \times D}$ be a matrix containing the transition weight vectors of $d_1, \ldots, d_D$, let $\omega_1, \ldots, \omega_M$ be the rows of Ω, and let $\tilde{C} = 1 + \max\{|\omega_i \alpha^{(l)} - \omega_j \alpha^{(l)}| \mid i, j \in \{1, \ldots, M\}, l \in \{1, \ldots, k\}\}$. For $I \subseteq \{1, \ldots, M\}$, we let $D_I = \{l \in \{1, \ldots, D\} \mid d_l =$

$(\bar{q}_1, \dots, \bar{q}_m, \bar{a}, (\mathbf{q}, P, V, W, \bar{a})) \in \Delta_{\bar{\mathcal{U}}}$ such that $\bar{a}[i] = 1 \leftrightarrow i \in I\}$ be the set of all indices of transitions whose root state indicates brokenness of exactly the coordinates in I. Furthermore, for every $l \in \{1, \dots, D\}$ we let $\alpha^{(l)}[1], \dots, \alpha^{(l)}[D]$ be the entries of $\alpha^{(l)}$ and $\beta^{(l)}[1], \dots, \beta^{(l)}[D]$ be the rows of $\beta^{(l)}$. It is then elementary to show that every set $I \subseteq \{1, \dots, M\}$ is separable iff it is $\tilde{C}$-separable iff for some $l \in \{1, \dots, M\}$, the system of linear inequalities below possesses an integer solution. The satisfiability of systems of linear inequalities over the rationals with integer solutions is decidable [30][9, Theorem 3.4]. There are only finitely many such systems to consider, so it is decidable whether I is separable. To decide whether $\boldsymbol{\mathcal{U}}$ is broken, it suffices to check whether there exists a separable subset $I \subseteq \{1, \dots, M\}$.

$$(\omega_i \beta^{(l)} - \omega_j \beta^{(l)})\bar{X} \geq \omega_j \alpha^{(l)} - \omega_i \alpha^{(l)} + \tilde{C} \qquad \bar{X} \geq 0 \qquad (i \in I, j \in I^c)$$

$$\sum_{d \in D_I} \beta^{(l)}[d]\bar{X} \geq 1 - \sum_{d \in D_I} \alpha^{(l)}[d] \qquad - \sum_{I \subsetneq I' \subseteq M} \sum_{d \in D_{I'}} \beta^{(l)}[d]\bar{X} \geq \sum_{I \subsetneq I' \subseteq M} \sum_{d \in D_{I'}} \alpha^{(l)}[d]$$

3.2 Necessity

To show that $[\![\mathcal{A}]\!]$ is not finitely sequential if $\boldsymbol{\mathcal{U}}$ is broken, we assume that $[\![\mathcal{A}]\!]$ can be represented as a finite maximum of deterministic max-plus-WTA $\mathcal{A}_1, \dots, \mathcal{A}_N$ and employ Ramsey's Theorem [37] to obtain a contradiction. Although not stated explicitly, Bala's proof for words [3] most likely also involves some form of Ramsey's Theorem as his proof of $\mathcal{U}$ being broken implying $[\![\mathcal{A}]\!]$ to not be finitely sequential "deals with colorings of finite hypercubes". In our proof for tree automata, we are able to handle fork-brokenness without employing Ramsey's Theorem. This suggest that applying our approach to word automata yields a proof which is simpler than the corresponding one used in [3]. The reason for this is that our separation property considers sets of coordinates instead of the single coordinates which the A-Fork property considers. For the separable sets $I \in \mathcal{I}$ which are minimal with respect to set inclusion, we are able to prove a statement for I-C-separated pairs $(t, \mathbf{r})$ which greatly facilitates dealing with fork-brokenness and enables us to deal with split-brokenness in the first place. Namely, if $(t, \mathbf{r})$ is I-C-separated for a sufficiently large C and no subset of I is separable, then for every $\mathbf{p} \in \mathbf{r}(\mathrm{pos}(t))$, every Γ-word s with $\mathrm{height}(s) \leq 4|\mathbf{Q}|^2$ and $\mathrm{Run}^{\diamond}_{\boldsymbol{\mathcal{U}}}(\mathbf{p}, s, \mathbf{p}) \neq \emptyset$, and every two coordinates $i, j \in I$ we have $\mathbf{wt}^{\diamond}_i(\mathbf{p}, s, \mathbf{p}) = \mathbf{wt}^{\diamond}_j(\mathbf{p}, s, \mathbf{p})$.

For the proof, we choose a sufficiently large C, a set $I \in \mathcal{I}$ which is minimal with respect to set inclusion, and an I-C-separated pair $(t, \mathbf{r})$. Then we construct from $(t, \mathbf{r})$ new trees which require more than N deterministic max-plus-WTA in order to be assigned the correct weight. If $(t, \mathbf{r})$ is fork-broken, we construct trees and runs of $\boldsymbol{\mathcal{U}}$ with increasingly more alterations of forks and distinguishers. This approach is similar to the method used in [4] and [34] to deal with fork-brokenness. The challenge we face in adapting the proof from [34] to our situation is that we have to ensure that in the runs we construct, the coordinates from I dominate the other coordinates. In our constructions we may therefore only make "small" modifications to $(t, \mathbf{r})$. Our solution relies on the minimality of I and involves constructing more than the $N + 1$ trees sufficient for the proofs in [4, 34]. The case where $(t, \mathbf{r})$ is split-broken is much more complicated and is in fact the only reason we have to use the covering automaton $\boldsymbol{\mathcal{U}}$ instead of $\mathcal{U}$. As split-brokenness does not apply to words, this was not an issue in [3]. Our approach vastly extends the idea used to deal with split-brokenness in [34]. In [34], we relied on replacing the subtrees below the prefix-independent rivals of a split-broken run by other suitable trees. However, Example 5 shows that this is not possible in our scenario as these subtrees may be indispensable to ensure that broken coordinates dominate all non-broken coordinates. Here, we instead modify the subtrees present and construct trees and runs of $\mathcal{U}$. For this, we employ the properties of $\boldsymbol{\mathcal{U}}$, pumping techniques, and Ramsey's Theorem.

3.3 Sufficiency

To show that $[\![\mathcal{A}]\!]$ is finitely sequential if $\boldsymbol{\mathcal{U}}$ is not broken, we show that in this case we can construct M unambiguous max-plus-WTA which all do not satisfy the tree fork property and whose pointwise maximum is equivalent to $[\![\mathcal{A}]\!]$. By Theorem 2, we obtain a finitely sequential representation of $\mathcal{A}$ by constructing one for each of the unambiguous max-plus-WTA. We essentially construct the unambiguous automata by removing problematic runs from $\boldsymbol{\mathcal{U}}$ and then projecting to the coordinates $1, \ldots, M$. Our fundamental idea is the following. First, let ξ be the smallest difference between the weights of two coordinates of a loop in a Γ-word of height at most $4|\mathbf{Q}|^2$, i.e., for $X = \{|\mathbf{wt}^{\diamond}_i(\mathbf{p}, s, \mathbf{p}) - \mathbf{wt}^{\diamond}_j(\mathbf{q}, s, \mathbf{q})| \mid \mathbf{p}, \mathbf{q} \in \mathbf{Q}, i, j \in \{1, \ldots, M\}, s$ is a Γ-word with $\mathrm{height}(s) \leq 4|\mathbf{Q}|^2, \mathrm{Run}^{\diamond}_{\boldsymbol{\mathcal{U}}}(\mathbf{p}, s, \mathbf{p}) \neq \emptyset, \mathrm{Run}^{\diamond}_{\boldsymbol{\mathcal{U}}}(\mathbf{q}, s, \mathbf{q}) \neq \emptyset\}$, let $\xi = \min X \setminus \{0\}$. Then assume that $(t, \mathbf{r})$ is i-**p**-**q**-broken and that the maximum of $\mathrm{wt}_{\boldsymbol{\mathcal{U}}}(t, \mathbf{r})$ is in coordinate i. Furthermore, assume that in $\mathbf{r}$, some i-**p**-**q**-distinguisher s of height at most $4|\mathbf{Q}|^2$ loops N times in $\mathbf{p}$, where $N \in \mathbb{N}$ is some integer, and that $\mathbf{wt}_i(\mathbf{p}, s, \mathbf{p}) < \mathbf{wt}_i(\mathbf{q}, s, \mathbf{q})$. By removing the loops of s in $\mathbf{p}$ from $(t, \mathbf{r})$ and inserting them back as loops in $\mathbf{q}$, we increase the weight of coordinate i by $N\xi$, but leave the weights of all non-broken coordinates unchanged. Thus, coordinate i then dominates all non-broken coordinates by a margin of at least $N\xi$. As i cannot dominate all non-broken coordinates by an arbitrarily large margin, N cannot be arbitrarily large. In turn, this means that if N is sufficiently large, then $\mathrm{wt}_{\boldsymbol{\mathcal{U}}}(t, \mathbf{r})$ cannot take its maximum weight in coordinate i. This implies that the weight of coordinate i can be discarded if some distinguisher loops in both of its rivals too many times.

We employ this idea in the following way. We define the set $R = \{(i, \mathbf{p}, \mathbf{q}, s) \in \{1, \ldots, M\} \times \mathbf{Q}^2 \times T_{\Gamma_\diamond} \mid i \in \{1, \ldots, M\}$, s is an i-**p**-**q**-distinguisher, $\mathrm{height}(s) \leq 4|\mathbf{Q}|^2\}$ and define the constant $N = \lceil M\tilde{C}\xi^{-1} \rceil$, where $\tilde{C}$ is as in Section 3.1. We note that R is computable, as by Lemma 10, we can decide for every two states $\mathbf{p}, \mathbf{q} \in \mathbf{Q}$ whether they are rivals or not. Let $t \in T_\Gamma$, $\mathbf{r} \in \mathrm{Run}_{\boldsymbol{\mathcal{U}}}(t)$, $(i, \mathbf{p}, \mathbf{q}, s) \in R$, $\mathbf{r_p} \in \mathrm{Run}^{\diamond}_{\boldsymbol{\mathcal{U}}}(\mathbf{p}, s, \mathbf{p})$, and $\mathbf{r_q} \in \mathrm{Run}^{\diamond}_{\boldsymbol{\mathcal{U}}}(\mathbf{q}, s, \mathbf{q})$. We call $(t, \mathbf{r})$

- $(i, \mathbf{p}, \mathbf{q}, s)$*-fork-broken* if there exist positions $u_\mathbf{p}, v_\mathbf{p}, w_\mathbf{p}, w_\mathbf{q}, u_\mathbf{q}, v_\mathbf{q} \in \mathrm{pos}(t)$ with $v_\mathbf{q} <_{\mathrm{P}} u_\mathbf{q} \leq_{\mathrm{P}} w_\mathbf{q} <_{\mathrm{P}} w_\mathbf{p} \leq_{\mathrm{P}} v_\mathbf{p} <_{\mathrm{P}} u_\mathbf{p}$ such that $(t, \mathbf{r})\langle \diamond \to u_\mathbf{p} \rangle\!\upharpoonleft_{v_\mathbf{p}} \text{✂} (s, \mathbf{r_p})^{N+1}$, $(t, \mathbf{r})\langle \diamond \to u_\mathbf{q} \rangle\!\upharpoonleft_{v_\mathbf{q}} \text{✂} (s, \mathbf{r_q})^{N+1}$, $\mathbf{r}(w_\mathbf{p}) = \mathbf{p}$, $\mathbf{r}(w_\mathbf{q}) = \mathbf{q}$, and $t\langle \diamond \to w_\mathbf{p} \rangle\!\upharpoonleft_{w_\mathbf{q}}$ is a **p**-**q**-fork.
- $(i, \mathbf{p}, \mathbf{q}, s)$*-split-broken* if there exist positions $u_\mathbf{p}, v_\mathbf{p}, u_\mathbf{q}, v_\mathbf{q} \in \mathrm{pos}(t)$ such that $v_\mathbf{p} <_{\mathrm{P}} u_\mathbf{p}$, $v_\mathbf{q} <_{\mathrm{P}} u_\mathbf{q}$, $v_\mathbf{p}$ and $v_\mathbf{q}$ are prefix-independent, $(t, \mathbf{r})\langle \diamond \to u_\mathbf{p} \rangle\!\upharpoonleft_{v_\mathbf{p}} \text{✂} (s, \mathbf{r_p})^{N+1}$, and $(t, \mathbf{r})\langle \diamond \to u_\mathbf{q} \rangle\!\upharpoonleft_{v_\mathbf{q}} \text{✂} (s, \mathbf{r_q})^{N+1}$.

Following the idea above, we can show that if $(t, \mathbf{r})$ is $(i, \mathbf{p}, \mathbf{q}, s)$-broken, then $\mathbf{wt}_i(t, \mathbf{r}) < [\![\mathcal{A}]\!](t)$. Furthermore, we can show that for every $i \in \{1, \ldots, M\}$, we can construct a complete and deterministic FTA $\mathcal{B}_i$ over the alphabet $\Gamma \times \mathbf{Q}$ which accepts a tree $(t, \mathbf{r}) \in T_{\Gamma \times \mathbf{Q}}$ if and only if there does not exist $(i, \mathbf{p}, \mathbf{q}, s) \in R$ such that $(t, \mathbf{r})$ is $(i, \mathbf{p}, \mathbf{q}, s)$-broken. Via a product-like construction, we can employ $\mathcal{B}_i$ to construct a WTA $\mathcal{C}_i$ which "filters" the runs of $\boldsymbol{\mathcal{U}}$ so that the runs of $\mathcal{C}_i$ correspond exactly to those runs of $\boldsymbol{\mathcal{U}}$ which are not $(i, \mathbf{p}, \mathbf{q}, s)$-broken for any $(i, \mathbf{p}, \mathbf{q}, s) \in R$. Then $\mathcal{C}_i$ is not i-broken as otherwise, we can construct an accepting run r of $\mathcal{C}_i$ on a tree t whose projection to $\mathbf{Q}$ yields an i-broken pair $(t, \mathbf{r})$ which loops an i-**p**-**q**-distinguisher s for $N + 1$ times in both $\mathbf{p}$ and $\mathbf{q}$. As by Lemma 10, s can be truncated to a distinguisher of height at most $4|\mathbf{Q}|^2$, $(t, \mathbf{r})$ is thus $(i, \mathbf{p}, \mathbf{q}, s)$-broken. We obtain the contradiction that r is not accepting. Consequently, projecting the weights of each automaton $\mathcal{C}_i$ to the i-th coordinate yields M unambiguous max-plus-WTA whose pointwise-maximum coincides with $[\![\mathcal{A}]\!]$ and which all do not satisfy the tree fork property.

Abstract

The Skolem problem and the related Positivity problem for linear recurrence sequences are outstanding number-theoretic problems whose decidability has been open for many decades. In this paper, the inherent mathematical difficulty of a series of optimization problems on Markov decision processes (MDPs) is shown by a reduction from the Positivity problem to the associated decision problems which establishes that the problems are also at least as hard as the Skolem problem as an immediate consequence. The optimization problems under consideration are two non-classical variants of the stochastic shortest path problem (SSPP) in terms of expected partial or conditional accumulated weights, the optimization of the conditional value-at-risk for accumulated weights, and two problems addressing the long-run satisfaction of path properties, namely the optimization of long-run probabilities of regular co-safety properties and the model-checking problem of the logic frequency-LTL. To prove the Positivity- and hence Skolem-hardness for the latter two problems, a new auxiliary path measure, called weighted long-run frequency, is introduced and the Positivity-hardness of the corresponding decision problem is shown as an intermediate step. For the partial and conditional SSPP on MDPs with non-negative weights and for the optimization of long-run probabilities of constrained reachability properties ($a \,\mathrm{U}\, b$), solutions are known that rely on the identification of a bound on the accumulated weight or the number of consecutive visits to certain sates, called a saturation point, from which on optimal schedulers behave memorylessly. In this paper, it is shown that also the optimization of the conditional value-at-risk for the classical SSPP and of weighted long-run frequencies on MDPs with non-negative weights can be solved in pseudo-polynomial time exploiting the existence of a saturation point. As a consequence, one obtains the decidability of the qualitative model-checking problem of a frequency-LTL formula that is not included in the fragments with known solutions.

1 Introduction

Markov decision processes (MDPs) (see, e.g., [40]) constitute one of the most prominent classes of operational models combining randomization and non-determinism and are widely used in verification, articifical intelligence, robotics and operations research. Consequently, a vast landscape of optimization problems on MDPs has been studied. The task usually is to find a strategy resolving the non-deterministic choices, called a *scheduler*, such that a certain objective quantity is optimized or to decide whether the optimal value exceeds a given rational threshold (*threshold problem*).

Stochastic shortest path problems (SSPPs) are one important type of such optimization problems on MDPs equipped with weights. These problems ask for a scheduler maximizing or minimizing the expected accumulated weight before reaching a designated goal state. In the classical setting, only schedulers reaching the goal almost surely are taken into consideration. This *classical SSPP* is known to be solvable in polynomial time using graph-based algorithms and linear-programming techniques [10, 20, 3]. For various purposes, the requirement that the goal has to be reached almost surely, however, is not appropriate. This applies, e.g., to work on the semantics of probabilistic programs when no guarantee on almost sure termination can be given [25, 30, 9, 15, 36], to the analysis of the behavior of fault-tolerant systems in error scenarios which occur with low probability, or to the trade-off analysis when combinations of utility and cost constraints can be achieved with positive probability, but not almost surely (see, e.g., [5]). This motivates a switch to non-classical variants of the SSPP: The *conditional SSPP* [8] asks for a scheduler optimizing the conditional expected accumulated weight before reaching the goal under the condition that the goal will indeed be reached and the *partial SSPP* [16, 38] assigns weight 0 to all executions not reaching the goal. Both variants increase the algorithmic difficulties. In the special case of MDPs with non-negative weights, exponential-time algorithms for the partial and conditional SSPP exploit the monotonicity of accumulated weights and rely on the existence of a *saturation point* (a bound for the accumulated weight) from which on optimal schedulers behave memorylessly. Apart from a PSPACE lower bound and approximation algorithms [38], no algorithms are known for solving the partial or conditional SSPP in integer-weighted MDPs.

Conditional expectations also play a crucial role in risk management: The *conditional value-at-risk* is an established risk measure quanitfying the expected loss in bad cases [45, 1]. Given a probability value p, the *value-at-risk* of a random variable X is defined as the worst p-quantile. Quantile queries on the distribution of path lengths have been studied in [44]. The conditional value-at-risk is the expectation of X under the condition that the outcome is worse than the value-at-risk. For MDPs, the conditional value-at-risk has been studied for mean-payoffs and for weighted reachability where on each run only once a terminal weight is collected when a target state is reached [31]. In this paper, we consider the conditional value-at-risk for the more general accumulated weight before reaching the goal, i.e. for the classical SSPP. To the best of our knowledge, this problem has not been studied.

Other typical optimization problems arise in the context of verification, asking for worst-case schedulers that minimize or maximize the probability of a given path property. While such problems are well-understood, e.g., for properties given by linear temporal logic (LTL)-formulas or non-deterministic Büchi-automata [19], there has been increasing interest in ways to quantify the degree to which a property is satisfied not only by the probability (see [28]). Approaches in this direction include the work on robust satisfaction of temporal specifications [32, 43], coverage semantics [17], robustness distances [13], and the more general model-measurement semantics [29] among others. Furthermore, this has lead to different notions quantifying to which degree a property is satisfied in the long-run: *Frequency-LTL* has been introduced in [23, 24] as an extension of LTL by a frequency modality that makes assertions on the portion of time (or relative frequency of positions in paths) where a given event holds. While [23, 24] presents model-checking algorithms for Markov chains and arbitrary frequency-LTL formulas, the presented model checking algorithms for MDPs are restricted to fragments of frequency-LTL. We address the model checking problem for frequency-LTL formulas not contained in these fragments. Further, the concept of *long-run probabilities* [4] has been introduced for reasoning about the probabilities of path properties when the system is in equilibrium and can, e.g., be useful to formalize refined notions of long-run availability. In [4], a pseudo-polynomial time algorithm that exploits the existence of a saturation point for the computation of optimal long-run probabilities of constrained reachability properties ($a \,\mathrm{U}\, b$) is provided. Here, we study long-run probabilities of general regular co-safety properties.

Contributions. The main contribution of the paper is to provide evidence for the mathematical difficulty of the series of decision problems described above in terms of a reduction from the *Positivity problem* of linear recurrence sequences. The Positivity problem is closely related to the *Skolem problem*, a prominent number-theoretic decision problem for linear recurrence sequences, and the decidability of both problems has been open for many decades (see, e.g., [27]). As it is well-known that the Skolem problem is reducible to the Positivity problem, the provided reductions establish that the investigated decision problems are also at least as hard as the Skolem problem. In the middle column of Table 1, these Skolem-hardness results are listed:

Table 1 Overview of the results.

optimization problem on MDPs	threshold problem Positivity- and hence Skolem-hard for	exponential-time algorithm using a saturation point for
partial SSPP (1)	weights in $\mathbb{Z}$, *Thm. 3*	weights in $\mathbb{N}$ [16] (PSPACE-hard, *Prop. 15*)
conditional SSPP (2)	weights in $\mathbb{Z}$, *Thm. 5*	weights in $\mathbb{N}$ [8] (PSPACE-hard [8])
conditional value-at-risk for the classical SSPP (3)	weights in $\mathbb{Z}$, *Thm. 6*	weights in $\mathbb{N}$, *Thm. 12*
long-run probability (4)	regular co-safety properties, *Thm. 9*	constrained reachability $a \,\mathrm{U}\, b$ [4] (NP-hard [4])
model checking of frequency-LTL (5)	$\Pr^{\max}_{\mathcal{M}}(G^{>\vartheta}_{\inf}(\varphi)) = 1?$ for an LTL-formula φ, *Thm. 11*	$\Pr^{\max}_{\mathcal{M}}(G^{>\vartheta}_{\inf}(a \,\mathrm{U}\, b)) = 1?$ *Cor. 14*

To obtain these results, we construct an MDP-gadget in which a linear recurrence relation can be encoded. Together with different gadgets encoding initial values of a linear recurrence sequence, we use this gadget to establish Positivity-hardness for problems (1)-(3). Afterwards, we introduce a notion of *weighted long-run frequency* for constrained reachability properties that can be seen as a generalization of classical limit-average weights and serves here as a technical vehicle to provide a connective link to long-run probabilities and the model-checking problem of frequency-LTL. The Positivity-hardness for problems (4) and (5) is obtained via the Positivity-hardness of the threshold problem for weighted long-run frequencies by showing how to encode integer weights in terms of the satisfaction of a fixed co-safety property. The

Positivity-hardness of (4) and (5) is somehow surprising: The non-probabilistic variant (4) is shown to be decidable in [4], while our results show that Positivity-hardness of (4) holds even for a simple fixed co-safety property given by a very small counter-free non-deterministic finite automaton. Likewise, Positivity-hardness of (5) is established already for the restriction to the almost-sure satisfaction problem of a simple fixed frequency-LTL formula.

For special cases of some of the problems studied here it is known that optimal values can be computed in exponential time exploiting a saturation point. We extend this picture by showing analogous results for problems (3) and (5) (see Table 1). In particular, we provide a simple exponential time algorithm for the computation of the optimal conditional value-at-risk for the classical SSPP. Further, we pinpoint where the Positivity-hardness of the model checking problem of frequency-LTL arises: We observe that the techniques of [4] allow to solve the qualitative model-checking problem for a frequency-LTL formula with only one constrained reachability ($a\,\mathrm{U}\,b$) property under a frequency-globally modality. Our Positivity-hardness result for model checking frequency-LTL uses an only slightly more complicated fixed formula where a Boolean combination of atomic propositions and constrained reachability properties occurs in the scope of the frequency-globally modality. In particular, the Positivity-hardness does not require deeper nesting of temporal operators.

Related work. Besides the above cited work that presents algorithms for special cases of the investigated problems, closest to our work is [2] where Skolem-hardness for decision problems for Markov chains have been established. The problems are to decide whether for given states s, t and rational number p, there is a positive integer n such that the probability to reach t from s in n steps equals p and the model checking problem for a probabilistic variant of monadic logic and a variant of LTL that treats Markov chains as linear transformers of probability distributions. These decision problems are of quite different nature than the problems studied here, and so are the reductions from the Skolem problem. In this context also the results of [18] and [34] are remarkable as they show the decidability (subject to Schanuel's conjecture) of reachability problems in continuous linear dynamical systems and continuous-time MDPs, respectively, as instances of the continuous Skolem problem.

A class of problems related to SSPPs concerns the optimization of probabilities for weight-bounded reachability properties and also exhibits increasing algorithmic difficulty (for an overview see [41]): For non-negative weights, schedulers optimizing the probability for reaching a target while the accumulated weight stays below a given bound are computable in pseudo-polynomial time and the corresponding probability-threshold problem is in P for qualitative probability thresholds (">0" or "$=1$") and PSPACE-hard in the general case [44, 26]. For integer weights even in finite-state Markov chains, the probabilities for a weight-bounded reachability property can be irrational. Still, decidability for analogous problems for integer-weighted MDPs have been established for certain cases. Examples are pseudo-polynomial algorithms for qualitative threshold problems in integer-weighted MDPs [14, 12, 35, 3] or an exponential-time algorithm and a PSPACE lower bound for the almost-sure termination problem in one-counter MDPs [11].

Switching to more expressive models typically leads to the undecidability of infinite-horizon verification problems. This applies, e.g., to recursive MDPs [21], MDPs with two or more weight functions [7, 42] or partially observable MDPs [33, 6]. However, we are not aware of natural decision problems for standard (finite-state) MDPs with a single weight function and single objective that are known to be undecidable.

2 Preliminaries

We give basic definitions and present our notation (for more details see, e.g., [40]). We then formally define the quantitative objectives studied in this paper.

Notations for Markov decision processes. A *Markov decision process* (MDP) is a tuple $\mathcal{M} = (S, Act, P, s_{init}, wgt, \mathsf{AP}, L)$ where S is a finite set of states, Act a finite set of actions, $s_{init} \in S$ the initial state, $P\colon S \times Act \times S \to [0,1] \cap \mathbb{Q}$ is the transition probability function, $wgt\colon S \times Act \to \mathbb{Z}$ the weight function, AP a finite set of atomic propositions, and $L\colon S \to 2^{\mathsf{AP}}$ a labeling function. If not needed, we might drop the weight function or the labeling. We require that $\sum_{t\in S} P(s,\alpha,t) \in \{0,1\}$ for all $(s,\alpha) \in S \times Act$. We say that action α is enabled in state s iff $\sum_{t\in S} P(s,\alpha,t) = 1$. We assume that for all states s there is an enabled action and that all states are reachable from s_{init}. We call a state absorbing if there is only one enabled action, returning to the state with probability 1 and weight 0. The paths of $\mathcal{M}$ are finite or infinite sequences $s_0\,\alpha_0\,s_1\,\alpha_1 \dots$ where states and actions alternate such that $P(s_i, \alpha_i, s_{i+1}) > 0$ for all $i \geq 0$. For $\pi = s_0\,\alpha_0\,s_1\,\alpha_1\,\dots\alpha_{k-1}\,s_k$, $wgt(\pi) = wgt(s_0, \alpha_0) + \dots + wgt(s_{k-1}, \alpha_{k-1})$ denotes the accumulated weight of π, $P(\pi) = P(s_0, \alpha_0, s_1) \cdot \ldots \cdot P(s_{k-1}, \alpha_{k-1}, s_k)$ its probability, and $last(\pi) = s_k$ its last state. Further, we also write π to denote the word $L(s_0), L(s_1), \dots$. The *size* of $\mathcal{M}$ is the sum of the number of states plus the total sum of the logarithmic lengths of the non-zero probability values $P(s,\alpha,s')$ as fractions of co-prime integers and the weight values $wgt(s,\alpha)$. An end component of $\mathcal{M}$ is a strongly connected sub-MDP.

Scheduler. A *scheduler* for $\mathcal{M}$ is a function $\mathfrak{S}$ that assigns to each finite path π a probability distribution over $Act(last(\pi))$. If there is a finite set X of memory modes and a memory update function $U : S \times Act \times S \times X \to X$ such that the choice of $\mathfrak{S}$ only depends on the current state after a finite path and the memory mode obtained from updating the memory mode according to U in each step, we say that $\mathfrak{S}$ is a finite-memory scheduler. If the choice depends only on the current state, we say that $\mathfrak{S}$ is memoryless. A scheduler $\mathfrak{S}$ is called deterministic if $\mathfrak{S}(\pi)$ is a Dirac distribution for each path π. Given a scheduler $\mathfrak{S}$, $\zeta = s_0\,\alpha_0\,s_1\,\alpha_1 \dots$ is a $\mathfrak{S}$-path iff ζ is a path and $\mathfrak{S}(s_0\,\alpha_0 \dots \alpha_{k-1}\,s_k)(\alpha_k) > 0$ for all $k \geq 0$.

Probability measure. We write $\Pr^{\mathfrak{S}}_{\mathcal{M},s}$ or briefly $\Pr^{\mathfrak{S}}_{s}$ to denote the probability measure induced by $\mathfrak{S}$ and s. For details, see [40]. We will use LTL-like formulas to denote measurable sets of paths. Given a measurable set ψ of infinite paths, we define $\Pr^{\min}_{\mathcal{M},s}(\psi) = \inf_{\mathfrak{S}} \Pr^{\mathfrak{S}}_{\mathcal{M},s}(\psi)$ and $\Pr^{\max}_{\mathcal{M},s}(\psi) = \sup_{\mathfrak{S}} \Pr^{\mathfrak{S}}_{\mathcal{M},s}(\psi)$ where $\mathfrak{S}$ ranges over all schedulers for $\mathcal{M}$. For a random variable X defined on infinte paths in $\mathcal{M}$, we denote the expected value of X under the probability measure induced by a scheduler $\mathfrak{S}$ and state s by $\mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}(X)$. Furthermore, for a measurable set of paths ψ with positive probability, $\mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}(X|\psi)$ denotes the conditional expectation of X under ψ. If $s = s_{init}$, we sometimes drop the subscript s.

Partial and conditional SSPP. Let $\mathcal{M}$ be an MDP with an absorbing state *goal*. On infinite paths ζ, we define the random variable $\oplus goal(\zeta)$ to be $wgt(\zeta)$ if $\zeta \vDash \Diamond goal$, and to be 0 otherwise. The *partial expectation* $PE^{\mathfrak{S}}_{\mathcal{M},s}$ of a scheduler $\mathfrak{S}$ is defined as $\mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}(\oplus goal)$. The maximal partial expectation is $PE^{\max}_{\mathcal{M},s} = \sup_{\mathfrak{S}} PE^{\mathfrak{S}}_{\mathcal{M},s}$. The *conditional expectation* $CE^{\mathfrak{S}}_{\mathcal{M},s}$ is defined as the conditional expected value $\mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s}(\oplus goal|\Diamond goal)$ for all schedulers reaching *goal* with positive probability, and the maximal conditional expectations is $CE^{\max}_{\mathcal{M},s} = \sup_{\mathfrak{S}} CE^{\mathfrak{S}}_{\mathcal{M},s}$ where $\mathfrak{S}$ ranges over all schedulers $\mathfrak{S}$ with $\Pr^{\mathfrak{S}}_{\mathcal{M},s}(\Diamond goal) > 0$. The *partial SSPP* asks for the maximal partial expectations and the *conditional SSPP* for the maximal conditional expectation. These problems were first considered in [16] and [8]. For more details see [8, 38].

Conditional value-at-risk. Given an MDP $\mathcal{M}$ with a scheduler $\mathfrak{S}$, a random variable X defined on runs of the MDP with values in $\mathbb{R}$ and a value $p \in [0,1]$, we define the *value-at-risk* as $\mathit{VaR}^{\mathfrak{S}}_{p}(X) = \sup\{r \in \mathbb{R} | \Pr^{\mathfrak{S}}_{\mathcal{M}}(X \leq r) \leq p\}$. So, the value-at-risk is the point at which the cumulative distribution function of X reaches or exceeds p. Denote $\mathit{VaR}^{\mathfrak{S}}_{p}(X)$ by v. The *conditional value-at-risk* is now the expectation of X under the condition that the outcome belongs to the p worst outcomes. Following the treatment of random variables that are not continuous in general in [31], we define the conditional value-at-risk as follows:

$$\mathit{CVaR}^{\mathfrak{S}}_{p}(X) = 1/p(\Pr^{\mathfrak{S}}_{\mathcal{M}}(X < v) \cdot \mathbb{E}^{\mathfrak{S}}_{\mathcal{M}}(X | X < v) + (p - \Pr^{\mathfrak{S}}_{\mathcal{M}}(X < v)) \cdot v).$$

Outcomes of X which are less than v are treated differently to outcomes equal to v as it is possible that the outcome v has positive probability and we only want to account exactly for the p worst outcomes. Hence, we take only $p - \Pr^{\mathfrak{S}}_{\mathcal{M}}(X < v)$ of the outcomes which are exactly v into account as well.

