
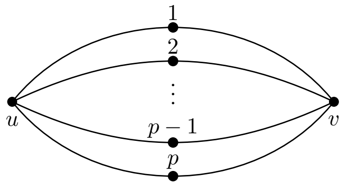

Figure 5 The edge gadget S_2T_pe, $e=(u,v)$ with the edge weight matrix $(ADA)^{\odot p}$.

where σ is a permutation of $[m]$. Denote $t(\sigma) = |\{i \mid \sigma(i) \neq i\}|$. Then

$$\prod_{i=1}^{m} A'_{i\sigma(i)} \leq \gamma^{t(\sigma)} \prod_{i=1}^{m} \sqrt{A'_{ii}} \prod_{i=1}^{m} \sqrt{A'_{\sigma(i)\sigma(i)}} = \gamma^{t(\sigma)} \prod_{i=1}^{m} A'_{ii}.$$

Consider the p-thickening of A' for $p \geq 1$. Each term of $\det\left((A')^{\odot p}\right)$ has the form $\pm \prod_{i=1}^{m} A'^{\,p}_{i\sigma(i)}$ for some permutation σ of $[m]$. Now

$$|\{\sigma \mid t(\sigma) = j\}| \leq \binom{m}{j} j! \leq m^j,$$

for $0 \leq j \leq m$. By separating out the identity permutation and all other terms, for $p \geq \lfloor \ln(2m)/\ln(1/\gamma) \rfloor + 1$, we have $2m\gamma^p < 1$, and

$$\begin{aligned} \det\left((A')^{\odot p}\right) &\geq \left(\prod_{i=1}^{m} A'_{ii}\right)^p - \left(\prod_{i=1}^{m} A'_{ii}\right)^p \sum_{j=1}^{m} m^j \gamma^{pj} \\ &\geq \left(\prod_{i=1}^{m} A'_{ii}\right)^p \left(1 - \frac{m\gamma^p}{1-m\gamma^p}\right) = \left(\prod_{i=1}^{m} A'_{ii}\right)^p \left(\frac{1-2m\gamma^p}{1-m\gamma^p}\right) > 0. \end{aligned}$$ ◀

7 Hardness for $Z_A(\cdot)$ on simple graphs for real symmetric A

There is a more direct approach to prove the #P-hardness part of the Bulatov-Grohe dichotomy (Theorem 3) for simple graphs. Although this method does not handle degree-boundedness, we can apply it more generally to the problem EVAL(A, D) when the matrix A is real symmetric and D is positive diagonal. In particular, we will prove the #P-hardness part of the dichotomy for counting GH by Goldberg et al. [12] (the problem EVAL(A) without vertex weights, where A is a real symmetric matrix) for simple graphs.

We first prove the following theorem.

▶ **Theorem 11.** *Let A and D be $m \times m$ matrices, where A is real symmetric and D is positive diagonal. Then* EVAL$(A, D) \leq_{\mathrm{T}}^{\mathrm{P}}$ EVAL$_{\mathrm{simp}}(A, D)$.

Proof. We may assume A is not identically 0, for otherwise the problem is trivial. Let $G = (V, E)$ be an input graph to the problem EVAL(A, D). For any $n \geq 1$, let $G_n = S_n^{(F)}(G)$ where $F \subseteq E$ is the subset consisting of the edges of G each of which is parallel to at least one other edge. In other words, we obtain G_n by replacing every parallel edge e by its n-stretching $S_n e$. We will refer to these as paths of length n in G_n. Note that $G_1 = G$. Moreover, for every $n \geq 2$, the graph G_n is simple and loopless, and has polynomial size in the size of G and n.

A path of length $n \geq 1$ has the edge weight matrix

$$M^{(n)} = \underbrace{ADA \ldots ADA}_{D \text{ appears } n-1 \,\geq\, 0 \text{ times}} = A(DA)^{n-1} = D^{-1/2}(D^{1/2}AD^{1/2})^n D^{-1/2}.$$

Here $D^{1/2}$ is a diagonal matrix with the positive square roots of the corresponding entries of D on the main diagonal, and $D^{-1/2}$ is its inverse.

Since A is real symmetric and D is positive diagonal, the matrix $\widetilde{A} = D^{1/2}AD^{1/2}$ is real symmetric. Then $\widetilde{A}$ is orthogonally diagonalizable over $\mathbb{R}$, i.e., there exist a real orthogonal matrix S and a real diagonal matrix $J = (\lambda_i)_{i=1}^m$ such that $\widetilde{A} = S^T JS$. If A has rank r, then $1 \leq r \leq m$, and we may assume that $\lambda_i \neq 0$ for $1 \leq i \leq r$ and $\lambda_i = 0$ for $i > r$.

We have $\widetilde{A}^n = S^T J^n S$, so the edge weight matrix for a path of length $n \geq 1$ can be written as

$$M^{(n)} = D^{-1/2}\widetilde{A}^n D^{-1/2} = D^{-1/2}S^T J^n S D^{-1/2}.$$

We can write $M_{ij}^{(n)} = \sum_{\ell=1}^r a_{ij\ell}\lambda_\ell^n$ by a formal expansion, for every $n \geq 1$ and some real $a_{ij\ell}$'s that are dependent on D and S, but independent of n and λ_ℓ, where $1 \leq i, j \leq m$ and $1 \leq \ell \leq r$. By the formal expansion of the symmetric matrix $M^{(n)}$ above, we have $a_{ij\ell} = a_{ji\ell}$. Let $t = |F|$, which is the number of edges in G subject to the stretching operator S_n to form G_n.

In the evaluation of the partition function $Z_{A,D}(G_n)$, we stratify the vertex assignments in G_n as follows. Denote by $\kappa = (k_{ij})_{1 \leq i \leq j \leq m}$ a nonnegative tuple with entries indexed by ordered pairs of nonnegative numbers that satisfy $\sum_{1 \leq i \leq j \leq m} k_{ij} = t$. Let $\mathcal{K}$ denote the set of all such possible tuples κ. In particular, $|\mathcal{K}| = \binom{t+m(m+1)/2-1}{m(m+1)/2-1}$. For a fixed m, this is a polynomial in t, and thus a polynomial in the size of G. Let c_κ be the sum over all assignments of all vertex and edge weight products in $Z_{A,D}(G_n)$, except the contributions by the paths of length n formed by stretching parallel edges in G, such that the endpoints of precisely k_{ij} constituent paths of length n receive the assignments (i, j) (in either order of the end points) for every $1 \leq i \leq j \leq m$. Technically we can call a vertex assignment on G consistent with κ (where $\kappa \in \mathcal{K}$), if it satisfies the stated property. Note that the contribution by each such path does not include the vertex weights of the two end points (but does include all vertex weights of the internal $n - 1$ vertices of the path). We can write

$$c_\kappa = \sum_{\substack{\xi\colon V(G)\to[m] \\ \xi \text{ is consistent with } \kappa}} \prod_{w \in V} D_{\xi(w)} \prod_{(u,v) \in E \setminus F} A_{\xi(u),\xi(v)}$$

for $\kappa \in \mathcal{K}$.

In particular, the values c_κ are independent of n. Thus for some polynomially many values c_κ, where $\kappa \in \mathcal{K}$, we have for all $n \geq 1$,

$$Z_{A,D}(G_n) = \sum_{\kappa \in \mathcal{K}} c_\kappa \prod_{1 \leq i \leq j \leq m} (M_{ij}^{(n)})^{k_{ij}} = \sum_{\kappa \in \mathcal{K}} c_\kappa \prod_{1 \leq i \leq j \leq m} (\sum_{\ell=1}^r a_{ij\ell}\lambda_\ell^n)^{k_{ij}}.$$

Expanding out the last sum and rearranging the terms, for some values $b_{i_1,\ldots,i_r}$ independent of n, we get

$$Z_{A,D}(G_n) = \sum_{\substack{i_1+\ldots+i_r=t \\ i_1,\ldots,i_r \geq 0}} b_{i_1,\ldots,i_r} (\prod_{\ell=1}^r \lambda_\ell^{i_\ell})^n \tag{4}$$

for all $n \geq 1$.

This can be viewed as a linear system with the unknowns $b_{i_1,\ldots,i_r}$ with the rows indexed by n. The number of unknowns is $\binom{t+r-1}{r-1}$ which is polynomial in the size of the input graph G, since $r \le m$ is a constant. The values $\prod_{\ell=1}^r \lambda_\ell^{i_\ell}$ can all be computed in polynomial time.

We show how to compute the value $Z_{A,D}(G) = \sum_{\substack{i_1+\ldots+i_r=t \\ i_1,\ldots,i_r \ge 0}} b_{i_1,\ldots,i_r} \prod_{\ell=1}^r \lambda_\ell^{i_\ell}$, from the values $Z_{A,D}(G_n)$ where $n \ge 2$ in polynomial time (recall that G_n is simple and loopless for $n \ge 2$). The coefficient matrix of the linear system (4) is a Vandermonde matrix. However, it might not be of full rank because the coefficients $\prod_{\ell=1}^r \lambda_\ell^{i_\ell}$ do not have to be pairwise distinct, and therefore it can have repeating columns. Nevertheless, when there are two repeating columns we replace the corresponding unknowns $b_{i_1,\ldots,i_r}$ and $b_{i'_1,\ldots,i'_r}$ with their sum as a new variable; we repeat this replacement procedure until there are no repeating columns. Since all $\lambda_\ell \ne 0$, for $1 \le \ell \le r$, after the replacement, we have a Vandermonde system of full rank. Therefore we can solve this modified linear system in polynomial time. This allows us to obtain the value $Z_{A,D}(G) = \sum_{\substack{i_1+\ldots+i_r=t \\ i_1,\ldots,i_r \ge 0}} b_{i_1,\ldots,i_r} \prod_{\ell=1}^r \lambda_\ell^{i_\ell}$, which also has exactly the same pattern of repeating multipliers $\prod_{\ell=1}^r \lambda_\ell^{i_\ell}$.

We have shown how to compute the value $Z_{A,D}(G)$ in polynomial time by querying the oracle $\mathrm{EVAL}(A, D)$ on polynomially many instances G_n, for $n \ge 2$. It follows that $\mathrm{EVAL}(A, D) \le_{\mathrm{T}}^{\mathrm{P}} \mathrm{EVAL}_{\mathrm{simp}}(A, D)$. ◀

We are ready to prove the #P-hardness part of the dichotomy by Goldberg et al. [12] (Theorem 1.1) for simple graphs. Let A be a real symmetric $m \times m$ matrix. Assuming that A does not satisfy the tractability conditions of the dichotomy theorem of Goldberg et al., the problem $\mathrm{EVAL}(A)$ is #P-hard. By Theorem 11 (with $D = I_m$), $\mathrm{EVAL}(A) \le_{\mathrm{T}}^{\mathrm{P}} \mathrm{EVAL}_{\mathrm{simp}}(A)$. It follows that $\mathrm{EVAL}_{\mathrm{simp}}(A)$ is #P-hard.

Hence the dichotomy theorem by Goldberg et al. can improve to apply to simple graphs.

▶ **Theorem 12.** *Let A be a real symmetric matrix. Then either $\mathrm{EVAL}(A)$ is in polynomial time or $\mathrm{EVAL}_{\mathrm{simp}}(A)$ is #P-hard (a fortiori, $\mathrm{EVAL}(A)$ is #P-hard).*

Moreover, there is a polynomial time algorithm that, given the matrix A, decides which case of the dichotomy it is.

▶ Remark 13. The interpolation argument in Theorem 11 works even if G is a multigraph possibly with multiple loops at any vertex in the following sense. In Definition 4, we treat the loops of G as edges. We think of them as mapped to the entries A_{ii} in the evaluation of the partition function $Z_{A,D}$. However, we need to slightly change the way we define the graphs G_n. In addition to n-stretching the parallel edges of G, we also need to n-stretch each loop of G (i.e., replacing a loop by a closed path of length n). Now F is the set of parallel edges *and* loops in G. This way each $G_n = S_n^{(F)}(G)$ for $n \ge 2$ is simple and loopless. The rest of the proof goes through. In other words, the statement of Theorem 11 extends to a reduction from the $\mathrm{EVAL}(A, D)$ problem that allows input G to have multiloops, to the standard problem $\mathrm{EVAL}_{\mathrm{simp}}(A, D)$ not allowing loops.

Abstract

The lexicographic depth-first search (Lex-DFS) is one of the first basic graph problems studied in the context of space-efficient algorithms. It is shown independently by Asano et al. [ISAAC 2014] and Elmasry et al. [STACS 2015] that Lex-DFS admits polynomial-time algorithms that run with $O(n)$-bit working memory, where n is the number of vertices in the graph. Lex-DFS is known to be P-complete under logspace reduction, and giving or ruling out polynomial-time sublinear-space algorithms for Lex-DFS on general graphs is quite challenging. In this paper, we study Lex-DFS on graphs of bounded treewidth. We first show that given a tree decomposition of width $O(n^{1-\epsilon})$ with $\epsilon > 0$, Lex-DFS can be solved in sublinear space. We then complement this result by presenting a space-efficient algorithm that can compute, for $w \leq \sqrt{n}$, a tree decomposition of width $O(w\sqrt{n}\log n)$ or correctly decide that the graph has a treewidth more than w. This algorithm itself would be of independent interest as the first space-efficient algorithm for computing a tree decomposition of moderate (small but non-constant) width. By combining these results, we can show in particular that graphs of treewidth $O(n^{1/2-\epsilon})$ for some $\epsilon > 0$ admits a polynomial-time sublinear-space algorithm for Lex-DFS. We can also show that planar graphs admit a polynomial-time algorithm with $O(n^{1/2+\epsilon})$-bit working memory for Lex-DFS.

1 Introduction

1.1 Background and Motivation

Depth-First Search (DFS) is one of the most fundamental and elementary graph search algorithms with a huge number of applications. Lexicographic DFS (Lex-DFS) is a popular variant of DFS, which requires the search head always moves to the *first* undiscovered neighbor in the adjacency list of the current vertex (as long as it exists). Recently, the space-efficient implementation of fundamental graph algorithms, including (Lex-)DFS, receives much attention [3, 6, 15, 16, 23, 26, 30]. These researches are roughly motivated by the

two aspects as follows: First, the space matter is serious in the big-data (i.e., too large inputs) and/or IoT (i.e., too small computational devices) era. Second, the challenge of proving space-complexity lower bounds for problems within class P still lies at the core of computational complexity theory. One of the ultimate goals on this research direction is to prove or disprove the seminal P $\neq$ L conjecture [2]. We focus on the space complexity of Lex-DFS, particularly the algorithms using memory below the trivial $O(n \log n)$-bit bound. This can be motivated from both sides but much leans against the second one. The sublinear-space Lex-DFS problem is formulated as the one of outputting the Lex-DFS ordering of all vertices in streaming way, and its space complexity is measured by the required working-memory size, as the classical read-only model [25].

To argue the complexity of sublinear-space algorithms, the notion of P-completeness under logspace reduction plays an important role, which is analogous to NP-completeness in P $\neq$ NP conjecture. Reif [40] shows that Lex-DFS is P-complete under logspace reduction. It implies that no Lex-DFS algorithm only using $O(\log n)$-bit working memory exists unless P = L holds. A counterpart from the upper-bound side is recently obtained by a few literatures [3, 6, 23, 26]. They focus on the implementation of (Lex-)DFS achieving both polynomial time and $o(n \log n)$-bit space complexity, where n is the number of vertices in the input graph. Initiated by Asano et al. [3] and Elmasry et al. [23], a series of papers by several authors explore the time-space tradeoffs of (Lex-)DFS in the area of $o(n \log n)$-bit space-complexity. The state-of-the-art bounds are threefolds, $O(m \log^* n)$ running time and $O(n)$-bit working memory, $O(m + n)$ running time and $O(n \log \log(4 + m/n))$-bit working memory, and $O(m + n)$ running time and $O(n \log^{(k)} n)$-bit working memory for any integer $k > 1$, which are all proposed by Hagerup [26]. Looking at hidden coefficients, the smallest-space algorithm is the one by Asano et al. [3], which achieves a polynomial running time (with a large exponent) using the working memory of $n + o(n)$ bits. No algorithm so far attains cn-bit space complexity for $c < 1$, and obtaining such an algorithm is commonly recognized as a very challenging problem. This open problem is also supported from yet another context of computational complexity theory. Lex-DFS on directed graphs is at least as hard as the directed s-t reachability problem, which is known to be NL-complete and thus its space-efficient (ideally, logspace) solution is closely related to the seminal L = NL? problem. In fact, any directed Lex-DFS algorithm achieving $O(n^{1-\epsilon})$-bit space complexity for any small constant $\epsilon > 0$ would be a breakthrough result on this research line.

1.2 Our Result

In the context of directed s-t reachability, there are many attempts of attaining $O(n^{1-\epsilon})$-bit space complexity for a specific graph class such as planar or bounded treewidth graphs [1, 4, 5, 12, 13, 27, 29], which naturally yields the interest to the feasibility of sublinear-space Lex-DFS for those classes. It should be noted that Lex-DFS is P-complete even for planar graphs [2], and thus its difficulty under log-space solvability is the same as the general case. One of the main results presented in this paper is a sublinear-space Lex-DFS algorithm for bounded treewidth graphs. The first theorem is stated as follows.

▶ **Theorem 1.** *Let $0 < \epsilon < 1$ be an arbitrary positive constant, G be any n-vertex directed graph of treewidth w, and $(\mathcal{T}, \{B_x\}_{x \in V_\mathcal{T}})$ be its tree decomposition of width $w' \geq w$, where $\mathcal{T} = (V_\mathcal{T}, E_\mathcal{T})$ is a tree and each node x in $\mathcal{T}$ is associated with a subset B_x of vertices in G. Assume a polynomial-time algorithm Alg enumerating the vertices in B_x for all $x \in V_\mathcal{T}$ and the edges in $E_\mathcal{T}$. Then there exists a Lex-DFS algorithm of running time $O(n^{O(1/\epsilon)})$ using $O(\epsilon^{-1} w' n^\epsilon \log n)$-bit memory (except for the space used by Alg).*

[2] L is the class of problems decidable with $O(\log n)$-bit working space (and thus in poly(n) time).

It should be noted that Lex-DFS does not necessarily lie on the seminal framework known as Courcelle's theorem [19] and its logspace version [22] because the output depends on the order of vertices in the adjacency list of the input graph.

To figure out a "purely" sublinear-space Lex-DFS algorithm, it is necessary to implement a tree decomposition algorithm using only sublinear space. Elberfeld et al. [22] presents a logspace tree-decomposition algorithm for $w = O(1)$, but no sublinear-space algorithm covering the case of $w = \omega(1)$ has been known so far. Our second theorem provides a sublinear-space solution for tree decomposition:

▶ **Theorem 2.** *There exists an algorithm that, given a graph G of n vertices and $w \leq n^{1/2}$, either provides a tree decomposition of width $O(wn^{1/2} \log n)$ or correctly decides that the treewidth of G is more than w. This algorithm runs in a polynomial time and uses $O(wn^{1/2} \log^2 n)$-bit space.*

To the best of our knowledge, this is the first non-trivial tree-decomposition algorithm attaining both sublinear-space and polynomial time for $w = \omega(1)$. It is also worth noting that planar graphs admit a space-efficient algorithm of finding a balanced separator of size $O(\sqrt{n})$ using $\tilde{O}(\sqrt{n})$-bit space [27], which can be translated into a small-space tree decomposition algorithm of width $O(\sqrt{n} \log n)$. Putting all the results above together, we obtain the following consequence:

▶ **Corollary 3.** *Let $\epsilon > 0$ be any positive constant. There exist the polynomial-time Lex-DFS algorithms respectively satisfying the following properties*[3]*.*

- *Using $O(n^{\epsilon})$-bit working memory for directed graphs of treewidth $w = O(1)$.*
- *Using $O(wn^{1/2+\epsilon})$-bit working memory for directed graphs of treewidth $w = O(n^{1/2})$.*
- *Using $O(n^{1/2+\epsilon})$-bit working memory for directed planar graphs.*

1.3 Related Work

As stated above, the space complexity of Lex-DFS is one of the classical problems in the context of logspace computability. Following the P-completeness result by Reif [40], Anderson and Mayr [2] also shows a weaker variant of Lex-DFS (lexicographically first maximal path) is also P-complete even for planar graphs. The main interest of those earlier results is closely related to the s-t reachability problem. It is known that the space complexity of undirected s-t connectivity drops into $O(\log n)$ bits for any input graphs, which is proved in Reingold's celebrating paper [41]. The best space upper bound of all polynomial-time directed s-t reachability algorithms is $O(n/2^{\Omega(\sqrt{\log n})})$ bits by Barnes et al. [9]. Its near optimality within a (naturally) restricted class of algorithms, called NNJAG [39], is also shown by Edmonds et al. [21].

More recently, the space-complexity matter of the directed s-t reachability problem for specific graph classes receives much attention, and a number of papers try to expand the graph class allowing sublinear-space directed reachability algorithms. Grid graphs [1, 5, 28], planar graphs [1, 4, 13, 27], bounded-genus graphs [12], and bounded-treewidth graphs [29] have been considered so far. Notice that the algorithms presented in [12] and [29] for bounded-genus graphs and bounded-treewidth graphs respectively require the surface embedding and the tree decomposition of the input graph (as Theorem 1), but it is not addressed how to compute them using sublinear space. Our tree-decomposition algorithm (by Theorem 2) yields the first

[3] Since one can choose an arbitrary $\epsilon > 0$, polylog(n) factors are absorbed in the part of n^{ϵ} in the statements of this corollary.

purely sublinear-space directed reachability algorithm for graphs of treewidth $w = O(n^{1/2-\epsilon})$. Very recently, an $O(1)$-approximate tree decomposition algorithm using $O(wn)$-bit space is presented [31], which attains a non-trivial space complexity for $w = o(\log n)$.

Despite relatively rich literatures on directed s-t reachability, the space complexity of Lex-DFS receives less attention until recently. After the two concurrent results by Asano et al. [3] and Elmasry et al. [23], a few follow-up papers propose fundamental graph algorithms using only $o(n \log n)$-bit working memory, which cover Lex-BFS [6, 23], single-source shortest path [23], biconnected component decomposition [15, 30], s-t numbering [15], maximum cardinality search [16], and so on. It is also becoming active to consider sublinear-space algorithms for fundamental non-graph problems [7, 20, 34, 36, 42].

On the side of computational models, the read-only model is one of the classical models to consider the complexity of working memory. An earlier topic in this model is the time-space tradeoffs for sorting and/or selection [10, 17, 18, 25, 37, 38]. Recently, more unconventional models are also investigated; Stream model [33], restore model (algorithms can manipulate input memory but after the computation the initial input data must be recovered) [14, 32], and catalytic model (algorithms can use a large memory which are already used for other purpose, and after the computation the memory state must be recovered to the initial one) [11]. Some of the results in those models allow a Lex-DFS algorithm using only a small (exclusive) working memory, but they are incomparable to the ones in the standard read-only model. Barba et al. [8] provides a general scheme of realizing stack machines using only a small memory space. While the dominant part of the memory usage in Lex-DFS algorithms is the storage for a stack, the technique by Barba et al. only applies to the algorithms whose access pattern to stacks are non-adaptive. Thus that scheme does not work for saving the space complexity of Lex-DFS algorithms.

1.4 Organization of Paper

In Section 2, we introduce the model, notations, and several auxiliary matters for our Lex-DFS problem. Sections 3 and 4 respectively show the proofs of Theorem 1 and 2. Finally the paper is concluded in Section 5.

2 Preliminaries

2.1 Model and Notation

As stated in the introduction, this paper adopts the *read-only model* [25], where the space complexity of an algorithm is measured by the number of bits used for the working space, excluding the memory for inputs and outputs. The input memory is read-only, and the output memory is write-only. The memory-access model follows the standard RAM of $(\log n)$-bit words. Let G be any directed input graph of n vertices and m edges, which is stored in the form of the adjacency list A_G. For any graph G, we denote the sets of the vertices and edges in G by V_G and E_G respectively. We assume $V_G = [0, n-1]$, that is, each vertex in V_G is uniquely identified by an integer in $[0, n-1]$. Letting $N_G(v) \subseteq V_G$ be the set of v's neighbors in G, we refer to the neighbor list of $v \in V_G$ as $A_{G,v}$ and denote the i-th vertex in $A_{G,v}$ by $A_{G,v}[i]$ (index i starts from value zero). We use notation $u <_v u'$ for $u, u' \in N_G(v)$ if u precedes u' in $A_{G,v}$. We define the inverse mapping of $A_{G,v}$ as $A^{-1}_{G,v}$, that is, for any neighbor u of v, $A^{-1}_{G,v}[u]$ returns the position of u in $A_{G,v}$. When we consider a subgraph $H \subseteq G$, the adjacency list of H is inherited from that of G. More precisely, when we delete an edge $(u, v) \in E_G$, the adjacency list $A_{H,u}$ after deletion is defined as the one such that

$A_{H,u}[i] = A_{G,u}[i]$ for any $i < A^{-1}_{G,u}[v]$ and $A_{H,u}[i-1] = A_{G,u}[i]$ for any $i > A^{-1}_{G,u}[v]$. Since any subgraph is obtained by iterative deletion of edges (and removal of isolated vertices), the specification of the adjacency list after deletion of one edge also specifies the adjacency list A_H for any subgraph H.

Letting X be a set of vertices or edges, we denote by $G - X$ the graph obtained from G by removing all the elements in X (if X is a vertex set, all the edges incident to a vertex in X are also deleted). The subgraph of G induced by X is denoted by $G[X]$. If there is a polynomial-time algorithm *Alg* enumerating all the elements in X, it naturally provides an access to the adjacency list A_H for $H = G[X]$ or $H = G - X$ without explicitly constructing it in the working memory (i.e., *Alg* works as a filter extracting the elements in $G[X]$ or $G - X$ from the adjacency list of A_G). Then we call *Alg* an *emulator* of H. The overhead of accessing to A_H is a polynomial time (depending on the running time of *Alg*) per one access. Thus we can run any polynomial-time algorithm taking H as its input within a polynomial time. In the following argument, we often omit the subscript G of the notations defined above if there is no ambiguity.

2.2 Lex-DFS

In what follows, we fix a starting vertex s of Lex-DFS tasks. A Lex-DFS algorithm is presented in Algorithm 1. In the algorithm, we introduce the notion of time. At each time, the search head v_{cur} moves to a neighbor decided by the algorithm. The search starts at time $t = 1$ and finishes at time $t = 2n$. We define h_t as the vertex pointed by the search head at the beginning of time t in the Lex-DFS on G. For vertex $v \in V$, the *discovery time* $d(v)$ of v is defined as the first time when the search head moves to v. Similarly, we define the *leaving time* $l(v)$ of v as the last time when the search head moves from v. The discovery time of s is defined as zero. Following the terminology in [3], a vertex v is called a *gray* vertex at t if $d(v) \leq t \leq l(v)$ holds. The (path) subgraph corresponding to the sequence of all gray vertices at time t sorted by their discovery times is called the *gray path* at t, which is denoted by S_t[4]. For any vertex $u \in V_{S_t}$, we also denote by $p_t(u)$ and $s_t(u)$ the (immediate) predecessor and successor of u in S_t, and by $S_t(u)$ the prefix of S_t terminating at u. We define $p_t(s) = \perp$ and $s_t(h_t) = \perp$.

In Algorithm 1, we encapsulate the space-consuming parts of the algorithm by two abstract procedures called Pivot(t) and Parent(t). The procedure Pivot(t) tries to find the first undiscovered neighbor of h_t with respect to the order $<_{h_t}$. If there is no undiscovered neighbor, it returns -1. The procedure Parent(t) returns the predecessor $p_t(h_t)$ in the current gray path. It returns -1 if $h_t = s$ holds. It is obvious that Lex-DFS is implemented with the working memory of $f(n) + O(\log n)$ bits if both of Pivot(t) and Parent(t) are implemented with $f(n)$ bits.

2.3 Tree Decomposition and Balanced Separator

We first present the definition of tree decomposition.

▶ **Definition 4.** *A tree decomposition of an undirected graph G is a pair $(\mathcal{T}, \{B_x\}_{x \in V_{\mathcal{T}}})$, where $\mathcal{T}$ is a tree and each node $x \in V_{\mathcal{T}}$ is associated with a subset B_x of vertices in V_G (called the bag x) satisfying the following conditions:*

- *Any edge in G is covered by at least one bag, i.e., $\forall (u, v) \in E_G : \exists x : u, v \in B_x$.*
- *Letting $\mathcal{T}(u)$ be the subgraph of $\mathcal{T}$ induced by the bags containing u, for any $u \in V_G$, $\mathcal{T}(u)$ is non-empty and connected.*

[4] Intuitively, the gray path S_t is the path from s to h_t in the Lex-DFS tree of G.

Algorithm 1 Lex-DFS Algorithm for graph G starting from s.

```
$v_{cur} \leftarrow s$; $t \leftarrow 1$                          ▷ $v_{cur}$ is the search head
while true do
    $v \leftarrow$ PIVOT($t$)                      ▷ Find the first undiscovered neighbor of $v_{cur}$ in $A_{G,s}$.
    if $v = -1$ then                               ▷ All neighbors have been already visited
        $v \leftarrow$ PARENT($t$)                 ▷ Find the parent in the gray path
        if $v = -1$ then halt                      ▷ All vertices are visited
    else
        Output $v$                                 ▷ Discovery of a new vertex
    $v_{cur} \leftarrow v$
    $t \leftarrow t + 1$
```

Note that tree decomposition is defined for undirected graphs. When we consider the tree decomposition of directed graphs G, we naturally adapt the same definition to the undirected graph obtained from G by omitting the orientation of all edges[5]. Each bag is identified by an integer value in $[0, |V_{\mathcal{T}}| - 1]$. Throughout this paper, we assume that any decomposition tree $\mathcal{T}$ is rooted, and that a tree decomposition is encoded as the sequence $(B_1, q(1)), (B_2, q(2)), \ldots, (B_x, q(x)), \ldots, (B_{|V_{\mathcal{T}}|-1}, q(|V_{\mathcal{T}}| - 1))$, where $q(x)$ is the ID of the parent of x in $\mathcal{T}$. The parent of the root bag is defined as -1. A sublinear-space tree decomposition algorithm must output this sequence in a streaming way. The *width* w of a tree decomposition $(\mathcal{T}, \{B_x\}_{x \in V_{\mathcal{T}}})$ is defined as the maximum bag size minus one, i.e., $w = (\max_{x \in V_{\mathcal{T}}} |B_x|) - 1$. The *treewidth* of a graph G is the minimum width over all tree decompositions of G. It is a fundamental property that the removal of the vertices in any (non-leaf) bag B_x from G splits G into several connected components, each of which corresponds to a subtree of $\mathcal{T}$ obtained by the removal of x from $\mathcal{T}$.

Tree decomposition is closely related to the notion of balanced vertex separators. Let $G = (V, E)$ be any directed graph and $\mu \colon V_G \to \mathbb{N}$ be any vertex-weight function. We define $\mu(X) = \sum_{v \in X} \mu(v)$ for any $X \subseteq V_G$. A vertex subset $U \subseteq V$ is called a *weighted α-balanced separator of G with respect to μ* if any weakly-connected component C in $G - U$ satisfies $\mu(V_C)/\mu(V_G) \leq \alpha$. If μ is a constant function, it is simply called an *α-balanced separator of G*. Throughout this paper, we often consider a subgraph obtained by recursively removing separators. Let $cc(H, U)$ be the set of connected components in $H - U$ for any graph H and its vertex subset $U \subseteq V_H$, and $vcc(H, U) = \{V_C \mid C \in cc(H, U)\}$. The following lemma holds.

▶ **Lemma 5.** *Let $H_0, H_1, H_2, \ldots, H_{k-1}$ and $U_0, U_1, \ldots, U_{k-1}$ be respectively the sequences of subgraphs of G and their vertex subsets such that $H_i \in cc(H_{i-1}, U_{i-1})$ holds. Assuming k algorithms respectively enumerating the vertices in U_i for each $i \in [0, k-1]$, there exists a logspace algorithm of enumerating all the vertex subsets in $vcc(H_{k-1}, U_{k-1})$ using them as black-box subroutines.*

Proof. Since the straightforward recursive emulation of H_{k-1} takes the overhead exponential of k, such an approach applies only to the case of $k = O(1)$. Instead of emulating $H_{i-1} - U_{i-1}$ recursively, we use the emulation of $G - U$ for $U = \bigcup_{0 \leq i \leq k-1} U_i$. Since we assume the algorithms of enumerating U_i for all $i \in [0, k-1]$, this emulation works with a polynomial-time overhead independent of k. We have $cc(H_{k-1}, U_{k-1}) \subseteq cc(G, U)$ obviously. While

[5] Precisely, if two directed edges (u, v) and (v, u) exist, omitting their orientation causes two multiedges between u and v. Then those edges are merged into a single undirected edge.

$cc(G, U)$ might contain a connected component not in $cc(H_{k-1}, U_{k-1})$, one can identify $C \in cc(H_{k-1}, U_{k-1})$ by checking if C has an outgoing edge to a neighbor in U_{k-1} because any component $C \notin cc(H_{k-1}, U_{k-1})$ is separated from H_{k-1} by $U_0, U_1, \ldots$ or U_{k-2}. Thus, letting ∂U_{k-1} be the set of vertices in $G - \bigcup_{0 \leq i \leq k-1} U_i$ adjacent to a node in U_{k-1}, it suffices to obtain an algorithm enumerating all the components in $cc(G, U)$ intersecting ∂U_{k-1}. It is realized by the following procedure.

1. Let $c = 1$, and $v_0, v_1, \ldots, v_{l-1}$ be the sequence of the vertices in ∂U_{k-1} sorted by their IDs, which can be enumerated using logarithmic space and the algorithms for $U_0, U_1, \ldots, U_{k-1}$.
2. For each v_i, check if a vertex v_j satisfying $j < i$ is reachable to v_i in $G - U$. If such a vertex exists, repeat this step for v_{i+1} (unless $i = l - 1$). Otherwise, go to step 3.
3. Enumerate all the vertices reachable from v_i as the vertices in the c-th component in $cc(H_{k-1}, U_{k-1})$. After the enumeration, increment c by one, and go back to step 2 for v_{i+1}.

The procedure above is implemented with $O(\log n)$-bit space by utilizing the logspace undirected s-t connectivity algorithm [41] (since $cc(H_{k-1}, U_{k-1})$ is a set of weakly-connected components, undirected s-t connectivity suffices). Letting v_j be the vertex with the minimum ID in $V_C \cap \partial U_{K-1}$ for a component $C \in cc(H_{k-1}, U_{k-1})$, C is necessarily enumerated when the procedure above processes v_j. In addition, it is never enumerated twice because any other vertex in $V_C \cap \partial U_{k-1}$ has an ID larger than v_j and is reachable to v_j in $G - U$. ◀

The lemma above implies that one can associate an unique integer ID with each connected component in $H_{k-1} - U_{k-1}$, and can emulate with a polynomial-time overhead the connected component in $H_{k-1} - U_{k-1}$ specified by a given ID. We also have the lemma below.

▶ **Lemma 6.** *Let $G = (V, E)$ be any graph of treewidth w, and $0 < \delta < 1$ be an arbitrary positive constant. Assume an algorithm outputting a tree decomposition of width at most w' for G. Then, there exists an algorithm outputting an $O(n^{-\delta})$-balanced vertex separator U of size $O(w'n^{\delta})$ for G, which uses only $O(w'n^{\delta} \log n)$-bit space (except for the space used by the tree-decomposition algorithm).*

Proof. Let $(\mathcal{T}, \{B_x\}_{x \in V_{\mathcal{T}}})$ be the (rooted) tree decomposition constructed by the algorithm. For any subgraph $\mathcal{T}' \subseteq \mathcal{T}$ and a subset $X \subseteq V_G$, we define $\mathrm{vol}(\mathcal{T}', X) = |\bigcup_{y \in V_{\mathcal{T}'}} B_y \setminus X|$. We also define $\mathcal{T}(x)$ as the subtree of $\mathcal{T}$ rooted by $x \in V_{\mathcal{T}}$.

The proof is constructive. The algorithm finds the $O(n^{\delta})$ bags whose removal splits $\mathcal{T}$ into a small subtrees $\mathcal{T}_0, \mathcal{T}_1, \ldots, \mathcal{T}_{M-1}$ satisfying $\mathrm{vol}(\mathcal{T}_i, U) \leq n^{1-\delta}$ for any $i \in [1, M]$. The algorithm manages two sets U' and U. The set U' stores the set of bag IDs constituting the vertex subset U, i.e., $U = \bigcup_{x \in U'} B_x$. The construction of U is done by iteratively adding a vertex in $V_{\mathcal{T}}$ to U'. Let x_i be the vertex added to U' at the i-th iteration, and U_i and U'_i be respectively the contents of U and U' when $|U'| = i$ holds. We further define $\mathcal{T}^R_i$ as the connected component of $\mathcal{T} - U'_i$ containing the root. The algorithm chooses as x_i the deepest vertex in $\mathcal{T}^R_{i-1}$ such that $\mathrm{vol}(\mathcal{T}^R_{i-1}(x_i), U_{i-1}) \geq n^{1-\delta}$ holds. The iteration terminates when $\mathrm{vol}(\mathcal{T}^R_i, U_i)$ becomes smaller than $n^{1-\delta}$. Since one iteration decreases $\mathrm{vol}(\mathcal{T}^R_*, U_*)$ by at least $n^{1-\delta}$, the algorithm terminates within n^{δ} iterations. In addition, for any children y of x_i, we have $\mathrm{vol}(\mathcal{T}^R_{i-1}(y), U_{i-1}) < n^{1-\delta}$ because x_i is the deepest vertex. It implies that any connected component in $G - U$ contains at most $n^{1-\delta}$ vertices.

The remaining issue is the time and space complexities for implementing the algorithm. Since the tree decomposition algorithm provides the whole topological information on $\mathcal{T}$, one can use it as the adjacency list of $\mathcal{T}$ incurring a polynomial-time overhead. Since U' is stored in the working memory, it is possible to emulate $\mathcal{T}^R_i$ for any i. The computation of $\mathrm{vol}(\mathcal{T}_i^R(x), U_i)$ for any $x \in V_{\mathcal{T}_i^R}$ can be done in a polynomial time using the membership test of $v \in B_y$ for all pairs of $v \in V_G \setminus U_i$ and $y \in V_{\mathcal{T}_i^R(x)} \setminus \{x\}$. Consequently, the proposed algorithm can be implemented with the storage cost for U and U'. Since each bag contains at most w' vertices, the space complexity is $O(w' n^\delta \log n)$ bits. ◀

3 Small-Space Lex-DFS Algorithm for Graphs of Bounded Treewidth

3.1 Reduction to (Approximate) Gray-Path Membership

The algorithms shown in [3] reduces the procedures of $\textsc{Pivot}(t)$ and $\textsc{Parent}(t)$ to a single abstract task called $\textsc{IsGray}(u, v)$, which tests if v belongs to the prefix of the gray path by u (i.e., tests if $v \in V_{S_{d(u)}}$ holds or not). The following lemma is proved in [3].

▶ **Lemma 7** (Asano et al. [3]). *Assume that there exists a polynomial-time algorithm $\textsc{IsGray}(u, v)$ which is executable at any time $d(u) \le t \le l(u)$ and determines if $v \in V_{S_{d(u)}}$ holds or not. Letting $f(n)$ be the space complexity of that algorithm and $g(n)$ be the space-complexity of solving the directed s-t reachability problem, we have two polynomial-time algorithms which respectively implement $\textsc{Pivot}(t)$ and $\textsc{Parent}(t)$ using the memory of $f(n) + g(n)$ bits.*

We slightly extend this lemma by introducing a new primitive called $\textsc{AIsGray}(u, v)$ (approximate testing of gray vertex), which is a one-sided-error version of $\textsc{IsGray}(u, v)$ satisfying the following two conditions:

1. If $v \in V_{S_{d(u)}}$ holds, $\textsc{AIsGray}(u, v)$ always returns true.
2. If $d(v) > d(u)$ holds, $\textsc{AIsGray}(u, v)$ always returns false.

The following lemma implies that we can replace $\textsc{IsGray}(u, v)$ in Lemma 7 by $\textsc{AIsGray}(u, v)$.

▶ **Lemma 8.** *Assume a polynomial-time algorithm $\textsc{AIsGray}(u, v)$ executable at any time $d(u) \le t \le l(u)$ using $f(n)$-bit space, and a polynomial-time tree decomposition algorithm outputting the decomposition of width at most w' for any input graphs of treewidth w. Then we have the polynomial-time algorithm which implements $\textsc{IsGray}(u, v)$ using the space of $f(n) + O(w' \log n)$ bits (except for the space used by the tree decomposition algorithm).*

Proof. To implement $\textsc{IsGray}(u, v)$, it suffices to enumerate all the vertices in $S_t(u)$, which can be realized by repeatedly using an algorithm outputting $s_t(x)$ for given $x \in V_{S_t(u)} \setminus \{h_t\}$. Let $V'(x)$ be the set of the vertices v' such that $\textsc{AIsGray}(x, v')$ returns true. It has been shown in [3] that $s_t(x)$ is the first vertex $y \in N(x)$ with respect to the order of A_x such that y is reachable to h_t in $G - V_{S_t(x)}$. We first show that this fact still holds even if we replace $V_{S_t(x)}$ by $V'(x)$. Any y preceding $s_t(x)$ in A_x is unreachable to h_t in $G - V'(x)$ because it is unreachable in $G - V_{S_t(x)}$ and $V_{S_t(x)} \subseteq V'(x)$ holds by the first condition of $\textsc{AIsGray}$. Letting X be the graph corresponding to the suffix of S_t from $s_t(x)$ to h_t, any vertex in V_X has a discovery time larger than $d(x)$, and thus $V_X \cap V'(x) = \emptyset$ holds by the second condition of $\textsc{AIsGray}$. It implies that $s_t(x)$ is reachable to h_t in $G - V'(x)$, and concludes that $s_t(x)$ is the first vertex $y \in N(x)$ such that y is reachable to h_t in $G - V'(x)$. Since the procedure $\textsc{AIsGray}(x, v')$ works as the emulator of $G - V'(x)$, we can obtain an algorithm of computing $s_t(x)$ using any directed s-t reachability algorithm. The algorithm by Jain et al. [29] matches our goal. It uses any tree decomposition of width w' as a side information, and runs in a polynomial time using $O(w' \log n)$-bit space. The memory complexity is $f(n)$ bits for $\textsc{AIsGray}$, and $O(w' \log n)$ bits for deciding s-t reachability and for managing a constant number of pointers to vertices in V_G. ◀

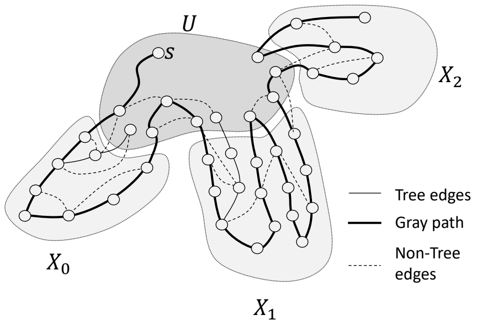

Figure 1 An example of decomposition by U.

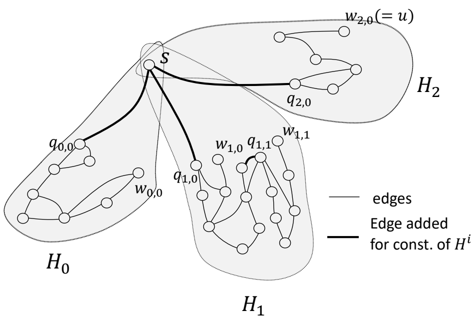

Figure 2 Construction of H_i.

3.2 Implementation of AIsGray(u, v)

As utilized in the proof of Lemma 8, directed s-t reachability is solvable using $O(w' \log n)$-bit space with the side information of a tree decomposition of width w' [29]. Thus we have Lemma 7 with $g(n) = O(w' \log n)$. The remaining part of our algorithm is to implement AIsGray(u, v) executable at any $d(u) \leq t \leq l(u)$. Let U be the set shown in Lemma 6, and $\mathcal{X} = \{X_0, X_1, \ldots, X_{N-1}\}$ be the set of the connected components in $G - U$ (Figure 1). At each time t, our algorithm keeps track of the information of $(d(x), p_t(x), s_t(x))$ for any $x \in V_{S_t} \cap U$. Specifically, we prepare the dictionary Z which maps any vertex x in U to the corresponding triple $(d(x), p_t(x), s_t(x))$ if $x \in S_t$ holds. We refer to the three elements in the triple for x as $Z[x].d$, $Z[x].p$, and $Z[x].s$ respectively. The contents of Z is updated in the main routine of Lex-DFS when the search head moves. Let ℓ_i be the number of connected components in the subgraph $S_{d(u)}[V_{X_i}]$. For each connected component C in $S_{d(u)}[V_{X_i}]$, we define its *entrance* and *exit* as the vertices with the minimum and maximum discovery times in V_C respectively. Let $\mathcal{C}_i = C_{i,0}, C_{i,1}, \ldots, C_{i,\ell_i-1}$ be the sequence of the connected components in $S_{d(u)}[V_{X_i}]$ sorted by the discovery times of their entrances. We also define the exit of $C_{i,-1}$ as s, which works as a sentinel value. Let $Q_i = (q_{i,0}, q_{i,1}, \ldots, q_{i,\ell_i-1})$ and $W_i = (w_{i,-1}, w_{i,0}, w_{i,1}, \ldots, w_{i,\ell_i-1})$ be the sequences of the entrances and exits associated with each component in $\mathcal{C}_i$ respectively. Now we construct the graph H_i from G by the following procedure:

1. Remove all the vertices not in $V_{X_i} \cup \{s\}$ as well as their incident edges.
2. For all $0 \leq j \leq \ell_i - 1$, contract the gray path from $w_{i,j-1}$ to $q_{i,j}$ into an edge. The positions of $q_{i,j}$ in $A_{w_{i,j-1}}$ and $w_{i,j-1}$ in $A_{q_{i,j}}$ are equal to those of $s_t(w_{i,j-1})$ and $p_t(q_{i,j})$ respectively.

Note that $s = w_{i,-1} = q_{i,0}$ holds if $s \in V_{X_i}$. We illustrate an example of the construction in Figure 2. Consider the run of any Lex-DFS algorithm in H_i until the discovery of w_{i,ℓ_i-1}, which outputs a vertex set $L_i \subseteq V_{X_i} \cup \{s\}$. Let $L(u) = L_0 \cup L_1 \cup \cdots \cup L_{N-1} \cup (S_{d(u)} \cap U)$. An important fact is that AIsGray(v, u) can be implemented using the query if $v \in L(u)$ or not. The following lemma holds.

▶ **Lemma 9.** *Let L_i be the output sequence of the Lex-DFS running in H_i until the discovery of w_{i,ℓ_i-1}. Any vertex in $V_{S_{d(u)}[V_{X_i}]}$ is contained in L_i, and $d(x) \leq d(w_{i,\ell_i-1}) \leq d(u)$ holds for any $x \in L_i$.*

Proof. For any $v \in V$, let $\mathcal{P}_{G,v}$ be the set of all simple paths from s to v in G, and $\mathcal{P}_G = \bigcup_{v \in V_G} \mathcal{P}_{G,v}$. For any path $P = s, u_1, \ldots, u_j, v$ in $\mathcal{P}_{G,v}$, we define its *word* $\gamma_G(P)$ as the sequence $A_s^{-1}[u_1], A_{u_1}^{-1}[u_2], \ldots, A_{u_k}^{-1}[v]$. Letting $\prec$ be the lexicographic order over all words, the *minimum path* $\pi_G(v) \in \mathcal{P}_{G,v}$ of a vertex $v \in V$ is defined as the one satisfying

$\gamma_G(\pi_G(v)) \prec \gamma_G(P)$ for any $P \in \mathcal{P}_{G,v}$. For any two vertices $v, v' \in V_{H_i}$, the gray paths in H_i to v and v' are respectively obtained by contracting several common subpaths in the gray paths to v and v' in G. Hence it is easy to check $\gamma_G(\pi_G(v)) \prec \gamma_G(\pi_G(v'))$ holds if and only if $\gamma_{H_i}(\pi_{H_i}(v)) \prec \gamma_{H_i}(\pi_{H_i}(v'))$ holds for any $v, v' \in V_{H_i}$. Since it is well-known that the total ordering of V_G with respect to $\prec$ over $\{\gamma_G(\pi_G(v))\}_{v \in V_G}$ is equivalent to the Lex-DFS ordering of V_G, this fact implies that L_i contains all the vertices in V_{X_i} discovered earlier than $w_{i,\ell-1}$ in the Lex-DFS search in G, and contains no vertex in V_{X_i} whose discovery time in the Lex-DFS search in G is later than $d(w_{i,\ell-1})$. The lemma is proved. ◀

Since H_i is a minor of G, its treewidth is also bounded by w. Thus we can perform our Lex-DFS algorithm recursively for graph H_i of $O(n^{1-\epsilon})$ vertices to output L_i. The graph H_i can be emulated using the subset U and the information stored in Z. Outputting L_i for all $i \in [0, N-1]$ can answer the query if $v \in L(u)$ holds or not.

3.3 Algorithm Details for Lex-DFS

The pseudocode of our algorithm is given in Algorithm 2. It is defined as a recursive procedure Lex-DFS(G, s, u), which outputs the Lex-DFS sequence of G starting from s until u is discovered. If the procedure runs with $u \notin V_G$, it outputs the whole Lex-DFS sequence of G starting from s. Note that the dictionary Z is independently defined in each recursive call for the computed separator U. In addition, the size $O(n^\epsilon)$ of separator U is fixed independently of recursion depth. That is, the variable n in the size parameter $O(n^\epsilon)$ is always the number of vertices in the original input graph, not the number of vertices in the input graph taken as an argument of Lex-DFS. The main routine Lex-DFS almost follows Algorithm 1, except for using AIsGray to compute Pivot and Parent and managing Z. The core of the algorithm is the implementation of AIsGray, in particular, the emulation of H_i for each V_i $(0 \leq i \leq N-1)$. That part corresponds to the lines 23-30. First, we identify the set Q_i and W_i, which can be done by extracting the nodes $x \in U$ satisfying $Z[x].s \in V_i$ as a member of Q_i (or those satisfying $Z[x].p \in V_i$ as W_i). Since each node in $S_t(u) \cap U$ stores its discovery time in Z, we can add the nodes into Q_i or W_i in the order of their discovery times. Following the order of Q_i and W_i, we create the edge set F, which corresponds to the edges obtained by the contraction of gray subpaths in the step 2 of the construction.

3.4 Complexity

Since Pivot and Parent are called at most $2n$ times in each recursive call, a polynomial-time invocations of AIsGray suffices to implement them. Let n^c be the upper bound for the number of invocations of AIsGray in one execution of Pivot or Parent. One invocation of AIsGray calls Lex-DFS at most n times. Putting all them together, n^{c+2} recursive invocations of Lex-DFS occur per one call of Lex-DFS. Since the recursion depth is obviously bounded by $O(1/\epsilon)$, at most $O(n^{(c+2)/\epsilon})$ calls of Lex-DFS are invoked in total. By Lemma 5, the input graph to each recursive call can be emulated with a polynomial-time overhead, and thus one invocation of Lex-DFS excepting the run of recursive calls has a polynomially-bounded running time. Consequently, the total running time is $n^{O(1/\epsilon)}$.

In each recursive call, the information on U and Z is stored in the working memory. The space for storing U and Z are bounded by $O(w'n^\epsilon \log n)$ bits. Except for the space used by the tree decomposition algorithm, the space of $O(w' \log n)$ bits is necessary for implementing Parent and Pivot from AIsGray. Since the recursion depth is $O(1/\epsilon)$, the total space complexity is $O(w'\epsilon^{-1}n^\epsilon \log n)$ bits.

Algorithm 2 Lex-DFS Algorithm for graph G of treewidth k (starting from s).

```
function Lex-DFS$(G, s, u)$
    if $|V_G| \leq n^\epsilon$ then run the standard Lex-DFS algorithm and halt
    Find a separator $U$ of size $O(n^\epsilon)$
    Initialize $Z : U \to [0, n-1] \times V_G \times V_G$
    $v_{cur} \leftarrow s$; $t \leftarrow 1$
    output $s$; $Z[s] \leftarrow (1, \perp, \perp)$
    while true do
        $v \leftarrow$ Pivot$(t)$ using AIsGray$(v_{cur}, \cdot)$
        if $v = -1$ then                         ▷ All neighbors have been already visited
            $v \leftarrow$ Parent$(t)$ using AIsGray$(v_{cur}, \cdot)$
            $Z[v_{cur}] \leftarrow$ null; $Z[v] \leftarrow (Z[v].d, Z[v].p, \perp)$
            if $v = -1$ then halt                ▷ All vertices are visited
        else
            $Z[v_{cur}] \leftarrow (Z[v_{cur}].d, Z[v_{cur}].p, v)$; $Z[v] \leftarrow (t, v_{cur}, \perp)$
            Output $v$
            if $v = u$ then halt
        $v_{cur} \leftarrow v$
        $t \leftarrow t + 1$
    function AIsGray$(u, v)$
        if $Z[v] \neq$ null then return true
        Let $X_0, X_1, \ldots, X_{N-1}$ be the connected components in $G - U$
        for $i = 0, 1, \ldots, N-1$ do
            $Q \leftarrow ()$; $W \leftarrow (s)$
            for $\forall x \in U$: $Z[x] \neq$ null in ascending order of $Z[x].d$ do
                if $Z[x].s \in V_{X_i}$ then append $Z[x].s$ to $Q$
                if $Z[x].p \in V_{X_i}$ then append $Z[x].p$ to $W$
            if $u \in V_{X_i}$ then append $u$ to $W$
            $\ell_i \leftarrow |Q|$
            for $j = 0, 1, \ldots, \ell_i - 1$ do
                $F \leftarrow F \cup \{(W[j], Q[j])\}$
            $H_i \leftarrow G[V_i] + F$                ▷ Not explicitly constructed
            if $v \in$ Lex-DFS$(H_i, s, W[\ell_i - 1])$ then return true
        return false
```

4 Tree Decomposition using Small Space

In this section, we present a tree-decomposition algorithm, which uses $O(wn^{1/2} \log n)$-bit space and outputs a decomposition of width $O(wn^{1/2} \log n)$ for any undirected graph $G = (V, E)$ of treewidth $w \leq \sqrt{n}$. We first introduce a space-saving variant of the known weighted balanced separator algorithm.

▶ **Lemma 10** (Extended from Theorem 1.1 of Fomin et al. [24]). *There exists a polynomial-time algorithm that, given a graph G on n vertices, any vertex-weight function μ, and a positive integer k, either provides a weighted $O(1)$-balanced separator of G with respect to μ consisting* *of $O(k^2)$ vertices, or concludes that the treewidth of G is more than k. The algorithm uses the memory space required for finding the minimum unweighted s-t vertex cut in G plus $O(k^2 \log n)$ bits.*

Proof. We refer to the algorithm proposed in Theorem 1.1 of [24] as SEP. Except for the space complexity matter, the correctness of the lemma completely follows that of SEP presented in [24]. Thus it suffices to show how SEP is implemented using the memory space claimed in this lemma. The algorithm SEP roughly works as follows. Let G be any input graph of treewidth at most k.

1. First the algorithm SEP constructs any rooted spanning tree T of G, and decomposes it into a set $\mathcal{X}$ of $\Theta(k)$ connected subtrees such that at most $O(k)$ vertices can belong to two or more subtrees in $\mathcal{X}$: Let $T(x)$ be the subtree of T rooted by x. The algorithm SEP starts with $T' = T$, and for $i = 0, 1, \dots,$ iteratively finds the deepest vertex x_i such that $|V_{T'(x_i)}| \geq \alpha n/k$ holds for an appropriate constant α. Then the subtree $T'(x_i)$ is split into several subtrees of size $\Theta(n/k)$ sharing x_i, each of which becomes a member of $\mathcal{X}$. After updating T' as $T' \leftarrow T' - T'(x_i)$, the algorithm proceeds to the next iteration.
2. For any $X_i, X_j \in \mathcal{X}$ such that $V_{X_i} \cap V_{X_j} = \emptyset$, SEP emulates the graph $H_{i,j}$ obtained from G by contracting X_i and X_j into two vertices x_i and x_j. Then it computes the minimum x_i-x_j vertex cut in $H_{i,j}$. If there exists a pair (i, j) such that the output cut contains at most k vertices, the algorithm adds it to the separator set U.
3. The steps 1 and 2 are iteratively applied to the largest connected component after the removal of the computed vertex cut, until U becomes an $O(1)$-balanced separator of G. It is proved in [24] that this iteration terminates within $O(k)$ times if the treewidth of the input graph is at most k.

The small-space implementation of step 1 is very similar with the algorithm shown in the proof of Lemma 6. With the support of the emulator of T, finding x_i and the emulation of T' can be done in the same way as the proof of Lemma 6. The spanning tree T can be emulated using the logspace undirected connectivity: We introduce an arbitrary logspace-computable edge-weight function $g \colon E_G \to \mathbb{N}$ which assigns all edges with different weights. Let $e_0, e_1, \dots, e_{m-1}$ be the sequence of all edges sorted in the ascending order of their weights, and $E_i = \{e_0, e_1, \dots, e_{i-1}\}$. Then an edge $e_i = (u, v)$ is contained in the minimum spanning tree of G with respect to g if and only if u and v is connected in $G[E_i]$, which directly deduces the emulator of the minimum spanning tree.

Assuming an algorithm computing the set $\mathcal{X}$, $H_{i,j}$ can be emulated with a polynomial-time overhead. Thus the step 2 can be implemented within a polynomial time using $O(k^2 \log n)$ bits (except for the space used by the vertex-cut algorithm). ◀

4.1 A Small-Space Balanced Separator Algorithm

Let $I(G)$ be the maximum independent set of G, (if two or more maximum independent sets exist, an arbitrary one is chosen), and $\overline{I}(G) = V \setminus I(G)$ for short. The first key ingredient of our algorithm is a space-saving algorithm for the minimum s-t vertex cut problem.

▶ **Lemma 11.** *Let G be any n-vertex undirected graph. For any $s, t \in V_G$, the minimum (unweighted) s-t vertex cut of G can be found in a polynomial time using $O(|\overline{I}(G)| \log n)$ bits.*

Proof. The algorithm basically follows the vertex-cut version of Ford-Fulkerson algorithm, which manages a set of augmenting paths for recognizing the current residual graph (see Section 3.5 in [35] for example). In the case of unweighted vertex cuts, any set of augmenting paths is a set of vertex-disjoint s-t paths in G. Letting L be the maximum total length of managed s-t paths, the algorithm can be implemented using $O(L \log n)$-bit space. Thus it suffices to show that $L = O(|\overline{I}(G)|)$ holds for any instance G. Let $R_1, R_2, \ldots, R_y$ be any set of vertex-disjoint s-t paths in G. Since no two vertices in $I(G)$ consecutively appears in any path, we have $|V_{R_i} \cap I(G)| \leq |V_{R_i} \cap \overline{I}(G)| + 1$ for any $i \in [1, y]$. Then $|V_{R_i}| \leq 3|V_{R_i} \cap \overline{I}(G)|$ holds. Since V_{R_i} for all $i \in [1, y]$ are mutually disjoint, it follows $\sum_{1 \leq i \leq y} |V_{R_i}| = O(|\overline{I}(G)|)$. The lemma is proved. ◀

Consider a partition of V_G into a family $\mathcal{P} = \{P_0, P_2, \ldots, P_{N-1}\}$ of N subsets such that $G[P_i]$ is a connected subgraph of G. We denote by $G/\mathcal{P}$ the graph obtained by contracting each subgraph P_i into a single vertex u_i with weight $\mu(u_i) = |V_{P_i}|$ (parallel edges are merged into the single one). The second key ingredient is to reduce the (approximate) tree decomposition of G into that of another graph $G/\mathcal{P}$ for an appropriate partition $\mathcal{P}$ such that $|\overline{I}(G/\mathcal{P})|$ becomes small. Since treewidth never increases by edge contraction, $G/\mathcal{P}$ also has a treewidth at most k. Thus we can run the balanced-separator algorithm obtained from Lemmas 10 and 11 on $G/\mathcal{P}$ using only $O((|\overline{I}(G/\mathcal{P})| + k^2) \log n)$-bit space. For the computed separator B, we replace each $u_i \in B$ by V_{P_i}. That is, we create a vertex subset $B' = \bigcup_{u_i \in B} V_{P_i}$, which is obviously a balanced separator of G consisting of $O(k^2 \max_i\{|V_{P_i}|\})$ vertices. To attain the space complexity of Theorem 2 following this approach, we have to construct a polynomial-time algorithm outputting the partition $\mathcal{P}$ satisfying $|\overline{I}(G/\mathcal{P})| = O(kn^{1/2})$ and $|P_i| = O(n^{1/2}/k)$ for any $P_i \in \mathcal{P}$. In addition, we have to guarantee that the algorithm uses only $O(kn^{1/2} \log n)$ bits.

We argue the implementation of such an algorithm. Let us define an arbitrary total ordering of edges in E_G. This can be easily realized by any ordering function $f \colon E \to \mathbb{N}$ which can be computed in logarithmic space (e.g., the lexicographic ordering of endpoint ID pairs). Let $e_1, e_2, \ldots, e_m$ be the sequence of all edges sorted in this order, and $E_i = \{e_1, e_2, \ldots, e_i\}$. For any subgraph $H \subseteq G$, we also define $S(H, v, i)$ as the set of the vertices which are reachable from v in $H[E_i]$. The partition is constructed by the following algorithm:

1. Let $\mathcal{P} = \emptyset$, $R \leftarrow \emptyset$, and $H \leftarrow G$.
2. Find the minimum ℓ such that the largest connected component C in $H[E_\ell]$ contains at least $n^{1/2}/k$ vertices, and add V_C to $\mathcal{P}$. Letting v be the vertex with the smallest ID in V_C, we store the pair (v, ℓ) into R.
3. Update $H \leftarrow G - \bigcup_{(v,\ell) \in R} S(G, v, \ell)$.
4. Repeat steps 2 and 3 until the size of any connected component in H becomes less than $n^{1/2}/k$.
5. Letting $Q = \bigcup_{P_i \in \mathcal{P}} P_i$, add $V_{C'}$ to $\mathcal{P}$ for any connected component C' in $G - Q$.

The actual algorithm does not store $\mathcal{P}$ explicitly. Except for step 5, the set $\mathcal{P}$ is write-only, and it is easy to verify that steps 1-4 can be implemented only with the space for storing R. The matter of the space complexity relies on how to restore the set Q in step 5 only from the information of R. Let C_i be the connected component found in the i-th iteration of step 2, and (u_i, j_i) be the entries added to R then. We denote by H_i the graph stored in H immediately after the i-th iteration of step 2. It is easy to enumerate the vertices in $S(G, u, j)$ by the logspace undirected s-t connectivity algorithm [41] (recall that we omit the orientation of edges in considering the tree decomposition for directed graphs), and thus we obtain an emulator of H_i using the information in R and extra $O(\log n)$-bit space. It also yields an algorithm for enumerating $C_i = S(H_{i-1}, u_i, j_i)$. Consequently, this algorithm works using only $O(|R| \log n)$-bit space. The following lemma guarantees the correctness of the output.

▶ **Lemma 12.** *Let $\mathcal{P} = \{P_0, P_1, \ldots, P_{N-1}\}$ be the partition outputted by the algorithm above. Then for any $P_i \in \mathcal{P}$, $|P_i| \leq 2n^{1/2}/k$ holds. In addition, $|\overline{I}(G/\mathcal{P})| \leq kn^{1/2}$ holds.*

Proof. We first show that $\mathcal{P}$ is actually a partition of V_G. By step 5, it is obvious that any vertex in V_G is contained in at least one subset $P_i \in \mathcal{P}$. The subset added in step 5 does not intersect other subsets. Consider any two subsets C_i and C_k added in step 2 ($i < k$). By the construction of C_i and C_k, we have $C_i = S(H_{i-1}, u_i, j_i)$ and $C_k = S(H_{k-1}, u_k, j_k)$. Since $i < k$ holds, H_{k-1} does not contain any vertex in $S(G, u_i, j_i)$. It implies H_{k-1} does not contain any vertex in $C_i = S(H_{i-1}, u_j, j_i)$ because of $H_{i-1} \subseteq G$. That is, C_i and C_k are mutually disjoint. Next, we bound the size of each P_i. Any subset added in step 5 has a cardinality less than $n^{1/2}/k$. Since the algorithm finds the smallest ℓ such that the cardinality of C becomes at least $n^{1/2}/k$, any connected component in $H_{i-1}[E_{\ell-1}]$ has a size less than $n^{1/2}/k$. Thus the size of any connected component in $H_{i-1}[E_\ell]$ is at most $2n^{1/2}/k$. Finally, we show $|\overline{I}(G/\mathcal{P})| \leq kn^{1/2}$. We call a subset $P_i \in \mathcal{P}$ a *red subset* if P_i is added in step 5, and also call the corresponding vertex $u_i \in V_{G/\mathcal{P}}$ a *red vertex*. It is obvious that any red subset P_i has no outgoing edge to other red subsets in G, the set of all red vertices forms an independent set of $G/\mathcal{P}$. Since the cardinality of any non-red subset is at least $n^{1/2}/k$, at most $kn^{1/2}$ non-red vertices exist in $G/\mathcal{P}$. It implies $\overline{I}(G/\mathcal{P}) \leq kn^{1/2}$. The lemma is proved. ◀

This lemma also implies that the size of R is at most $kn^{1/2}$. Thus the space complexity of the algorithm is bounded by $O(kn^{1/2} \log n)$ bits. The combination of Lemmas 10, 11, and 12 yields the following lemma.

▶ **Lemma 13.** *There exists a polynomial-time algorithm that, given a graph G on n vertices and a positive integer k, either provides an $O(1)$-balanced separator of G consisting of $O(kn^{1/2})$ vertices, or concludes that the treewidth of G is more than k. The algorithm uses $O(kn^{1/2} \log n)$-bit space.*

The remaining part is to transform the separator algorithm into a tree-decomposition algorithm. The following lemma obviously deduces Theorem 2.

▶ **Lemma 14.** *Assume an algorithm Alg which outputs an $O(1)$-balanced separator of size $k(w, n)$ for any graph G of treewidth w using $g(n)$-bit space. Then there exists a polynomial-time tree decomposition algorithm which outputs a tree decomposition of width $O(k(w, n) \log n)$ using $O(g(n) + k(w, n) \log^2 n)$-bit working memory.*

Proof. The proof is constructive. We refer to the constructed algorithm as *Alg*. The algorithm *Alg* first computes an $O(1)$-balanced separator U of G, and then recursively constructs the tree decomposition of each connected component in $G - U$ whose size is larger than $k(w, n)$. A component having at most $k(w, n)$ vertices is treated as the subgraph with the tree decomposition consisting of a single bag of the whole component. Let $H_0, H_1, \ldots, H_{\ell-1}$ be the connected components in $G - U$ sorted in the order specified by the enumeration algorithm of Lemma 5, and T_i be the output sequence of the recursive call for H_i. Defining the binary operator $\circ$ for concatenating two sequences, let $T = T_0 \circ T_1 \circ \cdots \circ T_{\ell-1}$. We further define $m_i = \sum_{0 \leq j \leq i} |T_i|$. The algorithm *Alg* modifies the sequence T in the following way: Any pair $(B, q) \in T_i$ is replaced by $(B \cup U, q + m_i)$ if $q \neq -1$ or $(B \cup U, m_{\ell-1})$ otherwise. Finally, we append the pair $(U, -1)$ at the tail of T. Intuitively, this modification is for relabeling bag identifiers to guarantee their uniqueness, and for merging all the subgraph decompositions into a single one rooted by the last bag $(U, -1)$. It is easy to verify that the modified sequence is a tree decomposition of G. By Lemma 5, the input graph at any recursion level is emulated with a polynomial-time overhead. Thus the running time at any recursion level is a polynomial time. One recursive call remove one bag from the input graph, the number of recursive calls is bounded by n. Totally the algorithm *Alg* finishes within a polynomial time.

Let w_i be the maximum width of all the output tree decompositions at the i-th recursion level. Then we have the inequality $w_{i+1} \leq k(w,n) + w_i$. Since the separator is $O(1)$-balanced, the recursion finishes at the depth of $O(\log n)$. It implies that the maximum bag size is $O(k(w,n)\log n)$. The modification of the sequence T can be done in a streaming way. Thus the space complexity of *Alg* is $O(|U|\log n) = O(k(w,n)\log n)$ bits per one recursion. The largest space consumption is at the bottom-level recursion, where *Alg* uses $O(k(w,n)\log^2 n)$ bits in total. ◀

The lemma above also deduces the consequence for planar graphs in Corollary 3. Since planar graphs admit a $\widetilde{O}(\sqrt{n})$-bit space $O(1)$-balanced separator algorithm [27], we can use it instead of Lemma 13.

5 Conclusion

In this paper, we presented a Lex-DFS algorithm for directed graphs of bounded treewidth w. It is not only the first algorithm solving Lex-DFS using sublinear space for $w = \omega(1)$, but also the first algorithm solving directed s-t reachability in the same situation. One of the key tools is a new sublinear-space tree decomposition algorithm covering the case of moderate (small but non-constant) treewidth. The authors believe that this is a strong tool for designing small-space algorithms for other fundamental graph problems on bounded-treewidth graphs.

Abstract

Makespan minimization on identical machines is a fundamental problem in online scheduling. The goal is to assign a sequence of jobs to m identical parallel machines so as to minimize the maximum completion time of any job. Already in the 1960s, Graham showed that *Greedy* is $(2-1/m)$-competitive [18]. The best deterministic online algorithm currently known achieves a competitive ratio of 1.9201 [14]. No deterministic online strategy can obtain a competitiveness smaller than 1.88 [34].

In this paper, we study online makespan minimization in the popular random-order model, where the jobs of a given input arrive as a random permutation. It is known that *Greedy* does not attain a competitive factor asymptotically smaller than 2 in this setting [32]. We present the first improved performance guarantees. Specifically, we develop a deterministic online algorithm that achieves a competitive ratio of 1.8478. The result relies on a new analysis approach. We identify a set of properties that a random permutation of the input jobs satisfies with high probability. Then we conduct a worst-case analysis of our algorithm, for the respective class of permutations. The analysis implies that the stated competitiveness holds not only in expectation but with high probability. Moreover, it provides mathematical evidence that job sequences leading to higher performance ratios are extremely rare, pathological inputs. We complement the results by lower bounds for the random-order model. We show that no deterministic online algorithm can achieve a competitive ratio smaller than 4/3. Moreover, no deterministic online algorithm can attain a competitiveness smaller than 3/2 with high probability.

1 Introduction

We study one of the most basic scheduling problems. Consider a sequence of jobs $\mathcal{J} = J_1, \ldots, J_n$ that has to be assigned to m identical parallel machines. Each job J_t has an individual processing time p_t, $1 \leq t \leq n$. Preemption of jobs is not allowed. The goal is to minimize the *makespan*, i.e. the maximum completion time of any job in the constructed schedule. Both the offline and online variants of this problem have been studied extensively, see e.g. [4, 11, 14, 18, 20, 33] and references therein.

We focus on the online setting, where jobs arrive one by one. Whenever a job J_t is presented, its processing time p_t is revealed. The job has to be scheduled immediately on one of the machines without knowledge of any future jobs J_s, with $s > t$. Given a job sequence $\mathcal{J}$,

let $A(\mathcal{J})$ denote the makespan of an online algorithm A on $\mathcal{J}$. Let $OPT(\mathcal{J})$ be the optimum makespan. A deterministic online algorithm A is *c-competitive* if $A(\mathcal{J}) \leq c \cdot OPT(\mathcal{J})$ holds for all $\mathcal{J}$ [38]. The best competitive ratio that can be achieved by deterministic online algorithms is in the range $[1.88, 1.9201]$. No randomized online algorithm is known that beats deterministic ones, for general m.

In this paper we investigate online makespan minimization in the random-order model. Here an input instance / job sequence is chosen by an adversary. Then a random permutation of the input elements / jobs arrives. The random-order model was considered by Dynkin [10] and Lindley [28] for the secretary problem. Over the last years the framework has received quite some research interest and many further problems have been studied. These include generalized secretary problems [2, 3, 13, 27, 28], the knapsack problem [2, 27], bin packing [25], facility location [30], matching problems [16, 21, 29], packing LPs [26] and convex optimization [19].

We present an in-depth study of online makespan minimization in the random-order model. As a main contribution we devise a new deterministic online algorithm that achieves a competitive ratio of 1.8478. After almost 20 years this is the first progress for the pure online setting, where an algorithm does not resort to extra resources in handling a job sequence.

Previous work. We review the most important results relevant to our work and first address the standard setting where an online algorithm must schedule an arbitrary, worst-case job sequence. Graham in 1966 showed that the famous *Greedy* algorithm, which assigns each job to a least loaded machine, is $(2 - \frac{1}{m})$-competitive. Using new deterministic strategies the competitiveness was improved in a series of papers. Galambos and Woeginger [15] gave an algorithm with a competitive ratio of $(2 - \frac{1}{m} - \epsilon_m)$, where ϵ_m tends to 0 as $m \to \infty$. Bartal et al. [4] devised a 1.986-competitive algorithm. The bound was improved to 1.945 [22] and 1.923 [1]. Fleischer and Wahl [14] presented an algorithm that attains a competitive ratio of 1.9201 as $m \to \infty$. Chen et al. [7] gave an algorithm whose competitiveness is at most $1 + \varepsilon$ times the best possible factor, but no explicit bound was provided. Lower bounds on the competitive ratio of deterministic online algorithms were shown in [1, 5, 12, 17, 34, 35]. For general m, the bound was raised from 1.707 [12] to 1.837 [5] and 1.854 [17]. Rudin [34] showed that no deterministic strategy has a competitiveness smaller than 1.88.

For randomized online algorithms, there is a significant gap between the best known upper and lower bounds. For $m = 2$ machines, Bartal et al. [4] presented an algorithm that achieves an optimal competitive ratio of 4/3. To date, there exists no randomized algorithm whose competitiveness is smaller than the deterministic lower bound, for general m. The best known lower bound on the performance of randomized online algorithms tends to $e/(e-1) \approx 1.581$ as $m \to \infty$ [6, 37].

Recent research on makespan minimization has examined settings where an online algorithm is given extra resources when processing a job sequence. Specifically, an algorithm might have a buffer to reorder the incoming job sequence [11, 24] or is allowed to migrate jobs [36]. Alternatively, an algorithm has information on the job sequence [8, 9, 23, 24], e.g. it might know the total processing time of the jobs or even the optimum makespan.

In the random-order model only one result is known for makespan minimization on identical machines. Osborn und Torng [32] showed that *Greedy* does not achieve a competitive ratio smaller than 2 as $m \to \infty$. Recently Molinaro [31] studied online load balancing with the objective to minimize the l_p-norm of the machine loads. He considers a general scenario with machine-dependent job processing times. For makespan minimization he presents an algorithm that, in the worst case, is $O(\log m/\varepsilon)$-competitive and, in the random-order model, has an expected makespan of $(1+\varepsilon)OPT(\mathcal{J}) + O(\log m/\varepsilon)$, for any $\varepsilon \in (0, 1]$.

Our contribution. We investigate online makespan minimization in the random-order model, a sensible and widely adopted input model to study algorithms beyond the worst case. Specifically, we develop a new deterministic algorithm that achieves a competitive ratio of 1.8478 as $m \to \infty$. This is the first improved performance guarantee in the random-order model. The competitiveness is substantially below the best known ratio of 1.9201 in the worst-case setting and also below the corresponding lower bound of 1.88 in that framework.

A new feature of our algorithm is that it schedules an incoming job on one of three candidate machines in order to maintain a certain load profile. The best strategies in the worst-case setting use two possible machines, and it is not clear how to take advantage of additional machines in that framework. The choice of our third, extra machine is quite flexible: An incoming job is placed either on a least loaded, a heavily loaded or – as a new option – on an intermediate machine. The latter one is the $(h+1)$-st least loaded machine, where h may be any integer with $h \in \omega(1)$ and $h \in o(\sqrt{m})$.

When assigning a job to a machine different from the least loaded one, an algorithm has to ensure that the resulting makespan does not exceed c times the optimum makespan, for the targeted competitive ratio c. All previous strategies in the literature lower bound the optimum makespan by the current average load on the machines. Our new algorithm works with a refined lower bound that incorporates the processing times of the largest jobs seen so far. The lower bound is obvious but has not been employed by previous algorithms.

The analysis of our algorithm proceeds in two steps. First we define a class of *stable job sequences*. These are sequences that reveal information on the largest jobs as processing volume is scheduled. More precisely, once a certain fraction of the total processing volume $\sum_{t=1}^{n} p_t$ has arrived, one has a good estimate on the h-th largest job and has encountered a certain number of the $m+1$ largest jobs in the input. The exact parameters have to be chosen carefully.

We prove that with high probability, a random permutation of a given input of jobs is stable. We then conduct a worst-case analysis of our algorithm on stable sequences. Using their properties, we show that if the algorithm generates a flat schedule, like *Greedy*, and can be hurt by a huge job, then the input must contain many large jobs so that the optimum makespan is also high. A new ingredient in the worst-case analysis is the processing time of the h-th largest job in the input. We will relate it to machine load in the schedule and to the processing time of the $(m+1)$-st largest job; twice the latter value is a lower bound on the optimum makespan.

The analysis implies that the competitive ratio of 1.8478 holds with high probability. Input sequences leading to higher performance ratios are extremely rare. We believe that our analysis approach might be fruitful in the study of other problems in the random-order model: Identify properties that a random permutation of the input elements satisfies with high probability. Then perform a worst-case analysis.

Finally in this paper we devise lower bounds for the random-order model. We prove that no deterministic online algorithm achieves a competitive ratio smaller than 4/3. Moreover, if a deterministic online algorithm is c-competitive with high probability, then $c \geq 3/2$.

2 Strong competitiveness in the random-order model

We define competitiveness in the random-order model and introduce a stronger measure of competitiveness that implies high-probability bounds. Recall that traditionally a deterministic online algorithm A is c-competitive if $A(\mathcal{J}) \leq c \cdot OPT(\mathcal{J})$ holds for all job sequences $\mathcal{J} = J_1, \ldots, J_n$. We will refer to this worst-case model also as the *adversarial model*.

In the *random-order model* a job sequence $\mathcal{J} = J_1, \ldots, J_n$ is given, which may be specified by an adversary. (Alternatively, a set of jobs could be specified.) Then a random permutation of the jobs arrives. We define the expected cost / makespan of a deterministic online algorithm. Let S_n be the permutation group of the integers from 1 to n, which we consider a probability space under the uniform distribution, i.e. each permutation in S_n is chosen with probability $1/n!$. Given $\sigma \in S_n$, let $\mathcal{J}^\sigma = J_{\sigma(1)}, \ldots, J_{\sigma(n)}$ be the *job sequence permuted by* σ. The expected makespan of A on $\mathcal{J}$ in the random-order model is $A^{\text{rom}}(\mathcal{J}) = \mathbf{E}_{\sigma\sim S_n}[A(\mathcal{J}^\sigma)] = \frac{1}{n!}\sum_{\sigma\in S_n} A(\mathcal{J}^\sigma)$. The algorithm A is *c-competitive in the random-order model* if $A^{\text{rom}}(\mathcal{J}) \le c \cdot OPT(\mathcal{J})$ holds for all job sequences $\mathcal{J}$.

We next define the notion of a deterministic online algorithm A being *nearly c-competitive*. The second condition in the following definition requires that the probability of A not meeting the desired performance ratio must be arbitrarily small as m grows and a random permutation of a given job sequence arrives. The subsequent Lemma 2 states that a nearly c-competitive algorithm is c-competitive in the random-order model.

▶ **Definition 1.** *A deterministic online algorithm A is called* nearly c-competitive *if the following two conditions hold.*

- *The algorithm A achieves a constant competitive ratio in the adversarial model.*
- *For every $\varepsilon > 0$, there exists an $m(\varepsilon)$ such that for all machine numbers $m \ge m(\varepsilon)$ and all job sequences $\mathcal{J}$ there holds $\mathbf{P}_{\sigma\sim S_n}[A(\mathcal{J}^\sigma) \ge (c+\varepsilon)OPT(\mathcal{J})] \le \varepsilon$.*

▶ **Lemma 2.** *If a deterministic online algorithm is nearly c-competitive, then it is c-competitive in the random-order model as $m \to \infty$.*

Proof. Let C be the constant such that A is C-competitive in the adversarial model. We may assume that $C > c$. Given $0 < \delta \le C - c$, we show that there exists an $m(\delta)$ such that, for all $m \ge m(\delta)$, we have $A^{\text{rom}}(\mathcal{J}) \le (c+\delta)OPT(\mathcal{J})$ for every job sequences $\mathcal{J}$. Let $\varepsilon = \delta/(C - c + 1)$. Since A is nearly c-competitive, there exists an $m(\varepsilon)$ such that, for all $m \ge m(\varepsilon)$ and all inputs $\mathcal{J}$, there holds $P_\varepsilon(\mathcal{J}) = \mathbf{P}_{\sigma\sim S_n}[A(\mathcal{J}^\sigma) \ge (c+\varepsilon)OPT(\mathcal{J})] \le \varepsilon$. Set $m(\delta) = m(\varepsilon)$. We obtain

$$\begin{aligned} A^{\text{rom}}(\mathcal{J}) &\le (1 - P_\varepsilon(\mathcal{J}))(c+\varepsilon)OPT(\mathcal{J}) + P_\varepsilon(\mathcal{J}) \cdot C \cdot OPT(\mathcal{J}) \\ &\le ((1-\varepsilon)(c+\varepsilon) + \varepsilon C)OPT(\mathcal{J}) \\ &\le (c + \varepsilon(C - c + 1))OPT(\mathcal{J}) \\ &= (c+\delta)OPT(\mathcal{J}). \end{aligned}$$ ◀

3 Description of the new algorithm

The deficiency of *Greedy* is that it tends to generate a flat, balanced schedule in which all the machines have approximately the same load. An incoming large job can then enforce a high makespan relative to the optimum one. It is thus crucial to try to avoid flat schedules and maintain steep schedules that exhibit a certain load imbalance among the machines.

However, in general, this is futile. Consider a sequence of m identical jobs with a processing time of, say, P_{m+1} (refering to the size of the $(m+1)$-st largest job in an input). Any online algorithm that is better than 2-competitive must schedule these m jobs on separate machines, obtaining the flattest schedule possible. An incoming even larger job of processing time $p_{\max}$ will now enforce a makespan of $P_{m+1} + p_{\max}$. Observe that $\text{OPT} \ge \max\{2P_{m+1}, p_{\max}\}$ since there must be one machine containing two jobs. In particular $P_{m+1} + p_{\max} \le 1.5\text{OPT}$. Hence sensible online algorithms do not perform badly on this sequence.

This example summarizes the quintessential strategy of online algorithms that are good on all sequences: Ensure that in order to create a schedule that is very flat, i.e. such that all machines have high load λ, the adversary must present m jobs that all are large relative to λ. In order to exploit this very flat schedule and cause a high makespan the adversary needs to follow up with yet another large job. But with these $m+1$ jobs, the optimum scheduler runs into the same problem as in the example: Of the $m+1$ large jobs, two have to be scheduled on the same machine. Thus the optimum makespan is high, compensating to the high makespan of the algorithm.

Effectively realizing the aforementioned strategy is highly non-trivial. In fact it is the central challenge in previous works on adversarial makespan minimization that improve upon *Greedy* [1, 4, 14, 15, 22]. These works gave us clear notions of how to avoid flat schedules, which form the basis for our approaches. Instead of simply rehashing these ideas, we want to outline next how we profit from random-order arrival in particular.

3.1 How random-order arrival helps

The first idea to profit from random-order arrival addresses the lower bound on OPT sophisticated online algorithms need. In the literature only the current average load has been considered, but under random-order arrival another bound comes to mind: The largest job seen so far. In order for an algorithm to perform badly, a large job needs to come close to the end of the sequence. Under random-order arrival, it is equally likely for such a job to arrive similarly close to the beginning of the sequence. In this case, the algorithm knows a better lower bound for OPT. The main technical tool will be our *Load Lemma*, which allows us to relate what a job sequence should reveal early from an analysis perspective to the actual fraction of jobs scheduled. This idea does not work for worst-case orders since they tend to order jobs by increasing processing times.

Recall that the general challenge of our later analysis will be to establish that there had to be m large jobs once the schedule gets very flat. In classical analyses, which consider worst-case orders, these jobs appear with increasing density towards the end of the sequence. In random orders this is unlikely, which can be exploited by the algorithm.

The third idea improves upon the first idea. Suppose, that we were to modify our algorithm such that it could handle one very large job arriving close to the end of the sequence. In fact, assume that it could only perform badly when confronted with h very large jobs. We can then disregard any sequence which contains fewer such jobs. Recall that the first idea requires one very large job to arrive sufficiently close to the beginning. Now, as h grows, the probability of the latter event grows as well and approaches 1. This will not only improve our competitive ratio tremendously, it also allows us to adhere to the stronger notion of nearly competitiveness introduced in Section 2. Let us discuss how such a modification is possible: The first step is to design our algorithm in a way that it is reluctant to use the h least loaded machines. Intuitively, if the algorithm tries to retain machines of small load it will require very large jobs to fill them. In order to force these filling jobs to actually be large enough, our algorithm needs to use a very high lower bound for OPT. In fact, here it uses another lower bound for the optimum makespan, $2P^t_{m+1}$, twice the $(m+1)$-st largest job seen so far at time t. Common analysis techniques can only make predictions about P^t_{m+1} at the very end of the sequence. It requires very subtle use of the random-order model to work around this.

3.2 Formal definition

Formally our algorithm ALG is nearly c-competitive, where c is the unique real root of the polynomial $Q[x] = 4x^3 - 14x^2 + 16x - 7$, i.e.

$$c = \frac{7+\sqrt[3]{28-3\sqrt{87}}+\sqrt[3]{28+3\sqrt{87}}}{6} < 1.8478.$$

Given $\mathcal{J}$, ALG is presented with a job sequence/permutation $\mathcal{J}^\sigma = J_{\sigma(1)}, \ldots, J_{\sigma(n)}$ that must be scheduled in this order. Throughout the scheduling process ALG always maintains a list of the machines sorted in non-increasing order of current *load*. At any time the load of a machine is the sum of the processing times of the jobs already assigned to it. After ALG has processed the first t jobs $J_{\sigma(1)}, \ldots, J_{\sigma(t)}$, let $M_1^t, \ldots, M_m^t$ be any ordering of the m machines according to non-increasing load. More specifically, let l_j^t denote the load of machine M_j^t. Then $l_1^t \geq \ldots \geq l_m^t$ and l_1^t is the makespan of the current schedule.

ALG places each incoming job $J_{\sigma(t)}$, $1 \leq t \leq n$, on one of three candidate machines. The choice of one machine, having an intermediate load, is flexible. Let $h = h(m)$ be an integer with $h(m) \in \omega(1)$ and $h(m) \in o(\sqrt{m})$. We could use e.g. $h(m) = \lfloor \sqrt[3]{m} \rfloor$ or $h(m) = \lfloor \log m \rfloor$. Let

$$i = \lceil (2c - 3)m \rceil + h \approx 0.6956m.$$

ALG will assign the incoming job to the machine with the smallest load, the $(h + 1)$-st smallest load or the i-th largest load.

When scheduling a job on a machine that is different from the least loaded one, an algorithm has to ensure that the resulting makespan does not exceed c^* times the optimum makespan, where c^* is the desired competitiveness. All previous algorithms lower bound the optimum makespan by the current average machine load. Algorithm ALG works with a refined lower bound that incorporates the processing time of the largest job and twice the processing time of the $(m + 1)$-st largest job seen so far. These lower bounds on the optimum makespan are immediate but have not been used in earlier strategies.

Formally, for $j = 1, \ldots, m$, let L_j^t be the *average load* of the $m - j + 1$ least loaded machines $M_j^t, \ldots, M_m^t$, i.e. $L_j^t = \frac{1}{m-j+1}\sum_{r=j}^m l_r^t$. We let $L^t = L_1^t = \frac{1}{m}\sum_{s=1}^t p_s$ be the average load of all the machines. For any $j = 1, \ldots, n$, let P_j^t be the processing time of the j-th largest job among the first t jobs $J_{\sigma(1)}, \ldots, J_{\sigma(t)}$ in $\mathcal{J}^\sigma$. If $t < j$, we set $P_j^t = 0$. We let $p_{\max}^t = P_1^t$ be the processing time of the largest job among the first t jobs in $\mathcal{J}^\sigma$. Finally, let $L = L^n$, $P_j = P_j^n$ and $p_{\max} = p_{\max}^n$.

The value $O^t = \max\{L^t, p_{\max}^t, 2P_{m+1}^t\}$ is a common lower bound on the optimum makespan for the first t jobs and hence $OPT(\mathcal{J})$, see Proposition 5 in the next section. Note that immediately before $J_{\sigma(t)}$ is scheduled, ALG can compute L^t and hence O^t because L^t is $1/m$ times the total processing time of the jobs that have arrived so far.

We next characterize load imbalance. Let

$$k = 2i - m \approx (4c - 7)m \approx 0.3912m$$

and

$$\alpha = \frac{2(c-1)}{2c-3} \approx 2.7376.$$

The *schedule at time t* is the one immediately before $J_{\sigma(t)}$ has to be assigned. The schedule is *flat* if $l_k^{t-1} < \alpha L_{i+1}^{t-1}$. Otherwise it is *steep*. Job $J_{\sigma(t)}$ is scheduled *flatly* (*steeply*) if the schedule at time t is flat (steep).

ALG handles each incoming job $J_{\sigma(t)}$, with processing time $p_{\sigma(t)}$, as follows. If the schedule at time t is steep, the job is placed on the least loaded machine M_m^{t-1}. On the other hand, if the schedule is flat, the machines M_i^{t-1}, M_{m-h}^{t-1} and M_m^{t-1} are probed in this order. If $l_i^{t-1} + p_{\sigma(t)} \le c \cdot O^t$, then the new machine load on M_i^{t-1} will not violate the desired competitiveness. The job is placed on this machine M_i^{t-1}. Otherwise, if the latter inequality is violated, *ALG* checks if a placement on M_{m-h}^{t-1} is safe, i.e. if $l_{m-h}^{t-1} + p_{\sigma(t)} \le c \cdot O^t$. If this is the case, the job is put on M_{m-h}^{t-1}. Otherwise, $J_{\sigma(t)}$ is finally scheduled on the least loaded machine M_m^{t-1}. A pseudo-code description of *ALG* is given below. The job assignment rules are also illustrated in Figures 1 and 2.

Algorithm 1 The scheduling algorithm *ALG*.

```
Let $J_{\sigma(t)}$ be the next job to be scheduled.
if the schedule at time $t$ is steep then
    Assign $J_{\sigma(t)}$ to the least loaded machine $M_m^{t-1}$;
else // the schedule is flat
    if $l_i^{t-1} + p_{\sigma(t)} \le c \cdot O^t$ then Assign $J_{\sigma(t)}$ to $M_i^{t-1}$;
    else if $l_{m-h}^{t-1} + p_{\sigma(t)} \le c \cdot O^t$ then Assign $J_{\sigma(t)}$ to $M_{m-h}^{t-1}$;
    else Assign $J_{\sigma(t)}$ to $M_m^{t-1}$;
```

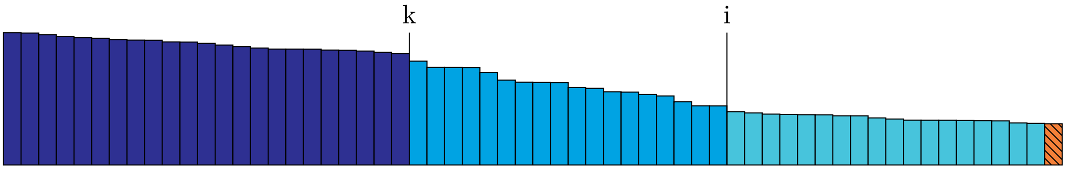

Figure 1 A steep schedule. *ALG* only considers the least loaded machine.

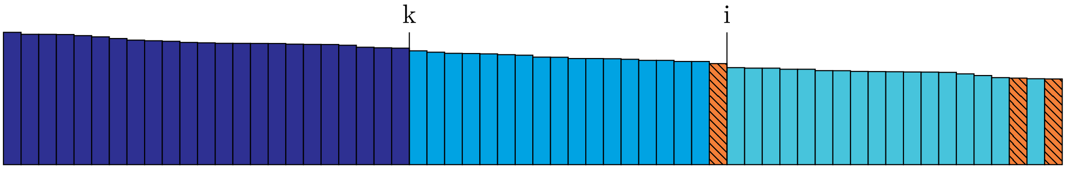

Figure 2 A flat schedule. The three machines considered by *ALG* are marked for $h = 2$.

In the next section we will prove the following theorem, Theorem 3, which uses the notion from Section 2. Lemma 2 then immediately gives the main result, Corollary 4.

▶ **Theorem 3.** *ALG is nearly c-competitive, with $c < 1.8478$ defined as above.*

▶ **Corollary 4.** *ALG is c-competitive in the random-order model as $m \to \infty$.*

From our analysis it can be verified that the number of machines required to be $(c + \varepsilon)$-competitive is bounded by a small polynomial of degree 4 in $1/\varepsilon$. For ease of presentation, we made no optimizations in that regard.

4 Analysis of the algorithm

4.1 Analysis basics

We present some results for the adversarial model so that we can focus on the true random-order analysis of *ALG* in the next sections. First, recall the three common lower bounds used for online makespan minimization.

▶ **Proposition 5.** *For any $\mathcal{J}$, there holds $OPT(\mathcal{J}) \geq \max\{L, p_{\max}, 2P_{m+1}\}$. Moreover, for any permutation J^σ, there holds $O^1 \leq O^2 \leq \ldots \leq O^n \leq OPT(\mathcal{J})$.*

Proof. The optimum makespan $OPT(\mathcal{J})$ cannot be smaller than the average machine load L for the input, even if all the jobs are distributed evenly among the m machines. Moreover, the job with the largest processing time $p_{\max}$ must be scheduled non-preemptively on one of the machines in an optimal schedule. Thus $OPT(\mathcal{J}) \geq p_{\max}$. Finally, among the $m+1$ largest jobs of the input, two must be placed on the same machine in an optimal solution. Hence $OPT(\mathcal{J}) \geq 2P_{m+1}$. For any permutation J^σ, the value O^t cannot decrease as jobs J_t arrive. ◀

For any job sequence $\mathcal{J} = J_1, \ldots, J_n$, let $R(\mathcal{J}) = \min\{\frac{L}{p_{\max}}, \frac{p_{\max}}{L}\}$. Intuitively, this measures the complexity of $\mathcal{J}$.

▶ **Proposition 6.** *For any $\mathcal{J} = J_1, \ldots, J_n$, there holds $ALG(\mathcal{J}) \leq \max\{1+R(\mathcal{J}), c\}OPT(\mathcal{J})$.*

Proof. Let $\mathcal{J} = J_1, \ldots, J_n$ be an arbitrary job sequence and let J_t be the job that defines ALG's makespan. If the makespan exceeds $c \cdot OPT(\mathcal{J})$, then it exceeds $c \cdot O^t$. Thus ALG placed J_t on machine M_m^{t-1}, cf. lines 4 and 5 of the algorithm. This machine was a least loaded one, having a load of at most L. Hence $ALG(\mathcal{J}) \leq L + p_t \leq L + p_{\max} \leq \frac{L+p_{\max}}{\max\{L, p_{\max}\}} \cdot OPT(\mathcal{J}) = (1 + R(\mathcal{J})) \cdot OPT(\mathcal{J})$. ◀

Since $R(\mathcal{J}) \leq 1$ we immediately obtain the following result, which ensures that ALG satisfies the first condition of a nearly c-competitive algorithm, see Definition 1.

▶ **Corollary 7.** *ALG is 2-competitive in the adversarial model.*

We next identify a class of *plain* job sequences that we do not need to consider in the random-order analysis because ALG's makespan is upper bounded by c times the optimum on these inputs.

▶ **Definition 8.** *A job sequence $\mathcal{J} = J_1, \ldots, J_n$ is called* plain *if $n \leq m$ or if $R(\mathcal{J}) \leq c - 1$. Otherwise it is called* proper*.*

Let $\mathcal{J} = J_1, \ldots, J_n$ be any job sequence that is processed/scheduled in this order. Observe that if it contains at most m jobs, i.e. $n \leq m$, and ALG cannot place a job J_t on machines M_i^{t-1} or M_{m-h}^{t-1} because the resulting load would exceed $c \cdot O^t$, then the job is placed on an empty machine. Using Proposition 6 we derive the following fact.

▶ **Lemma 9.** *For any plain job sequence $\mathcal{J} = J_1, \ldots, J_n$, there holds $ALG(\mathcal{J}) \leq c \cdot OPT(\mathcal{J})$.*

If a job sequence $\mathcal{J}$ is plain (proper), then every permutation of it is. Hence, given Lemma 9, we may concentrate on proper job sequences in the remainder of the analysis. We finally state a fact that relates to the second condition of a nearly c-competitive algorithm, see again Definition 1. The proof is given in the full version.

▶ **Lemma 10.** *Let $\mathcal{J} = J_1, \ldots, J_n$ be any job sequence that is scheduled in this order and let J_t be a job that causes ALG's makespan to exceed $(c + \varepsilon)OPT(\mathcal{J})$, for some $\epsilon \geq 0$. Then both the load of ALG's least loaded machine at the time of the assignment as well as p_t exceed $(c - 1 + \varepsilon)OPT(\mathcal{J})$.*

Proof. ALG places J_t on machine M_m^{t-1}, which is a least loaded machine when the assignment is done. If l_m^{t-1} or p_t were upper bounded by $(c - 1 + \varepsilon)OPT(\mathcal{J})$, then the resulting load would be $l_m^{t-1} + p_t \leq (c - 1 + \varepsilon)OPT(\mathcal{J}) + \max\{L, p_t\} \leq (c - 1 + \varepsilon)OPT(\mathcal{J}) + OPT(\mathcal{J}) = (c + \varepsilon)OPT(\mathcal{J})$. ◀

4.2 Stable job sequences

We define the class of stable job sequences. These sequences are robust in that they will admit an adversarial analysis of ALG. Intuitively, the sequences reveal information on the largest jobs when a significant fraction of the total processing volume $\sum_{t=1}^{n} p_t$ has been scheduled. More precisely, one gets an estimate on the processing time of the h-th largest job in the entire sequence and encounters a relevant number of the $m+1$ largest jobs. If a job sequence is unstable, large jobs occur towards the very end of the sequence and can cause a high makespan relative to the optimum one.

We will show that ALG is adversarially $(c+\varepsilon)$-competitive on stable sequences, for a given $\varepsilon > 0$. Therefore, the definition of stable sequences is formulated for a fixed $\varepsilon > 0$. Given $\mathcal{J}$, let $\mathcal{J}^\sigma = J_{\sigma(1)}, \ldots, J_{\sigma(n)}$ be any permutation of the jobs. Furthermore, for every $j \leq n$ and in particular $j \in \{h, m+1\}$, the *set of the j largest jobs* is a fixed set of cardinality j such that no job outside this set has a strictly larger processing time than any job inside the set.

▶ **Definition 11.** *A job sequence $\mathcal{J}^\sigma = J_{\sigma(1)}, \ldots, J_{\sigma(n)}$ is* stable *if the following conditions hold.*

- *There holds $n > m$.*
- *Once $L^t \geq (c-1)\frac{i}{m}L$, there holds $p^t_{\max} \geq P_h$.*
- *For every $j \geq i$, the sequence ending once we have $L^t \geq (\frac{j}{m} + \frac{\varepsilon}{2})L$ contains at least $j+h+2$ many of the $m+1$ largest jobs in $\mathcal{J}$.*
- *The sequence ending right before either (a) $L^t \geq \frac{i}{m}(c-1)\varepsilon L$ holds or (b) the h-th largest job of $\mathcal{J}$ is scheduled contains at least $h+1$ many of the $m+1$ largest jobs in $\mathcal{J}$.*

Otherwise the job sequence is unstable.

Given $\varepsilon > 0$ and m, let $P_\varepsilon(m)$ be the infimum, over all proper job sequences $\mathcal{J}$, that a random permutation of $\mathcal{J}$ is stable, i.e.

$$P_\varepsilon(m) = \inf_{\mathcal{J} \text{ proper}} \mathbf{P}_{\sigma \sim S_n}[\mathcal{J}^\sigma \text{ is stable}].$$

As the main result of this section we will prove that this probability tends to 1 as $m \to \infty$.

▶ **Main Lemma 1.** *For every $\varepsilon > 0$, there holds $\lim_{m \to \infty} P_\varepsilon(m) = 1$.*

The above lemma implies that for any $\varepsilon > 0$ there exists an $m(\varepsilon)$ such that, for all $m \geq m(\varepsilon)$ and all $\mathcal{J}$, there holds $\mathbf{P}_{\sigma \sim S_n}[\mathcal{J}^\sigma \text{ is stable}] \geq 1 - \varepsilon$. In Section 4.3 we will show that ALG is $(c+\varepsilon)$-competitive on stable job sequences. This implies $\mathbf{P}_{\sigma \sim S_n}[ALG(\mathcal{J}^\sigma) \geq (c+\varepsilon)OPT(\mathcal{J})] \leq \varepsilon$. Given Lemma 7, we obtain the following corollary.

▶ **Corollary 12.** *If ALG is adversarially $(c+\varepsilon)$-competitive on stable sequences, for every $\varepsilon > 0$ and $m \geq m(\varepsilon)$ sufficiently large, then it is nearly c-competitive.*

In the remainder of this section we describe how to establish Main Lemma 1. Full proofs of all the lemmas of this section are given in the full version. We need some notation. In Section 3 the value L^t_j was defined with respect to a fixed job sequence that was clear from the context. We adopt the notation $L^t_j[\mathcal{J}^\sigma]$ to make this dependence visible. We adopt a similar notation for the variables L, P^t_j, P_j, $p^t_{\max}$ and $p_{\max}$. For an input $\mathcal{J}$ and $\sigma \in S_n$, we will use the notation $L^t_j[\sigma] = L^t_j[\mathcal{J}^\sigma]$. Again, we use a similar notation for the variables P^t_j and $p^t_{\max}$.

At the heart of the proof of Main Lemma 1 is the Load Lemma. Observe that after t time steps in a random permutation of an input $\mathcal{J}$, each job has arrived with probability t/n. Thus the expected total processing time of the jobs seen so far is $t/n \cdot \sum_{s=1}^{n} p_s$. Equivalently, in expectation L^t equals $t/n \cdot L$. The Load Lemma proves that this relation holds with high probability. We set $t = \varphi n$.

▶ **Load Lemma.** *Given any $\varepsilon > 0$ and $\varphi \in (0,1]$, there exists an $m(\varepsilon, \varphi)$ such that for all $m \geq m(\varepsilon, \varphi)$ and all proper sequences $\mathcal{J}$, there holds*

$$\mathbf{P}_{\sigma \sim S_n}\left[\left|\frac{L^{\lfloor \varphi n \rfloor}[\mathcal{J}^\sigma]}{\varphi L[\mathcal{J}^\sigma]} - 1\right| \geq \varepsilon\right] \leq \varepsilon.$$

Proof sketch. By scaling all job processing times by a common factor we may assume that $p_{\max} = 1$. Then $L = \Theta(m)$ because $\mathcal{J}$ is proper. The main idea of the proof is to show that the variance of the random variable $L^{\lfloor \varphi n \rfloor}[\mathcal{J}^\sigma]$ lies in $O(m) = O(L)$. Using Chebyshev's inequality we show that the probability of $L^{\lfloor \varphi n \rfloor}[\mathcal{J}^\sigma]$ deviating by its expected value φL by more than some term in $\Theta(m^{-1/4})$ is in $O(m^{-1/2})$. The lemma then follows by choosing m sufficiently large. ◀

We note that the Load Lemma does not hold for general sequences. A counterexample is a job sequence in which one job carries all the load, while all the other jobs have a negligible processing time. The proof of the Load Lemma relies on a lower bound of $R(\mathcal{J})$, which is $c - 1$ for proper sequences.

We present two consequences of the Load Lemma that will allow us to prove that stable sequences reveal information on the largest jobs when a certain processing volume has been scheduled. Consider a proper $\mathcal{J}$. Given $\mathcal{J}^\sigma = J_{\sigma(1)}, \ldots, J_{\sigma(n)}$ and $\varphi > 0$, let $N(\varphi)[\mathcal{J}^\sigma]$ be the number of jobs $J_{\sigma(t)}$ that are among the $m+1$ largest jobs in $\mathcal{J}$ and such that $L^t \leq \varphi L$.

▶ **Lemma 13.** *Let $\varepsilon > 0$ and $\varphi \in (0,1]$. Then there holds*

$$\lim_{m \to \infty} \inf_{\mathcal{J} \text{ proper}} \mathbf{P}_{\sigma \sim S_n}\left[N(\varphi + \varepsilon)[\mathcal{J}^\sigma] \geq \lfloor \varphi m \rfloor + h + 2\right] = 1.$$

Proof sketch. The Load Lemma basically matches load ratios L^t/L with ratios t/n on the time line of job arrivals, up to some margin of error. We can then infer that at least $\lfloor \varphi m \rfloor + h + 1$ of the $m+1$ largest jobs are among the first $(\varphi + \varepsilon)n$ jobs in a job sequence $\mathcal{J}^\sigma$, with a probability that tends to 1 as $m \to \infty$. In expectation $(\varphi + \varepsilon)(m+1)$ of the $m+1$ largest jobs occur in this prefix, which is strictly more than $\lfloor \varphi m \rfloor + h + 1$, for m large enough. Formally, we show that (a slight variant of) the random variable $N(\varphi + \varepsilon)[\mathcal{J}^\sigma]$ is hypergeometrically distributed and has variance at most $m+1$. Using Chebyshev's inequality we derive Lemma 13. ◀

▶ **Lemma 14.** *Let $\varepsilon > 0$ and $\varphi \in (0,1]$. Then there holds*

$$\lim_{m \to \infty} \inf_{\mathcal{J} \text{ proper}} \mathbf{P}_{\sigma \sim S_n}\left[\forall_{\tilde{\varphi} \geq \varphi}\ N(\tilde{\varphi} + \varepsilon)[\mathcal{J}^\sigma] \geq \lfloor \tilde{\varphi} m \rfloor + h + 2\right] = 1.$$

Proof sketch. By rounding the values $\tilde{\varphi}$ we may restrict ourselves to finitely many $\tilde{\varphi}$. Using the Union Bound and Lemma 13 we can prove Lemma 14. ◀

Proof sketch for Main Lemma 1. We consider the properties in the definition of stable job sequences. Since $\mathcal{J}$ is proper, there holds $n > m$. By the Load Lemma the second property translates to one of the h largest jobs being among the first $(c-1)\frac{i}{m}n$ jobs in the permuted sequence $\mathcal{J}^\sigma$. The corresponding probability is roughly $1 - (1 - (c-1)\frac{i}{m})^h$ and (quickly) approaches 1 as m and thus h tends to infinity. The third property is a consequence of Lemma 14. For the fourth property we use Lemma 13, considering the sequence ending once $L^t \geq (\frac{j}{m} + \frac{\varepsilon}{2})L$ holds. Finally, the probability of the h-th largest job being preceded by at least $h+1$ of the $m+1$ largest jobs approaches 1 since $h \in o(\sqrt{m})$. Again a full proof is given in the full version. ◀

4.3 An adversarial analysis

In this section we prove the following main result.

▶ **Main Lemma 2.** *For every $\varepsilon > 0$ and $m \geq m(\varepsilon)$ sufficiently large, ALG is adversarially $(c+\varepsilon)$-competitive on stable job sequences.*

Consider a fixed $\varepsilon > 0$. Given Lemma 7, we may assume that $0 < \varepsilon < 2 - c$. Suppose that there was a stable job sequence $\mathcal{J}^\sigma$ such that $ALG(\mathcal{J}^\sigma) > (c+\varepsilon)OPT(\mathcal{J}^\sigma)$. We will derive a contradiction, given that m is large. In order to simplify notation, in the following let $\mathcal{J} = \mathcal{J}^\sigma$ be the stable job sequence violating the performance ratio of $c+\varepsilon$. Let $\mathcal{J} = J_1, \ldots, J_n$ and $OPT = OPT(\mathcal{J})$.

Let $J_{n'}$ be the first job that causes ALG to have a makespan greater than $(c+\varepsilon)OPT$ and let $b_0 = l_m^{n'-1}$ be the load of the least loaded machine $M_m^{n'-1}$ right before $J_{n'}$ is scheduled on it. The makespan after $J_{n'}$ is scheduled, called the *critical makespan*, is at most $b_0 + p_{n'} \leq b_0 + OPT$. In particular $b_0 > (c-1+\varepsilon)OPT$ as well as $p_{n'} > (c-1+\varepsilon)OPT$, see Lemma 10. Let

$$\lambda_{\text{start}} = \tfrac{c-1}{1+2c(2-c)} \approx 0.5426 \quad \text{and} \quad \lambda_{\text{end}} = \tfrac{1}{2(c-1+\varepsilon)} \approx 0.5898.$$

There holds $\lambda_{\text{start}} < \lambda_{\text{end}}$. The critical makespan of ALG is bounded by $b_0 + OPT < (1 + \frac{1}{c-1+\varepsilon})b_0 = (c+\varepsilon)\frac{b_0}{c-1+\varepsilon} = (c+\varepsilon)2\lambda_{\text{end}}b_0$. Since ALG does not achieve a performance ratio of $c+\varepsilon$ on $\mathcal{J}$ we have

$$P_{m+1} \leq OPT/2 < \lambda_{\text{end}}b_0. \tag{1}$$

Our main goal is to derive a contradiction to this inequality.

The impact of the variable P_h

A new, crucial aspect in the analysis of ALG is P_h, the processing time of the h-th largest job in the sequence $\mathcal{J}$. Initially, when the processing of $\mathcal{J}$ starts, we have no information on P_h and can only infer $P_{m+1} \geq \lambda_{\text{start}}b_0$. The second property in the definition of stable job sequences ensures that $p^t_{\max} \geq P_h$ once the load ratio L^t/L is sufficiently large. Note that ALG then also works with this estimate because $P_h \leq p^t_{\max} \leq O^t$. This will allow us to evaluate the processing time of flatly scheduled jobs. In order prove that P_{m+1} is large, we will relate P_{m+1} and P_h, i.e. we will lower bound P_{m+1} in terms of P_h and vice versa. Using the relation we can then conclude $P_{m+1} \geq \lambda_{\text{end}}b_0$. In the analysis we repeatedly use the properties of stable job sequences and will explicitly point to it when this is the case. The omitted proofs of propositions and lemmas are given in the full version of the paper.

We next make the relationship between P_h and P_{m+1} precise. Given $0 < \lambda$, let $f(\lambda) = 2c\lambda - 1$ and given $w > 0$, let $g(w) = (c(2c-3)-1)w + 4 - 2c \approx 0.2854 \cdot w + 0.3044$. We set $g_b(\lambda) = g\left(\frac{\lambda}{b}\right)b$ and $f_b(w) = f\left(\frac{w}{b}\right)b$, for any $b > 0$. Then we will lower bound P_{m+1} by $g_{b_0}(P_h)$ and P_h by $f_{b_0}(P_{m+1})$. We state two technical propositions.

▶ **Proposition 15.** *For $\lambda > \lambda_{\text{start}}$, we have $g(f(\lambda)) > \lambda$.*

▶ **Proposition 16.** *For $0 < \varepsilon \le 1$, we have $g(1-\varepsilon) > \lambda_{\text{end}}$.*

We leave the proof of Proposition 15 to the full version of the paper. Proposition 16 determines the choice of our competitive ratio c. Recall that c is chosen minimal such that $Q[c] = 4c^3 - 14c^2 + 16c - 7 \ge 0$.

Proof of Proposition 16. We calculate that

$$\begin{aligned} g(1-\varepsilon) - \lambda_{\text{end}} &= (c(2c-3)-1)(1-\varepsilon) + 4 - 2c - \frac{1}{2(c-1+\varepsilon)} \\ &= \frac{2(c-1+\varepsilon)(2c^2-5c+3-(2c^2-3c-1)\varepsilon) - 1}{2(c-1+\varepsilon)} \\ &= \frac{4c^3-14c^2+16c-7+(4-2c)\varepsilon - 2(2c^2-3c-1)\varepsilon^2}{2(c-1+\varepsilon)}. \end{aligned}$$

Recall that $Q[c] = 4c^3 - 14c^2 + 16c - 7 = 0$. For $0 < \varepsilon \le 1$ we have

$$(4-2c)\varepsilon - (2c^2-3c-1)\varepsilon^2 \approx 0.3044 \cdot \varepsilon - 0.2854 \cdot \varepsilon^2 > 0.$$

Thus we see that $g(1-\varepsilon) - \lambda_{\text{end}} > 0$ and can conclude the lemma. ◀

4.3.1 Analyzing large jobs towards lower bounding P_h and P_{m+1}

Let $b > (c-1+\varepsilon)OPT$ be a value such that immediately before $J_{n'}$ is scheduled at least $m-h$ machines have a load of at least b. Note that $b = b_0$ satisfies this condition but we will be interested in larger values of b as well. We call a machine *b-full* once its load is at least b; we call a job J a *b-filling job* if it causes the machine it is scheduled on to become b-full. We number the b-filling jobs according to their order of arrival $J^{(1)}, J^{(2)}, \ldots$ and let $t(j)$ denote the time of arrival of the j-th filling job $J^{(j)}$.

Recall that our main goal is to show that $P_{m+1} \ge \lambda_{\text{end}} b_0$ holds. To this end we will prove that the *b_0-filling jobs* have a processing time of at least $\lambda_{\text{end}} b_0$. As there are m such jobs, the bound on P_{m+1} follows by observing that $J_{n'}$ arrives after all *b_0-filling jobs* are scheduled and that its processing time exceeds $\lambda_{\text{end}} b_0$ as well. In fact, since $OPT \ge b_0$, we have

$$p_{n'} > (c-1)OPT > 0.847 \cdot OPT > \lambda_{\text{end}} b_0 \approx 0.5898 \cdot b_0. \tag{2}$$

We remark that different to previous analyses in the literature we do not solely rely on lower bounding the processing time of filling jobs. By using the third property of stable job sequences, we can relate load and the size of the $(m+1)$-st largest job at specific points in the time horizon, cf. Lemma 22.

In the following we regard b as fixed and omit it from the terms *filling job* and *full*. Let $\lambda = \max\{\lambda_{\text{start}} b, \min\{g_b(P_h), \lambda_{\text{end}} b\}\}$. We call a job *large* if it has a processing time of at least λ. Let $\tilde{t} = t(m-h)$ be the time when the $(m-h)$-th filling job arrived. The remainder of this section is devoted to showing the following important Lemma 17. Some of the underlying lemmas, but not all of them, hold if $m \ge m(\varepsilon)$ is sufficiently large. We will make the dependence clear.

▶ **Lemma 17.** *At least one of the following statements holds:*

- *All filling jobs are large.*
- *If $m \ge m(\varepsilon)$, there holds $P^{\tilde{t}}_{m+1} \ge \lambda = \max\{\lambda_{\text{start}} b, \min\{g_b(P_h), \lambda_{\text{end}} b\}\}$, i.e. there are at least $m+1$ large jobs once the $(m-h)$-th filling job is scheduled.*

Before we prove the lemma we derive two important implications towards a lower bound of P_{m+1}.

▶ **Lemma 18.** *We have* $P_{m+1} \geq \lambda = \max\{\lambda_{\text{start}} b_0, \min\{g_{b_0}(P_h), \lambda_{\text{end}} b_0\}\}$.

Proof. Apply the last lemma, taking into account that $b \geq b_0$, and use that there are m many b_0-filling jobs followed by $J_{n'}$. The latter has size at least λ by inequality (2). ◀

We also want to lower bound the processing time of the $(m+1)$-st largest job at time $\tilde{t}$. However, at that time only $m-h$ filling jobs have arrived. The next lemma ensures that, if additionally P_h is not too large, this is not a problem.

▶ **Lemma 19.** *If* $P_h \leq (1-\varepsilon)b$ *and* $m \geq m(\varepsilon)$, *the second statement in Lemma 17 holds, i.e.* $P_{m+1}^{\tilde{t}} \geq \lambda = \max\{\lambda_{\text{start}} b, \min\{g_b(P_h), \lambda_{\text{end}} b\}\}$.

The proof of the lemma makes use of the fourth property of stable job sequences.

We introduce late and early filling jobs. We need a certain condition to hold, see Lemma 22, in order to show that the early filling jobs are large. We show that if this condition is not met, the fact that the given job sequence is stable ensures that $P_m^{\tilde{t}} \geq \lambda$.

Let s be chosen maximal such that the s-th filling job is scheduled steeply. If $s \leq i$, then set $s = i+1$ instead. We call all filling jobs $J^{(j)}$ with $j > i$ that are scheduled flatly *late filling jobs*. All other filling jobs are called *early filling jobs*. In particular the job $J^{(s+1)}$ and the filling jobs afterwards are late filling jobs. The following proposition implies that the fillings jobs after $J^{(m-h)}$, if they exist, are all late, i.e. scheduled flatly.

▶ **Proposition 20.** *We have* $s \leq m-h$ *if* $m \geq m(\varepsilon)$.

We need a technical lemma. For any time t, let $\overline{L}_s^t = \frac{1}{m-h-s+1} \sum_{j=s}^{m-h} l_j^t$ be the average load on the machines numbered s to $m-h$.

▶ **Lemma 21.** *If* $\overline{L}_s^{t(s)-1} \geq \alpha^{-1} b$ *holds and* $m \geq m(\varepsilon)$, *we have* $L^{t(s)-1} > \left(\frac{s}{m} + \frac{\varepsilon}{2}\right) \cdot L$.

▶ **Lemma 22.** *If the late filling jobs are large,* $\overline{L}_s^{t(s)-1} \geq \alpha^{-1} b$ *and* $m \geq m(\varepsilon)$, *we have* $P_{m+1}^{\tilde{t}} \geq \lambda$.

Proof. Assume that the conditions of the lemma hold. By Lemma 21 we have $L^{t(s)-1} > \left(\frac{s}{m} + \frac{\varepsilon}{2}\right) \cdot L$. By the third property of stable sequences, at most $m+1-(s+h+2) = m-s-h-1$ of the largest $m+1$ jobs appear in the sequence starting after time $t(s)-1$. However, this sequence contains $m-h-s$ late filling jobs. Thus there exists a late filling job that is not among the $m+1$ largest jobs. As it has a processing time of at least λ, by the assumption of the lemma, $P_{m+1} \geq \lambda$ holds.

Now consider the $m+1$ largest jobs of the entire sequence that arrive before $J^{(s)}$ as well as the jobs $J^{(s+1)}, \ldots, J^{(m-h)}$. There are at least $s+h+2$ of the former and $m-h-s$ of the latter. Thus we have found a set of at least $m+1$ jobs arriving before (or at) time $\tilde{t} = t(m-h)$. Moreover, we argued that all these jobs have a processing time of at least λ. Hence $P_{m+1}^{\tilde{t}} \geq \lambda$ holds true. ◀

We are ready to evaluate the processing time of filling jobs to prove Lemma 17.

▶ **Lemma 23.** *The processing time of late filling jobs strictly exceeds* $\max\{\lambda_{\text{start}} b, g_b(P_h)\}$.

▶ **Lemma 24.** *If* $\overline{L}_s^{t(s)-1} < \alpha^{-1} b$ *holds, the early filling jobs have a processing time of at least* $\lambda_{\text{end}} b$.

Before proving Lemma 24 let us observe the following, strengthening its condition.

▶ **Lemma 25.** *We have*

$$L_{i+1}^{t(i+1)-1} \leq L_{i+2}^{t(i+2)-1} \leq \dots L_s^{t(s)-1}.$$

Proof. Let $i+1 \leq j < s$. It suffices to verify that

$$L_j^{t(j)-1} \leq L_{j+1}^{t(j)} \leq L_{j+1}^{t(j+1)-1}.$$

The second inequality is obvious because for every r the loads l_r^t can only increase as t increases. For the first inequality we note that by definition the job $J^{(j)}$ was scheduled steeply and hence on a least loaded machine. This machine became full. Thus it is not among the $m-j$ least loaded machines at time $t(j)$. In particular $L_{j+1}^{t(j)}$, the average over the $m-j$ smallest loads at time $t(j)$, is also the average of the $m-j+1$ smallest loads excluding the smallest load at time $t(j)-1$. Therefore it cannot be less than $L_j^{t(j)-1}$. ◀

Proof of Lemma 24. Let $i < j \leq s$ such that $J^{(j)}$ was an early filling job. By Lemma 25 we have $L_j^{t(j)-1} \leq L_s^{t(s)-1} < \alpha^{-1}b = b - \frac{b}{2(c-1)} < b - \lambda_{\text{end}}b$. By definition $J^{(j)}$ was scheduled on a least loaded machine $M_m^{t(j)-1}$ which had load less than $L_j^{t(j)-1} < b - \lambda_{\text{end}}b$ before and at least b afterwards because it became full. In particular $J^{(j)}$ had size $\lambda_{\text{end}}b$.

For $k < j \leq i$ the job $J^{(j)}$ is scheduled steeply because we have by Lemma 25

$$l_k^{t(j)-1} \geq b > \alpha L_s^{t(s)-1} \geq \alpha L_{i+1}^{t(i+1)-1} \geq \alpha L_{i+1}^{t(j)-1}.$$

Thus for $k < j \leq i$ the job $J^{(j)}$ is scheduled on the least loaded machine $M_m^{t(j)-1}$, whose load $l_m^{t(j)-1}$ is bounded by

$$l_m^{t(j)-1} \leq L_{i+1}^{t(j)-1} \leq L_s^{t(s)-1} < \alpha^{-1}b = b - \frac{b}{2(c-1)} < b - \lambda_{\text{end}}b.$$

Hence the job $J^{(j)}$ had a size of at least $\lambda_{\text{end}}b$. We also observe that we have

$$l_i^{t(k)-1} \leq l_{i+1}^{t(k+1)-1} \leq \dots \leq l_{i+(m-i)}^{t(k+(m-i))-1} = l_m^{t(i)-1} < b - \lambda_{\text{end}}b.$$

In particular for $1 \leq j \leq k$ any filling job $J^{(j)}$ filled a machine with a load of at most $\max\{l_m^{t(k)}, l_i^{t(k)}\} = l_i^{t(k)} < b - \lambda_{\text{end}}b$. Hence it had a size of at least $\lambda_{\text{end}}b$. ◀

We now conclude the main lemma of this subsection, Lemma 17.

Proof of Lemma 17. By Lemma 23, all late filling jobs are large. We distinguish two cases depending on whether or not $\overline{L}_s^{t(s)-1} < \alpha^{-1}b$ holds. If it does, all filling jobs are large by Lemma 24 and the first statement in Lemma 17 holds. Otherwise, the second statement in Lemma 17 holds by Lemma 22. ◀

4.3.2 Lower bounding P_h and P_{m+1}

In this section we establish the following relations on P_h and P_{m+1}.

▶ **Lemma 26.** *There holds $P_h > (1-\varepsilon)b_0$ or $P_{m+1} \geq \lambda_{\text{end}}b_0$ if $m \geq m(\varepsilon)$.*

For the proof we need a way to lower bound the processing time of a job J_t depending on P_{m+1}^t:

▶ **Lemma 27.** *Let J_t be any job scheduled flatly on the least loaded machine and let $b = l_{m-h}^{t-1}$ be the load of the $(h+1)$-th least loaded machine. Then J_t has a processing time of at least $f_b(P_{m+1}^t)$.*

Proof. From the fact that J_t was not scheduled on the $(h+1)$-th least loaded machine M^t_{m-h} we derive that $p_t > c \cdot O^t - b \geq c \cdot P^t_{m+1} - b = f_b(P^t_{m+1})$ holds. ◀

Proof of Lemma 26. Assume for a contradiction that we had $P_h \leq (1-\varepsilon)b_0$. Let $J = J_t$ be the smallest among the h last b_0-filling jobs. Then J has a processing time $p \leq P_h$. We want to derive a contradiction to that. Let $b_1 = l^{t-1}_{m-h}$ be the load of the $(m-h)$-th machine right before J was scheduled. Because this machine was b_0-full at that time we know that $b_1 \geq b_0 > (c - 1 + \varepsilon)OPT$ holds and it makes sense to consider b_1-filling jobs. Let $\tilde{t}$ be the time the $(m-h)$-th b_1-filling job arrived. By Lemma 17 we have $P^{\tilde{t}}_{m+1} \geq \lambda = \max\{\lambda_{\text{start}} b_1, \min\{g_{b_1}(P_h), \lambda_{\text{end}} b_1\}\}$.

If we have $\lambda = \lambda_{\text{end}} b_1 \geq \lambda_{\text{end}} b_0$ we have already proven $P_{m+1} \geq \lambda_{\text{end}} b_0$ and the lemma follows. So we are left to treat the case that we have $P^{\tilde{t}}_{m+1} \geq \lambda = \max\{\lambda_{\text{start}} b_1, g_{b_1}(P_h)\}$.

Now we can derive the following contradiction:

$$P^{\tilde{t}}_{m+1} \geq g_{b_1}(P_h) \geq g_{b_1}(p) \geq g_{b_1}\left(f_{b_1}\left(P^{\tilde{t}}_{m+1}\right)\right) = g\left(f\left(\frac{P^{\tilde{t}}_{m+1}}{b_1}\right)\right) b_1 > P^{\tilde{t}}_{m+1}.$$

For the second inequality, we use the monotonicity of $g_{b_1}(-)$. The third inequality follows from Lemma 27 and the last one from Proposition 15. ◀

4.3.3 Establishing Main Lemma 2

Let $m \geq m(\varepsilon)$ be sufficiently large. The machine number $m(\varepsilon)$ is determined by the proofs of Proposition 20 and Lemma 21, and then carries over to the subsequent lemmas. Let us assume for a contradiction sake that there was a stable sequence $\mathcal{J}$ such that $ALG(\mathcal{J}) > (c+\varepsilon)OPT(\mathcal{J})$. As argued in the beginning of Section 4.3, see (1), it suffices to show that $P_{m+1} \geq \lambda_{\text{end}} b_0$. If this was not the case, we would have $P_h \geq (1-\varepsilon)b_0$ by Lemma 26. In particular by Proposition 16 we had $g_{b_0}(P_h) = g(1-\varepsilon)b_0 > \lambda_{\text{end}} b_0$. But now Lemma 18 shows that $P_{m+1} \geq \max\{\lambda_{\text{start}} b_0, \min\{g_{b_0}(P_h), \lambda_{\text{end}} b_0\}\} = \lambda_{\text{end}} b_0$.

We conclude, by Corollary 12, that ALG is nearly c-competitive.

5 Lower bounds

We present lower bounds on the competitive ratio of any deterministic online algorithm in the random-order model. Theorem 29 implies that if a deterministic online algorithm is c-competitive with high probability as $m \to \infty$, then $c \geq 3/2$.

▶ **Theorem 28.** *Let A be a deterministic online algorithm that is c-competitive in the random-order model. Then $c \geq 4/3$ if $m \geq 8$.*

▶ **Theorem 29.** *Let A be a deterministic online algorithm that is nearly c-competitive. Then $c \geq 3/2$.*

A basic family of inputs are job sequences that consist of jobs having an identical processing time of, say, 1. We first analyze them and then use the insight to derive our lower bounds. Let $m \geq 2$ be arbitrary. For any deterministic online algorithm A, let $r(A,m)$ be the maximum number in $\mathbb{N} \cup \{\infty\}$ such that A handles a sequence consisting of $r(A,m) \cdot m$ jobs with an identical processing time of 1 by scheduling each job on a least loaded machine.

▶ **Lemma 30.** *Let $m \geq 2$ be arbitrary. For every deterministic online algorithm A, there exists a job sequence $\mathcal{J}$ such that $A^{\text{rom}}(\mathcal{J}) \geq (1 + \frac{1}{r(A,m)+1})OPT(\mathcal{J})$. We use the convention that $\frac{1}{\infty+1} = 0$.*

Proof. For $r(A,m) = \infty$ there is nothing to show. For $r(A) < \infty$, consider the sequence $\mathcal{J}$ consisting of $(r(A,m)+1) \cdot m$ identical jobs, each having a processing time of 1. It suffices to analyze the algorithm adversarially as all permutations of the job sequence are identical. After having handled the first $r(A,m) \cdot m$ jobs, the algorithm A has a schedule in which every machine has load of $r(A,m)$. By the maximality of $r(A,m)$, the algorithm A schedules one of the following m jobs on a machine that is not a least loaded one. The resulting makespan is $r(A,m)+2$. The lemma follows since the optimal makespan is $r(A,m)+1$. ◀

Proof of Theorem 28. Let $m \geq 8$ be arbitrary. Consider any deterministic online algorithm A. If $r(A,m) \leq 2$, then, by Lemma 30, there exists a sequence $\mathcal{J}$ such that $A^{\text{rom}}(\mathcal{J}) \geq \frac{4}{3} \cdot OPT(\mathcal{J})$. Therefore, we may assume that $r(A,m) \geq 3$. Consider the input sequence $\mathcal{J}$ consisting of $4m-4$ identical small jobs of processing time 1 and one large job of processing time 4. Obviously $\text{OPT}(\mathcal{J}) = 4$.

Let i be the number of small jobs preceding the large job in $\mathcal{J}^\sigma$. The random variable i takes any (integer) value between 0 and $4m-4$ with probability $\frac{1}{4m-3}$. Since $r(A,m) \geq 3$ the least loaded machine has load of at least $l = \left\lfloor \frac{i}{m} \right\rfloor$ when the large job arrives. Thus $A(\mathcal{J}^\sigma) \geq l + 4$. The load l takes the values 0, 1 and 2 with probability $\frac{m}{4m-3}$ and the value 3 with probability $\frac{m-3}{4m-3}$. Hence the expected makespan of algorithm A is at least

$$A^{\text{rom}}(\mathcal{J}) \geq \frac{m}{4m-3} \cdot (0+1+2) + \frac{m-3}{4m-3} \cdot 3 + 4 = \frac{6m-9}{4m-3} + 4 > \frac{16}{3} = \frac{4}{3}\text{OPT}(\mathcal{J}).$$

For the last inequality we use that $m \geq 8$. ◀

Proof of Theorem 29. Let $m \geq 2$ be arbitrary and let A be any deterministic online algorithm. If $r(A,m) = 0$, then consider the sequence $\mathcal{J}$ consisting of m jobs with a processing time of 1 each. On every permutation of $\mathcal{J}$ algorithm A has a makespan of 2, while the optimum makespan is 1. If $r(A,m) \geq 1$, then consider the sequence $\mathcal{J}$ consisting of $2m-2$ small jobs having a processing time of 1 and one large job with a processing time of 2. Obviously $OPT(\mathcal{J}) = 2$. If the permuted sequence starts with m small jobs, the least loaded machine has load 1 once the large job arrives. Under such permutations $A(\mathcal{J}^\sigma) \geq 3 = \frac{3}{2} \cdot \text{OPT}(\mathcal{J})$ holds true. The probability of this happening is $\frac{m-1}{2m-1}$. The probability approaches $\frac{1}{2}$ and in particular does not vanish, for $m \to \infty$. Thus, if A is nearly c-competitive, then $c \geq 3/2$. ◀

Abstract

In this paper, we initiate the study of the weighted paging problem with predictions. This continues the recent line of work in online algorithms with predictions, particularly that of Lykouris and Vassilvitski (ICML 2018) and Rohatgi (SODA 2020) on unweighted paging with predictions. We show that unlike unweighted paging, neither a fixed lookahead nor knowledge of the next request for every page is sufficient information for an algorithm to overcome existing lower bounds in weighted paging. However, a combination of the two, which we call the strong per request prediction (SPRP) model, suffices to give a 2-competitive algorithm. We also explore the question of gracefully degrading algorithms with increasing prediction error, and give both upper and lower bounds for a set of natural measures of prediction error.

1 Introduction

The paging problem is among the most well-studied problems in online algorithms. In this problem, there is a set of n pages and a cache of size $k < n$. The online input comprises a sequence of requests for these pages. If the requested page is already in the cache, then the algorithm does not need to do anything. But, if the requested page is not in the cache, then the algorithm suffers what is known as a *cache miss* and must bring the requested page into the cache. If the cache is full, then an existing page must be evicted from the cache to make room for the new page. The goal of the online algorithm is to minimize the total number of cache misses in the *unweighted paging* problem, and the total weight of the evicted pages in the *weighted paging* problem. It is well-known that for both problems, the best deterministic algorithms have a competitive ratio of $O(k)$ and the best randomized algorithms have a competitive ratio of $O(\log k)$ (see, e.g., [4, 2]).

Although the paging problem is essentially solved from the perspective of competitive analysis, it also highlights the limitations of this framework. For instance, it fails to distinguish between algorithms that perform nearly optimally in practice such as the *least recently used* (LRU) rule and very naïve strategies such as *flush when full* that evicts all pages whenever the cache is full. In practice, paging algorithms are augmented with predictions about the future (such as those generated by machine learning models) to improve their empirical performance. To model this, for unweighted paging, several lookahead models have been proposed where only a partial prediction of the future leads to algorithms that are significantly better than what can be obtained in traditional competitive analysis. But, to the best of our knowledge, no such results were previously known for the weighted paging problem. In this paper, we initiate the study of the *weighted paging problem with future predictions*.

For unweighted paging, it is well-known that evicting the page whose next request is *farthest in the future* (also called Belady's rule) is optimal. As a consequence, it suffices for an online algorithm to simply predict the next request of every page (we call this *per request prediction* or PRP in short) in order to match offline performance. In fact, Lykouris and Vassilvitskii [9] (see also Rohatgi [13]) showed recently that in this prediction model, one can simultaneously achieve a competitive ratio of $O(1)$ if the predictions are accurate, and $O(\log k)$ regardless of the quality of the predictions. Earlier, Albers [1] used a different prediction model called *ℓ-strong lookahead*, where we predict a sequence of future requests that includes ℓ distinct pages (excluding the current request). For $\ell = n-1$, this prediction is stronger than the PRP model, since the algorithm can possibly see multiple requests for a page in the lookahead sequence. But, for $\ell < n-1$, which is typically the setting that this model is studied in, the two models are incomparable. The main result in [1] is to show that one can obtain a constant approximation for unweighted paging for $\ell \geq k-2$.

Somewhat surprisingly, we show that neither of these models are sufficient for weighted paging. In particular, we show a lower bound of $\Omega(k)$ for deterministic algorithms and $\Omega(\log k)$ for randomized algorithms in the PRP model. These lower bounds match, up to constants, standard lower bounds for the online paging problem (without prediction) (see, e.g., [11]), hence establishing that the PRP model does not give any advantage to the online algorithm beyond the strict online setting. Next, we show that for ℓ-strong lookahead, even with $\ell = k$, there are lower bounds of $\Omega(k)$ for deterministic algorithms and $\Omega(\log k)$ for randomized algorithms, again asymptotically matching the lower bounds from online paging without prediction. Interestingly, however, we show that a combination of these prediction models is sufficient: if $\ell = n-1$ in the strong lookahead setting, then we get predictions that subsume both models; and, in this case, we give a simple deterministic algorithm with a competitive ratio of 2 for weighted paging, thereby overcoming the online lower bounds.

Obtaining online algorithms with predictions, however, is fraught with the risk that the predictions are inaccurate which renders the analysis of the algorithms useless. Ideally, one would therefore, want the algorithms to also be robust, in that their performance gracefully degrades with increasing prediction error. Recently, there has been significant interest in designing online algorithms with predictions that achieve both these goals, of matching nearly offline performance if the predictions are correct, and of gracefully degrading as the prediction error increases. Originally proposed for the (unweighted) paging problem [9], this model has gained significant traction in the last couple of years and has been applied to problems in data structures [10], online decision making [12, 6], scheduling theory [12, 8], frequency estimation [7], etc. Our final result contributes to this line of research.

First, if the online algorithm and offline optimal solution both use a cache of size k, then we show that no algorithm can asymptotically benefit from the predictions while achieving sublinear dependence on the prediction error. Moreover, if we make the relatively modest assumption that the algorithm is allowed a cache that contains just 1 extra slot than that of the optimal solution, then we can achieve constant competitive ratio when the prediction error is small.

1.1 Overview of models and our results

Our first result is a lower bound for weighted paging in the PRP model. Recall that in the PRP model, in addition to the current page request, the online algorithm is provided the time-step for the next request of the same page. For instance, if the request sequence is $(a, b, a, c, d, b, \ldots)$, then at time-step 1, the algorithm sees request a and is given position 3, and at time-step 2, the algorithm sees request b and is given position 6.

▶ **Theorem 1.** *For weighted paging with PRP, any deterministic algorithm is $\Omega(k)$-competitive, and any randomized algorithm is $\Omega(\log k)$-competitive.*

Note that these bounds are tight, because there exist online algorithms without prediction whose competitive ratios match these bounds (see Chrobak *et al.* [4] and Bansal *et al.* [2]).

Next, for the ℓ-strong lookahead model, we show lower bounds for weighted paging. Recall that in this model, the algorithm is provided a lookahead into future requests that includes ℓ distinct pages. For instance, if $\ell = 3$ and the request sequence is $(a, b, a, c, d, b, \ldots)$, then at time-step 1, the algorithm sees request a and is given the lookahead sequence (b, a, c) since it includes 3 distinct pages. At time step 2, the algorithm sees request b and is given (a, c, d). Note the difference with the PRP model, which would not be give the information that the request in time-step 5 is for page d, but does give the information that the request in time-step 6 is for page b.

▶ **Theorem 2.** *For weighted paging with ℓ-strong lookahead where $\ell \leq n-k$, any deterministic algorithm is $\Omega(k)$-competitive, and any randomized algorithm is $\Omega(\log k)$-competitive.*

For weighted paging with ℓ-strong lookahead where $n-k+1 \leq \ell \leq n-1$, any deterministic algorithm is $\Omega(n-\ell)$-competitive, and any randomized algorithm is $\Omega(\log(n-\ell))$-competitive.

In contrast to these lower bounds, we show that a prediction model that combines features of these individual models gives significant benefits to an online algorithm. In particular, combining PRP and ℓ-strong lookahead, we define the following prediction model:

SPRP ("strong per-request prediction"): On a request for page p, the predictor gives the next time-step when p will be requested *and all page requests till that request.*

This is similar to $(n-1)$-strong lookahead, but is slightly weaker in that it does not provide the first request of every page at the outset. After each of the n pages has been requested, SPRP and $(n-1)$-strong lookahead are equivalent.

▶ **Theorem 3.** *There is a deterministic 2-competitive for weighted paging with SPRP.*

So far, all of these results assume that the prediction model is completely correct. However, in general, predictions can have errors, and therefore, it is desirable that an algorithm gracefully degrades with increase in prediction error. To this end, we also give upper and lower bounds in terms of the prediction error.

For unweighted paging, Lykouris and Vassilvitski [9] basically considered two measures of prediction error. The first, called ℓ_{pd} in this paper, is defined as follows: For each input request p_t, we increase ℓ_{pd} by $w(p_t)$ times the absolute difference between the predicted next-arrival time and the actual next-arrival time. For unweighted paging, Lykouris and Vassilvitskii [9] gave an algorithm with cost $O(\mathsf{OPT} + \sqrt{\ell_{pd} \cdot \mathsf{OPT}})$. Unfortunately, we rule out an analogous result for weighted paging.

▶ **Theorem 4.** *For weighted paging with SPRP, there is no deterministic algorithm whose cost is $o(k)\cdot\mathsf{OPT}+o(\ell_{pd})$, and there is no randomized algorithm whose cost is $o(\log k)\cdot\mathsf{OPT}+o(\ell_{pd})$.*

It turns out that the ℓ_{pd} error measure is closely related to another natural error measure that we call the ℓ_1 measure. This is defined as follows: for each input request p_t, if the prediction q_t is not the same as p_t, then increase ℓ_1 by the sum of weights $w(p_t)+w(q_t)$. (This is the ℓ_1 distance between the predictions and actual requests in the standard weighted star metric space for the weighted paging problem.) The lower bound for ℓ_{pd} continues to hold for ℓ_1 as well, and is tight.

▶ **Theorem 5.** *For weighted paging with SPRP, there is no deterministic algorithm whose cost is $o(k)\cdot\mathsf{OPT}+o(\ell_1)$, and there is no randomized algorithm whose cost is $o(\log k)\cdot\mathsf{OPT}+o(\ell_1)$. Furthermore, there is a deterministic algorithm with SPRP with cost $O(\mathsf{OPT}+\ell_1)$.*

One criticism of both the ℓ_{pd} and ℓ_1 error measures is that they are not robust to insertions or deletions from the prediction stream. To counter this, Lykouris and Vassilvitski [9] used a variant of the classic edit distance measure, and showed a constant competitive ratio for this error measure. For weighted paging, we also consider a variant of edit distance, called ℓ_{ed} and formally defined in Section 5, which allows insertions and deletions between the predicted and actual request streams.[2] Unfortunately, as with ℓ_{pd} and ℓ_1, we rule out algorithms that asymptoticaly benefit from the predictions while achieving sublinear dependence on ℓ_{ed}. Furthermore, if the algorithm were to use a cache with even one extra slot than the optimal solution, then we show that even for weighted paging, we can achieve a constant competitive algorithm. We summarize these results in the next theorem.

▶ **Theorem 6.** *For weighted paging with SPRP, there is no deterministic algorithm whose cost is $o(k)\cdot\mathsf{OPT}+o(\ell_{ed})$, and there is no randomized algorithm whose cost is $o(\log k)\cdot\mathsf{OPT}+o(\ell_{ed})$. In the same setting, there exists a randomized algorithm that uses a cache of size $k+1$ whose cost is $O(\mathsf{OPT}+\ell_{ed})$, where OPT uses a cache of size k.*

1.2 Related work

We now give a brief overview of the online paging literature, highlighting the results that consider a prediction model for future requests. For unweighted paging, the optimal offline algorithm is Belady's algorithm, which always evicts the page that appears farthest in the future [3]. For online paging, Sleator and Tarjan [14] gave a deterministic k-competitive algorithm, and Fiat et al. [5] gave a randomized $O(\log k)$-competitive algorithm; both results were also shown to be optimal. For weighted online paging, Chrobak *et al.* [4] gave a deterministic k-competitive algorithm, and Bansal *et al.* [2] gave an $O(\log k)$-competitive randomized algorithm, which are also optimal by extension.

Recently, Lykouris and Vassilvitskii [9] introduced a prediction model that we call PRP in this paper: on each request p, the algorithm is given a prediction of the next time at which p will be requested. For unweighted paging, they gave a randomized algorithm, based on the "marker" algorithm of Fiat et al. [5], with competitive ratio $O(\min(\sqrt{\ell_{pd}/\mathsf{OPT}},\log k))$. Here, ℓ_{pd} is the absolute difference between the predicted arrival and actual arrival times of requests, summed across all requests. They also perform a tighter analysis yielding a competitive ratio of $O(\min(\eta_{ed}/\mathsf{OPT},\log k))$, where η_{ed} is the edit distance

[2] For technical reasons, neither ℓ_{ed} in this paper nor the edit distance variant in [9] exactly match the classical definition of edit distance.

between the predicted sequence and the actual input. Subsequently, Rohatgi [13] improved the former bound to $O(1 + \min((\ell_{pd}/\mathsf{OPT})/k, 1) \log k)$ and also proved a lower bound of $\Omega(\log \min((\ell_{pd}/\mathsf{OPT})/(k \log k), k))$.

Albers [1] studied the ℓ-strong lookahead model: on each request p, the algorithm is shown the next ℓ distinct requests after p and all pages within this range. For unweighted paging, Albers [1] gave a deterministic $(k - \ell)$-competitive algorithm and a randomized $2H_{k-\ell}$-competitive algorithm. Albers also showed that these bounds are essentially tight: if $l \leq k - 2$, then any deterministic algorithm has competitive ratio at least $k - \ell$, and any randomized algorithm has competitive ratio at least $\Omega(\log(k - \ell))$.

Finally, we review the paging model in which the offline adversary is restricted to a cache of size $h < k$, while the online algorithm uses a larger cache of size k. For this model, Young [16] gave a deterministic algorithm with competitive ratio $k/(k - h + 1)$ and showed that this is optimal. In another paper, Young [15] showed that the randomized "marker" algorithm is $O(\log(k/k - h))$-competitive and this bound is optimal up to constants.

Roadmap

In Section 2, we show the lower bounds stated in Theorem 1 for the PRP model. The lower bounds for the ℓ-strong lookahead model stated in Theorem 2 are proven in Section 3. In Section 4, we state and analyze the algorithm for the SPRP model with no error, thereby proving Theorem 3. Finally, in Section 5, we consider the SPRP model with errors, and focus on the upper and lower bounds in Theorems 4, 5, and 6. Detailed proofs of these bounds appear in the full version of this paper.

2 The Per-Request Prediction Model (PRP)

In this section, we give the lower bounds stated in Theorem 1 for the PRP model. Our strategy, at a high level, will be the same in both the deterministic and randomized cases: we consider the special case where the cache size is exactly one less than the number of distinct pages. We then provide an algorithm that generates a specific input. In the deterministic case, this input will be adversarial, based on the single page not being in the cache at any time. In the randomized case, the input will be oblivious to the choices made by the paging algorithm but will be drawn from a distribution. We will give a brief overview of the main ideas that are common to both lower bound constructions first, and then give the details of the randomized construction in this section. The details of the deterministic construction are deferred to the full paper.

Let us first recall the $\Omega(k)$ deterministic lower bound for unweighted caching without predictions. Suppose the cache has size k and the set of distinct pages is $\{a_0, a_1, \ldots, a_k\}$. At each step, the adversary requests the page a_ℓ not contained in the cache of the algorithm ALG. Then ALG incurs a miss at every step, while OPT, upon a miss, evicts the page whose next request is furthest in the future. Therefore, ALG misses at least k more times before OPT misses again.

Ideally, we would like to imitate this construction. But, the adversary cannot simply request the missing page a_ℓ because that could violate the predictions made on previous requests. Our first idea is to replace this single request for a_ℓ with a "block" of requests of pages *containing* a_ℓ in a manner that all the previous predictions are met, but ALG still incurs the cost of page a_ℓ in serving this block of requests.

But, how do we guarantee that OPT only misses requests once for every k blocks? Indeed, it is not possible to provide such a guarantee. Instead, as a surrogate for OPT, we use an array of k algorithms ALG_i for $1 \leq i \leq k$, where each ALG_i follows a fixed strategy: maintain all pages except a_0 and a_i permanently in the cache, and swap a_0 and a_i as required to serve their requests. Our goal is to show that the sum of costs of all these algorithms is a lower bound (up to constants) on the cost of ALG; this would clearly imply an $\Omega(k)$ lower bound.

This is where the weights of pages come handy. We set the weight $w(a_i)$ of page a_i in the following manner: $w(a_i) = c^i$ for some constant $c \geq 2$. Now, imagine that a block requested for a missing page a_ℓ only contains pages $a_0, a_1, \ldots, a_\ell$ (we call this an ℓ-block). The algorithms ALG_i for $i \leq \ell$ suffer a cache miss on page a_i in this block, while the remaining algorithms ALG_i for $i > \ell$ do not suffer a cache miss in this block. Moreover, the sum of costs of all the algorithms ALG_i for $i \leq \ell$ in this block is at most a constant times that of the cost of ALG alone, because of the geometric nature of the cost function.

The only difficulty is that by constructing blocks that do not contain pages a_i for $i > \ell$, we might be violating the previous predictions for these pages. To overcome this, we create an invariant where for every i, an $(i+1)$-block must be introduced after a fixed number of i-blocks. Because of this invariant, we are sometimes forced to introduce a larger block than that demanded by the missing page in ALG. To distinguish between these two types of blocks, we call the ones that exactly correspond to the missing page a *regular* block, and the ones that are larger *irregular* blocks. Irregular blocks help preserve the correctness of all previous predictions, but the sum of costs of ALG_i's on an irregular block can no longer be bounded against that of ALG. Nevertheless, we can show that the number of irregular blocks is small enough that this extra cost incurred by ALG_i's in irregular blocks can be charged off to the regular blocks, thereby proving the deterministic lower bound:

▶ **Theorem 7.** *For weighted paging with PRP, any deterministic algorithm is $\Omega(k)$-competitive.*

A formal proof of this theorem is deferred to the full paper. Instead, we focus on proving the lower bound for randomized algorithms.

2.1 Randomized Lower Bound

This subsection is devoted to proving the following theorem:

▶ **Theorem 8.** *For weighted paging with PRP, any randomized algorithm is $\Omega(\log k)$-competitive.*

Here, we still use the same idea of request blocks, but now the input is derived from a fixed distribution and is not aware of the state of ALG. The main idea is to design a distribution over block sizes in a manner that still causes any fixed deterministic algorithm ALG to suffer a large cost *in expectation*, and then invoke Yao's minimax principle to translate this to a randomized lower bound.

Let $H_k = 1 + 1/2 + \cdots + 1/k \approx \ln k$ denote the k-th harmonic number. The input is defined as follows:

```
1. For $0 \leq i \leq k$, set $u_i = (2ckH_k + 2)^i$ and let $y_i = 0$ for $i < k$.
2. Repeat the following:
   a. Select a value of $\ell$ according to the following probability distribution: $\Pr[\ell = j] = \frac{c-1}{c^{j+1}}$
      for $j \in \{0, 1, \ldots, k-1\}$ and $\Pr[\ell = k] = \frac{1}{c^k}$.
   b. Increase $\ell$ until $\ell = k$ or $y_\ell < 2ckH_k$.
   c. For $j$ from 0 to $\ell$,
      i. Set all requests from time $t + 1$ through $u_j - 1$ as $a_{j-1}$. (Note: If $j = 0$, then
         $u_j = t + 1$, so this step is empty.)
      ii. Set the request at time $u_j$ as $a_j$.
      iii. Let $t = u_j$.
```

d. For $0 \leq j \leq \ell$, let $u_j = t + (2ckH_k + 2)^j$.
e. For $0 \leq j < \ell$, let $y_j = 0$. If $\ell < k$, increase y_ℓ by one.

Note that if ℓ is not increased in Step 2b, then this block is *regular*; otherwise, it is *irregular*. Let v_i denote the number of regular i-blocks, and let v'_i denote the number of irregular i-blocks. A j-block is an *i-plus* block if and only if $j \geq i$. We first lower bound the cost of ALG by the number of blocks.

▶ **Lemma 9.** *Every requested block increases $\mathbb{E}\left[\mathsf{cost}(\mathsf{ALG})\right]$ by at least a constant.*

Proof. At every time step, the cache of ALG is missing some page a_j. The probability that a_j is requested in the next block is at least $\Pr[\ell = j] \geq \frac{1}{2c^j}$, so the expected cost of serving this block is at least $c^j \cdot \Pr[\ell = j] = \Omega(1)$. ◀

For the rest of the proof, we upper bound the cost of OPT. We first upper bound the number of regular blocks, and then we use this to bound the number of irregular blocks.

▶ **Lemma 10.** *For every $i \in \{0, 1, \ldots, k\}$, we have $\mathbb{E}\left[v_i\right] \leq 2c^{-i}m$.*

Proof. Consider the potential function $\phi(y) = \sum_{i=0}^{k-1} y_i \geq 0$. The initial value of $\phi(y)$ is 0. Notice that whenever a regular block is generated, $\phi(y)$ increases by at most 1, and whenever an irregular block is generated, $\phi(y)$ decreases by at least $2ckH_k$. Thus, the number of irregular blocks is at most the number of regular blocks, so the total number of blocks is at most $2m$. The lemma follows by noting that the probability that a block is a regular i-block is at most c^{-i}. ◀

▶ **Lemma 11.** *For every $i \in \{0, 1, \ldots, k\}$, we have $\mathbb{E}\left[v'_i\right] \leq \frac{2m}{c^i kH_k}$.*

Proof. Observe that $v'_i \leq \frac{1}{2ckH_k}(v'_{i-1} + v_{i-1})$ and $v'_1 \leq \frac{1}{2ckH_k} v_0$. Repeatedly applying this inequality yields

$$\mathbb{E}\left[v'_i\right] \leq \sum_{j=0}^{i-1} \frac{\mathbb{E}\left[v_j\right]}{(2ckH_k)^{i-j}} \leq \sum_{j=0}^{i-1} \frac{2c^{-j}m}{(2ckH_k)^{i-j}} = \frac{2m}{c^i} \sum_{j=0}^{i-1} \frac{1}{(2kH_k)^{i-j}} \leq \frac{2m}{c^i kH_k},$$

where the second inequality holds due to Lemma 10. ◀

Now let A denote the entire sequence of requests, B the subsequence of A comprising all regular blocks, and m the number of blocks in B. We bound $\mathsf{OPT} = \mathsf{OPT}(A)$ in terms of the optimal cost on B and the number of irregular blocks.

▶ **Lemma 12.** *Let $\mathsf{OPT}(A)$ and $\mathsf{OPT}(B)$ denote the optimal offline algorithm on request sequences A and B respectively. Then $\mathsf{cost}(\mathsf{OPT}(A)) \leq \mathsf{cost}(\mathsf{OPT}(B)) + 4c \sum_{i=0}^{k} v'_i c^i$.*

Proof. Consider the following algorithm ALG_A on request sequence A:

1. For requests in regular blocks, imitate $\mathsf{OPT}(B)$. That is, copy the cache contents when $\mathsf{OPT}(B)$ serves this block.
2. Upon the arrival of an irregular i-block, let a_ℓ denote the page not in the cache.
   a. If $\ell > i$, then the cost of serving this block is 0.
   b. If $1 \leq \ell \leq i$, evict a_0 when a_ℓ is requested. Then evict a_ℓ and fetch a_0 at the end of this block; the cost of this is $2(c^i + 1)$.
   c. If $\ell = 0$, we evict a_1 and fetch a_0 when a_0 is requested. Then we evict a_0 and fetch a_1 when a_1 is requested or at the end of this block (if a_1 is not requested in this block). The cost is $2(c + 1)$.

For each irregular block, notice that the cache of ALG_A is the same at the beginning and the end of the block. So Step 2 does not influence the imitation in Step 1. The cost of serving an irregular i-block is at most $4c^{i+1}$. Combining these facts proves the lemma. ◀

To bound $\mathsf{OPT}(B)$, we divide the sequence B into phases. Each phase is a contiguous sequence of blocks. Phases are defined recursively, starting with 0-phases all the way through to k-phases. A 0-phase is defined as a single request. For $i \geq 1$, let M_i denote the first time that an i-plus-block is requested and let Q_i denote the first time that c $(i-1)$-phases have appeared. An i-phase ends immediately after M_i and Q_i have both occurred. In other words, an i-phase is a minimal contiguous subsequence that contains c $(i-1)$-phases and an i-plus block. (Notice that for a fixed i, the set of i-phases partition the input sequence.)

For any k-phase, we upper bound OPT by considering an algorithm ALG_B^k that is optimal for B subject to the additional restriction that a_0 is not in the cache at the beginning or end of any k-phase. We bound the cost of ALG_B^k in any k-phase using a more general lemma.

▶ **Lemma 13.** *For any i, let ALG_B^i be an optimal algorithm on B subject to the following: a_0 is not in the cache at the beginning or the end of any i-phase. Then the cost of ALG_B^i within an i-phase is at most $4c^{i+1}$. In particular, in each k-phase, the algorithm ALG_B^k incurs cost at most $4c^{k+1}$.*

Proof. We shall prove this by induction on i. If $i = 0$, then the phase under consideration is one step. To serve one step, we can evict a_1 to serve a_0, and then evict a_0 if necessary for a total cost of $4c$. Now assume that the lemma holds for all values in $\{0, \dots, i-1\}$. Let s_i denote the first i-plus block; there are two possible cases for the structure of an i-phase:

1. s_i appears after the c $(i-1)$-phases: In this case, the i-phase ends after this block. Thus, one strategy to serve the phase is to evict a_i at the beginning and evict a_0 when a_i is requested within s_i. These two evictions cost at most $4c^{i+1}$.
2. s_i appears within the first c $(i-1)$-phases: By the inductive hypothesis, the algorithm can serve these c $(i-1)$-phases with total cost at most $c \cdot 4c^i = 4c^{i+1}$. ◀

Finally, we lower bound the expected number of blocks in an i-phase. Since the total number of blocks is fixed, this allows us to upper bound the number of k-phases in the entire sequence. The next proposition forms the technical core of the lower bound:

▶ **Proposition 14.** *For $i \geq 1$, the expected number of blocks in an i-phase is at least $c^i H_i/4$.*

We defer the proof of Proposition 14 to the end of this section; first, we use it to prove Theorem 8.

Proof of Theorem 8. Let $\mathsf{OPT}(A)$ denote the cost of an optimal algorithm on the request sequence A, and let $\mathsf{OPT}(B)$ denote the cost of an optimal algorithm on the regular blocks B. Then we have the following:

$$\begin{aligned}
\mathbb{E}\left[\mathsf{cost}(\mathsf{OPT}(A))\right] &\leq \mathbb{E}\left[\mathsf{cost}(\mathsf{OPT}(B))\right] + 4c\sum_{i=0}^{k} c^i \cdot \mathbb{E}\left[v_i'\right] && \text{(Lemma 12)} \\
&\leq \mathbb{E}\left[\mathsf{cost}(\mathsf{ALG}_B^k)\right] + 4c\sum_{i=0}^{k} c^i \cdot \frac{2m}{c^i k H_k} && \text{(Lemma 11)} \\
&\leq 4c^{k+1} \cdot \mathbb{E}\left[N_k(B)\right] + \frac{16cm}{H_k}, && \text{(Lemma 13)}
\end{aligned}$$

where $N_k(B)$ denotes the number of k-phases in B. According to Proposition 14, the expected number of blocks in a k-phase is at least $c^k H_k/4$, which implies $\mathbb{E}[N_k(B)] \leq \frac{4m}{c^k H_k}$. Combining this with the above, we get

$$\mathbb{E}[\mathsf{cost}(\mathsf{OPT}(A))] \leq \frac{16cm}{H_k} + \frac{16cm}{H_k} = O\left(\frac{m}{H_k}\right).$$

Since any algorithm incurs at least some constant cost in every block by Lemma 9, its cost is $\Omega(m)$, which concludes the proof. ◀

Proof of Proposition 14

Let z_i be a random variable denoting the number of i-plus blocks in a fixed i-phase. We will first prove a sequence of three lemmas to yield a lower bound on $\mathbb{E}[z_i]$.

▶ **Lemma 15.** *For any $i \geq 1$, we have $\mathbb{E}[z_i] = \mathbb{E}[z_{i-1}] + \Pr\{M_i > Q_i\}$.*

Proof. Recall that an i-phase ends once it contains c $(i-1)$-phases and an i-plus block. In each of the $(i-1)$-phases, the expected number of $(i-1)$-plus blocks is $\mathbb{E}[z_{i-1}]$, so the total expected number of $(i-1)$-plus blocks in the first c $(i-1)$-phases of an i-phase is $c \cdot \mathbb{E}[z_{i-1}]$.

An elementary calculation shows that an $(i-1)$-plus block is an i-plus block with probability $1/c$. Thus, in expectation, the first c $(i-1)$-phases of this i-phase contain $\mathbb{E}[z_{i-1}]$ i-plus blocks.

If there are no i-plus blocks in the first c $(i-1)$-phases, then the i-phase ends as soon as an i-plus block appears. In this case, we have $z_i = 1$, and this happens with probability exactly $\Pr\{M_i > Q_i\}$. Otherwise, the i-phase ends immediately after the c $(i-1)$-phases, in which case no additional term is added. ◀

▶ **Lemma 16.** *For any $i \geq 1$, we have $\Pr\{M_i > Q_i\} \geq e^{-2\mathbb{E}[z_{i-1}]}$.*

Proof. We let $v_1, \ldots, v_c$ denote the number of i-plus blocks in the first c $(i-1)$-phases and let $V = \sum_{i=1}^{c} v_i$. As we saw in the proof of Lemma 15, an $(i-1)$-plus block is an i-plus block with probability $1/c$, so the probability that an $(i-1)$-plus block is an $(i-1)$-block is $1 - 1/c$. Thus, we have

$$\Pr\{M_i > Q_i\} = \mathbb{E}_{v_1, v_2, \ldots, v_c}\left[\left(1 - \frac{1}{c}\right)^V\right] \geq \left(1 - \frac{1}{c}\right)^{\mathbb{E}[V]} = \left(1 - \frac{1}{c}\right)^{c \cdot \mathbb{E}[z_{i-1}]}$$

where the inequality follows from convexity and the second equality holds due to linearity of expectation. The lemma follows from this and the fact that $c \geq 2$. ◀

▶ **Lemma 17.** *For any $i \geq 0$, we have $\mathbb{E}[z_i] \geq \frac{1}{4}H_i$.*

Proof. When $i \leq 4$, we have $\mathbb{E}[z_i] \geq 1 \geq \frac{1}{4}H_i$. Now for induction, assume the statement holds for $j < i$, and consider the two possible cases:

1. If $\mathbb{E}[z_{i-1}] \geq \frac{1}{2}H_{i-1}$, then Lemma 15 implies $\mathbb{E}[z_i] \geq \mathbb{E}[z_{i-1}] \geq \frac{1}{4}H_i$.
2. If $\mathbb{E}[z_{i-1}] < \frac{1}{2}H_{i-1} < \frac{1}{2}(1 + \ln(i-1))$, then $\mathbb{E}[z_i] = \mathbb{E}[z_{i-1}] + \Pr\{M_i > Q_i\} \geq \frac{1}{4}H_{i-1} + e^{-2\cdot\mathbb{E}[z_{i-1}]}$, where the equality follows from Lemma 15 and the inequality holds by the induction hypothesis and Lemma 16. Thus, $\mathbb{E}[z_i] \geq \frac{1}{4}H_{i-1} + \frac{1}{e} \cdot \frac{1}{i-1} \geq \frac{1}{4}H_i$. ◀

Now let L_i denote the number of blocks in an i-phase; recall that our goal is to lower bound its expectation by $c^i H_i/4$. The following lemma relates L_i to z_i.

▶ **Lemma 18.** *For any $i \geq 0$, we have $\mathbb{E}[L_i] = c^i \cdot \mathbb{E}[z_i]$.*

Proof. When $i = 0$, the lemma holds because $E[L_0] = E[z_0] = 1$, so now we assume $i \geq 1$. Recall that an i-phase contains at least c $(i-1)$-phases, so the expected total number of blocks in the first c $(i-1)$-phases of this i-phase is $c \cdot \mathbb{E}[L_{i-1}]$.

If there are no i-plus-blocks in these c $(i-1)$-phases, we need to wait for an i-plus block to appear in order for the i-phase to end. This is a geometric random variable with expectation c^i. Thus, we have: $\mathbb{E}[L_i] = c \cdot \mathbb{E}[L_{i-1}] + c^i \cdot \Pr\{M_i > Q_i\}$. Applying this recursively,

$$\mathbb{E}[L_i] = c^i \left(\sum_{j=1}^{i} \Pr\{M_j > Q_j\} + \mathbb{E}[L_0] \right) = c^i \left(\sum_{j=1}^{i} \Pr\{M_j > Q_j\} + 1 \right)$$

Furthermore, from Lemma 15, we have

$$\mathbb{E}[z_i] = \mathbb{E}[z_{i-1}] + \Pr\{M_i > Q_i\} = \mathbb{E}[z_0] + \sum_{j=1}^{i} \Pr\{M_j > Q_j\} = 1 + \sum_{j=1}^{i} \Pr\{M_j > Q_j\}.$$

Combining the two equalities yields the lemma. ◀

We conclude by proving Proposition 14. Fix some $i \geq 1$. Using Lemma 18 and Lemma 17, we get $\mathbb{E}[L_i] = c^i \cdot \mathbb{E}[z_i] \geq \frac{c^i H_i}{4}$.