Threshold problems for the conditional value-at-risk in weighted MDPs have been studied in [31] for two random variables: the mean-payoff and weighted reachability where a set of final states is equipped with terminal weights obtained when reaching these states while all other transitions have weight 0. In this paper, we will address the conditional value-at-risk for the accumulated weight before reaching *goal* in MDPs with an absorbing state *goal*: Define $\Diamond\!\!\!\!+\,\mathit{goal}(\zeta)$ to be $\mathit{wgt}(\zeta)$ if $\zeta \vDash \Diamond \mathit{goal}$ and leave it undefined otherwise. The optimization of the expectation of $\Diamond\!\!\!\!+\,\mathit{goal}$ is known as the *classical SSPP*. Note that the expectation of this random variable is only defined under schedulers reaching *goal* with probability 1.

Long-run probability. Let $\mathcal{M}$ be an MDP with states labeled by atomic propositions from AP. Let φ be a path property, i.e., a measurable set of paths. The *long-run probability* for φ of a path ζ under a scheduler $\mathfrak{S}$ is $\mathit{lrp}^{\mathfrak{S}}_{\varphi}(\zeta) = \liminf_{n\to\infty} \frac{1}{n+1} \cdot \sum_{i=0}^{n} \Pr^{\mathfrak{S}\uparrow\zeta[0\ldots i]}_{\mathcal{M},\zeta[i]}(\varphi)$. Here, $\zeta[0\ldots i]$ denotes the prefix from position 0 to i of ζ, $\zeta[i]$ denotes the state after i steps, and $\mathfrak{S}\uparrow\zeta[0\ldots i]$ denotes the residual scheduler defined by $\mathfrak{S}\uparrow\zeta[0\ldots i](\pi) = \mathfrak{S}(\zeta[0\ldots i] \circ \pi)$ for all finite paths π starting in $\zeta[i]$. The long-run probability of φ under scheduler $\mathfrak{S}$ is $\mathbb{LP}^{\mathfrak{S}}_{\mathcal{M}}(\varphi) = \mathbb{E}^{\mathfrak{S}}_{\mathcal{M}}(\mathit{lrp}^{\mathfrak{S}}_{\varphi})$. The maximal long-run probability for φ is $\mathbb{LP}^{\max}_{\mathcal{M}}(\varphi) = \sup_{\mathfrak{S}} \mathbb{E}^{\mathfrak{S}}_{\mathcal{M}}(\mathit{lrp}^{\mathfrak{S}}_{\varphi})$. This notion was introduced in [4]. In this paper, we are interested in two kinds of path properties: Constrained reachability, $a \, \mathrm{U} \, b$, where a and b are atomic propositions and the more general regular co-safety properties given by a finite non-deterministic automaton (NFA) $\mathcal{A}$ accepting "good" prefixes of a run. For a co-safety property given by an NFA $\mathcal{A}$, we also write $\mathbb{LP}^{\max}_{\mathcal{M}}(\mathcal{A})$.

3 Skolem-hardness

The *Skolem problem* and the closely related *Positivity problem* are outstanding problems in the fields of number theory and theoretical computer science (see, e.g., [27, 37]). Their decidability has been open for many decades. We call a problem to which the Skolem problem is reducible *Skolem-hard*. This is a hardness result in the sense that a decision procedure would imply a major breakthrough by settling the decidability of the Skolem problem and it shows that a problem possesses an inherent mathematical difficulty.

Skolem problem. Given a natural number $k \geq 2$, and rationals α_i and β_j with $1 \leq i \leq k$ and $0 \leq j \leq k-1$, let $(u_n)_{n\geq 0}$ be defined by the initial values $u_0 = \beta_0, \ldots, u_{k-1} = \beta_{k-1}$ and the linear recurrence relation $u_{n+k} = \alpha_1 u_{n+k-1} + \cdots + \alpha_k u_n$ for all $n \geq 0$. The Skolem problem is to decide whether there is an $n \in \mathbb{N}$ with $u_n = 0$.

A closely related problem is the *Positivity problem.* It asks whether $u_n \geq 0$ for all n. It is folklore that the Skolem problem is polynomial-time reducible to the positivity problem (see, e.g., [22]). We will use the Positivity problem for our reductions leading to the main result:

▶ **Main result** (Theorems 3, 5, 6, 9, 11). *The Positivity problem and hence the Skolem problem are polynomial-time reducible to the threshold problems for the partial and conditional SSPP, the conditional value-at-risk in the classical SSPP, and long-run probabilities of regular co-safety properties, as well as to the qualitative model checking problem of frequency-LTL.*

For this purpose, we will construct an MDP gadget depicted in Figure 1a that encodes a linear recurrence relation in terms of the optimal values of different quantitative objectives. For the different problems, we then provide gadgets encoding the initial values of a linear recurrence sequence. We can plug these gadgets together to obtain an MDP and a scheduler $\mathfrak{S}$ such that $\mathfrak{S}$ maximizes the respective objective iff the linear recurrence sequence has no negative member. By computing the optimal values under $\mathfrak{S}$ in the MDPs – which turn out to be rational – we provide reductions from the positivity problem to the respective threshold problems with strict inequality (see also Remark 4).

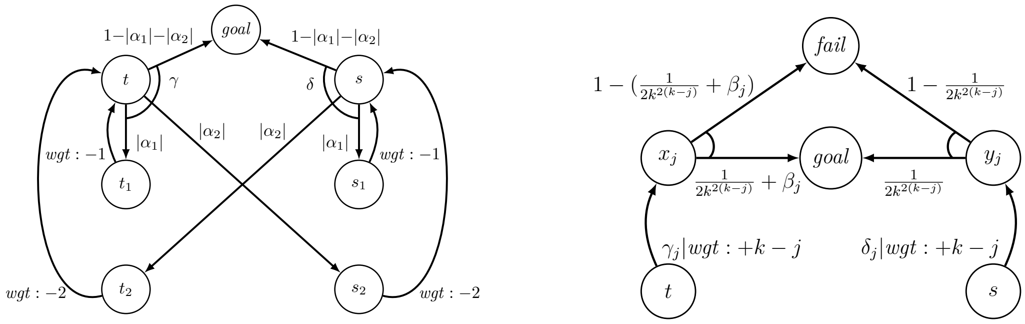
3.1 Partial and Conditional SSPP

Given a linear recurrence sequence, we construct an MDP in which the sequence is encoded in terms of optimal partial expectations. So let k be a natural number and let $(u_n)_{n\geq 0}$ be the linear recurrence sequence given by rationals α_i for $1 \leq i \leq k$ and β_j for $0 \leq j \leq k-1$ as above. As $u_{n+k} = \alpha_1 u_{n+k-1} + \cdots + \alpha_k u_n$ for all n, we see that for any positive $\lambda \in \mathbb{Q}$ the sequence $(v_n)_{n\geq 0}$ defined by $v_n = \lambda^{n+1} u_n$ satisfies $v_{n+k} = \lambda^1 \alpha_1 v_{n+k-1} + \cdots + \lambda^k \alpha_k v_n$ for all n. Furthermore, v_n is non-negative if and only if u_n is. W.l.o.g., we hence can assume that $\sum_i |\alpha_i| < \frac{1}{4}$ and that $0 \leq \beta_j < \frac{1}{4k^{2k+2}}$ for all j (for details, see the extended version [39]).

Now, we construct an MDP-gadget with an example depicted in Figure 1a. This gadget contains states *goal*, s, and t, as well as $s_1, \dots, s_k$ and $t_1, \dots, t_k$. In state t, an action γ is enabled which has weight 0 and leads to state t_i with probability α_i if $\alpha_i > 0$ and to state s_i with probability $|\alpha_i|$ if $\alpha_i < 0$ for all i. The remaining probability leads to *goal*. From each state t_i, there is an action leading to t with weight $-i$. The action δ enabled in s as well as the actions leading from states s_i to s are constructed in the same way. This gadget will be integrated into a larger MDP where there are no other outgoing edges from states $s_1, \dots, s_k, t_1, \dots, t_k$. Now, for each state q and each integer w, let $e(q, w)$ be the optimal partial expectation when starting in state q with accumulated weight w. Further, let $d(w) = e(t, w) - e(s, w)$. The simple proof of the following lemma can be found in [39] and uses that optimal partial expectations satisfy that $e(q, w) = \sum_r P(q, \alpha, r) e(r, w+wgt(q, \alpha))$ if an optimal scheduler chooses action α in state q when the accumulated weight is w.

▶ **Lemma 1.** *Let $w \in \mathbb{Z}$. If an optimal scheduler chooses action γ in t and δ in s if the accumulated weight is w, then $d(w) = \alpha_1 d(w-1) + \cdots + \alpha_k d(w-k)$.*

Now we construct a gadget that encodes the initial values $\beta_0, \dots, \beta_{k-1}$. The gadget is depicted in Figure 1b and contains states t, s, *goal*, and *fail*. For each $0 \leq j \leq k-1$, it additionally contains states x_j and y_j. In state x_j, there is one action enabled that leads to *goal* with probability $\frac{1}{2k^{2(k-j)}} + \beta_j$ and to *fail* otherwise. From state y_j, *goal* is reached with probability $\frac{1}{2k^{2(k-j)}}$ and *fail* otherwise. In state t, there is an action γ_j leading to x_j with weight $+k-j$ for each $0 \leq j \leq k-1$. Likewise, in state s there is an action δ_j leading to y_j with weight $k-j$ for each $0 \leq j \leq k-1$. We now glue together the two gadgets at states s, t, and *goal*. The cumbersome choices of probability values lead to the following lemma via straight-forward computations presented in [39].



(a) In the depicted example, the recurrence depth is 2, $\alpha_1 > 0$, and $\alpha_2 < 0$.

(b) The gadget contains the depicted states and actions for each $0 \le j \le k-1$.

Figure 1 The gadget (a) encoding the linear recurrence relation in all reductions and (b) encoding the intial values in the reduction to the partial SSPP.

▶ **Lemma 2.** *Let $0 \le j \le k-1$. Starting with weight $-(k-1)+j$ in state t or s, action γ_j and δ_j maximize the partial expectation. For positive starting weight, γ and δ are optimal.*

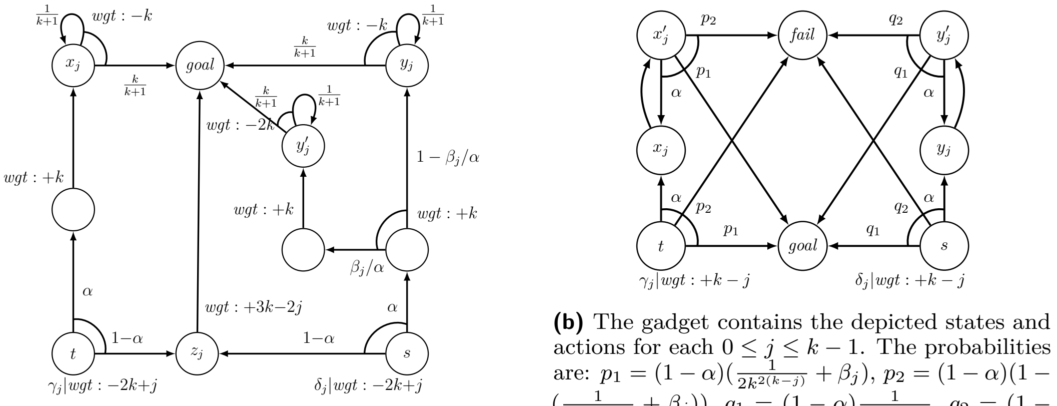
Comparing action γ_j and δ_j for starting weight $-(k-1)+j$, we conclude that the difference between optimal values $d(-(k-1)+j)$ is equal to β_j, for $0 \le j \le k-1$, and hence $d(-(k-1)+n) = u_n$ for all n. Finally, we equip the MDP with a simple initial gadget (see [39]): From the initial state s_{init}, one action with weight $+1$ is enabled. This action leads to a state c with probability $\frac{1}{2}$ and loops back to s_{init} with probability $\frac{1}{2}$. In c, the decision between action τ leading to state t and action σ leading to state s has to be made. So for any $n > 0$, state c is reached with accumulated weight n with positive probability. An optimal scheduler now has to decide whether the partial expectation when starting with weight n is better in state s or t: Action τ is optimal in c for accumulated weight w if and only if $d(w) \ge 0$. Further, the scheduler $\mathfrak{S}$ always choosing τ in c and actions $\gamma, \gamma_0, \dots, \gamma_{k-1}, \delta, \dots$ as described in Lemma 2 is optimal iff the given linear recurrence sequence is non-negative. We can compute the partial expectation of scheduler $\mathfrak{S}$ in the constructed MDP. The partial expectation turns out to be a rational. Hence, using this partial expectation as the threshold ϑ, we obtain the first main result. The technical proof computing the value of $\mathfrak{S}$ in the constructed MDP is given in the extended version [39].

▶ **Theorem 3.** *The Positivity problem is polynomial-time reducible to the following problem: Given an MDP $\mathcal{M}$ and a rational ϑ, decide whether $PE^{\max}_{\mathcal{M}} > \vartheta$.*

▶ **Remark 4.** There is no obvious way to adjust the construction such that the Skolem-hardness of the question whether $PE^{\max}_{\mathcal{M}} \ge \vartheta$ would follow. One attempt would be to provide an ε such that $PE^{\max}_{\mathcal{M}} > \vartheta$ iff $PE^{\max}_{\mathcal{M}} \ge \vartheta + \varepsilon$. This, however, probably requires a bound on the position at which the given linear recurrence sequence first becomes negative. But this question lies at the core of the positivity and the Skolem problem. All Skolem-hardness results in this paper hence concern only threshold problems with strict inequality.

The Skolem-hardness of the threshold problem for the conditional SSPP is obtained by a simple reduction showing that the threshold problems of the partial SSPP is polynomial-time reducible to the threshold problem of the conditional SSPP (see [39]).

▶ **Theorem 5.** *The Positivity problem is reducible in polynomial time to the following problem: Given an MDP $\mathcal{M}$ and a rational ϑ, decide whether $CE^{\max}_{\mathcal{M}} > \vartheta$.*



(a) The gadget contains the depicted states and actions for each $0 \le j \le k-1$. $\alpha = \sum_{1=i}^{k} |\alpha_i|$.

(b) The gadget contains the depicted states and actions for each $0 \le j \le k-1$. The probabilities are: $p_1 = (1-\alpha)(\frac{1}{2k^{2(k-j)}} + \beta_j)$, $p_2 = (1-\alpha)(1-(\frac{1}{2k^{2(k-j)}} + \beta_j))$, $q_1 = (1-\alpha)\frac{1}{2k^{2(k-j)}}$, $q_2 = (1-\alpha)(1-\frac{1}{2k^{2(k-j)}})$. All actions except for γ_j and δ_j have weight 0.

Figure 2 The gadgets encoding initial values for (a) the conditional value-at-risk for the classical SSPP and (b) weighted long-run frequencies.

3.2 Conditional value-at-risk for the classical SSPP

We reuse the gadget depicted in Figure 1a to prove the following result:

▶ **Theorem 6.** *The Positivity problem is polynomial-time reducible to the following problem: Given an MDP $\mathcal{M}$ and rationals ϑ and $p \in (0,1)$, decide whether $CVaR_p^{\max}(\diamondplus goal) > \vartheta$.*

We begin by the following consideration: Given an MDP $\mathcal{M}$ with initial state s_{init}, we construct a new MDP $\mathcal{N}$. We add a new initial state s'_{init}. In s'_{init}, there is only one action with weight 0 enabled leading to s_{init} with probability $\frac{1}{3}$ and to $goal$ with probability $\frac{2}{3}$. So, at least two thirds of the paths accumulate weight 0 before reaching the goal. Hence, we can already say that $VaR^{\mathfrak{S}}_{1/2}(\diamondplus goal) = 0$ in $\mathcal{N}$ under any scheduler $\mathfrak{S}$. Note that schedulers for $\mathcal{M}$ can be seen as schedulers for $\mathcal{N}$ and vice versa. This considerably simplifies the computation of the conditional value-at-risk in $\mathcal{N}$. Define the random variable $\diamondminus goal(\zeta)$ to be $\diamondplus goal(\zeta)$ if $\diamondplus goal \le 0$ and to be 0 otherwise. Now, the conditional value-at-risk for the probability value 1/2 under a scheduler $\mathfrak{S}$ in $\mathcal{N}$ is given by $CVaR^{\mathfrak{S}}_{1/2}(\diamondplus goal) = 2 \cdot \mathbb{E}^{\mathfrak{S}}_{\mathcal{N},s_{init}}(\diamondminus goal) = \frac{2}{3} \cdot \mathbb{E}^{\mathfrak{S}}_{\mathcal{M},s_{init}}(\diamondminus goal)$. So, the result follows from the following lemma:

▶ **Lemma 7.** *The Positivity problem is polynomial-time reducible to the following problem: Given an MDP $\mathcal{M}$ and a rational ϑ, decide whether $\mathbb{E}^{\max}_{\mathcal{M},s_{init}}(\diamondminus goal) > \vartheta$.*

We adjust the MDP used for the Skolem-hardness proof for the partial SSPP. So, let k be a natural number, $\alpha_1, \dots, \alpha_k$ be rational coefficients of a linear recurrence sequence, and $\beta_0, \dots, \beta_{k-1} \ge 0$ the rational initial values. W.l.o.g. we again assume these values to be small, namely: $\sum_{1\le i\le k} |\alpha_i| \le \frac{1}{5(k+1)}$ and for all j, $\beta_j \le \frac{1}{3}\alpha$ where $\alpha = \sum_{1\le i\le k} |\alpha_i|$.

The first important observation is that the optimal expectation of $\diamondminus goal$ for different starting states and starting weights behaves very similar to optimal partial expectations: For each state q and each integer w, let $e(q,w)$ be the optimal expectation of $\diamondminus goal$ when starting in state q with accumulated weight w. If an optimal scheduler chooses α when in q with accumulated weight w, then $e(q,w) = \sum_{r\in S} P(q,\alpha,r) \cdot e(r, w{+}wgt(q,\alpha))$. Reusing the MDP-gadget depicted in 1a, we observe that if we again let $d(w) = e(t,w) - e(s,w)$, the following holds as before: For any $w \in \mathbb{Z}$, if an optimal scheduler chooses action γ in t and δ in s if the accumulated weight is w, then $d(w) = \alpha_1 d(w-1) + \dots + \alpha_k d(w-k)$.

Now, we construct a new gadget that encodes the initial values of a linear recurrence sequence. The new gadget is depicted in Figure 2a. Besides the actions γ_j and δ_j for $0 \leq j \leq k-1$ there are no non-deterministic choices. Again, we glue together the two gadgets in states s, t, and *goal*. The main idea is that for non-negative starting weights in state s or t actions γ_j and δ_j lead to a larger expected tail loss than actions γ and δ. For $0 \leq j \leq k{-}1$ and an accumulated weight $-k{+}j$ in state t or s, the actions γ_j and δ_j are, however, optimal for maximizing the expectation of ⟠*goal* sinve the goal is reached with non-negative weights with high probability under these actions (details in [39]). The difference of optimal values satisfies $e(t, -k+j) - e(s, -k+j) = \beta_j$ for $0 \leq j \leq k{-}1$ again. Finally, we add the same initial component as in the previous section and see that the scheduler $\mathfrak{S}$ always choosing τ in state c is optimal iff the linear recurrence sequence stays non-negative. As the expectation of ⟠*goal* under $\mathfrak{S}$ is again a rational (see [39]), this finishes the proof analogously to the previous section.

3.3 Long-run probability and frequency-LTL

In order to transfer the Skolem-hardness results to long-run probabilities and frequency-LTL, we introduce the auxiliary notion of *weighted long-run frequency*. Let $\mathcal{M}$ be an MDP with a weight function $\mathit{wgt} : S \times \mathit{Act} \to \mathbb{Z}$ and two disjoint sets of states $\mathit{Goal}, \mathit{Fail} \subseteq S$. On an infinite paths $\pi = s_0, \alpha_0, s_1, \dots$, we define the random variable wlf as follows:

$$\mathit{wlf}(\pi) = \liminf_{n \to \infty} \frac{1}{n+1} \sum\nolimits_{i=0}^{n} \mathit{wgt}(s_i, \alpha_i) \cdot \mathbb{1}_{\pi[i\dots] \models \neg \mathit{Fail} \,\mathrm{U}\, \mathit{Goal}}$$

where $\mathbb{1}_{\pi[i\dots] \models \neg \mathit{Fail} \,\mathrm{U}\, \mathit{Goal}}$ is 1 if the suffix $\pi[i\dots] = s_i, \alpha_i, s_{i+1}, \dots$ satisfies $\neg \mathit{Fail} \,\mathrm{U}\, \mathit{Goal}$, and 0 otherwise. Given a scheduler $\mathfrak{S}$, we define the weighted long-run frequency $\mathit{WLF}^{\mathfrak{S}}_{\mathcal{M}} = \mathbb{E}^{\mathfrak{S}}_{\mathcal{M}}(\mathit{wlf})$ and $\mathit{WLF}^{\max}_{\mathcal{M}} = \sup_{\mathfrak{S}} \mathit{WLF}^{\mathfrak{S}}_{\mathcal{M}}$. This can be seen as a long-run average version of partial expectations. Weights are only received if afterwards *Goal* is visited before *Fail* and we measure the average weight received per step according to this rule. Note that we only consider the path property $\neg \mathit{Fail} \,\mathrm{U}\, \mathit{Goal}$ in this paper and hence do not include this property in our notation and terminology. An illustrating example can be found in [39].

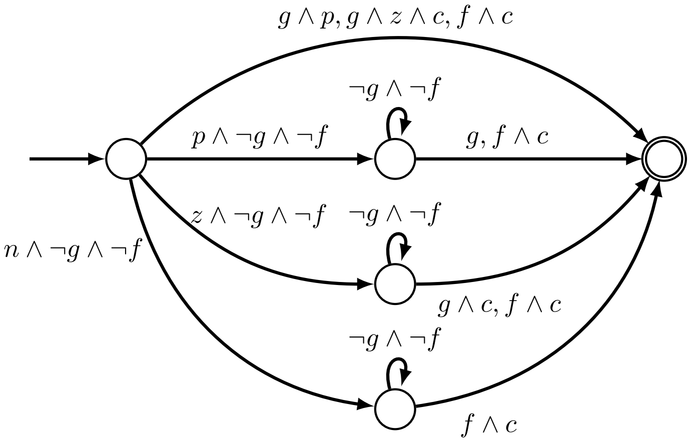
We modifiy the MDP that was constructed in Section 3.1 for the Skolem-hardness of the partial SSPP. We replace the gadget encoding the initial values with the gadget depicted in Figure 2b. This gadget differs from the gadget used for partial expectations only in the expected time it takes to reach *goal* or *fail* under γ_j or δ_j. It is constructed in a way such that the expected time to reach *goal* or *fail* from s_{init} does not depend on the scheduler. Finally, we add a transition leading back to the initial state from *goal* and *fail*. An optimal scheduler for weighted long-run frequencies in the constructed MDP $\mathcal{K}$ now just has to maximize the partial expectation leading to the Skolem-hardness result (for more details see [39]).

▶ **Theorem 8.** *The Positivity problem is polynomial-time reducible to the following problem: Given an MDP $\mathcal{M}$ and a rational ϑ, decide whether $\mathit{WLF}^{\max}_{\mathcal{M}} > \vartheta$.*

This result now serves as a tool to establish analogous results for long-run probabilities. The key idea is to encode integer weights via a labelling of states and to use a simple regular co-safety property to mimic the reception of weights in weighted long-run frequencies.

▶ **Theorem 9.** *The Positivity problem is polynomial-time reducible to the following problem: Given an MDP $\mathcal{M}$, an NFA $\mathcal{A}$, and a rational ϑ, decide whether $\mathbb{LP}^{\max}_{\mathcal{M}}(\mathcal{A}) > \vartheta$.*

In the sequel, we consider weighted states instead of weighted state-action pairs. Further, we assume that the weights are only -1, 0, and $+1$. This assumption leads to a pseudo-polynomial blow-up in the general case. The weights in the MDP $\mathcal{K}$ constructed for Theorem



$g \wedge p, g \wedge z \wedge c, f \wedge c$
$\neg g \wedge \neg f$
$p \wedge \neg g \wedge \neg f$
$g, f \wedge c$
$z \wedge \neg g \wedge \neg f$
$\neg g \wedge \neg f$
$n \wedge \neg g \wedge \neg f$
$g \wedge c, f \wedge c$
$\neg g \wedge \neg f$
$f \wedge c$

Figure 3 The NFA $\mathcal{A}$ expressing a property of the form $d \vee \bigvee_{i=1}^{3}(c_i \wedge (a \,\mathrm{U}\, b_i))$.

8 above are, however, at most k. As the MDP has more than $2k$ states, transforming $\mathcal{K}$ to weights -1, 0, and $+1$ only leads to a polynomial blow-up. As this MDP has no non-trivial end-components, $\{goal, fail\}$ is visited infinitely often with probability 1 under any scheduler. Let $\mathsf{AP} = \{n, z, p, c, g, f\}$ be a set of atomic propositions representing *negative* (-1), *zero* (0), and *positive* $(+1)$ weight, *coin flip*, *goal*, and *fail*, respectively. We construct an MDP $\mathcal{L}$: The states *goal* and *fail* are duplicated while one copy of each is labeled with c and whenever *goal* or *fail* are entered in the MDP $\mathcal{K}$, both of the two copies in $\mathcal{L}$ are equally likely. For a formal definition see [39]. In Figure 3, we depict the NFA $\mathcal{A}$ used for the encoding. The NFA $\mathcal{A}$ is constructed such that in $\mathcal{L}$ any run starting in a state labeled *zero* or reaching *fail* before *goal* is accepted with probability 1/2 due to the *coin flips*. A run starting in a state labeled *positive* and reaching *goal* before *fail* is accepted while such a path starting in a state labeled *negative* is not. This leads to the following lemma that proves Theorem 9.

▶ **Lemma 10.** *For the MDPs $\mathcal{K}$ and $\mathcal{L}$ constructed above, we have $WLF_{\mathcal{K}}^{\max} = \frac{1}{2} + \frac{1}{2}\mathbb{LP}_{\mathcal{L}}^{\max}(\mathcal{A})$.*

Proof sketch. It is quite easy to see that the claim holds for finite-memory schedulers as we can rely on steady state probabilities in the resulting Markov chain. That the supremum over all schedulers agrees with the supremum over finite-memory schedulers on both sides follows from Fatou's lemma. Details can be found in [39]. ◀

A consequence of this result is that model checking of frequency-LTL in MDPs is at least as hard as the Skolem problem. The decidability of the model-checking problem for the full logic frequency-LTL has been left open, but set as a goal in [23, 24]. Obtaining this goal by proving the decidability of the model-checking problem hence would settle the decidability of the Skolem problem. The frequency-globally modality $G_{\inf}^{>\vartheta}(\varphi)$ is defined to hold on a path π iff $\liminf_{n\to\infty} \frac{1}{n+1} \sum_{i=0}^{n} \mathbb{1}_{\pi[i\ldots]\models\varphi} > \vartheta$, i.e. iff the long-run average number of positions at which a suffix satisfying φ starts exceeds ϑ.

▶ **Theorem 11.** *There is a polynomial-time reduction from the Positivity problem to the following qualitative model checking problem for frequency LTL for a fixed LTL-formula φ: Given an MDP $\mathcal{M}$ and a rational ϑ, is $\Pr_{\mathcal{M}}^{\max}(G_{\inf}^{>\vartheta}(\varphi)) = 1$?*

Proof sketch. The proof uses the reduction to the threshold problem for the long-run probability of the co-safety property expressed by $\mathcal{A}$. This property is captured by a simple LTL-formula φ (see Figure 3). For finite-memory schedulers $\mathfrak{S}$ inducing a single bottom strongly connected component, we see that $G^{>\vartheta}_{\inf}(\varphi)$ holds with probability 1 iff the expected long-run probability of φ is greater than ϑ. That it is enough to consider such schedulers follows from the argument using Fatou's lemma again. For more details see [39]. ◀

4 Saturation points

Despite the inherent mathematical difficulty shown by the Skolem-hardness results so far, all of the problems studied here are solvable in exponential time under a natural restriction. For the problems on weighted MDPs, this restriction only allows non-negative weights while for the long-run notions the restriction to constrained reachability properties ($a\,\mathrm{U}\,b$) leads to solvability. For the partial and the conditional SSPP [8, 16] and for long-run probabilities [4], the computability of optimal values under these restrictions has been shown. The algorithms exploit the existence of *saturation points*, a bound on the accumulated weight or the consecutive visits to certain states before optimal schedulers can behave memorylessly. We will extend this picture by providing a simple saturation point for the computation of the optimal conditional value-at-risk for the classical SSPP in MDPs with non-negative weights. Afterwards, we transfer the saturation-point algorithm from [4] to weighted long-run frequencies in the setting of non-negative weights. As a consequence, we obtain an exponential-time algorithm for the qualitative model-checking problem of a frequency-LTL formula for which no solutions were known. To conclude the section, we provide accompanying PSPACE lower bounds for the partial SSPP and weighted long-run frequencies with non-negative weights.

4.1 Conditional value-at-risk for the classical SSPP

Let $\mathcal{M}$ be an MDP with non-negative weights. In the classical SSPP, it is decidable in polynomial time whether the optimal expected accumulated weight before reaching the goal is bounded. If this is the case, the usual preprocessing step removes end components [20, 3] and transforms the MDP such that exactly the schedulers reaching the goal with probability 1 can be mimicked in the transformed MDP. So in the sequel, we assume that the absorbing state *goal* forms the only end component. Given a rational probability value $p \in (0,1)$, we are interested in the value $CVaR^{\max}_p(\oplus goal)$. Note that in our formulation the worst outcomes are the paths with the lowest accumulated weight before reaching the goal. Below we will sketch how to treat the case where high outcomes are considered bad.

▶ **Theorem 12.** *Given an MDP $\mathcal{M} = (S, s_{init}, Act, P, wgt, goal)$ with non-negative weights and no end-components except for one absorbing state goal as well as a rational probability value $p \in (0,1)$, the value $CVaR^{\max}_p(\oplus goal)$ is computable in pseudo-polynomial time.*

Proof sketch. As there are no end components, we can provide a *saturation point* $K \in \mathbb{N}$ such that paths accumulate a weight of more than K with probability less than $1-p$. Then, paths reaching an accumulated weight of K do not belong to the worst p outcomes. We construct an MDP with the state space $S \times \{0, \ldots, K\}$ that encodes the accumulated weight of a path up to K. Letting states of the form $(goal, i)$ be terminal with weight i and of the form (s, K) be terminal with weight K, we can then rely on the algorithm computing the conditional value-at-risk for weighted reachability in [31]. As K can be chosen of pseudo-polynomial size and this algorithm runs in time polynomial in the size of the constructed MDP, this leads to a pseudo-polynomial time algorithm. For details see [39]. ◀

Note that the behavior of a scheduler on paths with accumulated weight above K does not matter at all for the conditional value-at-risk. If we want to consider the case where long paths are considered as bad, we can multiply all weights by -1 and use the definitions as before. The idea here now is to compute a saturation point $-K$ such that the probability for a path to accumulate weight less than $-K$ is smaller than p. So, we know that a path with weight less than $-K$ belongs to the p worst paths. On these paths, the best thing to do in order to maximize the conditional value-at-risk is to maximize the expected accumulated weight before reaching the goal. This can be done by a memoryless deterministic scheduler simultaneously for all states and the values are computable in polynomial time [20]. Then we construct the MDP $\mathcal{N}$ as above but change the terminal weights as follows: states of the form $(goal, i)$ get weight $-i$ and states of the form (s, K) get weight $-K + \mathbb{E}^{\max}_{\mathcal{M},s}(\oplus goal)$ where $\mathcal{M}$ is the MDP in which all weights are already multiplied by -1. Afterwards the problem can be solved by the techniques for weighted reachability from [31] again.

4.2 Weighted long-run frequencies and frequency-LTL

The existence of a saturation point for long-run probabilities of constrained reachability properties was shown in [4]. This result can easily be adapted to weighted long-run frequencies following the same arguments. First, it is shown by an application of Fatou's lemma that optimal weighted long-run frequency can be approximated by finite-memory schedulers. Afterwards, it is shown that the memory needed for the optimization can be restricted further: A saturation point $K \in \mathbb{N}$ is provided such that only scheduler keeping track of the accumulated weight up to K have to be considered. The adaptions necessary to the proof in [4] are worked out in the extended version [39] and lead to the following result:

▶ **Theorem 13.** *The maximal value $WLF^{\max}_{\mathcal{M}}$ in an MDP $\mathcal{M}$ with non-negative weights is computable in pseudo-polynomial time.*

▶ **Corollary 14.** *Given an MDP $\mathcal{M}$ and a rational ϑ, it can be checked in pseudo-polynomial time whether $\Pr^{\max}_{\mathcal{M}}(G^{>\vartheta}_{\inf}(a \,\mathrm{U}\, b)) = 1$.*

Proof. The semantics of $G^{>\vartheta}_{\inf}(\neg Fail \,\mathrm{U}\, Goal)$ on a path π agree with the semantics of $wlf(\pi) > \vartheta$ if all weights are set to $+1$. Now, we can check for each end component $\mathcal{E}$ of $\mathcal{M}$ whether $WLF^{\max}_{\mathcal{E}} > \vartheta$. If that is the case, there is a finite memory scheduler for $\mathcal{E}$ inducing only one BSCC achieving a weighted long-run frequency greater than ϑ. Under this scheduler almost all paths π satisfy $wlf(\pi) > \vartheta$. Afterwards, it remains to check whether end components with such a scheduler can be reached with probability 1 in $\mathcal{M}$. ◀

In [24], the fragment of frequency-LTL in which no until-operators occur in the scope of a globally operator has been studied. The formula in the corollary is hence of the simplest form of frequency-LTL formulas for which no solution to the qualitative model-checking problem has been known. Remarkably, the formula used in the Skolem-hardness proof (Theorem 11) is only slightly more complicated as it contains a Boolean combination of constrained reachability properties and atomic propositions under the frequency-globally operator.

4.3 PSPACE lower bounds

For the conditional SSPP with non-negative weights [8] and the long-run probability of constrained reachability properties [4], PSPACE and NP lower bounds, respectively, are known indicating that the pseudo-polynomial time algorithms for the computation can probably not be significantly improved. The threshold problem of the conditional SSPP is already PSPACE-hard in acyclic MDPs with non-negative weights as shown in [8]. In [38], it has been shown that the threshold problem of the conditional SSPP is polynomial-time reducible to the threshold problem for the partial SSPP. This reduction generates an MDP with negative weights, even when all weights in the original MDP are non-negative. Here, we provide a new polynomial reduction for acyclic MDPs from the threshold problem for the conditional SSPP to the threshold problem of the partial SSPP that preserves the non-negativity of weights (see [39]).

▶ **Proposition 15.** *The threshold problem of the partial SSPP is PSPACE-hard in acyclic MDPs with non-negative weights. It is contained in PSPACE for acyclic MDPs with arbitrary integer weights.*

In an acyclic MDP, we can add intermediate states on transitions such that all paths have the same length ℓ. If we additionally add transitions form *goal* and *fail* back to the initial state, the maximal weighted long-run frequency is just the maximal partial expectation divided by ℓ. This allows us to conclude:

▶ **Proposition 16.** *The threshold problem for weighted long-run frequencies, "Does $WLF^{\max}_{\mathcal{M}} \bowtie \vartheta$ hold?", in MDPs with non-negative weights is PSPACE-hard.*

5 Conclusion

We identified a variety of optimization problems – some of which seemed rather unrelated on first sight – with a Skolem-hard threshold problem on MDPs. The results show that an algorithm for the exact solution to these optimization problems would imply a major breakthrough. For the partial and conditional SSPP, however, approximation algorithms were provided in [38]. Investigating the possibility to approximate optimal values might lead to algorithms useful in practice for the other objectives studied here. Further, the problems have a pseudo-polynomial solution under natural restrictions. The key result, the existence of a saturation point, has been established in the setting of stochastic multiplayer games for partial expectations [16]. This raises the question to which extend the saturation point results for the other problems can be transferred to stochastic multiplayer games.

To the best of our knowledge, the conditional value-at-risk for accumulated weights has not been addressed before. While we showed Skolem-hardness in the general setting, the computation of the optimal value is possible in exponential time in the setting of non-negative weights. Studying lower bounds for the complexity of the threshold problem and the combination of constraints on the expected accumulated weight before reaching the goal, the value-at-risk, and the conditional value-at-risk in this setting are left as future work.

The Power of a Single Qubit: Two-Way Quantum Finite Automata and the Word Problem

Zachary Remscrim
Department of Mathematics, MIT, Cambridge, MA, USA
remscrim@mit.edu

Abstract

The two-way finite automaton with quantum and classical states (2QCFA), defined by Ambainis and Watrous, is a model of quantum computation whose quantum part is extremely limited; however, as they showed, 2QCFA are surprisingly powerful: a 2QCFA, with a single qubit, can recognize, with bounded error, the language $L_{eq} = \{a^m b^m : m \in \mathbb{N}\}$ in expected polynomial time and the language $L_{pal} = \{w \in \{a,b\}^* : w \text{ is a palindrome}\}$ in expected exponential time.

We further demonstrate the power of 2QCFA by showing that they can recognize the word problems of many groups. In particular 2QCFA, with a single qubit and algebraic number transition amplitudes, can recognize, with bounded error, the word problem of any finitely generated virtually abelian group in expected polynomial time, as well as the word problems of a large class of linear groups in expected exponential time. This latter class (properly) includes all groups with context-free word problem. We also exhibit results for 2QCFA with any constant number of qubits.

As a corollary, we obtain a direct improvement on the original Ambainis and Watrous result by showing that L_{eq} can be recognized by a 2QCFA with better parameters. As a further corollary, we show that 2QCFA can recognize certain non-context-free languages in expected polynomial time.

In a companion paper, we prove matching lower bounds, thereby showing that the class of languages recognizable with bounded error by a 2QCFA in expected *subexponential* time is properly contained in the class of languages recognizable with bounded error by a 2QCFA in expected *exponential* time.

1 Introduction

The theory of quantum computation has made amazing strides in the last several decades. Landmark results, like Shor's polynomial time quantum algorithm for integer factorization [31], Grover's algorithm for unstructured search [14], and the linear system solver of Harrow, Hassidim, and Lloyd [15], have provided remarkable examples of natural problems for which quantum computers seem to have an advantage over their classical counterparts. These theoretical breakthroughs have provided strong motivation to construct quantum computers. However, while significant advancements have been made, the experimental

quantum computers that exist today are still quite limited, and are certainly not capable of implementing, on a large scale, algorithms designed for general quantum Turing machines. This naturally motivates the study of more restricted models of quantum computation.

In this paper, our goal is to understand the computational power of a small number of qubits, especially the power of a single qubit. To that end, we study two-way finite automata with quantum and classical states (2QCFA), introduced by Ambainis and Watrous [1]. Informally, a 2QCFA is a two-way deterministic finite automaton (2DFA) that has been augmented with a quantum register of constant size, i.e., a constant number of qubits. The quantum part of the machine is extremely limited; however, the model is surprisingly powerful. In particular, Ambainis and Watrous [1] showed that a 2QCFA, using only one qubit, can recognize, with bounded error, the language $L_{eq} = \{a^m b^m : m \in \mathbb{N}\}$ in expected polynomial time and the language $L_{pal} = \{w \in \{a, b\}^* : w \text{ is a palindrome}\}$ in expected exponential time. This clearly demonstrated that 2QCFA are more powerful than 2DFA, which recognize precisely the regular languages [26]. Moreover, as it is known that two-way probabilistic finite automata (2PFA) can recognize L_{eq} with bounded error in exponential time [11], but not in subexponential time [13], and cannot recognize L_{pal} with bounded error in any time bound [10], this result also demonstrated the superiority of 2QCFA over 2PFA.

We investigate the ability of 2QCFA to recognize the word problem of a group. Informally, the word problem for a group G involves determining if the product of a finite sequence of group elements $g_1, \ldots, g_k \in G$ is equal to the identity element of G. Word problems for various classes of groups have a rich and well-studied history in computational complexity theory, as there are many striking relationships between certain algebraic properties of a group G and the computational complexity of its word problem W_G. For example, $W_G \in \mathsf{REG} \Leftrightarrow G$ is finite [3], $W_G \in \mathsf{CFL} \Leftrightarrow W_G \in \mathsf{DCFL} \Leftrightarrow G$ is a finitely generated virtually free group [23], and $W_G \in \mathsf{NP} \Leftrightarrow G$ is a finitely generated subgroup of a finitely presented group with polynomial Dehn function [5].

For a quantum model, such as the 2QCFA, word problems are a particularly natural class of languages to study. There are several results [6, 37, 36] which show that certain (generally significantly more powerful) QFA variants can recognize the word problems of particular classes of groups (see the excellent survey [2] for a full discussion of the many QFA variants). Moreover, there are also results concerning the ability of QFA to recognize certain languages that are extremely closely related to word problems; in fact, the languages L_{eq} and L_{pal} considered by Ambainis and Watrous [1] are each closely related to a word problem.

Fundamentally, the laws of quantum mechanics sharply constrain the manner in which the state of the quantum register of a 2QCFA may evolve, thereby forcing the computation of a 2QCFA to have a certain algebraic structure. Similarly, the algebraic properties of a particular group G impose a corresponding algebraic structure on its word problem W_G. For certain classes of groups, the algebraic structure of W_G is extremely compatible with the algebraic structure of the computation of a 2QCFA; for other classes of groups, these two algebraic structures are in extreme opposition.

In this paper, we show that there is a broad class of groups for which these algebraic structures are quite compatible, which enables us to produce 2QCFA that recognize these word problems. As a corollary, we show that L_{eq} can be recognized by a 2QCFA with better parameters than in the original Ambainis and Watrous result [1].

In a separate paper [27], we establish matching lower bounds on the running time of a 2QCFA (and, more generally, a *quantum Turing machine* that uses sublogarithmic space) that recognizes these word problems, thereby demonstrating the optimality of these results; this allows us to prove that the class of languages recognizable with bounded error by 2QCFA in expected *subexponential* time is properly contained in the class of languages recognizable with bounded error by 2QCFA in expected *exponential* time.

1.1 Statement of the Main Results

We begin by formally defining the word problem of a group; for more extensive background, see, for instance, [21]. Let $F(S)$ denote the free group on the set S. For sets S and R, where $R \subseteq F(S)$, let $\langle R^{F(S)} \rangle$ denote the normal closure of R in $F(S)$; we say that a group G has *presentation* $\langle S|R \rangle$ if $G \cong F(S)/\langle R^{F(S)} \rangle$, in which case we write $G = \langle S|R \rangle$. For a set S, we define the set of formal inverses S^{-1}, such that for each $s \in S$, there is a unique corresponding $s^{-1} \in S^{-1}$, and $S \cap S^{-1} = \emptyset$.

▶ **Definition 1.** Suppose $G = \langle S|R \rangle$, where S is finite. Let $\Sigma = S \sqcup S^{-1}$, let Σ^* denote the free monoid over Σ, let $\phi : \Sigma^* \to G$ denote the natural monoid homomorphism that takes each string in Σ^* to the element of G that it represents, and let 1_G denote the identity element of G. The word problem of G with respect to the presentation $\langle S|R \rangle$ is the language $W_{G=\langle S|R \rangle} = \{w \in \Sigma^* : \phi(w) = 1_G\}$ consisting of all strings that represent 1_G.

Note that if $G = \langle S|R \rangle$, then S (or more precisely the image of S in G under ϕ) is a generating set for G. We say that G is *finitely generated* if it has a generating set S that is finite. If G also has presentation $\langle S'|R' \rangle$, where S' is also finite, then for any complexity class $\mathcal{C}$ closed under inverse homomorphism, $W_{G=\langle S|R \rangle} \in \mathcal{C} \Leftrightarrow W_{G=\langle S'|R' \rangle} \in \mathcal{C}$ [16]. As each complexity class $\mathcal{C}$ considered in this paper is closed under inverse homomorphism, we will use W_G to denote the word problem of a finitely generated group G, and we will write $W_G \in \mathcal{C}$ if $W_{G=\langle S|R \rangle} \in \mathcal{C}$ for some (equivalently, every) presentation $\langle S|R \rangle$ of G with S finite.

We show that, for many groups G, the corresponding word problem W_G is recognized by a 2QCFA with "good" parameters. In order to state these results, we must make use of some terminology and notation concerning 2QCFA and various classes of groups whose word problems are of complexity theoretic interest. We define the 2QCFA model in Section 2. For other definitions and additional background, we refer the reader to the full version of this paper [28]. We use $\mathbb{R}_{>0}$ to denote the positive real numbers.

▶ **Definition 2.** For $T : \mathbb{N} \to \mathbb{N}$, $\epsilon \in \mathbb{R}_{>0}$, $d \in \mathbb{N}$, and $\mathbb{A} \subseteq \mathbb{C}$, let the complexity class $\mathsf{coR2QCFA}(T, \epsilon, d, \mathbb{A})$ consist of all languages $L \subseteq \Sigma^*$ for which there is a 2QCFA M, which has d quantum basis states and transition amplitudes in $\mathbb{A}$, such that, $\forall w \in \Sigma^*$, the following holds: M runs in expected time $O(T(|w|))$, $\Pr[M \text{ accepts } w] + \Pr[M \text{ rejects } w] = 1$, $w \in L \Rightarrow \Pr[M \text{ accepts } w] = 1$, and $w \notin L \Rightarrow \Pr[M \text{ rejects } w] \geq 1 - \epsilon$.

The focus on the transition amplitudes of a 2QCFA warrants a bit of additional justification, as while it is standard to limit the transition amplitudes of a Turing machine in this way, it is common for finite automata to be defined without any such limitation. For many finite automata models, applying such a constraint would be superfluous; for example, the class of languages recognized with bounded error and in expected time $2^{n^{o(1)}}$ by a 2PFA with no restriction at all on its transition amplitudes is precisely the regular languages [9]. However, the power of the 2QCFA model is quite sensitive to the choice of transition amplitudes. A 2QCFA with non-computable transition amplitudes can recognize undecidable languages, with bounded error and in expected polynomial time [29]; whereas, 2QCFA with transition amplitudes restricted to the algebraic numbers $\overline{\mathbb{Q}}$ can only recognize languages in $\mathsf{P} \cap \mathsf{L}^2$, even if permitted unbounded error and exponential time [34]. In particular, the algebraic numbers are arguably the "standard" choice for the permitted transition amplitudes of a quantum Turing machine (QTM). It is desirable for the definition of 2QCFA to be consistent with that of QTMs as such consistency makes it more likely that techniques developed for 2QCFA could be applied to QTMs. Therefore, $\overline{\mathbb{Q}}$ is the the natural choice for the permitted transition amplitudes of a 2QCFA, though we do also consider the impact of allowing transition amplitudes in the slightly broader class $\widetilde{\mathbb{C}} = \overline{\mathbb{Q}} \cup \{e^{\pi i r} : r \in (\overline{\mathbb{Q}} \cap \mathbb{R})\}$.

We begin with a simple motivating example. For a finite alphabet Σ, a symbol $\sigma \in \Sigma$, and a word $w \in \Sigma^*$, let $\#(w, \sigma)$ denote the number of appearances of σ in w. Then the word problem for the group $\mathbb{Z}$ (the integers, where the group operation is addition) is the language $W_{\mathbb{Z}} = \{w \in \{a, b\}^* : \#(w, a) = \#(w, b)\}$. This language is closely related to the language $L_{eq} = \{a^m b^m : m \in \mathbb{N}\}$; in particular, $L_{eq} = (a^* b^*) \cap W_{\mathbb{Z}}$. More generally, the word problem for the group $\mathbb{Z}^k$ (the direct product of k copies of $\mathbb{Z}$) is the language $W_{\mathbb{Z}^k} = \{w \in \{a_1, b_1, \ldots, a_k, b_k\}^* : \#(w, a_i) = \#(w, b_i), \forall i\}$.

Ambainis and Watrous [1] showed that $L_{eq} \in \mathsf{coR2QCFA}(n^4, \epsilon, 2, \widetilde{\mathbb{C}})$, $\forall \epsilon \in \mathbb{R}_{>0}$. We note that the same method would easily imply the same result for $W_{\mathbb{Z}}$, and could be further adapted to produce a similar result for $W_{\mathbb{Z}^k}$. Our first main theorem generalizes and improves upon these results in several ways. Let $\widehat{\Pi}_1$ denote the collections of all finitely generated virtually abelian groups (i.e., all groups that have a finite-index subgroup isomorphic to $\mathbb{Z}^k$, for some $k \in \mathbb{N}$, where $\mathbb{Z}^0$ is the trivial group); we will explain this choice of notation shortly.

► **Theorem 3.** $\exists C \in \mathbb{R}_{>0}$ *such that* $\forall G \in \widehat{\Pi}_1, \forall \epsilon \in \mathbb{R}_{>0}$, $W_G \in \mathsf{coR2QCFA}(n^3, \epsilon, 2, \widetilde{\mathbb{C}}) \cap \mathsf{coR2QCFA}(n^C, \epsilon, 2, \overline{\mathbb{Q}})$.

By the above observation that $L_{eq} = (a^* b^*) \cap W_{\mathbb{Z}}$, the following corollary is immediate.

► **Corollary 4.** $\exists C \in \mathbb{R}_{>0}, \forall \epsilon \in \mathbb{R}_{>0}$, $L_{eq} \in \mathsf{coR2QCFA}(n^3, \epsilon, 2, \widetilde{\mathbb{C}}) \cap \mathsf{coR2QCFA}(n^C, \epsilon, 2, \overline{\mathbb{Q}})$.

The above corollary improves upon the result of Ambainis and Watrous [1] in two distinct senses. Firstly, using the same set of permissible transition amplitudes, our result has a better expected running time. Secondly, our result shows that L_{eq} can be recognized by a 2QCFA with transition amplitudes in $\overline{\mathbb{Q}}$, which still runs in expected polynomial time.

Let CFL denote the context-free languages (languages recognized by non-deterministic pushdown automata), OCL denote the one-counter languages (languages recognized by non-deterministic pushdown automata with single-symbol stack alphabet) and $\mathsf{poly{-}CFL}$ (resp. $\mathsf{poly{-}OCL}$) denote the intersection of finitely many context-free (resp. one-counter) languages. As $W_G \in \mathsf{poly{-}OCL} \Leftrightarrow G \in \widehat{\Pi}_1$ [17], the following corollary is also immediate.

► **Corollary 5.** $\exists C \in \mathbb{R}_{>0}, \forall W_G \in \mathsf{poly{-}OCL}, \forall \epsilon \in \mathbb{R}_{>0}$, $W_G \in \mathsf{coR2QCFA}(n^3, \epsilon, 2, \widetilde{\mathbb{C}}) \cap \mathsf{coR2QCFA}(n^C, \epsilon, 2, \overline{\mathbb{Q}})$.

Moreover, as $W_G \in \mathsf{poly{-}OCL} \cap \mathsf{CFL} \Leftrightarrow G$ is a finitely generated virtually cyclic group [17], the above corollary exhibits a wide class of non-context-free languages that are recognizable by a 2QCFA in polynomial time: the word problem of any group that is virtually $\mathbb{Z}^k$, $k \geq 2$.

Next, let F_k denote the free group of rank k, for $k \in \mathbb{N}$; in particular, F_0 is the trivial group, F_1 is the group $\mathbb{Z}$, and, for any $k \geq 2$, F_k is non-abelian. Notice that W_{F_2} is closely related to the language L_{pal}. Ambainis and Watrous [1] showed that, $\forall \epsilon \in \mathbb{R}_{>0}$, $\exists D \in \mathbb{R}_{\geq 1}$, such that $L_{pal} \in \mathsf{coR2QCFA}(D^n, \epsilon, 2, \overline{\mathbb{Q}})$, and the same method would show the same result for W_{F_2}. We show that the same result holds for any group built from free groups, using certain operations. Let $\widehat{\Pi}_2$ denote the collection of all finitely generated groups that are virtually a subgroup of a direct product of finitely many finite-rank free groups.

► **Theorem 6.** $\forall G \in \widehat{\Pi}_2, \forall \epsilon \in \mathbb{R}_{>0}, \exists D \in \mathbb{R}_{\geq 1}$, *such that* $W_G \in \mathsf{coR2QCFA}(D^n, \epsilon, 2, \overline{\mathbb{Q}})$.

As $W_G \in \mathsf{CFL} \Leftrightarrow G$ is a finitely generated virtually free group [23], we obtain the following.

► **Corollary 7.** $\forall W_G \in \mathsf{CFL}, \forall \epsilon \in \mathbb{R}_{>0}, \exists D \in \mathbb{R}_{\geq 1}$, *such that* $W_G \in \mathsf{coR2QCFA}(D^n, \epsilon, 2, \overline{\mathbb{Q}})$.

Consider the homomorphism $\pi : F_2 \times F_2 \to \mathbb{Z}$, where π takes each free generator of each copy of F_2 to a single generator of $\mathbb{Z}$; then $K = \ker \pi$ is finitely generated, but not finitely presented [32]. All groups G for which $W_G \in \mathsf{CFL} \cup \mathsf{poly{-}OCL}$ are finitely presented [16]. As $K \in \widehat{\Pi}_2$, we have the following corollary.

▶ **Corollary 8.** *There is a finitely generated group K, which is not finitely presented (hence, $W_K \notin$ CFL∪poly−OCL), where $\forall \epsilon \in \mathbb{R}_{>0}, \exists D \in \mathbb{R}_{\geq 1}$, such that $W_K \in$ coR2QCFA$(D^n, \epsilon, 2, \overline{\mathbb{Q}})$.*

▶ Remark 9. It is known that, if $G \in \widehat{\Pi}_2$, then $W_G \in$ poly−CFL [7]. Moreover, it is conjectured that $\widehat{\Pi}_2$ is precisely the class of groups whose word problem is in poly−CFL [7] (cf. [8]).

We next consider a broader class of groups. Let $Z(H)$ denote the center of a group H, let $\mathrm{U}(d, \overline{\mathbb{Q}})$ denote the group of $d \times d$ unitary matrices with entries in $\overline{\mathbb{Q}}$, let $\mathrm{PU}(d, \overline{\mathbb{Q}}) = \mathrm{U}(d, \overline{\mathbb{Q}})/Z(\mathrm{U}(d, \overline{\mathbb{Q}}))$, and let $(\mathrm{PU}(d, \overline{\mathbb{Q}}))^k$ denote the direct product of k copies of $\mathrm{PU}(d, \overline{\mathbb{Q}})$.

▶ **Theorem 10.** *If G is a finitely generated group that is virtually a subgroup of $(\mathrm{PU}(d, \overline{\mathbb{Q}}))^k$, for some $d, k \in \mathbb{N}_{\geq 1}$, then $\forall \epsilon \in \mathbb{R}_{>0}, \exists D \in \mathbb{R}_{\geq 1}$, such that $W_G \in$ coR2QCFA$(D^n, \epsilon, d, \overline{\mathbb{Q}})$.*

In order to state our final main result, as well as to provide appropriate context for the results listed above, we define the classes of groups Σ_j and Π_j, for $j \in \mathbb{N}$, inductively. First $\Sigma_0 = \Pi_0 = \{\mathbb{Z}, \{1\}\}$ (i.e., both classes consist of the two groups $\mathbb{Z}$ and the trivial group $\{1\}$). We use $\times$ to denote the direct product and $*$ to denote the free product. For $j > 1$, we define $\Pi_j = \{H_1 \times \cdots \times H_t : t \in \mathbb{N}_{\geq 1}, H_1, \ldots, H_t \in \Sigma_{j-1}\}$ and $\Sigma_j = \{H_1 * \cdots * H_t : t \in \mathbb{N}_{\geq 1}, H_1, \ldots, H_t \in \Pi_{j-1}\}$. These groups comprise an important subclass of a particularly important class of groups: the right-angled Artin groups. Note that every $G \in \bigcup_j (\Pi_j \cup \Sigma_j)$ is finitely generated. Also note that the Π_j and Σ_j form a hierarchy in the obvious way. We further define $\widehat{\Pi}_j$ (resp. $\widehat{\Sigma}_j$) as the set of all finitely generated groups that are virtually a subgroup of some group in Π_j (resp. Σ_j), which also form a hierarchy in the obvious way.

In particular, $\widehat{\Pi}_1$ (resp. $\widehat{\Pi}_2$) is precisely the class of groups for which Theorem 3 (resp. Theorem 6) demonstrates the existence of a 2QCFA that recognizes the corresponding word problem with bounded error in expected polynomial (resp. exponential) time. We next consider the class $\widehat{\Pi}_3$. While the relationship of this class to the class of groups to which Theorem 10 applies is unclear to us, we can show that the word problem of any group in this class can be recognized by a 2QCFA with negative one-sided *unbounded* error. Let coN2QCFA$(T, d, \mathbb{A})$ be defined as in Definition 2, except we now only require that $\Pr[N \text{ rejects } w] > 0, \forall w \notin L$.

▶ **Theorem 11.** *If $G \in \widehat{\Pi}_3$, then $W_G \in$ coN2QCFA$(n, 2, \widetilde{\mathbb{C}})$.*

▶ Remark 12. $\mathbb{Z} * \mathbb{Z}^2 \in \Sigma_2 \subseteq \widehat{\Pi}_3$. It is conjectured [7, 18] that $W_{\mathbb{Z}*\mathbb{Z}^2} \notin$ poly−CFL ∪ coCFL.

Lastly, we consider 2QCFA with no restrictions on their transition amplitudes, as well as the measure-once one-way quantum finite automaton (MO-1QFA) defined by Moore and Crutchfield [22]. Let coN1QFA denote the class of languages recognizable with negative one-sided unbounded error by a MO-1QFA (with any constant number of states).

▶ **Theorem 13.** *If G is a finitely generated group that is virtually a subgroup of $(\mathrm{PU}(d))^k$, for some $d, k \in \mathbb{N}_{\geq 1}$, then $W_G \in$ coN2QCFA$(n, d, \mathbb{C}) \cap$ coN1QFA.*

Let $\mathcal{D}$ denote the class of groups to which the preceding theorem applies (which includes all groups to which all earlier theorems apply). Let S denote the stochastic languages (the class of languages recognizable by PFA with strict cut-points). By [6, Theorem 3.6], coN1QFA ⊆ coS, which implies the following corollary.

▶ **Corollary 14.** *If $G \in \mathcal{D}$, then $W_G \in$ coS.*

▶ Remark 15. For many $G \in \mathcal{D}$, the fact that $W_G \in$ coS was already known: $W_{F_k} \in$ coS, $\forall k$ [6], which implies (by standard arguments from computational group theory, see for instance [23]) that $\forall G \in \widehat{\Pi}_2$, $W_G \in$ coS. However, for $G \in \mathcal{D} \setminus \widehat{\Pi}_2$, this result appears to be new.

2 Quantum Computation and the 2QCFA

In this section, we briefly recall the fundamentals of quantum computation and the definition of 2QCFA. For further background on quantum computation, see, for instance, [24, 35].

A natural way of understanding quantum computation is as a generalization of probabilistic computation. One may consider a probabilistic system defined over some finite set of states $C = \{c_1, \dots, c_k\}$, where the state of that system, at any particular point in time, is given by a probability distribution over C. Such a probability distribution may be described by a vector $v = (v_{c_1}, \dots, v_{c_k})$, where $v_c \in \mathbb{R}_{\geq 0}$ denotes the probability that the system is in state $c \in C$, and $\sum_c v_c = 1$, i.e., v is simply an element of $\mathbb{R}^k_{\geq 0}$ with L^1-norm 1.

Similarly, consider some finite set of *quantum basis states* $Q = \{q_1, \dots, q_k\}$, which correspond to an orthonormal basis $|q_1\rangle, \dots, |q_k\rangle$ of $\mathbb{C}^k$ (here and throughout the paper we use the standard bra-ket notation). The state of a quantum system over Q, at any particular time, is given by some *superposition* $|\psi\rangle = \sum_q \alpha_q |q\rangle$ of the basis states, where each $\alpha_q \in \mathbb{C}$ and $\sum_q |\alpha_q|^2 = 1$; i.e., a superposition $|\psi\rangle$ is simply an element of $\mathbb{C}^k$ with L^2-norm 1.

Let $\mathrm{U}(k)$ denote the group of $k \times k$ unitary matrices. Given a quantum system currently in the superposition $|\psi\rangle$, one may apply a transformation $t \in \mathrm{U}(k)$ to the system, after which the system is in the superposition $t\,|\psi\rangle$. One may also perform a *projective measurement in the computational basis*, which is specified by some partition $B = \{B_0, \dots, B_l\}$ of Q. Measuring a system that is in the superposition $|\psi\rangle = \sum_q \alpha_q |q\rangle$ with respect to B gives the result $B_r \in B$ with probability $p_r := \sum_{q \in B_r} |\alpha_q|^2$; additionally, if the result of the measurement is B_r, then the state of the system *collapses* to the superposition $\frac{1}{\sqrt{p_r}} \sum_{q \in B_r} \alpha_q |q\rangle$. We emphasize that measuring a quantum system changes the state of that system.

We now define a 2QCFA, essentially following the original definition in [1]. Informally, a 2QCFA is a two-way deterministic finite automaton that has been augmented with a finite size quantum register. Formally, a 2QCFA M is given by an 8-tuple, $M = \{Q, C, \Sigma, \delta, q_{start}, c_{start}, c_{acc}, c_{rej}\}$, where Q (resp. C) is the finite set of quantum (resp. classical) states, Σ is a finite alphabet, δ is the transition function, $q_{start} \in Q$ (resp. $c_{start} \in C$) is the quantum (resp. classical) start state, and $c_{acc}, c_{rej} \in C$, where $c_{acc} \neq c_{rej}$, are the accepting and rejecting states. The *quantum register* of M is given by the quantum system with basis states Q. We define the tape alphabet $\Gamma := \Sigma \sqcup \{\#_L, \#_R\}$ where the two distinct symbols $\#_L, \#_R \notin \Sigma$ will be used to denote, respectively, a left and right end-marker.

Each step of the computation of the 2QCFA M involves either performing a unitary transformation or a projective measurement on its quantum register, updating the classical state, and moving the tape head. This behavior is encoded in the transition function δ. For each $(c, \gamma) \in (C \setminus \{c_{acc}, c_{rej}\}) \times \Gamma$, $\delta(c, \gamma)$ specifies the behavior of M when it is in the classical state c and the tape head currently points to a tape alphabet symbol γ. There are two forms that $\delta(c, \gamma)$ may take, depending on whether it encodes a unitary transformation or a projective measurement. In the first case, $\delta(c, \gamma)$ is a triple (t, c', h) where $t \in \mathrm{U}(|Q|)$ is a unitary transformation to be performed on the quantum register, $c' \in C$ is the new classical state, and $h \in \{-1, 0, 1\}$ specifies whether the tape head is to move left, stay put, or move right, respectively. In the second case, $\delta(c, \gamma)$ is a pair (B, f), where B is a partition of Q specifying a projective measurement, and $f : B \to C \times \{-1, 0, 1\}$ specifies the mapping from the result of that measurement to the evolution of the classical part of the machine, where, if the result of the measurement is B_r, and $f(B_r) = (c', h)$, then $c' \in C$ is the new classical state and $h \in \{-1, 0, 1\}$ specifies the movement of the tape head.

The computation of M on an input $w \in \Sigma^*$ is then defined as follows. If w has length n, then the tape will be of size $n + 2$ and contain the string $\#_L w \#_R$. Initially, the classical state is c_{start}, the quantum register is in the superposition $|q_{start}\rangle$, and the tape head points to the leftmost tape cell. At each step of the computation, if the classical state is currently c and the tape head is pointing to symbol γ, the machine behaves as specified by $\delta(c, \gamma)$. If, at some point in the computation, M enters the state c_{acc} (resp. c_{rej}) then it immediately halts and accepts (resp. rejects) the input w. As quantum measurement is a probabilistic process, the computation of M is probabilistic. For any $w \in \Sigma^*$, we write $\Pr[M \text{ accepts } w]$ (resp. $\Pr[M \text{ rejects } w]$) for the probability that M will accept (resp. reject) the input w.

Let $\mathcal{T} = \{t \in \mathrm{U}(|Q|) : \exists (c, \gamma) \in ((C \setminus \{c_{acc}, c_{rej}\}) \times \Gamma) \text{ such that } \delta(c, \gamma) = (t, \cdot, \cdot)\}$ denote the set of all unitary transformations that M may perform. The *transition amplitudes* of M are the set of numbers $\mathbb{A}$ that appear as entries of some $t \in \mathcal{T}$.