3 The ℓ-Strong Lookahead Model

Now we consider the following prediction model: at each time t, the algorithm can see request p_t as well as $L(t)$, which is the set of all requests through the ℓ-th distinct request. In other words, the algorithm can always see the next contiguous subsequence of ℓ distinct pages (excluding p_t) for a fixed value of ℓ. This model was introduced by Albers [1], who (among other things) proved the following lower bounds on algorithms with ℓ-strong lookahead.

▶ **Lemma 19** ([1]). *For unweighted paging with ℓ-strong lookahead where $\ell \leq k-2$, any deterministic algorithm is $\Omega(k-\ell)$-competitive. For randomized algorithms, the bound is $\Omega(\log(k-\ell))$.*

Notice that Lemma 19 implies that for small values of ℓ, ℓ-strong lookahead provides no asymptotic improvement to the competitive ratio of any algorithm. The proof proceeds by constructing a particular sequence of requests and analyzing the performance of any algorithm on this sequence. By slightly modifying the sequence, we can prove a similar result for the weighted paging problem.

▶ **Theorem 20.** *For weighted paging with ℓ-strong lookahead where $n-k+1 \leq \ell \leq n-1$, any deterministic algorithm is $\Omega(n-\ell)$-competitive, and any randomized algorithm is $\Omega(\log(n-\ell))$-competitive.*

Proof. We modify the adversarial input in Lemma 19 as follows: insert $n-k-1$ distinct pages with very low weight between every two pages. This causes the lookahead to have effective size $\ell' = \ell - (n-k-1)$, because at any point $L(t)$ contains at most ℓ' pages with normal weight. Note that if $\ell \leq n-k$, then $\ell' \leq 1$, and from Lemma 19, a lookahead of size 1 provides no asymptotic benefit to any algorithm.

If $\ell \leq n-3$, then $\ell' \leq k-2$. Thus, we can apply Lemma 19 to conclude that for any deterministic algorithm, the competitive ratio is $\Omega(k-\ell') = \Omega(n-\ell-1)$, and for any randomized algorithm, the competitive ratio is $\Omega(\log(n-\ell-1))$. Otherwise, if $\ell \geq n-2$, then the lower bounds continue to hold because when $\ell = n-3$, they are $\Omega(1)$. ◀

4 The Strong Per-Request Prediction Model (SPRP)

In this section, we define a simple algorithm called STATIC that is 2-competitive when the SPRP predictions are always correct. At any time step t, let $L(t)$ denote the set of pages in the current prediction. The STATIC algorithm runs on "batches" of requests. The first batch starts at $t = 1$ and comprises all requests in $L(1)$. The next batch starts once the first batch ends, i.e. at $|L(1)| + 1$, and comprises all predicted requests at that time, and so on. Within each batch, the STATIC algorithm runs the optimal offline strategy, computed at the beginning of the batch on the entire set of requests in the batch.

▶ **Theorem 21.** *The STATIC algorithm is 2-competitive when the predictions from SPRP are entirely correct.*

Proof. In this proof, we assume w.l.o.g. that evicting page p costs $w(p)$, and fetches can be performed for free.

Suppose the algorithm runs a total of m batches $B_1, \dots, B_m$. Consider a page p in some batch B_i where $i < m$. If p appears again after B_i, then upon seeing the last request for p in B_i, SPRP will include p in the next batch B_{i+1}. (If p does not appear again, then the next batch must be the last batch.) Therefore, the batches satisfy $B_1 \subseteq B_2 \subseteq \cdots \subseteq B_{m-1}$.

Now let OPT denote a fixed optimal offline algorithm for the entire sequence, and let OPT_i denote the cost of OPT incurred in B_i. Similarly, let S denote the total cost of STATIC, and let S_i denote the cost that STATIC incurs in B_i. So we have $\mathsf{OPT} = \sum_{i=1}^{m} \mathsf{OPT}_i$ and $S = \sum_{i=1}^{m} S_i$.

Fix a batch index $j \in \{2, 3, \dots, m\}$ and let $C(\mathsf{OPT}_{j-1})$ and $C(S_{j-1})$ denote the cache states of OPT and STATIC immediately before batch B_j. We know that STATIC runs an optimal offline algorithm on B_j. One feasible solution is to immediately change the cache state to $C(\mathsf{OPT}_{j-1})$, and then imitate what OPT does to serve B_j. Since we charge for evictions, we have

$$S_j \leq \mathsf{OPT}_j + \sum_{p \in C(S_{j-1}) \setminus C(\mathsf{OPT}_{j-1})} w(p), \text{ for every } j \in \{2, 3, \dots, m\}.$$

Consider some $p \in C(S_{j-1}) \setminus C(\mathsf{OPT}_{j-1})$: since $p \in C(S_{j-1})$, we know p must have appeared before the start of B_j (because STATIC does not fetch pages that have never been requested). Since B_{j-1} contains all pages that appeared before, in particular, p must be in B_{j-1}. Furthermore, since $p \notin C(\mathsf{OPT}_{j-1})$, then at some point while serving B_{j-1}, OPT must have evicted p. Thus, $S_j \leq \mathsf{OPT}_j + \mathsf{OPT}_{j-1}$. Summing over all $j \geq 2$ and $S_1 \leq \mathsf{OPT}_1$ proves the theorem. ◀

5 The SPRP Model with Prediction Errors

In this section, we consider the SPRP prediction model with the possibility of prediction errors. We first define three measurements of error and then prove lower and upper bounds on algorithms with imperfect SPRP, in terms of these error measurements.

Let A denote a prediction sequence of length m, and let B denote an input sequence of length n. For any time t, let A_t and B_t denote the t-th element of A and B, respectively. We also define the following for any time step t:

- $\mathsf{prev}(t)$: The largest $i < t$ such that $B_i = B_t$ (or 0 if no such if no such i exists).
- $\mathsf{next}(t)$: The smallest $i > t$ such that $B_i = B_t$ (or $n + 1$ if no such i exists).
- $\mathsf{pnext}(t)$: The smallest $i > t$ such that $A_i = B_t$ (or $m + 1$ if no such i exists).
- We say two requests $A_i = B_j = p$ can be *matched* only if $\mathsf{pnext}(\mathsf{prev}(j)) = i$. In other words, A_i must be the earliest occurrence of p in A after the time of the last p in B before B_j. Furthermore, no edges in a matching are allowed to cross.

First, we define a variant of edit distance between the two sequences.

▶ **Definition 22.** *The* edit distance ℓ_{ed} *between A and B is the total minimum weight of unmatched elements of A and B.*

Next, we define an error measure based on the metric 1-norm distance between corresponding requests on the standard weighted star metric denoting the weighted paging problem.

▶ **Definition 23.** *The* 1-norm distance ℓ_1 *between A and B is defined as follows:*

$$\ell_1 = \sum_{\substack{i=1 \\ A_i \neq B_i}}^{n} \left(w(A_i) + w(B_i) \right). \tag{1-norm}$$

Third, we define an error measure inspired by the PRP model that was also used in [9].

▶ **Definition 24.** *The* prediction distance ℓ_{pd} *between A and B is defined as follows:*

$$\ell_{pd} = \sum_{i=1}^{n} w(B_i) \cdot |\mathsf{next}(i) - \mathsf{pnext}(i)|.$$

5.1 Lower Bounds

In this section, we give an overview of the lower bounds stated in Theorems 4, 5, and 6. We focus on the ℓ_{ed} (i.e., Theorem 6) error measurement; the proofs for ℓ_1 and ℓ_{pd} follow similarly. We defer some of the proofs to the full paper.

Our high-level argument proceeds as follows: recall that in Section 2, we showed a lower bound of $\Omega(k)$ on the competitive ratio of deterministic PRP-based algorithms. Given an SPRP algorithm ALG, we design a PRP algorithm ALG' specifically for the input generated by the procedure described in Section 2. (Recall that this input is a sequence of blocks, where a *block* is a string of a_0's, a_1's, and so on, ending with a single page a_ℓ for some ℓ.)

We show that if ALG has cost $o(k) \cdot \mathsf{OPT} + o(\ell_{ed})$ (where OPT is the optimal cost of the SPRP instance), then ALG' will have cost $o(k) \cdot \mathsf{OPT}'$ (where OPT' is the optimal cost of the PRP instance), which contradicts our PRP lower bound of $\Omega(k)$ on this input. For the randomized lower bound, we use the same line of reasoning, but replace $\Omega(k)$ with $\Omega(\log k)$.

Let k' denote the cache size of ALG'. Recall that the set of possible page requests received by ALG' is $A = \{a_0, a_1, \ldots, a_{k'}\}$ where $w(a_i) = c^i$ for some constant $c \geq 2$. The oracle ALG, maintained by ALG', has cache size $k = k' + 1$. The set of possible requests received by ALG is $A \cup \{b\}$ where $w(b) = 1/v$ for some sufficiently large value of v. (Thus, the instance for ALG has $k + 1$ distinct pages.) Our PRP algorithm ALG' must define a prediction and an input sequence for ALG.

The prediction sequence for ALG. For any strings X and Y, let $X + Y$ denote the concatenation of X and Y and let $\lambda \cdot X$ denote the concatenation of λ copies of X. Let $L = 2ck'H_{k'} + 1$, and consider the series of strings: $S_0 = 2 \cdot a_0$, and $S_i = L \cdot S_{i-1} + a_i$ for $i \in \{1, \ldots, k'\}$. We fix $S := M \cdot S_{k'}$, for some sufficiently large M, as the prediction sequence for the SPRP algorithm. (Observe that S only contains k distinct pages, and the oracle ALG has cache size k.)

ALG' and the request sequence for ALG. Our PRP algorithm ALG' will simultaneously construct input for ALG while serving its own requests. Since randomized and fractional algorithms are equivalent up to constants (see Bansal et al. [2]), we view the SPRP algorithm ALG from a fractional perspective. Let $q_i \in [0,1]$ denote the fraction of page a_i not in the cache of ALG. Notice that the vector $q = (q_0, q_1, \ldots, q_{k'})$ satisfies $\sum_{i=0}^{k'} q_i \geq 1$. (A deterministic algorithm is the special case where every $q_i \in \{0,1\}$.) Similarly, let $q' = (q'_0, q'_1, \ldots, q'_{k'})$, where q'_i denotes the amount of request for a_i that is not in the cache in ALG'.

When a block ending with a_i is requested, ALG' scans S for the next appearance of a_i. It then feeds the scanned portion to ALG, followed by a single request for page b. In this case, the prediction error only occurs due to the requests for this page b. After serving this request b, the cache of ALG contains at most k' pages in A. This enables ALG' to mimic the behavior of ALG upon serving the current block. This process continues for every block: ALG' modifies the input by inserting an extra request b into the input for ALG, and mimics the resulting cache state of ALG. The details of our algorithm ALG' are given below:

1. Initially, let S be the input for ALG and $t = 0$. (We will modify S as time passes.)
2. For all $0 \leq i \leq k'$, let $q'_i = 1$. (Note that the initial value of every q_i is also 1.)
3. On PRP request block $s_i = (a_0, a_1, \ldots, a_i)$ (for some unknown i):
   a. Let $q' = (q'_0, q'_1, \ldots, q'_{k'})$ denote the current cache state.
   b. Set $q' = (0, \min\{1, q'_0 + q'_1\}, q'_2, q'_3, \ldots, q'_{k'})$ to serve a_0. Note that after we serve a_0, the PRP prediction tells us the value of i.
   c. Find the first time t' after t when S requests a_i and set $t = t' + 2$.
   d. Change the request at time t into b. (Note that the original request is a_0.)
   e. Run ALG until this b is served to obtain a vector $q = (q_0, q_1, \ldots, q_{k'})$.
   f. If $i \geq 1$, set $q' = (\min\{1, \sum_{j=0}^{i} q'_j\}, 0, 0, \ldots, 0, q'_{i+1}, q'_{i+2}, \ldots, q'_{k'})$; this serves the requests $(a_1, a_2, \ldots, a_i)$.
   g. Set $q' = (q_0, q_1, \ldots, q_{k'})$.

Bounding the costs. The main idea in the analysis is the following: since the input sequences to ALG and ALG' are closely related, and they maintain similar cache states, we can show that they are coupled both in terms of the algorithm's cost and the optimal cost. Therefore, the ratio of $\Omega(k)$ for ALG' (from Theorem 7) translates to a ratio of $\Omega(k)$ for ALG. Furthermore, since the only prediction errors are due to the additional requests for page b, and this page has a very small weight, the cost of ALG is at least the value of ℓ_{ed}. (The same line of reasoning is used for randomized algorithms, but $\Omega(k)$ is replaced by $\Omega(\log k)$.)

We now formalize the above line of reasoning with the following lemmas.

▶ **Lemma 25.** *Using any SPRP algorithm* ALG *as a black box, the PRP algorithm* ALG' *satisfies the following:* $\mathsf{cost}(\mathsf{ALG}') \leq 2(c+1) \cdot \mathsf{cost}(\mathsf{ALG})$.

Proof. Note that $q = q'$ at the beginning and end of Step 3. For convenience, let q' denote the vector at the beginning of Step 3, and let q denote the vector at the end of Step 3. Let $\mathsf{cost}_{\mathsf{ALG}}$ and $\mathsf{cost}_{\mathsf{ALG}'}$ denote the cost of ALG and ALG' respectively incurred in a fixed Step 3.

Each time ALG' enters Step 3, the cost incurred is at most:

Step 3b: $q'_0 \cdot (1+c)$,

Step 3f: $(q'_0 + q'_1) \cdot (1+c) + \sum_{j=2}^{i} q'_j \cdot (1+c^j)$,

Step 3g: $\left(\sum_{j=1}^{i} q_j \cdot (1+c^j)\right) + \left(\sum_{j=i+1}^{k} \left|q'_j - q_j\right| \cdot (1+c^j)\right)$.

Summing the above yields the following:

$$\mathsf{cost}_{\mathsf{ALG}'} \leq 2(c+1) \cdot \left(\left(\sum_{j=0}^{i} c^j \cdot \left(q_j + q'_j\right)\right) + \left(\sum_{j=i+1}^{k} c^j \cdot \left|q_j - q'_j\right|\right)\right).$$

Now we consider ALG. For each j, at the beginning of Step 3, there is q'_j amount of a_j not in the cache, and at the end of Step 3, there is q_j amount of a_j not in the cache.

If $j > i$, the cost incurred due to a_j is at least $c^j \cdot \left|q_j - q'_j\right|$. If $j \leq i$, ALG' must serve a_j at some point in Step 3e, so the incurred cost due to a_j is at least $c^j \cdot \left(q_j + q'_j\right)$. Summing the above yields the following:

$$\mathsf{cost}_{\mathsf{ALG}} \geq \left(\sum_{j=0}^{i} c^j \cdot \left(q_j + q'_j\right)\right) + \left(\sum_{j=i+1}^{k} c^j \cdot \left|q_j - q'_j\right|\right).$$

Combining the two inequalities above proves the lemma. ◀

Now let OPT denote the optimal SPRP algorithm for the input sequence served by ALG, and let OPT' denote the optimal PRP algorithm for the input sequence served by ALG'. We can similarly prove the following lemma (proof in full paper):

▶ **Lemma 26.** *The algorithms* OPT *and* OPT' *satisfy* $\mathsf{cost}(\mathsf{OPT}) \leq 2 \cdot \mathsf{cost}(\mathsf{OPT}')$.

We are now ready to bound the cost of any algorithm with SPRP (proof in full paper):

▶ **Theorem 27.** *For weighted paging with SPRP, there is no deterministic algorithm whose cost is* $o(k) \cdot \mathsf{OPT} + o(\ell_{ed})$*, and there is no randomized algorithm whose cost is* $o(\log k) \cdot \mathsf{OPT} + o(\ell_{ed})$.

Proof (Sketch). From Theorem 7, we know $\mathsf{ALG}' = \Omega(k) \cdot \mathsf{OPT}'$. Thus, applying Lemmas 25 and 26, we have $\mathsf{ALG} = \Omega(k) \cdot \mathsf{OPT}$. Furthermore (as we saw in Section 2), each PRP block increases ALG by at least a constant. At the same time, for each block, we can show that ℓ_{ed} increases by at most 2. As a result, we can conclude that $\mathsf{ALG} = \Omega(\ell_1)$. The theorem follows by combining these facts. For randomized algorithms, the same line of reasoning holds, but with $\Omega(\log k)$ instead of $\Omega(k)$. ◀

5.2 Upper Bounds

In this section, we give algorithms whose performance degrades with the value of the SPRP error. In particular, we first prove the upper bound in Theorem 6 for the ℓ_{ed} measurement, and then analyze the FOLLOW algorithm, which proves the upper bound in Theorem 5.

Now we present an algorithm that uses a cache of size $k+1$ whose cost scales linearly with $\mathsf{OPT} + \ell_{ed}$. Following our previous terminology, let A denote a prediction sequence of length m, and let B denote an input sequence of length n.

Our algorithm, which we call Learn, relies on an algorithm that we call Idle. At a high level, Idle resembles Static (see Section 4): it partitions the prediction sequence A into batches and runs an optimal offline algorithm on each batch. The Learn algorithm tracks the cost of imitating Idle: if the cost is sufficiently low, then it will imitate Idle on k of its cache slots; otherwise, it will simply evict the page in the extra cache slot.

Before formally defining Idle, we consider a modified version of caching. Our cache has $k+1$ slots, where one slot is *memoryless*: it always immediately evicts the page it just fetched. In other words, this slot can serve any request, but it cannot store any pages. Let OPT^{+1} denote the optimal algorithm that uses a memoryless cache slot.

▶ **Lemma 28.** *For any sequences A and B, $\mathsf{cost}(\mathsf{OPT}^{+1}(A)) \leq \mathsf{cost}(\mathsf{OPT}(B)) + 2\ell_{ed}$, where ℓ_{ed} is the edit distance between A and B.*

Proof. Let M denote the optimal matching between A and B (for ℓ_{ed}). One algorithm for $\mathsf{OPT}^{+1}(A)$ is the following: imitate what $\mathsf{OPT}(B)$ does for requests matched by M, and use the memoryless slot for unmatched requests. The cost of this algorithm is $\mathsf{OPT}(B)+2\ell_{ed}$. ◀

Recall that the Static algorithm requires the use of an optimal offline algorithm. Similarly, for our new problem with a memoryless cache slot, we require a constant-approximation offline algorithm on A. This can be obtained from the following lemma (proof in full paper):

▶ **Lemma 29.** *Given a prediction sequence A, there is a randomized offline algorithm whose cost is at most a constant times the cost of $\mathsf{OPT}^{+1}(A)$.*

The Idle algorithm

Assume that our cache has size $k+1$ and the extra slot is memoryless (as defined above). For any time step t, let $L(t)$ denote the set of pages predicted to arrive starting at time $t+1$. At time step 1 (i.e., initially), Idle runs the offline algorithm from Lemma 29 on $L(1)$, ignoring future requests. After the requests in $L(1)$ have been served, i.e., at time $|L(1)|+1$, Idle then consults the predictor and runs the offline algorithm on the next "batch". The algorithm proceeds in this batch-by-batch manner until the end. We can show that the competitive ratio of this algorithm is at most a constant (see full paper).

▶ **Lemma 30.** *On the prediction sequence A, we have $\mathsf{cost}(\text{Idle}) = O(1) \cdot \mathsf{cost}(\mathsf{OPT}^{+1}(A))$.*

The Learn algorithm

Before defining the algorithm, we introduce another measurement of error that closely approximates ℓ_{ed}. Recall that A denotes a prediction sequence of length m and B denotes an input sequence of length n. In defining ℓ_{ed}, two elements $A_i = B_j$ can be matched only if $\mathsf{pnext}(\mathsf{prev}(j)) = i$, and no matching edges are permitted to cross.

▶ **Definition 31.** *The* constrained edit distance *ℓ'_{ed} is the minimum weight of unmatched elements of A and B, with the following additional constraint: if $|P(A_i)| \geq 2$, then A_i can only be matched with the latest-arriving element in $P(A_i)$.*

We note that ℓ'_{ed} is a constant approximation of ℓ_{ed} (proof in full paper):

▶ **Lemma 32.** *For any sequences A, B, we have $\ell_{ed} \leq \ell'_{ed} \leq 3\ell_{ed}$.*

Now we are ready to define the Learn algorithm. For any $i \leq j$, we let $A(i,j)$ denote the subsequence $(A_i, A_{i+1}, \ldots, A_j)$. For any set (or multiset) of pages S, we let $w(S)$ denote the total cost of pages in S. The algorithm is the following:

1. Let $s = 0$; the variable s always denotes that we have imitated the IDLE algorithm through the first s requests of the prediction.
2. Let $S = \emptyset$ be an empty queue.
3. On the arrival of request p, add p to S.
   a. If there is a t (in $[s+1, L]$ where L is the end of the current prediction) such that

   $$\ell'_{ed}(A(s+1,t), S) < \frac{1}{3}(w(A(s+1,t)) + w(S)), \tag{1}$$

   then imitate IDLE through position t, empty S and let $s = t$. (If more than one t satisfies the above, select the minimum.)

   b. Otherwise, evict the page in the final slot.

We first observe that the algorithm is indeed feasible (proof in full paper).

▶ **Lemma 33.** *In the LEARN algorithm, Step 3a is feasible, i.e., if t satisfies* (1)*, then* $A_t = p$.

Now we arrive at the heart of the analysis: we upper bound the cost of LEARN against the cost of IDLE (i.e., a surrogate for $\mathsf{OPT}(B)$) and the constrained edit distance ℓ'_{ed}. In particular, we sketch a proof of the following lemma and defer the full proof to the full paper.

▶ **Lemma 34.** *The algorithms LEARN and IDLE satisfy* $\mathsf{cost}(\text{LEARN}) \leq \mathsf{cost}(\text{IDLE}) + 12\ell'_{ed}$.

Proof (Sketch). Let cost_1 denote the total cost of Step 3a, and cost_2 denote the total cost of Step 3b so that $\mathsf{cost}(\text{LEARN}) = \mathsf{cost}_1 + \mathsf{cost}_2$. From the algorithm, we see that $\mathsf{cost}_1 \leq \mathsf{cost}(\text{IDLE})$, so now we must prove $\mathsf{cost}_2 \leq 12\ell'_{ed}$.

Now we establish some notation. Let $\ell'_{ed}((a,b)(c,d)) = \ell'_{ed}(A(a,b), B(c,d))$, and let $w_A(a,b) = w(A(a,b))$ and $w_B(a,b) = w(B(a,b))$.

We proceed by induction on the number of times we went Step 3a. Consider the first time we enter Step 3a; suppose we have read the input $B(1,b)$ and we now imitated IDLE through $A(1,a)$ for some values a, b. Since the matched edges for ℓ'_{ed} do not cross, there exists some c such that $\ell'_{ed} = \ell'_{ed}(A, B)$ satisfies

$$\ell'_{ed} = \ell'_{ed}((1,a),(1,c)) + \ell'_{ed}((a+1,m),(c+1,n)).$$

We consider the case where $c < b$; the other cases follow similarly. Let $\mathsf{cost}(x,y)$ denote the cost incurred by the algorithm when serving $B(x,y)$ and notice that

$$\mathsf{cost}_2 \leq \mathsf{cost}(1,c) + \mathsf{cost}(c+1,b) + \mathsf{cost}(b+1,n).$$

The cost of serving $B(1,c)$ is at most the weight of the requested pages, so $\mathsf{cost}(1,c) \leq w_B(1,c)$. Furthermore, we can upper bound $\mathsf{cost}(c+1,b)$ by a constant times $w_A(1,a)$ by analyzing a particular matching for $\ell'_{ed}((1,a)(1,c))$. Combining this together, we have

$$\mathsf{cost}(1,c) + \mathsf{cost}(c+1,b) \leq 4(w_B(1,c) + w_A(1,a)) \leq 12 \cdot \ell'_{ed}((1,a),(1,c)),$$

where the second inequality follows from that we did not enter Step 3a when c arrived. Finally, applying the inductive hypothesis to $B(b+1,n)$ and substituting the definition of c yields the lemma. ◀

The proof of Theorem 6 follows from Lemmas 28, 30, and 34.

The Follow algorithm

Now we show that the $\Omega(\ell_1)$ lower bound in Theorem 5 is tight, that is, we will give an SPRP algorithm Follow that has cost $O(1) \cdot (\mathsf{OPT} + \ell_1)$. Recall the Static algorithm from Theorem 21. The algorithm Follow ignores its input: it simply runs Static on the prediction sequence A and imitates its fetches/evictions on the input sequence B.

▶ **Theorem 35.** *The Follow algorithm has cost $O(1) \cdot (\mathsf{OPT} + \ell_1)$.*

Proof. Recall from Theorem 21 that $\mathsf{cost}(\text{Static}) \leq O(1) \cdot \mathsf{OPT}(A)$. Furthermore, we claim $\mathsf{OPT}(A) \leq \mathsf{OPT}(B) + 2\ell_1$. This is because on A, there exists an algorithm that imitates the movements of B: say at time t, $\mathsf{OPT}(B)$ evicts some element b that had appeared in B at time $v(t)$. Then $\mathsf{OPT}(A)$ can also evict whatever element appeared at time $v(t)$ in A, and if this is not b, then this cost can be charged to the $v(t)$ term of ℓ_1. Each term of ℓ_1 is charged at most twice because a specific request can be evicted and fetched at most once respectively.

By the same argument, we have $\mathsf{cost}(\text{Follow}) \leq \mathsf{cost}(\text{Static}) + 2\ell_1$. Combining these inequalities proves the theorem. ◀

6 Conclusion

In this paper, we initiated the study of weighted paging with predictions. This continues the recent line of work in online algorithms with predictions, particularly that of Lykouris and Vassilvitski [9] on unweighted paging with predictions. We showed that unlike in unweighted paging, neither a fixed lookahead not knowledge of the next request for every page is sufficient information for an algorithm to overcome existing lower bounds in weighted paging. However, a combination of the two, which we called the strong per request prediction (SPRP) model, suffices to give a constant approximation. We also explored the question of gracefully degrading algorithms with increasing prediction error, and gave both upper and lower bounds for a set of natural measures of prediction error. The reader may note that the SPRP model is rather optimistic and requires substantial information about the future. A natural question arises: can we obtain constant competitive algorithms for weighted paging with fewer predictions? While we refuted this for the PRP and fixed lookahead models, being natural choices because they suffice for unweighted paging, it is possible that an entirely different parameterization of predictions can also yield positive results for weighted paging. We leave this as an intriguing direction for future work.

Popular Matchings with One-Sided Bias

Telikepalli Kavitha
Tata Institute of Fundamental Research, Mumbai, India
kavitha@tifr.res.in

Abstract

Let $G = (A \cup B, E)$ be a bipartite graph where A consists of agents or *main players* and B consists of jobs or *secondary players*. Every vertex has a strict ranking of its neighbors. A matching M is *popular* if for any matching N, the number of vertices that prefer M to N is at least the number that prefer N to M. Popular matchings always exist in G since every stable matching is popular.

A matching M is A-*popular* if for any matching N, the number of *agents* (i.e., vertices in A) that prefer M to N is at least the number of agents that prefer N to M. Unlike popular matchings, A-popular matchings need not exist in a given instance G and there is a simple linear time algorithm to decide if G admits an A-popular matching and compute one, if so.

We consider the problem of deciding if G admits a matching that is both popular and A-popular and finding one, if so. We call such matchings *fully popular*. A fully popular matching is useful when A is the more important side – so along with overall popularity, we would like to maintain "popularity within the set A". A fully popular matching is not necessarily a min-size/max-size popular matching and all known polynomial time algorithms for popular matching problems compute either min-size or max-size popular matchings. Here we show a linear time algorithm for the fully popular matching problem, thus our result shows a new tractable subclass of popular matchings.

1 Introduction

Let $G = (A \cup B, E)$ be a bipartite graph where vertices in A are called *agents* and those in B are called *jobs*. Every vertex has a strict ranking of its neighbors. Such a graph, also called a *marriage* instance, is a very well-studied model in two-sided matching markets. A matching M in G is *stable* if there is no *blocking pair* with respect to M, i.e., no pair (a, b) such that a and b prefer each other to their respective assignments in M. Gale and Shapley [10] in 1962 showed that stable matchings always exist in G and can be efficiently computed.

Stable matching algorithms have applications in several real-world problems. For instance, stable matchings have been extensively used to match students to schools and colleges [1, 3] and one of the oldest applications here is to match medical residents to hospitals [4, 21]. It is known that all stable matchings in G have the same size [11] and this may only be half the size of a max-size matching in G. Consider the following instance on 4 vertices a_0, a_1, b_0, b_1.

$$a_0 : b_1 \qquad a_1 : b_1 \succ b_0 \qquad b_0 : a_1 \qquad b_1 : a_1 \succ a_0.$$

Here a_1 and b_1 are each other's top choices. There is no edge between a_0, b_0. Note that $M_{\max} = \{(a_0, b_1), (a_1, b_0)\}$ has size 2 while the only stable matching $S = \{(a_1, b_1)\}$ has size 1.

Hence forbidding blocking edges constrains the size of the resulting matching. Rather than empower every edge with a "veto power" to block matchings (this is the notion of stability), we would like to relax stability so that only a *strict majority vote* from the entire vertex set has the power to block matchings. The motivation is to obtain a larger pool of feasible matchings so as to allow better matchings with respect to our objective.

The notion of *popularity* is a natural relaxation of stability that captures the notion of "majority preference". Preferences of a vertex over its neighbors extend naturally to preferences over matchings: consider an election between 2 matchings M and N where vertices are voters. In this M versus N election, every vertex (say, u) votes for the matching in $\{M, N\}$ that it prefers, i.e., where it gets a better assignment (being unmatched is its worst choice), and u abstains from voting if it has the same assignment in both M and N. Let $\phi(M, N)$ (resp., $\phi(N, M)$) be the number of votes for M (resp., N) in this election.

▶ **Definition 1.** *A matching M is* popular *if $\phi(M, N) \geq \phi(N, M)$ $\forall$ matchings N in G.*

So a popular matching never loses a head-to-head election against any matching, i.e., it is a weak *Condorcet winner* [5, 6] in the voting instance where matchings are candidates and vertices are voters. The notion of popularity was introduced by Gärdenfors [12] who showed that every stable matching is popular. So popular matchings always exist in any marriage instance. In fact, every stable matching is a *min-size* popular matching [14] and there are efficient algorithms to compute a *max-size* popular matching [14, 16].

Popular matchings are suitable for applications such as matching students to projects (where students and project advisers have strict preferences) – by relaxing stability to popularity, we can obtain better matchings in terms of size or our desired objective. We consider a natural and relevant objective here: observe that the two sides of $G = (A \cup B, E)$ are *asymmetric* in this application - students are *doers* of the projects, i.e., they are the main or more active players while project advisers are the secondary or more passive players. So along with overall popularity, we would like to maintain "popularity within the set A".

That is, we would like the popular matching that we compute to be popular even when we *only* count the votes of vertices in A, i.e., there should be no matching that is preferred by more vertices in A. Popularity within the set A is the notion of popularity with *one-sided* preferences and we will refer to this as *A-popularity* here. In the M versus N election, let $\phi_A(M, N)$ (resp., $\phi_A(N, M)$) be the number of vertices in A that vote for M (resp., N).

▶ **Definition 2.** *A matching M is* A-popular *if $\phi_A(M, N) \geq \phi_A(N, M)$ $\forall$ matchings N in G.*

A-popular matchings have been well-studied and are relevant in applications such as assigning training posts to applicants [2] and housing allocation schemes [19] where vertices on only one side of the graph have preferences over their neighbors. An A-popular matching need not necessarily exist in a given instance as shown below.

$$a_1 : b_1 \succ b_2 \succ b_3 \qquad a_2 : b_1 \succ b_2 \succ b_3 \qquad a_3 : b_1 \succ b_2 \succ b_3.$$

There are 3 agents here and they have identical preferences. It is easy to check that none of the matchings in this instance is A-popular. Let $M_0 = \{(a_1, b_1), (a_2, b_2), (a_3, b_3)\}$ and $M_1 = \{(a_1, b_3), (a_2, b_1), (a_3, b_2)\}$, we have $\phi_A(M_1, M_0) = 2 > 1 = \phi_A(M_0, M_1)$ since a_2, a_3 prefer M_1 to M_0 while a_1 prefers M_0 to M_1. Here we are interested in matchings that are both popular *and* A-popular.

▶ **Definition 3.** *A popular matching M is* fully popular *if M is also A-popular. So for any matching N in G, we have: $\phi(M, N) \geq \phi(N, M)$ and $\phi_A(M, N) \geq \phi_A(N, M)$.*

There may be exponentially many popular matchings in $G = (A \cup B, E)$. So when A is the more important/active side, say it consists of those doing their projects/internships/jobs, it is natural to seek a popular matching that is A-popular as well, i.e., a *fully popular* matching. Thus we seek a matching M such that (1) a majority of the vertices weakly prefer M to any matching, i.e., $\phi(M, N) \geq \phi(N, M)$ for all matchings N, and moreover, (2) a majority of the agents (those in A) weakly prefer M to any matching, i.e., $\phi_A(M, N) \geq \phi_A(N, M)$ for all N.

We show the following result here.

▶ **Theorem 4.** *There is a linear time algorithm to decide if a marriage instance $G = (A \cup B, E)$ with strict preferences admits a fully popular matching or not. If so, our algorithm returns a max-size fully popular matching.*

Another model for popularity in matchings with main players in A and secondary players in B is to scale the votes of those in A by a suitable factor $c \geq 1$ and count the weighted sum of votes in favor of M versus the weighted sum of votes in favor of N in the M versus N election. That is, M is *weighted popular* if $c \cdot \phi_A(M, N) + \phi_B(M, N) \geq c \cdot \phi_A(N, M) + \phi_B(N, M)$ for every matching N, where c is the scaling factor and $\phi_B(\cdot, \cdot)$ is analogous to $\phi_A(\cdot, \cdot)$. No results are currently known for the weighted popular matching problem with $c > 1$ in a marriage instance. Observe that a fully popular matching is a weighted popular matching for every scaling factor $c \geq 1$.

1.1 Background and Related results

The notion of popularity was proposed by Gärdenfors [12] in 1975. Algorithms in the domain of popular matchings were first studied in 2005 for *one-sided* preferences or the A-popular matching problem. Efficient algorithms were given in [2] to decide if a given instance (with ties permitted in preference lists) admits an A-popular matching or not; in particular, a linear time algorithm was given for the case with strict preference lists. An efficient algorithm for the weighted A-popular matching problem, where each agent's vote is scaled by its weight (these weights are a part of the input), was given in [20].

Algorithms for popular matchings in a marriage instance $G = (A \cup B, E)$ or *two-sided* preferences have been well-studied in the last decade. The max-size popular matching algorithms in [14, 16] compute special popular matchings called *dominant* matchings. A linear time algorithm for finding a popular matching with a given edge e was given in [7] (such an edge is called a popular edge). It was shown in [7] that if e is a popular edge then there is either a stable matching or a dominant matching with e. Popular half-integral matchings in $G = (A \cup B, E)$ were characterized in [17] as stable matchings in a larger graph related to G. The popular fractional matching polytope was analyzed in [15] where the half-integrality of this polytope was shown. Other than algorithms for min-size/max-size popular matchings and for popular edge, no other polynomial time algorithms are currently known for finding popular matchings with special properties.

To complete the picture, it was shown in [9] that it is NP-hard to decide if G admits a popular matching that is neither a min-size nor a max-size popular matching. A host of hardness results in [9] painted a bleak picture for efficient algorithms for popular matching problems (other than what is already known). For instance, it is NP-hard to find a popular matching in G with a given pair of edges. Thus finding a max-weight (similarly, min-cost) popular matching is NP-hard when there are weights (resp., costs) on edges.

1.2 Our Result and Techniques

It may be the case that no min-size/max-size popular matching in G is A-popular, however G admits a fully popular matching: Section 2 has such an example. As there are instances where it is NP-hard to decide if there is a popular matching that is neither a min-size nor a max-size popular matching [9], a first guess may be that the fully popular matching problem is NP-hard.

Though an A-popular matching is constrained to use only some special edges in G (see Theorem 5), this does not seem very helpful since it is NP-hard to solve the popular matching problem with forced/forbidden edges [9]. Note that a rival matching (wrt popularity) is free to use any edge in G. It was not known if there was any tractable subclass of popular matchings other than the classes of *stable matchings* [10] and *dominant matchings* [7, 14, 16].

We show the set of fully popular matchings is a new tractable subclass of popular matchings: unlike the classes of stable matchings and dominant matchings which are always non-empty, there need not be a fully popular matching in G. Our algorithm for finding a fully popular matching is based on the classical Gale-Shapley algorithm and works in a new graph H; this graph is essentially two copies of G and is a variant of the graph seen in [17] to study popular *half-integral* matchings. There is a natural map from stable matchings in H to popular half-integral matchings in G. Our goal is to compute a stable matching with sufficient symmetry in H so that we can obtain a popular *integral* matching in G.

We achieve this symmetry by using properties of both popular and A-popular matchings. These properties allow us to identify certain edges that have to be excluded from our matching. If there is no stable matching in H without these edges then we use the lattice structure on stable matchings [13] to show that G has no fully popular matching. Else we obtain a matching M in G from this "partially symmetric" stable matching in H. The most technical part of our analysis is to prove M's popularity in G.

2 Preliminaries

Our input is a bipartite graph $G = (A \cup B, E)$ where every vertex has a strict preference list ranking its neighbors. Let us augment G with self-loops, i.e., each vertex is assumed to be at the bottom of its own preference list.

We will first present the characterization of A-popular matchings in G – note that preferences of vertices in B play no role here. For each $a \in A$, define the vertex $f(a)$ to be a's top choice neighbor and let $s(a)$ be a's most preferred neighbor that is nobody's top choice neighbor. We assume every $a \in A$ has at least one neighbor other than itself, so $f(a) \in B$, however it may be the case that $s(a) = a$. Let $E' = E \cup \{(u,u) : u \in A \cup B\}$.

▶ **Theorem 5** ([2]). *A matching M in $G = (A \cup B, E')$ is A-popular if and only if:*
1. $M \subseteq \{(a, f(a)), (a, s(a)) : a \in A\}$.
2. *M matches all in A and all in $\{f(a) : a \in A\}$.*

Popular matchings. We will use an LP-based characterization of popular matchings [17, 18] in a marriage instance $G = (A \cup B, E')$. Observe that any matching in G can be regarded as a perfect matching by including self-loops for all vertices left unmatched. Let M be any perfect matching in G. For any pair of adjacent vertices u, v, let u's vote for v (vs its partner $M(u)$) be 1 if u prefers v to $M(u)$, it is -1 if u prefers $M(u)$ to v, else 0 (i.e., $M(u) = v$). In order to check if M is popular or not in G, the following edge weight function wt_M will be useful. Here $\mathsf{wt}_M(a, b)$ is the sum of votes of a and b for each other.

$$\text{Let } \mathsf{wt}_M(a,b) = \begin{cases} 2 & \text{if } (a,b) \text{ is a blocking edge to } M; \\ -2 & \text{if both } a \text{ and } b \text{ prefer their partners in } M \text{ to each other;} \\ 0 & \text{otherwise.} \end{cases}$$

Thus $\mathsf{wt}_M(a,b) = 0$ for every $(a,b) \in M$. We need to define wt_M for self-loops as well. For any $u \in A \cup B$, let $\mathsf{wt}_M(u,u) = 0$ if $(u,u) \in M$, else $\mathsf{wt}_M(u,u) = -1$. For any perfect matching N in G, observe that $\mathsf{wt}_M(N) = \sum_{e \in N} \mathsf{wt}_M(e) = \phi(N,M) - \phi(M,N)$. Thus M is popular if and only if $\mathsf{wt}_M(N) \le 0$ for every perfect matching N in G.

Consider the max-weight perfect matching LP in G with the edge weight function wt_M. This linear program is (LP1) given below and (LP2) is the dual of (LP1). The variables x_e for $e \in E'$ are primal variables and the variables y_u for $u \in A \cup B$ are dual variables. Here $\delta'(u) = \delta(u) \cup \{(u,u)\}$.

$$\begin{aligned} \max \sum_{e \in E'} \mathsf{wt}_M(e) \cdot x_e & & \text{(LP1)} \\ \text{s.t.} \quad \sum_{e \in \delta'(u)} x_e = 1 & \quad \forall\, u \in A \cup B \\ x_e \ge 0 & \quad \forall\, e \in E'. \end{aligned}$$

$$\begin{aligned} \min \sum_{u \in A \cup B} y_u & & \text{(LP2)} \\ \text{s.t.} \quad y_a + y_b \ge \mathsf{wt}_M(a,b) & \quad \forall\, (a,b) \in E \\ y_u \ge \mathsf{wt}_M(u,u) & \quad \forall\, u \in A \cup B. \end{aligned}$$

M is popular if and only if the optimal value of (LP1) is at most 0. In fact, the optimal value is exactly 0 since M is a perfect matching in G and $\mathsf{wt}_M(M) = 0$. Thus M is popular if and only if the optimal value of (LP2) is 0 (by LP-duality).

▶ **Theorem 6** ([17, 18])**.** *A matching M in $G = (A \cup B, E)$ is popular if and only if there exists $\vec{\alpha} \in \{0, \pm 1\}^n$ (where $|A \cup B| = n$) such that $\sum_{u \in A \cup B} \alpha_u = 0$ along with*

$$\alpha_a + \alpha_b \ge \mathsf{wt}_M(a,b) \quad \forall (a,b) \in E \qquad \textit{and} \qquad \alpha_u \ge \mathsf{wt}_M(u,u) \quad \forall u \in A \cup B.$$

Proof. Since E is the edge set of a bipartite graph, the constraint matrix of (LP2) is totally unimodular. So (LP2) admits an optimal solution that is integral. The vector $\vec{\alpha}$ is an integral optimal solution of (LP2). We have $\alpha_u \ge \mathsf{wt}_M(u,u) \ge -1$ for all u.

We now claim $\alpha_u \in \{0, \pm 1\}$ for all vertices u. Since M is an optimal solution to (LP1), complementary slackness implies $\alpha_u + \alpha_v = \mathsf{wt}_M(u,v) = 0$ for each edge $(u,v) \in M$. Thus $\alpha_u = -\alpha_v \le 1$ for every vertex u matched to a non-trivial neighbor v in M. Regarding any vertex u such that $(u,u) \in M$, we have $\alpha_u = \mathsf{wt}_M(u,u) = 0$ (by complementary slackness). Hence $\vec{\alpha} \in \{0, \pm 1\}^n$. ◀

For any popular matching M, a vector $\vec{\alpha}$ as given in Theorem 6 will be called a *witness* of M's popularity. Note that a popular matching may have several witnesses. A stable matching S has 0^n as a witness since $\mathsf{wt}_S(e) \le 0$ for all $e \in E'$.

Recall that our problem is to compute a *fully popular* matching, i.e., a popular matching that is also A-popular. It is easy to construct instances that admit A-popular matchings but admit no fully popular matching. It could also be the case that no min-size or max-size popular matching in $G = (A \cup B, E)$ is A-popular, however G has a fully popular matching. Consider the instance G given in Fig. 1. Vertex preferences are indicated on edges: 1 denotes top choice, and so on.

We list the vertices $f(u)$ and $s(u)$ for each $u \in A$ in this instance. The vertex b' is *not* $s(a)$ since a prefers q' to b' and $q' \ne f(u)$ for any $u \in A$.

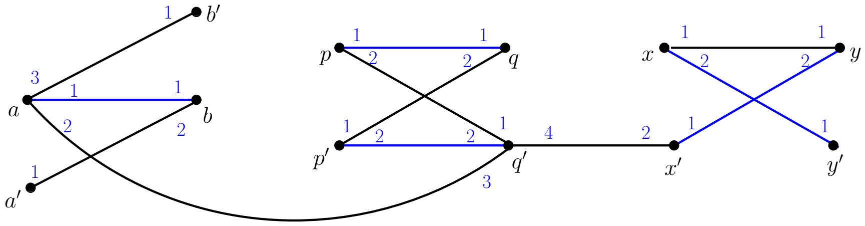

Figure 1 An instance on $A = \{a, a', p, p', x, x'\}$ and $B = \{b, b', q, q', y, y'\}$ where no min-size/max-size popular matching is A-popular. There is a fully popular matching (on blue edges) here.

- We have $f(a) = f(a') = b$, $f(p) = f(p') = q$, and $f(x) = f(x') = y$.
- We have $s(a) = s(p) = s(p') = s(x') = q'$, $s(x) = y'$, and $s(a') = a'$.

Since $s(u) \neq u$ for $u \in \{a, p, p', x, x'\}$, any A-popular matching M has to match these 5 vertices to neighbors in B (by Theorem 5). So $M(a) = f(a) = b$ which implies $M(a') = s(a') = a'$, i.e., after pruning self-loops from M, the vertex a' has to be left unmatched in M. So M has size 5. It is easy to check that a stable matching (thus any min-size popular matching) in G has size 4; also any max-size popular matching has size 6. Thus no min-size or max-size popular matching in G can be fully popular. Interestingly, this instance admits a fully popular matching: $M = \{(a, b), (p, q), (p', q'), (x, y'), (x', y)\}$ is fully popular.

3 Fully Popular Matchings

The input is a marriage instance $G = (A \cup B, E)$. Our algorithm will work in a bipartite graph H which is essentially 2 copies of the graph G as shown in Fig. 2. The vertex set of H is $A_L \cup B_L$ on the left and $B_R \cup A_R$ on the right. Here $A_L = \{a_\ell : a \in A\}$ and $A_R = \{a_r : a \in A\}$. Similarly, $B_L = \{b_\ell : b \in B\}$ and $B_R = \{b_r : b \in B\}$.

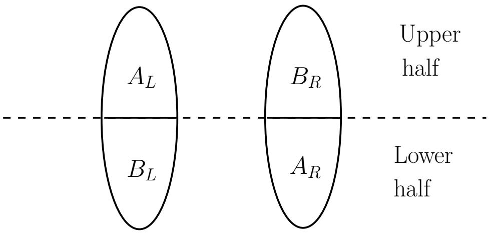

Figure 2 The bipartite graph H consists of 2 copies of the graph $G = (A \cup B, E)$.

The *upper half* of H consists of the set A_L of agents on the left and the set B_R of jobs on the right while the *lower half* of H consists of the set B_L of jobs on the left and the set A_R of agents on the right. Thus every vertex $u \in A \cup B$ has two copies in H: one as u_ℓ on the left of H and another as u_r on the right of H.

For every edge in E, there will be four edges in H: a pair of parallel edges in the upper half and a pair of parallel edges in the lower half. In order to distinguish two parallel edges with the same endpoints, we use superscripts $+$ and $-$ on the endpoints. For $(a, b) \in E$:

- in the upper half, we have two parallel edges (a_ℓ^+, b_r^-) and (a_ℓ^-, b_r^+) between a_ℓ and b_r;
- in the lower half, we have two parallel edges (b_ℓ^+, a_r^-) and (b_ℓ^-, a_r^+) between b_ℓ and a_r.

Corresponding to every vertex $u \in A \cup B$, there will be a *single* edge (u_ℓ^-, u_r^+) in H: this edge corresponds to the self-loop (u, u) and it will be convenient to use $+/-$ superscripts on the endpoints of this edge also. These edges (u_ℓ^-, u_r^+) for all u are the only edges in H that go across the two halves of H.

Vertices in H have preferences on their incident *edges* rather than their neighbors. However it would be more convenient to say u prefers v^- to w^+ rather than say u prefers (u^+, v^-) to (u^-, w^+). In fact, H is equivalent to a conventional graph H^* (with preferences on neighbors) that was used to study popular *half-integral* matchings in [17]: there were 4 vertices in H^* for each $u \in A \cup B$. The graph H is a sparser version of H^* with only 2 vertices u_ℓ and u_r for each $u \in A \cup B$ and a pair of parallel edges between every pair of adjacent vertices. We now describe the preferences of vertices in H.

Every vertex prefers superscript $-$ neighbors to superscript $+$ neighbors: among superscript $-$ neighbors (similarly, superscript $+$ neighbors), it will be its original preference order. Consider any vertex $u \in A \cup B$. Suppose u's preference list in G is $v \succ v' \succ \cdots \succ v''$, i.e., v is u's top choice, next comes v', and so on. In H, the preference list of u_ℓ is as follows:

$$\underbrace{v_r^- \succ v_r'^- \succ \cdots \succ v_r''^-}_{\text{superscript } - \text{ neighbors}} \succ \underbrace{v_r^+ \succ v_r'^+ \succ \cdots \succ v_r''^+ \succ u_r^+}_{\text{superscript } + \text{ neighbors}},$$

where $v_r, v'_r, \ldots$ correspond to the copies of $v, v', \ldots$ on the right side of H.

The vertex u_r^+ is the last choice of u_ℓ. In H, the preference list of u_r is as follows:

$$\underbrace{v_\ell^- \succ v_\ell'^- \succ \cdots \succ v_\ell''^- \succ u_\ell^-}_{\text{superscript } - \text{ neighbors}} \succ \underbrace{v_\ell^+ \succ v_\ell'^+ \succ \cdots \succ v_\ell''^+}_{\text{superscript } + \text{ neighbors}},$$

where $v_\ell, v'_\ell, \ldots$ correspond to the copies of $v, v', \ldots$ on the left side of H. This is analogous to u_ℓ's preference list: the main difference is in the position of its "twin" - the vertex u_r prefers u_ℓ^- to all its superscript $+$ neighbors.

Blocking edges. Let $u_\ell \in A_L \cup B_L$ and $v_r \in A_R \cup B_R$. For any matching M in H, we say an edge (u_ℓ^+, v_r^-) *blocks* M if (i) u_ℓ prefers v_r^- to its assignment in M and (ii) v_r prefers u_ℓ^+ to its assignment in M. Similarly, we say edge (u_ℓ^-, v_r^+) *blocks* M if (i) u_ℓ prefers v_r^+ to its assignment in M and (ii) v_r prefers u_ℓ^- to its assignment in M.

▶ **Definition 7.** *A matching M in H is* stable *if no edge in H blocks M.*

▷ Claim 8. Let S be a stable matching in $G = (A \cup B, E)$. The matching $S' = \{(a_\ell^-, b_r^+), (b_\ell^-, a_r^+) : (a, b) \in S\} \cup \{(u_\ell^-, u_r^+) : u \text{ is unmatched in } S\}$ is stable in H.

Proof. We need to show that no edge in H blocks S'. Note that S' is a perfect matching in H. Consider any edge (c_ℓ^+, d_r^-) in H where $c \in A$ and $d \in B$. Since every vertex prefers superscript $-$ neighbors to superscript $+$ neighbors, the vertex d_r prefers its partner in S' to c_ℓ^+. So consider any edge (c_ℓ^-, d_r^+) in H. If $(c, d) \in S$ then $(c_\ell^-, d_r^+) \in S'$ and so it does not block S'. If $(c, d) \notin S$ then it follows from the stability of S in G that either (1) c is matched to a neighbor b preferred to d or (2) d is matched to a neighbor a preferred to c. In case (1), c_ℓ is matched in S' to a neighbor b_r^+ preferred to d_r^+; in case (2), d_r is matched in S' to a neighbor a_ℓ^- preferred to c_ℓ^-. Thus (c_ℓ^-, d_r^+) does not block S'.

It can analogously be shown that neither (d_ℓ^-, c_r^+) nor (d_ℓ^+, c_r^-) blocks S'. Also (u_ℓ^-, u_r^+) for any $u \in A \cup B$ does not block S' since u_r^+ is u_ℓ's least preferred neighbor in H. Hence S' is a stable matching in H. ◁

Thus the graph H admits a perfect stable matching. Since all stable matchings in H have the same size [11], every stable matching in H has to be perfect. We seek to compute a "special" stable matching in H: one that has no edge that is *forbidden*. The edges marked forbidden are those that no fully popular matching uses. The definition of *valid* edges below is as given in Theorem 5: any A-popular matching in G can contain only these edges/self-loops.

▶ **Definition 9.** *Edges/self-loops in* $\{(a, f(a)), (a, s(a)) : a \in A\}$ *are* valid. *So are self-loops in* $\{(b, b) : b \neq f(a)$ for any $a \in A\}$.

All other edges and self-loops are *invalid*. Thus every $a \in A$ has exactly 2 valid edges incident to it: one of these may be the self-loop (a, a).

An edge e in G is *popular* if there exists a popular matching M in G such that $e \in M$. Call a vertex *stable* if it is matched in some (equivalently, every [11]) stable matching. It is known that every popular matching in G has to match all stable vertices to non-trivial neighbors [14]. So the self-loop (u, u) is popular if and only if u is unstable.

▶ **Definition 10.** *Call an edge e in $E \cup \{(u, u) : u \in A \cup B\}$* legal *if e is valid and popular.*

Forbidden edges. A fully popular matching, by definition, has to contain only legal edges. So if (a, b) is not legal then (a^+_ℓ, b^-_r), (a^-_ℓ, b^+_r), (b^+_ℓ, a^-_r), and (b^-_ℓ, a^+_r) are *forbidden* edges in the stable matching that we seek to compute in H. Similarly, for any $u \in A \cup B$, if (u, u) is not legal then (u^-_ℓ, u^+_r) is a forbidden edge in our algorithm.

▶ **Definition 11.** *A matching M in H is* legal *if M has no forbidden edge.*

Call a matching M in H *symmetric* if for each edge (a, b) in E, we have both (a_ℓ, b_r) and (b_ℓ, a_r) in M or neither (for convenience, we are ignoring $+/-$ superscripts on a_ℓ, a_r, b_ℓ, b_r), i.e., loosely speaking, M has the same edges in the upper and lower halves of H. A symmetric matching M in H will be called a *realization* of $\tilde{M} = \{(a, b) : (a_\ell, b_r)$ and (b_ℓ, a_r) are in $M\}$. Note that $\tilde{M}$ is a matching in G.

▶ **Lemma 12.** *Every fully popular matching in G has a realization as a legal stable matching in the instance H.*

Proof. Let N be a fully popular matching in G and let $\vec{\alpha} \in \{0, \pm 1\}^n$ be a witness of N's popularity (see Theorem 6). For $i \in \{0, \pm 1\}$, let A_i be the set of vertices $a \in A$ with $\alpha_a = i$ and let B_i be the set of vertices $b \in B$ with $\alpha_b = i$. Thus we have $A = A_0 \cup A_1 \cup A_{-1}$ and $B = B_0 \cup B_1 \cup B_{-1}$. Note that $\alpha_a + \alpha_b = \mathsf{wt}_N(a, b) = 0$ for each edge $(a, b) \in N$: this is by complementary slackness on (LP2) corresponding to N. So the matching $N \subseteq (A_0 \times B_0) \cup (A_{-1} \times B_1) \cup (A_1 \times B_{-1})$ (see Fig. 3).

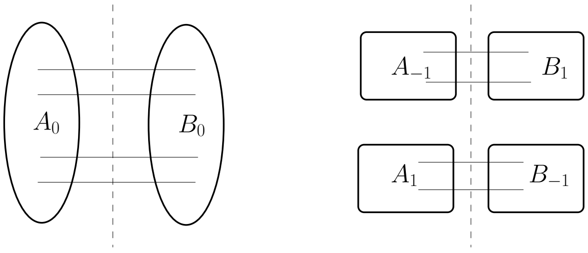

Figure 3 The partition $A_0 \cup A_1 \cup A_{-1}$ of A and $B_0 \cup B_{-1} \cup B_1$ of B.

We need to show a realization of N in H that is stable. We will use N's witness $\vec{\alpha}$ in G to define the following matching N^*_α in H: this is similar to how popular half-integral matchings were realized as stable matchings in a larger graph H^* in [17].

- For all $(a, b) \in N \cap (A_{-1} \times B_1)$ do: add edges (a^-_ℓ, b^+_r) and (b^+_ℓ, a^-_r) to N^*_α.
- For all $(a, b) \in N \cap (A_1 \times B_{-1})$ do: add edges (a^+_ℓ, b^-_r) and (b^-_ℓ, a^+_r) to N^*_α.
- For all $(a, b) \in N \cap (A_0 \times B_0)$ do: add edges (a^-_ℓ, b^+_r) and (b^-_ℓ, a^+_r) to N^*_α.

For each u such that $(u, u) \in N$, add (u_ℓ^-, u_r^+) to N^*_α. Using the constraints that $\vec{\alpha}$ has to satisfy, it is easy to argue that N^*_α is a stable matching in H. Moreover, the fact that N is a fully popular matching in G implies that N^*_α is a *legal* matching in H: since N is A-popular (resp., popular) in G, every edge used in N is valid (resp., popular). So N^*_α has no forbidden edge. Thus N^*_α is a legal stable matching in H. ◀

A variant of Gale-Shapley algorithm. A stable matching that avoids all forbidden edges (if such a matching exists) can be computed in linear time by running a variant of Gale-Shapley algorithm in H where proposals made along forbidden edges are rejected. Once a proposal made along a forbidden edge is rejected by a vertex, all further proposals made on *worse* edges also have to rejected by this vertex. If some vertex is left unmatched at the end of this algorithm, then there is no stable matching in H that avoids all forbidden edges; else we have a desired stable matching in H. We refer to [13] for details on this variant of Gale-Shapley algorithm.

Thus it can be efficiently checked if H admits a legal stable matching or not. If such a matching does not exist in H then there is no fully popular matching in G (by Lemma 12). So we will assume henceforth that there exists a legal stable matching in H. However the fact that such a stable matching exists in H does not imply that G admits a fully popular matching. This is because any matching M^* in H can only be mapped to a *half-integral* matching in G.

In order to claim the resulting matching in G is integral, we need M^* to be symmetric, i.e., have the same edges in both halves of H. We will not construct such a symmetric stable matching in H. The matching we compute will have a certain amount of symmetry and this will be enough to obtain a fully popular matching in G. If H does not admit such a "partially symmetric" stable matching, then we show that G has *no* fully popular matching.

3.1 Two partitions of the vertex set

We run Gale-Shapley algorithm that avoids all forbidden edges [13] in H. In this algorithm, vertices on the left of H propose and vertices on the right of H dispose. When $u_\ell \in A_L \cup B_L$ proposes to v_r^-, this proposal is made along (u_ℓ^+, v_r^-): so v_r sees this as u_ℓ^+'s proposal; when u_ℓ proposes to v_r^+, this proposal is made along (u_ℓ^-, v_r^+): so v_r sees this as u_ℓ^-'s proposal. If u_ℓ proposes to a neighbor v_r along (u_ℓ^+, v_r^-) or (u_ℓ^-, v_r^+), then v_r accepts u_ℓ's proposal only if the edge (u, v) is legal; otherwise v_r rejects u_ℓ's proposal since this is a forbidden edge. Edges ranked worse than $(u_\ell^+, v_r^-)/(u_\ell^-, v_r^+)$ (as the case may be) will be deleted from the current instance on whose edges proposals are made – this ensures that once v_r receives a proposal along a certain edge, whether this proposal is accepted or not, v_r cannot accept proposals made along *worse* edges. Let S_0 be the legal stable matching in H that is obtained.

- Let $U_A \subseteq A$ be the set of agents a such that $(a_\ell^-, a_r^+) \in S_0$ and let $U_B \subseteq B$ be the set of jobs b such that $(b_\ell^-, b_r^+) \in S_0$.

We know that H is made up of two halves: the upper half and the lower half. Since S_0 is stable and thus perfect (recall that any stable matching in H is perfect), the set of agents matched to *genuine* neighbors – not to their twins – in each half of H is $A \setminus U_A$ and similarly, the set of jobs matched to genuine neighbors in each half of H is $B \setminus U_B$. We now form sets $A_+, A_-, B_+, B_-, A'_+, A'_-, B'_+, B'_-$ corresponding to S_0: initially they are empty.

- For every $(a^+_\ell, b^-_r) \in S_0$ where $a \in A$ and $b \in B$: add a to A_+ and b to B_-.
- For every $(a^-_\ell, b^+_r) \in S_0$ where $a \in A$ and $b \in B$: add a to A_- and b to B_+.
- For every $(b^+_\ell, a^-_r) \in S_0$ where $a \in A$ and $b \in B$: add b to B'_+ and a to A'_-.
- For every $(b^-_\ell, a^+_r) \in S_0$ where $a \in A$ and $b \in B$: add b to B'_- and a to A'_+.

Figure 4 Two partitions of the set $(A \cup B) \setminus (U_A \cup U_B)$ induced by the matching S_0.

We have $A \setminus U_A = A_+ \cup A_- = A'_+ \cup A'_-$ and $B \setminus U_B = B_+ \cup B_- = B'_+ \cup B'_-$. Fig. 4 denotes these partitions of $A \setminus U_A$ and $B \setminus U_B$ induced by the matching S_0 in the upper and lower halves of H. In this figure, the set U_A has been included in the upper half and the set U_B in the lower half.

We will use $(a^-_\ell, *)$ to denote any edge in the set $\{(a^-_\ell, b^+_r) : b \in B\} \cup \{(a^-_\ell, a^+_r)\}$. Similarly $(*, a^+_r)$ denotes any edge in the set $\{(b^-_\ell, a^+_r) : b \in B\} \cup \{(a^-_\ell, a^+_r)\}$. Similarly for $(b^-_\ell, *)$ and $(*, b^+_r)$. Recall that every popular matching has a *witness* $\vec{\alpha} \in \{0, \pm 1\}^n$ (see Theorem 6).

▶ **Lemma 13.** *Let N be a fully popular matching in G and let $\vec{\alpha}$ be any witness of N. If $a \in A_- \cap A'_+$ then $\alpha_a = 0$.*

Proof. We have vertex $a \in A_- \cap A'_+$, where the sets A_- and A'_+ are defined above. Let $\mathcal{D}_0$ be the set of legal stable matchings in H. The set $\mathcal{D}_0$ forms a sublattice of the lattice[1] of stable matchings in H and the matching S_0 is the $(A_L \cup B_L)$-*optimal* matching in $\mathcal{D}_0$ [13]. Since $a \in A_-$, we have $(a^-_\ell, c^+_r) \in S_0$ for some neighbor c^+_r of a_ℓ. Thus c^+_r is the most preferred partner for $a_\ell \in A_L$ in all matchings in $\mathcal{D}_0$. Recall that every vertex prefers superscript $-$ neighbors to superscript $+$ neighbors. Hence no matching in $\mathcal{D}_0$ matches a_ℓ to a superscript $-$ neighbor, i.e., every legal stable matching in H has to contain $(a^-_\ell, *)$.

S_0 is also the $(A_R \cup B_R)$-*pessimal* matching in $\mathcal{D}_0$ [13]. Since $a \in A'_+$, we have $(d^-_\ell, a^+_r) \in S_0$ for some neighbor d^-_ℓ of a_r. So every matching in $\mathcal{D}_0$ has to match $a_r \in A_R$ to a neighbor at least as good as d^-_ℓ, i.e., every legal stable matching in H has to contain $(*, a^+_r)$.

Suppose N is a fully popular matching with a witness $\vec{\alpha}$ such that $\alpha_a \in \{\pm 1\}$. If $\alpha_a = 1$, i.e., if $a \in A_1$ (see Fig. 3), then there is a legal stable matching N^*_α in H such that $(a^+_\ell, *) \in N^*_\alpha$ (see the proof of Lemma 12). This contradicts our claim above that every legal stable matching in H has to contain $(a^-_\ell, *)$. So $\alpha_a = -1$, i.e., $a \in A_{-1}$. Then there is a legal stable matching N^*_α in H such that $(*, a^-_r) \in N^*_\alpha$ (by the proof of Lemma 12). This again contradicts our claim above that every legal stable matching in H has to contain $(*, a^+_r)$. Thus $\alpha_a \notin \{\pm 1\}$, hence $\alpha_a = 0$. ◀

[1] The meet of 2 stable matchings M and M' is the stable matching where every u in $A_L \cup B_L$ (resp., $A_R \cup B_R$) is matched to its *more* (resp., *less*) preferred partner in $\{M(u), M'(u)\}$. The join of M and M' is the stable matching where every u in $A_L \cup B_L$ (resp., $A_R \cup B_R$) is matched to its *less* (resp., *more*) preferred partner in $\{M(u), M'(u)\}$.

The proof of Lemma 14 is analogous to the proof of Lemma 13.

▶ **Lemma 14.** *Let N be a fully popular matching in G and let $\vec{\alpha}$ be any witness of N. If $b \in B_+ \cap B'_-$ then $\alpha_b = 0$.*

We will use $G_0 = (A \cup B, E_0)$ to denote the *popular subgraph* of G. The edge set E_0 of G_0 is the set of popular edges, i.e., those present in some popular matching in G. The subgraph G_0 need not be connected and Lemma 15 will be useful to us.

▶ **Lemma 15** ([8]). *Let C be any connected component in the popular subgraph G_0. For any popular matching N in G and any witness $\vec{\alpha}$ of N: if $\alpha_v = 0$ for some $v \in C$ then $\alpha_u = 0$ for all $u \in C$.*

Proof. Consider any popular edge (a, b). So there is some popular matching M with the edge (a, b). The matching M is an optimal solution to the max-weight perfect matching LP with edge weight function wt_N since $\mathsf{wt}_N(M) = \phi(M, N) - \phi(N, M) = 0$: recall that M and N are popular matchings in G. We know that $\vec{\alpha}$ is an optimal solution to the dual LP. So it follows from complementary slackness conditions that $\alpha_a + \alpha_b = \mathsf{wt}_N(a, b)$. Since $\mathsf{wt}_N(a, b) \in \{\pm 2, 0\}$ (an even number), the integers α_a and α_b have the same parity.

Let u and v be any 2 vertices in the same connected component in the popular subgraph G_0. So there is a u-v path ρ in G such that every edge in ρ is a popular edge. We have just seen that the endpoints of each popular edge have the same parity in $\vec{\alpha}$. Hence α_u and α_v have the same parity. Thus $\alpha_v = 0$ implies $\alpha_u = 0$. ◀

3.2 Our algorithm

Lemmas 13-15 motivate our algorithm which is described as Algorithm 1. The main step of the algorithm is the *while* loop that takes any unmarked vertex v in $(A_- \cap A'_+) \cup (B_+ \cap B'_-)$. Initially all vertices are unmarked. Consider the first iteration of the algorithm: let $v \in A$.

Lemma 13 tells us that for any fully popular matching N and any witness $\vec{\alpha}$ of N, we have $\alpha_v = 0$. Lemma 15 tells us that $\alpha_u = 0$ for every vertex u in the component C, where C is v's connected component in G_0. The proof of Lemma 12 shows N has a realization N^*_α in H such that N^*_α contains $(a^-_\ell, *)$ and $(*, a^+_r)$ for every agent $a \in C$.

Thus we are interested in those legal stable matchings in H that contain $(a^-_\ell, *)$ and $(*, a^+_r)$ for every agent $a \in C$. Hence our algorithm *forbids* all edges $(a^+_\ell, *)$ and $(*, a^-_r)$ for every agent $a \in C$ in the stable matching that we compute here. This step is implemented by making every neighbor reject offers from a^+_ℓ (this may induce other rejections) and symmetrically, a_r rejects all offers from superscript + neighbors. Note that the resulting matching may contain (a^-_ℓ, a^+_r) for some of the agents a in C. All vertices in C get marked in this iteration.

Let $\mathcal{D}_1 \subseteq \mathcal{D}_0$ be the set of all legal stable matchings in H that contain $(a^-_\ell, *)$ and $(*, a^+_r)$ for every agent $a \in C$. Thus $\mathcal{D}_1$ is a sublattice of $\mathcal{D}_0$. We know from the proof of Lemma 12 that $N^*_\alpha \in \mathcal{D}_1$ where N is a fully popular matching in G and $\vec{\alpha}$ any witness of N. So if $\mathcal{D}_1$ is empty then we can conclude that G has *no* fully popular matching.

Algorithm 1 *Input: $G = (A \cup B, E)$ with strict preferences.*

```
1:  Compute a legal stable matching $S_0$ in $H$ by running Gale-Shapley algorithm with
    forbidden edges.
    {Vertices in $A_L \cup B_L$ propose and those in $B_R \cup A_R$ dispose.}
2:  Let $A_-, A'_+$ and $B_+, B'_-$ be as defined earlier (see the start of Section 3.1).
3:  Initially all vertices are unmarked and $i = 0$.
4:  while there exists an unmarked vertex $v \in (A_- \cap A'_+) \cup (B_+ \cap B'_-)$ do
5:      $i = i + 1$.
6:      Modify $S_{i-1}$ to $S_i$ so as to forbid all edges $(a^+_\ell, *)$ and $(*, a^-_r)$ for every agent $a$ in $v$'s
        component in the popular subgraph $G_0$.
        ($S_i$ is the $(A_L \cup B_L)$-optimal legal stable matching in $H$ that avoids all forbidden edges
        identified in the first $i$ iterations of the while-loop.)
7:      if there is no such legal stable matching $S_i$ in $H$ then
8:          Return "No fully popular matching in $G$".
9:      end if
10:     Update the sets $A_-, A'_+$ and $B_+, B'_-$: these correspond to $S_i$ now.
11:     Mark all vertices in $v$'s component in the popular subgraph $G_0$.
12: end while
13: Return $M = \{(a, b) \in E : (a^+_\ell, b^-_r)$ or $(a^-_\ell, b^+_r)$ is in $S_i\}$.
```

Let us assume we are now in the i-th iteration and let $\mathcal{D}_i$ be the set of legal stable matchings in H that avoid all edges forbidden by our algorithm in the first i iterations. In other words, $\mathcal{D}_i$ is the set of those matchings in $\mathcal{D}_{i-1}$ where no edge forbidden in the i-th iteration is present. We have $\mathcal{D}_0 \supseteq \mathcal{D}_1 \supseteq \cdots \supseteq \mathcal{D}_{i-1} \supseteq \mathcal{D}_i$. For all $0 \le j \le i$, the set $\mathcal{D}_j$ forms a sublattice of the lattice of all stable matchings in H [13].

▶ **Lemma 16.** *For every fully popular matching N in G and every witness $\vec{\alpha}$ of N, the realization N^*_α is an element of $\mathcal{D}_i$.*

Proof. We will prove the lemma by induction. We know from Lemma 12 that the base case is true, i.e., $N^*_\alpha \in \mathcal{D}_0$. By induction hypothesis, let us assume that for every fully popular matching N and every witness $\vec{\alpha}$, the realization N^*_α is an element of $\mathcal{D}_{i-1}$. Since the algorithm entered the i-th iteration of the while loop, there was an unmarked vertex x in $(A_- \cap A'_+) \cup (B_+ \cap B'_-)$ at the start of this iteration.

▷ Claim 17. For any fully popular matching N and any witness $\vec{\alpha}$ of N, we have $\alpha_x = 0$.

Proof. The matching S_{i-1} computed in Step 6 of the $(i-1)$-th iteration is the $(A_L \cup B_L)$-optimal matching in the lattice $\mathcal{D}_{i-1}$. Hence if $(x^-_\ell, *) \in S_{i-1}$ for some $x_\ell \in A_L \cup B_L$ then $(x^-_\ell, *)$ belongs to every matching in $\mathcal{D}_{i-1}$. The matching S_{i-1} is also the $(A_R \cup B_R)$-pessimal matching in the set $\mathcal{D}_{i-1}$. Hence if $(*, x^+_r) \in S_{i-1}$ for some $x_r \in A_R \cup B_R$ then $(*, x^+_r)$ belongs to every matching in $\mathcal{D}_{i-1}$.

If the above claim is false then there is a fully popular matching N and a witness $\vec{\alpha}$ of N with $\alpha_x \in \{\pm 1\}$. If $\alpha_x = 1$ then there is a legal stable matching N^*_α in H such that $(x^+_\ell, *) \in N^*_\alpha$. If $\alpha_x = -1$ then there is a legal stable matching N^*_α in H such that $(*, x^-_r) \in N^*_\alpha$. Since $N^*_\alpha \in \mathcal{D}_{i-1}$, both cases contradict our earlier observation that every matching in $\mathcal{D}_{i-1}$ has to contain $(x^-_\ell, *)$ and $(*, x^+_r)$. Thus for any fully popular matching N and any witness $\vec{\alpha}$ of N, we have $\alpha_x = 0$. ◁

Claim 17 along with Lemma 15 tells us that for all vertices u in x's component C' in G_0, we have $\alpha_u = 0$. The proof of Lemma 12 shows us that N^*_α contains $(a^-_\ell, *)$ and $(*, a^+_r)$ for every agent $a \in C'$. Since $N^*_\alpha \in \mathcal{D}_{i-1}$, it follows that N^*_α is an element in $\mathcal{D}_i$. This finishes the proof of this lemma. ◀

Hence if $\mathcal{D}_i = \emptyset$, i.e., if the algorithm says "no" in Step 8, then there is indeed no fully popular matching in G. This finishes one part of our proof of correctness. We now need to show that if our algorithm returns a matching M, then M is a fully popular matching in G.

4 Correctness of our algorithm

In this section we show that the matching returned by Algorithm 1 is a fully popular matching in G. Let S_i be the matching in H computed in the final iteration of Algorithm 1. Let M be the matching (in G) induced by S_i in the upper half of H: this is as defined in Step 13 of Algorithm 1.

Note that $M \subseteq (A_+ \times B_-) \cup (A_- \times B_+)$, where the sets A_+, B_-, A_-, B_+ are defined at the beginning of Section 3.1: the matching S_i replaces S_0 in these definitions now. Similarly, let L be the matching (in G) induced by S_i in the lower half of H. So

$$L = \{(a,b) \in E : (b^+_\ell, a^-_r) \text{ or } (b^-_\ell, a^+_r) \text{ is in } S_i\}.$$

Thus $L \subseteq (A'_+ \times B'_-) \cup (A'_- \times B'_+)$. Let U_A (resp., U_B) be the set of vertices u in A (resp., B) such that $(u^-_\ell, u^+_r) \in S_i$. The vertices in $U_A \cup U_B$ are unmatched in both M and L. Since S_i is a legal stable matching in H, it matches all vertices in H using valid edges. Thus by Theorem 5, M is A-popular.[2] We need to show that M is popular in G. Theorem 18 will be our starting point.

▶ **Theorem 18.** *The matching M is popular in the subgraph $G \setminus U_B$. Also, the matching L is popular in the subgraph $G \setminus U_A$.*

Proof. The popularity of L in $G \setminus U_A$ will be shown using the witness $\vec{\beta}$ defined below and the popularity of M in $G \setminus U_B$ will be shown using the witness $\vec{\gamma}$ defined below.

1. $\beta_u = 1$ for $u \in A'_+ \cup B'_+$, $\beta_u = -1$ for $u \in A'_- \cup B'_-$, and $\beta_u = 0$ for $u \in U_B$.
2. $\gamma_u = 1$ for $u \in A_+ \cup B_+$, $\gamma_u = -1$ for $u \in A_- \cup B_-$, and $\gamma_u = 0$ for $u \in U_A$.

Since $L \subseteq (A'_+ \times B'_-) \cup (A'_- \times B'_+)$, we have $\sum_{u \in (A \cup B) \setminus U_A} \beta_u = 0$. Note that $\mathsf{wt}_L(u,u) = 0$ for $u \in U_B$ and $\mathsf{wt}_L(u,u) = -1$ for all other u. Thus $\beta_u \geq \mathsf{wt}_L(u,u)$ for all $u \in (A \cup B) \setminus U_A$.

Similarly, $\sum_{u \in (A \cup B) \setminus U_B} \gamma_u = 0$. Also, $\gamma_u \geq \mathsf{wt}_M(u,u)$ for all $u \in (A \cup B) \setminus U_B$.

▷ Claim 19. $\beta_a + \beta_b \geq \mathsf{wt}_L(a,b)$ for all edges (a,b) where $a \in A \setminus U_A$ and $b \in B$.

▷ Claim 20. $\gamma_a + \gamma_b \geq \mathsf{wt}_M(a,b)$ for all edges (a,b) where $a \in A$ and $b \in B \setminus U_B$.

We will prove Claim 20 below. The proof of Claim 19 is analogous.

- Consider $a \in U_A$. We set $\gamma_a = 0$ and we know that $(a^-_\ell, a^+_r) \in S_i$. Recall that a^+_r is a_ℓ's least preferred neighbor, thus a_ℓ must have been rejected by all its more preferred neighbors in our variant of the Gale-Shapley algorithm in H. That is, every neighbor b^+_r of a_ℓ received a proposal from a^-_ℓ. Since b_r prefers superscript $-$ neighbors to superscript $+$

[2] In order to apply Theorem 5, we ought to say $M \cup \{(u,u) : u \in U_A \cup U_B\}$ is A-popular.

neighbors, this means $(d_\ell^-, b_r^+) \in S_i$ for some neighbor d_ℓ^- that b_r prefers to a_ℓ^-, i.e., b prefers d to a. Thus $b \in B_1$ (so $\gamma_b = 1$) and moreover, $\mathsf{wt}_M(a,b) = 0$. Hence we have $\gamma_a + \gamma_b = 1 > \mathsf{wt}_M(a,b)$.

- We will next show this constraint holds for all edges (a,b) incident to $a \in A_-$. There are 2 cases: (1) $b \in B_-$ and (2) $b \in B_+$. In case (1), we have (a_ℓ^-, c_r^+) and (d_ℓ^+, b_r^-) in S_i. Since every vertex prefers superscript $-$ neighbors to superscript $+$ neighbors, it means a_ℓ proposed to b_r^- and got rejected, i.e., b_r prefers its partner d_ℓ^+ to a_ℓ^+. We also claim a_ℓ prefers its partner c_r^+ to b_r^+. This is because b_r prefers a_ℓ^- to d_ℓ^+ (superscript $-$ neighbors over superscript $+$ neighbors): so if a_ℓ^- had proposed to b_r, then b_r would have rejected its partner d_ℓ^+. This means both a and b prefers their partners in M to each other. Thus $\mathsf{wt}_M(a,b) = -2 = \gamma_a + \gamma_b$.
  In case (2) above, either (i) $(a_\ell^-, b_r^+) \in S_i$ or (ii) (a_ℓ^-, c_r^+) and (d_ℓ^-, b_r^+) are in S_i: since S_i is stable, a_ℓ prefers c_r^+ to b_r^+ or b_r prefers d_ℓ^- to a_ℓ^-. Thus $\mathsf{wt}_M(a,b) \le 0 = \gamma_a + \gamma_b$.
- Finally, we will show this constraint holds for all edges (a,b) incident to $a \in A_+$. There are 2 cases: $b \in B_+$ and $b \in B_-$. In the first case, we have $\gamma_a + \gamma_b = 2$ and since $\mathsf{wt}_M(a,b) \le 2$, the constraint $\mathsf{wt}_M(a,b) \le \gamma_a + \gamma_b$ obviously holds.
  In the second case, either (i) $(a_\ell^+, b_r^-) \in S_i$ or (ii) (a_ℓ^+, c_r^-) and (d_ℓ^+, b_r^-) are in S_i: since S_i is stable, a_ℓ prefers c_r^- to b_r^- or b_r prefers d_ℓ^+ to a_ℓ^+. Thus $\mathsf{wt}_M(a,b) \le 0 = \gamma_a + \gamma_b$.

This finishes the proof of M's popularity in $G \setminus U_B$ (by Theorem 6). ◀

Thus the matching M is popular in the subgraph $G \setminus U_B$. However we need to prove the popularity of M in the *entire* graph G, i.e., we need to include vertices in U_B as well. Setting $\gamma_b = 0$ for $b \in U_B$ will not cover edges in $A_- \times U_B$. Now we will use the fact that L is popular in $G \setminus U_A$ and that M and L have several edges in common (as shown in Lemma 22).

Let Z be the set of all vertices outside $U_A \cup U_B$ that got marked in our algorithm. So these are the marked vertices that are matched in S_i to genuine neighbors (not to their twins). Since we marked entire connected components in the popular subgraph G_0 in Algorithm 1, both M and L match vertices in Z to each other.

Lemma 22 shows that the matching S_i has "partial symmetry" across the upper and lower halves of the graph H; more precisely, M and L are identical on the set Z. This will be key to showing M's popularity. The following lemma will be useful in proving Lemma 22.

▶ **Lemma 21.** *M and L are stable matchings when restricted to vertices in $Z \cup U_A \cup U_B$.*

Proof. Let $Z_A = Z \cap A$ and let $Z_B = Z \cap B$. It follows from our algorithm that $Z_A \subseteq A_- \cap A'_+$ and $Z_B \subseteq B_+ \cap B'_-$ (see Fig. 5).

We need to show that M (similarly, L) has no blocking edge in $(Z_A \cup U_A) \times (Z_B \cup U_B)$. Consider any edge $(a,b) \in Z_A \times Z_B$. We know from Claim 20 (in the proof of Theorem 18) that $\mathsf{wt}_M(a,b) \le \gamma_a + \gamma_b = -1 + 1 = 0$. Similarly, $\mathsf{wt}_L(a,b) \le \beta_a + \beta_b = 1 - 1 = 0$. Thus (a,b) is not a blocking edge to either M or L.

Thus neither M nor L has a blocking edge in $Z_A \times Z_B$. Moreover, G has no edge in $U_A \times U_B$. This is because each vertex $u \in U_A \cup U_B$ is unstable – otherwise (u_ℓ^-, u_r^+) is an unpopular edge and thus forbidden. Consider any edge $(a,b) \in U_A \times Z_B$. We have $\mathsf{wt}_M(a,b) \le \gamma_a + \gamma_b = 0 + 1 = 1$. Since $\mathsf{wt}_M(a,b)$ is an even number, this means $\mathsf{wt}_M(a,b) \le 0$. Thus (a,b) is not a blocking edge to M.

We will now show that (a,b) is not a blocking edge to L. Since $a \in U_A$ and $b \in Z_B \subseteq B'_-$, we have (a_ℓ^-, a_r^+) and (b_ℓ^-, c_r^+) in S_i, where c is some neighbor of b. Note that a_ℓ^- is a_r^+'s least preferred superscript $-$ neighbor in H. Thus a_r^+ did not receive any offer from b_ℓ^- in Algorithm 1. Because S_i is stable, it has to be the case that b_ℓ prefers c_r^+ to a_r^+. Since $(c,b) \in L$, we have $\mathsf{wt}_L(a,b) = 0$. Thus (a,b) is not a blocking edge to L.

It can similarly be shown that no edge in $Z_A \times U_B$ blocks either M or L. Thus M and L are stable matchings when restricted to vertices in $Z \cup U_A \cup U_B$. ◀

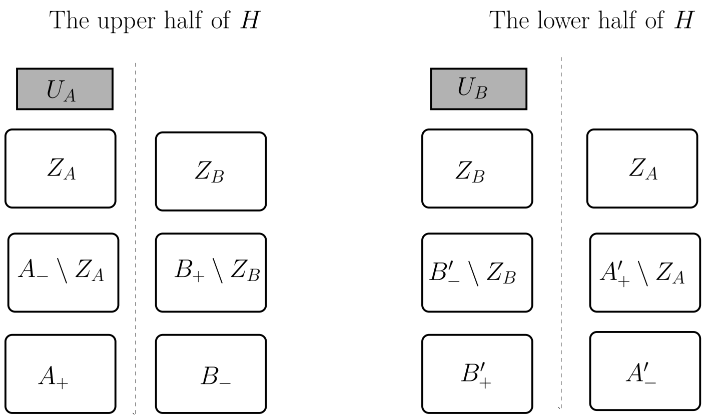

Figure 5 The final picture of the partitions created by M and L in the upper and lower halves of H, resp. The while-loop termination condition implies $(A_- \setminus Z_A) \subseteq A'_-$ and $(A'_+ \setminus Z_A) \subseteq A_+$, so on.

▶ **Lemma 22.** *The matching M restricted to vertices in Z is the same as the matching L restricted to vertices in Z.*

Proof. Consider any connected component C in the popular subgraph G_0. The component C splits into sub-components $C'_1, \ldots, C'_t$ when we restrict edges to only those marked "valid". We claim there is exactly *one* stable matching $T_{C'_j}$ in each such sub-component C'_j. Assume C'_j contains a job b that is a top choice neighbor for some agent.[3] Then b has to be matched in $T_{C'_j}$ to its most preferred neighbor a in C'_j, otherwise (a, b) would be a blocking edge to $T_{C'_j}$. Recall that every agent has exactly 2 valid edges incident to it. So fixing one edge (a, b) in the matching fixes $T_{C'_j}$.

In more detail, every agent $a' \neq a$ in C'_j such that $f(a') = b$ has to be matched in $T_{C'_j}$ to $s(a')$ (call it b'). Given that a' is matched to b', every agent $a'' \neq a'$ in C'_j such that $s(a'') = b'$ has to be matched in $T_{C'_j}$ to $f(a'')$ and so on. Thus the matching $T_{C'_j}$ gets fixed. The same happens with every sub-component in C and so the only stable matching in C is $T_C = \cup_{j=1}^{t} T_{C'_j}$.

Let $C_1, \ldots, C_r$ be the connected components of G_0 that contain vertices in Z. So all vertices in $\cup_{i=1}^{r} C_i$ are marked, thus $\cup_{i=1}^{r} C_i \subseteq Z \cup U_A \cup U_B$. We know from Lemma 21 that both M and L are stable matchings in each C_i, where $1 \leq i \leq r$. So M (similarly, L) restricted to $\cup_{i=1}^{r} C_i$ is $\cup_{i=1}^{r} T_{C_i}$. Thus M and L have the same edges on Z. ◀

Lemma 22 helps us in defining an appropriate witness $\vec{\alpha}$ to show M's popularity in G. Recall $\vec{\gamma}$ from Theorem 18: we will set $\alpha_u = 0$ for all $u \in Z \cup U_B$ and $\alpha_u = \gamma_u$ otherwise. Before we prove the popularity of M in Theorem 25, we need the following two lemmas.

▶ **Lemma 23.** *For every $a \in A_- \setminus Z_A$, a likes $M(a)$ at least as much as $L(a)$.*

Proof. Suppose not. Then $M(a) = s(a)$ while $L(a) = f(a)$. We claim $f(a) \in B_+$. Otherwise $f(a) \in B_-$, however for every edge $(x, y) \in A_- \times B_-$, we have $\mathsf{wt}_M(x, y) \leq \gamma_x + \gamma_y = -2$. But a prefers $f(a)$ to its partner in M, thus $\mathsf{wt}_M(a, f(a)) \geq 0$. Hence $f(a) \in B_+$. Since $\mathsf{wt}_M(x, y) \leq 0$ for every edge $(x, y) \in A_- \times B_+$, we can conclude that $\mathsf{wt}_M(a, f(a)) = 0$, i.e., $f(a)$ is matched in M to a neighbor $a' \in A_-$ that it prefers to a. Since S_i uses only valid edges, this means $f(a) = f(a')$, i.e., $f(a)$ is the top choice neighbor of a'.

[3] Otherwise C'_j consists of a single edge $(a, s(a))$ for some $a \in A$; if there was another agent u in C'_j then $s(u) = s(a)$ and so one of a, u would be left unmatched in S_i, a contradiction to S_i's stability in H.

We now move to the lower half of H: observe that both a and a' are in A'_-. This is because there is no unmarked vertex in $A_- \cap A'_+$ by the termination condition of our while-loop. Note that a is unmarked since $a \notin Z_A$. Thus a' is also unmarked since $(a, f(a))$ and $(a', f(a))$ are popular edges – hence a and a' are in the same connected component in G_0. Since $a \in A'_-$, $L(a) = f(a)$ is in B'_+. Consider the edge $(a', f(a)) \in A'_- \times B'_+$: both a' and $f(a)$ prefer each other to their respective partners in L. This means $\mathsf{wt}_L(a', f(a)) = 2$. However for each edge $(x, y) \in A'_- \times B'_+$, we have $\mathsf{wt}_L(x, y) \leq \beta_x + \beta_y = 0$, a contradiction. So any $a \in A_- \setminus Z_A$ likes $M(a)$ at least as much as $L(a)$. ◀

▶ **Lemma 24.** *For every $a \in A_+ \cap A'_+$, a likes $M(a)$ at least as much as $L(a)$.*

Proof. Suppose not. Then $M(a) = s(a)$ while $L(a) = f(a)$. Since $a \in A'_+$, $L(a) = f(a) \in B'_-$. This implies $f(a) \in B_-$ since there is no unmarked vertex in $B_+ \cap B'_-$ by the termination condition of our while-loop. We know $f(a)$ is unmarked since a (its partner in L) is unmarked and this is because $a \in A_+$. Since $a \in A_+$ and $f(a) \in B_-$, we have $\mathsf{wt}_M(a, f(a)) \leq \gamma_a + \gamma_b = 0$ and so $f(a)$ has to be matched in M to a more preferred neighbor $a' \in A_+$. As argued in the proof of Lemma 23, it follows from the legality of S_i that $f(a)$ is the top choice neighbor of a'.

Consider the matching L in the lower half of H. Since $L(a) = f(a)$, $\mathsf{wt}_L(a', f(a)) = 2$. That is, $(a', f(a))$ is a blocking edge to L. We need $\beta_{a'} = \beta_{f(a)} = 1$ to ensure $\beta_{a'} + \beta_{f(a)} \geq \mathsf{wt}_L(a', f(a)) = 2$. However $f(a) \in B'_-$ since $a \in A'_+$. This means $\beta_{f(a)} = -1$, a contradiction. Thus any $a \in A_+ \cap A'_+$ likes $M(a)$ at least as much as $L(a)$. ◀

▶ **Theorem 25.** *The matching M is popular in G.*

Proof. The popularity of M in G will be shown using $\vec{\alpha}$ defined below: (recall that $Z_A = Z \cap A$ and $Z_B = Z \cap B$)

- set $\alpha_u = 0\ \forall\, u \in Z \cup U_A \cup U_B$.
- set $\alpha_u = 1\ \forall\, u \in A_+ \cup (B_+ \setminus Z_B)$ and $\alpha_u = -1\ \forall\, u \in B_- \cup (A_- \setminus Z_A)$.

Since $M \subseteq (A_+ \times B_-) \cup (Z_A \times Z_B) \cup ((A_- \setminus Z_A) \times (B_+ \setminus Z_B))$ (see Fig. 5), we have $\sum_{u \in A \cup B} \alpha_u = 0$. Also $\alpha_u \geq \mathsf{wt}_M(u, u)$ for all vertices $u \in A \cup B$ since $\alpha_u = 0 = \mathsf{wt}_M(u, u)$ for $u \in U_A \cup U_B$ and $\alpha_u \geq -1 = \mathsf{wt}_M(u, u)$ for all other u. To use Theorem 6, we need to show $\alpha_a + \alpha_b \geq \mathsf{wt}_M(a, b)$ for all edges (a, b).

We will first show this constraint holds for edges incident to vertices in U_B. It is easy to show that the neighborhood of U_B is in A'_+ and also that each $a \in A'_+$ prefers its partner in L to $b \in U_B$. This is because $(b^-_\ell, b^+_r) \in S_i$ and b^+_r is b_ℓ's least preferred neighbor, thus b_ℓ must have been rejected by all its more preferred neighbors in our algorithm, i.e., every neighbor a^+_r of b_ℓ received a proposal from b^-_ℓ. Since a_r prefers superscript $-$ neighbors to superscript $+$ neighbors, this means $(c^-_\ell, a^+_r) \in S_i$ for some neighbor c^-_ℓ that a_r prefers to b^-_ℓ, i.e., a prefers c to b. Thus $a \in A'_+$.

We have $A'_+ = Z_A \cup (A'_+ \setminus Z_A)$ and $A'_+ \setminus Z_A \subseteq A_+$ (by the while-loop termination condition). Lemma 22 and Lemma 24 showed that for $a \in Z_A \cup (A_+ \cap A'_+)$, we have $M(a) \succeq_a L(a)$, i.e., a likes $M(a)$ at least as much as $L(a)$, and we showed above that each $a \in A'_+$ prefers $L(a)$ to b. Thus $\mathsf{wt}_M(a, b) = 0$. Since we set $\alpha_a = 0$ for $a \in Z_A$ and $\alpha_a = 1$ for $a \in A_+$, we have $\alpha_a + \alpha_b \geq 0 = \mathsf{wt}_M(a, b)$.

We now need to show $\alpha_a + \alpha_b \geq \mathsf{wt}_M(a, b)$ holds for all edges (a, b) in $G \setminus U_B$. Recall the witness $\vec{\gamma}$ defined in the proof of Theorem 18 to show the popularity of M in the subgraph $G \setminus U_B$. Observe that it is only for vertices u in Z that we have $\alpha_u \neq \gamma_u$. Moreover, $\alpha_a > \gamma_a$ for $a \in Z_A$. Thus we only have to worry about edges (a, b) in $G \setminus U_B$ where $b \in Z_B$ and check that $\mathsf{wt}_M(a, b) \leq \alpha_a + \alpha_b$. All other edges in $G \setminus U_B$ are covered by $\vec{\alpha}$ (since $\vec{\gamma}$ covers these edges). Let $b \in Z_B \subseteq B_+ \cap B'_-$.

1. Suppose $a \in U_A \cup Z_A$. For any $(a,b) \in (U_A \cup A_-) \times B_+$, we have $\mathsf{wt}_M(a,b) \le \gamma_a + \gamma_b \le 0+1$. Since $\mathsf{wt}_M(a,b)$ is an even number, this means $\mathsf{wt}_M(a,b) \le 0 = \alpha_a + \alpha_b$.
2. Suppose $a \in A_- \setminus Z_A$. Then $a \in A'_-$ by the termination condition of the while-loop in our algorithm. Since $\mathsf{wt}_L(x,y) \le \beta_x + \beta_y = -2$ for every edge $(x,y) \in A'_- \times B'_-$, it follows that $b \in Z_B \subseteq B'_-$ prefers $L(b)$ to a and similarly, $a \in A'_-$ prefers $L(a)$ to b.
   We know from Lemma 22 that $M(b) = L(b)$, so b prefers $M(b)$ to a. We know from Lemma 23 that $M(a) \succeq_a L(a)$ (i.e., a likes $M(a)$ at least as much as $L(a)$), so a prefers $M(a)$ to b. Thus $\mathsf{wt}_M(a,b) = -2 < \alpha_a + \alpha_b$ since $\alpha_a = -1$ and $\alpha_b = 0$.
3. Suppose $a \in A_+$. There are two sub-cases here: (i) $a \in A'_-$ and (ii) $a \in A'_+$. In sub-case (i), $\mathsf{wt}_L(a,b) \le \beta_a + \beta_b = -2$. Since $M(b) = L(b)$ (by Lemma 22), it means that b prefers $M(b)$ to a. Hence $\mathsf{wt}_M(a,b) \le 0 < \alpha_a + \alpha_b$ since $\alpha_a = 1$ and $\alpha_b = 0$ here.
   Consider sub-case (ii). We have $\mathsf{wt}_L(a,b) \le \beta_a + \beta_b = 0$. So either (1) b prefers $L(b)$ to a or (2) a prefers $L(a)$ to b. In case (1), we have $\mathsf{wt}_M(a,b) \le 0$ since $M(b) = L(b)$ (by Lemma 22). In case (2) also, we have $\mathsf{wt}_M(a,b) \le 0$ since $M(a) \succeq_a L(a)$ (by Lemma 24). So in both cases we have: $\mathsf{wt}_M(a,b) \le 0 < \alpha_a + \alpha_b$ since $\alpha_a = 1$ and $\alpha_b = 0$ here.

Thus $\vec{\alpha}$ is a witness of M's popularity (by Theorem 6). So M is popular in G. ◀

Since M is A-popular, Theorem 25 immediately implies that M is fully popular in G. Moreover, M is a *max-size* fully popular matching in G, as shown below.

▶ **Lemma 26.** *The matching M is a max-size fully popular matching in G.*

Proof. Observe that $U_A \cup U_B$ is the set of vertices left unmatched in the matching M. We claim the vertices in $U_A \cup U_B$ are left unmatched in any fully popular matching N. This claim holds because the matching S_i is the $(A_L \cup B_L)$-optimal matching in the lattice $\mathcal{D}_i$. Thus if $(a^-_\ell, a^+_r) \in S_i$, i.e., if a_ℓ is matched to its least preferred neighbor a^+_r in S_i then a_ℓ has to be matched to a^+_r in the realization N^*_α of N as well (for any witness $\vec{\alpha}$ of N), i.e., $(a^-_\ell, a^+_r) \in N^*_\alpha$; equivalently, a is left unmatched in N (after removing self-loops from N). Similarly, if $(b^-_\ell, b^+_r) \in S_i$ then b_ℓ has to be matched to its least preferred neighbor b^+_r in N^*_α as well, i.e., $(b^-_\ell, b^+_r) \in N^*_\alpha$; equivalently, b is left unmatched in N. ◀

Running time of the algorithm. The set of popular edges can be computed in linear time [7]. Similarly, the set of valid edges can be computed in linear time [2]. Gale-Shapley algorithm and in particular, the variant of Gale-Shapley algorithm used here – to compute a stable matching that avoids all forbidden edges – can be implemented to run in linear time [13]. Hence it can be shown that Algorithm 1 runs in linear time. Thus Theorem 4 stated in Section 1 follows.

Abstract

We consider the setting of combinatorial auctions when the agents are single-minded and have no contingent reasoning skills. We are interested in mechanisms that provide the right incentives to these imperfectly rational agents, and therefore focus our attention to *obviously strategyproof (OSP)* mechanisms. These mechanisms require that at each point during the execution where an agent is queried to communicate information, it should be "obvious" for the agent what strategy to adopt in order to maximise her utility. In this paper we study the potential of OSP mechanisms with respect to the approximability of the optimal social welfare.

We consider two cases depending on whether the desired bundles of the agents are *known* or *unknown* to the mechanism. For the case of known-bundle single-minded agents we show that OSP can actually be as powerful as (plain) strategyproofness (SP). In particular, we show that we can implement the very same algorithm used for SP to achieve a $\sqrt{m}$-approximation of the optimal social welfare with an OSP mechanism, m being the total number of items. Restricting our attention to declaration domains with two values, we provide a 2-approximate OSP mechanism, and prove that this approximation bound is tight. We also present a randomised mechanism that is universally OSP and achieves a finite approximation of the optimal social welfare for the case of arbitrary size finite domains. This mechanism also provides a bounded approximation ratio when the valuations lie in a bounded interval (even if the declaration domain is infinitely large). For the case of unknown-bundle single-minded agents, we show how we can achieve an approximation ratio equal to the size of the largest desired set, in an OSP way. We remark this is the first known application of OSP to multi-dimensional settings, i.e., settings where agents have to declare more than one parameter.

Our results paint a rather positive picture regarding the power of OSP mechanisms in this context, particularly for known-bundle single-minded agents. All our results are constructive, and even though some known strategyproof algorithms are used, implementing them in an OSP way is a non-trivial task.

1 Introduction

Algorithms might not have direct access to their inputs. This is by now a well-known issue, motivated by the internet and the self interests thereon. A body of work in computer science has been devoted to the design of algorithms that can faithfully elicit the input from their selfish sources. Typically, this is achieved through so-called mechanism design, a subdiscipline of game theory that studies the design of functions, or *mechanisms*, where the input is provided by multiple self-interested agents, and the output, or *outcome*, needs to satisfy a set of pre-specified desirable objectives. Each agent has a certain utility for each outcome. In its most general definition, a mechanism is given by a multi-round interaction protocol between a central authority and the agents, defining a game wherein the central authority wants to compute a certain function of the agents' inputs and the agents choose a strategy leading to the outcome that maximises their own utility. The main design requirements for such mechanisms are:

Strategyproofness (SP). There is a strategy for each agent that is guaranteed to result in a better outcome than any other strategy that the agent may adopt, irrespective of the other agents' strategies.

(Approximate) economic efficiency. The outcome of the mechanism must have a quality that is close to a theoretical optimum; this is often measured in terms of *social welfare*, i.e., the sum of all the agents' utilities.

Combinatorial auctions (CAs) have emerged as the paradigmatic problem in the area, exemplifying the tension between these two desiderata and the polynomial-time computation of the outcome. In CAs, we are given a set of items that need to be sold among a set of agents who are interested in buying the items. These agents express valuations for each of the items, or certain bundles of items, or even each possible bundle of items, depending on the level of complexity of the utility model that is assumed. A mechanism in this setting must determine how the items are allocated to the agents, and how much each agent is going to be charged.

Whilst it is not known to what extent it is possible to guarantee the properties above with polynomial-time algorithms, the design of mechanisms that satisfy these objectives is reasonably well-understood for some sufficiently simple auction settings. This is the case for the optimization problem of interest to this study, *single-minded combinatorial auctions*. In such a setting, there are multiple agents and multiple items to be allocated. An agent's utility function has a simple form: It is determined by a *valuation* of the set of items that the agent gets allocated, from which a potential payment charged by the mechanism is subtracted. The valuation function has the following structure: For an agent, say i, there is a number v_i and a subset of items R_i such that her valuation is v_i whenever the allocated bundle contains R_i, and 0 otherwise. The utility of each agent is therefore determined by a single pair (v_i, R_i). This simple setting has been the central object of study of the celebrated paper [17], where the authors design a simple greedy mechanism that is strategyproof and approximates the optimal social welfare to within a factor of $\sqrt{m}$, where m is the number of items. It is well-known that this combinatorial optimisation problem is NP-hard and inapproximable within a factor of $\sqrt{m}$ unless $\mathsf{NP} = \mathsf{ZPP}$ [14].

In many important cases, however, the implementation of strategyproof mechanisms can be too complex, unintelligible, unintuitive, or cognitively too demanding due to the limited ability of typical agents, such as, the capability to carry out *contingent reasoning*. Even for the simple setting of one-item auctions, a special case of single-minded agents, it is known how implementation details matter, see, for example, [2], for a discussion on the differences between sealed bid versus ascending bid auctions, and [15] for a related experimental study. We refer furthermore to [6] and [4] for further reading on the issue of contingent reasoning. Hence, the theoretically strong mechanisms that have been proposed in past mechanism design literature may be too difficult to understand and to use for agents with imperfect rationality.

This problem motivates the design of mechanisms with a reduced *cognitive burden* for agents who participate in the mechanism: Mechanisms should be very easy to understand, and transparent to participate in. While it is somewhat of a challenge to satisfactorily define formally what a "low cognitive burden" comprises, the concept of *obvious strategyproofness* (OSP) which has been introduced in [18] provides a strong and reasonably satisfactory notion in the context of agents unable to reason contingently. Informally, OSP requires that at each point during the execution of a mechanism where an agent is queried to reveal information (i.e., point where an agent is asked to make a decision about how the execution of the mechanism should proceed), it should be "obvious" for the agent what strategy to adopt in order to maximise her utility: For the agent, there must be a single choice for which it holds that all outcomes that can result from that choice are better for her than any other outcome that can result from an alternative choice. OSP therefore strengthens the classical notion of strategyproofness.

Our contributions. We study the extent to which OSP mechanisms can return good approximations to the optimal social welfare in the setting of single-minded combinatorial auctions. We measure the quality of mechanisms in terms of a relative approximation ratio. As in much of the literature on OSP, we assume that the set of possible types that the agents can have (which we refer to as the *declaration domain*) is publicly known; this is either finite or contained in a closed interval. As for the agents, we prove results depending on whether they are *known-bundle single-minded* – whereby the valuation v_i for agent i's desired bundle R_i is not known but R_i is – or, *unknown-bundle single-minded*, for which neither v_i nor R_i is known and must be elicited in an OSP way.

For the case of known-bundle single-minded agents, we provide the following results.

- If there are only two possible valuations, i.e., a low valuation L and a high valuation H, we express the characterisation of OSP mechanisms in [7] conveniently and design a deterministic OSP mechanism with an approximation ratio of 2, which we show to be the best possible. We give explicit payment functions for this mechanism and we can prove that truthtelling agents always have non-negative utility (a property known as individual rationality (IR)). We furthermore show that if the OSP mechanism were to use a fixed ordering of agents that does not depend on the instance, then the approximation guarantee of the mechanism is unbounded.
- If the declaration domain is an arbitrarily large finite set, we derive an OSP mechanism that achieves an approximation ratio of $\sqrt{m}$ to the optimal social welfare. This mechanism can be regarded as an obviously strategy-proof implementation of the mechanism in [17]. The payments here are implicitly given through the *cycle monotonicity* technique developed in [7]. Our mechanism makes use of the fact that the domain is finite and that the desired bundles are known.
- We further provide a randomised OSP and IR mechanism that achieves an approximation ratio strictly less than d, where d is the cardinality of the declaration domain. In particular, for arbitrary size finite domains of d valuations $V_1 < \cdots < V_d$, our mechanism achieves a $(d - V_1/V_2 - \cdots - V_{d-1}/V_d)$-approximation of the optimal social welfare. The idea behind this mechanism is to simply draw at random (with a carefully chosen probability

distribution) one value from the domain and ask agents if their valuation is at least as big; the mechanism thus stays OSP even if agents had access to the randomness used (i.e., they are "universally OSP"). We note that this result improves the aforementioned bound of 2 for two-value domains, and approaches 2 as $V_1/V_2 \to 0$. We also generalise this result for (uncountable) valuations contained in an interval $[a, b]$ and derive the continuous limit of the above mechanism, which results in an OSP and IR mechanism for this setting that achieves an approximation ratio of $1 + \ln(b/a)$ to the optimal social welfare. This means that the approximation ratio only grows logarithmically in the relative size of the interval.

The results above paint a rather positive picture regarding the power of OSP mechanisms for CAs with known-bundle single-minded agents. Firstly, our upper bound of $\sqrt{m}$, for finite valuation domains, matches what is known for strategyproofness – this is, to best of our knowledge, the first case in which OSP has been proved to be *as powerful as* SP. ([16] proves an asymptotic equivalence for randomised OSP without money for a variant of a scheduling problem.) The only additional time we need is used to sweep through the declaration domain of the agents, a seemingly unavoidable step to guarantee an OSP implementation of direct-revelation mechanisms. Secondly, this result shows that Deferred Acceptance (DA) auctions, whilst being OSP, are not the right algorithmic approach to optimise the approximation guarantee of OSP mechanisms. We in fact beat the lower bounds proved in [5] regarding the approximation guarantee of DA auctions in this setting. This observation reinforces the findings in [7, 9] concerning the power of DAs vs OSP, in the context of scheduling related machines. Thirdly, our tight bounds for two-value domains show (i) how the graph-theoretic approach to OSP in [7] can be made operational; and, (ii) that the order in which the mechanism queries the set of agents is of crucial importance in the design of the mechanism. Finally, our randomised OSP mechanisms show how it is possible to leverage "internal" chance nodes [18] and beat deterministic mechanisms, whilst agents do not need to compute expectations. This is to our knowledge the first known application of randomisation over OSP mechanisms.

OSP has so far only been considered for single-parameter settings, i.e., where the agents' private information is a single number, as no explicit technique is known to implement OSP mechanisms for higher dimensional settings. However, we complete this paper by giving the *first* OSP mechanism for agents with richer declaration domains. We in fact provide an OSP mechanism for the case of unknown-bundle single-minded agents, that returns an approximation of the optimal social welfare equal to the maximum size of a desired set R_i. This is an OSP implementation of the well-known Greedy-by-valuation algorithm for CAs. To obtain this result, we leverage the cycle monotonicity characterisation of OSP in [7] and an approach recently used in [10] to deal with long negative cycles. The idea is to give a structural property of the negative-weight cycles that have more than two vertices, for mechanisms that satisfy a natural notion of monotonicity between two instances. We then prove that any such mechanism that additionally queries the agents monotonically (that is, from an extreme of the domain to the other, irrespective of the desired set) cannot have any long negative-weight cycle. This is only proved to be a sufficient condition; the extent to which this is also necessary (proved to be true for single-parameter settings in [10]) will say whether our bound can be improved or not. This is the main open problem left by our work.

Further Related Work. The notion of OSP introduced in [18] has spawned numerous subsequent studies in both the computer science and economics community.

In [1], the authors study the OSP concept in the context of stable matchings and provide a suitable mechanism under an acyclicity assumption, as well as an impossibility result for a more general setting. The paper [3] further studies this concept for housing markets, single-peaked domains, and a general quasi-linear mechanism design setting. In [20] the authors study OSP mechanisms in general design domains where monetary transfers are not possible, and they provide a useful characterisation of OSP mechanisms in this setting.

OSP was investigated in machine scheduling domains and set system problems in [7], published in [9, 8], and furthermore a study was done in [11] where the authors prove that a restriction on the agents' declaration called *monitoring* can help obtain OSP mechanisms with a good approximation ratio in various mechanism design domains. The paper [16] builds forth on this by studying machine scheduling in the absence of monetary payments. For machine scheduling, a generalisation of OSP is furthermore studied in [13] where the restriction on the ability of agents to reason contingently is weakened, and the authors show that a large amount of "look-ahead"-ability is required for the agents in any mechanism that achieves a good approximation ratio in the considered scheduling setting. Another study that considers OSP under a restriction on the agents' behavior is [12], where the authors assume that non-truthful behaviour can be detected and penalised with a certain probability.

In [19] a revelation principle is presented that states that every social choice function implementable through an OSP mechanism can be implemented using a certain structured OSP protocol where agents take turns making announcements about their valuations.

2 Preliminaries

In a combinatorial auction we have a set U of m items and a set N of n agents. Each agent i has a *private* valuation function v_i and, in the general case, is interested in obtaining only one set in a *private* collection $\mathcal{S}_i$ of subsets of U, also called bundles. Thus, the valuation function maps subsets of items to nonnegative real numbers ($v_i(\emptyset)$ is normalised to be 0). The agents' valuations are monotone: for $S \supseteq T$ we have $v_i(S) \geq v_i(T)$. In single minded combinatorial auctions, $|\mathcal{S}_i| = 1$, each agent i is interested in obtaining only one particular subset of U; we denote i's desired bundle by R_i. This implies that agent i's valuation is the same for all supersets of R_i, while it is 0 otherwise. Formally, consider agent i and let $\mathcal{S}_i = \{R_i\}$. The valuation function of agent i for a given set S is

$$v_i(S) = \begin{cases} v_i & \text{if } S \supseteq R_i, \\ 0 & \text{otherwise.} \end{cases} \tag{1}$$

where (with a slight notation overloading) $v_i \in \mathbf{R}_{\geq 0}$ is a non-negative real number. Note that the valuation function of an agent i is fully represented by her desired set R_i and her valuation for that set v_i. The goal is to find a partition $(S_1, \ldots, S_n)$ of U such that $\sum_{i=1}^{n} v_i(S_i)$ –the *social welfare (SW)*– is maximised. We denote the optimal (maximum possible) social welfare by SW^* (we omit the dependence on the instance as it will be clear from the context).

We consider two versions of single-minded combinatorial auctions. In the case of *unknown-bundle single-minded agents*, we assume that the desired sets R_i and the valuations v_i are private knowledge of the agents, while in the *known-bundle single-minded agents* case, we assume that the desired sets R_i are known and only the valuations v_i are private knowledge of the agents. In each case, we refer to the private information of an agent as her *type*. Agents are typically asked to declare their types. We use D_i, the *declaration domain* of agent i, to denote the set of all possible types of agent i. In this paper we will consider declaration domains that are identical for all agents i, i.e., $D_i = D$. We use $\mathbf{b} = (b_1, \ldots, b_n)$ to denote declaration profiles, so that $b_i \in D$ stands for an agent i's demanded set R_i along with the valuation v_i that she has for it.

We want to design an auction mechanism that interacts with the agents in any sequence, and outputs (based on this interaction) an allocation A_i of items to each agent i, along with a payment $P_i > 0$ that is charged to each agent i. The *allocation function* satisfies that each item is allocated to exactly one agent. We refer to such a pair $(A = (A_1, \dots, A_n), P = (P_1, \dots P_n))$ as an *outcome.* We assume that agents have quasi-linear utility functions, that is, agent i with type b_i has a utility of

$$u_i(b_i, \mathbf{b}_{-i}) = v_i(A_i) - P_i$$

for outcome (A, P). Each agent will interact strategically with the mechanism, so as to make it output an outcome that maximises her utility.

When designing the mechanism, we want to define allocations and payments in such a way that they induce a certain type of behaviour of the strategically acting agents, while simultaneously ensuring that the outcome maximises or approximately maximises the social welfare. In particular, we aim to design *obviously strategyproof (OSP)* mechanisms. To define this notion, we view a mechanism in the form of an *implementation tree* $\mathcal{T}$ that captures the way in which the mechanism interacts with the agents [18, 7].

We now introduce some notation around $\mathcal{T}$ before we formally define the OSP notion. Each internal node u of $\mathcal{T}$ is labeled with an agent $\mathcal{Q}(u)$, called the *divergent agent* at u, and the outgoing edges from u are labeled with sets of types in the declaration domain of $\mathcal{Q}(u)$. At node u, the agent $\mathcal{Q}(u)$ is queried and asked to choose an action, that corresponds to selecting one of u's outgoing edges. The labels of the outgoing edges of u form a partition of the *current domain* of i, denoted as $D_i(u)$. The current domain $D_i(u)$ is equal to the label of the last edge e in the path from the root to u that i chose as an action. When player $\mathcal{Q}(u)$ chooses an outgoing edge at node u, we say that the chosen action *signals* that the type of $\mathcal{Q}(u)$ is in the set of types labeling the chosen edge. If a pair of types in the current domain of agent i occur in the labels of two distinct outgoing edges of u, we say that i is asked to *separate* the two possible types at u. The leaves of the tree will thus be linked to (a set of) type profiles; and at each leaf the mechanism will return an outcome (A, P) accordingly; in other words, each leaf corresponds to an outcome of the mechanism. (Observe that this means that the domain of A and P is effectively given by the leaves of $\mathcal{T}$.)

A mechanism (viewed in the form of an implementation tree as described above) is said to be OSP if at each node where an agent is asked to diverge, she *always* maximises her utility by choosing the edge (u, u') with the label containing her own type, in every node. That is, if we call the latter strategy s, then a mechanism is said to be OSP if the worst possible outcome after signaling her true type (taken over all the reachable outcomes in the leaves of the subtree rooted at u', with respect to s) gives her a utility *at least as good* as when she would get the best possible outcome after choosing any other edge (u, u'') at that particular point in the implementation tree (taken over all the outcomes in the leaves of the subtree rooted at u''). The corresponding utility-maximising strategies played by the players are called the *OSP strategies.* In cases where we discuss any particular OSP mechanism, we use $(A(\mathbf{b}), P(\mathbf{b}))$ to denote the outcome (i.e., allocation and payment vector) that results from agents playing their OSP strategies, i.e., strategy profiles where each agent at every node in the mechanism follows the edge containing her type.

We call a type profile $\mathbf{b}$ *compatible with* $u \in \mathcal{T}$ iff for each edge (u', u'') on the path from the root to u, the label of (u', u'') contains $b_{\mathcal{Q}(u')}$. We furthermore say that two type profiles $(t, \mathbf{b}_{-i})$ and $(b, \mathbf{b}'_{-i})$ *diverge* at u if $i = \mathcal{Q}(u)$ and t and b are labels of different edges outgoing from u (we sometimes will abuse this terminology and we also say that t and b diverge at u). For every agent i and types $t, b \in D_i$, we let $u^i_{t,b}$ denote a vertex u in the implementation tree $\mathcal{T}$, such that $(t, \mathbf{b}_{-i})$ and $(b, \mathbf{b}'_{-i})$ are compatible with u, but diverge at u for some $\mathbf{b}_{-i}, \mathbf{b}'_{-i} \in D_{-i}(u) = \times_{j \neq i} D_j(u)$. Note that such a vertex might not be unique as agent i will be asked to separate t from b in different paths from the root (but only once for every such path). We call these vertices of $\mathcal{T}$ *tb-separating* for agent i. For example, the node r in the tree in Figure 1 is an LH-separating node for agent 1; while v and w are two LH-separating nodes for agent 2.

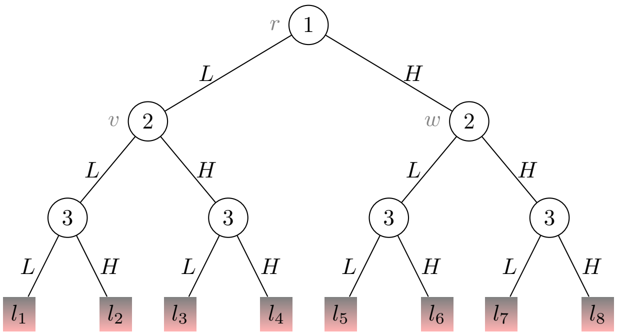

Figure 1 An implementation tree with three agents with two-value domains $\{L, H\}$; each agent separates the domain types upon playing; at each leaf l_i the mechanism computes $A(\mathbf{b})$ and $P(\mathbf{b})$, $\mathbf{b}$ being the declaration vector at l_i.

We also consider randomised mechanisms that are *universally OSP*, in Section 5. Such mechanisms are probability distributions on OSP mechanisms.

Besides the OSP requirement, we would like our mechanisms to satisfy *(ex-post) individual rationality (IR)*, i.e., when an agent plays an OSP strategy, the agent is guaranteed an outcome that gives her a non-negative utility. We measure the quality of mechanisms in terms of a relative *approximation ratio*, i.e., an upper bound on the ratio of the optimal social welfare and the social welfare of the outcome of the mechanism.

3 Deterministic mechanisms for known-bundle single-minded agents

We now focus on the case of known-bundle single-minded agents, i.e. the desired sets of the agents are known by the mechanism, and only the valuations of the agents for their corresponding desired set is private information. We let $v_i, i \in N$ denote the valuation of agent i for her desired bundle, and slightly abusing notation, we use $SW(I) = \sum_{i \in I} v_i$ where I is a set of agents who can be allocated their desired bundles at the same time.

3.1 Domains of size 2

We first restrict attention to the case where the declaration domain of each agent has two possible values and begin with a simple and elegant characterisation of individually rational OSP mechanisms for the case of known-bundle single-minded agents with two-value domains $D_i = \{L, H\}$, for $i \in N$.

▶ **Definition 1** ($\mathcal{C}$ mechanisms). *We define a class $\mathcal{C}$ of mechanisms, that only use the following types of queries:*

- L-query: *The divergent agent is asked to separate L and H. If she signals L then she will not get her desired bundle (regardless of the future).*
- H-query: *The divergent agent is asked to separate L and H. If she signals H then she is guaranteed to get her desired bundle.*

▶ **Theorem 2.** *The class $\mathcal{C}$ of mechanisms characterises deterministic IR and OSP mechanisms for the case where the declaration domain is $\{L, H\}$ and the desired bundles are known, in the following sense:*

- *There exist payments such that every mechanism in $\mathcal{C}$ is deterministic IR and OSP.*
- *Every deterministic IR OSP mechanism is equivalent to a mechanism in $\mathcal{C}$ with respect to their allocations, i.e. for every possible valuation profile of the agents, the allocations resulting from both mechanisms are identical.*

Proof. Regarding the first claim, fix the payment of an agent who is allocated her bundle to be L, and the payment to be 0 otherwise. It should be straightforward to see why pairing mechanisms in $\mathcal{C}$ with these payment yields a deterministic IR mechanism. Moreover, observe that regardless of the query, if an agent has valuation L, then her utility will be 0 regardless of her signals and allocation (even if she is allocated her bundle, then she will be asked to pay L). If an agent has valuation H and she is asked an L-query, she can only get positive utility for signaling her true valuation H, while if she is asked an H-query, she can guarantee herself the maximum possible utility under the mechanism $(H - L)$ again by reporting her true valuation H. This demonstrates that whenever an agent is asked to diverge, she is not worse off by acting according to her true type in *any* possible future scenario, hence OSP is satisfied.

Regarding the second claim, consider any OSP mechanism and its associated implementation tree $\mathcal{T}$. Clearly, since we are dealing with the case of two-type domains, if $\mathcal{T}$ has a node with more than two children, then this node can be pruned to yield an OSP mechanism where the node has exactly two children. Furthermore, nodes that have only one child are trivial and can be removed from the tree. So, at every node in $\mathcal{T}$ an agent is asked to separate L and H, and at any path from the root to a leaf in $\mathcal{T}$ each agent is only asked to diverge at most once.

Next, fix a node $u \in \mathcal{T}$ and let agent $i = \mathcal{Q}(u)$ be the divergent agent at u. Suppose for a contradiction that if i signals L when queried at u, then it is possible that i gets her desired bundle, while if i signals H then it is possible that i is not allocated her desired bundle. In other words, the corresponding subtrees of $\mathcal{T}$ have outcomes o_L where i gets her desired bundle when signaling L, and o_H where i doesn't get her desired bundle when signaling H. In this case the OSP condition would be violated at node u when $v_i = H$, as i's utility under o_H is lower than under o_L (by IR the payment under o_H is 0, while the payment under o_L is at most L). We can conclude that at any node $w \in \mathcal{T}$, either all possible outcomes when the divergent agent $j = \mathcal{Q}(w)$ signals L do not allocate j's desired bundle to j, or all outcomes when j signals H allocate j's desired bundle to j. These two alternatives correspond to the L-queries and H-queries in the definition of $\mathcal{Q}$. ◀

Next, we use the above characterisation theorem[1] to provide a tight bound on the approximability of the optimal social welfare under OSP mechanisms.

▶ **Theorem 3.** *The IS mechanism described in Algorithm 1 is an OSP mechanism that achieves an approximation ratio $\rho \leq 2$ for the case of known-bundle single-minded agents and domains of size 2.*

Proof. Consider any instance of the problem, let $I \subseteq N$ be the allocation output by IS, and let $I^* \subseteq [n]$ be the SW-maximising allocation according to the true valuations. Also fix $\mathcal{N}$ to its value at the last iteration of IS. At the last iteration of IS it holds that every agent in

[1] Note that Theorem 2 essentially expresses the cycle monotonicity property of [7] in a convenient way.

Algorithm 1 The IS mechanism.

```
1  $\mathcal{N} \leftarrow N$ ($\mathcal{N}$ is the set of agents currently under consideration) $A_q \leftarrow \emptyset$ ($A_q$ is the set of agents who have already been queried) $I \leftarrow \emptyset$ ($I$ is the set of agents currently allocated their desired bundle) $v_i = L$, for $i \in N$ (Our mechanism originally assumes that all agents have valuation $L$)
2  Compute the SW-maximising feasible allocation and update set $I$ accordingly
3  while there exists an agent $i \in \mathcal{N} \setminus A_q$ who is not in $I$ do
4      Perform an $L$-query to $i$ (break ties arbitrarily)
5      if $i$ signals $L$ then
6          $\mathcal{N} = \mathcal{N} \setminus \{i\}$
7      else
8          $v_i = H$
9      Compute the SW-maximising feasible allocation of items to agents in $\mathcal{N}$ and update $I$
10 Return $I$
11 If an agent $i$ is allocated her desired bundle, i.e. $i \in I$, charge her $L$, otherwise charge 0.
```

$N \setminus I$ has been queried. Mechanism IS belongs to the class $\mathcal{C}$ of mechanisms (Definition 1), and hence by Theorem 2 is IR and OSP. So, we can assume that the agents who have been queried have signaled their true valuation. Regarding the agents that have not been queried, the mechanism assumes valuation L when computing the SW-maximising allocation, while their true valuation could potentially be higher; all these agents have been allocated their desired bundle. This leads to the conclusion that I is the SW-maximising allocation of $\mathcal{N}$ with respect to the true valuations, which in turn implies that $SW(I) \geq SW(I^* \cap \mathcal{N})$.

We now claim that $SW(I) \geq SW(I^* \setminus \mathcal{N})$. Observe that any agent who does not belong to $\mathcal{N}$ has valuation L. All these agents were considered in line 2 of Algorithm 1 as having valuation L indeed; denote SW_1 the SW computed in line 2 of Algorithm 1. So, it holds that $SW(I^* \setminus \mathcal{N}) \leq SW_1 \leq SW(I)$, where the second inequality holds because the SW computed in Algorithm 1 can only increase between rounds.

Combining the above, we derive that $SW(I^*) = SW(I^* \cap \mathcal{N}) + SW(I^* \setminus \mathcal{N}) \leq 2SW(I)$, as desired. ◀

Next, we show that the above bound is tight by designing a family of instances where no mechanism can achieve an approximation ratio better than 2. This results shows a separation between obviously strategy proof mechanisms and strategy proof mechanisms, in terms of social welfare.

▶ **Theorem 4.** *For the setting that the domain is of size* 2 *and desired bundles are known, no OSP and IR mechanism can achieve an approximation ratio better than* 2.

Proof. By Theorem 2 we may restrict our analysis to mechanisms in class $\mathcal{C}$ as defined in Definition 1. Consider any such mechanism $M \in \mathcal{C}$.

Consider an instance with m items and a set N of $n = 2\sqrt{m}$ agents. For $i \in \{1, \ldots, \sqrt{m}\}$, define sets $S_i = \{(i-1)\sqrt{m}, (i-1)\sqrt{m}+1, \ldots, (i-1)\sqrt{m} + (\sqrt{m}-1)\}$ and $T_i = \{i-1, (i-1) + \sqrt{m}, (i-1) + 2\sqrt{m}, \ldots, i + (\sqrt{m}-1)\sqrt{m}\}$. Let agent $i \in \{1, \ldots, \sqrt{m}\}$ desire bundle S_i, and let agent $i \in \{\sqrt{m}+1, \ldots, 2\sqrt{m}\}$ desire bundle T_i. Note that the agents are intuitively split in two equal-sized groups, A and B, such that the desired bundle of an agent in A

overlaps with the desired bundle of all agents in B and vice versa. Consider such a split and let $G(i) \in \{A, B\}$ denote the group of agents that i belongs to, and $\overline{G(i)} = N \setminus G(i)$. The valuations of the agents in our instance depend on the sequence of queries made in the implementation tree $\mathcal{T}$ of mechanism M. We let $H = n/2$ and $L = 1$, and we define the valuations of the divergent agents in turn, starting with the first divergent agent and considering divergent agents in a sequence on the path of $\mathcal{T}$, where previous agents have signaled their true valuation. Let i refer to the agent whose valuation we define at the current step:

(i) If agent i is asked an L-query, no agent has been asked an H-query so far, and at least 3 agents in $\overline{G(i)}$ have not been queried at this point: Set $v_i = L$.

(ii) If i is the first agent that is asked an H-query, and there are at least 3 agents in $\overline{G(i)}$ that have not been queried at this point: Set $v_i = H$, set $v_j = L$ for each agent $j \in G(i)$ that has not been queried at this point, and set $v_j = H$ for each $j \in \overline{G(i)}$ that has not been queried at this point.

(iii) If no agent has been asked an H-query so far, and exactly 2 agents in $G(i) \setminus \{i\}$ have not been queried at this point: Set $v_i = H$, and set $v_j = L$ for every agent j that has not been queried at this point.

Observe that the above three points yield a complete and consistent specification of the valuations of all agents.

Clearly, in any mechanism with bounded approximation ratio, one of cases (ii) or (iii) in the definition of valuations above is realised, since otherwise, M will not allocate any desired bundle to any agent. Assume first that case (ii) is realised, and let i' be the agent who is H-queried at that point. i' will signal her true valuation H, and will be allocated her desired bundle by the definition of an H-query. Hence, no agent in $\overline{G(i')}$ can be allocated her desired bundle and there are at least 3 such agents with valuation H. Therefore the optimal social welfare in this case is at least $3H + (n/2 - 3)L$, but the mechanism can only allocate to a subset of $G(i)$, resulting in a social welfare of at most $H + (n/2 - 1)L$. Thus, the approximation ratio of M in this case is at least

$$\frac{3H + (n/2 - 3)L}{H + (n/2 - 1)L} = \frac{2n - 3}{n - 1} \tag{2}$$

on this instance.

Suppose now that case (iii) in the definition of valuations above is realised, and let i^* be the agent who is queried at that point. By definition of the instance, the optimal social welfare now is $H + (n/2 - 1)L$. In case M gives the desired bundles to a subset of agents in $G(i^*)$, then this subset may contain only agent i^* and the remaining two agents of $G(i^*)$ who have not been queried yet with valuation L, yielding a social welfare of $H + 2L$. Recall that everyone else in $G(i^*)$ has signaled L to an L-query, hence can not be allocated her desired bundle. In case M gives the desired bundles to a subset of agents in $\overline{G(i^*)}$, then the social welfare of M is at most $(n/2)L$. Thus, the approximation ratio of M in this case is at least $\frac{H+(n/2-1)L}{\max\{H+2L,(n/2)L\}}$. By setting $H = n/2$ and $L = 1$ we get

$$\frac{H + (n/2 - 1)L}{\max\{H + 2L, (n/2)L\}} = \frac{n - 1}{n/2 + 2} = \frac{2n - 2}{n + 4}. \tag{3}$$

The limit of both bounds (2) and (3) as $n \to \infty$ is 2, and this proves the claim. ◀

We now provide a stronger inapproximability bound for the case where the mechanism is restricted to be *instance-independent*, i.e., the mechanism's implementation tree is not dependent on the demanded bundles of the agents. That is, there is a mapping from nodes in the implementation tree to queried players and respective query types, and this mapping is *fixed*, i.e., it is *not* a function of the demanded bundles of the agents. Note that e.g. the mechanism of Theorem 3 is *not* instance-independent, because the order in which the players are queried and the types of queries that the mechanism asks, do depend on the demanded bundles of the players.

▶ **Theorem 5.** *No instance-independent mechanism has a bounded approximation ratio.*

Proof. Consider any instance-independent OSP and IR mechanism M. We define the instance (valuations and desired bundles) that yields the upper bound by considering the sequence of queries made in the implementation tree $\mathcal{T}$ of M. We start with the first divergent agent and consider divergent agents in a sequence on the path of $\mathcal{T}$, where previous agents have signaled their true valuation. Let i refer to the ith queried agent, whose valuation is v_i and whose desired bundle is R_i. Let $\overline{Q(i)}$ denote the set of agents who have not been queried yet at the time that i is queried by the mechanism. As $\mathcal{T}$ is instance-independent, we may construct an instance with a bad approximation ratio for this mechanism by letting the agents' valuation and demanded bundles depend on the sequence of queries that the mechanism asks. We do this as follows:

(i) If agent i is asked an L-query: Set $v_i = L$ and let R_i comprise a single item that does not belong to the desired bundle of any other agent.

(ii) If agent i is asked an H-query: Set $v_i = H$ and $v_j = H$ for each agent $j \in \overline{Q(i)}$. Let R_j comprise a single item, distinct for each $j \in \overline{Q(i)}$ and not being desired by any previously considered agent. Also, let $R_i = \cup_{j \in \overline{Q(i)}} R_j$.

In any mechanism with a finite approximation ratio, case (ii) in the definition of the instance above is realised, since otherwise, M will not allocate any desired bundle to any agent. Suppose ℓ L-queries are asked before the first H-query on the path of $\mathcal{T}$ discussed in the definition of the instance. The optimal social welfare is at least $\ell L + (n - \ell - 1)H$, while M can only obtain social welfare equal to H by allocating to the agent who got the H-query. Thus, the approximation ratio ρ of M is at least

$$\rho \geq \frac{\ell L + (n - \ell - 1)H}{H} = \frac{(n-1)H - \ell(H - L)}{H} \geq \frac{(n-1)L}{H}, \tag{4}$$

since $\ell \leq n - 1$. The ratio can be made arbitrarily high, for suitable values of L and H. ◀

3.2 Large domains

In this section we prove an upper bound of $\sqrt{m}$ for the approximation ratio of OSP mechanisms for known-bundle single minded agents and arbitrary domains. We begin with definitions of classes of mechanisms that are of interest. First, we define extremal mechanisms. Informally, the queries of an extremal mechanism always separate an extreme of the current domain of the queried agent from the rest of her current domain (the same extreme is chosen consistently). Formally,

▶ **Definition 6** (Extremal mechanism). *A mechanism with implementation tree $\mathcal{T}$ is an extremal mechanism if for each internal node $u \in \mathcal{T}$, and divergent agent $i = \mathcal{Q}(u)$ at u, agent i's current domain $D_i(u)$ is partitioned by the query at u into a singleton, containing the maximum element (or minimum element, consistently), and the remaining elements of $D_i(u)$.*

Algorithm 2 An extensive-form implementation of the Greedy algorithm in [17] for known-bundle single-minded agents.

```
1  Define function $\Phi_i$ as $\Phi_i(x) = x/\sqrt{|R_i|}$.
2  $\mathcal{P} \leftarrow \emptyset$ ($\mathcal{P}$ is the set of bundles that have already been allocated) $\mathcal{N} \leftarrow N$ ($\mathcal{N}$ is the
     set of agents currently under consideration) $\mathcal{D}_i \leftarrow D_i$ for all $i \in N$ ($\mathcal{D}_i$ is the set of
     values in $i$'s domain currently under consideration)
3  while $\mathcal{N} \neq \emptyset$ do
4      Let $j = \arg\max_{k \in \mathcal{N}} \Phi_k(\max \mathcal{D}_k)$
5      if there is $S$ in $\mathcal{P}$ such that $R_j \cap S \neq \emptyset$ then
6          $\mathcal{N} = \mathcal{N} \setminus \{j\}$
7      else
8          Ask $j$ if her valuation is $\max \mathcal{D}_j$
9          if yes then
10             $\mathcal{P} \leftarrow \mathcal{P} \cup \{R_j\}$
11             $\mathcal{N} = \mathcal{N} \setminus \{j\}$
12         else
13             $\mathcal{D}_j = \mathcal{D}_j \setminus \{\max \mathcal{D}_j\}$
14 Return $\mathcal{P}$
```

▶ **Definition 7** ($\mathcal{C}_d$ mechanisms)**.** *We define a class $\mathcal{C}_d$ of mechanisms, whose implementation tree $\mathcal{T}$ satisfies:*

- *Consider a divergent agent i who is asked to separate between valuations v_i and v_i' with $v_i < v_i'$ at some internal node $u \in \mathcal{T}$. Consider any outcome o_{v_i} in the subtree rooted at u consistent with signaling valuation v_i. Then if i is allocated her desired bundle under o_{v_i}, she also gets her desired bundle in all possible outcomes consistent with signaling valuation v_i' at u.*

▶ **Theorem 8.** *Every extremal mechanism that belongs to class $\mathcal{C}_d$ is OSP.*

Theorem 8 is a special case of Theorem 12 which we present in Section 4. We note that Theorem 8 is one direction of the characterisation in [10].

▶ **Theorem 9.** *Algorithm 2 is an OSP mechanism that achieves an approximation ratio $\rho \leq \sqrt{m}$, for the case of known-bundle single-minded agents.*

Proof. The approximation guarantee of the algorithm is well known in the literature, cf. [17]. By Theorem 8, it remains to prove that Algorithm 2 is extremal and belongs to class $\mathcal{C}_d$. Indeed, observe that queries only take place in line 8 of the algorithm, where the corresponding divergent agent is asked to separate the maximum value in her current domain from all other possible values.

We will now prove that the algorithm belongs to class $\mathcal{C}_d$ (see Definition 7). Indeed, when an agent is queried in line 8 then she is allocated her set when replying yes (as feasibility has been previously guaranteed). Since we only query for the maximum in the current domain of each agent, this implies that the agent would still be allocated her desired bundle had her true valuation (and signals) been higher. ◀

4 Deterministic mechanisms for unknown-bundle single-minded agents

In this section we prove an upper bound to the approximability of the optimal social welfare of single-minded combinatorial auctions by OSP mechanisms. It is now assumed that both the desired bundle of the agent and her valuation for it belong to her type, hence are private information. We first define a general class of mechanisms which we prove are OSP. We then provide an implementation of the known Greedy-by-valuation mechanism and prove that it belongs to this class.

Let us define the class of valuation-extremal mechanisms. Informally, the queries of a valuation-extremal mechanism at every node separates extreme valuations in the current domain of the queried agent from the rest of her current domain (where the same extreme is chosen consistently). Formally,

▶ **Definition 10** (Valuation-extremal mechanism). *A mechanism with implementation tree $\mathcal{T}$ is a valuation-extremal mechanism if for each internal node $u \in \mathcal{T}$, and divergent agent $i = \mathcal{Q}(u)$ at u, it holds that either agent i's current domain, $D_i(u)$, comprises a single valuation, or $D_i(u)$ is partitioned by the query at u into a set containing all the pairs $(v, S) \in D_i(u)$, where v is the maximum valuation (or minimum valuation, consistently) in $D_i(u)$, and the remaining elements of $D_i(u)$.*

▶ **Definition 11** ($\mathcal{C}^u_d$ mechanisms). *We define a class $\mathcal{C}^u_d$ of mechanisms, whose implementation tree $\mathcal{T}$ satisfies:*

- *Consider a divergent agent i who is asked to separate between $(v_i, S_i) \neq (v'_i, S'_i)$ with $v'_i \geq v_i$ and $S' \subseteq S$, at some internal node $u \in \mathcal{T}$. Consider any outcome $o_{(v_i,S_i)}$ in the subtree rooted at u consistent with signalling type (v_i, S_i). Then if i is allocated her desired bundle under $o_{(v_i,S_i)}$, she also gets her desired bundle in all possible outcomes consistent with signalling type (v'_i, S'_i) at u.*

▶ **Theorem 12.** *Every valuation-extremal mechanism that belongs to class $\mathcal{C}^u_d$ is OSP.*

Theorem 12 extends the result in [10] to the more general case of multi-dimensional agents. Due to lack of space, the proof is omitted.

Algorithm 3 presents an implementation of the known Greedy-by-valuation mechanism for the case of unknown-bundle single minded agents.

▶ **Theorem 13.** *Algorithm 3 is an OSP mechanism that achieves an approximation ratio $\rho \leq \delta$ for the case of unknown-bundle single-minded agents, where δ is the size of the largest desired set.*

Proof. The approximation guarantee of the algorithm is folklore. By Theorem 12, it remains to prove that Algorithm 3 is valuation-extremal and belongs to class $\mathcal{C}^u_d$. Indeed, note that when an agent is queried in line 4 then she is separating all types with valuation v', which is the maximum compatible valuation at this point of the execution, with all types consistent to smaller values v (regardless of the desired bundles).

We will now prove that the algorithm belongs to class $\mathcal{C}^u_d$ (see Definition 11). Let u be the node of the implementation tree in which (v, S) is separated from (v', S') with $v' \geq v$ and $S' \subseteq S$; clearly there is nothing to separate if $v = v'$ and $S = S'$. Consider first the case that $v' > v$; u corresponds to a query at line 4. Assume that there exists $\mathbf{b}_{-i} \in D_{-i}(u)$ for which S is won by agent i when playing according to (v, S). This means that S is feasible

Algorithm 3 An extensive-form implementation of the Greedy-by-valuation algorithm.

```
1  $\mathcal{P} \leftarrow \emptyset$ ($\mathcal{P}$ is the set of bundles that have already been allocated) $\mathcal{N} \leftarrow N$ ($\mathcal{N}$ is the
   set of agents currently under consideration) $\mathcal{D}_i \leftarrow D_i$ for all $i \in N$ ($\mathcal{D}_i$ is the set of
   values in $i$'s domain currently under consideration)
2  while $\mathcal{N} \neq \emptyset$ do
3      Let $j = \arg\max_{k \in \mathcal{N}} \max \mathcal{D}_k$
4      Ask $j$ if her valuation is $\max \mathcal{D}_j$
5      if yes then
6          Ask agent $j$ to reveal her desired set $R_j$
7          if there is $S$ in $\mathcal{P}$ such that $R_j \cap S \neq \emptyset$ then
8              $\mathcal{N} = \mathcal{N} \setminus \{j\}$
9          else
10             $\mathcal{P} \leftarrow \mathcal{P} \cup \{R_j\}$
11             $\mathcal{N} = \mathcal{N} \setminus \{j\}$
12     else
13         $\mathcal{D}_j = \mathcal{D}_j \setminus \{\max \mathcal{D}_j\}$
14 Return $\mathcal{P}$
```

at u; since $S' \subseteq S$ then S' is also feasible at that point. Therefore, the feasibility check in line 7 is successful and S' is won by agent i playing according to (v', S') irrevocably at that point, that is for any $\mathbf{b}_{-i} \in D_{-i}(u)$, as requested. Consider now the case in which $v' = v$ and $S' \subset S$; u corresponds to a query at line 6. Again, if S is feasible at this point of the execution, so is S'. Therefore, S' is allocated if S is, and the proof is complete. ◀

5 Randomised mechanisms for known-bundle single-minded agents

In this section we consider randomised mechanisms that are universally OSP. We note that the bounded rationality assumption that motivates OSP does not prevent agents from using and understanding such a mechanism, as they do not need to compute expected utilities to determine obvious dominance. We start by presenting a class of randomised mechanisms that are universally OSP.

▶ **Definition 14** ($\mathcal{M}_R$ mechanisms)**.** *We define a class $\mathcal{M}_R$ of randomised mechanisms, that work as follows:*

- *Fix some probability distribution F on the domain D of valuations of all agents. A mechanism $M \in \mathcal{M}_R$ selects one of the values v in D according to F and asks every agent if her valuation is at least equal to v. M selects the maximum number of agents whose requests can be satisfied simultaneously, allocates them their desired bundles and charges each of them v.*

▶ **Lemma 15.** *Any mechanism $M \in \mathcal{M}_R$ is universally OSP.*

Proof. We claim that any mechanism that belongs to class $\mathcal{M}_R$ is a randomisation among different deterministic OSP mechanisms. Indeed, fix a value $v \in D$ and consider the mechanism that queries all agents if their valuation is at least equal to v and outputs a feasible solution that allocates their desired bundles to the maximum number of agents who reply *yes*. It should be easy to see that if, when queried, an agent signals *yes* when her true valuation is smaller than v, then the best she can achieve is 0 utility, which is what she would achieve by signalling truthfully. On the other hand, if, when queried, an agent signals *no* when her true valuation is at least equal to v, then the best she can achieve is 0 utility, which is at least what she would achieve by signalling truthfully. ◀

▶ **Theorem 16.** *Consider mechanism $M_F \in \mathcal{M}_R$ (Definition 14), where F is a probability distribution assigning probability p_j to value $V_j \in D$, with $V_j > V_{j-1}$, for $j \in \{1, \dots, d\}$ (set $V_0 = 0$), as follows:*

$$p_1 = \left(d - \sum_{j \le d} \frac{V_{j-1}}{V_j} \right)^{-1} \quad \textit{and} \quad p_j = p_1 \left(1 - \frac{V_{j-1}}{V_j} \right), \textit{ for } j \in \{2, \dots, d\}.$$

Then M_F is a universally OSP randomised mechanism that achieves a $\min \left\{ d, 1 + \ln \left(\frac{V_d}{V_1} \right) \right\}$-approximation of the optimal SW for known-bundle single-minded agents, where $d = |D|$.

Proof. Lemma 15 straightforwardly implies that M_F is universally OSP. Denote by T_j the set of agents who are allocated their desired bundles after M_F selects V_j with probability p_j. Also, let T_j^* denote the set of agents i such that $v_i = V_j$ who are allocated their desired bundle in the optimal allocation.

For the optimal social welfare, SW^*, it holds that

$$SW^* = \sum_{j \le d} V_j \cdot |T_j^*|$$

We bound the social welfare SW of M_F as follows.

$$\begin{aligned} SW &= \sum_{j \le d} p_j V_j \cdot |T_j| \ge \sum_{j \le d} p_j V_j \left(\sum_{j \le \ell \le d} |T_\ell^*| \right) \\ &= \sum_{j \le d} |T_j^*| \cdot \sum_{\ell \le j} p_\ell V_\ell = \sum_{j \le d} |T_j^*| \sum_{\ell \le j} p_1 \left(1 - \frac{V_{\ell-1}}{V_\ell} \right) V_\ell \\ &= p_1 \sum_{j \le d} |T_j^*| \sum_{\ell \le j} (V_\ell - V_{\ell-1}) = p_1 \sum_{j \le d} |T_j^*| \cdot V_j \\ &= p_1 \cdot SW^*, \end{aligned}$$

where the inequality holds because by definition of mechanism M_F, T_j is the maximum cardinality set of agents with valuations at least V_j that can be satisfied simultaneously, and the third equality uses the definition $V_0 = 0$.

Thus, the approximation ratio ρ of this mechanism satisfies

$$\rho \le \frac{1}{p_1} = d - \sum_{2 \le j \le d} \frac{V_{j-1}}{V_j} \tag{5}$$

So, the right-hand-side of (5) is strictly less than d. It remains to prove that $\rho \le 1 + \ln(\frac{V_d}{V_1})$. The expression in (5) is maximised if $\sum_{2 \le j \le d} V_{j-1}/V_j$ is minimised. Letting $X_1, \dots, X_{d-1}$ denote the ratios $V_1/V_2, \dots, V_{d-1}/V_d$, and letting c denote the ratio V_1/V_d, this amounts to minimising $\sum_{i \in [d-1]} X_i$ subject to $\prod_{i \in [d-1]} X_i = c$. By the inequality of arithmetic and geometric means it holds that $\sum_{i \in [d-1]} X_i \ge n \cdot c^{1/d-1}$ for any solution to this minimisation problem, and furthermore this holds with equality for the solution where $X_i = c^{1/d-1}$ for all

$i \in [d-1]$. We conclude from this that the expression in (5)) is maximised if all the ratios V_{j-1}/V_j in the summation are equal (for a fixed choice of V_d/V_1), and this is achieved by setting $V_j = V_d^{\frac{j-1}{d-1}}$ so that $V_{j-1}/V_j = (V_d/V_1)^{-1/(d-1)}$, for all $2 \leq j \leq d$. Inequality (5) then yields

$$\rho \leq d - (d-1)\left(\frac{V_d}{V_1}\right)^{\frac{-1}{d-1}} \leq 1 + \ln\left(\frac{V_d}{V_1}\right), \tag{6}$$

where the last inequality holds because $1 + \ln(V_d/V_1)$ is the limit of the left hand side, and the left hand side is increasing in d. This completes the proof. ◀

We note that a similar bound of $O(\ln(r))$ can be achieved in settings where the valuation space is uncountable and contained in an interval $[a, b]$ with $b/a = r$. One can define a continuous version of M_F by deriving its limit running on D_ϵ as ϵ approaches 0. The mechanism would then work as follows:

(i) Draw a valuation $x \in [a, b]$ according to the cumulative distribution function F, with $F(x) = \frac{\ln(x/a)+1}{\ln(r)+1}$.

(ii) Ask each agent whether her valuation exceeds x.

(iii) Compute the maximum cardinality feasible solution T_x among all yes-responding agents.

A similar analysis to that in the proof of Theorem 16 yields the desired bound.

Abstract

The random-order or *secretary* model is one of the most popular beyond-worst case model for online algorithms. While this model avoids the pessimism of the traditional adversarial model, in practice we cannot expect the input to be presented in perfectly random order. This has motivated research on *best of both worlds* (algorithms with good performance on both purely stochastic and purely adversarial inputs), or even better, on inputs that are a *mix* of both stochastic and adversarial parts. Unfortunately the latter seems much harder to achieve and very few results of this type are known.

Towards advancing our understanding of designing such robust algorithms, we propose a random-order model with *bursts* of adversarial time steps. The assumption of burstiness of unexpected patterns is reasonable in many contexts, since changes (e.g. spike in a demand for a good) are often triggered by a common external event. We then consider the *Knapsack Secretary* problem in this model: there is a knapsack of size k (e.g., available quantity of a good), and in each of the n time steps an item comes with its value and size in $[0,1]$ and the algorithm needs to make an irrevocable decision whether to accept or reject the item.

We design an algorithm that gives an approximation of $1-\tilde{O}(\Gamma/k)$ when the adversarial time steps can be covered by $\Gamma \geq \sqrt{k}$ intervals of size $\tilde{O}(\frac{n}{k})$. In particular, setting $\Gamma = \sqrt{k}$ gives a $(1-O(\frac{\ln^2 k}{\sqrt{k}}))$-approximation that is resistant to up to a $\frac{\ln k}{\sqrt{k}}$-fraction of the items being adversarial, which is almost optimal even in the absence of adversarial items. Also, setting $\Gamma = \tilde{\Omega}(k)$ gives a constant approximation that is resistant to up to a constant fraction of items being adversarial. While the algorithm is a simple "primal" one it does not possess the crucial symmetry properties exploited in the traditional analyses. The strategy of our analysis is more robust and significantly different from previous ones, and we hope it can be useful for other beyond-worst-case models.

1 Introduction

In standard competitive analysis of online algorithms, one assumes that an adversary completely defines the input. While this is a useful model for designing algorithms for many problems, for many others this model is too pessimistic and no algorithm can outperform the trivial ones. One classical example is the *Secretary Problem* and its generalizations. In this problem, one is presented a sequence of n items of values $v_1, \ldots, v_n$. Upon each arrival,

47th International Colloquium on Automata, Languages, and Programming (ICALP 2020).

one has to decide *irrevocably* if one accepts or rejects the item, without knowing the value of future items in the sequence. The goal is to select a single item in order to maximize the value obtained. It is easy to see that in the adversarial model the best guarantee possible is to obtain expected value that is a $\frac{1}{n}$-fraction of the offline optimum, and this is achieved by the trivial algorithm that chooses one of the n time steps at random and blindly accepts the item in this time step.

In order to avoid the pessimism of this model and allow for the design of non-trivial algorithms with *hopefully* better performance in practice, there has been a push to consider *beyond worst-case* models. One of the most prominent such models is the *random-order model*, where the adversary can choose the set of items in the instance, but they are presented in uniformly random order. This model has been studied since at least the 60s and has seen a lot of developments in the past decade, and several problems are now well-understood under this model, such as Knapsack and more generally Packing LPs [21, 3, 2, 28, 18, 16, 1], assignment problems [8, 12, 18], matroid optimization [4, 6, 23, 13, 14], and many more. For example, for the Secretary Problem in the random-order model one can obtain a $\frac{1}{e}$-fraction of the offline optimal value (as $n \to \infty$) with the following classical threshold-based algorithm: reject the first $\frac{1}{e}$-fraction of items but note their maximum value, then select the next element which exceeds this value if such an element appears.

However, in practice we cannot expect the sequence to arrive exactly in random order. This has motivated research on *best of both worlds*, namely algorithms with good performance on both purely stochastic and purely adversarial inputs [25, 26, 22, 27]. Even more interesting are algorithms that work well on inputs that are a *mix* of both stochastic and adversarial parts. But this seems to be much harder to achieve: in online algorithms we are only aware of the results of [11] on budgeted allocation (see Section 1.3 for a description of their model and assumptions), while in online learning results of this type have only been obtained very recently for multi-armed bandits [29, 24, 30, 15]. We note that all these results are for settings in which non-trivial guarantees can be achieved for pure adversarial inputs.

Towards advancing our understanding of designing such robust algorithms, we introduce a model that mixes random-order and adversarial time steps, assuming that the latter comes in *bursts*. The random-order times represent when the environment is in a "stationary" or "predictable" state, while the adversarial times represent "unexpected" patterns. The assumption of burstiness of unexpected patterns is reasonable in many contexts, since changes are often triggered by an external common event, e.g., the surge in gun sales after news of possible changes in gun control regulations. See [19, 20, 9, 7] for examples of the different ways in which burstiness can be modeled and areas of applications.

1.1 The *Bursty Adversary plus Random Order* (BARO) model

We describe more formally the general version of the proposed model BARO. Consider an online problem where decisions are made sequentially and irrevocably at times $1, 2, \ldots, n$. In our model, the adversary first chooses some the time steps $Adv \subseteq [n]$ to be "adversarial" and leaves the others $RO = [n] \setminus Adv$ as "random-order" times. In order to capture the burstiness of the adversarial time steps in a clean way, let $\mathbb{W}$ be the partition of $[n]$ into disjoint intervals of length ℓ. We then assume that the adversarial times Adv are covered by at most Γ intervals in $\mathbb{W}$. Notice that this allows various patterns in the adversarial part of the input, including individual (non-bursty) adversarial times as well as bursts of size much larger than ℓ, for a total of up to $\Gamma\ell$ adversarial times. As in the standard random-order model, the items/inputs on the random-order times RO are arbitrary but presented in uniformly random order. The *sequence* items/inputs on the adversarial times Adv is fully adversarial that can be adaptively generated based on an algorithm's behavior and may even depend on the *order* of the items in RO.

It is important to highlight that the algorithm does not know which time steps are adversarial or random-order, and that in each time step only one item arrives (i.e., the adversarial items do not come in batches).

Note that in many problems this adversary can make an instance completely adversarial by sending "dummy" random-order items. For example, in the Secretary Problem the adversary can set the value of all random-order items to be 0; so again no non-trivial guarantees is possible in this case. In order to obtain meaningful guarantees, we compare the algorithm's performance only to the optimum over the random-order times RO, which we denote by OPT_{RO}. Thus, in a maximization problem we say that an algorithm is *α-competitive* in the BARO model if the expected value of the algorithm is at least $\alpha \mathrm{OPT}_{RO}$.

1.2 Our Results

In this paper we use the BARO model to obtain a more robust algorithm for the *Knapsack Secretary* problem, a well-studied generalization of the Secretary Problem. The offline version of the problem is the standard Knapsack Problem: there are n items, each with a value $v_i \geq 0$ and size $w_i \in [0,1]$, and we have a knapsack of size k; the goal is to select a subset of items with total size at most k, and with total value as large as possible.

Our main result is an algorithm for the Knapsack Problem in the BARO model that is resistant to a fraction of items being adversarial.

▶ **Theorem 1.** *There is a* $\big(1 - O\big(\frac{\Gamma\ell}{n} \ln \frac{n}{\Gamma\ell}\big)\big) = \big(1 - O\big(\frac{\Gamma \ln k}{k} \ln \frac{k}{\Gamma \ln k}\big)\big)$*-competitive algorithm for the Knapsack Problem in the BARO model where the adversarial times can be covered by* $\Gamma \geq \sqrt{k}$ *windows of size* $\ell = \frac{n \ln k}{k}$.

Notice that the term $\frac{\Gamma\ell}{n}$ in the guarantee is precisely the fraction of adversarial items that the algorithm can cope with. For example, setting $\Gamma = \sqrt{k}$, our algorithm obtains a $(1 - O(\frac{\ln^2 k}{\sqrt{k}}))$-approximation in the presence of up to a $O(\frac{\ln k}{\sqrt{k}})$-fraction of items being adversarial. For large k this approximation is almost optimal: even in the absence of adversarial items (and even when all items are unit-sized) the best approximation possible is $1 - \Omega(\frac{1}{\sqrt{k}})$ [21] (and this is achieved for example by [28, 18, 1, 16]). Note that these competitive ratios go to 1 as the budget $k \to \infty$ (recall the normalization of sizes being at most 1). Moreover, with $\Gamma = \Omega(\frac{n}{\ell})$ the algorithm achieves a constant approximation in the presence of a constant fraction of adversarial items.

Primal Algorithm with Time-Based Constraints. Our starting point is the *primal* strategy for the random-order model, whose high-level idea is the following: At time t, one solves a knapsack LP with the items seen so far but with budget proportionally scaled to be $\lceil \frac{t}{n} k \rceil$, and pick (a fraction of) the item at time t exactly as prescribed by the optimal LP solution, if there is space available in the full budget of k.

While this strategy obtains the optimal guarantee in the random-order model [18], it fails in the presence of adversarial items. One way in which it fails is by picking "too many items": Suppose that the first k items are adversarial, have size 1, and they all have infinitesimal values but sorted in increasing order, and the random-order items have all value and size equal to 1; it is easy to see that the primal algorithm will pick all the adversarial items, filling up the budget with items of infinitesimal value. (Similar examples exist where the adversarial items are not in the beginning of the sequence.) To counter this, in our algorithm we add additional restrictions, outside of the LP, that the algorithm can only pick a constant mass of items in each window of size $\ell \approx \frac{n}{k}$, which is roughly the behavior of the optimal solution if the n items were in random order.

However, the algorithm may now fail by picking "too few" items: consider the same example as before but now all the adversarial items have value $1+\varepsilon$, thus slightly more valuable than the random-order items. The algorithm will then only pick 1 of these adversarial items (by the new restriction added) and will not pick any of the random-order items, since the LP will always fill up its budget with the better adversarial items; so the algorithm obtains value $1+\varepsilon$, while the $\mathrm{OPT}_{RO} = k$. To avoid this, we also add additional constraints *to the LP* that its solution can select at most a constant number of items in each window of size $\ell \approx \frac{n}{k}$ (note there are $\frac{t}{n}k$ disjoint such windows in $[t]$ and the LP selects total size $\approx \frac{t}{n}k$, again on average 1 per window).

The main difficulty is analyzing the algorithm in the presence of the additional restrictions/constraints. Previous analyses of primal-style algorithms crucially relied on the fact the LP (and its optimal solution) was invariant to the permutation of items/coordinates. This brings about some crucial independence properties: Decisions at time t are independent of the *order* of the arrivals at times $1,\ldots,t-1$ and therefore of the respective decisions. This property allows for the direct use of known concentration inequalities to control the total occupation incurred by the algorithm.

Since our new restrictions/constraints are not permutation invariant, we need to use a different type of analysis. The main handle is what we call the *weighted rank* of an item: the sum of the weights of items with higher value density $\frac{v_i}{w_i}$ than this item, divided by the knapsack capacity. That is, it is by how much one would have to scale the knapsack capacity before the offline optimum would start picking this item. The very high-level idea of the analysis is intuitive: The higher the weighted rank of an item, the smaller its probability of being picked by the LP, even with the new constraints. In addition, while there are complicated dependencies between the events "the algorithms picks the item at time t", the weighted ranks of the items in the random-order times are almost independent: they are just sampled without replacement. We leverage this to obtain custom concentration inequalities that control the algorithm's occupation of the different restrictions/constraints.

1.3 Related Work

As already pointed out above, many algorithms have been proposed for online optimization problems with random arrival order. However, these algorithms usually break when moving to the BARO model. For concreteness, let us illustrate the effect on Kleinberg's algorithm [21] for the multiple-choice secretary problem, a special case of our problem. The algorithm is allowed up to k selections. Throughout the sequence, it never picks items which are not among the best k so far. Therefore, we can construct the following counterexample. Consider a sequence starting with an adversarial burst of k items of very high value, followed by a random-order sequence with items of smaller values. On this sequence, the algorithm will not pick any random-order items at all. If $n \gg k$, then with high probability (over the randomness of the algorithm) none of the adversarial items are picked either (the threshold-based algorithm for the secretary problem is applied to the first $\approx \frac{n}{k}$ items w.h.p., in which case the first $\approx \frac{1}{e}\frac{n}{k} \gg k$ items are rejected). This argument transfers immediately to other algorithms, such as [2, 18]. Other algorithms such as the one by [1] or by [4] use the beginning of the sequence to estimate the optimal value, which also fails in this sequence.

There is only surprisingly little work when it comes to non-uniform random order model. Recently, [17] introduced models where the order of the items is "much less random" than the uniform random order. Among other results, they show that it is possible to obtain constant-competitive algorithms for the Multiple-choice Secretary Problem under these weaker assumptions, and quantify the minimum entropy of the distribution over orders that admits constant-competitive algorithms for the Secretary Problem. We remark that these models do not explicitly contain adversarial items.

Closer in spirit to our model, [11] consider online budgeted allocation in an online model that mixes both stochastic and adversarial inputs. They provide algorithms that are optimal when the input is totally adversarial, and whose performance improves when the instance becomes "more stochastic". There are two crucial differences between our proposed model and Esfandiari et al.'s model: in the latter, while the adversarial items may appear at any point in the sequence (i.e., no burstiness assumption), it is assumed that the algorithm *knows* the distribution of the items in the non-adversarial times, unlike in our model. Also, unlike the Knapsack Problem studied here, the budgeted allocation problem has constant-competitive algorithms even in the adversarial model. Thus, while to some extent an algorithm does not need to worry about "losing everything" if it is fooled by the adversarial part of the instance, its design and analysis have to be delicate enough to obtain fine control over the constants in the competitive-ratio in order to yield interesting results.

In a very recent paper, Bradac et al. [5] present several results for robust secretary problems in a mixed model very similar to ours, which was inspired by a discussion about a preliminary version of this present paper. In contrast to our model, there is no assumption on the number or burstiness of adversarial rounds, making the results incomparable. Our focus is to understand situations in which we are close to the optimal guarantee without adversarial rounds. Since their adversary is more powerful, the guarantees are worse in two ways: (i) Their benchmark is weakened by leaving out the best item. (ii) The guarantees depend on the overall number of rounds n, whereas ours only depend on k. The techniques are also quite different.

2 BARO Knapsack: model and algorithm

Model. We consider an online knapsack problem. The algorithm knows upfront the knapsack size k and the number of items n, and the items are presented online, one-by-one. In the t-th time step, the current item's value V_t and size W_t are revealed, and the algorithm needs to irrevocably decide what fraction $X_t^{alg} \in [0,1]$ of this item to select. Our algorithm's selection is always integral, i.e., $X_t^{alg} \in \{0,1\}$, but our point of comparison is the best fractional solution. The selections made by the algorithm need to fit the knapsack, namely $\sum_{t\in[n]} W_t X_t^{alg} \leq k$ with probability 1, and it tries to maximize the total value of its selections: $\sum_{t\in[n]} V_t X_t^{alg}$. Importantly, the choice in the t-th step has to be made only knowing $V_1, \dots V_t$ and $W_1, \dots, W_t$ (as well as k and n).

The sequences $V_1, \dots, V_n \geq 0$ and $W_1, \dots, W_n \in [0,1]$ are generated by the following *Bursty Adversary plus Random Order* (BARO) model. Let us fix a window size ℓ, and let $\mathbb{W}$ denote the collection of disjoint windows of size ℓ that partitions the time steps $[n]$, that is, $\mathbb{W} = \{\{1,2,\dots,\ell\}, \{\ell+1,\dots,2\ell\}, \dots\}$. For concreteness we will use window size $\ell := \frac{n \ln k}{k}$. The adversary first partitions the n times steps into sets *Adv* (adversarial) and *RO* (random-order) with the property that *Adv* can be covered by Γ windows in $\mathbb{W}$; we use $\mathbb{W}^{adv} \subseteq \mathbb{W}$ to denote one such cover, fixed throughout. The adversary also fixes the items for the random-order times, namely the value/size pairs $(v_1, w_1), (v_2, w_2), \dots, (v_{|RO|}, w_{|RO|})$, with $w_i \in [0,1]$ for all i. Moreover, for each random-order time $t \in RO$, nature samples *without replacement* an index I_t from $\{1, 2 \dots, |RO|\}$, i.e., randomly chooses which random-order item will appear at that time. Then, for each time step t the adversary outputs an item with value V_t and size $W_t \in [0,1]$ as follows:

- (Adversarial) If $t \in Adv$, the adversary outputs an item with arbitrary value V_t and size $W_t \in [0,1]$; this may depend on an algorithm's behavior and on the I_t's.
- (Random-order) If $t \in RO$, the adversary outputs the item indexed by I_t, namely that with value $V_t := v_{I_t}$ and size $W_t := w_{I_t}$.

Note that there is a subtle difference between capital and small letters here. By V_t and W_t, we refer to the value and weight of the item *arriving in the t-th step.* By v_i and w_i we refer to the i-th random-order item specified by the adversary *before the random permutation is applied.* Consequently, V_t and W_t are random variables whereas v_i and w_i are not. Furthermore, since the I_t's are sampled without replacement, the items $((V_t, W_t))_{t \in RO}$ in the random-order times are precisely the items $(v_1, w_1), (v_2, w_2), \ldots, (v_{|RO|}, w_{|RO|})$ randomly permuted.

Again we highlight that the algorithm does not know which time steps are adversarial and which are random-order, and that the adversarial items do not come in batches. As mentioned before, the benchmark for comparison is the offline optimum for the problem on the random-order items alone, namely $\mathrm{OPT}_{RO} := \max\{\sum_i v_i x_i : \sum_i w_i x_i \leq k,\ x \in [0,1]^{|RO|}\}$.