3 Distinguishing Families of Representations

The landmark result of Lipton and Zalcstein [20] showed that, if G is a finitely generated linear group over a field of characteristic zero, then $W_G \in \mathsf{L}$. The key idea behind their logspace algorithm was to make use of a carefully chosen *representation* of the group G in order to recognize W_G (see, for instance, [19] or the full version of our paper [28] for the notation and terminology from representation theory used in this section). Our 2QCFA algorithm will operate in a similar manner; however, the constraints of quantum mechanics will require us to make many modifications to their approach.

A (unitary) representation of a (topological) group G is a continuous homomorphism $\rho : G \to \mathrm{U}(\mathcal{H})$, where $\mathcal{H}$ is a Hilbert space, and $\mathrm{U}(\mathcal{H})$ is the group of unitary operators on $\mathcal{H}$. The Gel'fand-Raikov theorem states that the elements of any locally compact group G are separated by its unitary representations; i.e., $\forall g \in G$ with $g \neq 1_G$, there is some $\mathcal{H}$ and some $\rho : G \to \mathrm{U}(\mathcal{H})$ such that $\rho(g) \neq \rho(1_G)$. For certain groups, stronger statements can be made; in particular, one calls a group maximally almost periodic if the previous condition still holds when $\mathcal{H}$ is restricted to be finite-dimensional.

The core idea of our approach to recognizing the word problem W_G of a particular group G is to construct what we have chosen to call a *distinguishing family of representations* (DFR) for G, which is a refinement of the above notion. Informally, a DFR is a collection of a small number of unitary representations of G, all of which are over a Hilbert space of small dimension, such that, for any $g \in G$ other than 1_G, there is some representation ρ in the collection for which $\rho(g)$ is "far from" $\rho(1_G)$, relative to the "size" of g. The following definition formalizes this, by introducing parameters to quantify the above fuzzy notions. In this definition, and in the remainder of the paper, let $\mathrm{U}(d)$ denote the group of $d \times d$ unitary matrices, let $M(d, \mathbb{A})$ denote the set of $d \times d$ matrices with entries in some set $\mathbb{A}$, let $\mathrm{U}(d, \mathbb{A}) = \mathrm{U}(d) \cap M(d, \mathbb{A})$, and let $G_{\neq 1} = G \setminus \{1_G\}$. For a group $G = \langle S | R \rangle$, let $l(g)$ denote the length of any $g \in G$ relative to the generating set S (i.e., $l(g)$ is the minimum value of m for which $\exists g_1, \ldots, g_m \in S \cup S^{-1}$ such that $g = \phi(g_1 \cdots g_m)$). For a representation $\rho : G \to \mathrm{U}(d)$, let $\chi_\rho : G \to \mathbb{C}$ denote the *character* of ρ (i.e., $\chi_\rho(g) = \mathrm{Tr}(\rho(g))$).

▶ **Definition 16.** Consider a group $G = \langle S | R \rangle$, with S finite. For $k \in \mathbb{N}_{\geq 1}, d \in \mathbb{N}_{\geq 2}$, $\tau : \mathbb{R}_{>0} \to \mathbb{R}_{>0}$ a monotone non-increasing function, and $\mathbb{A} \subseteq \mathbb{C}$, we define a $[k, d, \tau, \mathbb{A}]$-*distinguishing family of representations* (DFR) for G to be a set $\mathcal{F} = \{\rho_1, \ldots, \rho_k\}$ where the following conditions hold.

(a) $\forall j \in \{1, \ldots, k\}$, $\rho_j : G \to \mathrm{U}(d)$ is a representation of G.

(b) $\forall g \in G_{\neq 1}$, $\exists j \in \{1, \ldots, k\}$ such that $|\chi_{\rho_j}(g)| \leq d - \tau(l(g))$.

(c) $\forall \sigma \in S \cup S^{-1}, \forall j \in \{1, \ldots, k\}$, $\exists Y_1, \ldots, Y_t \in \mathrm{U}(d, \mathbb{A})$, such that $\rho_j(\sigma) = \prod_i Y_i$.

Suppose $\mathcal{F} = \{\rho_1, \ldots, \rho_k\}$ is a $[k, d, \tau, \mathbb{A}]$-DFR for $G = \langle S|R\rangle$. We write $I_d = 1_{\mathrm{U}(d)} \in \mathrm{U}(d)$ for the $d \times d$ identity matrix, $\ker(\rho_j) = \{g \in G : \rho_j(g) = I_d\}$ for the kernel of ρ_j, $Z(\mathrm{U}(d)) = \{e^{ir} I_d : r \in \mathbb{R}\}$ for the center of $\mathrm{U}(d)$, and $\mathrm{Pker}(\rho_j) = \{g \in G : \rho_j(g) = Z(\mathrm{U}(d))\}$ for the quasikernel of ρ_j. Clearly, $1_G \in \mathrm{Pker}(\rho_j), \forall j$, but, as ρ_j is not assumed to be P-faithful or even faithful, there may be $g \in G_{\neq 1}$ for which, for certain j, we have $g \in \mathrm{Pker}(\rho_j)$. However, due to the fact that $g \in \mathrm{Pker}(\rho_j)$ exactly when $|\chi_{\rho_j}(g)| = d$, the second defining property of a DFR guarantees not only that $\bigcap_j \mathrm{Pker}(\rho_j) = \{1_G\}$, but, much more strongly, that all $g \in G_{\neq 1}$ are "far from" being in $\bigcap_j \mathrm{Pker}(\rho_j)$. That is to say, $\forall g \in G_{\neq 1}, \exists j$ such that $|\chi_{\rho_j}(g)|$ is at distance at least $\tau(l(g))$ from having value d. The following proposition is then immediate, but we explicitly state it as it is the central notion in our quantum approach to the word problem.

▶ **Proposition 17.** *Suppose $G = \langle S|R\rangle$ has a $[k, d, \tau, \mathbb{A}]$-DFR $\mathcal{F} = \{\rho_1, \ldots, \rho_k\}$. Then, $\forall g \in G$, $g = 1_G \Leftrightarrow \forall j,\ |\chi_{\rho_j}(g)| = d$ and $g \in G_{\neq 1} \Leftrightarrow \exists j$ such that $|\chi_{\rho_j}(g)| \leq d - \tau(l(g))$.*

Note that, in the preceding proposition, $\rho_1 \oplus \cdots \oplus \rho_k : G \to \mathrm{U}(kd)$ is simply a faithful representation of G, decomposed into subrepresentations in a convenient way. Next, we establish some terminology that will better allow us to describe particular types of DFR.

▶ **Definition 18.** Suppose $\mathcal{F} = \{\rho_1, \ldots, \rho_k\}$ is a $[k, d, \tau, \mathbb{A}]$-DFR for a group G.

(a) If $\mathbb{A} = \overline{\mathbb{Q}}$ (equivalently, if $\rho_j(G) \subseteq \mathrm{U}(d, \overline{\mathbb{Q}}), \forall j$), we say $\mathcal{F}$ is an *algebraic* DFR.

(b) If $\rho_j(g)$ is a diagonal matrix $\forall j, \forall g$, then we say $\mathcal{F}$ is a *diagonal* DFR.

(c) If H is a finite-index overgroup of G, we say that H *virtually* has a $[k, d, \tau, \mathbb{A}]$-DFR.

When $\mathcal{F}$ is an algebraic DFR, we will often only write $[k, d, \tau]$ to denote its parameters. Note that only abelian groups have diagonal DFRs, and any DFR of an abelian group can be converted to a diagonal DFR; we define diagonal DFRs for convenience.

Using a $[k, d, \tau, \mathbb{A}]$-DFR for a group G, it will be possible to construct a 2QCFA that recognizes the word problem W_H of any finite-index overgroup H of G, where the parameters of the DFR will strongly impact the parameters of the resulting 2QCFA. In particular, in Section 4, we produce a 2QCFA with d quantum states and transition amplitudes in $\mathbb{A}$ that recognizes W_H, with expected running time approximately $O(\tau(n)^{-1})$. The goal is then to show that a wide collection of groups virtually have DFRs with good parameters.

3.1 Diophantine Approximation

Our constructions of DFRs rely crucially on certain results concerning Diophantine approximation. Most fundamentally, the Diophantine approximation question asks how well a particular real number α can be approximated by rational numbers. Of course, as $\mathbb{Q}$ is dense in $\mathbb{R}$, one can choose $\frac{p}{q} \in \mathbb{Q}$ so as to make the quantity $|\alpha - \frac{p}{q}|$ arbitrarily small; for this reason, one considers $\frac{p}{q}$ to be a "good" approximation to α only when $|\alpha - \frac{p}{q}|$ is small compared to a suitable function of q. One then considers α to be poorly approximated by rationals if, for some "small" constant $d \in \mathbb{R}_{\geq 2}$, $\exists C \in \mathbb{R}_{>0}$ such that, $\forall (p, q) \in \mathbb{Z} \times \mathbb{Z}_{\neq 0}$, we have $|\alpha - \frac{p}{q}| \geq C|q|^{-d}$, where the smallness of d determines just how poorly approximable α is. For $\alpha \in \mathbb{R}$, let $\|\alpha\| = \min_{m \in \mathbb{Z}} |\alpha - m|$ denote the distance between α and its nearest integer. Notice that $\left|\alpha - \frac{p}{q}\right| \geq C|q|^{-d}$, $\forall (p, q) \in \mathbb{Z} \times \mathbb{Z}_{\neq 0} \Leftrightarrow \|q\alpha\| \geq C|q|^{-(d-1)}$, $\forall q \in \mathbb{Z}_{\neq 0}$. Of particular relevance to us is the following result, due to Schmidt [30], that real irrational algebraic numbers are poorly approximated by rationals.

▶ **Proposition 19** ([30])**.** *$\forall \alpha_1, \ldots, \alpha_k \in (\mathbb{R} \cap \overline{\mathbb{Q}})$ where $1, \alpha_1, \ldots, \alpha_k$ are linearly independent over $\mathbb{Q}$, $\forall \epsilon \in \mathbb{R}_{>0}$, $\exists C \in \mathbb{R}_{>0}$ such that $\forall q \in \mathbb{Z}_{\neq 0}$, $\exists j$ such that $\|q\alpha_j\| \geq C|q|^{-(\frac{1}{k}+\epsilon)}$.*

We also require the following result concerning the Diophantine properties of linear forms in logarithms of algebraic numbers, due to Baker [4].

▶ **Proposition 20** ([4]). *Let $L = \{\beta \in \mathbb{C}_{\neq 0} : e^{\beta} \in \overline{\mathbb{Q}}\}$. $\forall \beta_1, \dots, \beta_k \in L$ that are linearly independent over $\mathbb{Q}$, $\exists C \in \mathbb{R}_{>0}$ such that, $\forall (q_1, \dots, q_k) \in \mathbb{Z}^k$ with $q_{max} := \max_j |q_j| > 0$, we have $|q_1\beta_1 + \cdots + q_k\beta_k| \geq (eq_{max})^{-C}$.*

Gamburd, Jakobson, and Sarnak [12] established a particular result concerning the Diophantine properties of $\mathrm{SU}(2, \overline{\mathbb{Q}})$. The following lemma generalizes their result to $\mathrm{U}(d, \overline{\mathbb{Q}})$; a proof of this lemma appears in the full version [28].

▶ **Lemma 21.** *Consider a group $G = \langle S|R \rangle$, with S finite, and a representation $\rho : G \to \mathrm{U}(d, \overline{\mathbb{Q}})$. Then $\exists C \in \mathbb{R}_{\geq 1}$ such that $|\chi_\rho(g)| \leq d - C^{-l(g)}$, $\forall g \in (G \setminus \mathrm{Pker}(\rho))$.*

3.2 Constructions of DFRs

We now show that a wide collection of groups virtually have DFRs with good parameters. We accomplish this by first constructing DFRs for only a small family of special groups. We then present several constructions in which a DFR for a group, or more generally a family of DFRs for a family of groups, is used to produce a DFR for a related group.

We begin with a straightforward lemma expressing a useful character bound. In this lemma, and throughout this section, we continue to write group operations multiplicatively, and so, for $g \in G$ and $h \in \mathbb{Z}$, if $h > 0$ (resp. $h < 0$) then g^h denotes the element of G obtained by combining h copies of g (resp. g^{-1}) with the group operation, and if $h = 0$ then $g^h = 1_G$. Let $S_1 = \{e^{ir} : r \in \mathbb{R}\} \subseteq \mathbb{C}^*$ denote the circle group and let $\mathrm{T}(d) \subseteq \mathrm{U}(d)$ denote the group of all $d \times d$ diagonal matrices where each diagonal entry lies in S_1. For $\mathbb{A} \subseteq \mathbb{C}$, let $S_1(\mathbb{A}) = S_1 \cap \mathbb{A}$ and $\mathrm{T}(d, \mathbb{A}) = \mathrm{T}(d) \cap M(d, \mathbb{A})$. Let $\mathbf{1}_d : G \to \mathrm{U}(d)$ denote the trivial representation of dimension d (i.e., $\mathbf{1}_d(g) = I_d = 1_{\mathrm{U}(d)}$, $\forall g \in G$). For a cyclic group $G = \langle a|R_G \rangle$ and for some $r \in \mathbb{R}$, define the representation $\widehat{\gamma}_r : G \to S_1 \cong \mathrm{U}(1)$ such that $a \mapsto e^{2\pi i r}$; furthermore, define the representation $\gamma_r : G \to \mathrm{T}(2)$ by $\gamma_r = \widehat{\gamma}_r \oplus \mathbf{1}_1$.

▶ **Lemma 22.** *Consider the cyclic group $G = \langle a|R_G \rangle$. Fix $r \in \mathbb{R}$ and define $\gamma_r : G \to \mathrm{T}(2)$ as above. Suppose that $h \in \mathbb{Z}$ and $\epsilon \in \mathbb{R}_{>0}$ satisfy $\|hr\| \geq \epsilon$. Then $\chi_{\gamma_r}(a^h) \leq 2 - \frac{19\pi^2}{24}\epsilon^2$.*

Proof. We have $\chi_{\gamma_r}(a^h) = e^{2\pi i h r} + 1 = 2e^{\pi i h r}\cos(\pi h r)$. Clearly, $\epsilon \leq \frac{1}{2}$. Therefore,

$$|\chi_{\gamma_r}(a^h)| = 2|\cos(\pi h r)| \leq 2\cos(\pi\epsilon) \leq 2\left(1 - \frac{(\pi\epsilon)^2}{2} + \frac{(\pi\epsilon)^4}{24}\right) \leq 2 - \frac{19\pi^2}{24}\epsilon^2.$$ ◀

We first construct DFRs for a very narrow class of special groups: (i) $\mathbb{Z}_m = \langle a|a^m \rangle$, the integers modulo m, where the group operation is addition, (ii) $\mathbb{Z} = \langle a| \rangle$, the integers, where the group operations is addition, and (iii) $F_2 = \langle a, b| \rangle$ the (non-abelian) free group of rank 2.

▶ **Lemma 23.** *$\mathbb{Z}_m = \langle a|a^m \rangle$ has a diagonal algebraic $\left[1, 2, \frac{19\pi^2}{24m^2}\right]$-DFR, $\forall m \in \mathbb{N}_{\geq 2}$.*

Proof. Fix $m \in \mathbb{N}_{\geq 2}$ and let $r = \frac{1}{m}$. Define $\gamma_r : \mathbb{Z}_m \to \mathrm{T}(2)$ as above, and notice that $\gamma_r(\mathbb{Z}_m) \subseteq \mathrm{T}(2, \overline{\mathbb{Q}})$. Consider any $q \in \mathbb{Z}_m$, where $q \not\equiv 0 \mod m$. Then q can be expressed as $q = a^h$, for $h \in \mathbb{Z}$, $h \not\equiv 0 \mod m$. As $\|hr\| \geq \frac{1}{m}$, Lemma 22 implies $|\chi_{\gamma_r}(q)| \leq 2 - \frac{19\pi^2}{24m^2}$. Therefore, $\{\gamma_r\}$ is a diagonal algebraic DFR for $\mathbb{Z}_m$, with the desired parameters. ◀

▶ **Lemma 24.** *$\forall \delta \in \mathbb{R}_{>0}, \exists C \in \mathbb{R}_{>0}$, $\mathbb{Z} = \langle a| \rangle$ has a diagonal $[1 + \lfloor \frac{2}{\delta} \rfloor, 2, Cn^{-\delta}, \widetilde{\mathbb{C}}]$-DFR.*

Proof. Let $k = 1+\lfloor\frac{2}{\delta}\rfloor$ and $\eta = \frac{\delta}{2}-\frac{1}{k} > 0$. Fix $\alpha_1, \ldots, \alpha_k \in (\overline{\mathbb{Q}}\cap\mathbb{R})$ such that $1, \alpha_1, \ldots, \alpha_k$ are linearly independent over $\mathbb{Q}$. For each $j \in \{1, \ldots, k\}$ define the representation $\gamma_{\alpha_j} : \mathbb{Z} \to \mathrm{T}(2)$ as above, and notice that $\gamma_{\alpha_j}(\mathbb{Z}) \subseteq \mathrm{T}(2, \widetilde{\mathbb{C}})$. By Proposition 19, $\exists D \in \mathbb{R}_{>0}$, such that $\forall q \in \mathbb{Z}_{\neq 0}$ (i.e., $\forall q \in \mathbb{Z}$ where $q \neq 0 = 1_{\mathbb{Z}}$), $\exists j$ such that $\|q\alpha_j\| \geq D|q|^{-(\frac{1}{k}+\eta)} = D|q|^{-\frac{\delta}{2}}$. Therefore, for any $q \in \mathbb{Z}_{\neq 0}$, if we take j as above, then by Lemma 22 (with $r = \alpha_j$, $\epsilon = D|q|^{-\frac{\delta}{2}}$, and $h = q$) we have $|\chi_{\gamma_{\alpha_j}}(q)| \leq 2 - \frac{19\pi^2}{24}D^2|q|^{-\delta}$. Therefore, $\{\gamma_{\alpha_1}, \ldots, \gamma_{\alpha_k}\}$ is a diagonal $[1 + \lfloor\frac{2}{\delta}\rfloor, 2, \frac{19\pi^2}{24}D^2 n^{-\delta}, \widetilde{\mathbb{C}}]$-DFR for $\mathbb{Z}$. ◀

▶ **Lemma 25.** *$\exists C_1, C_2 \in \mathbb{R}_{>0}$ such that $\mathbb{Z} = \langle a|\rangle$ has a diagonal algebraic $[1, 2, C_2 n^{-C_1}]$-DFR.*

Proof. As in Proposition 20, let $L = \{\beta \in \mathbb{C}_{\neq 0} : e^{\beta} \in \overline{\mathbb{Q}}\}$ and notice that $\pi i \in L$. Let $R = \{r \in ((\mathbb{R} \setminus \mathbb{Q}) \cap (0, 1)) : 2\pi i r \in L\}$ (e.g., $\hat{r} = \frac{1}{2\pi}\cos^{-1}\left(\frac{3}{5}\right)$ is irrational and has $e^{2\pi i\hat{r}} = \frac{3+4i}{5}$, and so $\hat{r} \in R$). Fix $r \in R$. By definition, $2\pi i r \in L$, which immediately implies $\pi i r \in L$. Also by definition, $r \notin \mathbb{Q}$, which implies $\pi i r$ and πi are linearly independent over $\mathbb{Q}$. Therefore, by Proposition 20, $\exists D \in \mathbb{R}_{>0}$ such that $\forall (q, m) \in \mathbb{Z}^2$ where $q_{max} := \max(|q|, |m|) > 0$, we have $|q\pi i r - m\pi i| \geq (eq_{max})^{-D}$.

For fixed $q \in \mathbb{Z}_{\neq 0}$ and varying $m \in \mathbb{Z}$, $|q\pi i r - m\pi i|$ attains its minimum when $m = \mathrm{round}(qr)$, the closest integer to qr. Notice that $|\mathrm{round}(qr)| \leq |q|$, as $r \in (0, 1)$ and $q \in \mathbb{Z}$. Therefore, for any $q \in \mathbb{Z}_{\neq 0}$, we have

$$\|qr\| = \min_{m\in\mathbb{Z}}|qr - m| = \frac{1}{\pi}\min_{m\in\mathbb{Z}}|q\pi i r - m\pi i| = \frac{1}{\pi}|q\pi i r - \mathrm{round}(qr)\pi i| \geq \frac{1}{\pi}|eq|^{-D}.$$

Define $\gamma_r : \mathbb{Z} \to \mathrm{T}(2)$ as above. By Lemma 22, $|\chi_{\gamma_r}(q)| \leq 2 - \frac{19}{24}|eq|^{-2D}$. Clearly, $\gamma_r(\mathbb{Z}) \subseteq \mathrm{T}(2, \overline{\mathbb{Q}})$. Therefore, $\{\gamma_r\}$ is a diagonal algebraic $[1, 2, \frac{19}{24}e^{-2D}n^{-2D}]$-DFR for $\mathbb{Z}$. ◀

▶ Remark 26. We note that the above constructions of DFRs for $\mathbb{Z}$ are quite similar to the technique used by Ambainis and Watrous [1] to produce a 2QCFA that recognizes L_{eq} (cf. [6, 25]). In particular, their approach relied on the fact that the number $\sqrt{2} \in \overline{\mathbb{Q}}$ is poorly approximated by rationals; our constructions make use of more general Diophantine approximation results. This allows us to produce 2QCFA with improved parameters.

▶ **Lemma 27.** *$\exists C \in \mathbb{R}_{\geq 1}$, such that $F_2 = \langle a, b|\rangle$ has an algebraic $[1, 2, C^{-n}]$-DFR.*

Proof. First, define the representation $\pi : F_2 \to SO(3, \mathbb{Q})$ by

$$a \mapsto \frac{1}{5}\begin{pmatrix} 3 & -4 & 0 \\ 4 & 3 & 0 \\ 0 & 0 & 5 \end{pmatrix} \text{ and } b \mapsto \frac{1}{5}\begin{pmatrix} 5 & 0 & 0 \\ 0 & 3 & -4 \\ 0 & 4 & 3 \end{pmatrix}.$$

This is the “standard” faithful representation of F_2 into SO(3) used in many treatments of the Banach-Tarski paradox. Recall that SU(2) is the double cover of SO(3), i.e., $\mathrm{SU}(2)/Z(\mathrm{SU}(2)) \cong \mathrm{SO}(3)$. Then π induces a homomorphism $\widehat{\pi} : F_2 \to \mathrm{SU}(2)/Z(\mathrm{SU}(2))$ in the obvious way, which, by the universal property of the free group, can be lifted to the representation $\rho : F_2 \to \mathrm{SU}(2, \overline{\mathbb{Q}})$ given by

$$a \mapsto \frac{1}{\sqrt{5}}\begin{pmatrix} 2+i & 0 \\ 0 & 2-i \end{pmatrix} \text{ and } b \mapsto \frac{1}{\sqrt{5}}\begin{pmatrix} 2 & i \\ i & 2 \end{pmatrix}.$$

As π is faithful, we conclude that $\rho(g) \notin Z(\mathrm{SU}(2))$, $\forall g \in (F_2 \setminus 1_{F_2})$. Therefore, by Lemma 21, $\{\rho\}$ is an algebraic $[1, 2, C^{-n}]$-DFR for F_2. ◀

▶ Remark 28. Note that the proof of the preceding lemma uses, fundamentally, the same construction used by Ambainis and Watrous [1] to produce a 2QCFA for L_{pal} (which is closely related to F_2). The algebraic structure of F_2 allows a substantially simpler argument.

We now present several constructions of new DFRs from existing DFRs. We emphasize that all results in the following lemmas are constructive in the sense that, given the supposed DFR or collection of DFRs, each corresponding proof provides an explicit construction of the new DFR. Due to space restrictions, all proofs are omitted and may be found in the full version [28]. We begin by considering conversions of a DFR of a group G to a DFR with different parameters of the same group G. For $C \in \mathbb{R}_{>0}$, let $\eta_C : \mathbb{R}_{>0} \to \mathbb{R}_{>0}$ be given by $\eta_C(n) = Cn$.

▶ **Lemma 29.** *Suppose $\mathcal{F}$ is a $[k, d, \tau, \mathbb{A}]$-DFR for a group $G = \langle S|R\rangle$, with S finite. The following statements hold.*

(i) *G has a $[1, kd, \tau, \mathbb{A}]$-DFR.*

(ii) *If $d' \in \mathbb{N}$ and $d' > d$, then G has a $[k, d', \tau, \mathbb{A}]$-DFR.*

(iii) *Suppose G also has presentation $\langle S'|R'\rangle$, with S' finite. Then $\exists C \in \mathbb{R}_{>0}$ such that $\mathcal{F}$ is also a $[k, d, \tau \circ \eta_C, \mathbb{A}]$-DFR for $G = \langle S'|R'\rangle$.*

Moreover, if $\mathcal{F}$ is a diagonal DFR, then each newly constructed DFR is also diagonal.

Next, we show that a DFR of G and a DFR of H can be used to produce a DFR of $G \times H$, the direct product of G and H. In the following, for a group Q, let $[q_1, q_2] = q_1^{-1}q_2^{-1}q_1q_2$ denote the commutator of elements $q_1, q_2 \in Q$. For functions $\tau, \tau' : \mathbb{R}_{>0} \to \mathbb{R}_{>0}$, we define the function $\tau^{\min}_{\tau,\tau'} : \mathbb{R}_{>0} \to \mathbb{R}_{>0}$ by $\tau^{\min}_{\tau,\tau'}(n) := \min(\tau(n), \tau'(n))$, $\forall n \in \mathbb{R}_{>0}$.

▶ **Lemma 30.** *Consider groups $G = \langle S_G|R_G\rangle$ and $H = \langle S_H|R_H\rangle$, with S_G and S_H finite, and $S_G \cap S_H = \emptyset$. Let $R_{com} = \{[g, h] : g \in S_G, h \in S_H\}$. If G has a $[k, d, \tau, \mathbb{A}]$-DFR and H has a $[k', d', \tau', \mathbb{A}]$-DFR, then $G\times H = \langle S_G \sqcup S_H|R_G \cup R_H \cup R_{com}\rangle$ has a $[k+k', \max(d, d'), \tau^{\min}_{\tau,\tau'}, \mathbb{A}]$-DFR. Moreover, if G and H have diagonal DFRs with the above parameters, then $G \times H$ has a diagonal DFR with the above parameters.*

Now, we show that a DFR of a group G can be used to produce a DFR of a finitely generated subgroup of G, or of a finite-index overgroup of G.

▶ **Lemma 31.** *Suppose $\mathcal{F}_G$ is a $[k, d, \tau, \mathbb{A}]$-DFR for a group $G = \langle S_G|R_G\rangle$, with S_G finite. The following statements hold.*

(i) *Suppose $H \leq G$, where $H = \langle S_H|R_H\rangle$, with S_H finite. Then $\exists C \in \mathbb{R}_{>0}$ such that H has a $[k, d, \tau \circ \eta_C, \mathbb{A}]$-DFR. If, moreover, $\mathcal{F}_G$ is a diagonal DFR, then H will also have a diagonal DFR with the claimed parameters.*

(ii) *Suppose $G \leq Q$, where $Q = \langle S_Q|R_Q\rangle$, with S_Q finite, $S_G \subseteq S_Q$, and $r := [Q : G]$ finite. Then $\exists C \in \mathbb{R}_{>0}$ such that Q has a $[k, dr, \tau \circ \eta_C, \mathbb{A}]$-DFR.*

▶ Remark 32. By the preceding lemma, any group G that virtually has a DFR also has a DFR, but with worse parameters. As will be shown, it is possible to recognize W_G using a DFR for a finite-index subgroup of G, thereby avoiding this worsening of parameters.

We now construct DFRs, with good parameters, for a wide class of groups. Recall that any finitely generated abelian group G admits a unique decomposition $G \cong \mathbb{Z}^r \times \mathbb{Z}_{m_1} \times \cdots \times \mathbb{Z}_{m_t}$, where m_i divides m_{i+1}, $\forall i \in \{1, \ldots, t-1\}$, and each $m_i \in \mathbb{N}_{\geq 2}$. Let $R(r, m_1, \ldots, m_t) = \{a_i^{m_i} : i \in \{1, \ldots, t\}\} \cup \{[a_i, a_j] : i, j \in \{1, \ldots, r+t\}\}$.

▶ **Lemma 33.** *Consider the finite (hence finitely generated) abelian group $G = \mathbb{Z}_{m_1} \times \cdots \times \mathbb{Z}_{m_t} = \langle a_1, \ldots, a_t|R(0, m_1, \ldots, m_t)\rangle$. If $t = 0$ (i.e., G is the trivial group), then G has a diagonal algebraic $[1, 2, 2]$-DFR. Otherwise, G has a diagonal algebraic $\left[t, 2, \frac{19\pi^2}{24m_t^2}\right]$-DFR.*

Proof. If $t = 0$, the claim is obvious. Suppose $t > 0$. By Lemma 23, each factor $\mathbb{Z}_{m_i} = \langle a | a^{m_i} \rangle$ has a diagonal algebraic $\left[1, 2, \frac{19\pi^2}{24m_i^2}\right]$-DFR. Notice that $m_1 \leq \cdots \leq m_t$, as each m_i divides m_{i+1}. The existence of the desired DFR follows from Lemma 30. ◀

▶ **Theorem 34.** *$\exists C_1 \in \mathbb{R}_{>0}$ such that, for any finitely generated abelian group $G = \mathbb{Z}^r \times \mathbb{Z}_{m_1} \times \cdots \times \mathbb{Z}_{m_t} = \langle a_1, \ldots, a_{r+t} | R(r, m_1, \ldots, m_t) \rangle$, the following statements hold.*

(i) *$\exists C_2 \in \mathbb{R}_{>0}$ such that G has a diagonal algebraic $\left[r + t, 2, C_2 n^{-C_1}\right]$-DFR.*

(ii) *$\forall \delta \in \mathbb{R}_{>0}$, $\exists C_3 \in \mathbb{R}_{>0}$, such that G has a diagonal $\left[r\left(1 + \lfloor \frac{2}{\delta} \rfloor\right) + t, 2, C_3 n^{-\delta}, \widetilde{\mathbb{C}}\right]$-DFR.*

Proof. By Lemma 25, $\exists D_1, D_2 \in \mathbb{R}_{>0}$ such that $\mathbb{Z}$ has a diagonal algebraic $[1, 2, D_2 n^{-D_1}]$-DFR, which we call $\mathcal{F}$. We set $C_1 = D_1$. Let $H_1 = \mathbb{Z}^r$ and $H_2 = \mathbb{Z}_{m_1} \times \cdots \times \mathbb{Z}_{m_t}$. If $r = 0$, both claims follow trivially from Lemma 33. Suppose $r > 0$.

(i) Using the DFR $\mathcal{F}$ of $\mathbb{Z}$, Lemma 30 implies H_1 has a diagonal algebraic $[r, 2, D_2 n^{-C_1}]$-DFR $\mathcal{H}_1$. If $t = 0$, then $G = H_1$; therefore, $\mathcal{H}_1$ is the desired DFR for G, with $C_2 = D_2$, and we are done. If $t > 0$, Lemma 33 implies H_2 has a diagonal algebraic $\left[1, 2, \frac{19\pi^2}{24m_t^2}\right]$-DFR $\mathcal{H}_2$. Set $C_2 = \min(D_2, \frac{19\pi^2}{24m_t^2})$. By Lemma 30, we conclude $G = H_1 \times H_2$ has a DFR with the claimed parameters.

(ii) By Lemma 24, $\exists D \in \mathbb{R}_{>0}$ such that $\mathbb{Z}$ has a diagonal $\left[1 + \lfloor \frac{2}{\delta} \rfloor, 2, D n^{-\delta}, \widetilde{\mathbb{C}}\right]$-DFR, $\mathcal{F}'$. The remainder of the proof is analogous to that of part (i), using $\mathcal{F}'$ in place of $\mathcal{F}$. ◀

As in Section 1.1, $\widehat{\Pi}_1$ denotes the set of all finitely generated virtually abelian groups. For $G \in \widehat{\Pi}_1$, there is a unique $r \in \mathbb{N}$ such that G is virtually $\mathbb{Z}^r$. We have the following corollary.

▶ **Corollary 35.** *$\exists C \in \mathbb{R}_{>0}$ such that, $\forall G \in \widehat{\Pi}_1$, the following holds.*

(i) *$\exists D \in \mathbb{R}_{>0}, \exists K \in \mathbb{N}_{\geq 1}$, such that G virtually has a diagonal algebraic $[K, 2, D n^{-C}]$-DFR.*

(ii) *$\forall \delta \in \mathbb{R}_{>0}$, $\exists D \in \mathbb{R}_{>0}, \exists K \in \mathbb{N}_{\geq 1}$, G virtually has a diagonal $\left[K, 2, D n^{-\delta}, \widetilde{\mathbb{C}}\right]$-DFR.*

Next, we consider groups that can be built from finitely generated free groups.