Algorithm. The algorithm we propose is a modification of the primal method of [18] and can be described as follows. Let $\mathbb{W}_t$ be the collection of windows $\mathbb{W}$ truncated to the prefix $[t]$, namely $\{1, \ldots, \ell\}, \{\ell+1, \ldots, 2\ell\}, \ldots, \{\lfloor \frac{t}{\ell} \rfloor \ell + 1, \ldots, t\}$. At time t, in order to compute its selection $X^{alg}_t \in \{0,1\}$ of the current item, the algorithm first finds an optimal solution X^t to the following (random) linear program LP_t:

$$\begin{aligned} &\max \sum_{t' \leq t} V_{t'} X_{t'} \\ &s.t. \sum_{t' \leq t} W_{t'} X_{t'} \leq c_t \frac{t}{n} k && \text{(main inner budget)} \\ &\qquad \sum_{t' \in B} W_{t'} X_{t'} \leq a_1 \frac{\ell}{n} k, \quad \forall B \in \mathbb{W}_t && \text{(inner constraints)} \\ &\qquad X \in [0,1]^t, \end{aligned}$$

where we introduce the slight budget scaling $c_t := (1 - \frac{4\Gamma\ell}{t})$, and set the constant $a_1 := 601$. If $X^t_t > 0$, we say that the algorithm *tentatively picks* the item at time t. The algorithm checks if it can permanently pick this item by verifying whether its past selections $X^{alg}_1, \ldots, X^{alg}_{t-1}$ satisfy the following constraints:

$$\begin{aligned} &\sum_{t' < t} W_{t'} X_{t'} \leq k - 1 && \text{(main budget)} \\ &\sum_{t' \in B_{\text{last}}} W_{t'} X_{t'} \leq a_4 \frac{\ell}{n} k - 1, && \text{(outer constraint)} \end{aligned}$$

where B_{last} denotes the last window in $\mathbb{W}_{t-1}$, and a_4 is a sufficiently large constant (set in Lemma 13). If so, the algorithm fully picks the item, namely it sets $X^{alg}_t = 1$; otherwise we say that it is *blocked* and it does not pick the item at all, setting $X^{alg}_t = 0$.

To get some intuition why the algorithm is reasonable, let us observe how the "offline optimum" OPT_{RO} builds up over time. We can define random variables X^*_t indicating what fraction of the item arriving at time t is packed in OPT_{RO}. Because the permutation is uniformly random, these random variables are identically distributed for all $t \in RO$. More specifically, we have $\mathbb{E}[V_t X^*_t] = \mathrm{OPT}_{RO}/|RO| \approx \mathrm{OPT}_{RO}/n$ and $\mathbb{E}[W_t X^*_t] \leq k/|RO| \approx k/n$. So, *in expectation*, slightly scaled versions of the random variables fulfill all constraints stated above. Our algorithm, of course, does not know X^*_t but tries to mimic this process. Particularly, the goal of (inner constraints) and (outer constraint) is to spread out the choices made by the algorithm over time so that the consequences of adversarial bursts are mitigated.

Notice that by construction the solution X^{alg} returned by the algorithm is always feasible, namely $\sum_{t \le n} W_t X^{alg}_t \le k$. Thus, we only need to argue that it obtains enough value.

▶ **Theorem 2** (Total value). *The expected value of the solution X^{alg} returned by the algorithm satisfies*

$$\mathbb{E}\left[\sum_{t \in RO} V_t X^{alg}_t\right] \ge \left(1 - O\left(\frac{\Gamma \ell}{n} \ln \frac{n}{\Gamma \ell}\right)\right) OPT_{RO}.$$

Roadmap of the analysis. In Section 3 we upper bound for each random-order time t the probability that the algorithm tentatively selects that item. Next, we boost this per-time upper bound into concentration inequalities for the volume of the selections made up to a given point, and use it to upper bound the probability that the algorithm is blocked by constraint (main budget) or (outer constraint), in which case it would not be able to make permanent its tentative selection (Section 4). Using this, we lower bound the value obtained by the algorithm in each (free) random-order time step (Section 5), and add over all such time steps to show that the algorithm obtains the desired value (Section 6). Due to space constraints, the proofs of several lemmas are deferred to the full version of the paper.

Without loss of generality we assume that the random-order times are sorted in decreasing order of value density, namely $\frac{v_1}{w_1} \ge \frac{v_2}{w_2} \ge \ldots \ge \frac{v_{|RO|}}{w_{|RO|}}$. Also, we say that an item is **better** than another if it has higher value density. For simplicity, we also assume that no item has value or weight equal to 0 (else automatically exclude/include in the solution), and that the sum of all item sizes is at least the knapsack size k. We also assume that there are no ties in the value densities $\frac{v_i}{w_i}$; this can be accomplished by infinitesimal perturbations to the values, for example. We also assume $\frac{n}{2} \ge k \ge 80$ and that $\frac{\Gamma \ell}{n} \le \frac{1}{2}$, so at most half of the windows can have adversarial items. With overload of notation, we use I_t to denote the actual item (pair (V_t, W_t)) at time t, even when t is an adversarial time.

3 Controlling tentative selections via weighted rank

We use $T_t := \mathbf{1}(X^t_t > 0)$ to denote the indicator of *tentative* selection by the algorithm at time t. Our goal in this section is to argue that the algorithm does not tentatively select too many items. As mentioned before, the main handle for making this formal is the notion of *weighted rank*. The weighted rank of the random-order item i is a $\frac{1}{k}$ scaling of the sum of the weights of random-order items better than it (recall these items are sorted in decreasing order of value density $\frac{v_i}{w_i}$).

▶ **Definition 3** (Weighted rank). *The* weighted rank *of the random-order item i is $r_i := \frac{1}{k} \sum_{i' < i} w_{i'}$ (we also define $r_{|RO|+1} = \frac{1}{k} \sum_i w_i$ for convenience). For a random-order time t, we use $R_t := r_{I_t}$ to denote the total weighted rank of the item I_t at this time.*

As before, one interpretation of the weighted rank r_i is the following: considering the offline problem with only random-order items, r_i is by how much we need to scale the knapsack of size k before the optimal fractional solution wants to pick a strictly positive fraction of item i. Thus, the higher the rank the worse the item is.

The main result of this section says that the worse the item at time t is, the less likely the algorithm is to tentatively pick it (the extra conditioning on items $(I_{t'})_{t' \in S}$ will be technically useful later and may be ignored throughout at a first read).

▶ **Lemma 4** (UB tentative selection). *Consider a random-order time $t \geq 8\ell(\Gamma+1)$, and a set S of random-order times with $|S| \leq \frac{\ln k}{4}$. Then*

$$\Pr\left(T_t = 1 \;\middle|\; R_t,\, (I_{t'})_{t' \in S}\right) \leq \psi(R_t), \qquad \textit{where } \psi(\gamma) = \begin{cases} 1, & \textit{if } \gamma < 1 \\ \frac{2}{k}, & \textit{if } \gamma \in [1, 50] \\ 4ke^{-\frac{\gamma}{20}\ln k}, & \textit{if } \gamma > 50. \end{cases}$$

For the rest of the section we prove this result. At its heart is the following deterministic monotonicity property of the LP: Fix a scenario (so the LP is deterministic); if there *is* a solution for the LP with only items better than I_t that saturates the main budget, then I_t is not included at all in the *optimal* LP solution. This is clear if we did not have the inner constraints: The optimal LP solution is obtained by the greedy procedure, and if we can saturate the budget with only better items the greedy will stop before reaching I_t. While this does not necessarily hold in the presence of general side constraints, we show it still does under the simple inner constraints. The proof is deferred to the full version of the paper.

▶ **Lemma 5.** *Consider a time $t \in [n]$, and fix a scenario $I_1, I_2, \ldots, I_n$. Suppose that there is a feasible solution $\bar{X}$ of LP_t with $\sum_{t' \leq t} W_{t'} \bar{X}_{t'} = c_t \frac{tk}{n}$ and whose support only includes times with items strictly better than I_t (i.e., $\bar{X}_{t'} > 0$ implies that $I_{t'}$ is strictly better than I_t, for all $t' \in [t]$). Then in any optimal solution X^* of LP_t we have $X^*_t = 0$. (Thus, I_t is not tentatively selected by our algorithm.)*

Our next lemma will leverage this result to show that if there are many items in random-order-only windows better than I_t, then the probability of tentatively selecting the latter is small. Before that, we need to introduce the definition of *free time*, the ones we will focus on for most of the analyses.

▶ **Definition 6** ($\textsc{Free}_t$ and RO_t). *A time is* free *if it does not belong to one of the adversarial windows $\mathbb{W}^{adv}$. We use $\textsc{Free}_t$ to denote the collection of free times in $[t]$. Furthermore, $\mathbb{W}^{free}_t$ denotes the windows from $\mathbb{W}_t$ that only contain free times.*

We also use $RO_t := RO \cap [t]$ to denote all the random-order times (free or otherwise) in $[t]$. With slight abuse in notation, we also use RO_t to denote the cardinality *of RO_t.*

The following estimates follow directly from the assumption that there are at most Γ adversarial windows, each of size ℓ.

▶ **Observation 7.** *The following holds: (a) If $t \geq 2\Gamma\ell$ then $|\textsc{Free}_t| \geq \frac{t}{2}$; (b) $\frac{1}{RO_n} \leq \frac{1}{|\textsc{Free}_n|} \leq \frac{1}{n}(1 + \frac{2\Gamma\ell}{n})$.*

▶ **Lemma 8.** *Consider a random-order time $t \geq 2(\Gamma\ell + 1)$. For a value $\gamma \geq 0$, let G_γ be the event that the sum of the sizes of the items in the times $\textsc{Free}_t$ that are better than I_t equals $\gamma c_t \frac{tk}{n}$ (i.e., $\sum_{t' \in \textsc{Free}_t : I_{t'} < I_t} W_{t'} = \gamma c_t \frac{tk}{n}$). Then for any set of random-order times $S \subseteq RO$ with $|S| \leq \frac{\ln k}{4}$, we have*

$$\Pr(T_t = 1 \mid G_\gamma, I_t, (I_{t'})_{t' \in S}) \leq \frac{1}{2}\psi(\gamma) = \begin{cases} \frac{1}{k}, & \textit{if } \gamma \in [1, 50] \\ 2ke^{-\frac{\gamma}{20}\ln k}, & \textit{if } \gamma > 50. \end{cases}$$

Proof. Condition on I_t, $(I_{t'})_{t' \in S}$, and on the *set* of items $\{I_{t'}\}_{t' \in \textsc{Free}_{t-1}}$ in the free times in a way that the event G_γ holds; let ω denote this conditioning. If suffices to show the upper bound $\Pr(T_t = 1 \mid \omega) \leq \frac{1}{2}\psi(\gamma)$, and the lemma follows by taking expectation with respect to multiple of these ω's. Also notice that this conditioning does not fix the *relative order* of the items in $\textsc{Free}_{t-1} \setminus S$, thus: ($\star$) The items at times $\textsc{Free}_{t-1} \setminus S$ are in random order even when conditioning on ω.

Let E be the event that there is a feasible solution X for LP_t whose support only has items better than I_t and that saturates the main budget, i.e., $\sum_{t' \leq t} W_{t'} X_{t'} = c_t \frac{tk}{n}$. From Lemma 5, whenever E holds I_t is *not* tentatively selected, so it suffices to *lower bound* the probability $\Pr(E \mid \omega)$.

Case 1: $\gamma \in [\mathbf{1}, \mathbf{50}]$**.** If for each of the free windows $\mathbb{W}^{\mathit{free}}_{t-1}$ the total size of items better than I_t in the window is at most $a_1 \ell \frac{k}{n}$ (not "too many good items" in any free window), then any (fractional) selection of these items of total size $c_t \frac{tk}{n}$ gives a feasible solution for LP_t saturating the main budget, so E holds; notice that it is possible to select this much size because we are in the case $\gamma \geq 1$. The intuition is that since the total size of these good items is $\gamma c_t \frac{tk}{n} \leq 50 \frac{tk}{n}$, each window should have about $\frac{\ell}{t} \cdot 50 \frac{tk}{n} = 50 \ell \frac{k}{n}$ of their size in it, so with high probability no window has more than $a_1 \ell \frac{k}{n}$ of their size (recall $a_1 \gg 50$). More formally, consider a free window $B \in \mathbb{W}^{\mathit{free}}_{t-1}$. Let $Z_{B \setminus S} = \sum_{t' \in B \setminus S} \mathbf{1}(I_{t'} < I_t) \cdot W_{t'}$ be the sum of sizes of items in $B \setminus S$ better than I_t, and let $Z = \sum_{t' \in \textsc{Free}_{t-1} \setminus S} \mathbf{1}(I_{t'} < I_t) \cdot W_{t'}$. Notice that under the conditioning ω, Z is a fixed number satisfying $Z \leq \gamma c_t \frac{tk}{n} \leq \gamma \frac{tk}{n}$, and that $Z_{B \setminus S}$ is a sum of terms sampled without replacement from the terms in Z (because of observation ($\star$)). Thus, we have

$$\begin{aligned} \mathbb{E}\left[Z_{B \setminus S} \mid \omega\right] &= \frac{|B \setminus S|}{|\textsc{Free}_{t-1} \setminus S|} \mathbb{E}[Z \mid \omega] \leq \frac{\ell}{|\textsc{Free}_{t-1}| - \ln k} \cdot \frac{\gamma t k}{n} \\ &= \frac{t}{|\textsc{Free}_{t-1}| - \ln k} \cdot \gamma \ell \frac{k}{n} \leq 3 \gamma \ell \frac{k}{n}, \end{aligned}$$

where the last inequality uses the fact that $t \geq 2\Gamma\ell + 1$, Observation 7, and the assumptions $\Gamma \geq \sqrt{k}$ and $k \geq 80$. Moreover, we can apply the Bernstein's Inequality for sampling without replacement (Corollary 2.3 of [16]) conditionally to the sum $Z_{B \setminus S}$ to obtain

$$\Pr\left[Z_{B \setminus S} \geq 600 \ell \frac{k}{n} \;\middle|\; \omega \right] \leq 2 \exp\left(-\frac{9}{7} 3 \gamma \ell \frac{k}{n} \right) \leq 2 \frac{1}{k^3} \leq \frac{1}{k^2},$$

where in the first inequality we also used that $\tau \geq 3 \cdot 3 \gamma \ell \frac{k}{n}$ because $\gamma \leq 50$, and in the last inequality that $k \geq 80$. Since $|S| \leq \frac{\ln k}{4}$ and each item has size at most 1, the items in $B \cap S$ have total size less than $\ell \frac{k}{n}$. Thus, the conditional probability is at most $\frac{1}{k^2}$ that the total size of items in B better than I_t is at least $a_1 \ell \frac{k}{n}$ ("too many good items"). Since there are fewer than k windows, by taking a union bound over all free windows $B \in \mathbb{W}^{\mathit{free}}_t$ we see that with probability at least $1 - \frac{1}{k}$ none of these windows has too many good items. Thus, $\Pr(E \mid \omega) \geq 1 - \frac{1}{k}$.

Case 2: $\gamma > \mathbf{50}$**.** The number of windows in $\mathbb{W}^{\mathit{free}}_{t-1}$ of size ℓ (i.e., possibly excluding the last window) is at least $\mathit{num} := \frac{t}{\ell} - \Gamma - 1$. If in each such window the total size of items better than I_t is at least $2\ell \frac{k}{n}$ ("good items everywhere"), then one can (fractionally) select up to $2\ell \frac{k}{n}$-mass of them in each window and get a feasible solution for LP_t that saturates the main budget; this saturation is possible because this can give a total of size $(2\ell \frac{k}{n}) \cdot \mathit{num} \geq c_t \frac{t}{n} k$ of these better items, where the last inequality uses $t \geq 2\ell(\Gamma + 1)$. Since in this case event E holds, it suffices to lower bound the probability of having good items everywhere. The intuition again is that by assumption there is total mass $\gamma c_t \frac{tk}{n} \geq 12 \frac{tk}{n}$ of these better items, so each window should have about $\frac{\ell}{t} \cdot 12 \frac{tk}{n} = 12 \ell \frac{k}{n}$ size in it, and with high probability all of them should have at least $2\ell \frac{k}{n}$ size in it.

More precisely, considering any fixed window $B \in \mathbb{W}^{free}_{t-1}$ it is easy to obtain the lower estimate $\mathbb{E}\left[Z_{B\setminus S} \,\middle|\, \omega\right] \geq \frac{\gamma \ell k}{3n}$ and again applying Bernstein's Inequality we get $\Pr\left[Z_{B\setminus S} \leq 2\ell\frac{k}{n} \,\middle|\, \omega\right] \leq 2\exp\left(-\frac{\gamma}{20}\ln k\right)$. Taking a union bound over the at most k such windows, the probability that we have enough good items in each window in $\mathbb{W}^{free}_{t-1}$ of size ℓ is at least $1 - 2ke^{-\frac{\gamma}{20}\ln k}$. This concludes the proof. ◀

To conclude the proof of Lemma 4, we show that the item at time t having rank R_t implies with high probability that G_{R_t} holds (actually that the weight in $\textsc{Free}_t$ of items better than I_t is *at least* $R_t c_t \frac{tk}{n}$); this is a consequence of the definition of rank and concentration. With these final details, presented in the full version of the paper, we have the proof of Lemma 4.

4 Controlling the probability of being blocked

In this section we show that with good probability, when the algorithm tentatively selects an item, it also permanently selects it, i.e., it is not blocked by the constraints (main budget) and (outer constraint). More precisely, let $O_t := W_t X^{alg}_t$ be the actual occupation incurred by the the algorithm at time t. We use F_t to denote the indicator of the event that the algorithm is *not* blocked at time t, i.e., $F_t = 1$ if (again B_{last} is the last window in $\mathbb{W}_{t-1}$)

$$\sum_{t' \in B_{\text{last}}} O_{t'} \leq a_4 \frac{\ell}{n} k - 1 \qquad \text{and} \qquad \sum_{t'<t} O_{t'} \leq k - 1, \tag{4.1}$$

otherwise $F_t = 0$. The following is the main result of this section.

▶ **Lemma 9** (Probability of being blocked). *For all free times $t \geq 8\ell(\Gamma+2)$, the probability of being blocked is upper bounded as $\Pr(F_t = 0 \mid I_t) \leq \frac{O(1)}{k\left(1-\frac{t}{n}-a_5\frac{\Gamma \ln k}{k}\right)^2}$, for some constant a_5.*

To prove this lemma, we will upper bound the probability that either of the two parts of (4.1) is violated. For the first part, this will be Lemma 13. The bound for the second part is Lemma 14. Lemma 9 then follows by a union bound.

While the first part of (4.1) only concerns the occupation from free time steps, the second part also includes non-free ones. To control this second part, we will nonetheless focus on the occupation over the free windows; for non-free windows B the outer constraints guarantee $\sum_{t' \in B} O_{t'} \leq O(\frac{\ell k}{n}) = O(\ln k)$, and so all the Γ of these windows combined can consume only $O(\Gamma \ln k)$ of the budget (so, for example, in the important case $\Gamma = \sqrt{k}$ this is negligible).

For the free time steps, it suffices to upper bound the (permanent) occupation O_t by the *tentative occupation* $O'_t := W_t T_t$: For the algorithm to select the item at time t, it is necessary but not sufficient that $T_t = 1$. Therefore, we have $O_t \leq O'_t$ and we focus on controlling the O'_t's from now on.

As a start, we use Lemma 4 to show that in each free time step the expected tentative occupation $\mathbb{E}[O'_t]$ is at most $\approx \frac{k}{n}$; thus, essentially both (4.1) hold in expectation. While what we actually need is a generalization of this result, we present it to illustrate the techniques in a clearer way.

▶ **Lemma 10** (UB tentative occupation). *For all free times $t \geq 8\ell(\Gamma+1)$, we have $\mathbb{E}\left[O'_t\right] \leq \frac{k}{RO_n}\left(1 + O\left(\frac{1}{k}\right)\right)$.*

Proof. Since fixing I_t fixes W_t, using Lemma 4 we have

$$\begin{aligned} \mathbb{E}\, O'_t = \mathbb{E}\, W_t T_t &= \mathbb{E}_{I_t}\left[W_t \cdot \mathbb{E}[T_t \mid I_t]\right] \\ &= \mathbb{E}_{I_t}\left[W_t \cdot \Pr(T_t = 1 \mid I_t)\right] \overset{L.4}{\leq} \mathbb{E}_{I_t}\left[W_t \cdot \psi(R_t)\right] = \frac{1}{RO_n}\sum_i w_i\, \psi(r_i). \end{aligned}$$

Since by definition of rank $r_j = \frac{1}{k}\sum_{j'<j} w_{j'}$, we have $r_{i+1} - r_i = \frac{w_i}{k}$, and thus $w_i = k \cdot \int_{r_i}^{r_{i+1}} 1 \,\mathrm{d}x$. Applying this to the last displayed inequality we get

$$\mathbb{E}\, O'_t \leq \frac{k}{RO_n} \sum_i \int_{r_i}^{r_{i+1}} \psi(r_i)\,\mathrm{d}x. \tag{4.2}$$

Since the item sizes are at most 1, we have $r_{i+1} \leq r_i + \frac{1}{k}$ and so $x - \frac{1}{k} \leq r_i$ for all $x \in [r_i, r_{i+1}]$. Thus, as the function ψ is nonincreasing, the right-hand side of (4.2) is at most

$$\frac{k}{RO_n} \sum_i \int_{r_i}^{r_{i+1}} \psi(x - 1/k)\,\mathrm{d}x \leq \frac{k}{RO_n} \int_0^{\infty} \psi(x - 1/k)\,\mathrm{d}x.$$

Finally, inspecting $\psi(x)$ we see that it takes value 1 for $x < 1$, takes value $\frac{2}{k}$ for $x \in [1, 50]$, and has exponential decay $\leq \frac{e^{-x}}{k}$ after that. Thus, it is easy to see that the integral on the right-hand side is at most $1 + O(\frac{1}{k})$. This concludes the proof. ◀

However, what we actually need is to show that (4.1) (with O'_t's) holds with good probability; for that we need concentration inequalities for the sums of the tentative occupations O'_t's. The biggest problem is that the tentative selections induced by the LP are correlated in a non-trivial way. In particular, it is not clear whether they are negatively associated: for example, if the items up to time $t-1$ are all "very good" the algorithm will not tentatively select at times t, $t+1$, etc., indicating possibility of positive correlations on these times. Thus, the O'_t's are also correlated and it is not clear how to apply standard concentrations inequalities.

4.1 Concentration I: controlling the outer constraint

However, as the example above illustrates, we still have hopes of obtaining good *upper bounds* on the probability of multiple tentative selections. In fact, the probability of multiple selection of items $I_{t_1}, \ldots, I_{t_m}$ is at most the probability that the "worst" of these items is selected; more precisely:

▶ **Lemma 11.** *Consider $m \leq \frac{\ln k}{4}$ random-order times $t_1, \ldots, t_m \geq 8\ell(\Gamma + 1)$. Then*

$$\Pr\left(T_{t_1} = \ldots = T_{t_m} = 1 \;\middle|\; R_{t_1}, \ldots, R_{t_m}\right) \leq \psi\left(\max_i R_{t_i}\right).$$

Proof. The inequality follows from the fact $\Pr(X_1 = \ldots = X_m = 1 \mid E) \leq \min_i \Pr(X_i = 1 \mid E)$, Lemma 4, and $\min_i \psi(R_{t_i}) = \psi(\max_i R_{t_i})$ (by the monotonicity of ψ). ◀

The main advantage of this bound is that the ranks R_{t_i} are "almost" independent (they would be independent if the input sequence was generated by sampling items *with* replacement).

Moreover, this lemma allows us to upper bound products of tentative occupation $\prod_i O'_{t_i}$: for this product to be strictly positive, all these items have to be tentatively selected. In fact, one can prove such upper bound using a similar strategy as in Lemma 10, with a main new element: a simple but general comparison for the expectation of a *non-negative* function under sampling with and without replacement, that allow us to work with a decoupled (independent) version $R'_{t_1}, \ldots, R'_{t_m}$ of the ranks. Formally we have the following, which is deferred to the full version of the paper.

▶ **Lemma 12** (Control of products). *Fix a random-order time t. Consider a set of $m \leq \frac{\ln k}{4}$ distinct RO times $t_1, \dots, t_m$, all of which are at least $8\ell(\Gamma+1)$ and less than t. Then there are constants $a_2, a_3 > 1$ such that $\mathbb{E}\left[\prod_{i\in[m]} O'_{t_i} \,\middle|\, I_t\right] \leq \left(1 + \frac{a_2^m}{k}\right)\left(1 + \frac{4m^2}{RO_n}\right)\left(\frac{k}{RO_n}\right)^m \leq \left(a_3 \frac{k}{n}\right)^m$. In particular, choosing $a_2 = 500$ and $a_3 = 8a_2$ is sufficient.*

Finally, these product estimates can be converted into raw moments/tail inequalities using reasonably standard estimates (e.g., Section 3.4 of [10]), giving the desired control of the outer constraint's occupation (the proof is deferred to the full version of the paper).

▶ **Lemma 13** (Control of outer constraints). *Consider a free time $t \geq 8\ell(\Gamma+1)$, and let B be the last window in $\mathbb{W}_{t-1}$. Then $\Pr\left(\sum_{t'\in B} O'_{t'} > a_4 \ell \frac{k}{n} \,\middle|\, I_t\right) \leq \frac{1}{k}$, where $a_4 \geq 2e^6 a_3$, and a_3 is the constant from Lemma 12.*

4.2 Concentration II: control of main budget

In order to obtain Lemma 9 we need to show that the second part of (4.1) holds with reasonable probability *even when $t \approx n$*; but since $\mathbb{E}O'_t \approx \frac{k}{n}$, the expected cumulative occupation by the end of the game $\mathbb{E}[\sum_{t'=1}^{t} O'_{t'}]$ is $\approx k$ for $t \approx n$, so we do not have much room. So unlike the previous section, we are interested in "'medium deviations", where the variance is the right quantity to look at. While Lemma 12 directly gives that the cumulative variance until time t is $\lesssim (\frac{tk}{n})^2$, we actually need an upper bound of order $O(\frac{tk}{n})$, which is what one would expect from independent Bernoulli's with success probability $\frac{k}{n}$. Since $\text{Var}(Z) = \mathbb{E}Z^2 - (\mathbb{E}Z)^2$, to obtain variance upper bounds we will obtain an upper bound on the second raw moment and a *lower bound on the expectation.*

For that we actually prove concentration for a modified occupation that upper bounds O'_t in every scenario: $\bar{O}'_t = W_t \bar{T}_t$, where $\bar{T}_t := \max\{T_t, \mathbf{1}[R_t \leq 1]\}$, that is $\bar{T}_t$ equals 1 if either $T_t = 1$ or the weighted rank R_t is at most 1. While Lemma 12 still holds for these variables, we can now get almost matching lower bounds on $(\mathbb{E}\sum_{t'=1}^{t} \bar{O}'_{t'})^2$, giving the desired variance bound $\text{Var}[\sum_{t'=1}^{t} \bar{O}'_{t'}] \leq O(\frac{tk}{n})$. Essentially using the bound in expectation from Lemma 10 and Chebychev's inequality with this variance control gives the following (see the full version of the paper).

▶ **Lemma 14** (Control of main budget). *For every random-order time t, the probability we are blocked by the main budget can be upper bounded as $\Pr\left[\sum_{t'<t} O'_t > k - 1 \,\middle|\, I_t\right] \leq \frac{O(1)}{k\left(1 - \frac{t}{n} - O\left(\frac{\Gamma \ln k}{k}\right)\right)^2}$.*

Taking a union bound over Lemma 13 and Lemma 14 proves Lemma 9.

5 Lower bounding the value obtained

Recall that $X_t^{alg} = T_t F_t$, i.e., the item is permanently selected exactly when it is tentatively selected and it fits the budgets, and that V_t is the value of the item at time t. The following is then our main lower bound on the value obtained by the algorithm.

▶ **Lemma 15** (Value lower bound). *Consider a free time $t \geq 1{,}212\Gamma\ell$. Then $\mathbb{E}[V_t T_t F_t] \geq \left(c_t - \varepsilon_t - p_t - \frac{2}{k}\right) \frac{OPT_{RO}}{RO_n}$, where p_t is the bound from Lemma 9 and $\varepsilon_t = (a_1 + 3)\frac{\Gamma\ell}{t} + \sqrt{10 \ln k}\sqrt{\frac{2n}{tk}}$.*

To prove this, the first step is to obtain the following “dual” to Lemma 4, which says that if the item has low (i.e. good) rank then it is fully tentatively selected with good probability.

▶ **Lemma 16.** *For any free time* $t \geq 1{,}212\Gamma\ell$ *we have that the probability of fully tentatively selecting item* I_t *satisfies:* $\Pr\left(X_t^t = 1 \;\middle|\; R_t \leq c_t - \varepsilon_t\right) \geq 1 - \frac{1}{k}$.

This is proved via a “dual” of Lemma 5 plus concentration. Given that good items are tentatively selected with good probability and it is likely to fit the budget (Lemma 9), final difficulty in proving Lemma 15 is the correlation between these quantities and the value V_t. This is why most previous bounds actually work even conditioned on the item I_t; notice that fixing I_t, fixes V_t as a deterministic constant. We sketch the argument.

Proof sketch of Lemma 15. Using the non-negativity of V_t, T_t, and F_t, we have

$$\begin{aligned}\mathbb{E}[V_t T_t F_t] = \mathbb{E}_{I_t}\left[V_t\, \mathbb{E}\left[T_t F_t \mid I_t\right]\right] &\geq \mathbb{E}_{I_t}\big(V_t\, \mathbb{E}\left[T_t F_t \mid I_t\right] \;\big|\; R_t \leq c_t - \varepsilon_t\big) \Pr(R_t \leq c_t - \varepsilon_t)\\ &\geq \left(1 - p_t - \frac{1}{k}\right) \mathbb{E}_{I_t}\big(V_t \;\big|\; R_t \leq c_t - \varepsilon_t\big) \Pr(R_t \leq c_t - \varepsilon_t),\end{aligned}$$

where the second inequality uses Lemmas 16 and 9 (via the definition of p_t). Since $c_t - \varepsilon_t \approx 1$ and essentially OPT_{RO} gets value exactly from items of rank at most 1, the last two factors in the inequality together give roughly the expected value OPT_{RO} gets in a time step. ◀

6 Wrapping up: finishing the proof of Theorem 2

To finish the proof we just need to add Lemma 15 over all free time steps except the ones very early or very late in the sequence. More precisely, let $t_0 = 1{,}212\Gamma\ell$ and $\gamma = 1 - (a_5 + 1)\frac{\Gamma\ell}{n}$, and define $T = \{t \in \textsc{Free}_n : t_0 \leq t \leq \gamma n\}$. For $t \notin T$, we use the trivial bound $V_t \geq 0$. For the other time steps we use Lemma 15. With the fact $RO_n \leq n$ we have

$$\mathbb{E}\left[\sum_{t \in RO} V_t X_t^{alg}\right] \geq \sum_{t \in T} \mathbb{E}[V_t T_t F_t] \geq \left(\sum_{t \in T} c_t - \sum_{t \in T} \varepsilon_t - \sum_{t \in T} p_t - \frac{2n}{k}\right) \frac{\mathrm{OPT}_{RO}}{n}. \tag{6.3}$$

We bound each of the remaining sums:

- $\sum_{t \in T} c_t = |T| - \sum_{t \in T} \frac{4\Gamma\ell}{t} \geq (n - O(\Gamma\ell)) - \int_{t_0 - 1}^{n} \frac{4\Gamma\ell}{t}\,\mathrm{d}t = n - O(\Gamma\ell \ln \frac{n}{\Gamma\ell})$.
- $\sum_{t \in T} p_t \leq O\left(\frac{1}{k}\right) \cdot \int_0^{\gamma n} \frac{1}{\left(1 - \frac{t}{n} - a_5 \frac{\Gamma \ln k}{k}\right)^2}\,\mathrm{d}t = O\left(\frac{n}{k}\right) \int_0^{\gamma} \frac{1}{(a - x)^2}\,\mathrm{d}x$, where in the last step we set $a = 1 - a_5 \frac{\Gamma \ln k}{k}$ and use change of variables $x = \frac{t}{n}$. The remaining integral equals $\frac{1}{a - x}\Big|_0^{\gamma} \leq \frac{1}{a - \gamma}$. By our setting of γ we have $a - \gamma = \frac{\Gamma\ell}{n}$, so we obtain $\sum_{t \in T} p_t \leq O\left(\frac{n}{\Gamma}\right)$.
- $\sum_{t \in T} \varepsilon_t \leq \int_{t_0 - 1}^{n} (a_1 + 3) \frac{\Gamma\ell}{t}\,\mathrm{d}t + \int_{t_0 - 1}^{n} \sqrt{\frac{20 n \ln k}{kt}}\,\mathrm{d}t \leq O(\Gamma\ell \ln \frac{n}{\Gamma\ell}) + O(\frac{n\sqrt{\ln k}}{\sqrt{k}})$.

Using these bounds on (6.3) and the assumption $\Gamma \geq \sqrt{k}$ concludes the proof of the theorem.

7 Conclusions

A natural follow-up question is how our results could generalize to other settings. In particular, it would be interesting to extend our algorithm and analysis to packing LPs. The difficulty in using our technique is that there is no natural notion similar to the weighted rank for this setting.

It would also be interesting to better understand the limitations and trade-offs in this and similar models. For example, what regimes of parameter allow constant-competitive or $(1 - \varepsilon)$-competitive algorithms?

The Iteration Number of Colour Refinement

Sandra Kiefer

Abstract

The Colour Refinement procedure and its generalisation to higher dimensions, the Weisfeiler-Leman algorithm, are central subroutines in approaches to the graph isomorphism problem. In an iterative fashion, Colour Refinement computes a colouring of the vertices of its input graph.

A trivial upper bound on the iteration number of Colour Refinement on graphs of order n is $n-1$. We show that this bound is tight. More precisely, we prove via explicit constructions that there are infinitely many graphs G on which Colour Refinement takes $|G|-1$ iterations to stabilise. Modifying the infinite families that we present, we show that for every natural number $n \geq 10$, there are graphs on n vertices on which Colour Refinement requires at least $n-2$ iterations to reach stabilisation.

1 Introduction

Colour Refinement, which is also known as Naïve Vertex Classification or the 1-dimensional Weisfeiler-Leman algorithm (1-WL), is an important combinatorial algorithm in theoretical and practical approaches to the graph isomorphism problem. In an iterative fashion, it refines an isomorphism-invariant partition of the vertex set of the input graph. This process stabilises at some point and the final partition can often be used to distinguish non-isomorphic graphs [3]. Colour Refinement can be implemented to run in time $O((m+n)\log n)$, where n is the order of the input graph and m is its number of edges [6, 29]. Most notably, its efficient implementations are used in all competitive graph isomorphism solvers (such as `Nauty` and `Traces` [30], `Bliss` [19] and `saucy` [7]).

Colour Refinement has been rediscovered many times, one of its first occurences being in a paper on chemical information systems from the 1960s [31]. The procedure is applied in plenty of other fields, for example, it can be modified to reduce the dimension of linear programs significantly [14]. Other applications are in the context of graph kernels [34] or static program analysis [27]. A recently discovered connection to deep learning shows that the expressive power of Colour Refinement is captured by graph neural networks [32].

As described above, Colour Refinement computes a stable colouring of its input graph. It is known that two given graphs result in equal colourings, i.e. are not distinguished by Colour Refinement, if and only if there is a fractional isomorphism between them [12, 33, 35]. Moreover, the graphs which Colour Refinement identifies up to isomorphism (i.e. distinguishes from all non-isomorphic ones) have been completely characterised [2, 24].

To obtain its final colouring, the algorithm proceeds in iterations. In this paper, we investigate how many iterations it takes for the algorithm to terminate. More specifically, for $n \in \mathbb{N}$, we are interested in $\mathrm{WL}_1(n)$, the maximum number of iterations required to reach stabilisation of Colour Refinement among all graphs of order n.

While not directly linked to the running time on a sequential machine, the iteration number corresponds to the parallel running time of Colour Refinement (on a standard PRAM model) [17, 25]. Furthermore, via a connection to counting logics, a bound on the iteration number for graphs of a fixed size directly translates into a bound on the descriptive complexity of the difference between the two graphs, namely into a bound on the quantifier depth of a distinguishing formula in the extension of the 2-variable fragment of first-order logic by counting quantifiers [5, 18]. Moreover, the iteration number of 1-WL equals the depth of a graph neural network that outputs the stable vertex colouring of the underlying graph with respect to Colour Refinement [32].

Considering paths, one quickly determines that $\mathrm{WL}_1(n) \geq \frac{n}{2} - 1$ holds for every $n \in \mathbb{N}$. By contrast, on random graphs, the iteration number is asymptotically almost surely 2 [3]. The best published lower bound on the iteration number of Colour Refinement on n-vertex graphs is $n - O(\sqrt{n})$ [26]. Concerning the upper bound, the trivial inequality $\mathrm{WL}_1(n) \leq n-1$ holds for every repeated partitioning of a set of size n and it does not take into account any further properties of the input graph or of the algorithm used to execute the partitioning. Still, no improvement over this upper bound has been established.

Our first main result reads as follows.

▶ **Theorem 1.** *For every $n \in \mathbb{N}_{\geq 10}$ with $n = 12$ or $n \bmod 18 \notin \{6, 12\}$, it holds that* $\mathrm{WL}_1(n) = n - 1$.

Thus, there are infinitely many $n \in \mathbb{N}$ with $\mathrm{WL}_1(n) = n - 1$. We can even determine the iteration number up to an additive constant of 1 for all $n \in \mathbb{N}$ (where the precise numbers for $n \leq 9$ can easily be determined computationally), as stated in our second main result.

▶ **Theorem 2.** *For every $n \in \mathbb{N}_{\geq 10}$, it holds that* $\mathrm{WL}_1(n) \in \{n-2, n-1\}$.

We obtain our bounds via an empirical approach. More precisely, we have designed a procedure that enables us to systematically generate for all $n \leq 64$ graphs of order n that obey certain constraints (to render the procedure tractable) and on which Colour Refinement takes $n - 1$ iterations to stabilise. Analysing the graphs, we have determined the connections between colour classes during the execution of the algorithm in detail. If the vertex degrees that are present in the graph are low, then the connections between colour classes of size 2 are restricted. This allows us to develop an elegant graphical visualisation and a compact string representation of the graphs with low vertex degrees that take $n - 1$ iterations to stabilise. Using these encodings, we are able to provide infinite families with $n - 1$ Colour Refinement iterations until stabilisation.

Our analysis enables a deep understanding of the families that we present. Via slight modifications of the graph families, we can then cover a large portion of graph sizes and, allowing to go from connected graphs to general graphs, we can construct the graphs that yield Theorem 2.

Due to space limits, we omit some of the proof details here and defer the reader to the full version for them [21].

Related work

Colour Refinement is the 1-dimensional version of the so-called Weisfeiler-Leman algorithm. For every $k \in \mathbb{N}$, there exists a generalisation of it (k-WL), which colours vertex k-tuples in the input graph instead of single vertices only. See [20] for an in-depth study of the main parameters of Colour Refinement and k-WL.

Similarly as for Colour Refinement, one can consider the number $\mathrm{WL}_k(n)$ of iterations of k-WL on graphs of order n. Notably, contrasting our results for Colour Refinement, in [22], it was first proved that the trivial upper bound of $\mathrm{WL}_2(n) \leq n^2 - 1$ is not even asymptotically tight (see also the journal version [23]). This foundation fostered further work, leading to an astonishingly good new upper bound of $O(n \log n)$ on the iteration number of 2-WL [28].

For fixed $k > 1$, it is already non-trivial to show linear lower bounds on $\mathrm{WL}_k(n)$. Modifying a construction of Cai, Fürer, and Immerman [5], this was achieved by Fürer [9], who showed that $\mathrm{WL}_k(n) \in \Omega(n)$, remaining to date the best known lower bound when the input is supposed to be a graph. Only when considering structures with relations of higher arity than 2 as input, better lower bounds on the iteration number of k-WL have been proved [4].

For $k > 2$, regarding upper bounds on the iteration number of k-WL, without further knowledge about the input graph, no significant improvements over the trivial $n^k - 1$ are known.[1] Still, when the input graph has bounded treewidth or is a 3-connected planar graph, polylogarithmic bounds on the iteration number of k-WL needed to identify the graph have been published [17, 36].

Although for every k, there are non-isomorphic graphs that are not distinguished by k-WL [5], it is known that for every graph class with a forbidden minor, a sufficiently high-dimensional Weisfeiler-Leman algorithm correctly decides isomorphism [13]. Recent results give new upper bounds on the dimension needed for certain interesting graph classes [15, 16]. A closely-related direction of research investigates what properties the Weisfeiler-Leman algorithm can detect in graphs [1, 8, 10].

2 Preliminaries

By $\mathbb{N}$, we denote the set of natural numbers, i.e. $\{1, 2, \dots\}$. We set $\mathbb{N}_0 := \mathbb{N} \cup \{0\}$ and, for $k, \ell \in \mathbb{N}_0$, we define $[k, \ell] := \{n \in \mathbb{N}_0 \mid k \leq n \leq \ell\}$ and $[k] := [1, k]$. For a set S, a *partition* of S is a set Π of non-empty sets such that $\bigcup_{M \in \Pi} M = S$ and for all $M, M' \in \Pi$ with $M \neq M'$, it holds that $M \cap M' = \emptyset$. For two partitions Π and Π' of the same set S, we say that Π' is *finer* than Π (or Π' *refines* Π) if every element of Π' is a (not necessarily proper) subset of an element of Π. We write $\Pi \succeq \Pi'$ (and equivalently $\Pi' \preceq \Pi$) to express that Π' is finer than Π. Concurrently, we say that Π is *coarser* than Π'. Note that if both $\Pi \succeq \Pi'$ and $\Pi' \succeq \Pi$ hold, then $\Pi = \Pi'$.

For $S \neq \emptyset$, the partition $\{S\}$ is the *unit* partition of S. The partition $\big\{\{s\} \mid s \in S\big\}$ is called the *discrete partition* of S. A set of cardinality 1 is a *singleton*.

All graphs that we consider in this paper are finite and simple, i.e. undirected without self-loops at vertices. For a graph with vertex set $V(G)$ and edge set $E(G)$, its *order* is $|G| := |V(G)|$. For a vertex $v \in V(G)$, we denote by $N(v)$ the neighbourhood of v in G, i.e. the set $\{w \mid \{v, w\} \in E(G)\}$. Similarly, for a vertex set W, we set $N(W) := \big\{v \mid v \notin W, \exists w \in W \colon v \in N(w)\big\}$. The *degree* of a vertex v is $\deg(v) := |N(v)|$. (Since the graph G

[1] The bound $n^k - 1$ is not tight, since the initial partition of the k-tuples already has multiple classes, for example, one consisting of all tuples of the form $(v, v, \dots, v)$.

will be clear from the context, we do not need to include it in our notation.) We also set $\deg(G) \coloneqq \{\deg(v) \mid v \in V(G)\}$. If there is a $d \in \mathbb{N}_0$ such that $\deg(G) = \{d\}$, the graph G is d-regular. A *regular* graph is a graph that is d-regular for some $d \in \mathbb{N}_0$. By a *matching*, we mean a 1-regular graph.

Let G be a graph with at least two vertices. If there are sets $\emptyset \neq P, Q \subseteq V(G)$ such that $V(G) = P \cup Q$ and $P \cap Q = \emptyset$ and $E(G) \cap \{\{v,w\} \mid v,w \in P\} = \emptyset = E(G) \cap \{\{v,w\} \mid v,w \in Q\}$, then G is *bipartite (on bipartition* (P,Q)*)*. If, additionally, $\big\{\{v,w\} \mid v \in P, w \in Q\big\} = E(G)$, the graph G is *complete bipartite*.

For $k, \ell \in \mathbb{N}_0$, a *(k,ℓ)-biregular graph (on bipartition (P,Q))* is a bipartite graph on bipartition (P,Q) such that for every $v \in P$, it holds that $|N(v)| = k$, and for every $w \in Q$, it holds that $|N(w)| = \ell$. A *biregular* graph is a graph G for which there are $P, Q \subseteq V(G)$ and $k, \ell \in \mathbb{N}_0$ such that G is (k,ℓ)-biregular on bipartition (P,Q).

For a graph G and a set $V' \subseteq V(G)$, we let $G[V']$ be the *induced subgraph of G on V'*, i.e. the subgraph of G with vertex set V' and edge set $E(G) \cap \{\{v,w\} \mid v,w \in V'\}$. We define $G - V' \coloneqq G[V(G) \setminus V']$. Furthermore, for vertex sets $V_1, V_2 \subseteq V(G)$, we denote by $G[V_1, V_2]$ the graph with vertex set $V_1 \cup V_2$ and edge set $E(G) \cap \{\{v_1, v_2\} \mid v_1 \in V_1, v_2 \in V_2\}$.

A *coloured graph* is a tuple (G, λ), where G is a graph and $\lambda\colon V(G) \to \mathcal{C}$ is a function that assigns colours (i.e. elements from a particular set $\mathcal{C}$) to the vertices. We interpret all graphs treated in this paper as coloured graphs. If the colouring is not specified, we assume a monochromatic colouring, i.e. all vertices have the same colour.

For a coloured graph G with colouring λ, a *(vertex) colour class* of G is a maximal set of vertices that all have the same λ-colour. Every graph colouring λ induces a partition $\pi(\lambda)$ of $V(G)$ into the vertex colour classes with respect to λ.

3 Colour Refinement

Colour Refinement proceeds by iteratively refining a partition of the vertex set of its input graph until the partition is stable with respect to the refinement criterion.

▶ **Definition 3** (Colour Refinement). *Let $\lambda\colon V(G) \to \mathcal{C}$ be a colouring of the vertices of a graph G, where $\mathcal{C}$ is some set of colours. The colouring computed by Colour Refinement on input (G,λ) is defined recursively: we set $\chi_G^0 \coloneqq \lambda$, i.e. the initial colouring is λ. For $i \in \mathbb{N}$, the colouring χ_G^i computed by Colour Refinement after i iterations on G is defined as $\chi_G^i(v) \coloneqq \big(\chi_G^{i-1}(v), \{\!\{\chi_G^{i-1}(w) \mid w \in N(v)\}\!\}\big)$.*

That is, $\chi_G^i(v)$ consists of the colour of v from the previous iteration as well as the multiset of colours of neighbours of v from the previous iteration. It is not difficult to see that $\pi(\chi_G^{i-1}) \succeq \pi(\chi_G^i)$ holds for every graph G and every $i \in \mathbb{N}$. Therefore, there is a unique minimal integer j such that $\pi(\chi_G^j) = \pi(\chi_G^{j+1})$. For this value j, we define the *output* of Colour Refinement on input G to be $\chi_G \coloneqq \chi_G^j$ and call χ_G and $\pi(\chi_G)$ *the stable colouring* and *the stable partition*, respectively, of G. Accordingly, executing i *Colour Refinement iterations* on G means computing the colouring χ_G^i. We call a graph G with initial colouring λ and the induced partition $\pi(\lambda)$ *stable* if $\pi(\lambda) = \pi(\chi_G)$. Note that if λ is stable, then for all $P, Q \in \pi(\lambda)$ with $P \neq Q$, the graph $G[P]$ is regular and the graph $G[P,Q]$ is biregular.

Colour Refinement can be used to check whether two given graphs G and G' are non-isomorphic by computing the stable colouring on the disjoint union of the two. If there is a colour C such that, in the stable colouring, the numbers of vertices of colour C differ in G and G', they are non-isomorphic. However, even if they agree in every colour class size in the stable colouring, the graphs might not be isomorphic. It is non-trivial to describe for which graphs this isomorphism test is always successful (see [2, 24]).

▶ **Notation 4.** *We write* $\mathrm{WL}_1(G)$ *for the number of iterations of Colour Refinement on input* G*, that is,* $\mathrm{WL}_1(G) = j$*, where* j *is the minimal integer for which* $\pi(\chi_G^j) = \pi(\chi_G^{j+1})$*. Similarly, for* $n \in \mathbb{N}$*, we write* $\mathrm{WL}_1(n)$ *to denote the maximum number of iterations that Colour Refinement needs to reach stabilisation on an* n*-vertex graph.*

We call every graph G with $\mathrm{WL}_1(G) = |G| - 1$ a *long-refinement graph.*

▶ **Fact 5.** *Let* G *be an uncoloured path with* n *vertices. Then* $\mathrm{WL}_1(G) = \lfloor \frac{n-1}{2} \rfloor$.

Proof sketch. In the first iteration, the two end vertices are distinguished from all others because they are the only ones with degree 1. Then in each iteration, the information of being adjacent to a "special" vertex, i.e. the information about the distance to a vertex of degree 1, is propagated one step closer to the vertices in the centre of the path. This procedure takes $\lfloor \frac{n-1}{2} \rfloor$ iterations. ◀

In 2015, Krebs and Verbitsky improved on the explicit linear lower bound for graphs of order n given by Fact 5 by constructing a family of pairs of graphs whose members of order n can only be distinguished after $n - 8\sqrt{n}$ Colour Refinement iterations (see [26, Theorem 4.6]). Hence, since for a set $\{v_1, \dots, v_n\} =: S$ and every sequence $\pi_1, \dots, \pi_\ell$ of partitions of S that satisfy

$$\pi_1 \gneqq \pi_2 \gneqq \dots \gneqq \{\{v_1\}, \dots \{v_n\}\} = \pi_\ell,$$

it holds that $\ell \leq n - 1$, we obtain the following corollary.

▶ **Corollary 6.** *For every* $n \in \mathbb{N}$*, it holds that* $n - 8\sqrt{n} \leq \mathrm{WL}_1(n) \leq n - 1$.

It has remained open whether any of the two bounds is tight. In preliminary research conducted together with Gödicke and Schweitzer, towards improving the lower bound, the first author took up an approach to reverse-engineer the splitting of colour classes. Gödicke's implementation of those split procedures led to the following result.

▶ **Theorem 7** ([11])**.** *For every* $n \in \{1, 10, 11, 12\}$*, it holds that* $\mathrm{WL}_1(n) = n - 1$*. For* $n \in [2, 9]$*, it holds that* $\mathrm{WL}_1(n) < n - 1$.

Unfortunately, due to computational exhaustion, it was not possible to test for larger graph sizes. Also, the obtained graphs do not exhibit any structural properties that would lend themselves for a generalisation to larger orders. Using a fast implementation of Colour Refinement, we could verify that there are exactly 16 long-refinement graphs of order 10, 24 long-refinement graphs of order 11, 32 of order 12, and 36 of order 13. However, again, with simple brute-force approaches, we could not go beyond this number exhaustively.

4 Compact Representations of Long-Refinement Graphs

In the light of the previous section, the question whether the lower bound obtained by Krebs and Verbitsky is asymptotically tight has remained open. With the brute-force approach, it becomes infeasible to test all graphs of orders much larger than 10 exhaustively for their number of Colour Refinement iterations until stabilisation. Still, knowing that there exist long-refinement graphs, it is natural to ask whether the ones presented in [11] are exceptions or whether there are infinitely many such graphs. We show that the latter is the case.

When the input is a coloured graph with at least two vertex colours, the initial partition already has two elements. Hence, all long-refinement graphs are monochromatic. Therefore, in the following, all initial input graphs are considered to be monochromatic.

▶ **Proposition 8.** *Let G be a graph and let $n := |G|$. If there exists an $i \in \mathbb{N}_0$ such that $|\{\chi_G^{i+1}(v) \mid v \in V(G)\}| - |\{\chi_G^{i}(v) \mid v \in V(G)\}| \geq 2$ holds, then G is not a long-refinement graph.*

Proof. Every pair of partitions π, π' with $\pi \supsetneq \pi'$ satisfies $|\pi'| \geq |\pi| + 1$. Thus, every sequence of partitions of the form

$$\pi_1 := \{\{v_1, \dots, v_n\}\} \supsetneq \pi_2 \supsetneq \dots \supsetneq \{\{v_1\}, \dots \{v_n\}\} =: \pi_n$$

must satisfy $|\pi_i| = |\pi_{i-1}| + 1$ for all $i \in [2, n]$. ◀

The proposition implies that, in order to find long-refinement graphs, we have to look for graphs in which, in every Colour Refinement iteration, only one additional colour class appears. That is, in each iteration, only one colour class is split and the splitting creates exactly two new colour classes.

▶ **Corollary 9.** *Let G be a long-refinement graph with at least two vertices. Then there exist $d_1, d_2 \in \mathbb{N}_0$ with $d_1 \neq d_2$ and such that $\deg(G) = \{d_1, d_2\}$.*

Proof. This is a direct consequence of Proposition 8: every (monochromatic) regular graph G satisfies $\mathrm{WL}_1(G) = 0$ and if there were more than two vertex degrees present in G, we would have $|\{\chi_G^1(v) \mid v \in V(G)\}| - |\{\chi_G^0(v) \mid v \in V(G)\}| \geq 3 - 1 \geq 2$. ◀

We can thus restrict ourselves to graphs with exactly two vertex degrees.

▶ **Notation 10.** *For a graph G and $i \in \mathbb{N}_0$, we let π_G^i denote the partition induced by χ_G^i on $V(G)$, i.e. after i Colour Refinement iterations on G. If G is clear from the context, we omit it in the expression.*

As a result of the regularity conditions that must hold for the bipartite graph $G[V_1, V_2]$, we make the following observation. It implies that, in a long-refinement graph, to determine the class C that is split in iteration i, it suffices to consider the neighbourhood of an arbitrary class obtained in the preceding iteration.

▶ **Lemma 11.** *Let G be a graph. Suppose there are $i \in \mathbb{N}$ and C_1, C_2, C' with $\pi^i \setminus \pi^{i-1} = \{C_1, C_2\}$ and $C' \in \pi^i \setminus \pi^{i+1}$. Then there are vertices $v_1', v_2' \in C'$ such that $|N(v_1') \cap C_1| \neq |N(v_2') \cap C_1|$.*

Proof. Note that there must be a $C \in \pi^{i-1} \setminus \pi^i$ with $C_1 \cup C_2 = C$. Since $C' \in \pi^i$ and $C \in \pi^{i-1}$, there is a $d \in \mathbb{N}_0$ such that for every $v \in C'$, it holds that $d = |N(v) \cap C|$. Since $\{C_1, C_2\} = \pi^i \setminus \pi^{i-1}$ and $C' \notin \pi^{i+1}$, there are vertices $v_1', v_2' \in C'$ such that $|N(v_1') \cap C_1| \neq |N(v_2') \cap C_1|$ or $|N(v_1') \cap C_2| \neq |N(v_2') \cap C_2|$. In the first case, we are done. In the second case, we obtain $|N(v_1') \cap C_1| = d - |N(v_1') \cap C_2| \neq d - |N(v_2') \cap C_2| = |N(v_2') \cap C_1|$. ◀

Note that the validity of the lemma depends on the assumption $\{C_1, C_2\} = \pi^i \setminus \pi^{i-1}$, which by Proposition 8 is always fulfilled in long-refinement graphs as long as $\pi^{i-1} \neq \pi^i$.

▶ **Corollary 12.** *No graph with more than one connected component is a long-refinement graph.*

Proof. By Corollary 9, the graph cannot have isolated vertices, since the subgraph formed by the other connected components would have to be d-regular for some $d \geq 1$. Therefore, the stable partition would not be discrete.

Suppose G is a long-refinement graph in which every connected component has size at least 2. Then there is an iteration i for which there is a unique connected component with vertex set V' such that the current partition is discrete on V' but not discrete on the other connected components. Then the vertex sets C_1, C_2 from Lemma 11 must be subsets of V'. However, the lemma implies that no further classes are split because none is adjacent to C_1 or C_2. ◀

We can therefore restrict ourselves to connected graphs. The only connected graphs G with $\deg(G) = \{1, 2\}$ are paths and, by Fact 5, they are not long-refinement graphs. Thus, the smallest degree pairs for a search for candidates are $\{1, 3\}$ and $\{2, 3\}$.

▶ **Lemma 13.** *Let G be a long-refinement graph. Then $|\{v \in V(G) \mid \deg(v) = 1\}| \leq 2$.*

Table 1 displays the adjacency lists of two long-refinement graphs on 12 and 14 vertices, respectively, which each have exactly one vertex of degree 1.

Table 1 Adjacency lists of long-refinement graphs G with $\deg(G) = \{1, 5\}$ (left) and $\deg(G) = \{1, 3\}$ (right), respectively.

The lemma allows us to reduce the decision problem whether there are infinitely many long-refinement graph with degrees in $\{1, 2, 3\}$ to the question whether there are such families with degrees in $\{2, 3\}$. The proof of the lemma as well as this reduction can be found in [21]. With the help of the tool `Nauty` [29], our quest for long-refinement graphs with degrees 2 and 3 was successful. Exploiting the degree restrictions and some other conditions that we imposed to render the search tractable, it was possible to test for graphs up to order 64. We found graphs G with $n - 1$ Colour Refinement iterations, where $n = |G|$, for all even $n \in [10, 64] \setminus \{24, 30, 42, 48, 60\}$ and for all odd $n \in [11, 63] \setminus \{21, 27, 39, 45, 57, 63\}$.

In the following, in order to generalise the results, we analyse the obtained graphs. Among our computational results, the even-order graphs G have the following property in common: there is an iteration j such that for every $c \in \chi_G^j(V(G))$, it holds that $|\{v \in V(G) \mid \chi_G^j(v) = c\}| = 2$. That is, with respect to their assigned colours, the vertices remain in pairs until there are no larger colour classes left. Then the first such pair is split into singletons, which must induce a splitting of another pair, and so on, until the discrete partition is obtained. (Similar statements hold for the odd-order long-refinement graphs, but are more technical.) In the following, a *pair* is a set of two vertices which occurs as a colour class during the execution of Colour Refinement. That is, vertices v, v' form a pair if and only if $\{v, v'\}$ is an element of π^i for some $i \in \mathbb{N}_0$.

As just argued, there is a splitting order on the pairs, i.e., a linear order $\prec$ induced by the order in which pairs are split into singletons. We now examine the possible connections between pairs.

From now on, we make the following assumption.

▶ **Assumption 14.** *G is a long-refinement graph with $\deg(G) = \{2, 3\}$ and such that there is an $i \in \mathbb{N}_0$ for which π^i contains only pairs. Let $\prec$ be the splitting order of these pairs.*

We call pairs $P_1, P_2 \subseteq V(G)$ *successive* if P_2 is the successor of P_1 with respect to $\prec$. Note that for successive pairs P_1, P_2, in the graph $G[P_1, P_2]$, every $v_2 \in P_2$ must have the same number of neighbours in P_1, otherwise it would hold that $P_2 \prec P_1$. By a simple case analysis, together with an application of Lemma 11, this rules out all connections but matchings for successive pairs.

▶ **Corollary 15.** *Let P_1 and P_2 be successive pairs. Then $G[P_1, P_2]$ is a matching.*

Towards a compact representation of the graphs, we further examine the connections between pairs P_1 and P_2 with $S(P_1) \prec P_2$, where $S(P_1)$ is the successor of P_1 with respect to $\prec$.

▶ **Lemma 16.** *Let P_1 be a pair. Then exactly one of the following holds.*

- *$P_1 \neq \min(\prec)$ and for every pair P_2 with $S(P_1) \prec P_2$, it holds that $E(G[P_1, P_2]) = \emptyset$.*
- *$P_1 = \min(\prec)$ and there are exactly two choices P_2, P_2' for a pair P' with $S(P_1) \prec P'$ such that $E(G[P_1, P']) \neq \emptyset$. Furthermore, there is a vertex $v_1 \in P_1$ such that $G[\{v_1\}, P_2]$ and $G[P_1 \setminus \{v_1\}, P_2']$ are complete bipartite and $E(G[\{v_1\}, P_2']) = E(G[P_1 \setminus \{v_1\}, P_2]) = \emptyset$.*

Proof. Suppose $P_1 \neq \min(\prec)$. If $P_1 = \max(\prec)$, the statement trivially holds. Otherwise, by Corollary 15, every vertex $v_1 \in P_1$ has exactly one neighbour in $S(P_1)$ and exactly one neighbour in the predecessor of P_1, i.e. in the unique pair $A(P_1)$ such that $P_1 = S(A(P_1))$. Thus, due to the degree restrictions, v_1 can have at most one additional neighbour in a pair P' with $P_1 \prec P'$ and $P' \neq S(P_1)$. However, if v_1 had a neighbour in such a P', the graph $G[\{v_1\}, P']$ would not be biregular, implying that $P' = S(P_1)$, a contradiction. Therefore, $N(v_1) \subseteq A(P_1) \cup P_1 \cup S(P_1)$ and thus, $N(P_1) \subseteq A(P_1) \cup S(P_1)$. In particular, for every pair P_2 with $P_1 \prec P_2$ and $P_2 \neq S(P_1)$, it holds that $E(G[P_1, P_2]) = \emptyset$.

Now suppose that $P_1 = \min(\prec)$. Since the splitting of P_1 must be induced by a splitting of a union of two pairs and $G[P_1, S(P_1)]$ is biregular and $G[P_1]$ is regular, we cannot have $N(P_1) \subseteq S(P_1)$. Thus, there is a pair P_2 with $S(P_1) \prec P_2$ and such that $E(G[P_1, P_2]) \neq \emptyset$. Let $v_1 \in P_1$ be a vertex with $N(v_1) \cap P_2 \neq \emptyset$. Then $P_2 \subseteq N(v_1)$, otherwise $P_2 = S(P_1)$. Thus, $G[\{v_1\}, P_2]$ is complete bipartite. Therefore and due to the degree restrictions, v_1 has exactly three neighbours: one in $S(P_1)$ and two in P_2. In particular, for every pair P_2' with $P_2 \neq P_2' \neq S(P_1)$, it holds that $E(G[\{v_1\}, P_2']) = \emptyset$.

Let $v_1' \neq v_1$ be the second vertex in P_1. Since the splitting of P_1 induces the splitting of $S(P_1)$, by Proposition 8, for every pair P' with $P_1 \neq P' \neq S(P_1)$, the graph $G[\{v_1'\}, P']$ must be biregular, i.e. either empty or complete bipartite.

Moreover, since $\deg(v_1) = 3$, also $\deg(v_1') = 3$. By Corollary 15, $|N(v_1') \cap S(P_1)| = 1$. Therefore, there is exactly one pair P_2' such that $G[\{v_1'\}, P_2']$ is complete bipartite and for all other pairs P' with $P_1 \neq P' \neq S(P_1)$, the graph $G[\{v_1'\}, P']$ is empty.

Suppose $P_2' = P_2$. Choose i such that $\pi^i \setminus \pi^{i+1} = \{P_1\}$. Then the unique element in $\pi^{i-1} \setminus \pi^i$ is a union of two pairs, whose splitting induces the splitting of P_1. However, $N(P_1) = S(P_1) \cup P_2$ and both graphs $G[P_1, S(P_1)]$ and $G[P_1, P_2]$ are biregular.

Thus, $P_2' \neq P_2$, which concludes the proof. ◀

Corollary 15 and Lemma 16 characterise $G[P_1, P_2]$ for all pairs $P_1 \neq P_2$. Thus, all additional edges must be between vertices from the same pair. Hence, we can use the following compact graphical representation to fully describe the graphs of order at least 12 that we found. As the set of nodes, we take the pairs. We order them according to $\prec$ and connect successive pairs with an edge representing the matching. If the two vertices of a pair are adjacent, we indicate this with a loop at the corresponding node. The only other type of connection between pairs is constituted by the edges from $\min(\prec)$ to two other pairs which form the last colour class of size 4, i.e. a colour class of size 4 in the partition π^i for which $\pi^{i+1} \setminus \pi^{i+2} = \{\min(\prec)\}$. We indicate this type of edge with a dotted curve.

An example graph as well as the evolution of the colour classes computed by Colour Refinement on the graph is depicted in Figure 1.

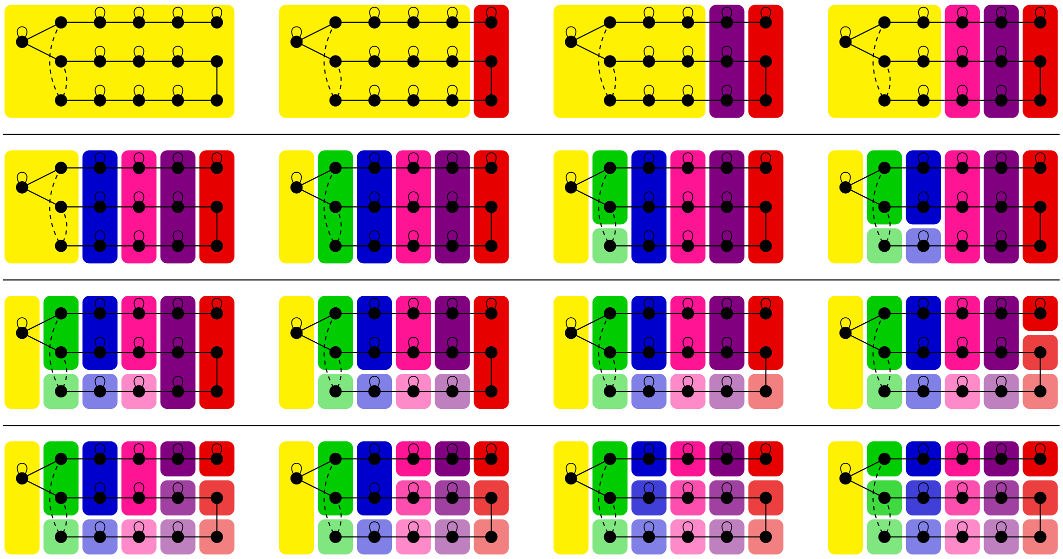

Figure 1 Top left: A long-refinement graph G on 32 vertices. The subsequent pictures show the partitions of $V(G)$ after the first 15 Colour Refinement iterations. There are 16 further iterations not depicted here, which consist in the splitting of the pairs into singletons.

In fact, there is an even more compact representation for our even-order long-refinement graphs.

▶ **Notation 17.** *Since $\prec$ is a linear order, we can also use a string representation to fully describe the graphs. For this, we introduce the following notation, letting $A(P)$ and $S(P)$ be the predecessor and successor of P, respectively, with respect to $\prec$.*

- *0 represents a pair of vertices of degree 2.*
- *1 represents a pair P of vertices of degree 3 that is not the minimum of $\prec$ and for which $N(P) \subseteq A(P) \cup S(P)$. (This implies that $P \in E(G)$.)*
- *X represents a pair P of vertices of degree 3 that is not the minimum of $\prec$ and for which $N(P) \nsubseteq A(P) \cup S(P)$.*
- *S represents the minimum of $\prec$.*

Thus, by Lemma 16, there are exactly two pairs of type X, namely P_2 and P_2' from the lemma. Now we can use the alphabet $\Sigma = \{0, 1, \mathrm{S}, \mathrm{X}\}$ and the order $\prec$ to encode the graphs in strings. The i-th letter of a string is the i-th element of $\prec$. Note that S is always a pair of non-adjacent vertices of degree 3 due to the degree restrictions. For example, the string representation for the graph in Figure 1 is S11100111X1X1110.

Formally, for every $\ell \geq 3$ and every string $\Xi\colon [\ell] \to \{0, 1, \mathrm{S}, \mathrm{X}\}$ with $\Xi(1) = \mathrm{S}$ and $\Xi^{-1}(\mathrm{X}) = \{r, r'\}$ for some $r, r' \in [\ell]$ with $r < r'$, we define the corresponding graph $G := G(\Xi)$ with $V(G) = \{v_{i,j} \mid i \in [\ell], j \in [2]\}$ and

$$\begin{aligned} E(G) = {} & \bigl\{\{v_{i,1}, v_{i,2}\} \bigm| i \in [\ell], \Xi(i) = 1\bigr\} \cup \\ & \bigl\{\{v_{i,j}, v_{i+1,j}\} \bigm| i \in [\ell - 1], j \in [2]\bigr\} \cup \\ & \bigl\{\{v_{r,j}, v_{1,1}\} \bigm| j \in [2]\bigr\} \cup \\ & \bigl\{\{v_{r',j}, v_{1,2}\} \bigm| j \in [2]\bigr\}. \end{aligned}$$

We use this encoding in the next section, which contains our main results.

5 Infinite Families of Long-Refinement Graphs

In this section, we present infinite families of long-refinement graphs. We adapt them further to deduce that $\mathrm{WL}_1(n) \geq n - 2$ holds for all $n \in \mathbb{N}_{\geq 10}$.

For $w \in \{0, 1\}^*$, the notation $(w)^k$ abbreviates the k-fold concatenation of w. We let $1^k := (1)^k$.

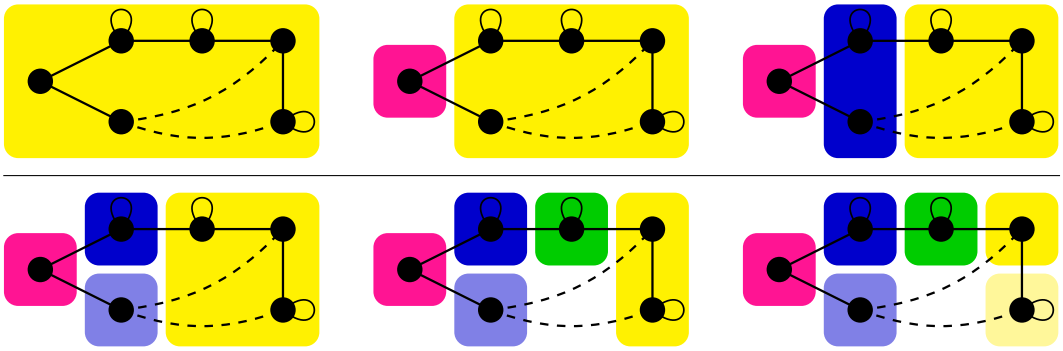

Figure 2 A visualisation of the graph with string representation S011XX and the evolution of the colour classes in the first 5 Colour Refinement iterations on the graph.

Theorem 18. *For every string Ξ contained in the following sets, the graph $G(\Xi)$ is a long-refinement graph.*

- $\{\mathrm{S011XX}\}$
- $\{\mathrm{S1}^k\mathrm{001}^k\mathrm{X1X1}^k\mathrm{0} \mid k \in \mathbb{N}_0\}$
- $\{\mathrm{S1}^k\mathrm{11001}^k\mathrm{XX1}^k\mathrm{0} \mid k \in \mathbb{N}_0\}$
- $\{\mathrm{S1}^k\mathrm{0011}^k\mathrm{XX1}^k\mathrm{10} \mid k \in \mathbb{N}_0\}$
- $\{\mathrm{S011(011)}^k\mathrm{00(110)}^k\mathrm{XX(011)}^k\mathrm{0} \mid k \in \mathbb{N}_0\}$
- $\{\mathrm{S(011)}^k\mathrm{00(110)}^k\mathrm{1X0X1(011)}^k\mathrm{0} \mid k \in \mathbb{N}_0\}$

We only present the parts of the proof that are most essential for an intuition why the graphs are indeed long-refinement graphs. The full proof can be found in [21].

Proof. Let $G := G(\mathrm{S011XX})$ (cf. Figure 2). The vertices $v_{2,1}$ and $v_{2,2}$ are the only ones of degree 2. Thus,

$$\begin{aligned} \pi^1 &= \bigl\{\{v_{2,1}, v_{2,2}\}, V(G) \setminus \{v_{2,1}, v_{2,2}\}\bigr\}, \\ \pi^2 &= \bigl\{\{v_{2,1}, v_{2,2}\}, \{v_{i,j} \mid i \in \{1, 3\}, j \in [2]\}, \{v_{i,j} \mid i \in [4, 6], j \in [2]\}\bigr\}. \end{aligned}$$

Then

$$\pi^3 = \bigl\{\{v_{1,1}, v_{1,2}\}, \{v_{2,1}, v_{2,2}\}, \{v_{3,1}, v_{3,2}\}, \{v_{i,j} \mid i \in [4,6], j \in [2]\}\bigr\},$$

since the vertices in the S-pair have no neighbours in $\{v_{i,j} \mid i \in \{1,3\}, j \in [2]\}$. Similarly,

$$\pi^4 = \bigl\{\{v_{1,1}, v_{1,2}\}, \{v_{2,1}, v_{2,2}\}, \{v_{3,1}, v_{3,2}\}, \{v_{4,1}, v_{4,2}\}, \{v_{i,j} \mid i \in [5,6], j \in [2]\}\bigr\},$$
$$\pi^5 = \bigl\{\{v_{i,j} \mid j \in [2]\} \mid i \in [6]\bigr\}.$$

Now the splitting of the last colour class of size 4 into two X-pairs induces the splitting of the S-pair into singletons, which is propagated linearly according to $\prec$, adding 6 further iterations, thus summing up to 11 iterations.

We now consider the various infinite families of graphs. The proofs for them work similarly by induction over k. Therefore, we only present the full detailed proof for the family $\{\mathrm{S}1^k001^k\mathrm{X}1\mathrm{X}1^k0 \mid k \in \mathbb{N}_0\}$, which includes the graph from Figure 1.

For $k = 0$, the graph $G_0 := G(\mathrm{S00X1X0})$ has 14 vertices. It is easy to verify that it indeed takes 13 Colour Refinement iterations to stabilise. We sketch how Colour Refinement processes the graph: for this, for $i \in \mathbb{N}_0$, we let π_0^i denote the partition of $V(G_0)$ induced by $\chi_{G_0}^i$, i.e. after i iterations of Colour Refinement on G_0. First, vertices are assigned colours indicating their degrees. That is,

$$\pi_0^1 = \bigl\{\{v_{i,j} \mid i \in \{2,3,7\}, j \in [2]\}, \{v_{i,j} \mid i \in \{1,4,5,6\}, j \in [2]\}\bigr\}.$$

Now

$$\pi_0^2 = \bigl\{\{v_{i,j} \mid i \in \{2,3,7\}, j \in [2]\}, \{v_{i,j} \mid i \in \{1,4,6\}, j \in [2]\}, \{v_{5,i} \mid i \in [2]\}\bigr\},$$

since the vertices contained in the 1-pair are not adjacent to vertices from 0-pairs. Since no vertex contained in the S-pair is adjacent to any vertex from the 1-pair, we obtain

$$\pi_0^3 = \bigl\{\{v_{i,j} \mid i \in \{2,3,7\}, j \in [2]\}, \{v_{i,j} \mid i \in \{4,6\}, j \in [2]\}, \{v_{5,i} \mid j \in [2]\},$$
$$\{v_{1,j} \mid j \in [2]\}\bigr\}.$$

Furthermore,

$$\pi_0^4 = \bigl\{\{v_{i,j} \mid i \in \{3,7\}, j \in [2]\}, \{v_{i,j} \mid i \in \{4,6\}, j \in [2]\}, \{v_{5,i} \mid j \in [2]\},$$
$$\{v_{1,j} \mid j \in [2]\}, \{v_{2,j} \mid j \in [2]\}\bigr\},$$
$$\pi_0^5 = \bigl\{\{v_{7,j} \mid j \in [2]\}, \{v_{i,j} \mid i \in \{4,6\}, j \in [2]\}, \{v_{5,i} \mid j \in [2]\},$$
$$\{v_{1,j} \mid j \in [2]\}, \{v_{2,j} \mid j \in [2]\}, \{v_{3,j} \mid j \in [2]\}\bigr\},$$
$$\pi_0^6 = \bigl\{\{v_{i,j} \mid j \in [2]\} \mid i \in [7]\bigr\},$$

i.e. with respect to the order $\prec$ induced by the string representation, the first 0-pair, the second 0-pair, and the first X-pair are separated from the others. Once the two X-pairs form separate colour classes, this induces the splitting of S into two singletons, which is propagated linearly through the entire string, adding 7 further iterations, thus summing up to 13 iterations.

For general $k \geq 1$, let $G_k := G(\mathrm{S}1^k001^k\mathrm{X}1\mathrm{X}1^k0)$. To count the iterations of Colour Refinement, we introduce some vocabulary for the pairs in G_k (see also Figure 1). We let $V := \{v_{i,j} \mid i \in [2, k{+}1] \cup [k{+}4, 2k{+}3] \cup [2k{+}7, 3k{+}6], j \in [2]\}$. Note that V is the set of vertices contained in the subgraphs corresponding to the substrings 1^k in the string representation.

Furthermore, for all $i \in [k+2]$, we call the set $\{v_{i',j} \mid i' \in \{i, 2k+5-i, 2k+5+i\}, j \in [2]\}$ the *i-th column* and denote it by V_i. The *0-th column* is the set $\{v_{2k+5,j} \mid j \in [2]\}$. Thus,

$$V = \bigcup_{2 \le i \le k+1} V_i.$$

For every $j \in [2]$, the sets $\{v_{i,j} \mid i \in [1, k+2]\}$, $\{v_{i,j} \mid i \in [k+3, 2k+4]\}$, and $\{v_{i,j} \mid i \in [2k+6, 3k+7]\}$ are called *rows*. In accordance with Figure 1, we fix an ordering on the rows: the *first row* is $\{v_{i,1} \mid i \in [2k+6, 3k+7]\}$, the *second row* is $\{v_{i,2} \mid i \in [2k+6, 3k+7]\}$, $\dots$, the *sixth row* is $\{v_{i,2} \mid i \in [1, k+2]\}$. To be able to refer to the vertices in V and the adjacent columns more easily, we relabel them: for $i \in [k+2], j \in [6]$, the vertex $w_{i,j}$ is defined to be the unique vertex in the i-th column and the j-th row.

The following observation is the crucial insight for counting the iterations of Colour Refinement on G_k. We will use it to show that, informally stated, the subgraph $G_k[V]$ delays the propagation of the splitting of the colour classes in the remainder of the graph by k iterations whenever the splitting of a colour class contained in V_1 or V_{k+2} initiates a splitting of a colour class contained in V.

▷ Claim 19. Consider a colouring λ of G_k and its induced partition π_k of $V(G_k)$. For $t \in \mathbb{N}_0$, let π_k^t be the partition induced by $\chi_{G_k}^t$ on input (G_k, λ). Suppose G_k, λ, π_k satisfy the following conditions.

1. There exist $\ell \in [6]$ and $I_1, \dots, I_\ell \subseteq [6]$ such that $\bigcup_{i \in [\ell]} I_i = [6]$ and $I_i \cap I_j = \emptyset$ for $1 \le i < j \le \ell$ and for every $i \in [\ell]$, it holds that $\{w_{k+2,j'} \mid j' \in I_i\} \in \pi_k^0$. That is, V_{k+2} is a union of colour classes with respect to λ.
2. $\pi_k^1 = \big\{\{w_{k+1,j'} \mid j' \in I_i\} \,\big|\, i \in [\ell]\big\} \cup \big\{C \setminus V_{k+1} \,\big|\, C \in \pi_k, C \setminus V_{k+1} \neq \emptyset\big\}$.
3. For all $C, C' \subseteq V_{k+1}$ with $C, C' \in \pi_k^1$, the graph $G_k[C]$ is regular and $G_k[C, C']$ is biregular.

Then for every $t \in [k]$, it holds that

$$\pi_k^t = \bigcup_{i' \in [t]} \big\{\{w_{k+2-i',j'} \mid j' \in I_i\} \,\big|\, i \in [\ell]\big\} \cup \left\{C \setminus \Big(\bigcup_{i' \in [t]} V_{k+2-i'}\Big) \,\middle|\, C \in \pi_k^0, C \setminus \Big(\bigcup_{i' \in [t]} V_{k+2-i'}\Big) \neq \emptyset\right\}.$$

The proof of the claim follows by induction on t. For $t = 1$, the statement is exactly the second item from the assumptions. The induction step is quite technical and we defer the reader to the full version for the details [21]. Informally speaking, the idea is to show that, within one iteration of Colour Refinement, if there is a a column V_i with $i \in [2, k+1]$ whose partition into row indices is strictly coarser than the partition of the column V_{i+1}, then V_i copies the partition from V_{i+1} and all other colour classes remain intact.

We call the property described in the claim *path propagation from right to left.* Modifying the indices, a similar statement yields *path propagation from left to right*, as formulated in the following claim.

▷ Claim 20. Consider a colouring λ of G_k and its induced partition π_k of $V(G_k)$. For $t \in \mathbb{N}_0$, let π_k^t be the partition induced by $\chi_{G_k}^t$ on input (G_k, λ). Suppose G_k, λ, π_k satisfy the following conditions.

1. There exist $\ell \in [6]$ and $I_1, \dots, I_\ell \subseteq [6]$ such that $\bigcup_{i \in [\ell]} I_i = [6]$ and $I_i \cap I_j = \emptyset$ for $1 \le i < j \le \ell$ and for every $i \in [\ell]$, it holds that $\{w_{1,j'} \mid j' \in I_i\} \in \pi_k$. That is, the first column is a union of colour classes with respect to λ.

2. $\pi_k^1 = \{\{w_{2,j'} \mid j' \in I_i\} \,|\, i \in [\ell]\} \cup \{C \setminus V_2 \,|\, C \in \pi_k, C \setminus V_2 \neq \emptyset\}$.
3. For all $C, C' \subseteq V_2$ with $C, C' \in \pi_k^1$, the graph $G_k[C]$ is regular and $G_k[C, C']$ is biregular.

Then for every $t \in [k]$, it holds that

$$\pi_k^t = \bigcup_{i' \in [t]} \{\{w_{i'+1,j'} \mid j' \in I_i\} \,|\, i \in [\ell]\} \cup \left\{C \setminus \Big(\bigcup_{i' \in [t]} V_{i'+1}\Big) \,\middle|\, C \in \pi_k^0, C \setminus \Big(\bigcup_{i' \in [t]} V_{i'+1}\Big) \neq \emptyset\right\}.$$

Again, we defer the reader to the full version for the proof details for the path propagation. We are now ready to analyse the run of Colour Refinement on input G_k. Recall that π_0^t denotes the partition induced by $\chi_{G_0}^t$ on $V(G_0) \subseteq V(G_k)$. For the following arguments, see also Figure 1.

In π_k^1, the vertices are distinguished according to their degrees. We can then use path propagation from right to left to deduce that

$$\pi_k^{k+1} = \pi_0^1 \cup \{V_i \,|\, i \in [2, k+1]\} \quad \text{and thus} \quad \pi_k^{k+2} = \pi_0^2 \cup \{V_i \,|\, i \in [2, k+1]\},$$
$$\pi_k^{k+3} = \pi_0^3 \cup \{V_i \,|\, i \in [2, k+1]\} \quad \text{and also} \quad \pi_k^{k+4} = \pi_0^4 \cup \{V_i \,|\, i \in [2, k+1]\}.$$

Now path propagation from left to right yields that

$$\pi_k^{2k+4} = \pi_0^4 \cup \{\{w_{i,j} \mid j \in [4]\} \,|\, i \in [2, k+1]\} \cup \{\{w_{i,j} \mid j \in \{5,6\}\} \,|\, i \in [2, k+1]\}$$

and $\pi_k^{2k+5} = \pi_0^5 \cup (\pi_k^{2k+4} \setminus \pi_0^4)$. With three more combinations of path propagation from right to left and path propagation from left to right, we obtain

$$\pi_k^{6k+13} = \pi_0^{13} \cup \{\{w_{i,j}\} \,|\, i \in [2, k+1], j \in [6]\},$$

which is the discrete partition by the induction assumption for $k = 0$.

This implies that on input G_k, Colour Refinement takes $6k + 13$ iterations to stabilise and, since $|G_k| = 6k + 14$, it holds that $\mathrm{WL}_1(G_k) = n - 1$, where $n = |G_k|$. ◀

▶ **Corollary 21.** *There are infinitely many $n \in \mathbb{N}$ with $\mathrm{WL}_1(n) = n - 1$.*

▶ **Corollary 22.** *For every even $n \in \mathbb{N}_{\geq 12}$ such that $n = 12$ or $n \bmod 18 \notin \{6, 12\}$, there is a long-refinement graph G with $|G| = n$. The graph G can be chosen to satisfy $\deg(G) = \{2, 3\}$.*

Proof. The string representation S011XX covers $n = 12$. The first infinite family from Theorem 18 covers all even $n \in \mathbb{N}_{\geq 14}$ with $n = 2 \mod 6$, i.e. with $n \bmod 18 \in \{2, 8, 14\}$. The second and the third infinite family both cover all even $n \in \mathbb{N}_{\geq 16}$ with $n = 4 \mod 6$, i.e. with $n \bmod 18 \in \{4, 10, 16\}$. The fourth and the fifth infinite family cover all even $n \in \mathbb{N}_{\geq 18}$ with $n = 0 \mod 18$. Thus, among the even graph orders larger than 12, only the ones with $n \bmod 18 \in \{6, 12\}$ remain not covered. ◀

We now turn to the long-refinement graphs G of odd order with vertex degrees in $\{2, 3\}$. If the graph has odd order, we cannot represent it just with pairs. For this, we relax Assumption 14 as follows.

▶ **Assumption 23.** *G is a long-refinement graph with $\deg(G) = \{2, 3\}$ and such that there is an $i \in \mathbb{N}_0$ for which π^i contains only pairs and at most one singleton.*

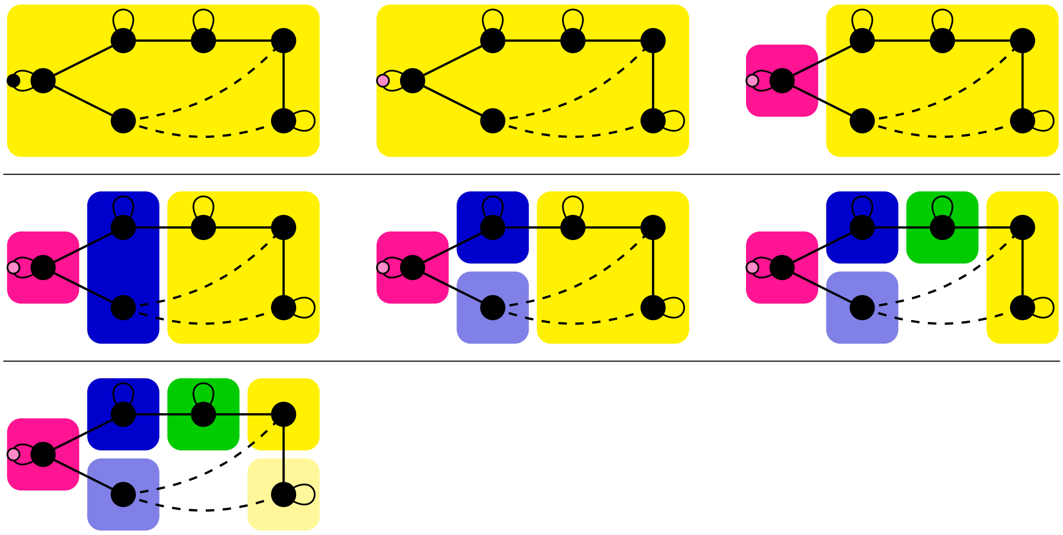

Figure 3 A visualisation of the graph with string representation S$\hat{1}$11XX and the evolution of the colour classes in the first 6 Colour Refinement iterations on the graph.

We maintain the vocabulary and notation from the long-refinement graphs of even order, i.e. 0, 1, S, X will be used in the same way as before. However, in order to fully describe the odd-order graphs via strings, we have to extend the string alphabet by fresh letters $\hat{1}$ and $\hat{\mathrm{X}}$, which represent particular pairs with attached vertices as follows. For a string $\hat{\Xi}\colon [\ell] \to \{0, 1, \mathrm{S}, \mathrm{X}, \hat{1}, \hat{\mathrm{X}}\}$, we define the *base string* Ξ as the string obtained by removing hats. More precisely, we replace every $\hat{\mathrm{X}}$ with an X, and we replace every $\hat{1}$ with a 1 if it is non-terminal (i.e. if it is not at position ℓ) and with a 0 otherwise. Let $I(\hat{\Xi}) \subseteq [\ell]$ be the set of positions i with $\hat{\Xi}(i) \in \{\hat{1}, \hat{X}\}$. If, in the base graph $G(\Xi)$, every vertex pair corresponding to a position in $I(\hat{\Xi})$ (a *hat vertex pair*) is adjacent, we call $\hat{\Xi}$ a *hat string*.

Similarly as for the even-order long-refinement graphs, to every hat string $\hat{\Xi}$, we assign a graph $G(\hat{\Xi})$. We obtain the graph $G(\hat{\Xi})$ by subdividing in $G(\Xi)$ each edge connecting a hat vertex pair with a new fresh vertex, which we call a *hat*. Additionally, if the vertices of the hat vertex pair have degree 2, we now insert another edge between them. (This can only happen if the hat vertex pair corresponds to a terminal 0.) For a hat $\hat{v}$, we call the neighbourhood $N(\hat{v}) \subseteq V\big(G(\hat{\Xi})\big)$ the *hat base* of $\hat{v}$. Note that every vertex in the hat base has degree 3 by construction. Also, a hat always has degree 2 and thus, with respect to $\chi^1_{G(\hat{\Xi})}$, it has a different colour than its hat base.

Graphically, we represent a hat by a loop attached to the corresponding hat vertex pair, which we subdivide by inserting a small vertex (see Figure 3). It is not difficult to see that every graph $G(\hat{\Xi})$ corresponding to a hat string $\hat{\Xi}$ has exactly one hat and that the hat is the first vertex forming a singleton colour class during the execution of Colour Refinement on $G(\hat{\Xi})$. Thus, $|G(\hat{\Xi})| = |G(\Xi)| + 1$.

▶ **Theorem 24.** *For every string $\hat{\Xi}$ contained in the following sets, the graph $G(\hat{\Xi})$ is a long-refinement graph.*

- $\{\mathrm{S}\hat{1}11\mathrm{XX}\}$
- $\{\mathrm{S0X1}\hat{\mathrm{X}}\} \cup \{\mathrm{S1}^k\mathrm{1011}^k\mathrm{X1X1}^k\hat{1} \mid k \in \mathbb{N}_0\}$
- $\{\mathrm{S110X}\hat{\mathrm{X}}\} \cup \{\mathrm{S111}^k\mathrm{1011}^k\mathrm{XX1}^k\hat{1} \mid k \in \mathbb{N}_0\}$
- $\{\mathrm{S1}^k\mathrm{01}^k\mathrm{1XX1}^k\hat{1} \mid k \in \mathbb{N}_0\}$
- $\{\mathrm{S(011)}^k\mathrm{00(110)}^k\mathrm{X}\hat{1}\mathrm{X(011)}^k\mathrm{0} \mid k \in \mathbb{N}_0\}$

Proof sketch. The proof techniques for the infinite families are very similar to the ones presented for Theorem 18. Therefore, we only sketch the proof on two concrete examples containing $\hat{1}$ and $\hat{\mathrm{X}}$, respectively. To be able to refer to vertices explicitly, recall the formal definition of $G := G(\Xi)$ from Section 4. Since for a hat string $\hat{\Xi}$, it holds that $|G(\hat{\Xi})| = |G(\Xi)| + 1$, we can use the same indexing of vertices, additionally letting $\hat{v}$ be the unique hat in $G(\hat{\Xi})$.

In the graph $G := G(\mathrm{S}\hat{1}11\mathrm{XX})$ (cf. Figure 3), the only vertex of degree 2 is $\hat{v}$. Thus, in π^1, it forms a singleton colour class. In π^2, the hat base $\{v_{2,1}, v_{2,2}\}$ forms a new colour class.

In general, for $i \in \mathbb{N}$, we have that $\pi^i_G = \pi^{i-1}_{G'} \cup \{\hat{v}\}$, where $G' = G(\mathrm{S}011\mathrm{XX})$ (cf. Theorem 18 and Figure 2).

Thus,

$$\begin{aligned}
\pi^1 &= \big\{\{\hat{v}\}, V(G) \setminus \{\hat{v}\}\big\},\\
\pi^2 &= \big\{\{\hat{v}\}, \{v_{2,1}, v_{2,2}\}, V(G) \setminus \{\hat{v}, v_{2,1}, v_{2,2}\}\big\},\\
\pi^3 &= \big\{\{\hat{v}\}, \{v_{2,1}, v_{2,2}\}, \{v_{i,j} \mid i \in \{1,3\}, j \in [2]\}, \{v_{i,j} \mid i \in [4,6], j \in [2]\}\big\},\\
\pi^4 &= \big\{\{\hat{v}\}, \{v_{1,1}, v_{1,2}\}, \{v_{2,1}, v_{2,2}\}, \{v_{3,1}, v_{3,2}\}, \{v_{i,j} \mid i \in [4,6], j \in [2]\}\big\},\\
\pi^5 &= \big\{\{\hat{v}\}, \{v_{1,1}, v_{1,2}\}, \{v_{2,1}, v_{2,2}\}, \{v_{3,1}, v_{3,2}\}, \{v_{4,1}, v_{4,2}\}, \{v_{i,j} \mid i \in [5,6], j \in [2]\}\big\},\\
\pi^6 &= \big\{\{\hat{v}\}\big\} \cup \big\{\{v_{i,j} \mid j \in [2]\} \mid i \in [6]\big\}.
\end{aligned}$$

Now in 6 further iterations, the splitting of the pairs is propagated linearly according to the order $\prec$.

Next, let G be the graph $G(\mathrm{S}0\mathrm{X}1\hat{\mathrm{X}})$, i.e. a member of the first infinite family from Theorem 24. It has three vertices of degree 2, namely $\hat{v}$, $v_{2,1}$, and $v_{2,2}$, which therefore form a colour class in π^1. Also, the vertices contained in the 1-pair are the only vertices of degree 3 that are not adjacent to any vertex of degree 2. Thus,

$$\pi^2 = \big\{\{\hat{v}, v_{2,1}, v_{2,2}\}, \{v_{4,1}, v_{4,2}\}, V(G) \setminus \{\hat{v}, v_{2,1}, v_{2,2}, v_{4,1}, v_{4,2}\}\big\},$$

and similarly,

$$\pi^3 = \big\{\{\hat{v}, v_{2,1}, v_{2,2}\}, \{v_{4,1}, v_{4,2}\}, \{v_{1,1}, v_{1,2}\}, \{v_{i,j} \mid i \in \{3,5\}, j \in [2]\}\big\}.$$

Now the hat forms a singleton since, in contrast to the vertices of the 0-pair, it is not adjacent to any vertex in the S-pair. We obtain:

$$\begin{aligned}
\pi^4 &= \big\{\{\hat{v}\}, \{v_{2,1}, v_{2,2}\}, \{v_{4,1}, v_{4,2}\}, \{v_{1,1}, v_{1,2}\}, \{v_{i,j} \mid i \in \{3,5\}, j \in [2]\}\big\},\\
\pi^5 &= \big\{\{\hat{v}\}\big\} \cup \big\{\{v_{i,j} \mid j \in [2]\} \mid i \in [5]\big\}.
\end{aligned}$$

Then in 5 further iterations, the splitting of the pairs is propagated linearly according to the order $\prec$. ◀

As an example, Figure 3 shows the evolution of the colour classes of the graph with string representation $\mathrm{S}\hat{1}11\mathrm{XX}$.

▶ **Corollary 25.** *For every odd $n \in \mathbb{N}_{\geq 11}$ with $n \bmod 18 \notin \{3, 9\}$, there is a long-refinement graph G with $|G| = n$. The graph G can be chosen to satisfy* $\deg(G) = \{2, 3\}$.

Proof. The string representation $\mathrm{S}\hat{1}11\mathrm{XX}$ covers $n = 13$. The first infinite family covers all odd $n \in \mathbb{N}_{\geq 11}$ with $n = 5 \mod 6$, i.e. with $n \bmod 18 \in \{5, 11, 17\}$. The second and the third infinite family both cover all all odd $n \in \mathbb{N}_{\geq 13}$ with $n = 1 \mod 6$, i.e. with $n \bmod 18 \in \{1, 7, 13\}$. The fourth infinite family covers all odd $n \in \mathbb{N}_{\geq 15}$ with $n = 15 \mod 18$. Thus, among the odd orders larger than 10, only the ones with $n \bmod 18 \in \{3, 9\}$ are skipped. ◀

We summarise the results from Corollaries 22 and 25.

▶ **Corollary 26.** *For every $n \in \mathbb{N}_{\geq 11}$ such that $n = 12$ or $n \bmod 18 \notin \{3, 6, 9, 12\}$, there is a long-refinement graph G with $|G| = n$. The graph G can be chosen to satisfy* $\deg(G) = \{2, 3\}$.

The following lemma allows to cover more graph sizes.

▶ **Lemma 27.** *Let $n \in \mathbb{N}$ be arbitrary. Suppose there is a long-refinement graph G such that $|G| = n$. If there is a $d \in \mathbb{N}$ with* $\deg(G) = \{d, d+1\}$ *such that* $|\{v \in V(G) \mid \deg(v) = d\}| \neq d + 1$, *then there is also a long-refinement graph G' with $|G'| = n + 1$.*

Proof. We can insert an isolated vertex w into G and insert edges from w to every vertex $v \in V(G)$ with $\deg(v) = d$. In the new graph G', the vertex w has a degree other than $d+1$, whereas all other vertices have degree $d+1$. Thus, the colour classes in $\pi^1_{G'}$ are $\{w\}$ and $V(G') \setminus \{w\}$. After the second iteration, the neighbours of w are distinguished from all other vertices, just like they are in π^1_G. Inductively, it is easy to see that for $i \in \mathbb{N}$, it holds that $\pi^i_{G'} = \pi^{i-1}_G \cup \big\{\{w\}\big\}$. Thus, Colour Refinement takes $n - 1 + 1 = n$ iterations to stabilise on G'. ◀

▶ **Corollary 28.** *For every odd $n \in \mathbb{N}_{\geq 11}$, there is a long-refinement graph G with $|G| = n$.*

Proof. By Corollary 25, it suffices to provide long-refinement graphs of order n for every odd $n \in \mathbb{N}_{\geq 11}$ with $n \bmod 18 \in \{3, 9\}$. We will accomplish this by applying Lemma 27 to suitable graphs of orders n' with $n' \bmod 18 \in \{2, 8\}$. Every graph G with a string representation contained in one of the infinite families from Theorem 18 has an even number of vertices of degree 2. In particular, it satisfies $|\{v \in V(G) \mid \deg(v) = 2\}| \neq 3$. Furthermore, every even graph order larger than 10 not covered by Corollary 22 is a multiple of 6. Hence, since $N := \{n \in \mathbb{N}_{\geq 18} \mid n \bmod 18 \in \{2, 8\}\}$ contains only even numbers and no multiples of 6, for every $n' \in N$, there is a graph of order n' that satisfies the prerequisites of Lemma 27 with $d = 2$. (Actually, we can cover all of these graph orders with the family $\{\mathrm{S}1^k 001^k \mathrm{X}1\mathrm{X}1^k 0 \mid k \in \mathbb{N}_0\}$.)

Thus, applying the lemma, we can construct for every $n \in \mathbb{N}_{\geq 18}$ with $n \bmod 18 \in \{3, 9\}$ a long-refinement graph G' of order n. ◀

Note that, since we apply Lemma 27 to close the gaps, we cannot guarantee anymore that the vertex degrees are 2 and 3, as we could in Corollary 26.

We are ready to prove Theorem 1.

Proof of Theorem 1. The theorem follows from combining Corollaries 22 and 28 with Theorem 7. ◀

Although the theorem leaves some gaps, we can show that, starting from $n = 10$, the worst-case number of Colour Refinement iterations until stabilisation on graphs of order n is always either $n - 2$ or $n - 1$.

Proof of Theorem 2. By Theorem 1, we only need to consider the numbers $n \geq 24$ for which $n \bmod 18 \in \{6, 12\}$. Since these numbers are all even, for every such n, we can use Corollary 28 to obtain a long-refinement graph G' with $|G'| = n - 1$. Let v be a fresh vertex not contained in $V(G')$. Now define $G := (V, E)$ with $V := V(G') \cup \{v\}$ and $E := E(G')$. Then $\pi^i_G = \pi^i_{G'} \cup \{\{v\}\}$ for every $i \in \mathbb{N}$. In particular, $\mathrm{WL}_1(G) = \mathrm{WL}_1(G') = n - 2$. ◀

6 Conclusion

With Theorem 2, it holds for all $n \in \mathbb{N}_{\geq 10}$ that $\mathrm{WL}_1(n) \geq n-2$. In particular, this proves that the trivial upper bound $\mathrm{WL}_1(n) = n-1$ is tight, up to an additive constant of 1.

For infinitely many graph orders, the graph G can even be chosen to have vertex degrees 2 and 3, as Theorems 18 and 24 show. We applied Lemma 27 to cover some of the remaining sizes. However, no order $n \in \mathbb{N}_{\geq 18}$ with $n \bmod 18 \in \{6, 12\}$ is covered by Theorem 18. Also, for $|G| \in \{n \in \mathbb{N}_{\geq 18} \mid n \bmod 18 \in \{5, 11\}\}$, all the long-refinement graphs G we have found satisfy $|\{v \in V(G) \mid \deg(v) = 2\}| = 3$ (see the first infinite family in Theorem 24). Thus, these graphs do not satisfy the prerequisites of Lemma 27. Note that we cannot apply the construction from the proof if $|\{v \in V(G) \mid \deg(v) = d\}| = d+1$, since the new graph G' would be $(d+1)$-regular and would thus satisfy $\mathrm{WL}_1(G') = 0$. Hence, it is not clear how to apply our techniques to construct a long-refinement graph of order 24. Altogether, the values $n \in \mathbb{N}_{\geq 24}$ with $n \bmod 18 \in \{6, 12\}$ are precisely the graph orders for which it remains open whether there is a graph G with $\mathrm{WL}_1(G) = |G| - 1$.

A related question is for which values $d_1 \neq d_2$ there are long-refinement graphs G with $\deg(G) = \{d_1, d_2\}$. It would be nice to know whether we have actually found all long-refinement graphs G with $\deg(G) = \{2, 3\}$. Similarly, we can ask for long-refinement graphs when fixing other parameters. For example, since all long-refinement graphs that we found have girth at most 4, it would be interesting to know whether there exists any long-refinement graph with larger girth, or infinite families with unbounded girth.

Also, in the light of the graph isomorphism problem, it is a natural follow-up task to find for each order n pairs of non-isomorphic graphs G, H for which it takes $n-1$ Colour Refinement iterations to distinguish the graphs from each other. A first step towards this goal is the search for pairs of long-refinement graphs of equal order. It is easy to see that for infinitely many n, Theorems 18 and 24 yield such pairs of graphs. Still, for example, when evaluating the colourings computed by Colour Refinement on the graphs with string representations S1100XX0 and S001XX10, they differ after less than $n-1$ iterations. To see this, observe that in G(S1100XX0), all vertices of degree 2 have paths of length 3 to a vertex of degree 2 whose inner vertices only have degrees other than 2. This is not the case for G(S001XX10) and this property is detected by Colour Refinement after at most 4 iterations. Thus, finding for $n \in \mathbb{N}_{\geq 10}$ two graphs of order n which Colour Refinement only distinguishes after $n-1$ iterations remains a challenge.

Abstract

In the online *set-disjointness* problem the goal is to preprocess a family of sets $\mathcal{F}$, so that given two sets $S, S' \in \mathcal{F}$, one can quickly establish whether the two sets are disjoint or not. If $N = \sum_{S\in\mathcal{F}} |S|$, then let N^p be the preprocessing time and let N^q be the query time. The most efficient known combinatorial algorithm is a generalization of an algorithm by Cohen and Porat [TCS'10] which has a tradeoff curve of $p + q = 2$. Kopelowitz, Pettie, and Porat [SODA'16] showed that, based on the 3SUM hypothesis, there is a conditional lower bound curve of $p + 2q \geq 2$. Thus, the current state-of-the-art exhibits a large gap.

The online *set-intersection* problem is the reporting version of the online set-disjointness problem, and given a query, the goal is to report all of the elements in the intersection. When considering algorithms with N^p preprocessing time and $N^q + O(op)$ query time, where op is the size of the output, the combinatorial algorithm for online set-disjointess can be extended to solve online set-intersection with a tradeoff curve of $p + q = 2$. Kopelowitz, Pettie, and Porat [SODA'16] showed that, assuming the 3SUM hypothesis, for $0 \leq q \leq 2/3$ this curve is tight. However, for $2/3 \leq q < 1$ there is no known lower bound.

In this paper we close both gaps by showing the following:

- For online set-disjointness we design an algorithm whose runtime, assuming $\omega = 2$ (where ω is the exponent in the fastest matrix multiplication algorithm), matches the lower bound curve of Kopelowitz et al., for $q \leq 1/3$. We then complement the new algorithm by a matching conditional lower bound for $q > 1/3$ which is based on a natural hypothesis on the time required to detect a triangle in an unbalanced tripartite graph. Remarkably, even if $\omega > 2$, the algorithm matches the lower bound curve of Kopelowitz et al. for $p \geq 1.73688$ and $q \leq 0.13156$.
- For set-intersection, we prove a conditional lower bound that matches the combinatorial upper bound curve for $q \geq 1/2$ which is based on a hypothesis on the time required to enumerate all triangles in an unbalanced tripartite graph.
- Finally, we design algorithms for detecting and enumerating triangles in unbalanced tripartite graphs which match the lower bounds of the corresponding hypotheses, assuming $\omega = 2$.

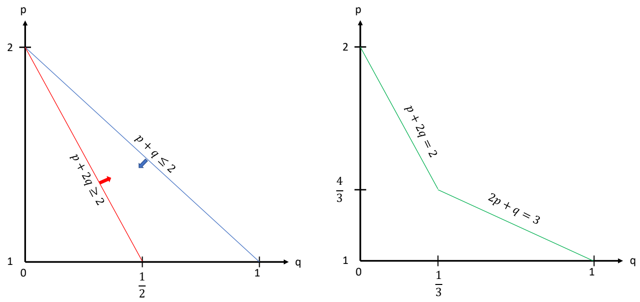

Figure 1 The left graph depicts the gap between the upper bound and lower bound curves for online SetDisjointness prior to this work. The lower bound tradeoff (red curve) is based on the 3SUM hypothesis and the upper bound tradeoff (blue curve) is a variation of the algorithm of Cohen and Porat [14]. The right graph depicts the optimal online SetDisjointness tradeoff (green curve) shown in this paper, assuming that $\omega = 2$.

1 Introduction

In the *online SetDisjointness* problem the goal is to preprocess a family F of subsets from universe U such that given a query pair $(S, S') \in \mathcal{F} \times \mathcal{F}$, one can quickly establish whether S and S' are disjoint or not. The *online SetIntersection* problem is the reporting version of the online SetDisjointness problem, where given a query pair $(S, S') \in \mathcal{F} \times \mathcal{F}$ one must enumerate all of the elements in $S \cap S'$.

Set-disjointness problems at large, including both online SetDisjointness and online SetIntersection, are fundamental algorithmic problems, and have many applications, for example, in information retrieval [14, 24, 20], graph related problems [28, 5, 29, 33, 34], and data structures [27, 16, 29]. Moreover, both problems have played a crucial role in obtaining conditional lower bounds (CLB) in fine-grained complexity. Specifically, many CLBs that are based on the 3SUM hypothesis[1] are reductions from 3SUM to versions of SetDisjointness or SetIntersection, which are further reduced to other algorithmic problems [32, 1, 29, 27, 5, 4, 22, 23]. The Boolean matrix multiplication (BMM) problem can be interpreted as online SetDisjointness with the requirement that the answers to all of the queries must be computed and stored during the preprocessing phase. Thus, the "combinatorial" BMM hypothesis[2] and the CLBs that follow [1, 37, 10] are closely related to online SetDisjointness. Another example is the orthogonal vectors (OV) hypothesis[3] [1, 37], which can be interpreted as asking whether a given family of sets contains two disjoint sets.

[1] The 3SUM hypothesis states that in the Word RAM model of computation with $O(\log n)$ bit words, determining whether a set of n integers contains three that sum to 0, requires $n^{2-o(1)}$ time.

[2] This hypothesis roughly states that algorithms for $n \times n$ BMM that are simple and do not use Strassen-like techniques must take $n^{3-o(1)}$ time in the Word RAM Model with $O(\log n)$ bit words.

[3] The OV hypothesis states that in the Word RAM model with $O(\log n)$ bit words, an algorithm that can decide whether a set of n binary vectors of dimension d contains two orthogonal vectors, must take $n^{2-o(1)}d^{O(1)}$ time.

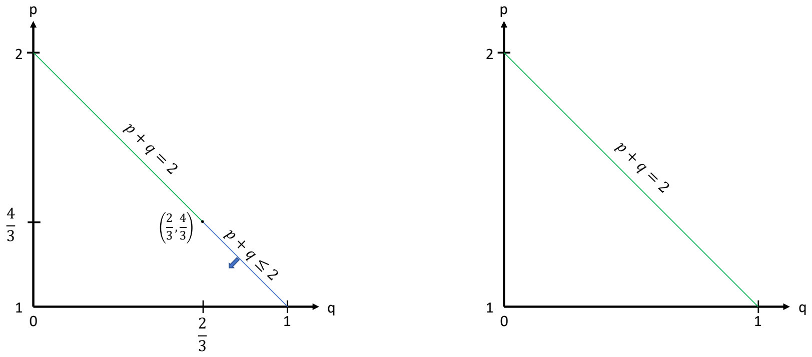

Figure 2 The left graph depicts the gap between the upper bound and lower bound curves for online SetIntersection prior to this work. The green curve (for $q \leq \frac{2}{3}$) is optimal, while the blue curve is an upper bound with no matching lower bound. The right graph depicts the optimal online SetIntersection tradeoff (green curve) shown in this paper, for all values of q.

Measuring efficiency. We measure the efficiency of algorithms for online SetDisjointness and online SetIntersection in terms of $N = \sum_{S\in\mathcal{F}} |S|$. For online SetDisjointness, let N^p and N^q be the preprocessing and query time, respectively. For online SetIntersection, let N^p and $N^q + O(op)$ be the preprocessing and query time, respectively, where op is the size of the output.

When discussing tradeoffs between p and q we make the standard assumption that the preprocessing phase must scan the input at least once, and so $p \geq 1$. Moreover, there is no advantage in allowing $p > 2$ since for $p = 2$ it is straightforward to obtain a constant query time. Thus we assume that $1 \leq p \leq 2$. Similarly, a trivial query algorithm is to scan the entire instance in $O(N)$ time, so we assume that $0 \leq q \leq 1$.

A brief history and the gaps. A variation of the algorithm of Cohen and Porat [14] for online SetDisjointness has $p + q = 2$ (see Section 2.1). A straightforward variation of this algorithm also solves online SetIntersection with $p+q = 2$ (see Section 2.1). To our knowledge, for any values of p and q, there is no published algorithm with a better upper-bound tradeoff.

Regarding lower bounds, assuming the 3SUM hypothesis, Pătraşcu [32] proved that for online SetDisjointness whenever $1 \leq p < 4/3$ we have $q \geq 1/3$. Pătraşcu's CLB is fairly limited with regard to the range of options for p and q. The CLB tradeoff was later improved by Kopelowitz, Pettie and Porat [29] to $p + 2q \geq 2$ for the full range of p and $0 \leq q \leq 1/2$. Kopelowitz et al. [29] also showed that, assuming the 3SUM hypothesis, for online SetIntersection, whenever $4/3 \leq p < 2$ and $0 \leq q \leq 2/3$ we have $p + q \geq 2$. Thus, the combinatorial algorithm is tight for $q \leq \frac{2}{3}$.

In both problems, a large gap remains; see Figures 1 and 2. The goal of this paper is to close the gaps for both problems.

1.1 Our Results

In this paper we take a step towards closing the gaps for both online SetDisjointness and online SetIntersection as follows.

New algorithm for online SetDisjointness. For online SetDisjointness we design an algorithm that utilizes fast matrix multiplication (FMM) (see [15, 36, 35, 31]) and, assuming $\omega = 2$ (where ω is the exponent in the fastest matrix multiplication algorithm), matches the lower bound curve of Kopelowitz et al. [29] for $q \leq 1/3$. The algorithm borrows some ideas from the fast sparse matrix multiplication algorithm of Yuster and Zwick [38], and is stated in the following theorem whose proof appears in Section 2.2.

▶ **Theorem 1.** *There exists an algorithm for the online* SetDisjointness *problem where*

$$\begin{array}{ll} p + \frac{2}{\omega-1}q = 2, & \text{for } 0 \leq q \leq \frac{\omega-1}{\omega+1} \\ \frac{2}{\omega-1}p + q = 1 + \frac{2}{\omega-1}, & \text{for } \frac{\omega-1}{\omega+1} \leq q \leq 1 \end{array}.$$

If $\omega > 2$, the time bounds of Theorem 1 can be improved using fast rectangular matrix multiplication (FRMM) (see [30]). In particular, if we denote by $\omega(1, 1, k)$ the exponent of n in the time required to multiply an $n \times n^k$ matrix by an $n^k \times n$ matrix, then the following corollary is straightforward from the proof of Theorem 1 (see Section 2.2).

▶ **Corollary 2.** *There exists an algorithm for the online* SetDisjointness *problem where*

$$p = (1 - q) \cdot \omega(1, 1, \frac{2-p}{1-q}).$$

We note that, since $\omega(1, 1, k) = 2$ for $k \leq 0.30298$ [30, 21], for the range of $p \geq \frac{4}{2.30298} = 1.73688$ and $q \leq \frac{0.30298}{2.30298} = 0.13156$, the tradeoff becomes $p + 2q = 2$, which is optimal by the 3SUM conjecture.

Unbalanced triangle detection. We complement our new algorithm with a matching CLB for the case of $q \geq 1/3$ which is based on the problem of detecting a triangle in an unbalanced tripartite graph.

▶ **Problem 3** (Unbalanced Triangle Detection). *In the* Unbalanced Triangle Detection *(UTD) problem the goal is to determine whether an undirected tripartite graph $G = (A \cup B \cup C, E)$ contains a triangle or not, where $m_1 = |E \cap (A \times B)|$, $m_2 = |E \cap (B \times C)|$, $m_3 = |E \cap (C \times A)|$, and $m_1 \leq m_2 \leq m_3$.*

▶ **Hypothesis 4** (UTD hypothesis). *Assuming $\omega = 2$, any algorithm for the UTD problem in the word RAM model with $O(\log m_3)$ bit words, for any $m_1 \leq m_2 \leq m_3$, has time cost*

$$\Omega\left((m_1 \cdot m_2)^{\frac{1}{3}} (m_3)^{\frac{2}{3} - o(1)}\right).$$

The UTD hypothesis is the natural extension of the popular Triangle Detection hypothesis [1, 11, 26, 32] which states that, assuming $\omega = 2$, the current best known running time $O(m^{4/3})$ for triangle detection in m-edge graphs is optimal, up to $m^{o(1)}$ factors . To see this, just set $m_1 = m_2 = m_3$ in the UTD hypothesis and the Triangle Detection Hypothesis is obtained by noting that when it comes to triangle problems, without loss of generality, the input graph is tripartite[4].

[4] The reduction works by creating 3 copies of the vertex set, each of which is an independent set, and placing copies of the original edges between copies of vertices (but each vertex copy is in a different copy of the vertex set). Each triangle in the original graph appears 6 times.

We remark an important subtlety in the UTD hypothesis: in order to disprove the hypothesis, it is enough to design an algorithm that beats the hypothesized lower bound for a single combination of m_1, m_2 and m_3. Nevertheless, the CLBs that we prove based on the UTD hypothesis hold even if we restrict the UTD hypothesis to be true for the restricted cases of $m_2 = m_3$.

UTD algorithm. In Section 3 We design a new algorithm for UTD which matches the lower bounds of the UTD hypothesis if $\omega = 2$. The algorithm is a natural (albeit not exactly straightforward) extension of the best known algorithms for triangle detection [3].

▶ **Theorem 5.** *There exists an algorithm for the UTD problem whose time cost is*

$$O\left(m_3 + (m_1 \cdot m_2)^{\frac{\omega-1}{\omega+1}}(m_3)^{\frac{2}{\omega+1}}\right).$$

CLB for online SetDisjointness. In Section 4 we prove a CLB for online SetDisjointness which is conditioned on the UTD hypothesis. The CLB, which matches the upper bound of Theorem 1 for $q \geq \frac{1}{3}$, assuming $\omega = 2$, is summarized in the following theorem.

▶ **Theorem 6.** *Assuming $\omega = 2$, any algorithm for online SetDisjointness that has $\frac{1}{3} \leq q < 1$ must obey $2p + q \geq 3$, unless the UTD hypothesis is false.*

Assuming that $\omega = 2$, Theorems 6 and 1 combined with the 3SUM CLB of Kopelowitz et al. [29] provide a (conditionally) optimal curve, as depicted in Figure 1.

Unbalanced triangle enumeration. For set-intersection, we prove a conditional lower bound that matches the combinatorial upper bound curve for $q \geq 1/2$ which is based on a hypothesis on the time required to enumerate all triangles in an unbalanced tripartite graph.

▶ **Problem 7** (Unbalanced Triangle Enumeration)**.** *In the* Unbalanced Triangle Enumeration *(UTE) problem the goal is to enumerate all triangles in a given undirected tripartite graph $G = (A \cup B \cup C, E)$, where $m_1 = |E \cap (A \times B)|$, $m_2 = |E \cap (B \times C)|$, $m_3 = |E \cap (C \times A)|$, and $m_1 \leq m_2 \leq m_3$.*

▶ **Hypothesis 8** (UTE hypothesis)**.** *Assuming $\omega = 2$, any algorithm for the UTE problem on a graph with t triangles must have time cost $t^{\frac{1}{3}}(m_1 m_2 m_3)^{\frac{1}{3}} m_3^{-o(1)}$ in the word RAM model with $O(\log m_3)$ bit words.*

Similar to the UTD hypothesis, the UTE hypothesis implies that, assuming $\omega = 2$, the current best known running time of $O(m + m^{\frac{4}{3}} + t^{\frac{1}{3}} m)$ for triangle enumeration in m-edge graphs by Bjørklund et al. [9] is optimal, up to $m^{o(1)}$ factors (just set $m_1 = m_2 = m_3$).

UTE algorithm. In Section 5 we design a new algorithm for UTE which, assuming $\omega = 2$, matches the lower bounds of the UTE hypothesis. The algorithm is a natural (albeit not exactly straightforward) extension of the best known algorithms for output-sensitive triangle enumeration [9].

▶ **Theorem 9.** *There exists an algorithm for UTE on graphs with at most t triangles whose time cost is*

$$\tilde{O}\left(m_3 + m_3^{\frac{2}{\omega+1}}(m_1 m_2)^{\frac{\omega-1}{\omega+1}} + t^{\frac{3-\omega}{\omega+1}}(m_1 m_2 m_3)^{\frac{\omega-1}{\omega+1}}\right).$$

CLB for online SetIntersection In Section 6, we prove the following CLB for SetIntersection based on the UTE hypothesis, which matches the algorithm of Section 2.1 for $q \geq 1/2$.

▶ **Theorem 10.** *Any algorithm for online SetIntersection that has $\frac{1}{2} \leq q < 1$ must obey $p + q \geq 2$, unless the UTE hypothesis is false.*

1.2 More Related Work

SetDisjointness and SetIntersection. Many existing set intersection data structures, e.g., [17, 7, 6], work in the comparison model in which sets are represented as sorted lists or arrays. The benchmark in this model is the minimum number of comparisons needed to answer a query. Bille, Pagh, and Pagh [8] used word-packing techniques to evaluate expressions of set intersections and unions. Their query algorithm finds the intersection of k sets with a total of n elements in $O(n/\frac{w}{\log^2 w} + k \cdot op)$ time, where op is the size of the output and w is the size of a machine word. Cohen and Porat [13] designed a *static* $O(N)$-space data structure for answering online SetIntersection queries in $O(\sqrt{N(1 + |S \cap S'|)})$ time. Kopelowitz, Porat and Pettie [28] designed an incremental algorithm for online SetDisjointness where both queries and element insertions into sets cost $O(\sqrt{\frac{N}{\log n/\log\log n}})$ time.

Kopelowitz, Porat and Pettie [28] also designed a fully dynamic algorithm for both online SetDisjointness and online SetIntersection which uses M words of space, each update costs $O(\sqrt{M}\log N)$ expected time, each SetIntersection query costs $O(\frac{N\sqrt{\log N}}{\sqrt{M}}\sqrt{op+1})$ expected time where op is the size of the output, and each online SetDisjointness query costs $O(\frac{N\sqrt{\log N}}{\sqrt{M}} + \log N)$ expected time. The relationship between the space usage and query time was also investigated by Afshani and Neilsen [2] and Goldstein et al. [23].

Triangle Enumeration. Itai and Rodeh [25] showed that all t triangles in a graph could be enumerated in $O(m^{3/2})$ time. Thirty years ago Chiba and Nishizeki [12] generalized [25] to show that $O(m\alpha)$ time suffices, where α is the *arboricity* of the graph. Kopelowitz, Pettie, and Porat [28] proved that enumerating t triangles takes $O(m\lceil\alpha/\frac{\log n}{\log\log n}\rceil + t)$ time. Eppstein et al. [19] designed an algorithm for the w-bit word RAM model running in $O(m\lceil\alpha/\frac{w}{\log w}\rceil + t)$ time.

The fastest algorithm for triangle enumeration in general m-edge, n-node graphs is the algorithm of Bjørklund, Pagh, Williams, and Zwick [9] which if $\omega = 2$, runs in $\tilde{O}(\min\{n^2 + nt^{2/3}, m^{4/3} + mt^{1/3}\})$ time.

Duraj et al. [18] showed that the related problem of establishing for each edge e in a graph the number of triangles that contain e is equivalent to several natural range query problems.

2 SetDisjointness Algorithms

Before we describe our new algorithm, we begin by presenting a simple algorithm for online SetDisjointness which is a variation of the algorithm of Cohen and Porat [14], and has a efficiency tradeoff of $p + q = 2$. This algorithm is a building block for our new algorithm.

2.1 Heavy-Light Decomposition

▶ **Lemma 11.** *There exists an algorithm for the online SetDisjointness problem with $p+q = 2$.*

Proof. Let $0 \leq \alpha \leq 1$. A set S is said to be *light* if $|S| \leq N^\alpha$, and *heavy* otherwise. Notice that the number of heavy sets is at most $N^{1-\alpha}$.

The algorithm stores each set via a lookup table, and precomputes the answers to all $O(N^{2-2\alpha})$ heavy pairs (pairs of heavy sets). Specifically, for a heavy pair S and S', the algorithm checks for each element $e \in S$ whether $e \in S'$. The sets S and S' are disjoint if and only if all of the tests fail. Notice that during the precomputation, an element in a heavy set is looked up at most $N^{1-\alpha}$ times, once for each heavy set. Since the number of elements in all heavy sets is at most N, the total preprocessing cost is $O(N^{2-\alpha})$ time and $p = 2 - \alpha$.

For the query, if both of the queries sets are heavy then the answer is obtained from the precomputed information, and if at least one query set is light then the algorithm scans the at most N^{α} elements in the light set to test whether any of these elements are in the other set (regardless of whether the other set is heavy or light). Thus, the query cost is $O(N^{\alpha})$ and $q = \alpha$. Finally, $p + q = 2 - \alpha + \alpha = 2$ as required. ◀

SetIntersection Algorithm. It is fairly straightforward to convert the algorithm of Lemma 11 to also solve online SetIntersection with $p + q = 2$: for each pair of heavy sets, instead of storing only an indication of whether the sets are disjoint or not the algorithm stores the entire intersection.

2.2 Improved algorithm

▶ **Theorem 1.** *There exists an algorithm for the online SetDisjointness problem where*

$$\begin{array}{ll} p + \frac{2}{\omega-1}q = 2, & \textit{for } 0 \le q \le \frac{\omega-1}{\omega+1} \\ \frac{2}{\omega-1}p + q = 1 + \frac{2}{\omega-1}, & \textit{for } \frac{\omega-1}{\omega+1} \le q \le 1 \end{array}.$$

Proof. The algorithm is similar to the algorithm in the proof of Lemma 11, but with a faster method for precomputing all of the answers for heavy pairs. Thus, assume without loss of generality that there are at most $N^{1-\alpha}$ sets, where α is taken from the proof of Lemma 11.

For every element $e \in U$, let $f_e = |\{S \in \mathcal{F} : e \in S\}|$ be the number of sets in $\mathcal{F}$ that contain e. For a parameter $0 \le \beta \le 1$, an element $e \in U$ is said to be *frequent* if $f_e > N^{\beta}$, and *rare* otherwise. Let F be the set of frequent elements and let R be the set of rare elements. Notice that $|F| \le N^{1-\beta}$ and $\sum_{e\in R} f_e \le N$.

For each rare element e, there are at most $O((f_e)^2) = O(N^{2\beta})$ heavy pairs that contain e in their intersection, and enumerating these pairs costs $O((f_e)^2)$ time. In order to efficiently enumerate these pairs for all rare elements, the algorithm computes for each element e a list of sets that contain e by scanning the entire instance in linear time. Given these lists, the algorithm enumerates all of the heavy pairs that have a rare element in their intersection in $O(\sum_{e\in R}(f_e)^2) = O(\sum_{e\in R} N^{\beta} f_e) = O(N^{\beta}\sum_{e\in R} f_e) = O(N^{1+\beta})$ time.

The algorithm is now left with the task of establishing which heavy pairs have at least one frequent element in their intersection. However, enumerating all heavy pairs that have a frequent element in their intersection is too expensive. In order to reduce the time cost, the algorithm constructs a Boolean matrix M such that the columns of M correspond to frequent elements and the rows of M correspond to characteristic vectors of the heavy sets after removing all of the rare elements. Thus, the size of M is $|H| \times |F|$ where H is the set of heavy sets. Let $P = M \cdot M^T$ where the product is a Boolean product. Notice that $p_{i,j} = 1$ if and only if there exists an element e such that the both $m_{i,e} = 1$ and $m^T_{e,j} = m_{j,e} = 1$. Thus, the non-zero entries of P exactly correspond to the heavy pairs that have a frequent element in their intersection. The time cost of computing P using FMM is

$$O\left(\frac{|H|^2|F|}{\min(|H|,|F|)^{3-\omega}}\right) = O\left(N^{\omega-2\alpha-\beta+(3-\omega)(\max(\alpha,\beta))}\right).$$

Thus, the total preprocessing time is $N^p = O\left(N^{1+\beta} + N^{\omega-2\alpha-\beta+(3-\omega)(\max(\alpha,\beta))}\right)$, which is minimized whenever $1+\beta = \omega - 2\alpha - \beta + (3-\omega)(\max(\alpha,\beta))$, and then $p = 1+\beta$. Recall that the query time is $O(N^\alpha)$ and so $q = \alpha$.

If $\alpha \leq \beta$, then $\beta = 1 - \frac{2\alpha}{\omega-1}$, the preprocessing time is given by $p = 1+\beta = 2 - \frac{2q}{\omega-1}$, and so $p + \frac{2}{\omega-1}q = 2$. Notice that in order for this case to hold, it must be that $\alpha \leq \beta = 1 - \frac{2\alpha}{\omega-1}$ implying that $q = \alpha \leq \frac{\omega-1}{\omega+1}$.

If $\alpha > \beta$, then $\alpha = 1 - \frac{2\beta}{\omega-1}$, the query time is given by $q = \alpha = 1 - \frac{2(p-1)}{\omega-1}$, and so $\frac{2}{\omega-1}p + q = 1 + \frac{2}{\omega-1}$. Notice that in order for this case to hold, it must be that $\alpha = 1 - \frac{2\beta}{\omega-1} \geq 1 - \frac{2\alpha}{\omega-1}$ implying that $q = \alpha \geq \frac{\omega-1}{\omega+1}$. ◀

▶ **Corollary 2.** *There exists an algorithm for the online* SetDisjointness *problem where*

$$p = (1-q) \cdot \omega(1, 1, \frac{2-p}{1-q}).$$

Proof. When using FRMM, the cost to compute P is $O\left(|H|^{\omega(1,1,\log_{|H|}\frac{|F|}{|H|})}\right) = O\left(N^{(1-\alpha)\cdot\omega(1,1,\frac{1-\beta}{1-\alpha})}\right)$ time. Thus, the total preprocessing time is $N^p = O\left(N^{1+\beta} + N^{(1-\alpha)\cdot\omega(1,1,\frac{1-\beta}{1-\alpha})}\right)$, which is minimized whenever $1+\beta = (1-\alpha)\cdot\omega(1,1,\frac{1-\beta}{1-\alpha})$, and so $p = (1-q)\cdot\omega(1,1,\frac{2-p}{1-q})$. ◀

3 Unbalanced Triangle Detection Algorithm

▶ **Theorem 5.** *There exists an algorithm for the UTD problem whose time cost is*

$$O\left(m_3 + (m_1 \cdot m_2)^{\frac{\omega-1}{\omega+1}}(m_3)^{\frac{2}{\omega+1}}\right).$$

Proof. The algorithm uses three positive integer parameters to be set later: τ_A, τ_B, and τ_C. A vertex $a \in A$ is said to be light if the number of edges $(a,b) \in E \cap (A \times B)$ is at most τ_A, and heavy otherwise. Thus, the number of heavy nodes in A is at most $\frac{m_1}{\tau_A}$. A vertex $b \in B$ is said to be light if the number of edges $(b,c) \in E \cap (B \times C)$ is at most τ_B, and heavy otherwise. Thus, the number of heavy nodes in B is at most $\frac{m_2}{\tau_B}$. A vertex $c \in C$ is said to be light if the number of edges $(c,a) \in E \cap (C \times A)$ is at most τ_C, and heavy otherwise. Thus, the number of heavy nodes in C is at most $\frac{m_3}{\tau_C}$.

Light vertices. For each light $a \in A$ the algorithm enumerates all pairs of edges touching a where one edge touches a vertex in B and the other edge touches a vertex in C, and for each such pair the algorithm tests (in constant time) whether the pair is part of a triangle. If there exists a triangle that contains a light $a \in A$ then one of the enumerated pairs must be two edges from this triangle and thus the algorithm will detect this triangle. Let $d_B(a)$ be the number of edges of a whose other endpoint is in B, and let $d_C(a)$ be the number of edges of a whose other endpoint is in C. Thus, the total number of pairs for a given $a \in A$ is $d_B(a) \cdot d_C(a)$. Notice that $\sum_{a\in A} d_C(a) = m_3$, and recall that since a is light then $d_B(a) \leq \tau_A$. Thus, the time cost for testing whether there exists a triangle with a light $a \in A$ vertex is

$$O(\sum_{a\in A} d_B(a) \cdot d_C(a)) \leq O(\tau_A \sum_{a \in A} d_C(a)) = O(\tau_A \cdot m_3).$$

Similarly, the algorithm checks whether there is exists a triangle with a light $b \in B$ or a light $c \in C$ in $O(\tau_B \cdot m_1 + \tau_C \cdot m_2)$. Thus, the total cost of detecting whether there exists a triangle with at least one light vertex is $O(m_3 + \tau_A \cdot m_3 + \tau_B \cdot m_1 + \tau_C \cdot m_2)$ time, where the first m_3 term comes for the necessity of scanning the entire graph.

Heavy vertices. If there is no triangle that contains at least one light vertex, then there can only be a triangle with three heavy vertices. Here the algorithm utilizes the upper bound on the number of heavy vertices in each part of the tripartite graph. Without loss of generality, let $a_1, a_2, \dots, a_{\frac{m_1}{\tau_A}}$ be the set of heavy vertices in A, let $b_1, b_2, \dots, b_{\frac{m_2}{\tau_B}}$ be the set of heavy vertices in B, and let $c_1, c_2, \dots, c_{\frac{m_3}{\tau_C}}$ be the set of heavy vertices in A. Let L be a $\frac{m_1}{\tau_A} \times \frac{m_2}{\tau_B}$ Boolean matrix where $q_{i,j} = 1$ if and only if $(a_i, b_j) \in E$. Similarly, let R be a $\frac{m_2}{\tau_B} \times \frac{m_3}{\tau_C}$ Boolean matrix where $r_{i,j} = 1$ if and only if $(b_i, c_j) \in E$, and let T be a $\frac{m_1}{\tau_A} \times \frac{m_3}{\tau_C}$ Boolean matrix where $t_{i,j} = 1$ if and only if $(a_i, c_j) \in E$.

The algorithm computes $Z = (L \cdot R) \bigwedge T$ where the first operator is a BMM and the second operator is an entry-wise AND.

▷ Claim 12. $Z \neq 0$ if and only if there exists a triangle in G whose vertices are all heavy.

Proof. Let $X = L \cdot R$. If there exists an entry $z_{i,j} = 1$ then $x_{i,j} = t_{i,j} = 1$. Since $t_{i,j} = 1$, then by definition $(a_i, c_j) \in E$. Since $x_{i,j} = 1$, then there must exist an integer $1 \le k \le \frac{m_2}{\tau_B}$ such that $l_{i,k} = 1$ and $r_{k,j} = 1$, and so $(a_i, b_k), (b_k, c_j) \in E$, implying that the triangle (a_i, b_k, c_j) is in G, and all of the vertices of this triangle are heavy.

For the other direction, suppose that the triangle (a_i, b_k, c_j) is in G, and all of the vertices of this triangle are heavy. Then in particular $l_{i,k} = r_{k,i} = t_{i,j} = 1$. Thus, it must be that $x_{i,j} = 1$ and so $z_{i,j} = 1$. ◁

The cost of computing Z is dominated by the cost of computing the BMM of L and R, which is

$$O\left(\frac{m_1 m_2 m_3}{\tau_A \cdot \tau_B \cdot \tau_C \cdot (\min(\frac{m_1}{\tau_A}, \frac{m_2}{\tau_B}, \frac{m_3}{\tau_C}))^{3-\omega}}\right).$$

Time cost. The total time cost is

$$O\left(m_3 + \tau_A \cdot m_3 + \tau_B \cdot m_1 + \tau_C \cdot m_2 + \frac{m_1 m_2 m_3}{\tau_A \cdot \tau_C \cdot (\min(\frac{m_1}{\tau_A}, \frac{m_2}{\tau_B}, \frac{m_3}{\tau_C}))^{3-\omega}}\right).$$

The time cost is minimized when the last four[5] terms in the summation are all equal:

$$\tau_A \cdot m_3 = \tau_B \cdot m_1 = \tau_C \cdot m_2 = \frac{m_1 m_2 m_3}{\tau_A \cdot \tau_B \cdot \tau_C \cdot (\min(\frac{m_1}{\tau_A}, \frac{m_2}{\tau_B}, \frac{m_3}{\tau_C}))^{3-\omega}}.$$

Since $m_1 \le m_2 \le m_3$ it must be that $\tau_A \le \tau_C \le \tau_B$, and so $\frac{m_2}{\tau_B} \le \frac{m_3}{\tau_C}$. Moreover, $m_2 \tau_A \le m_2 \tau_C = m_1 \tau_B$ and so $\frac{m_2}{\tau_B} \le \frac{m_1}{\tau_A}$. Thus, $\min(\frac{m_1}{\tau_A}, \frac{m_2}{\tau_B}, \frac{m_3}{\tau_C}) = \frac{m_2}{\tau_B}$. By plugging in $\tau_B = \frac{m_3}{m_1}\tau_A$ and $\tau_C = \frac{m_3}{m_2}\tau_A$, we have

$$\begin{aligned}\tau_A \cdot m_3 &= \frac{m_1 m_2 m_3}{\tau_A \cdot \tau_B \cdot \tau_C \cdot (\min(\frac{m_1}{\tau_A}, \frac{m_2}{\tau_B}, \frac{m_3}{\tau_C}))^{3-\omega}} \\ &= \frac{m_1 m_2 m_3}{\tau_A \cdot \frac{m_3}{m_1}\tau_A \cdot \frac{m_3}{m_2}\tau_A \cdot (\frac{m_2}{\frac{m_3}{m_1}\tau_A})^{3-\omega}} = \frac{(m_1 m_2)^{\omega-1}}{\tau_A^{\omega} \cdot (m_3)^{\omega-2}},\end{aligned}$$

and so $\tau_A = (\frac{m_1 m_2}{m_3})^{\frac{\omega-1}{\omega+1}}$. Finally, the time cost is

$$O(m_3 + \tau_A \cdot m_3) = O(m_3 + (m_1 m_2)^{\frac{\omega-1}{\omega+1}} (m_3)^{\frac{2}{\omega+1}}).$$

[5] The reason for focusing only on the last four terms and not on the first term is that the last four terms contain parameters which we can control, while the first term m_3 is always set.

Notice that with an $O(m_3)$ time preprocessing we can ensure that every vertex in A has at least one edge to B and to C (process the vertices in B and C similarly), by removing any vertex (and its incident edges) without this property. This procedure never removes any triangles, and ensures that $m_1 \geq \max\{|A|, |B|\}$, $m_2 \geq \max\{|C|, |B|\}$, and $m_3 \geq \max\{|A|, |C|\}$. As $m_3 \leq |A| \cdot |C| \leq m_1 \cdot m_2$, $\tau_A \geq 1$. Similarly, $\tau_B, \tau_C \geq 1$, so the thresholds used by the algorithm make sense. ◀

4 Optimal Conditional Lower Bound for SetDisjointness

▶ **Theorem 6.** *Assuming $\omega = 2$, any algorithm for online SetDisjointness that has $\frac{1}{3} \leq q < 1$ must obey $2p + q \geq 3$, unless the UTD hypothesis is false.*

Proof. To prove the theorem we first describe a reduction from the UTD problem to the online SetDisjointness problem by describing an algorithm for UTD that uses an algorithm for online SetDisjointness as a black box. We then show that if the online SetDisjointness algorithm obeys $2p + q = 3 - \epsilon$ for $\frac{1}{3} \leq q \leq 1$, for some constant $\epsilon > 0$, then there exists an algorithm contradicting the UTD Hypothesis.

Reduction from UTD to online SetDisjointness. Given an instance $G = (A \cup B \cup C, E)$ of UTD, for each $x \in A \cup B$ define the set S_x to be the set of vertices from C that are neighbors of x. All of the sets are given as input for the preprocessing phase of the online SetDisjointness algorithm. Notice that the sum of the sizes of the sets is exactly $N = m_2 + m_3 = \Theta(m_3)$, since each edge touching a vertex in C contributes exactly one element to exactly one of the sets. Next, for each of the m_1 edges $(a, b) \in E \cup (A \times B)$, the algorithm performs an online SetDisjointness query on S_a and S_b. If any of the queries returns a false (meaning that the intersection of the two sets is not empty) then the algorithm returns that there is a triangle in G, and otherwise, the algorithm returns that there is no triangle in G.

▷ Claim 13. There exists an edge $(a, b) \in E \cap (A \times B)$ such that $S_a \cap S_b \neq \emptyset$ if and only if G contains a triangle.

Proof. If there exists a triangle $(a, b, c) \in A \times B \times C$ in G, then both S_a and S_b contain c. Thus, $S_a \cap S_b \neq \emptyset$. For the other direction, if there exists an edge $(a, b) \in E \cap (A \times B)$ such that $S_a \cap S_b \neq \emptyset$ then there exists some $c \in S_a \cap S_b$ which implies that $(a, c), (b, c) \in E$, and so (a, b, c) is a triangle in G. ◁

Finally, the time cost of solving UTD is $O(N^p + m_1 \cdot N^q) = O((m_3)^p + m_1 \cdot (m_3)^q)$.

The lower bound. Suppose that there exists an online SetDisjointness algorithm with $\frac{1}{3} \leq q < 1$ and $2p + q = 3 - \epsilon$ for some positive $\epsilon > 0$. By rearranging,

$$3(p - 1) = \frac{3(1 - q)}{2} - \frac{3}{2}\epsilon.$$

Thus, there exist constant positive numbers x and $\epsilon_q = \frac{3}{4}\epsilon$ such that

$$3(p - 1) + \epsilon_q = x = \frac{3(1 - q)}{2} - \epsilon_q.$$

Notice that, since $q \geq \frac{1}{3}$, then $x < \frac{3(1-q)}{2} \leq 1$. Moreover, by rearranging, there exists a constant $\epsilon' = \frac{1}{3}\epsilon_q$ such that

$$p \leq \frac{x + 3}{3} - \epsilon'$$

and

$$q + x \leq \frac{x+3}{3} - \epsilon'.$$

Thus, since the UTD hypothesis holds for any combination of m_1, m_2 and m_3 (as long as $m_1 \leq m_2 \leq m_3$), we set $m_1 = (m_3)^x$ and $m_2 = m_3$ (recall that $x < 1$). The UTD hypothesis states that the time cost for solving UTD on this setting of m_1, m_2 and m_3 is $\Omega\left((m_3)^{\frac{x+3}{3}}\right)$, while the time cost of solving UTD using the reduction is

$$O((m_3)^p + m_1 \cdot (m_3)^q) = O((m_3)^p + (m_3)^{x+q}) = O\left((m_3)^{\frac{x+3}{3} - \epsilon'}\right),$$

thereby obtaining a contradiction. ◀

5 Unbalanced Triangle Enumeration

We begin with an algorithm which does not care about the number of triangles in the input.

▶ **Lemma 14.** *There exists an algorithm for the UTE problem whose time cost is*

$$O\left(m_3 + \sqrt{m_1 \cdot m_2 \cdot m_3}\right).$$

Proof. The algorithm uses the same definition and treatment of light vertices as in the algorithm in the proof of Theorem 5, but instead of stopping once a triangle is found, the algorithm continues until all triangles that contain at least one light vertex are enumerated. Recall that this process costs $O(m_3 + \tau_A \cdot m_3 + \tau_B \cdot m_1 + \tau_C \cdot m_2)$ time.

Heavy vertices. Since there can be at most $\frac{m_1}{\tau_A}$ heavy vertices in A, at most $\frac{m_2}{\tau_B}$ heavy vertices in B, and at most $\frac{m_3}{\tau_C}$ heavy vertices in C, there can be at most $\frac{m_1 \cdot m_2 \cdot m_3}{\tau_A \cdot \tau_B \cdot \tau_C}$ triangles whose vertices are *all* heavy. Thus, for each triplet of a heavy vertex $a \in A$, a heavy vertex $b \in B$, and a heavy vertex $c \in C$, the algorithm spends constant time looking up whether (a, b, c) is a triangle or not. The time cost of enumerating all such triplets is $O\left(\frac{m_1 \cdot m_2 \cdot m_3}{\tau_A \cdot \tau_B \cdot \tau_C}\right)$.

Time cost. The total time cost is

$$O(m_3 + \tau_A \cdot m_3 + \tau_B \cdot m_1 + \tau_C \cdot m_2 + \frac{m_1 \cdot m_2 \cdot m_3}{\tau_A \cdot \tau_B \cdot \tau_C}).$$

The time cost is minimized when the last four terms in the summation are all equal:

$$\tau_A \cdot m_3 = \tau_B \cdot m_1 = \tau_C \cdot m_2 = \frac{m_1 \cdot m_2 \cdot m_3}{\tau_A \cdot \tau_B \cdot \tau_C}.$$

By plugging in $\tau_B = \frac{m_3}{m_1}\tau_A$ and $\tau_C = \frac{m_3}{m_2}\tau_A$, we have

$$\begin{aligned} \tau_A \cdot m_3 &= \frac{m_1 \cdot m_2 \cdot m_3}{\tau_A \cdot \tau_B \cdot \tau_C} \\ &= \frac{m_1 \cdot m_2 \cdot m_3}{\tau_A \cdot \frac{m_3}{m_1}\tau_A \cdot \frac{m_3}{m_2}\tau_A} \\ &= \frac{(m_1 \cdot m_2)^2}{(\tau_A)^3 \cdot m_3}. \end{aligned}$$

Therefore, $\tau_A = \sqrt{\frac{m_1 \cdot m_2}{m_3}}$, and the total time cost is $O(m_3 + \tau_A \cdot m_3) = O(m_3 + \sqrt{m_1 \cdot m_2 \cdot m_3})$.

Similarly to the UTD algorithm, notice that with an $O(m_3)$ time preprocessing we can ensure that every vertex in A has at least one edge to B and to C (process the vertices in B and C similarly), by removing any vertex (and its incident edges) without this property. This procedure never removes any triangles, and ensures that $m_1 \geq \max\{|A|, |B|\}$, $m_2 \geq \max\{|C|, |B|\}$, and $m_3 \geq \max\{|A|, |C|\}$. As $m_3 \leq |A| \cdot |C| \leq m_1 \cdot m_2$, $\tau_A \geq 1$. Similarly, $\tau_B, \tau_C \geq 1$, so the thresholds the algorithm uses make sense. ◀

Now we give an algorithm for UTE, assuming that the input graph has t triangles. Notice that our algorithm for UTD can count the number of triangles, so we can assume that we know t.

▶ **Theorem 9.** *There exists an algorithm for UTE on graphs with at most t triangles whose time cost is*

$$\tilde{O}\left(m_3 + m_3^{\frac{2}{\omega+1}}(m_1 m_2)^{\frac{\omega-1}{\omega+1}} + t^{\frac{3-\omega}{\omega+1}}(m_1 m_2 m_3)^{\frac{\omega-1}{\omega+1}}\right).$$

Proof. Let L, D_1, D_2, D_3 be parameters to be chosen later; we will make sure that all of these parameters are at least 1. Recall that $m_1 = E \cap (A \times B), m_2 = E \cap (B \times C), m_3 = E \cap (A \times C)$.

For every $a \in A$ with at most D_1 neighbors in C, list all triangles through a by going through all pairs of neighbors of a. The total time over all low-degree $a \in A$ is $O(m_1 D_1)$ time. Similarly, in $O(m_2 D_2)$ time list all triangles through all $b \in B$ with at most D_2 neighbors in A and in $O(m_3 D_3)$ time list all triangles through all $c \in C$ with at most D_3 neighbors in B.

Now let us set $D_1 = \frac{m_3 D_3}{m_1}$ and $D_2 = \frac{m_3 D_3}{m_2}$. As $m_3 \geq m_1, m_2$, $D_1, D_2 \geq 1$. This makes the total time so far $O(m_3 D_3)$.

Any triangle (a, b, c) that has not been listed must have that a has at least D_1 neighbors in C, b has at least D_2 neighbors in A and c has at least D_3 neighbors in B. Thus we can restrict to a subset A' of A of size at most $n_A = m_1/D_2 = (m_1 m_2)/(m_3 D_3)$, a subset B' of B of size at most $n_B = m_2/D_3$ and a subset C' of C of size at most $n_C = m_3/D_1 = m_1/D_3$. Notice that

$$n_A = (m_1/D_3) \cdot (m_2/m_3) \leq (m_1/D_3) = n_C \leq (m_2/D_3) = n_B.$$

Bjørklund et al. [9] give an $\tilde{O}(L^{3-\omega} n^{\omega})$ time algorithm that given a tripartite graph G' with n nodes in each partition, every edge e of G' the algorithm lists L triangles that contain e, for some parameter $L \geq 1$, or all triangles containing e if e is in fewer than L triangles. Our algorithm reduces to this balanced case.

Since $n_A \leq n_C \leq n_B$, the algorithm splits the larger partitions into parts of size roughly n_A, thereby obtaining $(n_B n_C)/n_A^2$ instances of balanced graphs, where every partition has n_A vertices. On each one of these instances the algorithm executes the algorithm of [9] to list up to L triangles for every edge in the remaining graph. The running time of this step is

$$\tilde{O}\left(n_B n_C n_A^{\omega-2} L^{3-\omega}\right) = \tilde{O}\left(\frac{(m_1 m_2)^{\omega-1}}{D_3^{\omega} m_3^{\omega-2}} L^{3-\omega}\right).$$

To minimize the total runtime we set

$$m_3 D_3 = \frac{(m_1 m_2)^{\omega-1}}{D_3^{\omega} m_3^{\omega-2}} L^{3-\omega}.$$

This sets $D_3 = L^{\frac{3-\omega}{\omega+1}}(m_1 m_2/m_3)^{\frac{\omega-1}{\omega+1}}$. Notice that as long as $L \geq 1$, $D_3 \geq 1$, just as with the UTD algorithm the algorithm can execute an $O(m_3)$ time preprocessing phase to make sure that $m_3 \leq m_1 m_2$.

With this setting of D_3, the runtime of this step becomes

$$O\left(m_3^{\frac{2}{\omega+1}}(m_1m_2)^{\frac{\omega-1}{\omega+1}}L^{\frac{3-\omega}{\omega+1}}\right).$$

Now, set $L = \max\{1, 6t/m_3\}$. The total runtime of the algorithm so far becomes:

$$\tilde{O}\left(m_3 + m_3^{\frac{2}{\omega+1}}(m_1m_2)^{\frac{\omega-1}{\omega+1}} + (m_1m_2m_3)^{\frac{\omega-1}{\omega+1}}T^{\frac{3-\omega}{\omega+1}}\right).$$

The only triangles remaining are those through edges that are contained in more than L triangles. As the number of triangles is t and since each triangle has 3 edges, the total number of edges whose triangles the algorithm has not found is at most $3t/L$. Notice that from the earlier steps of the algorithm we know for every edge e how many triangles contain e. Thus, the algorithm also knows the $3t/L$ edges that are left.

If $L = 1$ and so $6t/m_3 \leq 1$, we must have $t \leq m_3/6$ and so $3t/L = 3t \leq m_3/2$. Otherwise, if $L = 6t/m_3$, then we also get $3t/L = m_3/2$. In both cases, the total number of remaining edges is at most $m_3/2$, and so the algorithm recurses, applying the same steps but on an unbalanced graph with at most m_1, m_2 and $m_3/2$ edges and still at most t triangles. When the number of edges becomes constant, the algorithm solves the problem via brute force.

Since in each recursive step the current largest edge set shrinks by a factor of 2, the number of recursive steps is $O(\log n)$ and we at most tack on a logarithmic factor to the runtime. ◀

6 Optimal Conditional Lower Bound for SetIntersection

▶ **Theorem 10.** *Any algorithm for online SetIntersection that has $\frac{1}{2} \leq q < 1$ must obey $p + q \geq 2$, unless the UTE hypothesis is false.*

Proof. To prove the theorem we first describe a reduction from the UTE problem to the online SetIntersection problem by describing an algorithm for UTE that uses an algorithm for online SetIntersection as a black box. We then show that if the online SetIntersection algorithm obeys $p + q \geq 2 - \epsilon$ for $\frac{1}{2} \leq q < 1$ and some constant $\epsilon > 0$, then there exists an algorithm contradicting the UTE Hypothesis.

Reduction from UTE to online SetIntersection. The reduction is the same as the reduction given in the proof of Theorem 6, except that instead of using online SetDisjointness, the reduction algorithm uses SetIntersection. Specifically, the reduction algorithm does not stop after it is established that two sets are not disjoint. Instead, for each of the m_1 edges $(a, b) \in E \cup (A \times B)$, the algorithm performs an online SetIntersection query, and for each c in the output the algorithm enumerates triangle (a, b, c). The correctness of the reduction follows from the following claim.

▷ Claim 15. For every edge $(a, b) \in E \cap (A \times B)$ there is a bijection between every $c \in S_a \cap S_b$ and every triangle in G containing (a, b).

Proof. If there exists a triangle $(a, b, c) \in A \times B \times C$ in G, then both S_a and S_b contain c, and so $c \in S_a \cap S_b$. For the other direction, for every edge $(a, b) \in E \cap (A \times B)$ and every $c \in S_a \cap S_b$, the edges (a, c) and (b, c) must be in E, and so (a, b, c) is a triangle in G. ◁

As in the proof of Theorem 6, the sum of the sizes of the sets in the online SetIntersection instance is exactly $N = m_2 + m_3 = \Theta(m_3)$, and the size of the output is $O(t)$. Finally, the time cost of solving UTE is $O(N^p + m_1 \cdot N^q + t) = O((m_3)^p + m_1 \cdot (m_3)^q + t)$.

The lower bound. Suppose that there exists an online SetIntersection algorithm with $\frac{1}{2} \leq q < 1$ and $p + q \leq 2 - \epsilon$ for some positive $\epsilon > 0$. Without loss of generality, assume that $\epsilon < 2 - 2q$, which is okay since $q < 1$.

By rearranging, $2p - 2 \leq 2 - 2q - 2\epsilon$. Thus, there exists a constant positive number x such that

$$2p - 2 + \epsilon \leq x \leq 2 - 2q - \epsilon.$$

Notice that since $q \geq \frac{1}{2}$ then $x < 2 - 2q \leq 1$. Moreover, by rearranging, there exists a constant $\epsilon' > 0$ such that $p \leq 1 + \frac{x}{2} - \epsilon'$ and $q + x \leq 1 + \frac{x}{2} - \epsilon'$.

Since the UTE hypothesis holds for any combination of m_1, m_2 and m_3 (as long as $m_1 \leq m_2 \leq m_3$), we set $m_3 = m_2$ and $m_1 = (m_3)^x$. Moreover, let $t = (m_3)^y$ where $y = 1 + \frac{x}{2} - \epsilon'$.

Notice that the maximum number of triangles in an unbalanced tripartite graph with edge set sizes m_1, m_2, m_3 is $\sqrt{m_1 m_2 m_3} = m_3^{1+x/2}$, so that the number of triangles we need to list here is just a bit smaller than this.

The UTE hypothesis states that the time cost for solving UTE on this setting of m_1, m_2 and m_3 is

$$\Omega\left(t^{\frac{1}{3}}(m_1 m_2 m_3)^{\frac{1}{3}}\right) = \Omega\left(m_3^{\frac{2+x+y}{3}}\right) = \Omega\left(m_3^{(1+\frac{x}{2})-\frac{1}{3}\epsilon'}\right).$$

However, the time cost of solving UTE using the reduction is

$$\begin{aligned} O((m_3)^p + m_1 \cdot (m_3)^q + t) &= O((m_3)^p + (m_3)^{x+q} + (m_3)^y) \\ &= O((m_3)^{1+\frac{x}{2}-\epsilon'}) << \Omega((m_3)^{1+\frac{x}{2}-\frac{\epsilon'}{3}}), \end{aligned}$$

where the last transition is due to $\epsilon' > 0$. Thus, we have obtained a contradiction. ◀

Abstract

We study the geodesic Voronoi diagram of a set S of n linearly moving sites inside a static simple polygon P with m vertices. We identify all events where the structure of the Voronoi diagram changes, bound the number of such events, and then develop a kinetic data structure (KDS) that maintains the geodesic Voronoi diagram as the sites move. To this end, we first analyze how often a single bisector, defined by two sites, or a single Voronoi center, defined by three sites, can change. For both these structures we prove that the number of such changes is at most $O(m^3)$, and that this is tight in the worst case. Moreover, we develop compact, responsive, local, and efficient kinetic data structures for both structures. Our data structures use linear space and process a worst-case optimal number of events. Our bisector KDS handles each event in $O(\log m)$ time, and our Voronoi center handles each event in $O(\log^2 m)$ time. Both structures can be extended to efficiently support updating the movement of the sites as well. Using these data structures as building blocks we obtain a compact KDS for maintaining the full geodesic Voronoi diagram.

1 Introduction

Polygons are one of the most fundamental objects in computational geometry. As such, they have been used for many different purposes in different contexts. Within the path planning community, polygons are often used to model different regions. A simple example is when we have a robot moving within a building: in such a case we model all possible locations that a robot can reach by a polygon (the walls or any obstacle in the way form the boundary of this polygon). Then, the goal is to find a path that connects the source point and the destination and that minimizes some objective function. There are countlessly many results that depend on the exact function used (distance traveled [10], time needed to reach [18], number of required turns [27], etc.) Paths that minimize distance are often called *geodesics*.

Two of the most fundamental problems in this setting are constructing *shortest path maps* and *augmented Voronoi diagrams*. A shortest path map (or SPM for short) is a partition of the space into regions so that points in the same region travel in the same way to the fixed source [10, 13]. The exact definition of "in the same way" depends on the exact problem setting, but it often means that paths are *combinatorially* the same, that is, they have the same internal vertices. Augmented Voronoi diagrams are a generalization of SPMs for the case in which we have more than one fixed source and we are interested in the topology of the path to the closest source [3]. See Fig. 1 for an illustration. These structures are of critical importance in obtaining efficient solutions to related problems such as finding center points, closest pairs, nearest neighbors, and constructing spanners [22, 23].

It often happens that while we are moving to our destination, that destination is also moving. For example, when two agents try to meet, one wants to evade the other, or one simply needs to meet up with a second one that is doing a different task [17]. Since it is very costly to recompute the solution after each infinitesimal movement, the aim is to somehow maintain some information from which we can easily obtain the solution, and update this information only when the solution has significant changes. A data structure that can handle such a setting is known as a *kinetic data structure* (or KDS for short) [6]. There is a wide range of problems that have been studied in this setting. We refer to the survey by Basch et al. [6] for an overview of these results.

Surprisingly, there is very little work that combines all three of the above concepts (polygons, shortest paths, and kinetic data structures). We are aware of only two results. Aronov et al. [5] present a KDS for maintaining the shortest path map of a single point

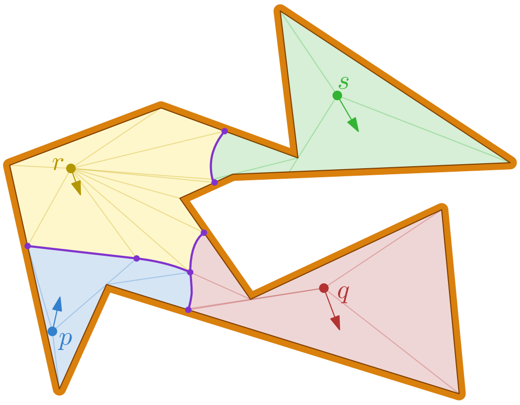

Figure 1 The (augmented) geodesic Voronoi diagram of four moving sites p, q, r, and s.

moving inside a simple polygon, and Karavelas and Guibas [14] give a KDS to maintain a *constrained Delaunay triangulation* of a set of moving points. This allows them to maintain nearest neighbors and the geodesic hull.

We present the first KDS to maintain the full (augmented) geodesic Voronoi diagram of a set of point sites moving inside a simple polygon, thus generalizing the above results. We carefully analyze when and how often it can change. To this end, we prove tight bounds on the number of combinatorial changes in a single bisector, and on the trajectory of a Voronoi center. Our results provide an important tool for maintaining related structures in which the agents (sites) move linearly within the simple polygon (e.g. minimum spanning trees, nearest-neighbors, closest pairs, etc.).

Related Work. Our data structures are based on the Kinetic Data Structures (KDS) framework introduced by Basch et al. [6]. In this framework motions are assumed to be known in advance. Each KDS maintains a set of *certificates* that together certify that the KDS currently correctly represents the target structure. Typically these certificates involve a few objects each and represent some simple geometric primitive. For example a certificate may indicate that three points form a clockwise oriented triangle. As the points move these certificates may become invalid, requiring the KDS to update. This requires repairing the target structure and creating new certificates. Such a certificate failure is called an (*internal*) *event*. An event is *external* if the target structure also changes. The performance of a KDS is measured according to four measures. A KDS is considered *compact* if it requires little space, generally close to linear, *responsive* if each event is processed quickly, generally polylogarithmic time, *local* if each site participates in few events, and *efficient* if the ratio between external and internal events is small, generally polylogarithmic. Note that for efficiency it is common to compare the worst-case number of events for either case.

Let S be a set of n point sites moving linearly in a space P, that is, each point moves with a fixed speed and direction. The *Voronoi diagram* $\mathrm{VD}_P(S)$ of S is a partition of P into n regions, one per site $s \in S$, such that for any point q in such a region $\mathcal{V}_s$ is closer to s than to any other site from S. Guibas et al. [11] studied maintaining the Voronoi diagram in case $P = \mathbb{R}^2$ and distance is measured by the Euclidean distance. They prove that $\mathrm{VD}_{\mathbb{R}^2}(S)$ may change $\Omega(n^2)$ times, and present an a KDS that handles at most $O(n^3\beta_4(n))$ events, each in $O(\log n)$ time. Here, $\beta_z(n) = \lambda_z(n)/n$ and $\lambda_z(n)$ is the maximum length of a Davenport-Schinzel sequence of n symbols of order z [25]. Their results actually extend to slightly more general types of movement. It is one of the long outstanding open problems if this bound can be improved [8, 9]. Only recently, Rubin [24] showed that if all sites move linearly and with the same speed, the number of changes is at most $O(n^{2+\varepsilon})$ for some arbitrarily small $\varepsilon > 0$. For arbitrary speeds, the best known bound is still $O(n^3\beta_4(n))$. When the distance function is specified by a convex k-gon the number of changes is $O(k^4n^2\beta_z(n))$ [2]. Here, and throughout the rest of the paper z denotes some small constant.

Let P be a simple polygon with m vertices, and let $\pi(s, q)$ be the shortest path between s and q that stays entirely inside P. We measure length of a path by the sum of the Euclidean edge lengths. Such a shortest path $\pi(s, q)$ is known as a geodesic, and its length as the *geodesic distance* between s and q. With some abuse of notation we use $\pi(s, q)$ to denote both the shortest path and its length.

Aronov was the first to study the geodesic Voronoi diagram [3]. He proved that when the sites in S are static, $\mathrm{VD}_P(S)$ has complexity $O(n + m)$. The same bound applies for the augmented geodesic Voronoi diagram. Moreover, he presented an $O((n+m)\log(n+m)\log n)$ time algorithm for constructing $\mathrm{VD}_P(S)$, which was improved to $O((n + m)\log(n + m))$ by

Table 1 The different types of events at which the geodesic Voronoi diagram changes, and their number. At an a, b-collapse event two vertices of $\mathrm{VD}_P(S)$ with degrees a and b collide and one disappears. Similarly, at an a, b-expand one such a vertex appears. At a vertex event a vertex of $\mathrm{VD}_P(S)$ collides with a vertex of P.

Event	Lower bound	Upper bound
$1, 2$-collapse/expand	$\Omega(m^2n)$	$O(m^2n^2)$
$1, 3$-collapse/expand	$\Omega(mn \min\{n, m\})$	$O(m^2n^2 \min\{m\beta_z(n), n\})$
$2, 2$-collapse/expand	$\Omega(m^3n)$	$O(m^3n\beta_4(n))$
$2, 3$-collapse/expand	$\Omega(mn^2 + m^3n)$	$O(m^3n^2\beta_4(n)\beta_z(n))$
$3, 3$-collapse/expand	$\Omega(mn^2 + m^2n)$	$O(m^3n^3\beta_z(n))$
vertex	$\Omega(m^2n)$	$O(m^2n\beta_4(n))$

Papadopoulou and Lee [23]. Recently, there have been several improved algorithms [16, 21] which ultimately lead to an optimal $O(m + n \log n)$ time algorithm by Oh [20]. Furthermore, Agarwal et al. [1] recently showed that finding the site in S closest to an arbitrary query point $q \in P$ – a key application of geodesic Voronoi diagrams – can be achieved efficiently even if sites may be added to, or removed from, S. Note however, that their result cannot be used directly to maintain a substructure of the Voronoi diagram (e.g. an MST).

There are no known results on maintaining an (augmented) geodesic Voronoi diagram when multiple sites S move continuously in a simple polygon P. In case there is only one site s, Aronov et al. [5] presented a KDS that maintains the shortest path map SPM_s of s. Their data structure uses $O(m)$ space, and processes a total of $O(m)$ events in $O(\log m)$ time each[1]. Karavelas and Guibas [14], provide a KDS to maintain a constrained Delaunay triangulation of S. This allows them to maintain the geodesic hull of S w.r.t. P, and the set of nearest neighbors in S (even in case P has holes). Their KDS processes $O((m+n)^3\beta_z(n+m))$ events in $O(\log(n + m))$ time each.

Organization and Results. We present a kinetic data structure to maintain the geodesic Voronoi diagram $\mathrm{VD}_P(S)$ of a set S of n sites moving linearly inside a simple polygon P with m vertices. To this end, we prove a tight $O(m^3)$ bound on the number of combinatorial changes in a single bisector, and develop a compact, efficient, and responsive KDS to maintain it (Section 3). Our KDS for the bisector uses $O(m)$ space and processes events in $O(\log m)$ time. We then show that the movement of the Voronoi center c_{pqs} – the point equidistant to three sites $p, q, s \in S$ – can also change $O(m^3)$ times (Section 4). We again show that this bound is tight, and develop a compact, efficient, and responsive KDS to maintain c_{pqs}. The space usage is linear, and handling an event takes $O(\log^2 m)$ time. Both our KDSs can be made local as well, and therefore efficiently support updates to the movement of the sites. Building on these results we then analyze the full Voronoi diagram $\mathrm{VD}_P(S)$ of n moving sites (Section 5). We identify the different types of events at which $\mathrm{VD}_P(S)$ changes, and bound their number. Table 1 gives an overview of our bounds. We then develop a compact KDS to maintain $\mathrm{VD}_P(S)$. Omitted proofs are in the full version of this paper [15].

[1] The original description by Aronov et al. [5] uses a dynamic convex hull data structure that supports $O(\log^2 m)$ time queries and updates. Instead, we can use the data structure by Brodal and Jacob [7] which supports these operations in $O(\log m)$ time.

2 Preliminaries

We first review some properties of geodesic Voronoi diagrams and shortest path maps that we will use. Let SPM_s be the shortest path map of s, hence for all points in a region of SPM_s the shortest path from s has the same internal vertices. Each such region R is star-shaped with respect to the last internal vertex v on the shortest path. Often it will be useful to refine R into triangles incident to v. We refer to the resulting subdivision of P as the *extended* shortest path map. With some abuse of notation we will use SPM_s to denote this subdivision as well. An edge in SPM_s that starts in a vertex v that is colinear with the last edge in $\pi(s, v)$ is called an *extension segment* $E_{vs} = E_v$.

Let $\mathbb{T} = \mathbb{R}$ denote the time domain. We consider each site $s \in S$ as a function from $\mathbb{T}$ to P. For functions we will not distinguish between the function itself and its graph. We say that a function is *simple* if it is continuous, i.e. if it has no break points.

Given two sites p and q, the bisector B_{pq} is the set of all points that are equidistant to p and q. If no vertex of P lies on the bisector, then B_{pq} is a piecewise curve connecting two points on ∂P. Each curve on B_{pq} is a subarc of a hyperbola [3, 19].

▶ **Lemma 1** (Aronov [3]). *$\mathrm{VD}_P(S)$ consists of $O(n)$ vertices with degree 1 or 3, and $O(m)$ vertices of degree 2. For each degree 2 vertex v there is are $p, q \in S$ so that v lies on the bisector B_{pq} and v lies on extension segment of SPM_p or SPM_q. All edges of $\mathrm{VD}_P(S)$ are hyperbolic arc segments. Every vertex v of P contributes at most one extension segment E_v.*

▶ **Lemma 2** (Aronov et al. [5]). *Let s be a point moving linearly inside a simple polygon P with m vertices. The extended shortest path map SPM_s changes at most $O(m)$ times.*

▶ **Lemma 3.** *Let v be a vertex of P, there are $O(mn\beta_4(n))$ time intervals in which v has a unique closest site $s \in S$, and the distance from v to s over time is a hyperbolic function.*

3 A Single Bisector

Fix a pair of sites p and q, and let $b_{pq}(t)$ and $b_{qp}(t)$ be the endpoints of the bisector B_{pq} defined so that p lies to the right of $B_{pq}(t)$ when following the bisector from $b_{pq}(t)$ to $b_{qp}(t)$. As p and q move, the structure of B_{pq} changes at discrete times, or events. We distinguish between the following types of events (see Fig. 2):

- *vertex* events, at which an endpoint of B_{pq} coincides with a vertex of P,
- $1, 2$-*collapse* events, at which a degree 2 vertex (an interior vertex) of B_{pq} disappears as it collides with a degree 1 vertex (an endpoint),
- $1, 2$-*expand* events, at which a new degree 2 vertex appears from a degree 1 vertex,

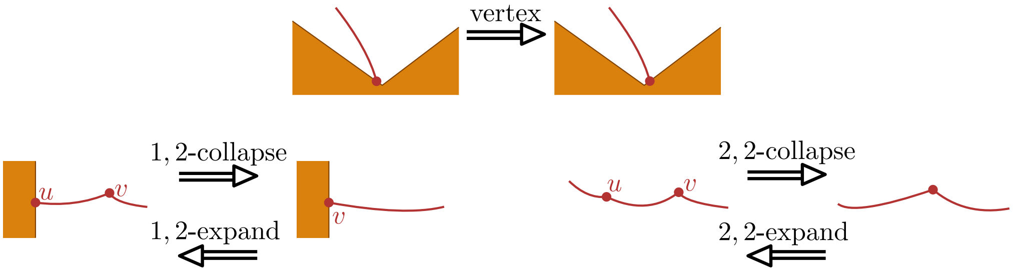

Figure 2 The types of events during which the structure of B_{pq} changes.

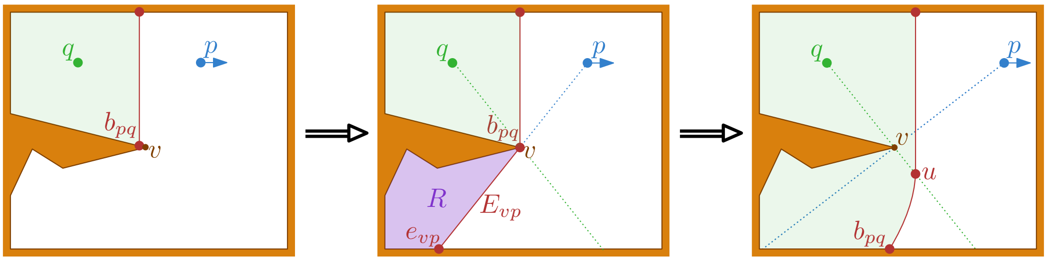

Figure 3 A vertex event at v may coincide with a $1,2$-expand event. At the time of the event all points in R are equidistant to p and q, and b_{pq} jumps from v to e_{vp}.

- $2,2$-*collapse* events at which a degree 2 vertex disappears by colliding with an other degree 2 vertex, and
- $2,2$-*expand* events, at which a new degree 2 vertex appears from a degree 2 vertex.

In Section 3.1 we prove that there are at most $O(m^2)$ vertex and $1,2$-collapse events, and at most $O(m^3)$ $2,2$-collapse events. The number of expand events can be similarly bounded. Some of these events may actually happen simultaneously. See for example Fig. 3, where B_{pq} changes when a vertex event and a $1,2$-expand event coincide. So we are double-counting these simultaneous events. Despite this, we show that our $O(m^3)$ bound on the number of changes of B_{pq} is tight in the worst case. In Section 3.2 we then argue that there is a KDS that can maintain B_{pq} efficiently.

3.1 Bounding the Number of Events

We start by showing that a bisector B_{pq} of p and q may change $\Omega(m^3)$ times. We then argue that there is also an $O(m^3)$ upper bound on the number of such changes.

▶ **Lemma 4.** *The bisector $B_{pq}(t)$ can change $\Omega(m^3)$ times.*

Proof. The main idea is to construct a bisector B_{pq}, a piecewise hyperbolic curve, of complexity $\Omega(m)$ in the middle of a region that consists of $\Omega(m^2)$ cells. These cells are defined by the extension segments in SPM_p and SPM_q that extend from the vertices on two convex chains of the polygon; one chain on either side of B_{pq}. See the top area in Fig. 4. In each cell the distance functions to p and q are different, thus if B_{pq} moves across a cell this causes a change in the bisector. The two upper convex chains in P have size $\Omega(m)$ and are placed such that as p moves towards the left (and q remains in place), the bisector sweeps from left to right over $\Omega(m^2)$ middle cells, thus causing $\Omega(m^2)$ changes to B_{pq}.

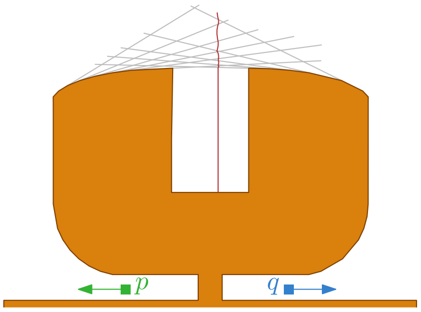

Figure 4 The bisector B_{pq} may be involved in $\Omega(m^3)$ $2,2$-collapse events.

Next, we argue that B_{pq} can be moved back and forth across these cells $\Omega(m)$ times by adding two convex chains of size $\Omega(m)$ to the bottom of the polygon, just above p and q. This way we can ensure that p and q alternate being the closest to the top of the polygon. Thus, when p is closest the bisector will move to the right and when q is the closest the bisector will move to the left. By making p and q move at the same speed and having the segments defining the convex chain on q's side start and end in the middle of where the segments of the convex chain on p's side, we can cause this alternation. It follows that the bisector sweeps over the $\Omega(m^2)$ middle cells $\Omega(m)$ times and thus it changes $\Omega(m^3)$ times. ◀

In the above proof one can observe that the counted events are only the 2,2-collapse events. For 2,2-collapse and 2,2-expand events there is also a $O(m^3)$ upper bound. For other events there is a $O(m^2)$ upper bound (proofs are in the full version [15]). Hence the bisector B_{pq} may change at most $O(m^3)$ times. Even though the entire bisector may change $O(m^3)$ times, the trajectories of its intersection points with the boundary of P have complexity at most $O(m^2)$. The following theorem summarizes these results.

▶ **Theorem 5.** *Let p and q be two points moving linearly inside P. The bisector B_{pq} of p and q can change $O(m^3)$ times. This bound is tight in the worst case. The trajectories of the endpoints of B_{pq} have $O(m^2)$ edges, each corresponding to a low-degree algebraic curve.*

3.2 A Kinetic Data Structure to Maintain a Bisector

We first describe a simple, yet naive, KDS to maintain B_{pq} that is not responsive and then show how to improve it to obtain a responsive KDS.

A Non-Responsive KDS to Maintain a Bisector. Our naive KDS for maintaining B_{pq} stores: (i) the extended shortest path maps of p and q using the data structure of Aronov et al. [5], (ii) the vertices of B_{pq}, ordered along B_{pq} from b_{pq} to b_{qp} in a balanced binary search tree, and (iii) for every vertex u of B_{pq}, the cell of SPM_p and of SPM_q that contains u. Since all cells in SPM_p and SPM_q are triangles, this requires only $O(1)$ certificates per vertex. We store these certificates in a priority queue $\mathcal{Q}$.

At any time where B_{pq} changes combinatorially (i.e. at an event) the shortest path to a vertex v of B_{pq} changes combinatorially, which indicates a change in the SPM cells that contain v. Hence, we detect all events. Conversely, when any vertex v of B_{pq} moves to a different SPM cell there is a combinatorial change in the bisector, so each event triggered by parts (ii) and (iii) of the KDS is an external event. The events at which SPM_p or SPM_q changes are internal (unless they also cause a change in a shortest path to a vertex of B_{pq}).

The changes to SPM_p and SPM_q are handled as in Aronov et al. and we update our other structures accordingly (see the full version for details [15]). This leads to a compact and efficient KDS to maintain the bisector. However, when the shortest path from p or q to some polygon vertex v changes this affects all bisector vertices whose shortest paths go through v. Hence, a single change in SPM_p or SPM_q may lead to a large number of updates to the certificates of bisector vertices. Therefore, the KDS is not responsive. To solve this issue we need a more refined data structure.

A Responsive KDS to Maintain a Bisector. First we dissect in some more detail the anatomy of a bisector. Each bisector consists of two endpoints which are degree 1 vertices and a chain of degree 2 vertices connecting them. We can further divide this chain based on which parts are directly visible from the sites defining the bisector. This division results in

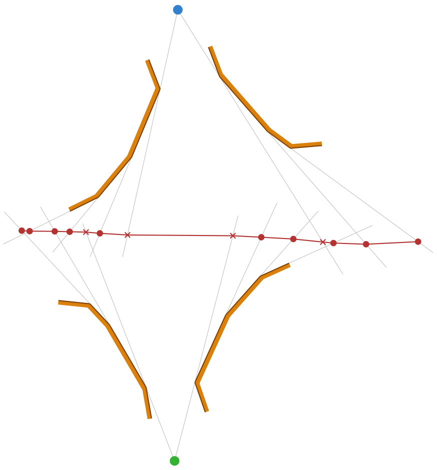

Figure 5 A bisector can be split into at most five pieces, here separated by degree 2 vertices marked as crosses.

at most 5 pieces, as illustrated in Fig. 5; some pieces may not be present in every bisector. First there is a *double-visible* piece that is visible from both sites p and q. Since P is a simple polygon, this piece consists of a single line segment. Adjacent to the double-visible piece on either side there may be a *single-visible* piece that is only visible to p or to q, but not both. Lastly, there are up to two *non-visible* pieces that are not directly visible from either p or q.

We will still store the bisector vertices in a balanced binary tree ordered along the bisector, but we will store the certificates for the degree 2 vertices a little differently. For each of the at most four degree 2 vertices that separate the pieces as well as the degree 1 endpoints, we store the cells of SPM_p and SPM_q that contain them. Then we observe that for internal vertices of the single-visible piece there can be no events. Each of these internal vertices lies on an extension segment of a single convex chain of vertices in the simple polygon and these extension segments do not intersect. Therefore no 2,2-collapses can occur.

The non-visible pieces are trickier, since 2,2-collapses may occur when a vertex moving on an extension segment of SPM_q moves to a different cell of SPM_p. Fortunately such potential events on a single non-visible bisector piece are related and form a strict ordering, regardless of the exact distance functions of the various vertices to p and q.

We define *event points* to be the locations at which 2,2-collapses that may occur. Consider two degree 2 vertices v and w that are internal to a non-visible piece of bisector between sites p and q, such that v and w are adjacent on the bisector and we have that v is on an extension segment of SPM_p and w is on an extension segment of SPM_q. Let the *event point* $\mathrm{ep}_{v,w}$ denote the intersection between these two extension segments. A 2,2-event between v and w corresponds to the event point being on the bisector between p and q. Without loss of generality assume that the event point currently lies in the Voronoi cell of p. We can then use the certificate $\pi(\mathrm{ep}_{v,w}, p) < \pi(\mathrm{ep}_{v,w}, q)$ to detect the 2,2-event between v and w. As we saw above maintaining these certificates explicitly is not efficient as any change in the shortest path towards p or q requires us to recompute the failure time. Instead we will store all event points in the Voronoi cell of p in one balanced binary tree ordered along the bisector and those in q in another. For each node in such a tree, we maintain the event point in its subtree that will be the first to be on the bisector, similar to a kinetic tournament (this, in turn requires maintaining distances between some of the relevant event points in the subtree). With this representation, we have to compute explicit failure times only for the two event points stored in the roots of the trees. Using these ideas we obtain the following result:

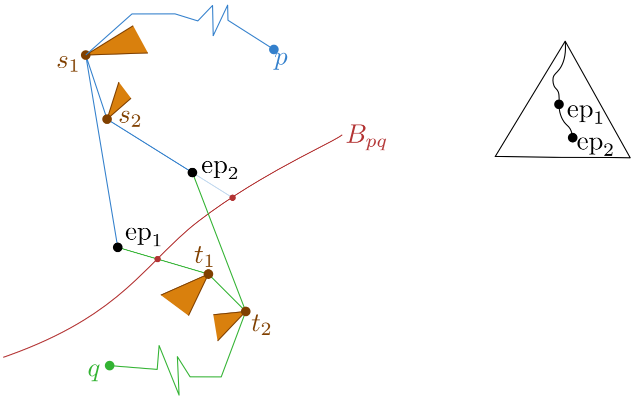

Figure 6 On the left is a schematic drawing of the event points ep_1 and ep_2 with their shortest paths towards p and q. On the right how (the certificates of) ep_1 and ep_2 are stored in the BST.

▶ **Theorem 6.** *Let p and q be two sites moving linearly inside a simple polygon P with m vertices. There is a KDS that maintains the bisector B_{pq} that uses $O(m)$ space and processes at most $O(m^3)$ events, each of which can be handled in $O(\log m)$ time. Additionally it can support movement changes of p and q in $O(\log m)$ time and splitting the bisector at any given vertex in $O(\log^2 m)$ time.*

Proof. For a single non-visible bisector piece between sites p and q, Consider event points ep_1 and ep_2 where ep_2 is a child of ep_1 in the tree. Let s_1 and t_1 denote the first polygon vertex on the shortest path from ep_1 towards p and q respectively and let s_2 and t_2 be defined symmetrically. See Fig. 6. Then we can rewrite the certificate for ep_1 as

$$\pi(\mathrm{ep}_1, s_1)+\pi(s_1, p) < \pi(\mathrm{ep}_1, t_1)+\pi(t_1, q) \quad \equiv \quad \pi(\mathrm{ep}_1, s_1)-\pi(\mathrm{ep}_1, t_1) < \pi(t_1, q)-\pi(s_1, p),$$

and the certificate for ep_2 similarly. Then observe that if $s_1 = s_2$ and $t_1 = t_2$, then ep_1 will be on the bisector before ep_2 if and only if $\pi(\mathrm{ep}_1, s_1) - \pi(\mathrm{ep}_1, t_1) > \pi(\mathrm{ep}_2, s_2) - \pi(\mathrm{ep}_2, t_2)$. This creates a strict ordering of the event points in the Voronoi cell of p. Unfortunately in many cases the first vertex on the path towards p or q will not be the same for every vertex on the bisector. Therefore we introduce an offset value to allow comparing event points that have different first vertices on their paths towards p and q.

If $s_1 \neq s_2$ and $t_1 \neq t_2$, we should compare based on a common node on the paths towards p and q, which may be any combination of s_1 or s_2 and t_1 or t_2. As these cases are analogous, we consider the case where s_1 and t_2 are on the shortest paths towards p and q respectively for both event points. (Intuitively s_1 and t_2 are further towards p and q). Now the values we would like to compare are $\pi(\mathrm{ep}_1, s_1) - \pi(\mathrm{ep}_1, t_2) > \pi(\mathrm{ep}_2, s_1) - \pi(\mathrm{ep}_2, t_2)$. However these are not what we stored. With some rewriting, we find that the above inequality holds if and only if

$$\pi(\mathrm{ep}_1, s_1) - \pi(\mathrm{ep}_1, t_1) > \pi(\mathrm{ep}_2, s_2) - \pi(\mathrm{ep}_2, t_2) - \pi(s_1, s_2) - \pi(t_1, t_2).$$

We call $-\pi(s_1, s_2) - \pi(t_1, t_2)$ the offset of ep_2 with respect to ep_1. Each node will store the maximum event value in its subtree as follows. For a leaf the maximum is its own event value. For an internal node, it is the maximum over its own event value and the maximum values of its children with the offset added. The maximum value of the root can then be used to determine the first time an $2, 2$-event happens among the bisector vertices stored in the tree.

Note that the above data structure stores only a constant number of certificates directly involving p or q, all of which are stored at the root of the tree. Therefore, it can be made to support changes in the movement of p and q in $O(\log m)$ time. Furthermore, we can support splitting the bisector at a vertex in $O(\log^2 m)$ time, since a split affects $O(\log m)$ nodes in the balanced binary search tree, and recomputing the offsets (and thus updating the certificates) takes $O(\log m)$ time per node.

By replacing part (iii) of the naive structure with this data-structure we are still guaranteed to detect all events, but now when SPM_p changes, we have to update only a constant number of certificates (rather than $\Theta(m)$). As the certificates are stored in a binary tree it is easy to add or remove vertices when the bisector is expanded or shrinks. This proves the theorem. ◀

4 A Voronoi Center

Let $c_{pqs}(t)$ be the point equidistant to $p(t)$, $q(t)$, and $s(t)$ if it exists. By Aronov et al. [4] (Lemma 2.3.5) there is indeed at most one such a point. We refer to c_{pqs} as the *Voronoi center* of p, q, and s. Note that there may be times at which c_{pqs} does not exist. We identify five types of events at which c_{pqs} may appear or disappear, or at which the movement of c_{pqs} can change (see Fig. 7). They are:

- $1,3$-*collapse* events in which c_{pqs} collides with the boundary of the polygon (in a bisector endpoint) and disappears from P,
- $1,3$-*expand* events in which c_{pqs} appears on the boundary of P as two bisector endpoints intersect, creating a point equidistant to all three sites,
- *vertex-events* where c_{pqs} appears or disappears strictly inside P, as two sites, say p and q, are equidistant to a vertex v that appears on the shortest paths to c_{pqs},
- $2,3$-*collapse* events where one of the geodesics from either p, q, or s to c_{pqs} loses a vertex,
- $2,3$-*expand* events where one of the shortest paths gains a new vertex.

Observe that, as the name suggests, at a $1,3$-collapse event the Voronoi center (a degree 3 vertex in $\mathrm{VD}_P(\{p,q,s\})$) disappears as it collides with the endpoint of a bisector (a degree 1 vertex). Similarly, at a $2,3$-collapse event a degree 2 vertex on one of the bisectors disappears as it collides with a degree 3 vertex (the Voronoi center c_{pqs}). As in case of the bisector, some of these events may coincide. In the next section, we bound the number of events, and thus the complexity of the trajectory of c_{pqs}. We then present a kinetic data structure to maintain c_{pqs} in Section 4.2.

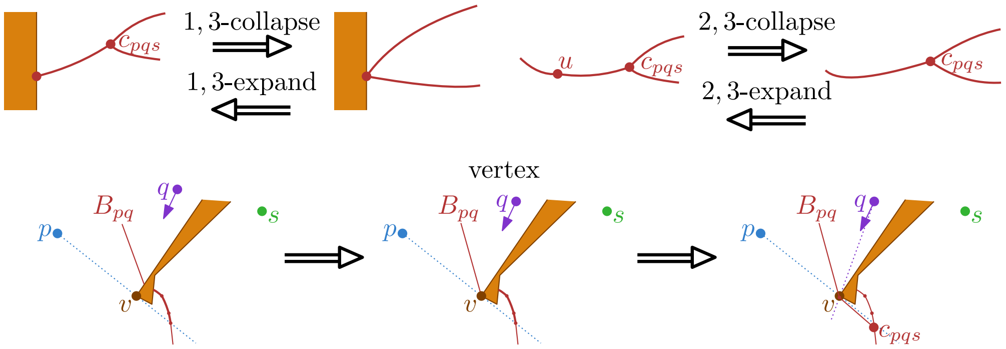

Figure 7 The events that can happen during the movement of a Voronoi center.

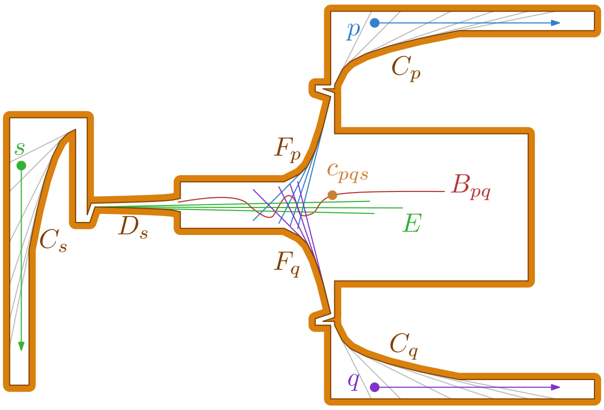

Figure 8 A polygon in which the trajectory of a voronoi center c_{pqs} has complexity $\Omega(m^3)$.

4.1 Bounding the Number of Events

We give a construction in which the trajectory of c_{pqs} has complexity $\Omega(m^3)$, and then prove a matching upper bound.

▶ **Lemma 7.** *The trajectory of the Voronoi center c_{pqs} of three points p, q, and s, each moving linearly, may have complexity $\Omega(m^3)$.*

Proof. The main idea is that we can construct a trajectory for c_{pqs} of complexity $\Omega(m^2)$, even when two of the three sites, say p and q, are static. We place p and q so that their bisector B_{pq}, a piecewise hyperbolic curve of complexity $\Omega(m)$, intersects an (almost) horizontal line E $\Omega(m)$ times. We can realize this using two convex chains F_p and F_q in ∂P. See Fig. 8 for an illustration. We now construct a third convex chain D_s in ∂P and place the third site s so that the extension segments in SPM$_s$ incident to the vertices of D_s all lie very close to E. Thus, each such segment intersects B_{pq} $\Omega(m)$ times. We choose the initial distances so that the voronoi center c_{pqs} lies on the rightmost segment of B_{pq}. Now observe that as s moves away from D_s, the center $c_{pqs}(t)$ will move to the left on B_{pq}, and thus it will pass over all $\Omega(m^2)$ intersection points of B_{pq} with the extension segments of the vertices in D_s. At each such time, the structure of one of the shortest paths $\pi(p(t), c_{pqs}(t))$, $\pi(q(t), c_{pqs}(t))$, or $\pi(s(t), c_{pqs}(t))$ changes (they gain or lose a vertex from F_p, F_q, or D_s, respectively). Hence, the trajectory of c_{pqs} changes $\Omega(m^2)$ times.

Next, we argue that we can make c_{pqs} "swing" back and forth $\Omega(m)$ times by having p and q move as well. The voronoi center c_{pqs} will then encounter every intersection point on B_{pq} $\Omega(m)$ times. It follows that the complexity of the trajectory of c_{pqs} is $\Omega(m^3)$ as claimed.

The idea is to add two additional convex chains, C_s and C_p, that make the bisector B_{ps} between p and s "zigzag" $\Omega(m)$ times throughout the movement of p and s. We can achieve this using a similar construction as in Lemma 4. To make sure that the bisector $B_{pq} = B_{pq}(t)$ between p and q remains static, we create a third chain C_q, which is a mirrored copy of C_p, and we make q move along a trajectory identical to that of p. See Fig. 8. Finally, observe that $c_{pqs}(t) = B_{pq} \cap B_{ps}(t)$, and thus $c_{pqs}(t)$ will indeed encounter all $\Omega(m^2)$ intersection points on B_{pq} $\Omega(m)$ times. The lemma follows. ◀

▶ **Lemma 8.** *The number of $1,3$-collapse events is at most $O(m^2)$.*

▶ **Theorem 9.** *The trajectory of the Voronoi center c_{pqs} has complexity $O(m^3)$. Each edge is a constant degree algebraic curve.*

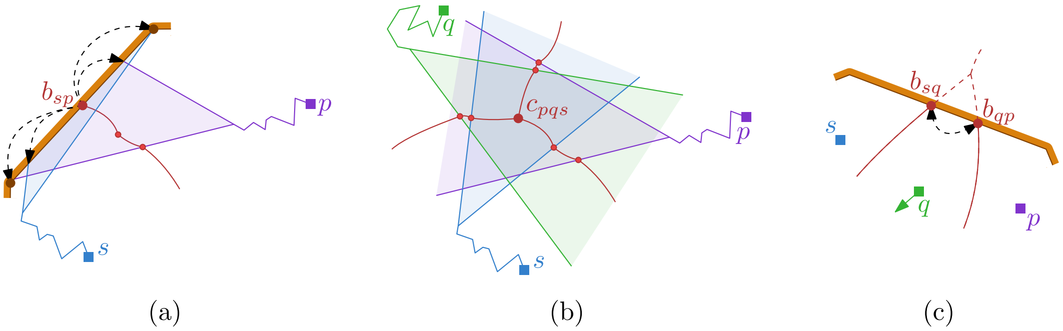

Figure 9 In black the certificates that we maintain in order to detect: (a) events where b_{sp} changes movement, (b) $1,3$-collapse, $2,3$-collapse and $2,3$-expand events, and (c) $1,3$-expand events.

4.2 A Kinetic Data Structure to Maintain a Voronoi Center

Our KDS for maintaining c_{pqs} stores: (i) the extended shortest path maps of p, q, and s, (ii) the cells of these shortest path maps containing c_{pqs} (when c_{pqs} lies inside P), and (iii) the endpoints of all bisectors (for all pairs), and their cyclic order on ∂P. In particular, for each such endpoint b_{sp} we keep track of the cells of SPM_p and SPM_s that contain it. See Fig. 9. At any time we maintain $O(m)$ certificates, which we store in a global priority queue.

Observe that at $1,3$-collapse, $2,3$-collapse, and $2,3$-expand events the shortest path from c_{pqs} to one of the sites changes combinatorially. Hence, we can detect all such events. At a vertex event a vertex is equidistant to two sites, say p and q. At such a time, one of the two endpoints of B_{pq} leaves an edge of P, and thus exits a shortest path map cell in SPM_p (and SPM_q). Since we explicitly track all bisector endpoints, we can thus detect this vertex event of c_{pqs}. Finally, at every $1,3$-expand event two such bisector endpoints collide, and thus change their cyclic order along ∂P. We detect such events due to certificates of type (iii).

Any time at which c_{pqs} changes cells in a shortest path map the movement of c_{pqs} changes combinatorially. Hence, any failure of a certificate of type (ii) is an external event (a $1,3$-collapse, $2,3$-collapse, or $2,3$-expand). The certificates of types (i) and (iii) may be internal or external.

▶ **Theorem 10.** *Let p, q and s be three sites moving linearly inside a simple polygon P with m vertices. There is a KDS that maintains the Voronoi center c_{pqs} that uses $O(m)$ space and processes at most $O(m^3)$ events, each of which can be handled in $O(\log^2 m)$ time. Updates to the movement of p, q, and s, can be handled in $O(\log^2 m)$ time.*

Proof. Certificate failures of type (i) are handled exactly as described by Aronov et al. [5]. This takes $O(\log^2 m)$ time. Note that changes to the shortest path maps may affect the certificates that guarantee that c_{pqs} or a bisector endpoint lies in a particular SPM cell. In these cases we trigger a type (ii) or type (iii) certificate failure. At a certificate failure of type (ii) at which c_{pqs} exits a shortest path map cell, we remove all certificates of type (ii) from the event queue. Next, for each site p, q, and s, we compute the new cell in the shortest path map containing c_{pqs} (if c_{pqs} still lies inside P). Finally, we create the appropriate new type (ii) certificates. Since all cells have constant complexity, the total number of certificates affected is also $O(1)$. Computing them can easily be done in $O(\log^2 m)$ time.

Certificate failures of type (iii) where the movement of a bisector endpoint changes are handled using the same approach as in Section 3.2. Furthermore, at such an event we check if c_{pqs} appears or disappears, that is, if the event is actually a vertex event of c_{pqs}. This can be done in $O(\log^2 m)$ time [21]. If c_{pqs} disappears then we delete all type (ii) certificates.

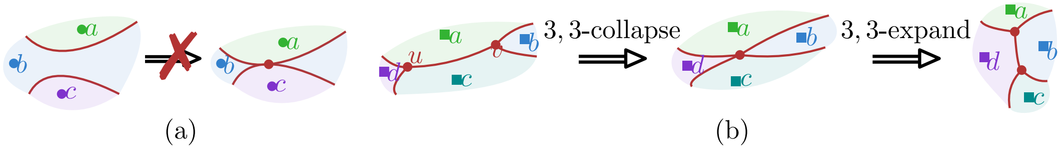

Figure 10 (a) Voronoi edges cannot intersect in their interior. (b) The 3, 3-collapse/expand events.

If c_{pqs} appears then we locate the cell of SPM_p, of SPM_q, and of SPM_s that contains c_{pqs}, and insert new type (ii) certificates that certify this. Finding the cells and updating the certificates can be done in $O(\log^2 m)$ time. At a certificate failure of type (iii) where two bisector endpoints collide, we check if the intersection point is equidistant to all three sites, and is thus a 1, 3-expand event. Similarly to the approach described above, we add new type (ii) certificates in this case. Again this takes $O(\log^2 m)$ time.

Maintaining the extended shortest path maps requires handling $O(m)$ events [5]. Events where c_{pqs} crosses a boundary of an extended SPM correspond to changes in the trajectory of c_{pqs}. By Theorem 9 there are at most $O(m^3)$ such events. This dominates the $O(m^2)$ events that we have to handle to maintain the bisector endpoints in cyclic order around ∂P (Theorem 5 and Lemma 8).

Since in addition to SPM_p, SPM_q, and SPM_s, we maintain only a constant amount of extra information. Since the KDS to maintain such a shortest path map SPM_s is local and can be updated to changes in the movement of s in $O(\log^2 m)$ time. The same applies for our data structure as well. Thus we obtain a compact, responsive, local, and efficient KDS. ◀

5 The Geodesic Voronoi Diagram

In this section we consider maintaining the geodesic Voronoi diagram $\mathrm{VD}_P(S)$ as the sites in S move. As a result of the sites in S moving, the Voronoi vertices and edges in $\mathrm{VD}_P(S)$ will also move. However, we observe that all events involving Voronoi edges involve their endpoints; two edges cannot start to intersect in their interior as this would split a Voronoi region, see Fig. 10(a). Similarly, the interior of a Voronoi edge cannot start to intersect the polygon boundary. This means we can distinguish the following types of events that change the combinatorial structure of the Voronoi diagram.

- Edge collapses, at which an edge between vertices u and v shrinks to length zero. Let d_u, d_v, with $d_u \leq d_v$, be the degrees of u and v, respectively. We then have a d_u, d_v*-collapse.*
- Edge expands. These are symmetric to edge collapses.
- Vertex events, where a degree 1 vertex of $\mathrm{VD}_P(S)$ crosses over a polygon vertex.

Indeed, we have seen most of these events when maintaining an individual bisector or Voronoi center (a degree 3 vertex in $\mathrm{VD}_P(S)$). The only new types of events are the 3, 3-collapse and 3, 3-expand events which involve two degree 3 vertices. They are depicted in Fig. 10.(b). We again note that some of these events may happen simultaneously.

▶ **Theorem 11.** *Let S be a set of n sites moving linearly inside a simple polygon P with m vertices. During the movement of the sites in S, the combinatorial structure of the geodesic Voronoi diagram $\mathrm{VD}_P(S)$ changes at most $O(m^3 n^3 \beta_z(n))$ times. In particular, the events at which $\mathrm{VD}_P(S)$ changes, and the number of such events, are listed in Table 1.*

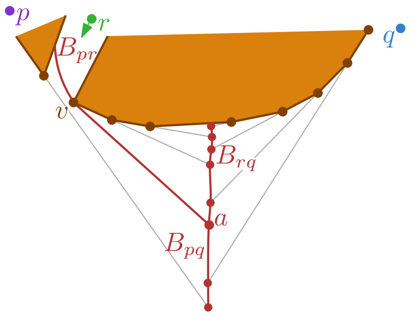

Figure 11 A vertex event may cause a bisector (here B_{pq}) to split, and a degree 3 vertex crossing an SPM extension segment may merge two bisectors.

We prove these bounds in the full version [15]. For most of the lower bounds we generalize the constructions from Sections 3 and 4. For the upper bounds we typically fix a site or vertex (or both), and map the remaining sites to a set of functions in which we are interested in the lower envelope. In Section 5.1 we develop a kinetic data structure to maintain $\mathrm{VD}_P(S)$.

5.1 A KDS for a Voronoi Diagram

In this section we develop a KDS to maintain the Voronoi diagram of S. Our KDS essentially stores for each site the extended shortest path map of its Voronoi cell, and a collection of certificates that together guarantee that the shortest paths from the sites to all Voronoi vertices remain the same (and thus the KDS correctly represents $\mathrm{VD}_P(S)$). The main difficulties that we need to deal with are shown in Fig. 11. Here, r becomes the site closest to vertex v, and as a result a part of the polygon moves from the Voronoi cell V_p of p to the Voronoi cell V_r of r. Our KDS should therefore support transplanting this region from the SPM representation of V_p into V_r or vice versa. Moreover, part of the bisector B_{pq} becomes a bisector B_{pr}, which means that any certificates internal to the bisector (such as those needed to detect 2,2-events) change from being dependent on the movement of p to being dependent on the movement of r. Next, we show how to solve the first problem, transplanting part of the shortest path map. Our KDS for the bisector from Theorem 6 essentially solves the second problem. All that then remains is to describe how to handle each event.

5.1.1 Maintaining Partial Shortest Path Maps

To support transplanting a part of SPM_s into SPM_q we extend the data structure of Aronov et al. [5]. Observe that SPM_s is a tree rooted at s, and we transplant only subtrees, rooted at some polygon vertex v. Our representation of SPM_s should support: (i) link operations in which we add the subtree rooted at v as a child of u, (ii) cut operations in which we cut an edge (u, v), (iii) shortest path queries in which we report the length of the shortest path from some vertex u to the root s, and (iv) principal-child queries in which we report the *principal child* c of some non-root node u. The principal child is the child of u for which the angle between $\overline{cu}$ and $\overline{up(u)}$, where $p(u)$ is the parent of u, is minimal. We need this operation to support updating the certificates of SPM_s[2]. To support these operations,

[2] Since the root is the only node storing a moving point, all certificates involve only nodes from the first three layers of the tree. Hence, it suffices to compute the principal child only for direct children of the root.

we store SPM_s twice: once in a link-cut tree [26] and once in an Euler tour tree [12]. Both these structures support link and cut operations in $O(\log m)$ time. The link-cut trees support query operations on node-to-root paths, and hence we use them to answer shortest path queries in $O(\log m)$ time (plus $O(k)$ time to report the actual path, if desired). The Euler tour trees support query operations on subtrees, and hence we use them to answer principal child queries. In particular, we maintain the children of u in cyclic order around u, starting with c. This way link and cut operations still take $O(\log m)$ time, and the principal child of u can be reported in constant time.

5.1.2 The data structure

The full KDS thus consists of an extended shortest path map for every Voronoi cell maintained as described above; and certificates for each degree three vertex, degree one vertex, and each bisector. For every degree three vertex c_{pqs} we maintain the cells of SPM_p, SPM_q and SPM_s that contain it and its distance to neighboring vertices. For every degree one vertex b_{pq}, we store the cells of SPM_p and SPM_q that contain it, which edge of P it is on, and if applicable its separation from neighboring degree one vertices on the same edge. For each bisector, we store the data structure of Theorem 6. Our data structure uses a total of $O(n + m)$ space.

It is not to difficult to see that this certificate structure captures all external events. For collapse and expand events involving degree three vertices we explicitly certify that the distance to its adjacent vertices is non-zero. For events involving degree one vertices we explicitly track which edge contains each such a vertex. This allows us to detect vertex events. Furthermore, we maintain distance of each degree one vertex to other degree one vertices on the same edge. Thus we can detect 1,3-expand events. Furthermore, we maintain which cells of the SPM the vertex is contained in, which allows us to detect 1,2-expand and $1, 2$-collapse events. What remains are the 2,2-events. These are detected by the data structure of Theorem 6.

5.1.3 Handling events

Handling the events is similar to what we described in Sections 3.2 and 4.2. Hence, we describe only what is new or different here.

At all external-events we have to update the shortest path map representations of the Voronoi cells. In most cases, this involves adding or removing a single vertex to the shortest path map. This can easily be handled using local computations in $O(\log^2 m)$ time. In case of vertex events, we may have to move an entire region in SPM_s to SPM_p. Since all shortest paths in such a region go via the vertex involved, we can perform these updates in $O(\log^2 m)$ time using the above data structure.

Since there are now n sites, we maintain $O(n + m)$ certificates, and thus updating the event queue takes $O(\log(n + m))$ time. Furthermore, we now have multiple degree three vertices, and thus we have to handle $3, 3$-collapse and expand events. These are handled in a similar fashion to the other events; we update the Voronoi regions, and compute new certificates certifying the movement of the vertices involved from scratch. All these updates can be done in $O(\log^2 m + \log n)$ time.

At a vertex event where p and r are equidistant to a vertex v, the region R that moves from SPM_p to SPM_r may now be bounded by a bisector B_{rq} rather than B_{pq} (see Fig. 11). Since, at the time of the event, the relevant parts of B_{pq} and B_{rq} coincide we can obtain the new part of B_{rq} by splitting B_{pq}, and updating the movement of the associated sites. In particular, replacing the function expressing the distance p to v by the distance from r to v. Our bisector KDS allows such updates in $O(\log^2 m)$ time.

Finally, we may have to update the certificates associated with the Voronoi vertices as a result of changes to the individual shortest path maps. For example, when a site s can no longer see polygon vertex v, this affects all Voronoi certificates of vertices for which the shortest path goes through v. While our KDS for the bisector (Theorem 6) can update the affected certificates of such a change efficiently, this unfortunately does not hold for the certificates associated with degree one or degree three vertices. Updating these requires $O(k(\log^2 m + \log n))$ time, where k is the number of neighbors of s in $\mathrm{VD}_S(P)$. It is an interesting open question to try and handle such events implicitly as well. We therefore obtain the following result:

▶ **Theorem 12.** *Let S be a set of n sites moving linearly inside a simple polygon P with m vertices. There is a KDS that maintains the geodesic Voronoi diagram $\mathrm{VD}_P(S)$ that uses $O(n+m)$ space and processes at most $O(m^3 n^3 \beta_z(n))$ events, each of which can be handled in $O(k(\log^2 m + \log n))$ time, where k is the number of neighbors of the affected Voronoi cell.*

Polytopes, Lattices, and Spherical Codes for the Nearest Neighbor Problem

Thijs Laarhoven
Eindhoven University of Technology, The Netherlands
http://www.thijs.com/
mail@thijs.com

Abstract

We study locality-sensitive hash methods for the nearest neighbor problem for the angular distance, focusing on the approach of first projecting down onto a random low-dimensional subspace, and then partitioning the projected vectors according to the Voronoi cells induced by a well-chosen spherical code. This approach generalizes and interpolates between the fast but asymptotically suboptimal hyperplane hashing of Charikar [STOC 2002], and asymptotically optimal but practically often slower hash families of e.g. Andoni–Indyk [FOCS 2006], Andoni–Indyk–Nguyen–Razenshteyn [SODA 2014] and Andoni–Indyk–Laarhoven–Razenshteyn–Schmidt [NIPS 2015]. We set up a framework for analyzing the performance of any spherical code in this context, and we provide results for various codes appearing in the literature, such as those related to regular polytopes and root lattices. Similar to hyperplane hashing, and unlike e.g. cross-polytope hashing, our analysis of collision probabilities and query exponents is *exact* and does not hide any order terms which vanish only for large d, thus facilitating an easier parameter selection in practical applications.

For the two-dimensional case, we analytically derive closed-form expressions for arbitrary spherical codes, and we show that the equilateral triangle is optimal, achieving a better performance than the two-dimensional analogues of hyperplane and cross-polytope hashing. In three and four dimensions, we numerically find that the tetrahedron and 5-cell (the 3-simplex and 4-simplex) and the 16-cell (the 4-orthoplex) achieve the best query exponents, while in five or more dimensions orthoplices appear to outperform regular simplices, as well as the root lattice families A_k and D_k in terms of minimizing the query exponent. We provide lower bounds based on spherical caps, and we predict that in higher dimensions, larger spherical codes exist which outperform orthoplices in terms of the query exponent, and we argue why using the D_k root lattices will likely lead to better results in practice as well (compared to using cross-polytopes), due to a better trade-off between the asymptotic query exponent and the concrete costs of hashing.

1 Introduction

Given a large database of high-dimensional vectors, together with a target data point which does not lie in this database, a natural question to ask is: which item in the database is the

47th International Colloquium on Automata, Languages, and Programming (ICALP 2020).

most similar to the query? And can we somehow preprocess and store the database in a data structure that allows such queries to be answered faster? These and related questions have long been studied in various contexts, such as machine learning, coding theory, pattern recognition, and cryptography [14,19,20,25,30,32], under the headers of *similarity search* and *nearest neighbor searching.* Observe that a naive solution might consist of simply storing the data set in a big list, and to search this list in linear time to find the nearest neighbor to a query point. This solution requires an amount of time and space scaling linearly in the size of the data set, and solutions we are interested in commonly require more preprocessed space (and time), but achieve a sublinear query time complexity to find the nearest neighbor.

Depending on the context of the problem, different solutions for these problems have been proposed and studied. For the case where the dimensionality of the original problem is constant, efficient solutions are known to exist [8]. Throughout the remainder of the paper, we will therefore assume that the dimensionality of the data set is superconstant. In the late 1990s, Indyk–Motwani [22] proposed the *locality-sensitive hashing* framework, and until today this method remains one of the most prominent and popular methods for nearest neighbor searching in high-dimensional vector spaces, both due to its asymptotic performance when using theoretically optimal hash families [4,5], and due to its practical performance when instantiated with truly efficient locality-sensitive hash functions [1,13,16]. And whereas many other methods scale poorly as the dimensionality of the problem increases, locality-sensitive hashing remains competitive even in high-dimensional settings.

Although solutions for both asymptotic and concrete settings have been studied over the years, there is often a separation between both worlds: some methods work well in practice but do not scale optimally when the parameters increase (e.g. Charikar's hash family [16]); while some other methods are known to achieve a superior performance for sufficiently large parameter sizes, but may not be quite as practical in some applications due to large hidden order terms in the asymptotic analysis (e.g. hash families studied in [3–5] and filter families from [6,11,17]). Moreover, the latter methods are often not as easy to deploy in practice due to these unspecified hidden order terms, making it hard to choose the scheme parameters that optimize the performance. A key problem in this area thus remains to close the gap between theory and practice, and to offer solutions that interpolate between *quick–and–dirty* simple approaches that might not scale well with the problem size, and more sophisticated methods that only start outperforming these simpler methods as the parameters are sufficiently large.

1.1 Related work

In this paper we will focus on methods for solving the nearest neighbor problem for the *angular distance*, which is closely related to the nearest neighbor problem in various ℓ_p-norms: as shown by Andoni and Razenshteyn [7], a solution for the nearest neighbor problem for the angular distance (or the Euclidean distance on the sphere) can be optimally extended to a solution for the ℓ_2-norm for all of $\mathbb{R}^d$. Solutions for the ℓ_2-norm can further be translated to e.g. solutions for the ℓ_1-norm via appropriate embeddings.

For the angular distance, perhaps the most well-known and widely deployed approach for finding similar items in a large database is to use the hyperplane hash family of Charikar [16]. For spherically-symmetric, random data sets on the sphere of size n, it can find a nearest neighbor at angle at most e.g. $\theta = \frac{\pi}{3}$ in sublinear time $\tilde{O}(n^\rho)$ and space $\tilde{O}(n^{1+\rho})$, with $\rho \approx 0.5850$. Various improvements later showed that smaller query exponents ρ can be achieved in sufficiently high dimensions [3,5], the most practical of which is based on cross-polytopes or orthoplices [4,24,35]: for large d and for the same target angle $\theta = \frac{\pi}{3}$, the query time complexity scales as $n^{\rho+o(1)}$ with $\rho = 1/3$. Note that the convergence to the limit is rather slow [4, Theorem 1] and depends on both d and n being sufficiently large – for fixed d and large n, the exponent is still larger than $1/3$. In certain practical applications with moderate-sized data sets, hyperplane hashing still appears to outperform cross-polytope hashing and other advanced hashing and filtering schemes [2, 11, 12, 28, 29] due to its low cost for hashing, and the absence of lower order terms in the exponent.

Related to the topic of this paper, various other works have further observed the relation between finding good locality-sensitive hash families for the angular distance and finding "nice" spherical codes that partition the sphere well, and allow for efficient decoding [3, 4, 11, 15, 35, 36]. The requirements on a spherical code to be a *good* spherical code are somewhat intricate to state, and to date it is an open problem to exactly quantify which spherical codes are the most suited for nearest neighbor searching. It may well be possible to improve upon the state-of-the-art orthoplex (cross-polytope) locality-sensitive hash family [4, 31] in practice with a method achieving the same asymptotic scaling, but with a faster convergence to the limit, and thus potentially a better performance in practice for large problem instances.

1.2 A framework for evaluating spherical codes

As a first contribution of this paper, we provide a framework for analyzing the performance of arbitrary spherical codes in the context of locality-sensitive hashing for the angular distance, where we focus on the approach of (1) projecting down onto a random low-dimensional subspace, and (2) partitioning the resulting subspace according to the Voronoi cells induced by a spherical code. More specifically, we relate the collision probabilities appearing in the analysis of these hash functions to so-called *orthant probabilities* of multivariate normal distributions with non-trivial correlation matrices. Below we informally state this relation for general spherical codes, which provides us a recipe for computing the collision probabilities (and the query exponent) as a function of the set of vertices $\mathcal{C}$ of the corresponding spherical code. Here a hash family being (θ, p_1, p_2)-sensitive means that uniformly random vectors on the sphere collide with probability at most p_2, and target nearest neighbors at angle at most θ from a random query vector collide in a random hash function with probability at least p_1. Further details and a more formal statement can be found in the full version.

▶ **Theorem 1** (Spherical code locality-sensitive hashing). *Let $\mathcal{C} \subset \mathcal{S}^{k-1}$ be a k-dimensional spherical code, and consider a hash family where:*

- *We first project onto a k-dimensional subspace using a random matrix $\mathbf{A} \sim \mathcal{N}(0,1)^{k \times d}$;*
- *We then assign hash values based on which $\mathbf{c} \in \mathcal{C}$ is nearest to the projected vector.*

Then for any $\theta \in (0, \frac{\pi}{2})$, this family is (θ, p_1, p_2)-sensitive, where p_2 can be expressed in terms of the relative volumes of the Voronoi cells induced by $\mathcal{C}$, and p_1 can be expressed as a sum of orthant probabilities $\Pr_{\boldsymbol{z} \sim \mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma}_i)}(\boldsymbol{z} \geq \mathbf{0})$, where each $\boldsymbol{\Sigma}_i$ has size $(2k) \times (2k)$.

The locality-sensitive hashing exponent $\rho = \log p_1 / \log p_2$ describes the distinguishing power of a hash family, as for large n this tells us that we can solve the (average-case) nearest neighbor problem with target angle θ in query time $\tilde{O}(n^\rho)$ with space $\tilde{O}(n^{1+\rho})$. The theorem above essentially provides us a recipe which, given any spherical code $\mathcal{C}$ and target angle θ as input, tells us how to compute these probabilities p_1 and p_2 (and thus ρ) exactly.

While the above theorem is somewhat abstract, we show how to explicitly construct the correlation matrices $\boldsymbol{\Sigma}_i$ appearing in the theorem, allowing us to always at least obtain numerical estimates on the performance of different spherical codes in the context of nearest neighbor searching. We further study how to reduce the dimensionality of the problem (and in particular, the sizes of the matrices $\boldsymbol{\Sigma}_i$) when the spherical code exhibits many symmetries, such as being isogonal, and we show how using only the *relevant vectors* of each code word can further simplify the computations. In most cases the resulting orthant probabilities will still remain too complex to evaluate analytically, but in some cases we can obtain exact expressions this way.

1.3 A survey of known spherical codes

One and two dimensions. Using this new framework, in the full version we then apply it to various spherical codes, starting in very low dimensions. For the one-dimensional case we rederive the celebrated result of Charikar [16] for one-dimensional spherical codes, noting that the collision probability analysis in fact dates back to an old result from the late 1800s [33]. Applying the same framework to two-dimensional codes, among others we establish a general formula for collision probabilities and query exponents for arbitrary polygons, as well as a more compact description of the collision probabilities for regular polygons.

▶ **Theorem 2** (Collision probabilities for regular polygons). *Let $\mathcal{C} \subset \mathcal{S}^1$ consist of the vertices of the regular c-gon, for $c \geq 2$, and let $\theta \in (0, \frac{\pi}{2})$. Then the corresponding project–and–partition hash family $\mathcal{H}$ is (θ, p_1, p_2)-sensitive, with:*

$$p_1 = \frac{1}{c} + c\left(\frac{\pi - \theta}{2\pi}\right)^2 - c\left(\frac{\arccos(-\cos\theta\cos\frac{2\pi}{c})}{2\pi}\right)^2, \qquad p_2 = 1/c. \tag{1}$$

As a direct corollary of the above theorem, we establish that *triangular locality-sensitive hashing* achieves a superior asymptotic performance to hyperplane hashing, and achieves the lowest query exponents ρ among all regular polygons.

▶ **Corollary 3** (Triangular locality-sensitive hashing). *Consider the hash family where we first project onto a random plane using a random projection matrix $\mathbf{A} \sim \mathcal{N}(0,1)^{2\times d}$, and then decode to the nearest corner of a fixed equilateral triangle centered at $(0,0)$. Then, for target angles $\theta \in (0, \frac{\pi}{2})$, this hash family achieves query exponents ρ of the form:*

$$\rho = \ln\left[\frac{1}{3} + 3\left(\frac{\pi - \theta}{2\pi}\right)^2 - 3\left(\frac{\arccos(\frac{1}{2}\cos\theta)}{2\pi}\right)^2\right] \Big/ \ln\left[\frac{1}{3}\right]. \tag{2}$$

Among all such project–and–partition hash families based on regular k-gons, this family achieves the lowest values ρ for any target angle $\theta \in (0, \frac{\pi}{2})$.

Note again that the above statement of ρ is exact, and does not hide any order terms in d or n – in fact, the collision probabilities do not depend on d at all, due to our choice of $\mathbf{A}$ being Gaussian. Further note that the 2-gon in the plane corresponds to the one-dimensional antipodal code of Charikar, and triangular hashing therefore strictly improves upon hyperplane hashing for any θ in terms of the query exponent ρ. For instance, we can find neighbors at angle at most $\frac{\pi}{3}$ in time $\tilde{O}(n^\rho)$ with $\rho \approx 0.56996$, offering a concrete but minor improvement over the hyperplane hashing approach of Charikar [16] with query exponent $\rho \approx 0.5850$. This is the best we can do with any two-dimensional isogonal spherical code, and we numerically predict that this code achieves the lowest values ρ among all (not necessarily isogonal) two-dimensional spherical codes as well.

Three and four dimensions. For three-dimensional codes, through numerical integration of the resulting orthant probabilities we conclude that the *tetrahedron* appears to minimize the query exponent ρ out of all three-dimensional codes, beating the three-dimensional analogues of e.g. the cross-polytope and hypercube, as well as various sphere packings and other regular polytopes appearing in the literature, such as the Platonic and Archimedean solids. In four dimensions an interesting phenomenon occurs: the so-called 5-*cell* (4-simplex) and 16-*cell* (4-orthoplex) are optimal in different regimes, with the 5-cell inducing a more coarse-grained partition of the space and achieving a better performance when the nearest neighbor lies relatively far away from the data set, and the 16-cell inducing a more fine-grained partition, and working better when the nearest neighbor lies relatively close to the target vector. This crossover effect is also visualized in Figure 1, and it strengthens our intuition that as the dimensionality goes up, or as the nearest neighbor lies closer to the query, more fine-grained partitions are necessary to obtain the best performance. An overview of some of the exponents ρ for various low-dimensional spherical codes, for different target angles $\theta \in \frac{\pi}{12}\{1, 2, 3, 4, 5\}$, is given in Table 1. The best exponents ρ are highlighted in bold.

Five and more dimensions. For higher-dimensional spherical codes, we obtain further improvements in the query exponents ρ through the use of suitable spherical codes, as shown in Table 1 and Figures 1–4. For dimensions 5 and 6, the corresponding orthoplices achieve a better performance than the simplices, and the exotic polytopes 1_{21} and 2_{21}, related to the root lattice E_6, seem useful in the context of nearest neighbor searching as well.

In the full version we further study the performance of the following five non-trivial infinite families of spherical codes. Color codes below correspond to the same colors used in Table 1 and Figures 1–4 to differentiate these families of codes.

- The **simplices** S_k on $k + 1$ vertices;
- The **orthoplices** O_k on $2k$ vertices (also known as cross-polytopes [4, 36]);
- The **hypercubes** C_k on 2^k vertices (as studied in [27]);
- The **expanded simplices** A_k on $k(k + 1)$ vertices;
- The **rectified orthoplices** D_k on $2k(k - 1)$ vertices.

The latter two families are connected to the root lattices A_k and D_k, while the first three are related to the lattice $\mathbb{Z}^k$. We conjecture that, should other nice families of dense lattices be found (e.g. the recent [37]), these may give rise to suitable spherical codes in nearest neighbor applications as well. For each of the above five families we give closed-form expressions on the correlation matrices $\mathbf{\Sigma}$, but the resulting orthant probabilities that need to be evaluated for computing ρ do not appear to admit simple closed-form expressions. Apart from the family of hypercubes, these are all asymptotically optimal (with $\rho \to (1 - \cos\theta)/(1 + \cos\theta)$ as $k \to \infty$), although the convergence to the limit may differ for each family.

1.4 Lower bounds via spherical caps

Although this work tries to be exhaustive in covering as many (families of) spherical codes as possible, better spherical codes may exist, achieving even lower query exponents ρ. As these codes may be hard to find, and as it may be difficult to rule out the existence of other, better spherical codes, the next best thing one might hope for is a somewhat tight lower bound on the performance of any k-dimensional spherical code in our framework, which hopefully comes close to the performance of the spherical codes we have considered in this survey.

As has been established in several previous works on nearest neighbor searching on the sphere [3, 5, 6, 11, 17, 26], ideally we would like the hash regions induced by the partitions to take the shape of a spherical cap. Such a shape minimizes the angular radius, given that the region has a fixed volume, and in a sense it is the most natural and smoothest shape that a region on a sphere can take. So in a utopian world, one might hope that a spherical code partitions the sphere into c regions, and each region corresponds exactly to a spherical cap of volume $\mathrm{Vol}(\mathcal{S}^{k-1})/c$. Clearly such spherical codes do not exist for $k > 2$ and $c > 2$, but such an extremal example does give us an indication on the limits of what might be achievable in dimension k, and how the optimal ρ decreases with k. Note that random spherical codes might approach this utopian setting in high dimensions.

Following the above reasoning, and using a classic result of Baernstein–Taylor [10], we state a formal lower bound on the performance parameter ρ of any k-dimensional spherical code of size c, and by minimizing over c for given k, one obtains a lower bound for any spherical code living in k dimensions. Here $I_x(a, b)$ denotes the regularized incomplete beta function, which comes from computing the volume of a sphere in k dimensions, while $\| \cdot \|$ denotes the Euclidean norm.

▶ **Theorem 4** (Spherical cap lower bounds). *Let $\mathcal{C} \subset \mathcal{S}^{k-1}$ be a spherical code, and let $\mathcal{H}$ be the associated project–and–partition hash family. Then the parameter ρ for $\mathcal{C}$, for target angle $\theta \in (0, \frac{\pi}{2})$, must satisfy:*

$$\rho(\theta) \geq \rho_k(\theta) := \min_{c \geq 2} \rho_k(c, \theta), \tag{3}$$

where, with $\alpha_k(c)$ denoting the solution α to $\frac{1}{2} \cdot I_{1-\alpha^2}(\frac{k-1}{2}, \frac{1}{2}) = \frac{1}{c}$, $\rho_k(c, \theta)$ is given by:

$$\rho_k(c, \theta) := \log \left\{ \Pr_{\boldsymbol{x}, \boldsymbol{y} \sim \mathcal{N}(0,1)^k} \left(\frac{x_1}{\|\boldsymbol{x}\|} \geq \alpha_k(c), \frac{x_1 \cos\theta + y_1 \sin\theta}{\|\boldsymbol{x} \cos\theta + \boldsymbol{y} \sin\theta\|} \geq \alpha_k(c) \right) \right\} \Big/ \log \left(\frac{1}{c} \right).$$

The above minimization over $c \geq 2$ concerns the possible code sizes, and $\rho_k(c, \theta)$ describes the parameter ρ one would obtain when indeed, the code consisted of c equivalent regions of equal volume, and each region was shaped like a spherical cap. Equivalently, one could state that any spherical code of size exactly c must satisfy $\rho(\theta) \geq \rho_k(c, \theta)$.

Numerical evaluation of these expressions $\rho_k(c, \theta)$, and the resulting minimization over c, leads to the values in Table 1 in the rows indicated by *spherical caps.* The superscripts denote the values c that numerically solve the minimization problems. These results in low dimensions suggest that, especially for small angles, the optimal code size should increase superlinearly with the dimension. This inspires the following conjecture, stating that the use of orthoplices is likely not optimal in higher dimensions.

▶ **Conjecture 5** (Orthoplices are suboptimal for large k). *For arbitrary $\theta \in (0, \frac{\pi}{2})$, there exists a dimension $k_0 \in \mathbb{N}$ such that, for all dimensions $k \geq k_0$, there exist spherical codes $\mathcal{C} \subset \mathcal{S}^{k-1}$ whose query exponents ρ in the project–and–partition framework are smaller than the exponents ρ of the k-orthoplex.*

Actually finding such spherical codes, or finding families of spherical codes that outperform orthoplices may again be closely related to the problem of finding nice families of dense lattices with efficient decoding algorithms. We informally conjecture that in high dimensions, and for sufficiently large code sizes c, random spherical codes may be close to optimal. If we care only about minimizing ρ, then a further study might focus on (1) getting a better grip of the optimal scaling of $c = c(k)$ with k, and (2) estimating the asymptotic performance of using random spherical codes of size $c(k)$, for large k. We predict this will lead to better values ρ than those obtained with cross-polytope hashing.

1.5 Selecting spherical codes in practice

Although the exponent ρ, and therefore the probabilities p_1 and p_2, directly imply the main performance parameters to assess the asymptotic performance of a locality-sensitive hash family, in practice we are always dealing with concrete, non-asymptotic values n, d, and θ – if the convergence to the optimal asymptotic scaling is slow, or if the hash functions are too expensive to evaluate in practice, then hash families with lower query exponents ρ may actually be less practical for small, concrete values of n and d than fast hash families with larger ρ. For example, the hash family from [3] may be "optimal", but appears to be only of theoretical interest. In practice one needs to find a balance between decreasing ρ and using hash functions which are fast to evaluate.

As a more concrete example, consider how hyperplane hashing [16] allows us to partition a sphere in 2^k regions with a single random projection matrix $\mathbf{A} \in \mathbb{R}^{k \times d}$ (or equivalently k matrices $\mathbf{A}_1, \dots, \mathbf{A}_k \in \mathbb{R}^{1 \times d}$ merged into one large matrix). For cross-polytope hashing [4] a k-dimensional projection would only divide the k-dimensional sphere into $2k$ regions. As the total required number of hash buckets in the data structure is often roughly the same, regardless of the chosen hash family,[1] this means that if we wish to divide the sphere into 2^k hash regions with cross-polytope hashing, we would need $m = k/\log_2(2k)$ independent random projection matrices $\mathbf{A}_1, \dots, \mathbf{A}_m \in \mathbb{R}^{k \times d}$ to hash a vector to one of 2^k buckets. So even though the resulting partitions for cross-polytope hashing generate smaller exponents ρ, in practice this improvement may not offset the additional costs of computing the projections/rotations, which is almost a linear factor $O(d)$ more than for hyperplane hashing. So especially for data sets of small/moderate sizes, hyperplane hashing may be more practical than cross-polytope hashing, as also observed in e.g. [12, 25, 28, 29].

We explicitly quantify the trade-off between the complexity of the hash functions and the asymptotic query exponents ρ in Figure 3, where on the vertical axis we plotted the query exponents ρ as computed in this paper, and on the horizontal axis we plotted the number of bits extracted per row of a projection matrix; for hyperplane hashing we extract 1 bit per projection, while e.g. for cross-polytope hashing in dimension k we only extract $\log(2k)/k$ bits per projection. Depending on the application, it may be desirable to choose hash families with slightly larger values ρ, if this means the cost of the hashing becomes less. Figure 3 makes a case for using hashes induced by the root lattices D_k, as well as those induced by exotic polytopes such as the 2_{21}-polytope; compared to e.g. the 5-orthoplex, the D_{10} lattice achieves lower values ρ and extracts more bits per projection, while the 2_{21}-polytope further improves upon D_{10} by extracting more hash bits per projection.

To further illustrate how these trade-offs might look in a real-world setting, Figure 4 describes a case study for average-case nearest neighbor searching with different sizes n for the data sets. For small data sets, hyperplane hashing is quite competitive, and the best other spherical codes are those induced by the D_k lattices (for small k), and spherical codes generated by the polytopes $1_{21}, 1_{31}$ and 2_{21}. This case study matches the recommendations from Figure 3. For large n, the role of ρ becomes more prominent, and higher-dimensional orthoplices and D_k lattices attain the best performance. In the full version we further describe how one might choose the best codes in practice.

1.6 Summary and open problems

With the project–and–partition framework outlined in this paper, we can now easily formalize and analyze the performance of any spherical code in this framework, and analyze the collision probabilities and query exponents either analytically (by attempting to simplify the corresponding multivariate orthant probabilities) or numerically (by evaluating these multivariate integrals with mathematical software, such as the mvtnorm package [21]). We observed that already in two dimensions, it is possible to improve upon hyperplane hashing with a smaller exponent ρ by using triangular partitions, and we described closed-form

[1] While a hash family with lower query exponents ρ does require a smaller number of hash buckets per hash table, this effect is marginal compared to the increase in the number of projections/rotations required by e.g. cross-polytope hashing compared to hyperplane hashing.

formulas for the resulting parameters ρ. In three and four dimensions the improvements in the exponent ρ become more significant, with e.g. the tetrahedron, the 5-cell, and the 16-cell achieving the best exponents ρ in these dimensions. For higher dimensions the simplices and orthoplices seem to achieve the best performance in theory, thus making a strong case for the use of these partitions as advertised in [4, 24, 35, 36], and as observed in nearest neighbor benchmarks [9, 13, 31]. The family of D_k lattices and the generalized m-max hash functions however seem to offer better practical trade-offs between the asymptotic performance in terms of ρ and the costs of computing hashes, as discussed in the full version.

Finding better spherical codes. An important open problem, both for our project–and–partition framework and for arbitrary hash families for the angular distance, is to find (if they exist) other nice families of spherical codes which achieve an even better performance than the family of orthoplices. Numerics in the full version suggest that as k increases, the optimal code size c should increase faster than the linear scaling of $c = 2k$ offered by orthoplices. Finding the optimal scaling of c as a function of k, and finding nicer spherical codes closely matching this appropriate scaling of c is left for future work.

Faster pseudorandom projections. To make e.g. hyperplane and cross-polytope hashing more practical, various ideas were proposed in e.g. [1, 4] to work with sparse projections and pseudorandom rotation matrices. Similar ideas can be used for any hash family, to reduce the cost of multiplication by a random Gaussian matrix $\mathbf{A}$. Concretely, one can often replace it with a sparse, "sufficiently random" pseudorandom matrix $\mathbf{A}$ while still achieving good query exponents ρ in practice. Depending on how these pseudorandom projections are instantiated, this may lead to a different practical evaluation than what we described in our practical case analyses. In particular, as this reduces the relative cost of the hashing, this will further favor schemes which reduce ρ at the cost of increasing the (naive) complexity of hashing.

Using orthogonal projection matrices. In our framework, we focused on projecting down onto a low-dimensional subspace using Gaussian matrices $\mathbf{A} \sim \mathcal{N}(0,1)^{k \times d}$. For $k \ll d$, using Gaussian matrices or orthogonal matrices (i.e. $\mathbf{A}\mathbf{A}^T = I_k$) is essentially equivalent [18, 23], but for large k it may be beneficial to use proper rotations induced by orthogonal matrices. For instance, recent work [27] showed that for hypercube hashing in the ambient space, there is a clear gap between using random or orthogonal matrices; using orthogonal matrices generally works better than using random Gaussian projection matrices.

The main issue when analyzing the same framework with orthogonal matrices is that the dependence on d then does not disappear; the distribution of $\mathbf{A}\boldsymbol{x}$ then relies on both k and d, rather than only on $\boldsymbol{k}$. Our framework is in a sense dimensionless, as the performance can be computed without knowledge of d, and for $k = 2$ this even allowed us to obtain explicit analytic expressions for the collision probabilities for arbitrary k-gons. Using orthogonal matrices, the collision probabilities will likely become complicated functions of d, and comparing different spherical codes may then become a more difficult task. We leave it as an open problem to adjust the above framework to the setting where $\mathbf{A}$ is orthogonal, and to see how much can be gained by using orthogonal rather than Gaussian matrices[2].

The remainder of the paper can be found in the full version at `[arXiv:1907.04628]`.

[2] Note that one obtains different asymptotics when analyzing the hypercube for Gaussian [16] and orthogonal projection/rotation matrices [27]. For constant $k = O(1)$ and large d both approaches are asymptotically equivalent, but for large $k = O(d)$ we expect orthogonal matrices to give better results.

Table 1 Parameters ρ for various spherical codes. Sphere packings are from [34]. Rows labeled "spherical caps" are lower bounds (Theorem 4). Superscripts refer to the number of caps minimizing ρ_θ. Bold values indicate the best values ρ encountered up to this dimension. Results for $k = 1, 2, d$, were obtained analytically; for $k = 3, 4, 5, 6$ most results were obtained through numerical integration and Monte Carlo simulation.

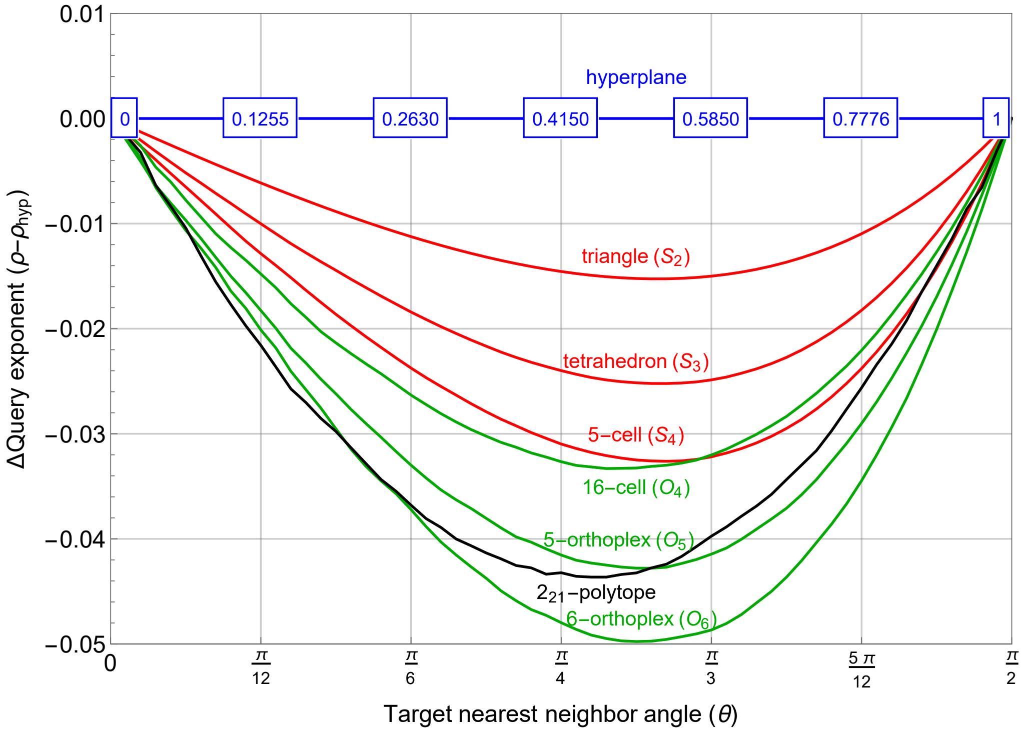

Figure 1 Comparison of the improvements in the query exponent ρ over hyperplane hashing [16] with query exponents ρ_{hyp}. The horizontal blue line denotes the baseline hyperplane hashing approach, with $\rho - \rho_{\text{hyp}} \equiv 0$. Lower curves denote improvements to ρ_{hyp} using various spherical codes. The measurements at the five vertical gridlines correspond to the values in Table 1. For instance, at $\theta = \pi/6$ the triangle has query exponent approximately 0.011 lower than hyperplane hashing (which has exponent 0.2630), leading to $\rho \approx 0.2520$; from Table 1 we get the more precise estimate $\rho \approx 0.2518$; while the theory in the full version allows us to compute ρ exactly through a closed-form expression. The polytopes in this figure are those achieving the lowest exponents ρ in their respective dimensions at one of these grid lines, as highlighted in boldface in Table 1.

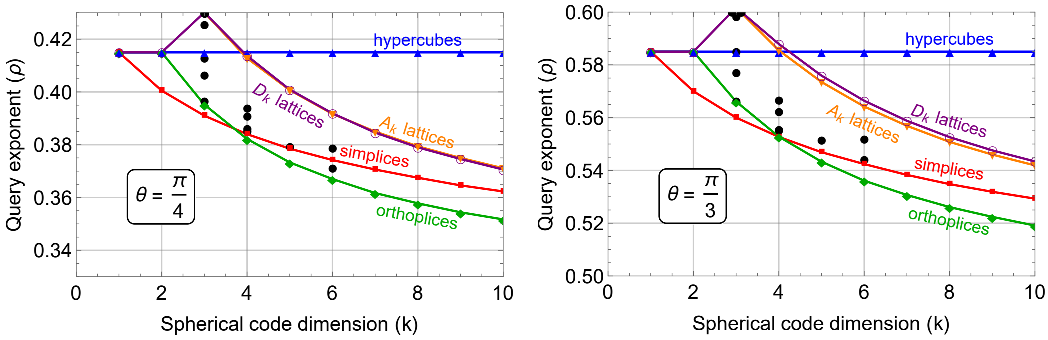

Figure 2 Query exponents ρ for project–and–partition hash families based on the spherical codes listed in Table 1. Lower query exponents ρ are generally better, and for these hash families the best exponents ρ are achieved by the simplex for $k \leq 3$ and by the orthoplex for $k \geq 5$. For $k = 4$ the simplex and orthoplex are close, and which of the two achieves a better performance depends on the target nearest neighbor angle θ.

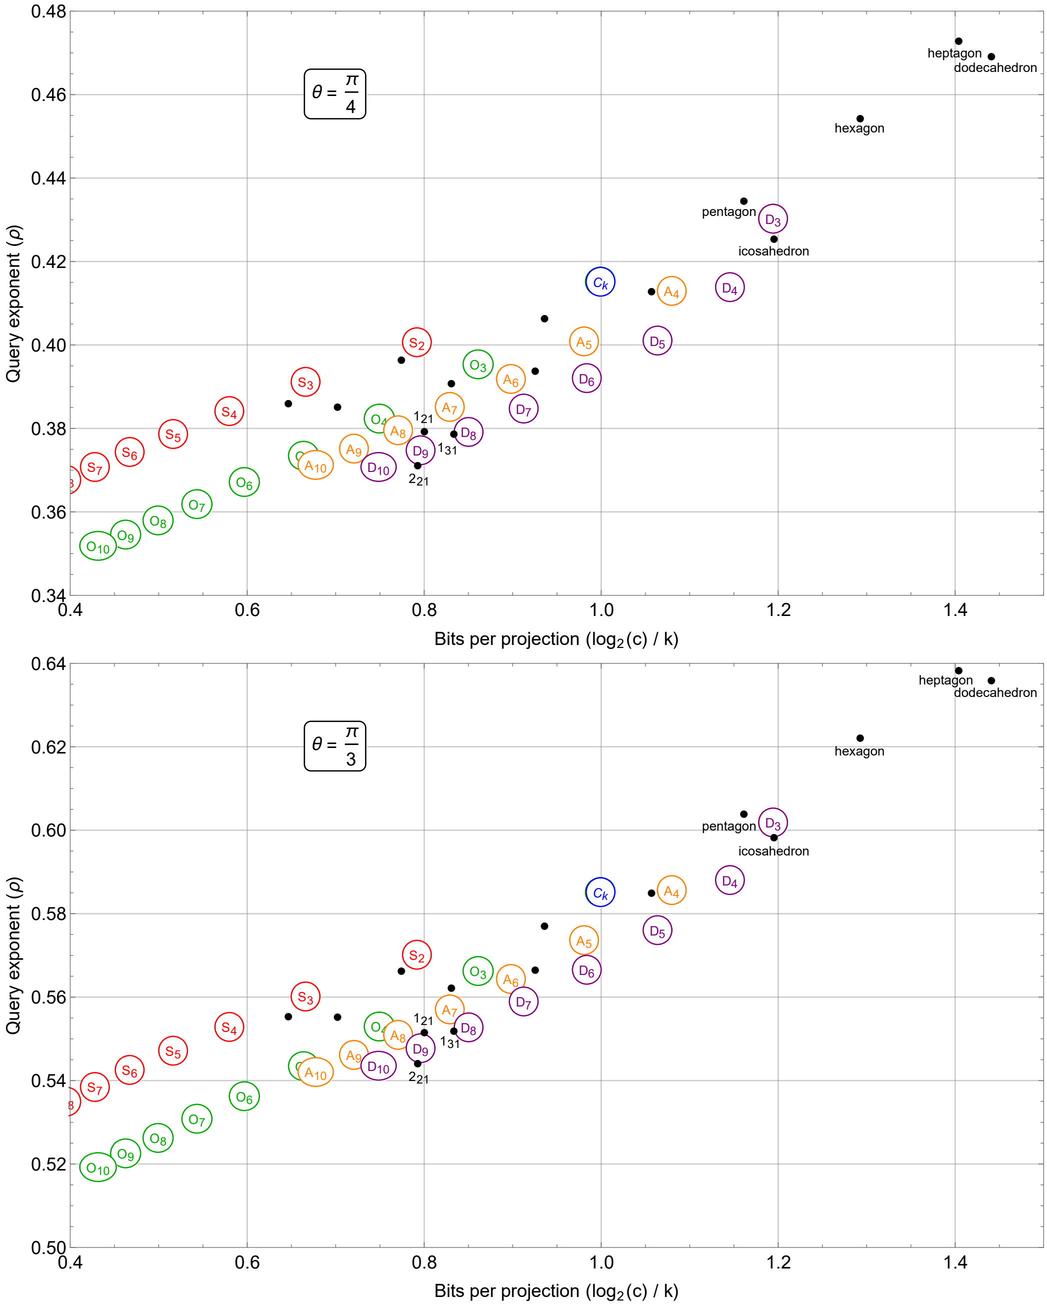

Figure 3 A comparison between different spherical codes in terms of the query exponent ρ (vertical axis) and the bits of information extracted from each row of the projection matrix $\mathbf{A}$ (horizontal axis). The top figure corresponds to target angle $\theta = \frac{\pi}{4}$ (or approximation factor $c = \sqrt{2 + \sqrt{2}}$), the bottom figure to target angle $\theta = \frac{\pi}{3}$ (or $c = \sqrt{2}$). Codes further down generate hash functions with a more discriminative power (a lower value ρ), while codes further to the right extract more bits per projection, therefore requiring fewer inner product computations to compute hash values. So for our purposes, the best codes would be as far to the right and as far down as possible. Hypercubes C_k all achieve the same value ρ and the same value $\log_2(c)/k = 1$.

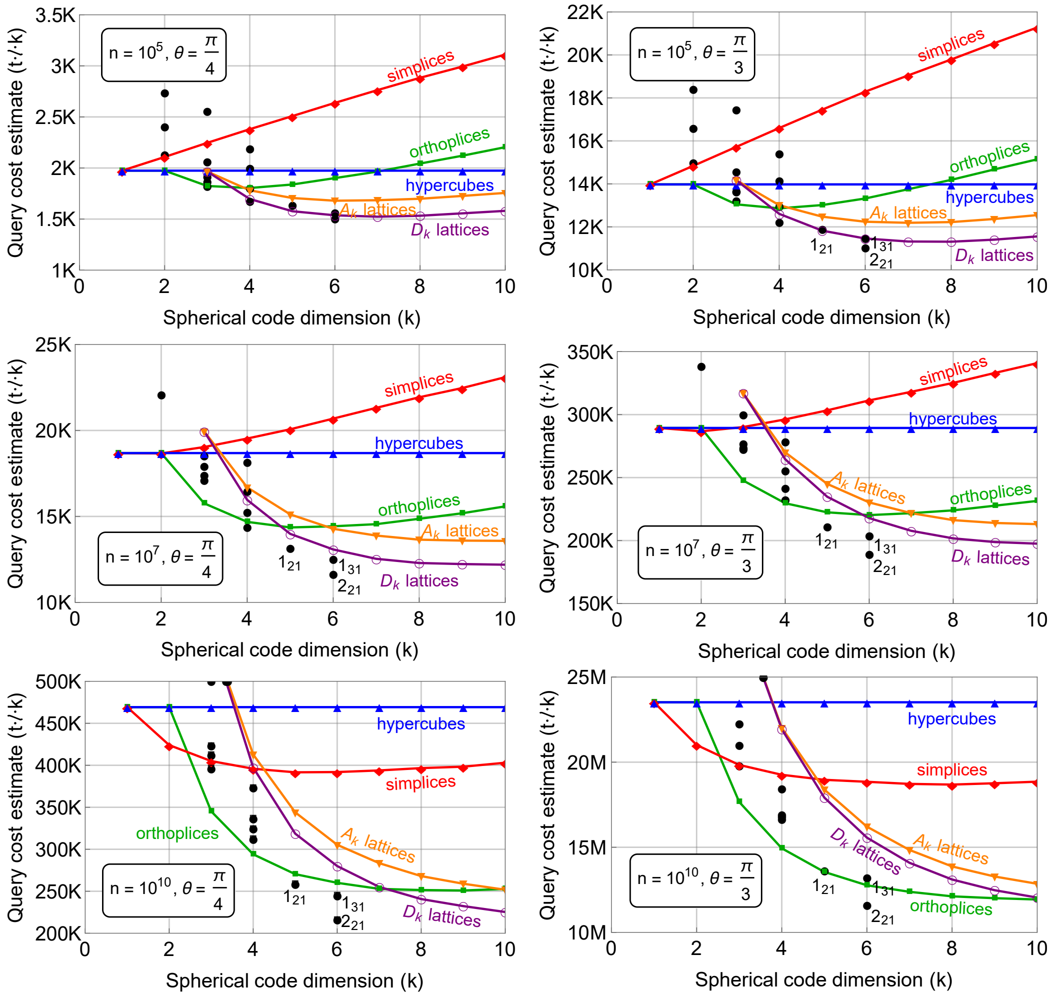

Figure 4 Comparison of the query cost estimates $t \cdot \ell \cdot k$ for different parameters $n \in \{10^5, 10^7, 10^{10}\}$ and $\theta \in \{\frac{\pi}{4}, \frac{\pi}{3}\}$, when using $t = n^\rho$ hash tables and a hash length $\ell = \log(n)/\log(1/p_2)$. The curves correspond to the regular convex polytope families and the root lattice families A_k and D_k, while single black points for $k \le 6$ correspond to spherical codes described in Table 1. As n increases, the role of a smaller ρ becomes bigger, and so larger spherical codes with smaller values ρ become more suitable choices than those with bigger values ρ but with lower hash costs. The cost of the projections increases linearly with k, while ρ decreases rather slowly with k, suggesting that for each n and θ there is an optimal spherical code dimension $k \ll d$ to project down to, and an optimal spherical code in this dimension to use. Note that other spherical codes than those from the five families of codes sometimes achieve better query cost estimates; in particular, the 2_{21}-polytope (which is connected to the E_6 lattice) might be useful in practice as well, and we cannot rule out the existence of other exotic spherical codes with good properties for nearest neighbor searching.

One of the conclusions one might draw from these figures is that indeed orthoplices (cross-polytopes) perform very well [4], but depending on the parameters it may be better to use the D_k lattices instead – the trends suggest that as k increases further, the query costs of using the D_k lattices will be smaller than those of the orthoplices.

Abstract

In this paper we revisit the deterministic version of the Sparse Fourier Transform problem, which asks to read only a few entries of $x \in \mathbb{C}^n$ and design a recovery algorithm such that the output of the algorithm approximates $\widehat{x}$, the Discrete Fourier Transform (DFT) of x. The randomized case has been well-understood, while the main work in the deterministic case is that of Merhi et al. (J Fourier Anal Appl 2018), which obtains $O(k^2 \log^{-1} k \cdot \log^{5.5} n)$ samples and a similar runtime with the ℓ_2/ℓ_1 guarantee. We focus on the stronger ℓ_∞/ℓ_1 guarantee and the closely related problem of incoherent matrices. We list our contributions as follows.

1. We find a deterministic collection of $O(k^2 \log n)$ samples for the ℓ_∞/ℓ_1 recovery in time $O(nk \log^2 n)$, and a deterministic collection of $O(k^2 \log^2 n)$ samples for the ℓ_∞/ℓ_1 sparse recovery in time $O(k^2 \log^3 n)$.
2. We give new deterministic constructions of incoherent matrices that are row-sampled submatrices of the DFT matrix, via a derandomization of Bernstein's inequality and bounds on exponential sums considered in analytic number theory. Our first construction matches a previous randomized construction of Nelson, Nguyen and Woodruff (RANDOM'12), where there was no constraint on the form of the incoherent matrix.

Our algorithms are nearly sample-optimal, since a lower bound of $\Omega(k^2 + k \log n)$ is known, even for the case where the sensing matrix can be arbitrarily designed. A similar lower bound of $\Omega(k^2 \log n / \log k)$ is known for incoherent matrices.

1 Introduction

Compressed sensing is a subfield of discrete signal processing, based on the principle that a high-dimensional signal can be approximately reconstructed, by exploiting its sparsity, in fewer samples than those demanded by the Shannon-Nyquist theorem. An important subtopic is the Sparse Fourier Transform, where we desire to detect and approximate the largest coordinates of a high-dimensional signal, given a few samples from its Fourier spectrum. Fewer samples play a crucial role, for example, in medical imaging, where reconstructing an image corresponds exactly to reconstructing a signal from its Fourier representation. Thus, the number of Fourier coefficients needed for (approximate) reconstruction is proportional to the radiation dose a patient receives as well as the time the patient needs to remain in the scanner. Furthermore, exploiting the sparsity of the signal has given researchers the hope of defeating the FFT algorithm of Cooley and Tukey, in the special (but of high practical value) case where the signal is approximately sparse. Thus, since FFT serves as an important computational primitive, and has been recognized as one of the 10 most important algorithms of the 20th century [16], every place where it has found application can possibly be benefited from a faster algorithm. The main intuition and hope is that signals arising in practice often exhibit certain structure, such as concentration of energy in a small number of Fourier coefficients.

Since vectors in practice are never exactly sparse, and it is impossible to reconstruct a generic vector $\widehat{x} \in \mathbb{C}^n$ from $o(n)$ samples, researchers resort to approximation. More formally, a sparse recovery scheme consists of a sample set $S \subseteq \{1, \ldots, n\}$ and a recovery algorithm $\mathcal{R}$ such that for any given $x \in \mathbb{C}^n$, the scheme approximates $\widehat{x}$ by $\widehat{x}' = \mathcal{R}(x_S)$, where x_S denotes the vector of x restricted to the coordinates in S. The fineness of approximation is measured with respect to the best k-sparse approximation to $\widehat{x}$. The breakthrough work of Candès, Tao and Donoho [12, 20] first showed that $k \log^{O(1)} n$ samples of $x \in \mathbb{C}^n$ suffices to reconstruct a $O(k)$-sparse vector $\widehat{x}'$ which is "close" to the best k-approximation of $\widehat{x}$. More formally, the reconstruction $\widehat{x}'$ satisfies the so-called ℓ_2/ℓ_1 guarantee, i.e.,

$$\|\widehat{x} - \widehat{x}'\|_2 \leq \frac{1}{\sqrt{k}} \|\widehat{x}_{-k}\|_1,$$

where $\widehat{x}_{-k}$ is the tail vector, obtained from restricting $\widehat{x}$ to its smallest $n-k$ coordinates in magnitude. The strength of their algorithms lies in the uniformity, in the sense that the samples at the same coordinates can be used to approximate every $x \in \mathbb{C}^n$. However, the running time is polynomial in the vector length n, giving thus only sample-efficient, but not necessarily time-efficient algorithms. Furthermore, the samples are not obtained via a deterministic procedure, but are chosen at random. Regarding non-uniform randomized algorithms that run in sublinear time, numerous researchers have worked on the problem and obtained a series of algorithms with different recovery guarantees [29, 46, 42, 24, 3, 27, 30, 31, 43, 38, 53, 34, 33, 39, 40, 41, 50]. See Table 1 for a list of common recovery guarantees. The state of the art is the seminal algorithm of Kapralov [40], which shows that $O(k \log n)$ samples and $O(k \log^{O(1)} n)$ time are simultaneously possible for the ℓ_2/ℓ_2 guarantee (which is strictly stronger[1] than the ℓ_2/ℓ_1). The fastest algorithm is due to [30], needing $O(k \log n \cdot \log(n/k))$ time and samples. We note also the algorithm of Indyk and Kapralov [33] that runs in $O(n \log^2 n)$ time, uses $O(k \log n)$ samples but gives a stronger

[1] Here we mean that given an algorithm giving the ℓ_2/ℓ_2 guarantee, one can create an algorithm, using the ℓ_2/ℓ_2 algorithm as a black box, with sparsity parameter $k' = O(k)$, achieving the ℓ_2/ℓ_1 guarantee with the same order of number of samples.

Table 1 Common guarantees of sparse recovery. Only the ℓ_2/ℓ_2 case requires a parameter $C > 1$. The guarantees are listed in the descending order of strength.

Guarantee	Formula	Deterministic Lower Bound
ℓ_∞/ℓ_2	$\|\widehat{x} - \widehat{x}'\|_\infty \leq \|\widehat{x}_{-k}\|_2/\sqrt{k}$	$\Omega(n)$ [17]
ℓ_2/ℓ_2	$\|\widehat{x} - \widehat{x}'\|_2 \leq C\|\widehat{x}_{-k}\|_2$	$\Omega(n)$ [17]
ℓ_∞/ℓ_1	$\|\widehat{x} - \widehat{x}'\|_\infty \leq \|\widehat{x}_{-k}\|_1/k$	$\Omega(k^2 + k\log n)$ [23, 21]
ℓ_2/ℓ_1	$\|\widehat{x} - \widehat{x}'\|_2 \leq \|\widehat{x}_{-k}\|_1/\sqrt{k}$	$\Omega(k\log(n/k))$ [23, 21]

ℓ_∞/ℓ_2 guarantee than the ℓ_2/ℓ_2 guarantee in the previous two papers. We refer the reader to the next section for comparison of the different guarantees appearing in the literature. Recently there has been also considerable work on recovering k-sparse signals from their continuous Fourier Transform, see [9, 55, 14, 6].

Although our understanding on randomized algorithms is almost complete, there are still important gaps in our knowledge regarding deterministic schemes. The following natural open-ended question has theoretical and practical interest and remains in principle highly unexplored, touching a variety of fields including (sublinear-time) algorithms, pseudorandomness and computational complexity, Additive Combinatorics [10] and analytic number theory.

▶ **Question 1.** *What are the best bounds we can obtain for the different versions of the deterministic Sparse Fourier Transform problem?*

With sublinear runtime, the earliest work of Iwen [36, 37] gives $O(k^2\log^4 n)$ samples and time, albeit in a significantly easier (although similar) model: where one wants to learn a band-limited function $f : [0, 2\pi) \to \mathbb{C}$ and can evaluate f at any point. In the discrete case which we are interested in, the state of the art is the work of Merhi et al. [47], which obtains $O(k^2\log^{11/2} n/\log k)$ samples and the same runtime. A recent work of Bittens et al. [8] showed that the quadratic dependence can be dropped if the signals are sufficiently structured, namely, if the Fourier coefficients are generated by an unknown but small degree polynomial. On the related problem of the Walsh-Hamadard Transform, Indyk and Cheraghchi [15] showed that roughly $O(k^{1+\alpha}\log^{O(1)+6/\alpha} n)$ samples and similar run-time are possible, if one resorts to a slightly weaker guarantee. Interestingly, their approach resides in a novel connection between the Walsh-Hadamard matrix and linear lossless condensers. However, this connection does not extend to the Fourier Transform over $\mathbb{Z}_n$, which is our focus and the most interesting case. Interesting ideas appear also in the work of Akavia [1, 2], where it is shown how to approximate the Fourier Transform of an arithmetic progression in poly-logarithmic time in the length of the progression; due to the worse dependence on the quality of approximation, however, that work obtained an algorithm with sample complexity $(k \cdot \text{(signal-to-noise ratio)})^4$.

The papers above showed how to achieve the ℓ_2/ℓ_1 guarantee in a number of samples that is quadratic in the signal sparsity. It is already known that a nearly linear dependence is possible [12]; however, we do not have efficient deterministic algorithms for finding these samples. The work of [12], as well as subsequent works, proceeds by sampling with repetition rows of the DFT matrix, and showing that the RIP condition (see Definition 5) holds, which in turn implies the desired result, but via a super-linear algorithm. The state-of-the-art analysis of such row subsampling is due to Haviv and Regev [32], who showed that $O(k\log^2 k\log n)$ samples suffice. A lower bound of $\Omega(k\log n)$ rows for this subsampling process has been shown in [7]. In this paper, we follow a different avenue and give a new set of schemes for the Sparse Fourier Transform which allow uniform reconstruction. Although our dependence is still quadratic in k, it is necessary, in contrast to the previous works: our results satisfy the strictly stronger ℓ_∞/ℓ_1 guarantee, for which a quadratic lower bound is known [23], and hence one cannot hope for a sub-quadratic dependence. We also note the deterministic algorithm of [41], which needs a cubic dependence on k but solves a somewhat different problem of finding the multidimensional sparse Fourier transform of a signal with at most k non-zeros in the frequency domain, and thus is not robust to noise.

The focus of our work is the ℓ_∞/ℓ_1 guarantee, defined formally as follows.

▶ **Definition 2** (ℓ_∞/ℓ_1 guarantee). *A sparse recovery scheme is said to satisfy the ℓ_∞/ℓ_1 guarantee with parameter k, if given access to vector x, it outputs a vector $\widehat{x}'$ such that*

$$\|\widehat{x} - \widehat{x}'\|_\infty \leq \frac{1}{k}\|\widehat{x}_{-k}\|_1. \tag{1}$$

ℓ_∞/ℓ_1 versus ℓ_2/ℓ_1: A matter of "find all" versus "miss all"

As we have discussed, previous works satisfied the ℓ_2/ℓ_1 guarantee, while our target is the ℓ_∞/ℓ_1 guarantee. Any algorithm for the latter guarantee also satisfies the former one. But, as we shall demonstrate in Section 2.3, the ℓ_∞/ℓ_1 guarantee is much stronger: there exists an infinite family of vectors for which an ℓ_2/ℓ_1 algorithm might detect none of the heavy frequencies, while an ℓ_∞/ℓ_1 algorithm must detect all of them. This happens because the ℓ_∞/ℓ_1 is a **worst-case** guarantee, in the sense that it requires detection of every frequency just above the noise level, in contrast to the ℓ_2/ℓ_1, which should be regarded as an **average-case** guarantee in the sense that it allows missing a subset of the heavy frequencies if they carry the energy proportional to the noise level.

Previous Work on ℓ_∞/ℓ_1 with arbitrary linear measurements

All approaches described above concerned Fourier measurements, but compressed sensing has a long history using arbitrary linear measurements, for example [19, 56, 35, 25, 28, 48, 26, 45, 44, 49]. Regarding ℓ_∞/ℓ_1, the work of [51] indicated a connection between the aforementioned guarantee and incoherent matrices. More specifically, it was shown that given a $(1/k)$-incoherent matrix one can design an algorithm satisfying the ℓ_∞/ℓ_1 guarantee. The existence of a matrix with $O(k^2 \min\{\log n, (\log n/\log k)^2\})$ rows was also proved. Reconstruction needed $\Omega(nk)$ time, something which was partially remedied by Li and Nakos [44] with a scheme of $O(k^2 \log n \cdot \log^* k)$ measurements and $\mathrm{poly}(k, \log n)$ decoding time. Incoherent matrices are interesting objects on their own, and have been studied before, as they can be used to obtain RIP matrices. Deterministic constructions of $O(k^2(\log n/\log k)^2)$ rows were obtained by DeVore [18] using deep results from the theory of Gelfand widths and by Amini and Marvasti [5] via binary BCH code vectors, where the zeros are replaced by -1s. We note that incoherent matrices matching this bound also follow immediately from the famous Nisan-Wigderson combinatorial designs [52], and serve as a cornerstone for constructions of pseudorandom generators and extractors [59]. Incoherent matrices are also connected with ϵ-biased codes, and thus an almost optimal strongly explicit construction can be obtained by the recent breakthrough work of [57]. On the lower bound side, Alon has shown that $\Omega(k^2 \log n/\log k)$ rows are necessary for a $(1/k)$-incoherent matrix [4].

Our Contribution

In this work we offer several new results for the Sparse Fourier Transform problem across different axis, some of which are nearly optimal. We show how to find in polynomial time a deterministic collection of samples from the time domain, such that we can solve the Sparse Fourier Transform problem in linear and sublinear time and achieve nearly optimal sample complexity. For the closely related problem of incoherent matrices from DFT rows, which is of independent interest, we obtain a nearly optimal derandomized construction via Bernstein's inequality. We also demonstrate strongly explicit constructions, by invoking heavy number-theoretical machinery.

We note that the bounds of our constructions have been known for more than a decade if the sensing/incoherent matrix is allowed to be arbitrary. However, the previous arguments did not facilitate the frequent and relevant scenario where we have access to rows only from the Fourier ensemble. Part of our work is to show that some of these results carry over to the significantly more constrained case. We also note that any progress to deterministic ℓ_2/ℓ_1 schemes with subquadratic sample complexity is connected to the very challenging problem of obtaining a deterministic DFT row-subsampled RIP matrices with subquadratic number of rows[2] which possibly out of reach at the moment.

2 Technical Results

2.1 Preliminaries

For a positive integer n, we define $[n] = \{0, 1 \ldots, n-1\}$ and we shall index the coordinates of a n-dimensional vector or the rows/columns of an $n \times n$ matrix from 0 to $n-1$. We define the Discrete Fourier Transform (DFT) matrix $F \in \mathbb{C}^{n\times n}$ to be the unitary matrix such that $F_{ij} = \frac{1}{\sqrt{n}} e^{2\pi\sqrt{-1}\cdot ij/n}$, and the Discrete Fourier Transform of a vector $x \in \mathbb{C}^n$ to be $\widehat{x} = Fx$.

For a set $S \subseteq [n]$ we define x_S to be the vector obtained from x after zeroing out the coordinates not in S. We also define $H(x, k)$ to be the set of the indices of the largest k coordinates (in magnitude) of x, and $x_{-k} = x_{[n]\setminus H(x,k)}$. We say x is k-sparse if $x_{-k} = 0$. We also define $\|x\|_p = \left(\sum_{i=0}^{n-1} |x_i|^p\right)^{1/p}$ for $p \geq 1$ and $\|x\|_0$ to be the number of nonzero coordinates of x.

For a matrix $F \in \mathbb{C}^{n\times n}$ and subsets $S, T \subseteq [n]$, we define $F_{S,T}$ to be the submatrix of F indexed by rows in S and columns in T.

The median of a collection of complex numbers $\{z_i\}$ is defined to be $\operatorname{median}_i z_i = \operatorname{median}_i \operatorname{Re}(z_i) + \sqrt{-1}\operatorname{median}_i \operatorname{Im}(z_i)$, i.e., taking the median of the real and the imaginary component separately.

For two points x and y on the unit circle, we use $|x-y|_\circ$ to denote the circular distance (in radians, i.e. modulo 2π) between x and y.

2.1.1 ℓ_∞/ℓ_1 Gurantee and incoherent matrices

The quality of the approximation is usually measured in different error metrics, and the main recovery guarantee we are interested in is called the ℓ_∞/ℓ_1 guarantee, as defined in Definition 2. Other types of recovery guarantee, such as the ℓ_∞/ℓ_2, the ℓ_2/ℓ_2 and the

[2] Note that [10] breaks the quadratic barrier for RIP matrices but does not use the Fourier ensemble; the rows are picked from the *discrete chirp-Fourier* ensemble, where the linear functions are substituted by quadratic polynomials.

ℓ_2/ℓ_1, are defined similarly, where (1) is replaced with the respective expression in Table 1. Note that these are definitions of the error guarantee per se and do not have algorithmic requirements on the scheme.

Highly relevant with the ℓ_∞/ℓ_1 guarantee is a matrix condition which we call incoherence.

▶ **Definition 3** (Incoherent Matrix). *A matrix $A \in \mathbb{C}^{m \times n}$ is called ϵ-incoherent if $\|A_i\|_2 = 1$ for all i (where A_i denotes the i-th column of A) and $|\langle A_i, A_j \rangle| \leq \epsilon$.*

▶ **Lemma 4** ([51]). *There exist an absolute constant $c > 0$ such that for any (c/k)-incoherent matrix A, there exists a ℓ_∞/ℓ_1-scheme which uses A as the measurement matrix and whose recovery algorithm runs in polynomial time.*

2.1.2 The Restrictred Isometry Property and its connection with incoherence

Another highly relevant condition is called the renowned restricted isometry property, introduced by Candès et al. in [11]. We show how incoherent matrices are connected to it.

▶ **Definition 5** (Restricted Isometry Property). *A matrix $A \in \mathbb{C}^{m \times n}$ is said to satisfy the (k, ϵ) Restricted Isometry Property (RIP), if for all $x \in \mathbb{C}^n$ with $\|x\|_0 \leq k$, it holds that $(1 - \epsilon)\|x\|_2 \leq \|Ax\|_2 \leq (1 + \epsilon)\|x\|_2$.*

Candès et al. proved in their breakthrough paper [11] that any RIP matrix can be used for sparse recovery with the ℓ_2/ℓ_1 error guarantee. The following formulation comes from [22, Theorem 6.12].

▶ **Lemma 6.** *Given a $(2k, \epsilon)$-RIP matrix A with $\epsilon < 4/\sqrt{41}$, we can design a ℓ_2/ℓ_1-scheme that uses A as the measurement matrix and has a recovery algorithm that runs in polynomial time.*

Although randomly subsampling the DFT matrix gives an RIP matrix with $O(k\text{log}^2k\text{log}n)$ rows [32], no algorithm for finding these rows in polynomial time is known; actually, even for $o(k^2) \cdot \text{poly}(\log n)$ rows the problem remains wide open[3]. It is a very important and challenging problem whether one can have an explicit construction of RIP matrices from Fourier measurements that break the quadratic barrier on k.

We state the following two folklore results, connecting the two different guarantees, and their associated combinatorial objects. This indicates the importance of incoherent matrices for the field of compressed sensing.

▶ **Proposition 7** (folklore). *An ℓ_∞/ℓ_1 scheme with a measurement matrix of m rows and recovery time T induces an ℓ_2/ℓ_1 scheme of a measurement matrix of $O(m)$ rows and recovery time $O(T + \|\widehat{x}'\|_0)$, where $\widehat{x}'$ is the output of the ℓ_∞/ℓ_1 scheme.*

▶ **Proposition 8** (folklore). *A (c/k)-incoherent matrix is also a (k, c)-RIP matrix.*

[3] In fact, one of the results of our paper gives the state-of-the-art result even for this problem, with $O(k^2 \log n)$ rows, see Theorem 12.

Table 2 Comparison of our results and the previous results. All O- and Ω-notations are suppressed. The result in the first row follows from Lemma 6 and the RIP matrix in [32].Our algorithms adopt the common assumption in the sparse FT literature that the signal-to-noise ratio is bounded by n^c for some absolute constant $c > 0$.

	Samples	Run-time	Guarantee	Explict Construction	Lower Bound
[32]	$k \log^2 k \log n$	$\mathrm{poly}(n)$	ℓ_2/ℓ_1	No	$k \log(n/k)$
[47]	$k^2 \log^{5.5} n / \log k$	$k^2 \log^{5.5} n / \log k$	ℓ_2/ℓ_1	Yes	$k \log(n/k)$
Theorem 9	$k^2 \log n$	$nk \log^2 n$	ℓ_∞/ℓ_1	Yes	$k^2 + k \log n$[51]
Theorem 10	$k^2 \log^2 n$	$k^2 \log^3 n$	ℓ_∞/ℓ_1	Yes	$k^2 + k \log n$[51]

2.2 Our results

2.2.1 Sparse Fourier Transform Algorithms

▶ **Theorem 9** (Deterministic SFT with super-linear time). *Let n be a power of 2. There exist a set $S \subseteq [n]$ with $|S| = O(k^2 \log n)$ and an absolute constant $c > 0$ such that the following holds. For any vector $x \in \mathbb{C}^n$ with $\|\widehat{x}\|_\infty \leq n^c \|\widehat{x}_{-k}\|_1/k$, one can find an $O(k)$-sparse vector $\widehat{x}' \in \mathbb{C}^n$ such that*

$$\|\widehat{x} - \widehat{x}'\|_\infty \leq \frac{1}{k}\|\widehat{x}_{-k}\|_1,$$

in time $O(nk \log^2 n)$ by accessing $\{x_i\}_{i \in S}$ only. Moreover, the set S can be found in $\mathrm{poly}(n)$ *time.*

▶ **Theorem 10** (Deterministic SFT with sublinear time,). *Let n be a power of 2. There exist a set $S \subseteq [n]$ with $|S| = O(k^2 \log^2 n)$ and an absolute constant $c > 0$ such that the following holds. For any vector $x \in \mathbb{C}^n$ with $\|\widehat{x}\|_\infty \leq n^c \|\widehat{x}_{-k}\|_1/k$, one can find an $O(k)$-sparse vector $\widehat{x}' \in \mathbb{C}^n$ such that*

$$\|\widehat{x} - \widehat{x}'\|_\infty \leq \frac{1}{k}\|\widehat{x}_{-k}\|_1,$$

in time $O(k^2 \log^3 n)$ by accessing $\{x_i\}_{i \in S}$ only. Moreover, the set S can be found in $\mathrm{poly}(n)$ *time.*

▶ Remark 11. The condition $\|\widehat{x}\|_\infty \leq n^c \|\widehat{x}_{-k}\|_1/k$ upper bounds the "signal-to-noise ratio", a common measure in engineering that compares the level of a desired signal to the level of the background noise. This is a common assumption in most algorithms in the Sparse Fourier Transform literature, see, e.g. [30, 33, 39, 13, 40], where the ℓ_2-norm variant $\|\widehat{x}\|_\infty \leq n^c \|\widehat{x}_{-k}\|_2/\sqrt{k}$ was assumed.

2.2.2 From DFT to incoherent matrices

This section contains deterministic constructions of incoherent matrices.

An Explicit Construction: Derandomization in poly(n) time

▶ **Theorem 12** (Incoherent matrices by derandomized subsampling of DFT). *There exists a set $S \subseteq [n]$ with of cardinality $O(k^2 \log n)$ such that the matrix $\sqrt{\frac{n}{m}} F_{S,[n]}$ is $(1/k)$-incoherent. Moreover, S can be found in* $\mathrm{poly}(n)$ *time.*

The above Theorem yields immediately a different algorithm for ℓ_∞/ℓ_1 Sparse Fourier Tranform with $O(k^2 \log n)$ samples, via the reduction in [51].

Strongly explicit constructions: Derandomization in sub-linear time

▶ **Theorem 13** (Incoherent matrices from DFT via low-degree polynomials). *Let $\epsilon > 0$ be a constant small enough, p be a prime and $d \geq 2$ be an integer. There exists a strongly explicit construction of an $O(m^\epsilon(\frac{1}{m} + \frac{p}{m^d})^{2^{1-d}})$-incoherent matrix $M \in \mathbb{C}^{m\times p}$ such that the rows of $\sqrt{m}M$ are rows of the DFT matrix (a row may appear more than once). The hidden constant in the O-notation depends on d and ϵ. Finding the indices of the rows takes $\widetilde{O}(m)$ time.*

To get an idea of the above result one could for example set $d = 3$ and observe that the results translates to the following: for every $k \geq p^{1/8}$ one can get a $(1/k)$-incoherent matrix with $O(k^{4+\epsilon})$ rows. One needs the condition on k (or equivalently the condition on m) to bound the term p/m^d. The larger the degree d, the looser this condition, but also the worse the dependence of m on k. For example, when $d = 4$, we can expand the regime of k to approximately $k \geq p^{1/24}$, but obtain approximately $m = O(k^{8+\epsilon})$.

The following is a different construction, incomparable with Theorem 13 in multiple ways. First, the construction runs in sublinear time in p but it is not strongly explicit. Second, it gives different trade-offs between the sparsity parameter and the number of rows. Last but not least, the construction depends on the factorization of $p-1$.

▶ **Theorem 14** (Incoherent matrices from DFT via multiplicative subgroupss). *Let p be a prime number. For every divisor d of $p-1$ such that $d > \sqrt{p}$ we can find in time $O(d\log p)$ a matrix $M \in \mathbb{C}^{d\times p}$ with rows being the rows of the DFT matrix such that $\frac{1}{d}M$ is $(\sqrt{p}/d)$-incoherent.*

This result could give (depending on the factorization of $p-1$) a better polynomial dependence of m on k in the high-sparsity regime. If $p-1$ has a large divisor about $p^{1-\gamma}$, this would yield a matrix with sparsity parameter $k \approx p^\gamma$ and $m \approx k^{1/\gamma-1}$ rows. For example, when $\gamma = 1/4$, we obtain $k \approx p^{1/4}$ and $m \approx k^3$, which cannot be obtained from Theorem 13. In general, Theorem 14 will yield useful matrices as long as $p-1$ has divisors in the range $[\sqrt{p}, p-1]$, ideally as many as possible. An extreme case is Fermat primes, which have $(\log p)/2$ divisors in the aforesaid interval.

The reader might ask the question if the polynomial dependence of k on p is necessary; ideally one would like a logarithmic dependence, since the polynomial dependence is interesting only in the high-sparsity regime. Regarding strongly explicit constructions, we provide some evidence why this might be a very hard problem in the remark below.

▶ Remark 15. The inferiority of our bounds in the low-sparsity regime is justifiable to some extent: it is because of a common obstacle that has persisted more than a century in the theory of exponential sums, due to the lack of techniques to account for sparse character sums (either additive or multiplicative). In general, the fewer summands the sum has, the harder it is to prove a tight cancellation bound. Thus, owing to the use of heavy machinery from analytic number theory and more specifically the theory of exponential sums over finite fields, our bounds for strongly explicit constructions are quite suboptimal.

2.3 Comparing ℓ_2/ℓ_1 with ℓ_∞/ℓ_1

In this subsection we elaborate why ℓ_∞/ℓ_1 is much stronger than ℓ_2/ℓ_1, and not just a guarantee that implies ℓ_2/ℓ_1. Let $\gamma < 1$ be a constant and consider the following scenario. There are three sets A, B, C of size γk, $(1-\gamma)k$, $n-k$ respectively, and for every $i \in A$ we have $|\widehat{x}_i| = \frac{2}{k}\|\widehat{x}_C\|_1 = \frac{2}{k}\|\widehat{x}_{-k}\|_1$, while every coordinate in B and C has the equal magnitude. It follows immediately that

$$\|\widehat{x}_C\|_1 = \frac{n-k}{n-\gamma k}\|\widehat{x}_{B\cup C}\|_1.$$

Now assume that $k \le \gamma n$, then $(n - \gamma k)/(n - k) \le 1 + \gamma$. We claim that the zero vector is a valid solution for the ℓ_2/ℓ_1 guarantee, since

$$\begin{aligned}\|\vec{0} - \widehat{x}\|_2^2 &= \|\widehat{x}_A\|_2^2 + \|\widehat{x}_{B\cup C}\|_2^2 \\ &\le \gamma k \cdot \frac{4}{k^2}\|\widehat{x}_{-k}\|_1^2 + \frac{1}{(n-\gamma k)}\|\widehat{x}_{B\cup C}\|_1^2 \\ &\le \frac{4\gamma}{k}\|\widehat{x}_{-k}\|_1^2 + \frac{n-\gamma k}{(n-k)^2}\|\widehat{x}_C\|_1^2 \\ &\le \left(\frac{4\gamma}{k} + \frac{1+\gamma}{n-k}\right)\|\widehat{x}_{-k}\|_1^2 \\ &\le \frac{5\gamma}{k}\|\widehat{x}_{-k}\|_1^2,\end{aligned}$$

where the last inequality follows provided it further holds that $k \le \gamma n/(2\gamma + 1)$. Hence when $\gamma \le 1/5$, we see that the zero vector satisfies the ℓ_2/ℓ_1 guarantee.

Since $\vec{0}$ is a possible output, we may not recover any of the coordinates in S, which is the set of "interesting" coordinates. On the other hand, the ℓ_∞/ℓ_1 guarantee does allow the recovery of **every** coordinate in S. This is a difference of recovering all γk versus 0 coordinates. We conclude from the discussion above that in the case of too much noise, the ℓ_2/ℓ_1 guarantee becomes much weaker than the ℓ_∞/ℓ_1, possibly giving meaningless results in some cases.

3 Overview

Sparse Fourier Transform Algorithms

We first show how to achieve the for-all schemes, i.e., schemes that allow universal reconstruction of all vectors, and then derandomize them. Similarly to the previous works [31, 33, 40], our algorithm hashes, with the filter in [40], the spectrum of x to $O(k)$ buckets using pseudorandom permutations, and repeat $O(k \log n)$ times with fresh randomness. The main part of the analysis is to show that for any vector $\widehat{x} \in \mathbb{C}^n$ and any set $S \subseteq [n]$ with $|S| \le k$, each $i \in S$, in a constant fraction of the repetitions, receives "low noise" from all other elements, under the pseudorandom permutations. This will boil down to a set of $\Theta(n^2)$ inequalities involving the filter and the pseudorandom permutations. We prove these inequalities with full randomness, and then derandomize the pseudorandom permutations using the method of conditional expectations. This will give us Theorem 9. To do so, we choose the pseudorandom permutations one at a time, repetition by repetition, and keep an (intricate) pessimistic estimator , which we update accordingly. Our argument extends the arguments in [51] and [54], and could be of independent interest. To compare with [51] we have the following observation. The construction in [51] consists of $O(k \log n)$ matrices, joined vertically, each having $O(k)$ rows and exactly one 1 per column. This ensures a small incoherence of the concatenated matrix and gives the ℓ_∞/ℓ_1 guarantee. In the Fourier case, the convolution with the filter functions behaves analogously: instead of having exactly one non-zero element, each column in the ℓ-th matrix has a contiguous segment of 1s of size $\approx n/k$ (where the center of that segment is depends on the choice of the ℓ-th pseudorandom permutation) and polynomially decaying entries away from this segment. Moreover, the positions of the segments across the columns are not fully independent and are defined via the pseudorandom permutations. We show that even in this more restricted setting, derandomization is possible in polynomial time. Several details are omitted in the preceding high-level discussion and we suggest the reader look at the corresponding sections for the complete argument.

The sublinear-time algorithm (Theorem 10) is obtained by bootstrapping the derandomized scheme above with an identification procedure in each bucket, as most previous algorithms have done (e.g. [30]). The major difference is that our identification procedure needs to be deterministic. We show an explicit set of samples that allow the implementation of the desired routine. To illustrate our idea, let us focus on the following 1-sparse case: $\widehat{x} \in \mathbb{C}^n$ and $|\widehat{x}_{i^*}| \geq 3\|\widehat{x}_{[n]\setminus i^*}\|_1$ for some i^*, which we want to locate. Let

$$\theta_j = \left(\frac{2\pi}{n}j\right) \bmod 2\pi,$$

and consider the $\log n$ samples $x_0, x_1, x_2, x_4, \ldots, x_{2^{r-1}}, \ldots$.

Observe that (ignoring $1/\sqrt{n}$ factors)

$$x_\beta = \widehat{x}_{i^*} e^{\sqrt{-1}\beta\theta_{i^*}} + \sum_{j \neq i^*} \widehat{x}_j e^{\sqrt{-1}\beta\theta_j},$$

we can find $\beta\theta_{i^*} + \arg \widehat{x}_{i^*}$ up to $\pi/8$, just by estimating the phase of x_β. Thus we can estimate $\beta\theta_{i^*}$ up to $\pi/4$ from the phase of x_β/x_0. If $i^* \neq j$, then there exists a $\beta \in \{1, 2, 2^2, \ldots, 2^{r-1}, \ldots\}$ such that $|\beta\theta_{i^*} - \beta\theta_j|_\circ > \pi/2$, and so $\beta\theta_j$ will be more than $\pi/4$ away from the phase of the measurement. Thus, by iterating over all $j \in [n]$, we keep the index j for which $\beta\theta_j$ is within $\pi/4$ from $\arg(x_\beta/x_0)$, for every β that is a power of 2 in $\mathbb{Z}_n$.

Unfortunately, although this is a deterministic collection of $O(\log n)$ samples, the above argument gives only $O(n \log n)$ time. For sublinear-time decoding we use x_1/x_0 to find a sector S_0 of the unit circle of length $\pi/4$ that contains θ_{i^*}. Then, from x_2/x_0 we find two sectors of length $\pi/8$ each, the union of which contains θ_{i^*}. Because these sectors are antipodal on the unit circle, the sector S_0 intersects exactly one of those, let the intersection be S_1. The intersection is a sector of length at most $\pi/8$. Proceeding iteratively, we halve the size of the sector at each step, till we find θ_{i^*}, and infer i^*. Plugging this idea in the whole k-sparse recovery scheme yields the desired result. Our argument crucially depends on the fact that in the ℓ_1 norm the phase of θ_{i^*} will always dominate the phase of all samples we take.

Incoherent Matrices from the Fourier ensemble

Our first result for incoherent matrices (Theorem 12) is more general and works for any matrix that has orthonormal columns with entries bounded by $O(1/\sqrt{n})$. We subsample the matrix, invoke a Chernoff bound and Bernstein's inequality to show the small incoherence of the subsampled matrix. We follow a derandomization procedure which essentially mimics the proof of Bernstein's inequality, keeping a pessimistic estimator which corresponds to the sum of the generating functions of the probabilities of all events we want to hold, evaluated at specific points. We obtain an explicit construction, i.e. a derandomization in poly(n) time. This argument could be of independent interest for its generality. As there are many technical obstacles to overcome, we suggest the reader take a careful look at the proof to gain a clearer picture of the argument.

Our next results (Theorem 13 and Theorem 14) construct *strongly explicit* incoherent matrices by making use of technology from the fruitful theory of exponential sums in analytic number theory and additive combinatorics. Roughly speaking, to bound a complex exponential sum over a set S, one would expect that specific choices of the set S lead to non-trivial bounds, i.e. $o(|S|)$, since cancellation takes place in the summation. Ideally, one would desire that the exponentials behave like a random walk and give the optimal cancellation of $O(\sqrt{|S|})$. This intuition is clearly not true, but the results by Weyl and others show that certain sets S can exhibit a nicer behaviour. We exploit their results to build incoherent matrices by taking the rows of the DFT matrix indexed by the "nice" sets. This connection also yields an immediate improvement on the lower bound of an exponential sum obtained by Winterhof [60].

4 Open Problems and Future Direction

A direction of research is to design deterministic schemes that break the quadratic barrier for signals with structured Fourier support. For example, subsampling the rows of the DFT matrix to obtain RIP matrices depends highly on the structure of the vectors we would like to preserve. The more additive structure the support of a k-sparse vector x has, the worse is the concentration of a random Fourier coefficient of x. Equivalently, the less additive structure the support of x has, the flatter its Fourier transform is, and hence, the better concentration bounds we obtain. The concentration in the extreme case, when the support of x is "dissociated", is captured by the renowned Rudin's inequality in additive combinatorics (see, e.g. [58, Lemma 4.33]). We thus believe that it is an interesting direction to use machinery from the field of additive combinatorics and the relevant fields in order to obtain new constructions and algorithms, at least for interesting subclasses of structured signals.

Abstract

We describe an algorithm to solve the problem of Boolean CNF-Satisfiability when the input formula is chosen randomly.

We build upon the algorithms of Schöning 1999 and Dantsin et al. in 2002. The Schöning algorithm works by trying many possible random assignments, and for each one searching systematically in the neighborhood of that assignment for a satisfying solution. Previous algorithms for this problem run in time $O(2^{n(1-\Omega(1)/k)})$.

Our improvement is simple: we count how many clauses are satisfied by each randomly sampled assignment, and only search in the neighborhoods of assignments with abnormally many satisfied clauses. We show that assignments like these are significantly more likely to be near a satisfying assignment. This improvement saves a factor of $2^{n\Omega(\lg^2 k)/k}$, resulting in an overall runtime of $O(2^{n(1-\Omega(\lg^2 k)/k)})$ for random k-SAT.

Acknowledgements We are very grateful to Greg Valiant, Virginia Williams, and Nikhil Vyas for their helpful conversations and kind support. Additionally, we are very appreciative of the email correspondence we had with Amin Coja-Oghlan, Allan Sly, and Nike Sun, who answered our many questions. We would also like to thank reviewers for their comments and suggestions. We would especially like to thank an exceptionally detailed and helpful review that we received on our paper last year.

1 Introduction

The Boolean Satisfiability problem, known as SAT for short, is one of the best-known and most well-studied problems in computer science (e.g. [28, 1, 19, 3, 14]). In its general form, it describes the following problem: given an input formula ϕ composed of conjunctions, disjunctions, and negations of a list of Boolean-valued variables $(x_1, x_2, \ldots, x_n)$, determine whether or not there exists an assignment of variables to Boolean values such that ϕ evaluates to TRUE. SAT was the first problem shown to be NP-complete [12, 24].

Every Boolean formula ϕ can be written in *conjunctive normal form*, meaning that it is written as the logical conjunction of a series of disjunctive clauses. Each disjunctive clause takes as its value the logical disjunction of a series of *literals*, which takes on either the same value of one of the variables x_i or the negation of that value.

If we constrain the input formula ϕ to contain only disjunctive clauses that are of size k or smaller, then that more constrained problem is known as *k-Satisfiability*, or *k-SAT* for short. When $k > 2$ it is known to be NP-complete [22]. As k grows, the best known runtime of the worst-case k-SAT problem, $O(2^{1-1/\Theta(k)})$, grows [21, 28].

It is well-known that in real-world Boolean Satisfiability problems, SAT solvers often vastly outperform the best known theoretical runtimes [15, 31]. One possible explanation for this gap in performance is that most input formulas are easily solved without much computation being necessary, but that there exists a "hard core" of difficult-to-solve formulas that are responsible for the apparent difficulty of worst-case SAT.

Another possible explanation for this gap in performance is that, in practice, people usually care about highly structured formulas that are much easier to solve than typical formulas – according to this explanation, there would be an "easy core" of tractable formulas that are responsible for the apparent simplicity of most practical SAT problems.

To try to distinguish between these two explanations, one can study *random Satisfiability*: Boolean Satisfiability for which the input formula ϕ is chosen according to some known uniform probability distribution D_Φ, and where we expect to be able to return the correct answer (satisfiable or unsatisfiable) with probability that is exponentially close to 1 in the size of the input. Random k-SAT is a very well studied problem (e.g. [3, 16, 27, 10, 7, 26, 33]).

Typically, attention is restricted to k-CNF formulas whose ratio of clauses to variables is *at the threshold*, meaning that the number of clauses m is drawn from a Poisson distribution centered at $d_k n$, where n is the number of variables and d_k is a function of k close to $2^k \ln(2) - \frac{1}{2}(1 + \ln(2))$ [16]. Such formulas are conjectured to be the hardest instances for a given n [13, 31]. It was shown by Ding, Sly, and Sun [16] that away from this threshold, formulas are either overwhelmingly satisfied or overwhelmingly unsatisfied, making the problem less interesting. Notably, away from this threshold one can simply return True or False based on the number of clauses and give the correct answer with high probability. For our purposes, this is a very useful guarantee to have; this is why we use their definition throughout the paper. We go into much greater detail about D_Φ and the threshold in Section 2.

Away from the threshold, polynomial-time algorithms for SAT have been found and analyzed, first by Chao and Franco [26], and later by Coja-Oghlan et al. [10, 7]. Additionally, a recent result by Vyas and Williams [33] re-analyzes the algorithm of Paturi et al. [29] in the case when the input is drawn from a random distribution, and finds the algorithm to run faster on average in this case by a factor of $2^{n\Omega(\lg k)/k}$, giving a running time of $O(2^{n(1-\Omega(\lg k)/k)})$.

We build upon the work of Schöning [30] and Dantsin et al [14] to solve random k-SAT in time $O(2^{n(1-\Omega(\lg^2 k)/k)})$. This represents an algorithmic improvement of $2^{n\Omega(\lg^2 k)/k}$ over the runtime of the algorithm of Paturi et al. as analyzed by Vyas and Williams in [33].

1.1 A New Algorithm

In this paper, we restrict our attention to the problem of random k-CNF Satisfiability in the limit of large k, which approaches general Boolean CNF-Satisfiability. Our algorithm improves upon the previous best known algorithm for solving random k-SAT in the limit of large k, assuming that the input formulas are chosen according to a known uniform distribution.

Our algorithm improves the running time of k-CNF Satisfiability at the threshold by modifying the algorithms of Schöning and Dantsin et al. to only explore in the neighborhood of those sampled assignments that pass an additional test. By adding this test, we get a $2^{n\Omega(\lg^2 k)/k}$ improvement in the runtime of the algorithm. The test is simple: we count how many clauses are satisfied, and if that number is large, only then do we search in the neighborhood of the assignment. In Appendix G.2 of our full version [25], we provide additional motivation for why our improved running time is remarkable.

▶ **Theorem 1** (Main Theorem Informal). *Let ϕ be drawn uniformly at random from formulas at the threshold (defined formally in Section 2). There exists an algorithm, α-*SampleAndTest *(described in Section 3), such that:*

- *If ϕ is satisfiable, then with probability at least $1-3\cdot 2^{-n/(3\ln(2)2^k)}$, α-*SampleAndTest *returns an assignment $\vec{a}$ that satisfies ϕ.*
- *If ϕ is not satisfiable, then α-*SampleAndTest *will return False with certainty.*
- *α-*SampleAndTest*(ϕ) will run in time $O(2^{n(1-\Omega(\lg^2 k)/k)})$.*

A key technique in the proof of our result is connecting a different distribution over inputs (the *planted k-SAT distribution*) to the uniformly random k-SAT distribution. Reductions between planted k-SAT and random k-SAT have been shown in previous work as well [6, 4, 33]. In the planted k-SAT distribution, an assignment, $\vec{a}$, is picked first. The formula ϕ is selected uniformly over k-SAT clauses *conditioned on* $\vec{a}$ satisfying those clauses. As a result, the planted distribution has a bias towards picking formulas that have many satisfying assignments, relative to the uniform distribution over all satisfiable formulas. For this reason, the planted distribution tends to generate easier-to-solve formulas ϕ than the uniform distribution [18]. We also find that the planted distribution is more easily analyzed.

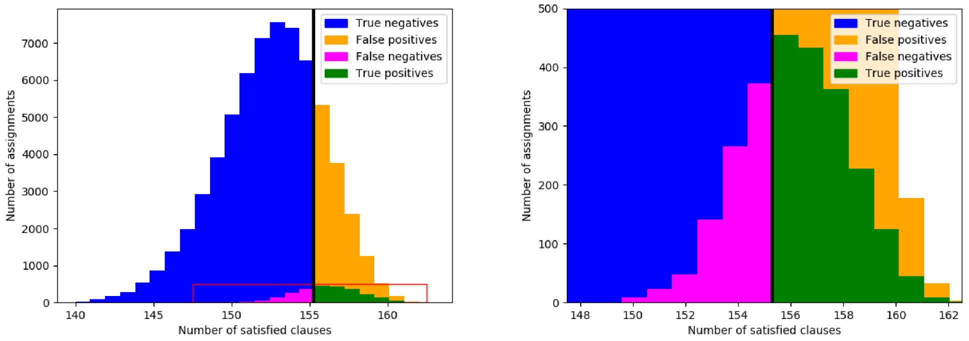
It would be possible, and simpler, to analyze our algorithm only in the planted distribution over formulas. This would *not*, however, correspond to a complete analysis of the algorithm in the random case. In this work, we begin by analyzing the performance of our algorithm when run on inputs drawn from the planted distribution. We show that algorithms with a sufficiently low probability of failure in the planted distribution over input formulas continue to have a low probability of failure in the uniform distribution over input formulas; see Lemma 37 of our full version [25]. Similar reductions have been proven in previous work [6, 4, 33].

The bulk of the analysis of our algorithm presented in this paper will focus on four quantities. Informally:

1. The *true positive rate p_{TP}* describes the fraction of all assignments that are both close to a satisfying assignment in Hamming distance and satisfy a large number of clauses.
2. The *false negative rate p_{FN}* describes the fraction of all assignments that are close to a satisfying assignment in Hamming distance, but do not satisfy a large number of clauses.
3. The *false positive rate p_{FP}* describes the fraction of all assignments that are not close to any satisfying assignment in Hamming distance, but satisfy a large number of clauses.
4. The *true negative rate p_{TN}* describes the fraction of all assignments that are neither close to any assignment in Hamming distance, nor satisfy a large number of clauses.

By showing that the true positive rate is large enough relative to the false positive rate, we show that we do not too often perform a "useless search," i.e. one that will not find a satisfying assignment. And by showing that the true positive rate is large enough relative to the total number of possible assignments, we show that we eventually do find a satisfying assignment without needing to take too many samples. See Fig. 1 for an illustration of these concepts.

To show that our algorithm achieves the desired runtime, we must demonstrate two things. First, we must show that false positives are sufficiently rare; in other words, conditioned on an assignment passing our test, it is sufficiently likely to be a small-Hamming-distance assignment. We prove this in Appendix A of our full version [25]. Second, we must show



(a) The full histogram.

(b) A magnification of the red region shown on the left.

Figure 1 A histogram of how many clauses are satisfied by every possible assignment. In this example, there are $n = 16$ variables, $m = 163$ clauses, and $k = 4$ literals per clause. For the example, we take $T = 155.5$ to be the clause-satisfaction threshold above which we explore further, and $\alpha n = 4$ to be the small-Hamming-distance threshold at which the exhaustive search algorithm finishes. (In actual runs of the algorithm, both of these parameters are selected more conservatively; we chose these parameters for clarity.)

that true positives are sufficiently common; in other words, conditioned on an assignment being close in Hamming distance to a satisfying assignment, it is sufficiently likely to pass our test. We prove this in Appendix B of our full version [25].

We also note that our algorithm can potentially be used as the seed for a worst-case algorithm. Informally, the correctness of the analysis in this paper depends only on the false positive and false negative rates being sufficiently low. As long as the inputs are guaranteed to come from a family of formulas for which this is the case, our algorithm will work even in the worst case. Or, to put it another way, to build a working worst-case algorithm using our algorithm as a template, one may now restrict one's attention to solving input formulas for which assignments in the neighborhood of the solution do *not* have an abnormally-high number of satisfied clauses; our algorithm can solve the others.

1.2 Previous work

Satisfiability and k-SAT have been thoroughly studied. We will cover some of the previous work in the area, focusing on the Random k-SAT problem.

Structural Results About Random k-SAT

To make the study of the Satisfiability of random formulas interesting, it is important to choose the probability distribution over formulas D_ϕ judiciously. In particular, D_ϕ must contain formulas where the ratio of Boolean variables to disjunctive clauses is such that the resulting formulas are neither overwhelmingly satisfiable, nor overwhelmingly unsatisfiable. Let n be the number of variables, and m be the number of clauses. If $n \gg m$, then nearly all formulas chosen uniformly from D_ϕ will be satisfiable; if $m \gg n$, then nearly all formulas will be unsatisfiable. In order for the problem of correctly identifying formulas as satisfiable or unsatisfiable to be nontrivial, we must choose m and n to be at the right ratio. Throughout this paper we will refer to the ratio of m to n as the *density* of a formula.

In work by Ding, Sly and Sun [16], it was shown that a sharp threshold exists between formulas which are satisfied with high probability and those that are unsatisfied with high probability. More precisely, they describe what happens when the number of clauses m is drawn from a Poisson distribution with mean $d_k n$. When the number of clauses drawn is below $(d_k - \epsilon)n$, only an exponentially small fraction of formulas will be unsatisfiable; when the number of clauses drawn is greater than $(d_k + \epsilon)n$, only an exponentially small fraction of formulas will be satisfiable. This holds true for any $\epsilon > 0$ constant in n.

Previous Average-Case k-SAT Algorithms

Feldman et al. studied planted random k-SAT and found that given $m = \Omega(n \lg n)$ clauses, the planted solution can be determined using statistical queries [18]. Feldman et al. also conjecture that planted k-SAT is easier than random k-SAT more generally. Previous work has shown a connection between algorithms that work in the planted distribution and algorithms that work in the random distribution [4, 6, 33]. An algorithm was found by Valiant which runs in time $O(2^{n(1-\Omega(\log(k))/k)})$ at the threshold [32], improving upon PPSZ [28]. Additionally, Vyas and Williams [33] obtained the same runtime by re-analyzing the algorithm of Paturi et al. [29] in the random case.

Some studies of random k-SAT have focused on refutation [9, 8, 20, 5]. Refutation aims to return a short certificate of unsatisfiability. For example Coja-Oghlan, Goerdt, and Lanka give an algorithm that provides refutations with high probability when $k = 3$ and $m > \ln(n)^6 n^{3/2}$. Refutation is quite difficult; note that the m is much larger than the threshold which sits at $\Theta(2^k n)$. We, however, focus on returning a satisfying assignment if the formula is satisfied with high probability.

Some studies of random k-SAT focus on the case where k is small (e.g. [9, 8, 2, 17]). We, however, focus on the asymptotic behavior when k is large.

Worst-Case k-SAT Algorithms

The previously best-known worst-case k-SAT algorithms for large k are due to Paturi et al. who get a running time of $O(2^{n(1-\Omega(1)/k)})$ [28]. Previous work by Schöning gave an algorithm to solve k-SAT in the worst case with an expected running time of $O(2^{n(1-\Omega(1)/k)})$ [30]. Dantsin et al. make the algorithm deterministic [14]. Our algorithm is a modification of the algorithms of both Schöning's and Dantsin et al. Their algorithm runs by choosing an assignment at random, and searching in the immediate neighborhood of that assignment by repeatedly choosing an unsatisfied clause and flipping a variable in that clause to satisfy it. They perform the search near the randomly chosen assignment via an exhaustive search. Their algorithm is an improvement over a naive brute-force algorithm because of the savings that result from only considering variable-flips that could possibly cause the formula to become satisfied (rather than also exploring variable-flips that can't possibly be helpful).

2 Preliminaries

In this section we will give the definition of random k-CNF Satisfiability (random k-CNF SAT) at the threshold. We additionally present definitions of several important distributions and functions that are used later in the paper.

Notation for This Paper

We use $x \sim D$ to indicate that x is a random value drawn from the distribution D.

We use the standard notation that $\lg(n) = \log_2(n)$.

We use $f(x) = O^*(g(x))$ to denote that there exists some constant c such that $f(x) = O(g(x)x^c)$. So, to say it another way, $f(x)$ grows at most as quickly as $g(x)$, ignoring polynomial and constant factors.

We often use "small-Hamming-distance assignment" to mean an assignment that is a small Hamming distance from a satisfying assignment.

Definitions for This Paper

▶ **Definition 2.** *Let $D_{replace}(n, k)$ be the uniform distribution over clauses on k variables where those k variables are chosen with replacement (e.g. $(\bar{x} \vee x \vee y)$ would be a valid clause). Under this definition, there are $n^k 2^k$ possible clauses.*

▶ **Definition 3.** *The density of a formula ϕ with m clauses and n variables is m/n.*

We will now define the *satisfiability threshold.* Informally, this is a density of clauses such that formulas drawn from below this threshold are with high probability (whp) satisfied, and those formulas drawn from above the threshold are whp unsatisfied.

▶ **Definition 4.** *The satisfiability threshold, d_k, is a ratio of clauses to variables such that for all $\epsilon > 0$:*

- *If m is drawn from $Pois[(d_k - \epsilon)n]$, the Poisson distribution with mean $(d_k - \epsilon)n$, and ϕ is formed by picking m clauses independently at random from $D_{replace}(n, k)$, then ϕ is whp **satisfied**.*
- *If m is drawn from $Pois[(d_k + \epsilon)n]$, the Poisson distribution with mean $(d_k + \epsilon)n$, and ϕ is formed by picking m clauses independently at random from $D_{replace}(n, k)$, then ϕ is whp **unsatisfied**.*

▶ **Definition 5.** *Let d_k be the density of clauses such that SAT is at its threshold.*

Note that it is not immediate that a satisfiability threshold exists for any given k. However, Jian Ding, Allan Sly, and Nike Sun showed that this threshold exists for sufficiently large k [16]. It has been proven that

$$2^k \ln(2) - \frac{1}{2}(1 + \ln(2)) - \epsilon_k \leq d_k \leq 2^k \ln(2) - \frac{1}{2}(1 + \ln(2)) + \epsilon_k,$$

where ϵ_k is a term that tends to 0 as k grows [23, 11]. It follows that there exists a large enough k such that $2^k \ln(2) - 1 \leq d_k$. Also, there exists a large enough k such that $2^k \ln(2) \geq d_k$.

This density determines the distribution over the number of clauses put in the formula. Specifically, m is drawn from $Pois[d_k n]$. However, we can say that with high probability the number of clauses is nearly $d_k n$ (see Lem. 9).

For many proofs it is convenient to assume k is large (e.g. when k is large, $2^k > 10k$ not just asymptotically but also numerically). We will now define $k^\star$. It will be a value such that $k = k^\star$ is large enough that both d_k is known to be close to $2^k \ln(2) - \frac{1}{2}(1 + \ln(2))$ and large enough for our proofs that depend on k being large.

▶ **Definition 6.** *Let $\epsilon_k = |d_k - 2^k \ln(2) + \frac{1}{2}(1 + \ln(2))|$.*

▶ **Definition 7.** *Let k_ϵ be the minimum value such that for all $k \geq k_\epsilon$ we have that $\epsilon_k < \frac{1+\ln(2)}{2}$.*

▶ **Definition 8.** *Let* $k^\star = \max(60, k_\epsilon)$.

Our choice of 60 in the above is somewhat arbitrary. When $k \geq 60$ the proofs in Appendix C of our full version [25] are simpler, so we analyze our core algorithm in that regime.

▶ **Lemma 9.** *If* $\epsilon_k < \frac{1+\ln(2)}{2}$ *then* $Pr[m > (d_k+1)n] + Pr[m < (d_k-1)n] \leq 2 \cdot 2^{-n/(3\ln(2)2^k)}$.

Proof. We apply the multiplicative form of the Chernoff bound. We have that $(d_k + 1)n/(d_k n) = 1 + 1/d_k$. We also have that $(d_k - 1)n/(d_k n) = 1 - 1/d_k$. This gives us

$$Pr[m > (d_k+1)n] + Pr[m < (d_k-1)n] \leq 2^{-(d_k)^{-2} d_k n/3} + 2^{-(d_k)^{-2} d_k n/2}.$$

Which means

$$Pr[m > (d_k+1)n] + Pr[m < (d_k-1)n] \leq 2^{-n/(3d_k)} + 2^{-n/(2d_k)}.$$

$$Pr[m > (d_k+1)n] + Pr[m < (d_k-1)n] \leq 2 \cdot 2^{-n/\left(3(\ln(2)2^k - \frac{1}{2}(1+\ln(2))\right)}.$$

$$Pr[m > (d_k+1)n] + Pr[m < (d_k-1)n] \leq 2 \cdot 2^{-n/(3\ln(2)2^k)}.$$ ◀

It follows that if our algorithm works efficiently for all values of $m \in [(d_k-1)n, (d_k+1)n]$, then it works with high probability at the threshold.

Below are some definitions used in later sections.

▶ **Definition 10.** *Let* $D_\Phi(n,k)$ *be the distribution over formulas* ϕ *where all clauses are chosen independently from* $D_{replace}$ *and the number of clauses is chosen from a Poisson distribution with mean* $d_k n$.

▶ **Definition 11.** *Let* $D_R(m,n,k)$ *be the distribution over formulas* ϕ *where all* m *clauses are chosen independently from* $D_{replace}$.

▶ **Definition 12.** *Let* $D_S(m,n,k)$ *be the uniform distribution over* satisfied *formulas* ϕ *where all* m *clauses are chosen from* $D_{replace}$.

▶ **Definition 13.** *Let* $D_{pc}(n,k,\vec{a})$ *(which we refer to as "the planted-clause distribution") be the uniform distribution over the* $(2^k-1)n^k$ *clauses* c *which are satisfied by* $\vec{a}$.

▶ **Definition 14.** *Let* $D_{pa}(m,n,k,\vec{a})$ *(which we refer to as "the planted distribution") be the distribution over formulas* ϕ *where every clause is picked IID from* $D_{pc}(n,k,\vec{a})$. *Note that this is equivalent to the uniform distribution over formulas* ϕ *which are satisfied by* $\vec{a}$ *and where all* m *clauses are in the support of* $D_{replace}$.

▶ **Definition 15.** *Let* $U_{\vec{a}}(n)$ *be the uniform distribution over assignments of length* n, $\{0,1\}^n$.

▶ **Definition 16.** *Let* $\textsc{NumClausesSAT}(\phi,\vec{v})$ *be the number of clauses in* ϕ *satisfied by the assignment* $\vec{v}$.

▶ **Definition 17.** *Let* $\textsc{NumClausesUnSAT}(\phi,\vec{v})$ *be the number of clauses in* ϕ *left unsatisfied by the assignment* $\vec{v}$.

3 Algorithm

We will describe our algorithm for random k-SAT in this section.

Informally, our algorithm works as follows. Given an input formula, we will sample many randomly-chosen assignments. On those that have a high number of satisfied clauses, we will run the deterministic algorithm for finding a satisfying assignment given an assignment that is within a Hamming distance of at most αn of that satisfying assignment (i.e. a small-Hamming-distance assignment).

Unsurprisingly, in the average case, small-Hamming-distance assignments satisfy more clauses than random assignments[1]. In fact, for many choices of criterion there will be a discrepancy between the values achieved by small-Hamming-distance assignments and random assignments. Lemma 30 of our full version [25], which characterizes this discrepancy, is general enough to be applied immediately to analyzing algorithms that make use of any clause-specific criterion.

We note the following from previous work:

▶ **Lemma 18** (Small Hamming Distance Search [14]). *There is a deterministic algorithm SAT-FROM-α-SMALL-HD$(\phi, \vec{v})$ which given*

- *a k-CNF formula ϕ on m clauses and n variables, and*
- *an assignment $\vec{v}$ which has Hamming distance αn from a true satisfying assignment $\vec{a}^*$,*

will return a satisfying assignment within Hamming distance αn of $\vec{v}$ if one exists in $k^{\alpha n}$ time.

This algorithm simply takes the assignment $\vec{a}$ and branches on the first unsatisfied clause, trying all possible variable flips. For each assignment resulting from these possible variable flips, the algorithm repeats the process in what is now the first unsatisfied clause, until it either finds a satisfying assignment or has searched αn flips from the original assignment. This will deterministically yield a satisfying assignment, should one exist, within a Hamming distance of αn of the original assignment.

So, if we find a small-Hamming-distance assignment and run SAT-FROM-α-SMALL-HD$(\phi, \vec{a})$ on this assignment, we are guaranteed to find the satisfying assignment. Therefore, we could randomly sample points until we expect to find an assignment at Hamming distance αn from the satisfying assignment (call this an α-small-Hamming-distance assignment). This is indeed what Schöning's algorithm does for $\alpha = \Theta(1/k)$ [30].

A general class of improvements to this algorithm work by running SAT-FROM-α-SMALL-HD$(\phi, \vec{a})$ on only a cleverly-chosen subset of these sampled assignments. In our case, we choose this set to be assignments that satisfy an unusually large number of clauses, but in principle one could use any membership criterion for this set.

Let M be the runtime of the membership test for the set of assignments, and let p_{TP}, p_{FP}, p_{FN}, and p_{TN} represent the fraction of assignments that are true positives, false positives, false negatives, and true negatives respectively. Here, just as in Section 1.1, we use "positive" or "negative" to mean an assignment that passes or doesn't pass the test for membership, respectively. The truth or falsehood of that positive or negative represents whether or not that assignment actually has a satisfying assignment within small Hamming distance.

[1] Consider changing one variable's assignment at random; in this case, almost all clauses will remain satisfied. This phenomenon persists even when we flip several variables at once.

We will have to draw samples until we would have found a satisfying assignment with high probability were one to exist. Next, we will have to run SAT-FROM-α-SMALL-HD$(\phi, \vec{a})$ at least once to find the satisfying assignment itself. Finally, we will have to run it once more for every false positive we find. Hence, the the generalized running time of this class of algorithms is

$$O^*\left(\frac{M}{p_{TP}} + k^{\alpha n} + \left(\frac{p_{FP}}{p_{TP}}\right) k^{\alpha n}\right). \tag{1}$$

This general formula is a powerful tool for analyzing the runtimes of algorithms from this class. For example, if we apply it to analyzing the algorithm of [14], i.e. the special case where the test we use always returns a positive, we see that the third term in Equation (1) dominates, and that $p_{FP} \approx 1$ and $p_{TP} \approx \frac{\binom{n}{\alpha n}}{2^n}$, giving an overall expected runtime of $O^*(2^{n(1-\Theta(\frac{1}{k}))})$ when we choose $\alpha = \Theta(\frac{1}{k+1})$ (using tail bounds to convert $\binom{n}{\alpha n}$ to an exponential). In Appendix G.3 of our full version [25] we discuss a different deterministic search algorithm with a slightly improved runtime (yielding no relevant improvement on the runtime of the overall algorithm for our analysis).

Our algorithm presents improvements for large k, but for small k we will simply use the previous algorithm of Dantsin et al [14].

▶ **Lemma 19** (Algorithm for Small k [14]). *For $k \leq k^\star$ there exists a deterministic algorithm, DANTSINLS, that solves k-SAT in the worst case in time $2^{n(1-\gamma)}$ for some constant $\gamma > 0$.*

We will now give pseudocode for the α-SAMPLEANDTEST algorithm in Algorithm 1. Let NUMCLAUSESSAT$(\phi,\vec{a})$ return the number of clauses in ϕ satisfied by the assignment $\vec{a}$. In Appendix G.1 of our full version [25] we describe a different set of concepts with which the algorithm can be understood.

Note that our algorithm as stated is non-constructive due to our use of the constant $k^\star$. Other than this constant, our algorithm is explicit. While $k^\star$ is known to be constant [11], its exact value is currently unknown. We note in Appendix E of our full version [25] that finding the value of $k^\star$ is an open problem which, if solved, would make our algorithm constructive.

3.1 Correctness and Running Time

We will include the theorem statement of correctness and running time here. Its proof depends on bounds on the false positive rate and the true positive rate, which we prove in later sections. In particular, we show in Appendix A of our full version [25] that conditioned on an assignment passing the test, it is sufficiently likely to be an α-small-Hamming-distance assignment. We additionally show in Appendix B of our full version [25] that conditioned on an assignment being an α-small-Hamming-distance assignment, it is sufficiently likely to pass the test.

Note that much of our probability of returning the wrong value comes from our bounds on the probability that we are drawing a formula with length $m < (d_k - 1)n$. If we knew m to be fixed and greater than $(d_k - 1)n$, we would have a lower error probability.

We will show that α-SAMPLEANDTEST(ϕ) has one-sided error and returns the correct answer with high probability. Note that it returns the correct answer with high probability even conditioned on the input being unsatisfied or satisfied. We use Theorem 26 of our full version [25] to bound the false positive rate and use Lemma 43 of our full version [25] to bound the true positive rate, which gives us the desired result.

Algorithm 1 α-SampleAndTest(ϕ).

```
α-SampleAndTest(φ):
if $k < k^\star$ then
    return DantsinLS($\phi$)
end
Initialize $S$ to the empty set.
▷ For $k \geq k^\star$ we run our variant of local search:
for $i \in [0, n^2 \cdot 2^n / \binom{n}{\alpha n}]$ do
    Sample an assignment $\vec{a}$ uniformly at random from $\{0,1\}^n$.
    ▷ Only keep assignments which satisfy abnormally many clauses.
    if NumClausesSAT($\phi$,$\vec{a}$) $\geq (1 - \frac{1-(1-\alpha)^{2k}}{2^k-1})m$ then
        Add $\vec{a}$ to $S$.
        if $|S| > 4n^3 2^n / \left(\binom{n}{\alpha n} k^{\alpha n}\right) + 1$ then
            return False
        end
        Run SAT-from-$\alpha$-Small-HD($\phi, \vec{a}$).
        If an assignment was found, return it.
    end
end
return False
```

In the theorem that follows, we choose α such that αn is an integer. Specifically, we choose:

$$\alpha = \frac{\lfloor \frac{\lg(k)}{16k} n \rfloor}{n}.$$

Note that when we choose α to take on this value, it will always lie in the range $\frac{\lg(k)}{20k} \leq \alpha \leq \frac{\lg(k)}{16k}$ for large n.

▶ **Theorem 20.** *Assume ϕ is drawn from $D_\Phi(n,k)$. Let $\alpha = \frac{\lfloor n \lg(k)/(16k) \rfloor}{n}$.*

Conditioned on there being at least one satisfying assignment to ϕ, α-SampleAndTest(ϕ) will return some satisfying assignment with probability at least $1 - 3 \cdot 2^{-n/(3\ln(2)2^k)}$.

Conditioned on there being no satisfying assignment to ϕ, α-SampleAndTest(ϕ) will return False with probability 1.

α-SampleAndTest(ϕ) will run in time

$$O\left(2^{n(1-\Omega(\lg^2(k)/k))}\right).$$

Proof. Proof given in Appendix D of our full version [25]. ◀

Abstract

The membership problem asks to maintain a set $S \subseteq [u]$, supporting insertions and *membership queries*, i.e., testing if a given element is in the set. A data structure that computes exact answers is called a *dictionary*. When a (small) false positive rate ϵ is allowed, the data structure is called a *filter*.

The space usages of the standard dictionaries or filters usually depend on the upper bound on the size of S, while the actual set can be much smaller.

Pagh, Segev and Wieder [28] were the first to study filters with varying space usage based on the *current* $|S|$. They showed in order to match the space with the current set size $n = |S|$, any filter data structure must use $(1 - o(1))n(\log(1/\epsilon) + (1 - O(\epsilon)) \log \log n)$ bits, in contrast to the well-known lower bound of $N \log(1/\epsilon)$ bits, where N is an upper bound on $|S|$. They also presented a data structure with almost optimal space of $(1 + o(1))n(\log(1/\epsilon) + O(\log \log n))$ bits provided that $n > u^{0.001}$, with expected amortized constant insertion time and worst-case constant lookup time.

In this work, we present a filter data structure with improvements in two aspects:

- it has constant worst-case time for all insertions and lookups with high probability;
- it uses space $(1 + o(1))n(\log(1/\epsilon) + \log \log n)$ bits when $n > u^{0.001}$, achieving optimal leading constant for all $\epsilon = o(1)$.

We also present a dictionary that uses $(1 + o(1))n \log(u/n)$ bits of space, matching the optimal space in terms of the current size, and performs all operations in constant time with high probability.

1 Introduction

Membership data structures are fundamental subroutines in many applications, including databases [9], content delivery network for web caching [24], image processing [17], scanning for viruses [14], etc. The data structure maintains a set of keys from a key space $[u]$,[1] supporting the following two basic operations:

- insert(x): insert x into the set;
- lookup(x): return YES if x is in the set, and NO otherwise.

When false positive errors are allowed, such a data structure usually is referred as a *filter*. That is, a filter with false positive rate ϵ may answer YES with probability ϵ when x is not in the set (but it still needs to always answer YES when x is in the set).

In the standard implementations, a initialization procedure receives the key space size u and a *capacity* N, i.e., an upper bound on the number of keys that can simultaneously exist in the database. Then it allocates sufficient space for the data structure, e.g., a hash table consisting of $\Theta(N)$ buckets. Thereafter, the memory usage is always staying at the maximum, as much space as N keys would take. It introduces inefficiency in the space, when only few keys have been inserted so far. On the other hand, it could also happen that only a rough estimation of the maximum size is known (e.g. [16, 1, 22]). Therefore, to avoid overflowing, one has to set the capacity conservatively. The capacity parameter given to the initialization procedure may be much more than the actual need. To avoid such space losses, a viable approach is to dynamically allocate space such that at any time, the data structure occupies space depending only on the *current* database size (rather than the maximum possible).

For exact membership data structures, it turns out that such promise is not too hard to obtain if one is willing to sacrifice an extra constant factor in space and accept amortization: When the current database has n keys, we set the capacity to $2n$; after n more keys are inserted, we construct a new data structure with capacity equal to $4n$ and transfer the whole database over. The amortized cost to transfer the database is $O(1)$ per insertion. Raman and Rao [29] showed that the extra constant factor in space is avoidable, they designed a *succinct*[2] membership data structure using space $(1 + o(1)) \log \binom{u}{n}$,[3] where n is the *current* database size, supporting insertions in expected amortized constant time, and lookup queries in worst-case constant time.

For filters, the situation is more complicated. The optimal space to store at most N keys while supporting approximate membership queries with false positive rate ϵ is $N \log 1/\epsilon$ [8, 23] (Pagh, Pagh and Rao [27] achieved $(1 + o(1))N \log 1/\epsilon$ bits). However, the above trick to reduce the space may not work in general. This is because the filter data structures do not store perfect information about the database, and therefore, it is non-trivial to transfer to the new data structure with capacity $4n$, as one might not be able to recover the whole database from the previous data structure. In fact, Pagh, Segev and Wieder [28] showed an information theoretical space lower bound of $(1 - o(1))n(\log 1/\epsilon + (1 - O(\epsilon)) \log \log n)$ bits, regardless of the insertion and query times. That is, one has to pay extra $\approx \log \log n$ bits per key in order to match the space with the current database size. They also proposed a data structure with a nearly matching space of $(1 + o(1))n \log 1/\epsilon + O(n \log \log n)$ bits when $n > u^{0.001}$, while supporting insertions in expected amortized constant time and lookup

[1] Throughout the paper, $[u]$ stands for the set $\{0, \ldots, u - 1\}$.

[2] A succinct data structure uses space equal to the information theoretical minimum plus an asymptotically smaller term called *redundancy*.

[3] All logarithms are base 2.

queries in worst-case constant time. When ϵ is at least $1/\text{poly}\log n$, the extra $\log\log n$ bits per key is dominating. It was proposed as an open problem in [28] whether one can make the $\log\log n$ term succinct as well, i.e., to pin down its leading constant.

On the other hand, an amortized performance guarantee is highly undesirable in many applications. For instances, IP address lookups in the context of router hardware [7, 19], and timing attacks in cryptography [21, 20, 26, 25]. When the database size is always close to the capacity (or when the space is not a concern), it was known how to support all operations in worst-case constant time [13, 3] with high probability. That is, except for a probability of $1/\text{poly}\, n$, the data structure handles *every* operation in a sequence of length $\text{poly}\, n$ in constant time.[4] However, it was not known how to obtain such a guarantee when the space is succinct with respect to the current database size, i.e., $(1+o(1))\log\binom{u}{n}$. For filters, Pagh et al. [28] showed it is possible to get worst-case constant time with high probability, at the price of a constant factor more space $O(n\log 1/\epsilon + n\log\log n)$. They asked if there is a data structure which enjoys the succinct space usage and the worst-case constant time with high probability simultaneously.

1.1 Main Results

In this paper, we design a new dynamic filter data structure that answers both questions. Our data structure has both worst-case constant time with high probability and is succinct in space in terms of the current database size.

▶ **Theorem 1** (Dynamic filter – informal). *There is a data structure for approximate membership with false positive rate ϵ that uses space $(1+o(1))n(\log(1/\epsilon)+\log\log n)$ bits, where $n > u^{0.001}$ is the current number of keys in the database, such that every insertion and lookup takes constant time in the worst case with high probability.*

We also present a dictionary data structure with the space depending on the current n. A dictionary is a generalization of membership data structures, it maintains a set of key-value pairs, supporting

- insert(x, y): insert a key-value pair (x, y) for $x \in [u]$ and v-bit y ;
- lookup(x): if $\exists(x, y)$ in the database, output y; otherwise output `NO`.

By setting $v = 0$, the lookup query simply tests if x is in the database.

▶ **Theorem 2** (Dynamic dictionary – informal). *There is a dictionary data structure that uses space $(1+o(1))n(\log(u/n)+v+O(\log\log\log u))$ bits, where $n > u^{0.001}$ is the current number of key-value pairs in the database, such that every insertion and lookup takes constant time in the worst case with high probability.*

1.2 Related Work

Membership with Constant Time Worst-Case Guarantee. The FKS perfect hashing [15] stores a set of n *fixed* (i.e., static) keys using $O(n)$ space, supporting membership queries in worst-case constant time. Dietzfelbinger, Karlin, Mehlhorn, Meyer auf der Heide, Rohnert and Tarjan [12] introduced an extension of the FKS hashing, which is the first dynamic membership data structure with worst-case constant query time and the expected amortized constant insertion time. Later, Dietzfelbinger and Meyer auf der Heide [13] improved

[4] This is stronger guarantee than expected constant time, since when the unlikely event happened, one could simply rebuild the data structure in linear time. The expected time is still a constant.

the insertion time to worst-case constant, with an overall failure probability of $1/\text{poly}\, n$. Demaine, Meyer auf der Heide, Pagh and Pǎtraşcu [11] improved the space to $O(n \log(u/n))$ bits of space. Arbitman, Naor and Segev [2] proved that a de-amortized version of cuckoo hashing [19] has constant operation time in the worst case with high probability.

On the other hand, filters can be reduced to dictionaries with a hash function $h : [u] \to [n/\epsilon]$, and thus, all the dictionaries imply similar upper bounds for filters [8].

Succinct Membership. Raman and Rao [29] presented the first succinct dictionary with constant time operations, while the insertion time is amortized. Arbitman, Naor and Segev [3] refined the schema of [2], suggested a succinct dictionary with worst case operation time with high probability.

By using the reduction from [8] and the succinct dictionary from [29], Pagh, Pagh and Rao [27] provided a succinct filter with constant time, while the insertion time is amortized due to [29]. Bender, Farach-Colton, Goswami, Johnson, McCauley and Singh [5] suggested a succinct *adaptive filter*[5] with constant time operation in the worst case with high probability.

Membership for Sets of Unknown Sizes. The data structure of Raman and Rao [29] can be implemented such that the size of the data structure always depends on the "current n". Pagh, Segev and Wieder [28] were the first to study dynamic filters in this setting from a foundational perspective. As we mentioned above, they proved an information-theoretical space lower bound of $(1 - o(1))n(\log(1/\epsilon) + (1 - O(\epsilon)) \log \log n)$ bits for filter, and presented a filter data structure using $n(\log(1/\epsilon) + O(\log \log n))$ bits of space with constant operation time when $n > u^{0.001}$. Indeed, the insertion time is expected amortized, since the succinct dictionary of Raman and Rao is applied as a black box (it was not clear if any succinct dictionary with worst-case operational time can be generalized to this setting).

Very recently, Bercea and Even [6] proposed a succinct membership data structure for maintaining *dictionaries* and *random multisets* with constant operation time. While their data structure is originally designed for the case where an upper bound N on the keys is given (and the space usage is allowed to depend on N), we note that it is possible to extend their solution and reduce the space to depend only on the current n. However, their data structure assumes free randomness, and straightforward extension results in an additive $\Omega(n \log \log u)$ term in space. The redundancy makes their data structure space-inefficient for filters, since the space lower bound is $(1 - o(1))n(\log(1/\epsilon) + (1 - O(\epsilon)) \log \log n)$.

1.3 Previous Construction

As we mentioned earlier, for dynamic membership data structures, if we are willing to pay an extra constant factor in space, one way to match the space with the "current" n is to set the capacity to be $2n$. When the data structure is full after another n insertions, we double the capacity, and transfer the database to the new data structure. However, the standard way to construct an efficient filter is to hash $[u]$ to $[n/\epsilon]$ (where ϵ is the false positive rate) and store all n hash values in a membership data structure, which takes $O(n \log 1/\epsilon)$ bits of space. As we insert more keys and increase the capacity to $4n$, the range of the hash value needs to increase as well. Unfortunately, it cannot be done, because the original keys are not stored, and we have lost the information in order to save space (this is exactly the point of a filter). On the other hand, we could choose to keep the previous

[5] In an adaptive filter, for a negative query x, the false positive event is independent of previous queries.

data structure(s), and only insert the future keys to the new data structure. For each query, if it appears in any of the (at most $\log n$) data structures, we output YES. By setting the false positive rate for the data structure with capacity 2^i to $O(\epsilon/i^2)$, the overall false positive rate is at most $\epsilon \cdot \sum_i O(1/i^2) \leq \epsilon$ by union bound. The total space usage becomes roughly $n\log(\log^2 n/\epsilon) = n(\log 1/\epsilon + O(\log\log n))$.

To avoid querying all $\log n$ filters for each query, the previous solution by Pagh et al. [28] uses a *single* global hash function h that maps $[u]$ to $\log(u/\epsilon)$-bit strings for all $\log n$ filters. For a key x in the i-th data structure (with capacity 2^i), one simply takes the first $i + \log 1/\epsilon + 2\log i$ bits of $h(x)$ as its hash value. Then querying the i-th data structure on y is to check whether the $(i + \log 1/\epsilon + 2\log i)$-bit prefix of $h(y)$ exists. Since all filters use the same hash function, the overall task is to check whether *some* prefix of $h(y)$ appears in the database, which now consists of strings of various lengths. Note that there are very few short strings in the database, the previous solution extends all short strings to length $\log(n/\epsilon)$ by duplicating the string and appending all possible suffixes, e.g., a string of length $\log(n/\epsilon) - c$ is duplicated into 2^c strings by appending all possible c-bit suffixes. Then all strings are stored in one single dictionary (longer strings are stored according to their first $\log(n/\epsilon)$ bits), and the query becomes to check if the $\log(n/\epsilon)$-bit prefix of $h(y)$ is in the dictionary, which is solved by invoking Raman and Rao [29]. One may verify that duplicating the short strings does not significantly increase the total space, and comparing only the $\log(n/\epsilon)$-bit prefix of a longer string does not increase the false positive rate by much.

1.4 Our Techniques

Our new construction follows a similar strategy, but the "prefix matching" problem is solved differently. Given a collection of $2^{i-1} < n \leq 2^i$ strings of various lengths, we would like to construct a data structure such that given any query $h(y)$, we will be able to quickly decide if any prefix of $h(y)$ appears in the database. The first observation is that the short strings in the database can be easily handled. In fact, all strings shorter than i bits can be stored in a "truth table" of size $2^i = O(n)$. That is, we simply store for all i-bit strings, whether any of its prefix appears in the database. For a query $h(y)$, by checking the corresponding entry of its i-bit prefix, one immediately resolves all short strings. On the other hand, for strings longer than $\log m$ bits, we propose a new (exact) membership data structure, and show that it in fact, automatically solves prefix matching when all strings are long. Before describing its high-level construction in Section 1.4.1, let us first see what it can do and how it is applied to our filter construction.

When the capacity is set to m, the membership data structure stores $n \leq m$ keys from $[u]$ using space $n(\log(u/m) + O(\log\log\log u)) + O(m)$ bits, supporting insertion and membership query in worst-case constant time with high probability. When applying to prefix matching, it stores n strings of length at most ℓ (and more than $\log m$) using $n(\log(2^\ell/m) + O(\log\log \ell)) + O(m)$ bits. Using this data structure with the capacity set to $m = 2^i$, we are able to store the database succinctly when $m/2 < n \leq m$. As we insert more keys to the database, the capacity needs to increase. Another advantage of our membership data structure is that the data can be transferred from the old data structure with capacity m to a new one with capacity $2m$ in $O(m)$ time. More importantly, the transfer algorithm runs almost "in-place", and the data structure remains "queryable" in the middle of the execution. That is, one does not need to keep both data structures in full, at any time the total memory usage is still $n(\log(2^\ell/n) + O(\log\log \ell)) + O(m)$, and the data structure can be queried. Therefore, as n is increasing from $m/2$ to m, we gradually build a new data structure with capacity $2m$. Every time a key is inserted, the background data-transfer algorithm is run for constant steps. By the time n reaches m, we will have already transferred everything to the new data structure, and will be ready to build the next one with capacity $4m$. Overall, the data structure is going to have $\log n$ stages, the i-th stage handles the $(2^{i-1}+1)$-th to the 2^i-th insertion. In each stage, the database size is doubled, and the data structure also gradually doubles its capacity. This guarantees that the total space is succinct with respect to the current database size, and every operation is handled in constant time with high probability.