▶ **Lemma 36.** *$\forall r \in \mathbb{N}$, $\exists C \in \mathbb{R}_{\geq 1}$, $F_r = \langle a_1, \ldots, a_r | \rangle$ has an algebraic $[1, 2, C^{-n}]$-DFR.*

Proof. As $F_0 = \{1\}$ and $F_1 = \mathbb{Z}$, Theorem 34 immediately implies the claim when $r \in \{0, 1\}$. Next, consider the case in which $r = 2$. By Lemma 27, $\exists C \in \mathbb{R}_{\geq 1}$ such that $F_2 = \langle a_1, a_2 | \rangle$ has an algebraic $[1, 2, C^{-n}]$-DFR. Finally, suppose $r > 2$. By the Nielsen-Schreier theorem, F_2 has a finite-index subgroup isomorphic to F_r; the claim immediately follows from Lemma 31(i). ◀

▶ **Theorem 37.** *Suppose $G = \langle S | R \rangle$, with S finite, such that $G \leq F_{r_1} \times \cdots \times F_{r_t}$, for some $r_1, \ldots, r_t \in \mathbb{N}$. Then $\exists C \in \mathbb{R}_{\geq 1}$ such that G has an algebraic $[t, 2, C^{-n}]$-DFR.*

Proof. By Lemma 36, each F_{r_i} has an algebraic $[1, 2, C_i^{-n}]$-DFR, for some $C_i \in \mathbb{R}_{\geq 1}$. Lemma 30 implies that $F_{r_1} \times \cdots \times F_{r_t}$ has an algebraic $[t, 2, C^{-n}]$-DFR, where $C = \max_i C_i$, and Lemma 31(i) then implies G has a DFR with the claimed parameters. ◀

As in Section 1.1, $\widehat{\Pi}_2$ denotes the class of finitely generated groups that are virtually a subgroup of a direct product of finitely-many finite-rank free groups.

▶ **Corollary 38.** *$\forall G \in \widehat{\Pi}_2, \exists K \in \mathbb{N}_{\geq 1}, \exists C \in \mathbb{R}_{\geq 1}$, such that G virtually has an algebraic $[K, 2, C^{-n}]$-DFR.*

We conclude with a "generic" construction that covers all groups that have algebraic DFRs. We remark that while this does partially subsume all other results in this section, it does not do so completely, as the earlier constructions of DFRs, for certain particular groups, yield better parameters.

▶ **Theorem 39.** *Consider a group $G = \langle S|R \rangle$, with S finite, where G is not the trivial group. Suppose G has a faithful representation $\pi : G \to \mathrm{U}(l, \overline{\mathbb{Q}})$. Then π has a (unique, up to isomorphism) set of irreducible subrepresentations $\{\pi_j : G \to \mathrm{U}(d_j, \overline{\mathbb{Q}})\}_{j=1}^{m}$ such that $\pi \cong \pi_1 \oplus \cdots \oplus \pi_m$. Let $d_{\max} = \max_j d_j$. Define the value d as follows: if $\bigcap_j \mathrm{Pker}(\pi_j) = \{1_G\}$, let $d = d_{\max}$, otherwise, let $d = d_{\max} + 1$. Partition the non-trivial π_j into isomorphism classes (i.e., only consider those π_j which are not the trivial representation; π_{j_1} and π_{j_2} belong to the same isomorphism class if $\pi_{j_1} \cong \pi_{j_2}$) and let k denote the number of isomorphism classes that appear. Then $\exists C \in \mathbb{R}_{\geq 1}$ such that G has an algebraic $[k, d, C^{-n}]$-DFR.*

Proof. Notice that, as G is not the trivial group, $d \geq 2$. Assume that the π_j are ordered such that $\pi_1, \ldots, \pi_k$ are representatives of the k distinct isomorphism classes of the non-trivial representations that appear among the π_j. For each $j \in \{1, \ldots, k\}$, define the representation $\rho_j = \pi_j \oplus \mathbf{1}_{d-d_j} : G \to \mathrm{U}(d, \overline{\mathbb{Q}})$. By Lemma 21, $\forall j \in \{1, \ldots, k\}, \exists C_j \in \mathbb{R}_{\geq 1}$ such that, $\forall g \notin \mathrm{Pker}(\rho_j)$, $|\chi_{\rho_j}(g)| \leq d - C_j^{-l(g)}$. Set $C = \max_j C_j$.

Next, notice that $\bigcap_j \mathrm{Pker}(\rho_j) = \{1_G\}$. If $\bigcap_j \mathrm{Pker}(\pi_j) = \{1_G\}$, then this is obvious. Suppose $\bigcap_j \mathrm{Pker}(\pi_j) \neq \{1_G\}$. Then $d = d_{\max} + 1 > d_j$, $\forall j$, which implies $\rho_j = \pi_j \oplus \mathbf{1}_{t_j}$, where $t_j := d - d_j \geq 1$. Therefore, for each j, $\rho_j(G) \cap Z(\mathrm{U}(d, \overline{\mathbb{Q}})) = I_d$, and so, by definition, $\mathrm{Pker}(\rho_j) = \ker(\rho_j)$. As π is faithful, $\{1_G\} = \bigcap_{j=1}^{m} \ker(\pi_j) = \bigcap_{j=1}^{k} \ker(\rho_j) = \bigcap_{j=1}^{k} \mathrm{Pker}(\rho_j)$.

Thus, $\forall g \in G_{\neq 1}$, $\exists j$ such that $g \notin \mathrm{Pker}(\rho_j)$, which implies $|\chi_{\rho_j}(g)| \leq d - C_j^{-l(g)} \leq d - C^{-l(g)}$. Therefore, $\{\rho_1, \ldots, \rho_k\}$ is an algebraic $[k, d, C^{-n}]$-DFR for G. ◀

3.3 Projective DFRs

A DFR $\mathcal{F} = \{\rho_1, \ldots, \rho_j\}$ of a group G is a set of unitary representations of G, i.e., group homomorphisms $\rho_j : G \to \mathrm{U}(d)$. We next consider a slight generalization. A *projective* unitary representation of G is a group homomorphism $\rho : G \to \mathrm{PU}(d) = \mathrm{U}(d)/Z(\mathrm{U}(d))$. We may (non-uniquely) lift any such ρ to a function $\widehat{\rho} : G \to \mathrm{U}(d)$ (i.e., $\gamma \circ \widehat{\rho} = \rho$, where $\gamma : \mathrm{U}(d) \to \mathrm{PU}(d)$ is the canonical projection). Note that $\widehat{\rho}$ is not necessarily a group homomorphism and that certain projective representations ρ cannot be lifted to an ordinary representation. However, for any two lifts, $\widehat{\rho}_1$ and $\widehat{\rho}_2$, of ρ, we have $|\chi_{\widehat{\rho}_1}(g)| = |\chi_{\widehat{\rho}_2}(g)|$, $\forall g \in G$. Therefore, the function $|\chi_\rho(\cdot)| : G \to \mathbb{R}$ given by $|\chi_\rho(g)| = |\chi_{\widehat{\rho}}(g)|$ is well-defined.

We then define a $[k, d, \tau, \mathbb{A}]$-PDFR as a set of projective representations $\mathcal{F} = \{\rho_1, \ldots, \rho_j\}$ that satisfies Definition 16 where "representation" is replaced by "projective representation" in that definition. As we will observe in the following section, the same process that allows a DFR for a group G to be used to produce a 2QCFA for the word problem W_G, can also be applied to a PDFR. If a PDFR consists entirely of representations into $\mathrm{PU}(d, \overline{\mathbb{Q}}) = \mathrm{U}(d, \overline{\mathbb{Q}})/Z(\mathrm{U}(d, \overline{\mathbb{Q}}))$, we say it is an *algebraic* PDFR. The following variant of Theorem 39 follows by a precisely analogous proof.

▶ **Theorem 40.** *Suppose the group $G = \langle S|R \rangle$, with S finite, has a family $\mathcal{F} = \{\rho_1, \ldots, \rho_k\}$ of projective representations $\rho_j : G \to \mathrm{PU}(d, \overline{\mathbb{Q}})$, such that $\bigcap_j \ker(\rho_j) = \{1_G\}$. Then $\exists C \in \mathbb{R}_{\geq 1}$ such that $\mathcal{F}$ is an algebraic $[k, d, C^{-n}]$-PDFR for G.*

3.4 Unbounded-Error DFRs

If $\mathcal{F} = \{\rho_1, \ldots, \rho_k\}$ is a DFR for a group G, then $\bigcap_j \mathrm{Pker}(\rho_j) = \{1_G\}$. However, a crucial element in the definition of a DFR is the requirement that, much more strongly, all $g \in G_{\neq 1}$ are "far" from being in $\bigcap_j \mathrm{Pker}(\rho_j)$; in particular, if $\mathcal{F}$ is a $[k, d, \tau, \mathbb{A}]$-DFR, then $\forall g \in G_{\neq 1}, \exists j$ such that $|\chi_{\rho_j}(g)| \leq d - \tau(l(g))$. This requirement is essential in order for our construction of a 2QCFA, that recognizes W_G using a DFR for G, to operate with *bounded* error. We next consider a generalization of a DFR, where this requirement is removed, which will then yield a 2QCFA that recognizes W_G with *unbounded* error.

We say $\mathcal{F} = \{\rho_1, \dots, \rho_k\}$ is an *unbounded-error* $[k, d, \mathbb{A}]$-DFR for a group $G = \langle S|R \rangle$ if the conditions of Definition 16 hold, where Definition 16(b) is replaced by Definition 16(b)': $\forall g \in G_{\neq 1}$, $\exists j$ such that $|\chi_{\rho_j}(g)| < d$. This condition is equivalent to $\bigcap_j \operatorname{Pker}(\rho_j) = \{1_G\}$.

Note that, by Lemma 21, any algebraic unbounded-error $[k, d]$-DFR is also an algebraic $[k, d, C^{-n}]$-DFR, for some $C \in \mathbb{R}_{\geq 1}$; furthermore, as noted in the discussion following Definition 18, only a finitely generated abelian group could have a diagonal unbounded-error $[k, d]$-DFR, and all finitely generated abelian groups were shown to have DFRs in Theorem 34. Therefore, in order to obtain something new, we must consider unbounded-error DFRs that are neither algebraic nor diagonal. Due to space restrictions, we omit the proof of the following theorem, which may be found in the full version [28].

▶ **Theorem 41.** $\forall G \in \widehat{\Pi}_3, \exists k \in \mathbb{N}$ *such that* G *virtually has an unbounded-error* $[k, 2, \widetilde{\mathbb{C}}]$*-DFR.*

4 Recognizing the Word Problem of a Group with a 2QCFA

Consider a group $G = \langle S|R \rangle$, with S finite. As before, let $\Sigma = S \sqcup S^{-1}$, let $\phi : \Sigma^* \to G$ denote the natural map that takes each string in Σ^* to the element of G that it represents, and let $W_G := W_{G=\langle S|R \rangle} = \{w \in \Sigma^* : \phi(w) = 1_G\}$ denote the word problem of G with respect to the given presentation. Suppose $\mathcal{F} = \{\rho_1, \dots, \rho_k\}$ is a $[k, d, \tau, \mathbb{A}]$-DFR (or PDFR) for G. By Proposition 17, if $w \in W_G$, then $|\chi_{\rho_j}(\phi(w))| = d$, $\forall j$, and if $w \notin W_G$, then $\exists j$ where $|\chi_{\rho_j}(\phi(w))| \leq d - \tau(l(\phi(w)))$. Let $G_j = \{g \in G : |\chi_{\rho_j}(g)| \leq d - \tau(l(g))\}$. A 2QCFA can recognize W_G by checking if $\phi(w) \in \bigcup_j G_j = G_{\neq 1}$. The well-known Hadamard test may be used to estimate $\chi_{\rho_j}(\phi(w)) = \operatorname{Tr}(\rho_j(\phi(w)))$; however, as we wish to produce a 2QCFA that has as few quantum states as possible, we wish to avoid the use of ancilla, and so we follow a slightly different approach. We begin by defining several useful 2QCFA subroutines.

▶ **Definition 42.** Suppose M is a 2QCFA with $d \geq 2$ quantum basis states $Q = \{q_1, \dots, q_d\}$, quantum start state $q_1 \in Q$, and alphabet Σ.

(a) Suppose $|\psi_1\rangle = \sum_q \alpha_q |q\rangle$ and $|\psi_2\rangle = \sum_q \beta_q |q\rangle$, where $\alpha_q, \beta_q \in \overline{\mathbb{Q}}, \forall q \in Q$. There are (many) $t \in \operatorname{U}(d, \overline{\mathbb{Q}})$ such that $t|\psi_1\rangle = |\psi_2\rangle$. Let $\mathcal{T}_{|\psi_1\rangle \to |\psi_2\rangle}$ denote an arbitrary such t.

(b) Let $\pi : G \to \operatorname{U}(d)$ be a representation of G and let $|\psi\rangle = \sum_q \beta_q |q\rangle$, where $\beta_q \in \overline{\mathbb{Q}}$, $\forall q \in Q$. Then the *unitary round* $\mathcal{U}(\pi, |\psi\rangle)$ is a particular sub-computation of M on w, defined as follows. The round begins with the quantum register in the superposition $|q_1\rangle$ and the tape head at the right end of the tape. On reading $\#_R$, M performs the unitary transformation $\mathcal{T}_{|q_1\rangle \to |\psi\rangle}$ to its quantum register, and moves its head to the left. On reading a symbol $\sigma \in \Sigma$, M performs the unitary transformation $\pi(\phi(\sigma))$ to the quantum register and moves its head left. When the tape head first reaches the left end of the tape (i.e., the first time the symbol $\#_L$ is read), M performs the identity transformation to its quantum register, and does not move its head, at which point the round ends. As ϕ is a (monoid) homomorphism and π is a (group) homomorphism, we immediately conclude that, at the end of the round, the quantum register is in the superposition $\pi(\phi(w))|\psi\rangle$.

(c) For $t \in \operatorname{U}(d)$, a *measurement round* $\mathcal{M}(\pi, |\psi\rangle, t)$ is a sub-computation of M that begins with the unitary round $\mathcal{U}(\pi, |\psi\rangle)$. Then M performs the unitary transformation t, and does not move its head. After which M performs the quantum measurement specified by the partition $B = \{B_0, B_1\}$ of Q given by $B_0 = \{q_2, \dots, q_d\}$ and $B_1 = \{q_1\}$, producing some *result* $r \in \{0, 1\}$; then M records r in its classical state, and does not move its head, at which point the round is over.

▶ **Lemma 43.** *Consider a group $G = \langle S|R\rangle$, with S finite, and let $W_G = W_{G=\langle S|R\rangle}$. The following statements hold.*

(i) *If G has a diagonal $[k, d, C_1 n^{-C_2}, \mathbb{A}]$-DFR (or PDFR), for some $C_1, C_2 \in \mathbb{R}_{>0}$, then $\forall \epsilon \in \mathbb{R}_{>0}$, $W_G \in \mathsf{coR2QCFA}(n^{\lceil C_2 \rceil + 2}, \epsilon, d, \overline{\mathbb{Q}} \cup \mathbb{A})$.*

(ii) *If G has a $[k, d, C_1^{-n}, \mathbb{A}]$-DFR (or PDFR), for some $C_1 \in \mathbb{R}_{\geq 1}$, then $\forall \epsilon \in \mathbb{R}_{>0}$, $\exists C_2 \in \mathbb{R}_{\geq 1}$ such that $W_G \in \mathsf{coR2QCFA}(C_2^n, \epsilon, d, \overline{\mathbb{Q}} \cup \mathbb{A})$.*

(iii) *If G has an unbounded-error $[k, d, \mathbb{A}]$-DFR (or PDFR), then $W_G \in \mathsf{coN1QFA} \cap \mathsf{coN2QCFA}(n, d, \overline{\mathbb{Q}} \cup \mathbb{A})$.*

Proof Sketch. Suppose $\mathcal{F} = \{\rho_1, \dots, \rho_k\}$ is a $[k, d, \tau, \mathbb{A}]$-DFR of G. Consider any $w \in \Sigma^*$. A 2QCFA M can perform a constant number of measurement rounds (i.e., the number of rounds only depends on k and d, not on $|w|$) using any representation ρ_j such that the following holds: (1) if $\phi(w) \in G_j \subseteq G_{\neq 1}$, then, with probability $\Omega(\tau(|w|))$, the results of those measurement rounds will allow M to be able to conclude *with certainty* that $w \notin W_G$, (2) if $\phi(w) = 1_G \notin G_j$, then the results of those measurement rounds will *never* cause M to incorrectly conclude that $w \notin W_G$. After running this procedure approximately $\tau(n)$ times, for each j, the following holds: (1) if $\phi(w) \in G_{\neq 1} = \bigcup_j G_j$, then $\phi(w) \in G_j$ for at least some j, and so, with probability $\Omega(1)$, M is able to conclude (with certainty) that $w \notin W_G$, (2) if $\phi(w) = 1_G$, then M will never incorrectly conclude that $w \notin W_G$. As soon as M performs a measurement round whose result allows it to conclude that $w \notin W_G$, M immediately rejects. In order to correctly accept all $w \in W_G$, M will run a procedure between measurement rounds that will cause it to accept *any* input w with some small probability, and otherwise continue; by setting this acceptance probability small enough, we assure that any $w \notin W_G$ is not (incorrectly) accepted with high probability. A formal proof can be found in the full version [28]. ◀

Moreover, if H is a finite-index subgroup of G, a 2QCFA that recognizes W_G can be constructed from a 2QCFA that recognizes W_H.

▶ **Lemma 44.** *Consider a group $H = \langle S_H|R_H\rangle$, with S_H finite, and suppose that A_H is a 2QCFA that recognizes W_H, which operates in the manner of our proof of Lemma 43. Further suppose G is a group such that $H \leq G$ and $[G : H]$ is finite. Then G admits a presentation $G = \langle S_G|R_G\rangle$, with S_G finite, such that there is a 2QCFA A_G that recognizes W_G. Moreover, A_G has the same acceptance criteria, asymptotic expected running time, number of quantum basis states, and class of transition amplitudes as A_H.*

Using the above results, and the constructions of DFR from Section 3, the theorems stated in Section 1.1 concerning the recognizability of word problems by 2QCFA easily follow; proofs of the above results and of these theorems appear in the full version [28].

5 Discussion

In this paper, we have shown that 2QCFA can recognize the word problems of many groups. In particular, let $\widehat{\Pi}_1$ (resp. $\widehat{\Pi}_2$) denote the collection of all finitely generated groups that are virtually abelian (resp. virtually a subgroup of a direct product of finitely-many finite-rank free groups), and let $\mathcal{Q}$ denotes the class of groups for which Theorem 10 applies. Then a 2QCFA, with a single-qubit quantum register and algebraic number transition amplitudes, can recognize, with one-sided bounded error, the word problem W_G of any $G \in \widehat{\Pi}_1$ (resp. $G \in \widehat{\Pi}_2$) in expected polynomial (resp. exponential) time. Moreover, if allowed a quantum register of any constant size, such a 2QCFA may recognize the word problem of any group $G \in \mathcal{Q}$ with one-sided bounded error in expected exponential time.

In a companion paper [27], we establish a lower bound on the running time of any 2QCFA (with any size quantum register and no restrictions placed on its transition amplitudes) that recognizes a word problem W_G with bounded error (even under the more generous notion of two-sided bounded error); more strongly, we establish a lower bound on the running time of *any quantum Turing machine* that uses *sublogarithmic* space, though we will not discuss that here. In particular, we show that, $\forall G \in \mathcal{Q} \setminus \widehat{\Pi}_1$, W_G *cannot* be recognized by such a 2QCFA is expected time $2^{o(n)}$. Therefore, the algorithm exhibited in this paper for recognizing the word problem of any group $G \in \mathcal{Q} \setminus \widehat{\Pi}_1$ has (essentially) optimal expected running time; moreover, we have obtained the first provable separation between the classes of languages recognizable with bounded error by 2QCFA in expected exponential time and in expected subexponential time. In that same paper, we also show that if a 2QCFA of this most general type recognizes a word problem W_G in expected polynomial time, then $G \in \mathcal{G}_{vNilp}$, where $\mathcal{G}_{vNilp}$ denotes the finitely generated virtually nilpotent groups, and $\widehat{\Pi}_1 \subsetneq \mathcal{G}_{vNilp}$. This naturally raises the following question.

▶ Open Problem 1. Is there a group $G \in (\mathcal{G}_{vNilp} \setminus \widehat{\Pi}_1)$ such that W_G can be recognized by a 2QCFA with bounded error in expected polynomial time?

We have shown that the (three-dimensional discrete) Heisenberg group $H \in (\mathcal{G}_{vNilp} \setminus \widehat{\Pi}_1)$ is "complete" for this question, in the sense that if W_H *cannot* be recognized with bounded error by a 2QCFA in expected polynomial time, then no such G can [27].

Let $\mathcal{G}_{vSolvLin}$ denote the finitely generated virtually solvable linear groups over a field of characteristic zero, and note that $\mathcal{G}_{vNilp} \subsetneq \mathcal{G}_{vSolvLin}$. Furthermore, note that $W_G \in \mathsf{L}$, $\forall G \in \mathcal{G}_{vSolvLin}$ [20]. However, every $G \in \mathcal{G}_{vSolvLin} \setminus \widehat{\Pi}_1$ *does not* have a faithful finite-dimensional unitary representation (see, for instance, [33, Proposition 2.2]) and, therefore, does not have a DFR (even an unbounded-error DFR); this prevents the techniques of this paper from producing a 2QCFA that recognizes the corresponding W_G.

▶ Open Problem 2. Is there a finitely generated group G that does not have a faithful finite-dimensional unitary representation (for example, any $G \in \mathcal{G}_{vSolvLin} \setminus \widehat{\Pi}_1$ or any finitely generated infinite Kazhdan group) such that W_G can be recognized with bounded error by a 2QCFA at all (i.e., in any time bound)?

Consider the group $\mathbb{Z} * \mathbb{Z}^2 \in \Sigma_2 \subsetneq \widehat{\Pi}_3$, and note that $\mathbb{Z} * \mathbb{Z}^2 \notin \widehat{\Pi}_2$. The complexity of $W_{\mathbb{Z}*\mathbb{Z}^2}$ has been considered by many authors and it is conjectured that $W_{\mathbb{Z}*\mathbb{Z}^2} \notin \mathsf{poly{-}CFL}$ [7] (cf. [8]) and that $W_{\mathbb{Z}*\mathbb{Z}^2} \notin \mathsf{coCFL}$ [18]. By Theorem 11, $W_{\mathbb{Z}*\mathbb{Z}^2}$ is recognizable with one-sided *unbounded* error by a 2QCFA. We ask the following questions.

▶ Open Problem 3. Can $W_{\mathbb{Z}*\mathbb{Z}^2}$ be recognized by a 2QCFA with bounded error? More generally, is $W_{\mathbb{Z}*\mathbb{Z}^r}$ recognizable by a 2QCFA with bounded error, $\forall r \in \mathbb{N}$?

▶ Open Problem 4. Does $\mathbb{Z} * \mathbb{Z}^2$ have an algebraic DFR. More generally, does $\mathbb{Z} * \mathbb{Z}^r$ have an algebraic DFR, $\forall r \in \mathbb{N}$? Even more generally, is the class of groups which have algebraic DFRs closed under free product?

Hardness Results for Constant-Free Pattern Languages and Word Equations

Aleksi Saarela
Department of Mathematics and Statistics, University of Turku, Finland
amsaar@utu.fi

Abstract

We study constant-free versions of the inclusion problem of pattern languages and the satisfiability problem of word equations. The inclusion problem of pattern languages is known to be undecidable for both erasing and nonerasing pattern languages, but decidable for constant-free erasing pattern languages. We prove that it is undecidable for constant-free nonerasing pattern languages. The satisfiability problem of word equations is known to be in PSPACE and NP-hard. We prove that the nonperiodic satisfiability problem of constant-free word equations is NP-hard. Additionally, we prove a polynomial-time reduction from the satisfiability problem of word equations to the problem of deciding whether a given constant-free equation has a solution morphism α such that $\alpha(xy) \neq \alpha(yx)$ for given variables x and y.

1 Introduction

The first topic of this article is pattern languages. If we fix an alphabet of variables and an alphabet of constants, we can define a pattern as a word consisting of variables and constant letters (constants are often called terminals). Given a pattern U, the nonerasing pattern language of U is the set of images of U under all morphism that map the variables to nonempty constant words and preserve the constants. The erasing pattern language of U is defined in a similar way, except that the variables can be mapped also to the empty word. Nonerasing pattern languages were introduced by Angluin [1] and erasing pattern languages by Shinohara [33].

There are many interesting algorithmic questions about pattern languages, and they are related to applications such as pattern matching and inductive inference. The membership problem of pattern languages, which can also be called the matching problem, is NP-complete in both the nonerasing and erasing case, and so are many of its variations, see, e.g., [10] and [24]. Checking the emptiness of the intersection of two pattern languages is essentially a special case of the satisfiability problem of word equations (discussed later in the introduction), and can therefore be done in polynomial space.

The equivalence problem of two pattern languages is almost trivially decidable in the nonerasing case: If the alphabet of constants is not unary, the nonerasing pattern languages of two patterns are the same if and only if the patterns are identical up to a renaming of the variables [1] (if the alphabet of constants is unary, the problem is a bit more complicated but still easily decidable). In the erasing case, however, the decidability of the equivalence problem is an open question.

The inclusion problem of pattern languages was mentioned as an open question in [1]. It was proved to be undecidable in both the nonerasing and erasing case by Jiang, Salomaa, Salomaa and Yu [18]. They reduced the undecidable problem of determining whether a

nondeterministic two-counter automaton without input has an accepting computation to the inclusion problem of erasing pattern languages, which they then reduced to the inclusion problem of nonerasing pattern languages. Both proofs are very complicated. They also proved that the inclusion problem of constant-free erasing pattern languages is decidable. This proof is simpler but not trivial.

Analyzing the equivalence and inclusion of pattern languages naturally leads to eight decision problems depending on whether we consider the nonerasing or erasing case and whether we consider patterns with or without constants. By the results mentioned above, the decidability status of six of these eight problems was known after [18], but two questions were left open: Is the equivalence problem decidable for erasing pattern languages, and is the inclusion problem decidable for constant-free nonerasing pattern languages? In [18], a positive answer was conjectured for the first question. The second one was only stated as an open problem with no conjecture. The questions have remained open since then.

The results in [18] were very interesting for many reasons. First, they solved a famous problem that had been open for many years. Second, the inclusion problem is important for inductive inference of pattern languages, see, e.g., the articles of Ng and Shinohara [25] and Reidenbach [28]. Third, nonerasing pattern languages became perhaps the first example of a family of formal languages with a trivially decidable equivalence problem but undecidable inclusion problem. Some other families where the equivalence problem is decidable but the inclusion problem is undecidable are the family of languages accepted by finite deterministic multitape automata (decidability of equivalence proved by Harju and Karhumäki [12]) and the family of deterministic context-free languages (decidability of equivalence proved later by Sénizergues [32]), but in these cases the undecidability result is the easier one. It is also interesting that for the equivalence problem of patterns, the nonerasing case is easier, while for the inclusion problem of constant-free patterns, the erasing case is easier.

A lot of further research on the inclusion problem has been done. For example, Freydenberger and Reidenbach [11] proved that the inclusion problem remains undecidable if the size of the alphabet of constants is fixed to be a positive integer k, as long as $k \geq 2$ in the erasing case and $k \geq 4$ in the nonerasing case. Both variants of the inclusion problem are decidable if the alphabet of constants is unary or infinite. Bremer and Freydenberger [4] proved stronger results: Both the erasing and the nonerasing inclusion problem are undecidable even for a fixed number of variables, as long as this number is large enough, and even if the size of the alphabet of constants is two. This result holds also if the second pattern is required to be constant-free.

In this article, we answer one of the open questions by proving that the inclusion problem of constant-free nonerasing pattern languages is undecidable. The result holds even for a fixed number of variables, as long as this number is large enough, and even if the size of the alphabet of constants is two. Among the problems we have discussed, our new result provides the first example where the constant-free version of a problem is undecidable, and the first example where the decidability status of the nonerasing and erasing version has been proved to be different. See Table 1 for a summary.

Let us now move to the topic of equations. A word equation can be defined as a pair (U, V) of patterns, and a solution can be defined as a constant-preserving morphism α such that $\alpha(U) = \alpha(V)$. Like in the case of pattern languages, there are a couple of variations of word equations. First, we can study either the general case of equations with constants, or the restricted case of constant-free equations. Algorithmic questions are usually studied for equations with constants. Some other questions, such as independence [13, 26] and parameterizability [14, 30], are more often studied for constant-free equations. Second, we

Table 1 The decidability of the equivalence (=) and inclusion (⊆) problem of nonerasing (NE) and erasing (E) languages of constant-free patterns (CF) and patterns with constants (C). The decidable problems have been marked with a plus and the undecidable ones with a minus. The new result proved in this article has been circled.

=	NE	E
CF	+	+
C	+	?

⊆	NE	E

C	−	−

can either allow a solution α to be erasing or require it to be nonerasing. This does not usually make as big of a difference as in the case of the equivalence and inclusion of pattern languages, but it can have an effect on some things, for example, the size of largest known independent systems of equations [20]. We allow solutions to be erasing in this article.

The satisfiability problem of word equations, that is, the problem of deciding whether a given word equation (or a system of equations) has a solution, is one of the major algorithmic problems on words. The satisfiability problem was proved to be decidable by Makanin [23]. A survey of Makanin's algorithm can be found in [8]. The first PSPACE algorithm was given by Plandowski [27]. Jeż gave a simpler PSPACE algorithm [16] and proved that the satisfiability problem is in NSPACE(n) [17]. Linear integer programming and the membership problem of pattern languages can both be easily reduced to the satisfiability problem, so it is NP-hard. The NP-completeness of the satisfiability problem is a big open question.

Many special cases have been analyzed. For one-variable equations, the satisfiability problem can be solved in linear time, as proved by Jeż [15], for two-variable equations, in time $O(n^5)$, as proved by Dąbrowski and Plandowski [7], and for quadratic equations, it is NP-hard, as proved by Robson and Diekert [29]. Some other results can be found in the article of Day, Manea and Nowotka [6]. Some quite powerful generalizations of word equations were proved to be solvable in polynomial space by Diekert and Elder [9].

There is not much research about the satisfiability of constant-free word equations. Constant-free equations always have solutions (at least the one mapping all variables to the empty word, and usually infinitely many other trivial ones), so the natural decision problem for them is to ask whether an equation has a nontrivial solution, for some definition of "nontrivial". It is known that deciding whether a constant-free three-variable equation has a nonperiodic solution is in NP [30]. Nontrivial constant-free equations on one or two variables have only periodic solutions.

Constant-free equations might seem much simpler than general ones, but we prove that deciding whether a given constant-free equation has a nonperiodic solution is NP-hard, and for a given constant-free equation and given variables x, y, deciding whether there exists a solution α such that $\alpha(xy) \neq \alpha(yx)$ is as hard as the general version of the satisfiability problem.

Our proofs are based on the idea of simulating constants by variables in a certain way: We replace the constants by words consisting of new variables, and then we make sure that these words behave sufficiently much like constants by adding prefixes and suffixes to the patterns or new equations to a system of equations. The details differ quite a bit depending on the problem.

2 Preliminaries

First, we recall some standard notation, definitions, and results related to combinatorics on words and free monoids. For more, see [5, 21, 3].

The symbols Σ, Γ, Ξ are always used to denote alphabets. Alphabets are usually finite, but at one point, we use an infinite alphabet. For $k \geq 1$, let $\Sigma_k = \{0, \ldots, k-1\}$. When we need an alphabet of size k, we often use specifically the alphabet Σ_k. The empty word is denoted by ε.

A word U is a *factor* of a word V if there exist words X, Y such that $V = XUY$. If we can choose $X = \varepsilon$, then U is a *prefix*, if we can choose $Y = \varepsilon$, then U is a *suffix*, and if we can choose $X \neq \varepsilon \neq Y$, then U is an *internal factor* of V.

A nonempty word is *primitive* if it is not a power of a shorter word. If $U = V^n$ and V is primitive, then V is a *primitive root* of U.

A language $M \subseteq \Sigma^*$ is a *submonoid* of Σ^* if it is closed under concatenation and contains ε. Let M_1 and M_2 be submonoids of Σ^* and Γ^*. A mapping $\alpha : M_1 \to M_2$ is a *morphism* if $\alpha(UV) = \alpha(U)\alpha(V)$ for all $U, V \in M_1$. The most common case is $M_1 = \Sigma^*$ and $M_2 = \Gamma^*$.

Let $L \subseteq M_1$. A morphism $\alpha : M_1 \to M_2$ is *nonerasing* if $\alpha(x) \neq \varepsilon$ for all $x \neq \varepsilon$, *L-preserving* if $\alpha(x) = x$ for all $x \in L$, *L-periodic* if $\alpha(xy) = \alpha(yx)$ for all $x, y \in L$, and *L-nonperiodic* if $\alpha(xy) \neq \alpha(yx)$ for some $x, y \in L$.

In the following theorem, we have collected some folklore results related to these definitions.

▶ **Theorem 1.** *Let U and V be words.*

1. *$UV = VU$ if and only if there exists a word R such that $U, V \in R^*$.*
2. *Every nonempty word has a unique primitive root.*
3. *If U is primitive, then it is not an internal factor of U^2.*
4. *If $|\Sigma| = 2$, then every Σ-nonperiodic morphism $\Sigma^* \to \Gamma^*$ is injective.*

If every element of a submonoid M of Σ^* has a unique representation as a product of elements of some subset $B \subseteq M$, then M is a *free monoid* and B is its *basis.* Of course, Σ^* is a free monoid and Σ is its basis.

If M is a free monoid with a basis B, then every mapping $\alpha : B \to \Gamma^*$ can be extended to a morphism $M \to \Gamma^*$ in a unique way, and every injective mapping $\alpha : B \to \Gamma$ can be extended to an injective morphism $M \to \Gamma^*$. Moreover, if $L \subseteq B \cap \Gamma$, then every mapping $\alpha : B \setminus L \to \Gamma^*$ can be extended to an L-preserving morphism $M \to \Gamma^*$ in a unique way. Therefore, we often define a morphism α by just saying that it is L-preserving and giving the values $\alpha(x)$ for all $x \in B \setminus L$.

We need the following well-known characterization of free monoids.

▶ **Theorem 2.** *Let M be a submonoid of Σ^*. M is a free monoid if and only if there does not exist words $U, V, W \in \Sigma^*$ such that $U, VW, UV, W \in M$ but $V \notin M$.*

Let Ξ be an alphabet of variables and Σ an alphabet of constants. The alphabets Ξ and Σ are assumed to be disjoint. A *pattern over* (Ξ, Σ) is a word $U \in (\Xi \cup \Sigma)^+$. The pattern U is *constant-free* if $U \in \Xi^+$. The *nonerasing pattern language* of U, denoted by $L_{\mathrm{NE}}(U)$, is the set of images of U under all nonerasing Σ-preserving morphisms $(\Xi \cup \Sigma)^* \to \Sigma^*$.

In the following definitions, by an alphabet of size $\star$, we mean an alphabet of arbitrary finite size. For $m, n, k \in \mathbb{Z}_+ \cup \{\star\}$, we define the following decision problems related to patterns:

- Inclusion problem of nonerasing pattern languages $\mathrm{PatIncl}_{\mathrm{NE}}(m, n, k)$: Given alphabets Ξ_1, Ξ_2, Σ of sizes m, n, k, respectively, a pattern U over (Ξ_1, Σ), and a pattern V over (Ξ_2, Σ), decide whether $L_{\mathrm{NE}}(U) \subseteq L_{\mathrm{NE}}(V)$.
- Inclusion problem of constant-free nonerasing pattern languages $\mathrm{PatIncl}^{\mathrm{CF}}_{\mathrm{NE}}(m, n, k)$: Given alphabets Ξ_1, Ξ_2, Σ of sizes m, n, k, respectively, a constant-free pattern U over (Ξ_1, Σ), and a constant-free pattern V over (Ξ_2, Σ), decide whether $L_{\mathrm{NE}}(U) \subseteq L_{\mathrm{NE}}(V)$.

As mentioned in the introduction, $\mathrm{PatIncl}_{\mathrm{NE}}(\star, \star, \star)$ was shown to be undecidable already in [18]. We need the following stronger result from [4].

▶ **Theorem 3** ([4], Theorem 3.10). $\mathrm{PatIncl}_{\mathrm{NE}}(3, 2554, 2)$ *is undecidable.*

▶ Remark 4. Often, we use symbols from the end of the English alphabet (e.g., u, v, w, x, y, z in the next example) for ordinary variables, symbols from the beginning of the alphabet (e.g., a, b) for special variables that end up playing the role of constants in some sense, and nonnegative integers (e.g., $0, 1$) for the actual constants.

▶ **Example 5.** It is mentioned in several articles [18, 24] that one reason why the inclusion problem of nonerasing pattern languages is so difficult is that many unavoidability properties can be formulated in terms of pattern languages. In our new undecidability proof, an important role is played by one unavoidability result, although an extremely simple one: Every binary word of length at least 4 has a nonempty square factor, and therefore every binary word of length at least 6 has a nonempty internal square factor. By considering patterns over $(\{u, v, w, x, y, z\}, \Sigma_2)$, this can be expressed as $L_{\mathrm{NE}}(uvwxyz) \subseteq L_{\mathrm{NE}}(xy^2z)$. More specifically, we will need the fact that $L_{\mathrm{NE}}(x^2y^2) \smallsetminus L_{\mathrm{NE}}(xy^2z) = \{0011, 1100\}$.

A *word equation over* (Ξ, Σ) is a pair of patterns over (Ξ, Σ). A *solution* of an equation (U, V) is a Σ-preserving morphism $\alpha : (\Xi \cup \Sigma)^* \to \Sigma^*$ such that $\alpha(U) = \alpha(V)$. A *system of equations* is a set of equations. A *solution* of a system is a morphism that is a solution of every equation in the system.

An equation (U, V) is *constant-free* if $U, V \in \Xi^+$. For constant-free equations, Ξ-periodic solutions are considered trivial. We often call these solutions just *periodic* and the others *nonperiodic*.

▶ **Example 6.** Consider word equations over $(\{x, y, z\}, \Sigma_2)$. The equation $(x^2, y0y)$ has no solutions, because $|\alpha(x^2)|$ is even and $|\alpha(y0y)|$ is odd for all Σ_2-preserving morphisms α. The constant-free equation (x^2, yzy) has nonperiodic solutions α defined by

$$\alpha(x) = (PQ)^{i+1}P, \qquad \alpha(y) = (PQ)^iP, \qquad \alpha(z) = QPPQ$$

for all $P, Q \in \Sigma_2^*$, $PQ \neq QP$, $i \in \mathbb{Z}_{\geq 0}$, and periodic solutions α defined by

$$\alpha(x) = P^{i+j}, \qquad \alpha(y) = P^i, \qquad \alpha(z) = P^{2j}$$

for all $P \in \Sigma_2^*$, $i, j \in \mathbb{Z}_{\geq 0}$.

By the theorem of Lyndon and Schützenberger [22], if $\Xi = \{x, y, z\}$ and $k, m, n \geq 2$, then the word equation $(x^k, y^m z^n)$ has only periodic solutions. In other words, if α is a $\{y, z\}$-nonperiodic morphism, then $\alpha(y^m z^n)$ is primitive. In Theorem 7, we state a generalization of this result that we need later. It was proved by Spehner [34] and by Barbin-Le Rest and Le Rest [2]. A shorter proof can be found in [31].

▶ **Theorem 7.** *Let $W \in \{y, z\}^*$ be a primitive word that has at least two occurrences of both letters y and z. Let α be a $\{y, z\}$-nonperiodic morphism. Then $\alpha(W)$ is primitive.*

For $n, k \in \mathbb{Z}_+ \cup \{\star\}$, we define the following decision problems related to systems of word equations:

- Satisfiability problem of word equations $\mathrm{EqSat}(n, k)$: Given alphabets Ξ, Σ of sizes n, k, respectively, and a system S of equations over (Ξ, Σ), decide whether S has a solution.
- Nonperiodic satisfiability problem of constant-free word equations $\mathrm{EqSat}^{\mathrm{CF}}_{\mathrm{NP}}(n, k)$: Given alphabets Ξ, Σ of sizes n, k, respectively, and a system S of constant-free equations over (Ξ, Σ), decide whether S has a nonperiodic solution.
- Noncommuting satisfiability problem of constant-free word equations $\mathrm{EqSat}^{\mathrm{CF}}_{\mathrm{NC}}(n, k)$: Given alphabets Ξ, Σ of sizes n, k, respectively, a system S of constant-free equations over (Ξ, Σ), and variables $x, y \in \Xi$, decide whether S has a $\{x, y\}$-nonperiodic solution.

As mentioned in the introduction, $\mathrm{EqSat}(\star, \star)$ is known to be in PSPACE and NP-hard. If Σ is unary, then word equations are essentially linear Diophantine equations, so $\mathrm{EqSat}(\star, 1)$ is equivalent to linear integer programming in unary notation, which is known to be NP-complete.

We have defined the above decision problems for systems of equations. Studying single equations instead of systems would not make them much easier, except in the case where Σ is unary. If there are at least two distinct constant letters, then for every finite system of word equations, we can find an equation that has exactly the same solutions as the system, and for every finite system of constant-free word equations, we can find a constant-free equation that has exactly the same nonperiodic solutions as the system, as proved by Hmelevskii [14]. Moreover, these equations can be constructed in polynomial time.

If A and B are decision problems and A is polynomial-time reducible to B, we use the notation $A \leq_p B$. If A and B are polynomially equivalent, that is, $A \leq_p B$ and $B \leq_p A$, then we use the notation $A \equiv_p B$.

3 Inclusion problem of pattern languages

We are going to prove that $\mathrm{PatIncl}_{\mathrm{NE}}(\star, \star, 2) \leq_p \mathrm{PatIncl}_{\mathrm{NE}}^{\mathrm{CF}}(\star, \star, 2)$. Let the alphabet of constants be Σ_2. Let a and b be new variables that are supposed to represent the constants 0 and 1. Nonerasing morphisms that map a to 0 and b to 1 or vice versa can be called *good*, and other nonerasing morphism can be called *bad*. For all patterns U, V, we must construct constant-free patterns U', V' such that $L_{\mathrm{NE}}(U') \subseteq L_{\mathrm{NE}}(V')$ if and only if $L_{\mathrm{NE}}(U) \subseteq L_{\mathrm{NE}}(V)$. In other words, we must show that the following conditions are satisfied:

1. If $L_{\mathrm{NE}}(U) \subseteq L_{\mathrm{NE}}(V)$, then for all good morphisms α', there exists a nonerasing morphism β' such that $\beta'(V') = \alpha'(U')$.
2. If $L_{\mathrm{NE}}(U) \subseteq L_{\mathrm{NE}}(V)$, then for all bad morphisms α', there exists a nonerasing morphism β' such that $\beta'(V') = \alpha'(U')$.
3. If $L_{\mathrm{NE}}(U) \not\subseteq L_{\mathrm{NE}}(V)$, then there exists a nonerasing morphism α' such that for all nonerasing morphisms β', $\beta'(V') \neq \alpha'(U')$.

Before giving the definition of U' and V' and the formal proofs, we explain some ideas behind the construction.

The simplest idea would be to replace 0 and 1 by a and b. Let U_1, V_1 be the constant-free patterns we get from U, V this way. If we use U_1, V_1 as U', V', then the first condition is satisfied. However, the next example shows that the third condition does not hold in general.

▶ **Example 8.** Let $U = 0x$, $V = 1x$, $U' = ax$, $V' = bx$. Then clearly $L_{\mathrm{NE}}(U) \not\subseteq L_{\mathrm{NE}}(V)$ and $L_{\mathrm{NE}}(U') \subseteq L_{\mathrm{NE}}(V')$, so the third condition does not hold.

The problem with the third condition is that β' does not necessarily map a and b in the same way as α'. To solve this, we use an idea that is somewhat similar to one used in [4, Subsection 5.2], where prefixes are added to patterns to ensure that certain variables must be mapped in a certain way. Consider the patterns

$$U_2 = a^2 b^2 c^2 U_1, \qquad V_2 = a^2 b^2 c^2 V_1,$$

where c is a new variable. If α' is good and $\alpha'(c)$ is a third letter that does not appear in $\alpha'(U_1)$, then it is quite easy to see that $\beta'(V_2) = \alpha'(U_2)$ is possible only if $\beta'(x) = \alpha'(x)$ for all $x \in \{a, b, c\}$. Of course, there is no third letter in Σ_2, but we can define $\alpha'(c) \in \Sigma_2^+$ so that it still acts as a separator in the same way a unique letter would. If we use U_2, V_2 as U', V', then the first and the third condition are satisfied.

Satisfying the second condition without interfering with the third condition is the most difficult part. To solve the problems, consider patterns of the form

$$U_4 = W_1 pq^2 r W_2 a^2 b^2 W_3, \qquad V_4 = W_4 pq^2 r W_5,$$

where p, q, r are new variables and $W_1, \dots, W_5$ are constant-free patterns. The factors pq^2r and a^2b^2 act as a "switch". If $\beta'(pq^2r) = \alpha'(pq^2r)$, then we can say that the switch is in the first position. If $\beta'(pq^2r) = \alpha'(a^2b^2)$, then we can say that the switch is in the second position. For any α', we can define β' so that $\beta'(pq^2r) = \alpha'(pq^2r)$, so the first position is always possible. On the other hand, we can define β' so that $\beta'(pq^2r) = \alpha'(a^2b^2)$ if and only if α' is bad, so the second position is possible for the bad morphisms but not for the good. This allows us to handle the second condition without causing problems with the other two.

Putting these ideas together leads to the following construction. Let U be a pattern over (Ξ_1, Σ_2) and V a pattern over (Ξ_2, Σ_2). Let a, b, c, p, q, r, s, t be new variables not in $\Xi_1 \cup \Xi_2$. We define a $(\Xi_1 \cup \Xi_2)$-preserving morphism

$$\sigma : (\Xi_1 \cup \Xi_2 \cup \Sigma_2)^* \to (\Xi_1 \cup \Xi_2 \cup \{a, b\})^*, \ \sigma(0) = a, \ \sigma(1) = b.$$

We can construct the constant-free patterns

$$\begin{aligned} U' &= a^2b^2c^2 \cdot c^2 \cdot \sigma(U) \cdot c^2pq^2rc \cdot \sigma(V) \cdot c^2a^2b^2c \cdot a \\ V' &= a^2b^2c^2 \cdot sc \cdot \sigma(V) \cdot c^2pq^2rc \cdot t \end{aligned} \tag{1}$$

where U' is a pattern over $(\Xi_1 \cup \Xi_2 \cup \{a, b, c, p, q, r\}, \Sigma_2)$ and V' is a pattern over $(\Xi_2 \cup \{a, b, c, p, q, r, s, t\}, \Sigma_2)$.

▶ **Lemma 9.** *If $L_{\mathrm{NE}}(U) \subseteq L_{\mathrm{NE}}(V)$, then $L_{\mathrm{NE}}(U') \subseteq L_{\mathrm{NE}}(V')$,*

Proof. Let $\alpha' : (\Xi_1 \cup \Xi_2 \cup \{a, b, c, p, q, r\})^* \to \Sigma_2^*$ be a nonerasing morphism. We must find a nonerasing morphism $\beta' : (\Xi_2 \cup \{a, b, c, p, q, r, s, t\})^* \to \Sigma_2^*$ such that $\beta'(V') = \alpha'(U')$. There are two cases depending on whether α' is good or bad.

If α' is good, then we can define a nonerasing morphism

$$\alpha : (\Xi_1 \cup \Xi_2 \cup \Sigma_2)^* \to \Sigma_2^*, \ \alpha = \alpha' \circ \sigma \circ \alpha' \circ \sigma.$$

It is easy to check that α is Σ_2-preserving. By the assumption $L_{\mathrm{NE}}(U) \subseteq L_{\mathrm{NE}}(V)$, there exists a nonerasing Σ_2-preserving morphism $\beta : (\Xi_2 \cup \Sigma_2)^* \to \Sigma_2^*$ such that $\beta(V) = \alpha(U)$. We can define a morphism

$$\begin{aligned} \beta' : (\Xi_2 \cup \{a, b, c, p, q, r, s, t\})^* \to \Sigma_2^*, \ &\beta'(x) = \alpha'(\sigma(\beta(x)) \text{ for all } x \in \Xi_2, \\ &\beta'(x) = \alpha'(x) \text{ for all } x \in \{a, b, c, p, q, r\}. \\ &\beta'(s) = \alpha'(c), \\ &\beta'(t) = \alpha'(\sigma(V)c^2a^2b^2ca). \end{aligned}$$

It follows directly from the definition of β' that

$$\begin{aligned} &\beta'(a^2b^2c^2sc) = \alpha'(a^2b^2c^4), \\ &\beta'(c^2pq^2rct) = \alpha'(c^2pq^2rc\sigma(V)c^2a^2b^2ca). \end{aligned} \tag{2}$$

Showing that $\beta'(\sigma(V)) = \alpha'(\sigma(U))$ requires some computations. By using the definition of β' and the fact that σ is Ξ_2-preserving and β is Σ_2-preserving, we get

$$\begin{aligned} &\beta'(\sigma(x)) = \beta'(x) = \alpha'(\sigma(\beta(x))) \text{ for all } x \in \Xi_2, \\ &\beta'(\sigma(x)) = \alpha'(\sigma(x)) = \alpha'(\sigma(\beta(x))) \text{ for all } x \in \Sigma_2. \end{aligned} \tag{3}$$

We have

$$\beta'(\sigma(V)) = \alpha'(\sigma(\beta(V))) = \alpha'(\sigma(\alpha(U))) = \alpha(\alpha'(\sigma(U))) = \alpha'(\sigma(U)), \tag{4}$$

where the first equality follows from $V \in (\Xi_2 \cup \Sigma_2)^+$ and (3), the second from $\beta(V) = \alpha(U)$, the third from $(\alpha' \circ \sigma) \circ \alpha = \alpha \circ (\alpha' \circ \sigma)$, and the fourth from α being Σ_2-preserving. It follows from (2) and (4) that $\beta'(V') = \alpha'(U')$

If α' is bad, then $\alpha'(a^2b^2)$ is either 0^4, 1^4, or a binary word of length at least six. In all cases, it has a nonempty internal factor that is a square, so there exists $P, Q, R \in \Sigma_2^+$ such that $\alpha'(a^2b^2) = PQ^2R$. We can define a morphism

$$\begin{aligned} \beta' : (\Xi_2 \cup \{a, b, c, p, q, r, s, t\})^* \to \Sigma_2^*, \ & \beta'(x) = \alpha'(x) \text{ for all } x \in \Xi_2 \cup \{a, b, c\}, \\ & \beta'(p) = P, \\ & \beta'(q) = Q, \\ & \beta'(r) = R, \\ & \beta'(s) = \alpha'(c^2\sigma(U)c^2pq^2r), \\ & \beta'(t) = \alpha'(a). \end{aligned}$$

It follows directly from the definition of β' that $\beta'(V') = \alpha'(U')$. ◀

▶ **Lemma 10.** *If $L_{\mathrm{NE}}(U) \not\subseteq L_{\mathrm{NE}}(V)$, then $L_{\mathrm{NE}}(U') \not\subseteq L_{\mathrm{NE}}(V')$.*

Proof. By the assumption $L_{\mathrm{NE}}(U) \not\subseteq L_{\mathrm{NE}}(V)$, there exist a nonerasing Σ_2-preserving morphism $\alpha : (\Xi_1 \cup \Sigma_2)^* \to \Sigma_2^*$ such that $\beta(V) \neq \alpha(U)$ for all nonerasing Σ_2-preserving morphisms $\beta : (\Xi_2 \cup \Sigma_2)^* \to \Sigma_2^*$. We can define a morphism

$$\begin{aligned} \alpha' : (\Xi_1 \cup \Xi_2 \cup \{a, b, c, p, q, r\})^* \to \Sigma_2^*, \ & \alpha'(x) = \alpha(x) \text{ for all } x \in \Xi_1, \\ & \alpha'(a) = 0, \\ & \alpha'(b) = 1, \\ & \alpha'(c) = 10^N1, \\ & \alpha'(x) = 1 \text{ for all } x \in \Xi_2 \cup \{p, q, r\}, \end{aligned}$$

where $N = 1 + \max\{2, |\alpha'(\sigma(U))|, |\alpha'(\sigma(V))|\}$.

It is easy to see that $\alpha'(U')$ does not contain any other occurrences of $\alpha'(c)$ than the ten obvious ones. We can show that if A^2 is a nonempty square prefix of $\alpha'(U')$, then $A = \alpha'(a) = 0$. First, if $\alpha'(a^2b^2c^3)$ is a prefix of A, then $A\alpha'(a^2b^2c^3)$ is a prefix of $\alpha'(U')$, which is impossible, because $\alpha'(c^3)$ does not have any occurrences in $\alpha'(U')$ starting after the prefix $\alpha'(a^2b^2c^3)$. Second, if A is a prefix of $\alpha'(a^2b^2c^3)$ and $|A| \geq 5$, then $A00111$ is a prefix of $\alpha'(a^2b^2c^4)$, which is impossible, because 111 does not have any occurrences in $\alpha'(c^4)$. Finally, if $|A| \leq 4$, then clearly the only possibility is $A = 0$. Similarly, we can show that if W is the word such that $U' = a^2b^2W$, then the only nonempty square prefix of $\alpha'(b^2W)$ is $\alpha'(b^2) = 11$, and the only nonempty square prefixes of $\alpha'(W)$ are $\alpha'(c^2)$ and $\alpha'(c^4)$.

To complete the proof of the theorem, we assume that

$$\beta' : (\Xi_2 \cup \{a, b, c, p, q, r, s, t\})^* \to \Sigma_2^*$$

is a nonerasing morphism such that $\beta'(V') = \alpha'(U')$ and derive a contradiction. Because $\beta'(V')$ has the nonempty square prefix $\beta'(a^2)$, and the only nonempty square prefix of $\alpha'(U')$ is 00, it must be $\beta'(a) = 0$. Similarly, we see that $\beta'(b) = 1$ and $\beta'(c) \in \{\alpha'(c), \alpha'(c^2)\}$. If $\beta'(c) = \alpha'(c^2)$, then $\beta'(c^2) = \alpha'(c^4)$ has two occurrences in $\alpha'(U')$, which is not possible, so it must be $\beta'(c) = \alpha'(c)$. It follows that

$$\beta'(sc\sigma(V)c^2pq^2rct) = \alpha'(c^2\sigma(U)c^2pq^2rc\sigma(V)c^2a^2b^2ca).$$

Here on the right-hand side, there are only two occurrences of $\alpha'(c^2)$ as an internal factor, so either

$$\beta'(sc\sigma(V)) = \alpha'(c^2\sigma(U)) \qquad \text{and} \qquad \beta'(pq^2rct) = \alpha'(pq^2rc\sigma(V)c^2a^2b^2ca) \tag{5}$$

or

$$\beta'(sc\sigma(V)) = \alpha'(c^2\sigma(U)c^2pq^2rc\sigma(V)) \qquad \text{and} \qquad \beta'(pq^2rct) = \alpha'(a^2b^2ca). \tag{6}$$

There is only one occurrence of $\alpha'(c)$ as an internal factor in $\alpha'(c^2\sigma(U))$, so (5) implies $\beta'(\sigma(V)) = \alpha'(\sigma(U)) = \alpha(U)$, which is a contradiction because $\beta' \circ \sigma$ is a nonerasing Σ_2-preserving morphism. There is only one occurrence of $\alpha'(c)$ as an internal factor in $\alpha'(a^2b^2ca)$, so (6) implies $\beta'(pq^2r) = \alpha'(a^2b^2) = 0011$, which is a contradiction because 0011 does not have a nonempty internal square factor. These contradictions show that the morphism β' does not exist, and therefore $L_{\mathrm{NE}}(U') \not\subseteq L_{\mathrm{NE}}(V')$. ◀

▶ **Theorem 11.** *For all $m, n \in \mathbb{Z}_+$,*

$$\mathrm{PatIncl}_{\mathrm{NE}}(m, n, 2) \leq_p \mathrm{PatIncl}_{\mathrm{NE}}^{\mathrm{CF}}(\max\{m, n\} + 6, n + 8, 2).$$

Proof. Let U be a pattern over (Ξ_1, Σ_2) and V a pattern over (Ξ_2, Σ_2), where $|\Xi_1| = m$ and $|\Xi_2| = n$. Because renaming the variables in one of U and V does not change the pattern language, we can assume that one of Ξ_1 and Ξ_2 is a subset of the other, and therefore $|\Xi_1 \cup \Xi_2| = \max\{m, n\}$. The constant-free patterns U' and V' defined in (1) can be constructed in polynomial time. By Lemmas 9 and 10, $L_{\mathrm{NE}}(U) \subseteq L_{\mathrm{NE}}(V)$ if and only if $L_{\mathrm{NE}}(U') \subseteq L_{\mathrm{NE}}(V')$. The claim follows. ◀

▶ **Corollary 12.** *The decision problem* $\mathrm{PatIncl}_{\mathrm{NE}}^{\mathrm{CF}}(2560, 2562, 2)$ *is undecidable.*

Proof. By Theorem 3, $\mathrm{PatIncl}_{\mathrm{NE}}(3, 2554, 2)$ is undecidable. It follows from Theorem 11 that $\mathrm{PatIncl}_{\mathrm{NE}}^{\mathrm{CF}}(2560, 2562, 2)$ is undecidable. ◀

4 Nonperiodic satisfiability

We are going to prove that the decision problem $\mathrm{EqSat}_{\mathrm{NP}}^{\mathrm{CF}}(\star, 2)$ is NP-hard. This is based on the NP-hardness of $\mathrm{EqSat}(\star, 1)$. Before the proofs, we give a brief informal explanation of the idea.

We are going to transform a system of word equations over (Ξ, Σ_1) into a similarly-behaving system of constant-free word equations over $(\Xi \cup \{a, b\}, \Sigma_2)$, where a and b are new variables. The letter 0 in the original system has two important properties: It is primitive, and the images of all variables are powers of it. We want to replace 0 by a word consisting of variables that has similar properties. We can use the word a^2b^2. For all $\{a, b\}$-nonperiodic solutions β, the word $\beta(a^2b^2)$ is primitive, and we can force $\beta(x)$ to be a power of $\beta(a^2b^2)$ by adding the equation (xa^2b^2, a^2b^2x) for all $x \in \Xi$. Finally, adding the equation (xy, yx) for all $x, y \in \Xi$ makes sure that every $\{a, b\}$-periodic solution is periodic.

▶ **Theorem 13.** *For all $n \in \mathbb{Z}_+$,*

$$\mathrm{EqSat}(n, 1) \leq_p \mathrm{EqSat}_{\mathrm{NP}}^{\mathrm{CF}}(n + 2, 2) \qquad \textit{and} \qquad \mathrm{EqSat}(\star, 1) \leq_p \mathrm{EqSat}_{\mathrm{NP}}^{\mathrm{CF}}(\star, 2).$$

Proof. Let S be a system of word equations over (Ξ, Σ_1). Let a, b be new variables not in Ξ. Let us define a Ξ-preserving morphism

$$\sigma : (\Xi \cup \Sigma_1)^* \to (\Xi \cup \{a, b\})^*,\ \sigma(0) = a^2b^2,$$

and a morphism

$$\tau : \{a, b\}^* \to \Sigma_2^*,\ \tau(a) = 0,\ \tau(b) = 1.$$

We can construct in polynomial time a system of constant-free word equations

$$S' = \{(\sigma(U), \sigma(V)) \mid (U, V) \in S\} \cup \{(x\sigma(0), \sigma(0)x) \mid x \in \Xi\} \cup \{(xy, yx) \mid x, y \in \Xi\}$$

over $(\Xi \cup \{a, b\}, \Sigma_2)$. To complete the proof of the theorem, we show that S' has a nonperiodic solution if and only if S has a solution.

First, assume that S has a solution α. We can define a nonperiodic Σ_2-preserving morphism

$$\begin{aligned}\beta : (\Xi \cup \{a, b\} \cup \Sigma_2)^* \to \Sigma_2^*,\ \beta(x) &= \tau(x) \text{ for all } x \in \{a, b\},\\ \beta(x) &= \tau(\sigma(\alpha(x))) \text{ for all } x \in \Xi\end{aligned}$$

and show that it is a solution of S'. By using the definition of β and the fact that α is Σ_1-preserving and σ is Ξ-preserving, we get

$$\begin{aligned}&\beta(\sigma(0)) = \tau(\sigma(0)) = \tau(\sigma(\alpha(0))),\\ &\beta(\sigma(x)) = \beta(x) = \tau(\sigma(\alpha(x))) \text{ for all } x \in \Xi.\end{aligned} \tag{7}$$

For all $(U, V) \in S$, from $U, V \in (\Xi \cup \Sigma_1)^*$, (7), and $\alpha(U) = \alpha(V)$, it follows that

$$\beta(\sigma(U)) = \tau(\sigma(\alpha(U))) = \tau(\sigma(\alpha(V))) = \beta(\sigma(V)).$$

Thus β is a solution of $(\sigma(U), \sigma(V))$ for all $(U, V) \in S$. For all $x \in \Xi$, we have $\alpha(x) \in 0^*$ and therefore

$$\beta(x) = \tau(\sigma(\alpha(x))) \in \tau(\sigma(0))^* = \beta(\sigma(0))^*.$$

Thus β is a solution of all the other equations in S' as well.

Second, assume that S' has a nonperiodic solution β. From $\beta(xy) = \beta(yx)$ for all $x, y \in \Xi \cup \{\sigma(0)\}$ it follows that there exists a primitive word R such that $\beta(x) \in R^*$ for all $x \in \Xi \cup \{\sigma(0)\}$. If β is $\{a, b\}$-periodic, then $\beta(\sigma(0)) = \beta(a^2b^2) \in R^*$ implies $\beta(a), \beta(b) \in R^*$, and then β is periodic, a contradiction. Therefore β must be $\{a, b\}$-nonperiodic. It follows from Theorem 7 that $\beta(\sigma(0))$ is primitive and therefore $\beta(\sigma(0)) = R$. We can define a bijective morphism

$$\phi : R^* \to \Sigma_1^*,\ \phi(R) = 0,$$

and a morphism

$$\alpha : (\Xi \cup \Sigma_1)^* \to \Sigma_1^*,\ \alpha = \phi \circ \beta \circ \sigma.$$

Then α is well-defined because the image of $\beta \circ \sigma$ is a subset of R^*, and α is Σ_1-preserving because $\alpha(0) = \phi(R) = 0$, and α is a solution of S because

$$\alpha(U) = \phi(\beta(\sigma(U))) = \phi(\beta(\sigma(V))) = \alpha(V)$$

for all $(U, V) \in S$. ◀

▶ **Corollary 14.** *The decision problem* $\mathrm{EqSat}^{\mathrm{CF}}_{\mathrm{NP}}(\star, 2)$ *is NP-hard.*

Proof. Follows from Theorem 13 because $\mathrm{EqSat}(\star, 1)$ is NP-hard. ◀

5 Noncommuting satisfiability

We have proved that $\mathrm{EqSat}_{\mathrm{NP}}^{\mathrm{CF}}$ is NP-hard, but based on this result alone, it might be possible that, for example, $\mathrm{EqSat}_{\mathrm{NP}}^{\mathrm{CF}}$ is NP-complete but EqSat is not in NP. We would like to prove that constant-free equations are, in some sense, as hard as general word equations. We are going to prove this kind of a result for the decision problem $\mathrm{EqSat}_{\mathrm{NC}}^{\mathrm{CF}}$.

When trying to generalize the ideas of the previous section to the case where the alphabet of constants is Σ_k with $k > 1$, it is quite easy to define words $C_i \in \{a, b\}$ for all $i \in \Sigma_k$ so that for all $\{a, b\}$-nonperiodic morphisms β, the words $\beta(C_i)$ are distinct primitive words and $\{\beta(C_0), \dots, \beta(C_{k-1})\}$ is the basis of a free monoid. The problem is that we cannot make sure that $\beta(x)$ is in this free monoid for all original variables x. (This difficulty is related to the fact that if $X \in \Sigma^*$, $\Gamma \subsetneq \Sigma$, $|\Gamma| \geq 2$, then the property $X \in \Gamma^*$ cannot be expressed by word equations, see [19].) However, we can make sure that $\beta(x)$ is in a certain larger free monoid whose basis contains the words $\beta(C_0), \dots, \beta(C_{k-1})$. This is sufficient to prove the results.