Finally, to pin down the leading constant in the extra $O(\log\log n)$ bits, we show that for the n-th inserted key x for $2^{i-1} < n \leq 2^i$, storing the $(i + \log(i/\epsilon) + \log\log\log u)$-bit prefix of $h(x)$ balances the false positive rate and the space. Since our new membership data structure only introduces an extra $\approx \log\log i \approx \log\log\log n$ bits of space per key, it is not hard to verify that the total space of our construction is $(1+o(1))n(\log(1/\epsilon) + \log\log n)$.

1.4.1 Membership Data Structure

In the following, let us briefly describe how our new membership data structure works. The data structure works in the *extendable array* model, as the previous solution by Raman and Rao. See Section 2.2.2 or [29] for more details.

Our main technique contribution is the idea of *data block*. Without the data blocks, our data structure degenerates into a variant of the one proposed in [6]. Instead of a redundancy of $O(n\log\log\log u)$ bits, the degeneration contributes a redundancy of $O(n\log\log u)$ bits, which makes the data structure space-inefficienct for filters as we discussed early.

For simplicity, let us for now assume that we have free randomness, and the first step is to randomly permute the universe. Thus, we may assume that at any time, the database is a uniformly random set (of certain size). We divide the universe into $m/\log u$ *buckets*, e.g., according to the top $\log(m/\log u)$ bits of the key. Then with high probability, every bucket will have $O(\log u)$ keys. We will then dynamic allocate space for each bucket. Note that given that a key is a bucket b, we automatically know that its top $\log(m/\log u)$ bits is "b". Therefore, within each bucket, we may view the keys have lengths only $\log u - \log(m/\log u) = \log((u\log u)/m)$, or equivalently, the universe size being $(u\log u)/m$ (recall that the goal is to store each key using $\approx \log(u/m)$ bits on average).

To store the keys in a bucket, we further divide it into *data blocks* consisting of $O(\log u/\log\log u)$ keys each, based on the time of insertion. That is, the first $O(\log u/\log\log u)$ keys inserted to this bucket will form the first data block, the next $O(\log u/\log\log u)$ keys will be the second data block, etc. Since each data block has few enough keys, they can be stored using a *static* constructions (supporting only queries) using nearly optimal space of $\approx \log\binom{(u\log u)/m}{O(\log u/\log\log u)}$, which is $\log((u\log\log u)/m) = \log(u/m) + \log\log\log u$ bits per key, or a dynamic constructions use $\log(u/m) + O(\log\log u)$ bits per key. The latest data block, which we always insert the new key into, is maintained using the dynamic construction. When it becomes full, we allocate a new data block, and at the same time, we run a in-place *reorganization* algorithm in the background. The reorganization algorithm runs in $O(\log u/\log\log u)$ time, and convert the dynamic construction into the static construction, which uses less space. For each insertion in the future, the reorganization algorithm is run for constant steps, thus, it finishes before the next data block becomes full. Finally, for each bucket, we maintain an *adaptive prefixes* structure [4, 5] to navigate the query to the relevant data block. Roughly speaking, when all $O(\log u)$ keys in the bucket are random, most keys will have a unique prefix of length $\log\log u$. In fact, Bender et al. [4, 5] showed that for every keys, the shortest prefix that is unique in the bucket can be implicitly maintained in constant time, and the total space for all $O(\log u)$ keys is $O(\log u)$ bits with high probability.[6] We further store for each such unique prefix, which data block contains the corresponding key. It costs $O(\log\log\log u)$ bits per key. Given a query, the adaptive prefix structure is able to locate the prefix that matches the query in constant time, which navigates the query algorithm to the (only) relevant data block. We present the details in Section 4.

2 Preliminaries

2.1 String Notations

Let $\{0,1\}^{\le \ell} \triangleq \bigcup_{0\le i\le \ell}\{0,1\}^i$ and $\{0,1\}^* \triangleq \bigcup_{i\ge 0}\{0,1\}^i$. Given a string $x\in\{0,1\}^\ell$, we use $|x|=\ell$ to denote its length. We denote by $a\circ b$ the concatenation of two strings $a,b\in\{0,1\}^*$. We denote the concatenation of k ones or zeros by 1^k or 0^k, respectively.

For $x,y\in\{0,1\}^*$, we use $x\sqsubseteq y$ (or $y \sqsupseteq x$) to denote that y is a *prefix* of x, formally:

$$x\sqsubseteq y \iff x=y\circ a \text{ for some } a\in\{0,1\}^*. \tag{1}$$

Note that our notation is unconventional: we use $x\sqsubseteq y$ for y prefixing x, to reflect that the Hamming cube identified by x is contained by the Hamming cube for its prefix y.

For two strings x,y such that $|x|\le|y|$, to compare x and y in lexicographical order, we compare $x\circ \perp^{|y|-|x|}$ and y in lexicographical order, where $\perp$ is a special symbol which is smaller than any other symbol.

Recall that an injection (code) on strings is a *prefix-free code* if no codeword is a prefix of another codeword.

▷ Claim 3. There is a prefix-free code $\texttt{PFC}:\{0,1\}^{\le\ell}\to\{0,1\}^{\ell+1}$ for strings of length $\le \ell$.

Proof. Given any $x\in\{0,1\}^{\le\ell}$, the codeword $\texttt{PFC}(x)$ is $1^{\ell-|x|}\circ 0\circ x$. ◁

2.2 Computational Models

2.2.1 Random Access Machine

Throughout the paper, we use w to denote the word size: each memory word is a Boolean string of w bits. We assume that the total number of memory words is at most 2^w, and each memory word has an unique address from $[2^w]$, so that any pointer fits in one memory word. We also assume CPU has constant number of registers of size w, and any datapoint fits in constant number of words (i.e. $w=\Omega(v+\log u)$). During each CPU clock tick, CPU may load one memory word to one of its register, write the content of some register to some memory word, or execute the basic operations on the registers. Specifically, the basic operations include four arithmetic operations (addition, subtraction, multiplication, and division), bitwise operations (AND, OR, NOT, XOR, shifting), and comparison.

2.2.2 Memory Models

We use a memory access model known as the *extendable arrays* [29] to model the dynamic space usage.

The extendable array is one of the most fundamental data structures in practice. It is implemented by the standard libraries of most popular programming languages, such as `std::vector` in `C++`, `ArrayList` in `java` and `list` in `python`.

[6] The $O(\log u)$-bit representation is implicit.

▶ **Definition 4** (Extendable arrays). *An* extendable array *of length n maintains a sequence of n fixed-sized elements, each assigned a unique address from $[n]$, such that the following operations are supported:*

- `access`(i)*: access the element with address i;*
- `grow`*: increment the length n, creating an arbitrary element with address $n+1$;*
- `shrink`*: decrement the length n, remove the element with address n.*

A collection of extendable arrays *supports*

- `create`(r)*: create an empty extendable array with element of size r and return its name;*
- `destroy`(A)*: destroy the empty extendable array A;*
- `access`(A, i), `grow`(A), `shrink`(A)*: apply the corresponding operations on array A.*

Each of above operations takes constant time. The space overhead of an extendable array is $O(w) + nr$, where w, n, r are the word size, the length of the array, and the element size respectively. Indeed, the space overhead of a collection of extendable arrays is $O(|\mathcal{A}|w) + \sum_{A\in\mathcal{A}} n_A r_A$, where $\mathcal{A}$, n_A and r_A are the set of extendable arrays, the length of array A, and the element size of array A respectively.

We also consider the following *allocate-free* model.

▶ **Definition 5** (Allocate and free). *In the* allocate-free *model, there are two built-in procedures:*

- `allocate`(b)*: return a pointer to a block of b consecutive memory words which is uninitialized;*
- `free`(p)*: free the block of consecutive memory words which is pointed by p and have been initialized to 0s.*

Each of above operations takes constant time. The total space overhead is $O(|\mathcal{A}|w) + \sum_{A\in\mathcal{A}} n_A w$, where $\mathcal{A}$ is set of all memory blocks and n_A is the length of memory block A.

We discuss the space usages of our data structures in allocate-free model in Section 7.

To avoid the pointer being too expensive in the dynamic memory models, we assume $w = \Theta(\log u)$.

2.3 Random Functions

▶ **Definition 6** (k-wise independent random function). *A random function $h : [u] \to [r]$ is called k-*wise independent *if for any distinct $x_1, \cdots, x_k \in [u]$, and any $y_1, \cdots, y_k \in [r]$,*

$$\Pr_h\left[\bigwedge_{i\le k} h(x_i) = y_i\right] = 1/r^k.$$

▶ **Theorem 7** ([31, 10]). *Let $[u]$ be a universe, $w = \Omega(\log u)$, $c_1 > 0$, $r = \mathrm{poly}(u)$, and $k = u^{o(1)}$. There exists a data structure for a random function $h : [u] \to [r]$ such that*

- *with probability $\ge 1 - 1/u$, the data structure is constructed successfully;*
- *upon successful construction of the data structure, h is k-wise independent;*
- *the data structure uses space u^{c_1} bits;*
- *for each $x \in [u]$, $h(x)$ is evaluated in $\tilde{O}(1/c_1)$ time in the worst case in the RAM model.*

▶ **Theorem 8** (Chernoff bound with limited independence [30]). *Let $X_1, \cdots, X_n$ be arbitrary k-wise independent boolean random variables with $\Pr[X_i = 1] = p$ for any $i \in [n]$. Let $X \triangleq \sum_i X_i, \mu \triangleq \mathbb{E}[X] = np$, then for any $\delta > 0$, it holds that*

$$\Pr\left[\, X \ge (1+\delta)\mu \,\right] \le \exp(-\mu\delta^2/2),$$

as long as $k \ge \lceil \frac{\mu\delta}{1-p} \rceil$.

2.4 Adaptive Prefixes

Given a sequence $S = (x_1, x_2, \ldots)$ of strings, let $\alpha_m(S) = \{\alpha_m(x_1), \alpha_m(x_2), \ldots\}$ be a collection of prefixes, such that for every $x_i \in S$, the $\alpha_m(x_i)$ is the shortest prefix, of length at least m, of the binary representation of x_i, such that $\alpha_m(x_i)$ prefixes no other $x_j \in S$. Note that for any string y, there is at most one $x \in S$ such that $\alpha_m(x) \sqsupseteq y$ as long as $\alpha_m(S)$ exists. In particular, $\alpha_m(S)$ does not exist if there are $i \neq j$ such that $x_i = x_j$.

The prefixes are stored in lexicographical order, thus we refer k-th prefix as the prefix with rank k in lexicographical order.

▶ **Theorem 9** (Refined from [4, 5]). *Let $c_0, c_1 > 1$ be two constants where $c_0 > c_1$. For a random sequence $S = (x_1, \cdots)$ of strings drawn from $(\{0,1\}^{c_0 \log u})^{\leq c_3 \log u}$ uniformly at random with replacement, with probability at least $1 - u^{-c_1}$, the prefix collection $\alpha_{\log\log u}(S)$ exists and can be represented with at most $c_2 \log u$ bits, where $c_2 > 0$ is determined by c_1, c_3. Furthermore, the following operations are supported in constant time:*

- insert(y)*: update the representation by inserting a new string $y \in \{0,1\}^{c_0 \log u}$ to S, when there is at most one $x \in S$ such that $\alpha_{\log\log u}(x) \sqsupseteq y$;*
- lookup(y)*: given any query $y \in \{0,1\}^{c_0 \log u}$, return the rank of the only $z \in \alpha_{\log\log u}(S)$ that prefixes y, and return `NO` if there does not exist such a z;*
- lowerbound(y)*: given any query $y \in \{0,1\}^{\log\log u}$, return the lowest rank of all $z \in \alpha_{\log\log u}(S)$ that $z \sqsubseteq y$, and return 0 if there is no $z \sqsubseteq y$ in the collection;*

For completeness, a proof is provided in the full version of this paper.

3 Data Structures for Sets of Unknown Sizes

In this section, we present our filter and dictionary data structures for sets of unknown sizes.

3.1 The Succinct Dynamic Filters

The following theorem is a formal restatement of Theorem 1.

▶ **Theorem 10** (Dynamic filter – formal). *Let $0 < \epsilon < 1$, $[u]$ the data universe, and $\delta = u^{-C}$, where $C > 1$ is an arbitrary constant. Assume the word size $w = \Theta(\log u)$. There exists a data structure for approximate membership for subsets of unknown sizes of $[u]$, such that*

1. *for any $n = \omega(\log u)$ and $n < u$, the data structure uses $n(\log(1/\epsilon) + \log\log n + O(\log\log\log u))$ bits of space after insertions of any n key, and extra u^c precomputed bits that are independent of the input, where $0 < c < 1$ is an arbitrary small constant;*
2. *each insertion and membership query takes $O(1)$ time in the worst case;*
3. *after each insertion, a failure may be reported by the data structure with some probability, and for any sequence of insertions, the probability that a failure is ever reported is at most δ, where the probability is taken over the precomputed random bits;*
4. *conditioned on no failure, each membership query is answered with false positive rate at most ϵ.*

As we mentioned in the introduction, our data structure has $\log n$ stages when handling n insertions. The i-th stage is from the insertion of the $(2^{i-1}+1)$-th key to the 2^i-th key – the database size doubles after each stage.

The main strategy is to reduce the problem of (approximate) membership to (exact) *prefix matching*. More formally, in the *prefix matching* problem, we would like to maintain a set of binary strings $\{s_1, s_2, \ldots\}$ of possibly different lengths, supporting

- insert(s): add string s to the set;
- query(y): decide of any string s in the set is a prefix of y.

To this end, our filter first applies a *global* hash function h such that $h : [u] \to [u^{c_2}]$ is $(c_1 \log u)$-wise independent according to Theorem 7, where $c_1 > 0$ is a constant to be fixed later, and c_2 is a sufficiently large constant (which in fact, is the c_0 in Theorem 9). To insert a key x in stage i, we calculate its hash value $h(x)$, and then insert the ℓ_i-bit prefix of $h(x)$, for some parameter ℓ_i. To answer a membership query y, we simply calculate $h(y)$ and search if any prefix of $h(y)$ is in the database. If no prefix of $h(y)$ is in the database, we output `NO`; otherwise, we output `YES`. It is easy to see that this strategy will never output any false negatives. On the other hand, by union bound, if the query y is not in the set, the probability that the query algorithm outputs `YES` is at most

$$\sum_{i=1}^{\log u} 2^i \cdot 2^{-\ell_i},$$

since h is $(c_1 \log u)$-wise independent (in particular, it is pairwise independent), then the probability that the ℓ_i-bit prefix of $h(y)$ matches with the prefix of the hash value $h(x)$ of key x is $2^{-\ell_i}$. Hence, by setting

$$\ell_i \triangleq i + \log(1/\epsilon) + \log i + \log\log\log u + 2, \tag{2}$$

the false positive rate is at most

$$\sum_{i=1}^{\log u} 2^i \cdot 2^{-i-\log(1/\epsilon)-\log i-\log\log\log u-2} = \epsilon \cdot \sum_{i=1}^{\log u} \frac{1}{4i \log\log u} < \epsilon.$$

We use $\mathcal{D}_{c_1 \log u}$ to denote the distribution of the random insertion sequence $y_1, y_2, \dots, y_n$ for prefix matching constructed above. Formally, $\mathcal{D}_{c_1 \log u}$ is the distribution of a sequence of random strings $y_1, y_2, \dots, y_n$ obtained from $(c_1 \log u)$-wise independent sequence $z_1, z_2, \dots, z_n \in [u^{c_2}]$ by truncating: $\forall 1 \le j \le n$, $y_j = (z_j)_{\le \ell_i}$, where $i = \lceil \log j \rceil$.

▶ **Lemma 11** (Prefix matching). *Let $\delta = u^{-C}$, where $C > 1$ is an arbitrary constant. There exist a constant c_1 and a deterministic data structure for prefix matching such that*

1. *for any $n = \omega(\log u)$ and $n < u$, the data structure uses $n(\ell_{\lceil \log n \rceil} - \log n + O(\log\log\log u))$ bits of space after n insertions, and extra u^c precomputed bits, where $0 < c < 1$ is an arbitrary small constant;*
2. *each insertion and query takes $O(1)$ time in the worst case;*
3. *after each insertion, a failure may be reported by the data structure, and for a random sequence of insertions drawn from $\mathcal{D}_{c_1 \log u}$, the probability that a failure is ever reported is at most δ, where the probability is taken over $\mathcal{D}_{c_1 \log u}$;*
4. *every query is answered correctly if no "fail" is reported.*

We present the construction in Section 4. Using this prefix matching data structure, the space usage of the filter is

- $n(\ell_{\lceil \log n \rceil} - \log n + O(\log\log\log u)) = n(\log(1/\epsilon) + \log\log n + O(\log\log\log u))$ bits,
- and u^c bits for storing h by Theorem 7 and for the precomputed lookup tables described in the appendix of the full version of this paper, both independent of the operation sequence.

Each insertion and query can be handled in constant time given the data structure does not fail. This proves Theorem 10.

3.2 The Succinct Dynamic Dictionaries

The data structure for prefix matching also works well as a dictionary data structure for the insertions with keys are sampled uniformly at random. A worst-case instance can be converted into a random instance by a random permutation $\pi : [u] \to [u]$. Assuming an idealized $(c_1 \log u)$-wise independent random permutation whose representation and evaluation are efficient, the data structure for prefix matching in Lemma 11 can be immediately turned to a dictionary. However, the construction of k-wise independent random permutation with low space and time costs is a longstanding open problem [18].

We show that our data structure can solve the dictionary problem in the worst case unconditionally, at the expense of extra u^c bits of space for storing random bits which are independent of the input.

▶ **Theorem 12** (Dynamic dictionary – formal). *Let $[u] \times \{0,1\}^v$ be the data universe, and $\delta = u^{-C}$, where $C > 1$ is an arbitrary constant. Assume the word size $w = \Theta(v + \log u)$. There exists a data structure for dictionary for sets of unknown sizes of key-value pairs from $[u] \times \{0,1\}^v$, such that*

1. *for any $n = \omega(\log u)$ and $n < u$, the data structure uses $n(\log(u/n) + v + O(\log\log\log u))$ bits of space after insertions of any n key-value pairs, and extra u^c precomputed bits that are independent of the input, where $0 < c < 1$ is an arbitrary small constant;*
2. *each insertion and query takes $O(1)$ time in the worst case;*
3. *after each insertion, a failure may be reported by the data structure with some probability, and for any sequence of insertions, the probability that a failure is ever reported is at most δ, where the probability is taken over the precomputed random bits;*
4. *conditioned on no failure, each query is answered correctly.*

The details of the data structure are postponed to Secion 6.

4 Prefix Matching Upper Bound

In this section, we prove Lemma 11.

Recall the distribution $\mathcal{D}_{c_1 \log u}$ of random insertion sequence $y_1, y_2, \ldots, y_n$ assumed in Lemma 11. Given an insertion sequence $\bar{y} = (y_1, y_2, \ldots, y_n) \sim \mathcal{D}_{c_1 \log u}$, we define the *core set* $B(\bar{y}) \triangleq \{x \in \bar{y} : \forall x' \in \bar{y}, x = x' \vee x' \not\sqsupseteq x\}$, and its subset $B^{(a,b]} \triangleq \{x \in B : |x| \in (a,b]\}$ for any $a < b$. Let $\mathcal{D}^{(a,b]}_{c_1 \log u}$ denote the distribution of $B^{(a,b]}$. We say that a random sequence Y of strings is drawn from $\mathcal{D}^{(a,b]}_{c_1 \log u}$ if it can be obtained by permuting the random core set $B^{(a,b]}$.

We show that Lemma 11 is true as long as there exist a family of deterministic data structures for prefix matching with known capacity m. An instance of the data structure $D = D(m, \ell)$ is parameterized by capacity $m < u$, and string length upper bound $\ell \geq \log m$. The data structure uses u^c bits extra space whose contents are precomputed lookup tables, and supports following functionalities with good guarantees:

- initialize(D) and destroy(D): subroutines for initializing and destroying D respectively. The data structure is successfully initialized (or destroyed) after invoking initialize(D) (destroy(D)) consecutively for $O(m)$ times. When successfully initialized, D uses space $O(m)$ bits. The initialize(D)'s are invoked before all other subroutines and destroy(D)'s are invoked after all other subroutines.
- insert(D, x): insert string x to D, where $\log m < |x| \leq \ell$. After n insertions, D uses at most $n(\ell - \log m + 2\log\log\log u) + O(m)$ bits. Each insertion may cause D to fail. A failure ever occurs for a random insertion sequence Y with probability at most u^{-2C}, as long as Y is drawn from $\mathcal{D}^{(\log m, \ell]}_{c_1 \log u}$, where c_1 is suitably determined by constant C.

- $\mathsf{query}(D,x)$: return one bit to indicate whether there exists a prefix of x in D. The correct answer is always returned as long as D has not failed.
- $\mathsf{decrement}(D)$: try to delete an arbitrary string y in D and return the y if y is deleted. An invoking may delete nothing and hence nothing is returned, but it guarantees that the total number of such empty invoking is at most m. Each invoking that successfully deletes a string frees space $\ell - \log m$ bits. The $\mathsf{decrement}(D)$'s are invoked after all insertions.

▷ Claim 13. Given the deterministic data structures supporting above functionalities in constant time in the worst case, Lemma 11 is true.

Proof. We use an auxiliary structure called *truth table* to deal with short strings. A truth table T_i is a bitmap (i.e. array of bits) of length 2^i and supports the required functionalities in the worst cases:

- T_i is initialized to the all-0 string 0^{2^i}, where each invoking of $\mathsf{initialize}(T_i)$ extends T_i by one 0 until T_i is of length 2^i, and each invoking of $\mathsf{destroy}(T_i)$ shrinks T_i by one bit until T_i is fully destroyed;
- to insert x where $|x| = i$, we set $T_i[x+1] \leftarrow 1$;[7]
- to query x where $|x| = i$, we return `YES` if $T_i[x+1] = 1$ and return `NO` if otherwise;
- to decrement T_i, we maintain a j that traverses from 1 to 2^i, and at each time set $T_i[j] \leftarrow 0$, return $j-1$ if $T_i[j] = 1$, and increment j by 1.

Initially, the prefix matching data structure required by Lemma 11 consists of T_0, T_1 and $D_0 = D(1, \ell_0), D_1 = D(2, \ell_1)$ respectively with capacities $1, 2$, and string lengths ℓ_0, ℓ_1, where ℓ_i is defined in Eq(2).

To insert x, which is the n-th insertion, we set $i \leftarrow \lceil \log n \rceil$, invoke $\mathsf{insert}(D_i, x)$ if there is no prefix of x has been inserted. Then we execute the following procedure for 10 times to maintain our data structure:

1. If T_{i-1} is non-empty, we decrement it by invoking $\mathsf{decrement}(T_{i-1})$. If a y is returned, we insert it into T_i by invoking $\mathsf{insert}(T_i, y \circ 0)$ and $\mathsf{insert}(T_i, y \circ 1)$.
2. If D_{i-1} is non-empty, we invoke $\mathsf{decrement}(D_{i-1})$. If a y is returned, we insert it into D_i by invoking $\mathsf{insert}(D_i, y)$ when $|y| > i$ and insert y into T_i by invoking $\mathsf{insert}(T_i, y)$ otherwise.
3. If T_{i-1} (or D_{i-1}) is empty but not destroyed yet, we invoke $\mathsf{destroy}(T_{i-1})$ (or $\mathsf{destroy}(D_{i-1})$).
4. If T_{i-1} (or D_{i-1}) has been destroyed, we invoke $\mathsf{initialize}(T_{i+1})$ (or $\mathsf{initialize}(D_{i+1})$ for $D_{i+1} = D(2^{i+1}, \ell_{i+1})$ with capacity 2^{i+1} and string length upper bound ℓ_{i+1}), where ℓ_i is defined in Eq(2).

A failure is reported whenever a failure is reported during insertion to D_i.

Clearly, for any integer $n \in [2^i, 2^{i+1})$, after n insertions, all inserted strings are stored in either D_{i-1}, T_{i-1} or D_i, T_i. By the time n reaches 2^{i+1}, D_{i+1}, T_{i+1} have been initialized, all inserted strings are stored in D_i, T_i, and D_{i-1}, T_{i-1} have been destroyed.

Consider the insertion sequence for a fixed D_i. Observe that the strings inserted into D_i must be in the core set $B^{(i,\ell_i]}(\bar{y})$. Therefore the insertion sequence is drawn from $\mathcal{D}^{(i,\ell_i]}_{c_1 \log u}$, which means that insertions to each D_i ever failed with probability at most δ. By union bound, a failure is ever reported with probability at most $\sum_{i=1}^{\log u} u^{-2C} \le u^{-C} = \delta$.

Overall, the data structure uses at most $n(\ell_{\lceil \log n \rceil} - \log n + O(\log\log\log u)) \le n(\log(1/\epsilon) + \log\log n + O(\log\log\log u))$ bits after n insertions, besides the u^c precomputed bits.

[7] For A, a list or array of items, we let $A[i]$ denote the i-th item of A.

Suppose n strings has been inserted, let $i \leftarrow \lceil \log n \rceil$. To query x, we invoke $\mathsf{query}(D_{i-1}, x)$, $\mathsf{query}(D_i, x)$, $\mathsf{query}(T_{i-1}, x_{\leq i-1})$, $\mathsf{query}(T_i, x_{\leq i})$ simultaneously, and return YES if any one of the invokings returns YES.

Obviously each insertion and query takes constant time in the worst case, and it is easy to check that every query is correctly answered as long as no failure is reported. ◁

5 Succinct Prefix Matching with Known Capacity

We now describe the data structures required by Claim 13. The pseudocodes are given in the appendix of the full version of this paper.

The data structure consists of a main table and $m/\log u$ subtables.

We partition each binary string x into four consecutive parts: $st(x), hd(x), hs(x), rt(x)$ of lengths $\log(m/\log u), \log(\log u/\log\log u), \log\log\log u, |x| - \log m$ respectively. Roughly speaking, a datapoint x will be distributed into a subtable according to $st(x)$, then be put into a data block of size $\log u/\log\log u$ according to the order it is inserted, therefore we can save $|st(x)| + |hd(x)| - O(1)$ bits for each datapoint by properly encoding.

Main Table. The main table consists of $m/\log u$ entries, each of which contains a pointer to a subtable. Each insertion/query x is distributed into an entry of the main table addressed by $st(x)$. Recall the word size $w = \Theta(\log u)$. The main table uses $mw/\log u = O(m)$ bits.

Recall that $\bar{y} = (y_1, y_2, \ldots, y_n) \sim \mathcal{D}_{c_1 \log u}$ is transformed from a $(c_1 \log u)$-wise independent sequence $Z = (z_1, z_2, \cdots, z_n)$ by truncating. The insertion sequence Y is drawn from $\mathcal{D}_{c_1 \log u}^{(\log m, \ell]}$ by permuting $B^{(\log m, \ell]}$, the restriction of the core set $B(\bar{y})$ to the strings whose lengths ranges within $(\log m, \ell]$.

Let Y_i, Z_i denote the subsequences of Y, Z which contain all the strings that have prefix i, respectively. By definitions, $|Y_i| \leq |Z_i|$. Recall that Z are $(c_1 \log u)$-wise independent. Due to Theorem 8, the load of entry i exceeds $c_3 \log u$ with probability

$$\Pr[\, |Y_i| \geq c_3 \log u \,] \leq \Pr[\, |Z_i| \geq c_3 \log u \,] \leq \exp(-(c_3 - 1)^2 \log u/2), \tag{3}$$

as long as $c_1 \geq \lceil 2(c_3 - 1)^2 \rceil$. Therefore the max-load of entries of the main table is upper bounded by $c_3 \log u$ with probability at least $1 - (m/\log u)\exp(-(c_3 - 1)^2 \log u/2)$. The data structure reports failure if any entry of the main table overflows. In the rest of the proof, we fairly assume $|Y_i| \leq |Z_i| \leq c_3 \log u$ for all i.

Observe that a datapoint x can be identified with $hd(x) \circ hs(x) \circ rt(x)$ if the entry $i = st(x)$ it is distributed into is fixed. Therefore we let Y_i', Z_i' denote the subsequences generated from Y_i, Z_i by discarding the left-most $\log(m/\log u)$ bits.

Subtable. Each subtable i consists of the following parts to be specified later:

- a collection of fingerprints $\alpha_{\log\log u}(Y_i')$ and its indicator list I_i;
- an (extendable) array of navigators N_i;
- an (extendable) array of data blocks A_i;
- two buffers, $B_{i,u}, B_{i,r}$;
- constant many other local variables.

All the datapoints are stored in array A_i. Given a datapoint x, it is easy to see that the addresses of the entries which contains the information of x is high correlated with the order it is inserted, since any insertion takes constant time in the worst case. Hence we take the fingerprints $\alpha_{\log\log u}(Y_i')$, indicators I_i, navigators N_i, and a tricky way to encode a data block as clues to locate the entries which maintain x. Recall that new insertions is put into the latest data block using a dynamic construction, and we reorganize the full dynamic data block into a static construction. We use buffer $B_{i,u}$ to maintain the dynamic block, and use buffer $B_{i,r}$ to "de-amortize" the reorganization.

At first consider a static version of our data structure. In the static version, the buffers and the indicator list are unnecessary. Let $n_i \triangleq |Y_i|$.

Fingerprints. The collection of fingerprints $\alpha_{\log\log u}(Y_i')$ is obtained by applying Theorem 9 on Y_i' with guarantee $c_1 \geq c_3$. Note that Z_i' are mutually independent as long as $c_1 \geq c_3$. Due to Theorem 9, there exists a constant $c'' > 0$ such that a fingerprint collection $\alpha_{\log\log u}(Z_i')$ for Z_i' can be represented in $c'' \log u$ bits with probability $1 - u^{-c_5}$.

We show that there exists a injective function $P : [|Y_i'|] \to [|Z_i'|]$ such that $\forall j \in [|Y_i'|], Y_i'[j] \sqsupseteq Z_i'[P(j)]$. Due to the injective function P and the guarantee that Y is prefix-free, the fingerprint collection of Y_i' can be represented with the same space and probability guarantees as above.

We define $P : [|Y_i|] \to [|Z_i|]$ by $P(j) \triangleq \min\{k \in [|Z_i|] : Y_i[j] \sqsupseteq Z_i[k]\}$. By the definition, for any $y \in Y_i$, there is $z \in Z$ such that $y \sqsupseteq z$. Recall that all the strings in Y_i has prefix i. Hence for any $y \in Y_i, z \in Z$ such that $y \sqsupseteq z$, it holds that $i \sqsupseteq z$, i.e. $z \in Z_i$. Thus for any $j \in [|Y_i|], \{k \in [n] : Y_i[j] \sqsupseteq Z_i[k]\} \neq \emptyset$. Therefore P is well-defined. On the other hand, for distinct $j, l \in [|Y_i|]$, $\{k \in [n] : Y_i[j] \sqsupseteq Z_i[k]\}$ and $\{k \in [n] : Y_i[l] \sqsupseteq Z_i[k]\}$ are disjoint, since Y_i is prefix-free and there is no such z that x, y prefix z simultaneously for distinct $x, y \in Y_i$. Therefore P is injective. Recall that Y_i', Z_i' are generated by removing the prefix i from the strings in Y_i, Z_i: $\forall j, Y_i[j] = i \circ Y_i'[j], Z_i[j] = i \circ Z_i'[j]$. Therefore P works for Y_i', Z_i' too, i.e. $\forall j \in [|Y_i'|], Y_i'[j] \sqsupseteq Z_i'[P(j)]$.

A failure is reported if any fingerprint collection can not be represented within $c'' \log u$ bits, which occurs with probability at most u^{-c_5}.

The fingerprints are sorted lexicographically, so that by the j-th fingerprint we mean the j-th in lexicographical order. For simplicity, we write $\alpha_i \triangleq \alpha_{\log\log u}(Y_i')$.

A failure is reported if there are more than $c_4 \log u / \log\log u$ datapoints share identical $hd(x)$ and $hs(x)$, which occurs with probability at most

$$\binom{c_3 \log u}{c_4 \log u/\log\log u}\left(\frac{1}{\log u}\right)^{c_4 \log u/\log\log u} < u^{-(c_4 - 0.01)}. \tag{4}$$

The fingerprints cost $O(\log u)$ bits per subtable if no failures.

Navigators. N_i is an array of pointers. For any datapoint, the rank of its fingerprint is synchronized with the index of its navigator. In particular, for the k-th fingerprint in α_i, $N_i[k]$ is the address of the data block which maintains the datapoint with the fingerprint. A data block maintains up to $\log u/\log\log u$ datapoints, thus there are at most $c_3 \log\log u$ data blocks. The navigators cost at most $n_i \log\log\log u + O(n_i)$ bits of space.

Data Blocks. A_i is interpreted as an array of data blocks, with each data block holding up to $\log u/\log\log u$ datapoints.

Consider the following succinct binary representation (called *pocket dictionary* in [6]) of a collection of datapoints $F \in \binom{\{0,1\}^\ell}{m}$: The representation consists of two parts $header(F)$ and $body(F)$. Let $header(x), body(x)$ denote the left-most $\log m$ bits and the right-most $\ell - \log m$ bits of x. Let $n_i' \triangleq |\{x \in F | header(x) = i\}|$, and $F = (x_1, \cdots, x_m)$ sorted lexicographically. Then $header(F) \triangleq 0 \circ 1^{n_0'} \circ 0 \circ 1^{n_1'} \circ 0 \cdots 1^{n_{m-1}'}$ and $body(F) \triangleq body(x_1) \circ body(x_2) \cdots \circ body(x_m)$. It is easy to see that this representation uses $2m + m(\ell - \log m)$ bits of space.

Our static data block is a variant of this representation. Let $(x_1, \cdots, x_{\log u/\log\log u})$ be the sorted list of datapoints maintained by data block j. Data block j consists of a list of headers $(hd(x_1), \cdots, hd(x_{\log u/\log\log u}))$, a list of identities $(hs(x_1), \cdots, hs(x_{\log u/\log\log u}))$ and an array of the rest part of datapoints $(rt(x_1), \cdots, rt(x_{\log u/\log\log u}))$. The header list are represented in the same way as in the pocket dictionary, the identity list is the concatenation $hs(x_1) \circ hs(x_2) \cdots \circ hs(x_{x/\log\log u})$, and the rest part array is the concatenation $\mathtt{PFC}(rt(x_1)) \circ \mathtt{PFC}(rt(x_2)) \cdots \circ \mathtt{PFC}(rt(x_{x/\log\log u}))$, where $\mathtt{PFC}(\cdot)$ is the prefix-free code in Claim 3.

Recall that $|hd(x)| = \log(\log u/\log\log u), |hs(x)| = \log\log\log u$. Therefore the data blocks for the subtable cost at most $O(n_i) + n_i(\ell - \log m + \log\log\log u)$ bits of space.

Query in a Static Data Block. Recall that the fingerprints are sorted in lexicographical order, and the indices of the navigators are synchronized with the ranks of corresponding fingerprints. Also note that a navigator costs $\log\log\log u + O(1)$ bits, there are at most $c_4 \log u/\log\log u$ datapoints share $hd(x) \circ hs(x)$ with any query x. By putting everything together, we can retrieve all the navigators of the datapoints which have the same $hd(x) \circ hs(x)$ with query x, and learn a k' such that the unique suspected datapoint is the k'-th datapoint among the datapoints which share the $hd(x) \circ hs(x)$ in its data block. On the other hand, we can retrieve the header list and identity list with constant number of memory accesses. Consequently, we can retrieve the rest part of the suspected datapoint efficiently. See the pseudocode in the appendix of the full version of this paper for more details.

The space usage is upper bounded by $m + (m/\log u) \cdot O(\log u) + n \log\log\log u + O(n) + n(\ell - \log m + \log\log\log u) \leq n(\ell - \log m + 2\log\log\log u) + O(m)$ bits. And the query time is clearly constant.

Insertion. The new insertions will be put into a data block under construction temporarily, and the data block will be reorganized to the static version as long as the data block is full (which means, there are $\log u/\log\log u$ datapoints stored in it). A data block under construction consists of two incomplete lists for headers and identities, and an (extendable) array of the rest parts of datapoints. Note that the space usages of incomplete lists are identical with the ones of the complete lists, it wastes at most $O(\log u)$ bits per dynamic data block.

Reorganizing a data block (i.e. sorting a data block) can be expensive, therefore we finish this work during the procedure that a new data block under construction is being filled. Hence there are two dynamic data blocks, one under construction and one under reorganization, besides the static ones.

Note that the collection of fingerprints α_i can be updated dynamically with small costs. To retrieve the datapoint y with fingerprint $\alpha(y)$, the only things we need are the address of the data block which maintains y and the in-block index of y. (recall that $hd(y)$ and $hs(y)$ are known due to the fingerprint collection.) It is easy to learn the address as long as we know that y is in a dynamic data block, since there are at most two dynamic blocks. We use the buffers to record the in-block index, and use the indicators to inform whether y is in a dynamic data block.

The list of indicators is a string from $\{1, 2, 3\}^{n_i}$. The value of i-th indicator implies which kind of data block the datapoint corresponding to i-th fingerprint is stored in. For a static data block, the query algorithm works in previous way. For a dynamic data block, the address of the data block can be easily learnt with the counter n_i.

The two buffers are arrays of pointers from $[\log u/\log\log u]^{\log u/\log\log u}$, so they fit in constant number of memory cells. In particular, for a indicator $I_i[j]$ which is the k-th indicator has value 2 (or 3), $B_{i,u}[k]$ (or $B_{i,r}[k]$) is the in-block index of the rest part which corresponds to j-th fingerprint.

The new insertion is not a prefix of some preceded insertion due to our guarantees. Therefore, to insert x, we simply append $hs(x), rt(x)$ to the identity list and rest part array, update the header list, fingerprint collection, and indicator list, and insert a proper pointer into $B_{i,u}$, which overall takes constant time. And to query x in a dynamic data block, where x corresponds to a datapoint y stored in the data block, we need to retrieve the address of the data block with counter n_i and the in-block index of y with the buffers, then retrieve $rt(y)$. See the pseudocodes in the appendix of the full version of this paper for more details.

Reorganizing a Data Block. The reorganization procedure starts as long as the data block under construction is full. Informally, the reorganization procedure works as follows:

1. Update the list of indicators and copy $B_{i,r} \leftarrow B_{i,u}$. (We guarantee that the preceded reorganization process has been finished before the buffer $B_{i,u}$ is full)
2. Insert the address of the data block in proper positions of the navigator list.
3. Sort the array of rest parts and the list of identities according to the pointers in the buffer $B_{i,r}$ while keep the buffer updated. Note that the sorting can be done within time cost $O(\log u/\log\log u)$: we enumerate $j \in [\log u/\log\log u]$, find j' such that $B_{i,r}[j'] = j$, swap $hs_j, rt_j, B_{i,r}[j]$ with $hs_{B_{i,r}[j]}, rt_{B_{i,r}[j]}, B_{i,r}[j']$ one by one, where hs_j, rt_j is the j-th item of the corresponding list and array.
4. Update indicator list.

The total time cost is $O(\log u/\log\log u)$, which can be simulated by $\log u/\log\log u$ operations, each costing $O(1)$ time, within a data block. See the appendix of the full version of this paper for more details.

The two dynamic data blocks waste at most $O(\log u)$ bits on the two incomplete lists for headers and identities, therefore we uses at most extra $O(m)$ bits of space.

Setting the Constant Parameters. Our data structure may fail at the load balancing on subtables, constructing the fingerprint collections for subtables, and the load balancing on headers of fingerprint collections. By the union bound, the failure probability is at most

$$\frac{m}{\log u}\left(\exp(-(c_3-1)^2\log u/2) + u^{-c_5}\right) + m2^{-(c_4-0.01)\log u}, \tag{5}$$

when $c_1 \geq \max\{\lceil 2(c_3-1)^2\rceil, c_3\}$. Since $m < u$,the failure probability can be as small as $\delta = u^{-2C}$ if we set the constants c_1, c_3, c_4, c_5 to be sufficiently large.

The initialize, decrement, and destroy subroutines are easy to implement, which are postponed to the appendix of the full version of this paper

6 Unconditional Succinct Dictionary

We show that our data structure can solve the dictionary in the worst case unconditionally. In our data structure for prefix matching, the randomness is used only for:

1. load balancing on the subtables;
2. the representation of the adaptive prefixes;
3. load balancing on the $hd(x) \circ hs(x)$'s.

Note that we should decode $st(x)$ from subtable index i, decode $hd(x) \circ hs(x)$ from bucket index in adaptive prefixes, and decode $hd(x)$ from bucket index in data block. To achieve the identical guarantees with prefix matching, we apply a weaker but strong enough random permutation.

▶ **Definition 14** (Feistel permutation). *Given any $x \in [u]$, let x_L, x_R respectively denote the $\log m$ left-most bits and the $\log(u/m)$ right-most bits of the binary representation of x, so that $x = x_L \circ x_R$. Given any $f : \{0,1\}^{\log(u/m)} \to \{0,1\}^{\log m}$, the* Feistel permutation *$\pi_f : [u] \to [u]$ is defined as*

$$\pi_f(x) = (x_L \oplus f(x_R)) \circ x_R.$$

It is easy to verify that π_f is indeed a permutation. In fact, $\pi_f(\pi_f(x)) = x$ for any x and f.

Our dictionary data structure works with three $(c_1 \log u)$-wise independent hash functions $f : [\frac{u \log u}{m}] \to [m/\log u]$, $g : [u/m] \to [\log u]$, and $h : [u/m] \to [u^{c_2}]$. Given a key $x \in [u]$, we let $st'(x) = \pi_f(x), hd'(x) \circ hs'(x) = \pi_g(hd(x) \circ hs(x) \circ rt(x))$ and $hss(x) = h(rt(x))$. Then we distribute x into subtable $st'(x)$, insert/query $hd'(x) \circ hs'(x) \circ hss(x)$ to the fingerprint collection, and encode $hd'(x) \circ hs'(x) \circ rt(x)$, instead of $hd(x) \circ hs(x) \circ rt(x)$, in its data block.

Consider two datapoints x, x'. If $hd(x) \circ hs(x) \circ rt(x) \neq hd(x') \circ hs(x') \circ rt(x')$, then $st'(x)$ and $st'(x')$ are independent; otherwise $st'(x) \neq st'(x')$. Therefore for any i, c,

$$\Pr\left[\,|\{x \in Y : st'(x) = i\}| \geq c\,\right] \leq \Pr\left[\,|\{x \in Y' : st(x) = i\}| \geq c\,\right], \tag{6}$$

where Y are the insertion sequence, Y' are $(c_1 \log u)$-wise independent random insertion sequence. Hence the load balancing is not worse than the one in the prefix matching case.

Due to Theorem 9 and Eq(6), the fingerprint collection works with the same guarantees. Clearly $hd(x) \circ hs(x) = (hd'(x) \circ hs'(x)) \oplus g(rt(x)), st(x) = st'(x) \oplus f(hd(x) \circ hs(x) \circ rt(x))$, thus the keys can be retrieved precisely. For the values, we store $rt(x)$ and its value together as a tuple in the data block.

7 Upper Bounds in Allocate-Free Model

We mimic the extendable arrays in the allocate-free model. For simplicity, we modify the navigator list from extendable array to an array of length $c_3 \log u$.

Suppose we are dealing with D_i. The main table can be implemented easily since it has fixed length. Let $s = c_3(\log u)(\log(1/\epsilon) + \log i + O(\log\log\log u))$ be the space usage upper bound of any single subtable. For a subtable i, we maintain a pointers array of length $\lceil\sqrt{s/w}\rceil$ to mimic the extendable array. Every pointer in the array points to a memory block of $\lceil\sqrt{sw}\rceil$ bits. Therefore we waste at most

$$(2^i/\log u) \cdot O(w \cdot \sqrt{s/w} + \sqrt{sw}) = O(2^i\sqrt{\log(1/\epsilon) + \log i + \log\log\log u})$$

bits of space. In conclusion, after n insertions our data structure for filters uses at most

$$n(\log(1/\epsilon) + \log\log n + O(\log\log\log u)) + O(n\sqrt{\log(1/\epsilon) + \log\log n + \log\log\log u})$$

bits of space in the allocate-free model.

Similarly, our data structure for dictionaries uses at most

$$n(\log(u/n) + v + O(\log\log\log u)) + O(n\sqrt{\log(u/n) + v + \log\log\log u})$$

bits of space after n insertions in the allocate-free model.

Abstract

In the Split Vertex Deletion (SVD) problem, the input is an n-vertex undirected graph G and a weight function $w\colon V(G) \to \mathbb{N}$, and the objective is to find a minimum weight subset S of vertices such that $G-S$ is a split graph (i.e., there is bipartition of $V(G-S) = C \uplus I$ such that C is a clique and I is an independent set in $G-S$). This problem is a special case of 5-Hitting Set and consequently, there is a simple factor 5-approximation algorithm for this. On the negative side, it is easy to show that the problem does not admit a polynomial time $(2-\delta)$-approximation algorithm, for any fixed $\delta > 0$, unless the Unique Games Conjecture fails.

We start by giving a simple quasipolynomial time ($n^{\mathcal{O}(\log n)}$) factor 2-approximation algorithm for SVD using the notion of *clique-independent set separating collection*. Thus, on the one hand SVD admits a factor 2-approximation in quasipolynomial time, and on the other hand this approximation factor cannot be improved assuming UGC. It naturally leads to the following question: Can SVD be 2-approximated in polynomial time? In this work we almost close this gap and prove that for any $\varepsilon > 0$, there is a $n^{\mathcal{O}(\log \frac{1}{\varepsilon})}$-time $2(1+\varepsilon)$-approximation algorithm.

1 Introduction

The Hitting Set problem encompasses a large number of well studied problems in Computer Science. Here, the input is a family $\mathcal{F}$ of sets over an n-element universe U and a weight function $w\colon U \to \mathbb{N}$, and the objective is to compute a hitting set of minimum weight. A *hitting set* is a subset $S \subseteq U$ such that for any $F \in \mathcal{F}$, $F \cap S \neq \emptyset$ and the weight of S is $w(S) = \sum_{u \in S} w(u)$. This problem generalizes a number of other well studied problems in computer science, and consequently it is very hard to approximate: it can not be approximated within a factor $2^{\log^{1-\delta_c(n)} n}$ in polynomial time, for any constant $c < 1/2$, unless SAT can be decided in slightly subexponential time, where $\delta_c(n) = 1/(\log\log n)^c$ [11]. A restricted version of this problem, is the d-Hitting Set problem, where $d \in \mathbb{N}$ and the cardinality of every set in $\mathcal{F}$ is at most d. This problem also generalizes a number of well studied problems, and it admits a simple factor d-approximation algorithm: Solve the natural LP relaxation and select all elements whose corresponding variable in the LP is set to at least $1/d$. Unfortunately, this simple algorithm is likely to be the best possible. That is, assuming Unique Game Conjecture (UGC), there is no c-factor approximation algorithm for d-Hitting Set, for any $c < d$ in the general case [7].

A number of vertex deletion problems on graphs can be considered as special cases of d-Hitting Set, and it is of great interest to devise factor-α approximation algorithm for them where $\alpha < d$, or rule out any such algorithm. For example, in the Vertex Cover problem, the input is a graph G and a weight function $w\colon V(G) \to \mathbb{N}$, and the objective is to find a subset of vertices of minimum weight that hits all edges in G. This is same as 2-Hitting Set, and assuming the Unique Games Conjecture we cannot do better than a factor-2 approximation in polynomial time. However, there are other examples of vertex deletion problems on graphs, that are special cases of d-Hitting Set, for which we can indeed do better than a factor-d approximation. Consider the Cluster Vertex Deletion problem, where the input is a graph G and a weight function $w\colon V(G) \to \mathbb{N}$, and the objective is to find a minimum weight subset S of vertices such that S is a cluster graph. Equivalently, S hits all induced paths of length 3 in G. Hence, it is a special case of 3-Hitting Set and admits a simple 3-approximation algorithm. You et al. [13] showed that the unweighted version of Cluster Vertex Deletion admits a 5/2 approximation algorithm. Recently, this was improved to factor 9/4 by Fiorini et al. [5]. The problem also admits an approximation-preserving reduction from Vertex Cover and hence there is a lower bound of 2 on the approximation-factor assuming UGC [5]. Fiorini et al. [5] have conjectured that Cluster Vertex Deletion admits a 2-approximation algorithm. Another example is the Tournament Feedback Vertex Set (TFVS) problem, which is equivalent to hitting all directed triangles in a digraph. It is very well studied in the realm of approximation algorithms [3, 1, 10, 9], and very recently a 2-approximation algorithm was designed by Lokshtanov et al. [9], matching the lower-bound under UGC [12]. Similarly, a number of such "implicit" d-Hitting Set problems are studied in Computer Science, and it is of great interest to settle their approximation complexity.

In this work we study another implicit d-Hitting Set problem called Split Vertex Deletion(SVD) (defined below). A subset S of vertices in a graph G is a split vertex deletion set if $G - S$ is a split graph (i.e., there is bipartition of $V(G-S) = C \uplus I$ such that C is a clique and I is an independent set in $G - S$).

Split Vertex Deletion (SVD)
Input: An undirected graph G and a weight function $w : V(G) \to \mathbb{N}$.
Output: A split vertex deletion set $S \subseteq V(G)$ of G of the smallest weight (an *optimum* split vertex deletion set of G).

A graph G is a split graph if and only if it does not contain C_4, C_5 and $2K_2$ as induced subgraphs in G [6]. This implies that SVD is special case of 5-Hitting Set and hence it admits a simple 5-approximation algorithm. Furthermore, it is interesting to note that we can obtain a 2-approximation algorithm for SVD in time $n^{O(\log n)}$ using the notion of *clique-independent set separating collection* [4]. For a graph G, a clique-independent set separating collection is a family $\mathcal{C}$ of vertex subsets of $V(G)$ such that for a clique C and an independent set I in G such that $C \cap I = \emptyset$, there is subset X in the collection $\mathcal{C}$ such that $C \subseteq X$ and $I \subseteq V(G) \setminus X$. Thus, if there is a "small" clique-independent set separating collection, then we can enumerate such a collection $\mathcal{C}$ and solve Vertex Cover of $\overline{G}[X]$ and $G - X$ for each $X \in \mathcal{C}$. Notice that for any $X \in \mathcal{C}$, the union of the two solutions of the two Vertex Cover instances on $\overline{G}[X]$ and $G - X$, respectively, is a solution to SVD. Moreover, the best c-approximation solutions over all choices of X, is a c-approximate solution of SVD. It is known that for any n-vertex graph, there is clique-independent set separating collection of size $n^{\mathcal{O}(\log n)}$ and this can be enumerated in time linear in the size of the collection [4]. This along with a 2-approximation algorithm of Vertex Cover leads to an $n^{\mathcal{O}(\log n)}$-time 2-approximation algorithm for SVD. There is also a simple approximation preserving reduction from Vertex Cover to SVD, which shows that we cannot improve upon factor 2-approximation algorithm, unless UGC fails. The reduction is as follows: Given an instance (G, w) of Vertex Cover, we add a large complete graph H of size $2|V(G)|$ into G with weight of each vertex in H to be $\max\{w(u) \,:\, u \in V(G)\}$. One can easily verify that this is an approximation preserving reduction.

Thus, on the one hand SVD admits a 2-approximation in quasipolynomial ($n^{\mathcal{O}(\log n)}$) time, and on the other hand this approximation factor cannot be improved assuming UGC. It naturally leads to the following question: Can SVD be 2-approximated in polynomial time? This is precisely the question we address in this paper, and obtain the following result.

▶ **Theorem 1.** *Let G be a graph on n vertices, w a weight function on $V(G)$ and let $\varepsilon > 0$ be a constant. Then there exists a randomized algorithm that runs in time $\mathcal{O}(n^{g(\varepsilon)})$ and outputs $S \subseteq V(G)$ such that $G - S$ is a split graph and $w(S) \leq 2(1+\varepsilon)w(OPT)$ with probability at least $1/2$. Here OPT is a minimum weight split vertex deletion set of G, and $g(\varepsilon) = 6 + 8\log(80(1+\frac{12}{\varepsilon})) \cdot \log(\frac{30}{\varepsilon})/\log(4/3)$.*

Overview of Theorem 1. At a very high level the algorithm described in Theorem 1 is inspired from the algorithm developed for factor 2-approximation algorithm for TFVS [9]. In TFVS knowing just one vertex is sufficient to completely split the instance into two independent sub-instances and thus leading to a natural divide and conquer scheme. However, in our case (SVD) the instances don't become truly independent before every vertex is classified as either *potential clique* or *potential independent set vertex.* Classifying all the vertices requires several new ideas and insights in the problem. This classification could be vaguely viewed as a polynomial time algorithm that quickly navigates through sets in clique-independent set separating collection $\mathcal{C}$, and almost reaches a correct partition.

Our algorithm in fact finds a $(2+\varepsilon)$-factor approximate solution for a more general *annotated* variant of the problem, where the solution must obey certain additional constraints.

Annotated Split Vertex Deletion (A-SVD)
Input: An undirected graph G, a weight function $w : V(G) \to \mathbb{N}$, and a partition of $V(G)$ into three parts $V(G) = C \uplus I \uplus U$, where at most two of these parts may be empty.
Output: A set $S^\star \subseteq V(G)$ of G of the smallest weight such that $G - S^\star$ is a split graph with a split partition $(C^\star, I^\star)$ where $C^\star \subseteq (C \cup U)$ and $I^\star \subseteq (I \cup U)$ hold.

A *feasible solution* to an instance $(G, w, (C, I, U))$ of Annotated Split Vertex Deletion is a split vertex deletion set S of G such that the split graph $G - S$ has a split partition (C', I') where no vertex in the specified set I goes to the split part C' and no vertex in the specified set C goes to the independent part I'. Thus, each vertex in the set I is either deleted as part of S or ends up in the independent set I' in graph $G - S$, and each vertex in C is either deleted or ends up in the clique C' in $G - S$. There are no restrictions on where the vertices in the "unconstrained" set U may go. We call a feasible solution of A-SVD an *annotated split vertex deletion set* of the instance $(G, w, (C, I, U))$; the A-SVD problem asks for an *optimum* annotated split vertex deletion set of the input instance.

First we show that we can, in polynomial time, find 2-factor approximate solutions to A-SVD instances which are of the form $(G, w, (C, I, U = \emptyset))$ (Lemma 12). Let $(G, w, (C, I, U))$ be an instance of A-SVD, let OPT be an (unknown) optimum solution to $(G, w, (C, I, U))$, let $(C^\star \subseteq (C \cup U), I^\star \subseteq (I \cup U))$ be a split partition of $G - OPT$, and let $C^\star_U = (C^\star \cap U), I^\star_U = (I^\star \cap U)$. We show that if $w(C^\star_U \setminus \{c^\star\}) \leq \frac{\varepsilon \cdot w(OPT)}{2}$ holds for some $c^\star \in C^\star_U$ or $w(I^\star_U \setminus \{i^\star\}) \leq \frac{\varepsilon \cdot w(OPT)}{2}$ holds for some $i^\star \in I^\star_U$ then we can, in polynomial time, find a $(2+\varepsilon)$-factor approximate solution to $(G, w, (C, I, U))$ (Lemma 16, Lemma 18). These constitute the base cases of our algorithm. It is not difficult to see that moving a vertex $x \in C^\star_U$ to the set C and moving a vertex $y \in I^\star_U$ to the set I are approximation-preserving transformations. At a high level, our algorithm starts with an arbitrary instance $(G, w, (C, I, U))$ of A-SVD, correctly identifies – with a constant probability of success – a good fraction of vertices which belong to the sets $C^\star_U$ or $I^\star_U$, and moves these vertices to the sets C or I, respectively. It then recurses on the resulting instance, till it reaches one of the base cases described above.

We now briefly and informally outline how our algorithm identifies vertices as belonging to $C^\star_U$ or $I^\star_U$. Consider the bipartite subgraph H of G induced by the pair $(C^\star_U, I^\star_U)$. Define the weight of an edge to be the product of the weights of its two end-points, and suppose the total weight of edges in H is at least half the maximum possible weight. Then each of a constant fraction (by weight) of the vertices in $I^\star_U$ has a constant fraction (by weight) of $C^\star_U$ in its neighborhood (Lemma 4). If we can identify one of these special vertices of $I^\star_U$ then we can safely move all its neighbors in U to the set C while reducing the weight of $C^\star_U$ by a constant fraction. The catch, of course, is that we have no idea what the set $I^\star_U$ is.

To get around this, we find an approximate solution X of the Split Vertex Deletion instance defined by the induced subgraph $G[U]$. Let (C_X, I_X) be a split partition of $G - X$. We show that we can, in polynomial time and with constant probability, sample a vertex from the set $X \cup (I_X \setminus C^\star_U)$ (Lemma 26). We further show that the weight of $X \cup (I_X \setminus C^\star_U)$ is at most a *constant multiple* of the weight of $I^\star_U$ (Lemma 22). So if $I^\star_U \subseteq (X \cup (I_X \setminus C^\star_U))$ holds then we can, with good probability, sample a vertex from the set $I^\star_U$. The hard part is when this condition does not hold. We show using a series of lemmas (summarized in Lemma 25) that we can, even in this case, sample a vertex from one of the two sets $C^\star_U, I^\star_U$ with constant probability. A symmetric analysis applies when the total weight of *non-edges* across $(C^\star_U, I^\star_U)$ is at least half the maximum possible weight.

2 Preliminaries

We use $\uplus$ to denote the disjoint union of sets. Moreover, when we write $X \uplus Y$ we implicitly assert that the sets X and Y are disjoint. We use $V(G)$ (respectively, $E(G)$) to denote the vertex set (respectively, the edge set) of graph G. For a subset $S \subseteq V(G)$ of vertices of G we use $G[S]$ to denote the subgraph of G *induced* by S and $G - S$ to denote the subgraph of G obtained by deleting all vertices in S (and their incident edges) from G. A *non-edge* in a graph G is any 2-subset $\{x, y\} \subseteq V(G)$ of vertices such that xy is not an edge in G. For the sake of brevity we use the notation xy to denote a non-edge $\{x, y\}$. For a finite set U, weight function $w : U \to \mathbb{N}$, and subset $X \subseteq U$ we use w_X to denote the weight function w *restricted to the subset* X, and $w(X)$ to denote the sum $\sum_{x \in X} w(x)$ of weights of all the elements in X. For the sake of brevity we drop the subscript X from the expression w_X when there is no risk of ambiguity.

The operation of *sampling (or picking) proportionately at random* from U according to the weight function w chooses one element from U, where each element $x \in U$ is chosen with probability $w(x)/w(U)$. We use $\overline{G}$ to denote the *complement* of a graph G, defined as follows: The vertex set of $\overline{G}$ is $V(G)$. For every two vertices $\{u, v\} \subseteq V(G)$ there is an edge uv in $\overline{G}$ if and only if uv is *not* an edge in graph G. A *vertex cover* of graph G is any subset $S \subseteq V(G)$ of its vertex set such that the graph $G - S$ has no edges. A *clique* in graph G is any non-empty subset $S \subseteq V(G)$ of its vertex set such that (i) $|S| = 1$, or (ii) if $|S| \geq 2$ then for every two vertices u, v in S, the edge uv is present in graph G.

▶ **Observation 2.** *For an undirected graph G and any $S \subseteq V(G)$, the vertex set $V(G) \setminus S$ is a clique in G if and only if S is a vertex cover of the complement graph $\overline{G}$.*

For a graph G and two disjoint vertex subsets $X, Y \subseteq V(G)$; $X \cap Y = \emptyset$ *the bipartite subgraph of G induced by the pair* (X, Y) has vertex set $X \cup Y$ and edge set $\{xy \mid x \in X, y \in Y, xy \in E(G)\}$. Note that the bipartite subgraph of G induced by the pair (X, Y) is not necessarily identical to the subgraph $G[X \cup Y]$ induced by the subset $X \cup Y$, and is defined even if the induced subgraph $G[X \cup Y]$ is not bipartite. For a bipartite graph H with vertex bipartition $V(H) = V_1 \uplus V_2$ we define $\widehat{E(H)} = \{v_1v_2 \mid v_1 \in V_1, v_2 \in V_2, v_1v_2 \notin E\}$ to be the set of all **non-edges** of H *with one end in* V_1 *and the other end in* V_2. Further, for a weight function $w : V(H) \to \mathbb{N}$ defined on the vertex set of a bipartite graph H we define the weight of its edge set to be $w(E(H)) = \sum_{v_1v_2 \in E(H)}(w(v_1) \cdot w(v_2))$ and the weight of its set of non-edges to be $w(\widehat{E(H)}) = \sum_{v_1v_2 \in \widehat{E(H)}}(w(v_1) \cdot w(v_2))$.

▶ **Definition 3.** *Let G be an undirected graph and $w : V(G) \to \mathbb{N}$ a weight function. Let X, Y be two disjoint vertex subsets of G and let H be the bipartite subgraph of G induced by the pair (X, Y). Let $w(E(H))$ and $w(\widehat{E(H)})$ be defined as above. We say that (X, Y) is a* heavy pair *if $w(E(H)) \geq \frac{w(X) \cdot w(Y)}{2}$ holds, and is a* light pair *if $w(\widehat{E(H)}) \geq \frac{w(X) \cdot w(Y)}{2}$ holds.*

▶ **Lemma 4 (♣).** [1] *Let $H = (V, E)$ be a bipartite graph, let $V = V_1 \uplus V_2$ be a bipartition of H, and let $w : V(H) \to \mathbb{N}$ be a weight function. Then (V_1, V_2) is either a heavy pair or a light pair. Moreover,*

1. *Suppose (V_1, V_2) is a heavy pair, and let $X = \{x \in V_1 \mid w(N(x)) \geq \frac{w(V_2)}{4}\}$ be the set of all vertices x in the set V_1 such that the total weight of the neighborhood of x in the set V_2 is at least one-fourth the total weight of the set V_2. Then $w(X) > \frac{w(V_1)}{4}$.*
2. *Suppose (V_1, V_2) is a light pair, and let $Y = \{y \in V_1 \mid w(V_2 \setminus N(y)) \geq \frac{w(V_2)}{4}\}$ be the set of all vertices y in the set V_1 such that the total weight of the* non-neighbors *of y in the set V_2 is at least one-fourth the total weight of the set V_2. Then $w(Y) > \frac{w(V_1)}{4}$.*

For a graph G given together with a weight function $w : V(G) \to \mathbb{N}$, an *optimum vertex cover* of G is any vertex cover of G with the least total weight.

[1] Proofs of statements labeled with a ♣ will appear in the full version of the paper.

Weighted Vertex Cover (wVC)
Input: An undirected graph G and a weight function $w : V(G) \to \mathbb{N}$.
Output: An optimum vertex cover $S \subseteq V(G)$ of G

▶ **Theorem 5** ([2]). *There is an algorithm which, given an instance (G, w) of Weighted Vertex Cover as input, runs in $\mathcal{O}(|E(G)|)$ time and outputs a vertex cover S of G whose weight is at most twice the weight of an optimum vertex cover of G.*

3 The Algorithm

Let (G, w) be an instance of Split Vertex Deletion. Since deleting vertices conserves the property of being a split graph one can safely add zero-weight vertices to any split vertex deletion set. So we assume without loss of generality that $w(v) \geq 1$ holds for every $v \in V(G)$. Split Vertex Deletion is NP-complete by the meta-result of Lewis and Yannakakis [8], and has a simple 5-factor approximation algorithm based on the Local Ratio Technique.

▶ **Theorem 6** (♣). *There is a deterministic algorithm which, given an instance (G, w) of SVD, runs in $\mathcal{O}(|V(G)|^6)$ time and outputs a split vertex deletion set $S \subseteq V(G)$ of G such that $w(S) \leq 5 \cdot w(OPT)$ where OPT is an optimum split vertex deletion set of G.*

We describe a randomized polynomial-time algorithm which outputs a $(2+\varepsilon)$-factor approximate solution for this problem for any fixed $\varepsilon > 0$.

Note that in an instance $(G, w, (C, I, U))$ of Annotated Split Vertex Deletion the set C is not necessarily a clique, nor is I necessarily an independent set in G. But we have the following.

▶ **Observation 7.** *Let S be a feasible solution of an A-SVD instance $(G, w, (C, I, U))$ and let (C', I') be a split partition of $G - S$ where $C' \subseteq (C \cup U)$ and $I' \subseteq (I \cup U)$ hold. Then $C \setminus S \subseteq C'$ and $I \setminus S \subseteq I'$ hold. Hence $C \setminus S$ is a clique in G and $I \setminus S$ is an independent set in G.*

From Observations 2 and 7 we get

▶ **Corollary 8.** *Let S be a feasible solution of an A-SVD instance $(G, w, (C, I, U))$. Let VC_C be an optimum solution of the wVC instance $(\overline{G[C]}, w)$ and let VC_I be an optimum solution of the wVC instance $(G[I], w)$. Then $w(VC_C) \leq w(S \cap C)$ and $w(VC_I) \leq w(S \cap I)$ hold.*

A-SVD is clearly a generalization of SVD: Given an instance (G, w) of SVD, construct the instance $(G, w, (C = \emptyset, I = \emptyset, U = V(G)))$ of A-SVD. Every split vertex deletion set of graph G is a feasible solution of the A-SVD instance, and every annotated split vertex deletion set of $(G, w, (\emptyset, \emptyset, V(G)))$ is a split vertex deletion set of graph G. It follows that for any constant c, a c-factor approximate solution to the A-SVD instance is a c-factor approximate solution to the SVD instance as well.

We can find feasible solutions to an A-SVD instance $(G, w, (C, I, U))$ by computing vertex covers for certain pairs of subgraphs derived from G.

▶ **Observation 9** (♣). *Let $(G, w, (C, I, U))$ be an instance of A-SVD.*

1. *Let V_1 be a vertex cover of the graph $G[I \uplus U]$ and let V_2 be a vertex cover of the graph $\overline{G[C]}$. Then $V_1 \uplus V_2$ is a feasible solution to $(G, w, (C, I, U))$.*
2. *Let V_3 be a vertex cover of the graph $G[I]$ and let V_4 be a vertex cover of the graph $\overline{G[C \uplus U]}$. Then $V_3 \uplus V_4$ is a feasible solution to $(G, w, (C, I, U))$.*

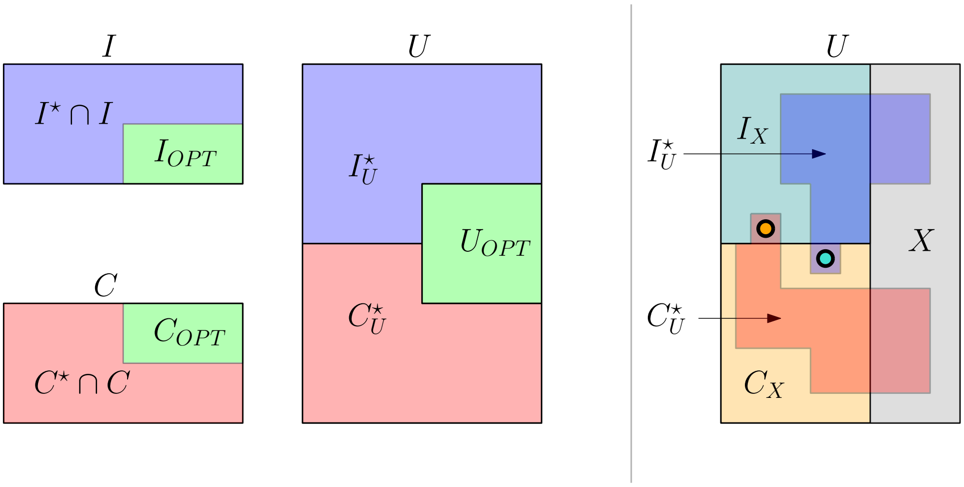

Figure 1 Illustration of Definition 13.

▶ **Observation 10** (♣). *Let $(G, w, (C, I, U))$ be an instance of A-SVD and let $u \in U$.*

1. *Let V_1 be a vertex cover of the graph $G[I \uplus (U \setminus \{u\})]$ and let V_2 be a vertex cover of the graph $\overline{G[C \cup \{u\}]}$. Then $V_1 \uplus V_2$ is a feasible solution to $(G, w, (C, I, U))$.*
2. *Let V_3 be a vertex cover of the graph $G[I \cup \{u\}]$ and let V_4 be a vertex cover of the graph $\overline{G[C \uplus (U \setminus \{u\})]}$. Then $V_3 \uplus V_4$ is a feasible solution to $(G, w, (C, I, U))$.*

Observation 9 has some interesting consequences. For instance, it implies that when the “unconstrained” set U in an A-SVD instance is *empty*, an optimum solution to the A-SVD instance corresponds to optimum solutions of two Weighted Vertex Cover instances derived from the A-SVD instance in a natural fashion.

▶ **Lemma 11** (♣). *Let $S^\star$ be an optimum solution to an A-SVD instance $(G, w, (C, I, U = \emptyset))$. Then the set $(S^\star \cap I)$ is an optimum solution to the wVC instance $(G[I], w)$, and the set $(S^\star \cap C)$ is an optimum solution to the wVC instance $(\overline{G[C]}, w)$.*

This in turn implies that given an A-SVD instance in which the unconstrained set U is empty, we can find a 2-factor approximate solution to the instance in polynomial time.

▶ **Lemma 12** (♣). *There is a deterministic algorithm that finds a 2-factor approximate solution to an A-SVD instance that is of the form $(G, w, (C, I, U = \emptyset))$, in $\mathcal{O}(|E(G)|)$ time.*

This idea generalizes as follows. Let OPT be an optimum solution to an A-SVD instance $(G, w, (C, I, U))$. Suppose the split graph $G - OPT$ has a split partition $(C^\star, I^\star)$ such that vertices from the unconstrained set U *contribute a small weight* to either the clique $C^\star$ or the independent set $I^\star$. Then a variant of the algorithm in the proof of Lemma 12 yields a small-factor approximate solution to the instance, in polynomial time. We state this formally in Lemma 16 below, for which we need some notation (see Figure 1).

▶ **Definition 13.** *Let $(G, w, (C, I, U))$ be an instance of A-SVD, and let $\varepsilon \geq 0$ be a constant. Let $OPT \subseteq V(G)$ be an optimum solution of $(G, w, (C, I, U))$ and let $(C^\star, I^\star)$ be a split partition of the split graph $G^\star = (G - OPT)$ such that $C^\star \subseteq (C \cup U)$ and $I^\star \subseteq (I \cup U)$ hold. Let $C^\star_U = (C^\star \cap U)$ be the set of vertices from the unconstrained set U which become part of the clique $C^\star$ and let $I^\star_U = (I^\star \cap U)$ be the set of vertices from U which become part of the independent set $I^\star$ in $G^\star$. Let $U_{OPT} = (U \cap OPT)$, $C_{OPT} = (C \cap OPT)$ and $I_{OPT} = (I \cap OPT)$.*

Further, let X be a 5-factor approximate solution of the Split Vertex Deletion *instance* $(G[U], w_U)$ defined by the induced subgraph $G[U]$*, and let* (C_X, I_X) *be a split partition of the split graph* $G[U] - X$*.*

▶ Remark 14. Given an instance $(G, w, (C, I, U))$ of A-SVD we can, using Theorem 6, compute such a set X and partition (C_X, I_X) in polynomial time.

▶ **Observation 15 (♣).** *Let* $(G, w, (C, I, U)), X, I_X, C_X, I_U^\star, C_U^\star$ *be as in Definition 13. Then both* $|I_U^\star \setminus (X \cup (I_X \setminus C_U^\star))| \leq 1$ *and* $|C_U^\star \setminus (X \cup (C_X \setminus I_U^\star))| \leq 1$ *hold.*

▶ **Lemma 16 (♣).** *Let* $(G, w, (C, I, U)), \varepsilon, OPT, C_U^\star, I_U^\star$ *be as in Definition 13. Let* S_1 *be a 2-factor approximate solution for the* WVC *instance* $(G[I \cup U], w)$ *and* S_2 *a 2-factor approximate solution for the* WVC *instance* $(\overline{G[C]}, w)$*. Let* $S_{12} = (S_1 \cup S_2)$*. Let* S_3 *be a 2-factor approximate solution for the* WVC *instance* $(\overline{G[C \cup U]}, w)$ *and* S_4 *a 2-factor approximate solution for the* WVC *instance* $(G[I], w)$*. Let* $S_{34} = (S_3 \cup S_4)$*. Then the sets* S_{12} *and* S_{34} *can be computed in* $\mathcal{O}(|E(G)|)$ *time. Further,*

1. *If* $w(C_U^\star) \leq \frac{\varepsilon \cdot w(OPT)}{2}$ *holds then the set* S_{12} *is a* $(2+\varepsilon)$*-factor approximate solution for the* Annotated Split Vertex Deletion *instance* $(G, w, (C, I, U))$*.*
2. *If* $w(I_U^\star) \leq \frac{\varepsilon \cdot w(OPT)}{2}$ *holds then the set* S_{34} *is a* $(2+\varepsilon)$*-factor approximate solution for the* Annotated Split Vertex Deletion *instance* $(G, w, (C, I, U))$*.*

▶ Remark 17. Note that these two cases are neither exclusive nor exhaustive.

By repeatedly applying the procedure in the proof of Lemma 16 and taking the minimum, we can find a $(2+\varepsilon)$-factor approximate solution in polynomial time even in the more general case where there is at most one "heavy" vertex in $C_U^\star$ or $I_U^\star$ that

▶ **Lemma 18 (♣).** *Let* $(G, w, (C, I, U)), \varepsilon, OPT, C_U^\star, I_U^\star$ *be as in Definition 13. For each vertex* $u \in U$ *let* S_1^u *be a 2-factor approximate solution for the* WVC *instance* $(G[I \cup (U \setminus \{u\})], w)$*,* S_2^u *a 2-factor approximate solution for the* WVC *instance* $(\overline{G[C \cup \{u\}]}, w)$*, and let* $S_{12}^u = S_1^u \cup S_2^u$*. Let* S_3^u *be a 2-factor approximate solution for the* WVC *instance* $(\overline{G[C \cup (U \setminus \{u\})]}, w)$*,* S_4^u *a 2-factor approximate solution for the* WVC *instance* $(G[I \cup \{u\}], w)$*, and let* $S_{34}^u = S_3^u \cup S_4^u$*. Finally, let* $S^\dagger$ *be a set of the form* S_{12}^u *of the minimum weight and let* $S^\ddagger$ *be a set of the form* S_{34}^u *of the minimum weight, both minima taken over all vertices* $u \in U$*.*

The sets $S^\dagger$ *and* $S^\ddagger$ *can be computed in* $\mathcal{O}(|V(G)| \cdot |E(G)|)$ *time. Further,*

1. *If* $w(C_U^\star \setminus \{c^\star\}) \leq \frac{\varepsilon \cdot w(OPT)}{2}$ *holds for some vertex* $c^\star \in C_U^\star$ *then the set* $S^\dagger$ *is a* $(2+\varepsilon)$*-factor approximate solution for the A-SVD instance* $(G, w, (C, I, U))$*.*
2. *If* $w(I_U^\star \setminus \{i^\star\}) \leq \frac{\varepsilon \cdot w(OPT)}{2}$ *holds for some vertex* $i^\star \in I_U^\star$ *then the set* $S^\ddagger$ *is a* $(2+\varepsilon)$*-factor approximate solution for the A-SVD instance* $(G, w, (C, I, U))$*.*

▶ Remark 19. Note that these two cases are neither exclusive nor exhaustive.

▶ **Definition 20.** *Let* $(G, w, (C, I, U)), \varepsilon, OPT, C^\star, I^\star, C_U^\star, I_U^\star$ *be as in Definition 13. We say that* $(G, w, (C, I, U))$ *is an* easy *instance if* $U = \emptyset$ *holds, or if* at least one *of the following holds: (i)* $w(C_U^\star) \leq \frac{\varepsilon \cdot w(OPT)}{2}$*, (ii)* $w(I_U^\star) \leq \frac{\varepsilon \cdot w(OPT)}{2}$*, (iii)* $w(C_U^\star \setminus \{c^\star\}) \leq \frac{\varepsilon \cdot w(OPT)}{2}$ *holds for some vertex* $c^\star \in C_U^\star$*, (iv)* $w(I_U^\star \setminus \{i^\star\}) \leq \frac{\varepsilon \cdot w(OPT)}{2}$ *holds for some vertex* $i^\star \in I_U^\star$*. We say that* $(G, w, (C, I, U))$ *is a* hard *instance otherwise.*

From Lemma 12, Lemma 16 and Lemma 18 we get

▶ **Corollary 21.** *There is an algorithm which, given an* easy *instance* $(G, w, (C, I, U))$ *of A-SVD and a constant* $\varepsilon > 0$ *as input, computes a* $(2+\varepsilon)$*-factor approximate solution for* $(G, w, (C, I, U))$ *in deterministic polynomial time.*

▶ **Lemma 22 (♣).** *Let $(G, w, (C, I, U))$ be a* hard *instance of A-SVD and let $\varepsilon, C^{\star}_{U}, I^{\star}_{U}, X, I_X, C_X$ be as in Definition 13. Then the following hold:*

1. $w(X \cup (I_X \setminus C^{\star}_{U})) < (1 + \frac{12}{\varepsilon}) \cdot w(I^{\star}_{U})$
2. $w(X \cup (C_X \setminus I^{\star}_{U})) < (1 + \frac{12}{\varepsilon}) \cdot w(C^{\star}_{U})$

Recall the notion of heavy and light pairs from Definition 3.

▶ **Lemma 23 (♣).** *Let $(G, w, (C, I, U))$ be a* hard *instance of A-SVD and let $\varepsilon, OPT, C^{\star}, I^{\star}, C^{\star}_{U}, I^{\star}_{U}$ be as in Definition 13. Suppose $(I^{\star}_{U}, C^{\star}_{U})$ is a* heavy *pair. Let $I^{\bigcirc} = \{v \in I^{\star}_{U} \; ; \; w(N(v) \cap C^{\star}_{U}) \geq \frac{w(C^{\star}_{U})}{4}\}$ be the set of vertices in $I^{\star}_{U}$ which have a "heavy" neighborhood in $C^{\star}_{U}$, and let $i^{\bigcirc}$ be a heaviest vertex in $I^{\bigcirc}$, i.e. a vertex of maximum weight. Let $C^{\bigcirc} = \{v \in C^{\star}_{U} \; ; \; w((I^{\star}_{U} \setminus \{i^{\bigcirc}\}) \setminus (N(v) \cap I^{\star}_{U})) \geq \frac{w(I^{\star}_{U} \setminus \{i^{\bigcirc}\})}{4}\}$ be the set of vertices in $C^{\star}_{U}$ which have a "heavy"* non-neighborhood *in the subset $I^{\star}_{U} \setminus \{i^{\bigcirc}\}$, and let $c^{\bigcirc}$ be a heaviest vertex in $C^{\bigcirc}$. Let $I^{\square} = \{v \in (I^{\star}_{U} \setminus \{i^{\bigcirc}\}) \; ; \; w(N(v) \cap (C^{\star}_{U} \setminus \{c^{\bigcirc}\})) \geq \frac{w(C^{\star}_{U} \setminus \{c^{\bigcirc}\})}{4}\}$ be the set of vertices in $I^{\star}_{U} \setminus \{i^{\bigcirc}\}$ which have a "heavy" neighborhood in $C^{\star}_{U} \setminus \{c^{\bigcirc}\}$, and let $C^{\square} = \{v \in (C^{\star}_{U} \setminus \{c^{\bigcirc}\}) \; ; \; w((I^{\star}_{U} \setminus \{i^{\bigcirc}\}) \setminus (N(v) \cap I^{\star}_{U})) \geq \frac{w(I^{\star}_{U} \setminus \{i^{\bigcirc}\})}{4}\}$ be the set of vertices in $(C^{\star}_{U} \setminus \{c^{\bigcirc}\})$ which have a "heavy"* non-neighborhood *in $I^{\star}_{U} \setminus \{i^{\bigcirc}\}$.*

Then at least one of the following statements holds:

(1a) *Picking a vertex proportionately at random from the set $X \cup (I_X \setminus C^{\star}_{U})$ yields a vertex $v \in I^{\bigcirc}$ with probability at least $1/(20(1 + \frac{12}{\varepsilon}))$.*

(1b) *Picking a vertex proportionately at random from the set $X \cup (I_X \setminus C^{\star}_{U})$ yields a vertex $v \in I^{\square}$ with probability at least $1/(4(1 + \frac{12}{\varepsilon}))$.*

(2a) *Picking a vertex proportionately at random from the set $X \cup (C_X \setminus I^{\star}_{U})$ yields a vertex $v \in C^{\bigcirc}$ with probability at least $1/(20(1 + \frac{12}{\varepsilon}))$.*

(2b) *Picking a vertex proportionately at random from the set $X \cup (C_X \setminus I^{\star}_{U})$ yields a vertex $v \in C^{\square}$ with probability at least $1/(4(1 + \frac{12}{\varepsilon}))$.*

▶ **Lemma 24 (♣).** *Let $(G, w, (C, I, U))$ be a* hard *instance of A-SVD and let $\varepsilon, OPT, C^{\star}, I^{\star}, C^{\star}_{U}, I^{\star}_{U}$ be as in Definition 13. Suppose $(I^{\star}_{U}, C^{\star}_{U})$ is a* light *pair. Let $C^{\|} = \{v \in C^{\star}_{U} \; ; \; w(I^{\star}_{U} \setminus (N(v) \cap I^{\star}_{U})) \geq \frac{w(I^{\star}_{U})}{4}\}$ be the set of vertices in $C^{\star}_{U}$ which have a "heavy"* non-neighborhood *in $I^{\star}_{U}$, and let $c^{\|}$ be a heaviest vertex in $C^{\|}$. Let $I^{\|} = \{v \in I^{\star}_{U} \; ; \; w(N(v) \cap (C^{\star}_{U} \setminus \{c^{\|}\})) \geq \frac{w(C^{\star}_{U} \setminus \{c^{\|}\})}{4}\}$ be the set of vertices in $I^{\star}_{U}$ which have a "heavy" neighborhood in the subset $C^{\star}_{U} \setminus \{c^{\|}\}$, and let $i^{\|}$ be a heaviest vertex in $I^{\|}$. Let $C^{\ddagger} = \{v \in (C^{\star}_{U} \setminus \{c^{\|}\}) \; ; \; w((I^{\star}_{U} \setminus \{i^{\|}\}) \setminus (N(v) \cap I^{\star}_{U})) \geq \frac{w(I^{\star}_{U} \setminus \{i^{\|}\})}{4}\}$ be the set of vertices in $C^{\star}_{U} \setminus \{c^{\|}\}$ which have a "heavy"* non-neighborhood *in $I^{\star}_{U} \setminus \{i^{\|}\}$, and let $I^{\ddagger} = \{v \in (I^{\star}_{U} \setminus \{i^{\|}\}) \; ; \; w(N(v) \cap (C^{\star}_{U} \setminus \{c^{\|}\})) \geq \frac{w(C^{\star}_{U} \setminus \{c^{\|}\})}{4}\}$ be the set of vertices in $(I^{\star}_{U} \setminus \{i^{\|}\})$ which have a "heavy" neighborhood in $C^{\star}_{U} \setminus \{c^{\|}\}$.*

Then at least one of the following statements is true.

(1a) *Picking a vertex proportionately at random from the set $X \cup (C_X \setminus I^{\star}_{U})$ yields a vertex $v \in C^{\|}$ with probability at least $1/(20(1 + \frac{12}{\varepsilon}))$, or*

(1b) *Picking a vertex proportionately at random from the set $X \cup (C_X \setminus I^{\star}_{U})$ yields a vertex $v \in C^{\ddagger}$ with probability at least $1/(4(1 + \frac{12}{\varepsilon}))$.*

(2a) *Picking a vertex proportionately at random from the set $X \cup (I_X \setminus C^{\star}_{U})$ yields a vertex $v \in I^{\|}$ with probability at least $1/(20(1 + \frac{12}{\varepsilon}))$, or*

(2b) *Picking a vertex proportionately at random from the set $X \cup (I_X \setminus C^{\star}_{U})$ yields a vertex $v \in I^{\ddagger}$ with probability at least $1/(4(1 + \frac{12}{\varepsilon}))$.*

From Lemma 23 and Lemma 24 we get

▶ **Lemma 25.** *Let $(G, w, (C, I, U))$ be a* hard *instance of A-SVD and let $\varepsilon, OPT, C^\star, I^\star, C^\star_U$, $I^\star_U$ be as in Definition 13. Then one of the following statements is true.*

(1a) *Picking a vertex proportionately at random from $X \cup (I_X \setminus C^\star_U)$ yields a vertex from $\{v \in I^\star_U \mid w(N(v) \cap C^\star_U) \geq \frac{w(C^\star_U)}{4}\}$ with probability at least $1/20(1+\frac{12}{\varepsilon})$.*

(1b) *Picking a vertex proportionately at random from $X \cup (I_X \setminus C^\star_U)$ yields a vertex from $\{v \in I^\star_U \mid w(N(v) \cap (C^\star_U \setminus \{c^\star\})) \geq \frac{w(C^\star_U \setminus \{c^\star\})}{4}\}$ with probability at least $1/20(1+\frac{12}{\varepsilon})$, for some vertex $c^\star \in C^\star_U$.*

(2a) *Picking a vertex proportionately at random from $X \cup (C_X \setminus I^\star_U)$ yields a vertex from $\{v \in C^\star_U \mid w(I^\star_U \setminus N(v)) \geq \frac{w(I^\star_U)}{4}\}$ with probability at least $1/20(1+\frac{12}{\varepsilon})$.*

(2b) *Picking a vertex proportionately at random from $X \cup (C_X \setminus I^\star_U)$ yields a vertex from $\{v \in C^\star_U \mid w((I^\star_U \setminus \{i^\star\}) \setminus N(v)) \geq \frac{w(I^\star_U \setminus \{i^\star\})}{4}\}$ with probability at least $1/20(1+\frac{12}{\varepsilon})$, for some vertex $i^\star \in I^\star_U$.*

Proof. From Lemma 4 we get that $(I^\star_U, C^\star_U)$ is either a heavy pair or a light pair. If $(I^\star_U, C^\star_U)$ is a heavy pair then Lemma 23 applies, and at least one of the four options of that lemma holds. Option **(1a)** of Lemma 23 implies option **(1a)** of the current lemma. Option **(1b)** of Lemma 23 implies option **(1b)** of the current lemma. Options **(2a)** and **(2b)** of Lemma 23 both imply option **(2b)** of the current lemma.

If $(I^\star_U, C^\star_U)$ is a light pair then Lemma 24 applies, and at least one of the four options of that lemma holds. Option **(1a)** of Lemma 24 implies option **(2a)** of the current lemma. Option **(1b)** of Lemma 24 implies option **(2b)** of the current lemma. Options **(2a)** and **(2b)** of Lemma 24 both imply option **(1b)** of the current lemma.

Thus in every case, one of the four options of the current lemma holds. ◀

▶ **Lemma 26 (♣).** *Let $(G, w, (C, I, U))$ be a* hard *instance of A-SVD and let $\varepsilon, OPT, C^\star, I^\star$, $C^\star_U, I^\star_U$ be as in Definition 13.*

1. *There is a randomized polynomial-time algorithm which, given $(G, w, (C, I, U))$ as input, picks a vertex proportionately at random from the set $X \cup (I_X \setminus C^\star_U)$ with probability at least $\frac{1}{2}$. That is, the algorithm runs in polynomial time and outputs a vertex v, and the following hold with probability at least $\frac{1}{2}$: (i) $v \in X \cup (I_X \setminus C^\star_U)$, and (ii) for any $x \in (X \cup (I_X \setminus C^\star_U))$, $Pr[v = x] = w(x)/w(X \cup (I_X \setminus C^\star_U))$.*
2. *There is a randomized polynomial-time algorithm which, given $(G, w, (C, I, U))$ as input, picks a vertex proportionately at random from the set $X \cup (C_X \setminus I^\star_U)$ with probability at least $\frac{1}{2}$. That is, the algorithm runs in polynomial time and outputs a vertex v, and the following hold with probability at least $\frac{1}{2}$: (i) $v \in X \cup (C_X \setminus I^\star_U)$, and (ii) for any $x \in (X \cup (C_X \setminus I^\star_U))$, $Pr[v = x] = w(x)/w(X \cup (C_X \setminus I^\star_U))$.*

3.1 Polynomially Bounded Weights

Let us first consider instances (G, w) of SVD which have polynomially bounded weights. Let $n = |V(G)|$. Recall that $w(v) \geq 1$ holds for each vertex v of G. We say that the weight function w is *polynomially bounded* if, in addition, $\sum_{v \in V(G)} w(v) \leq c_1 n^{c_0}$ holds for every $v \in V(G)$ and some constants c_0, c_1. For such instances we have the following theorem.

▶ **Theorem 27.** *There exists a randomized algorithm that given a graph G, a polynomially bounded weight function w on $V(G)$ and $\varepsilon > 0$, runs in time $\mathcal{O}(n^{f(\varepsilon)})$ and outputs $S \subseteq V(G)$ such that $G - S$ is a split graph and $w(S) \leq (2+\varepsilon)w(OPT)$ with probability at least $1/2$, where OPT is a minimum weight split vertex deletion set of G. Here, $f(\varepsilon) = 6 + \log(80(1 + \frac{12}{\varepsilon})) \cdot 4c_0 \log(c_1)/\log(4/3)$, where c_0, c_1 are constants such that $w(V(G)) \leq c_1 \cdot n^{c_0}$.*

Algorithm 1 Approximation algorithm for the case of polynomially bounded weights.

```
  Input: An instance $(G, w, (C, I, U))$ of A-SVD, a tuples $(\beta_1^C, \beta_2^C, \beta_1^I, \beta_2^I)$ and $\varepsilon > 0$.
  Output: A $(2+\varepsilon)$-factor approximate solution to $(G, w, (C, I, U))$.
procedure ASVD-Approx($(G, w, (C, I, U)), \varepsilon, \beta_1^C, \beta_2^C, \beta_1^I, \beta_2^I$)

    return $S$
end procedure
```

Proof. Let us fix an optimum solution OPT to (G, w). We treat the instance (G, w) of SVD as an instance $(G, w, (C = \emptyset, I = \emptyset, U = V(G)))$ of A-SVD, and apply Algorithm 1 to it, along with the given value of ε and four integers $\beta_1^C, \beta_2^C, \beta_1^I, \beta_2^I$ each set to $\lceil \log_{4/3}(w(V(G)))\rceil$. Note that, as w is polynomially bounded, we have $w(V(G)) \leq c_1 n^{c_0}$ for some constants c_0, c_1, and hence $\beta' \leq c_2 \log(n)$ for every $\beta' \in \{\beta_1^C, \beta_2^C, \beta_1^I, \beta_2^I\}$ where c_2 is a constant. We will show that the value $\beta = 1 + \beta_1^C + \beta_2^C + \beta_1^I + \beta_2^I \leq 1 + 4c_2 \log(n)$ is an upper-bound on the depth of the recursion tree of Algorithm 1, and that in each recursive call this value drops by 1. Hence the depth of recursion is bounded by β. Each recursive call is made on more constrained sub-instances of A-SVD where the underlying graph G, weight function w, and the value of ε remain fixed. When one of $\{\beta_1^C, \beta_2^C, \beta_1^I, \beta_2^I\}$ falls to -1, we argue that the current instance must be an easy instance (see Definition 20), assuming all the recursive calls leading the current call were "good" (as defined below). During its run the algorithm also computes a 5-approximate solution X to $(G[U], w)$ using Theorem 6; let (I_X, C_X) be a fixed split partition of $G[U] - X$. We have a split partition $(C^\star, I^\star)$ of $G - OPT$ and we define $I_U^\star = I^\star \cap U, C_U^\star = C^\star \cap U$. These sets, introduced in Definition 13, play an important role in Algorithm 1 and its analysis.

To argue the correctness of Algorithm 1, we require the following definition. An invocation ASVD-Approx$(G, w, (C, I, U), \varepsilon, \beta_1^C, \beta_2^C, \beta_1^I, \beta_2^I)$ is *good* if the following conditions are true:

- $\beta_1^C \geq \log_{4/3}(w(C_U^\star))$,
- $\beta_2^C \geq \log_{4/3}(w(C_U^\star \setminus \{c\}))$ for some $c \in C_U^\star$,
- $\beta_1^I \geq \log_{4/3}(w(I_U^\star))$, and
- $\beta_2^I \geq \log_{4/3}(w(I_U^\star \setminus \{i\}))$ for some $i \in I_U^\star$.

Note that the definitions of $C_U^\star$ and $I_U^\star$ depend only on $(G, w, (C, I, U))$ and on the optimum solution OPT that was fixed at the beginning. These sets are hypothetical and unknown, and we can't directly test if an invocation of Algorithm 1 is a good invocation. However, observe that in the initial call, $U = V(G)$ and we set each of $\beta_1^C, \beta_2^C, \beta_1^I, \beta_2^I$ to $\lceil \log_{4/3}(w(V(G))) \rceil$, and hence the initial invocation is good. We will argue that if the current invocation is good and the instance of A-SVD is a hard instance (see Definition 20), then each recursive call made by the algorithm is good with a constant probability (which depends on ε). Then (via an induction) we argue that a good recursive call will return a $(2+\varepsilon)$-approximate solution with probability at least $\frac{1}{2}$, and hence with constant probability we obtain a $(2+\varepsilon)$-approximate solution from a recursive call. To boost the probability of success to $\frac{1}{2}$, we need to repeat this process constantly many times, so we make constantly many recursive calls. Finally, to bound the running time, we argue that the depth of the recursion tree is bounded by $\beta = \mathcal{O}(\log n)$, and we make constantly many recursive calls in each invocation of the algorithm. So the total number of calls made to this algorithm, which is upper-bounded by the size of the recursion tree, is $n^{\mathcal{O}(1)}$. This means that in polynomial time, with probability at least 1/2, we obtain a $(2+\varepsilon)$-approximate solution to (G, w). Let us now present these arguments formally.

Let us recall the optimum solution OPT to (G, w) that was fixed at the beginning. We say that an instance $(G, w, (C, I, U))$ is a *nice instance* if the solution OPT is also an optimum solution to this A-SVD instance. This means that a split partition $(C^\star, I^\star)$ of $G - OPT$ satisfies, $C^\star \cap I = \emptyset$ and $I^\star \cap C = \emptyset$. Note that this condition is trivially satisfied at the beginning for the starting instance $(G, w, (C = \emptyset, I = \emptyset, U = V(G))$. Let us consider an invocation of Algorithm 1 on a nice instance of $(G, w, (C, I, U))$ with polynomially bounded weight function w and $\beta_1^C, \beta_2^C, \beta_1^I, \beta_2^I$ such that it is a good invocation. Let S denote the solution returned by it. We will show that S is a $(2+\varepsilon)$-approximate solution with probability at least $\frac{1}{2}$, by an induction on $|U|$. Suppose that $|U| = 0$, i.e. $U = \emptyset$. Then Lemma 12 ensures that S is a 2-approximate solution. This forms the base case of our induction on $|U|$.

Now suppose that $|U| > 0$, and we have two cases depending on whether $(G, w, (C, I, U))$ is an easy instance or not. If it is an easy instance, then either the premise of Lemma 16 or the premise of Lemma 18 holds. Hence, one of $S_{12}, S_{34}, S^\dagger, S^\ddagger$ is a $(2+\varepsilon)$-approximation to $(G, w, (C, I, U))$. Moreover, we claim that if any one of $\beta_1^C, \beta_2^C, \beta_1^I, \beta_2^I$ drops to -1, then the instance $(G, w, (C, I, U))$ is an easy instance. Consider the case when $\beta_2^C = -1$. Then $\log_{4/3}(w(C_U^\star \setminus \{c\})) = -1$ for some $c \in C_U^\star$. This means $w(C_U^\star \setminus \{c\}) < 3/4$, and since $w(v) \geq 1$ for every $v \in V(G)$, it must be the case that $C_U^\star = \{c\}$. Hence, the premise of Lemma 18 holds and we obtain a $(2+\varepsilon)$-approximate solution for $(G, w, (C, I, U))$. Similar arguments apply to the other cases, i.e. when $\beta_1^C = -1$, or $\beta_1^I = -1$ or $\beta_2^I = -1$, and we can obtain a $(2+\varepsilon)$-approximation in all these cases. Therefore, in all these cases S is a $(2+\varepsilon)$-approximation to $(G, w, (C, I, U))$.

Now, consider the case when the given instance is a hard instance, i.e. $U \neq \emptyset$ and the premises of Lemma 16 and Lemma 18 don't hold. In this case $\beta_1^C, \beta_2^C, \beta_1^I, \beta_2^I \geq 0$. Recall that X is a 5-approximate solution to SVD in the subgraph $G[U]$, and hence $w(X) \leq 5 \cdot w(OPT)$. We will make recursive calls on instances of A-SVD of the form $(G, w, (C', I', U'))$ such that $C \subseteq C', I \subseteq I'$ and $U' \subsetneq U$. Suppose that $(G, w, (C', I', U'))$ is a nice instance. Then by the induction hypothesis, as $|U'| < |U|$, we can assume that Algorithm 1 returns a $(2+\varepsilon)$-approximate solution $\widehat{S}$ to this instance with probability at least 1/2. This is an approximate solution to the current instance as well:

▷ Claim 28. $\widehat{S}$ is a $(2+\varepsilon)$-approximate solution to $(G, w, (C, I, U))$

Proof. Observe that, since $\widehat{S}$ is feasible solution to the nice instance $(G, w, (C', I', U'))$, there is a split partition $(C_{\widehat{S}}, I_{\widehat{S}})$ of $G - \widehat{S}$ such that $C' \cap I_{\widehat{S}} = \emptyset$ and $I' \cap C_{\widehat{S}} = \emptyset$. Therefore, we have $C \cap I_{\widehat{S}} = \emptyset$ and $I \cap C_{\widehat{S}} = \emptyset$, i.e. $\widehat{S}$ is a feasible solution to $(G, w, (C, I, U))$. Since $w(\widehat{S}) \leq (2+\varepsilon)w(OPT)$, the claim is true. ◁

Let us now consider the recursive calls made by the algorithm for each $j \in \{1, 2, \ldots, b(\varepsilon) = \lceil 80(1 + \frac{12}{\varepsilon})\rceil\}$, and argue that with a constant probability (depending on ε) we can obtain a $(2+\varepsilon)$-approximation to the given instance. In each recursive call, one of $\beta_1^C, \beta_2^C, \beta_1^I, \beta_2^I$ drops by exactly 1. Let us fix $j \in \{1, 2, \ldots, b(\varepsilon)\}$ and consider the two vertices v_I, v_C sampled using Lemma 26. Since $(G, w, (C, I, U))$ is a hard instance, the following hold.

- With probability at least 1/2, $v_I \in X \cup (I_X \setminus C_U^\star)$, and for any $x \in (X \cup (I_X \setminus C_U^\star))$, $Pr[v_I = x] = w(x)/w(X \cup (I_X \setminus C_U^\star))$.
- With probability at least 1/2, $v_C \in X \cup (C_X \setminus I_U^\star)$, and for any $x \in (X \cup (C_X \setminus I_U^\star))$, $Pr[v_C = x] = w(x)/w(X \cup (C_X \setminus I_U^\star))$.

By the induction hypothesis, any good invocation ASVD-Approx$(G, w, (C', I', U'), \varepsilon, \widehat{\beta_1^C}, \widehat{\beta_2^C}, \widehat{\beta_1^I}, \widehat{\beta_2^I})$ where $(G, w, (C', I', U'))$ is a nice instance and $|U'| < |U|$ holds, returns a $(2+\varepsilon)$-approximate solution to $(G, w, (C', I', U'))$ with probability at least $\frac{1}{2}$. We now have four cases, depending on which of the four statements in Lemma 25 is true for $(G, w, (C, I, U))$. In each case we will argue that with constant probability, we make a good recursive call on a nice instance and obtain a $(2+\varepsilon)$-approximate solution from it.

(i) Suppose that statement (1a) of Lemma 25 is true. That is, picking a vertex proportionally at random from $X \cup (I_X \setminus C_U^\star)$ yields a vertex from $\{v \in I_U^\star \mid w(N(v) \cap C_U^\star) \geq \frac{w(C_U^\star)}{4}\}$ with probability at least $1/20(1+\frac{12}{\varepsilon})$. Then $v_I \in \{v \in I_U^\star \mid w(N(v) \cap C_U^\star) \geq \frac{w(C_U^\star)}{4}\}$ with probability at least $1/40(1+\frac{12}{\varepsilon})$. As $v_I \in I_U^\star$, every vertex in $Z_C = N(v_I) \cap U$ must either be in OPT_U or in $C_U^\star$. Furthermore, $w(Z_C \cap C_U^\star) \geq \frac{w(C_U^\star)}{4}$. Let $U' = U \setminus Z_C$, $C' = C \cup Z_C$ and consider the invocation ASVD-Approx$(G, w, (C', I, U'), \varepsilon, \beta_1^C - 1, \beta_2^C, \beta_1^I, \beta_2^I)$. Let us argue that it is a good invocation. By definition $C_{U'}^\star = C^\star \cap U'$ satisfies $w(C_{U'}^\star) \leq \frac{3}{4} w(C_U^\star)$. Therefore, as $\beta_1^C \geq \log_{4/3}(w(C_U^\star))$, we have $\beta_1^C - 1 \geq \log_{4/3}(w(C_{U'}^\star))$. Furthermore, observe that $\beta_C^2 \geq \log_{4/3}(w(C_{U'}^\star \setminus \{c^\star\}))$, and I, β_1^I, β_2^I remain unchanged. Hence, assuming that the current invocation is good, this invocation is also good. Let us argue that $(G, w, (C', I, U'))$ is a nice instance, i.e. OPT is an optimum solution to it. Towards this, recall that $C' = C \cup Z_C$ where $Z_C = N(v_I) \cap U$ and $v_I \in I_U^\star \subseteq I^\star$. Hence, every vertex in Z_C is either in OPT or in $C^\star$, i.e. $Z_C \cap I^\star = \emptyset$. Since OPT is feasible for $(G, w, (C, I, U))$ we have that $C \cap I^\star = \emptyset$. Therefore, $C' \cap I^\star = (C \cup Z_C) \cap I^\star = \emptyset$, and hence OPT is a feasible solution for $(G, w, (C', I, U'))$. Finally, as any feasible solution for $(G, w, (C', I, U'))$ is also feasible for (G, w), OPT is an optimum solution for $(G, w, (C', I, U'))$. Now $|U'| < |U|$, and by the induction hypothesis, this invocation returns a solution $S^C_{j,1}$ to $(G, w, (C', I, U'))$ with probability at least 1/2. By Claim 28, $S^C_{1,j}$ is a $(2+\varepsilon)$-approximate solution to $(G, w, (C, I, U))$. Hence, we obtain a solution $S^C_{1,j}$ that is a $(2+\varepsilon)$-approximation to $(G, w, (C, I, U))$, and this event happens with probability at least $1/80(1+\frac{12}{\varepsilon})$. Note that β^C_1 drops by 1 in the recursive call .

(ii) Suppose that statement (1b) of Lemma 25 is true. That is, picking a vertex proportionately at random from $X \cup (I_X \setminus C^\star_U)$ yields a vertex from $\{v \in I^\star_U \mid w(N(v) \cap (C^\star_U \setminus \{c^\star\})) \geq \frac{w(C^\star_U)\setminus\{c^\star\}}{4}\}$ with probability at least $1/20(1+\frac{12}{\varepsilon})$, for some vertex $c^\star \in C^\star_U$ (as determined by Lemma 25). Then, with probability at least $1/40(1+\frac{12}{\varepsilon})$, $v_I \in \{v \in I^\star_U \mid w(N(v) \cap (C^\star_U \setminus \{c^\star\})) \geq \frac{w(C^\star_U)\setminus\{c^\star\}}{4}\}$. As $v_I \in I^\star_U$, every vertex in $Z_C = N(v_I) \cap U$ must either be in OPT or in $C^\star_U$. Let $C' = C \cup Z_C, U' = U \setminus Z_C$ and consider the invocation ASVD-Approx$(G, w, (C', I, U'), \varepsilon, \beta^C_1, \beta^C_2 - 1, \beta^I_1, \beta^I_2)$. Let us argue that it is a good invocation. Let $\widehat{C} = (C^\star_U \setminus \{c^\star\}) \setminus N(v_I)$ and $C^\star_{U'} = C^\star \cap U'$, and note that either $C^\star_{U'} = \widehat{C}$ or $C^\star_{U'} = \widehat{C} \cup \{c^\star\}$. Since $w(\widehat{C}) \leq \frac{3}{4}w(C^\star_U \setminus \{c^\star\})$ by the choice of v_I, we have $\log_{4/3}(w(\widehat{C})) \leq \log_{4/3}(w(C^\star_U \setminus \{c^\star\}) - 1 \leq \beta^C_2 - 1$. Therefore, if $C^\star_{U'} = \widehat{C}$, then for any arbitrary $c' \in C^\star_{U'}$ we have $\beta^C_2 - 1 \geq \log_{4/3}(w(C^\star_{U'} \setminus \{c'\}))$; otherwise $C^\star_{U'} = \widehat{C} \cup \{c^\star\}$, and $\beta^C_2 - 1 \geq \log_{4/3}(w(C^\star_{U'} \setminus \{c^\star\}))$. Furthermore, observe that β^C_1 is unchanged and $C^\star_{U'} \subseteq C^\star_U$, we have $\log_{4/3}(w(C^\star_{U'})) \leq \beta^C_1$. Similarly, I, β^I_1, β^I_2 are also unchanged. Hence, this invocation is good. Next, as in the previous case, we can argue that $(G, w, (C', I, U')$ is a nice instance. Then, as $|U'| < |U|$, by the induction hypothesis the invocation returns a $(2+\varepsilon)$-approximate solution $S^C_{j,2}$ to $(G, w, (C', I, U'))$ with probability at least 1/2. By Claim 28, $S^C_{j,2}$ is a $(2+\varepsilon)$-approximate solution to $(G, w, (C, I, U))$. Hence, we obtain a solution $S^C_{j,2}$ that is a $(2+\varepsilon)$-approximation to $(G, w, (C, I, U))$, and this event happens with probability at least $1/80(1+\frac{12}{\varepsilon})$. Note that β^C_2 drops by 1 in recursive call made here.

(iii) Suppose that statement (2a) of Lemma 25 is true. This case is symmetric to Case-(i), above, where the arguments are made with respect to $v_C \in X \cup (C_X \setminus I^\star_U)$. Here $v_C \in \{v \in C^\star_U \mid w(I^\star_U \setminus N(v)) \geq \frac{w(I^\star_U)}{4}\}$ with probability at least $1/40(1+\frac{12}{\varepsilon})$. We consider the instance $(G, w, (C, I', U'))$ where $Z_I = U \setminus N(v_C)$, $I' = I \cup Z_I$ and $U' = U \setminus Z_I$. We can argue that this invocation is good and the instance $(G, w, (C, I', U'))$ is nice. Then, as $|U'| \leq |U|$, by the induction hypothesis, this invocation returns a $(2+\varepsilon)$-approximate solution to $(G, w, (C, I', U'))$ with probability at least 1/2. Let $S^I_{j,1}$ denote this solution, and we argue that it is also a $(2+\varepsilon)$-approximate solution to $(G, w, (C, I, U))$. In conclusion, we obtain a solution $S^I_{j,1}$ that is a $(2+\varepsilon)$-approximation to $(G, w, (C, I, U))$, and this event happens with probability at least $1/80(1+\frac{12}{\varepsilon})$. Note that β^I_1 drops by 1 in recursive call made here.

(iv) Suppose that statement (2b) of Lemma 25 is true. This case is symmetric to Case-(ii) above. Here we have a vertex $v_C \in \{v \in C^\star_U \mid w(I^\star_U \setminus N(v)) \geq \frac{w(I^\star_U)}{4}\}$ with probability at least $1/40(1+\frac{12}{\varepsilon})$. We make a recursive call ASVD-Approx$(G, w, (C, I', U'), \varepsilon, \beta^C_1, \beta^C_2, \beta^I_1, \beta^I_2 - 1)$, where $I' = I \cup Z_I$, $U' = U \setminus Z_I$ and $Z_I = U \setminus N(v_C)$. Here, we obtain a solution $S^I_{j,2}$ that is a $(2+\varepsilon)$-approximation to $(G, w, (C, I, U))$, and this event happens with probability at least $1/80(1+\frac{12}{\varepsilon})$. Note that β^I_2 drops by 1 in recursive call made here.

Therefore, if $(G, w, (C, I, U))$ is a hard instance, then for each $j \in \{1, 2, \ldots, b(\varepsilon)\}$, one of $S^C_{j,1}, S^C_{j,2}, S^I_{j,1}, S^I_{j,2}$ is a $(2+\varepsilon)$-approximate solution to it with probability at least $1/80(1+\frac{12}{\varepsilon})$. Note that the recursive calls made for any two distinct $j, j' \in \{1, 2, \ldots, b(\varepsilon)\}$ are independent events. Therefore, by setting $b(\varepsilon) = \lceil 80(1+\frac{12}{\varepsilon})\rceil$, we obtain that with probability at least $1/2$ there exists $j \in \{1,2,\ldots,b(\varepsilon)\}$ such that one of $S^C_{j,1}, S^C_{j,2}, S^I_{j,1}, S^I_{j,2}$ is a $(2+\varepsilon)$-approximate solution to $(G,w,(C,I,U))$.

Finally, let us bound the running time of this algorithm. Towards this, we must bound the total number of calls made to Algorithm 1, when run on an instance (G,w) with polynomially bounded weights. Observe that, we start with an instance $(G,w,(C=\emptyset, I=\emptyset, U=V(G)))$ of A-SVD along with $\beta^C_1, \beta^C_2, \beta^I_1, \beta^I_2$ set to $\lceil \log_{4/3}(w(V(G))\rceil = c_2\log(n)$ for some constant c_2. Then, for each instance $(G,w,(C,I,U))$, we make $b(\varepsilon)$ recursive calls and at least one of $\beta^C_1, \beta^C_2, \beta^I_1, \beta^I_2$ drops by 1 in each of these calls. Additionally U drops to a strict subset in each of these calls. Hence in a finite number of steps, either U becomes empty, or one of $\beta^C_1, \beta^C_2, \beta^I_1, \beta^I_2$ becomes equal to -1, and we reach an easy instance. Observe that this must happen at some point before the depth of recursion exceeds $\beta = 1+4c_2\log(n)$. Hence, the number of recursive calls made for the instance (G,w) is upper bounded by $b(\varepsilon)^\beta = \mathcal{O}(n^{h(\varepsilon)})$ where $h(\varepsilon) = \log(80(1+\frac{12}{\varepsilon}))\cdot 4c_0\log(c_1)/\log(4/3)$. Recall that c_0, c_1 are constants such that $w(V(G)) \leq c_1 \cdot n^{c_0}$. Observe that in each recursive call, we spend $O(n^6)$ time (excluding the recursive calls). Hence the total running time is upper-bounded by $n^{f(\varepsilon)}$ where $f(\varepsilon) = 6+\log(80(1+\frac{12}{\varepsilon}))\cdot 4c_0\log(c_1)/\log(4/3)$. Alternatively, this bound on the running time can be obtained from the Master Theorem. ◀

3.2 General Weight Functions

In this section, we extend Theorem 27 to instances of SVD with general weight function. In particular we show that given an instance with general weights, we can construct an instance with polynomially-bounded weights such that an approximate solution to the new instance can be lifted back to the original instance.

▶ **Lemma 29** (♣). *Let (G,w) be an instance of SVD, and $\varepsilon > 0$ be a constant. Then we can construct another instance (G',w') of SVD such that G' is a subgraph of G and given any α-approximate solution to (G',w') where $\alpha \leq 5$, we can obtain an $(\alpha+\varepsilon)$-approximate solution to (G,w). Moreover, the weight function w' is polynomially bounded, and $w'(V(G')) \leq \frac{30n^2}{\varepsilon}$.*

We have the following corollary of Theorem 27 and Lemma 29.

▶ **Theorem 30.** *There exists a randomized algorithm that given a graph G, a weight function w on $V(G)$ and $\varepsilon > 0$, runs in time $\mathcal{O}(n^{g(\varepsilon)})$ and outputs $S \subseteq V(G)$ such that $G-S$ is a split graph and $w(S) \leq 2(1+\varepsilon)w(OPT)$ with probability at least $1/2$, where OPT is a minimum weight split vertex deletion set of G. Here, $g(\varepsilon) = 6+8\log(80(1+\frac{12}{\varepsilon}))\cdot\log(\frac{30}{\varepsilon})/\log(4/3)$.*

Proof. Given the instance (G,w) and ε, we apply Lemma 29 and obtain an instance (G',w'), where $w'(V(G')) \leq \frac{30n^2}{\varepsilon}$. We then apply Theorem 27 to (G',w') and ε and obtain a solution S' to it. This algorithm runs in time $|V(G')|^{g(\varepsilon)} \leq n^{g(\varepsilon}$, where $g(\varepsilon) = 6+8\log(80(1+\frac{12}{\varepsilon}))\cdot\log(\frac{30}{\varepsilon})/\log(4/3)$, and with probability at least $1/2$ S' is a $(2+\varepsilon)$-approximate solution to (G',w'). Then by Lemma 29, S' can be lifted to a $2(1+\varepsilon)$-approximate solution S to (G,w). ◀

4 Conclusion

One of the natural open question is to obtain a polynomial time 2-approximation algorithm for SVD and match the lower bound obtained under UGC. It will be interesting to find other implicit d-Hitting Set problems and find its correct "approximation complexity". Towards this we restate the conjecture of Fiorini et al. [5] about a concrete implicit 3-Hitting Set problem: there is a 2-approximation algorithm for Cluster Vertex Deletion matching the lower bound under UCG.

Abstract

In the Single Source Replacement Paths (SSRP) problem we are given a graph $G = (V, E)$, and a shortest paths tree $\widehat{K}$ rooted at a node s, and the goal is to output for every node $t \in V$ and for every edge e in $\widehat{K}$ the length of the shortest path from s to t avoiding e.

We present an $\tilde{O}(m\sqrt{n} + n^2)$ time randomized combinatorial algorithm for unweighted directed graphs[1]. Previously such a bound was known in the directed case only for the seemingly easier problem of replacement path where both the source and the target nodes are fixed.

Our new upper bound for this problem matches the existing conditional combinatorial lower bounds. Hence, (assuming these conditional lower bounds) our result is essentially optimal and completes the picture of the SSRP problem in the combinatorial setting.

Our algorithm naturally extends to the case of small, rational edge weights. In the full version of the paper, we strengthen the existing conditional lower bounds in this case by showing that any $O(mn^{1/2-\epsilon})$ time (combinatorial or algebraic) algorithm for some fixed $\epsilon > 0$ yields a truly sub-cubic algorithm for the weighted All Pairs Shortest Paths problem (previously such a bound was known only for the combinatorial setting).

1 Introduction

In the replacement paths (RP) problem, we are given a graph G and a shortest path P between two vertices s and t and the goal is to return for every edge e in P the length $d(s, t, G - e)$, where $G - e$ is the graph obtained by removing the edge e from G, and $d(s, t, G - e)$ is the distance between s and t in the resulted graph. In some cases the goal is to provide the shortest path itself and not only its length. The interest in replacement path problems stems from the fact that failures and changes in real world networks are inevitable, and in many cases we would like to have a solution or a data structure that can

[1] As usual, n is the number of vertices, m is the number of edges and the $\tilde{O}$ notation suppresses poly-logarithmic factors.

adapt to these failures. The replacement paths problem is a notable example where we would like to have backup paths between two distinguished vertices in the event of edge failures. The replacement paths problem is also very well motivated as it is used as an important ingredient in other applications such as the Vickrey pricing of edges owned by selfish agents from auction theory [14, 6]. Another application of the replacement path problem is finding the k shortest simple paths between a pair of vertices. The k shortest simple paths problem can be solved by invoking the replacement paths algorithm k times and adding a very small weight to the path found in each invocation. The k shortest simple paths problem has many applications by itself [4]. The replacement paths problem has been extensively studied and the literature covers many aspects of this problem with many near optimal solutions in many of the cases (see e.g. [11, 13, 12, 15, 3, 9, 19, 16, 2]).

In this paper we consider a natural and important generalization of the replacement paths problem, referred to as the single source replacement paths (SSRP) problem, which is defined as follows. Given a graph G and a shortest paths tree $\widehat{K}$ rooted at a node s, the SSRP problem is to compute the values of $d(s, t, G - e)$ for every vertex $t \in V(G)$ and for every edge $e \in E(\widehat{K})$. Note that as the number of edges in $\widehat{K}$ is $n - 1$, there are $O(n^2)$ different distances we need to evaluate. It follows that the size of the SSRP output is $O(n^2)$.

Despite of its natural flavor, the picture of the SSRP problem is not yet complete in many of the cases. To the best of our knowledge the first paper that considered the SSRP problem is by Hershberger et al. [7] who referred to the problem as edge-replacement shortest paths trees and showed that in the path-comparison model of computation of Karger et al. [8], there is a lower bound of $\Omega(mn)$ comparisons in order to solve the SSRP problem for arbitrarily weighted directed graphs.

For the directed weighted case it was shown by Vassilevska Williams and Williams [18] that any truly sub-cubic algorithm for the simpler problem of RP in **directed**, arbitrarily weighted graph admits a truly sub-cubic algorithm for the arbitrarily weighted All Pairs Shortest Paths (APSP) problem. The conditional lower bound from [18] holds only for the directed case, and quite interestingly for the undirected arbitrarily weighted case, the classical RP problem admits a near linear time algorithm [11, 13, 12]. However, the SSRP problem in undirected graphs appears to be much harder than the RP problem. In [2] it was shown by Chechik and Cohen that any truly sub-cubic solution for the SSRP problem in **undirected** arbitrarily weighted graphs, admits a truly sub-cubic algorithm for the arbitrarily weighted APSP problem. Therefore, it seems there is no hope to solve the SSRP problem in weighted graphs, both in the directed and undirected case. Meaning that if we seek for truly sub-cubic algorithms for the SSRP problem we must either consider unweighted graphs or restrict the edge weights in some other way.

One way to restrict the weights is to consider only bounded **integer** edge weights. This restriction was considered by Grandoni and Vassilevska Williams [5], who were also the ones to name this problem the single source replacement paths problem. Grandoni and Vassilevska Williams [5] gave the first non trivial upper bound for the SSRP problem. They showed that one can bypass the cubic lower bounds by using fast matrix multiplications and by restricting the weights to be integers in a bounded range. More precisely, they showed that for graphs with positive integer edge weights in the range $[1, M]$, SSRP can be computed in $\tilde{O}(Mn^{\omega})$ time (here $\omega < 2.373$ is the matrix multiplication exponent [17, 10]). This matches the current best known bound for the simpler problem of RP for directed graph with weights $[-M, M]$, by Vassilevska Williams [16]. Quite interestingly, for integer edge weights in the range $[-M, M]$, the authors of [5] gave a higher upper bound of $\tilde{O}(M^{\frac{1}{4-\omega}} n^{2+\frac{1}{4-\omega}})$ time, which creates an interesting gap between the SSRP problem and the RP problem for negative integer weights. Grandoni and Vassilevska Williams [5] conjectured that the gap between these two problems is essential and in fact they conjectured that the SSRP problem with negative weights is as hard as the directed APSP problem.

The algorithm described in [5] uses fast matrix multiplication tricks in order to break the trivial cubic upper bound, such algorithms are known as "algebraic algorithms". Algorithms that do not use any matrix multiplication tricks are known as "combinatorial algorithms". The interest in combinatorial algorithms mainly stems from the assumption that in practice combinatorial algorithms are much more efficient since the constants and sub-polynomial factors hidden in the matrix multiplication bounds are considered to be very high.

The SSRP problem was also recently considered in the combinatorial setting by Chechik and Cohen in [2] for undirected unweighted graphs. Specifically, Chechik and Cohen in [2] gave an $\tilde{O}(m\sqrt{n}+n^2)$ time randomized algorithm for SSRP in undirected unweighted graphs. Moreover, using conditional lower bounds Chechik and Cohen also showed that under some reasonable assumptions any combinatorial algorithm for the SSRP problem in unweighted undirected graphs requires $\tilde{\Omega}(m\sqrt{n})$ time.

Since there is little hope to solve the weighted case, the only missing piece in the picture of combinatorial SSRP is the case of directed unweighted graphs.

For the directed unweighted case it was shown earlier by Vassilevska Williams and Williams [18], using a conditional combinatorial lower bound that under some reasonable assumptions any combinatorial algorithm for the directed unweighted RP (and hence SSRP) problem requires $\tilde{\Omega}(m\sqrt{n})$ time. For the seemingly easier problem of replacement paths Roditty and Zwick [15] showed a near optimal solution of $\tilde{O}(m\sqrt{n})$ time for directed unweighted graphs.

Note that in the undirected unweighted case there is an essential gap between the RP and the SSRP problems. A natural question is whether such a gap also exists in the directed unweighted case. In this paper we show that this is not the case by providing a combinatorial near optimal $\tilde{O}(m\sqrt{n}+n^2)$ time algorithm for the case of directed unweighted graphs, which up to the n^2 factor (that is unavoidable as the output itself is of size $O(n^2)$) matches the running time of the algorithm in [15] (and also matches the running time of the undirected case in [2]). We therefore (up to poly-logarithmic factors) complete the picture of combinatorial SSRP.

Our main result is as follows.

▶ **Theorem 1.1.** *There exists an $\tilde{O}(m\sqrt{n}+n^2)$ time combinatorial algorithm for the SSRP problem on unweighted directed graphs. Our randomized algorithm is Monte Carlo with a one-sided error, as we always output distances which are at least the exact distances, and with high probability (of at least $1-n^{-C}$ for any constant $C>0$) we output the exact distance.*

Note that for unweighted directed graphs where $m=\tilde{O}(n^{1.5})$ our algorithm runs in $\tilde{O}(n^2)$ time, which is the time it takes just to output the result. Namely, in this range of density our algorithm surpasses the current best algebraic SSRP algorithm [5] (which has a running time complexity of $\tilde{O}(n^\omega)$) as long as $\omega>2$.

We will note that while we focus on the case of edge failures, in the directed case there is a well known reduction showing that edge failures can be used to simulate vertex failures. The reduction is as follows, replace every vertex v with two vertices v_{in} and v_{out}, and connect them by a direct edge $(v_{\text{in}}, v_{\text{out}})$. Then, for every incoming edge (u,v) add the edge (u, v_{in}), and for every outgoing edge (v,u) add the edge (v_{out}, u). The failure of the vertex v is now simulated by the failure of the edge $(v_{\text{in}}, v_{\text{out}})$.

Our main novelty is in the introduction of a tool which we refer to as *weight functions*. This tool proved to be very useful in order to apply a divide and conquer approach and could perhaps be utilized in other related problems.

1.1 Rational Weights

While we describe an algorithm for the problem of SSRP in unweighted graphs, our algorithm (much like the directed RP algorithm [15]) can be easily generalized to solve the case of weighted graphs for **rational** edge weights in the range $[1, C]$, for every constant $C \geq 1$, in the same time complexity. This is because the only place our algorithm (and the algorithm from [15]) uses the fact that the graph is unweighted is in the claim that a path of length l contains $\Theta(l)$ vertices, which is used in order to utilize sampling techniques. As this is also true for rational weights in the range $[1, C]$, our algorithm generalizes for this case trivially.

Algebraic algorithms inherently can not perform on graphs with rational weights. This is since algebraic algorithms use a reduction from a problem known as min-plus product [2] to the problem of matrix product, and this reduction works only for **integer** weights. Since in some use-cases (like the k-simple paths problem) it is very useful to have rational weights, this shows another potential interest in combinatorial algorithms.

We note that in order to store **rational** numbers, we must make some common assumptions regarding the model of computation. More specifically, we assume that computing the summation of n edge weights can be performed in $\tilde{O}(n)$ time and that all numbers we are dealing with can be stored in one (or $O(1)$) space unit. A realistic option is working in a word-RAM model, and considering only rational edge weights which are of the form $\frac{m}{2^k}$, where the two integers m and 2^k fit in the size of $O(1)$ computer words. This way, the summation of $O(n)$ numbers also fits in $O(1)$ computer words. This way of representing rational numbers is reminiscent of the floating-point representation, that is commonly used in practical applications.

In Section 7 in the full version of this paper, we show that any algorithm (combinatorial or not) for the SSRP problem for graphs with rational edge weights from the range $[1, 2)$, that runs in $O(mn^{1/2-\epsilon})$ time for any fixed $\epsilon > 0$ implies a truly sub-cubic algorithm for APSP over graphs with arbitrary integer weights. The claim is formally stated in Theorem 7.1. Previously such a conditional lower bound was only known for combinatorial algorithms using a reduction from Boolean Matrix Multiplication (see [2]).

2 Preliminaries

We will use the following notation: $\mathbb{N} = \{0, 1, 2, ...\}, \mathbb{N}^+ = \{1, 2, 3, ...\}, \forall a \in \mathbb{N}^+ : [a] = \{1, 2, ..., a\}$. Let G be a weighted directed graph then $E(G)$ denotes the set of edges in G and $V(G)$ the set of nodes. For a vertex v we say that $v \in G$ if $v \in V(G)$ and for an edge e we say that $e \in G$ if $e \in E(G)$. Let $u, v \in V(G)$ be two vertices, we denote by $d(u, v, G)$ the distance from u to v in the graph G, and denote by $R(u, v, G)$ **some** shortest path from u to v in G. Let $P \subseteq G$ be a path from u to v, we define $|P| = |E(P)| = |V(P)| - 1$. We also denote the length of P by $d(P)$. Note that $d(R(u, v, G)) = d(u, v, G)$. For a set of edges $A \subseteq E(G)$ we denote the graph $(V(G), E(G) \setminus A)$ by $G - A$. For an edge e we shortly denote $G - \{e\}$ by $G - e$, and for a path P we shortly denote $G - E(P)$ by $G - P$.

We denote by G^R the graph obtained by reversing the directions of all edges - that is the graph obtained by replacing each edge $(v, u) \in E(G)$ with the edge (u, v) with the same weight. Given a sub-graph $H \subseteq G$ we denote by $G[H]$ the sub-graph of G induced by the nodes in $V(H)$.

[2] Also known as funny matrix multiplication or distance product, see [1, 20]

Let $P \subseteq G$ be a shortest path from a node s to a node t. Let $u, v \in V(P)$ be two nodes in P, we say that u is **before** v in P if $d(u,t,G) \geq d(v,t,G)$ and that u is **after** v in P if $d(u,t,G) \leq d(v,t,G)$, For an edge $e = (u,v) \in E(P)$ and a node $a \in V(P)$ we say that a is **before** e in the path P if a is **before** u in P and say that a is **after** e in P if a is **after** v in the path P.

The following sampling Lemma is a folklore.

▶ **Lemma 2.1** (Sampling Lemma). *Consider n balls of which R are red and $n - R$ are blue. Let $C > 0, N > 0$ be two numbers such that $R > C \cdot \ln(N)$. Let B be a random set of balls such that each ball is chosen to be in B independently at random with probability $\frac{C \cdot \ln(N)}{R}$. Then w.h.p (with probability at least $1 - \frac{2}{N^c}$) there is a red ball in B and the size of B is $\tilde{O}(n/R)$.*

The following separation Lemma was used extensively in many divide and conquer algorithms on graphs including the algebraic SSRP algorithm from [5].

▶ **Lemma 2.2** (Separator Lemma). *Given a tree K with n nodes rooted at a node s, one can find in $O(n)$ time a node t that separates the tree K into 2 edge disjoint sub-trees S, T such that $E(S) \cup E(T) = E(K)$, $V(T) \cap V(S) = \{t\}$ and $\frac{n}{3} \leq |V(T)|, |V(S)| \leq \frac{2n}{3}$*

WLOG we always assume that $s \in V(S)$, which implies that t must be the root of T. Note that it might be the case that $t = s$.

2.1 The Generalized SSRP Problem

We next describe a generalization of the directed-SSRP problem that our algorithm works with. We start by describing the notation of weight functions, a new concept we developed that allows us to compress a lot of information into one recursive call of the algorithm. In the next section we will give more intuition about the weight functions and this specific generalization.

▶ **Definition 2.3** (Weight Function). *Let G be an* ***unweighted*** *directed graph. Let $s \in V(G)$ be some special source node. A function $w : V(G) \to \mathbb{N} \cup \{\infty\}$ is a weight function (with respect to the source node s) if $w(v) \geq d(s,v,G)$ for every vertex $v \in V(G)$. We refer to this requirement as the weight requirement.*

For a source node $s \in V(G)$ and a weight function w (with respect to the source node s) we define the **weighted** directed graph G_w by taking the unweighted graph G, and assigning each edge the weight 1. We then add for every node $v \in V(G)$ the edge (s,v) and assign to it the weight $w(v)$. Note that G is a sub-graph of G_w. Also, note that by the weight requirement, for every two nodes $u, v \in V(G) : d(u,v,G) = d(u,v,G_w)$.

The generalized SSRP problem is now defined as follows. The input consists of the following:

- An unweighted directed graph H and a source vertex $s \in V(H)$
- A BFS tree K in H rooted at the source s ($E(K) \subseteq E(H)$)
- A set of weight functions W (with respect to source node s)
- A set of queries $Q \subseteq E(K) \times V(H) \times W$

The goal is to output for every $(e,x,w) \in Q$ the distance $d(s,x,H_w - e)$. Note that this problem is indeed a generalization of the classic SSRP problem. In order to solve the SSRP problem on the initial graph G and the BFS tree $\widehat{K}$, we simply define a single weight function $w : V(G) \to \mathbb{N} \cup \{\infty\}$ that is defined to be $w \equiv \infty$. We then invoke our algorithm with the graph G, the BFS tree $\widehat{K}$, the set of weight functions $W = \{w\}$, and the query set $Q = E(\widehat{K}) \times V(G) \times W$. Note that G and G_w are the same graph in the sense that for every edge $e \in E(G)$ and destination $x \in V(G)$ we have that $d(s, x, G - e) = d(s, x, G_w - e)$. Hence, invoking our algorithm for the generalized SSRP would suffice. As we will only work with the generalized SSRP problem, we here after refer to it as the SSRP problem for simplicity.

3 Overview

Our algorithm uses a divide and conquer approach. Each recursive call works on a different sub-tree (K) of the original BFS tree ($\widehat{K}$), where both the destination and the edge failure are within this sub-tree (for the case when the edge failure and the destination are not in the same sub-tree our algorithm solves this in a non recursive manner to be described later in case 1 of the algorithm overview). The vertices of the sub-tree K induce a sub-graph H of the original graph G. Denote by $n = |V(G)|, m = |E(G)|, n_H = |V(H)|, m_H = |E(H)|$.

The first step of our algorithm is to separate the input BFS tree K into two edge disjoint sub-trees S and T using a balanced tree separator (see Lemma 2.2). We denote the root of the BFS tree K by s. We assume WLOG that the root of S is s and the root of T is some node t. It might be the case that $s = t$. We define P as the path from s to t in the BFS tree K. Note that $P \subseteq S$. An illustration of this separation can be found in Figure 1.

Let K' be one of the two sub-trees of K (that is S or T). If a replacement path is fully contained in the graph induced by K' then simply using the recursive call is enough in order to compute its length. The more challenging case is when the replacement path contains vertices that are not in K'.

In [5] the authors used a somewhat similar divide and conquer approach. Consider a recursive call on a sub-tree K' and consider the case when the edge failure and destination node are both in K'. In their algorithm, the authors of [5] used sampling techniques and a truncated version of the algebraic APSP algorithm (as presented in [21]) in order to create a compressed version of the subgraph induced over K' (by adding shortcuts between vertices in K'), which (w.h.p) preserves all information needed in order to compute the true distance.

However, in the combinatorial setting, one cannot use this sort of compression process for several reasons. Firstly, after the first call to the compression step (as described in the algorithm in [5]), the resulted graph could be very dense, maybe even complete. Since the conditional lower bound of $\tilde{\Omega}(m\sqrt{n} + n^2)$ for a combinatorial SSRP ([2, 18]) depends on the number of edges, we do not want to receive such dense graphs. Secondly, as we are in the combinatorial setting, we cannot use fast matrix multiplication in the compression step, which is a critical part of the algorithm described in [5]. Lastly, after the compression step the resulted graph is weighted which leaves us with a substantially more difficult problem. In fact in the combinatorial setting there is no sub-cubic time algorithm that solves the even seemingly easier problem of weighted RP (see [18] for conditional lower bounds).

So in the combinatorial setting we must devise a new, more restricted, compression technique. We will essentially show that if we add weighted edges only from the source s to all other vertices, and restrict the weights to be such that the weight of the edge (s, v) is at least $d(s, v, H)$, then solving replacement path on such a graph still requires only $\tilde{O}(m_H\sqrt{n_H} + n_H^2)$ time. We therefore would like to add only edges between s and all other nodes. However, this quickly proves to be difficult, and it seems that if we add only weighted edges from s to the compressed graph we either "under-shoot" and do not represent all replacement paths, or we "over-shoot" and represent replacement paths that does not really exist in the graph $H - e$ (for some edge failure e) - such paths will be called untruthful paths.

We have devised a technique to fix the over-shooting. That is, we give the recursive call weights that may represent untruthful replacement paths in $H - e$, but we force the recursive call to restrict the replacement paths it searches for, so we will be able to fix them before the algorithm outputs them, while maintaining optimality. The way we do so is by a novel concept we call weight functions. The idea is that the unweighted graph H will come equipped with a set of functions W, such that every $w \in W$ is a function from $V(H)$ to $\mathbb{N} \cup \{\infty\}$ and for every vertex v it holds that $w(v) \geq d(s, v, H)$. For every weight function $w \in W$ the weighted graph H_w is defined by adding for every node $v \in V$ the edge (s, v) with weight $w(v)$. The goal of the algorithm is then outputting $d(s, v, H_w - e)$ for every triplet $x \in V, w \in W, e \in E(K)$. By restricting the algorithm to only use a single, specific weight function we achieve enough "control" to fix the untruthful paths. In order to maintain the desired running time it will be critical to keep the number of weight functions ($|W|$) at most $\tilde{O}(\sqrt{n})$ (where n is the number of nodes of the original graph G).

3.1 Algorithm Overview

In the remainder of this section we sketch the ideas of our algorithm in high level. For the sake of simplicity, the algorithm in this section runs in $\tilde{O}(n^{2.5})$ time rather than $\tilde{O}(m\sqrt{n} + n^2)$ time. At the end of this section we will briefly describe how one can use some simple techniques to reduce the running time to the near optimal of $\tilde{O}(m\sqrt{n}+n^2)$. While sketching the algorithm, we also ignore the query set Q, as it is only necessary when reducing the running time of the algorithm to $\tilde{O}(m\sqrt{n} + n^2)$. So the goal of the algorithm in this section is to estimate $d(s, x, H_w - e)$ **for every** $e \in E(K), x \in V(H)$ and $w \in W$. The complete algorithm and proof of correctness can be found in Sections 4 and 5 in the full version of this paper.

In our algorithm we distinguish between a few cases according to where the edge failure and the destination are with respect to S and T. Note that for each edge failure e and destination node x we clearly know in which case we are. In each such case we distinguish between different sub-cases according to different properties of the replacement path. Clearly we do not know the replacement path a-priori, meaning that we do not know in which sub-case we are. So when proving the correctness of our algorithm in Section 5 we show that the estimation created for every sub-case is always at least the real value of $d(s, x, H_w - e)$, that is, we do not underestimate. Then we show that for the true sub-case (the sub-case describing the true replacement path) our estimation matches the true value of $d(s, x, H_w - e)$ w.h.p. By returning the minimum estimation from all of the sub-cases we are guaranteed to return the true distance w.h.p. To distinguish between the different sub-cases we first define two useful characterization of replacement paths in H_w.

▶ **Definition 3.1** (Weighted paths). *Let $e \in E(K), x \in V(H), w \in W$, and let R be a path from s to x in the graph $H_w - e$. The path R will be called weighted if it uses some edge from $E(H_w) - E(H)$. R will be called unweighted if it is fully contained in $H - e$.*

The following crucial observation allows us to handle many cases involving weighted replacement paths

▶ **Observation 3.2.** Let $e \in P$ be an edge failure, $x \in H$ be a destination node and $w \in W$ be a weight function. If the replacement path $R(s, x, H_w - e)$ is weighted then it leaves P at s and does not intersect with P until **after** the edge failure.

To see why this observation is true, first note that all the edges in $E(H_w) - E(H)$ begin at s by definition, so $R(s, x, H_w - e)$ indeed leaves P at s. Also, $R(s, x, H_w - e)$ does not intersect with P until after the edge failure as otherwise $R(s, x, H_w - e)$ could have used the path P to get from s to the intersection point, which is a shortest path by the weight requirements. In other words, the use of the weighted edge is unnecessary. An illustration of such path can be seen in Figure 6.

For edge failures from P we also define the following useful characterization

▶ **Definition 3.3** (Jumping and Departing Paths). *Let $e \in E(P), x \in V(H), w \in W$, and let R be a path from s to x in the graph $H_w - e$. The path R will be called jumping if it uses some node u such that $u \in P$ and u is **after** the edge failure e in the path P. A path that is not jumping will be called departing.*

First case – the failure is in P and the destination is in T

This case can be solved in a non-recursive manner, using observation 3.2 and somewhat similar observations to those that were used in [5]. We distinguish between 3 different forms the path $R(s, x, H_w - e)$ can take:

Case 1.1: $R(s, x, H_w - e)$ is departing and weighted.

Using observation 3.2, we can conclude that $R(s, x, H_w - e)$ is edge-disjoint from P as it does not intersect with P before the edge failure nor after (since it is departing). This implies that the length of $R(s, x, H_w - e)$ is $d(s, x, H_w - P)$. This value can easily be computed by running Dijkstra's algorithm from s in the graph $H_w - P$ for every weight function w.

Case 1.2: $R(s, x, H_w - e)$ is departing and unweighted.

An illustration of this case can be seen in Figure 3. In this case one can use a technique similar to the one used in [5] in order to compute length of the replacement path w.h.p. That is, if e is among the last $\sqrt{n_H}$ edges of P, then we can use a brute force solution to compute $d(s, x, H - e)$. If e is of distance at least $\sqrt{n_H}$ from t, then the length of the detour of $R(s, x, H_w - e)$ is at least $\sqrt{n_H}$ as this path departs before e and gets to T. So by sampling a set of nodes B of size $\tilde{O}(\sqrt{n_H})$, we hit every such detour w.h.p. Assuming we hit the detour using the pivot node $b \in B$, we can compute $d(s, b, H - e)$ rather easily, and have that $d(s, x, H - e) = d(s, b, H - e) + d(b, x, H - P)$.

In the full algorithm we denote the estimation obtained by the pivots sampling by $\text{Depart}(s, x, e)$. We show how to compute this estimation in step 5 of the full algorithm and prove its correctness in Claims 5.1 and 5.2.

Case 1.3: $R(s, x, H_w - e)$ is jumping.

As observed by the authors of [5], taking care of jumping replacement paths in the case when $x \in T$ essentially reduces to solving the RP problem, where the source node is s and the destination node is t. This is since a jumping replacement path passes WLOG through the separator node t.

So we focus on computing the length of $R(s, t, H_w - e)$ for every $e \in P$ and $w \in W$. Using observation 3.2, if $R(s, t, H_w - e)$ is weighted then its length is $\min\limits_{u \text{ after } e \text{ in } P} \{d(s, u, H_w - P) + d(u, t, H)\}$ as it does not intersect with P until after the edge failure and from the intersection node the replacement path can go to t using the shortest path P (as this subpath does not contain the edge failure e). Computing this value naively for every $w \in W$ and $e \in P$ takes $\tilde{O}(|W| {n_H}^2)$ time.

If $R(s, t, H_w - e)$ is unweighted, the algorithm of [15] can be used to compute its length.

Second case – the failure is in T and the destination is in T

We solve this case recursively. The recursive call will be invoked over the subgraph $H[T]$. Because the root of the tree T is t and not s, we must change the source of our SSRP. This implies that replacement paths that use the path P to get from s to t will be $d(s,t,H)$ units shorter in the recursive call than they truly are. So when we compress different forms of replacement paths using weight functions, for normalization reasons we must also subtract $d(s,t,H)$ from the weight function. For simplicity, we ignore this issue in the overview, but keep in mind that we always need to subtract $d(s,t,H)$ from every weight function before the algorithm passes them to the recursion call, and add this value back when it receives the recursion's estimation.

We distinguish between two possible forms of the replacement path: weighted and unweighted. Rather interestingly we will see that this separation provides enough information about the structure of the replacement path in order to compress it, and find its length recursively.

Case 2.1: The path $R(s,x,H_w - e)$ is weighted.

We claim that in this case, the only node from S that $R(s,x,H_w - e)$ uses is s. To see this note that for every node u from S that is not s, the path from s to u in the BFS tree K does not contain the edge failure e, since $e \in T$. By the weight requirement this path is a shortest path in H_w. Hence, if a weighted replacement path uses a node u from S, it can use the path from s to u in K. In other words, the use of a weighted edge was unnecessary. So in this case the replacement path is almost completely contained within $H[T]$. Therefore, in order to take care of this case, we simply need to pass the weight function w to the recursive call. We formally prove the correctness of this case in Claim 5.20.

Case 2.2: The path $R(s,x,H_w - e)$ is unweighted.

Let u be the last node of $R(s,x,H_w - e)$ that is from S. If u is t, then we can separate $R(s,x,H_w - e)$ into two subpaths: a path from s to t - that is the shortest path P WLOG, and the shortest path from t to x in $H[T] - e$. We can use the recursive call over $H[T]$ to compute the length of the second sub-path, and when we add $d(s,t,H)$ we will get the length of $R(s,x,H_w - e)$.

The more interesting case is when $u \neq t$. Let v denote the node right after u on $R(s,x,H_w - e)$. In this case we say that v gets "helped from above" by u, as illustrated in Figure 8. Since u is the last node in $R(s,x,H_w - e)$ that belongs to S the sub-path of $R(s,x,H_w - e)$ from v to x is fully contained in $H[T] - e$. So we only need to compress the sub-path of $R(s,x,H_w - e)$ from s to v. In order to do so we define a new weight function $c_T : V(T) \to \mathbb{N} \cup \{\infty\}$ where for every vertex v , $c_T(v)$ is defined to be $\min_{u \in V(S) - \{t\} : (u,v) \in E(H)} \{d(s,u,H) + 1\}$. The sub-path of $R(s,x,H_w - e)$ from s to v is represented in the graph $H[T]_{c_T} - e$ as the weighted edge (t,v). So by passing c_T to the recursion and computing $d(t,x,H[T]_{c_T} - e)$ we will be able to obtain the length of the replacement path. We formally prove the correctness of this case in Claim 5.19.

We note that c_T is truthful, in the sense that for every edge failure $e \in T$, $c_T(v)$ is the length of some path from s to v in $H - e$. This is since the path from s to u in K is of length $d(s,u,H)$ and does not contain e (as previously claimed), and the edge (u,v) is of length 1 and is not in T because u is not in T. We formally prove that c_T is truthful as part of Claim 5.18.

Third case – the failure is in $E(S) - E(P)$ and the destination is in S

We handle this case similarly to the way we handled the second case. However we still sketch the algorithm for this case as it will introduce the notation of a "help from bellow" replacement path, which will be useful in the fourth case. We solve this case recursively. The recursive call will be invoked over the subgraph $H[S]$. In order to take care of this case we distinguish between two forms of the replacement path $R(s, x, H_w - e)$.

Case 3.1: The path $R(s, x, H_w - e)$ uses only nodes from S.
In this case simply passing the weight function w to the recursive call would suffice in order to compute the length of $R(s, x, H_w - e)$.

Case 3.2: $R(s, x, H_w - e)$ uses a node from $V(T) - \{t\}$.
Let u be the last node in $R(s, x, H_w - e)$ that belongs to $V(T) - \{t\}$. Note that the path from s to u in the BFS tree K uses only edges from P and T, meaning that it does not use the edge failure $e \in E(S) - E(P)$. Hence, WLOG we may assume that the sub-path from s to u in $R(s, x, H_w - e)$ is the path from s to u in the BFS tree K as this is a shortest path by the weight requirements. Note that this implies in particular that $R(s, x, H_w - e)$ is unweighted. An illustration of this case can be found in Figure 4. We name this kind of paths "help from bellow" replacement paths. Let v be the node right after u in $R(s, x, H_w - e)$. Since u was the last node in $R(s, x, H_w - e)$ that belongs to $V(T) - \{t\}$ the sub-path of $R(s, x, H_w - e)$ from v to x is fully contained in $H[S] - e$.

So we only need to compress the sub-path of $R(s, x, H_w - e)$ from s to v. In order to do so we define a new weight function $c_S : V(S) \to \mathbb{N} \cup \{\infty\}$ where for every vertex v , $c_S(v)$ is defined to be $\min_{u \in V(T) - \{t\} : (u,v) \in E(H)} \{d(s, u, H) + 1\}$. The sub-path of $R(s, x, H_w - e)$ from s to v is represented in the graph $H[S]_{c_S}$ by the weighted edge (s, v). So by passing the weight function c_S to the recursive call over $H[S]$, and computing $d(s, x, H[S]_{c_S} - e)$, we will be able to compute the length of $R(s, x, H_w - e)$. We formally prove the correctness of this case in Claim 5.23.

We also claim that this function is truthful for edge failures from $E(S) - E(P)$ in the sense that for every $e \in E(S) - E(P)$, $c_S(v)$ is the weight of some path from s to v in $H - e$. This is since the path from s to u in K is of length $d(s, u, H)$ and does not contain e (as previously claimed), and the edge (u, v) is of length 1 and is not in S because u is not in S. We formally prove this fact as part of Claim 5.22.

Note that the weight function c_S is untruthful for edge failures from P, as the path from s to u in K contains the entire path P. But if we consider the recursion's estimation for $d(s, x, H[S]_{c_S} - e)$ **only** for an edge failure $e \in E(S) - E(P)$, we are promised that this estimation represents the length of a true path in $H - e$. If we were to add weighted edges instead of weight functions, we would lose the ability to consider $d(s, x, H[S]_{c_S} - e)$ as an estimation for $d(s, x, H_w - e)$ only for specific edge failures.

Fourth case – the failure is in P and the destination is in S

This case is the most complicated case in our algorithm. Since we cannot allow three recursive calls (in order to obtain the desired running time) and because we see no efficient way to solve this case in a non-recursive manner, we will need to use the same recursive call over $H[S]$ as in the previous case (the third case). We will do so by adding more weight functions.

We begin by making two simple observations that take care of some easy cases, so we could focus on the more involved ones.

- If the replacement path $R(s, x, H_w - e)$ uses no nodes from T then one can simply use a recursive call over the graph $H[S]$ to compute its length.
- If $R(s, x, H_w - e)$ is departing, then since we may assume it contains nodes from T, we can use observations similar to those made in cases (1.1) and (1.2) in order to compute its length.

So we now focus on the more interesting case when $R(s, x, H_w - e)$ uses nodes from T and is jumping. Note that since $R(s, x, H_w - e)$ is jumping it must leave the path P at some node v_i before the edge failure and return to P at some node v_j after the edge failure. We will in fact still need to separate this case into 3 further sub-cases, depending on the order $R(s, x, H_w - e)$ uses nodes from T. These 3 cases present the true power of weight functions, and their ability to compress graphs in a way that is sometimes untruthful but fixable.

Case 4.1: $R(s, x, H_w - e)$ uses a node from T after it uses v_j. An illustration for this case can be found in Figure 5.

We claim that in this case the length of $R(s, x, H_w - e)$ is $d(s, x, H[S]_{c_S} - e) - d(s, t, H) + d(s, t, H_w - e)$. While formally proving the correctness of this claim is rather technical we attempt to give some intuition for this claim. Note that since $R(s, x, H_w - e)$ uses a node from T after it uses v_j, it passes WLOG through t (as v_j is after the edge failure). So we can split $R(s, x, H_w - e)$ into two sub-paths: the replacement path from s to t - which is of length $d(s, t, H_w - e)$, and the path from t to x - which we denote by $R[t, x]$.

Lets us consider the path $P \circ R[t, x]$. We claim that even though the path $R[t, x]$ contains nodes from T, the recursive call over $H[S]$ can evaluate the length of the path $P \circ R[t, x]$. This is because, roughly speaking, the path $P \circ R[t, x]$ is a sort of "help from bellow" replacement path - as described in the the third case in which $e \in E(S) - E(P)$. So like in the "help from bellow" case, the path $P \circ R[t, x]$ would be represented in $H[S]_{c_S} - e$ as a weighted replacement path. When we receive the length of this weighted replacement path we remove P and replace it with the replacement path from s to t. That is, we subtract $d(s, t, H)$ and add $d(s, t, H_w - e)$. We formally prove the correctness of this estimation in Claim 5.12.As stated in the beginning of the overview, we do not know a-priori if the replacement path indeed falls in this sub-case, so we have to make sure that we never underestimate $d(s, x, H_w - e)$. We formally prove this in Claim 5.6.In this case we see that weight functions allow us to assign weights that are untruthful for some edge failures, but give us enough control in order to fix the untruthful replacement paths.

Note that $d(s, x, H[S]_{c_S} - e)$ is used regardless of which weight function w the true replacement path uses. The fact that we use one recursive call over all weight functions, allows us to compute this term only once, which we could not do if the algorithm would have used a different recursive call for each weight function.

Case 4.2: $R(s, x, H_w - e)$ is weighted and it uses no nodes from T after v_j. An illustration for this case can be found in Figure 6.

Let (s, v) be the weighted edge in the replacement path $R(s, x, H_w - e)$. Note that (s, v) is not in P (as P contains only unweighted edges from H). Hence, by definition the replacement path leaves the path P at s, that is, $v_i = s$.

This implies that the sub-path from s to v_j is edge disjoint to P and so its length is $d(s, v_j, H_w - P)$. So for every weight function $w \in W$, we would have wished to define a new weight function $w|_P$ such that $w|_P(v_j) = d(s, v_j, H_w - P)$ for every $v_j \in P$. We will then ask the recursive call to estimate $d(s, x, H[S]_{w|_P} - e)$. This will indeed suffice in order to compute the length of the replacement path recursively, as $R(s, x, H_w - e)$ uses no nodes from T after v_j.

However, by doing so we increase the number of weight function passed to the recursive call by a factor of 2. This sort of exponential growth will prevent us from achieving the desired running time. So instead we define a new weight function $w|_S$ such that $w|_S(x) = d(s, x, H_w - P)$ if $x \in P$ and $w|_S(x) = w(x)$ if $x \notin P$. Note that for every x it holds that $w|_S(x) \leq w(x)$, since the distance $d(s, x, H_w - P)$ is at most the weight of the edge $(s, x) \in H_w$ which is $w(x)$. This implies that the $w|_S$ function preserves information from both w and $w|_P$. So instead of passing w to the recursive call, we pass $w|_S$. Later in Claim 5.5 we prove that the new $w|_S$ function is truthful in the sense that for every $e \in S, x \in S$ it holds that $d(s, x, H[S]_{w|_S} - e)$ is at least $d(s, x, H_w - e)$, meaning we do not create underestimations by using $w|_S$ instead of w. In the full version of the algorithm, we prove the correctness of this case in Claim 5.13.

So as one can see, weight functions allow us to specifically choose special nodes and decrease their weights in order to compress more information, without sacrificing the truthfulness of the weight function.

Case 4.3: $R(s, x, H_w - e)$ is unweighted, it uses no nodes from T after v_j.

This is the most involved and interesting case our algorithm handles. Note that since we assume $R(s, x, H_w - e)$ uses a node from T, and since $R(s, x, H_w - e)$ uses no nodes from T after v_j, then the sub-path of $R(s, x, H_w - e)$ from v_i to v_j must contain a node from T. An illustration for this case can be found in Figure 7. Similarly to Case 1.2, we may assume that the edge failure is not among the last $\sqrt{n_H}$ edges of P as otherwise we can use a brute force solution to compute the length of the replacement path. Since the sub-path from v_i to v_j uses a node from T, its length is at least $d(v_i, t, H)$ that is at least $\sqrt{n_H}$. So w.h.p we have sampled some pivot node $b \in B$ on this sub-path. Note that the sub-path from s to b is departing as the replacement path returns to P only at v_j. So we can easily compute $d(s, b, H - e)$ as stated before in Case 1.2.

To compress the sub-path from b to v_j we define a weight function w_b for every pivot node. We would have wished to define $w_b(v_j) = d(b, v_j, H - P)$, recursively compute $d(s, x, H[S]_{w_b} - e)$ and add $d(s, b, H - e)$ when receiving the answer from the recursion. This will indeed suffice in order to compress the length of the sub-path from v_i to v_j as it is edge disjoint to P. However this is not a valid weight function as it does not necessarily fulfill the weight requirements. So instead we define $w_b(v_j) = d(s, b, H) + d(b, v_j, H - P)$ which is a valid weight function, and we fix the output of the recursion by replacing $d(s, b, H)$ with $d(s, b, H - e)$, i.e. subtracting the former and adding the latter. As in case 4.1, we need to prove that we never underestimate $d(s, x, H - e)$. This is formally done in Claim 5.7.

As we can see, while the weight function w_b is untruthful, in the sense that $w_b(v_j)$ is not necessarily the distance of a path from s to v_j in $H - e$, we are able to fix this untruthfulness as we know what pivot $b \in B$ is used in each weight function w_b. In a sense if we could have used a different recursive call for every $b \in B$ we could have used edges from s rather than weight functions but this would be very inefficient. The weight functions allow us to compress all these recursive calls into one.

In the full version of the algorithm we denote the estimation made using the w_b functions by Pivot(s, x, e). We show how to compute this estimation in step 9 of the algorithm and prove the correctness of this case in Claim 5.14.

3.2 Running Time Analysis

First we note that the number of weight functions in each recursive call increases by $\tilde{O}(\sqrt{n_H})$ in each level of the recursion, as we add the c_S, c_T and $\{w_b\}_{b\in B}$ weight functions, and $|B| = \tilde{O}(\sqrt{n_H})$. Since the number of the weight functions in the first call to the algorithm is 1 (the function $w \equiv \infty$), and since the depth of the recursion is logarithmic we have that $|W| = \tilde{O}(\sqrt{n})$ at all times. So if we simply analyze the non-recursive parts of the algorithm, we can conclude the algorithm spends $\tilde{O}(n_H^2\sqrt{n})$ times on the recursive call over the sub-graph H. One can rather easily see that since the BFS trees in each level of the recursion are edge disjoint sub-trees of the original BFS tree $\widehat{K}$, the total number of vertices in each level of the recursion is at most $2n$. We prove this formally in Section 6. So the total time the algorithm spends on each level of the recursion is $\tilde{O}(n^{2.5})$. Since the depth of the recursion is logarithmic the running time of the algorithm is $\tilde{O}(n^{2.5})$.

3.3 Going From $\tilde{O}(n^{2.5})$ to $\tilde{O}(m\sqrt{n} + n^2)$

In this section we sketch the ideas of improving the running time from $\tilde{O}(n^{2.5})$ to $\tilde{O}(m\sqrt{n}+n^2)$.

We first note that as the number of weight functions in our algorithm is $\tilde{O}(\sqrt{n})$ in each recursive call then even outputting $d(s, x, H_w - e)$ for every triplet $w \in W, x \in V(H), e \in E(K)$ is impossible (in the desired running time) as there are $\tilde{O}(n_H^{2.5})$ such triplets. In order to overcome this issue, the algorithm does not output distances to all such triplets but rather each recursive call is given as input a set of queries Q that is a small subset of all possible triplets (that is $Q \subseteq E(K) \times V(H) \times W$) and the goal is to output the distances only for the given set of queries. Initially, Q is set to be $E(\widehat{K}) \times V(G) \times \{w\}$, where $w \equiv \infty$, and so its size is $|Q| = \tilde{O}(n^2)$. Each recursive call over a graph H will make sure to ask only $\tilde{O}({n_H}^2)$ new queries (queries which it didn't received). Since the total number of vertices in each level is at most $2n$, the number of new queries added at each level of the recursion is $\tilde{O}(n^2)$. Since the depth of the recursion is logarithmic, the total number of queries asked is $\tilde{O}(n^2)$.

Secondly, recall that in Case 1.3, where the edge failure is in $E(P)$ and the destination is t, the algorithm computes the value of $\min_{u \text{ is after } e \text{ in } P}\{d(s, u, H_w - P) + d(u, t, H)\}$ naïvely for every $e \in E(P), w \in W$. This computation costs $\tilde{O}(|W|n_H^2)$ time. However for a specific function $w \in W$, this value can be computed for all $e \in E(P)$ in $\tilde{O}(n_H)$ time using a simple dynamic programming argument which will be shown in Section 5.2 in the complete algorithm. Hence, we can reduce the running time of this part to $\tilde{O}(|W|n_H)$.

Finally, and most importantly, when handling departing unweighted paths (Case 1.2) and when using the w_b weight function (Case 4.3) the algorithm samples a set B of pivots of size $\tilde{O}(\sqrt{n_H})$. Then for every edge failure $e \in P$ and destination node $x \in V(H)$ we iterate over B and find the pivot that provides the smallest distance estimation. This implies that the algorithm spends $\tilde{O}(|B||P||V(H)|)$ time to find these pivots, which is again $\tilde{O}(n_H^{2.5})$ time. The problem is that our estimation for the distance between an edge failure and the separator node t is too loose. On the one hand when sampling B we say that this distance is at least $\sqrt{n_H}$, but on the other hand when bounding $|P|$ we say that it is at most $O(n_H)$.

In order to solve this problem we use a standard scaling trick. More specifically, we consider a logarithmic number of sub-paths $\{P_k\}$, where P_k is the sub-path of P induced by the vertices $\{v \in V(P) : 2^{k+1}\sqrt{n_H} \geq d(v, t, H) \geq 2^k\sqrt{n_H}\}$. P_0 is defined to be the sub-path of P induced by the last $2\sqrt{n_H}$ vertices of P. Note that the set of paths $\{P_k\}$ is an edge disjoint partition of P, and that $|P_k| = O(2^k\sqrt{n_H})$. An illustration for this partition can be seen in Figure 2. For every index $k \neq 0$ we then sample a random set B_k of size $\tilde{O}(\frac{\sqrt{n_H}}{2^k})$

using the sampling lemma 2.1. Now, if we consider an edge failure $e \in P_k$ for $k \neq 0$, we know that the distance from e to t is at least $2^k\sqrt{n_H}$. So when we wish to estimate the length of the departing replacement path in Case 1.2 or send the query (e, x, w_b) to the recursive call over $H[S]$ in Case 4.3, we only need consider pivot nodes b that are from B_k.

Abstract

Given $x, y \in \{0,1\}^n$, Set Disjointness consists in deciding whether $x_i = y_i = 1$ for some index $i \in [n]$. We study the problem of computing this function in a distributed computing scenario in which the inputs x and y are given to the processors at the two extremities of a path of length d. Each vertex of the path has a quantum processor that can communicate with each of its neighbours by exchanging $\mathrm{O}(\log n)$ qubits per round. We are interested in the number of rounds required for computing Set Disjointness with constant probability bounded away from $1/2$. We call this problem "Set Disjointness on a Line".

Set Disjointness on a Line was introduced by Le Gall and Magniez [12] for proving lower bounds on the quantum distributed complexity of computing the diameter of an arbitrary network in the CONGEST model. However, they were only able to provide a lower bound when the local memory used by the processors on the intermediate vertices of the path is severely limited. More precisely, their bound applies only when the local memory of each intermediate processor consists of $\mathrm{O}(\log n)$ qubits.

In this work, we prove an unconditional lower bound of $\widetilde{\Omega}\big(\sqrt[3]{nd^2}+\sqrt{n}\,\big)$ rounds for Set Disjointness on a Line with $d+1$ processors. This is the first non-trivial lower bound when there is no restriction on the memory used by the processors. The result gives us a new lower bound of $\widetilde{\Omega}\big(\sqrt[3]{n\delta^2}+\sqrt{n}\,\big)$ on the number of rounds required for computing the diameter δ of any n-node network with quantum messages of size $\mathrm{O}(\log n)$ in the CONGEST model.

We draw a connection between the distributed computing scenario above and a new model of query complexity. In this model, an algorithm computing a bi-variate function f (such as Set Disjointness) has access to the inputs x and y through two separate oracles $\mathcal{O}_x$ and $\mathcal{O}_y$, respectively. The restriction is that the algorithm is required to alternately make d queries to $\mathcal{O}_x$ and d queries to $\mathcal{O}_y$, with input-independent computation in between queries. The model reflects a "switching delay" of d queries between a "round" of queries to x and the following "round" of queries to y. The technique we use for deriving the round lower bound for Set Disjointness on a Line also applies to this query model. We provide an algorithm for Set Disjointness in this query model with query complexity that matches the round lower bound stated above, up to a polylogarithmic factor. In this sense, the round lower bound we show for Set Disjointness on a Line is optimal.

1 Introduction

1.1 Context

The field of Distributed Computing aims to model a collection of processors or computers communicating with each other over some network with the goal of collectively solving a global computational task. This task may depend on the structure of the network and on some additional data distributed among the computers. For instance, one may want to compute the distance between two nodes of the network, or its diameter, a proper colouring, a spanning tree, or even all-pairs shortest paths. In the context of cloud computing, data centres serve as special nodes of the network where data are stored. These centres are usually spread all over the world in order to minimise access time by clients. Since some operations need to be performed in order to synchronise the centres, the distance between these centres influence the quality of the network. For instance, one may want to decide if there is any inconsistency between two or more remote databases, or check for the availability of a common slot for booking some service.

In this work, we focus on the case of two remote data centres deployed on two nodes of a distributed network, and consider the problem of computing Set Disjointness. This fundamental problem, which we denote by D_n, consists in deciding whether two n-bit input strings x and y modelling two remote databases have the bit 1 at the same position. (This may indicate a schedule conflict, for instance.) The problem has been studied extensively in Communication Complexity [20], due to its many applications in other contexts (see, for example, the survey by Chattopadhyay and Pitassi [6]). In the most basic setting, two remote parties, Alice and Bob, hold the inputs x and y, respectively. They communicate with each other directly in order to solve the problem, while minimising the total length of the messages exchanged. Depending upon the model of computation and the type of communication channel connecting the players, the messages may be deterministic, randomised, or quantum.

The two-party communication model may be too simplistic in some scenarios, since it assumes instantaneous communication and full access to the input (by the party that is "given" the input). To address the first issue, we may include the communication delay as a multiplicative factor in the communication complexity. However, this would not account for a potentially more sophisticated use of the communication channel between the two parties. Consider the case when the channel consists of a chain of d devices, say, repeaters. One could use the channel as a network of processors in order to minimise the communication delay, for instance using cached memories. With regard to the second issue – pertaining to access to the input – the standard two-party model may not be suitable when the inputs are massive, and may only be accessed in small parts. Such access is better modelled as in Query Complexity, in which inputs are accessed by querying *oracles* (see, e.g., Refs. [5, 7, 2]).

Motivated by a concrete problem in distributed computing, we define a new model of query complexity, two-oracle query complexity with a "switching delay". In this model we consider a single computer with access to two oracles, one for each input x or y, such that switching between queries to the two inputs involves a time delay d. The delay accounts for the lag in communication between the parties holding the inputs, for instance when the inputs are not physically at the same place. It might be advantageous to balance this delay by making several accesses to the same input, say x, before switching to the other input y; we also incorporate this feature in the model. The new model attempts to address both the issues discussed above, and is described more precisely in Section 4.1.

There are several bridges between query complexity and communication complexity, but we are not aware of any previous work in a query model such as the one above. The two models – communication through a chain of d devices, and two-oracle query algorithms with a switching delay of d – share some similarities but also have fundamental differences. In the first model, one node has full access to half of the input. In the second model, all the information obtained so far from the inputs x and y is kept in the same memory registers, even when the algorithm switches between inputs.

In this work, we show that the above refinements of the two-party communication model and the query model differ significantly from their standard versions for solving Set Disjointness in the quantum setting. Such a difference does not occur in the setting of deterministic or randomised computing, and we do not know whether such a difference arises for another "natural" problem.

1.2 Application to quantum distributed computing

This study was initially motivated by a problem left open by Le Gall and Magniez [12] in the context of distributed computing with congestion (CONGEST model). They demonstrated the superiority of quantum computing for computing the diameter δ of some n-node network (Diameter problem). They designed a quantum distributed algorithm using $\widetilde{\mathrm{O}}(\sqrt{n\delta}\,)$ synchronised rounds, where simultaneous messages of $\mathrm{O}(\log n)$ qubits are exchanged at each round between neighbouring nodes in the network. They also established a lower bound of $\widetilde{\Omega}(\sqrt{n}+\delta)$ rounds.

Classically the congested distributed complexity of Diameter is well understood, and requires $\widetilde{\Theta}(n)$ rounds [9, 16, 8]. The lower bound is based on the construction of a two-party communication protocol for Set Disjointness from any distributed algorithm for Diameter. From n-bit inputs x, y, two pieces of a $\widetilde{\Theta}(n)$-node network are constructed by the two players. Then the pieces are connected by paths of length d. The diameter of the resulting network is either $d+4$ or $d+5$ depending on the solution to Set Disjointness with inputs (x, y). Finally, the classical lower bound of $\Omega(n)$ for the communication complexity of Set Disjointness implies the same lower bound on the number of rounds for any distributed algorithm for computing Diameter.

In the quantum setting, the situation is much more complex since Set Disjointness has communication complexity $\Theta(\sqrt{n}\,)$ [17, 1]. This leads to the lower bound of $\widetilde{\Omega}(\sqrt{n}+\delta)$ rounds for computing the diameter of a quantum congested network, which is significantly smaller than the upper bound stated above. Nonetheless, Le Gall and Magniez improved the lower bound for a restricted set of protocols in which each node has memory of size at most $\mathrm{poly}(\log n)$ qubits. For this, they used a more refined lower bound for Set Disjointness for bounded-round protocols.

Recall that the number of rounds in a two-party protocol is the number of messages exchanged, where the length of the messages may vary. Braverman, Garg, Ko, Mao, and Touchette [3] showed that the communication complexity of r-round two-party quantum protocols for Set Disjointness is $\widetilde{\Omega}(n/r+r)$. Using this, Le Gall and Magniez showed that any quantum distributed protocol for Diameter with congestion $\mathrm{O}(\log n)$ and memory-size $\mathrm{poly}(\log n)$ per node requires $\widetilde{\Omega}(\sqrt{n\delta}\,)$ rounds. However, without any restriction on the memory size of the nodes, no better bound than $\widetilde{\Omega}(\sqrt{n}+\delta)$ was known.

1.3 Contributions

We prove that solving Set Disjointness with the two n-bit inputs given to the processors at the extremities of a line of $d+1$ quantum processors requires $\widetilde{\Omega}(\sqrt[3]{nd^2}\,)$ rounds of communication of messages of size $\mathrm{O}(\log n)$ (**Theorem 3**). As a corollary, we get a new lower bound of

$\widetilde{\Omega}(\sqrt[3]{n\delta^2}\,)$ rounds for quantum distributed protocols computing the diameter δ of an n-node network with congestion $\mathrm{O}(\log n)$ (**Corollary 4**). This bound improves on the previous bound of $\widetilde{\Omega}(\sqrt{n}\,)$ rounds when $\delta \in \widetilde{\Omega}(\sqrt[4]{n}\,)$. The improvement is obtained by a more refined analysis of a reduction similar to one due to Le Gall and Magniez [12].

We observe that the technique used to derive the above round lower bound for Set Disjointness also applies to two-oracle query algorithms with switching delay d (**Theorem 11**). We show that this bound, and the bound of $\Omega(\sqrt{n}\,)$ coming from the standard query complexity model, are tight to within polylogarithmic factors in different ranges of the parameters n and d (**Theorem 12**). This hints at the possibility that the round lower bound for Set Disjointness may be tight. We hope that these results and, more generally, the models we study also provide a better understanding of quantum distributed computing.

2 Preliminaries

We assume that the reader is familiar with the basic notions of quantum information and computation. We recommend the texts by Nielsen and Chuang [14] and Watrous [19], and the lecture notes by de Wolf [7] for a good introduction to these topics. We briefly describe some notation, conventions, and the main concepts that we encounter in this work.

We write pure quantum states using the ket notation, for example as $|\psi\rangle$. By a quantum register, we mean a sequence of quantum bits (qubits). We assume for simplicity (and without loss of generality) that the computations do not involve any intermediate measurements, i.e., they are unitary until the measurement that is made to obtain the output in the final step of the computation.

We use the notation $\widetilde{\mathrm{O}}(\cdot)$ to indicate that we are suppressing factors that are polylogarithmic in the stated expression. For a positive integer k, we denote the set $\{1, 2, \ldots, k\}$ by $[k]$. In the sequel, we consider the computation of Boolean bi-variate functions $f\colon \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ in several models of computation.

2.1 Quantum distributed computing in the CONGEST model

We consider the quantum analogue of the standard CONGEST communication model [15]. The topology of the network is given by some graph $G = (V, E)$. Each node in the network has a distinct identifier and represents a processor. Initially, the nodes know nothing about the topology of the network except the set of edges incident on them, and the total number of nodes $|V|$. The nodes of the network do not share any entanglement at the beginning of the protocol. Communication protocols are executed with round-based synchrony. In each round, each node may perform some quantum computation on its local memory and the message registers it uses to communicate with its neighbours. Then each node transfers one message with b qubits to each adjacent node to complete that round. The parameter b is called the *congestion* or *bandwidth* of the communication channels. Unless explicitly mentioned, we assume that the congestion b is of order $\log n$, and $|V| = \mathrm{poly}(n)$. All links and nodes in the network (corresponding to the edges and vertices of G, respectively) are reliable and do not suffer any faults.

In this paper we consider the special case of a d-line network, where G consists in a single path of length d. The nodes/processors at the extremities receive inputs $x, y \in \{0,1\}^n$, respectively, and the intermediate nodes get no input. In this setting, the quantum distributed complexity of f on a d-line is the minimum number of rounds of any quantum protocol that computes f with probability at least $2/3$ and congestion $\mathrm{O}(\log n)$. We assume that $d \le n$; otherwise the complexity of any non-trivial function f of both its arguments is $\Theta(d)$.

2.2 Quantum information theory

We refer the reader to the texts by Nielsen and Chuang [14] and Watrous [19] for the basic elements of quantum information theory.

Unless specified, we take the base of the logarithm function to be 2. Whenever we consider information-theoretic quantities involving quantum registers, we assume they are in a quantum state that is implied by the context. For ease of notation, we identify the register with the quantum state.

For a register X the *von Neumann entropy* of X is defined as $\mathrm{S}(X) \coloneqq -\operatorname{Tr}(X \log X)$. If the state space of X has dimension k, then $\mathrm{S}(X) \leq \log k$. Suppose that the registers $WXYZ$ are in some joint quantum state. The *mutual information* $\mathrm{I}(X : Y)$ of X and Y is defined as $\mathrm{I}(X : Y) \coloneqq \mathrm{S}(X) + \mathrm{S}(Y) - \mathrm{S}(XY)$. The *conditional mutual information* $\mathrm{I}(X : Y \,|\, Z)$ of X and Y given Z is defined as $\mathrm{I}(X : Y \,|\, Z) \coloneqq \mathrm{I}(X : YZ) - \mathrm{I}(X : Z)$. Conditional mutual information is invariant under the application of an isometry to any of its three arguments. The quantity also satisfies the following important property.

▶ **Lemma 1** (Data Processing Inequality). *$\mathrm{I}(X : WY \,|\, Z) \;\geq\; \mathrm{I}(X : Y \,|\, Z)$.*

We may also bound conditional mutual information as follows.

▶ **Lemma 2.** *$\mathrm{I}(X : WY \,|\, Z) \;\leq\; 2\,\mathrm{S}(W) + \mathrm{I}(X : Y \,|\, Z)$.*

2.3 Quantum communication complexity

We informally describe a two-party quantum communication protocol *without shared entanglement* for computing a bi-variate Boolean function $f(x, y)$ of n-bit inputs x, y. For a formal definition, we refer the reader to an article by Touchette [18]. In such a protocol, we have two parties, Alice and Bob, each of whom gets an input in registers X and Y, respectively. In the protocols we consider, the inputs are *classical*, i.e., the joint quantum state in the input registers XY is diagonal in the basis $(|x, y\rangle \;:\; x, y \in \{0, 1\}^n)$. Alice and Bob's goal is to compute the value of the function on the pair of strings in the input registers by interacting with each other.

The protocol proceeds in some number $m \geq 1$ of *rounds*. At the cost of increasing the number of rounds by 1, we assume that Alice sends the message in the first round, after which the parties alternate in sending messages. Each party holds a *work* register in addition to the input register. Initially, Alice has work register A_0, Bob has B_0. We denote the work register with Alice at the end of round $k \in [m]$ by A_k and that with Bob by B_k.

The qubits in the work registers $A_0 B_0$ are initialised to a fixed pure state $|\bar{0}\rangle$. Suppose that Alice is supposed to send the message in the k-th round, for some $k \in [m]$. Alice applies an isometry controlled by her input register X to the work register A_{k-1} to obtain registers $A_k M_k$. She then sends the message register M_k to Bob. Bob's work register at the end of the k-th round is then $B_k \coloneqq M_k B_{k-1}$. After the m-th round (the last round), the recipient of the last message, say Bob, measures his work register B_k, possibly controlled by his input register Y, to produce the binary output of the protocol.

The length of a message is the number of qubits in the message register for that round. The *communication complexity* of the protocol is the sum of the length of the m messages in it. We say the protocol computes the function f with success probability p if for all inputs x, y, the probability that the protocol outputs $f(x, y)$ is at least p. The goal of the two parties is to compute the function while minimising the communication between themselves. The *quantum communication complexity* of f is the minimum communication complexity of a quantum protocol that computes f with success probability at least $2/3$.

We analyse the *conditional information loss* of two-party protocols, a notion introduced by Jain, Radhakrishnan, and Sen [10]. We define this notion following the convention and notation given above. In particular, we assume that Alice sends the messages in the odd rounds and Bob sends the messages in the even rounds. Suppose the input registers XY are initialised to a pair of inputs drawn from a joint distribution over $\{0,1\}^n \times \{0,1\}^n$. We identify the registers with the jointly distributed input random variables. Suppose Z is some random variable correlated with XY. The *conditional information loss* $\mathrm{IL}(\Pi \,|\, XYZ)$ of a two-party protocol as above is defined as

$$\mathrm{IL}(\Pi \,|\, XYZ) \quad := \quad \sum_{i \in [m],\ i \text{ odd}} \mathrm{I}(X : B_i Y \,|\, Z) + \sum_{i \in [m],\ i \text{ even}} \mathrm{I}(Y : A_i X \,|\, Z) \ ,$$

where the registers are implicitly assumed to be in the state given by the protocol. Since Alice sends the messages in the odd rounds, and Bob in the even rounds, this quantity measures the cumulative information about the inputs leaked to the other party, over the course of the entire protocol.

2.4 Quantum query complexity

For a thorough introduction to the quantum query model, see, for example, the lecture notes by de Wolf [7] and the survey by Ambainis [2]. In this work, we study algorithms for computing a bi-variate Boolean function $f(x,y)$ as above, using *two* unitary operators $\mathcal{O}_x$ and $\mathcal{O}_y$ that provide access to the n-bit inputs x and y, respectively. For any $z \in \{0,1\}^n$, the operator $\mathcal{O}_z$ acts as $\mathcal{O}_z|i,b\rangle = |i, b \oplus z_i\rangle$ on the Hilbert space $\mathcal{H}$ spanned by the orthonormal basis $\{|i,b\rangle : i \in [n], b \in \{0,1\}\}$. We call operators of the form $\mathcal{O}_z$ an *oracle*, and each application of such an operator a *query*.

A query algorithm $\mathcal{A}$ with access to two oracles $\mathcal{O}_x$ and $\mathcal{O}_y$ is an alternating sequence of unitary operators $U_0, \mathcal{O}_{z_1}, U_1, \mathcal{O}_{z_2}, U_2, \mathcal{O}_{z_3}, U_3, \ldots, \mathcal{O}_{z_t}, U_t$, where the operators U_i act on a Hilbert space of the form $\mathcal{H} \otimes \mathcal{W}$ and are independent of the inputs x, y, and the $z_i \in \{x, y\}$. The computation starts in a fixed state $|\bar{0}\rangle \in \mathcal{H} \otimes \mathcal{W}$, followed by the sequence of unitary operators to get the final state $U_t \mathcal{O}_{z_t} \cdots U_3 \mathcal{O}_{z_3} U_2 \mathcal{O}_{z_2} U_1 \mathcal{O}_{z_1} U_0 |\bar{0}\rangle$. Finally, we measure the first qubit in the standard basis to obtain the output $\mathcal{A}(x,y)$ of the algorithm. We say the algorithm computes f with success probability p if for all inputs x, y, we have $\mathcal{A}(x,y) = f(x,y)$ with probability at least p.

As in the standard quantum query model, we focus on the number of applications of the operators $\mathcal{O}_x$ and $\mathcal{O}_y$ in an algorithm, and ignore the cost of implementing unitary operators that are independent of x and y. The *query complexity* of an algorithm is the number of queries made by the algorithm (t in the definition above). The *quantum query complexity* of a function f is the minimum query complexity of any quantum algorithm that computes f with probability at least $2/3$.

3 Set Disjointness on a Line

3.1 The problem and results

The Set Disjointness problem $\mathsf{L}_{n,d}$ on a line was introduced recently by Le Gall and Magniez [12] in the context of distributed computing. It is a communication problem involving $d+1$ communicating parties, $\mathsf{A}_0, \mathsf{A}_1, \ldots, \mathsf{A}_d$, arranged on the vertices of a path of length d. The edges of the path denote two-way quantum communication channels between the players. Parties A_0 and A_d receive n-bit inputs $x, y \in \{0,1\}^n$, respectively. The communication protocol proceeds in rounds. In each round, parties A_{i-1} and A_i may exchange b qubits in each direction, for each $i \in [d]$, i.e., the *bandwidth* of each communication channel is b. The goal of the parties is to determine if the sets x and y intersect or not. I.e., they would like to compute the Set Disjointness function $\mathsf{D}_n(x, y) := \bigvee_{i=1}^{n}(x_i \wedge y_i)$.

We are interested in the number of rounds required to solve $\mathsf{L}_{n,d}$. We readily get a quantum protocol Π_d for this problem with $\mathrm{O}(\sqrt{nd}\,)$ rounds by following an observation due to Zalka [22] on black-box algorithms that make "parallel" queries. Let Π denote the optimal two-party quantum communication protocol for Set Disjointness due to Aaronson and Ambainis [1]. In Π_d, we partition the n-bit inputs into d parts of length n/d each. Parties A_0 and A_d then simulate Π on each of the d corresponding pairs of inputs independently. The protocol Π runs in $\sqrt{n/d}$ rounds with $\mathrm{O}(1)$ qubits of communication per instance of length n/d, per round. So the total communication to or from A_0 due to one round of the d runs of Π is $\mathrm{O}(d)$. Since $\mathrm{O}(d)$ qubits can be transmitted across the path of length d in $\mathrm{O}(d)$ rounds of the multi-party protocol, the protocol Π_d simulates the d parallel runs of Π in $\mathrm{O}(\sqrt{nd}\,)$ rounds. Since Π finds an intersection with probability at least $3/4$ whenever there is one, and does not err when there is no intersection, the protocol Π_d also has the same correctness probability.

Le Gall and Magniez observed that a lower bound of $\Omega(\sqrt{n}/b)$ for the number of rounds follows from the $\Omega(\sqrt{n}\,)$ lower bound due to Razborov [17] on the quantum communication complexity of Set Disjointness in the two-party communication model. This is because two parties, Alice and Bob, may use any r-round protocol for $\mathsf{L}_{n,d}$ to solve Set Disjointness with $2rb$ qubits of communication: Alice simulates A_0 and Bob simulates the actions of the remaining parties $\mathsf{A}_1, \mathsf{A}_2, \ldots, \mathsf{A}_d$. An $\Omega(d)$ lower bound is also immediate due to the need for communication between A_0 and A_d.

Le Gall and Magniez devised a more intricate simulation of a protocol for $\mathsf{L}_{n,d}$ by two parties, thereby obtaining a two-party protocol for Set Disjointness. Using this, they obtained a round lower bound of $\widetilde{\Omega}(\sqrt{nd}\,)$ for $\mathsf{L}_{n,d}$ when the bandwidth b of each communication channel (in each round) and the local memory of the players $\mathsf{A}_1, \mathsf{A}_2, \ldots, \mathsf{A}_{d-1}$ are both $\mathrm{O}(\log n)$ qubits. We show that a similar simulation leads to an unconditional round lower bound of $\Omega(nd^2/b)^{1/3}$ by studying the *conditional information loss* of the resulting two-party protocol, a quantity introduced and analysed by Jain, Radhakrishnan, and Sen [10].

▶ **Theorem 3.** *Any quantum communication protocol with error probability at most* $1/3$ *for the Set Disjointness problem* $\mathsf{L}_{n,d}$ *on the line requires* $\Omega(\sqrt[3]{nd^2/b}\,)$ *rounds.*

This bound dominates the straightforward bound of $\Omega(\sqrt{n}/b)$ mentioned above when $d \geq \sqrt[4]{n/b}$, i.e., when $d \geq \sqrt[4]{n/\log n}$ when $b = \log n$. However, we do not know if either bound is achievable in their respective parameter regimes. We study the optimality via a related query model in Section 4.

Using the reduction from $\mathsf{L}_{n,d}$ to the problem of computing the diameter described in the proof of Theorem 1.3 in Ref. [12], we get a new lower bound for quantum distributed protocols for the diameter problem in the CONGEST model.

▶ **Corollary 4.** *Any quantum distributed protocol for computing the diameter* δ *of* n*-node networks with congestion* $\mathrm{O}(\log n)$ *requires* $\widetilde{\Omega}(\sqrt[3]{n\delta^2}\,)$ *rounds.*

3.2 Overview of the proof

We begin by giving an overview of the proof of Theorem 3. It rests on a simulation of a protocol for $\mathsf{L}_{n,d}$ by a two-party protocol for Set Disjointness similar to one designed by Le Gall and Magniez [12, Theorem 6.1]. (In fact, the simulation works for any multi-party protocol over the path of length d that computes some bi-variate function $g(x, y)$ of the inputs given to A_0 and A_d.) The idea underlying the simulation is the following. Suppose we have a protocol Π_d for the problem $\mathsf{L}_{n,d}$. In the two-party protocol Π, Alice begins by holding the registers used by parties $\mathsf{A}_0, \mathsf{A}_1, \ldots, \mathsf{A}_{d-1}$. She then simulates all the actions – local operations and communication – of the parties $\mathsf{A}_0, \mathsf{A}_1, \ldots, \mathsf{A}_{d-1}$ from the first round in Π_d, except for the communication between A_{d-1} and A_d. This is possible because these actions do not depend on the input y held by A_d. She can continue simulating the actions of $\mathsf{A}_0, \mathsf{A}_1, \ldots, \mathsf{A}_{d-2}$ from the second round, except the communication between A_{d-2} and A_{d-1}, as these do not depend on the message from A_d from the first round in Π_d. Continuing this way, Alice can simulate the actions of $\mathsf{A}_0, \mathsf{A}_1, \ldots, \mathsf{A}_{d-i}$ from round i of Π_d, except the communication between A_{d-i} and A_{d-i+1}, for all $i \in [d]$, all in one round of Π. These actions constitute Alice's local operations in the first round of Π.

Alice then sends Bob the local memory used by parties $\mathsf{A}_1, \ldots, \mathsf{A}_{d-1}$ in Π_d, along with the qubits sent by A_{i-1} to A_i in round i, for each $i \in [d]$. (Alice retains the input x and the memory used by party A_0.) This constitutes the first message from Alice to Bob in Π.

Given the first message, Bob can simulate the remaining actions of $\mathsf{A}_1, \mathsf{A}_2, \ldots, \mathsf{A}_d$ from the first d rounds of Π_d, except for the communication from A_1 to A_0. These constitute his local operations in the second round of Π. He then sends Alice the qubits sent by A_1 to A_0 in round d of Π_d along with the local memory used by the parties A_i, for $i \in [d-1]$. (Bob retains the input y and the local memory used by party A_d.) This constitutes the second message in Π.

In effect, the simulation implements the first d rounds of Π_d in two rounds of Π (see Figure 2). The same idea allows Alice and Bob to simulate the rest of the protocol Π_d while implementing each successive block of d rounds of Π_d in two rounds of Π, with communication per round of the order of $d(b + s)$, where b is the bandwidth of the communication channels in Π_d, and s is a bound on the number of qubits of local memory used by any of the parties $\mathsf{A}_1, \ldots, \mathsf{A}_{d-1}$. Building on the detailed description of protocols on the line in Section 3.3, we describe the simulation formally in Section 3.4, and show the following.

► **Lemma 5.** *Given any r-round quantum protocol Π_d for $\mathsf{L}_{n,d}$ over communication channels with bandwidth b in which each party uses local memory at most s, there is a two-party quantum protocol Π for Set Disjointness D_n that has $2\lceil r/d \rceil$ rounds, total communication of order $r(b + s)$, and has the same probability of success.*

The communication required by a k-round bounded-error two-party protocol for Set Disjointness is $\Omega(n/(k \log^8 k))$ [3, Theorem A]. This gives us the lower bound of $\widetilde{\Omega}(\sqrt{nd}\,)$ due to Le Gall and Magniez on the number of rounds r in Π_d, when $b + s$ is of order $\log n$.

In fact, we may derive an unconditional lower bound on the number of rounds from the same reduction, one that holds without any restriction on the local memory used by the parties in Π_d. This is because the state of the registers of any party A_i, with $i \in [d-1]$, in an r-round protocol has support on a fixed subspace of dimension at most $(2b)^r$, independent of the inputs, at any moment in the protocol. This follows from an argument due to Yao [21], by considering a two party protocol obtained by grouping all parties except A_i together. So the state of party A_i at any point in the protocol can be mapped to one over $r \log(2b)$ qubits. Using this for the bound s on the local memory, bandwidth $b \in \mathrm{O}(\log n)$, and the same reasoning as before, we get a lower bound of $\widetilde{\Omega}(nd)^{1/3}$ on the number of rounds r in Π_d.

We refine the analysis further to obtain Theorem 3, by appealing to an information-theoretic argument. The key insight is that regardless of the size of the local memory maintained by the parties A_i, for $i \in [d-1]$, the new *information* they get about either input x or y in one round is bounded by b, the length of the message from A_0 or A_d, respectively. Thus, the total information contained in the memory and messages of these parties about the inputs may be bounded by rb at any point in the protocol (see Lemma 8). This carries over to the information contained in the messages between Alice and Bob in the two-party protocol Π derived from Π_d. The conditional information loss of the two-party protocol may then be bounded by rbm, where m is the number of rounds in Π (for suitable distributions over the inputs).

▶ **Lemma 6.** *Let XYZ be jointly distributed random variables such that $X, Y \in \{0,1\}^n$, and X and Y are independent given Z. The conditional information loss of the two-party protocol Π for Set Disjointness D_n mentioned in Lemma 5 is bounded as $\mathrm{IL}(\Pi \,|\, XYZ) \in \mathrm{O}(r^2 b/d)$.*

We derive this as Corollary 9 in Section 3.5.

We now appeal to the following result due to Jain *et al.* [10] on the conditional information loss of bounded-round protocols for Set Disjointness. This result is implicit in the proof of the $\Omega(n/m^2)$ lower bound on the communication required by m-round quantum protocols for Set Disjointness.

▶ **Theorem 7** (Jain, Radhakrishnan, Sen [10])**.** *There is a choice of distribution for XYZ such that $X, Y \in \{0,1\}^n$, the random variables X and Y are independent given Z, and for any bounded-error two-party quantum communication protocol Γ for Set Disjointness D_n with m rounds, the conditional information loss $\mathrm{IL}(\Gamma \,|\, XYZ)$ is at least $\Omega(n/m)$.*

Since the number of rounds m in the two-party protocol Π is at most $2\lceil r/d \rceil$, we conclude the $\Omega(nd^2/b)^{1/3}$ lower bound stated in Theorem 3.

3.3 Formal description of protocols on the line

In order to establish the lemmas stated in Section 3.2, we introduce some conventions and notation associated with multi-party protocols on the line of the sort we study for $\mathsf{L}_{n,d}$. By using unitary implementations of measurements, we assume that all the local operations in the protocol, except the final measurement to obtain the outcome of the protocol, are unitary. We also assume that the parties do not share any entangled state at the beginning of the protocol, and that the input registers X with A_0 and Y with A_d are read-only. I.e., the input registers may only be used as control registers during the protocol, and are retained by the respective parties throughout.

For ease of exposition, we use subscripts on the registers held by all the parties to implicitly specify the state of the register and the party which last modified the state of the register. At the beginning of round $t+1$, for $t \in \{0, 1, \ldots, r-1\}$, party A_0 holds registers $X A_{0,t}\, L_{1,t}$, party A_d holds registers $R_{d-1,t}\, A_{d,t}\, Y$, and for $i \in [d-1]$, party A_i holds registers $R_{i-1,t}\, A_{i,t}\, L_{i+1,t}$. The registers $L_{i,t}$ and $R_{i,t}$, for $i \in [0,d]$ and $t \in [0,r]$, all have b qubits. Except in the first round, the first subscript at the beginning of the round, say i, indicates that party A_i held the register in the previous round, and sent the register to the neighbour that holds it in the current round.

At the beginning of the first round, registers X and Y are initialized to the input to the protocol. The qubits in the remaining registers are all initialized to a fixed pure state, say $|0\rangle$, independent of the inputs.

In round $t+1$, each party A_i applies a unitary operation to the registers they hold. We view the unitary operation as an isometry $U_{i,t+1}$ that maps the registers to another sequence of registers with the same dimensions. The registers $X A_{0,t}\, L_{1,t}$ with A_0 are mapped to $X A_{0,t+1}\, R_{0,t+1}$. The registers $R_{d-1,t}\, A_{d,t}\, Y$ with A_d are mapped to $L_{d,t+1}\, A_{d,t+1}\, Y$.

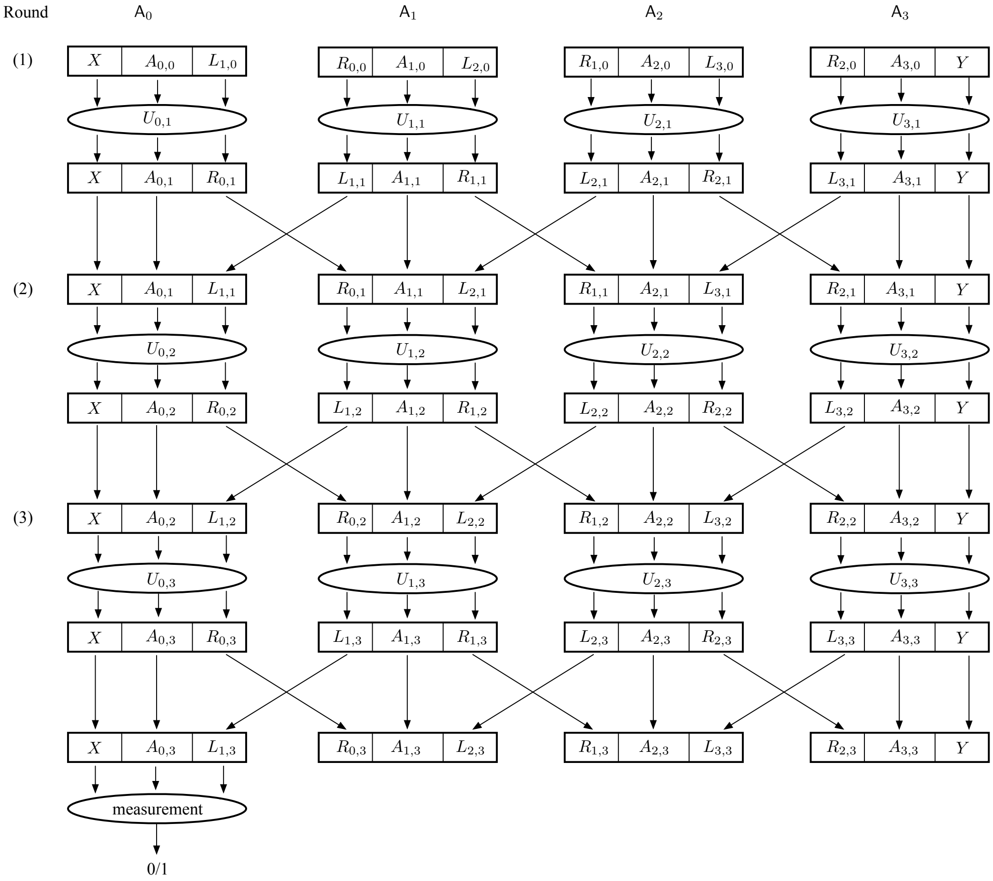

Figure 1 A multi-party communication protocol on the line with 4 parties and 3 rounds, of the type we study for $\mathsf{L}_{n,d}$. For $t \geq 1$, the subscripts i, t on a register indicate that the register was an "output" of the isometry applied by party A_i in round t, and that it is in the corresponding state. For example, the register $R_{1,3}$ was produced by the isometry applied by A_1 in the third round.

For $i \in [d-1]$, the registers $R_{i-1,t}\, A_{i,t}\, L_{i+1,t}$ with A_i are mapped to $L_{i,t+1}\, A_{i,t+1}\, R_{i,t+1}$. So for $t \geq 1$, the subscripts i, t on a register indicate that the register was an "output" of the isometry applied by party A_i in round t, and that it is in the corresponding state.

As the final action in round $t+1$, for $t < r$, if $i > 0$, party A_i sends $L_{i,t+1}$ to the party on the left (i.e., to A_{i-1}) and receives $R_{i-1,t+1}$ from her; and if $i < d$, she sends $R_{i,t+1}$ to the party on the right (i.e., to A_{i+1}) and receives register $L_{i+1,t+1}$ from her.

After the r rounds of the protocol have been completed, party A_0 makes a two-outcome measurement, possibly depending on her input, on the registers $A_{0,r}\, L_{1,r}$. The outcome is the output of the protocol. Figure 1 depicts such a protocol.

3.4 The two-party simulation

We now prove Lemma 5, by giving a formal description of the two-party protocol Π for Set Disjointness D_n derived from a protocol Π_d for $\mathsf{L}_{n,d}$. We use the notation and convention defined in Section 3.3 in our description below. For simplicity, we assume that the number of rounds r in Π_d is a multiple of d, by adding dummy rounds with suitable local operations, if necessary. Since D_n depends non-trivially on *both* inputs, the number of rounds r required to compute the function over a path of length d is at least d. So the addition of dummy rounds may at most double the number of rounds.

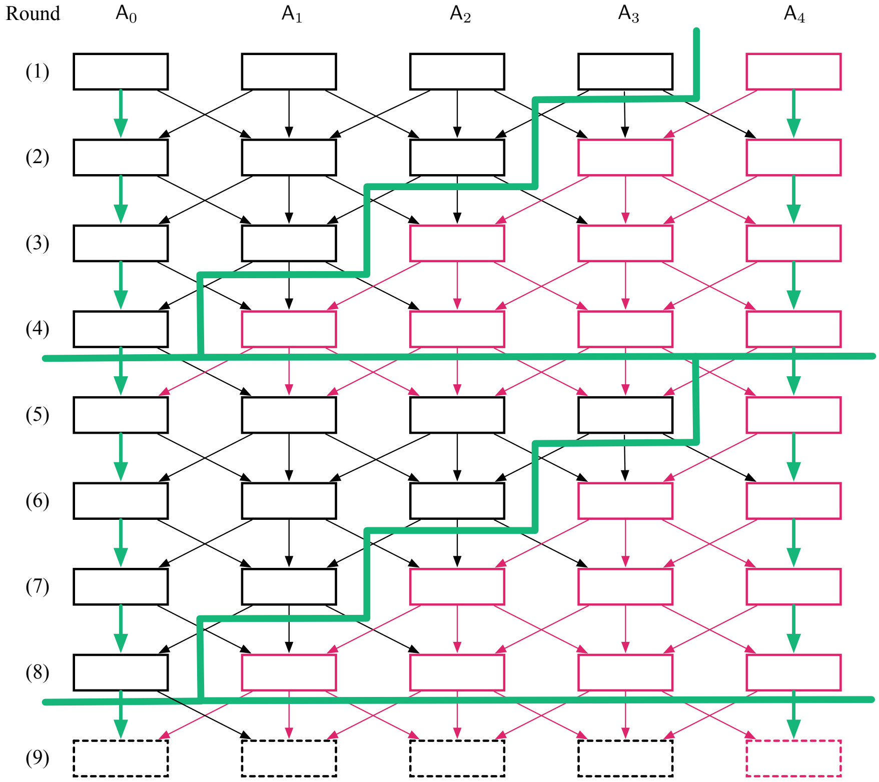

Figure 2 A depiction of the two-party simulation of a multi-party communication protocol of the type we study for $\mathsf{L}_{n,d}$. Here, we have 5 parties and show the simulation of the first 8 rounds of the original protocol. Each round in the two-party protocol is delineated by thick green lines. The black rectangular boxes represent the isometries implemented by Alice, and the black arrows going across the thick green lines represent the communication from her to Bob. The red rectangular boxes represent the isometries implemented by Bob, and the red arrows going across the thick green lines represent the communication from him to Alice. The green arrows indicate that the input register and the local memory of the parties at the extremities are retained by them throughout.

In the protocol Π, Alice initially holds all the registers with parties A_i for $i < d$ at the beginning of the first round, and Bob holds the registers with A_d. All of the registers are initialized as in Π_d. The simulation implements blocks of d successive rounds of Π_d with two rounds in Π, with Alice sending the message in the first of the two rounds and Bob in the second. See Figure 2 for a depiction of the simulation.

Assume that k blocks of d rounds each of Π_d have been implemented with $2k$ rounds in Π, for some $k \in [0, r/d - 1]$. We describe how the $(k+1)$-th block is implemented. Let $t := kd$. We maintain the invariant that at the beginning of the $(2k+1)$-th round in Π, Alice holds the registers $X A_{0,t}\, L_{1,t}$, and the registers $R_{i-1,t}\, A_{i,t}\, L_{i+1,t}$, for all $i \in [d-1]$. Alice's local operations in round $2k+1$ are as follows. For each $j \in \{t+1, t+2, t+3, \ldots, t+d\}$ in increasing order (where j denotes a round in Π_d),

1. Alice applies the isometry $U_{0,j}$ to the registers $XA_{0,j-1}\,L_{1,j-1}$ to get registers $XA_{0,j}\,R_{0,j}$.
2. For each l with $1 \leq l \leq d-(j-t)$ (denoting a party from Π_d), Alice applies the isometry $U_{l,j}$ to the registers $R_{l-1,j-1}\,A_{l,j-1}\,L_{l+1,j-1}$ to get registers $L_{l,j}\,A_{l,j}\,R_{l,j}$.
3. For each l with $1 \leq l \leq d-(j-t)$, Alice swaps registers $R_{l-1,j}$ and $L_{l,j}$.

At this point, Alice has implemented the left upper triangular "space-time slice" of the $(k+1)$-th block of d rounds of Π_d. She holds the registers

$$\begin{gathered} XA_{0,t+d}\,R_{0,t+d} \quad R_{0,t+d-1}\,A_{1,t+d-1}\,R_{1,t+d-1} \quad R_{1,t+d-2}\,A_{2,t+d-2}\,R_{2,t+d-2} \\ R_{2,t+d-3}\,A_{3,t+d-3}\,R_{3,t+d-3} \ \cdots \ R_{d-3,t+2}\,A_{d-2,t+2}\,R_{d-2,t+2} \quad R_{d-2,t+1}\,A_{d-1,t+1}\,R_{d-1,t+1} \ , \end{gathered} \tag{3.1}$$

in the state implicitly specified by the subscripts. (The registers have been grouped into threes, in the order of the parties that hold them in Π_d.) She sends all the registers *except* $XA_{0,t+d}$ to Bob. This concludes the $(2k+1)$-th round of Π.

We also maintain the invariant that at the beginning of the $(2k+2)$-th round of Π, Bob bolds all the registers in Eq. (3.1) except $XA_{0,t+d}$, in addition to the registers $R_{d-1,t}\,A_{d,t}Y$, where $t = kd$. Bob's local operations in round $2k+2$ are as follows. For each $j \in \{t+1, t+2, t+3, \ldots, t+d\}$ in increasing order (where j denotes a round in Π_d that Bob intends to complete),

1. Bob applies the isometry $U_{d,j}$ to the registers $R_{d-1,j-1}\,A_{d,j-1}Y$ to get registers $L_{d,j}\,A_{d,j}Y$.
2. For each l with $d-(j-t-1) \leq l \leq d-1$ (denoting a party from Π_d), Bob applies the isometry $U_{l,j}$ to the registers $R_{l-1,j-1}\,A_{l,j-1}\,L_{l+1,j-1}$ to get registers $L_{l,j}\,A_{l,j}\,R_{l,j}$.
3. For each l with $d-(j-t-1) \leq l \leq d$, Bob swaps registers $R_{l-1,j}$ and $L_{l,j}$.

At this point, Bob holds the registers

$$\begin{gathered} L_{1,t+d} \quad R_{0,t+d}\,A_{1,t+d}\,L_{2,t+d} \quad R_{1,t+d}\,A_{2,t+d}\,L_{3,t+d} \quad R_{2,t+d}\,A_{3,t+d}\,L_{4,t+d} \\ \cdots \ R_{d-2,t+d}\,A_{d-1,t+d}\,L_{d,t+d} \quad R_{d-1,t+d}\,A_{d,t+d}Y \ , \end{gathered} \tag{3.2}$$

in the state implicitly specified by the subscripts. The registers are thus all in the state at the end of the $(kd+d)$-th round in Π_d. Bob sends all the registers *except* $A_{d,t+d}Y$ to Alice. This concludes the $(2k+2)$-th round of Π, and the simulation of the $(k+1)$-th block of rounds of Π_d.

At the end of the simulation of the (r/d)-th block of rounds of Π_d, Alice measures the registers $A_{0,r}\,L_{1,r}$ as in Π_d to obtain the output. This completes the description of the two-party simulation. The correctness of the simulation follows by induction, by observing that Alice and Bob implement all the local operations and communication in Π_d in the correct order and with the correct registers. Lemma 5 thus follows.

3.5 Conditional information loss of the two-party protocol

We are now ready to bound the conditional information loss of the two-party protocol Π derived from the multi-party protocol Π_d. Suppose the input registers X and Y in Π_d (and therefore in Π) are initialised to a pair of n-bit strings drawn from some joint distribution. We use XY to also denote the corresponding random variables. Suppose that Z is a random variable jointly distributed with XY such that X and Y are independent given Z.

We first bound the information contained about any input in the registers held by all other players in Π_d, conditioned on Z. For ease of notation, for $t \geq 0$, we denote by D_t the entire sequence of registers held by the parties A_i, with $i \geq 1$, in the state at the end of the t-th round of Π_d. Similarly, we denote by C_t the entire sequence of registers held by the parties A_i, with $i \leq d-1$, in the state at the end of the t-th round of Π_d.

▶ **Lemma 8.** *For all $t \geq 0$, we have $\mathrm{I}(X : D_t \,|\, Z) \leq 2tb$, and $\mathrm{I}(Y : C_t \,|\, Z) \leq 2tb$.*

Proof. We prove the bound on $\mathrm{I}(X : D_t \,|\, Z)$ by induction. The second bound is obtained similarly.

The base case $t = 0$ is immediate, as the state of the registers of the parties A_i, for $i \in [d-1]$ is independent of the inputs, and the input Y is independent of X given Z.

Assume that the bound holds for $t = j$, with $j \geq 0$. Let G_{j+1} denote the sequence of registers with all the parties A_i, for $i \geq 2$, after the isometry in round $j + 1$ has been applied. Then we have

$$\mathrm{I}(X : L_{1,j+1}\, A_{1,j+1}\, R_{1,j+1} G_{j+1} \,|\, Z) \quad = \quad \mathrm{I}(X : D_j \,|\, Z) \quad \leq \quad 2jb \ ,$$

by the induction hypothesis. Let H_{j+1} denote all the registers of the parties A_i, for $i \geq 2$, after the communication in round $j + 1$. Then $L_{2,j+1}\, H_{j+1}$ and $R_{1,j+1}\, G_{j+1}$ consist of the same set of registers, but in different order. By the properties of entropy and conditional mutual information mentioned below,

$$\begin{aligned}
\mathrm{I}(X : D_{j+1} \,|\, Z) \quad &= \quad \mathrm{I}(X : R_{0,j+1}\, A_{1,j+1}\, L_{2,j+1}\, H_{j+1} \,|\, Z) \\
&= \quad \mathrm{I}(X : R_{0,j+1}\, A_{1,j+1}\, R_{1,j+1}\, G_{j+1} \,|\, Z) \\
&\leq \quad 2\,\mathrm{S}(R_{0,j+1}) + \mathrm{I}(X : A_{1,j+1}\, R_{1,j+1}\, G_{j+1} \,|\, Z) \\
&\leq \quad 2b + \mathrm{I}(X : L_{1,j+1}\, A_{1,j+1}\, R_{1,j+1} G_{j+1} \,|\, Z) \\
&\leq \quad 2b + 2jb \ .
\end{aligned}$$

The first inequality follows from Lemma 2, the second by the property that $\mathrm{S}(B)$ is bounded from above by the number of qubits in the register B and the data processing inequality (Lemma 1), and the final one by the induction hypothesis. ◀

For $k \in [2r/d]$, denote the message registers in the k-th round of the two-party protocol Π in the corresponding state together by M_k. Denote the registers with Alice at the end of the k-th round, in the corresponding state, by E_k, and the registers with Bob at the end of the k-th round, in the corresponding state, by F_k. Next, we observe from the definition of the protocol Π, that for odd numbered rounds $2k-1$, the state given by register D_{kd} is obtained by an isometry on the registers $M_{2k-1}F_{2k-2}$. The registers $M_{2k-1}F_{2k-2}$ (in the state implicitly specified by their definition) are precisely the registers Bob holds at the end of round $2k - 1$ of Π. Moreover, for even numbered rounds $2k$, the state given by the registers $E_{2k-1}M_{2k}$ is precisely the state given by the register C_{kd} in Π_d. The registers $E_{2k-1}M_{2k}$ are precisely the registers Alice holds at the end of round $2k$ of Π. Therefore, by Lemma 8 and the definition of conditional information loss, we have:

▶ **Corollary 9.** *For all $k \in [r/d]$, we have*

$$\begin{aligned}
\mathrm{I}(X : M_{2k-1}F_{2k-2} \,|\, Z) \quad &= \quad \mathrm{I}(X : D_{kd} \,|\, Z) \quad \leq \quad 2kdb \ , \qquad \textit{and} \\
\mathrm{I}(Y : E_{2k-1}M_{2k} \,|\, Z) \quad &= \quad \mathrm{I}(Y : C_{kd} \,|\, Z) \quad \leq \quad 2kdb \ .
\end{aligned}$$

Consequently, the conditional information loss of Π is bounded as $\mathrm{IL}(\Pi \,|\, XYZ) \leq 4r^2b/d$.

4 Two-oracle query algorithms with a switching delay

In this section, we define a new model of query complexity, two-oracle query complexity with a "switching delay", motivated by the study of Set Disjointness on a Line $\mathsf{L}_{n,d}$. The lower bound technique we use to establish Theorem 3 extends to the analogue of Set Disjointness D_n

in this model, with a switching delay of d queries. As a consequence, it yields the same lower bound on *query* complexity. Furthermore, we design a quantum algorithm that matches this bound up to a polylogarithmic factor, thus showing that the lower bound is, in a sense, optimal. We may also interpret this result as showing a limitation of the lower bound technique.

4.1 The new query model

Turning to the definition of the query model, we consider query algorithms for computing bi-variate functions $f : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$. We define the quantum version of the model; the classical versions may be defined analogously. The inputs x, y to the algorithm are provided indirectly, through oracles $\mathcal{O}_x$ and $\mathcal{O}_y$, as defined in Section 2.4. The query algorithm is defined in the standard manner, as an alternating sequence of unitary operators independent of the inputs x, y, and queries $\mathcal{O}_x$ or $\mathcal{O}_y$, applied to a fixed initial state (that is also independent of the inputs). Thus, the sequence of queries to the inputs is pre-determined. However, we define the complexity of the algorithm differently. In addition to the queries, we charge the algorithm for switching between a query to x and a query to y. We include a cost of d in the complexity whenever the algorithm switches between a query to x and a query to y. This cost parallels the cost of accessing the inputs in the distributed computing scenario in which the inputs are physically separated by distance d.

We may simplify the above model as follows, at the expense of increasing the complexity by a factor of at most 2. In the simplified model, we require that the queries be made in *rounds*. In each round, the algorithm makes d queries, but exclusively to one of the inputs x or y. Further, the algorithm alternates between the two oracles $\mathcal{O}_x$ and $\mathcal{O}_y$ in successive rounds. The complexity of the algorithm is now defined in the standard manner, as the total number of queries in the algorithm. Thus the complexity equals d times the number of rounds.

It is straightforward to verify that any algorithm with complexity q in the first model has complexity at most $2q$ in the second model, for computing any function f that depends on both inputs (i.e., when the algorithm in the first model queries both oracles). Furthermore, any algorithm with complexity q in the second model has complexity at most $2q$ in the first model. The two models are thus equivalent up to a factor of two in complexity.

The second model is also relevant in a "semi-parallel" scenario, where a sequence of d queries are made to x independently of the answers to d other queries made to y during the same time steps. Up to a factor of 2 in complexity, this semi-parallel model can be simulated by the second model above. We thus adopt the second model in the definition below.

▶ **Definition 10.** *A* two-oracle delay-d quantum query algorithm *is a query algorithm $\mathcal{A}$ with (predetermined) access to two oracles $\mathcal{O}_1, \mathcal{O}_2$, which may be decomposed into some number of contiguous sequences of unitary operators called rounds such that each round contains d queries to the same oracle, and the algorithm alternates between the two oracles in successive rounds. The* round complexity *of $\mathcal{A}$ is the number r of rounds in a decomposition of $\mathcal{A}$ as above. The* delay-d query complexity *of $\mathcal{A}$ is $d \times r$.*

We define the *quantum two-oracle delay-d round complexity* of a bi-variate function f as the minimum round-complexity of any two-oracle delay-d quantum query algorithm computing f with probability of error at most $1/3$, given oracles $\mathcal{O}_x, \mathcal{O}_y$ for the inputs x, y. We define the *quantum two-oracle delay-d query complexity* of f similarly. We may assume that $d \leq n$, as otherwise, an algorithm can learn x and y in two rounds.

Adapting the tools developed in Section 3 we get the following lower bound.

▶ **Theorem 11.** *Let $d \leq n$. The quantum two-oracle delay-d round complexity of Set Disjointness* D_n *is* $\Omega(\sqrt{n}/d)$ *and* $\Omega(\sqrt[3]{n/(d \log n)}\,)$. *The quantum two-oracle delay-d query complexity is* $\Omega(\sqrt{n}\,)$ *and* $\Omega(\sqrt[3]{nd^2/\log n}\,)$.

Note that the first expression for either bound dominates when $d^4 \in \mathrm{O}(n \log^2 n)$.

We briefly sketch the proof of Theorem 11. The query lower bound follows from the one on rounds. The $\Omega(\sqrt{n}/d)$ lower bound on rounds follows by observing that Set Disjointness D_n simplifies to the unordered search problem (OR function on n bits) in the standard quantum query model when we set y to be the all 1s string. For the second lower bound, we view a query to an oracle $\mathcal{O}_x$ or $\mathcal{O}_y$ as the exchange of of $2(\log n + 1)$ qubits between the algorithm and the oracle. So we can use any r-round algorithm for computing f in the two-oracle delay-d query model to derive a two-party communication protocol for computing f also with r rounds. The two parties run the query algorithm, sending all its registers to the corresponding player, whenever the algorithm switches between queries to x and queries to y. In each round, the state of the algorithm (therefore the corresponding message) accumulates at most $2d(\log n + 1)$ qubits of *additional* information about either input. This is a consequence of the same kind of reasoning as in Lemma 8. Thus the conditional information loss of the resulting two-party protocol may be bounded by $2r^2 d(\log n + 1)$. By Theorem 7, this is $\Omega(n/r)$, so we get the $\Omega(\sqrt[3]{n/(d \log n)}\,)$ lower bound for the number of rounds stated in Theorem 11.

4.2 Algorithm for Set Disjointness

Finally, we present an algorithm in the two-oracle model that matches the lower bounds stated in Theorem 11, up to polylogarithmic factors.

▶ **Theorem 12.** *Let $d \leq n$. The quantum two-oracle delay-d round and query complexity of Set Disjointness* D_n *are*

- $\mathrm{O}(\sqrt{n \log n}/d)$ *and* $\mathrm{O}(\sqrt{n \log n}\,)$, *respectively, when* $d^4 \leq n \log^3 n$; *and*
- $\mathrm{O}(\sqrt[3]{n/d}\,)$ *and* $\mathrm{O}(\sqrt[3]{nd^2}\,)$, *respectively, when* $d^4 \geq n \log^3 n$.

Proof. We present a quantum two-oracle delay-d query algorithm with a parameter $t \in [n]$, which gives the round and query bounds for suitable choices of t depending on how large d is as compared with n.

The quantum algorithm runs in two stages. First, it searches for a subset $I \subseteq [n]$ of size t such that it contains an index $i \in [n]$ with $x_i = y_i = 1$. If it succeeds in finding such a subset I, in the second stage, the algorithm looks for an index $i \in I$ such that $x_i = y_i = 1$. For this, it sequentially runs through the indices in I and checks if the requisite condition is satisfied. The second stage can thus be implemented in $\mathrm{O}(\max\{1, t/d\})$ rounds. The choice of t is such that the number of rounds in the first stage always dominates, and gives us the stated bounds.

We describe the first stage next. In order to identify a subset I containing an index i as above, if there is any, we implement a search algorithm based on a quantum walk on the Johnson Graph $J(n,t)$, following the framework due to Magniez, Nayak, Roland, and Santha [13]. The vertices of $J(n,t)$ are t-subsets of $[n]$. There is an edge between two vertices I, I' in $J(n,t)$ iff I and I' differ in exactly 2 elements: $(I \setminus I') \cup (I' \setminus I) = \{i,j\}$ for distinct elements $i, j \in [n]$.

The three building blocks of such an algorithm are as follows.

Set-up: Construct the following starting superposition:

$$\frac{1}{\binom{n}{t}^{1/2}} \sum_{I \subseteq [n] \,:\, |I| = t} |(i, x_i) : i \in I\rangle \enspace .$$

Checking: Check whether $x_i = y_i = 1$ for some $i \in I$:

$$|(i, x_i) : i \in I\rangle \quad \mapsto \quad \begin{cases} -|(i, x_i) : i \in I\rangle, & \text{if } x_i = y_i = 1 \text{ for some } i \in I \enspace ; \\ |(i, x_i) : i \in I\rangle, & \text{otherwise.} \end{cases}$$

Update: Replace some index $j \in I$ by an index $k \notin I$, and update the corresponding bit x_j to x_k:

$$|(i, x_i) : i \in I\rangle |j\rangle |k\rangle \quad \mapsto \quad |(i, x_i) : i \in (I \setminus \{j\}) \cup \{k\}\rangle |k\rangle |j\rangle \enspace .$$

Let ε be the probability that a uniformly random t-subset of $[n]$ contains an index i such that $x_i = y_i = 1$, given that such an element i exists. We have $\varepsilon \in \Omega(t/n)$. Then, according to Theorem 1.4 in Ref. [13], there is an algorithm based on quantum walk that finds a subset I such that $x_i = y_i = 1$ for some $i \in I$, if there is any such subset, with constant probability $> 1/2$. The algorithm uses one instance of Set-up, and $\mathrm{O}(\sqrt{1/\varepsilon}\,)$ alternations of one instance of Checking with a sequence of $\mathrm{O}(\sqrt{t}\,)$ instances of Update, interspersed with other unitary operations that are independent of the inputs x, y. (The spectral gap of the Johnson graph needed in the analysis of the algorithm may be derived from the results in Ref. [11], for example.)

Note that Set-up uses t queries to x, and thus can be implemented in $\max(1, 2\lceil t/d \rceil)$ rounds. Update only requires 2 queries to x. Thus a sequence of $\sqrt{t}$ sequential Update operations can be implemented in order $\max(1, 2\sqrt{t}/d)$ rounds. We would like to use the Grover algorithm for unordered search to implement the checking step. The Grover algorithm incurs non-zero probability of error in general, while the algorithm due to Magniez *et al.* assumes that the checking step is perfect. We therefore use an algorithm for unordered search with small error due to Buhrman, Cleve, de Wolf, and Zalka [4] to implement Checking with error at most $c\sqrt{t/n}$ for a suitable positive constant c with order $\sqrt{t \log(n/t)}$ queries to y. Using standard arguments, this only increases the error of the quantum walk algorithm by a small constant, say $1/10$. In effect, Checking (with the stated error) can be implemented in order $\max(1, \sqrt{t \log n}/d)$ rounds. Thus the bound on the round complexity of the quantum walk algorithm is of the order of

$$\max\left\{1, \frac{t}{d}\right\} + \sqrt{\frac{n}{t}} \left(\max\left\{1, \frac{\sqrt{t \log n}}{d}\right\} + \max\left\{1, \frac{\sqrt{t}}{d}\right\} \right) \enspace . \tag{4.1}$$

In order to derive the bounds stated in the theorem, we optimise over t. We consider intervals of values for t such that each of the expressions involving maximisation in Eq. (4.1) simplifies to one of the terms. The intervals are given by partitioning $[n]$ at the points $d, d^2/\log n, d^2$. (Note that d need not be smaller than $d^2/\log n$.) We optimise the number of rounds within each interval, which in turn gives us a relation between d and n for which the rounds are minimised.

We first consider $d \le \log n$, so that $d^2/\log n \le d$, and t in the intervals

$$[1, d^2/\log n], \quad [d^2/\log n, d], \quad [d, d^2], \quad \text{and } [d^2, n] \enspace .$$

We optimise the number of rounds with t in each of these intervals, to find that the number of rounds is $\mathrm{O}(\sqrt{n \log n}/d)$ when $t \coloneqq d$. The optimal values of t in the other intervals also give the same bound, but we stay with $t = d$ so as to minimise the rounds in the second stage of the algorithm.

Next we consider $d \ge \log n$, so that $d \le d^2/\log n \le d^2$. We again optimise over t in four intervals, and get the following bounds:

1. $t \in [1, d]$: $\mathrm{O}(\sqrt{n/d}\,)$ when $t := d$.
2. $t \in [d, d^2/\log n]$: $\mathrm{O}(\sqrt[3]{n/d}\,)$ when $t := \sqrt[3]{nd^2}$, *provided* $d^4 \geq n \log^3 n$. If $d^4 \leq n \log^3 n$, we get $\mathrm{O}(\sqrt{n \log n}/d)$ when $t := d^2/\log n$.
3. $t \in [d^2/\log n, d^2]$: $\mathrm{O}(\sqrt{n \log n}/d)$ when $t := d^2/\log n$ *provided* $d^4 \leq n \log^3 n$; If $d^4 \geq n \log^3 n$, we get $\mathrm{O}(d/\log n)$ with the same value of t.
4. $t \in [d^2, n]$: $\mathrm{O}(\sqrt{n \log n}/d)$ when $t := d^2$ *provided* $d^4 \leq n \log n$; If $d^4 \geq n \log n$, we get $\mathrm{O}(d)$ with the same value of t.

Since $\sqrt{n/d} \geq \sqrt{n \log n}/d$ when $d \geq \log n$, $\sqrt{n \log n}/d \leq d$ when $d^4 \geq n \log n$, and $(n/d)^{1/3} \leq d/\log n$ when $d^4 \geq n \log^3 n$, we conclude the bounds on round complexity stated in the theorem:

- $\mathrm{O}(\sqrt{n \log n}/d)$ with $t := d$ when $d \leq \log n$, or with $t := d^2/\log n$ when $\log^4 n \leq d^4 \leq n \log^3 n$, and
- $\mathrm{O}(\sqrt[3]{n/d}\,)$ with $t := \sqrt[3]{nd^2}$ when $d^4 \geq n \log^3 n$.

The bounds on query complexity follow. ◀

Note that in the range of parameters such that $n \log^2 n \leq d^4 \leq n \log^3 n$, the upper bound $\sqrt{n \log n}/d$ is at most $\sqrt{\log n}$ times the lower bound $\sqrt[3]{n/d \log n}$. So the bounds in Theorems 11 and 12 are indeed within polylogarithmic factors of each other for all values of d, n (such that $d \leq n$).

5 Conclusion

In this work, we studied a fundamental problem, Set Disjointness, in two concrete computational models. Set Disjointness on the Line $\mathsf{L}_{n,d}$ reveals new subtleties in distributed computation with quantum resources. It again puts the spotlight on the "double counting" of information in conditional information loss. One may think that the more sophisticated notion of *quantum information cost* introduced by Touchette [18], along with the results due to Braverman *et al.* [3], might help us overcome this drawback. Indeed, quantum information cost helps us overcome the limitation(s) of the former quantity in the case of Set Disjointness in the standard two-party communication model. Surprisingly, these techniques do not seem to help in obtaining a better lower bound for $\mathsf{L}_{n,d}$. We believe that new ideas may be needed to characterise the its asymptotic round complexity.

The two-oracle query model we introduce gives us a different perspective on Set Disjointness on a Line. It hints at the possibility of a better communication protocol for $\mathsf{L}_{n,d}$, although we may also interpret the optimal algorithm in this model as highlighting the limitation of the information loss technique. More generally, the new query model is tailored towards the study of distributed algorithms on the line and could shed light on protocols for other similar problems. Moreover, the model could also be of relevance in other distributed computation scenarios.

Abstract

Boneh, Bonneau, Bünz, and Fisch (CRYPTO 2018) recently introduced the notion of a *verifiable delay function* (VDF). VDFs are functions that take a long *sequential* time T to compute, but whose outputs $y \coloneqq \mathsf{Eval}(x)$ can be efficiently verified (possibly given a proof π) in time $t \ll T$ (e.g., $t = \mathrm{poly}(\lambda, \log T)$ where λ is the security parameter). The first security requirement on a VDF, called *uniqueness*, is that no polynomial-time algorithm can find a convincing proof π' that verifies for an input x and a different output $y' \neq y$. The second security requirement, called *sequentiality*, is that no polynomial-time algorithm running in time $\sigma < T$ for some parameter σ (e.g., $\sigma = T^{1/10}$) can compute y, even with $\mathrm{poly}(T, \lambda)$ many parallel processors. Starting from the work of Boneh et al., there are now multiple constructions of VDFs from various algebraic assumptions.

In this work, we study whether VDFs can be constructed from ideal hash functions in a black-box way, as modeled in the random oracle model (ROM). In the ROM, we measure the running time by the number of oracle queries and the sequentiality by the number of *rounds* of oracle queries. We rule out two classes of constructions of VDFs in the ROM:

- We show that VDFs satisfying *perfect* uniqueness (i.e., VDFs where no different convincing solution $y' \neq y$ exists) cannot be constructed in the ROM. More formally, we give an attacker that finds the solution y in $\approx t$ *rounds* of queries, asking only $\mathrm{poly}(T)$ queries in total.
- We also rule out *tight* verifiable delay functions in the ROM. Tight verifiable delay functions, recently studied by Döttling, Garg, Malavolta, and Vasudevan (ePrint Report 2019), require sequentiality for $\sigma \approx T - T^{\rho}$ for some constant $0 < \rho < 1$. More generally, our lower bound also applies to proofs of sequential work (i.e., VDFs without the uniqueness property), even in the private verification setting, and sequentiality $\sigma > T - {}^{T}\!/_{2t}$ for a concrete verification time t.

1 Introduction

A verifiable delay function (VDF) [5] with domain $\mathcal{X}$ and range $\mathcal{Y}$ is a function that takes long *sequential* time T to compute, but whose output can be efficiently verified in time $t \ll T$ (e.g., $t = \text{poly}(\lambda, \log T)$ where λ is a security parameter). More precisely, there exists an evaluation algorithm Eval that on input $x \in \mathcal{X}$ computes a value $y \in \mathcal{Y}$ and a proof π in time T. In addition, there is a verification algorithm Verify that takes as input a domain element $x \in \mathcal{X}$, a value $y \in \mathcal{Y}$, and a proof π and either accepts or rejects in time t. In some cases, a VDF might also have a setup algorithm Setup which generates a set of public parameters pp that is provided as input to Eval and Verify.[1] Typically, we require that the setup is also fast: namely, Setup runs in time $s = \text{poly}(\lambda, \log T)$ as well. The two main security requirements for a VDF are (1) *uniqueness* which says that for all inputs $x \in \mathcal{X}$, no adversary running in time $\text{poly}(\lambda, T)$ can find $y' \neq \mathsf{Eval}(x)$ and a proof π' such that $\mathsf{Verify}(x, y', \pi') = 1$; and (2) *sequentiality* with some parameter $\sigma < T$, which says that no adversary running in *sequential time* σ can compute $y = \mathsf{Eval}(x)$. The sequential time σ allows the adversary to have up to $\text{poly}(\lambda, T)$ parallel processors.

Verifiable delay functions have recently received extensive study, and have found numerous applications to building randomness beacons [5, 13] and cryptographic timestamping schemes [19]. Driven by these exciting applications, a sequence of recent works have developed constructions of verifiable delay functions from various algebraic assumptions [14, 24, 28, 29]. However, existing constructions still leave much to be desired in terms of concrete efficiency, and today, there are significant community-driven initiatives to construct, implement, and optimize more concretely-efficient VDFs [16]. One of the bottlenecks in existing constructions of VDFs is their reliance on structured algebraic assumptions (e.g., groups of unknown order [4, 26] or isogenies over pairing groups [14]).

A natural question to ask is whether we can construct VDFs generically from *unstructured* primitives, such as one-way functions, collision-resistant hash functions, or stronger forms of hash functions. In this work, we study whether black-box constructions of VDFs are possible starting from hash functions or other symmetric primitives. Specifically, we consider black-box constructions of VDFs from ideal hash functions (modeled as a random oracle). Similar to previous work (cf. [2, 21]) in the *parallel* random oracle model (ROM), we measure the running time of the adversary by the number of oracle queries it makes and the sequentiality of the adversary by the number of *rounds* of oracle queries it makes. However, we simply refer to the parallel ROM as the ROM.

1.1 Our Results

In this work, we rule out the existence of VDFs with *perfect* uniqueness (i.e., VDFs where for any $x \in \mathcal{X}$, there does not exist any (y', π) such that $\mathsf{Verify}(x, y', \pi) = 1$ and $y' \neq \mathsf{Eval}(x)$) in the random oracle model. Specifically, we construct an adversary that asks $O(t)$ rounds of queries and a total number of $\text{poly}(T)$ queries and breaks the uniqueness of VDFs with respect to *some* oracle.

A natural class of VDFs with perfect uniqueness is the class of *permutation* VDFs where the function $\mathsf{Eval}(\cdot)$ implements a permutation on the domain (specifically, $\mathcal{X} = \mathcal{Y}$), and verification consists of inverting y and checking if it is x or not. Recently, Abusalah et al. [1]

[1] Ideally, the public parameters can be sampled by a public-coin process [5, 24, 29]. Otherwise, we require a trusted setup to generate the public parameters [14, 28].

constructed permutation VDFs in the ROM, but they additionally relied on the assumptions used in the sloth functions of Lenstra and Wesolowski [20]. Our work shows that relying on some kind of structured assumption is *necessary* to achieve permutation VDFs.

We next show that in the "tight" regime of sequentiality, as recently studied in the concurrent work of Döttling et al. [10] (i.e., when the sequentiality parameter σ is quite close to T), even *proofs of sequential work* (PoSW) [7,12,22,25] cannot be based on random oracles. In particular, our result essentially applies to settings where $\sigma \gg T \cdot (1 - 1/t)$ where t is the verification time. A proof of sequential work is a relaxation of a VDF without the uniqueness or the public-verifiability properties. Thus, our lower bound for ruling out tight PoSW also rules out tight VDFs in the ROM. We note, however, that since (even publicly-verifiable) PoSW satisfying weaker notions of sequentiality (e.g., $\sigma = T/2$) are known to exist in the ROM [22], it is not clear whether this lower bound for PoSW can be extended to rule out (non-tight) VDFs, and we leave this as an intriguing open question.

We note that both of our lower bounds are proven in settings that have already been studied in previous (or concurrent) work. Namely, by ruling out permutation VFDs in the ROM, our first main result complements the previous work on permutation VDFs [1] by showing that the random oracle alone is not sufficient to realize such strong VDFs. Moreover, our second result shows that when it comes to the tight regime of sequentiality (studied in the concurrent work of [10]), VDFs as well as more relaxed notions like proofs of sequential work cannot be based on symmetric primitives in a black-box way.

1.1.1 Our Techniques

At a technical level, the proofs of our lower bounds start from the techniques of Mahmoody, Moran, and Vadhan [21] for ruling out time-lock puzzles in the random oracle model. In fact, for a special case of perfectly-unique VDFs where the VDF is a *permutation* on its domain $\mathcal{X} = \mathcal{Y}$, which we refer to as a "permutation VDF" (cf., [1,18,20]), we can use the impossibility result of [21] as a black-box by reducing the task of constructing time-lock puzzles in the ROM to constructing permutation-VDFs in the ROM.

For the more general case of perfectly-unique VDFs (that are not necessarily permutations) we cannot use the result of [21] as a black-box, but we can still adapt the ideas from their work that are reminiscent of similar techniques also used in [6,23,27]. Namely, our attacker will sample full executions of the evaluation function Eval in its head, while respecting answers to queries that it has already learned from the real oracle. At the end of each simulated execution, it will ask all previously-unasked queries in a *single round* to the oracle (and use those values in subsequent simulated executions). We show that using just $O(t)$ rounds of this form, we can argue that in most of these rounds, the adversary does not hit any "new query" in the verification process. Consequently, in most of the executions it is *consistent* with the verification procedure with respect to *some* oracle O', and thus by the *perfect uniqueness* property, the answer in those executions should be the correct one. Finally, by taking a majority vote over the executions, we obtain the correct answer with high probability. Observe that this argument critically relies on *perfect uniqueness.* The main open question remaining is whether a similar lower bound for *computational uniqueness* holds for VDF in the ROM or not. In this setting, the security requirement is that no *efficient* adversary can find a different value $y' \neq \mathsf{Eval}(x)$ with a proof π' that passes verification. (See Section 3.1.)

We then adapt this technique to additionally rule out *tight* proofs of sequential work in the ROM. Roughly, a scheme satisfies tight sequentiality if no adversary running in sequential time $\sigma = T - T^{\rho}$ for constant $\rho < 1$ can compute (y, π) such that $\mathsf{Verify}(x, y, \pi) = 1$. More generally, we consider a setting of parameters where $\sigma > T \cdot (1 - {}^{1}/_{2t})$, where t denotes the number of queries made by Verify. In this setting, we can construct an algorithm that simulates the answers to *some* but *not* all of the oracle queries made by the evaluation algorithm. The algorithm answers the remaining queries based on the real oracle evaluations. To simplify the description, in the following, assume that the setup algorithm is essentially nonexistent, and that the public parameter is fixed and publicly known ahead of time. Since the scheme is assumed to be *tightly* sequential, as long as the algorithm simulates sufficiently-many queries (e.g., $T/2t$ queries), it is possible to reduce the number of rounds of queries made to the real oracle (i.e., from T to $T - T/2t$). Moreover, if the number of "simulated responses" is small enough and if the set of queries for which the algorithm simulates is chosen at random, then there is a good chance that none of the simulated queries are asked during verification. If both of these properties hold simultaneously, then the algorithm successfully computes a response that verifies, thus breaking tight sequentiality. We provide the formal analysis in Section 3.2. However, the formal version of this argument needs to also incorporate the query complexity of the setup algorithm as well, leading to a weaker attack that only applies when $\sigma > T \cdot (1 - 1/2(s+t))$. However, in Section 4, we describe how to extend our lower bounds on tight proofs of sequential work (and correspondingly, tight VDFs) to additionally rule out tight proofs of sequential work with an *expensive* setup phase as well as tight proofs of sequential work in the random *permutation* model. In particular, we show how to leverage preprocessing to essentially eliminate the dependency of the attack's online phase on the query complexity of the setup.

1.2 Related Work

Verifiable delay functions are closely related to the notion of (publicly-verifiable) proofs of sequential work (PoSW) [1, 8, 11, 22]. The main difference between VDFs and PoSWs is *uniqueness*. More specifically, a VDF ensures that for every input x, an adversary running in time $\text{poly}(\lambda, T)$ can only find at most *one* output y (accompanied with a possibly non-unique proof π) that the verifier would accept (and if it does, the verifier is also convinced that the prover performed T sequential work). In contrast, a PoSW does not provide any guarantees on uniqueness. In particular, for every input x, there might be many possible pairs (y, π) that the verifier would accept, and as a result, in this setting there is no longer a need to distinguish between the output y and the proof π. Even more generally, proofs of work need not be publicly-verifiable [12], and one could only require sequentiality against adversaries who do not know a secret verification key generated during the setup. We emphasize that the uniqueness property in VDFs is important both for applications as well as constructions. Indeed, publicly-verifiable proofs of sequential work can be constructed in the random oracle model [8, 11, 22], while our work rules out a broad class of VDFs in the same model.

Time-lock puzzles. Time-lock puzzle [25] are closely related to VDFs as they are also based on the notion of sequentiality. In a time-lock puzzle, a puzzle generator can generate a puzzle x *together* with a solution y in time $t \ll T$, but computing y from x still requires sequential time T. The main difference between VDFs and time-lock puzzles is that time-lock puzzles might require knowledge of a *secret key* for efficient verification (in time t). In contrast, VDFs are publicly-verifiable (in time t). However, similar to VDFs, the output of a time-lock puzzle is *unique*. Mahmoody et al. [21] leverage this very uniqueness property *and* the fact that the solution is known ahead of the time to the verifier (because it is sampled during the puzzle generation) to show an impossibility result for time-lock puzzles in the random oracle model. While VDFs also require unique solutions, these solutions might not be known when we directly sample an input.

Concurrent work. In an independent and concurrent work, Döttling et al. [10] introduce and provide an in-depth study of tight verifiable delay functions. Their work both provides a positive construction of tight VDFs (from algebraic assumptions) as well as a negative result on the existence of *tight* VDFs in the random oracle model. In this work, we show that the lower bound on tight VDFs also extends to (even *privately*-verifiable) proofs of sequential work. At the same time, we note that (even publicly-verifiable) proofs of sequential work do exist in the *non-tight* regime (e.g., $\sigma = T/2$) in the ROM [22]. Thus, whether or not this lower bound in the random oracle model on tight VDFs can be extended to arbitrary (*non-tight*) VDFs or not still remains an intriguing open question.

2 Preliminaries

Throughout this work, we use λ to denote the security parameter. For an integer $n \in \mathbb{N}$, we write $[n]$ to denote the set $\{1, 2, \ldots, n\}$. We write $\text{poly}(\lambda)$ to denote a quantity that is bounded by a fixed polynomial in λ and $\text{negl}(\lambda)$ to denote a function that is $\lambda^{-\omega(1)}$. For a distribution D, we write $x \leftarrow D$ to denote that x is drawn from D. For a randomized algorithm Alg, we write $y \leftarrow \mathsf{Alg}(x)$ to denote the process of computing y by running Alg on input x with (implicitly-defined) randomness r of the appropriate length (based on the length of x). For a finite set $\mathcal{S}$, we write $x \overset{\$}{\leftarrow} \mathcal{S}$ to denote that x is sampled uniformly at random from $\mathcal{S}$. We say that an algorithm is efficient if it runs in probabilistic polynomial time in the length of its input. We now review the definition of a verifiable delay function.

▶ **Definition 1** (Verifiable Delay Function [5]). *A* verifiable delay function *is a tuple of algorithms* $\Pi_{\mathsf{VDF}} = (\mathsf{Setup}, \mathsf{Eval}, \mathsf{Verify})$ *with the following properties:*

- $\mathsf{Setup}(1^\lambda, T) \to \mathsf{pp}$*: On input the the security parameter* λ *and the time bound* T*, the setup algorithm outputs the public parameters* pp*. The public parameter determines a (uniformly)* samplable *input space* $\mathcal{X}_{\mathsf{pp}}$ *and an output space* $\mathcal{Y}_{\mathsf{pp}}$*. When the context is clear, we simply denote them as* $\mathcal{X}$ *and* $\mathcal{Y}$*.*
- $\mathsf{Eval}(\mathsf{pp}, x) \to (y, \pi)$*: On input the public parameters* pp *and an element* $x \in \mathcal{X}$*, the evaluation algorithm outputs a value* $y \in \mathcal{Y}$ *and a (possibly empty) proof* π*. Moreover, in case* Eval *is randomized, the first output* y *should be determined by* x *and* pp *(and be independent of the randomness used). We will typically refer to* y *as the "output" of the VDF on* x*, and since* y *is unique, when the context is clear, we simply write* $y = \mathsf{Eval}(\mathsf{pp}, x)$ *to denote the output of the VDF on* x*.*
- $\mathsf{Verify}(\mathsf{pp}, x, y, \pi) \to \{0, 1\}$*: On input the public parameters* pp*, an element* $x \in \mathcal{X}$*, a value* $y \in \mathcal{Y}$*, and a proof string* $\pi \in \{0, 1\}^*$*, the verification algorithm outputs a bit (*1 *means accept and* 0 *means reject).*

Moreover, the algorithms must satisfy the following efficiency requirements:

- *The setup algorithm* Setup *runs in time* $\text{poly}(\lambda, \log T)$*.*
- *The evaluation algorithm* Eval *runs in time* T*.*
- *The verification algorithm* Verify *runs in time* $\text{poly}(\lambda, \log T)$*.*

For simplicity of notation, in the following sections, we sometimes write s (resp., t) to denote the running time of Setup (resp., Verify). This additionally allow us to state our results more generally while also explicitly stating how our results depend on the precise bounds on the running time of Setup and Verify.

Completeness. We now define the completeness requirement on VDFs.

▶ **Definition 2** (Completeness of VDF). *A VDF* $\Pi_{\mathsf{VDF}} = (\mathsf{Setup}, \mathsf{Eval}, \mathsf{Verify})$ *has completeness error* γ *if for all* $\lambda \in \mathbb{N}$ *and* $T \in \mathbb{N}$*,*

$$\Pr\left[\mathsf{Verify}(\mathsf{pp}, x, y, \pi) = 1 \;:\; \begin{array}{c} \mathsf{pp} \leftarrow \mathsf{Setup}(1^\lambda, T), x \xleftarrow{\$} \mathcal{X}_{\mathsf{pp}} \\ (y, \pi) \leftarrow \mathsf{Eval}(\mathsf{pp}, x) \end{array}\right] \geq 1 - \gamma.$$

Unless stated otherwise, we assume $\gamma = 0$. For our first lower bound, we need perfect completeness $\gamma = 0$, but our second lower bound in the tight regime directly extends to more generalized settings where the completeness error γ is $\operatorname{negl}(\lambda)$ (or even a small constant).

Security. The two main security requirements we require on a VDF are *uniqueness* and *sequentiality*. We define these below.

▶ **Definition 3** (Uniqueness of VDF). *A VDF* $\Pi_{\mathsf{VDF}} = (\mathsf{Setup}, \mathsf{Eval}, \mathsf{Verify})$ *satisfies* uniqueness *for a class* $\mathcal{A}$ *of adversaries with error* $\varepsilon(\lambda)$*, if for all adversaries* $\mathsf{Adv} \in \mathcal{A}$*, we have that*

$$\Pr\left[y \neq \mathsf{Eval}(\mathsf{pp}, x) \wedge \mathsf{Verify}(\mathsf{pp}, x, y, \pi) \;:\; \begin{array}{c} \mathsf{pp} \leftarrow \mathsf{Setup}(1^\lambda, T) \\ (x, y, \pi) \leftarrow \mathsf{Adv}(1^\lambda, 1^T, \mathsf{pp}) \end{array} = 1\right] \leq \varepsilon(\lambda).$$

We say that Π_{VDF} *satisfies* statistical uniqueness *if* $\mathcal{A}$ *is the set of all (computationally unbounded) adversaries and* $\varepsilon(\lambda)$ *is negligible. We say* Π_{VDF} *satisfies* perfect uniqueness *if we further require* $\varepsilon(\lambda) = 0$*. We say that* Π_{VDF} *is* computationally unique *if* $\mathcal{A}$ *is the class of* $\operatorname{poly}(\lambda, T)$*-time adversaries and* $\varepsilon(\lambda)$ *is negligible.*

▶ **Definition 4** (Sequentiality of VDF). *A VDF* $\Pi_{\mathsf{VDF}} = (\mathsf{Setup}, \mathsf{Eval}, \mathsf{Verify})$ *is* σ*-sequential (where* σ *may be a function of* λ*,* T *and* t*) if for all adversaries* $\mathsf{Adv} = (\mathsf{Adv}_0, \mathsf{Adv}_1)$*, where* $\mathsf{Adv}_0, \mathsf{Adv}_1$ *both run in total time* $\operatorname{poly}(\lambda, T)$ *and* Adv_1 *runs in* parallel *time at most* σ*, we have that*

$$\Pr\left[y = \mathsf{Eval}(\mathsf{pp}, x) \;:\; \begin{array}{c} \mathsf{pp} \leftarrow \mathsf{Setup}(1^\lambda, T) \\ \mathsf{st}_{\mathsf{Adv}} \leftarrow \mathsf{Adv}_0(1^\lambda, 1^T, \mathsf{pp}) \\ x \xleftarrow{\$} \mathcal{X}, y \leftarrow \mathsf{Adv}_1(\mathsf{st}_{\mathsf{Adv}}, x) \end{array}\right] = \operatorname{negl}(\lambda).$$

We can view Adv_0 *as a "preprocessing" algorithm that precomputes some initial state* $\mathsf{st}_{\mathsf{Adv}}$ *based on the public parameters and* Adv_1 *as the "online" adversarial evaluation algorithm.*

▶ **Definition 5** (Decodable VDF [5]). *Let* t *be a function of* λ *and* T*. A VDF* $\Pi_{\mathsf{VDF}} = (\mathsf{Setup}, \mathsf{Eval}, \mathsf{Verify})$ *is* t-decodable *if there is no extra proof (i.e.,* $\pi = \perp$*) and there is a* decoder Dec *with the following properties:*

- Dec *runs in time* t*.*
- *For all* $x \in \mathcal{X}$*, if* $y = \mathsf{Eval}(\mathsf{pp}, x)$*, then* $\mathsf{Dec}(\mathsf{pp}, y) = x$*.*

We say that Π_{VDF} *is* strongly *decodable, if for all* $y' \neq y = \mathsf{Eval}(\mathsf{pp}, x)$*, it holds that* $\mathsf{Dec}(\mathsf{pp}, y) \neq x$*. Finally, we say a VDF is* efficiently *(strongly) decodable if it is (strongly)* t*-decodable for* $t = \operatorname{poly}(\lambda, \log T)$*.*

▶ Remark 6 (Strongly Decodable VDFs and Perfect Uniqueness). Strong decodability (Definition 5) implies *perfect* uniqueness (Definition 3). However, the reverse is not true in general.

▶ **Definition 7** (Random Oracle Model (ROM))**.** *A random oracle $\mathcal{O}$ implements a truly random function from $\{0,1\}^*$ to range $\mathcal{R}$.*[2] *Equivalently, one can use "lazy evaluation" to simulate the behavior of a random oracle as follows:*

- *If the oracle has not been queried on $x \in \{0,1\}^*$, sample $y \xleftarrow{\$} \mathcal{R}$. The oracle returns y and remembers the mapping (x, y).*
- *If the oracle was previously queried on $x \in \{0,1\}^*$, return the previously-chosen value of $y \in \mathcal{R}$ associated with x.*

▶ Remark 8 (Hardness in the Random Oracle Model). Note that constructions with unconditional security in the ROM use the oracle as the *only* source of hardness. In particular, as stated above, the number of rounds of queries to the oracle model the cost of the parallel computation. If one allows other sources of computational hardness, existing constructions of VDFs trivially also exist relative to the ROM (by ignoring the random oracle).

▶ **Definition 9** (VDFs in the ROM)**.** *We define uniqueness and sequentiality of a VDF in the ROM by allowing the components* Setup, Eval, Verify *of a VDF to be oracle-aided algorithms in the ROM and adjusting their notion of time and parallel time (in Definitions 3 and 4 according to Definition 7 and Remark 8). In particular, for sequentiality, we measure the running time of the adversary by the number of* rounds *of oracle queries the adversary makes (this is to model the capabilities of a* parallel *adversary). Furthermore, for the uniqueness property, we require that the probability of the adversary succeeding is taken over the random coins of* Setup *and of the adversary, but* not *over the choice of oracle.*

3 Lower Bounds for VDFs in the Random Oracle Model

In this section, we first show that perfectly unique VDFs (Definition 3) are impossible in the random oracle model. Then, as a corollary, we obtain barriers for strongly decodable VDFs as well. In particular, if a VDF in the ROM is perfectly unique, it means that for *every* sampled random oracle $O \leftarrow \mathcal{O}$, perfect uniqueness holds. Moreover, our result shows that a recent construction of [1] for reversible VDFs that is of the form of a permutation function and uses the sloth functions from [20] cannot be modified to only rely on a random oracle.

We then turn our attention to the case of tight VDFs (and more generally, tight proofs of sequential work) and show that they cannot be constructed in the ROM as well.

3.1 Case of Perfectly Unique VDFs

In this section, we give a lower bound for perfectly unique VDFs in the random oracle model. Specifically, we prove the following theorem:

▶ **Theorem 10** (Lower Bounds for Perfectly Unique VDFs in the ROM)**.** *Suppose $\Pi_{\mathsf{VDF}} =$ (*Setup, Eval, Verify*) is a VDF in the ROM with perfect uniqueness and perfect completeness in which (for a concrete choice of λ),* Setup *runs in time s,* Eval *runs in time T, and* Verify *runs in time t. Then, there is an adversary* Adv *that breaks sequentiality (Definition 4) by asking a total of $2T \cdot (s + t)$ queries in $2(s + t)$ rounds of queries.*

[2] There are multiple possible ways to model a random oracle in the literature. We describe three possibilities here. Sometimes, the range $\mathcal{R}$ is $\{0,1\}^\lambda$ where λ is a security parameter; other times, it is simply $\{0,1\}$, and sometimes it is a "length preserving" mapping that maps each input x to a string of the same length.

Before proving Theorem 10, we observe that this result already rules out the possibility of constructing strongly decodable VDFs (which are forced to be perfectly unique; see Remark 6) in the ROM. In fact, a special case of this theorem for the class of "permutation VDFs" can be derived from the impossibility result of [21] for time-lock puzzles [25].[3] We first define this class of special VDFs below and prove their impossibility in the ROM as a warm up.

3.1.1 Warm Up: The Special Case of Permutation VDFs

Permutation VDFs. As a special case of strongly decodable VDFs, one can further restrict the mapping from $\mathcal{X}$ to $\mathcal{Y}$ to be a *permutation* (instead of just being an injective function). Indeed, the recent construction of [1] has this exact property as they construct decodable/reversible VDFs where the evaluation function is a permutation on its domain. Indeed, [1] uses random oracles together with the sloth function from [20] to construct their permutation VDF, and thus it was left open whether random oracle would suffice for permutation VDFs. Our result rules this possibility out.

▶ **Proposition 11.** *Let Π_{VDF} be a permutation VDF in the ROM with a decoder* Dec *that runs in time t, and a setup algorithm* Setup *that runs in time s. Then, there is an adversary that breaks sequentiality (Definition 4) in $O(s+t)$ rounds of queries and $O(T \cdot (s+t))$ queries.*

Proof. Previously, Mahmoody et al. [21] showed an impossibility result for time-lock puzzles in the ROM. To prove the claim, we show how to construct a time-lock puzzle from a permutation VDF. The result then follows from the lower bound of [21]. The construction is as follows. The puzzle-generator would first run the setup algorithm Setup of the VDF to get the public parameter pp. Then, it samples $y \xleftarrow{\$} \mathcal{X} = \mathcal{Y}$ (here, we use the fact that $\mathcal{X}$ is efficiently-samplable, and that $\mathcal{X} = \mathcal{Y}$) and sets $x \leftarrow \mathsf{Dec}(\mathsf{pp}, y)$. It outputs x as the puzzle (and keeps y as the solution). Since Setup and Dec for a VDF are both efficient (i.e., run in time $\mathrm{poly}(\lambda, t)$), the puzzle-generator is also efficient.

We can now use the result of [21] which shows that any time-lock puzzle in the ROM where the puzzle-generation algorithm makes k queries and the puzzle-solving algorithm makes T queries can be broken by an adversary making $O(k)$ rounds of queries and a total of $O(k \cdot T)$ queries. For the time-lock puzzle based on the permutation VDF, $k = s + t$, where s is the number of queries made by the Setup algorithm and t is the number of queries made by the Dec algorithm. ◀

3.1.2 Proof of Theorem 10 in the General (Perfectly Unique) Case

We now give the proof of Theorem 10. It follows the ideas from [21] for ruling out time-lock puzzles in the ROM, but this time, we cannot simply reduce the problem to the setting of time-lock puzzles, and we need to go into the proof and extend it to our setting. We begin with an informal overview of the proof before providing the formal analysis.

Proof overview. We begin with an informal description of the main ideas behind the lower bound. Our goal is to construct an adversary that can efficiently find an output that passes verification, while asking fewer than T *rounds* of queries to the random oracle. To do so, we consider an algorithm that implements the honest evaluation algorithm, but instead of

[3] In a time-lock puzzle, there is a puzzle-generation algorithm that runs in time t and samples a puzzle x together with a solution y, and an evaluation algorithm that runs in sequential time T that takes an input x and outputs the solution y.

Algorithm 1 The adversary Adv that breaks sequentiality of the VDF.

```
1. At the beginning of the game, the adversary Adv receives the public parameters pp and a
   challenge $x \in \mathcal{X}$ from the sequentiality challenger.
2. Initialize a query set $Q_{\mathsf{Adv}} \leftarrow \varnothing$ and a set of query-answer pairs $P_{\mathsf{Adv}} \leftarrow \varnothing$.
3. Let $d = 2(s+t)+1$.
4. For $i \in [d]$, do the following:
   a. Initialize $P^{(i)}_{\mathsf{Adv}} \leftarrow \varnothing$ and $Q^{(i)}_{\mathsf{Adv}} \leftarrow \varnothing$.
   b. Execute $(y_i, \pi_i) \leftarrow \mathsf{Eval}(\mathsf{pp}, x)$ where the random oracle queries (made by Eval) are
      answered using the following procedure. On every oracle query $q$:
      - If $q \in Q_{\mathsf{Adv}}$, then reply with the value $r$ where $(q, r) \in P_{\mathsf{Adv}}$.
      - Otherwise, choose a uniformly random value $r \xleftarrow{\$} \mathcal{R}$ (where $\mathcal{R}$ is the range of the
        random oracle $\mathcal{O}$) and add $(q, r)$ to $P^{(i)}_{\mathsf{Adv}}$ and add $q$ to $Q^{(i)}_{\mathsf{Adv}}$.
   c. If $i < d$, then in *one round*, for all $(q, \star) \in P^{(i)}_{\mathsf{Adv}}$, query the real oracle $\mathcal{O}$ to get $r \leftarrow \mathcal{O}(q)$
      as the answer; and then add $(q, r)$ to $P_{\mathsf{Adv}}$ and add $q$ to $Q_{\mathsf{Adv}}$.
5. Output $\mathrm{Maj}(y_1, \ldots, y_d)$ where Maj denotes the majority operation (which outputs $\perp$ if no
   majority exists).
```

issuing queries to the actual random oracle, the algorithm will instead *sometimes* simulate the outputs from those queries itself (i.e., by sampling from the output distribution of the random oracle). Of course, if one of these "faked" or "simulated" queries was asked to the oracle by another algorithm in the system (e.g., by Setup or Verify), then our algorithm will almost certainly fail. On the other hand, if none of the simulated queries were asked to the oracle, then our attacker wins (because the set of "faked" queries and real queries together form an oracle that is consistent). This means that as long as the number of queries Setup and Verify make are much smaller than T and our algorithm is able to "identify" or "learn" those queries with fewer than T rounds of queries to the random oracle, then the algorithm succeeds in breaking sequentiality of the VDF.

Proof of Theorem 10. Without loss of generality, assume that Eval asks no repeated queries in a single execution. We construct an attacker Adv that breaks sequentiality of the VDF as follows. Our adversary is entirely online (i.e., there is no separate preprocessing step).

We now show that Adv in Algorithm 1 satisfies the properties needed in Theorem 10. Let Q_S be the queries made by the setup algorithm $\mathsf{Setup}(1^\lambda, T)$ to sample pp and Q_V be the queries made by $\mathsf{Verify}(\mathsf{pp}, x, y)$ where $y = \mathsf{Eval}(\mathsf{pp}, x)$ is the true solution.

For $i \in [d]$, we define H_i to be the event where there is a query $q \in Q^{(i)}_{\mathsf{Adv}} \cap (Q_S \cup Q_V)$ during the i^{th} round of emulation that was *not* previously asked by the adversary: $q \notin Q_{\mathsf{Adv}}$ *at that moment*. Equivalently, when q is asked, it holds that $q \in (Q^{(i)}_{\mathsf{Adv}} \cap (Q_S \cup Q_V)) \setminus Q_{\mathsf{Adv}}$.

The following claim shows that H_i cannot happen for too many rounds i.

▷ Claim 12. If $\mathcal{I} = \{i : H_i \text{ holds}\}$, then $|\mathcal{I}| \le s + t$.

Proof. If event H_i occurs as a result of some query q, then at the end of round i, Adv queries the oracle $\mathcal{O}$ on the input q. By construction, since $q \in (Q^{(i)}_{\mathsf{Adv}} \cap (Q_S \cup Q_V)) \setminus Q_{\mathsf{Adv}}$, it must be the case that Adv makes a *new* query on an input that was previously queried by either the Setup or Verify algorithms (but *not* queried in any of the previous rounds). However, since Setup and Verify together ask a combined total of (at most) $s + t$ queries, this event cannot happen more than $s + t$ times. ◁

▷ Claim 13. If H_i does not happen, then $y_i = y$.

Proof. Let $y_i \neq y$ for a round i in which H_i has not happened. This means that the set of oracle query-answer pairs used during Setup, and the i^{th} emulation of Eval by Adv are *consistent.* Namely, there is an oracle O', relative to which, we have $\mathsf{pp} \leftarrow \mathsf{Setup}^{O'}$, $(y', \pi') \leftarrow \mathsf{Eval}^{O'}(\mathsf{pp}, x)$, and $\mathsf{Verify}^{O'}(\mathsf{pp}, x, y, \pi) = 1$. However, this shows that the perfect uniqueness property is violated relative to O', because for input x, there is a "wrong" solution y (i.e., $y \neq y' = \mathsf{Eval}^{O'}(\mathsf{pp}, x)$) together with some proof π for y such that the verification passes $\mathsf{Verify}^{O'}(\mathsf{pp}, x, y, \pi) = 1$. ◁

By the above two claims, it holds that $y_i = y$ for at least $s+t+1$ values of $i \in [2(s+t)+1]$, and thus the majority gives the right answer y for Adv. ◀

3.2 Lower Bound for Tight Proofs of Sequential Work

We can apply similar techniques to rule out *tight* proofs of sequential work [22] in the random oracle model. At a high level, a (publicly-verifiable) proof of sequential work is a VDF without *uniqueness.* Namely, for an input x, there can be many pairs (y, π) that passes verification. In this setting, there is no need to distinguish y and π. While we have constructions of (publicly-verifiable) proofs of sequential work in the ROM, our results show that *tight* proofs of sequential work (see [10] for more discussion on this tightness notion) are impossible in this setting. In particular, the following barrier applies to settings where the sequentiality parameter σ is *very* close to T (e.g., this does not apply to $\sigma = T/2$). The following definition derives publicly-verifiable proofs of sequential work [7, 12, 22, 25] as a relaxation of VDFs.[4]

▶ **Definition 14** (Publicly-Verifiable Proofs of Sequential Work). *A* publicly-verifiable *proof of sequential work is a relaxation of a VDF where the uniqueness property is not needed. Hence, there is no need to distinguish between an output y and a proof π. In particular, $y = \pi$ can be the only (not-necessarily-unique) output of* Eval *that is still sequentially hard to compute.*

Proofs of sequential work in the ROM. While Definition 9 defines the notion of a VDF in the ROM, the same definition extends to the setting of (publicly-verifiable) proofs of sequential work in the ROM as well. Namely, we measure the running time in terms of the total number of oracle queries and the parallel time by the the number of rounds of oracle queries. We now show how to adapt our techniques for ruling our perfectly-unique VDFs in the ROM to also rule out tight proofs of sequential work.

▶ **Theorem 15** (Attacking Proofs of Sequential Work in the ROM). *Suppose $\Pi_{\mathsf{PSW}} =$ (Setup, Eval, Verify) is a publicly-verifiable proof of sequential work in the ROM in which (for a concrete choice of λ),* Setup *runs in time s,* Eval *runs in time T, and* Verify *runs in time t. Then, for any $1 < G < T$ there is an adversary* Adv *that asks a total of at most $T - G$ queries and breaks sequentiality (Definition 4) with probability at least $1 - (s+t) \cdot G/T$.*

▶ **Corollary 16** (Ruling Out Tight Proofs of Sequential Work in the ROM). *Let λ be a security parameter and T be the time bound parameter. For any choice of $s, t = \operatorname{poly}(\lambda, \log T)$, there does not exist a proof of sequential work in the ROM with sequentiality $\sigma = T \cdot (1 - 1/2(s+t))$. More generally, for any constant $0 < \rho < 1$, there does not exist a proof of sequential work in the ROM with sequentiality $\sigma = T - T^{\rho}$.*

[4] Definition 14 is even more general as it allows a setup phase.

Proof. The first statement follows by instantiating Theorem 15 with $G = {}^{T}\!/_{2(s+t)}$. For this setting of parameters, Theorem 15 implies an adversary that breaks sequentiality with probability at least $1/2$ and making only $T - G = T \cdot (1 - {}^{1}\!/_{2(s+t)})$ queries. For the more general statement, we take T to be a sufficiently large polynomial in the security parameter λ such that $s, t < T^{1-\rho}/4$. Note that this is always possible since $s, t = \mathrm{poly}(\lambda, \log T)$; that is, both s, t are poly-logarithmic in T and $0 < \rho < 1$ is constant. Then, we can again set $G = T - \sigma = T^{\rho}$ and appeal to Theorem 15 to obtain an adversary that makes $T - G = \sigma$ queries and breaks sequentiality with probability at least $1/2$. ◀

▶ Remark 17 (Secretly-Verifiable Tight Proofs of Sequential Work). We note that Theorem 15 also holds for secretly-verifiable proofs of sequential work as well. The proof for the secretly-verifiable setting is identical to that for the publicly-verifiable setting. For simplicity of notation we write the proof for the publicly-verifiable version (Definition 4) which uses pp as both the evaluation and the verification key.

▶ Remark 18 (Other Extensions). The extension from Remark 17 on ruling out secretly-verifiable tight proofs of sequential work relies on the same proof as that of Theorem 15. In Section 4, we show two extensions of this result by adapting the proof of Theorem 15. These include extending the lower bound to: (1) the setting where the Setup algorithm is "slow" (i.e., runs in time proportional to T); and (2) the random permutation model (rather than the random oracle model). We refer to Section 4 for the details on those extensions.

Proof of Theorem 15. Again, without loss of generality, we assume that Eval asks no repeated queries in a single execution. The attacker's algorithm Adv is defined as follows:

Algorithm 2 The adversary Adv that breaks sequentiality for the proof of sequential work.

```
1. At the beginning of the game, the adversary Adv receives the public parameters pp and a
   challenge $x \in \mathcal{X}$ from the sequentiality challenger.
2. Pick a random set $\mathcal{S} \subseteq [T]$ of size $T - G$.
3. Execute $(y, \pi) \leftarrow \mathsf{Eval}(\mathsf{pp}, x)$ where the $i^{\text{th}}$ oracle query $q_i$ is answered as follows:
     - If $i \in \mathcal{S}$, compute the response $r_i \leftarrow \mathcal{O}(q_i)$ from the true oracle $\mathcal{O}$.
     - Otherwise sample a uniformly random $r_i \leftarrow \mathcal{R}$ as the response for the query $q_i$.
4. Output $(y, \pi)$.
```

To analyze Algorithm 2, we compare the output of the attacker's experiment (Real) with the output in an "ideal" experiment (Ideal) where all of the oracle queries are answered using the real oracle. We define these two experiments below:

1. Sample $\mathsf{pp} \leftarrow \mathsf{Setup}(1^{\lambda}, T)$.
2. Sample $x \xleftarrow{\$} \mathcal{X}$.
3. In Experiment Real, run Algorithm 2 to obtain a pair (y, π). In Experiment Ideal, run Algorithm 2, except use the real oracle $\mathcal{O}$ to answer *all* of the oracle queries made by Eval (in Step 3 of Algorithm 2).
4. The output of the experiment is 1 if $\mathsf{Verify}(\mathsf{pp}, x, y, \pi) = 1$ and 0 otherwise.

Figure 1 The Real and Ideal experiments.

In the following, we write $\Pr_{\mathsf{real}}[\cdot]$ (resp., $\Pr_{\mathsf{ideal}}[\cdot]$) to denote the probability of an event E in the Real (resp., Ideal) experiment.

Events. Let Q_V be the set of oracle queries made by Verify and Q_S be the set of oracle queries made by Setup. Let Q_{Adv} be the set of oracle queries q_i that appears in Step 3 of Algorithm 2 where $i \notin \mathcal{S}$. Namely, these are the set of oracle queries q_i that Adv answers with uniformly random values in Real. We now define the following two events:

- Let W be the event that $\mathsf{Verify}(\mathsf{pp}, x, y, \pi) = 1$ when (y, π) is the output of the adversary (i.e., W is the event that the adversary wins and the experiment outputs 1).
- Let B be the "bad" event where $(Q_V \cup Q_S) \cap Q_{\mathsf{Adv}} \neq \varnothing$. Namely, this is the event that adversary makes up an answer to a query that is asked either by the setup algorithm or the verification algorithm.

With these definitions, the following claim trivially holds in the ideal experiment (by perfect completeness of the underlying proof of sequential work[5]), as all of the oracle queries q_i are computed using the real oracle $\mathcal{O}(q_i)$.

▷ Claim 19. $\Pr_{\mathsf{ideal}}[W] = 1$.

The following lemma states that until event B happens, the two experiments are identical.

▶ **Lemma 20.** $\Pr_{\mathsf{real}}[B] = \Pr_{\mathsf{ideal}}[B]$. *Moreover, conditioned on the event B not happening, the two experiments are identically distributed. In particular, for any event like W, it hold that* $\Pr_{\mathsf{real}}[W \vee B] = \Pr_{\mathsf{ideal}}[W \vee B]$.

Proof. Here, we make a crucial use of the fact that the oracle $\mathcal{O}$ is random. To prove the lemma, we run the two games *in parallel* using the *same* randomness for any query that is asked by any party, step by step. Namely, we start by executing the evaluation algorithm identically as much as possible until event B happens. More formally, we run both experiments by using fresh randomness to answer any new query asked during the execution, and we will *stop* the execution as soon as event B happens. Since until the event B happens both games proceed *identically* (in a perfect sense) and *consistently* according to their own distribution, it means that until event B happens, the two games have the same exact distributions. ◀

We now observe that the probability of the event B is small in the ideal game, and conclude that it is indeed small in both games.

▷ Claim 21. $\Pr_{\mathsf{ideal}}[B] \leq (s + t) \cdot \frac{G}{T}$.

Proof. In this game, the set $\mathcal{S}$ is independent of all other components in the experiment, so we can choose $\mathcal{S}$ *at the end* of the experiment (*after* Q_S and Q_V have been determined). By definition of Q_{Adv}, we have that $|Q_{\mathsf{Adv}}| \leq G$. This means that for any query $q \in Q_S \cup Q_V$ that is also queried by $\mathsf{Eval}(\mathsf{pp}, x)$, the probability that $q \in Q_{\mathsf{Adv}}$ is at most G/T. The claim now follows by a union bound. ◁

The above claims complete the proof of Theorem 15, as we now can conclude that the probability of W in both experiments is "close":

$$\left| \Pr_{\mathsf{real}}[W] - \Pr_{\mathsf{ideal}}[W] \right| \leq \Pr_{\mathsf{ideal}}[B].$$

We already know that $\Pr_{\mathsf{ideal}}[W] = 1$, therefore, we conclude that

$$\Pr_{\mathsf{real}}[W] \geq \Pr_{\mathsf{ideal}}[W] - \Pr_{\mathsf{ideal}}[B] \geq 1 - (s + t) \cdot \frac{G}{T}.$$ ◀

[5] Note that this argument extends also to the setting where we have completeness error γ (i.e., completeness holds with probability $1 - \gamma$ over the choice of the public parameters). This modification introduces a γ loss in the adversary's advantage in the real game.

4 Extensions to the Lower Bounds

In this section, we briefly discuss several extensions of our lower bounds on perfectly unique VDFs and tight proofs of sequential work by extending the proofs of Theorems 10 and 15.

4.1 Handling Expensive Setup Phase

Our lower bounds in Theorems 10 and 15 construct an adversary whose running time depends on both t (the verification time) as well as s (the setup time). When these bounds t, s are only $\text{poly}(\lambda, \log T)$, the running time of our attacker is much smaller compared to T, and thus, breaks the sequentiality of the scheme. However, one might argue that since the setup is executed only once, it is reasonable to consider a scenario where s is potentially as large as T. In this case, *both* of our lower bounds in Theorems 10 and 15 become meaningless.

Case of expensive *public* setup. If the setup algorithm is public coin (i.e, the randomness to Setup is publicly known), then both Theorems 10 and 15 directly extend to the setting where $s = \text{poly}(\lambda, T)$. Specifically, in this setting, the setup queries can be discovered publicly (i.e., by emulating an execution of Setup). Thus, the adversary can learn the oracle's values on the set of queries Q_S made by Setup. In the online phase, the adversary carries out its attack by *incorporating* the knowledge of Q_S when answering oracle queries. In other words, if during the emulation of the Eval algorithm, the adversary encounters a query $q \in Q_S$, it will use the known answer (saved as part of the state $\mathsf{st}_{\mathsf{Adv}}$) instead of asking it from the oracle or guessing its answer.

Case of expensive *private* setup for Theorem 15. When the setup algorithm uses *private* randomness, the above argument for extending Theorems 10 and 15 no longer applies. Nonetheless, we can still show how the proof of Theorem 15 (for ruling our tight proofs of sequential work) can be extended to this setting as well.

▶ **Theorem 22** (Attacking Tight Proofs of Sequential Work with Expensive Setup in the ROM)**.** *Suppose* $\Pi_{\mathsf{PSW}} = (\mathsf{Setup}, \mathsf{Eval}, \mathsf{Verify})$ *is a publicly-verifiable proof of sequential work in the ROM in which (for a concrete choice of* λ, T*),* Setup *runs in time* s*,* Eval *runs in time* T*,* Verify *runs in time* t*, and completeness error is at most* γ *(see Definition 2). Then, for any* $\varepsilon < 1$ *and* $1 < G < T$*, there is an adversary* $\mathsf{Adv} = (\mathsf{Adv}_0, \mathsf{Adv}_1)$ *where* Adv_0 *runs in time* $\text{poly}(s, T, t, 1/\varepsilon)$ *and* Adv_1 *makes at most* $T - G$ *queries (and run in total time* $\text{poly}(T)$*) and breaks sequentiality (Definition 4) with probability at least* $1 - \varepsilon - t \cdot G/T - \gamma$*.*

Before proving Theorem 22, we first derive a corollary, formally stating the range of tight sequentiality for which we rule out PoSWs in the ROM.

▶ **Corollary 23** (Ruling Out Tight Proofs of Sequential Work with Expensive Setup in the ROM)**.** *Let* λ *be a security parameter and* T *be the time bound parameter. For any choice of* $s = \text{poly}(\lambda, T), t = \text{poly}(\lambda, \log T)$*, and completeness error* $\gamma = \text{negl}(\lambda)$*, there does not exist a proof of sequential work in the ROM with sequentiality* $\sigma = T \cdot (1 - {}^1/_{2t})$ *and completeness error* γ*. In particular, for any constant* $0 < \rho < 1$*, there does not exist a proof of sequential work in the ROM with sequentiality* $\sigma = T - T^\rho$ *and completeness error* γ*.*

Proof. The proof is identical to that of Corollary 16, except here, we use the attack algorithm from Theorem 22 that relies on a preprocessing step with time complexity $\text{poly}(\lambda, T)$. The only difference is that we now also need to make sure $\varepsilon + \gamma < 1/2$, which is easily satisfied whenever $\gamma = \text{negl}(\lambda)$. For example, take $\varepsilon = 1/3$. ◀

Algorithm 3 The adversary Adv_0 that precomputes the ε-heavy queries of the Setup algorithm.

```
1. Initialize a set $Q \leftarrow \varnothing$.
2. Repeat the following procedure $k = s/\varepsilon = \mathrm{poly}(\lambda, T)$ times:
   a. Sample $x \overset{\$}{\leftarrow} \mathcal{X}$.
   b. Compute $(y, \pi) \leftarrow \mathsf{Eval}(\mathsf{pp}, x)$. Whenever Eval makes a query $q$ to the oracle $\mathcal{O}$, add
      the pair $(q, \mathcal{O}(q))$ to $Q$.
3. Output $\mathsf{st}_{\mathsf{Adv}} = Q$.
```

We now give the proof of Theorem 22.

Proof of Theorem 22. Here, Adv_0 will perform a precomputation and compute the so-called "ε-heavy" queries [3,17] of the setup algorithm. More precisely, we aim to find queries that are asked by the setup and have noticeable chance of being queried again during the evaluation. In particular, Algorithm Adv_0 outputs a set Q consisting of input-output pairs of the oracle $\mathcal{O}$. The online algorithm Adv_1 then follows Algorithm 2 from the proof of Theorem 15, except whenever Eval makes a query q where $q \in Q$, Adv_1 replies with the precomputed value of $\mathcal{O}(q)$ in Q. We now describe Adv_0:

We define Adv_1 as in Algorithm 2, except in Step 3, if the query q_i is contained in $\mathsf{st}_{\mathsf{Adv}} = Q$, then the adversary always replies with the precomputed value of $\mathcal{O}(q_i)$ in Q. Otherwise, it uses the same procedure as in Algorithm 3. The rest of the analysis proceeds similar to that in the proof of Theorem 15. Namely, let Q_S denote the set of oracle queries made by Setup and Q_V be the set of queries made by Verify in the real/ideal experiments. We define the events W and B exactly as in the proof of Theorem 15. We now show an analog of Claim 21:

▷ Claim 24. $\Pr_{\mathsf{ideal}}[B] \leq \varepsilon + t \cdot \frac{G}{T}$.

Proof. Recall that the event B occurs if $(Q_V \cup Q_S) \cap Q_{\mathsf{Adv}} \neq \varnothing$. We consider the following two setting. (All probabilities are stated in the ideal experiment.)

- Consider the probability that $Q_V \cap Q_{\mathsf{Adv}} \neq \varnothing$. By the same argument as in the proof of Claim 21, this event occurs with probability at most $|Q_V| \cdot G/T \leq t \cdot G/T$ over the randomness of $\mathcal{S}$.
- Consider the probability that $Q_S \cap Q_{\mathsf{Adv}} \neq \varnothing$. Take any query $q \in Q_S$ and consider the event H_q that $q \in Q_{\mathsf{Adv}}$ and $q \notin \mathsf{st}_{\mathsf{Adv}}$. By construction of Algorithm 3, for H_q to happen, the first k iterations of Adv_0 should *not* query q during Eval, and yet q *is* queried in the next (actual) execution of Eval. However, it is easy to show that for any Bernoulli variable (of arbitrary probability α) the probability of missing it k times and hitting it on the $(k+1)^{\text{st}}$ iteration is at most $1/k$. Since Setup makes at most s queries, $|Q_S| \leq s$, so by a union bound,

$$\Pr[Q_S \cap Q_{\mathsf{Adv}} \neq \varnothing] \leq \frac{s}{k} = \varepsilon.$$

The claim now follows by a union bound. ◁

The rest of the proof of Theorem 22 proceeds identically to the proof of Theorem 15 and noting that the probability of W in the ideal game is $1 - \gamma$. ◀

4.2 Extending to the Random Permutation Oracle Model

Random oracles can be used to instantiate all symmetric primitives (including the ideal cipher model [9,15]) with one exception: the random permutation oracle R that implements a random permutation on $\{0,1\}^n$ for all $n \in \mathbb{N}$. Indeed there are impossibility results showing that such a construction does not exist [23,27]. We can extend the proof of Theorem 15 to rule out constructions of tight proofs of sequential work in the random permutation oracle as well by developing a preprocessing attack and then using standard techniques based on the fact that a random permutation oracle and a random oracle over a large domain is statistically indistinguishable to any query-bounded algorithm [17].

Case of large input domains. More formally, let n be such that $(T+s+t)^2/2^n \leq \varepsilon$. Then, first suppose the only domain used by the three algorithms $(\mathsf{Setup}, \mathsf{Eval}, \mathsf{Verify})$ is $\{0,1\}^n$. In this case, the probability that a random oracle used by these three algorithms $\mathsf{Setup}, \mathsf{Eval}, \mathsf{Verify}$ has *any* collision during the course of their execution is at most $(T+s+t)^2/2^n \leq \varepsilon$. However, whenever there are no collisions, there is no way to distinguish between random permutations or random oracles. Therefore, our attack in Theorem 15 would automatically work (as is) up to a loss of ε in the success probability. This argument also works if the three algorithms $(\mathsf{Setup}, \mathsf{Eval}, \mathsf{Verify})$ ask their queries from input domains with *different* size as long as for any domain $\{0,1\}^n$ that they query, n satisfies $(T+s+t)^2/2^n \leq \varepsilon$.

General case. The above argument fails when any of the algorithms $(\mathsf{Setup}, \mathsf{Eval}, \mathsf{Verify})$ ask their queries from any domain $\{0,1\}^n$ where n is small (and as such, $(T+s+t)^2/2^n > \varepsilon$). However, the *total* number of queries over *all* such domains is at most

$$\tau = |\{0,1\}^1| + |\{0,1\}^2| + \cdots + |\{0,1\}^n|,$$

where $(T+s+t)^2/2^n = \varepsilon$, which means

$$\tau = 2 + 4 + \cdots + \frac{(T+s+t)^2}{\varepsilon} < \frac{2(T+s+t)^2}{\varepsilon} = \mathrm{poly}(\lambda, T).$$

Therefore, a preprocessing adversary Adv_0 can ask all of these $\tau = \mathrm{poly}(\lambda, T)$ queries from the real oracle $\mathcal{O}$ and send them together with their answers to the online adversary Adv_1 who will then use the answers to these queries whenever needed without asking them from $\mathcal{O}$ or guessing their answers. In this case, the analysis of our attack is identical to the aforementioned case with inputs drawn from a large domain.

5 Conclusion and Open Questions

In this work, we initiated a formal study of the assumptions behind VDFs and provided new lower bounds on basing VDFs with perfect uniqueness in the random oracle model as well as stronger lower bounds in the tight security regime in which the sequentiality guarantees a very close running time to the honest execution. The second lower bound applies not only to VDFs but also to relaxations of it such as sequential proofs of work. While our first lower bound captures existing notions [1], they do not extend to the full range of VDF notions.

The main open question remaining is whether we can extend our first lower bound to rule out VDFs satisfying *computational uniqueness* in the ROM, and ideally do so allowing negligible completeness error as well. Alternatively, the fact that our current lower bound critically relies on the perfect uniqueness property may suggest new approaches to basing

VDFs on weaker assumptions. Namely, any such approach must either rely on non-black-box techniques or leverage imperfect soundness in a critical manner. Both of these possibilities represent intriguing avenues for further research.

Abstract

We study the two-dimensional geometric knapsack problem for convex polygons. Given a set of weighted convex polygons and a square knapsack, the goal is to select the most profitable subset of the given polygons that fits non-overlappingly into the knapsack. We allow to rotate the polygons by arbitrary angles. We present a quasi-polynomial time $O(1)$-approximation algorithm for the general case and a polynomial time $O(1)$-approximation algorithm if all input polygons are triangles, both assuming polynomially bounded integral input data. Also, we give a quasi-polynomial time algorithm that computes a solution of optimal weight under resource augmentation, i.e., we allow to increase the size of the knapsack by a factor of $1 + \delta$ for some $\delta > 0$ but compare ourselves with the optimal solution for the original knapsack. To the best of our knowledge, these are the first results for two-dimensional geometric knapsack in which the input objects are more general than axis-parallel rectangles or circles and in which the input polygons can be rotated by arbitrary angles.

1 Introduction

In the two-dimensional geometric knapsack problem (2DKP) we are given a square knapsack $K := [0, N] \times [0, N]$ for some integer N and a set of n convex polygons $\mathcal{P}$ where each polygon $P_i \in \mathcal{P}$ has a weight $w_i > 0$; we write $w(\mathcal{P}') := \sum_{P_i \in \mathcal{P}'} w_i$ for any set $\mathcal{P}' \subseteq \mathcal{P}$. The goal is to select a subset $\mathcal{P}' \subseteq \mathcal{P}$ of maximum total weight $w(\mathcal{P}')$ such that the polygons in $\mathcal{P}'$ fit non-overlapping into K if we translate and rotate them suitably (by arbitrary angles). 2DKP is a natural packing problem, the reader may think of cutting items out of a piece of raw material like metal or wood, cutting cookings out of dough, or, in three dimensions, loading cargo into a ship or a truck. In particular, in these applications the respective items can have various kinds of shapes. Also note that 2DKP is a natural geometric generalization of the classical one-dimensional knapsack problem.

Our understanding of 2DKP highly depends on the type of input objects. If all polygons are axis-parallel squares there is a $(1 + \epsilon)$-approximation with a running time of the form $O_\epsilon(1)n^{O(1)}$ (i.e., an EPTAS) [6], and there can be no FPTAS (unless $\mathsf{P} = \mathsf{NP}$) since the problem is strongly NP-hard [11]. For axis-parallel rectangles there is a polynomial time $(17/9 + \epsilon) < 1.89$-approximation algorithm and a $(3/2 + \epsilon)$-approximation if the items can be rotated by exactly 90 degrees [5]. If the input data is quasi-polynomially bounded there is even a $(1 + \epsilon)$-approximation in quasi-polynomial time [2], with and without the possibility to rotate items by 90 degrees. For circles a $(1 + \epsilon)$-approximation is known under resource augmentation in one dimension if the weight of each circle equals its area [12].

To the best of our knowledge, there is no result known for 2DKP for shapes different than axis-parallel rectangles and circles. Also, there is no result known in which input polygons are allowed to be rotated by angles different than 90 degrees. However, in the applications of 2DKP the items might have shapes that are more complicated than rectangles or circles. Also, it makes sense to allow rotations by arbitrary angles, e.g., when cutting items out of some material. In this paper, we present the first results for 2DKP in these settings.

1.1 Our contribution

We study 2DKP for arbitrary convex polygons, allowing to rotate them by arbitrary angles. Note that due to the latter, it might be that some optimal solution places the vertices of the polygons on irrational coordinates, even if all input numbers are integers. Our first results are a quasi-polynomial time $O(1)$-approximation algorithm for general convex polygons and a polynomial time $O(1)$-approximation algorithm for triangles.

By rotation we can assume for each input polygon that the line segment defining its diameter is horizontal. We identify three different types of polygons for which we employ different strategies for packing them, see Figure 1a). First, we consider the *easy* polygons which are the polygons whose bounding boxes fit into the knapsack without rotation. We pack these polygons such that their bounding boxes do not intersect. Using area arguments and the Steinberg's algorithm [13] we obtain a $O(1)$-approximation for the easy polygons. Then we consider the *medium* polygons which are the polygons whose bounding boxes easily fit into the knapsack if we can rotate them by 45 degrees. We use a special type of packing in which the bounding boxes are rotated by 45 degrees and then stacked on top of each other, see Figure 1b). More precisely, we group the polygons by the widths of their bounding boxes and to each group we assign two rectangular containers in the packing. We compute the essentially optimal solution of this type by solving a generalization of one-dimensional knapsack for each group. Our key structural insight for medium polygons is that such a solution is $O(1)$-approximate. To this end, we prove that in OPT the medium polygons of

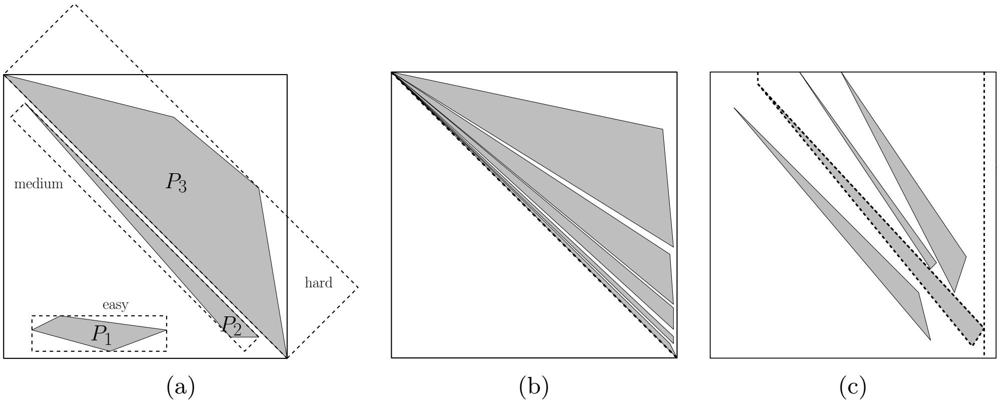

Figure 1 (a) An easy, a medium, and a hard polygon and their bounding boxes (b): Triangles packed in a top-left packing (c) The geometric DP subdivides the knapsack along the dashed lines and then recurses within each resulting area.

each group occupy an area that is by at most a constant factor bigger than the corresponding containers, and that a constant fraction of these polygons fit into the containers. In particular, we show that medium polygons with very wide bounding boxes lie in a very small hexagonical area close to the diagonal of the knapsack. Our routines for easy and medium polygons run in polynomial time.

It remains to pack the *hard* polygons whose bounding boxes just fit into the knapsack or do not fit at all, even under rotation. Note that this does not imply that the polygon itself does not fit. Our key insight is that there can be only $O(\log N)$ such polygons in the optimal solution, at most $O(1)$ from each group. Therefore, we can guess these polygons in quasi-polynomial time, assuming that N is quasi-polynomially bounded. However, in contrast to other packing problems, it is not trivial to check whether a set of given polygons fits into the knapsack since we can rotate them by arbitrary angles and we cannot enumerate all possibilities for the angles. However, we show that by losing a constant factor in the approximation guarantee we can assume that the placement of each hard polygon comes from a precomputable polynomial size set and hence we can guess the placements of the $O(\log N)$ hard polygons in quasi-polynomial time.

▶ **Theorem 1.** *There is a $O(1)$-approximation algorithm for 2DKP with a running time of $(nN)^{(\log nN)^{O(1)}}$.*

If all hard polygons are triangles we present even a *polynomial* time $O(1)$-approximation algorithm. We split the triangles in OPT into two types, for one type we show that a constant fraction of it can be packed in what we call *top-left-packings*, see Figure 1b). In these packings, the triangles are sorted by the lengths of their longest edges and placed on top of each other in a triangular area. We devise a dynamic program (DP) that essentially computes the most profitable top-left-packing. For proving that this yields a $O(1)$-approximation, we need some careful arguments for rearranging a subset of the triangles with large weight to obtain a packing that our DP can compute. We observe that essentially all hard polygons in OPT must intersect the horizontal line that contains the mid-point of the knapsack. Our key insight is that if we pack a triangle in a top-left-packing then it intersects this line to a similar extent as in OPT. Then we derive a sufficient condition when a set of triangles fits in a top-left-packing, based on by how much they overlap this line.

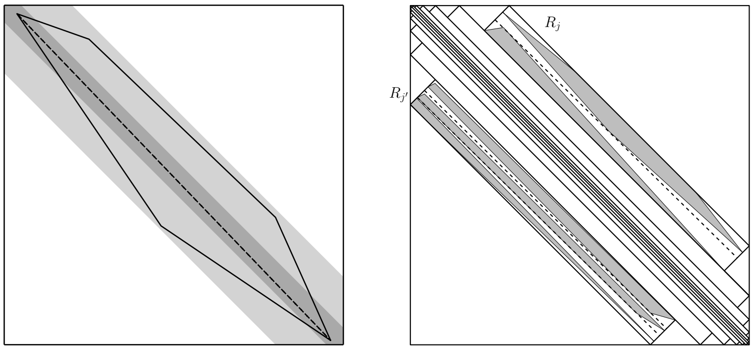

Figure 2 Left: Assume that the polygon (black line segments) is a medium polygon contained in the set $\mathcal{P}_j$. Then the diagonal (dashed) line segment must lie into the dark-gray area and the whole polygon must be contained in the light-gray area. Right: The containers for the medium polygons of the different groups. Within each container, the polygons are stacked on top of each other such that their respective bounding boxes do not intersect.

For the other type of triangles we use a geometric dynamic program. In this DP we recursively subdivide the knapsack into subareas in which we search for the optimal solution recursively, see Figure 1c). In the process we guess the placements of some triangles from OPT. Again, by losing a constant factor we can assume that for each triangle in OPT there are only a polynomial number of possible placements. By exploiting structural properties of this type of triangles we ensure that the number of needed DP-cells is bounded by a polynomial. A key difficulty is that we sometimes split the knapsack into two parts on which we recurse independently. Then we need to ensure that we do not select some (possibly high weight) triangle in both parts. To this end, we globally select at most one triangle from each of the $O(\log N)$ groups (losing a constant factor) and when we recurse, we guess for each subproblem from which of the $O(\log N)$ groups it contains a triangle in OPT. This yields only $2^{O(\log N)} = N^{O(1)}$ guesses.

▶ **Theorem 2.** *There is a $O(1)$-approximation algorithm for 2DKP with a running time of $(nN)^{O(1)}$ if all input polygons are triangles.*

Then we study the setting of resource augmentation, i.e., we compute a solution that fits into a larger knapsack of size $(1+\delta)N \times (1+\delta)N$ for some constant $\delta > 0$ and compare ourselves with a solution that fits into the original knapsack of size $N \times N$. We show that then the optimal solution can contain only *constantly* many hard polygons and hence we can guess them in *polynomial* time.

▶ **Theorem 3.** *There is a $O(1)$-approximation algorithm for 2DKP under $(1+\delta)$-resource augmentation with a running time of $n^{O_\delta(1)}$.*

Finally, we present a quasi-polynomial time algorithm that computes a solution of weight at least $w(\mathrm{OPT})$ (i.e., we do not lose any factor in the approximation guarantee) that is feasible under resource augmentation. This algorithm does not use the above classification of polygons into easy, medium, and hard polygons. Instead, we prove that if we can increase the size of the knapsack slightly we can ensure that for the input polygons there are only $(\log n)^{O_\delta(1)}$ different shapes by enlarging the polygons suitably. Also, we show that we need to allow only a polynomial number of possible placements and rotations for each input polygon, *without* sacrificing any polygons from OPT. Then we use a technique from [1] implying that there is a balanced separator for the polygons in OPT with only $(\log n)^{O_\delta(1)}$ edges and which intersects polygons from OPT with only very small area. We guess the separator, guess how many polygons of each type are placed inside and outside the separator, and then recurse on each of these parts. Some polygons are intersected by the balanced separator. However, we ensure that they have very small area in total and hence we can place them into the additional space of the knapsack that we gain due to the resource augmentation. This generalizes a result in [2] for axis-parallel rectangles.

▶ **Theorem 4.** *There is an algorithm for 2DKP under* $(1+\delta)$*-resource augmentation with a running time of* $n^{O_\delta(\log n)^{O(1)}}$ *that computes a solution of weight at least* $w(\mathrm{OPT})$*.*

In our approximation algorithms, we focus on a clean exposition of our methodology for obtaining $O(1)$-approximations, rather than on optimizing the actual approximation ratio. Due to space constraints, most proofs and details had to be ommited in this extended abstract.

1.2 Other related work

Prior to the results mentioned above, polynomial time $(2+\epsilon)$-approximation algorithms for 2DKP for axis-parallel rectangles were presented by Jansen and Zhang [10, 9]. For the same setting, a PTAS is known under resource augmentation in one dimension [7] and a polynomial time algorithm computing a solution with optimum weight under resource augmentation in both dimensions [6]. Also, there is a PTAS if the weight of each rectangle equals its area [3]. For squares, Jansen and Solis-Oba presented a PTAS [8].

2 Constant factor approximation algorithms

In this section we present our quasi-polynomial time $O(1)$-approximation algorithm for general convex polygons and our polynomial time $O(1)$-approximation algorithm for triangles., assuming polynomially bounded input data. Our strategy is to partition the input polygons $\mathcal{P}$ into three classes, easy, medium, and hard polygons, and then to devise algorithms for each class separately.

Let $K := [0,N] \times [0,N]$ denote the given knapsack. We assume that each input polygon is described by the coordinates of its vertices which we assume to be integral. First, we rotate each polygon in $\mathcal{P}$ such that its longest diagonal (i.e., the line segment that connects the two vertices of largest distance) is horizontal. For each polygon $P_i \in \mathcal{P}$ denote by $(x_{i,1}, y_{i,1}), ..., (x_{i,k_i}, y_{i,k_i})$ the new coordinates of its vertices. Observe that due to the rotation, the resulting coordinates might not be integral, and possibly not even rational. We will take this into account when we define our algorithms. For each $P_i \in \mathcal{P}$ we define its *bounding box* B_i to be the smallest axis-parallel rectangle that contains P_i. Formally, we define $B_i := [\min_\ell x_{i,\ell}, \max_\ell x_{i,\ell}] \times [\min_\ell y_{i,\ell}, \max_\ell y_{i,\ell}]$. For each polygon P_i let $\ell_i := \max_\ell x_{i,\ell} - \min_\ell x_{i,\ell}$ and $h_i := \max_\ell y_{i,\ell} - \min_\ell y_{i,\ell}$. If necessary we will work with suitable estimates of these values later, considering that they might be irrational and hence we cannot compute them exactly.

We first distinguish the input polygons into *easy*, *medium*, and *hard* polygons. We say that a polygon P_i is *easy* if B_i fits into K without rotation, i.e., such that $\ell_i \leq N$ and $h_i \leq N$. Denote by $\mathcal{P}_E \subseteq \mathcal{P}$ the set of easy polygons. Note that the bounding box of a polygon in $\mathcal{P} \setminus \mathcal{P}_E$ might still fit into K if we rotate it suitably. Intuitively, we define the medium polygons to be the polygons P_i whose bounding box B_i fits into K with quite some slack if we rotate B_i properly and the hard polygons are the remaining polygons (in particular those polygons whose bounding box does not fit at all into K).

Formally, for each polygon $P_i \in \mathcal{P}$ we define $h'_i := \sqrt{2}N - \ell_i$. The intuition for h'_i is that a rectangle of width ℓ_i and height h'_i is the highest rectangle of width ℓ_i that still fits into K.

▶ **Lemma 5.** *Let $P_i \in \mathcal{P}$. A rectangle of width ℓ_i and height h'_i fits into K (if we rotate it by 45°) but a rectangle of width ℓ_i and of height larger than h'_i does not fit into K.*

Hence, if h_i is much smaller than h'_i then B_i fits into K with quite some slack. Therefore, we define that a polygon $P_i \in \mathcal{P} \setminus \mathcal{P}_E$ is *medium* if $h_i \leq h'_i/8$ and *hard* otherwise. Denote by $\mathcal{P}_M \subseteq \mathcal{P}$ and $\mathcal{P}_H \subseteq \mathcal{P}$ the medium and hard polygons, respectively. We will present $O(1)$-approximation algorithms for each of the sets $\mathcal{P}_E, \mathcal{P}_M, \mathcal{P}_H$ separately. The best of the computed sets will then yield a $O(1)$-approximation overall.

For the easy polygons, we construct a polynomial time $O(1)$-approximation algorithm in which we select polygons such that we can pack their bounding boxes as non-overlapping rectangles using Steinberg's algorithm [4], see Section 2.1. The approximation ratio follows from area arguments.

▶ **Lemma 6.** *There is a polynomial time algorithm that computes a solution $\mathcal{P}'_E \subseteq \mathcal{P}_E$ with $w(\mathrm{OPT} \cap \mathcal{P}_E) \leq O(w(\mathcal{P}'_E))$.*

For the medium polygons, we obtain a $O(1)$-approximation algorithm using a different packing strategy, see Section 2.2.

▶ **Lemma 7.** *There is an algorithm with a running time of $n^{O(1)}$ that computes a solution $\mathcal{P}'_M \subseteq \mathcal{P}_M$ with $w(\mathrm{OPT} \cap \mathcal{P}_M) \leq O(w(\mathcal{P}'_M))$.*

The most difficult polygons are the hard polygons. First, we show that in quasi-polynomial time we can obtain a $O(1)$-approximation for them, see Section 2.3.

▶ **Lemma 8.** *There is an algorithm with a running time of $(nN)^{(\log nN)^{O(1)}}$ that computes a solution $\mathcal{P}'_H \subseteq \mathcal{P}_H$ with $w(\mathrm{OPT} \cap \mathcal{P}_H) \leq O(w(\mathcal{P}'_H))$.*

Combining Lemmas 6, 7, and 8 yields Theorem 1. If all polygons are triangles, we obtain a $O(1)$-approximation even in polynomial time. The following lemma is proved in Section 2.3.1 and together with Lemmas 6 and 7 implies Theorem 2.

▶ **Lemma 9.** *If all input polygons are triangles, then there is an algorithm with a running time of $(nN)^{O(1)}$ that computes a solution $\mathcal{P}'_H \subseteq \mathcal{P}_H$ with $w(\mathrm{OPT} \cap \mathcal{P}_H) \leq O(w(\mathcal{P}'_H))$.*

Orthogonal to the characterization into easy, medium and hard polygons, we subdivide the polygons in $\mathcal{P}$ further into classes according to the respective values ℓ_i. More precisely, we do this according to their difference between ℓ_i and the diameter of K, i.e., $\sqrt{2}N$. Formally, for each $j \in \mathbb{Z}$ we define $\mathcal{P}_j := \{P_i \in \mathcal{P} | \ell_i \in [\sqrt{2}N - 2^j, \sqrt{2}N - 2^{j-1})\}$ and additionally $\mathcal{P}_{-\infty} := \{P_i \in \mathcal{P} | \ell_i = \sqrt{2}N\}$. Note that for each polygon $P_i \in \mathcal{P}$ we can compute the group $\mathcal{P}_j$ even though ℓ_i might be irrational.

2.1 Easy polygons

We present a $O(1)$-approximation algorithm for the polygons in $\mathcal{P}_E$. First, we show that the area of each polygon is at least half of the area of its bounding box. We will use this later for defining lower bounds using area arguments.

▶ **Lemma 10.** *For each $P_i \in \mathcal{P}$ it holds that* $\mathrm{area}(P_i) \geq \frac{1}{2}\mathrm{area}(B_i)$.

On the other hand, it is known that we can pack any set of axis-parallel rectangles into K, as long as their total area is at most $\mathrm{area}(K)/2$ and each single rectangle fits into K.

▶ **Theorem 11** ([13]). *Let $r_1, ..., r_k$ be a set of axis-parallel rectangles such that $\sum_{i=1}^{k} \text{area}(r_i) \leq \text{area}(K)/2$ and each individual rectangle r_i fits into K. Then there is a polynomial time algorithm that packs $r_1, ..., r_k$ into K.*

We first compute (essentially) the most profitable set of polygons from $\mathcal{P}_E$ whose total area is at most $\text{area}(K)$ via a reduction to one-dimensional knapsack.

▶ **Lemma 12.** *In time $(\frac{n}{\epsilon})^{O(1)}$ we can compute a set of polygons $\mathcal{P}' \subseteq \mathcal{P}_E$ such that $w(\mathcal{P}') \geq (1-\epsilon)w(\text{OPT} \cap \mathcal{P}_E)$ and $\sum_{P_i \in \mathcal{P}_E} \text{area}(P_i) \leq \text{area}(K)$.*

The idea is now to partition $\mathcal{P}'$ into at most 7 sets $\mathcal{P}'_1, ..., \mathcal{P}'_7$. Hence, one of these sets must contain at least a profit of $w(\mathcal{P}')/7$. We define this partition such that each set $\mathcal{P}'_j$ contains only one polygon or its polygons have a total area of at most $\text{area}(K)/4$.

▶ **Lemma 13.** *Given a set $\mathcal{P}' \subseteq \mathcal{P}_E$ with $\sum\limits_{P_i \in \mathcal{P}_E} \text{area}(P_i) \leq \text{area}(K)$. In polynomial time we can compute a set $\mathcal{P}'' \subseteq \mathcal{P}'$ with $w(\mathcal{P}'') \geq \frac{1}{7}w(\mathcal{P}')$ and additionally $\sum\limits_{P_i \in \mathcal{P}''} \text{area}(P_i) \leq \text{area}(K)/4$ or $|\mathcal{P}''| = 1$.*

If $|\mathcal{P}''| = 1$ we simply pack the single polygon in $\mathcal{P}''$ into the knapsack. Otherwise, using Lemmas 10 and 12 and Theorem 11 we know that we can pack the bounding boxes of the polygons in $\mathcal{P}''$ into K. Note that their heights and widths might be irrational. Therefore, we slightly increase them such that these values become rational, before applying Theorem 11 to compute the actual packing. If as a result the total area of the bounding boxes exceeds $\text{area}(K)/2$ we partition them into two sets where each set satisfies that the total area of the bounding boxes is at most $\text{area}(K)/2$ or it contains only one polygon and we keep the more profitable of these two sets (hence losing a factor of 2 in the approximation ratio). This yields a $O(1)$-approximation algorithm for the easy polygons and thus proves Lemma 6.

2.2 Medium polygons

We describe a $O(1)$-approximation algorithm for the polygons in $\mathcal{P}_M$. In its solution, for each $j \in \mathbb{Z}$ we will define two rectangular containers R_j, R'_j for polygons in $\mathcal{P}_M \cap \mathcal{P}_j$, each of them having width $\sqrt{2}N - 2^{j-1}$ and height 2^{j-3}, see Figures 2. Let $\mathcal{R} := \cup_j \{R_j, R'_j\}$. First, we show that we can pack all containers in $\mathcal{R}$ into K (if we rotate them by 45°).

▶ **Lemma 14.** *The rectangles in $\mathcal{R}$ can be packed non-overlappingly into K.*

For each $j \in \mathbb{Z}$ we will compute a set of polygons $\mathcal{P}'_j \subseteq \mathcal{P}_M \cap \mathcal{P}_j$ of large weight. Within each container R_j, R'_j we will stack the bounding boxes of the polygons in $\mathcal{P}'_j$ on top of each other and then place the polygons in $\mathcal{P}'_j$ in their respective bounding boxes, see Figure 2. In particular, a set of items $\mathcal{P}''_j \subseteq \mathcal{P}_j$ fits into R_j (or R'_j) using this strategy if and only if $h(\mathcal{P}''_j) := \sum_{P_i \in \mathcal{P}''_j} h_i \leq 2^{j-3}$. Observe that for a polygon $P_i \in \mathcal{P}_j$ with $P_i \in \mathcal{P}_H$ it is not necessarily true that $h_i \leq 2^{j-3}$ and hence for hard polygons this strategy is not suitable. We compute the essentially most profitable set of items $\mathcal{P}'_j$ that fits into R_j and R'_j with the above strategy. For this, we need to solve a variation of one-dimensional knapsack with two knapsacks (instead of one) that represent R_j and R'_j. The value h_i for a polygon P_i might be irrational, therefore we work with a $(1+\epsilon)$-estimate of h_i instead. This costs only a factor $O(1)$ in the approximation guarantee.

▶ **Lemma 15.** *Let $\epsilon > 0$. For each $j \in \mathbb{Z}$ there is an algorithm with a running time of $n^{O(\frac{1}{\epsilon})}$ that computes two disjoint sets $\mathcal{P}'_{j,1}, \mathcal{P}'_{j,2} \subseteq \mathcal{P}_j \cap \mathcal{P}_M$ such that $h(\mathcal{P}'_{j,1}) \leq 2^{j-3}$ and $h(\mathcal{P}'_{j,2}) \leq 2^{j-3}$ and $w(\mathcal{P}^*{}_{j,1} \cup \mathcal{P}^*{}_{j,2}) \leq O(w(\mathcal{P}'_{j,1} \cup \mathcal{P}'_{j,2}))$ for any disjoint sets $\mathcal{P}^*{}_{j,1}, \mathcal{P}^*{}_{j,2} \subseteq \mathcal{P}_j \cap \mathcal{P}_M$ such that $h(\mathcal{P}^*_{j,1}) \leq 2^{j-3}$ and $h(\mathcal{P}^*_{j,2}) \leq 2^{j-3}$.*

For each $j \in \mathbb{Z}$ with $\mathcal{P}_j \cap \mathcal{P}_M \neq \emptyset$ we apply Lemma 15 and obtain sets $\mathcal{P}'_{j,1}, \mathcal{P}'_{j,2}$. We pack $\mathcal{P}'_{j,1}$ into R_j and $\mathcal{P}'_{j,2}$ into R'_j, using that $h(\mathcal{P}'_{j,1}) \leq h(R_j)$ and $h(\mathcal{P}'_{j,2}) \leq h(R'_j)$. Then we pack all containers R_j, R'_j for each $j \in \mathbb{Z}$ into K, using Lemma 14.

Let $\mathcal{P}'_M := \bigcup_j \mathcal{P}'_{j,1} \cup \mathcal{P}'_{j,2}$ denote the selected polygons. We want to show that $\mathcal{P}'_M$ has large weight; more precisely we want to show that $w(\mathrm{OPT} \cap \mathcal{P}_M) \leq O(w(\mathcal{P}'_M))$. First, we show that for each $j \in \mathbb{Z}$ the polygons in $\mathcal{P}_j \cap \mathcal{P}_M \cap \mathrm{OPT}$ have bounded area. To this end, we show that they are contained inside a certain (irregular) hexagon (see Figure 2) which has small area if the polygons $P_i \in \mathcal{P}_j$ are wide, i.e., if ℓ_i is close to $\sqrt{2}N$. The reason is that then P_i must be placed close to the diagonal of the knapsack and on the other hand h_i is relatively small (since P_i is medium), which implies that all of P_i lies close to the diagonal of the knapsack. For any object $O \subseteq \mathbb{R}^2$ we define area(O) to be its area.

▶ **Lemma 16.** *For each j it holds that* $\mathrm{area}(\mathcal{P}_j \cap \mathcal{P}_M) \leq O(\mathrm{area}(R_j \cup R'_j))$*.*

Using this, we can partition $\mathcal{P}_j \cap \mathcal{P}_M \cap \mathrm{OPT}$ into at most $O(1)$ subsets such that for each subset $\mathcal{P}'$ it holds that $h(\mathcal{P}') \leq 2^{j-3}$ and hence $\mathcal{P}'$ fits into R_j (and R'_j) using our packing strategy above. Here we use that each medium polygon $P_i \in \mathcal{P}_j$ satisfies that $h_i \leq 2^{j-3}$.

▶ **Lemma 17.** *For each $j \in \mathbb{Z}$ there are disjoint set $\mathcal{P}^*{}_{j,1}, \mathcal{P}^*{}_{j,2} \subseteq \mathcal{P}_j \cap \mathcal{P}_M \cap \mathrm{OPT}$ with $w(\mathcal{P}_j \cap \mathcal{P}_M \cap \mathrm{OPT}) \leq O(w(\mathcal{P}^*{}_{j,1} \cup \mathcal{P}^*{}_{j,2}))$ such that $h(\mathcal{P}^*_{j,1}) \leq 2^{j-3}$ and $h(\mathcal{P}^*_{j,2}) \leq 2^{j-3}$.*

By combining Lemmas 14, 15 and 17 we obtain the proof of Lemma 7.

2.3 Hard polygons

We first show that for each class $\mathcal{P}_j$ there are at most a constant number of polygons from $\mathcal{P}_j \cap \mathcal{P}_H$ in OPT, and that for only $O(\log N)$ classes $\mathcal{P}_j$ it holds that $\mathcal{P}_j \cap \mathcal{P}_H \neq \emptyset$.

▶ **Lemma 18.** *For each $j \in \mathbb{Z}$ it holds that $|\mathcal{P}_j \cap \mathcal{P}_H \cap \mathrm{OPT}| \leq O(1)$. Also, if $\mathcal{P}_j \cap \mathcal{P}_H \neq \emptyset$ then $j \in \{j_{\min}, ..., j_{\max}\}$ with $j_{\min} := -\lceil \log N \rceil$ and $j_{\max} := 1 + \lceil \log((\sqrt{2}-1)N) \rceil$.*

We describe now a quasi-polynomial time algorithm for hard polygons, i.e., we want to prove Lemma 8. Lemma 18 implies that $|\mathcal{P}_H \cap \mathrm{OPT}| \leq O(\log N)$. Therefore, we can enumerate all possibilities for $\mathcal{P}_H \cap \mathrm{OPT}$ in time $n^{O(\log N)}$. For each for each enumerated set $\mathcal{P}'_H \subseteq \mathcal{P}_H$ we need to check whether it fits into K. We cannot try all possibilities for placing $\mathcal{P}'_H$ into K since we are allowed tof rotate the polygons in $\mathcal{P}'_H$ by arbitrary angles. To this end, we show that there is a subset of $\mathcal{P}_H \cap \mathrm{OPT}$ of large weight which contains only a single polygon or it does not use the complete space of the knapsack but leaves some empty space. We use this empty space to move the polygons slightly and rotate them such that each of them is placed in one out of $(nN)^{O(1)}$ different positions that we can compute beforehand. Hence, we can guess all positions of these polygons in time $(nN)^{O(\log N)}$. We define that a *placement* of a polygon $P_i \in \mathcal{P}$ inside K is a polygon $\tilde{P}_i$ such that $d + \mathrm{rot}_\alpha(P_i) = \tilde{P}_i \subseteq K$ where $d \in \mathbb{R}^2$ and $\mathrm{rot}_\alpha(P_i)$ is the polygon that we obtain when we rotate P_i by an angle α clockwise around its first vertex.

▶ **Lemma 19.** *For each polygon $P_i \in \mathcal{P}_H$ we can compute a set of $(nN)^{O(1)}$ possible placements $\mathcal{L}_i$ in time $(nN)^{O(1)}$ such that there exists a set $\mathcal{P}'_H \subseteq \mathcal{P}_H \cap \mathrm{OPT}$ with $w(\mathcal{P}_H \cap \mathrm{OPT}) \leq O(w(\mathcal{P}'_H))$ which can be packed into K such that each polygon P_i is packed according to a placement in $\mathcal{L}_i$.*

This yields the proof of Lemma 8.

2.3.1 Hard triangles

In this section we present a $O(1)$-approximation algorithm in *polynomial* time for hard polygons assuming that they are all triangles, i.e., we prove Lemma 9. Slightly abusing notation, denote by OPT the set $\mathcal{P}'_H$ obtained by applying Lemma 19. We distinguish the triangles in OPT into two types: *edge-facing* triangles and *corner-facing* triangles. Let $P_i \in \mathrm{OPT} \cap \mathcal{P}_H$, let e_1, e_2 denote the two longest edges of P_i, and let v_i^* the vertex of P_i adjacent to e_1 and e_2. Let $R_i^{(1)}$ and $R_i^{(2)}$ be the two rays that originate at v_i^* and that contain e_1 and e_2, respectively, in the placement of P_i in OPT. We have that $R_i^{(1)} \setminus \{v_i^*\}$ and $R_i^{(2)} \setminus \{v_i^*\}$ intersect at most one edge of the knapsack each. If $R_i^{(1)} \setminus \{v_i^*\}$ and $R_i^{(2)} \setminus \{v_i^*\}$ intersect the same edge of the knapsack then we say that P_i is *edge-facing,* if one of them intersects a horizontal edge and the other one intersects a vertical edge we say that P_i is *corner-facing.* The next lemma shows that there can be only $O(1)$ triangles in $\mathrm{OPT} \cap \mathcal{P}_H$ that are neither edge- nor corner-facing, and therefore we compute a $O(1)$-approximation with respect to the total profit of such triangles by simply selecting the input triangle with maximum weight.

▶ **Lemma 20.** *There can be at most $O(1)$ triangles in $\mathrm{OPT} \cap \mathcal{P}_H$ that are neither edge-facing nor corner-facing.*

Let p_{TL}, p_{TR}, p_{BL}, and p_{BR} denote the top left, top right, bottom left, and bottom right corners of K, respectively, and let $p_M := \binom{N/2}{N/2}$, $p_L := \binom{0}{N/2}$, and $p_R := \binom{N}{N/2}$, see Figure 3. By losing a factor $O(1)$ we assume from now on that that OPT contains at most one hard triangle from each group $\mathcal{P}_j$, using Lemma 18.

Let $\mathrm{OPT}_{\mathrm{EF}} \subseteq \mathrm{OPT} \cap \mathcal{P}_H$ denote the edge-facing hard triangles in OPT and denote by $\mathrm{OPT}_{\mathrm{CF}} \subseteq \mathrm{OPT} \cap \mathcal{P}_H$ the corner-facing hard triangles in OPT. In the remainder of this section we present now $O(1)$-approximation algorithms for edge-facing and for corner-facing triangles in $\mathcal{P}_H$. By selecting the best solution among the two we obtain the proof of Lemma 9.

Edge-facing triangles

We define a special type of solutions called *top-left-packings* that our algorithm will compute. We will show later that there are solutions of this type whose profit is at least a constant fraction of the profit of $\mathrm{OPT}_{\mathrm{EF}}$.

For each $t \in \mathbb{N}$ let $p_t := p_M + \frac{t}{N^2}\binom{1}{0}$. Let $\mathcal{P}' = \{P_{i_1}, ..., P_{i_k}\}$ be a set of triangles that are ordered according to the groups $\mathcal{P}_j$, i.e., such that for any $P_{i_\ell}, P_{i_{\ell+1}} \in \mathcal{P}'$ with $P_{i_\ell} \in \mathcal{P}_j$ and $P_{i_{\ell+1}} \in \mathcal{P}_{j'}$ for some j, j' it holds that $j \leq j'$. We define a placement of $\mathcal{P}'$ that we call a *top-left-packing.* First, we place P_{i_1} such that $v_{i_1}^*$ concides with p_{TL} and one edge of P_{i_1} lies on the diagonal of K that connects p_{TL} and p_0. Note that there is a unique way to place P_{i_1} in this way. Iteratively, suppose that we have packed triangles $\{P_{i_1}, ..., P_{i_\ell}\}$ such that for each triangle $P_{i_{\ell'}}$ in this set its respective vertex $v_{i_{\ell'}}^*$ coincides with p_{TL}, see Figure 1c). Intuitively, we pack $P_{i_{\ell+1}}$ on top of P_{i_ℓ} such that $v_{i_{\ell+1}}^*$ coincides with p_{TL}. Let t be the smallest integer such that the line segment connecting p_t and p_R has empty intersection with each triangle $P_{i_1}, ..., P_{i_\ell}$ according to our placement. We place $P_{i_{\ell+1}}$ such that $v_{i_{\ell+1}}^*$ concides with p_{TL} and one of its edges lies on the line that contains p_{TL} and p_t. There is a unique way to place $P_{i_{\ell+1}}$ in this way. We continue until we placed all triangles in $\mathcal{P}'$. If all of them are placed completely inside K we say that the resulting solution is a *top-left-packing* and that $\mathcal{P}'$ is *top-left-packable.* We define *bottom-right-packing* and *bottom-right-packable* symmetrically, mirroring the above definition along the line that contains p_{BL} and p_{TR}.

In the next lemma we show that there is always a top-left-packable or a bottom-right-packable solution with large profit compared to $\mathcal{P}_H \cap \mathrm{OPT}$ or there is a single triangle with large profit.

▶ **Lemma 21.** *There exists a solution $\mathcal{P}_H^* \subseteq \mathcal{P}_H \cap \mathrm{OPT}_{\mathrm{EF}}$ such that $w(\mathcal{P}_H \cap \mathrm{OPT}_{\mathrm{EF}}) \leq O(w(\mathcal{P}_H^*))$ and*

- *$\mathcal{P}_H^*$ is top-left-packable or bottom-right-packable and for each j we have that $|\mathcal{P}_H^* \cap \mathcal{P}_j| \leq 1$,*
- *or it holds that $|\mathcal{P}_H^*| = 1$.*

Proof sketch. Let L be the line segment connecting p_L with p_R. Essentially, we can assume that the length of the longest edge of each triangle is close to $\sqrt{2}N$ (the length of the diagonal of the knapsack), e.g., $(1-\epsilon)\sqrt{2}N$ for some $\epsilon > 0$. One can show that this holds for all but $O_\epsilon(1)$ hard triangles in OPT. Our key observation is that in *any* packing each hard triangle P_i intersects L by the same amount (up to constant factors). Using this, we partition $\mathrm{OPT}_{\mathrm{EF}}$ into $O(1)$ groups such that in any packing each group intersects L by a smaller amount than $\mathrm{OPT}_{\mathrm{EF}}$ in the original packing. This guarantees that the bottom edge of each triangle fits in the top-left-packing for each group. Using that in the original packing the triangles in $\mathrm{OPT}_{\mathrm{EF}}$ were edge-facing, we show that also the entire triangle fits. ◀

We describe now a polynomial time algorithm that computes the most profitable solution that satisfies the properties of Lemma 21. To find the most profitable solution $\mathcal{P}_H^*$ that satisfies that $|\mathcal{P}_H^*| = 1$ we simply take the triangle with maximum weight, let P_{i^*} be this triangle. We establish now a dynamic program that computes the most profitable top-left-packable solution; computing the most profitable bottom-right-packable solution works analogously. Our DP has a cell corresponding to pairs (j,t) with $j,t \in \mathbb{Z}$. Intuitively, (j,t) represents the subproblem of computing a set $\mathcal{P}'_H \subseteq \mathcal{P}_H$ of maximum weight such that $\mathcal{P}'_H \cap \mathcal{P}_{j'} = \emptyset$ for each $j' < j$ and $|\mathcal{P}'_H \cap \mathcal{P}_{j''}| \leq 1$ for each $j'' \geq j$ and such that $\mathcal{P}'_H$ is top-left-packable inside the triangular area T_t defined by the line that contains p_{TL} and p_t, the top edge of K, and the right edge of K. Given a cell (j,t) we want to compute a solution $DP(j,t)$ associated with (j,t). Intuitively, we guess whether the optimal solution $\mathcal{P}'_H$ to (j,t) contains a triangle from $\mathcal{P}_H \cap \mathcal{P}_j$. Therefore, we try each triangle $P_i \in \mathcal{P}_H \cap \mathcal{P}_j$ and place it inside T_t such that v_i^* concides with p_{TL} and one of its edges lies on the line containing p_{TL} and p_t. Let $t'(P_i)$ denote the smallest integer such that $t'(P_i) \geq t$ and $p_{t'(P_i)}$ is not contained in the resulting placement of P_i inside T_t. We associate with P_i the solution $P_i \cup DP(j+1, t'(P_i))$. Finally, we define $DP(j,t)$ to be the solution of maximum profit among the solutions $P_i \cup DP(j+1, t'(P_i))$ for each $P_i \in \mathcal{P}_H \cap \mathcal{P}_j$ and the solution $DP(j+1,t)$.

We introduce a DP-cell $DP(j,t)$ for each pair $(j,t) \in \mathbb{Z}^2$ where $j_{\min} \leq j \leq j_{\max}$ and $0 \leq t \leq \log_{1+1/n}\left(\frac{N}{2}\right)$. Note that due to Lemma 18 for all other values of j we have that $\mathcal{P}_j \cap \mathcal{P}_H = \emptyset$. Also note that $p_t \notin K$ if $t \geq N^2/2$. This yields at most $(nN)^{O(1)}$ cells in total. Finally, we output the solution $DP(j_{\min}, 0)$.

In the next lemma we prove that our DP computes the optimal top-left-packable solution with the properties of Lemma 21.

▶ **Lemma 22.** *There is an algorithm with a running time of $(nN)^{O(1)}$ that computes the optimal solution $\mathcal{P}' \subseteq \mathcal{P}_H$ such that $\mathcal{P}'$ is top-left-packable or bottom-right-packable and such that for each j we have that $|\mathcal{P}' \cap \mathcal{P}_j| \leq 1$.*

We execute the above DP and its counterpart for bottom-right-packable solutions to obtain a top-left-packable solution $\mathcal{P}'_1$ and a bottom-right-packable solution $\mathcal{P}'_2$. We output the most profitable solution among $\{P_{i^*}\}, \mathcal{P}'_1, \mathcal{P}'_2$. Due to Lemma 21 this yields a solution with weight at least $\Omega(w(\mathcal{P}_H \cap \mathrm{OPT}))$.

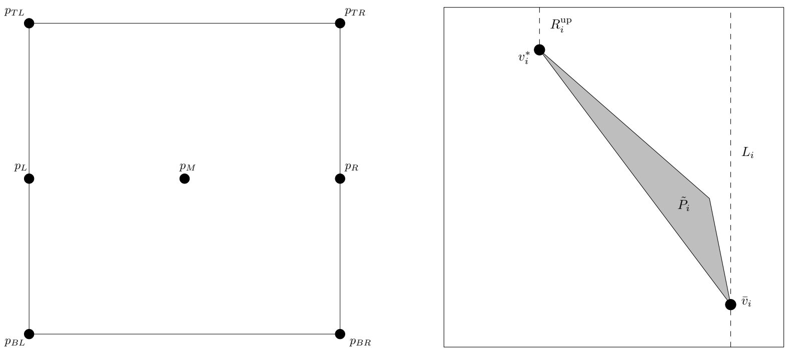

Figure 3 Left: The points $p_{TL}, p_{TR}, p_{BL}, p_{BR}, p_L, p_M, p_R$. Right: A corner-facing triangle, its vertices v_i^* and $\bar{v}_i$, and the lines L_i and R_i^{up}.

▶ **Lemma 23.** *There is an algorithm with a running time of $(nN)^{O(1)}$ that computes a solution $\mathcal{P}'_H \subseteq \mathcal{P}_H$ such that $w(\text{OPT}_{\text{EF}}) \leq O(w(\mathcal{P}'_H))$.*

Corner-facing triangles

We present now a $O(1)$-approximation algorithm for the corner-facing triangles in OPT, i.e., our algorithm computes a solution $\mathcal{P}' \subseteq \mathcal{P}$ of profit at least $\Omega(w(\text{OPT}_{\text{CF}}))$. We first establish some properties for OPT_{CF}. We argue that by losing a constant factor we can assume that each triangle in OPT_{CF} intuitively faces the bottom-right corner.

▶ **Lemma 24.** *By losing a factor 4 we can assume that for each triangle $P_i \in \text{OPT}_{\text{CF}}$ we have that $R_i^{(1)} \setminus \{v_i^*\}$ intersects the bottom edge of the knapsack and and $R_i^{(2)} \setminus \{v_i^*\}$ intersects the right edge of the knapsack, or vice versa.*

In the following lemma we establish a property that will be crucial for our algorithm. For each $P_i \in \text{OPT}_{\text{CF}}$ let R_i^{up} denote the ray originating at v_i^* and going upwards. We establish that we can assume that R_i^{up} does not intersect with any triangle $P_{i'} \in \text{OPT}_{\text{CF}}$, see Figure 3.

▶ **Lemma 25.** *By losing a factor $O(1)$ we can assume that for each $P_i, P_{i'} \in \text{OPT}_{\text{CF}}$ it holds that $R_i^{\text{up}} \cap P_{i'} = \emptyset$.*

Our algorithm is a dynamic program that intuively guesses the placements of the triangles in OPT_{CF} step by step. To this end, each DP-cell corresponds to a subproblem that is defined via a part $K' \subseteq K$ of the knapsack and a subset of the groups $J \subseteq \{j_{\min}, ..., j_{\max}\}$. The goal is to place triangles from $\bigcup_{j \in J} \mathcal{P}_j$ of maximum profit into K'. Formally, each DP-cell is defined by up to two triangles $P_i, P_{i'}$, placements $\tilde{P}_i, \tilde{P}_{i'}$ for them, and a set $J \subseteq \{j_{\min}, ..., j_{\max}\}$; if the cell is defined via exactly one triangle P_i then there is also a value $\text{dir} \in \{\text{left}, \text{mid}\}$. The corresponding region K' is defined as follows: if the cell is defined via zero triangles then the region is the whole knapsack K. Otherwise, let $\bar{v}_i$ denote the right-most vertex of $\tilde{P}_i$, i.e., the vertex of $\tilde{P}_i$ that is closest to the right edge of the knapsack (see Figure 3). Let L_i denote the vertical line that goes through $\bar{v}_i$ (and thus intersects the top and the bottom edge of the knapsack). If the cell is defined via one triangle P_i then observe that $K \setminus (\tilde{P}_i \cup R_i^{\text{up}} \cup L_i)$ has three connected components,

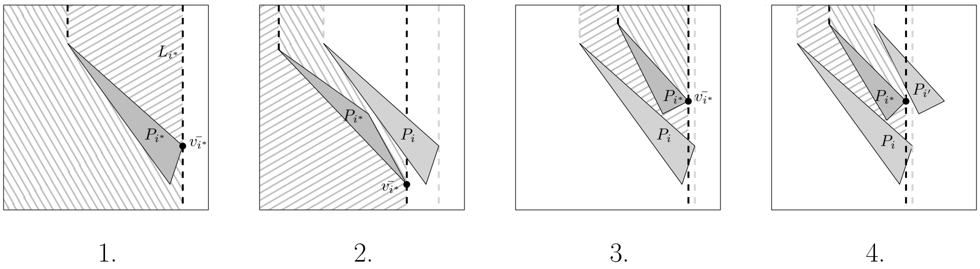

Figure 4 The cases in the transition of the DP for corner-facing triangles (see Lemma 26).

- one on the left, surrounded by R_i^{up}, parts of $\tilde{P}_i$, the left edge of the knapsack, and parts of the top and bottom edge of the knapsack
- one on the right, surrounded by L_i, the right edge of the knapsack, and parts of the top and bottom edge of the knapsack, and
- one in the middle, surrounded by the top edge of the knapsack, $\tilde{P}_i$, and L_i.

If dir = left then the region of the cell equals the left component, if dir = mid then the region of the cell equals the middle component. Assume now that the cell is defined via two triangles $P_i, P_{i'}$. Assume w.l.o.g. that $\bar{v}_i$ is closer to the right edge of the knapsack than $\bar{v}_{i'}$. Then $K \setminus (\tilde{P}_i \cup \tilde{P}_{i'} \cup R_i^{\text{up}} \cup R_{i'}^{\text{up}} \cup L_{i'})$ has one connected component that is surrounded by $\tilde{P}_i, \tilde{P}_{i'}, R_i^{\text{up}}, R_{i'}^{\text{up}}, L_{i'}$ and we define the region of the cell to be this component. Observe that the total number of DP-cells is bounded by $(nN)^{O(1)}$, using that there are only $(nN)^{O(1)}$ possible placements for each triangle.

We describe now a dynamic program that computes the optimal solution to each cell. Assume that we are given a cell C for which we want to compute the optimal solution. We guess the triangle P_{i^*} in the optimal solution to this cell such that $\bar{v}_{i^*}$ is closest to the right edge of the knapsack, and its placement $\tilde{P}_{i^*}$ in the optimal solution to C. Let j^* such that $P_{i^*} \in \mathcal{P}_{j^*}$. We will prove in the next lemma that the optimal solution to C consists of P_{i^*} and the optimal solutions to two other DP-cells, see Figure 4.

▶ **Lemma 26.** *Let C be a DP-cell, let $J \subseteq \{j_{\min}, ..., j_{\max}\}$, and let $P_i \in \mathcal{P}_\ell, P_{i'} \in \mathcal{P}_{\ell'}$ be two triangles with $\ell < \ell'$ and let $\tilde{P}_i, \tilde{P}_{i'}$ be placements for them. Then there are disjoint sets $J', J'' \subseteq J$ such that*

1. *if $C = (J)$, then its optimal solution consists of P_{i^*} and the optimal solutions to the cells $(J', P_{i^*}, \tilde{P}_{i^*}, \text{left})$ and $(J'', P_{i^*}, \tilde{P}_{i^*}, \text{mid})$,*
2. *if $C = (J, P_i, \tilde{P}_i, \text{left})$ then its optimal solution consists of P_{i^*} and the optimal solutions to the cells $(J', P_{i^*}, \tilde{P}_{i^*}, \text{left})$ and $(J'', P_i, \tilde{P}_i, P_{i^*}, \tilde{P}_{i^*})$,*
3. *if $C = (J, P_i, \tilde{P}_i, \text{mid})$ then its optimal solution consists of P_{i^*} and the optimal solutions to the cells $(J', P_{i^*}, \tilde{P}_{i^*}, \text{mid})$ and $(J'', P_i, \tilde{P}_i, P_{i^*}, \tilde{P}_{i^*})$,*
4. *if $C = (J, P_i, \tilde{P}_i, P_{i'}, \tilde{P}_{i'})$ then the optimal solution to C consists of P_{i^*} and the optimal solutions to the cells $(J', P_i, \tilde{P}_i, P_{i^*}, \tilde{P}_{i^*})$ and $(J'', P_{i^*}, \tilde{P}_{i^*}, P_{i'}, \tilde{P}_{i'})$.*

We guess the sets $J', J'' \subseteq J$ according to Lemma 26 and store in C the solution consisting of P_{i^*}, and the solutions stored in the two cells according to the lemma. At the end, the cell $C = (\{j_{\min}, ..., j_{\max}\})$ (whose corresponding region equals to K) contains the optimal solution. By combining Lemmas 23 and 27 we obtain the proof of Lemma 9.

▶ **Lemma 27.** *There is an algorithm with a running time of $(nN)^{O(1)}$ that computes a solution $\mathcal{P}' \subseteq \mathcal{P}$ such that $w(\text{OPT}_{\text{CF}}) \leq O(w(\mathcal{P}'))$.*

2.4 Hard polygons under resource augmentation

Let $\delta > 0$. We consider the setting of $(1+\delta)$-resource augmentation, i.e., we want to compute a solution $\mathcal{P}' \subseteq \mathcal{P}$ that is feasible for a knapsack of size $(1+\delta)N \times (1+\delta)N$ and such that $w(\mathrm{OPT}) \leq O(w(\mathcal{P}'))$ where OPT is the optimal solution for the original knapsack of size $N \times N$. Note that increasing K by a factor of $1+\delta$ is equivalent to shrinking the input polygons by a factor of $1+\delta$.