▶ **Lemma 15.** *Let $k \in \mathbb{Z}_+$ and let a, b be variables. Let*

$$\begin{aligned} A_i &= a^i b^2 a^{k-i+1} && \text{for all } i \in \{0, \dots, k+1\}, \\ B &= A_k^2 A_{k+1}^2 A_k^2, \\ C_i &= B A_i B && \text{for all } i \in \{0, \dots, k-1\}. \end{aligned}$$

Let $\beta : \{a, b\}^* \to \Sigma^*$ be an $\{a, b\}$-nonperiodic (and therefore injective) morphism and let

$$M = (\beta(B)\Sigma^* \cap \Sigma^* \beta(B)) \cup \{\varepsilon\}.$$

The following are true:

1. *$\beta(A_0), \dots, \beta(A_{k+1}), \beta(B)$ are primitive.*
2. *M is a free monoid.*
3. *$\beta(C_0), \dots, \beta(C_{k-1})$ are in the basis of M.*
4. *If $U \in M \smallsetminus \{\varepsilon\}$ and $UV = VU$, then $V \in M$.*

Proof.

1. The primitivity of the words $\beta(A_i)$ follows from Theorem 7. The word $\beta(B)$ is the image of 001100 under the morphism defined by $0 \mapsto \beta(A_k)$, $1 \mapsto \beta(A_{k+1})$, and $\beta(A_k A_{k+1}) \neq \beta(A_{k+1} A_k)$ because $A_k A_{k+1} \neq A_{k+1} A_k$, so also the primitivity of $\beta(B)$ follows from Theorem 7.
2. We use Theorem 2. Clearly M is a monoid. We have to show that if $U, V, W \in \Sigma^*$ and $U, VW, UV, W \in M$, then $V \in M$. If $V = \varepsilon$, then $V \in M$. If $|V| \geq |\beta(B)|$, then VW and thus also V begins with $\beta(P)$, and UV and thus also V ends with $\beta(P)$, so $V \in M$. If $0 < |V| < |\beta(B)|$, then we can write $U = X\beta(B)$, $UV = Y\beta(B)$, $UVW = X\beta(B)^2 Z$ for some words X, Y, Z such that $|X| < |Y| < |X\beta(B)|$, so $\beta(B)$ is an internal factor of $\beta(B)^2$, which contradicts the primitivity of $\beta(P)$. Thus M is a free monoid by Theorem 2.
3. Clearly $\beta(C_i) \in M$. If $\beta(C_i)$ is not in the basis for some $i \in \{0, \dots, k-1\}$, then it is a product of two nonempty elements of M, so it has a factor $\beta(B^2)$ and thus also a factor $\beta(A_k^4)$ and we can write
$$\beta(C_i) = \beta(A_k^2 A_{k+1}^2 A_k^2 A_i A_k^2 A_{k+1}^2 A_k^2) = U\beta(A_k^4)V. \tag{8}$$
for some words U, V. Let $l = |\beta(A_k)|$. Note that $l = |\beta(A_j)|$ for all j. If l divides $|U|$, then it follows from (8) that $\beta(A_k) = \beta(A_{k+1})$ or $\beta(A_k) = \beta(A_i)$, which contradicts the injectivity of β. If l does not divide $|U|$, then it follows from (8) that $\beta(A_k)$ is an internal factor of $\beta(A_k^2)$, which contradicts the primitivity of $\beta(A_k)$. This proves the claim.

4. If $V = \varepsilon$, then $V \in M$. If $|V| \geq |\beta(B)|$, then U and thus also V begins and ends with $\beta(B)$, so $V \in M$. If $0 < |V| < |\beta(B)|$, then $\beta(B) = R^k R'$, where R is the common primitive root of U and V, R' is a nonempty prefix of R, and $k \geq 1$. Because $\beta(B)$ is primitive, $0 < |R'| < |R|$. But R is a suffix of U and thus of $\beta(B) = R^k R'$, so R is an internal factor of R^2, which contradicts the primitivity of R. This proves the claim. ◀

▶ **Theorem 16.** *For all $n \in \mathbb{Z}_+$,*

$$\mathrm{EqSat}(n, \star) \leq_p \mathrm{EqSat}^{\mathrm{CF}}_{\mathrm{NC}}(2n+2, 2) \qquad \textit{and} \qquad \mathrm{EqSat}(\star, \star) \leq_p \mathrm{EqSat}^{\mathrm{CF}}_{\mathrm{NC}}(\star, 2).$$

Proof. Let S be a system of word equations over (Ξ, Σ_k), where $\Xi = \{x_1, \dots, x_n\}$. Let $a, b, y_1, \dots, y_n$ be new variables not in Ξ and let $\Xi' = \Xi \cup \{a, b, y_1, \dots, y_n\}$. Let B, C_i, M be as in Lemma 15. Let us define a Ξ-preserving morphism

$$\sigma : (\Xi \cup \Sigma_k)^* \to (\Xi \cup \{a, b\})^*, \ \sigma(i) = C_i \text{ for all } i \in \Sigma_k,$$

and a morphism

$$\tau : \{a, b\}^* \to \Sigma_2^*, \ \tau(a) = 0, \ \tau(b) = 1.$$

We can construct in polynomial time a system of constant-free word equations

$$S' = \{(\sigma(U), \sigma(V)) \mid (U, V) \in S\} \cup \{(x_i B y_i B, B y_i B x_i) \mid i \in \{1, \dots, n\}\}.$$

over (Ξ', Σ_2). To complete the proof of the theorem, we show that S' has an $\{a, b\}$-nonperiodic solution β if and only if S has a solution.

First, assume that S has a solution α. For all i, if $\sigma(\alpha(x_i)) = \varepsilon$, let $Y_i = \varepsilon$, and otherwise let $\sigma(\alpha(x_i)) = B Y_i B$. Such words Y_i exist by the definition of σ. We can define an $\{a, b\}$-nonperiodic Σ_2-preserving morphism

$$\begin{aligned} \beta : (\Xi' \cup \Sigma_2)^* \to \Sigma_2^*, \ & \beta(x) = \tau(x) \text{ for all } x \in \{a, b\}, \\ & \beta(x_i) = \tau(\sigma(\alpha(x_i))) \text{ for all } i, \\ & \beta(y_i) = \tau(Y_i) \text{ for all } i, \end{aligned}$$

and show that it is a solution of S'. By using the definition of β and the fact that α is Σ_k-preserving and σ is Ξ-preserving, we get

$$\begin{aligned} & \beta(\sigma(i)) = \tau(\sigma(i)) = \tau(\sigma(\alpha(i))) \text{ for all } i \in \Sigma_k, \\ & \beta(\sigma(x)) = \beta(x) = \tau(\sigma(\alpha(x))) \text{ for all } x \in \Xi. \end{aligned} \tag{9}$$

For all $(U, V) \in S$, from $U, V \in (\Xi \cup \Sigma_k)^*$, (9), and $\alpha(U) = \alpha(V)$, it follows that

$$\beta(\sigma(U)) = \tau(\sigma(\alpha(U))) = \tau(\sigma(\alpha(V))) = \beta(\sigma(V)).$$

Thus β is a solution of $(\sigma(U), \sigma(V))$ for all $(U, V) \in S$. We have $\beta(x_i) = \varepsilon$ or $\beta(x_i) = \tau(B Y_i B) = \beta(B y_i B)$ for all i, so β is a solution of the other equations $(x_i B y_i B, B y_i B x_i)$ in S' as well.

Second, assume that S' has an $\{a, b\}$-nonperiodic solution β. By Lemma 15, from $\beta(x_i B y_i B) = \beta(B y_i B x_i)$ it follows that $\beta(x_i) \in M$ for all i. Again by Lemma 15, M is free and the words $\beta(C_i)$ are in the basis of M, so there exists an infinite alphabet Γ containing Σ_k and an injective morphism

$$\phi : M \to \Gamma^* \text{ such that } \phi(\beta(C_i)) = i \text{ for all } i. \text{ We can define a } \Sigma_k\text{-preserving morphism}$$

$$\psi : \Gamma^* \to \Sigma_k^*, \ \psi(x) = \varepsilon \text{ for all } x \in \Gamma \setminus \Sigma_k$$

and a morphism

$$\alpha : (\Xi \cup \Sigma_k)^* \to \Sigma_k^*, \ \alpha = \psi \circ \phi \circ \beta \circ \sigma.$$

Then α is well-defined because $\beta(\sigma(x)) \in M$ for all $x \in \Xi \cup \Sigma_k$, and α is Σ_k-preserving because

$$\alpha(i) = \psi(\phi(\beta(C_i))) = \psi(i) = i$$

for all $i \in \Sigma_k$, and α is a solution of S because from $\beta(\sigma(U)) = \beta(\sigma(V))$ it follows that

$$\alpha(U) = \psi(\phi(\beta(\sigma(U)))) = \psi(\phi(\beta(\sigma(V)))) = \alpha(V)$$

for all $(U, V) \in S$. ◀

▶ **Corollary 17.** $\mathrm{EqSat}(\star, \star) \equiv_p \mathrm{EqSat}^{\mathrm{CF}}_{\mathrm{NC}}(\star, \star)$.

Proof. We proved in Theorem 16 that $\mathrm{EqSat}(\star, \star) \leq_p \mathrm{EqSat}^{\mathrm{CF}}_{\mathrm{NC}}(\star, \star)$. To prove the other direction, let S be a system of constant-free equations over (Ξ, Σ_k), $k \geq 2$, and $x, y \in \Xi$. Let p, q, r be new variables not in Ξ. It is easy to see that the system

$$S' = S \cup \{(xy, p0q), (yx, p1r)\}$$

over $(\Xi \cup \{p, q, r\}, \Sigma_k)$ has a solution if and only if S has a $\{x, y\}$-nonperiodic solution: If β is a solution of S', then the restriction of β on $(\Xi \cup \Sigma_k)^*$ is a solution of S, and it is $\{x, y\}$-nonperiodic because

$$\beta(xy) = \beta(p)0\beta(q) \neq \beta(p)1\beta(r) = \beta(yx).$$

On the other hand, if α is an $\{x, y\}$-nonperiodic solution of S, then we can write $\alpha(xy) = PaQ$ and $\alpha(yx) = PbR$ for some words P, Q, R and distinct letters a, b. Because S is constant-free, every morphism we get from α by permuting the constant letters in the images of the variables is also an $\{x, y\}$-nonperiodic solution of S, so we can assume that $a = 0$ and $b = 1$. Then we can extend α to a solution α' of S' by defining $\alpha'(p) = P$, $\alpha'(q) = Q$, $\alpha'(r) = R$. This completes the proof. ◀

6 Conclusion

We have proved that the inclusion problem of nonerasing pattern languages is undecidable even in the case of constant-free patterns. We have also proved that the nonperiodic satisfiability problem of constant-free word equations is NP-hard, and the noncommuting satisfiability problem of constant-free word equations is polynomially equivalent to the general satisfiability problem of word equations.

The following questions remain open:

- Is the equivalence problem of erasing pattern languages decidable?
- Is the satisfiability problem of word equations in NP?
- For some fixed $n \geq 3$, can we prove that $\mathrm{EqSat}(n, \star)$ is in P or NP or NP-hard?

There are also several smaller open questions raised by the new results:

- Can the numbers 2560 and 2562 in Corollary 12 be made significantly smaller? This would require either a rather different approach or improving the results in [4].
- Is EqSat$(\star, \star)$ polynomial-time reducible to $\mathrm{EqSat}^{\mathrm{CF}}_{\mathrm{NP}}(\star, \star)$?
- In Theorem 16, we used $n + 2$ new variables. Would a constant number of new variables be sufficient?
- The satisfiability problem remains NP-hard for several restricted subfamilies of word equations. Can we prove NP-hardness results for some interesting subfamilies of constant-free equations?

Abstract

Deciding bisimulation equivalence of two pushdown automata is one of the most fundamental problems in formal verification. Though Sénizergues established decidability of this problem in 1998, it has taken a long time to understand its complexity: the problem was proven to be non-elementary in 2013, and only recently, Jančar and Schmitz showed that it has an Ackermann upper bound. We improve the lower bound to Ackermann-hard, and thus close the complexity gap.

1 Introduction

In the area of formal verification, equivalence checking plays a central role in characterizing when two systems should be considered as the same. A classical equivalence is language equivalence, which asks if two processes recognize the same language. To characterize more refined behavioural relations, Milner proposed a fundamental equivalence called bisimulation equivalence (a.k.a. bisimilarity) [15]. Two processes are bisimilar to each other if every transition from one process can be simulated by the other one, and the resulting two processes keep in the same bisimilarity relation. If internal actions are allowed in a bisimulation step, we will get a more complicated equivalence called weak bisimilarity [15]. A seminal result proven in [1] shows that bisimulation equivalence is decidable for processes generated by context-free grammars, while the language equivalence between context-free grammars is well-known to be undecidable [6]. Extensive works followed up ever since, studying different equivalence relations on various infinite-state systems. See [13] for a survey.

Table 1 Complexity results of bisimulation equivalence problems for (variants of) PDA.

Model	Lower bound	Upper bound
DPDA	P-hard	TOWER [9, 28]
PDA	**Ackermann-hard**	ACKERMANN [10]
FOG	ACKERMANN-hard [9]	ACKERMANN [10]

Pushdown automata (PDA) extend finite-state automata with a stack memory and can be used to model recursive programs naturally. Since PDA recognize the same language as context-free grammars [6], language equivalence is undecidable. The language equivalence of deterministic PDA (DPDA), raised by Ginsburg and Greibach in [5], was first proved to be decidable for the real-time subclass, i.e., DPDA without internal actions [17, 16]. The decidable result was extended to DPDA in Sénizergues's remarkable work [23]. Observe that on DPDA, language equivalence coincides with weak bisimulation equivalence, which implies the decidability of weak bisimilarity for DPDA. Sénizergues later generalized the decidability result to weak bisimilarity of PDA with deterministic internal actions [22, 24]. An internal action is deterministic if there is no alternative. There are also quite a few works trying to simplify Sénizergues's proof [27, 25, 26, 7, 8]. Stirling revisited the decidability proof for DPDA via a tableau system [27]. He also generalized the tableau system for PDA [26]. Another line of work is conducted by Jančar in the framework of first-order grammars (FOG) [7, 8]. FOG has very close relationship with PDA [4]. It can describe PDA with deterministic internal actions by collapsed graphs where all internal actions are absorbed.

Concerning the complexity issue of bisimilarity of PDA, the best known upper bound for the deterministic case (DPDA) is TOWER [28, 9], while only P-hardness is known. For general PDA, EXPTIME-hardness was proven by Kučera and Mayr [14]. The EXPTIME-hardness even holds for a subclass of PDA, named BPA (Basic Process Algebra), of which the set of control states is a singleton [12]. The EXPTIME-hardness was further improved to non-elementary (TOWER-hard actually) [2]. This non-elementary lower bound also holds for the normed subclass, where every PDA process can empty its stack. As for the upper bound for bisimilarity of PDA, little was known until very recently. Jančar and Schmitz gave an ACKERMANN algorithm in [10]. This upper bound is actually proven in the framework of FOG. It also matches the ACKERMANN-hard lower bound for bisimilarity of FOG [9].

Observe that FOG are equivalent to PDA with deterministic internal actions. Without internal actions, the ACKERMANN-hardness of FOG cannot be applied to PDA. Thus the best known lower-bound for bisimilarity of PDA is still TOWER-hard.

Our Contribution. We show that bisimilarity of PDA is actually ACKERMANN-complete by improving the TOWER-hard lower bound to ACKERMANN-hard. This is done by a reduction from the coverability problem of reset Petri net [19]. Moreover, our reduction also gives rise to a parametric complexity result, i.e., $\mathbf{F}_{d-1}$-hardness if the number of control states $d \geq 4$ is fixed. Our proof extends an early work by Jančar [9], where similar results for first-order grammars are established. We improve the reduction by avoiding ε-rules.

We summarize some mentioned results in Table 1 with our result presented in bold.

Further Comments. According to Table 1, the complexity classes of bisimilarity problems for PDA and first-order grammars happen to be the same. Thus one may wonder whether these two models are actually equal with respect to bisimilarity. The answer was known to be negative [3]. In this paper, we present a new proof which shows that pushdown automata are strictly weaker than first-order grammars as far as bisimilarity is considered. It also demonstrates why the reduction in [9] cannot be applied to real-time PDA directly.

Organization. The rest of the paper is organized as follows. Section 2 introduces the background knowledge and necessary notations. Section 3 establishes the Ackermann hardness for bisimilarity of PDA. Section 4 shows that PDA are strictly weaker than FOG considering bisimilarity. Section 5 concludes this paper.

2 Preliminaries

2.1 Pushdown Automata

▶ **Definition 1** (PDA). *A* pushdown automaton $\mathcal{A} = (\mathcal{Q}, \Gamma, \Sigma, \mathcal{R})$ *consists of*

- *a finite set of control states* $\mathcal{Q}$ *ranged over by* r, p, q*;*
- *a finite set of stack symbols* Γ *ranged over by* X, Y, Z*;*
- *a finite set of actions* Σ *ranged over by* a, b, c, d, f*;*
- *a finite set of rules* $\mathcal{R} \subseteq \mathcal{Q} \times \Gamma \times \Sigma \times \mathcal{Q} \times \Gamma^*$*.*

The set Σ^* of words will be ranged over by u, v, w, and the set Γ^* of finite strings of stack symbols will be ranged over by α, β. We write $\alpha\beta$ (respectively uv) for the concatenation of α and β (respectively u and v). As usual, $|\alpha|$ and $|u|$ represent the length of α and u respectively. For $n \in \mathbb{N}$, we use a^n to denote n consecutive actions a, and similarly for X^n. We write $pX \xrightarrow{a} q\alpha$ to mean $(p, X, a, q, \alpha) \in \mathcal{R}$.

The syntax of a PDA process is $p\alpha$, where $p \in \mathcal{Q}$ and $\alpha \in \Gamma^*$. The size of process $p\alpha$, denoted by $|p\alpha|$, is defined as its stack height $|\alpha|$. The set of PDA processes $\mathcal{P}$ is ranged over by O, P, Q. The semantics of the PDA processes is defined by the following rule:

$$\frac{pX \xrightarrow{a} q\alpha \in \mathcal{R}}{pX\beta \xrightarrow{a} q\alpha\beta} \tag{1}$$

If $w = a_1 a_2 \ldots a_n$ with $a_i \in \Sigma$ $(i \in 1, \ldots, n)$, then $P \xrightarrow{w} Q$ stands for $P \xrightarrow{a_1} P_1 \xrightarrow{a_2} \ldots P_{n-1} \xrightarrow{a_n} Q$ for some $P_1, P_2, \ldots, P_{n-1}$. A process P is *normed* if $P \xrightarrow{w} p$ for some $w \in \Sigma^*$ and $p \in \mathcal{Q}$, i.e., P can empty its stack. A PDA $\mathcal{A}$ is *normed* (denoted as nPDA) if every process defined in $\mathcal{A}$ is normed.

▶ **Definition 2** (Bisimulation). *A binary relation* $R \subseteq \mathcal{P} \times \mathcal{P}$ *is a* bisimulation *if, for all* $a \in \Sigma$*, the following statements are valid:*

1. *whenever* $(P, Q) \in R$ *and* $P \xrightarrow{a} P'$*, then* $Q \xrightarrow{a} Q'$ *and* $(P', Q') \in R$ *for some* Q'*;*
2. *whenever* $(P, Q) \in R$ *and* $Q \xrightarrow{a} Q'$*, then* $P \xrightarrow{a} P'$ *and* $(P', Q') \in R$ *for some* P'*.*

The largest bisimulation relation, denoted by $\sim$, is an equivalence relation called *bisimulation equivalence* or *bisimilarity* [15].

When silent actions are considered, we use a special symbol ε to represent a silent action. Note that in Definition 1 we assume $\varepsilon \notin \Sigma$. PDA without silent actions are called *real-time* PDA. When silent actions are allowed, we will specify action set as $\Sigma_\varepsilon = \Sigma \uplus \{\varepsilon\}$. A rule of the form $pX \xrightarrow{\varepsilon} q\alpha$ is referred to as an ε-rule. For an ε-rule $pX \xrightarrow{\varepsilon} q\alpha$, we say it is popping if $|\alpha| < 1$; it is pushing if $|\alpha| > 1$; it is deterministic if $pX \xrightarrow{a} q'\alpha'$ implies $a = \varepsilon$, $q' = q$, and $\alpha' = \alpha$. We will write $\overset{\varepsilon}{\Longrightarrow}$ for the reflexive and transitive closure of $\xrightarrow{\varepsilon}$; and write $\overset{a}{\Longrightarrow}$ for $\overset{\varepsilon}{\Longrightarrow}\xrightarrow{a}\overset{\varepsilon}{\Longrightarrow}$ if $a \neq \varepsilon$.

▶ **Definition 3** (Weak Bisimulation). *A binary relation* $R \subseteq \mathcal{P} \times \mathcal{P}$ *is a* weak bisimulation *if for all* $a \in \Sigma_\varepsilon$*, the following statements are valid:*

1. *whenever* $(P, Q) \in R$ *and* $P \xrightarrow{a} P'$*, then* $Q \overset{a}{\Longrightarrow} Q'$ *and* $(P', Q') \in R$ *for some* Q'*;*
2. *whenever* $(P, Q) \in R$ *and* $Q \xrightarrow{a} Q'$*, then* $P \overset{a}{\Longrightarrow} P'$ *and* $(P', Q') \in R$ *for some* P'*.*

The largest weak bisimulation, denoted by $\approx$ is called weak bisimilarity [15], and is also an equivalence relation.

Fast-Growing Complexity. We will use an ordinal-indexed hierarchy of “fast-growing” complexity classes defined in [18]. This hierarchy grows as $\mathbf{F}_1, \mathbf{F}_2, \mathbf{F}_3, \ldots, \mathbf{F}_\omega, \mathbf{F}_{\omega+1} \ldots$ and allows the classification of many decision problems with a non-elementary complexity. Here $\mathbf{F}_3 = \textsc{Tower}$ is the lowest non-elementary complexity class; $\bigcup_{k \in \mathbb{N}} \mathbf{F}_k$ is the primitive-recursive complexity class; and $\mathbf{F}_\omega = \textsc{Ackermann}$ is the lowest non-primitive-recursive complexity class. A complexity class is closed under reduction functions from “lower” complexity class. For example, all classes starting from $\mathbf{F}_3$ are closed under elementary reduction.

Bisimilarity Problem for PDA. We are interested in the *bisimilarity problem* for PDA defined as follows. Given a PDA $\mathcal{A} = (\mathcal{Q}, \Gamma, \Sigma, \mathcal{R})$ and two process $p\alpha$ and $q\beta$, where $p, q \in \mathcal{Q}$ and $\alpha, \beta \in \Gamma^*$, the bisimilarity problem asks if $p\alpha \sim q\beta$.

Our main result stated as follows improves the previous Tower-hard lower bound [2].

▶ **Theorem 4.** *The bisimilarity problem for PDA is Ackermann-hard and is $\mathbf{F}_{d-1}$-hard if the number of control states $d \geq 4$ is fixed.*

Combining with Ackermann upper bound from [10], we have the following result.

▶ **Corollary 5.** *The bisimilarity problem for PDA is Ackermann-complete.*

2.2 Bisimulation Game

Bisimulation equivalence has a nice game characterization called the *bisimulation game.*

Bisimulation Game. Given a pair of processes (P_0, Q_0), a bisimulation game for (P_0, Q_0) is played between *Attacker* and *Defender.* The game is played in rounds. In round i, Attacker chooses a transition $P_{i-1} \xrightarrow{a_i} P_i$ (resp. $Q_{i-1} \xrightarrow{a_i} Q_i$), then Defender chooses a transition with a same action $Q_{i-1} \xrightarrow{a_i} Q_i$ (resp. $P_{i-1} \xrightarrow{a_i} P_i$). We use $(P_{i-1}, Q_{i-1}) \xrightarrow{a_i} (P_i, Q_i)$ to denote a round. Defender wins if it never gets stuck; otherwise Attacker wins. We say that one player has a winning strategy if it can always win no matter how the opponent plays. The following result is well known.

▶ **Lemma 6.** *$P \sim Q$ if and only if Defender has a winning strategy in the bisimulation game for (P, Q).*

Macro Rules. Following [2], we introduce two kinds of macro rules to facilitate the design of bisimulation game and make our presentation concise.

(1). A macro rule $(pX, qY) \overset{ATT}{\hookrightarrow} (p_1\alpha_1, q_1\beta_1)$ denotes a pair of transitions:

$$pX \xrightarrow{a} p_1\alpha_1 \qquad qY \xrightarrow{a} q_1\beta_1$$

Here action a is *fresh.* This macro rule favours Attacker. In a bisimulation game for (pX, qY), if Attacker chooses transition $pX \xrightarrow{a} p_1\alpha_1$ (or $qY \xrightarrow{a} q_1\beta_1$), then Defender is forced to choose transition $qY \xrightarrow{a} q_1\beta_1$ (or $pX \xrightarrow{a} p_1\alpha_1$).

(2). A macro rule $(pX, qY) \overset{DEF}{\hookrightarrow} \{(p_1\alpha_1, q_1\beta_1), (p_2\alpha_2, q_2\beta_2)\}$ denotes a set of transitions:

$$\begin{array}{llll}
pX \xrightarrow{a_1} pZ_1 & pX \xrightarrow{a_1} pZ_2 & pX \xrightarrow{a_1} pZ_3 & \\
qY \xrightarrow{a_1} pZ_2 & qY \xrightarrow{a_1} pZ_3 & & \\
pZ_1 \xrightarrow{a_2} p_1\alpha_1 & pZ_1 \xrightarrow{a_3} p_2\alpha_2 & pZ_2 \xrightarrow{a_2} p_1\alpha_1 & pZ_2 \xrightarrow{a_3} q_2\beta_2 \\
pZ_3 \xrightarrow{a_2} q_1\beta_1 & pZ_3 \xrightarrow{a_3} p_2\alpha_2 & &
\end{array}$$

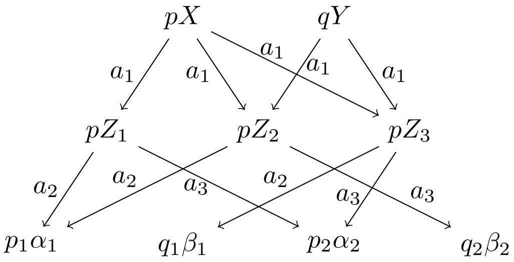

Figure 1 State transition diagram of macro rules $\xhookrightarrow{DEF}$.

Here a_1, a_2, a_3 are fresh actions, and Z_1, Z_2 and Z_3 are fresh stack symbols. This macro rule favours Defender. It is powered by a useful technique called *Defender's forcing* [11]. The state transition diagram of this macro rule is shown in Fig. 1. In a nutshell, with this macro rule, Defender can decide whether the game should continue with $(p_1\alpha_1\alpha, q_1\beta_1\alpha)$ or $(p_2\alpha_2\alpha, q_2\beta_2\alpha)$ in the bisimulation game for $(pX\alpha, qY\alpha)$.

Let us take a look at the development of the game for $(pX\alpha, qY\alpha)$.

1. If the game reaches a configuration with two identical processes, Defender wins immediately. Thus Attacker's optimal choice in the first step is $pX\alpha \xrightarrow{a_1} pZ_1\alpha$.
2. Then Defender can make a choice between $qY\alpha \xrightarrow{a_1} pZ_2\alpha$ and $qY\alpha \xrightarrow{a_1} pZ_3\alpha$. If Defender chooses transition $qY\alpha \xrightarrow{a_1} pZ_2\alpha$, the game continues with $(pZ_1\alpha, pZ_2\alpha)$. If Defender chooses transition $qY\alpha \xrightarrow{a_1} pZ_3\alpha$, the game continues with $(pZ_1\alpha, pZ_3\alpha)$.
3. In the case of $(pZ_1\alpha, pZ_2\alpha)$, Attacker is forced to choose action a_3, the game comes into $(p_2\alpha_2\alpha, q_2\beta_2\alpha)$. Similarly, in the case of $(pZ_1\alpha, pZ_3\alpha)$, Attacker is forced to choose action a_2 and the game reaches $(p_1\alpha_1\alpha, q_1\beta_1\alpha)$.

3 Lower Bound

We prove our main result by a reduction from the coverability problem of reset Petri net. We recall reset Petri net and its ACKERMANN-complete coverability problem in Section 3.1. We then construct an exponential time reduction in Section 3.2. Although the exponential time reduction suffices for our purpose, we revise it to a polynomial one in Section 3.3.

3.1 Reset Petri Net

Reset Petri Net (RPN). A reset Petri net is a tuple $\mathcal{N} = (\mathcal{S}, \mathcal{C}, \delta)$ consists of

- a finite set of control states $\mathcal{S}$ ranged over by s, t;
- a finite set of counters $\mathcal{C} = \{c_1, c_2, \ldots, c_d\}$;
- a finite set of instructions $\delta \subseteq \mathcal{S} \times \mathcal{O} \times \mathcal{S}$, where the set of operations $\mathcal{O}$ consists of $\mathsf{INC}(c_i)$, $\mathsf{DEC}(c_i)$ and $\mathsf{RESET}(c_i)$ for $i = 1, 2, \ldots, d$.

A configuration is a tuple $(s, n_1, \ldots, n_d)$ with $s \in \mathcal{S}$ representing the current state, and $n_1, \ldots, n_d \in \mathbb{N}$ representing the current contents of the counters. If $(s, op, t) \in \delta$ then we have $(s, n_1, \ldots, n_d) \to (t, n'_1, \ldots, n'_d)$ in the following cases:

- $op = \mathsf{INC}(c_i)$, $n'_i = n_i + 1$, and $n'_j = n_j$ for all $j \neq i$; or
- $op = \mathsf{DEC}(c_i)$, $n_i > 0$, $n'_i = n_i - 1$, and $n'_j = n_j$ for all $j \neq i$; or
- $op = \mathsf{RESET}(c_i)$, $n'_i = 0$, and $n'_j = n_j$ for all $j \neq i$.

By $\rightarrow^*$ we denote the reflexive and transitive closure of $\rightarrow$. We define a partial order $\leq$ on the configurations of $\mathcal{N}$:

$$(s, n_1, \ldots, n_d) \leq (t, m_1, \ldots, m_d) \text{ if } s = t \ \wedge \ n_1 \leq m_1 \ \wedge \ \ldots \ \wedge \ n_d \leq m_d.$$

We say σ_2 is *coverable* from σ_1 if there is some σ such that $\sigma_1 \rightarrow^* \sigma$ and $\sigma \geq \sigma_2$.

Coverability Problem of RPN. Given a Reset Petri Net $\mathcal{N} = (\mathcal{S}, \mathcal{C}, \delta)$, an initial configuration σ_1 and a final configuration σ_2, where the counters of σ_1 and σ_2 are given in binary, the *coverability* problem asks if σ_2 is coverable from σ_1.

We recall the following complexity result for coverability problem of RPN [19, 20, 21].

▶ **Theorem 7.** *The coverability problem of RPN is* Ackermann*-complete, and is* $\mathbf{F}_d$*-complete if the number of counters* $d \geq 3$ *is fixed.*

3.2 An Exponential Time Reduction

Given a RPN $\mathcal{N} = (\mathcal{S}, \mathcal{C}, \delta)$, an initial configuration σ_1, and a final configuration σ_2, we will construct a PDA $\mathcal{A} = (\mathcal{Q}, \Gamma, \Sigma, \mathcal{R})$ and two processes P, Q of $\mathcal{A}$ in exponential time such that

$$\sigma_2 \text{ is coverable from } \sigma_1 \text{ if and only if } P \not\sim Q. \qquad (\star)$$

Reduction Overview. Our reduction encodes the run of $\mathcal{N}$ from configuration σ_1 as a bisimulation game for (P, Q). In the bisimulation game, Attacker aims to show that σ_2 is coverable from σ_1, while Defender aims to show the opposite.

In order to complete the reduction, we should pay attention to the following aspects.

- A configuration σ' of $\mathcal{N}$ corresponds to a game for (P', Q') in the sense that the state and counter values of σ' are both encoded on the stack of both P' and Q'.
- To track the counters in the run from σ, the bisimulation game pushes every counter operation from the initial configuration on the stacks. Observe that the value of a counter of $\mathcal{N}$ can never become negative. Our reduction will guarantee that Attacker can never cheat by decreasing a counter with value zero. This is fulfilled by Defender's forcing. More specifically, for every $\mathsf{DEC}(c_i)$ operation, Defender has the power to verify its validity by initiating what we shall call a *zero check* for c_i.
- If a configuration that covers σ_2 is reached, Attacker wins the game. In the reduction, we will introduce a special witness action f. When a configuration $\sigma \geq \sigma_2$ is reached, the game will finally come into some (P', Q') where P' can do action f while Q' cannot.

As mentioned earlier, the basic idea of our reduction follows from [9], where Ackermann-hardness is proven for the bisimilarity problem of first-order grammars. However, as what will become clear in Section 4, first-order grammars are strictly more powerful than PDA w.r.t. bisimilarity. Here we highlight the main differences between our reduction and the one in [9].