Given a polygon P defined via coordinates $(x_1, y_1), ..., (x_k, y_k) \in \mathbb{R}^2$ we define $\mathrm{shr}_{1+\delta}(P)$ to be the polygon with coordinates $(\bar{x}_1, \bar{y}_1), ..., (\bar{x}_k, \bar{y}_k) \in \mathbb{R}^2$ where $\bar{x}_{k'} = x_{k'}/(1+\delta)$ and $\bar{y}_{k'} = y_{k'}/(1+\delta)$ for each k'. For each input polygon $P_i \in \mathcal{P}$ we define its shrunk counterpart to be $\bar{P}_i := \mathrm{shr}_{1+\delta}(P_i)$. Based on $\bar{\mathcal{P}}$ we define sets $\bar{\mathcal{P}}_E, \bar{\mathcal{P}}_M, \bar{\mathcal{P}}_H$ and the set $\bar{\mathcal{P}}_j$ for each $j \in \mathbb{Z}$ in the same way as we defined $\mathcal{P}_E, \mathcal{P}_M, \mathcal{P}_H$ and $\mathcal{P}_j$ based on $\mathcal{P}$ above.

For the sets $\bar{\mathcal{P}}_E$ and $\bar{\mathcal{P}}_M$ we use the algorithms due to Lemmas 6 and 7 as before. For the hard polygons $\bar{\mathcal{P}}_H$ we can show that there are only $O_\delta(1)$ groups $\bar{\mathcal{P}}_j$ that are non-empty, using that we obtained them via shrinking the original input polygons. Intuitively, this is true since $\bar{\ell}_i \leq \frac{\sqrt{2}N}{1+\delta}$ for each $\bar{P}_i \in \bar{\mathcal{P}}$ where $\bar{\ell}_i$ denotes the length of the longest diagonal of $\bar{P}_i$, and hence $\bar{\mathcal{P}}_j \cap \bar{\mathcal{P}}_H = \emptyset$ if $j < \log\left(\frac{\delta}{1+\delta}\sqrt{2}N\right)$.

▶ **Lemma 28.** *We have that $\bar{\mathcal{P}}_j = \emptyset$ if $j < \log\left(\frac{\delta}{1+\delta}\sqrt{2}N\right)$. Hence, there are only $\log\left(\frac{1+\delta}{\delta}\right)+1$ values $j \in \mathbb{Z}$ such that $\bar{\mathcal{P}}_j \neq \emptyset$.*

Lemmas 18 and 28 imply that $|\overline{\mathrm{OPT}} \cap \bar{\mathcal{P}}_H| \leq O(\log\left(\frac{1+\delta}{\delta}\right))$ where $\overline{\mathrm{OPT}}$ denotes the optimal solution for the polygons in $\bar{\mathcal{P}}$. Let $\bar{\mathcal{P}}'_H \subseteq \bar{\mathcal{P}}_H$ denote the set due to Lemma 19 when assuming that $\bar{\mathcal{P}}_H$ are the hard polygons in the given instance. Therefore, we guess $\bar{\mathcal{P}}'_H$ in time $n^{O(\log(\frac{1+\delta}{\delta}))}$. Finally, we output the solution of largest weight among $\bar{\mathcal{P}}'_H$ and the solutions due applying to Lemmas 6 and 7 to the input sets $\bar{\mathcal{P}}_E$ and $\bar{\mathcal{P}}_M$, respectively. This yields the proof of Theorem 3.

3 Optimal profit under resource augmentation

In this section we also study the setting of $(1+\delta)$-resource augmentation, i.e., we want to compute a solution $\mathcal{P}'$ which is feasible for an enlarged knapsack of size $(1+\delta)N \times (1+\delta)N$, for any constant $\delta > 0$. We present an algorithm with a running time of $n^{(\log(n)/\delta)^{O(1)}}$ that computes such a solution $\mathcal{P}'$ with $w(\mathcal{P}') \geq \mathrm{OPT}$ where OPT is the optimal solution for the original knapsack of size $N \times N$. In particular, we here do not lose any factor in our approximation guarantee.

First, we prove a set of properties that we can assume "by $(1+\delta)$-resource augmentation" meaning that if we increase the size of K by a factor $1+\delta$ then there exists a solution of weight $w(\mathrm{OPT})$ with the mentioned properties, or that we can modify the input in time $n^{O(1)}$ such that it has these properties and there still exists a solution of weight $w(\mathrm{OPT})$.

3.1 Few types of items

We want to establish that the input polygons have only $(\log(n)/\delta)^{O(1)}$ different shapes. Like in Section 2 for each polygon $P_i \in \mathcal{P}$ denote by B_i its bounding box with width ℓ_i and height h_i. Note that $\ell_i \geq h_i$. The bounding boxes of all polygons $P_i \in \mathcal{P}$ such that $h_i \leq \delta\frac{N}{n}$ have a total height of at most δN. Therefore, we can pack all these polygons into the extra capacity that we gain by increasing the size of K by a factor $1+\delta$ and therefore ignore them in the sequel.

▶ **Lemma 29.** *By $(1+\delta)$-resource augmentation we can assume for each $P_i \in \mathcal{P}$ that $\ell_i \geq h_i \geq \delta N/n$ and that $\text{area}(P_i) = \Omega(\text{area}(K)\delta^2/n^2)$.*

Next, intuitively we stretch the optimal solution OPT by a factor $1+\delta$ which yields a container C_i for each polygon $P_i \in$ OPT which contains P_i and which is slightly bigger than P_i. We define a polygon P'_i such that $P_i \subseteq P'_i \subseteq C_i$ and that globally there are only $(\log(n)/\delta)^{O_\delta(1)}$ different ways P'_i can look like, up to translations and rotations. We refer to those as a set $\mathcal{S}$ of *shapes* of input objects. Hence, due to the resource augmentation we can replace each input polygon P_i by one of the shapes in $\mathcal{S}$.

▶ **Lemma 30.** *By $(1+\delta)$-resource augmentation we can assume that there is a set of shapes $\mathcal{S}$ with $|\mathcal{S}| \leq (\log(n)/\delta)^{O_\delta(1)}$ such that for each $P_i \in \mathcal{P}$ there is a shape $S \in \mathcal{S}$ such that $P_i = S$ and S has only $\Lambda = (1/\delta)^{O(1)}$ many vertices.*

Finally, we ensure that for each polygon $P_i \in \mathcal{P}$ we can restrict ourselves to only $(n/\delta)^{O(1)}$ possible placements in K.

▶ **Lemma 31.** *By $(1+\delta)$-resource augmentation, for each polygon $P_i \in \mathcal{P}$ we can compute a set $\mathcal{L}_i$ of at most $(n/\delta)^{O(1)}$ possible placements for P_i in time $(n/\delta)^{O(1)}$ such that if $P_i \in$ OPT then in OPT the polygon P_i is placed inside K according to one placement $\tilde{P}_i \in \mathcal{L}_i$.*

3.2 Recursive algorithm

We describe our main algorithm. First, we guess how many polygons of each of the shapes in $\mathcal{S}$ are contained in OPT. Since there are only $(\log(n)/\delta)^{O_\delta(1)}$ different shapes in $\mathcal{S}$ we can do this in time $n^{(\log(n)/\delta)^{O_\delta(1)}}$. Once we know how many polygons of each shape we need to select, it is clear which polygons we should take since if for some shape $S_i \in \mathcal{S}$ we need to select n_i polygons with that shape then it is optimal to select the n_i polygons in $\mathcal{P}$ of shape S_i with largest weight. Therefore, in the sequel assume that we are given a set of polygons $\mathcal{P}' \subseteq \mathcal{P}$ and we want to find a packing for them inside K.

Our algorithm is recursive and it generalizes a similar algorithm for the special case of axis-parallel rectangles in [1]. On a high level, we guess a partition of K given by a separator Γ which is a polygon inside K. It has the property that at most $\frac{2}{3}|\text{OPT}|$ of the polygons of OPT lie inside Γ and at most $\frac{2}{3}|\text{OPT}|$ of the polygons of OPT lie outside Γ. We guess how many polygons of each shape are placed inside and outside Γ in OPT. Then we recurse separately inside and outside Γ. For our partition, we are looking for a polygon Γ according to the following definition.

▶ **Definition 32.** *Let $\ell \in \mathbb{N}$ and $\epsilon > 0$. Let $\bar{\mathcal{P}}$ be a set of pairwise non-overlapping polygons in K. A polygon Γ is a* balanced $\hat{\epsilon}$-cheap ℓ-cut *if*

- *Γ has at most ℓ edges,*
- *the polygons contained in Γ have a total area of at most $2/3 \cdot \text{area}(\bar{\mathcal{P}})$,*
- *the polygons contained in the complement of Γ, i.e., in $K \setminus \Gamma$, have a total area of at most $2/3 \cdot \text{area}(\bar{\mathcal{P}})$, and*
- *the polygons intersecting the boundary of Γ have a total area of at most $\hat{\epsilon} \cdot \text{area}(\bar{\mathcal{P}})$.*

In order to restrict the set of balanced cheap cuts to consider, we will allow only polygons Γ such that each of its vertices is contained in a set Q of size $(n/\delta)^{O(1)}$ defined as follows. We fix a triangulation for each placement $P'_i \in \mathcal{L}_i$ of each polygon $P_i \in \mathcal{P}'$. We define a set Q_0 where for each placement $P'_i \in \mathcal{L}_i$ for P_i we add to Q_0 the positions of the vertices of P'_i. Also, we add the four corners of K to Q_0. Let $\mathcal{V}$ denote the set of vertical lines $\{(\bar{x}, \bar{y})|\bar{y} \in \mathbb{R}\}$ such that $\bar{x}$ is the x-coordinate of one point in Q_0. We define a set Q_1 where for each placement $P_i' \in \mathcal{L}_i$ of each $P_i \in \mathcal{P}'$, each edge e of a triangle in the triangulation of P_i', and each vertical line $L \in \mathcal{V}$ we add to Q_1 the intersection of e and L. Also, we add to Q_1 the intersection of each line in $L \in \mathcal{V}$ with the two boundary edges of K. Let Q_2 denote the set of all intersections of pairs of line segments whose respective endpoints are in $Q_0 \cup Q_1$. We define $Q := Q_0 \cup Q_1 \cup Q_2$. A result in [1] implies that there exists a balanced cheap cut whose vertices are all contained in Q.

▶ **Lemma 33** ([1]). *Let $\epsilon > 0$ and let $\mathcal{P}'$ be a set of pairwise non-intersecting polygons in the plane with at most Λ edges each such that $\text{area}(P) < \text{area}(\mathcal{P}')/3$ for each $P \in \mathcal{P}$. Then there exists a balanced $O(\epsilon\Lambda)$-cheap $\Lambda(\frac{1}{\epsilon})^{O(1)}$-cut Γ whose vertices are contained in Q.*

Our algorithm is recursive and places polygons from $\mathcal{P}'$, trying to maximize the total area of the placed polygons. In each recursive call we are given an area $\bar{K} \subseteq K$ and a set of polygons $\bar{\mathcal{P}} \subseteq \mathcal{P}'$. In the main call these parameters are $\bar{K} = K$ and $\bar{\mathcal{P}} = \mathcal{P}'$. If $\bar{\mathcal{P}} = \emptyset$ then we return an empty solution. If there is a polygon $P_i \in \bar{\mathcal{P}}$ with $\text{area}(P_i) \geq \text{area}(\bar{\mathcal{P}})/3$ then we guess a placement $P_i' \in \mathcal{L}_i$ and we recurse on the area $K \setminus P_i'$ and on the set $\bar{\mathcal{P}} \setminus \{P_i\}$. Otherwise, we guess the balanced cheap cut Γ due to Lemma 33 with $\epsilon := \frac{\delta}{\Lambda \log(n/\delta)}$ and for each shape $S \in \mathcal{S}$ we guess how many polygons of $\mathcal{P}'$ with shape S are contained in $\Gamma \cap \bar{K}$, how many are contained in $\bar{K} \setminus \Gamma$, and how many cross the boundary of Γ (i.e., have non-empty intersection with the boundary of Γ). Note that there are only $n^{(\Lambda \log(n/\delta))^{O(1)}}$ possibilities to enumerate. Let $\bar{\mathcal{P}}_{\text{in}}, \bar{\mathcal{P}}_{\text{out}}$, and $\bar{\mathcal{P}}_{\text{cross}}$ denote the respective sets of polygons. Then we recurse on the area $\Gamma \cap \bar{K}$ with input polygons $\bar{\mathcal{P}}_{\text{in}}$ and on the area $\bar{K} \setminus \Gamma$ with input polygons $\bar{\mathcal{P}}_{\text{out}}$. Suppose that the recursive calls return two sets of polygons $\bar{\mathcal{P}}_{\text{in}}' \subseteq \bar{\mathcal{P}}_{\text{in}}$ and $\bar{\mathcal{P}}'_{\text{out}} \subseteq \bar{\mathcal{P}}_{\text{out}}$ that the algorithm managed to place inside the respective areas $\Gamma \cap \bar{K}$ and $\bar{K} \setminus \Gamma$. Then we return the set $\bar{\mathcal{P}}_{\text{in}}' \cup \bar{\mathcal{P}}_{\text{out}}'$ for the guesses of Γ, $\bar{\mathcal{P}}_{\text{in}}, \bar{\mathcal{P}}_{\text{out}}$, and $\bar{\mathcal{P}}_{\text{cross}}$ that maximize $\text{area}(\bar{\mathcal{P}}_{\text{in}}' \cup \bar{\mathcal{P}}_{\text{out}}')$. If we guess the (correct) balanced cheap cut due to Lemma 33 in each iteration then our recursion depth is $O(\log_{3/2}(n^2/\delta^2)) = O(\log(n/\delta))$ since the cuts are balanced and each polygon has an area of at least $\Omega(\text{area}(K)\delta^2/n^2)$ (see Lemma 29). Therefore, if in a recursive call of the algorithm the recursion depth is larger than $O(\log(n/\delta))$ then we return the empty set and do not recurse further. Also, if we guess the correct cut in each node of the recursion tree then we cut polygons whose total area is at most a $\frac{\delta}{\log(n/\delta)}$-fraction of the area of all remaining polygons. Since our recursion depth is $O(\log(n/\delta))$, our algorithm outputs a packing for a set of polygons in $\mathcal{P}'$ with area at least $(1 - \frac{\delta}{\log(n/\delta)})^{O(\log(n/\delta))} \bar{w}(\bar{\mathcal{P}}) = (1 - O(\delta))\text{area}(\bar{\mathcal{P}})$. This implies the following lemma.

▶ **Lemma 34.** *Assume that there is a non-overlapping packing for $\mathcal{P}'$ in K. There is an algorithm with a running time of $n^{(\Lambda \log(n/\delta))^{O(1)}}$ that computes a placement of a set of polygons $\bar{\mathcal{P}}' \subseteq \mathcal{P}'$ inside K such that $\text{area}(\bar{\mathcal{P}}') \geq (1 - O(\delta))\text{area}(\mathcal{P}')$.*

It remains to pack the polygons in $\tilde{\mathcal{P}}' := \mathcal{P}' \setminus \bar{\mathcal{P}}'$. The total area of their bounding boxes is bounded by $\sum_{P_i \in \tilde{\mathcal{P}}'} B_i \leq 2\text{area}(\tilde{\mathcal{P}}') \leq O(\delta)\text{area}(\mathcal{P}') \leq O(\delta)\text{area}(K)$. Therefore, we can pack them into additional space that we gain via increasing the size of K by a factor $1 + O(\delta)$, using the Next-Fit-Decreasing-Height algorithm [4].

▶ **Theorem 35.** *There is an algorithm with a running time of $n^{(\log(n)/\delta))^{O(1)}}$ that computes a set $\mathcal{P}'$ with $w(\mathcal{P}') \geq \text{OPT}$ such that $\mathcal{P}'$ fits into K under $(1 + \delta)$-resource augmentation.*

Abstract

In this work, we study fairness in centroid clustering. In this problem, k cluster centers must be placed given n points in a metric space, and the cost to each point is its distance to the nearest cluster center. Recent work of Chen et al. [8] introduces the notion of a *proportionally fair* clustering, in which no group of at least n/k points can find a new cluster center which provides lower cost to each member of the group. They propose a *greedy capture* algorithm which provides a $1 + \sqrt{2}$ approximation of proportional fairness for any metric space, and derive generalization bounds for learning proportionally fair clustering from samples in the case where a cluster center can only be placed at one of finitely many given locations in the metric space.

We focus on the case where cluster centers can be placed anywhere in the (usually infinite) metric space. In case of the L^2 distance metric over $\mathbb{R}^t$, we show that the approximation ratio of greedy capture improves to 2. We also show that this is due to a special property of the L^2 distance; for the L^1 and L^∞ distances, the approximation ratio remains $1 + \sqrt{2}$. We provide universal lower bounds which apply to all algorithms.

We also consider metric spaces defined on graphs. For trees, we show that an exact proportionally fair clustering always exists and provide an efficient algorithm to find one. The corresponding question for general graph remains an interesting open question.

Finally, we show that for the L^2 distance, checking whether a proportionally fair clustering exists and implementing greedy capture over an infinite metric space are NP-hard problems, but (approximately) solvable in special cases. We also derive generalization bounds which show that an approximately proportionally fair clustering for a large number of points can be learned from a small number of samples. Our work advances the understanding of proportional fairness in clustering, and points out many avenues for future work.

1 Introduction

Machine learning algorithms are increasingly being used for decision making in applications where they affect human lives; popular examples include resume screening, evaluation of loan applications, bail decisions, etc. [27]. This has led to growing concern as to whether these algorithms, which may view humans as "data points", treat them fairly [3, 25]. Consequently, research on designing fair machine learning algorithms is proliferating [24, 22].

Much of this literature focuses on fairness in classification [36, 35, 19], but the study of fairness in other settings such as regression [1] and clustering [8] is also on the rise. In this paper, we focus on fairness in clustering, specifically, in centroid clustering. In this problem, we are given a set $\mathcal{N}$ of data points in a metric space, and a set $\mathcal{M}$ of possible locations for cluster centers in the same metric space. Given $k \in \mathbb{N}$, the task is to select a set $X \subseteq \mathcal{M}$ consisting of $|X| = k$ cluster centers and assign each data point to a cluster center – usually the closest – with the goal that data points are close to their assigned cluster centers. Clustering has diverse applications in market research, pattern recognition, data analysis, image segmentation, and facility location. In applications like image segmentation or market research, often the goal is to simply identify different clusters of points among the data. However, in facility location [14, 21, 15], where data points may represent locations of houses in the neighborhood and cluster centers may represent locations where public facilities (such as parks) will be built, it is of paramount importance that the facilities be distributed to fairly serve the population.

Adapting an example given by Chen et al. [8], imagine that there is a dense urban area with a population of 10,000, and far from it, there are 10 small communities with a population of 100 each. The communities are closer to each other compared to how far they are from the urban area, but still well distinguished. With $k = 11$, a standard clustering algorithm such as k-means would identify the urban area as one cluster, and each small community as one cluster. However, building just one park that serves 10,000 people in the urban area, while each community of 100 people gets its own park violates the principle of *equal entitlement* [23]; this principle would suggest that when allocating 11 parks among a total of 11,000 people, the urban area consisting of 10,000 people should be allocated their proportional share of 10 parks, and one park should serve the 10 smaller communities consisting of 1,000 people altogether.

This notion of what a group deserves – *group fairness* – has been extensively studied in machine learning, and a variety of definitions have been proposed [7, 16, 24, 19, 32]. Borrowing from a long line of literature on fair resource allocation [34, 30, 12, 10], Chen et al. [8] proposed a novel definition of fairness in clustering that perfectly fits our motivation. Given a metric d over a set $\mathcal{N}$ of n points and a set $\mathcal{M}$ of feasible cluster centers, they say that a k-clustering X satisfies *proportional fairness* if there is no group of points $S \subseteq \mathcal{N}$ with $|S| \geq n/k$ and a new cluster location $y \in \mathcal{M}$ such that $d(i, y) < \min_{x \in X} d(i, x)$ for each member $i \in S$. Most fairness definitions in machine learning protect groups of individuals that are pre-defined based on certain *protected attributes* [4, 5, 9, 28] or that are sufficiently large [20]. In contrast, proportional fairness guarantees fairness to arbitrarily defined groups of all possible sizes. This may be helpful given recent observations that protecting groups defined based on individual attributes may allow an algorithm to circumvent fairness [20], or that information about which groups to protect may not be known in advance [17]. For references to other related work, we direct the reader to the work of Chen et al. [8].

1.1 Our Contribution

We build upon the work of Chen et al. [8]. While their work considers the metric d and the set of feasible cluster center locations $\mathcal{M}$ to be arbitrary (and $|\mathcal{M}|$ to be typically finite), we focus on the case where the metric consists of usual distance functions such as L^1, L^2, or L^∞ over $\mathbb{R}^t$, and cluster centers can be placed anywhere in the infinite metric space (i.e. $\mathcal{M} = \mathbb{R}^t$). While this change is seemingly simple, the infinite cardinality of $\mathcal{M}$ requires new algorithmic tools and generalization bounds, which we provide in this work. In some cases, we show that this in fact allows us to provide stronger approximation guarantees.

In Section 3, we analyze the greedy capture algorithm introduced by Chen et al. in the case where $d \in \{L^1, L^2, L^\infty\}$ and $\mathcal{M} = \mathbb{R}^t$. Chen et al. show that the algorithm provides $1 + \sqrt{2} \approx 2.414$ approximation to proportional fairness for all metric spaces. We show that for $d = L^2$ and $\mathcal{M} = \mathbb{R}^t$, it actually provides a better 2-approximation. We prove this via a refinement of the result of Chen et al.: we express the approximation ratio obtained by the algorithm in terms of a new characteristic of the metric that we term *Apollonius radius*, and show that this radius is small for the L^2 distance, allowing us to achieve a better approximation ratio. However, we show that for L^1 and L^∞, the approximation ratio of greedy capture is no better than $1 + \sqrt{2}$.

In Section 4, we provide universal lower bounds which apply to all algorithms. Specifically, we show that for $d = L^2$ and $\mathcal{M} = \mathbb{R}^t$, no algorithm achieves better than $2/\sqrt{3} \approx 1.155$ approximation ratio, whereas for $d \in \{L^1, L^\infty\}$ and $\mathcal{M} = \mathbb{R}^t$, we get a lower bound of 1.4. Note that these lower bounds are existential, and not computational.

In Section 5, we consider the case where $\mathcal{M}$ is the set of nodes of an unweighted graph, and d measures the shortest distance between two nodes on the graph. When the graph is a tree, we show that an exact proportionally fair clustering necessarily exists, and provide an efficient algorithm to find one. When the graph is arbitrary, but $k \geq n/2$ clusters need to be placed, we show that a proportionally fair clustering again necessarily exists and can be computed efficiently. Whether an exact proportionally fair clustering exists for all graphs remains an interesting open question.

Next, in Section 6, we show that for $d = L^2$ and $\mathcal{M} = \mathbb{R}^t$ for $t \geq 2$, checking whether a proportional clustering exists is NP-hard. When t is large, even implementing the greedy capture algorithm is NP-hard. However, this problem becomes efficiently solvable when t is constant, and when t is large, using a PTAS for an important sub-routine of greedy capture, we can efficiently compute a $2 \cdot (1 + \epsilon)$-proportionally fair clustering for any fixed $\epsilon > 0$.

Finally, in Section 7, we consider the problem of generalization: would a clustering that is proportionally fair with respect to samples drawn from $\mathcal{N}$ remain (approximately) proportionally fair with respect to the entire set $\mathcal{N}$? Chen et al. provide a positive answer for the case when $\mathcal{M}$ is finite. Using the framework of VC dimension, we show that, when $d = L^2$, the answer remains positive even when $\mathcal{M} = \mathbb{R}^t$.

2 Preliminaries

Let $\mathcal{N}$ be a set of n data points (or agents), which lie in a metric space $(\mathcal{X}, d)$, where $d : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ is a distance function satisfying the triangle inequality. For most of this work, we consider the case where $\mathcal{X} = \mathbb{R}^t$ for some $t \in \mathbb{N}$, but in Section 5, we consider the case where $\mathcal{X}$ is the set of nodes of a graph. We also focus on special distance functions such as the Euclidean distance (L^2), the Manhattan distance (L^1), and the L^∞ distance. Let $\mathcal{M} \subseteq \mathcal{X}$ be a the set of locations where cluster centers can be placed. In this work, we focus on the case where $\mathcal{M} = \mathcal{X}$. Let $k \in \mathbb{N}$. We denote by $[\mathcal{M}]^k$ the set of all subsets of M of size k. A k-clustering is a set $X \in [\mathcal{M}]^k$ containing k locations for cluster centers. We refer to each $x \in X$ as an *open* cluster center.

The cost to agent $i \in \mathcal{N}$ induced by a cluster center $x \in \mathcal{M}$ is the distance $d(i,x)$, and the cost to agent $i \in \mathcal{N}$ induced by a k-clustering X is the minimum distance from i to any cluster center, i.e., $d(i,X) \triangleq \min_{x\in X} d(i,x)$. Agent i is interested in minimizing her cost.

A set of points $S \subseteq \mathcal{N}$ containing at least $\lceil n/k \rceil$ is entitled at least one cluster center. If they can find a new cluster center that is better for each of them, we consider it a violation of fairness. Formally:

▶ **Definition 1.** *Given $\rho \geq 1$, we say a k-clustering $X \in [\mathcal{M}]^k$ is* ρ-proportionally fair *if there is no $S \subseteq \mathcal{N}$ with $|S| \geq \lceil n/k \rceil$ and $y \in \mathcal{M}$ such that $\rho \cdot d(i,y) < d(i,X)$ for all $i \in S$. If such a coalition S and point y exist, we refer to S as a* blocking coalition *and y as the center that they* deviate *to. When $\rho = 1$, we simply call this proportional fairness.*

The reason to define ρ-proportionally fair solutions for $\rho > 1$ is because (exactly) proportionally fair solutions may not exist [8].

In Section 5, we consider the problem of proportional fairness on graphs. Specifically, given an undirected graph $G = (V,E)$, we assume that $\mathcal{N} \subseteq V$, $\mathcal{M} = V$ (i.e. every node in the graph is a feasible cluster center), and the distance between two nodes $u, v \in V$, denoted by $d(u,v)$, is the length of the shortest path connecting them. Notice that d satisfies the triangle inequality.

3 Greedy Capture

In this section, we study the greedy capture algorithm defined by Chen et al. [8]. Put succinctly, the algorithm starts with $X = \emptyset$. It grows a ball at every location in $\mathcal{M}$ at the same rate. As soon as a ball contains at least $\lceil n/k \rceil$ points, the corresponding center is added to X and all the points covered by the ball are removed. As balls continue growing, balls centered at previously added locations in X also continue growing with them and any new points covered by such balls are immediately removed. We refer the reader to the work of Chen et al. for full description of the algorithm. They show that for any metric space, greedy capture is guaranteed to find a $(1+\sqrt{2})$-proportionally fair clustering.

We begin by providing a refined analysis of greedy capture by expressing the approximation ratio in terms of a characteristic of the metric we call the Apollonius radius.

▶ **Definition 2.** *Given $\rho \geq 1$, the ρ-Apollonius radius of a metric $(\mathcal{X}, d)$ is defined as $A_{\mathcal{X},d}(\rho) = \sup_{x,y\in\mathcal{X}} \Delta(\rho,x,y)/d(x,y)$, where $\Delta(\rho,x,y)$ is the radius of the smallest ball centered at some point in $\mathcal{X}$ that contains the entire set $\{p \in \mathcal{X} : \rho \cdot d(p,y) \leq d(p,x)\}$.*

The reason that we term it the Apollonius radius is because the renowned Greek geometer Apollonius of Perga was famously interested in the set $\{p \in \mathbb{R}^t : \rho \cdot d(p,y) \leq d(p,x)\}$ for $d = L^2$, and showed that this set is a ball already when $\rho > 1$. This special structure of L^2 is what will allow us to achieve a better approximation guarantee for it.

▶ **Theorem 3.** *For any metric $(\mathcal{X}, d)$ and $\mathcal{M} = \mathcal{X}$, greedy capture finds a ρ-proportionally fair clustering, where $\rho \geq 1$ is the smallest positive number satisfying $A_{\mathcal{X},d}(\rho) \cdot \frac{\rho+1}{\rho} \leq 1$.*

Proof. Let X be the clustering returned by the algorithm. Suppose that X is not ρ-proportionally fair for some ρ. Then, there exist $S \subseteq \mathcal{N}$ with $|S| \geq \lceil n/k \rceil$ and $y \in \mathcal{M}$ such that $\rho \cdot d(j,y) < d(j,X)$ for all $j \in S$.

Note that this implies $y \notin X$. Let i be the first point in S that was covered during the execution of greedy capture; suppose it was covered by a ball located at $x \in X$.

Note that for each $j \in S$, we have $\rho \cdot d(j,y) < d(j,X) \le d(j,x)$. Hence, $S \subseteq \{p \in \mathcal{X} : \rho \cdot d(p,y) < d(p,x)\}$. Hence, by definition of ρ-Apollonius radius, there exists a ball of radius at most $A_{\mathcal{X},d}(\rho) \cdot d(x,y)$ that contains all points in S. Since i was the first point in S covered by the ball centered at x, we must have $d(i,x) \le A_{\mathcal{X},d}(\rho) \cdot d(x,y)$, otherwise greedy capture would have selected the ball of radius at most $A_{\mathcal{X},d}(\rho) \cdot d(x,y)$ covering all points of S prior to i being covered by the ball centered at x. Further, since $i \in S$, we also have $d(i,y) < d(i,x)/\rho$. Using the triangle inequality, we get

$$d(x,y) \le d(i,x) + d(i,y) < d(i,x) \cdot \frac{\rho+1}{\rho} \le A_{\mathcal{X},d}(\rho) \cdot \frac{\rho+1}{\rho} \cdot d(x,y) \Rightarrow A_{\mathcal{X},d}(\rho) \cdot \frac{\rho+1}{\rho} > 1.$$

We have proved that if X is not ρ-proportionally fair, then $A_{\mathcal{X},d}(\rho) \cdot \frac{\rho+1}{\rho} > 1$. Hence, whenever $A_{\mathcal{X},d}(\rho) \cdot \frac{\rho+1}{\rho} \le 1$, we have that X is ρ-proportionally fair. ◀

Let us argue that Theorem 3 is in fact a refinement of the $(1+\sqrt{2})$-approximation proved by Chen et al. [8] that holds for all metrics.

▶ **Theorem 4.** *For any metric $(\mathcal{X}, d)$, the ρ-Apollonius radius is $A_{\mathcal{X},d}(\rho) \le \frac{1}{\rho-1}$. Hence, greedy capture finds a $(1+\sqrt{2})$-proportionally fair clustering for every metric.*

Proof. Consider the set $\{p \in \mathcal{X} : \rho \cdot d(p,y) \le d(p,x)\}$. For any point p in this set, we have that $\rho \cdot d(p,y) \le d(p,x) \le d(p,y) + d(x,y)$ by the triangle inequality. Hence, $d(p,y) \le d(x,y) \cdot \frac{1}{\rho-1}$ for all p in the set. Thus, a ball centered at $y \in \mathcal{M}$ with radius $\frac{d(x,y)}{\rho-1}$ certainly covers the entire set. Hence, $A_{\mathcal{X},d}(\rho) \le \frac{1}{\rho-1}$. Next, for $\rho = 1+\sqrt{2}$, we have

$$A_{\mathcal{X},d}(\rho) \cdot \frac{\rho+1}{\rho} \le \frac{\rho+1}{\rho \cdot (\rho-1)} = 1.$$

Hence, by Theorem 3, greedy capture finds a $(1+\sqrt{2})$-proportionally fair clustering. ◀

Next, we show that for $d = L^2$, the ρ-Apollonius radius is slightly better, leading to a better 2-approximation guarantee for greedy capture.

▶ **Theorem 5.** *For the metric space $(\mathbb{R}^t, L^2)$, where $t \in \mathbb{N}$, the ρ-Apollonius radius is $A_{\mathbb{R}^t,L^2}(\rho) \le \frac{\rho}{\rho^2-1}$, and hence, greedy capture finds a 2-proportionally fair clustering.*

Proof. For the L^2 norm in a Euclidean space, it is well-known that given $x, y \in \mathbb{R}^t$ and $\rho > 1$, the set of points $\{p \in \mathbb{R}^t : \rho \cdot d(p,y) \le d(p,x)\}$ is a ball of radius $d(x,y) \cdot \frac{\rho}{\rho^2-1}$. This is a simple algebraic exercise; its two-dimensional variant was known to Apollonius himself, after whom the result is named (the derivation is widely available online, e.g., see [11]). This immediately implies that $A_{\mathbb{R}^t,L^2}(\rho) \le \frac{\rho}{\rho^2-1}$.

Now, we have that

$$A_{\mathcal{X},d}(\rho) \cdot \frac{\rho+1}{\rho} \le \frac{\rho}{\rho^2-1} \cdot \frac{\rho+1}{\rho} = \frac{1}{\rho-1}.$$

This quantity is at most 1 when ρ is at least 2. Hence, by Theorem 3, greedy capture finds a 2-proportionally fair clustering for this metric. ◀

The obvious next question then is whether this refinement also provides an improved approximation bound for other distance metrics. Unfortunately, for two other prominent distance metrics, L^1 and L^∞, the answer is no. We show this by providing a direct counterexample where greedy capture finds a clustering that is no better than $(1+\sqrt{2})$-proportionally fair. The proof of the next result appears in the full version of the paper.

▶ **Theorem 6.** *For the metric space $(\mathbb{R}^t, d)$ where $t \ge 2$ and $d \in \{L^1, L^\infty\}$, and $\mathcal{M} = \mathbb{R}^t$, there exists an example in which the clustering produced by greedy capture is not ρ-proportionally fair for $\rho < 1+\sqrt{2}$.*

4 Universal Lower Bounds

In this section, we show lower bounds on approximation to proportional fairness that apply to all algorithms, as opposed to the lower bounds in the previous section that apply only to greedy capture. Chen et al. [8] show that when $\mathcal{N}$, $\mathcal{M}$, and the metric are arbitrary, ρ-proportional fairness cannot be guaranteed for $\rho < 2$. They also consider the special case where $\mathcal{N} = \mathcal{M}$, and prove a slightly weaker lower bound of 1.5. One question that they do not address is whether greedy capture provides better than $(1 + \sqrt{2})$-approximation in this special case; in the full version, we show that this is *not* the case.

In this section, we turn our attention to the case of our interest: $\mathcal{M} = \mathcal{X} = \mathbb{R}^t$ and $d \in \{L^1, L^2, L^{\text{inf}}\}$. When $t = 1$, it is easy to notice that an exactly proportionally fair clustering always exists.[1] When $t \geq 2$, we provide a lower bound of $2/\sqrt{3}$ for $d = L^2$ and a lower bound of 1.4 for $d \in \{L^1, L^\infty\}$.

▶ **Theorem 7.** *For the metric space $(\mathbb{R}^t, L^2)$ where $t \geq 2$ and $\mathcal{M} = \mathbb{R}^t$, there is an example in which no clustering is ρ-proportionally fair for $\rho < 2/\sqrt{3} \approx 1.155$.*

Proof. Once again, we set $t = 2$ without loss of generality. Consider an instance in which $|\mathcal{N}| = 6$ and $k = 3$. Suppose $|\mathcal{N}|$ consists of two isomorphic sets of 3 points each, where each set of 3 points forms an equilateral triangle of length 1 and the two sets are sufficiently far from each other. Then, by the pigeonhole principle, under any clustering X, at least one set of 3 points, say $\{p_1, p_2, p_3\}$, must derive their costs from a single cluster center x.

Let a denote the circumcenter of their triangle. Then, $d(a, p_1) = d(a, p_2) = d(a, p_3) = 1/\sqrt{3}$. Hence, $d(a, p_1) + d(a, p_2) + d(a, p_3) = \sqrt{3}$. Notice that in an equilateral triangle, the circumcenter is also the Fermat point, which minimizes the sum of distances from the three vertices. Hence, for the cluster center x, we have $d(x, p_1) + d(x, p_2) + d(x, p_3) \geq \sqrt{3}$. Without loss of generality, assume $d(x, p_1) \geq d(x, p_2) \geq d(x, p_3)$. Then, $d(x, p_1) + d(x, p_2) \geq 2/\sqrt{3}$.

Now, p_1 and p_2 can deviate, choose a location y on the line joining p_1 and p_2 such that $d(y, p_1)/d(y, p_2) = d(x, p_1)/d(x, p_2)$. Since $d(y, p_1) + d(y, p_2) = d(p_1, p_2) = 1$, this reduces the cost to each point by a factor of $2/\sqrt{3}$. Hence, the clustering is not ρ-proportionally fair for $\rho < 2/\sqrt{3}$. ◀

Note that the lower bound of 1.155 is significantly lower than the upper bound of 2 obtained by greedy capture for L^2 as shown in Theorem 5. Closing the gap is an interesting open question. Next, we show a lower bound for L^1 and L^∞. The proof appears in the full version of the paper.

▶ **Theorem 8.** *For the metric space $(\mathbb{R}^t, d)$, where $t \geq 2$ and $d \in \{L^1, L^\infty\}$, and $\mathcal{M} = \mathbb{R}^t$, there is an example in which no clustering is ρ-proportionally fair for $\rho < 1.4$.*

5 Clustering in Graphs

In this section, we consider the special case where the metric space $(\mathcal{X}, d)$ is induced by an undirected graph $G = (V, E)$. Specifically, we let $\mathcal{X} = V$ be the set of nodes of the graph, and assume that $d(x, y)$ measures the length of the shortest path between nodes x and y. As in the previous sections, we restrict our attention to the $\mathcal{M} = \mathcal{X}$ case, i.e., when every point of the metric space is a feasible cluster center.

[1] For instance, opening a cluster at every n/k-th data point from left to right is proportionally fair.

Graphs are an important special case since clustering and facility location in graphs and networks are very well studied. However, while objectives such as truthfulness [2] and social welfare maximization (or social cost minimization) [13] have received significant attention, fairness has not.

We study proportional fairness for this setting. Our first result shows that when the graph $G = (V, E)$ is a tree, an exact proportionally fair clustering always exists, and can be computed by an efficient algorithm. Intuitively, the algorithm works as follows. We first root the tree at an arbitrary node r to obtain a rooted tree (G, r). We denote with h the height of the rooted tree, and with level(x) the height of node x relative to the root r (with level$(r) = 1$). Let ST(x) denote the subtree of node x (i.e. the set of nodes v such that with level$(v) \geq$ level(x) and the unique path from v to r contains x). The algorithm starts from the highest level (the leaves), opens a center every time it finds a node whose subtree contains at least $\lceil n/k \rceil$ nodes, and deletes this subtree from the graph. At the end, the cost to each node is still defined using the closest node at which a center is opened by the algorithm.

Algorithm 1 Proportionally Fair Clustering for Trees.

```
Root the tree $G$ at an arbitrary node $r$
$X \leftarrow \emptyset$
$G^h \leftarrow G$
for $\ell = h$ to 1 do
    $G^{\ell-1} \leftarrow G^\ell$
    for every $x \in V$ with level$(x) = \ell$ and $|\mathrm{ST}(x)| \geq \lceil n/k \rceil$ do
        $X \leftarrow X \cup \{x\}$
        $G^{\ell-1} \leftarrow G^{\ell-1} \setminus \mathrm{ST}(x)$
if $G^0 \neq \emptyset$ then
    $X \leftarrow X \cup \{r\}$
return $X$
```

▶ **Theorem 9.** *Let $G = (V, E)$ be an undirected tree, (V, d) be the metric induced by G, $\mathcal{N} \subseteq V$, $\mathcal{M} = V$, and $k \in \mathbb{N}$. Then, Algorithm 1 yields a proportionally fair clustering.*

Proof. Let X be the clustering returned by Algorithm 1. First, we notice that X contains at most k centers. This is because every time the algorithm opens a center in the for loop, it deletes at least $\lceil n/k \rceil$ nodes from the graph. Hence, the for loop can add at most k centers. If it adds exactly k centers, then the remaining graph must be empty, and the if condition is not executed. If it adds at most $k - 1$ centers, then even if the root node is added later, there would be at most k centers.

Next, suppose for contradiction that X is not proportionally fair. Hence, there exists a set $S \subseteq V$ with $|S| \geq \lceil n/k \rceil$ and $y \in V$ such that $d(i, y) < d(i, X)$ for all $i \in S$.

For each node $i \in V$, define $p(i)$ to be its closest ancestor in X (i.e. $p(i) \in X$ and $i \in \mathrm{ST}(p(i))$, and $p(i)$ is the node of maximum level satisfying these two conditions). Note that because the algorithm always opens a center at the root node, $p(i)$ is well-defined for each node i.

Further, note that for each $i \in S$, $d(i, X) \leq d(i, p(i))$. And for nodes $j \notin \mathrm{ST}(p(i))$, $d(i, j) > d(i, p(i))$. Hence, the cost to i can only reduce if the deviating center is in $\mathrm{ST}(p(i))$. We now consider two cases.

- **Case 1: $\exists i, i' \in S : p(i) \neq p(i')$.** First, suppose that $p(i)$ and $p(i')$ are siblings (i.e. $\mathrm{ST}(p(i)) \cap \mathrm{ST}(p(i')) = \emptyset$). As i can only improve if the deviating center is in $\mathrm{ST}(p(i))$ and i' can only improve if the deviating center is in $\mathrm{ST}(p(i'))$, we obtain that no deviating center y can reduce the cost to i and i' simultaneously, which is a contradiction.

Next, suppose that $p(i) \in \mathrm{ST}(p(i'))$. Then, we must have $y \in \mathrm{ST}(p(i))$, otherwise the cost to i would not reduce. But then, $d(i', p(i)) \leq d(i', y)$. Hence, the cost to i' does not reduce due to y, which is also a contradiction.

The remaining case of $p(i') \in \mathrm{ST}(p(i))$ is symmetric to the last case.

- **Case 2: $\forall i \in S, p(i) = p^*$.** Let $O = X \cap \mathrm{ST}(p^*) \setminus \{p^*\}$ be the set of open centers in $\mathrm{ST}(p^*)$ except p^* itself. Note that by definition of p^*, we have that if $i \in S$, then $i \notin \mathrm{ST}(o)$ for any $o \in O$.

  This implies that if $y \in \mathrm{ST}(o)$ for some $o \in O$, then for every point $i \in S$, we have $d(i, y) \geq d(i, o) \geq d(i, X)$, meaning that y would not reduce the cost to any point in S. Hence, $y \in \mathrm{ST}(p^*) \setminus \cup_{o \in O} \mathrm{ST}(o)$.

  In other words, if center p^* was opened in the iteration with index ℓ (let $\ell = 0$ if p^* is the root node that was opened outside of the for loop), then $S \cup \{y\} \in G^\ell$ (any point from S or y could not have been deleted in any previous iteration). However, for y to reduce the cost to each $i \in S$, we must have $S \subseteq \mathrm{ST}(y)$. However, then, y is a node of higher level than p^* that still contains at least $|S| \geq \lceil n/k \rceil$ points, so it must have been removed in a previous iteration. This is the desired contradiction.

This concludes the proof. ◀

We remark that Theorem 9 identifies the broadest class of interesting metrics to date for which an exact proportionally fair clustering is known to always exist. This raises an immediate question: what about graphs that are not trees? We can consider the universal lower bound for the $(\mathbb{R}^2, L^1)$ metric from Theorem 8. If we construct a very dense grid graph (in which the shortest path distance mimics the L^1 distance in the plane) in the relevant region of $\mathbb{R}^2$ from that example, we can derive the same lower bound of 1.4 on the approximation ratio to proportional fairness for graphs. Whether better lower bounds exist is an open question. Similarly, the $1 + \sqrt{2}$ upper bound of greedy capture holds for all metrics, including those induced by a graph. However, whether its approximation ratio or running time can be improved for graphs, possibly with special properties such as planarity, remains to be seen.

It is worthwhile noting the special case of $\mathcal{N} = \mathcal{M} = V$, i.e., when every node of the graph is also a data point (besides being a feasible cluster center location). In this case, we do not know whether an exact proportionally fair clustering always exists, and leave this as an interesting open question. That said, we do note that if G is connected and we want to place a large number of clusters $k \geq n/2$, then it can be shown that a proportionally fair clustering exists. This is because a dominating set[2] of any size $k \geq n/2$ is guaranteed to exist in a graph with n nodes [26] and can be computed efficiently [18]. If nodes in such a set are chosen as the cluster centers, then every node in the graph already has cost at most 1. So to deviate, all nodes in the blocking coalition must achieve cost 0. However, since the blocking coalition must contain at least $\lceil n/k \rceil \geq 2$ nodes, this is impossible. Thus, the questions of existence and computation of a proportionally fair clustering in general graphs with $\mathcal{N} = \mathcal{M} = V$ become trivial when $k \geq n/2$, but remain open when $k < n/2$.

[2] A set of nodes is called a dominating set if every node in the graph is either in this set or adjacent to a node in this set.

6 Computational Aspects

In this section, we consider computational aspects of two problems: the problem of checking whether a proportionally fair clustering exists, and the problem of implementing the greedy capture algorithm when $\mathcal{M} = \mathbb{R}^t$. We begin by considering the former problem. The full proof appears in the full version of the paper, but we provide a sketch here.

▶ **Theorem 10.** *Given $\mathcal{X} = \mathbb{R}^2$, finite $N \subset \mathcal{X}$, finite $M \subset \mathcal{X}$, $k \in \mathbb{N}$, and $d = L^2$, checking whether a proportionally fair clustering exists is NP-hard.*

Proof Sketch. We first show a reduction which creates an instance of proportionally fair clustering with $n/k = 2$, and later show how to extend this to the case where n/k is any even integer. We use a polynomial-time reduction from the planar monotone rectilinear 3-SAT problem, where each clause c_j consists of only positive or only negative literals, each variable v_i is represented by a rectangle on the x-axis and each positive (resp. negative) clause is represented by a rectangle above (resp. below) the x-axis with three vertical lines or legs to its three variables. The graph that connects clauses to literals is planar. Figure 1 shows what a planar monotone rectilinear 3-SAT instance looks like.

Let I be an instance of a planar monotone rectilinear 3-SAT which consists of l boolean variables and m monotone clauses. Given I, we construct an instance I' of proportionally fair clustering with $|\mathcal{N}| = \Theta(lm^2)$ and $\mathcal{M} = \Theta(lm^2)$ such that I is satisfiable if and only if there exists a proportionally fair clustering in I'.

First, for each variable v_i, we construct a variable gadget which contains points $v_{i,j}$, $\bar{v}_{i,j}$, $a_{i,j}$ and $b_{i,j}$ for $j \in [m]$. They are all on the line, and belong to both $\mathcal{N}$ and $\mathcal{M}$. This gadget is shown in Figure 2. The point $v_{i,j}$ (resp. $\bar{v}_{i,j}$) corresponds to the positive (resp. negative) literal of v_i, specifically reserved for clause c_j (whether or not it appears in that clause). We set the distances in a way that the closest node to any node is the node on its right, while the closest node to the last node $b_{i,m}$ is its previous node $a_{i,m}$.

All variable gadgets are located on the x-axis in such a way that the gadget of variable v_i is on the left of the gadget of variable v_{i+1}, and from left to right, the distances between two adjacent variable gadgets are slightly decreasing. (The exact construction is provided in the full proof.)

Next, we construct two clause gadgets, a basic and an auxiliary one, for each clause. The auxiliary gadget of each clause is sufficiently far from all other gadgets in the construction. It consists of 3 points and 3 feasible centers such that at least two centers must be placed within each such gadget, otherwise, ρ-proportional fairness is violated for all $\rho < 1.214$. The purpose of this gadget is to make fewer than a proportional number of centers available for the rest of the construction.

In the basic gadget of a clause, we add points that form a rectangle with three legs. The interaction of this gadget with variable gadgets is shown in Figure 3. Let y_j be the y-coordinate where we place all the points that consist the virtual rectangle of c_j. We choose the values of $y_i, i \in [m]$, such that each point in a basic gadget has as closest neighbour a point in the same gadget. Let c_j be a positive clause which contains the positive literals of variables v_q, v_s and v_t with $q < s < t$ (respectively, if the clause is negative). We add a virtual rectangle in the interval $[(v_{q,j}, y_j), (v_{t,j}, y_j)]$ and add the three virtual legs that are vertical at x-coordinates $v_{q,j}$, $v_{s,j}$, and $v_{t,j}$, respectively. First, we place $2m(t-s)$ points in the interval $[(\bar{v}_{s,j}, 0), (v_{t,j}, 0)]$. Denote these points as $r^1_{j,k}$, $k \in [1, 2m(t-s)]$, where the x-coordinate of $r^1_{j,k}$ is less than the x-coordinate of $r^1_{j,k+1}$, and we set the distances such that $r^1_{j,k}$ has as its closest neighbor $r^1_{j,k+1}$. Second, we place in a similar way $2m(s-q)$ points in the interval $[(v_{q,j}, y_j), (a_{s,j-1}, y_j)]$ (or $[(v_{qj}, y_j), (a_{s-1,m}, y_j)]$ if $j = 1$). We denote these points as $r^2_{j,k}$, $k \in [1, 2m(s-q)]$, where the x-coordinate of point $r^2_{j,k}$ is larger than the x-coordinate of point $r^2_{j,k+1}$, and we set the distances such that $r^2_{j,k}$ has as its closest neighbor $r^2_{j,k+1}$.

It remains to construct the legs of each clause. First, we place $2n_j$ points (see the full version for the exact value of n_j), denoted by $l^1_{j,k}$, $k \in [1, 2n_j]$, with x-coordinate equal to $v_{q,j}$ and y-coordinate less than y_j. Specifically, we locate $l^1_{j,1}$ in a position such that the leftmost point in the rectangle of c_j has as its closest neighbor $l^1_{j,1}$, the closest neighbor of every $l^1_{j,k}$, $k \in [1, 2n_j - 1]$, is $l^1_{j,k+1}$, and the closest neighbor of $l^1_{j,2n_j}$ is $v_{q,j}$. For the remaining legs, we add points at exactly the same y-coordinates of the points in the first leg, but with x-coordinates equal to $v_{s,j}$ and $v_{t,j}$. Denote the points of the middle and the right leg as $l^2_{j,k}$ and $l^3_{j,k}$, $k \in [1, 2tn_j]$, respectively.

Lastly, for each clause we add one more point, denoted by o_j in a location such that it is the circumcenter of the triangle with nodes $r^1_{j,1}$, $r^2_{j,1}$, and $l^2_{j,1}$, and these are the (tied) closest neighbors of o_j. Figure 3 shows this entire construction for an example instance which consists of 2 positive clauses (only one of which is shown in the figure) and 3 variables.

In this construction, note that each clause gadget (the union of basic and auxiliary gadgets) has an even number of points equal to $2n'_j + 4$ (for some n'_j; see the full version for details), and each variable gadget has $4m$ of points. Hence, we choose $k = 2ml + \sum_{j=1}^{m}(n'_j + 2m)$, so that $n/k = 2$. Now, we are ready to prove that I is satisfiable if and only if there exists a proportionally fair clustering in I'.

Note that in each variable gadget we need at least $2m$ cluster centers in order for the clustering to be proportionally fair. This is because every pair of adjacent points can deviate if neither of them is a cluster center. There are only two ways to place exactly $2m$ centers: we can either open centers at $v_{i,j}$ and $a_{i,j}$ for all $j \in [4m]$, or open centers at $\bar{v}_{i,j}$ and $b_{i,j}$ for $j \in [4m]$. The first choice corresponds to an assignment where x_i is set to true, while the second corresponds to an assignment where x_i is set to false.

As we mentioned earlier, the auxiliary gadget of each clause needs at least two cluster centers placed within it, otherwise a proportionally fair clustering cannot exist. This leaves n'_j centers for every basic clause gadget. However, each basic gadget needs at least n'_j centers. To see this, notice that from point $r^2_{j,1}$ to the last point of the left leg, we need to add one center at every other point. Similarly, from point $r^1_{j,1}$ to the last point of the right leg, we

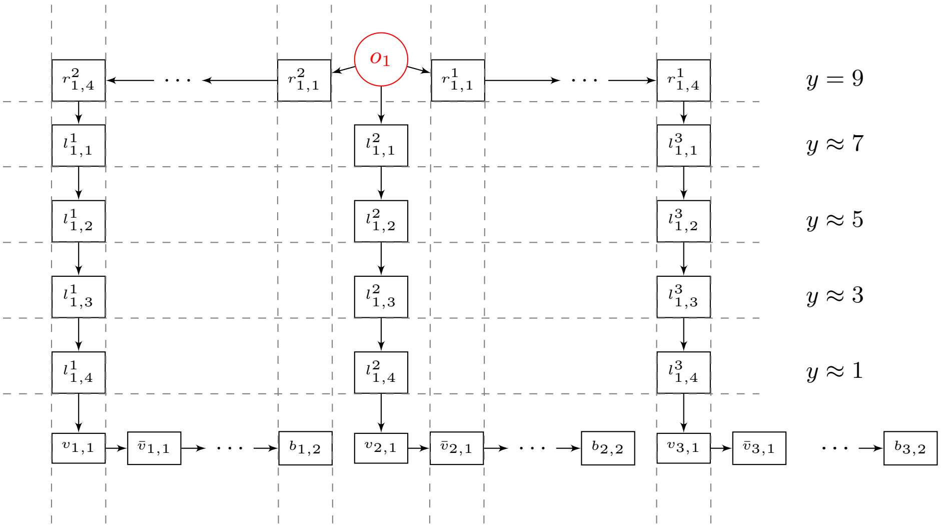

Figure 3 The rectangle and the legs of clause $c_1 = v_1 \vee v_2 \vee v_3$ in an instance with $m = 2$ and $l = 3$. A directed edge from one node points to the closest neighbor of the node.

also need a center at every other point. The same holds for the middle leg. As these are $2n'_j$ points in total, this requires at least n'_j centers in an alternating pattern. Notice that at least one of $r^1_{j,1}$, $r^2_{j,1}$ and $l^2_{j,1}$ must also be an open center, otherwise o_j can deviate with one of them. This is possible only if at least one of the corresponding variable nodes is an open center. The reason is that the last point of at least one leg is not an open center and this point should not want to deviate with its closest node (which corresponds to the literal of the clause). This happens if and only if this node is a center, and so the clause is satisfied.

This shows that I is satisfiable if and only if I' admits a proportionally fair clustering. ◀

Next, we consider implementing the greedy capture algorithm when $\mathcal{M} = \mathbb{R}^t$. Note that because the naive description of greedy capture requires simultaneously growing a ball from each point in $\mathcal{M}$, it is easy to implement when $\mathcal{M}$ is finite (as shown by Chen et al. [8]) but difficult when $\mathcal{M}$ is infinite.

To avoid this issue, one may consider restricting the set of feasible cluster center locations to a finite set $\mathcal{M}'$, and hope that running greedy capture (or any algorithm for that matter) on this finite set still yields a clustering that is approximately fair with respect to the original infinite $\mathcal{M}$. To that end, we show that restricting to $\mathcal{M}' = \mathcal{N}$ (i.e. choosing cluster centers from the set of data points) can only worsen the approximation factor of an algorithm by a factor of at most 2. The proof appears in the full version.

▶ **Theorem 11.** *For any metric space $(\mathcal{X}, d)$, $k \in \mathbb{N}$, $\mathcal{N}, \mathcal{M} \subseteq \mathcal{X}$, and $\rho \geq 1$, any ρ-proportionally fair k-clustering with respect to $(\mathcal{N}, \mathcal{M}' = \mathcal{N})$ is 2ρ-proportionally fair with respect to $(\mathcal{N}, \mathcal{M})$.*

For the metric $(\mathbb{R}^t, L^2)$, where $t \in \mathbb{N}$, recall that greedy capture produces a 2-proportionally fair clustering when $\mathcal{M} = \mathbb{R}^t$. Hence, Theorem 11 implies that running it on $\mathcal{M}' = \mathcal{N}$, for finite $\mathcal{N}$, would yield a 4-proportionally fair clustering in polynomial time. However, for this special case, we can in fact efficiently achieve $2 + \epsilon$ approximation for any constant $\epsilon > 0$, as we discuss below.

Let us consider the first cluster center added by greedy capture when $\mathcal{M} = \mathbb{R}^t$. It is the center of a smallest ball that contains at least n/k of the n given points. The problem of finding the smallest ball containing at least p of n given points is a well-studied problem in computational geometry. This is known to be NP-hard [31], which is what makes implementing greedy capture hard when $\mathcal{M} = \mathbb{R}^t$.

However, when t is constant, the problem is known to be solvable efficiently [31]; we show that in this case, greedy capture can also be implemented efficiently, and we can achieve the 2-approximation from Theorem 5.

Further, even when t is large, the problem admits a PTAS [31]. We show that this PTAS can be used to approximately implement greedy capture, and the approximation ratio only slightly worsens. The proof of the next result appears in the full version.

▶ **Theorem 12.** *Let $t \in \mathbb{N}$, finite $\mathcal{N} \subset \mathbb{R}^t$, and $k \in \mathbb{N}$ be given as input. Suppose $\mathcal{M} = \mathbb{R}^t$ and $d = L^2$. Then, the following hold.*

1. *The clustering returned by greedy capture algorithm cannot be computed in polynomial time unless $P = NP$.*
2. *If t is constant, then it can be computed in polynomial time.*
3. *Even if t is not constant, for any constant $\epsilon > 0$, there exists a polynomial-time algorithm which finds a $(2 + \epsilon)$-proportionally fair clustering.*

7 Learning Fair Clustering

A key concern in machine learning is generalization. In our context, the question is whether a clustering that is (approximately) proportionally fair with respect to random samples taken from an underlying population would remain (approximately) proportionally fair with respect to the whole population. A positive answer to this question could be useful in two ways.

First, sometimes we may have access only to samples from an underlying population. In this case, we can rest assured that by computing a clustering that is fair with respect to the samples, it is also fair with respect to the population. Second, even if the entire population is known, it may be very large. As we noticed in Section 6, finding a proportionally fair clustering or even running the greedy capture algorithm is NP-hard; thus, these tasks may be infeasible for a large population. However, it may be possible to do so on a smaller sample taken from the population, which is where the generalization guarantee can be useful.

Chen et al. [8] show that generalization indeed holds for proportional fairness. Specifically, they define the following relaxation of ρ-proportional fairness.

▶ **Definition 13.** *We say that a k-clustering X is ρ-proportionally fair to $(1 + \epsilon)$-deviations with respect to $\mathcal{N}$ if for all $S \subseteq \mathcal{N}$ with $|S| \geq |\mathcal{N}| \cdot (1 + \epsilon)/k$ and all $y \in \mathcal{M}$, there exists at least one $i \in S$ such that $\rho \cdot d(i, y) \geq d(i, X)$.*

Chen et al. show that if $N \subseteq \mathcal{N}$ is a uniformly random sample of size $|N| = \Omega\left(\frac{k^3}{\epsilon} \ln \frac{|\mathcal{M}|}{\delta}\right)$, and if X is ρ-proportionally fair with respect to N, then X is ρ-proportionally fair to $(1+\epsilon)$-deviations with respect to $\mathcal{N}$ with probability at least $1 - \delta$.

Unfortunately, this bound depends on $|\mathcal{M}|$, and breaks down when $|\mathcal{M}|$ is infinite, which is the focus of our work. We establish a stronger guarantee that does not depend on $|\mathcal{M}|$ by utilizing the framework of VC dimension [33] for binary classifiers. First, we show that there is a natural family of binary classifiers associated with a given clustering.

▶ **Definition 14.** *Given a set of points $\mathcal{N}$, a k-clustering $X \in [\mathcal{M}]^k$, and $y \in \mathcal{M}$, define the binary classifier $h_{X,y} : \mathcal{N} \to \{0, 1\}$ such that $h_{X,y}(i) = 1$ if and only if $\rho \cdot d(i, y) < d(i, X)$. Define the "error" of this classifier on a set of points $S \subseteq \mathcal{N}$ as $err_S(h_{X,y}) = (1/|S|) \cdot \sum_{i \in S} h_{X,y}(i)$.*

Intuitively, $h_{X,y}(i) = 1$ if and only if i can be part of a coalition that complains about the unfairness of X by demonstrating y as a location that provides them ρ-improvement. The use of the term "error" may be confusing. Unlike in traditional classification context, where there is a true classifier and the error is measured in terms of the fraction of points on which a given classifier differs from the true classifier, in our case the "error" is simply the fraction of points that can deviate. One can equivalently think of the "true classifier" as the one that outputs 0 on every point.

Note that X is ρ-proportionally fair to $(1+\epsilon)$-deviations with respect to $\mathcal{N}$ if and only if $\mathrm{err}_{\mathcal{N}}(X, y) \leq \frac{1+\epsilon}{k}$ for all $y \in \mathcal{M}$. Our goal is to show that given a sufficiently large random sample $N \subseteq \mathcal{N}$, if we have a clustering X that is ρ-proportionally fair with respect to N, then it is ρ-proportionally fair to $(1+\epsilon)$-deviations with respect to $\mathcal{N}$ with high probability. However, note that we have no control over what X or y are. This is where the stronger "uniform convergence" guarantee – this establishes that $|\mathrm{err}_N(h_{X,y}) - \mathrm{err}_{\mathcal{N}}(h_{X,y})|$ is bounded for all X, y – becomes useful. Let us begin by introducing the VC dimension and a well-known uniform convergence guarantee that depends on the VC dimension.

▶ **Definition 15** (VC Dimension). *Let $\mathcal{N}$ be a set of points. Let $\mathcal{H}$ be a family of binary classifiers over $\mathcal{N}$. We say that $\mathcal{H}$* shatters *$S \subseteq \mathcal{N}$ if for every labeling $\ell : S \to \{0, 1\}$, there exists a classifier $h \in \mathcal{H}$ such that $h(i) = \ell(i)$ for all $i \in S$. The VC dimension of $\mathcal{H}$, denoted* $\dim^{\mathrm{VC}}(\mathcal{H})$*, is the size of the largest S that can be shattered by $\mathcal{H}$.*

▶ **Proposition 16** ([29]). *Let $\mathcal{H}$ be a family of binary classifiers over a set of points $\mathcal{N}$. If $N \subseteq \mathcal{N}$ is a uniformly random sample with $|N| \geq \Omega\left(\frac{\dim^{\mathrm{VC}}(\mathcal{H})+\ln(1/\delta)}{\epsilon^2}\right)$, then with probability at least $1 - \delta$, $|err_N(h) - err_{\mathcal{N}}(h)| \leq \epsilon$ for all $h \in \mathcal{H}$.*

We show that the family of classifiers $\{h_{X,y} | X \in [\mathcal{M}]^k, y \in \mathcal{M}\}$ has finite VC dimension when $\mathcal{M} = \mathbb{R}^t$ with finite t. This, along with Proposition 16, gives us the desired result.

▶ **Theorem 17.** *Fix $\epsilon, \delta > 0$, $\rho \geq 1$, $k, t \in \mathbb{N}$, and metric $(\mathbb{R}^t, d)$ where $d = L^2$. Let $\mathcal{N}$ be a set of points and $\mathcal{M} = \mathbb{R}^t$ be the set of feasible cluster centers. Let $N \subseteq \mathcal{N}$ be sampled uniformly at random with $|N| \geq \Omega\left(\frac{k^2\cdot(tk\ln k+\ln(1/\delta))}{\epsilon^2}\right)$. Then, with probability at least $1 - \delta$, every k-clustering $X \in [\mathcal{M}]^k$ that is ρ-proportionally fair with respect to N is ρ-proportionally fair to $(1 + \epsilon)$-deviations with respect to $\mathcal{N}$.*

Proof. Given a pair of points x and y, note that the set of points i such that $\rho d(i, y) \geq d(i, x)$ is a half-space in $\mathbb{R}^t$ when $\rho = 1$ and a ball in $\mathbb{R}^t$ when $\rho > 1$. Hence, given $X \in [\mathcal{M}]^k$, the set of points i satisfying $\rho d(i, y) \geq d(i, X)$ is the union of k half-spaces or balls in $\mathbb{R}^t$. It is known that the VC dimension of unions of k half-spaces or balls in $\mathbb{R}^t$ is $O(tk \ln k)$ [6].

Substituting this bound in Proposition 16, we get that $|N| \geq \Omega\left(\frac{k^2\cdot(tk\ln k+\ln(1/\delta))}{\epsilon^2}\right)$ is sufficient to ensure that with probability at least $1 - \delta$, $\mathrm{err}_{\mathcal{N}}(h_{X,y}) \leq \mathrm{err}_N(h_{X,y}) + \epsilon/k$ for all X, y. In particular, when X is ρ-proportionally fair with respect to N, this ensures that with probability at least $1 - \delta$, X is ρ-proportionally fair to $(1 + \epsilon)$-deviations with respect to $\mathcal{N}$. ◀

While we do not formally consider the case of infinite set of points ($|\mathcal{N}| = \infty$) in this work, one can define $\mathcal{N}$ as a distribution over infinitely many points, and ask whether a probability mass of at least $1/k$ has a beneficial deviation. Note that Theorem 17 applies to this case as well because it does not depend on $|\mathcal{N}|$. On the other hand, note that Theorem 17 applies only for L^2 distance metric; deriving generalization bounds for other distance metrics remains an interesting challenge for future work.

8 Discussion

In this work, we advanced the study of proportionally fair clustering in a metric space, and focused on the case where the set of possible cluster center $\mathcal{M}$ is the entire (usually infinite) metric space. Our work leaves a number of open questions.

The most immediate question is to bridge the gap between our lower and upper bounds on the approximation ratio to proportional fairness from Sections 3 and 4. In particular, we believe that for L^2, the lower bound of $2/\sqrt{3}$ from Theorem 7 may be achievable. This specific number is reminiscent of Jung's theorem, which states that for L^2 distance in $\mathbb{R}^2$ (which is where the lower bound stems from), any set of points with diameter at most 1 is contained in a ball of radius at most $1/\sqrt{3}$. This could be useful in closing the gap for L^2. Section 5 leaves open an important question which is whether a proportionally fair clustering exists for all graphs when $\mathcal{N} = \mathcal{M}$ is the set of all nodes of the graph. Our hardness results from Section 6 and learnability results from Section 7 only apply to the L^2 distance because they use results and techniques from the literature that are only available for L^2. Deriving similar results for other distance metrics would be very interesting. While Chen et al. [8] show that achieving bounded approximation to proportional fairness is incompatible with achieving bounded approximation to three classic objective functions (k-center, k-means, and k-median), it would be interesting to study the tradeoff between fairness and these objectives in special cases (such as graphs).

In this paper, our focus was on the case where the set of possible cluster centers $\mathcal{M}$ is the entire metric space. In the case where the metric is induced by a graph $G = (V, E)$ (Section 5), it is also interesting to consider the case where $\mathcal{M} \subset V$. Does a proportionally fair clustering always exist for trees when $\mathcal{M} \subset V$, or for general graphs when $\mathcal{N} = \mathcal{M} \subset V$? These questions remain open.

More broadly, we find proportional fairness to be a very elegant fairness solution concept for clustering. Adapting this idea of proportional fairness to other machine learning settings such as regression or classification can lead to many avenues for future work.

Abstract

Packing problems are an important class of optimization problems. The probably most well-known problem if this type is knapsack and many generalizations of it have been studied in the literature like Two-dimensional Geometric Knapsack (2DKP) and Unsplittable Flow on a Path (UFP). For the latter two problems, recently the first polynomial time approximation algorithms with better approximation ratios than 2 were presented [Gálvez et al., FOCS 2017][Grandoni et al., STOC 2018]. In this paper we break the barrier of 2 for the Storage Allocation Problem (SAP), a problem which combines properties of 2DKP and UFP. In SAP, we are given a path with capacitated edges and a set of tasks where each task has a start vertex, an end vertex, a size, and a profit. We seek to select the most profitable set of tasks that we can draw as non-overlapping rectangles underneath the capacity profile of the edges where the height of each rectangle equals the size of the corresponding task.

The problem SAP appears naturally in settings of allocating resources like memory, bandwidth, etc. where each request needs a contiguous portion of the resource. The best known polynomial time approximation algorithm for SAP has an approximation ratio of $2+\varepsilon$ [Mömke and Wiese, ICALP 2015] and no better quasi-polynomial time algorithm is known. We present a polynomial time $(63/32+\varepsilon) < 1.969$-approximation algorithm for the important case of uniform edge capacities and a quasi-polynomial time $(1.997+\varepsilon)$-approximation algorithm for non-uniform quasi-polynomially bounded edge capacities. Key to our results are building blocks consisting of *stair-blocks, jammed tasks,* and *boxes* that we use to construct profitable solutions and which allow us to compute solutions of these types efficiently. Finally, using our techniques we show that under slight resource augmentation we can obtain even approximation ratios of $3/2+\varepsilon$ in polynomial time and $1+\varepsilon$ in quasi-polynomial time, both for arbitrary edge capacities.

1 Introduction

Packing problems play an important role in combinatorial optimization. The most basic packing problem is knapsack where we are given a knapsack of a certain capacity, a set of items with different sizes and profits, and we are looking for a subset of items of maximum profit that fit into the knapsack. Many generalizations of it have been studied. For example,

47th International Colloquium on Automata, Languages, and Programming (ICALP 2020).
Editors: Artur Czumaj, Anuj Dawar, and Emanuela Merelli; Article No. 86; pp. 86:1–86:19
Leibniz International Proceedings in Informatics

in the Two-dimensional Geometric Knapsack problem (2DKP) the items are axis-parallel rectangles and we seek to find the most profitable subset of them that fit non-overlappingly into a given rectangular knapsack. Another generalization of the knapsack problem is called Unsplittable Flow on a Path (UFP). We are given a path with capacities on its edges and each item can be interpreted as a commodity of flow that needs to send a given amount of flow from its start vertex to its end vertex in case that we select it. If the path consists of a single edge then UFP is identical to knapsack.

In this paper, we study the Storage Allocation Problem (SAP) which combines properties of 2DKP and UFP: We are given a path (V, E) where each edge $e \in E$ has a capacity $u_e \in \mathbb{N}$, and a set of tasks T where each task $i \in T$ is specified by a size $d_i \in \mathbb{N}$, a profit $w_i \in \mathbb{N}$, a start vertex $s_i \in V$, and an end vertex $t_i \in V$. Let $P(i)$ denote the path between s_i and t_i for each $i \in T$. The goal is to select a subset of tasks $T' \subseteq T$ and define a height level $h(i) \geq 0$ for each task $i \in T'$ such that the resulting rectangle $[s_i, t_i) \times [h(i), h(i) + d_i)$ lies within the profile of the edge capacities, and we require that the rectangles of the tasks in T' are pairwise non-overlapping. Formally, for each task $i \in T'$ we require that $h(i) + d_i \leq u_e$ for each edge $e \in P(i)$ and additionally for any two tasks $i, i' \in T'$ we require that if $P(i) \cap P(i') \neq \emptyset$, then $[h(i), h(i) + d_i) \cap [h(i'), h(i') + d_{i'}) = \emptyset$. Note that since we can choose $h(i)$ we can define the vertical position of the rectangle of each task i but not its horizontal position. Again, if E has only one edge then the problem is identical to knapsack.

The problem SAP is motivated by settings in which tasks need a contiguous portion of an available resource, e.g., a consecutive portion of the computer memory or a frequency bandwidth. Observe that in contrast to UFP, in many applications of SAP the instances have uniform edge capacities, e.g., if the available memory or frequency spectrum does not change over time. From a mathematical perspective, SAP and UFP are closely related. Every feasible SAP-solution T' satisfies $\sum_{i \in T': e \in P(i)} d_i \leq u_e$ on each edge e. This is exactly the condition when a solution to UFP is feasible (UFP and SAP have the same type of input). In SAP we require additionally that we can represent the tasks in T' as non-overlapping rectangles. Also, if all edges have the same capacity then SAP can be seen as a variant of 2DKP in which the horizontal coordinate of each item i is fixed and we can choose only the vertical coordinate.

For quite some time, the best known polynomial time approximation ratios for 2DKP and UFP had been $2 + \varepsilon$ [24, 2]. Recently, the barrier of 2 was broken for both problems and algorithms with strictly better approximation ratios have been presented [16, 20]. For SAP, the best known approximation ratio is still $2 + \varepsilon$ [27], even for uniform edge capacities and if we allow quasi-polynomial running time. In contrast, for 2DKP and UFP, better quasi-polynomial time algorithms had been known earlier [3, 9, 1].

1.1 Our contribution

In this paper, we break the barrier of 2 for SAP and present a polynomial time $(63/32 + \varepsilon) < 1.969$-approximation algorithm for uniform edge capacities and a quasi-polynomial time $(1.997 + \varepsilon)$-approximation algorithm for non-uniform edge capacities in a quasi-polynomial range. Key to our results is to identify suitable building blocks to construct profitable near-optimal solutions such that we can design algorithms that find profitable solutions of this type. We call a task *small* if its demand is small compared to the capacity of the edges on its path and *large* otherwise. One can show that each edge can be used by only relatively few large tasks which allows for a dynamic program that finds the best solution with large tasks only. However, there can be many small tasks using an edge and hence this approach fails for small tasks. We therefore consider *boxable solutions* in which the tasks

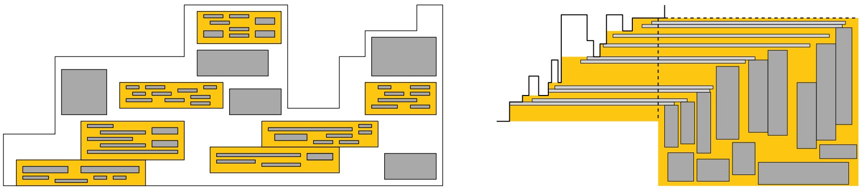

Figure 1 Left: a boxable solution in which the (gray) tasks are assigned into the (orange) boxes. Right: A stair-block into which small tasks (light gray) and large tasks (dark gray) are assigned. All small tasks need to cross the vertical dashed line and all large tasks need to be placed on the right of it underneath the dashed horizontal line. Therefore, the orange area denotes the space that is effectively usable for the tasks that we assign into the stair-block.

are assigned into rectangular boxes such that each edge is used by only $(\log n)^{O(1)}$ of these boxes, see Fig. 1. Using the latter property, we present a quasi-polynomial time algorithm that essentially finds the optimal boxable solution. Furthermore, for many types of instances we prove that there exist boxable solutions with high profit.

There are, however, instances for which it is not clear how to construct boxable solutions that yield a better approximation ratio than 2. This is where our second building block comes into play which are *stair-blocks*. Intuitively, a stair-block is an area into which we assign small and large tasks such that the small tasks are jammed between the large tasks and the capacity profile of the edges, see Fig. 1. We prove the crucial insight that if we fail to construct a good boxable solution then this is because a lot of profit of the optimum is due to small tasks in stair-blocks. We therefore devise a second algorithm that computes solutions for such instances, yielding an approximation ratio better than 2. The algorithm is based on a configuration-LP with a variable for each possible set of large tasks in each stair-block and additionally variables for placing the small tasks in the remaining space. We separate it via the dual LP in which the separation problem turns out to be a variation of SAP with large tasks only. Then we sample the set of large tasks according to the probabilities implied by the LP solution. As a result, there are some small tasks that we cannot pick anymore since they would overlap the sampled large tasks. For some small tasks this will happen with very large probability so most likely we will lose their profit. This is problematic if they represent a large fraction of the profit of the LP. We therefore introduce additional constraints that imply that if the latter happens then we can use another rounding routine for small tasks only that yields enough profit.

▶ **Theorem 1.** *There is a quasi-polynomial time* $(1.997+\varepsilon)$*-approximation algorithm for SAP if the edge capacities are quasi-polynomially bounded integers.*

Recall that in many applications of SAP the instances have uniform edge capacities. For our polynomial time algorithm for this setting the above building blocks are not sufficient since for example in our boxable solutions above an edge can be used by more than constantly many boxes and hence we cannot enumerate all possibilities for those in polynomial time. We therefore identify types of boxable solutions that are more structured and that allow us to find profitable solutions of these types in polynomial time. The first such type are boxable solutions in which each edge is used by only constantly many boxes. A major difficulty is here that for a small task there are possibly several boxes that we can assign it to and if we assign it to the wrong box then it occupies space that we should have used for other tasks instead (in our quasi-polynomial time algorithm above we use a method to address this which inherently needs quasi-polynomial time). We solve this issue by guessing the boxes in a suitable hierarchical order which is *not* the canonical linear order given by their

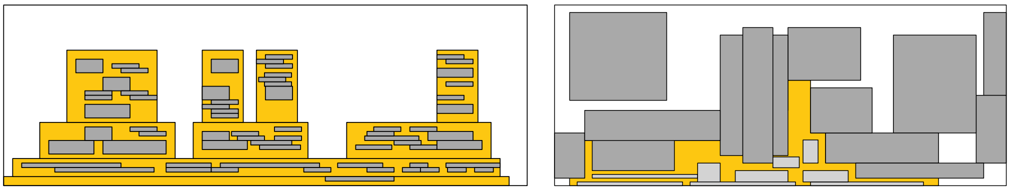

Figure 2 Left: a laminar boxable solution that consists of boxes of geometrically increasing sizes whose paths form a laminar family. Right: a jammed solution in which a set of small tasks (light gray) that are placed underneath some large tasks (dark gray). The small tasks are relatively large compared to the (orange) space underneath the large tasks.

respective leftmost edges and we assign the tasks into the boxes in the guessed order. With a double-counting argument we show that with our strategy we obtain a solution which has essentially at least the profit of the large tasks in the optimal boxable solution of the first type plus half of the profit of the small tasks. Our second special type of boxable solutions is the case in which the paths of the boxes form a laminar family and the sizes of the boxes are geometrically increasing, see Fig. 2. Even though there can be $\Omega(\log n)$ such boxes using an edge, we devise an algorithm with polynomial running time for this kind of solutions. It is a dynamic program inspired by [20] that guesses the boxes in the order given by the laminar family and assigns the tasks into them. Finally, there can be small tasks such that in the optimal solution the large tasks take away so much space that with respect to the remaining space those small tasks actually become relatively large. We say that a solution consisting of such small and large tasks forms a *jammed solution* which is our third type of building block, see Fig. 2. We extend an algorithm in [27] for instances with large tasks only to compute essentially the most profitable jammed solution. Our key technical lemma shows that for any instance there exists a profitable solution that uses only the building blocks above and we provide a polynomial time algorithm that finds such a solution.

▶ **Theorem 2.** *There is a polynomial time* $(63/32 + \varepsilon) < 1.969$*-approximation algorithm for SAP for uniform edge capacities.*

We would like to note that we did not attempt to optimize our approximation ratios up to the third decimal place but instead we focus on a clean exposition of our results (which are already quite complicated). Finally, we study the setting of $(1 + \eta)$-resource augmentation where we can increase the capacity of each edge by a factor of $1 + \eta$ for an arbitrarily small constant $\eta > 0$ while the compared optimal solution cannot do this. In this case we obtain even better approximation ratios and improve the factor of 2 for arbitrary edge capacities even with a polynomial time algorithm. Key for these results is to show that using the resource augmentation we can reduce the general case to the case of a constant range of edge capacities and then establish that there are essentially optimal boxable solutions in which each edge is used by a constant number of boxes. Using our algorithmic tools from above this implies the following theorem.

▶ **Theorem 3.** *In the setting of* $(1 + \eta)$*-resource augmentation there exists a polynomial time* $(3/2 + \varepsilon)$*-approximation algorithm and a quasi-polynomial time* $(1 + \varepsilon)$*-approximation algorithm for SAP with arbitrary edge capacities.*

Due to space constraints, this extended abstract intends to give only an overview of our methodology. For a complete presentation of our results we refer to [28].

1.2 Other related work

Previous to the mentioned $(2+\varepsilon)$-approximation algorithm for SAP [27], Bar-Noy et al. [6] found a 7-approximation algorithm if all edges have the same capacities which was improved by Bar-Yehuda et al. to a $(2+\varepsilon)$-approximation [7]. Bar-Yehuda et al. [8] presented the first constant factor approximation algorithm for SAP for arbitrary capacities, having an approximation ratio of $9+\varepsilon$. A related problem is the dynamic storage allocation problem (DSA) where in the input we are given a set of tasks like in SAP and we all need to pack all of them as non-overlapping rectangles, minimizing the maximum height of a packed item. The best known approximation ratio for DSA is a $(2+\varepsilon)$-approximation which in particular uses a $(1+\varepsilon)$-approximation if all tasks are sufficiently small [11]. This improves earlier results [25, 26, 17, 18].

For 2DKP for squares there is an EPTAS [21] which improves earlier PTASs [22, 23]. For rectangles, there was a $(2+\varepsilon)$-approximation known [24, 23] which was improved to a $(17/9+\varepsilon)$-approximation [16]. There is a PTAS if the profit of each item is proportional to its area [5]. Also, there is a QPTAS for quasi-polynomially bounded input data [1]. For UFP there is a long line of work on the case of uniform edge capacities [29, 6, 12], the no-bottleneck-assumption [13, 15], and the general case [3, 4, 14, 10, 2] which culminated in a QPTAS [3, 9], PTASs for several special cases [19, 9], a $(2+\varepsilon)$- approximation [2], which was improved to a $(5/3+\varepsilon)$-approximation [20].

2 Overview

In this section we present an overview of our methodology for our algorithms. Let $\varepsilon > 0$ and assume that $1/\varepsilon \in \mathbb{N}$. First, we classify tasks into large and small tasks. For each task $i \in T$ let $b(i) := \min_{e\in P(i)} u_e$ denote the *bottleneck capacity* of i. For constants $\mu, \delta > 0$ we define that a task i is *large* if $d_i > \delta \cdot b(i)$ and *small* if $d_i \leq \mu \cdot b(i)$. The constants δ, μ are chosen to be the values δ_{i^*} and μ_{i^*} due to the following lemma, which in particular ensures that the tasks i with $\mu \cdot b(i) < d_i \leq \delta \cdot b(i)$ contribute only a marginal amount to the optimal solution OPT whose weight we denote by opt.

▶ **Lemma 4.** *We can compute a set $(\mu_1, \delta_1), \dots, (\mu_{1/\varepsilon}, \delta_{1/\varepsilon})$ such that for each tuple (μ_k, δ_k) we have $\varepsilon^{O\left((1/\varepsilon)^{1/\varepsilon}\right)} \leq \mu_k \leq \varepsilon^{10}\delta_k^{1/\varepsilon}$, $\delta_i \leq \varepsilon$ and for one tuple $(\mu_{k^*}, \delta_{k^*})$ it holds that $w(\mathrm{OPT} \cap \{i \in T \mid \mu_{k^*} \cdot b(i) < d_i \leq \delta_{k^*} \cdot b(i)\}) \leq \varepsilon \cdot \mathrm{opt}$.*

Let T_L and T_S denote the sets of large and small input tasks, respectively. For each edge e let $T_e \subseteq T$ denote the set of tasks $i \in T$ for which $e \in P(i)$. We will show later that for many instances there are profitable solutions that are *boxable* which intuitively means that the tasks can be assigned into rectangular boxes such that each edge is used by only few boxes. A *box* B is defined by a start vertex s_B, an end vertex t_B, and a size d_B. We define $P(B)$ to be the path of B which is the path between s_B and t_B. A set of tasks $T' \subseteq T$ *fits* into B if

- for each $i \in T'$ we have that $P(i) \subseteq P(B)$, and
- there is a value $h(i) \in [0, d_B)$ for each $i \in T'$ such that (T', h) is feasible if each edge $e \in P(B)$ has capacity d_B, and
- $|T'| = 1$ or we have $d_i \leq \varepsilon^8 \cdot d_B$ for each $i \in T'$.

We say that a set of boxes $\mathcal{B}$ and a height level assignment $h : \mathcal{B} \to \mathbb{N}$ forms a feasible solution $(\mathcal{B}, h)$ if the boxes in $\mathcal{B}$ interpreted as tasks form a feasible solution with h (see Fig. 1), i.e., if the set $(T(\mathcal{B}), h')$ is feasible where $T(\mathcal{B})$ contains a task $i(B)$ for each $B \in \mathcal{B}$ such that $P(i(B)) = P(B)$, $d_i = d_{i(B)}$ and $h'(i(B)) = h(B)$.

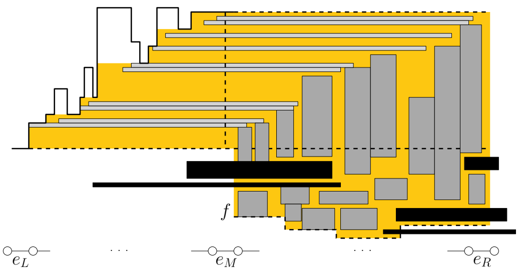

Figure 3 A stair-block $\mathcal{SB} = (e_L, e_M, e_R, f, T'_L, h')$. The black tasks are the tasks in T'_L. The orange area denotes the area that is effectively usable for the tasks that we assign to $\mathcal{SB}$. The light and dark gray tasks are small and large tasks, respectively, that together fit into $\mathcal{SB}$.

▶ **Definition 5.** *A solution (T', h') is a β-*boxable solution *if there exists a set of boxes $\mathcal{B} = \{B_1, \dots, B_{|\mathcal{B}|}\}$ and a partition $T' = T'_1 \dot\cup \dots \dot\cup T'_{|\mathcal{B}|}$ such that*

- *for each $j \in [|\mathcal{B}|]$, T'_j fits into the box B_j and if $T'_j \cap T_L \neq \emptyset$ then $|T'_j| = 1$,*
- *each edge $e \in E$ is used by the paths of at most β boxes in $\mathcal{B}$,*
- *there is a height level $h'(B)$ for each box $B \in \mathcal{B}$ such that $(\mathcal{B}, h')$ is feasible.*

In the following lemma we present an algorithm that essentially computes the optimal β-boxable solution. We will use it later with $\beta = (\log n)^{O(1)}$. Assume in the sequel that we are given a SAP-instance where $u_e \leq n^{(\log n)^c}$ for some $c \in \mathbb{N}$ for each $e \in E$.

▶ **Lemma 6.** *Let $\beta \in \mathbb{N}$ and let $(T_{\text{box}}, h_{\text{box}})$ be a β-boxable solution. There is an algorithm with running time $n^{(\beta \log n / aw\varepsilon)^{O(c)}}$ that computes a β-boxable solution (T', h') with $w(T') \geq w(T_{\text{box}})/(1+\varepsilon)$.*

Our second type of solutions are composed by *stair-blocks* (see Fig. 1 and Fig. 3). Intuitively, a stair-block is an area underneath the capacity profile defined by a function $f\colon E \to \mathbb{N}_0$ and three edges e_L, e_M, e_R, where e_M lies between e_L and e_R. The corresponding area contains all points above each edge between e_L and e_M whose y-coordinate is at least u_{e_L} and all points above each edge e between e_M and e_R whose y-coordinate is in $[f_e, u_{e_M})$. Additionally, there are some tasks $T'_L \subseteq T_L \cap (T_{e_M} \cup T_{e_R})$ and a function $h' : T'_L \to \mathbb{N}_0$ that assigns height levels to them where the intuition is that those tasks are given in advance and fixed. We require that each of them intersects the mentioned area below u_{e_L}, i.e., for each $i \in T'_L$ we have that $h'(i) + d_i \leq u_{e_L}$ and there is an edge $e \in P(i) \cap P_{e_M, e_R} \setminus \{e_M\}$ such that $h'(i) + d_i > f_e$ where P_{e_M, e_R} is the path that starts with e_M and ends with e_R. Also, we require that $f(e) = u_{e_L}$ for $e = e_M$ and each edge e on the left of e_M.

Given a stair-block, we will assign tasks T'' into the mentioned area such that we require that all small tasks in T'' use e_M and for each large tasks $i \in T''$ we require that $P(i) \subseteq P_{e_M, e_R}$. Due to the former condition, not all points with x-coordinate between e_L and e_M are actually usable for tasks assigned to $\mathcal{SB}$ and the usable ones form a staircase shape (see Fig. 1). Formally, we say that a solution (T'', h'') *fits into a stair-block* $\mathcal{SB} = (e_L, e_M, e_R, f, T'_L, h')$ if $P(i) \subseteq P_{e_M, e_R}$ and $f_e \leq h''(i) \leq u_{e_M} - d_i$ for each $i \in T'' \cap T_L$ and each $e \in P(i)$, $h''(i') \geq u_{e_L}$ and $i' \in T_{e_M}$ for each $i' \in T'' \cap T_S$, and additionally $(T'_L \cup T'', h' \cup h'')$ forms a feasible solution. Also, we require that $h''(i) < d_i$ for each $i \in T'' \cap T_L$ which is a technical condition that we need later in order to be able to compute a profitable stair solution efficiently. A set of tasks T'' fits into a stair-block $\mathcal{SB}$, if there is a function h'' such that the solution (T'', h'') fits into $\mathcal{SB}$. We will need later that the function f is simple and to this end we say that a stair-block $\mathcal{SB} = (e_L, e_M, e_R, f, T'_L, h')$ is a γ-*stair-block* if f is a a step-function with at most γ steps. Note that it can happen that e_R lies on the left of e_L and then we define P_{e_M,e_R} to be the path that starts with e_R and ends with e_M (one may imagine that Fig. 1 is mirrored).

We seek solutions that consist of stair-blocks and large tasks that are compatible with each other. To this end, for a stair-block $\mathcal{SB} = (e_L, e_M, e_R, f, T'_L, h')$ we define $P(\mathcal{SB})$ to be the path starting with the edge on the right of e_L and ending with e_R. A large task i with height $h(i)$ is *compatible with* $\mathcal{SB}$ if $i \notin T'_L$ and intuitively i does not intersect the area of the stair-block, i.e., if $h(i) \geq u_{e_M}$ or $h(i) + d_i \leq f_e$ for each $e \in P(i) \cap P(\mathcal{SB})$. We say that a task $i \in T_L$ with height $h(i)$ is *part of* $\mathcal{SB}$ if $i \in T'_L$ and $h(i) = h'(i)$. We say that stair-blocks $\mathcal{SB} = (e_L, e_M, e_R, f, T'_L, h')$ and $\overline{\mathcal{SB}} = (\bar{e}_L, \bar{e}_M, \bar{e}_R, \bar{f}, \bar{T}'_L, \bar{h}')$ are *compatible* if for each task $i \in \bar{T}'_L \cap T'_L$ we have $h'(i) = \bar{h}'(i)$, each task $i \in \bar{T}'{}_L \setminus T'_L$ is compatible with $\mathcal{SB}$, each task $i \in T'_L \setminus \bar{T}'_L$ is compatible with $\overline{\mathcal{SB}}$, and there is no task $i \in T$ that fits into both $\mathcal{SB}$ and $\overline{\mathcal{SB}}$ (for suitable heights $h''(i)$ and $\bar{h}''(i)$). Intuitively, a stair-solution consists of a set of stair-blocks and a set of large tasks T^0_L that are all compatible with each other.

▶ **Definition 7.** *A solution* (T'', h'') *is a* γ-stair-solution *if there exists a set of* γ*-stair-blocks* $\{\mathcal{SB}_1, \ldots, \mathcal{SB}_k\}$ *and partitions* $T'' \cap T_L = T^0_L \dot\cup T^1_L \dot\cup \ldots \dot\cup T^k_L$ *and* $T'' \cap T_S = T^1_S \dot\cup \ldots \dot\cup T^k_S$ *such that for each* $j \in [k]$*, the tasks* $T^j_L \cup T^j_S$ *fit into* $\mathcal{SB}_j$*, for any* $j, j' \in [|\mathcal{SB}|]$ *the stair-blocks* SB_j *and* $SB_{j'}$ *are compatible, for each stair-block* $\mathcal{SB}_j$ *and each task* $i \in T^0_L$ *with height* $h''(i)$*, the task* i *is compatible with* $\mathcal{SB}_j$ *or part of* $\mathcal{SB}_j$*, and each edge is contained in the path* $P(i)$ *of at most* γ *tasks* $i \in T^0_L$ *and in the path* $P(\mathcal{SB}_j)$ *of at most* γ *stair-blocks* $\mathcal{SB}_j$*.*

Our main structural lemma is that there exists a boxable solution or a stair solution whose profit is large enough so that we can get an approximation ratio better than 2.

▶ **Lemma 8** (Structural lemma). *There exists a* $(\log n/\delta^2)^{O(c+1)}$*-boxable solution* T_{box} *such that* $w(T_{\text{box}}) \geq \text{opt}/(1.997 + \varepsilon)$ *or there exists a* $(\log n/O(\delta))^{O(c+1)}$*-stair-solution* T_{stair} *with* $w(T_S \cap T_{\text{stair}}) \geq \frac{1}{\alpha} w(T_L \cap T_{\text{stair}})$ *for some value* $\alpha \geq 1$ *such that* $w(T_{\text{stair}} \cap T_L) + \frac{1}{8(\alpha+1)} w(T_{\text{stair}} \cap T_S) \geq \text{opt}/(1.997 + \varepsilon)$*.*

If the first case of Lemma 8 applies then the algorithm due to Lemma 6 yields a $(1.997+\varepsilon)$-approximation. In the second case the following algorithm yields a $(1.997+\varepsilon)$-approximation which completes the proof of Theorem 1.

▶ **Lemma 9.** *Let* $(T_{\text{stair}}, h_{\text{stair}})$ *be a* γ*-stair solution with* $w(T_S \cap T_{\text{stair}}) \geq \frac{1}{\alpha} w(T_L \cap T_{\text{stair}})$ *for some value* $\alpha \geq 1$*. There is an algorithm with running time* $(n \cdot \max_e u_e)^{O_\delta(\gamma^2 \log(\max_e u_e))}$ *that computes a stair solution* (T', h') *with* $w(T') \geq (1 - O(\varepsilon))(w(T_{\text{stair}} \cap T_L) + \frac{1}{8(\alpha+1)} w(T_{\text{stair}} \cap T_S))$*.*

2.1 Uniform edge capacities

Assume now that all edge capacities are identical, i.e., that there exists a value U such that $u_e = U$ for each edge $e \in E$ but that not necessarily $U \leq n^{(\log n)^c}$. For this case we want to design a *polynomial* time $(63/32 + \varepsilon)$-approximation algorithm. The above building blocks are not sufficient since the corresponding algorithms need quasi-polynomial time. Therefore, first we consider special cases of boxable solutions for which we design polynomial time algorithms. We begin with such an algorithm for β-boxable solutions for constant β that intuitively collects all the profit from the large tasks in the optimal β-boxable solution and half of the profit of its small tasks.

▶ **Lemma 10.** *Let* $\beta \in \mathbb{N}$ *and let* $(T_{\text{box}}, h_{\text{box}})$ *be a* β*-boxable solution. There is an algorithm with running time* $n^{O(\beta^3/\varepsilon)}$ *that computes a solution* (T', h') *with* $w(T') \geq w(T_{\text{box}} \cap T_L) + (1/2 - \varepsilon) w(T_{\text{box}} \cap T_S)$*.*

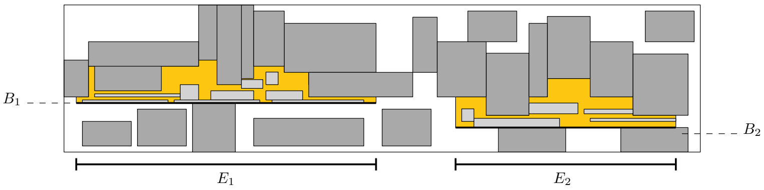

Figure 4 A jammed solution with two subpaths E_1, E_2 corresponding horizontal line segments $E_1 \times B_1$ and $E_1 \times B_2$, and small tasks (light gray) that are jammed in the respective orange areas between the large tasks (dark gray).

Next, we define laminar boxable solutions which are boxable solutions in which the paths of the boxes form a laminar family and the sizes of the boxes are geometrically increasing through the levels (see Fig. 2). A set of boxes $\mathcal{B} = \{B_1, \dots, B_{|\mathcal{B}|}\}$ with a height assignment $h : \mathcal{B} \to \mathbb{N}$ is a *laminar set of boxes* if

- the paths of the boxes form a laminar family, i.e., for any two boxes $B_k, B_{k'}$ we have that $P(B_k) \subseteq P(B_{k'})$, $P(B_{k'}) \subseteq P(B_k)$, or $P(B_k) \cap P(B_{k'}) = \emptyset$,
- there is a box $B^* \in \mathcal{B}$ with $P(B) \subseteq P(B^*)$ for each $B \in \mathcal{B}$,
- for each box $B \in \mathcal{B}$ we have that $d_B = (1+\varepsilon)^k$ for some $k \in \mathbb{N}_0$,
- for each box $B \in \mathcal{B}$ with $d_B = (1+\varepsilon)^k$ for some integer $k \geq 1$ there is a box $B' \in \mathcal{B}$ with $P(B) \subseteq P(B')$, $d_{B'} = (1+\varepsilon)^{k-1}$, and $h(B_k) = h(B_{k-1}) + d_{B_{k-1}}$.

We define $P(\mathcal{B}) := P(B^*)$. A *β-laminar boxable solution* is now a boxable solution whose boxes can be partitioned into sets $\mathcal{B} = \{\mathcal{B}_0, \mathcal{B}_1, \dots, \mathcal{B}_{|\mathcal{B}|-1}\}$ such that the boxes in the sets $\mathcal{B}_1, \dots, \mathcal{B}_{|\mathcal{B}|-1}$ are laminar sets of boxes whose respective paths $P(\mathcal{B}_j)$ are pairwise disjoint and each edge is used by at most β boxes from $\mathcal{B}_0$. Also, each box in $\mathcal{B}_0$ contains exactly one large task and each box in $\mathcal{B}_1, \dots, \mathcal{B}_{|\mathcal{B}|-1}$ contains only small tasks. We design a polynomial time algorithm for finding profitable laminar boxable solutions.

▶ **Lemma 11.** *Let $(T_{\text{lam}}, h_{\text{lam}})$ be a β-laminar boxable solution. There is an algorithm with a running time of $n^{O(\beta+1/\varepsilon^2)}$ that computes a β-laminar boxable solution (T', h') with $w(T') \geq w(T_{\text{lam}} \cap T_L) + w(T_{\text{lam}} \cap T_S)/(2+\varepsilon)$.*

The next class of solutions are pile boxable solutions. A set of boxes $\mathcal{B} = \{B_1, \dots, B_{|\mathcal{B}|}\}$ with a height assignment $h : \mathcal{B} \to \mathbb{N}$ is called a *β-pile of boxes* if $|\mathcal{B}| \leq \beta$, $P(B_k) \supseteq P(B_{k+1})$, $h(B_k) = (k-1)U/|\mathcal{B}|$ and $d_{B_k} = U/|\mathcal{B}|$ for each k. We define $P(\mathcal{B}) := P(B_1)$. A *β-pile boxable solution* is, similarly as above, a boxable solution whose boxes can be partitioned into sets of boxes $\mathcal{B} = \{\mathcal{B}_0, \mathcal{B}_1, \dots, \mathcal{B}_{|\mathcal{B}|-1}\}$ such that the boxes in the sets $\mathcal{B}_1, \dots, \mathcal{B}_{|\mathcal{B}|-1}$ are β-piles of boxes whose respective paths $P(\mathcal{B}_j)$ are pairwise disjoint and each edge is used by at most β boxes in $\mathcal{B}_0$. For β-pile boxable solutions we design a polynomial time algorithm that finds essentially the optimal solution of this type.

▶ **Lemma 12.** *Let $(T_{\text{pile}}, h_{\text{pile}})$ be a β-pile boxable solution. There is an algorithm with a running time of $n^{O(\beta+1/\delta)}$ that computes a β-pile boxable solution (T', h') with $w(T') \geq w(T_{\text{pile}})/(1+\varepsilon)$.*

Finally, we define jammed solutions (which are *not* defined via boxes). Intuitively, they consist of large and small tasks such that the small tasks are placed in areas between some horizontal line segments and the large tasks such that the small tasks are relatively large compared to the free space on each edge in these areas (see Fig. 2 and Fig. 4). Formally, given a solution (T', h') where we define $T'_L := T' \cap T_L$, let $E' \subseteq E$ be a subpath, and let $B \geq 0$ such that intuitively no task $i \in T'_L$ crosses the line segment $E' \times B$, i.e., for each task $i \in T'_L$ we have that $E' \cap P(i) = \emptyset$ or $h'(i) \geq B$ or $h'(i) + d_i \leq B$. The reader may imagine that we draw the line segment $E' \times B$ in the solution given by the large tasks T'_L and that we are interested in small tasks that are drawn above $E' \times B$. For each edge $e \in E'$ let $u'_e := \min_{i \in T'_L : e \in P(i) \wedge h(i) \geq B} h(i) - B$ and define $u'_e := U - B$ if there is no task $i \in T'_L$ with $e \in P(i)$ and $h(i) \geq B$. A task $i \in T' \cap T_S$ is a δ'*-jammed tasks for* (T'_L, E', B, h') if $P(i) \subseteq E'$, $B \leq h'(i) \leq h'(i) + d_i \leq u'_e$ for each edge $e \in P(i)$, and there exists an edge $e' \in P(i)$ such that $d_i > \delta' u'_{e'}$, i.e., intuitively i is relatively large for the edge capacities u'.

▶ **Definition 13.** *A solution solution (T', h') is a δ'-*jammed-solution *if there are pairwise disjoint subpaths $E_1, \ldots, E_k \subseteq E$, values $B_1, \ldots, B_k$, and a partition $T'_S := T' \cap T_S = T'_{S,1} \dot\cup \ldots \dot\cup T'_{S,k}$ such that $T'_{S,\ell}$ is a set of δ'-jammed tasks for $(T'_L, E_\ell, B_\ell, h')$ for each $\ell \in [k]$ with $T'_L := T' \cap T_L$.*

▶ **Lemma 14.** *Let $(T_{\text{jam}}, h_{\text{jam}})$ be a δ'-jammed solution. There is an algorithm with a running time of $n^{O_\varepsilon(1/(\delta \cdot \delta')^3)}$ that computes a $O(\delta')$-jammed solution (T', h') with $w(T') \geq w(T_{\text{lam}})/(1+\varepsilon)$.*

Our key structural lemma for the case of uniform edge capacities shows that for each instance there exists a solution of one of the above types for which the respective algorithm finds a solution of profit at least opt$/(63/32+\varepsilon)$. Then Theorem 2 follows from combining Lemmas 10, 11, 12, 14, and 15.

▶ **Lemma 15** (Structural lemma, uniform capacities)**.** *Given a SAP-instance (T, E) where $u_e = U$ for each edge $e \in E$ and some value U. There exists at least one of the following solutions*

- *a $O_\varepsilon(1)$-boxable solution $(T_{\text{box}}, h_{\text{box}})$ such that* $w(T_{\text{box}} \cap T_L) + w(T_{\text{box}} \cap T_S)/2 \geq \text{OPT}/(63/32+\varepsilon)$
- *a laminar boxable solution $(T_{\text{lam}}, h_{\text{lam}})$ with* $w(T_{\text{lam}} \cap T_L) + w(T_{\text{lam}} \cap T_S)/2 \geq \text{OPT}/(63/32+\varepsilon)$
- *a $O_\varepsilon(1)$-pile boxable solution $(T_{\text{pile}}, h_{\text{pile}})$ with $w(T_{\text{pile}}) \geq \text{OPT}/(63/32+\varepsilon)$*
- *a jammed-solution $(T_{\text{jam}}, h_{\text{jam}})$ with $w(T_{\text{jam}}) \geq \text{OPT}/(63/32+\varepsilon)$.*

2.2 Resource augmentation

We consider now again the case of arbitrary edge capacities but under $(1+\eta)$-resource augmentation. First, we show that due to the latter we can reduce the general case to the case of a constant range of edge capacities.

▶ **Lemma 16.** *If there is an α-approximation algorithm with a running time of $n^{O(f(\eta,M))}$ for the case of $(1+\eta)$-resource augmentation where $\eta < 1$ and $u_e \leq M u_{e'}$ for any two edges e, e' then there is an $\alpha(1+\varepsilon)$-approximation algorithm with a running time of $n^{O(f(\eta,1/(\varepsilon\eta)))}$ for the case of $(1+O(\eta))$-resource augmentation.*

Next, we show that if we are given an instance with a constant range of edge capacities, under $(1+\eta)$-resource augmentation we can guarantee that there is an $(1+\varepsilon)$-approximative $O_{\varepsilon,\eta}(1)$-boxable solution. Then Theorem 3 follows by combining Lemmas 6, 10, 16, and 17 with the $(1+\varepsilon)$-approximation algorithm for sufficiently small tasks in [27].

▶ **Lemma 17.** *Given an instance where $u_e \leq M u_{e'}$ for any two edges e, e' with optimal solution (T^*, h^*). If we increase the edge capacities by a factor of $1+\eta$, there is a $O_{\varepsilon,\eta}(1)$-boxable solution (T', h') such that $w(T') \geq w(T^*)/(1+\varepsilon)$.*

3 Structural lemma for uniform capacities

In the remaining part of this subsection, we sketch the proof of Lemma 15. Consider an optimal solution (OPT, h). We define $\mathrm{OPT}_L := \mathrm{OPT} \cap T_L$ and $\mathrm{OPT}_S := \mathrm{OPT} \cap T_S$.

Recall that our goal is to improve the approximation ratio of 2. Observe that OPT_L alone is a $1/\delta$-boxable solution and hence if $w(\mathrm{OPT}_L) \geq \frac{1}{(63/32+\varepsilon)}\mathrm{opt}$ then we obtain a $1/\delta$-boxable solution with the desired properties. Similarly, the set OPT_S yields a pile boxable solution with exactly 1 box B with $P(B) = E$ and $d_B = U$. Therefore, if $w(\mathrm{OPT}_S) \geq \frac{1}{(63/32+\varepsilon)}\mathrm{opt}$ then we are done. The reader may imagine that $w(\mathrm{OPT}_S) = w(\mathrm{OPT}_L) = \frac{1}{2}\mathrm{opt}$. We split the small tasks in OPT_S into three sets $\mathrm{OPT}_{S,\text{top}}, \mathrm{OPT}_{S,\text{mid}}, \mathrm{OPT}_{S,\text{bottom}}$. Intuitively, we draw a strip of height δU at the bottom of the capacity profile and a strip of height δU at the top of the capacity profile and assign to $\mathrm{OPT}_{S,\text{top}}$ all tasks in OPT_S whose top edge lies in the top strip, we assign to $\mathrm{OPT}_{S,\text{bottom}}$ all tasks in OPT_S whose bottom edge lies in the bottom strip, and we assign to $\mathrm{OPT}_{S,\text{mid}}$ all other small tasks. Formally, we define $\mathrm{OPT}_{S,\text{top}} := \{i \in \mathrm{OPT}_S \mid h(i) + d_i > (1-\delta)U\}$, $\mathrm{OPT}_{S,\text{bottom}} := \{i \in \mathrm{OPT}_S \mid h(i) < \delta U\}$, and $\mathrm{OPT}_{S,\text{mid}} := \mathrm{OPT}_S \setminus (\mathrm{OPT}_{S,\text{top}} \cup \mathrm{OPT}_{S,\text{bottom}})$.

Small tasks at bottom and large tasks. We define solutions that consists of OPT_L and subsets of $\mathrm{OPT}_{S,\text{bottom}}$. For each edge e let $u'_e := \min_{i \in T'_L : e \in P(i)} h(i)$ and define $u'_e := U$ if there is no task $i \in T'_L$ with $e \in P(i)$. One may think of u' as a pseudo-capacity profile for which $\mathrm{OPT}_{S,\text{bottom}}$ is a feasible solution. We the following lemma and obtain sets $\mathrm{OPT}_{S,\text{bottom},L}$, $\mathrm{OPT}_{S,\text{bottom},S}$ with $w(\mathrm{OPT}_{S,\text{bottom},L} \cup \mathrm{OPT}_{S,\text{bottom},S}) \geq (1-\varepsilon)w(\mathrm{OPT}_{S,\text{bottom}})$.

▶ **Lemma 18.** *Given a solution (T', h') for a SAP instance where $\max_e u_e \leq n^{(\log n)^c}$ for some constant c. Then there are sets $T'_L \subseteq T'$ and $T'_S \subseteq T'$ with $w(T'_L \cup T'_S) \geq (1-O(\varepsilon))w(T')$ and there is an $\eta = O_{\varepsilon,\delta}(1)$ such that*

1. *for each edge e it holds that $|T'_L \cap T_e| \leq (\log n)^{O_{\varepsilon,\delta}(c)}$, and*
2. *for each task $i \in T'_L$ there is an edge $e \in P(i)$ with $d_i \geq \eta u_e$,*
3. *there is a boxable solution for T'_S in which each edge e is used by at most $(\log n)^{O_\varepsilon(c)}$ boxes,*
4. *these boxes form groups of laminar sets of boxes.*

We have that for each task $i \in \mathrm{OPT}_{S,\text{bottom},L}$ there is an edge $e \in P(i)$ with $d_i > \delta u'_e$, therefore $\mathrm{OPT}_{S,\text{bottom},L}$ is a set of δ-jammed tasks for $(\mathrm{OPT}_L, E, 0, h)$ and hence $\mathrm{OPT}_L \cup \mathrm{OPT}_{S,\text{bottom},L}$ forms a δ-jammed-solution. Also, $\mathrm{OPT}_L \cup \mathrm{OPT}_{S,\text{bottom},S}$ forms a laminar boxable solution. Hence, if $w(\mathrm{OPT}_{S,\text{bottom},S})$ or $w(\mathrm{OPT}_{S,\text{bottom},L})$ is sufficiently large then we are done. Therefore, the reader may imagine that $w(\mathrm{OPT}_{S,\text{bottom},S}) = w(\mathrm{OPT}_{S,\text{bottom},L}) = 0$.

Small tasks at top and large tasks. We mirror OPT along the y-axis and do a symmetric construction with $\mathrm{OPT}_{S,\text{top}}$: we apply Lemma 18 which yields sets $\mathrm{OPT}_{S,\text{top},L}, \mathrm{OPT}_{S,\text{top},S}$ and a δ-jammed solution $\mathrm{OPT}_L \cup \mathrm{OPT}_{S,\text{top},L}$ and a laminar boxable solution $\mathrm{OPT}_L \cup \mathrm{OPT}_{S,\text{top},S}$. Like before, the reader may imagine that $w(\mathrm{OPT}_{S,\text{top},S}) = w(\mathrm{OPT}_{S,\text{top},L}) = 0$ and hence $w(\mathrm{OPT}_{S,\text{mid}}) = w(\mathrm{OPT}_S) = \frac{1}{2}\mathrm{opt}$.

Small and large tasks in the middle. Next, we split the large tasks OPT_L into three sets $\mathrm{OPT}_{L,\text{top}}$, $\mathrm{OPT}_{L,\text{mid}}$, and $\mathrm{OPT}_{L,\text{bottom}}$. Intuitively, $\mathrm{OPT}_{L,\text{top}}$ consists of all tasks in OPT_L whose top edge lies in the strip of height δU at the top of the capacity profile, $\mathrm{OPT}_{L,\text{bottom}}$ consists of all tasks in OPT_L whose bottom edge lies in the strip of height δU at the bottom of the capacity profile, and $\mathrm{OPT}_{L,\mathrm{mid}}$ contains all remaining tasks in OPT_L. Formally, $\mathrm{OPT}_{L,\mathrm{top}} := \{i \in \mathrm{OPT}_L | h(i) + d_i > (1-\delta)U\}$, $\mathrm{OPT}_{L,\mathrm{bottom}} := \{i \in \mathrm{OPT}_L | h(i) < \delta U\}$, and $\mathrm{OPT}_{L,\mathrm{mid}} := \mathrm{OPT}_L \setminus (\mathrm{OPT}_{L,\mathrm{top}} \cup \mathrm{OPT}_{L,\mathrm{bottom}})$.

Observe that no task in $\mathrm{OPT} \setminus (\mathrm{OPT}_{L,\mathrm{bottom}} \cup \mathrm{OPT}_{S,\mathrm{bottom}})$ touches the rectangle $E \times [0, \delta U)$. Using this, we define a boxable solution T_{box} that will consist essentially of all tasks in the set $\mathrm{OPT} \setminus (\mathrm{OPT}_{L,\mathrm{bottom}} \cup \mathrm{OPT}_{S,\mathrm{bottom}})$. Intuitively, we will use the free space $E \times [0, \delta U)$ in order to untangle the interaction between the large and small tasks. More precisely, T_{box} will be a $O_\delta(1)$-boxable solution in which all small tasks are assigned into boxes of height $\Theta_\delta(U)$ each. More formally, we apply the following lemma to $\mathrm{OPT} \setminus (\mathrm{OPT}_{L,\mathrm{bottom}} \cup \mathrm{OPT}_{S,\mathrm{bottom}})$ and denote by $(T'_{\mathrm{box}}, h'_{\mathrm{box}})$ the resulting solution.

▶ **Lemma 19.** *Given a solution (T', h') such that no task touches the rectangle $E \times [0, \delta U)$. Then there exists a $O_\delta(1)$-boxable solution (T', h_{box}).*

We apply Lemma 19 to the solution obtained by taking $\mathrm{OPT} \setminus (\mathrm{OPT}_{L,\mathrm{top}} \cup \mathrm{OPT}_{S,\mathrm{top}})$ and shifting each task up by δU units. Let $(T''_{\mathrm{box}}, h''_{\mathrm{box}})$ denote the resulting solution. Assume w.l.o.g. that $w(\mathrm{OPT}_{L,\mathrm{top}}) \le w(\mathrm{OPT}_{L,\mathrm{bottom}})$. Observe that if $w(\mathrm{OPT}_{L,\mathrm{mid}}) \ge \gamma\mathrm{opt}$ then

$$\begin{aligned} w(T' \cap T_L) &\ge w(\mathrm{OPT}_{L,\mathrm{bottom}}) + w(\mathrm{OPT}_{L,\mathrm{mid}}) \\ &\ge \frac{1}{2} w(\mathrm{OPT}_{L,\mathrm{top}} \cup \mathrm{OPT}_{L,\mathrm{bottom}}) + w(\mathrm{OPT}_{L,\mathrm{mid}}) \\ &\ge \frac{1+\gamma}{2} w(\mathrm{OPT}_L) \end{aligned}$$

and $w(T' \cap T_S) \ge w(\mathrm{OPT}_S \setminus \mathrm{OPT}_{S,\mathrm{bottom}})$. Therefore, the reader may imagine now that $w(\mathrm{OPT}_{L,\mathrm{mid}}) = 0$.

Types of points in the middle

We distinguish points in the rectangle $E \times [0, U]$ into different types and identify each task $i \in \mathrm{OPT}$ with a rectangle $R_i := P(i) \times [h(i), h(i) + d_i]$. For each point p let ℓ_p denote the maximally long horizontal line segment in $E \times [0, U]$ that contains p and that does not touch the relative interior of a task in $\mathrm{OPT}_{L,\mathrm{top}} \cup \mathrm{OPT}_{L,\mathrm{bottom}}$. We say that p is a *top-point* if no endpoint of ℓ_p touches a task in $\mathrm{OPT}_{L,\mathrm{bottom}}$, p is a *sandwich-point* if one of the end-points of ℓ_p touches a task in $\mathrm{OPT}_{L,\mathrm{top}}$ and the other end-point touches task in $\mathrm{OPT}_{L,\mathrm{bottom}}$, and p is a *bottom-point* if no endpoint of ℓ_p touches a task in $\mathrm{OPT}_{L,\mathrm{top}}$ and at least one endpoint of ℓ_p touches a task in $\mathrm{OPT}_{L,\mathrm{bottom}}$. Note that here we do not define stair-points since the edges have uniform capacities. Let $\mathcal{C}_{\mathrm{top}}, \mathcal{C}_{\mathrm{sw}}, \mathcal{C}_{\mathrm{bottom}}$ denote the set of connected components of top- sandwich-, and bottom-points, respectively.

Each edge is used by at most three connected components in $\mathcal{C}_{\mathrm{top}} \cup \mathcal{C}_{\mathrm{sw}} \cup \mathcal{C}_{\mathrm{bottom}}$.

▶ **Lemma 20.** *Each edge e can be used by at most one connected component of top-points, by at most one connected component of sandwich-points, and by at most one connected component of bottom-points.*

Let $\mathrm{OPT}_{S,\mathrm{cross}} \subseteq \mathrm{OPT}_{S,\mathrm{mid}}$ denote the tasks in $\mathrm{OPT}_{S,\mathrm{mid}}$ that intersect at least two different connected components, e.g., a connected component of top-points and a connected component of sandwich-points.

▶ **Lemma 21.** *Each edge is used by at most 2 different tasks in $\mathrm{OPT}_{S,\mathrm{cross}}$.*

In particular, $\mathrm{OPT}_L \cup \mathrm{OPT}_{S,\mathrm{cross}}$ forms a $O(1/\delta)$-boxable solution. If $w(\mathrm{OPT}_{S,\mathrm{cross}})$ is sufficiently large we are therefore done. The reader may imagine that $w(\mathrm{OPT}_{S,\mathrm{cross}}) = 0$.

Top points. Consider a connected component C of top-points. Let $\mathrm{OPT}_{S,\mathrm{mid},\mathrm{top}}(C) \subseteq \mathrm{OPT}_{S,\mathrm{mid}}$ denote the tasks in $\mathrm{OPT}_{S,\mathrm{mid}}$ contained in C. We apply Lemma 18 and obtain the sets $\mathrm{OPT}_{S,\mathrm{mid},\mathrm{top},S}(C)$ and $\mathrm{OPT}_{S,\mathrm{mid},\mathrm{top},L}(C)$. Let

$$\mathrm{OPT}_{S,\mathrm{mid},\mathrm{top},S} := \bigcup_{C \in \mathcal{C}_{\mathrm{top}}} \mathrm{OPT}_{S,\mathrm{mid},\mathrm{top},S}(C)$$

and

$$\mathrm{OPT}_{S,\mathrm{mid},\mathrm{top},L} := \bigcup_{C \in \mathcal{C}_{\mathrm{top}}} \mathrm{OPT}_{S,\mathrm{mid},\mathrm{top},L}(C).$$

We obtain that $\mathrm{OPT}_{L,\mathrm{top}} \cup \mathrm{OPT}_{L,\mathrm{bottom}} \cup \mathrm{OPT}_{S,\mathrm{mid},\mathrm{top},L}$ is a δ-jammed solution and $\mathrm{OPT}_{L,\mathrm{top}} \cup \mathrm{OPT}_{L,\mathrm{bottom}} \cup \mathrm{OPT}_{S,\mathrm{mid},\mathrm{top},S}$ is a laminar boxable solution. Intuitively, if $w(\mathrm{OPT}_{S,\mathrm{mid},\mathrm{top},L})$ or $w(\mathrm{OPT}_{S,\mathrm{mid},\mathrm{top},S})$ is sufficiently large then we are done. The reader may therefore imagine that both quantities are zero.

Bottom points. We do a symmetric operation for all connected components C of bottom-points, obtaining respective sets $\mathrm{OPT}_{S,\mathrm{mid},\mathrm{bottom},S}, \mathrm{OPT}_{S,\mathrm{mid},\mathrm{bottom},L}$, a δ-jammed solution

$$\mathrm{OPT}_{L,\mathrm{top}} \cup \mathrm{OPT}_{L,\mathrm{bottom}} \cup \mathrm{OPT}_{S,\mathrm{mid},\mathrm{bottom},L},$$

and a laminar boxable solution

$$\mathrm{OPT}_{L,\mathrm{top}} \cup \mathrm{OPT}_{L,\mathrm{bottom}} \cup \mathrm{OPT}_{S,\mathrm{mid},\mathrm{bottom},S}.$$

Like before, the reader may imagine that $w(\mathrm{OPT}_{S,\mathrm{mid},\mathrm{bottom},S}) = w(\mathrm{OPT}_{S,\mathrm{mid},\mathrm{bottom},L}) = 0$.

Sandwich points. Finally, let $\mathrm{OPT}_{S,\mathrm{mid},\mathrm{sw}}$ denote all points in $\mathrm{OPT}_{S,\mathrm{mid}}$ that are contained in a connected component in $\mathcal{C}_{\mathrm{sw}}$. We assume first that $w(\mathrm{OPT}_{L,\mathrm{top}}) \geq w(\mathrm{OPT}_{L,\mathrm{bottom}})$. We define a solution consisting of some tasks in $\mathrm{OPT}_{S,\mathrm{mid},\mathrm{sw}}$ and additionally all tasks in $\mathrm{OPT}_{L,\mathrm{top}}$. Let $C \in \mathcal{C}_{\mathrm{sw}}$ and denote by $\mathrm{OPT}_{S,\mathrm{mid}}(C)$ the set of tasks in $\mathrm{OPT}_{S,\mathrm{mid}}$ that are contained in C. Let E' denote the maximally long subpath between two vertices v, v' such that for each $x \in [v, v']$ the vertical line through x, i.e., $\{x\} \times \mathbb{R}$, has non-empty intersection with C. Note that the rectangle $E' \times [0, \delta U]$ has empty intersection with each tasks in $\mathrm{OPT}_{L,\mathrm{top}} \cup \mathrm{OPT}_{S,\mathrm{mid}}$. Intuitively, we use this free space in order to push all tasks in $\mathrm{OPT}_{S,\mathrm{mid}}(C)$ down by δU units. Then they all fit into $O_{\varepsilon}(1)$ boxes that have non-empty intersection with the tasks in $\mathrm{OPT}_{L,\mathrm{top}}$.

▶ **Lemma 22.** *Given $C \in \mathcal{C}_{\mathrm{sw}}$. There is a pile of boxes $\mathcal{B} = \{B_1, \ldots, B_{1/\delta}\}$ (with a height assignment $h \colon \mathcal{B} \to \mathbb{N}_0$) such that $P(B) \subseteq E'$ and there are pairwise disjoint sets $T_1, \ldots, T_{|\mathcal{B}|} \subseteq \mathrm{OPT}_{S,\mathrm{mid}}(C)$ such that for each j, the tasks in T_j fit into B_j. The weight of tasks in the boxes is at least $\sum_j w(T_j) \geq (1-\varepsilon) w(\mathrm{OPT}_{S,\mathrm{mid}}(C))$.*

Let $\mathrm{OPT}_{S,\mathrm{mid},\mathrm{sw}} := \bigcup_{C \in \mathcal{C}_{\mathrm{sw}}} \mathrm{OPT}_{S,\mathrm{mid},S}(C)$. We apply Lemma 22 to each component $C \in \mathcal{C}_{\mathrm{sw}}$ and hence we obtain a pile boxable solution whose profit is at least

$$(1-\varepsilon) w\left(\mathrm{OPT}_{L,\mathrm{top}} \cup \mathrm{OPT}_{S,\mathrm{mid},\mathrm{sw}}\right).$$

In a similar way we can construct a pile boxable solution of profit at least

$$(1-\varepsilon) w\left(\mathrm{OPT}_{L,\mathrm{bottom}} \cup \mathrm{OPT}_{S,\mathrm{mid},\mathrm{sw}}\right).$$

▶ **Lemma 23.** *There is a pile boxable solution* $(T'_{\mathrm{sw}}, h'_{\mathrm{sw}})$ *with profit at least*

$$(1-\varepsilon)w\left(\mathrm{OPT}_{L,\mathrm{top}} \cup \mathrm{OPT}_{S,\mathrm{mid},\mathrm{sw}} \cup \mathrm{OPT}_{S,\mathrm{cross}}\right)$$

and a pile boxable solution $(T''_{\mathrm{sw}}, h''_{\mathrm{sw}})$ *with profit at least*

$$(1-\varepsilon)w\left(\mathrm{OPT}_{L,\mathrm{bottom}} \cup \mathrm{OPT}_{S,\mathrm{mid},\mathrm{sw}} \cup \mathrm{OPT}_{S,\mathrm{cross}}\right).$$

Intuitively, since $w(\mathrm{OPT}_{L,\mathrm{mid}}) = 0$ we have $w(\mathrm{OPT}_{L,\mathrm{top}}) \geq \mathrm{opt}/4$ or $w(\mathrm{OPT}_{L,\mathrm{bottom}}) \geq \mathrm{opt}/4$. Also, since $w(\mathrm{OPT}_{S,\mathrm{mid},\mathrm{top}}) = w(\mathrm{OPT}_{S,\mathrm{mid},\mathrm{bottom}}) = w(\mathrm{OPT}_{S,\mathrm{cross}}) = 0$ and $w(\mathrm{OPT}_{S,\mathrm{mid}}) = \mathrm{opt}/2$ we have that $w(\mathrm{OPT}_{S,\mathrm{mid},\mathrm{sw}}) = \mathrm{opt}/2$. Hence, (T'_{sw}, h') or (T''_{sw}, h'') satisfies the claim of the lemma. Formally, our candidate solutions are

$$\begin{aligned}
\mathrm{OPT}^{(1)} &:= \mathrm{OPT}_S\,,\\
\mathrm{OPT}^{(2)} &:= \mathrm{OPT}_L \cup \mathrm{OPT}_{S,\mathrm{bottom},S}\,,\\
\mathrm{OPT}^{(3)} &:= \mathrm{OPT}_L \cup \mathrm{OPT}_{S,\mathrm{bottom},L}\,,\\
\mathrm{OPT}^{(4)} &:= \mathrm{OPT}_L \cup \mathrm{OPT}_{S,\mathrm{top},S}\\
\mathrm{OPT}^{(5)} &:= \mathrm{OPT}_L \cup \mathrm{OPT}_{S,\mathrm{top},L}\,,\\
\mathrm{OPT}^{(6)} &:= T'_{\mathrm{box}}\,,\\
\mathrm{OPT}^{(7)} &:= T''_{\mathrm{box}}\,,\\
\mathrm{OPT}^{(8)} &:= \mathrm{OPT}_L \cup \mathrm{OPT}_{S,\mathrm{cross}}\,,\\
\mathrm{OPT}^{(7)} &:= \mathrm{OPT}_{L,\mathrm{top}} \cup \mathrm{OPT}_{L,\mathrm{bottom}} \cup \mathrm{OPT}_{S,\mathrm{mid},\mathrm{top},S}\,,\\
\mathrm{OPT}^{(8)} &:= \mathrm{OPT}_{L,\mathrm{top}} \cup \mathrm{OPT}_{L,\mathrm{bottom}} \cup \mathrm{OPT}_{S,\mathrm{mid},\mathrm{top},L}\,,\\
\mathrm{OPT}^{(9)} &:= \mathrm{OPT}_{L,\mathrm{top}} \cup \mathrm{OPT}_{L,\mathrm{bottom}} \cup \mathrm{OPT}_{S,\mathrm{mid},\mathrm{bottom},S}\,,\\
\mathrm{OPT}^{(10)} &:= \mathrm{OPT}_{L,\mathrm{top}} \cup \mathrm{OPT}_{L,\mathrm{bottom}} \cup \mathrm{OPT}_{S,\mathrm{mid},\mathrm{bottom},L}\,,\\
\mathrm{OPT}^{(11)} &:= T'_{\mathrm{sw}}\,,\ \text{and}\\
\mathrm{OPT}^{(12)} &:= T''_{\mathrm{sw}}\,.
\end{aligned}$$

The sets $\mathrm{OPT}^{(1)}, \mathrm{OPT}^{(9)}$, and $\mathrm{OPT}^{(10)}$ are pile boxable solutions, $\mathrm{OPT}^{(2)}, \mathrm{OPT}^{(4)}, \mathrm{OPT}^{(7)}$, and $\mathrm{OPT}^{(9)}$ are laminar boxable solutions, $\mathrm{OPT}^{(3)}, \mathrm{OPT}^{(5)}, \mathrm{OPT}^{(8)}$, and $\mathrm{OPT}^{(10)}$ are δ-jammed solutions, and finally $\mathrm{OPT}^{(7)}$ and $\mathrm{OPT}^{(8)}$ are $O_\delta(1)$-boxable solutions.

Our insights above determine constraints of a linear program which provides an upper bound on the approximation ratio. Using LP duality, we are able to prove that the obtained value is at most 63/32, which completes the proof of Lemma 15.

4 Structural lemma for arbitrary capacities

In this section we prove Lemma 8. We first limit the number of large tasks per edge that can appear in a feasible solution.

▶ **Lemma 24.** *For each edge* e *and each feasible solution* (T_{SOL}, h_{SOL}) *it holds that* $|T_{SOL} \cap T_L \cap T_e| \leq (\log u_e)/\delta^2$.

Consider an optimal solution (OPT, h). Define $\mathrm{OPT}_L := \mathrm{OPT} \cap T_L$ and $\mathrm{OPT}_S := \mathrm{OPT} \cap T_S$. Since we assumed the maximum edge capacity to be quasi-polynomially bounded, Lemma 24 shows that each edge can be used by at most $1/\delta^2(\log n)^{O(1)}$ large tasks in OPT.

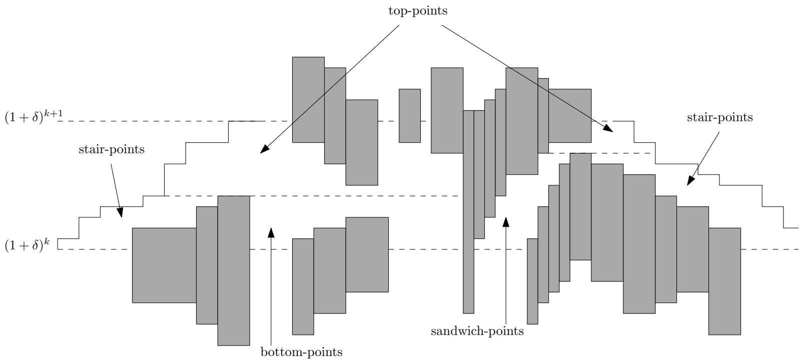

Figure 5 The different types of points within a corridor C_k. Note that the small tasks are not shown in the figure.

Therefore, the tasks in OPT_L alone form a boxable solution. Since our goal is to improve the approximation ratio of 2 in [27], we are done if $w(\mathrm{OPT}_L) \geq (\frac{1}{2}+\gamma)\mathrm{OPT}$ for some $\gamma > 0$. The reader may therefore imagine that $w(\mathrm{OPT}_L) \leq \mathrm{OPT}/2$ and hence that $w(\mathrm{OPT}_S) \geq \mathrm{OPT}/2$.

We partition the large tasks OPT_L into two groups. We define $\mathrm{OPT}_{L,\downarrow} := \{i \in \mathrm{OPT}_L \mid h(i) < d_i\}$ and $\mathrm{OPT}_{L,\uparrow} := \{i \in \mathrm{OPT}_L \mid h(i) \geq d_i\}$. In the next lemma we show that there is a boxable solution that contains essentially all tasks in $\mathrm{OPT}_S \cup \mathrm{OPT}_{L,\uparrow}$.

▶ **Lemma 25.** *For an arbitrary $0 < \varepsilon \leq 1/3$ there exists a boxable solution with profit at least $(1-\varepsilon)w(\mathrm{OPT}_S \cup \mathrm{OPT}_{L,\uparrow})$.*

Intuitively, if now $w(\mathrm{OPT}_{L,\uparrow}) \geq \gamma\mathrm{OPT}$ for some $\gamma > 0$ then $w(\mathrm{OPT}_S \cup \mathrm{OPT}_{L,\uparrow}) \geq (\frac{1}{2}+\gamma)\mathrm{OPT}$ and we are done, due to Lemma 6 and Lemma 25. The reader therefore may imagine that $w(\mathrm{OPT}_{L,\uparrow}) = 0$ and $w(\mathrm{OPT}_S) = \mathrm{OPT}/2$ and hence also $w(\mathrm{OPT}_{L,\downarrow}) = \mathrm{OPT}/2$.

Next, we define solutions that either consist of $\mathrm{OPT}_{L,\downarrow}$ or of a subset of $\mathrm{OPT}_{L,\downarrow}$ and additionally some small tasks. We will prove that one of the constructed sets or $\mathrm{OPT}_S \cup \mathrm{OPT}_{L,\uparrow}$ has large profit. In the sequel, we will identify the vertices $\{v_1,\ldots,v_{|V|}\}$ of (V,E) with the coordinates $1,\ldots,|V|$ and a path P between vertices $v_i, v_{i'}$ with the closed interval $[i,i']$. For each task $i \in \mathrm{OPT}$ define its rectangle $R_i := P(i) \times [h(i), h(i)+d_i]$. We will identify a task i with its rectangle R_i.

We define $(\log n)^{O_\delta(1)}$ corridors. We draw a horizontal line $\ell^{(k)}$ with y-coordinate $y = (1+\delta)^k$ for each $k \in \mathbb{N}$. For each $k \in \mathbb{N}$ we define the area $\mathbb{R} \times [\ell^{(k)}, \ell^{(k+1)})$ to be the *corridor* C_k. Consider a task $i \in \mathrm{OPT}_L$. Observe that for each task $i \in \mathrm{OPT}_L$ the rectangle R_i has to be intersected by at least one line $\ell^{(k)}$ since $d_i > \delta \cdot b(i)$. Also, observe that for each edge e and each corridor C_k there can be at most two tasks $i, i' \in \mathrm{OPT}_L$ whose respective paths $P(i), P(i')$ use e and whose respective rectangles $R_i, R_{i'}$ intersect C_k. If there are two such task i, i' then for one of them its rectangle must intersect $\ell^{(k)}$ and for the other its rectangle must intersect $\ell^{(k+1)}$.

Let C_k be a corridor. For a task $i \in \mathrm{OPT}_L$ with $R_i \cap C_k \neq \emptyset$ we say that i is a *top-large-task for* C_k if $h(i) \in [(1+\delta)^k, (1+\delta)^{k+1})$, a *bottom-large-task for* C_k if $h(i)+d_i \in [(1+\delta)^k, (1+\delta)^{k+1})$, and a *cross-large-task for* C_k if $h(i) < (1+\delta)^k$ and $h(i)+d_i \geq (1+\delta)^{k+1}$. We partition the area of C_k that is not used by large tasks into connected components of points. For each point p, let ℓ_p denote the maximally long horizontal line segment that contains p and that neither crosses a large task nor the capacity profile. We say that p is a *top-point* if each endpoint of ℓ_p touches a top-large-task or the capacity profile; p is a *sandwich-point* if one of the end-points of ℓ_p touches a top-large-task and the other end-point touches a bottom-large-task; p is a *stair-point* if one end-point of ℓ_p touches a bottom-large-task and the other end-point touches the capacity profile; and p is a *bottom-point*, if both end-points of ℓ_p touch a bottom-large-task, see Fig. 5. In each corridor C_k this yields connected components of top-, bottom-, sandwich-, and stair-points. In the remaining proof (see [28]) we show that for each of these types there exists a $(\log n/\delta)^{O_\varepsilon(c)}$-boxable solution or a $(\log n/\delta)^{O_\varepsilon(c)}$-stair solution that contains all tasks in $\mathrm{OPT}_{L,\downarrow}$ and a constant fraction of the small tasks in all connected components of the respective type, or of the small tasks that overlap more than one type of points. Hence, we obtain an approximation ratio strictly better than 2, unless essentially all small tasks lie in connected components of sandwich points. For this case, intuitively we prove that there is a $(\log n/\delta)^{O_\varepsilon(c)}$-boxable solution that contains all profit from the small tasks and a 1/4-fraction of the profit of the tasks in $\mathrm{OPT}_{L,\downarrow}$. We show that the best of our solutions yields an approximation ratio of $1.997+\varepsilon$ which proves Lemma 8.

5 Compute stair solution

In this section we prove Lemma 9. To this end, we first show how to compute a solution for a single stair-block $\mathcal{SB}$. Then we devise a dynamic program that intuitively sweeps the path from left to right, guesses the stair-blocks and the other large tasks, and then uses the subroutine for a single stair-block to assign tasks into each stair-block. Suppose that we are given a γ-stair-block $\mathcal{SB} = (e_L, e_M, e_R, f, T'_L, h')$. Let $\bar{T}$ denote the set of tasks $i \in T$ such that $\{i\}$ fits into $\mathcal{SB}$. In the sequel, we prove the following lemma.

▶ **Lemma 26.** *Let $T^* \subseteq \bar{T}$ be an unknown set of tasks that fits into $\mathcal{SB}$ such that $w(T_S \cap T^*) \geq \frac{1}{\alpha} w(T_L \cap T^*)$ for some value $\alpha \geq 1$. There is a $(n \cdot \max_e u_e)^{O_\delta(\log(\max_e u_e))}$ time algorithm that computes a set $\hat{T}$ that fits into $\mathcal{SB}$ such that*

$$w(\hat{T}) \geq (1 - O(\varepsilon)) \left(w(T_L \cap T^*) + \frac{1}{8(\alpha+1)} \cdot w(T_S \cap T^*) \right).$$

First, we guess $w(T_L \cap T^*)$ up to a factor $1+\varepsilon$, i.e., we guess a value W such that $w(T_L \cap T^*) \in [W, (1+\varepsilon)W)$. One can show that $(n/\varepsilon)^{O(1)}$ many guesses for W suffice. Our algorithm is based on a linear program that uses configurations for the sets of large tasks that fit into $\mathcal{SB}$. Formally, we define a pair $C = (\bar{T}', \bar{h}')$ to be a *configuration* if $\bar{T}' \subseteq \bar{T}$, $w(\bar{T}') \in [W, (1+\varepsilon)W)$, $\bar{h}'$ is a function $\bar{h}' : \bar{T}' \to \mathbb{N}$ such that $\bar{h}'(i) < d_i$ for each task $i \in \bar{T}'$, and $(\bar{T}', \bar{h}')$ fits into $\mathcal{SB}$. Let $\mathcal{C}$ denote the set of all configurations. We introduce a variable y_C for each configuration $C \in \mathcal{C}$. Intuitively, $y_C = 1$ indicates that the computed solution contains exactly the set of large tasks in C, each of them drawn at the height level determined by C. For each small task $j \in \bar{T}_S := \bar{T} \cap T_S$ and each $t \in \{0, \ldots, b(j) - d_j\}$ we introduce a variable $x_{j,t}$ indicating whether j is contained in the solution and drawn at height t. Note that we do not need variables $x_{j,t}$ for $t > b(j) - d_j$ since the upper edge of j has to have a height of at most $b(j)$.

We add constraints that ensure that the rectangles corresponding to the selected tasks do not overlap. To this end, for each small tasks $j \in \bar{T}_S$ and each possible height $t \in \{0, \ldots, b(j) - d_j\}$ we define a “rectangle” $p(j,t) = \{(e,t') \mid e \in P(j) \text{ and } t \leq t' < t + d_j\}$. For a pair (e,t) the reader may imagine that it represents the point whose x-coordinate is the mid-point of the edge e and whose y-coordinate is t. Similarly, for a configuration $C = (\bar{T}', \bar{h}') \in \mathcal{C}$ we define the “points” covered by C to be $p(C) := \{(e,t') \mid \exists i \in \bar{T}' : e \in P(i) \text{ and } \bar{h}'(i) \leq t' < \bar{h}'(i) + d_i\}$ and $w_C := w(\bar{T}')$.

Denote by $\mathrm{LP}_{\mathcal{SB}}$ the linear program below where for convenience we assume that all non-existing variables are set to zero.

$$\max \textstyle\sum_{C\in\mathcal{C}} y_C w_C + \sum_{j\in\bar{T}_S,t} x_{j,t} w_j \tag{1}$$

$$\text{s.t.} \quad \textstyle\sum_{C:\,(e,t)\in p(C)} y_C \tag{2}$$

$$+ \sum_{j\in\bar{T}_S,t':\,(e,t)\in p(j,t')} x_{j,t'} \leq 1 \quad \text{for all } e\in P_{e_M,e_R}, t\geq 0 \tag{3}$$

$$\textstyle\sum_{C:\,(e,t)\in p(C)} y_C + \sum_{t':\,t'\leq t} x_{j,t'} \leq 1 \quad \text{for all } e\in P_{e_M,e_R}, t\geq 0, j\in \bar{T}_S\cap T_e \tag{4}$$

$$\textstyle\sum_{C\in\mathcal{C}} y_C = 1 \tag{5}$$

$$\textstyle\sum_{t\geq 0} x_{j,t} \leq 1 \quad \text{for all } j\in\bar{T}_S \tag{6}$$

$$x_{j,t}, y_C \geq 0 \quad \text{for all } j\in\bar{T}_S, t\in\mathbb{N}, t\leq b(j)-d_j, C\in\mathcal{C}$$

The first set of constraints (3) expresses intuitively that no two rectangles overlap. Then (4) strengthens this condition by stating that if a configuration C covers a point (e,t) then no small task j using e can be selected such that it covers a point (e,t') with $t'\leq t$ (note that if C covers (e,t) then it also covers each point (e,t') with $t'\leq t$). Constraint (5) ensures that we select exactly one configuration. A task j still cannot be drawn at two positions simultaneously, which we ensure with (6). In the LP above, we introduce constraints (3) and (4) for each $t\geq 0$, however, it is sufficient to state those for each t such that $t\in\mathbb{N}$ since $d_i\in\mathbb{N}$ for each task $i\in T$ and we introduce the variables $x_{j,t}$ only for values t with $t\in\mathbb{N}$. This yields an equivalent formulation with only $(n\max_e u_e)^{O(1)}$ constraints (apart from the non-negativity constraints). The number of variables in $\mathrm{LP}_{\mathcal{SB}}$ is exponential. However, we can solve it in polynomial time via a suitable separation oracle for the dual.

▶ **Lemma 27.** *There is an algorithm with running time $(n\max_e u_e)^{O_\delta(\log(\max_e u_e))}$ that computes an optimal solution to $LP_{\mathcal{SB}}$.*

5.1 The rounding algorithm

Let (x^*,y^*) denote the optimal solution to $\mathrm{LP}_{\mathcal{SB}}$. We round (x^*,y^*) via randomized rounding. First, we sample a configuration $\hat{C}$ using the distribution determined by y^*, i.e., for each configuration $C\in\mathcal{C}$, we obtain $\hat{C}=C$ with probability y_C. Define $\bar{y}_{\hat{C}}:=1$ and $\bar{y}_C:=0$ for each $C\in\mathcal{C}\setminus\{\hat{C}\}$. Then we construct a new solution x for the small tasks where intuitively we remove all pairs (j,t) that overlap with $\hat{C}$, i.e., such that $p(j,t)\cap p(\hat{C})\neq\emptyset$. For each pair of the latter type we define $x_{j,t}:=0$ and we define $x_{j,t}:=x^*_{j,t}$ for all other pairs (j,t). Observe that x is a solution to the LP that is obtained by taking $\mathrm{LP}_{\mathcal{SB}}$ and removing all variables y_C and constraint (5). Denote by $\mathrm{LP}'_{\mathcal{SB}}$ the resulting LP. We can round it via randomized rounding with alteration, using that for two pairs $(j,t),(j',t')$ with $j,j'\in T_S$ the corresponding rectangles $p(j,t),p(j',t')$ overlap if and only if they overlap on a "vertical line segment above e_M", i.e., on $\cup_{t''\in[t,t+d_j)\cap[t',t'+d_{j'})}(e_M,t'')$.

▶ **Lemma 28.** *Given a solution x to $LP'_{\mathcal{SB}}$. In polynomial time we can compute an integral solution $\bar{x}$ to $LP'_{\mathcal{SB}}$ with expected value $\sum_{j\in\bar{T}_S,t}\bar{x}_{j,t}w_j \geq \frac{1}{4}\sum_{j\in\bar{T}_S,t}x_{j,t}w_j$ such that the support of $\bar{x}$ is contained in the support of x.*

Let $(\bar{x},\bar{y})$ denote the resulting solution. Secondly, we compute the optimal solution to $\mathrm{LP}'_{\mathcal{SB}}$ (hence ignoring the configurations of large tasks) and round it via Lemma 28, let $(\bar{x}',\bar{y}')$ denote the resulting solution. In the sequel we prove that the most profitable solution among $(\bar{x},\bar{y})$ and $(\bar{x}',\bar{y}')$ satisfies the claim of Lemma 9. Since we sampled $\hat{C}$ according to the distribution given by y^*, we have that $\mathbb{E}[w_{\hat{C}}] = \sum_{C\in\mathcal{C}} y^*_C w_C$. Recall that we discarded all pairs (j,t) such that $p(j,t)$ overlaps with $p(\hat{C})$. Hence, there are some pairs (j,t) that are discarded with very high probability. We call such a pair problematic where formally we say that a pair (j,t) with $j \in \bar{T}_S$ and $t \in \mathbb{N}$ is *problematic* if $\sum_{C\in\mathcal{C}:p(C)\cap p(j,t)\neq\emptyset} y^*_C > 1-\eta$ for some value $\eta > 0$ to be defined later. Let $T_{S!}$ denote the set of all problematic pairs. In the following lemma we prove that their contribution to the profit of (x^*, y^*) is only small and hence we can afford to ignore them, unless $(\bar{x}', \bar{y}')$ already has enough profit. Here we crucially need constraint (4). We define $\text{opt}_{LP} := \sum_{C\in\mathcal{C}} y^*_C w_C + \sum_{j\in\bar{T}_S,t} x^*_{j,t} w_j$.

▶ **Lemma 29.** *We have that* $\sum_{(j,t)\in T_{S!}} x^*_{j,t} w_j \le 4\eta \mathit{opt}_{LP}$ *or the profit of* $(\bar{x}', \bar{y}')$ *is at least* $\mathit{opt}_{LP} \ge w(T_L \cap T^*) + w(T_S \cap T^*)$.

Assume now that the first case of Lemma 29 applies. We argue that then the problematic pairs contribute at most half of the profit of all pairs (for all small tasks) and hence we can ignore the problematic pairs.

▶ **Lemma 30.** *Assume that* $\eta \le \frac{1}{8}\frac{1/\alpha - O(\varepsilon)}{1+1/\alpha-O(\varepsilon)}$. *Then* $\sum_{(j,t)\notin T_{S!}} x^*_{j,t} w_j \ge \frac{1}{2}\sum_{j\in\bar{T}_S,t} x^*_{j,t} w_j$.

Proof sketch. Let us pretend that $\sum_{C\in\mathcal{C}} y^*_C w_C = w(T_L \cap T^*)$. Then $\sum_{j\in\bar{T}_S,t} x^*_{j,t} w_j \ge w(T_S \cap T^*)$ since (x^*, y^*) is the optimal fractional solution. Therefore, $\sum_{j\in\bar{T}_S,t} x^*_{j,t} w_j \ge \frac{1}{\alpha}\sum_{C\in\mathcal{C}} y^*_C w_C$ and $(1+\frac{1}{\alpha})\sum_{j\in\bar{T}_S,t} x^*_{j,t} w_j \ge \frac{1}{\alpha}\left(\sum_{C\in\mathcal{C}} y^*_C w_C + \sum_{j\in\bar{T}_S,t} x^*_{j,t} w_j\right) = \frac{1}{\alpha}\text{opt}_{LP}$. This implies that $\sum_{j\in\bar{T}_S,t} x^*_{j,t} w_j \ge \text{opt}_{LP}/(\alpha+1)$. Since $\sum_{(j,t)\in T_{S!}} x^*_{j,t} w_j \le 4\eta\text{opt}_{LP} \le \frac{\text{opt}_{LP}}{2(\alpha+1)} \le \frac{1}{2}\sum_{j\in\bar{T}_S,t} x^*_{j,t} w_j$ the claim follows. ◀

Each non-problematic pair is discarded only with probability at most $1-\eta$. Therefore, the expected profit of the auxiliary solution x is at least an η-fraction of the profit of the non-problematic pairs. Due to Lemma 30 we can neglect the profit due to problematic pairs. For $\eta := \frac{1-O(\varepsilon)}{8(\alpha+1)}$ the claim of Lemma 26 follows from some simple calculation.

Arbitrary stair-solutions

In order to compute a profitable γ-stair-solution we device a DP that intuitively sweeps the path from left to right and guesses the stair-blocks in the optimal stair-solution. For each stair-block we invoke the algorithm above. Since each edge can be used by at most γ stair-blocks and large tasks we obtain a running time of $n^{(\gamma\log n)^{O(c/\delta)}}$. Since we require the stair-blocks to be compatible, there can be no task that can be assigned to more than one stair-block, even if the subproblems for each stair-block is solved independently. Recall that for a large task $i \in T_L$ we required that $h(i) < d_i$ for its computed height $h(i)$ and hence we cannot assign it into two stair-blocks, even if it would fit into the respective areas of the stair-blocks. We defer the details to the full version of the paper [28].

Abstract

The class MIP^* is the set of languages decidable by multiprover interactive proofs with quantum entangled provers. It was recently shown by Ji, Natarajan, Vidick, Wright and Yuen that MIP^* is equal to RE, the set of recursively enumerable languages. In particular this shows that the complexity of approximating the quantum value of a non-local game G is equivalent to the complexity of the Halting problem.

In this paper we investigate the complexity of deciding whether the quantum value of a non-local game G is *exactly* 1. This problem corresponds to a complexity class that we call *zero gap* MIP^*, denoted by MIP_0^*, where there is no promise gap between the verifier's acceptance probabilities in the YES and NO cases. We prove that MIP_0^* extends beyond the first level of the arithmetical hierarchy (which includes RE and its complement coRE), and in fact is equal to Π_2^0, the class of languages that can be decided by quantified formulas of the form $\forall y \, \exists z \, R(x,y,z)$.

Combined with the previously known result that MIP_0^{co} (the *commuting operator* variant of MIP_0^*) is equal to coRE, our result further highlights the fascinating connection between various models of quantum multiprover interactive proofs and different classes in computability theory.

1 Introduction

A two-player *non-local game* is played between a verifier and two cooperating players named Alice and Bob who cannot communicate with each other once the game starts. During the game, the verifier samples a pair of questions (x, y) from a joint distribution μ, sends x to Alice and y to Bob, who respond with answers a and b respectively. The verifier accepts if and only if $D(x, y, a, b) = 1$ for some predicate D. The *quantum value* of a non-local game G, denoted by $\omega_q(G)$, is defined to be the supremum of the verifier's acceptance probability over all possible finite dimensional quantum strategies of Alice and Bob for the game G.

What is the complexity of computing the quantum value of non-local games? In [16], Slofstra proved that the problem of determining whether a given game G has $\omega_q(G) = 1$ is *undecidable.* Recently, it was shown that *approximating* $\omega_q(G)$ up to any additive constant is also an uncomputable problem [11]. In particular, there is a computable reduction from Turing machines M to non-local games G_M such that if M halts (when run on an empty input), then $\omega_q(G_M) = 1$, and otherwise $\omega_q(G_M) \leq \frac{1}{2}$. Since determining whether a given Turing machine halts (i.e. the Halting problem) is undecidable, so is the problem of determining whether the quantum value of a non-local game is 1 or at most $\frac{1}{2}$.

Conversely, one can reduce the problem of approximating the quantum value of non-local games to the Halting problem; there is an algorithm that for every non-local game G exhaustively searches over finite-dimensional strategies of increasing dimension to find one that succeeds with probability close to 1 (above 0.99, say). If $\omega_q(G) = 1$ then the algorithm is guaranteed to find such a strategy; otherwise if $\omega_q(G) \leq 1/2$ the algorithm will run forever. In complexity-theoretic terms, this shows that the class MIP^*, the set of languages decidable by multiprover interactive proofs with quantum provers, is equal to RE, the set of recursively enumerable languages (i.e. the class for which the Halting problem is complete).

In this paper, we return to the problem originally investigated by Slofstra [16]: what is the complexity of deciding if $\omega_q(G)$ is *exactly* equal to 1 for nonlocal games G? This corresponds to the complexity class that we call *zero gap* MIP^*, denoted by MIP_0^*. In this model of interactive proofs, in the YES case (i.e. $x \in L$), there is a sequence of finite-dimensional prover strategies that cause the verifier to accept with probability approaching 1. In the NO case (i.e. $x \notin L$), all finite-dimensional prover strategies are rejected with positive probability – but could be arbitrarily close to 0. It is easy to see that $\mathsf{MIP}^* \subseteq \mathsf{MIP}_0^*$ and thus MIP_0^* contains undecidable languages. Furthermore, we know that MIP_0^* *cannot* be equal to MIP^*; the results of [16, 5] imply that coRE, the complement of RE, is also contained in MIP_0^*. Since $\mathsf{RE} \neq \mathsf{coRE}$, this implies that MIP_0^* strictly contains $\mathsf{MIP}^* = \mathsf{RE}$.

What problems can be reduced to the task of exactly computing the quantum value of non-local games, rather than "just" approximating it? We characterize the class MIP_0^* by showing that it is equal to Π_2^0, a class that belongs to the *arithmetical hierarchy* from computability theory. The arithmetical hierarchy is defined by classes of languages decidable via formulas with alternating quantifiers. For example, the class RE is equal to the class Σ_1^0, which is the set of languages L of the form $\{x : \exists y.\, R(x, y) = 1\}$ for some decidable predicate R. The class coRE is equal to Π_1^0, the set of languages of the form $\{x : \forall y.\, R(x, y) = 1\}$. The class Π_2^0 is the set of languages L of the form $\{x : \forall y.\, \exists z.\, R(x, y, z) = 1\}$.

An equivalent definition of the class Π_2^0 is that it is the set of languages L such that there is a Turing machine A that has *oracle access* to the Halting problem, and $x \notin L$ if and only if $A(x) = 1$. It is known that Π_2^0 strictly contains $\Sigma_1^0 = \mathsf{RE}$. This shows that MIP_0^* contains problems that are *harder* (in a computability sense) than the Halting problem.

We specifically show that there exists a computable reduction from Π_2^0 languages to the problem of deciding whether a *three-player* non-local game G has quantum value 1. It is likely that a similar reduction holds for two-player non-local games but we leave this for future work. We also show that the problem of deciding if a non-local game has quantum value 1 can be reduced to a Π_2^0 language, thus establishing the equality $\mathsf{MIP}_0^* = \Pi_2^0$.

This paper, combined with the results of [11] and [16], paints a fascinating landscape about the complexity of quantum multiprover interactive proofs, in which there are four different complexity classes to consider. The first two are MIP^* and MIP_0^*, which we defined already. The second two are $\mathsf{MIP}^{\mathsf{co}}$ and its zero-gap variant $\mathsf{MIP}_0^{\mathsf{co}}$. The class $\mathsf{MIP}^{\mathsf{co}}$ stands for languages that are decidable by quantum multiprover interactive proofs in the *commuting* *operator* model: here, the provers are allowed to use infinite-dimensional quantum strategies, and the measurement operators of Alice only need to commute with those of Bob (rather than be in tensor product).

$$\begin{tikzcd}
\Sigma_2^0 & & \boldsymbol{\Pi_2^0} = \mathsf{MIP}^*_{\boldsymbol{0}} \\
& \Delta_2^0 \arrow[ul] \arrow[ur] & \\
\mathsf{MIP}^* = \Sigma_1^0 \arrow[uu] \arrow[ur] & & \Pi_1^0 = \mathsf{MIP}_0^{\mathsf{co}} \overset{?}{=} \mathsf{MIP}^{\mathsf{co}} \arrow[uu] \arrow[ul] \\
& \Delta_1^0 \arrow[ul] \arrow[ur] &
\end{tikzcd}$$

Figure 1 The computability landscape of quantum multiprover interactive proofs. Arrows denote inclusion. The set Δ_1^0 denotes the set of all decidable languages. The set Σ_1^0 denotes the recursively enumerable languages, and Π_1^0 denotes the set of co-recursively enumerable languages. It is known that $\mathsf{MIP}^{\mathsf{co}} \subseteq \mathsf{MIP}_0^{\mathsf{co}}$, but unknown whether they are equal.

One of the consequences of the fact that $\mathsf{MIP}^* = \mathsf{RE}$ is that $\mathsf{MIP}^{\mathsf{co}} \neq \mathsf{MIP}^*$. This is because $\mathsf{MIP}^{\mathsf{co}} \subseteq \mathsf{coRE}$, due to the fact that the commuting operator value of a non-local game can be upper-bounded using a convergent sequence of semidefinite programs [14, 4]. It is also the case that $\mathsf{MIP}_0^{\mathsf{co}} \subseteq \mathsf{coRE}$, and in fact equality holds due to [16, 3]. It remains an open question to determine if $\mathsf{MIP}^{\mathsf{co}} = \mathsf{MIP}_0^{\mathsf{co}} = \mathsf{coRE}$.

There are a number of curious and counter-intuitive aspects about this landscape of complexity for non-local games. First, if $\mathsf{MIP}^{\mathsf{co}} = \mathsf{coRE}$, then there would be a pleasing symmetry in that $\mathsf{MIP}^* = \mathsf{RE}$ and $\mathsf{MIP}^{\mathsf{co}} = \mathsf{coRE}$ (even though the "co" refer to different things on each side of the equation!). On the other hand, we have that $\mathsf{MIP}_0^* = \Pi_2^0$ and $\mathsf{MIP}_0^{\mathsf{co}} = \mathsf{coRE}$, meaning that – in the zero gap setting – there are *more* languages that can be verified with provers using (a limit of) finite-dimensional strategies than can be decided with provers using infinite-dimensional commuting operator strategies! Of course, in the setting of interactive proofs, giving provers access to more resources can change the complexity of the interactive proof model in unexpected ways.

1.1 Proof overview

We prove the lower bound $\Pi_2^0 \subseteq \mathsf{MIP}_0^*$ by combining two components: first we leverage the result of [11] that $\mathsf{MIP}^* = \mathsf{RE}$ as a black box, which implies that there is a quantum multiprover interactive proof for the Halting problem. Next, we use a *compression theorem* for quantum multiprover interactive proofs that was proved in [5]. A compression theorem, roughly speaking, states that given a verifier V for a quantum multiprover interactive protocol (which can be modeled as a Turing machine with tapes to receive/send messages to the provers), one can compute a much more time-efficient verifier V' whose quantum value is related in some predictable way to the quantum value of V. Several recent results about the complexity of non-local games crucially rely on proving compression theorems with various properties [10, 5, 13, 11].

In more detail, the compression theorem of [5] (which in turn is a refinement of the compression theorem of [10]) states that given a description of a verifier V, one can compute a description of a three-player[1] non-local game G_V (which is a multiprover protocol with only one round of interaction) whose properties are as follows:

1. The time complexity of the verifier in G_V is *polylogarithmic* in the time complexity of V.
2. The quantum value of the protocol executed by V is related to the quantum value of G_V in the following manner:

$$\omega_q(G_V) \geq \frac{1}{2} + \frac{1}{2}\omega_q(V)$$

and furthermore if $\omega_q(V) < 1$ then $\omega_q(G_V) < 1$.

The utilization of the compression theorem of [5] is the reason why the main result of this paper holds for three-player non-local games, rather than two.

We call this compression theorem a "zero gap" compression theorem, because it does not preserve any promise gap on the value of the input verifier V: if the value of V is promised to be either 1 or 1/2, then G_V is only guaranteed to have value either 1 or 3/4. If we iterate this compression procedure, then we get a promise gap that goes to zero. In contrast, the compression theorem used to prove $\mathsf{MIP}^* = \mathsf{RE}$ *is* gap-preserving.

The zero gap compression theorem was used to prove that $\mathsf{coRE} \subseteq \mathsf{MIP}_0^*$ in [5]. At a high level, this is shown by constructing a verifier that recursively calls the zero gap compression procedure on itself. In this paper, we follow this approach, except we also embed an MIP^* protocol for RE inside the verifier that is recursively calling the zero gap compression procedure; this composition of protocols allows the verifier to verify languages in Π_2^0.

1.2 Further remarks

$\mathsf{MIP}^* = \mathsf{RE}$ is equivalent to gap-preserving compression

As mentioned, the key to proving $\mathsf{MIP}^* = \mathsf{RE}$ [11] was establishing a gap-preserving compression theorem for non-local games, albeit for a special case of non-local games satisfying a so-called "normal form" property. In Section 4, we present a relatively simple – but in our opinion quite interesting – observation that $\mathsf{MIP}^* = \mathsf{RE}$ is in some sense, *equivalent* to a gap-preserving compression theorem.

A proof of $\mathsf{MIP}_0^* = \Pi_2^0$ under weaker assumptions?

One might wonder if there might be an elementary way of proving that $\mathsf{MIP}_0^* = \Pi_2^0$, *without* relying on the statement that $\mathsf{MIP}^* = \mathsf{RE}$. For example, the results of [16, 5] show that $\mathsf{coRE} \subseteq \mathsf{MIP}_0^*$ and furthermore [16] shows that $\mathsf{coRE} = \mathsf{MIP}_0^{co}$. These previous "zero-gap results" do not appear to have the same mathematical consequences as $\mathsf{MIP}^* = \mathsf{RE}$ (e.g. yielding a negative answer to Connes' embedding problem if $\mathsf{RE} \subseteq \mathsf{MIP}^*(2)$, the two-player variant of MIP^*), which suggests the intuition that characterizing the complexity of *exactly* computing the quantum (or commuting operator) value of nonlocal games may be fundamentally easier than characterizing the complexity of *approximating* it.

This intuition is not entirely correct: the "zero-gap" statement $\mathsf{MIP}_0^* = \Pi_2^0$ is already enough to yield a negative answer to Tsirelson's problem: there exists a k where k-partite commuting operator correlations cannot be approximated by finite dimensional correlations.

[1] The results of [5] are stated for games with 15 players, but can be improved to hold for 3-player games by using a different error correcting code in the construction.

Put another way, if Tsirelson's problem has a positive answer, then the commuting operator and quantum values of games are always equal, and then $\mathsf{MIP}^*_0 = \mathsf{MIP}^{co}_0 = \mathsf{coRE}$. However, Π^0_2 strictly contains coRE – thus Tsirelson's problem has a negative answer. Furthermore, Tsirelson's problem for $k = 2$ is known to be equivalent to Connes' embedding problem [6, 12, 15].

This suggests that our characterization of the class MIP^*_0 must necessarily involve a nontrivial tool such as $\mathsf{MIP}^* = \mathsf{RE}$.

1.3 Open problems

We list some open problems.

1. Just as the complexity statement $\mathsf{MIP}^* = \mathsf{RE}$ has consequences for questions in pure mathematics (such as the Connes' embedding problem), does the equality $\mathsf{MIP}^*_0 = \Pi^0_2$ have any implications for operator algebras? We believe there may be a connection to model-theoretic approaches to the Connes' embedding problem (see, e.g., [8, 7]).
2. What is the complexity of $\mathsf{MIP}^{\mathsf{co}}$? Is it equal to coRE?
3. Can the reduction from Π^0_2 languages to the problem of deciding whether $\omega_q(G) = 1$ be improved to hold for two-player games G?
4. We showed that, essentially, $\mathsf{MIP}^* = \mathsf{RE}$ implies a gap-preserving compression theorem. Can one show that it also implies in a black-box fashion, a zero gap compression theorem, of the same kind as proved in [5]? This then proves that $\mathsf{MIP}^* = \mathsf{RE}$ directly implies $\mathsf{MIP}^*_0 = \Pi^0_2$.
5. Does $\mathsf{MIP}^*_0 = \Pi^0_2$ imply $\mathsf{MIP}^* = \mathsf{RE}$ in a "black-box" fashion?

2 Preliminaries

We write $\mathbb{N}$ to denote the natural numbers $\{1, 2, 3, \ldots\}$. All logarithms are base 2. For a string $x \in \{0,1\}^*$ let $|x|$ denote the length of x. We let

$$\log^*(n) = \begin{cases} 0, & n \le 1 \\ 1 + \log^*(\log(n)), & n > 1 \end{cases}$$

denote the iterated logarithm function.

2.1 Turing machines and the arithmetical hierarchy

A total Turing machine is one that halts on every input. Fix a string encoding of Turing machines, and for a Turing machine M, let $|M|$ denote the length of the encoding of M.