- The reduction in [9] records the increasing and decreasing operations of d counters into $2d$ sub-processes (i.e. sub-terms in the terminology of first-order grammars). These sub-processes can work "in parallel" and be accessed without being interfered by each other. Zero check of a specific counter is achieved by skipping irrelevant sub-processes and comparing the relevant ones directly. Due to the sequential nature of stacks, this is beyond the reach of (real-time) PDA (see also Section 4). Instead, the increasing and decreasing operations recorded on the stack are interfered by each other unavoidably. To check zero for a counter, we introduce a novel mechanism by comparing the stack as a whole (Lemma 11).

- Our reduction uses $d+1$ PDA control states to encode a RPN with d counters. This yields a $\mathbf{F}_{d-1}$-hardness result, a first parametric lower-bound for the bisimilarity problem for PDA. In contrast, parametric complexity is not studied in [9]. Moreover, if we transform the reduction for first-order grammars [9] directly to a new reduction for PDA, the resulting PDA would require (i) at least $2d$ control states and (ii) popping ε-rules.

▶ Remark 8. In [9], the Ackermann-hardness for bisimilarity of FOG is established by reduction from the *control state reachability problem* of RPN. When the counters in the configurations of RPN are given in binary, the coverability problem of RPN is equivalent to the control state reachability problem under exponential time reduction. Incorporating the counter encoding and zero check trick into the reduction of [9], we can get the Ackermann-hard lower bound for bisimilarity of PDA as well. The main reason that we choose the coverability problem of RPN instead is to build a parametric lower bound under polynomial time reduction.

The Reduction. We fix a RPN $\mathcal{N} = (\mathcal{S}, \mathcal{C}, \delta)$, an initial configuration $\sigma_1 = (t_s, n_1, \ldots, n_d)$, a final configuration $\sigma_2 = (t_f, m_1, \ldots, m_d)$ in this subsection. The corresponding PDA $\mathcal{A} = (\mathcal{Q}, \Gamma, \Sigma, \mathcal{R})$ and two processes P, Q are defined as follows.

1. We introduce $d+1$ control states:

$$\mathcal{Q} \overset{\text{def}}{=} \{p, q_1, q_2, \ldots, q_d\}$$

Here q_1, q_2, …, q_d correspond to c_1, c_2, …, c_d of $\mathcal{C}$, respectively. The usage of state p will become clear later.

2. To record the operations on counters in $\mathcal{C}$, we introduce the following stack symbols:

$$\Gamma_{\mathcal{C}} \overset{\text{def}}{=} \{X_i^+, X_i^-, X_i^0 : i = 1, 2, \ldots, d\} \subseteq \Gamma$$

Here X_i^+, X_i^- and X_i^0 represent operations $\mathsf{INC}(c_i)$, $\mathsf{DEC}(c_i)$ and $\mathsf{RESET}(c_i)$, respectively.

3. To record the states of $\mathcal{N}$, for every state $s \in \mathcal{S}$, we introduce a pair of stack symbols:

$$\{Y_s, Y_s'\} \subseteq \Gamma$$

4. The two processes P and Q of the initial bisimulation game configuration are defined by

$$P \overset{\text{def}}{=} pY_s(X_1^+)^{n_1} \ldots (X_d^+)^{n_d} \qquad Q \overset{\text{def}}{=} pY_s'(X_1^+)^{n_1} \ldots (X_d^+)^{n_d}$$

In the rest of this subsection, we will complete the definition of $\mathcal{A}$ to validate property ($\star$). We start with encoding counters of $\mathcal{N}$ on the stacks of PDA processes. We then introduce rules for $\mathcal{A}$ to manipulate counters and perform zero checks. Last we show how to verify the coverability property in bisimulation games.

Counter Encoding. For each $i = 1, 2, \ldots, d$, we introduce a function $\mathsf{count}_i : {\Gamma_{\mathcal{C}}}^* \to \mathbb{Z}$. Let $\alpha = X_n X_{n-1} \ldots X_1 \in {\Gamma_{\mathcal{C}}}^*$. Intuitively, $\mathsf{count}_i(\alpha)$ computes the value of c_i after a sequence of operations $X_1, X_2, \ldots, X_n$. More specifically, let K_i be the largest index such that $X_{K_i} = X_i^0$, i.e., the leftmost occurrence of a reset operation of counter c_i. If X_i^0 does not appear in α, then $K_i = 0$. Let I_i and D_i be the respective numbers of occurrences of X_i^+ and X_i^- in the subsequence $X_n X_{n-1} \ldots X_{K_i+1}$ of α. The function count_i is defined by $\mathsf{count}_i(\alpha) = I_i - D_i$.

▶ Remark 9. Since the counters in reset Petri net cannot be negative, some strings, e.g. $X_1^- X_1^- X_1^+$, are invalid. For simplicity, the functions count_i are defined on all strings in ${\Gamma_{\mathcal{C}}}^*$.

▶ **Example 10.** $\mathsf{count}_1(X_2^+ X_1^0 X_2^+ X_1^+) = 0$ and $\mathsf{count}_2(X_2^+ X_1^0 X_2^+ X_1^+) = 2$.

We next introduce rules for counter manipulations. The PDA processes record every operation to the counters on their stacks. The trick here is to avoid invalid operations on counters. For example, at configuration $(pY_s X_1^- X_1^+,\ pY_s' X_1^- X_1^+)$, the counter c_1 is zero and it is not supposed to push another X_1^-. Here we use the Defender's forcing technique to fulfill this goal. Defender has a chance to force Attacker to check whether a decrease operation is valid. If it is not valid, Defender can win the game.

Counter Manipulation. For each instruction $I = (s, op, t)$ of $\mathcal{N}$, we introduce a set of PDA rules to $\mathcal{R}$ for counter manipulations as follows.

- If $op = \mathsf{INC}(c_i)$, we introduce $(pY_s, pY_s') \xhookrightarrow{ATT} (pY_t X_i^+, pY_t' X_i^+)$.
- If $op = \mathsf{RESET}(c_i)$, we introduce $(pY_s, pY_s') \xhookrightarrow{ATT} (pY_t X_i^0, pY_t' X_i^0)$.
- If $op = \mathsf{DEC}(c_i)$, we introduce $(pY_s, pY_s') \xhookrightarrow{DEF} \{(pY_t X_i^-, pY_t' X_i^-), (p, q_i)\}$.

We will make more comments on the decrease operation. The control states q_1, q_2, …, q_d are mainly used to zero check the counters c_1, c_2, …, c_d, respectively. In the sequel, we will introduce some rules to ensure the correctness of zero checks as stated in the following lemma.

▶ **Lemma 11.** *$q_i\alpha \sim p\alpha$ if and only if $\mathsf{count}_i(\alpha) = 0$, where $\alpha \in {\Gamma_{\mathcal{C}}}^*$.*

By Lemma 11, if Attacker intends to do an invalid decrease operation on counter c_i, Defender can force the game to the branch of (p, q_i) and win. If Attacker intends to do a valid decrease operation on counter c_i, Defender would lose in the branch of (p, q_i). In that case, Defender will force the game to the branch of $(pY_t X_i^-, pY_t' X_i^-)$ and the game continues.

Zero Check. We introduce the following rules to ensure the correctness of zero check. For the sake of concision, we introduce another macro rule. Given $w = a_1 a_2 \ldots a_n$, we use $pX \xhookrightarrow{w} q\alpha$ to stand for the sequence of transitions $pX \xrightarrow{a_1} pX_1 \xrightarrow{a_2} \ldots \xrightarrow{a_{n-1}} pX_{n-1} \xrightarrow{a_n} q\alpha$. Note that these macro rules do not introduce any new state. All the stack symbols introduced in these macro rules are fresh.

$$
\begin{array}{rcll}
pX & \xhookrightarrow{b_{pop}b_{pop}} & p & \text{For } X \in \Gamma_{\mathcal{C}} \\
q_i X_i^- & \xhookrightarrow{b_{pop}} & q_i & \text{For } i = 1, 2, \ldots, d \\
q_i X_i^+ & \xhookrightarrow{b_{pop}b_{pop}b_{pop}} & q_i & \text{For } i = 1, 2, \ldots, d \\
q_i X_i^0 & \xhookrightarrow{b_{pop}b_{pop}} & p & \text{For } i = 1, 2, \ldots, d \\
q_i X & \xhookrightarrow{b_{pop}b_{pop}} & q_i & \text{For } i = 1, 2, \ldots, d, \qquad X \in \Gamma_{\mathcal{C}} \setminus \{X_i^-, X_i^+, X_i^0\}
\end{array}
$$

Proof of Lemma 11. Observe that the bisimilarity between $q_i\alpha$ and $p\alpha$ only depends on the total numbers of consecutive actions b_{pop} from $q_i\alpha$ and $p\alpha$. Process $p\alpha$ can do action b_{pop} twice for every stack symbol. Process $q_i\alpha$ can do three b_{pop} actions for each X_i^+ and one b_{pop} action for each X_i^- before it meets the first X_i^0. Let I_i and D_i be the numbers of X_i^+ and X_i^- before it meets the first X_i^0. It follows that $q_i\alpha \sim p\alpha$ if and only if $3I_i + D_i + 2(|\alpha| - I_i - D_i) = 2|\alpha|$. Note that $\mathsf{count}_i(\alpha) = I_i - D_i$. Thus $q_i\alpha \sim p\alpha$ if and only if $\mathsf{count}_i(\alpha) = 0$. ◀

▶ Remark 12. The implementation of counters and their zero check mechanism is the main technical difference of our reduction from the one for first-order grammars [9]. The reduction in [9] compares the increasing and decreasing operations of a counter directly, by skipping non-relevant operations. As will be seen in Section 4, the ability to skip non-relevant operations also makes first-order grammars more powerful than PDA.

Coverability Check. When the game reaches $(pY_{t_f}\alpha, pY'_{t_f}\alpha)$, Attacker can initiate a coverability check. Then Defender will choose a counter c_i and check if $\mathsf{count}_i(\alpha) \geq m_i$. To this end, we introduce $d+1$ pairs of stack symbols $(Z_1, Z'_1), \dots (Z_{d+1}, Z'_{d+1})$ for counter choice. For each $1 \leq i \leq d$, we introduce $m_i + 1$ pairs of stack symbols $(Z_{i,0}, Z'_{i,0}), \dots, (Z_{i,m_i}, Z'_{i,m_i})$ for coverability check of counter c_i.

(1). We first add rules to check coverability of a specific counter c_i $(1 \leq i \leq d)$. For the pair $(pZ_{i,n}, pZ'_{i,n})$, where $0 \leq n \leq m_i$, we introduce the following rules.

- $(pZ_{i,n}, pZ'_{i,n}) \xhookrightarrow{DEF} \{(pZ_{i,n-1}X_i^-, pZ'_{i,n-1}X_i^-), (p, q_i)\}$;
- $pZ_{i,0} \xrightarrow{f} p, \qquad pZ'_{i,0} \xrightarrow{b_{pop}} p.$

If $\mathsf{count}_i(\alpha) < m_i$, then by Defender's forcing, Defender can push $\mathsf{count}_i(\alpha)$ number of X_i^- to the stack and the game reaches $(p\gamma\alpha, p_i\gamma\alpha)$, where $\gamma = (X_i^-)^{\mathsf{count}_i(\alpha)}$. By Lemma 11, Defender wins. If $\mathsf{count}_i(\alpha) \geq m_i$, Defender's best strategy would lead the game into a configuration $(pZ_{i,0}\beta\alpha, pZ'_{i,0}\beta\alpha)$ where $\beta = (X_i^-)^{m_i}$. Attacker wins since $pZ_{i,0}\beta\alpha$ admits a fresh action f, while $pZ'_{i,0}\beta\alpha$ does not. As a result, we have the following lemma.

▶ **Lemma 13.** *$pZ_{i,m_i}\alpha \sim pZ'_{i,m_i}\alpha$ if and only if $\mathsf{count}_i(\alpha) < m_i$, where $\alpha \in \Gamma^*$.*

(2). We next introduce the following rules to help Defender pick a specific counter to perform coverability check.

- $(pY_{t_f}, pY'_{t_f}) \xhookrightarrow{ATT} (pZ_1, pZ'_1)$;
- $(pZ_i, pZ'_i) \xhookrightarrow{DEF} \{(pZ_{i,m_i}, pZ'_{i,m_i}), (pZ_{i+1}, pZ'_{i+1})\}$ for $i = 1, 2, \dots, d$;
- $pZ_{d+1} \xrightarrow{f} p, \qquad pZ'_{d+1} \xrightarrow{b_{pop}} p.$

Suppose that Attacker initiates a coverability check and the game reaches $(pZ_1\alpha, pZ'_1\alpha)$. Defender can choose a specific counter to verify by Defender's forcing. Indeed if $\mathsf{count}_i(\alpha) < m_i$ for some $1 \leq i \leq d$, Defender can force the game to $(pZ_{i,m_i}\alpha, pZ'_{i,m_i}\alpha)$. By Lemma 13, Defender wins. If $\mathsf{count}_i(\alpha) \geq m_i$ for all $1 \leq i \leq d$, then Defender's best strategy is leading the game to configuration $(pZ_{d+1}\alpha, pZ'_{d+1}\alpha)$. Attacker wins via a fresh action f.

▶ **Proposition 14.** *The coverability problem of RPN (with d counters) can be reduced to the complement of the bisimilarity problem for PDA (with $d+1$ states) in exponential time.*

Proof. We construct the reduction as described in the section and prove the property $(\star)$.
($\Rightarrow$). If $(t_f, m_1, \dots, m_d)$ is coverable from $(t_s, n_1, \dots, n_d)$, then there exists a configuration $(t_f, m'_1, \dots, m'_d) \geq (t_f, m_1, \dots, m_d)$, which is reachable from $(t_s, n_1, \dots, n_d)$. We describe a winning strategy for Attacker. Attacker simply follows the path from $(t_s, n_1, \dots, n_d)$ to $(t_f, m'_1, \dots, m'_d)$. Since every decrease operation is valid, Defender will not ask for zero checks. The bisimulation game will reach $(pY_{t_f}\alpha, pY'_{t_f}\alpha)$ such that $\mathsf{count}_i(\alpha) = m'_i$ for each $i \in \{1, 2, \dots, d\}$. Attacker starts a coverability check and wins the game.

($\Leftarrow$). If $(t_f, m_1, \dots, m_d)$ is not coverable from $(t_s, n_1, \dots, n_d)$, we describe a winning strategy for Defender. Defender just follows what Attacker does and asks for zero check if Attacker tries to decrease a zero counter. Whenever the game reaches $(pY_{t_f}\beta, pY'_{t_f}\beta)$ for some $\beta \in \Gamma^*$, there exists some $i \in \{1, 2, \dots, d\}$, $\mathsf{count}_i(\beta) < m_i$. If Attacker asks for a coverability check, then Defender can choose to verify the value of counter c_i. By Lemma 13, Defender wins. If Attacker never initiates a coverability check, Defender also wins as it will never get stuck. ◀

By Theorem 7 and Proposition 14, we have our main result Theorem 4. Observe that it is safe to introduce rules $pY_s \xrightarrow{b_{pop}} p$ and $pY'_s \xrightarrow{b_{pop}} p$ for every $s \in \mathcal{S}$ since these transitions will never be chosen by Attacker (or Attacker loses immediately). As a result, the PDA $\mathcal{A}$ is normed and our lower bound can be generalized to the normed case.

▶ **Corollary 15.** *The bisimilarity problem of normed PDA is* Ackermann*-complete and is* $\mathbf{F}_{d-1}$*-hard if the number of control states is* $d \geq 4$*.*

3.3 A Polynomial Time Reduction

Although an elementary reduction suffices for our purpose, we show that the exponential time reduction can be actually revised to be polynomial. There are two exponential factors in the reduction presented in Section 3.2: (i) the size of the initial configuration of the bisimulation game can be exponentially large; and (ii) the number of rules for coverability check can be exponentially many. We eliminate both by incorporating a binary representation of counters.

Counter Binary Encoding. Let m be the maximal number occurs in the initial and final configuration of $\mathcal{N}$, and k the smallest number such that $2^k \geq m$. For every counter c_i, we introduce two new stack symbols $X^+_{i,j}$ and $X^-_{i,j}$ for each $j \in \{0, 1, \dots, k\}$. Intuitively, $X^+_{i,j}$ (resp. $X^-_{i,j}$) represents 2^j increasing (resp. decreasing) operations on counter c_i. Stack symbol X^0_i is still used to represent operation $\mathsf{RESET}(c_i)$. We then replace the initial game configuration by this binary representation. The function count_i can also be revised easily by taking the binary representation into account. We omit the details.

▶ **Example 16.** An initial RPN configuration $\sigma_1 = (s, 6, 3)$ can be encoded by a game configuration $(pY_sX^+_{1,2}X^+_{1,1}X^+_{2,1}X^+_{2,0}, pY'_sX^+_{1,2}X^+_{1,1}X^+_{2,1}X^+_{2,0})$.

We next revise the rules to make zero check and coverability check work.

Zero Check. We introduce new rules for $X^+_{i,j}$ and $X^-_{i,j}$ for zero check, where $0 \leq j \leq k$.

- $pX^+_{i,j} \xhookrightarrow{b_{pop}b_{pop}} pX^+_{i,j-1} \dots X^+_{i,0}$, $\quad pX^+_{i,0} \xhookrightarrow{b_{pop}b_{pop}} p$;
- $pX^-_{i,j} \xhookrightarrow{b_{pop}b_{pop}} pX^-_{i,j-1} \dots X^-_{i,0}$, $\quad pX^-_{i,0} \xhookrightarrow{b_{pop}b_{pop}} p$;
- $q_iX^+_{i,j} \xhookrightarrow{b_{pop}b_{pop}b_{pop}} q_iX^+_{i,j-1} \dots X^+_{i,0}$, $\quad q_iX^+_{i,0} \xhookrightarrow{b_{pop}b_{pop}b_{pop}} q_i$;
- $q_iX^-_{i,j} \xhookrightarrow{b_{pop}} q_iX^-_{i,j-1} \dots X^-_{i,0}$, $\quad q_iX^-_{i,0} \xhookrightarrow{b_{pop}} q_i$;

Note that besides the rules introduced above, we keep the rule $q_iX^0_i \xhookrightarrow{b_{pop}b_{pop}} p$ for $i \in \{1, \dots, d\}$. Lemma 11 is still valid and can be proved along the same line.

Coverability Check. Let m_i be the value of c_i in the final configuration σ_2 and k_i be the least number such that $2^{k_i} - 1 \geq m_i$. We replace the rules for $(pZ_{i,j}, pZ'_{i,j})$ $(0 \leq j \leq m_i)$ by

- $(pZ_{i,m_i}, pZ'_{i,m_i}) \xhookrightarrow{ATT} (pW_{i,0}\beta, pW'_{i,0}\beta)$, $\quad (pW_{i,k_i}, pW'_{i,k_i}) \xhookrightarrow{ATT} (p, q_i)$;
- $(pW_{i,j}, pW'_{i,j}) \xhookrightarrow{DEF} \{(pW_{i,j+1}X^{-}_{i,j}, pW'_{i,j+1}X^{-}_{i,j}), (pW_{i,j+1}, pW'_{i,j+1})\}$ $\qquad (0 \leq j < k_i)$

Here $W_{i,0}, \ldots, W_{i,k_i}$ are new stack symbols for coverability check and β consists of the binary stack symbols introduced above such that $\mathsf{count}_i(\beta) = 2^{k_i} - m_i$.

We show that Lemma 13 still holds. Consider the bisimulation game for $(pZ_{i,m_i}\alpha, pZ'_{i,m_i}\alpha)$. Intuitively, the coverability check starts with increasing counter c_i with $2^{k_i} - m_i$. After that, Defender decreases c_i by a combination of k_i choices and the game reaches a configuration $(p\gamma\alpha, q_i\gamma\alpha)$. If $\mathsf{count}_i(\alpha) < m_i$, Defender can pick γ such that $\mathsf{count}_i(\gamma\alpha) = 0$. By Lemma 11, Defender wins. If $\mathsf{count}_i(\alpha) \geq m_i$, then $\mathsf{count}_i(\alpha) + (2^{k_i} - m_i) - (2^{k_i} - 1) > 0$. The counter c_i can never be decreased to zero and Attacker wins.

4 Relative Expressiveness of PDA

First-order grammars have close relationship with pushdown automata [7, 9, 10], as they are equivalent to PDA with deterministic and popping ε-rules. More specifically, any process T definable in a first-order grammar can be encoded into a PDA process P with deterministic and popping ε-rules, and vice versa. The processes T and P are weakly bisimilar. In the real-time case, i.e, when no ϵ-rules is allowed, FOG have strictly richer behaviours than PDA. This can be proved by considering the transition graph of real-time PDA and PDA with deterministic ε-rules (see, e.g., [3], Proposition 5.8).

Nevertheless, to build better intuition for this result and also demonstrate why the original reduction in [9] cannot be directly applied to real-time PDA, we give another proof in this section to show that FOG are strictly stronger than PDA, as far as bisimilarity is considered.

To avoid introducing the definition of FOG, we construct a special PDA with deterministic and popping ε-rules and show that it can define a process which cannot be bisimulated by any real-time PDA process. The special PDA $\mathcal{A}$ contains the following rules:

- $pX_0 \xrightarrow{a} pX$, $\quad pX \xrightarrow{a} pXX$, $\quad pX \xrightarrow{b} pYX$, $\quad pY \xrightarrow{b} pYY$;
- $pY \xrightarrow{c} p_1Y$, $\quad pY \xrightarrow{d} p_2Y$;
- $p_1Y \xrightarrow{\varepsilon} p_1$, $\quad p_1X \xrightarrow{a} p_1$, $\quad p_2Y \xrightarrow{b} p_2$, $\quad p_2X \xrightarrow{\varepsilon} p_2$.

Observe that pX_0 can do actions $a^m b^n$ and record m and n by pushing $Y^m X^n$ into stack. The popping ε-rules enable the process to recover the information of m or n immediately (via doing actions a^m after c or actions b^n after d). We will show that such ε-rules are necessary in the sense that no real-time PDA is weakly bisimilar to $\mathcal{A}$. Intuitively, any real-time PDA process, after executing actions $a^m b^n$, cannot access both the information of m and n on the stack without undesired interference. The necessity of ε-rules is also the basic reason why the reduction in the hardness proof for first-order grammars [9] fails for real-time PDA.

▶ **Proposition 17.** *For any real-time PDA process O, $O \not\approx pX_0$.*

A direct consequence is that first-order grammars are strictly stronger that PDA. Indeed, following the transformation in [10], one can construct a process T in a first-order grammar such that (i) $T \approx pX_0$ and (ii) T has no ε transitions (the ε transitions are absorbed in FOG during transformation). As a result T cannot be related to any PDA process by bisimilarity.

▶ **Corollary 18.** *There exists a process T definable by a first-order grammar, such that for any real-time PDA process O, $O \not\sim T$.*

We prove Proposition 17 in the rest of this section. To do that, we need a useful pumping property of pushdown automata. We say a transition sequence $\xi : P_0 \xrightarrow{a_1} P_1 \xrightarrow{a_2} \ldots \xrightarrow{a_k} P_k$ is *non-sinking* if $|P_i| \geq |P_0|$ for $1 \leq i \leq k$. Moreover, ξ is *pumpable* if (i) ξ is *non-sinking* and (ii) $P_0 = pZ\alpha$ and $P_k = pZ\beta\alpha$ for some $p \in \mathcal{Q}$, $Z \in \Gamma$, $\alpha \in \Gamma^*$, and $\beta \in \Gamma^+$.

▶ **Lemma 19.** *Suppose that P_0 is a PDA process defined in $\mathcal{A} = (\mathcal{Q}, \Gamma, \Sigma, \mathcal{R})$ and it holds that $|\alpha| \leq 2$ for each $(p, X, a, q, \alpha) \in \mathcal{R}$. If there exists a transition sequence $\xi : P_0 \xrightarrow{a_1} P_1 \xrightarrow{a_2} \ldots \xrightarrow{a_n} P_n$ such that (i) $n \geq |P_0| \cdot (|Q||\Gamma| + 1)^{|Q||\Gamma|+1}$ and (ii) $P_i \not\sim P_j$ $(\forall i \neq j, 0 \leq i, j \leq n)$, then ξ contains a pumpable transition subsequence.*

Proof. Let $\xi' : Q_0 \xrightarrow{b_1} Q_1 \xrightarrow{b_2} \ldots \xrightarrow{b_m} Q_m$ be a *non-sinking* transition sequence such that $Q_i \not\sim Q_j$ $(\forall i \neq j)$. Denote by $\mathsf{type}(\xi')$ the set of different pairs of state and top stack symbol that occur in ξ'. More specifically, $\mathsf{type}(\xi') \overset{\text{def}}{=} \{(q, Z) :$ there is a process $qZ\beta$ in $\xi'\}$. It is sufficient to prove the following property:

$$\text{if } m \geq (|\mathsf{type}(\xi')| + 1)^{|\mathsf{type}(\xi')|+1}, \text{ then } \xi' \text{ contains a pumpable transition subsequence.} \qquad (\star\star)$$

Our lemma is established by observing that ξ contains a non-sinking subsequence ξ' of length at least $(|\mathcal{Q}||\Gamma| + 1)^{|\mathcal{Q}||\Gamma|+1}$. Suppose otherwise, then in less than $|P_0| \cdot (|Q||\Gamma| + 1)^{|Q||\Gamma|+1}$ steps P_0 will reach a process $p'\varepsilon$ for some $p' \in \mathcal{Q}$. This contradicts with our assumption (i).

We next prove $(\star\star)$ by induction on $|\mathsf{type}(\xi')|$.

- $|\mathsf{type}(\xi')| = 1$. It is trivial since ξ' is pumpable.
- $|\mathsf{type}(\xi')| = k+1$. By assumption, ξ' is of length at least $(k+2)^{k+2}$. Since ξ' is non-sinking and any two processes in ξ' are not equal, there are no more than k other processes of the size $|Q_0|$. By removing these (shortest) processes, we get at most $k + 1$ transition subsequences. There must be a sequence (denoted as ξ'') of length at least $(k + 1)^{k+1}$. By assumption of $\mathcal{A}$, the stack height will increase at most by one in a transition. It follows that ξ'' is non-sinking. Let $Q_0 = qZ\alpha$. If $(q, Z) \in \mathsf{type}(\xi'')$, say $Q_j = qZ\beta\alpha$, then $Q_0 \xrightarrow{b_1} \ldots \xrightarrow{b_j} Q_j$ is pumpable. Otherwise $|\mathsf{type}(\xi'')| = k$. By induction hypothesis, ξ'' contains a pumpable transition subsequence. ◀

We are ready to prove Proposition 17.

Proof of Proposition 17. Suppose otherwise and let O be a process of a real-time PDA $\mathcal{B} = (\mathcal{Q}, \Gamma, \Sigma, \mathcal{R})$ and $O \approx pX_0$. W.l.o.g., we assume that $|\alpha| \leq 2$ for each $(p, X, q, \alpha) \in \mathcal{R}$. Let $N = |\mathcal{Q}||\Gamma| + 1$ and $m \geq 1$. Consider the following transition sequence of pX_0

$$pX_0 \xrightarrow{a^m} pX^m \xrightarrow{b} pYX^m \xrightarrow{b} \ldots \xrightarrow{b} pY^nX^m. \qquad (2)$$

Since $O \approx pX_0$ and O is real-time, there exists $O_{m,i}$ $(0 \leq i \leq n)$ such that

$$O \xrightarrow{a^m} O_{m,0} \xrightarrow{b} O_{m,1} \xrightarrow{b} \ldots \xrightarrow{b} O_{m,n} \qquad (3)$$

and $O_{m,i} \approx pY^iX^m$ for $0 \leq i \leq n$. Observe that $pY^iX^m \not\approx pY^jX^m$ $(\forall i \neq j)$. Hence $O_{m,i} \not\sim O_{m,j}$ $(\forall i \neq j)$. Let $n = |O_{m,0}|N^N$. By Lemma 19, we can find $q \in \mathcal{Q}$ and $Z \in \Gamma$ such that

(i) $qZ\alpha = O_{m,s}$ and $qZ\beta\alpha = O_{m,t}$ for some $0 \leq s < t \leq n$, $\alpha \in \Gamma^*$ and $\beta \in \Gamma^+$; and

(ii) the transition subsequence of $O_{m,s} \xrightarrow{b} O_{m,s+1} \xrightarrow{b} \ldots \xrightarrow{b} O_{m,t}$ is pumpable.

Let $k = t - s$, we can repeat the pumpable transition sequence as many times as we want

$$qZ\alpha \xrightarrow{b^k} qZ\beta\alpha \xrightarrow{b^k} qZ\beta\beta\alpha \xrightarrow{b^k} \dots \tag{4}$$

As $qZ\alpha = O_{m,s} \approx pY^sX^m$, the above sequence must be simulated by

$$pY^sX^m \xrightarrow{b^k} pY^{s+k}X^m \xrightarrow{b^k} pY^{s+2k}X^m \xrightarrow{b^k} \dots \tag{5}$$

such that $qZ\beta^i\alpha \approx pY^{s+ki}X^m$ for $i \geq 0$.

For different m, we can have different transition sequences (4) and (5), possibly with different $s > 0$, $k > 0$, $q \in \mathcal{Q}$, $Z \in \Gamma$, $\alpha \in \Gamma^*$ and $\beta \in \Gamma^+$. By the pigeonhole principle, there are two different numbers $1 \leq m_1 < m_2 \leq N$ so that q and Z are the same in transition sequence (4). Assume w.l.o.g. that $qZ\alpha_1 = O_{m_1,s_1} \approx pY^{s_1}X^{m_1}$, $qZ\alpha_2 = O_{m_2,s_2} \approx pY^{s_2}X^{m_2}$ and $qZ \xrightarrow{b^{k_1}} qZ\beta_1$ for some $s_1, s_2, k_1 > 0$, $\alpha_1, \alpha_2 \in \Gamma^*$ and $\beta_1 \in \Gamma^+$. The actions $O_{m_1,s_1} \xrightarrow{b^{k_1 \cdot N}} qZ\beta_1^N\alpha_1$ must be simulated by $pY^{s_1}X^{m_1} \xrightarrow{b^{k_1 \cdot N}} pY^{s_1+k_1\cdot N}X^{m_1}$. Similarly $O_{m_2,s_2} \xrightarrow{b^{k_1 \cdot N}} qZ\beta_1^N\alpha_2$ must be simulated by $pY^{s_2}X^{m_2} \xrightarrow{b^{k_1 \cdot N}} pY^{s_2+k_1\cdot N}X^{m_2}$. We also have that $pY^{s_1+k_1\cdot N}X^{m_1} \approx qZ\beta_1^N\alpha_1$ and $pY^{s_2+k_1\cdot N}X^{m_2} \approx qZ\beta_1^N\alpha_2$.

Consider the following transition sequence of $pY^{s_2+k_1\cdot N}X^{m_2}$

$$pY^{s_2+k_1\cdot N}X^{m_2} \xrightarrow{c} p_1Y^{s_2+k_1\cdot N}X^{m_2} \overset{\varepsilon}{\Longrightarrow} p_1X^{m_2} \xrightarrow{a^{m_1+1}} p_1X^{m_2-m_1-1}. \tag{6}$$

It can be matched by $qZ\beta_1^N\alpha_2 \xrightarrow{ca^{m+1}} P_1$ for some P_1. Since $qZ\beta_1^N\alpha_2$ is real-time and $N \geq m_1+1$, the actions ca^{m_1+1} from $qZ\beta_1^N\alpha_2$ only depend on $qZ\beta_1^N$. Thus $qZ\beta_1^N\alpha_1 \xrightarrow{ca^{m_1+1}} Q$ for some Q. This contradicts with $qZ\beta_1^N\alpha_1 \approx pY^{s_1+k_1\cdot N}X^{m_1}$, since after transition $pY^{s_1+k_1\cdot N}X^{m_1} \xrightarrow{c} p_1Y^{s_1+k_1\cdot N}X^{m_1}$, the longest non-$\varepsilon$ action sequence is a^{m_1}. ◀

5 Conclusion

In this paper, we show that the bisimilarity of PDA is Ackermann-hard. Combining with the result in [10], we can conclude that the bisimilarity of PDA is Ackermann-complete. The result can be generalized to normed PDA. Besides, we give another proof on that the so-called real-time pushdown processes are strictly weaker than first-order grammars. Our work answers the question proposed by Jančar and Schmitz in [10].

When the number of control states of PDA is fixed as $d \geq 4$, bisimilarity is $\mathbf{F}_{d-1}$-hard. An obvious open problem is to close the complexity gap with the $\mathbf{F}_{d+4}$ upper bound in [10].