▶ **Proposition 1** (Universal Turing machine). *There exists a universal constant $C > 0$ and a universal Turing machine $\mathfrak{U}$ that, given an input pair (M, x) where M is an encoding of a Turing machine, computes $M(x)$ in time $C \max(|M|, \mathsf{TIME}(M, x))^2$, where $\mathsf{TIME}(M, x)$ is the number of steps taken by M on input x before it halts.*

▶ **Definition 2.** *The i-th level of the* arithmetical hierarchy *contains 3 classes Σ^0_i, Π^0_i, and Δ^0_i. The class Σ^0_i is the set of languages defined as*

$$L = \{x \in \{0,1\}^* : \exists y_1 \forall y_2 \exists y_3 \cdots Q\, y_i\, R(x, y_1, \cdots, y_i) = 1\}$$

for some total Turing machine R, where Q is the $\forall$ quantifier when i is even and otherwise is the $\exists$ quantifier. The class Π^0_i is the complement of Σ^0_i, and $\Delta^0_i = \Sigma^0_i \cap \Pi^0_i$.

In particular the first level of the arithmetical hierarchy corresponds to the classes $\Sigma^0_1 = \mathsf{RE}$, $\Pi^0_1 = \mathsf{coRE}$, and Δ^0_1 the set of decidable languages $\mathsf{RE} \cap \mathsf{coRE}$.

2.2 Interactive verifiers

In this section, we model multiprover interactive protocols, which is specified by a *verifier V*, as a randomized algorithm. In the protocol, the verifier V interacts with multiple provers, and at the end of the protocol the verifier outputs a bit indicating whether to accept or reject. A verifier can be identified with the interactive protocol it executes, and vice versa.

In more detail, define a *k-input, r-prover verifier V* to be a randomized interactive Turing machine that has k designated input tapes, r communication tapes, a single workspace tape, and a single output tape. An interaction with r provers is executed in the following way: the Turing machine V alternates between computation and communication phases; in the computation phase, the Turing machine behaves like a normal Turing machine with $k+r+2$ tapes, and it may halt and indicate accept or reject on the output tape. It can also pause its computation and go into a communication phase, in which case the contents of each of i-th communication tape is read by the i-th prover, who then edits the i-th communication tape with its answer. After all the provers have finished with their responses, the next computation phase resumes. This is the standard way of modeling interactive Turing machines [1]. In this formulation, a non-local game is simply specified by a 0-input, 2-prover verifier V that has only one communication phase.

Given a k-input, r-prover verifier V, define its *time complexity* with respect to a k-tuple of inputs $(x_1, \ldots, x_k)$ to be the maximum number of time steps taken by the verifier V when it is initialized with $(x_1, \ldots, x_k)$ on its k input tapes, over all possible responses of the r-provers, before it halts. We denote this by $\mathsf{TIME}(V(x_1, \ldots, x_k))$.

We now define, in a somewhat informal level, *finite-dimensional prover strategies* (or simply a *strategy*) $\mathcal{S}$ for the interaction specified by a k-input, r-prover verifier V. This is a specification of the following data:

1. Local dimension $d \in \mathbb{N}$,
2. A state $|\psi\rangle \in (\mathbb{C}^d)^{\otimes r}$, and
3. For every prover i, for every round $t \in \mathbb{N}$, for every string $\pi \in \{0,1\}^*$, a POVM $\{M^a_{i,t,\pi}\}_a$ acting on $\mathbb{C}^d$.

Given a verifier V, a k-tuple $(x_1, \ldots, x_k)$, and a prover strategy $\mathcal{S}$ for V, the interaction proceeds as follows: at the beginning of the protocol, the provers share the state $|\psi\rangle$, and the verifier's input tapes are initialized to $(x_1, \ldots, x_k)$. At round t, the i-th prover performs the measurement $\{M^a_{i,t,\pi}\}_a$ on its local space to obtain an outcome a, where π is the *history* of all the messages seen by prover i in all previous rounds (including the message from the verifier in the t-th round). It then writes outcome a on the i-th communication tape of the verifier. Thus at each round the shared state between the provers depend on the outcomes of their measurements, and evolves probabilistically over time. The *value of strategy $\mathcal{S}$ in the interaction with verifier V on input* $(x_1, \ldots, x_k)$ is defined to be the probability that the verifier halts and accepts. We denote this by $\omega_q(V(x_1, \ldots, x_k), \mathcal{S})$. The *quantum value of verifier V on input* $(x_1, \ldots, x_k)$ is defined to be the supremum of $\omega_q(V(x_1, \ldots, x_k), \mathcal{S})$ over all finite-dimensional strategies $\mathcal{S}$, which we denote by $\omega_q(V(x_1, \ldots, x_k))$.

▶ **Definition 3.** *Let $m, r \in \mathbb{N}$ and let $0 \le s \le c \le 1$. The class $\mathsf{MIP}^*[m, r, c, s]$ is defined to be the set of languages L for which there exists a verifier V and a polynomial $p(n)$ with the following properties:*

1. *V is a 1-input, r-prover verifier that halts after m communication phases.*
2. *For all x, $\mathsf{TIME}(V(x)) \le p(|x|)$.*
3. *If $x \in L$, then $\omega_q(V(x)) \ge c$.*
4. *If $x \notin L$, then $\omega_q(V(x)) < s$.*

We define the class MIP^* to be the union of $\mathsf{MIP}^*[m, r, c, s]$ for all $m, r \in \mathbb{N}$ and $c > s$. We define the class MIP_0^* to be the union of $\mathsf{MIP}^*[m, r, 1, 1]$ over all $m, r \in \mathbb{N}$. In other words, in the YES case (i.e., $x \in L$), there is a sequence of finite-dimensional prover strategies that are accepted with probability approaching 1. In the NO case (i.e., $x \notin L$), there exists a positive $\varepsilon > 0$ (that generally depends on x) such that all finite dimensional strategies are rejected with probability at least ε.

2.3 Compression of quantum multiprover interactive protocols

In this section we formally present the two main ingredients used in our proof: the zero gap compression procedure of [5], and the reduction from the Halting problem to the problem of approximating the quantum value of a quantum multiprover interactive protocol.

First we introduce the definition of λ-boundedness, which specifies how both the description and time complexity of a verifier is bounded by a polynomial with exponent λ.

▶ **Definition 4.** *Let $\lambda \in \mathbb{N}$. A $(k+1)$-input r-prover verifier V is λ-bounded if for all integers $n \in \mathbb{N}$, $x_1, \ldots, x_k \in \{0,1\}^*$, we have $\mathsf{TIME}(V(n, x_1, ..., x_k)) \le \lambda(n \cdot |x_1| \cdots |x_k|)^{\lambda}$.*

Here, we assume that the first input to a verifier V is an integer $n \in \mathbb{N}$ which intuitively specifies a "complexity" parameter.

▶ **Theorem 5** (Zero-gap compression [5, Theorem 6.1])**.** *Let $r \ge 3$ be an integer. There exists a universal constant $C_{comp} \in \mathbb{N}$ such that for every $\lambda \in \mathbb{N}$, there exists a Turing machine $\mathrm{COMPRESS}_\lambda$ with the following properties. Given as input a $(k+1)$-input r-prover verifier V, the Turing machine $\mathrm{COMPRESS}_\lambda$ outputs a $(k+1)$-input r-prover verifier $V^\#$ in time $C_{comp}(|V| \cdot \lambda)^{C_{comp}}$ with the following properties: for all $x_1, \ldots, x_k \in \{0,1\}^*$, we have*

1. *if V is λ-bounded, then $\omega_q(V^\#(n, x_1, ...x_k)) \ge \frac{1}{2} + \frac{1}{2}\omega_q(V(2^n, x_1, ...x_k))$,*
2. *if V is λ-bounded and $\omega_q(V(2^n, x_1, ...x_k)) < 1$, then $\omega_q(V^\#(n, x_1, ...x_k)) < 1$,*
3. *for all integers $n \in \mathbb{N}$, $x_1, \ldots, x_k \in \{0,1\}^*$, we have $\mathsf{TIME}(V^\#(n, x_1, ..., x_k)) \le C_{comp}(\lambda \cdot n \cdot |x_1| \cdots |x_k|)^{C_{comp}}$.*

The zero-gap compression theorem, as presented here, differs from the one presented in [5, Theorem 6.1]. For example, verifiers in [5] are described using so-called "Gate Turing Machines" (GTMs). However, using the same oblivious Turing machine simulation techniques as discussed in the appendix of [5], from a verifier V (as defined in this paper), we can obtain a GTM that specifies the same interactive protocol. Another difference, as remarked in the introduction, is that here the compression result applies to protocols with three or more players, whereas it is stated for protocols with 15 or more players in [5]. However, the results of [5] can be adapted to the case of three players by using a $[[3, 1, 2]]_3$ error detecting code with qutrits (instead of using the 7-qubit Steane code with qubits) [2].

Next we present the main result of [11], which presents a computable reduction from the Halting problem to the problem of approximating the quantum value of a non-local game.

▶ **Theorem 6** ($\mathsf{MIP}^* = \mathsf{RE}$ [11])**.** *There exists a Turing machine H and a universal constant $C_{\mathrm{HALT}} \in \mathbb{N}$ with the following properties. Given as input a Turing machine M, it runs in time $C_{\mathrm{HALT}}|M|^{C_{\mathrm{HALT}}}$ and outputs a 0-input 2-prover verifier $V_{\mathrm{HALT},M}$ such that*

1. *If M halts on empty tape then $\omega_q(V_{\mathrm{HALT},M}) = 1$, and otherwise $\omega_q(V_{\mathrm{HALT},M}) \le \frac{1}{2}$.*
2. $\mathsf{TIME}(V_{\mathrm{HALT},M}) \le C_{\mathrm{HALT}}|M|^{C_{\mathrm{HALT}}}$.

3 $\mathsf{MIP}^*_0 = \Pi^0_2$

We start this section by showing the upper bound $\mathsf{MIP}^*_0 \subseteq \Pi^0_2$.

▶ **Theorem 7.** $\mathsf{MIP}^*_0 \subseteq \Pi^0_2$

Proof. Let $L \in \mathsf{MIP}^*_0$. There exists a 1-input r-prover verifier V such that $x \in L$ iff $\omega_q(V(x)) = 1$ for all $x \in \{0,1\}^*$. Let $\mathbb{S}_{\varepsilon,d}$ be an ε-net for the space of strategies of dimension d; in particular, for every dimension-d strategy $\mathcal{S}$ there exists a strategy $\mathcal{S}' \in \mathbb{S}_{\varepsilon,d}$ such that for all verifiers V we have that $|\omega_q(V,\mathcal{S}) - \omega_q(V,\mathcal{S}')| \leq \varepsilon$ (in other words, the winning probability of the strategies differ by at most ε). Because the set of strategies over a finite dimensional Hilbert space of a fixed dimension is a compact set [9], we can take $\mathbb{S}_{\varepsilon,d}$ to be a finite set. Let $\mathbb{S}_\varepsilon = \bigcup_{d\in\mathbb{N}} \mathbb{S}_{\varepsilon,d}$, and let $\{\mathcal{S}_\varepsilon(1), \mathcal{S}_\varepsilon(2), \ldots\}$ be an enumeration of strategies in $\mathbb{S}_\varepsilon$.

Consider the following total Turing machine T: On input triple (x,m,n) where $x \in \{0,1\}^*, m,n \in \mathbb{N}$. It outputs 1 if and only $\omega_q(V(x), \mathcal{S}_{1/2m}(n)) \geq 1 - 1/m$. Now it is easy to verify that

$$L = \{x : \forall m.\ \exists n.\, T(x,m,n) = 1\},$$

and therefore L is a Π^0_2 language.

To see this, let $x \in L$. Then $\omega_q(V(x)) = 1$, and for any gap (i.e. $\frac{1}{m}$) there exists a strategy S such that $\omega_q(V(x), S) \geq 1 - \frac{1}{2m}$. Choosing $\varepsilon = 1/2m$, then there must also exist a strategy $S' \in \mathbb{S}_{1/2m}$ such that $\omega_q(V(x), S') \geq \omega_q(V(x), S) - \frac{1}{2m} \geq 1 - \frac{1}{m}$. Therefore $\forall m.\ \exists n.\, T(x,m,n) = 1$.

Likewise, if $x \notin L$ then there exists $m \in \mathbb{N}$ for which $\omega_q(V(x)) < 1 - \frac{1}{m}$ and so no strategy can win with probability greater or equal to $1 - \frac{1}{m}$. Therefore $\exists m.\ \forall n.\, T(x,m,n) = 0$. ◀

Now we prove the reverse inclusion. Fix an $L \in \Pi^0_2$ and let R be a total Turing machine such that $L = \{x \in \{0,1\}^* : \forall m. \exists n. R(x,m,n) = 1\}$. To prove $L \in \mathsf{MIP}^*_0$, we construct a 2-input 3-prover verifier V that takes as input $m \in \mathbb{N}$ and $x \in \{0,1\}^*$, and has the key property that $\omega^*(V(m,x)) = 1$ if and only if $\forall m' \geq \log^*(m). \exists n. R(x,m',n) = 1$. Therefore $\omega_q(V(1,x)) = 1$ if and only if $x \in L$.

We first give the explicit description of a 3-input 3-prover verifier V' below. We then use that to construct V. In the description of V', we refer to the Turing machine $R_{x,m}$. For every $x \in \{0,1\}^*$ and $m \in \mathbb{N}$, $R_{x,m}$ is the Turing machine that on the empty tape enumerates over $n \in \mathbb{N}$ and accepts if $R(x,m,n) = 1$, otherwise it loops forever.

Now let V be the 2-input 3-prover verifier that on the input (m,x) runs $V'(m,x,V')$. Informally, $V(m,x)$ first decides $\exists n. R(x, \log^*(m), n) = 1$ by simulating the verifier in $V_{\text{HALT},R_{x,\log^*(m)}}$ from Theorem 6. Recall that the existence of the MIP^* protocol $V_{\text{HALT},R_{x,\log^*(m)}}$ is due to $\mathsf{MIP}^* = \mathsf{RE}$ and the fact that $\exists n. R(x,\log^*(m),n) = 1$ is an RE predicate. Now if $R(x,\log^*(m),n) = 0$ for all n, then $R_{x,\log^*(m)}$ never halts. This in turn implies that V rejects with probability at least 1/2. Otherwise, if $\exists n. R(x,\log^*(m),n) = 1$, V proceeds to run the compression algorithm to obtain $V'^{\#} = \text{COMPRESS}_\lambda(V')$. It then executes $V'^{\#}(m,x,V')$. Informally speaking, due to the compression theorem, the execution of $V'^{\#}(m,x,V')$ has the same effect as recursively executing $V(2^m,x)$. Now the first duty of the verifier $V(2^m,x)$ is to decide $\exists n. R(x, 1+\log^*(m), n) = 1$. So we can apply the above reasoning this time on $V(2^m,x)$ instead of $V(m,x)$. Following this reasoning ad infinitum, we establish that $\omega_q(V(m,x)) = 1$ if and only if $\forall m' \geq \log^*(m). \exists n. R(x,m',n) = 1$. This is made precise in the proof of Theorem 9.

Input: (m, x, W) where $m \in \mathbb{N}$, $x \in \{0,1\}^*$, W is a 3-input 3-prover verifier.
Perform the following steps:

1. Compute $V_{\text{HALT},R_{x,\log^*(m)}} = H(R_{x,\log^*(m)})$ (where H is from Theorem 6).
2. Execute the interactive protocol specified by the verifier $V_{\text{HALT},R_{x,\log^*(m)}}$. If the verifier $V_{\text{HALT},R_{x,\log^*(m)}}$ rejects then reject, otherwise continue.
3. Compute $W^\# = \text{COMPRESS}_\lambda(W)$ (where COMPRESS_λ is from Theorem 5).
4. Execute the interactive protocol specified by the verifier $W^\#(m, x, W)$ and accept if and only if the verifier $W^\#(m, x, W)$ accepts.

Figure 2 Specification of the 3-input 3-prover verifier V'.

Note that Theorem 5 relates $V^\#(m, x)$ to $V(2^m, x)$. That is the reason $\log^*(m)$ (as opposed to m) is appearing in Figure 2. Note that as m increases, $\log^*(m)$ ranges over all nonnegative integers.

In order to apply Theorem 5 to compress V in step 3, we must ensure that the verifier is λ-bounded for some $\lambda \in \mathbb{N}$.

▷ Claim 8. There exists a $\lambda \in \mathbb{N}$ such that V is λ-bounded.

Proof. We bound the running time of V by bounding the running time of each of the steps in its specification. The time to generate $R_{x,\log^*(m)}$, in step 1, is $C((|R| \cdot |x| \cdot m))$ for some constant C. The time to generate the encoding of $V_{\text{HALT},R_{x,\log^*(m)}}$ is $C_{\text{HALT}}(|R| \cdot |x| \cdot m)^{C_{\text{HALT}}}$. This also bounds the running time of $V_{\text{HALT},R_{x,\log^*(m)}}$. Therefore the time to simulate $V_{\text{HALT},R_{x,\log^*(m)}}$ is bounded by $C^2_{\text{HALT}}(|R| \cdot |x| \cdot m)^{2C_{\text{HALT}}}$. The time to simulate $\text{COMPRESS}_\lambda(V)$ is $C^2_{comp}(|V| \cdot \lambda)^{2C_{comp}}$. The time to simulate $V^\#(m, x)$ is bounded by $C^2_{comp}(\lambda \cdot m \cdot |x|)^{2C_{comp}}$. Therefore the running time of $V(m, x)$ is bounded above by

$$2C^2_{\text{HALT}}(|R| \cdot |x| \cdot m)^{2C_{\text{HALT}}} + C(|R| \cdot |x| \cdot m) + C^2_{comp}(|V| \cdot \lambda)^{2C_{comp}} + C^2_{comp}(\lambda \cdot m \cdot |x|)^{2C_{comp}}.$$

The values $C_{comp}, C_{\text{HALT}}, C$, and $|R|$ are all constants so we can choose $\lambda \in \mathbb{N}$ sufficiently large so that $\lambda(m \cdot |x|)^\lambda$ is larger then the quantity above and therefore V is λ-bounded. ◁

Now that we established that V is λ-bounded, we can apply Theorem 5 to get the main theorem of this paper.

▶ **Theorem 9.** *$x \in L$ if and only if $\omega_q(V(1, x)) = 1$*

Proof. First suppose $x \in L$. Then $\forall m. \exists n. R(x, m, n) = 1$. Since the Turing machine $R_{x,m}$ halts for every $m \in \mathbb{N}$, by Theorem 6, $\omega_q(V_{\text{HALT},R_{x,m}}) = 1$. Therefore $\omega_q(V(p, x)) = \omega_q(V^\#(p, x))$, for any $p \in \mathbb{N}$, by construction (step 4). Now, from Theorem 5, we have

$$\omega_q(V(p, x)) \geq \frac{1}{2} + \frac{\omega_q(V(2^p, x))}{2},$$

and by k applications of the theorem, we obtain

$$\omega_q(V(p, x)) \geq \frac{\omega_q(V(\overbrace{2^{2^{\cdots^{2^p}}}}^{k}, x))}{2^k} + \sum_{i=1}^{k} \frac{1}{2^i}.$$

for every k. Taking the limit $k \to \infty$, we have $\omega_q(V(p, x)) = 1$ for all $p \in \mathbb{N}$. In particular $\omega_q(V(1, x)) = 1$.

Now suppose $x \notin L$. Then $\exists m. \forall n. R(x,m,n) = 0$. We prove that $\omega(V(1,x)) < 1$. Let p be the smallest integer for which $R(x, \log^*(p), n) = 0$ for every n. In other words, the Turing machine $R_{x,\log^*(p)}$ does not halt. Therefore by Theorem 6 we have that $\omega_q(V(p,x)) \leq \omega_q(V_{\text{HALT},R_{x,\log^*(p)}}) \leq \frac{1}{2}$.

If $p = 1$, we are done. Suppose $p > 1$. For all $k < p$, the game $V_{\text{HALT},R_{x,\log^*(k)}}$ never rejects since the Turing machine $R_{x,\log^*(k)}$ halts, by the minimality of p. Therefore $\omega_q(V(k,x)) = \omega_q(V^{\#}(k,x))$. So by recursively applying Theorem 5, we have that

$$\omega_q(V(p,x)) < 1 \implies \omega_q(V(1,x)) < 1.$$

Since $\omega_q(V(p,x)) \leq \omega_q(V_{\text{HALT},R_{x,\log^*(p)}}) \leq \frac{1}{2}$ then $\omega_q(V(1,x)) < 1$. ◀

▶ **Corollary 10.** $\Pi_2^0 \subseteq \mathsf{MIP}_0^*$.

Proof. Let $L \in \Pi_2^0$ then $L = \{x \in \{0,1\}^* : \forall m. \exists n. R(x,m,n) = 1\}$. Let U be the 1-input 3-prover verifier, that on input x executes the verifier $V(1,x)$ where $x \in \{0,1\}^*$. By Claim 8, $\mathsf{TIME}(U(x)) = \mathsf{TIME}(V(1,x)) \leq \lambda(1+|x|)^{\lambda}$ and by Theorem 9, $x \in L$ iff $\omega^*(U(x)) = 1$. Thus U is an MIP_0^* protocol for the language L, and $L \in \mathsf{MIP}_0^*$. ◀

This concludes the proof of the main result of this paper.

4 MIP* = RE implies gap-preserving compression

As mentioned in the introduction, the key to proving $\mathsf{MIP}^* = \mathsf{RE}$ in [11] was establishing a gap-preserving compression theorem for non-local games. Here we observe that the reverse holds: $\mathsf{MIP}^* = \mathsf{RE}$ implies a gap-preserving compression theorem.

▶ **Theorem 11.** *If* $\mathsf{MIP}^* = \mathsf{RE}$*, then there exists a Turing machine* COMPRESS*, with the following properties. Given as input a k-input r-prover verifier V,* COMPRESS *outputs a k-input 2-prover verifier $V^{\#}$ in time polynomial in the description length of V, with the following properties:*

1. *if $\omega_q(V(x_1, ..., x_k)) = 1$ then $\omega_q(V^{\#}(x_1, ..., x_k)) = 1$*
2. *if $\omega_q(V(x_1, ..., x_k)) \leq \frac{1}{2}$ then $\omega_q(V^{\#}(x_1, ..., x_k)) \leq \frac{1}{2}$*
3. *The runtime of the verifier $V^{\#}$ is polynomial in the description length of V and its input.*

Proof. COMPRESS is the Turing machine that, when given input a verifier V, it returns the description of the verifier $V^{\#}$ from Figure 3.

In the description of $V^{\#}$, we refer to the Turing machine $T_{V,(x_1,...,x_k)}$. For every k-input r-prover verifier V and $x_1, \ldots, x_k \in \{0,1\}^*$, $T_{V,(x_1,...,x_k)}$ is the Turing machine that on empty tape enumerates over finite-dimensional quantum strategies for $V(x_1, ..., x_k)$ and only accepts if it finds a strategy that wins the game with probability greater than $\frac{1}{2}$. It does this via enumerating over ε-nets (for $\varepsilon = \frac{1}{4}$) for strategies of dimension d for all $d \in \mathbb{N}$, as with the proof of Theorem 7.

By Theorem 6, if the Turing machine $T_{V,(x_1,...,x_k)}$ halts then

$$\omega_q(V_{\text{HALT},T_{V,(x_1,\ldots,x_k)}}) = 1,$$

otherwise $\omega_q(V_{\text{HALT},T_{V,(x_1,\ldots,x_k)}}) \leq \frac{1}{2}$. Also the runtime of $V_{\text{HALT},T_{V,(x_1,\ldots,x_k)}}$ is $p(|V| + |x_1| + ... + |x_n|)$, for some polynomial p.

Then if $\omega_q(V(x_1, ..., x_k)) = 1$ the Turing machine $T_{V,(x_1,...,x_k)}$ finds a strategy that wins with probability greater than $\frac{3}{4}$ and halts. Therefore

$$\omega_q(V^{\#}(x_1, ..., x_k)) = \omega_q(V_{\text{HALT},T_{V,(x_1,\ldots,x_k)}}) = 1.$$

Input: $(x_1, ..., x_k)$, where $x_1, \ldots, x_k \in \{0,1\}^*$
Perform the following steps:

1. Compute $V_{\text{HALT},T_{V,(x_1,\ldots,x_k)}} = H(T_{V,(x_1,\ldots,x_k)})$ (where H is from Theorem 6).
2. Execute the interactive protocol specified by the verifier $V_{\text{HALT},T_{V,(x_1,\ldots,x_k)}}$ and accept if and only if the verifier accepts.

Figure 3 Specification of the compressed verifier $V^{\#}$.

Otherwise, if $\omega_q(V(x_1, ..., x_k)) \leq \frac{1}{2}$ then there is no strategy that wins the game with probability $\frac{1}{2}$ and the Turing machine $T_{V,(x_1,\ldots,x_k)}$ never halts. Therefore

$$\omega_q(V^{\#}(x_1, ..., x_k)) = \omega_q(V_{\text{HALT},T_{V,(x_1,\ldots,x_k)}}) \leq \frac{1}{2}. \qquad ◀$$

Note that in this gap-preserving compression theorem, the time complexity of the verifier $V^{\#}$ is polynomial in the *description length* of V and its input – rather than the *time complexity* of V.

Hypergraph Isomorphism for Groups with Restricted Composition Factors

Daniel Neuen
Max Planck Institute for Informatics, Saarland Informatics Campus, Saarbrücken, Germany
dneuen@mpi-inf.mpg.de

Abstract

We consider the isomorphism problem for hypergraphs taking as input two hypergraphs over the same set of vertices V and a permutation group Γ over domain V, and asking whether there is a permutation $\gamma \in \Gamma$ that proves the two hypergraphs to be isomorphic. We show that for input groups, all of whose composition factors are isomorphic to a subgroup of the symmetric group on d points, this problem can be solved in time $(n+m)^{\mathcal{O}((\log d)^c)}$ for some absolute constant c where n denotes the number of vertices and m the number of hyperedges. In particular, this gives the currently fastest isomorphism test for hypergraphs in general. The previous best algorithm for the above problem due to Schweitzer and Wiebking (STOC 2019) runs in time $n^{\mathcal{O}(d)}m^{\mathcal{O}(1)}$.

As an application of this result, we obtain, for example, an algorithm testing isomorphism of graphs excluding $K_{3,h}$ as a minor in time $n^{\mathcal{O}((\log h)^c)}$. In particular, this gives an isomorphism test for graphs of Euler genus at most g running in time $n^{\mathcal{O}((\log g)^c)}$.

1 Introduction

Luks's algorithm [21] is an important cornerstone of the algorithmic theory of the Graph Isomorphism Problem. With some additional improvements given later [6], it tests in time $n^{\mathcal{O}(d/\log d)}$ whether two given n-vertex graphs of maximum degree d are isomorphic. In the last four decades, Luks's algorithm has developed to a central building block for many algorithms tackling the isomorphism problem. Indeed, Luks's algorithmic framework has been used as a subroutine to design, for example, isomorphism tests for graphs of bounded genus [27], graphs of bounded tree-width [15], graphs excluding some fixed graph as a minor [31], and even graph classes that exclude some fixed graph as a topological minor [13]. Further examples include color-t-bounded graphs [4], defined by Babai et al. in the context of isomorphism testing of strongly regular graphs, unit square graphs [28], and graphs of bounded rank-width [17]. Moreover, Luks's algorithm has also played a role in the area of computational group theory for example for computing normalizers for certain groups [23].

Additionally, Luks's algorithm also forms the basis for Babai's recent quasipolynomial isomorphism test [1] as well as the corresponding canonization algorithm [2]. Indeed, Babai's algorithm follows the recursive framework of Luks's algorithm and attacks the obstacle cases where the recursion performed by Luks's algorithm does not lead to the desired running time. Hence, a natural question to ask is whether it is possible extend the group-theoretic methods added in Babai's algorithm to the setting of bounded degree graphs in order to

obtain improved algorithms also for the isomorphism problem for graphs of small degree. This question was answered in the affirmative by Grohe, Schweitzer and the author of this paper in [14] providing an isomorphism test for graphs of maximum degree d running in time $n^{\mathcal{O}((\log d)^c)}$ for some constant c.

With the large number of applications of Luks's algorithmic framework [21] over the last decades it is natural to ask for improvements of other algorithms that exploit Luks's methods as a subroutine. However, up to this point, the only application of the improved isomorphism test for graphs of small degree is a faster fixed-parameter tractable isomorphism test for graphs of bounded tree-width [15]. The reason for this mainly lies in the fact that most of the algorithms exploiting Luks's framework as a subroutine actually use this framework to solve more general problems than Luks's original algorithm.

To be more precise, Luks's original algorithm [21] attacks the *String Isomorphism Problem*. The input to the String Isomorphism Problem are two strings $\mathfrak{x}, \mathfrak{y} \colon \Omega \to \Sigma$, where Ω is a finite set and Σ a finite alphabet, and a permutation group $\Gamma \leq \mathrm{Sym}(\Omega)$ (given by a set of generators). The task of the String Isomorphism Problem is to decide whether there exists some $\gamma \in \Gamma$ that transforms $\mathfrak{x}$ into $\mathfrak{y}$. In order to solve the isomorphism problem for graphs of bounded degree, Luks [21] provides a polynomial-time algorithm solving the String Isomorphism Problem for all input groups Γ in the class $\widehat{\Gamma}_d$[1], the class of groups all of whose composition factors are isomorphic to a subgroup of S_d (the symmetric group on d points). To give a faster isomorphism test for graph of small degree, Grohe et al. [14] follow the same route of considering the String Isomorphism Problem and provide an algorithm solving the problem in time $n^{\mathcal{O}((\log d)^c)}$ for the class of $\widehat{\Gamma}_d$-groups.

On the other hand, many algorithms exploiting the methods of Luks do so by solving more general problems. Indeed, a common extension is the Hypergraph Isomorphism Problem for $\widehat{\Gamma}_d$-groups. Here, the input consists of two hypergraphs $\mathcal{H}_1 = (V, \mathcal{E}_1)$ and $\mathcal{H}_2 = (V, \mathcal{E}_2)$ over the same set of vertices and a $\widehat{\Gamma}_d$-group $\Gamma \leq \mathrm{Sym}(V)$, and the task is to decide whether there is some $\gamma \in \Gamma$ that transforms $\mathcal{H}_1$ into $\mathcal{H}_2$. As observed by Miller [26], with some small modifications, Luks's algorithm for the String Isomorphism Problem immediately extends to the Hypergraph Isomorphism Problem. To be more precise, by an extension of the arguments of Luks [21], the Hypergraph Isomorphism Problem for $\widehat{\Gamma}_d$-groups can be solved in time $(m+n)^{\mathcal{O}(d)}$ where n denotes the number of vertices and m the number of edges. This fact is exploited by several of the algorithms mentioned above. For example, this includes the isomorphism tests for graphs of bounded genus [27], graphs excluding some fixed graph as a (topological) minor [31], color-t-bounded graphs [4], and unit square graphs [28]. Recently, an improved algorithm for the Hypergraph Isomorphism Problem for $\widehat{\Gamma}_d$-groups running in time $n^{\mathcal{O}(d)}m^{\mathcal{O}(1)}$ was presented by Schweitzer and Wiebking [34]. While the algorithm of Schweitzer and Wiebking significantly improves the running for large numbers of hyperedges, this is irrelevant for the applications described above where the number of hyperedges is typically linearly bounded in the number of vertices of the original input graph.

The main contribution of this paper is to provide an algorithm for the Hypergraph Isomorphism Problem for $\widehat{\Gamma}_d$-groups running in time $(n+m)^{\mathcal{O}((\log d)^c)}$ for some absolute constant c. Besides its potential applications outlined above, the Hypergraph Isomorphism Problem is of course also interesting in its own right. Indeed, there is also a long history of studying the Hypergraph Isomorphism Problem in itself. One of the first results in this direction was an algorithm testing isomorphism of hypergraphs in time $2^{\mathcal{O}(n)}$ [22] where

[1] In [21] this class is denoted by Γ_d. However, in the more recent literature, Γ_d often refers to a more general class of groups.

n denotes the number of vertices. Assuming the hyperedges are not too large, this result was improved by Babai and Codenotti in [5] to a running of $n^{\widetilde{\mathcal{O}}(k^2 \cdot \sqrt{n})}$ where $\widetilde{\mathcal{O}}(\cdot)$ hides polylogarithmic factors and k denotes the maximal size of a hyperedge. Again assuming small hyperedges, another improvement follows from the work of Grohe et al. [14] resulting in an isomorphism test for hypergraphs running in time $n^{\mathcal{O}(k \cdot (\log n)^c)}$ for a constant c.

Results. The main result of this paper is a faster algorithm for the Hypergraph Isomorphism Problem for $\widehat{\Gamma}_d$-groups.

▶ **Theorem 1.** *The Hypergraph Isomorphism Problem for $\widehat{\Gamma}_d$-groups can be solved in time $(n+m)^{\mathcal{O}((\log d)^c)}$ for some absolute constant c where n denotes the number of vertices and m the number of edges of the input hypergraphs.*

An immediate consequence of this result is the fastest algorithm for testing isomorphism of hypergraphs in general (assuming the number of hyperedges is moderately exponentially bounded in the number of vertices, i.e., $m = 2^{\mathcal{O}(n^{1-\varepsilon})}$ for some $\varepsilon > 0$).

▶ **Corollary 2.** *The Hypergraph Isomorphism Problem can be solved in time $(n+m)^{\mathcal{O}((\log n)^c)}$ for some absolute constant c where n denotes the number of vertices and m the number of edges of the input hypergraphs.*

In particular, this result removes the dependence on k, the maximal size of a hyperedge, in the running time. Observe that this improvement is significant if k is large and m is small compared to $\binom{n}{k}$ (which is typical for many applications). Also, the last theorem generalizes the corresponding result for the String Isomorphism Problem for $\widehat{\Gamma}_d$-groups obtained in [14].

For the algorithm, we take a similar route than the algorithm from [14] first normalizing the input to ensure a suitable variant of Babai's Unaffected Stabilizers Theorem [1]. Based on this variant, Grohe et al. are able to extend the Local Certificates Routine, a key subroutine of Babai's quasipolynomial-time algorithm [1], to the setting of $\widehat{\Gamma}_d$-groups. Unfortunately, when going from strings to hypergraphs, there is no simple extension of the Local Certificates Routine even in the normalized setting from [14]. Intuitively speaking, the reason is that the Local Certificates Routine crucially exploits that positions in disjoint sets can be permuted independently of each other which is not the case for hypergraphs.

To circumvent this problem we introduce a novel simplification routine which is repeatedly executed during the Local Certificates Routine. The idea for the simplification is based on the following observation. Suppose that all hyperedges are identical on a window $W \subseteq V$ (i.e., $E_1 \cap W = E_2 \cap W$ for all hyperedges $E_1, E_2 \in \mathcal{E}$). In this case each permutation in $\Gamma_{(V \setminus W)}$ (the subgroup that fixes each position outside of W) is an automorphism as required by the Local Certificates Routine since there are no additional dependencies between W and $V \setminus W$ coming from the hyperedges. The main idea is to always reduce to this simple case. Intuitively speaking, this is achieved as follows. Two hyperedges $E_1, E_2 \subseteq V$ are *W-equivalent* if $E_1 \cap W = E_2 \cap W$. The algorithm creates, for each equivalence class, a copy of the vertex set and associates all hyperedges from the equivalence class with this copy. After this modification, each copy satisfies the requirement that all hyperedges are W-equivalent (actually, to realize this modification, we shall consider a more general problem). This enables us to implement a Local Certificates Routine for hypergraphs which builds the central subroutine of our isomorphism test. Unfortunately, while this settles the original problem, it also creates several additional issues that need to be addressed and which require various extensions of existing techniques making the entire algorithm quite complicated.

With the Hypergraph Isomorphism Problem for $\widehat{\Gamma}_d$-groups being used as a subroutine in a number of algorithms, it is natural to ask for the implications of this result. One of the first examples in this direction is Miller's algorithm for testing isomorphism of graphs of bounded genus [27]. However, Miller's algorithm reduces the isomorphism problem for graphs of genus g to the Hypergraph Isomorphism Problem where the input group is a Γ_d-*tower* rather than a $\widehat{\Gamma}_d$-group where $d = \mathcal{O}(g)$. The class of Γ_d-towers extends the class $\widehat{\Gamma}_d$ by, intuitively speaking, allowing to combine groups that are "almost" $\widehat{\Gamma}_d$-groups along a specified partition of the domain.

Since it is already completely unclear how to extend the algorithm of Grohe et al. [14] to Γ_d-towers it is not possible to use Miller's algorithm directly. To still obtain a faster isomorphism test for graphs of small genus, we strengthen Miller's result and develop a reduction from the isomorphism problem for graphs of genus g to the Hypergraph Isomorphism Problem for $\widehat{\Gamma}_d$-groups where $d \coloneqq 4g + 2$. Actually, our reduction works for any graph class that excludes $K_{3,h}$ as a minor (graphs of genus g exclude $K_{3,4g+3}$ as a minor [32, 18]).

To build the reduction, we introduce *t-CR-bounded graphs* which extend the notion of color-t-bounded graphs introduced in [4]. Intuitively speaking, a vertex-colored graph is t-CR-bounded if the vertex-coloring of the graph can be turned into a discrete coloring (i.e., each vertex has its own color) by repeatedly applying the standard Color Refinement algorithm (see, e.g., [10, 19]) and by splitting color classes of size at most t. We show that the isomorphism problem for t-CR-bounded graphs can be solved in time $n^{\mathcal{O}((\log t)^c)}$ by providing a reduction to the Hypergraph Isomorphism Problem for $\widehat{\Gamma}_t$-groups. While this result may already be interesting in its own right, the main purpose of the isomorphism problem for t-CR-bounded graphs in this paper is to serve as an intermediate problem.

We continue to prove that the isomorphism problem for graph classes that exclude $K_{3,h}$ as a minor is polynomial-time reducible to testing isomorphism of t-CR-bounded graphs where $t \coloneqq h - 1$. This implies the following theorem.

► **Theorem 3.** *The Graph Isomorphism Problem for graphs that exclude $K_{3,h}$ as a minor can be solved in time $n^{\mathcal{O}((\log h)^c)}$ for some absolute constant c where n denotes the number of vertices of the input graphs.*

The previous best algorithm for this setting is due to Ponomarenko [31] who provided a polynomial-time isomorphism test for graph classes that exclude an arbitrary minor. While Ponomarenko does not provide a precise analysis on the running time of his algorithm, the exponent depends at least linearly on h when excluding K_h as a minor. Hence, in the case of excluding $K_{3,h}$ as a minor, the above theorem significantly improves on all previous algorithms.

Finally, exploiting the fact that $K_{3,h}$ has Euler genus linear in h [32, 18], we obtain the following corollary.

► **Corollary 4.** *The Graph Isomorphism Problem for graphs of Euler genus at most g can be solved in time $n^{\mathcal{O}((\log g)^c)}$ for some absolute constant c where n denotes the number of vertices of the input graphs.*

While the isomorphism problem for graphs of bounded genus is also fixed-parameter tractable [20] (again, the author does not analyze the dependence of the running time on g), the algorithm from the previous corollary is guaranteed to be faster as soon as the genus passes a threshold that is polylogarithmic in the number of vertices. Also, I remark that the isomorphism problem for graphs of bounded genus can be solved in logarithmic space [12].

As a another application of the isomorphism problem for t-CR-bounded graphs, we consider the isomorphism problem for hereditarily finite sets (see also [34]). Intuitively speaking, a hereditarily finite set over ground set V is any type of combinatorial object that can be built by iteratively taking sets and tuples over previously created objects. In particular, hereditarily finite sets include graphs, vertex- and arc-colored graphs, hypergraphs and relational structures. We further extend our previous result on the Hypergraph Isomorphism Problem for $\widehat{\Gamma}_d$-groups and show that isomorphism for any pair of hereditarily finite sets with a $\widehat{\Gamma}_d$-group can be tested in time $(n+m)^{\mathcal{O}((\log d)^c)}$ where n denotes the size of the ground set and m the size of the hereditarily finite sets. In case m is only moderately exponential in n (i.e., $m = 2^{\mathcal{O}(n^{1-\varepsilon})}$ for some fixed $\varepsilon > 0$) this improves over a previous algorithm of Schweitzer and Wiebking [34] (although it should be noted that Schweitzer and Wiebking actually solve a slightly more general problem).

Related Work. Another extension of Babai's quasipolynomial-time algorithm has been independently proposed by Daniel Wiebking [37] providing another proof that the isomorphism problem for arbitrary hereditarily finite sets can be solved in quasipolynomial time. However, Wiebking not only solves the isomorphism problem for hereditarily finite sets as defined in this paper, but actually provides an algorithm for an extended setting where also implicitly represented labeling cosets are allowed as atomic objects for the hereditarily finite sets. Also, Wiebking gives a canonization algorithm which extends Babai's recent canonization algorithm for graphs [2].

But on the other hand, the algorithmic framework of Wiebking [37] is not able to exploit any restrictions on the input group. Hence, the two results are incomparable with respect to the power of the algorithms obtained.

This is also highlighted by the applications. While the results of this paper allow the design of an algorithm solving the isomorphism problem for graphs of Euler genus at most g running in time $n^{\mathcal{O}((\log g)^c)}$, Wiebking utilizes his algorithm to build an isomorphism test for graphs of tree-width at most k running in time $n^{\mathcal{O}((\log k)^c)}$.

2 Preliminaries

Graphs. A *graph* is a pair $G = (V(G), E(G))$ with vertex set $V(G)$ and edge set $E(G)$. Unless stated otherwise, all graphs are undirected and simple graphs, i.e., there are no loops or multiedges. In this setting an edge is denoted as vw where $v, w \in V(G)$. The *neighborhood* of a vertex v is denoted $N_G(v) := \{w \in V(G) \mid vw \in E(G)\}$. The *degree* of a vertex $v \in V(G)$, denoted $\deg_G(v)$, is the size of its neighborhood. Also, for a set of vertices $X \subseteq V(G)$, the neighborhood of X is defined as $N_G(X) := \left(\bigcup_{v\in X} N_G(v)\right) \setminus X$. Usually, we omit the index G if it is clear from the context and simply write $N(v)$, $N(X)$ and $\deg(v)$. For $X \subseteq V(G)$ the *induced subgraph on* X is $G[X] := (X, \{vw \mid v, w \in X, vw \in E(G)\})$. Also, $G - X := G[V(G) \setminus X]$ denotes the induced subgraph on the complement of X.

Two graphs G and H are isomorphic if there is a bijection $\varphi\colon V(G) \to V(H)$ such that $vw \in E(G)$ if and only if $\varphi(v)\varphi(w) \in E(H)$. In this case φ is an *isomorphism* from G to H, which is also denoted by $\varphi\colon G \cong H$. Moreover, $\mathrm{Iso}(G, H)$ denotes the set of all isomorphisms from G to H. The automorphism group of G is $\mathrm{Aut}(G) := \mathrm{Iso}(G, G)$. Observe that, if $\mathrm{Iso}(G, H) \neq \emptyset$, it holds that $\mathrm{Iso}(G, H) = \mathrm{Aut}(G)\varphi := \{\gamma\varphi \mid \gamma \in \mathrm{Aut}(G)\}$ for every isomorphism $\varphi \in \mathrm{Iso}(G, H)$. The Graph Isomorphism Problem takes as input two graphs G and H and asks whether they are isomorphic.

A *(vertex-)colored graph* is a tuple $G = (V(G), E(G), \chi_V)$ where $\chi_V \colon V(G) \to C$ is a mapping and C is some finite set of colors. A *vertex- and arc-colored graph* is a tuple $G = (V(G), E(G), \chi_V, \chi_E)$ where $\chi_V \colon V(G) \to C$ is a vertex-coloring and $\chi_E \colon \{(v, w) \mid vw \in E(G)\} \to C$ is an arc-coloring, where C is again some finite set of colors. Note that an uncolored graph can be interpreted as a vertex- and arc-colored graph where each vertex is assigned the same color as well as each (directed) edge is assigned the same color. The *vertex color classes* of a (colored) graph are the sets $\chi_V^{-1}(c)$ where $c \in C$. A vertex-coloring χ_V is *discrete* if all color classes are singletons, i.e., $\chi_V(v) \neq \chi_V(w)$ for all distinct $v, w \in V(G)$.

Permutation Groups. Next, we establish the basic notation for permutation groups required for this work. For a general background on group theory I refer to [33] whereas background on permutation groups can be found in [11].

A *permutation group* acting on a set Ω is a subgroup $\Gamma \leq \mathrm{Sym}(\Omega)$ of the symmetric group. The size of the permutation domain Ω is called the *degree* of Γ and, throughout this work, is denoted by $n = |\Omega|$. If $\Omega = [n]$ then we also write S_n instead of $\mathrm{Sym}(\Omega)$. Also, $\mathrm{Alt}(\Omega)$ denotes the alternating group on the set Ω and, similar to the symmetric group, we write A_n instead of $\mathrm{Alt}(\Omega)$ if $\Omega = [n]$. For $\gamma \in \Gamma$ and $\alpha \in \Omega$ we denote by α^γ the image of α under the permutation γ. The set $\alpha^\Gamma := \{\alpha^\gamma \mid \gamma \in \Gamma\}$ is the *orbit* of α. The group Γ is *transitive* if $\alpha^\Gamma = \Omega$ for some (and therefore every) $\alpha \in \Omega$.

For $\alpha \in \Omega$ the group $\Gamma_\alpha := \{\gamma \in \Gamma \mid \alpha^\gamma = \alpha\} \leq \Gamma$ is the *stabilizer* of α in Γ. The group Γ is *semi-regular* if $\Gamma_\alpha = \{\mathrm{id}\}$ for all $\alpha \in \Omega$ (id denotes the identity element of the group). For $A \subseteq \Omega$ and $\gamma \in \Gamma$ let $A^\gamma := \{\alpha^\gamma \mid \alpha \in A\}$. The *pointwise stabilizer* of A is the subgroup $\Gamma_{(A)} := \{\gamma \in \Gamma \mid \forall \alpha \in A \colon \alpha^\gamma = \alpha\}$. The *setwise stabilizer* of A is the subgroup $\Gamma_A := \{\gamma \in \Gamma \mid A^\gamma = A\}$. For a Γ-invariant set $A \subseteq \Omega$ we denote by $\Gamma[A]$ the induced natural action of Γ on A (i.e., restricting every permutation to the set A).

In order to perform computational tasks for permutation groups efficiently it is infeasible to list all elements of a permutation group. Instead, permutation groups are represented by generating sets of small size. A set $S \subseteq \Gamma$, where $\Gamma \leq \mathrm{Sym}(\Omega)$, is a *generating set* for Γ if every $\gamma \in \Gamma$ can be written as a product $\gamma = s_1 s_2 \dots s_k$ of elements $s_1, \dots, s_k \in S$. Indeed, most algorithms for permutation groups are based on so-called *strong generating sets*, which can be chosen of size quadratic in the degree of the group and can be computed in polynomial time given an arbitrary generating set (see, e.g., [35]). This enables the design of efficient algorithms for many basic computational problems for permutation groups (e.g., membership tests, computing the order of a group, the orbits of a group, and generating sets for pointwise stabilizers). For detailed background on algorithms for permutation groups I refer to [35].

Groups with Restricted Composition Factors. In this work we shall be interested in a particular subclass of permutation groups, namely groups with restricted composition factors. Let Γ be a group. A *subnormal series* is a sequence of subgroups $\Gamma = \Gamma_0 \trianglerighteq \Gamma_1 \trianglerighteq \dots \trianglerighteq \Gamma_k = \{\mathrm{id}\}$. The length of the series is k and the groups Γ_{i-1}/Γ_i are the factor groups of the series, $i \in [k]$. A *composition series* is a strictly decreasing subnormal series of maximal length. For every finite group Γ all composition series have the same family of factor groups considered as a multi-set (cf. [33]). A *composition factor* of a finite group Γ is a factor group of a composition series of Γ.

▶ **Definition 5.** *For $d \geq 2$ let $\widehat{\Gamma}_d$ denote the class of all groups Γ for which every composition factor of Γ is isomorphic to a subgroup of S_d.*

We want to stress the fact there are two similar classes of groups both typically denoted by Γ_d in the literature. One is the class we define as $\widehat{\Gamma}_d$ introduced by Luks [21] while the other one used in [3] in particular allows simple groups of Lie type of bounded dimension as composition factors.

3 Isomorphism for Hypergraphs

In the following we provide a very high-level sketch of the algorithm solving the Hypergraph Isomorphism Problem for $\widehat{\Gamma}_d$-groups. For all details I refer to the full version of this paper [30].

3.1 The Generalized String Isomorphism Problem

For the purpose of building a recursive algorithm, we consider a slightly different problem that crucially allows us to modify instances in a certain way exploited later on.

Let $\Gamma \leq \mathrm{Sym}(\Omega)$ be a group and let $\mathfrak{P}$ be a partition of the set Ω. The partition $\mathfrak{P}$ is Γ-*invariant* if $\mathfrak{P}^\gamma = \mathfrak{P}$ for all $\gamma \in \Gamma$ where $\mathfrak{P}^\gamma := \{P^\gamma \mid P \in \mathfrak{P}\}$. A $\mathfrak{P}$-*string* is a pair $(P, \mathfrak{x})$ where $P \in \mathfrak{P}$ and $\mathfrak{x}\colon P \to \Sigma$ is a string over a finite alphabet Σ. For $\sigma \in \mathrm{Sym}(\Omega)$ the string $\mathfrak{x}^\sigma$ is defined by $\mathfrak{x}^\sigma\colon P^\sigma \to \Sigma\colon \alpha \mapsto \mathfrak{x}(\alpha^{\sigma^{-1}})$. A permutation $\sigma \in \mathrm{Sym}(\Omega)$ is a Γ-*isomorphism* from $(P, \mathfrak{x})$ to a second $\mathfrak{P}$-string $(Q, \mathfrak{y})$ if $\sigma \in \Gamma$ and $(P^\sigma, \mathfrak{x}^\sigma) = (Q, \mathfrak{y})$.

▶ **Definition 6.** *The* Generalized String Isomorphism Problem *takes as input a permutation group* $\Gamma \leq \mathrm{Sym}(\Omega)$*, a* Γ*-invariant partition* $\mathfrak{P}$ *of the set* Ω*, and* $\mathfrak{P}$*-strings* $(P_1, \mathfrak{x}_1), \dots, (P_m, \mathfrak{x}_m)$ *and* $(Q_1, \mathfrak{y}_1), \dots, (Q_m, \mathfrak{y}_m)$*, and asks whether there is some* $\gamma \in \Gamma$ *such that*

$$\{(P_1^\gamma, \mathfrak{x}_1^\gamma), \dots, (P_m^\gamma, \mathfrak{x}_m^\gamma)\} = \{(Q_1, \mathfrak{y}_1), \dots, (Q_m, \mathfrak{y}_m)\}.$$

We usually denote $\mathfrak{X} = \{(P_1, \mathfrak{x}_1), \dots, (P_m, \mathfrak{x}_m)\}$ and $\mathfrak{Y} = \{(Q_1, \mathfrak{y}_1), \dots, (Q_m, \mathfrak{y}_m)\}$. Also, $\mathrm{Iso}_\Gamma(\mathfrak{X}, \mathfrak{Y})$ denotes the set of Γ-isomorphisms from $\mathfrak{X}$ to $\mathfrak{Y}$ and $\mathrm{Aut}_\Gamma(\mathfrak{X}) := \mathrm{Iso}_\Gamma(\mathfrak{X}, \mathfrak{X})$.

It is easy to see that the Hypergraph Isomorphism Problem can be reduced to the Generalized String Isomorphism Problem choosing $\mathfrak{P}$ to be the trivial partition consisting of one block and adding strings $\mathfrak{x}_E\colon V \to \{0,1\}$ for each hyperedge E where $\mathfrak{x}_E(v) = 1$ if and only if $v \in E$.

For the rest of this section we denote by $n := |\Omega|$ the size of the domain, and m denotes the size of $\mathfrak{X}$ and $\mathfrak{Y}$ (we always assume $|\mathfrak{X}| = |\mathfrak{Y}|$, otherwise the problem is trivial). The goal of this section is to provide an algorithm solving the Generalized String Isomorphism Problem for $\widehat{\Gamma}_d$-groups in time $(n+m)^{\mathcal{O}((\log d)^c)}$ for some absolute constant c.

We start by introducing some additional notation. For every $P \in \mathfrak{P}$ define $\mathfrak{X}[[P]] := \{\mathfrak{x}\colon P \to \Sigma \mid (P, \mathfrak{x}) \in \mathfrak{X}\}$ and also let $m_{\mathfrak{X}}(P) := |\mathfrak{X}[[\mathfrak{P}]]|$. We say that $\mathfrak{X}$ is *completely occupied* if $m_{\mathfrak{X}}(P) \geq 1$ for every $P \in \mathfrak{P}$. Also, we say that $\mathfrak{X}$ is *simple* if $m_{\mathfrak{X}}(P) \leq 1$ for every $P \in \mathfrak{P}$.

We will assume throughout this work that all sets of $\mathfrak{P}$-strings encountered are completely occupied, also if not explicitly stated. Note that an instance, which is not completely occupied, can be easily turned into one, that is completely occupied, by introducing additional $\mathfrak{P}$-strings. Also, for a set $A \subseteq \Omega$ and a set of $\mathfrak{P}$-strings $\mathfrak{X}$ define

$$\mathfrak{X}[A] := \{(P \cap A, \mathfrak{x}[A \cap P]) \mid (P, \mathfrak{x}) \in \mathfrak{X}, P \cap A \neq \emptyset\}$$

to be the subinstance induced by A where $\mathfrak{x}[A \cap P]$ denotes the substring induced by $A \cap P$.

3.2 Normalization of the Group Action

The main hurdle to build the algorithm for the Generalized String Isomorphism Problem is an extension of the Local Certificates Routine introduced by Babai for his quasipolynomial time isomorphism test [1]. Similar to [14], our algorithm exploits a variant of the Unaffected Stabilizers Theorem for $\widehat{\Gamma}_d$-group which builds the theoretical foundation for the Local Certificates algorithm.

However, this variant of the Unaffected Stabilizers Theorem for $\widehat{\Gamma}_d$-groups additionally requires the input group to have an *almost d-ary sequence of partitions.*

For a partition $\mathfrak{B}$ of the set Ω and $S \subseteq \Omega$ let $\mathfrak{B}[S] := \{B \cap S \mid B \in \mathfrak{B}, B \cap S \neq \emptyset\}$ denote the induced subpartition of $\mathfrak{B}$ on the set S. Let $\mathfrak{B}'$ be a second partition of Ω. We say that $\mathfrak{B}'$ *refines* $\mathfrak{B}$, denoted $\mathfrak{B}' \preceq \mathfrak{B}$, if for every $B' \in \mathfrak{B}'$ there is some $B \in \mathfrak{B}$ such that $B' \subseteq B$. If additionally $\mathfrak{B}' \neq \mathfrak{B}$ the partition $\mathfrak{B}'$ *strictly refines* $\mathfrak{B}$ which is denoted $\mathfrak{B}' \prec \mathfrak{B}$. Also, for a group $\Gamma \leq \mathrm{Sym}(\Omega)$ such that $\mathfrak{B}$ and $\mathfrak{B}'$ are Γ-invariant, let $\Gamma_B[\mathfrak{B}'[B]] \leq \mathrm{Sym}(\mathfrak{B}'[B])$ denote the induced natural action of Γ_B on $\mathfrak{B}'[B]$ for every $B \in \mathfrak{B}$. Finally, recall that a group $\Gamma \leq \mathrm{Sym}(\Omega)$ is semi-regular if the only element with fixed points is the identity.

▶ **Definition 7** (Almost d-ary Sequences of Partitions). *Let $\Gamma \leq \mathrm{Sym}(\Omega)$ be a group and let $\{\Omega\} = \mathfrak{B}_0 \succ \cdots \succ \mathfrak{B}_k = \{\{\alpha\} \mid \alpha \in \Omega\}$ be a sequence of Γ-invariant partitions. The sequence $\mathfrak{B}_0 \succ \cdots \succ \mathfrak{B}_k$ is* almost d-ary *if for every $i \in [k]$ and $B \in \mathfrak{B}_{i-1}$ it holds that*

1. $|\mathfrak{B}_i[B]| \leq d$, *or*
2. $\Gamma_B[\mathfrak{B}_i[B]]$ *is semi-regular.*

Since not every $\widehat{\Gamma}_d$-group $\Gamma \leq \mathrm{Sym}(\Omega)$ has an almost d-ary sequence of partitions, the first step of the algorithm is to normalize the input group. By a simple adaption of the arguments from [14] (see also [29]) we can obtain the following theorem normalizing the input to the Generalized String Isomorphism Problem.

▶ **Theorem 8.** *Let $(\Gamma, \mathfrak{P}, \mathfrak{X}, \mathfrak{Y})$ be an instance of the Generalized String Isomorphism Problem where $\Gamma \leq \mathrm{Sym}(\Omega)$ is a $\widehat{\Gamma}_d$-group.*

Then there is a set Ω^*, a monomorphism $\varphi\colon \Gamma \to \mathrm{Sym}(\Omega^*)$, an almost d-ary sequence of partitions $\mathfrak{B}_0^* \succ \mathfrak{B}_1^* \succ \cdots \succ \mathfrak{B}_\ell^*$ for Γ^φ, and an instance $(\Gamma^\varphi, \mathfrak{P}^*, \mathfrak{X}^*, \mathfrak{Y}^*)$ of the Generalized String Isomorphism Problem such that the following properties are satisfied:

1. $|\Omega^*| \leq n^{\mathrm{f}_{norm}(d)+1}$ *where* $\mathrm{f}_{norm}(d) = \mathcal{O}(\log d)$,
2. *there is some $i \in [k]$ such that $\mathfrak{P}^* = \mathfrak{B}_i^*$, and*
3. $\gamma \in \mathrm{Iso}_\Gamma(\mathfrak{X}, \mathfrak{Y})$ *if and only if* $\varphi(\gamma) \in \mathrm{Iso}_{\Gamma^\varphi}(\mathfrak{X}^*, \mathfrak{Y}^*)$ *for every* $\gamma \in \Gamma$.

Moreover, given $\Gamma \leq \mathrm{Sym}(\Omega)$, there is an algorithm computing the desired objects in time polynomial in the input size and the size of Ω^*.

Hence, in the following we restrict ourselves to the case where the input group has an almost d-ary sequence of partitions. In particular, this allows us to use the variant of the Unaffected Stabilizers Theorem proved in [14].

3.3 Creating Global Automorphisms from Local Information

The variant of the Unaffected Stabilizers Theorem from [14] provides us with the group-theoretic foundation to extend Babai's Local Certificates Routine [1] to the setting of hypergraphs. However, there is a second problem in generalizing the Local Certificates Routine that needs to be addressed.

Let $\Gamma \leq \mathrm{Sym}(\Omega)$ be a $\widehat{\Gamma}_d$-group, $\mathfrak{P}$ a Γ-invariant partition of Ω, and $\mathfrak{X}, \mathfrak{Y}$ two sets of $\mathfrak{P}$-strings. In a nutshell, the Local Certificates Routine considers a Γ-invariant window $W \subseteq \Omega$ such that $\Gamma[W] \leq \mathrm{Aut}(\mathfrak{X}[W])$ (i.e., the group Γ respects $\mathfrak{X}$ restricted to the window W) and aims at creating automorphisms of the entire structure $\mathfrak{X}$ (from the local information that Γ respects $\mathfrak{X}$ on the window W). In order to create these automorphisms the Local Certificates Routine considers the group $\Gamma_{(\Omega\setminus W)}$ fixing every point outside of W. Intuitively speaking, the Unaffected Stabilizers Theorem (resp. the variant suitable for $\widehat{\Gamma}_d$-groups) guarantees that the group $\Gamma_{(\Omega\setminus W)}$ is large. For the String Isomorphism Problem it is easy to see $\Gamma_{(\Omega\setminus W)}$ consists only of automorphisms of the input string since there are no dependencies between the positions within the window W and outside of W. However, for the Generalized String Isomorphism Problem, this is not true anymore. In other words, in order to compute $\mathrm{Aut}(\mathfrak{X})$, it is not possible to consider $\mathfrak{X}[W]$ and $\mathfrak{X}[\Omega \setminus W]$ independently.

Our solution to this problem is guided by the following simple observation. Suppose that $\mathfrak{X}[W]$ is simple, i.e., $m_{\mathfrak{X}[W]}(P) = 1$ for all $P \in \mathfrak{P}[W]$. In this case it is possible to consider $\mathfrak{X}[W]$ and $\mathfrak{X}[\Omega \setminus W]$ independently as the next lemma indicates.

▶ **Lemma 9.** *Let $\Gamma \leq \mathrm{Sym}(\Omega)$ be a permutation group, let $\mathfrak{P}$ be a Γ-invariant partition of Ω and $\mathfrak{X}$ a set of $\mathfrak{P}$-strings. Also suppose $W \subseteq \Omega$ is a Γ-invariant window such that $\mathfrak{X}[W]$ is simple and $\Gamma[W] \leq \mathrm{Aut}(\mathfrak{X}[W])$. Then $\Gamma_{(\Omega\setminus W)} \leq \mathrm{Aut}(\mathfrak{X})$.*

Proof. Let $\gamma \in \Gamma_{(\Omega\setminus W)}$ and $(P, \mathfrak{x}) \in \mathfrak{X}$. It suffices to show that $(P^\gamma, \mathfrak{x}^\gamma) \in \mathfrak{X}$. First suppose $P \subseteq W$. Then $(P, \mathfrak{x}) \in \mathfrak{X}[W]$ and $(P^\gamma, \mathfrak{x}^\gamma) \in \mathfrak{X}[W]$. Moreover, $P^\gamma \subseteq W$ since W is Γ-invariant. Hence, $(P^\gamma, \mathfrak{x}^\gamma) \in \mathfrak{X}$.

Otherwise $P \cap (\Omega \setminus W) \neq \emptyset$. Since $\alpha^\gamma = \alpha$ for all $\alpha \in \Omega \setminus W$ it follows that $P^\gamma \cap P \neq \emptyset$. Using the fact that $\mathfrak{P}$ is Γ-invariant this implies that $P^\gamma = P$. To complete the proof it is argued that $\mathfrak{x}^\gamma = \mathfrak{x}$. Let $\alpha \in P$. If $\alpha \notin W$ then $\mathfrak{x}^\gamma(\alpha) = \mathfrak{x}^\gamma(\alpha^\gamma) = \mathfrak{x}(\alpha^{\gamma\gamma^{-1}}) = \mathfrak{x}(\alpha)$. So assume $\alpha \in W$. Since $\gamma[W] \in \mathrm{Aut}(\mathfrak{X}[W])$ it holds that $((P \cap W)^\gamma, (\mathfrak{x}[P \cap W])^\gamma) = (P \cap W, (\mathfrak{x}[P \cap W])^\gamma) \in \mathfrak{X}[W]$. But this means $(\mathfrak{x}[P \cap W])^\gamma = \mathfrak{x}[P \cap W]$ since $\mathfrak{X}[W]$ is simple. Hence $\mathfrak{x}^\gamma(\alpha) = \mathfrak{x}(\alpha)$. ◀

Let $W \subseteq \Omega$ be a Γ-invariant set such that $\mathfrak{X}[W] \leq \mathrm{Aut}(\mathfrak{X}[W])$ (this is the case during the Local Certificates Routine). In order to solve the problem described above in general, the basic idea is to modify the instance in such a way that $\mathfrak{X}[W]$ becomes simple. This allows us to apply Lemma 9 and eventually, to extend the Local Certificates Routine to our setting. This modification is one of the key conceptual contributions of this work.

Consider a set $P \in \mathfrak{P}$. In order to "simplify" the instance we define an equivalence relation on the set $\mathfrak{X}[[P]]$ of all strings contained in P. Two $\mathfrak{P}$-strings $(P, \mathfrak{x}_1)$ and $(P, \mathfrak{x}_2)$ are W-equivalent if they are identical on the window W, i.e., $\mathfrak{x}_1[W] = \mathfrak{x}_2[W]$. For each equivalence class we create a new block P' containing exactly the strings from the equivalence class. Since the group Γ respects the induced subinstance $\mathfrak{X}[W]$ it naturally acts on the equivalence classes. This process is visualized in Figure 1 and formalized below.

Consider the natural homomorphism $\psi\colon \Gamma \to \mathrm{Sym}(\mathfrak{X}[W])$. Now let $\Omega' := \bigcup_{P\in\mathfrak{P}} P \times \{\mathfrak{x}[W \cap P] \mid (P, \mathfrak{x}) \in \mathfrak{X}\}$ and $\mathfrak{P}' := \{P \times \{\mathfrak{x}[W \cap P]\} \mid (P, \mathfrak{x}) \in \mathfrak{X}\}$. Also define

$$\mathfrak{X}' := \left\{ \Big(P \times \{\mathfrak{x}[W \cap P]\}, \mathfrak{x}'\colon P \times \{\mathfrak{x}[W \cap P]\} \to \Sigma\colon (\alpha, \mathfrak{x}[W \cap P]) \mapsto \mathfrak{x}(\alpha)\Big) \;\middle|\; (P, \mathfrak{x}) \in \mathfrak{X} \right\}$$

and similarly define $\mathfrak{Y}'$ for the instance $\mathfrak{Y}$. Note that $\mathfrak{X}'$ and $\mathfrak{Y}'$ are sets of $\mathfrak{P}'$-strings. Finally, the group Γ faithfully acts on the set Ω' via $(\alpha, \mathfrak{z})^\gamma = (\alpha^\gamma, \mathfrak{z}^\gamma)$ yielding an injective homomorphism $\psi\colon \Gamma \to \mathrm{Sym}(\Omega')$. Define $\Gamma' := \Gamma^\psi$. It can be easily checked that the updated instance is equivalent to the original instance. Also, $\mathfrak{X}'[W']$ is simple where $W' := \{(\alpha, \mathfrak{z}) \in \Omega' \mid \alpha \in W\}$.

While this simplification allows us to treat $\mathfrak{X}'[W']$ and $\mathfrak{X}'[W' \setminus \Omega']$ independently and thus solves the above problem, it creates several additional issues that need to be addressed. First, this modification may destroy the normalization property (i.e., the existence of an

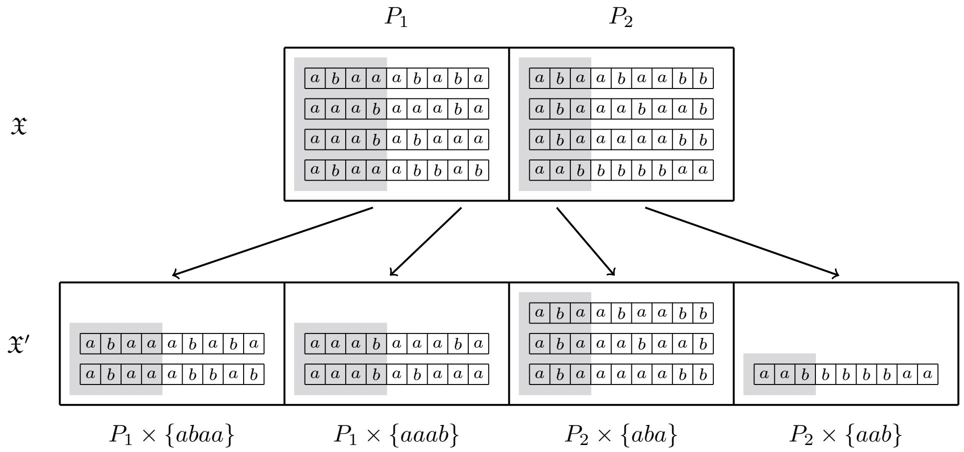

Figure 1 A set $\mathfrak{X}$ of $\mathfrak{P}$-strings is given in the top and the "simplified" instance $\mathfrak{X}'$ is given below. The window W is marked in gray. Note that $\mathfrak{X}'[W']$ is simple where W' denotes the window marked in gray in the bottom part of the figure.

almost d-ary sequence of partitions). As a result, the Local Certificates Routine constantly needs to renormalize the input instances which requires a precise analysis of the increase in size occurring from the renormalization (see Theorem 8). In order to be able to still analyze the progress made by the recursion, we introduce the notion of a *virtual size* of an instance.

▶ **Definition 10.** *Let $\mathfrak{P}$ be a partition of Ω and suppose $\mathfrak{X}$ is a set of $\mathfrak{P}$-strings. The* d-virtual size *of $\mathfrak{X}$ is defined by $s := \sum_{P \in \mathfrak{P}} |P| \cdot (m_{\mathfrak{X}}(P))^{\mathsf{f}_{\mathsf{norm}}(d)+1}$.*

Here, $\mathsf{f}_{\mathsf{norm}}(d) = \mathcal{O}(\log d)$ refers to the normalization cost defined in Theorem 8. Hence, the d-virtual size s of $\mathfrak{X}$ is bounded by $(m+n)^{\mathcal{O}(\log d)}$ and it suffices to analyze the running time of all subroutines in terms of the virtual size of the input instances. Intuitively speaking, the idea of the virtual size is to take into account the cost of all potential renormalization steps which means that, when the algorithm renormalizes an instance, while its actual size might grow significantly, its virtual size does not. This allows us to measure the progress made by the recursive algorithm although instances might grow significantly.

The renormalization of instances also creates another problem. In the *aggregation of local certificates*, the outputs of the Local Certificates Routine are compared with each other requiring the outputs to be isomorphism-invariant. However, the renormalization procedure is not isomorphism-invariant. Our solution to this problem is to run the Local Certificates Routine in parallel on all pairs of test sets compared later on. This way, we can ensure that all instances are normalized in the same way.

This simplification procedure is formalized by the next technical theorem which combines all the requirements outlined above, including the renormalization steps, into a single statement.

▶ **Theorem 11.** *Let $\Gamma \leq \mathrm{Sym}(\Omega)$ be a $\widehat{\Gamma}_d$-group and $\mathfrak{P}$ be a Γ-invariant partition of Ω. Also suppose $\{\Omega\} = \mathfrak{B}_0 \succ \mathfrak{B}_1 \succ \dots \succ \mathfrak{B}_\ell = \{\{\alpha\} \mid \alpha \in \Omega\}$ forms an almost d-ary sequence of Γ-invariant partitions such that $\mathfrak{P} = \mathfrak{B}_i$ for some $i \in [\ell]$. Let $(\mathfrak{X}_i)_{i \in [p]}$ be a list of sets of $\mathfrak{P}$-strings. Also let $W \subseteq \Omega$ be a Γ-invariant set such that $\Gamma[W] \leq \mathrm{Aut}(\mathfrak{X}_i[W])$ for all $i \in [p]$. Moreover, assume that $\mathfrak{X}_i[W] = \mathfrak{X}_j[W]$ for all $i, j \in [p]$.*

Then there is an equivalence relation $\sim$ on the set $[p]$ such that $\mathfrak{X}_i \cong_\Gamma \mathfrak{X}_j$ implies $i \sim j$ for all $i, j \in [p]$, and for each equivalence class $A \subseteq [p]$, we get the following:

A set Ω^*, a group $\Gamma^* \leq \mathrm{Sym}(\Omega)$, elements $\lambda_i \in \Gamma$ for all $i \in A$, a monomorphism $\varphi\colon \Gamma^* \to \Gamma$, a window $W^* \subseteq \Omega^*$, a sequence of partitions $\{\Omega^*\} = \mathfrak{B}_0^* \succ \mathfrak{B}_1^* \succ \dots \succ \mathfrak{B}_k^* = \{\{\alpha\} \mid \alpha \in \Omega^*\}$, and a list of $\mathfrak{P}^*$-strings $(\mathfrak{X}_i^*)_{i\in A}$, such that the following properties are satisfied:

(A) *the sequence $\mathfrak{B}_0^* \succ \dots \succ \mathfrak{B}_k^*$ forms an almost d-ary sequence of Γ^*-invariant partitions,*

(B) *W^* is Γ^*-invariant and $\Gamma^*[W^*] \leq \mathrm{Aut}(\mathfrak{X}_i^*[W^*])$ for all $i \in A$,*

(C) *there is some $i \in [k]$ such that $\mathfrak{P}^* = \mathfrak{B}_i^*$,*

(D) $\mathrm{Iso}_\Gamma(\mathfrak{X}_i, \mathfrak{X}_j) = \lambda_i^{-1}(\mathrm{Iso}_{\Gamma^*}(\mathfrak{X}_i^*, \mathfrak{X}_j^*))^\varphi \lambda_j$ *for all $i, j \in A$,*

(E) *$\mathfrak{X}_i^*[W^*]$ is simple for all $i \in A$,*

(F) *for s the virtual size of $\mathfrak{X}_i$ and s^* the virtual size of $\mathfrak{X}_i^*$ it holds that $s^* \leq s$, and*

(G) *for s the virtual size of $\mathfrak{X}_i[\Omega \setminus W]$ and s^* the virtual size of $\mathfrak{X}_i^*[\Omega^* \setminus W^*]$ it holds that $s^* \leq s$.*

Moreover, there is an algorithm computing the desired objects in time $p^2 \cdot (n+m)^{\mathcal{O}((\log d)^c)}$ for some absolute constant c.

3.4 The Local Certificates Routine

In this subsection the Local Certificates Routine originally introduced in [1] is lifted to the Generalized String Isomorphism Problem for $\widehat{\Gamma}_d$-group which builds the crucial step of extending the group-theoretic techniques of Babai's quasipolynomial time isomorphism test to the setting of this paper.

Let $\Gamma \leq \mathrm{Sym}(\Omega)$ be a permutation group and let $(\Gamma, \mathfrak{P}, \mathfrak{X}, \mathfrak{Y})$ be an instance of the Generalized String Isomorphism Problem. Furthermore let $\varphi\colon \Gamma \to S_k$ be a *giant representation*, i.e., a homomorphism $\varphi\colon \Gamma \to S_k$ such that $\Gamma^\varphi \geq A_k$. For the description of the Local Certificates Routine we extend the notation of set- and point-wise stabilizers for the group Γ to the action on the set $[k]$ defined via the giant representation φ. For a set $T \subseteq [k]$ let $\Gamma_T := \varphi^{-1}((\Gamma^\varphi)_T)$ and $\Gamma_{(T)} := \varphi^{-1}((\Gamma^\varphi)_{(T)})$.

The basic approach of the Local Certificates Routine is to consider *test sets* $T \subseteq [k]$ of logarithmic size.

▶ **Definition 12.** *A test set $T \subseteq [k]$ is* full *if $(\mathrm{Aut}_{\Gamma_T}(\mathfrak{X}))^\varphi[T] \geq \mathrm{Alt}(T)$. A* certificate of fullness *is a subgroup $\Delta \leq \mathrm{Aut}_{\Gamma_T}(\mathfrak{X})$ such that $\Delta^\varphi[T] \geq \mathrm{Alt}(T)$. A* certificate of non-fullness *is a non-giant $\Lambda \leq \mathrm{Sym}(T)$ such that $(\mathrm{Aut}_{\Gamma_T}(\mathfrak{X}))^\varphi[T] \leq \Lambda$.*

The central part of the algorithm is to determine for each test set $T \subseteq [k]$ (of size t approximately logarithmic in d) whether T is full and, depending on the outcome, compute a certificate of fullness or a certificate of non-fullness. Actually, in order to decide isomorphism, non-fullness certificates are also required for pairs of test sets. All of this is achieved by the following theorem.

▶ **Theorem 13.** *Let $\mathfrak{P}$ be a partition of Ω, $\mathfrak{X}$ and $\mathfrak{Y}$ two sets of $\mathfrak{P}$-strings. Let s be the d-virtual size of $\mathfrak{X}$ and $\mathfrak{Y}$. Also let $\Gamma \leq \mathrm{Sym}(\Omega)$ a $\widehat{\Gamma}_d$-group that has an almost d-ary sequence of partitions $\mathfrak{B}_0 \succ \dots \succ \mathfrak{B}_\ell$ such that $\mathfrak{P} = \mathfrak{B}_i$ for some $i \in [\ell]$. Furthermore suppose there is a giant representation $\varphi\colon \Gamma \to S_k$ and let $k \geq t > \max\{8, 2 + \log_2 d\}$. Finally, define $\mathcal{T} = \{(\mathfrak{X}, T), (\mathfrak{Y}, T) \mid T \subseteq [k], |T| = t\}$. For every $(\mathfrak{Z}_1, T_1), (\mathfrak{Z}_2, T_2) \in \mathcal{T}$ one can compute*

(i) *if T_1 is full with respect to $\mathfrak{Z}_1$, a group $\Delta := \Delta(\mathfrak{Z}_1, T_1) \leq \mathrm{Aut}_{\Gamma_{T_1}}(\mathfrak{Z}_1)$ such that $\Delta^\varphi[T_1] \geq \mathrm{Alt}(T_1)$, or*

(ii) *if T_1 is not full with respect to $\mathfrak{Z}_1$, a non-giant group $\Lambda := \Lambda(T_1, \mathfrak{Z}_1, T_2, \mathfrak{Z}_2) \leq \mathrm{Sym}(T_1)$ and a bijection $\lambda := \lambda(T_1, \mathfrak{Z}_1, T_2, \mathfrak{Z}_2)\colon T_1 \to T_2$ such that*

$$\left\{\gamma^\varphi|_{T_1} \;\middle|\; \gamma \in \mathrm{Iso}_\Gamma(\mathfrak{Z}_1, \mathfrak{Z}_2) \wedge T_1^{(\gamma^\varphi)} = T_2\right\} \subseteq \Lambda\lambda.$$

Moreover, the output is isomorphism-invariant, i.e., for every two pairs $(\mathfrak{Z}_1, T_1), (\mathfrak{Z}_2, T_2) \in \mathcal{T}$ *and* $(\mathfrak{Z}'_1, T'_1), (\mathfrak{Z}'_2, T'_2) \in \mathcal{T}$ *and isomorphisms* $\gamma_i \in \mathrm{Iso}_\Gamma((\mathfrak{Z}_i, T_i), (\mathfrak{Z}'_i, T'_i))$, $i \in \{1,2\}$, *it holds that*

(a) *if* T_1 *is full with respect to* $\mathfrak{Z}_1$, *then* $(\Delta(T_1, \mathfrak{Z}_1))^{\gamma_1} = \Delta(T'_1, \mathfrak{Z}'_1)$, *and*

(b) *if* T_1 *is not full with respect to* $\mathfrak{Z}_1$, *then*

$$\varphi(\gamma_1^{-1})\Lambda(T_1, \mathfrak{Z}_1, T_2, \mathfrak{Z}_2)\lambda(T_1, \mathfrak{Z}_1, T_2, \mathfrak{Z}_2)\varphi(\gamma_2) = \Lambda(T'_1, \mathfrak{Z}'_1, T'_2, \mathfrak{Z}'_2)\lambda(T'_1, \mathfrak{Z}'_1, T'_2, \mathfrak{Z}'_2).$$

Moreover, there are numbers $s_1, \dots, s_r \leq s/2$ *such that* $\sum_{i=1}^{r} s_i \leq 4k^{2t} \cdot t! \cdot s$ *and, for each* $i \in [r]$ *using a recursive call to the Generalized String Isomorphism Problem for instances of* d*-virtual size at most* s_i, *and* $k^{\mathcal{O}(t)} \cdot t! \cdot (n+m)^{\mathcal{O}((\log d)^c)}$ *additional computation steps, an algorithm can compute all desired objects.*

The algorithm is similar to the standard Local Certificates Routine implement in Babai's quasipolynomial-time isomorphism test [1]. A main difference is that, in each iteration, the algorithm runs the subroutine implemented in Theorem 11 to "simplify" all instances as described in the previous subsection. This guarantees that, throughout the execution of the algorithm, the prerequisites of Lemma 9 are satisfied allowing for the construction of global automorphisms from local information.

3.5 An Algorithm for the Generalized String Isomorphism Problem

With the Local Certificates Routine for sets of $\mathfrak{P}$-strings presented above it is possible to provide an algorithm for the Hypergraph Isomorphism Problem assuming the input group is equipped with an almost d-ary sequence of partitions. The algorithm mostly follows the same patterns as in [14] giving the corresponding result for the String Isomorphism Problem by replacing the Local Certificates Routine.

▶ **Theorem 14.** *There is an algorithm that, given a partition* $\mathfrak{P}$ *of* Ω, *a* $\widehat{\Gamma}_d$*-group* $\Gamma \leq \mathrm{Sym}(\Omega)$, *two sets of* $\mathfrak{P}$*-strings* $\mathfrak{X}, \mathfrak{Y}$ *and an almost* d*-ary sequence of partitions* $\mathfrak{B}_0 \succ \dots \succ \mathfrak{B}_\ell$ *for* Γ *such that* $\mathfrak{P} = \mathfrak{B}_i$ *for some* $i \in [\ell]$, *computes a representation for* $\mathrm{Iso}_\Gamma(\mathfrak{X}, \mathfrak{Y})$ *in time* $(n+m)^{\mathcal{O}((\log d)^c)}$, *for an absolute constant* c.

Combining Theorem 8 and 14 gives the main technical result of this work.

▶ **Theorem 15.** *The Generalized String Isomorphism Problem for* $\widehat{\Gamma}_d$*-groups can be solved in time* $(n+m)^{\mathcal{O}((\log d)^c)}$ *for some constant* c.

As an immediate consequence we obtain one of the main results of this paper.

▶ **Corollary 16** (Theorem 1 restated)**.** *The Hypergraph Isomorphism Problem for* $\widehat{\Gamma}_d$*-groups can be solved in time* $(n+m)^{\mathcal{O}((\log d)^c)}$ *for some constant* c.

4 Color Refinement and Small Color Classes

In the following two sections we present applications of the improvement obtained for the Hypergraph Isomorphism Problem for $\widehat{\Gamma}_d$-groups. Towards this end, we first introduce the notion of t-CR-bounded graphs and present an isomorphism test for such graphs running in time $n^{\mathcal{O}((\log t)^c)}$. The notion of t-CR-bounded graphs generalizes color-t-bounded graphs considered in [4] in the context of the isomorphism problem for strongly regular graphs. But more importantly, the isomorphism problem for t-CR-bounded graphs can serve as an intermediate problem for designing faster isomorphism tests for important classes of graphs.

For example, there is a simple polynomial-time Turing reduction from the isomorphism problem for graphs of maximum degree d to the isomorphism problem for d-CR-bounded graphs. Hence, our results may be seen as a generalization to the isomorphism test for graphs of small degree presented in [14]. Moreover, in the next section, we present a polynomial-time Turing reduction from the isomorphism problem for graphs of genus at most g to the isomorphism problem for $(4g+2)$-CR-bounded graphs. As a result, isomorphism for graphs of genus at most g can be tested in time $n^{\mathcal{O}((\log g)^c)}$.

The definition of t-CR-bounded graphs builds on the Color Refinement algorithm, a simple combinatorial algorithm that iteratively refines a vertex-coloring in an isomorphism-invariant manner and which forms a fundamental algorithmic tool in the context of the Graph Isomorphism Problem (see, e.g., [4, 7, 8, 24, 25, 36]). We start by formally defining the outcome of the Color Refinement algorithm in the next subsection.

4.1 The Color Refinement Algorithm

Let G be a graph with vertex coloring $\chi_V\colon V(G) \to C_V$ and arc coloring $\chi_E\colon \{(v,w) \mid vw \in E(G)\} \to C_E$. The *Color Refinement algorithm* is a procedure that, given a vertex- and arc-colored graph G, iteratively computes an isomorphism-invariant refinement $\chi_{\mathsf{CR}}[G]$ of the vertex-coloring χ_V.

Let $\chi_1, \chi_2\colon V \to C$ be colorings of vertices where C is some finite set of colors. The coloring χ_1 *refines* χ_2, denoted $\chi_1 \preceq \chi_2$, if $\chi_1(v) = \chi_1(w)$ implies $\chi_2(v) = \chi_2(w)$ for all $v,w \in V$. The colorings χ_1 and χ_2 are *equivalent*, denoted $\chi_1 \equiv \chi_2$, if $\chi_1 \preceq \chi_2$ and $\chi_2 \preceq \chi_1$.

Given a vertex- and arc-colored graph G, the Color Refinement algorithm computes an isomorphism-invariant coloring $\chi_{\mathsf{CR}}[G]$ as follows. The initial coloring for the algorithm is defined as $\chi_{(0)}[G] \coloneqq \chi_V$, the vertex-coloring of the input graph. The initial coloring is refined by iteratively computing colorings $\chi_{(i)}[G]$ for $i > 0$. For $i > 0$ define $\chi_{(i)}[G](v) \coloneqq (\chi_{(i-1)}[G](v), \mathcal{M}_i(v))$ where

$$\mathcal{M}_i(v) \coloneqq \{\{\big(\chi_{(i-1)}[G](w), \chi_E(v,w), \chi_E(w,v)\big) \mid w \in N_G(v)\}\}.$$

From the definition of the colorings it is immediately clear that $\chi_{(i+1)}[G] \preceq \chi_{(i)}[G]$. Now let $i \in \mathbb{N}$ be the minimal number such that $\chi_{(i)}[G] \equiv \chi_{(i+1)}[G]$. For this i, the coloring $\chi_{(i)}[G]$ is called the *stable* coloring of G and is denoted by $\chi_{\mathsf{CR}}[G]$.

The *Color Refinement algorithm* takes as input a (vertex- and arc-colored) graph G and computes (a coloring that is equivalent to) $\chi_{\mathsf{CR}}[G]$. I remark that this can be implemented in time almost linear in the number of vertices and edges (see, e.g., [9]).

4.2 Splitting Small Color Classes

Having defined the Color Refinement algorithm, we can now define the notion of t-CR-bounded graphs. The basic idea behind t-CR-bounded graphs is the following. Suppose (G,χ) is a vertex-colored graph. Then (G,χ) is t-CR-bounded if it is possible to transform χ into a discrete coloring (i.e., a coloring where each vertex has its own color) by repeatedly performing the following two operations: applying the Color Refinement algorithm and completely splitting color classes of size at most t (i.e., assigning every vertex in such a color class its own color).

For formal reasons, we actually define t-CR-bounded pairs where an additional set $S \subseteq V(G)$ is provided each vertex of which may also be individualized. The intuition behind this is that we may already have good knowledge about the structure of the automorphism group of (G,χ) on the set S which can be exploited for isomorphism testing.

▶ **Definition 17.** *A pair (G, S), where $G = (V, E, \chi_V, \chi_E)$ is a vertex- and arc-colored graph and $S = \chi_V^{-1}(c)$ for some color c (not necessarily in the image of χ_V, i.e., S may be the empty set), is* t-CR-bounded *if the sequence $(\chi_i)_{i \geq 0}$ reaches a discrete coloring where*

$$\chi_0(v) := \begin{cases} (v, 1) & \text{if } v \in S \\ (\chi_V(v), 0) & \text{if } v \notin S \end{cases},$$

$\chi_{2i+1} := \chi_{CR}[V, E, \chi_{2i}, \chi_E]$ and

$$\chi_{2i+2}(v) := \begin{cases} (v, 1) & \text{if } |\chi_{2i+1}^{-1}(\chi_{2i+1}(v))| \leq t \\ (\chi_{2i+1}(v), 0) & \text{otherwise} \end{cases}$$

for all $i \geq 0$. A graph G is t-CR-bounded *if the pair $(G, \emptyset)$ is t-CR-bounded.*

I remark that the name "t-CR-bounded" is inspired by color-t-bounded graphs [4] defined in a similar manner where the letters *CR* refer to the Color Refinement algorithm. Also, I note that a similar notion of graphs has been exploited in [28] for designing a polynomial-time isomorphism test for unit square graphs.

▶ **Theorem 18.** *Let (G_1, S_1) and (G_2, S_2) be two t-CR-bounded pairs and also let $\Gamma \leq \mathrm{Sym}(S_1)$ be a $\widehat{\Gamma}_t$-group and $\theta \colon S_1 \to S_2$ a bijection. Then a representation for the set*

$$\mathrm{Iso}_{\Gamma\theta}((G_1, S_1), (G_2, S_2)) := \{\sigma \colon G_1 \cong G_2 \mid \sigma|_{S_1} \in \Gamma\theta\}$$

can be computed in time $n^{\mathcal{O}((\log t)^c)}$ for some absolute constant c.

▶ **Corollary 19.** *The Graph Isomorphism Problem for t-CR-bounded graphs can be solved in time $n^{\mathcal{O}((\log t)^c)}$ for some absolute constant c.*

In particular, this includes color-t-bounded graphs considered in [4] in the context of the isomorphism problem for strongly regular graphs.

The algorithm underlying Theorem 18 actually describes a polynomial-time Turing reduction from the isomorphism problem for t-CR-bounded graphs to the Hypergraph Isomorphism Problem for $\widehat{\Gamma}_t$-groups. This result may be of independent interest.

▶ **Lemma 20.** *There is a polynomial-time Turing reduction from the Graph Isomorphism Problem for t-CR-bounded graphs to the Hypergraph Isomorphism Problem for $\widehat{\Gamma}_t$-groups.*

4.3 Hereditarily Finite Sets

As the first application to the isomorphism problem for t-CR-bounded pairs we consider hereditarily finite sets. Intuitively speaking, a hereditarily finite set over ground set V is any type of combinatorial object that can be build by iteratively taking sets and tuples over previously created objects.

In this section we extend the algorithm for solving the Hypergraph Isomorphism Problem for $\widehat{\Gamma}_d$-groups to work on any type of hereditarily finite set.

Let V be finite set of elements (e.g., the vertex of a graph). The class of *hereditarily finite sets* over universe (ground set) V is inductively defined as follows. Each $v \in V$ is an *atom* which in particular is a hereditarily finite set. Also, for hereditarily finite sets $\mathfrak{A}_1, \dots, \mathfrak{A}_k$ (over universe V) the set $\{\mathfrak{A}_1, \dots, \mathfrak{A}_k\}$ as well as the tuple $(\mathfrak{A}_1, \dots, \mathfrak{A}_k)$ is a hereditarily finite set (over universe V). Examples of hereditarily finite sets include graphs, hypergraphs and relational structures.

In order to apply the isomorphism test for t-CR-bounded graphs, we can transform a hereditarily finite set $\mathfrak{A}$ over ground set V into a graph $G(\mathfrak{A})$ in the natural way so that the pair $(G(\mathfrak{A}), V)$ is 0-CR-bounded.

▶ **Corollary 21.** *Let $\mathfrak{A}_1$ and $\mathfrak{A}_2$ be two hereditarily finite sets over the universe V and let $\Gamma \leq \mathrm{Sym}(V)$ be a $\widehat{\Gamma}_d$-group. Then a representation for the set $\mathrm{Iso}_\Gamma(\mathfrak{A}_1, \mathfrak{A}_2) := \{\gamma \in \Gamma \mid \gamma\colon \mathfrak{A}_1 \cong \mathfrak{A}_2\}$ can be computed in time $(n+m)^{\mathcal{O}((\log d)^c)}$ for some absolute constant c where $n := |V|$ and $m := |V(G(\mathfrak{A}_1))|$.*

▶ **Corollary 22.** *The isomorphism problem for hereditarily finite sets can be solved in time $(n+m)^{\mathcal{O}((\log n)^c)}$.*

I remark that a variant of the previous corollary was independently obtained by Daniel Wiebking [37] (see *Related Work*).

5 Isomorphism for Graphs of Bounded Genus

Next, we present a second, slightly more involved application of our results and give an algorithm solving the isomorphism problem for graphs of Euler genus at most g in time $n^{\mathcal{O}((\log g)^c)}$ for some absolute constant c. Actually, we prove a more general result.

Recall that a graph H is a minor of another graph G if H can be obtained from G by removing vertices as well as removing and contracting edges. Also define $K_{m,n}$ to be the complete bipartite graph with m vertices on the left side and n vertices on the right side. Let $h \geq 3$ and define $\mathcal{C}_h$ to be the class of graphs that exclude $K_{3,h}$ as a minor.

We present a polynomial-time reduction from the isomorphism problem for the class $\mathcal{C}_h$ to the isomorphism problem for t-CR-bounded graphs where $t := h-1$. The following lemma is the key tool for the reduction. Intuitively, it investigates the structure of certain colorings that are stable with respect to the Color Refinement algorithm for graphs in the class $\mathcal{C}_h$. Recall that a graph G is 3-*connected* if there are no two vertices $v, w \in V(G)$ such that $G - \{v, w\}$ is disconnected.

▶ **Lemma 23.** *Let (G, χ) be a 3-connected, colored graph that excludes $K_{3,h}$ as a minor and suppose $V_1 \uplus V_2 = V(G)$ such that*
1. *each $v \in V_1$ forms a singleton color class with respect to χ,*
2. *χ is stable with respect to the Color Refinement algorithm,*
3. *$|V_1| \geq 3$, and*
4. *$N(V_2) = V_1$.*

Then there is a color class $U \subseteq V_2$ with respect to χ of size $|U| \leq h-1$.

Proof. Let $C := \mathrm{im}(\chi)$, $C_1 := \chi(V_1)$ and $C_2 := \chi(V_2)$. Also define H to be the graph with vertex set $V(H) := C$ and edge set

$$E(H) = \{c_1c_2 \mid \exists v_1 \in \chi^{-1}(c_1), v_2 \in \chi^{-1}(c_2)\colon v_1v_2 \in E(G)\}.$$

Let $C' \subseteq C_2$ be the vertex set of a connected component of $H[C_2]$. Then $|N_H(C')| \geq 3$ since each $v \in V_1$ forms a singleton color class with respect to χ and G is 3-connected.

Now let $c_1, c_2, c_3 \in N_H(C')$ be distinct and also let $v_i \in \chi^{-1}(c_i)$ for $i \in [3]$. Also let T be a spanning tree of $H[C' \cup \{c_1, c_2, c_3\}]$ such that $c_1, c_2, c_3 \in L(T)$ where $L(T)$ denotes the set of leaves of T. Moreover, let T' be the subtree of T obtained from repeatedly removing all leaves $c \in C'$. Hence, $L(T') = \{c_1, c_2, c_3\}$. Then there is a unique color c such that $\deg_{T'}(c) = 3$. Also, for $i \in [3]$, define C_i' to be the set of internal vertices on the unique path from c_i to c in the tree T'.

Since $|\chi^{-1}(c_i)| = 1$ and χ is stable with respect to the Color Refinement algorithm it holds that

$$G\left[\chi^{-1}(C_i' \cup \{c_i\})\right]$$

is connected. Let $U_i \coloneqq \chi^{-1}(C_i' \cup \{c_i\})$, $i \in [3]$. Also let $U = \chi^{-1}(c)$ and suppose that $|U| \geq h$. Then $N(U_i) \cap U \neq \emptyset$ by the definition of the tree T. Moreover, this implies $U \subseteq N(U_i)$ since χ is stable with respect to the Color Refinement algorithm. Hence, G contains a minor isomorphic to $K_{3,h}$. ◀

▶ **Corollary 24.** *Let $(G, \chi_V, \chi_E) \in \mathcal{C}_h$ be a 3-connected, vertex- and arc-colored graph and let $v_1, v_2, v_3 \in V(G)$. Also define $\chi_V^*(v_i) \coloneqq (i, 1)$ for $i \in [3]$ and $\chi_V^*(v) \coloneqq (\chi_V(v), 0)$ for all $v \in V(G) \setminus \{v_1, v_2, v_3\}$. Then (G, χ_V^*, χ_E) is $(h-1)$-CR-bounded.*

Proof. Let $(\chi_i)_{i\geq 0}$ be the sequence of colorings obtained from the definition of $(h-1)$-CR-bounded graphs (Definition 17) for the graph (G, χ_V^*, χ_E). Let $\chi^* \coloneqq \chi_i$ for the minimal $i \geq 0$ such that $\chi_i \equiv \chi_{i+1}$.

Suppose towards a contradiction that χ^* is not discrete (i.e., not every color class is a singleton). Let $V_2 \coloneqq \{v \in V(G) \mid |(\chi^*)^{-1}(\chi^*(v))| > 1\}$ and let $V_1 \coloneqq N_G(V_2)$. Then $|V_1| \geq 3$ since $|V(G) \setminus V_2| \geq 3$ and G is 3-connected. Also note that $\chi^*|_{V_1 \cup V_2}$ is a stable coloring for the graph $G[V_1 \cup V_2]$. Hence, by Lemma 23, there is some color c such that $1 < |(\chi^*)^{-1}(c)| \leq h - 1$. But this contradicts the definition of the coloring χ^* (cf. Definition 17). ◀

The last corollary gives some insights into the structure of the automorphism group of graphs $G \in \mathcal{C}_h$.

▶ **Theorem 25.** *Let $G \in \mathcal{C}_h$ be a 3-connected graph and let $v_1, v_2, v_3 \in V(G)$ be distinct vertices. Then $(\mathrm{Aut}(G))_{(v_1,v_2,v_3)}$ is a $\widehat{\Gamma}_{h-1}$-group.*

Also, the corollary can be used to design an isomorphism test for the class $\mathcal{C}_h$.

▶ **Corollary 26** (Theorem 3 restated)**.** *The Graph Isomorphism Problem for the class $\mathcal{C}_h$ can be solved in time $n^{\mathcal{O}((\log h)^c)}$ for some absolute constant c.*

Proof. Let $G_1, G_2 \in \mathcal{C}_h$. By standard decomposition techniques it suffices to consider the case where G_1 and G_2 are (vertex- and arc-colored) 3-connected graphs.

Suppose $G_1 = (V_1, E_1, \chi_V^1, \chi_E^1)$ and $G_2 = (V_2, E_2, \chi_V^2, \chi_E^2)$. Let $v_1, v_2, v_3 \in V(G_1)$ be three arbitrary vertices. For every $w_1, w_2, w_3 \in V(G_2)$ it is checked whether there is some isomorphism $\varphi\colon G_1 \cong G_2$ such that $\varphi(v_i) = w_i$ for all $i \in [3]$. Towards this end, define $\widehat{\chi}_V^1(v_i) = (i, 1)$ for $i \in [3]$ and $\widehat{\chi}_V^1(v) = (\chi_V^1(v), 0)$ for all $v \in V(G_1) \setminus \{v_1, v_2, v_3\}$. Similarly, define $\widehat{\chi}_V^2(w_i) = (i, 1)$ for $i \in [3]$ and $\widehat{\chi}_V^2(w) = (\chi_V^2(w), 0)$ for all $w \in V(G_2) \setminus \{w_1, w_2, w_3\}$. Hence, it needs to be checked whether $\widehat{G}_1 \cong \widehat{G}_2$ where $\widehat{G}_j \coloneqq (V_j, E_j, \widehat{\chi}_V^j, \chi_E^j)$, $j \in [2]$. By Corollary 24 the graphs $\widehat{G}_1$ and $\widehat{G}_2$ are $(h-1)$-CR-bounded. Hence, isomorphism of the two graphs can be tested within the desired time by Corollary 19. ◀

Note that the algorithm from the corollary describes a polynomial-time Turing reduction from the Graph Isomorphism Problem for $\mathcal{C}_h$ to the Graph Isomorphism Problem for $(h-1)$-CR-bounded graphs. In combination with Lemma 20 this means the the Graph Isomorphism Problem for $\mathcal{C}_h$ is polynomial-time Turing reducible to the Hypergraph Isomorphism Problem for $\widehat{\Gamma}_{h-1}$-groups.

Since the class of graphs of Euler genus at most g excludes $K_{3,4g+3}$ as a minor [32, 18], we obtain the following result.

▶ **Corollary 27** (Corollary 4 restated)**.** *The Graph Isomorphism Problem for graphs of genus at most g can be solved in time $n^{\mathcal{O}((\log g)^c)}$ for some absolute constant c.*

6 Conclusion

We provided a faster algorithm for the Hypergraph Isomorphism Problem for $\widehat{\Gamma}_d$-groups running in time $(n+m)^{\mathcal{O}((\log d)^c)}$ for some absolute constant c. As an application, we obtained, for example, an algorithm testing isomorphism of graphs excluding $K_{3,h}$ as a minor in time $n^{\mathcal{O}((\log h)^c)}$. In particular, this gives an isomorphism test for graphs of Euler genus at most g running in time $n^{\mathcal{O}((\log g)^c)}$.

With the Hypergraph Isomorphism Problem for $\widehat{\Gamma}_d$-groups being exploited as a subroutine in a number of algorithms testing isomorphism, it seems plausible to hope for further applications beyond the ones presented in this paper. Indeed, a very recent work by Grohe, Wiebking and the present author [16] gives an isomorphism test running in time $n^{\mathcal{O}((\log h)^c)}$ for n-vertex graphs excluding an arbitrary h-vertex graph as a minor. This algorithm crucially builds on the isomorphism test for hypergraphs as well as the notion of t-CR-bounded graphs. Actually, extending the applicability of our techniques further, it might be possible to provide an algorithm with a similar running time for all classes excluding only a topological minor building on a decomposition theorem for such graph classes due to Grohe and Marx [13].

Another open question concerns the complexity of testing isomorphism of hypergraphs for a given $\widehat{\Gamma}_d$-group. The algorithm presented in this work is significantly faster than the previous best algorithm [34] running in time $n^{\mathcal{O}(d)}m^{\mathcal{O}(1)}$ only for small numbers of hyperedges. Indeed, for large numbers of hyperedges $m = n^{\Omega(d)}$, our algorithm becomes slower than the algorithm due to Schweitzer and Wiebking [34]. Can the Hypergraph Isomorphism Problem for $\widehat{\Gamma}_d$-groups be solved in time $n^{\mathcal{O}((\log d)^c)}m^{\mathcal{O}(1)}$ for some absolute constant c? Observe that it is already completely unclear whether isomorphism of hypergraphs can be tested in time $n^{\mathcal{O}((\log n)^c)}m^{\mathcal{O}(1)}$ for some absolute constant c.

On Solving (Non)commutative Weighted Edmonds' Problem

Taihei Oki

Abstract

In this paper, we consider computing the degree of the Dieudonné determinant of a polynomial matrix $A = A_\ell + A_{\ell-1}s + \cdots + A_0 s^\ell$, where each A_d is a linear symbolic matrix, i.e., entries of A_d are affine functions in symbols $x_1, \dots, x_m$ over a field K. This problem is a natural "weighted analog" of Edmonds' problem, which is to compute the rank of a linear symbolic matrix. Regarding $x_1, \dots, x_m$ as commutative or noncommutative, two different versions of weighted and unweighted Edmonds' problems can be considered. Deterministic polynomial-time algorithms are unknown for commutative Edmonds' problem and have been proposed recently for noncommutative Edmonds' problem.

The main contribution of this paper is to establish a deterministic polynomial-time reduction from (non)commutative weighted Edmonds' problem to unweighed Edmonds' problem. Our reduction makes use of the discrete Legendre conjugacy between the integer sequences of the maximum degree of minors of A and the rank of linear symbolic matrices obtained from the coefficient matrices of A. Combined with algorithms for noncommutative Edmonds' problem, our reduction yields the first deterministic polynomial-time algorithm for noncommutative weighted Edmonds' problem with polynomial bit-length bounds. We also give a reduction of the degree computation of quasideterminants and its application to the degree computation of noncommutative rational functions.

1 Introduction

The background of this paper goes back to Edmonds [10]. In 1967, Edmonds posed a question whether there exists a polynomial-time algorithm to compute the rank of a *linear* (*symbolic*) *matrix* B over a field K, which is in the form

$$B = B_0 + B_1 x_1 + \cdots + B_m x_m,$$

where $B_0, B_1 \ldots, B_m \in K^{n \times n}$ and $x_1, \ldots, x_m$ are commutative symbols. Here, B is regarded as a matrix over the polynomial ring $K[x_1, \ldots, x_m]$ or the rational function field $K(x_1, \ldots, x_m)$. In case where B is the Edmonds or Tutte matrix of a bipartite or nonbipartite graph G, the rank computation for B corresponds to solving the maximum matching problem on G. More generally, Lovász [27] showed that Edmonds' problem is equivalent to a linear matroid intersection problem if all B_i are of rank 1, and to a linear matroid parity problem if all B_i are skew-symmetric matrices of rank 2. For general linear matrices, the celebrated Schwartz–Zippel lemma [34] provides a simple randomized algorithm if $|K|$ is large enough [27]. However, no deterministic polynomial-time algorithm still has been known; the existence of such an algorithm would imply nontrivial circuit complexity lower bounds [22, 36].

Recent studies [11, 17, 20] address the noncommutative version of Edmonds' problem (nc-Edmonds' problem). This is a problem of computing the *noncommutative rank* (nc-rank) of B, which is the rank defined by regarding $x_1, \ldots, x_m$ as pairwise noncommutative, i.e., $x_i x_j \neq x_j x_i$ if $i \neq j$. In this way, B is viewed as a matrix over the free ring $K\langle x_1, \ldots, x_m \rangle$ generated by noncommutative symbols $x_1, \ldots, x_m$. The nc-rank of B is precisely the rank of B over a skew (noncommutative) field $K \langle\!(x_1, \ldots, x_m)\!\rangle$, called a *free skew field*, which is the quotient of $K\langle x_1, \ldots, x_m \rangle$ defined by Amitsur [2]. We call a linear matrix over K having noncommutative symbols an *nc-linear matrix* over K. The recent studies [11, 17, 20] revealed that nc-Edmonds' problem is deterministically tractable. For the case where K is the set $\mathbb{Q}$ of rational numbers, Garg et al. [11] proved that Gurvits' *operator scaling algorithm* [16] deterministically computes the nc-rank of B in poly(n, m) arithmetic operations on $\mathbb{Q}$. Algorithms over general field K were later given by Ivanyos et al. [20] and Hamada–Hirai [17] exploiting the min-max theorem established for nc-rank. In [16] and [20] applied to the case of $K = \mathbb{Q}$, bit-lengths of intermediate numbers are proved to be bounded by a polynomial of the input bit-length.

In this paper, we shall consider "weighted" versions of commutative and noncommutative Edmonds' problem introduced by Hirai [18]. First, consider commutative symbols $x_1, \ldots, x_m$ and an extra commutative symbol s. Define a matrix

$$A = A_\ell + A_{\ell-1} s + \cdots + A_0 s^\ell, \tag{1}$$

where $A_d = A_{d,0} + A_{d,1} x_1 + \cdots + A_{d,m} x_m \in K[x_1, \ldots, x_m]^{n \times n}$ is a linear matrix over K for $d = 0, \ldots, \ell$. We call (1) a *linear polynomial matrix* over K. The *weighted Edmonds' problem* (WEP) is the problem to compute the degree (in s) of the determinant of A. Analogously to Edmonds' problem, WEP includes a bunch of weighted combinatorial optimization problems as special cases, such as a maximum weighted perfect matching problem, a weighted linear matroid intersection problem and a weighted linear matroid parity problem; see [18, Section 5].

Defining *noncommutative weighted Edmonds' problem* (nc-WEP) requires some more involved algebraic notions due to noncommutativity. Let $x_1, \ldots, x_m$ be noncommutative symbols and s an extra symbol that commutes with any element in $K\langle x_1, \ldots, x_m \rangle$. An *nc-linear polynomial matrix* A over K is a matrix in the form of (1) with each A_d regarded as an nc-linear matrix. Then A can be viewed as a matrix over the rational function (skew) field $F(s)$ over $F := K \langle\!(x_1, \ldots, x_m)\!\rangle$. Since entries of A are noncommutative, the determinant of A is nontrivial. Here, we employ the *Dieudonné determinant* [9], which is a noncommutative generalization of the usual determinant defined for matrices over skew fields. We denote the Dieudonné determinant of A by $\operatorname{Det} A$. The Dieudonné determinant retains useful properties of the usual determinant such as $\operatorname{Det} AB = \operatorname{Det} A \operatorname{Det} B$. While the value of $\operatorname{Det} A$ is no longer in $F(s)$, its degree (in s) is well-defined [8, 35]. See Section 2.1 for the definition of Dieudonné determinant.

The nc-WEP is the problem to compute $\deg \mathrm{Det}$ of a given nc-linear polynomial matrix. Hirai [18] formulated the dual problem of nc-WEP as the minimization of an *L-convex function* on a *uniform modular lattice*, and gave an algorithm based on the steepest gradient descent. Hirai's algorithm uses $\mathrm{poly}(n, m, \ell)$ arithmetic operations on K while no bit-length bound has been given for $K = \mathbb{Q}$.

A weighted combinatorial optimization problem often reduces to an unweighted problem. This paper explores a reduction from (nc-)WEP (a weighted problem) to (nc-)Edmonds' problem (an unweighted problem). The main result of this paper is the following.

▶ **Theorem 1.** *The (nc-)WEP deterministically reduces to (nc-)Edmonds' problem for an (nc-)linear matrix of size ℓn^2 with m symbols.*

Theorem 1 provides an efficient randomized algorithm for WEP through the Schwartz–Zippel lemma and a deterministic polynomial-time algorithm for nc-WEP via the rank computation algorithms [11, 18, 20] for nc-linear matrices. This algorithm for nc-WEP is much different from Hirai's algorithm [18]; in particular, while Hirai's algorithm calls an oracle of nc-Edmonds' problem polynomially many times, our algorithm calls it only once (the matrix size would be augmented instead). Furthermore, in case of $K = \mathbb{Q}$, our reduction does not exponentially swell the input bit-length because every entry of the nc-linear matrix constructed in this reduction is some coefficient of an entry in the input nc-linear polynomial matrix. Thus, by employing an algorithm [11, 18] for nc-Edmonds' problem with bit-length bounds, we obtain the following.

▶ **Theorem 2.** *We can deterministically solve nc-WEP in* $\mathrm{poly}(n, m, \ell)$ *arithmetic operations on K. In addition, if $K = \mathbb{Q}$, the bit-lengths of intermediate numbers are bounded by a polynomial of the input bit-length.*

We also give a reduction from computing the degree of a *quasideterminant* [12, 13], which is another noncommutative analogy of the determinant, to computing the degree of Dieudonné determinant. This can be applied to the degree computation of noncommutative rational functions represented as a noncommutative formula with division. See Section 4 for details.

Techniques

Let A be an $n \times n$ (nc-)linear polynomial matrix over a field K and put $F := K(x_1, \dots, x_m)$ or $K\langle\!\langle x_1, \dots, x_m \rangle\!\rangle$. Slightly generalizing (nc-)WEP, we consider the problem to compute

$$d_k(A) := \max\{\deg \mathrm{Det}\, A[I, J] \mid |I| = |J| = k\} \tag{2}$$

for given k, where $A[I, J]$ denotes the submatrix of A indexed by a row set I and a column set J. Clearly $\deg \mathrm{Det}\, A = d_n(A)$. In view of combinatorial optimization, computation of $d_k(A)$ corresponds to solving weighted problems under cardinality constraints.

Our reduction scheme is based on a method, which we call *matrix expansion*, that constructs an (nc-)linear matrix $\Omega_\mu(A) \in F^{\mu n \times \mu n}$ obtained by arranging the coefficient matrices of A. Through a canonical form of A called the *Smith–McMillan form*, it is shown that the integer sequences of $(d_0(A), d_1(A), \dots, d_r(A))$ with $r := \mathrm{rank}\, A$ and $(\omega_0(A), \omega_1(A), \dots)$ with $\omega_\mu(A) := \mathrm{rank}\, \Omega_\mu(A)$ are concave and convex, respectively. In addition, they are in the relation of the *discrete Legendre conjugate*, that is, they satisfy

$$d_k(A) = \min_{\mu \geq 0}(\omega_\mu(A) - k\mu) \qquad (0 \leq k \leq r), \tag{3}$$

$$\omega_\mu(A) = \max_{0 \leq k \leq r}(d_k(A) + k\mu) \quad (\mu \geq 0). \tag{4}$$

The Legendre conjugacy is an important duality relation on discrete convex and concave functions treated in *discrete convex analysis* [32]. The formulas (3) and (4) are a generalization of results on matrix pencils over fields given by Murota [33] and on polynomial matrices over algebraically closed fields by Moriyama–Murota [28]. For proving the conjugacy, equalities connecting $d_k(A)$ and $\omega_\mu(A)$ are necessary. We present a new short and simple connection which works even on skew fields through the multiplicativity of Ω_μ, i.e.,

$$\Omega_\mu(A)\Omega_\mu(B) = \Omega_\mu(AB). \tag{5}$$

The conjugacy formula (3) reduces the computation of $d_k(A)$ to a one-dimensional discrete convex optimization problem, which can be efficiently done by binary search. In each iteration, the objective function can be evaluated by solving (nc-)Edmonds' problem. Moreover, we derive direct formulas with respect to r and $d_r(A)$ from (3), which proves Theorem 1.

Related Work

In the field of computer algebra, algorithms were proposed for computing various kinds of canonical forms of a polynomial matrix $A \in F[s]^{n \times n}$ (or of its generalization) such as the *Jacobson normal form* [26], the *Hermite normal form* [14], the *Popov normal form* [23] and their weaker form called a *row-reduced form* [1, 4]. These algorithms iteratively solve systems of linear equations over F whose coefficient matrices are variants of expanded matrices $\Omega_\mu(A)$ under the name of "linearized matrices" [23] or "striped Krylov matrices" [4]. While these algorithms can compute $\deg \operatorname{Det} A$, their running time is bounded in terms of the number of operations on F. Hence if $F = K(x_1, \ldots, x_m)$ or $F = K\langle\!\langle x_1, \ldots, x_m \rangle\!\rangle$, the expression size of intermediate numbers might be exponentially large.

Combinatorial relaxation [29, 30] is another framework for deg-det computation based on combinatorial optimization. Hirai's algorithm [18] for nc-WEP can also be viewed as a variant of combinatorial relaxation. Unlike the matrix expansion, it is difficult to give bit complexity bounds for combinatorial relaxation algorithms because they iteratively perform the Gaussian elimination on the same matrix and thus the magnitude of its entries might swell.

Organization

The rest of this paper is organized as follows. Section 2 provides preliminaries on matrices and polynomials over skew fields. Section 3 describes our proposed reductions after introducing the matrix expansion and the Legendre conjugacy. Section 4 describes the computation of the degree of quasideterminants and its application to the degree computation of noncommutative rational functions.

2 Preliminaries

Let $\mathbb{Z}$ denote the set of integers and $\mathbb{N}$ the set of nonnegative integers. For $n \in \mathbb{N}$, we denote the set $\{1, 2, \ldots, n\}$ by $[n]$ and $\{0, 1, 2, \ldots, n\}$ by $[0, n]$.

2.1 Matrices over Skew Fields

A *skew field*, or a *division ring* is a ring F such that every nonzero element has a multiplicative inverse in F. A right (left) F-module is especially called a *right (left) F-vector space*. The *dimension* of a right (left) F-vector space V is defined as the rank of V as a module, that is, the cardinality of any basis of V. The usual facts from linear algebra on independent sets and generating sets in vector spaces are valid even on skew fields [25].

A square matrix $A \in F^{n\times n}$ is said to be *nonsingular* if there exists a unique $n \times n$ matrix over F, denoted by A^{-1}, such that AA^{-1} and $A^{-1}A$ are the identity matrix I_n of size n. A square matrix is *singular* if it is not nonsingular. The *rank* $\operatorname{rank} A$ of a matrix $A \in F^{n\times n'}$ is the dimension of the right F-vector space spanned by the column vectors of A, and is equal to the dimension of the left F-vector space spanned by the row vectors of A. The rank is invariant under (right and left) multiplications of nonsingular matrices. It is observed that a square matrix $A \in F^{n\times n}$ is nonsingular if and only if $\operatorname{rank} A = n$.

The *Bruhat decomposition* uniquely factors a nonsingular matrix $A \in F^{n\times n}$ into the product of four $n \times n$ matrices over F as $A = LDPU$, where L is lower unitriangular, D is diagonal, P is a permutation matrix and U is upper unitriangular [7, Theorem 2.2 in Section 11.2]. Here, a lower (upper) unitriangular matrix is a lower (upper) triangular matrix whose diagonal entries are 1. Let $F^\times_{\mathrm{ab}} := F^\times / [F^\times, F^\times]$ denote the abelianization of the multiplicative subgroup $F^\times = F \setminus \{0\}$ of F, where $[F^\times, F^\times] := \langle \{aba^{-1}b^{-1} \mid a, b \in F^\times\} \rangle$ is the commutator subgroup of $F^\times$. The *Dieudonné determinant* $\operatorname{Det} A$ of a nonsingular matrix $A \in F^{n\times n}$, which is decomposed as $A = LDPU$, is an element of $F^\times_{\mathrm{ab}}$ defined by

$$\operatorname{Det} A := \operatorname{sgn}(P) e_1 e_2 \cdots e_n \bmod [F^\times, F^\times],$$

where $\operatorname{sgn}(P) \in \{-1, +1\}$ is the sign of the permutation P and $e_1, \ldots, e_n \in F^\times$ are the diagonal entries of D [9]. For a singular matrix $A \in F^{n\times n}$, define $\operatorname{Det} A$ as 0 for convenience. In case where F is commutative, the Dieudonné determinant coincides with the usual determinant. As the usual determinant, the Dieudonné determinant satisfies the following properties [3, Chapter 4.1]:

(D1) $\operatorname{Det} AB = \operatorname{Det} A \operatorname{Det} B$ for $A, B \in F^{n\times n}$.

(D2) $\operatorname{Det} \begin{pmatrix} A & * \\ O & B \end{pmatrix} = \operatorname{Det} \begin{pmatrix} A & O \\ * & B \end{pmatrix} = \operatorname{Det} A \operatorname{Det} B$ for $A \in F^{n\times n}$ and $B \in F^{n'\times n'}$, where blocks in O and $*$ represent zero and any matrices of appropriate size, respectively.

2.2 Polynomials over Skew Fields

Let us consider the polynomial ring $F[s]$ over a skew field F, where s is an indeterminate that commutes with any element of F. A nonzero polynomial $p \in F[s]$ is uniquely written as $p = \sum_{d=0}^{\ell} a_{\ell-d} s^d$, where $a_0, \ldots, a_\ell \in F$ with $a_0 \neq 0$. The addition and the multiplication in $F[s]$ are naturally defined. The *degree* $\deg p$ of p is defined by $\deg p := \ell$ and we set $\deg 0 := -\infty$. Then the minus of the degree enjoys the *discrete valuation* property, that is, deg satisfies $\deg(p + q) \leq \max\{\deg p, \deg q\}$ and $\deg pq = \deg p + \deg q$ for $p, q \in F[s]$.

The polynomial ring $F[s]$ is a (right and left) *Ore domain*, i.e., for each $p, q \in F[s] \setminus \{0\}$, there exists $u, u', v, v' \in F[s] \setminus \{0\}$ such that $pu = pv$ and $u'p = v'q$. This property enables $F[s]$ to have the (right and left) *Ore quotient ring*, which is a skew field of fractions each of whose elements is expressed as $f = pq^{-1} = q'^{-1}p'$ for some $p, p', q, q' \in F[s]$ with $q, q' \neq 0$. Elements of $F(s)$ are called *rational functions* over F and $F(s)$ is called the *rational function field* over F. See [7, Section 9.1] and [15, Chapter 6] for the construction of $F(s)$. The degree on $F[s]$ is uniquely extended to a valuation on $F(s)$ by $\deg f := \deg p - \deg q$ for $f = pq^{-1} \in F(s)$; see [8, Proposition 9.1.1]. A rational function $f \in F(s)$ is said to be *proper* if $\deg f \leq 0$.

The *Laurent series field* $F((s^{-1}))$ over F in s^{-1} is the set of formal power series over F in the form of

$$f = \sum_{d=-\ell}^{\infty} a_d s^{-d} \tag{6}$$

for some $\ell \in \mathbb{Z}$ and $a_{-\ell}, a_{-\ell+1}, \ldots \in F$. This skew field has the natural addition and multiplication. The rational function field $F(s)$ can be embedded in $F((s^{-1}))$ [6, Proposition 7.1]. Namely, any rational function $f \in F(s)$ can be uniquely expanded in form of (6). In particular, ℓ coincides with $\deg f$.

Let $A \in F(s)^{n \times n}$ be a square matrix over $F(s)$, called a *rational function matrix* over F. The degree of the Dieudonné determinant of A is well-defined since all commutators of $F(s)^\times$ have degree zero. Note that deg Det of singular matrices are $-\infty$. The following properties on deg Det are easily seen from (D1) and (D2).

(MV1) $\deg \operatorname{Det} AB = \deg \operatorname{Det} A + \deg \operatorname{Det} B$ for $A, B \in F(s)^{n \times n}$.

(MV2) $\deg \operatorname{Det} \begin{pmatrix} A & * \\ O & B \end{pmatrix} = \deg \operatorname{Det} \begin{pmatrix} A & O \\ * & B \end{pmatrix} = \deg \operatorname{Det}(A) + \deg \operatorname{Det}(B)$ for $A \in F(s)^{n \times n}$ and $B \in F(s)^{n' \times n'}$.

Recall the notation $d_k(A)$ in (2) for $A \in F(s)^{n \times n'}$. Note that $d_1(A)$ is the maximum degree of an entry in A, and we call $d_1(A)$ the *degree* of A. Similarly to (6), A can be uniquely expanded as

$$A = \sum_{d=-\ell}^{\infty} A_d s^{-d} \tag{7}$$

with $\ell = d_1(A)$ and some $A_{-\ell}, A_{-\ell+1}, \ldots \in F(s)^{n \times n'}$. The following proposition gives lower and upper bounds on $d_k(A)$.

► **Proposition 3.** *Let $A \in F(s)^{n \times n'}$ be a rational function matrix over a skew field F. For $k \in [0, n^*]$ with $n^* := \min\{n, n'\}$, the following hold:*

(1) *$d_k(As^\ell) = d_k(A) + \ell k$ for $\ell \in \mathbb{Z}$.*

(2) *$d_k(A) \leq \ell k$, where ℓ is the degree of A.*

(3) *$d_k(A) > -\infty$ if and only if $k \leq \operatorname{rank} A$. In addition, if A is a polynomial matrix, then $d_k(A) \geq 0$ for $k \leq \operatorname{rank} A$.*

Proof. (1) follows from the fact that for any $k \times k$ submatrix $A[I, J]$ of A, it holds

$$\begin{aligned} \deg \operatorname{Det} A[I, J] s^\ell &= \deg \operatorname{Det}(A[I, J] \cdot s^\ell I_k) \\ &= \deg \operatorname{Det} A[I, J] + \deg \det s^\ell I_k \\ &= \deg \operatorname{Det} A[I, J] + \ell k. \end{aligned}$$

(2) Let $\alpha_1, \ldots, \alpha_k$ be the exponents of the Smith–McMillan form of a nonsingular $k \times k$ submatrix $A[I, J]$ of A. Then the claim follows from $\deg \operatorname{Det} A[I, J] = \alpha_1 + \cdots + \alpha_k$ and $\ell \geq \alpha_1 \geq \cdots \geq \alpha_k$.

(3) The former part is obtained from the fact that rank A is equal to the maximum size of a nonsingular submatrix of A. The latter part can be proved using the *Smith normal form*, see e.g. [18, Lemma 2.11]. ◄

A rational function matrix is said to be *proper* if its degree is nonpositive. A square rational function matrix is said to be *biproper* if it is proper and nonsingular, and its inverse is also proper. We abbreviate proper and biproper rational function matrices as proper and biproper matrices, respectively. It is easy to see that the product of proper matrices are proper, which implies that the product of biproper matrices are biproper again. Equivalent conditions for proper matrices to be biproper are established as follows.

▶ **Lemma 4** ([18, Lemma 2.10])**.** *Let $A \in F(s)^{n\times n}$ be a square proper matrix over a skew field F. Then the following are equivalent:*

(1) *A is biproper.*

(2) $\deg \operatorname{Det} A = 0$.

(3) *The coefficient matrix A_0 of s^0 in the expansion* (7) *of A is nonsingular.*

A *biproper transformation* is a transformation of a rational function matrix $A \in F(s)^{n\times n'}$ in the form $A \mapsto SAT$, where $S \in F(s)^{n\times n}$ and $T \in F(s)^{n'\times n'}$ are biproper matrices. Under biproper transformations, we can establish a canonical form of rational function matrices, called the *Smith–McMillan form*. This is well-known for complex rational function matrices as the *Smith–McMillan form at infinity* [31, 37] in the context of control theory.

▶ **Proposition 5** (Smith–McMillan form)**.** *Let $A \in F(s)^{n\times n'}$ be a rational function matrix of rank r over a skew field F. There exist biproper matrices $S \in F(s)^{n\times n}$, $T \in F(s)^{n'\times n'}$ and integers $\alpha_1 \ge \alpha_2 \ge \cdots \ge \alpha_r$ such that*

$$SAT = \begin{pmatrix} \operatorname{diag}(s^{\alpha_1}, \ldots, s^{\alpha_r}) & O \\ O & O \end{pmatrix}.$$

The integer α_i is uniquely determined by

$$\alpha_i = d_i(A) - d_{i-1}(A) \tag{8}$$

for $i \in [r]$. In particular, $d_k(A)$ is invariant under biproper transformations for $k \in [0, r]$.

Proof. The proof is the same as that for nonsingular $A \in F(s)^{n\times n}$ in [18, Proposition 2.9], which iteratively determines α_i from $i = 1$ to n, except that the iterations stops when $i = r$. ◀

Solving (8) for $d_k(A)$, we obtain

$$d_k(A) = \sum_{i=1}^{k} \alpha_i \tag{9}$$

for $k \in [0, r]$. This is a key identity that connects $d_k(A)$ and the Smith–McMillan form of A. It is worth mentioning that all α_i are nonpositive for a proper matrix A since α_1 is equal to the degree $d_1(A)$ of A by (8).

3 Computing the Degree of Dieudonné Determinant

Let $A = \sum_{d=0}^{\ell} A_{\ell-d} s^d \in F[s]^{n\times n'}$ be a polynomial matrix over a skew field F; we typically consider an (nc-)linear polynomial matrix with $F \coloneqq K(x_1, \ldots, x_m)$ or $K\lbrace\!\!\lbrace x_1, \ldots, x_m \rbrace\!\!\rbrace$. In this section, we give reductions of computing $d_k(A)$ and $\operatorname{rank} A$ to rank computations over F. Instead of A, we deal with a proper matrix obtained from A by

$$As^{-\ell} = \sum_{d=0}^{\ell} A_d s^{-d} \in F(s)^{n\times n'}. \tag{10}$$

The value of $d_k(A)$ can be recovered from that of (10) through Proposition 3 (1).

Section 3.1 introduces *matrix expansion* which is our key tool. Section 3.2 connects the sequence of d_k to the rank of expanded matrices via the *Legendre conjugacy*. Making use of them, we give reductions and algorithms in Section 3.3, which proves Theorem 1.

3.1 Matrix Expansion

For a proper matrix $A \in F(s)^{n \times n'}$ and $\mu \in \mathbb{N}$, we define the *μth-order expanded matrix* $\Omega_\mu(A)$ of A as the following $\mu n \times \mu n'$ block matrix

$$\Omega_\mu(A) \coloneqq \begin{pmatrix} A_0 & A_1 & A_2 & \cdots & \cdots & A_{\mu-1} \\ O & A_0 & A_1 & A_2 & & \vdots \\ \vdots & O & A_0 & A_1 & \ddots & \vdots \\ \vdots & & \ddots & \ddots & \ddots & A_2 \\ \vdots & & & \ddots & A_0 & A_1 \\ O & \cdots & \cdots & \cdots & O & A_0 \end{pmatrix} \in F^{\mu n \times \mu n'},$$

where $A_0, \ldots, A_{\mu-1} \in F^{n \times n'}$ are matrices in the expansion (7) of A. Note that $\Omega_\mu(A)$ is an (nc-)linear matrix over K. Expanded matrices satisfy the multiplicativity (5).

▶ **Lemma 6.** *Let $A \in F(s)^{n \times n'}$ and $B \in F(s)^{n' \times n''}$ be proper matrices over a skew field F. Then it holds* (5) *for any $\mu \in \mathbb{N}$.*

Proof. Expand A and B by (7) as $A = \sum_{d=0}^{\infty} A_d s^{-d}$ and $B = \sum_{d=0}^{\infty} B_d s^{-d}$. By

$$AB = \left(\sum_{d=0}^{\infty} A_d s^{-d}\right)\left(\sum_{d=0}^{\infty} B_d s^{-d}\right) = \sum_{d=0}^{\infty} A_d \left(\sum_{j=0}^{d} B_{d-j} s^{-j}\right) = \sum_{j=0}^{\infty}\left(\sum_{d=0}^{j} A_d B_{d-j}\right) s^{-j},$$

the (i, j)th block in $\Omega_\mu(AB)$ is $\sum_{d=0}^{j-i} A_d B_{d-j}$ if $i \leq j$ and O otherwise. This coincides with the (i, j)th block in $\Omega_\mu(A)\Omega_\mu(B)$. ◀

Let $\omega_\mu(A)$ denote the rank of $\Omega_\mu(A)$. The following lemma claims that $\omega_\mu(A)$ coincides with that of the Smith–McMillan form of A.

▶ **Lemma 7.** *Let $A \in F(s)^{n \times n'}$ be a proper matrix over a skew field F. Then it holds $\omega_\mu(A) = \omega_\mu(D)$ for $\mu \in \mathbb{N}$, where D is the Smith–McMillan form of A.*

Proof. Let $S \in F(s)^{n \times n}$ and $T \in F(s)^{n' \times n'}$ be biproper matrices such that $SAT = D$. From Lemma 6, we have $\omega_\mu(D) = \operatorname{rank} \Omega_\mu(SAT) = \operatorname{rank} \Omega_\mu(S)\Omega_\mu(A)\Omega_\mu(T)$. Let S_0 and T_0 be the coefficient matrices of s^0 in the expansion (7) of S and T, respectively. Since S_0 and T_0 are nonsingular by Lemma 4,the block matrices $\Omega_\mu(S)$ and $\Omega_\mu(T)$ are also nonsingular. Therefore we have $\omega_\mu(D) = \omega_\mu(A)$. ◀

Let $0 \geq \alpha_1 \geq \cdots \geq \alpha_r$ be the exponents of the Smith–McMillan form of A with $r \coloneqq \operatorname{rank} A$. Put

$$N_d \coloneqq |\{i \in [r] \mid -\alpha_i \leq d\}| \tag{11}$$

for $d \in \mathbb{N}$. Lemma 7 leads us to the following lemma; a similar result based on the Kronecker canonical form is also known for matrix pencils over a field [21, Theorem 2.3].

▶ **Lemma 8.** *Let $A \in F(s)^{n \times n'}$ be a proper matrix over a skew field F. For $\mu \in \mathbb{N}$, it holds*

$$\omega_\mu(A) = \sum_{d=0}^{\mu-1} N_d, \tag{12}$$

where N_d is defined in (11)*.*

Proof. Let $D = \sum_{d=0}^{\infty} D_d s^{-d}$ be the Smith–McMillan form of A and $\alpha_1, \dots, \alpha_r$ the exponents of diagonal entries of D, where $r := \operatorname{rank} A$. The ith diagonal entry of D_d is 1 if $i \leq r$ and $\alpha_i = -d$, and 0 otherwise. Thus each row and column in $\Omega_\mu(D)$ has at most one nonzero entry. Hence $\omega_\mu(D)$, which is equal to $\omega_\mu(A)$ by Lemma 7, is equal to the number of nonzero entries in $\Omega_\mu(D)$. It is easily checked that the $(\mu - d)$th block row of $\Omega_\mu(D)$ contains N_d nonzero entries for $d = 0, \dots, \mu - 1$. ◀

The equality (12) is a key identity that connects $\omega_\mu(A)$ and the Smith–McMillan form of A. We remark that, for $d \in \mathbb{N}$, the equality (12) can be rewritten as

$$N_d = \omega_{d+1}(A) - \omega_d(A). \tag{13}$$

3.2 Legendre Conjugacy of $d_k(A)$ and $\omega_\mu(A)$

Let $A \in F(s)^{n \times n'}$ be a proper matrix of rank r and $\alpha_1 \geq \dots \geq \alpha_r$ the exponents of the Smith–McMillan form of A. Put $d_k := d_k(A)$ for $k = 0, \dots, r$. From $\alpha_k \geq \alpha_{k+1}$ and (8), the inequality $d_{k-1} + d_{k+1} \leq 2d_k$ holds for all $k \in [r-1]$. In addition, for $\mu \in \mathbb{N}$, put $\omega_\mu := \omega_\mu(A)$ and define N_μ by (11). From $N_{\mu-1} \leq N_\mu$ and (13), we have $\omega_{\mu-1} + \omega_{\mu+1} \geq 2\omega_\mu$ for all $\mu \geq 1$. These two inequalities for d_k and ω_μ indicate the *concavity* of d_k and the *convexity* of ω_μ in the following sense.

A (discrete) function $f \colon \mathbb{Z} \to \mathbb{Z} \cup \{+\infty\}$ is said to be *convex* if

$$f(x-1) + f(x+1) \geq 2f(x)$$

for all $x \in \mathbb{Z}$. We call a function $g \colon \mathbb{Z} \to \mathbb{Z} \cup \{-\infty\}$ *concave* if $-g$ is convex. An integer sequence $(a_k)_{k \in K}$ indexed by $K \subseteq \mathbb{Z}$ can be identified with a function $\check{a} \colon \mathbb{Z} \to \mathbb{Z} \cup \{+\infty\}$ by letting $\check{a}(k)$ be a_k if $k \in K$ and $+\infty$ otherwise. We can also identify a with $\hat{a} \colon \mathbb{Z} \to \mathbb{Z} \cup \{-\infty\}$ defined by $\hat{a}(k) := a_k$ if $k \in K$ and $\hat{a}(k) := -\infty$ otherwise. In this way, we identify integer sequences $(d_0, d_1, \dots, d_r)$ and $(\omega_0, \omega_1, \omega_2, \dots)$ with discrete functions $\check{d} \colon \mathbb{Z} \to \mathbb{Z} \cup \{-\infty\}$ and $\hat{\omega} \colon \mathbb{Z} \to \mathbb{Z} \cup \{+\infty\}$, respectively. From the argument in the previous paragraph, $(d_0, d_1, \dots, d_r)$ is concave and $(\omega_0, \omega_1, \omega_2, \dots)$ is convex.

Let $f \colon \mathbb{Z} \to \mathbb{Z} \cup \{+\infty\}$ be a function such that $f(x) \in \mathbb{Z}$ for some $x \in \mathbb{Z}$. The *concave conjugate* of f is a function $f^\circ \colon \mathbb{Z} \to \mathbb{Z} \cup \{-\infty\}$ defined by

$$f^\circ(y) := \inf_{x \in \mathbb{Z}} (f(x) - xy)$$

for $y \in \mathbb{Z}$. Similarly, for a function $g \colon \mathbb{Z} \to \mathbb{Z} \cup \{-\infty\}$ with $g(y) \in \mathbb{Z}$ for some $y \in \mathbb{Z}$, the *convex conjugate* of g is a function $g^\bullet \colon \mathbb{Z} \to \mathbb{Z} \cup \{+\infty\}$ given by

$$g^\bullet(x) := \sup_{y \in \mathbb{Z}} (g(y) + xy)$$

for $x \in \mathbb{Z}$. The maps $f \mapsto f^\circ$ and $g \mapsto g^\bullet$ are referred to as the *concave* and *convex discrete Legendre transform*, respectively. In general, f° is concave and $g^\bullet$ is convex. In addition, if f is convex and g is concave,

$$(f^\circ)^\bullet = f, \quad (g^\bullet)^\circ = g \tag{14}$$

hold. Hence the Legendre transformation establishes a one-to-one correspondence between discrete convex and concave functions. See [32] for details of discrete convex/concave functions and their Legendre transform.

Indeed, as explained in Section 1, the sequences of d_k and ω_μ are in the relation of Legendre conjugate. This can be shown from the key identities (9) and (12) that connect $d_k(A)$ and $\omega_\mu(A)$ through the Smith–McMillan form of A.

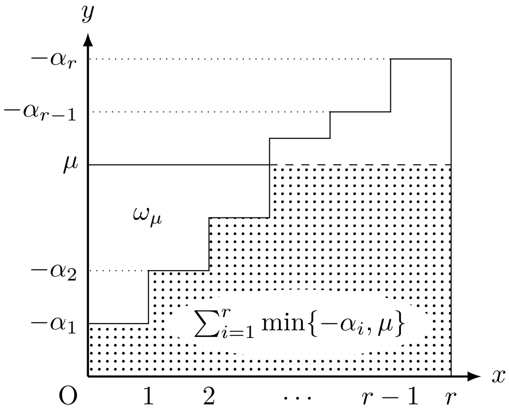

Figure 1 Graphic explanation of (15).

▶ **Theorem 9.** *Let $A \in F(s)^{n\times n'}$ be a proper matrix of rank r over a skew field F. Then* (3) *and* (4) *hold.*

Proof. Put $d_k := d_k(A)$ for $k = 0,\dots,r$ and $\omega_\mu := \omega_\mu(A)$ for $\mu \in \mathbb{N}$. Since $(d_0, d_1, \dots, d_r)$ is concave and $(\omega_0, \omega_1, \omega_2, \dots)$ is convex, (3) and (4) are equivalent by (14). We show (4).

First we give an equality

$$\omega_\mu = r\mu - \sum_{i=1}^{r}\min\{-\alpha_i,\mu\} \tag{15}$$

for $\mu \in \mathbb{N}$, where $\alpha_1 \geq \dots \geq \alpha_r$ are the exponents of the Smith–McMillan form of A. Figure 1 graphically shows this equality. Let x and y be the coordinates along the horizontal and vertical axes in Figure 1, respectively. For $i = 1,\dots,r$, the height of the dotted rectangle with $i-1 \leq x < i$ is $\min\{-\alpha_i,\mu\}$. Hence the area of the dotted region is equal to $\sum_{i=1}^{r}\min\{-\alpha_i,\mu\}$. In addition, the width of the white rectangle with $d \leq y < d+1$ is equal to N_d for $d = 0,\dots,\mu-1$, where N_d is defined by (11). Hence the area of the white stepped region is equal to $N_0 + \cdots + N_{\mu-1} = \omega_\mu$ by (12). Now we have (15) since the sum of the areas of these two regions is $r\mu$.

Substituting (9) into the right hand side of (4), we have

$$\max_{0\leq k\leq r}(d_k + k\mu) = \max_{0\leq k\leq r}\sum_{i=1}^{k}(\alpha_i+\mu) = \sum_{i=1}^{k^*}\alpha_i + k^*\mu, \tag{16}$$

where k^* is the maximum $0 \leq k \leq r$ such that $\alpha_k + \mu \geq 0$. Since $\min\{-\alpha_i,\mu\}$ is $-\alpha_i$ if $i \leq k^*$ and is μ if $i > k^*$, it holds

$$\sum_{i=1}^{r}\min\{-\alpha_i,\mu\} = -\sum_{i=1}^{k^*}\alpha_i + (r-k^*)\mu. \tag{17}$$

From (16) and (17), we have

$$\max_{0\leq k\leq r}(d_k + k\mu) = r\mu - \sum_{i=1}^{r}\min\{-\alpha_i,\mu\},$$

in which the right hand side is equal to ω_μ by (15). ◀

3.3 Reductions and Algorithms

Let $A = A_0 + A_1 s^{-1} + \cdots + A_\ell s^{-\ell} \in F(s)^{n \times n'}$ be the proper matrix (10) of rank r. The expression (15) of $d_k(A)$ indicates that $d_k(A)$ is equal to the optimal value of an minimization problem with objective function

$$f_k(\mu) \coloneqq \omega_\mu(A) - k\mu. \tag{18}$$

Since f_k is convex, it is minimized by the minimum μ such that $f_k(\mu+1) - f_k(\mu) \geq 0$. This can be found by the binary search in $\mathrm{O}(\log M)$ evaluations of f_k, where M is an upper bound on a minimizer of f_k. The following lemma claims that we can adopt ℓr as the upper bound.

▶ **Lemma 10.** *Let $A = \sum_{d=0}^{\ell} A_d s^{-d} \in F(s)^{n \times n'}$ be the proper matrix* (10) *of rank r. Then the following hold:*

(1) *The exponents $\alpha_1, \ldots, \alpha_r$ of the Smith–McMillan form of A are at least $-\ell r$.*

(2) *For $k \in [0, r]$, the function f_k in* (18) *has a minimizer μ^* satisfying $0 \leq \mu^* \leq \ell r$.*

Proof. The claims are trivial if $r = 0$. Suppose $r \geq 1$.

(1) It suffices to show $\alpha_r \geq -\ell r$. Since A is proper, $d_{r-1}(A)$ is nonpositive. In addition, since As^ℓ is a polynomial matrix of rank r, we have $0 \leq d_r(As^\ell) = d_r(A) + \ell r$ by Proposition 3 (1) and (3). Thus $\alpha_r = d_r(A) - d_{r-1}(A) \geq -\ell r$ holds.

(2) From Lemma 8, the objective function f_k can be written as

$$f_k(\mu) = \sum_{d=0}^{\mu-1} (N_d - k)$$

for $\mu \in \mathbb{N}$. Hence f_k is minimized by the maximum $\mu \in \mathbb{N}$ such that $N_\mu + k < 0$. Note that such μ exists since f_k has the minimum value. From the definition (11) of N_d, it holds $N_d = N_{-\alpha_r}$ for all $d \geq -\alpha_r$. Hence f_k has a minimizer less than or equal to $-\alpha_r$, which is at most ℓr by (1). ◀

Finally, we show direct formulas of rank A and $d_r(A)$ for a proper matrix A in (10). These formulas naturally yield efficient algorithms to compute them, which proves Theorem 1.

▶ **Lemma 11.** *Let $A = \sum_{d=0}^{\ell} A_d s^{-d} \in F(s)^{n \times n'}$ be the proper matrix* (10) *of rank r. Then it holds $r = \omega_{ln^*+1}(A) - \omega_{ln^*}(A)$ and $d_r(A) = \omega_{lr}(A) - lr^2$, where $n^* \coloneqq \min\{n, n'\}$.*

Proof. We first show the formula on r. We have $\omega_{\ell n^*+1}(A) - \omega_{\ell n^*}(A) = N_{\ell n^*}$ by (13). Since $-\alpha_i$ is at most $\ell r \leq \ell n^*$ for all $i \in [r]$ by Lemma 10 (1), we have $r = N_{\ell n^*}$.

Next we show the formula on $d_r(A)$. From (3) and (12), it holds

$$d_r(A) = \min_{\mu \geq 0} \sum_{d=0}^{\mu-1} (N_d - r). \tag{19}$$

Since $N_0 \leq N_1 \leq \cdots \leq N_{\ell r} = N_{\ell r+1} = \cdots = r$ by Lemma 10 (1), the minimum value of the right hand side of (19) is attained by $\mu = \ell r$. Thus we are done. ◀

▶ Remark 12. In view of combinatorial optimization, our algorithms are regarded as pseudo-polynomial time algorithms since the running time depends on a polynomial of the maximum exponent ℓ of s instead of $\mathrm{poly}(\log \ell)$. Thus it is natural to try to solve the following problem:

Sparse Degree of Determinant (SDD)

Input : $A = A_1 s^{w_1} + \cdots + A_m s^{w_m} \in K[s]^{n \times n}$, where $0 \leq w_1 \leq \ldots \leq w_m$ are integers.

Output: $\deg \det A$.

However, setting $w_k := (n+1)^k$ for $k \in [m]$ would make the rank of A the same as that of a linear matrix $A_1x_1 + \cdots + A_mx_m \in K[x_1, \ldots, x_m]^{n \times n}$ (known as the *Kronecker substitution* [24]). Since giving a deterministic polynomial-time algorithm for Edmonds' problem has still been open for more than half a century, SDD is also a quite challenging problem.

4 Computing the Degree of Quasideterminants

The *quasideterminant* [12, 13] is another noncommutative analogy of the determinant than the Dieudonné determinant. Let $A \in F^{n \times n}$ be a square matrix over a skew field F. Fix $i, j \in [n]$ and put $I := [n] \setminus \{i\}$, $J := [n] \setminus \{j\}$. The (i,j)th *quasideterminant* $|A|_{i,j}$ of A is defined if $A[I, J]$ nonsingular as

$$|A|_{i,j} := A[\{i\}, \{j\}] - A[I, \{j\}]A[I, J]^{-1}A[\{i\}, J] \in F.$$

Analogous to the usual determinant, A is nonsingular if and only if at least one quasideterminant of A is defined and nonzero [12, Proposition 1.4.6]. When A is nonsingular, $|A|_{i,j}$ is defined if and only if the (i,j)th entry a of A^{-1} is nonzero, and if this is the case, $|A|_{i,j} = a^{-1}$ holds.

Through the Dieudonné determinant, we can compute the degree of a quasideterminant of rational function matrices without computing the quasideterminant.

▶ **Proposition 13.** *Let $A \in F(s)^{n \times n}$ be a square rational function matrix over a skew field F. Then for $i, j \in [n]$ with $S := A[[n] \setminus \{i\}, [n] \setminus \{j\}]$ being nonsingular, it holds*

$$\deg |A|_{i,j} = \deg \operatorname{Det} A - \deg \operatorname{Det} S.$$

Proof. We assume $i = j = 1$ without loss of generality. Express A as

$$A = \begin{pmatrix} a & r \\ c & S \end{pmatrix},$$

where $a \in F(s), r \in F(s)^{1 \times (n-1)}$ and $c \in F(s)^{(n-1) \times 1}$. By elementary row and column operations, it holds

$$A = \begin{pmatrix} a & r \\ c & S \end{pmatrix} = \begin{pmatrix} 1 & rS^{-1} \\ 0 & I_{n-1} \end{pmatrix} \begin{pmatrix} |A|_{i,j} & 0 \\ 0 & S \end{pmatrix} \begin{pmatrix} 1 & 0 \\ S^{-1}c & I_{n-1} \end{pmatrix},$$

where we used $|A|_{i,j} = a - rS^{-1}c$. Hence $\deg \operatorname{Det} A = \deg |A|_{i,j} + \deg \operatorname{Det} S$, as required. ◀

Proposition 13 can be applied to the problem of computing the degree of a *noncommutative rational function* (nc-rational function) expressed by a *noncommutative formula* (nc-formula). Let K be a field and consider pairwise noncommutative symbols $x_1, \ldots, x_m$. An *nc-rational function* is an element of the free skew field $K\langle\!(x_1, \ldots, x_m)\!\rangle$. An *nc-formula* (with division) Φ is a binary tree, whose every leaf is labeled with an element of $\{x_1, \ldots, x_m\} \cup K$ and every non-leaf node is labeled with "+", "×" or "÷". Each node computes an nc-rational function in the obvious way, and the output of Φ is the rational function computed by the root. The *size* of Φ is the number of nodes.

Cohn [5] showed that for an nc-formula of size r computing f, we can construct a nonsingular $n \times n$ nc-linear matrix B with $n = \operatorname{poly}(r)$ such that the top-left entry of B^{-1} is f. In addition, the top-left entry of B^{-1} is nonzero if and only if the submatrix of B

without the first row and column is nonsingular as mentioned above. Therefore, as indicated by Hrubeš–Wigderson [19], the problem of checking if an nc-formula represents zero can be reduced to nc-Edmonds' problem.

We can consider a weighted analog of this reduction. Unlike the commutative case, an nc-rational function $f \in K\{\!\!\{x_1, \ldots, x_m\}\!\!\}$ cannot always be expressed as the ratio of two noncommutative polynomials. Nevertheless, we can define the (total) degree of f as the degree (in s) of the rational function $g \in K\{\!\!\{x_1, \ldots, x_m\}\!\!\}(s)$ obtained by replacing each x_i with $x_i s$. Then given an nc-formula computing f, we construct an nc-linear polynomial matrix A such that $|A|_{1,1} = f^{-1}$ and reduce the degree computation of f to nc-WEP using Proposition 13. By Theorem 2, we have:

▶ **Theorem 14.** *We can deterministically compute the degree of the nc-rational function represented by an nc-formula of size r over a field K in* poly(r) *arithmetic operations on K. If $K = \mathbb{Q}$, the bit-lengths of intermediate numbers are polynomially bounded.*

Abstract

We study the stabilization time of a wide class of processes on graphs, in which each node can only switch its state if it is motivated to do so by at least a $\frac{1+\lambda}{2}$ fraction of its neighbors, for some $0 < \lambda < 1$. Two examples of such processes are well-studied dynamically changing colorings in graphs: in majority processes, nodes switch to the most frequent color in their neighborhood, while in minority processes, nodes switch to the least frequent color in their neighborhood. We describe a non-elementary function $f(\lambda)$, and we show that in the sequential model, the worst-case stabilization time of these processes can completely be characterized by $f(\lambda)$. More precisely, we prove that for any $\epsilon > 0$, $O(n^{1+f(\lambda)+\epsilon})$ is an upper bound on the stabilization time of any proportional majority/minority process, and we also show that there are graph constructions where stabilization indeed takes $\Omega(n^{1+f(\lambda)-\epsilon})$ steps.

1 Introduction

Many natural phenomena can be modeled by graph processes, where each node of the graph is in a state (represented by a color), and each node can change its state based on the states of its neighbors. Such processes have been studied since the dawn of computer science, by, e.g., von Neumann, Ulam, and Conway. Among the numerous applications of these graph processes, the most eminent ones today are possibly neural networks, both biological and artificial.

Two fundamental graph processes are majority and minority processes. In a *majority process*, each node wants to switch to the most frequent color in its neighborhood. Such a process is a straightforward model of influence spreading in networks, and as such, it has various applications in social science, political science, economics, and many more [29, 9, 12, 18, 23].

In contrast, in a *minority process*, each node wants to switch to the least frequent color in its neighborhood. Minority processes are used to model scenarios where the nodes are motivated to anti-coordinate with each other, like frequency selection in wireless communication, or differentiating from rival companies in economics [24, 6, 7, 11, 8].

Majority and minority processes have been studied in several different models, the most popular being the synchronous model (where in each step, all nodes can switch simultaneously) and the sequential model (where in each step, exactly one node switches). Since in many application areas, it is unrealistic to assume that nodes switch at the exact same time, we focus on the sequential model in this paper. We are interested in the worst-case stabilization time of such processes, i.e. the maximal number of steps until no node wants to change its color anymore.

Our main parameter describes how easily nodes will switch their color. Previously, the processes have mostly been studied under the basic switching rule, when nodes are willing switch their color for any small improvement. However, it is often more reasonable to assume a *proportional switching rule*, i.e. that nodes only switch their color if they are motivated by at least, say, 70% of their neighbors to do so. In general, we describe such proportional processes by a parameter $\lambda \in (0, 1)$, and say that a node is switchable if it is in conflict with a $\frac{1+\lambda}{2}$ portion of its neighborhood. The stabilization time in such proportional processes (possibly as a function of λ) has so far remained unresolved.

The reason we can analyze proportional majority and minority processes together is that both can be viewed as a special case of a more general process of propagating conflicts through a network, where the cost of relaying conflicts through a node is proportional to the degree of the node. This more general process could also be used to model the propagation of information, energy, or some other entity through a network. This suggests that our results might also be useful for gaining insights into different processes in a wide range of other application areas, e.g. the behavior of neural networks.

In the paper, we provide a tight characterization of the maximal possible stabilization time of proportional majority and minority processes. We show that for maximal stabilization, a critical parameter is the portion φ of the neighborhood that nodes use as "outputs", i.e. neighbors they propagate conflicts to. Based on this, we prove that the stabilization time of proportional processes follows a transition between quadratic and linear time, described by the non-elementary function

$$f(\lambda) := \max_{\varphi \in (0, \frac{1-\lambda}{2}]} \frac{\log\left(\frac{1-\varphi}{\lambda+\varphi}\right)}{\log\left(\frac{1-\varphi}{\varphi}\right)}. \tag{1}$$

More specifically, for any $\epsilon > 0$, we show that on the one hand, $O(n^{1+f(\lambda)+\epsilon})$ is an upper bound on the number of steps of any majority/minority process, and on the other hand, there indeed exists a graph construction where the processes last for $\Omega(n^{1+f(\lambda)-\epsilon})$ steps.

2 Related Work

Various aspects of both majority and minority processes on two colors have been studied extensively. This includes basic properties of the processes [17, 36], sets of critical nodes that dominate the process [12, 15, 20], complexity and approximability results [21, 3, 10], threshold behavior in random graphs [14, 26], and the analysis of stable states in the process [16, 33, 4, 5, 34, 24]. Modified process variants have also been studied [35, 25], with numerous generalizations aiming to provide a more realistic model for social networks [2, 1].

However, the question of stabilization time in the processes has almost exclusively been studied for the basic switching rule (defined in Section 3.2). Even for the basic rule, apart from a straightforward $O(n^2)$ upper bound, the question has remained open for a long time in case of both processes. It has recently been shown in [13] and [27] that both processes can exhibit almost-quadratic stabilization time in case of basic switching, both in the sequential adversarial and in the synchronous model. On the other hand, the maximal stabilization time under proportional switching has remained open so far.

It has also been shown that if the order of nodes is chosen by a benevolent player, then the behavior of the two processes differs significantly, with the worst-case stabilization time being $O(n)$ for majority processes [13] and almost-quadratic for minority processes [27]. In weighted graphs, where the only available upper bound on stabilization time is exponential, it has been shown that both majority and minority can indeed last for an exponential number of steps in various models [22, 28]. The result of [28] is the only one to also study the proportional switching rule, showing that the exponential lower bound also holds in this case; however, since the paper studies weighted graphs with arbitrarily high weights, this model differs significantly from our unweighted setting.

Stabilization time has also been examined in several special cases, mostly assuming the synchronous model. The stabilization of a slightly different minority process variant (based on closed neighborhoods) has been studied in special classes of graphs including grids, trees and cycles [30, 31, 32]. The work of [19] describes slightly modified versions of minority processes which may take $O(n^5)$ or $O(n^6)$ steps to stabilize, but provide better local minima (stable states) upon termination. For majority processes, stabilization has mostly been studied from a random initial coloring, on special classes of graphs such as grids, tori and expanders [14, 26].

Various aspects of majority processes have also been studied under the proportional switching rule, including sets of critical nodes that dominate the process, and sets of nodes that always preserve a specific color [38, 37]. However, to our knowledge, the stabilization time of the processes with proportional switching has not been studied before.

3 Model and Notation

3.1 Preliminaries

We define our processes on simple, unweighted, undirected graphs $G(V, E)$, with V denoting the set of nodes and E the set of edges. We denote the number of nodes by $n = |V|$. The neighborhood of v is denoted by $N(v)$, the degree of v by $\deg(v) = |N(v)|$.

We also use simple directed graphs in our proofs. A directed graph is called a DAG if it contains no directed cycles. A *dipartitioning* of a DAG is a disjoint partitioning (V_1, V_2) of V such that each source node is in V_1, and all edges between V_1 and V_2 all go from V_1 to V_2. We refer to the set of edges from V_1 to V_2 as a *dicut*.

Given an undirected graph G with edge set E, we also define the *directed edge set* of G as $\widehat{E} = \{(u, v), (v, u) \,|\, (u, v) \in E\}$, i.e. the set of directed edges obtained by taking each edge with both possible orientations.

A *coloring* is a function $\gamma : V \to \{\text{black}, \text{white}\}$. A *state* is a current coloring of G. Under a given coloring, we define $N_s(v) = \{u \in N(v) | \gamma(v) = \gamma(u)\}$ and $N_o(v) = \{u \in N(v) | \gamma(v) \neq \gamma(u)\}$ as the same-color and opposite-color neighborhood of v, respectively.

We say that there is a *conflict* on edge (u, v), or that (u, v) is a *conflicting edge*, if $u \in N_o(v)$ in case of a majority process, and if $u \in N_s(v)$ in case of a minority process. In general, we denote the conflict neighborhood by $N_c(v)$, meaning $N_c(v) = N_o(v)$ and $N_c(v) = N_s(v)$ in case of majority and minority processes, respectively. We occasionally also use $N_{\neg c}(v) = N(v) \setminus N_c(v)$.

If a node v has more conflicts than a predefined threshold (depending on the so-called *switching rule* in the model, discussed later) in the current state, then v is *switchable*. Switching v changes its color to the opposite color. If edge (u, v) becomes (ceases to be) a conflicting edge when node v switches, then we say that v has *created* this conflict (*removed* this conflict, respectively).

A *majority/minority process* is a sequence of steps (states), where each state is obtained from the previous state by a set of switchable nodes switching. In this paper, we examine sequential processes, when in each step, exactly one node switches. Such a process is *stable* when there are no more switchable nodes in the graph. By *stabilization time*, we mean the number of steps until a stable state is reached.

3.2 Model and switching rule

We study the worst-case stabilization time of majority/minority processes, that is, the maximal number of steps achievable on any graph, from any initial coloring. In other words, we assume the *sequential adversarial model*, when the order of nodes (i.e., the next switchable node to switch in each time step) is chosen by an adversary who maximizes stabilization time.

It only remains to specify the condition that allows a node to switch its color. The most straightforward switching rule is the following:

▶ **Rule I** (Basic Switching). *Node v is switchable if* $|N_c(v)| - |N_{\neg c}(v)| > 0$.

An equivalent form of this rule is $|N_c(v)| > \frac{1}{2} \cdot \deg(v)$. This rule is shown to allow up to $\widetilde{\Theta}(n^2)$ stabilization time for both majority [13] and minority [27] processes. However, it is often more realistic to assume a proportional switching rule, based on a real parameter $\lambda \in (0, 1)$:

▶ **Rule II** (Proportional Switching). *Node v is switchable if* $|N_c(v)| - |N_{\neg c}(v)| \geq \lambda \cdot deg(v)$.

Since we have $|N_c(v)| + |N_{\neg c}(v)| = \deg(v)$, this is equivalent to saying that v is switchable exactly if $|N_c(v)| \geq \frac{1+\lambda}{2} \cdot \deg(v)$. In the limit when λ is infinitely small (or, equivalently, as $\frac{1+\lambda}{2}$ approaches $\frac{1}{2}$ from above), we obtain Rule I as a special case of Rule II.

In case of Rule I, whenever a node v switches, it is possible that the total number of conflicts in the graph decreases by 1 only. On the other hand, Rule II implies that the switching of v decreases the total number of conflicts at least by $\lambda \cdot \deg(v)$ (we say that v *wastes* these conflicts), so in case of Rule II, the total number of conflicts can decrease more rapidly, allowing only a smaller stabilization time. Our findings show that the maximal number of steps is different for every distinct λ.

3.3 On the $f(\lambda)$ function

While the processes have a symmetric definition on each edge by default, it turns out that in order to maximize stabilization time, each edge has to be used in an asymmetric way. The most important parameter at each node v is the ratio of neighbors v uses as "inputs" and as "outputs". That is, the optimal behavior for each node v is to select $\varphi \cdot \deg(v)$ of its neighbors as outputs (for some $\varphi \in (0, 1)$), and create all new conflicts on the edges leading to these output nodes, and similarly, mark the remaining $(1 - \varphi) \cdot \deg(v)$ neighbors as inputs, and only remove conflicts from the edges coming from these input nodes. Note that with Rule II, whenever a node switches, it can create at most $\left(1 - \frac{1+\lambda}{2}\right) \cdot \deg(v) = \frac{1-\lambda}{2} \cdot \deg(v)$ new conflicts, so it is reasonable to assume $\varphi \in \left(0, \frac{1-\lambda}{2}\right]$.

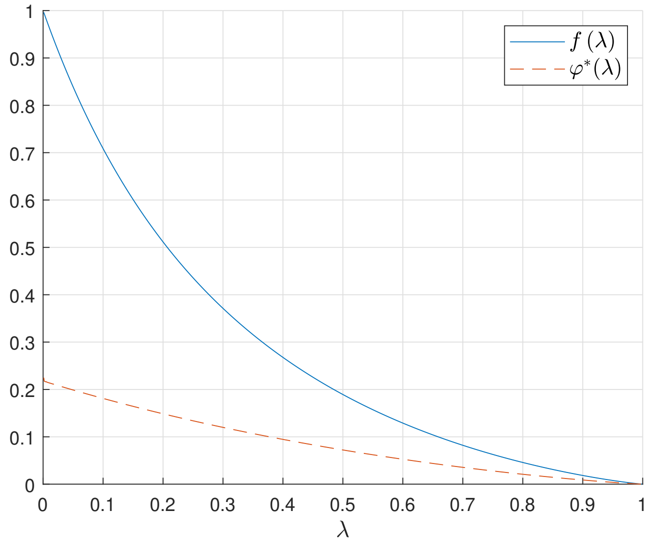

Figure 1 Plot of $f(\lambda)$ and $\varphi^*(\lambda)$ for $\lambda \in (0,1)$.

Our results show that if all nodes select φ as their output rate, then the maximal achievable stabilization time is a function of

$$\frac{\log\left(\frac{1-\varphi}{\lambda+\varphi}\right)}{\log\left(\frac{1-\varphi}{\varphi}\right)}. \tag{2}$$

As such, the largest stabilization time can be achieved by maximizing this expression by selecting the optimal φ value, as shown in the definition of f in Equation 1. We denote the optimal value of φ (i.e., the argmax of Equation 2) by φ^*. The function f has no straightforward closed form, as such a form would require solving

$$(\lambda+1)\cdot\varphi\cdot\log\left(\frac{1-\varphi}{\varphi}\right) = (\lambda+\varphi)\log\left(\frac{1-\varphi}{\lambda+\varphi}\right),$$

for φ, with λ as a parameter. We discuss f in more detail in the full version of the paper.

Figure 1 shows the values of f and φ^* as a function of λ. The figure shows that both $f(\lambda)$ and $\varphi^*(\lambda)$ are continuous, monotonically decreasing and convex.

It is visible that $\lim_{\lambda\to 0} f(\lambda) = 1$ and $\lim_{\lambda\to 1} f(\lambda) = 0$. This is in line with what we would expect: the simple switching rule allows a stabilization time up to $\widetilde{\Theta}(n^2)$ [13, 27], while even for any large $\lambda < 1$, it is still straightforward to present a graph with $\Omega(n)$ stabilization time. Our main result is showing that $f(\lambda)$ describes the continuous transition between these two extremes.

4 General intuition behind the proofs

Note that initially, each node v can have at most $\deg(v)$ conflicts on its incident edges, and each time when v switches, it wastes $\lambda \cdot \deg(v)$ conflicts. Therefore, if each node were to "use" its own initial conflicts only, then each node could switch at most $\frac{1}{\lambda}$ times, and stabilization time could never go above $O(n)$.

Instead, the idea is to take the high number of conflicts initially available at high-degree nodes, and use these conflicts to switch the less wasteful low-degree nodes many times. Specifically, we could have a set of $\Theta(n)$-degree nodes that initially have $\Omega(n^2)$ conflicts altogether on their incident edges, and somehow relay these conflicts to another set of $O(1)$-degree nodes, which only waste $O(1)$ conflicts at each switching. However, due to the large difference both in degree and in the number of switches, it is not possible to connect these two sets directly; instead, we need to do this through a range of intermediate levels, which exhibit decreasing degree and increasingly more switches. In order to maximize stabilization time, our main task is to move conflicts through these levels as efficiently (i.e., wasting as few conflicts in the process) as possible.

The formula of $f(\lambda)$ describes the efficiency of this process. The rate of inputs to outputs $\frac{1-\varphi}{\varphi}$ determines the factor by which the degree decreases at every new level. If φ is chosen small, then $\frac{1-\varphi}{\varphi}$ is high, so we only have a few levels until we reach constant degree, and hence the number of switches is increased only a few times. On the other hand, the increase in the number of switches per level is expressed by $\frac{1-\varphi}{\lambda+\varphi}$, which is a decreasing function of φ. If φ is too large, then although we execute this increase more times, each of these increases is significantly smaller.

With a degree decrease rate of $\frac{1-\varphi}{\varphi}$, we can altogether have about $\log_{\frac{1-\varphi}{\varphi}}(n)$ levels until the degree decreases from $\Theta(n)$ to $\Theta(1)$. If we increase the number of switches by a factor of $\frac{1-\varphi}{\lambda+\varphi}$ each time, then the $O(1)$-degree nodes will exhibit

$$\left(\frac{1-\varphi}{\lambda+\varphi}\right)^{\log_{\frac{1-\varphi}{\varphi}}(n)} = n^{\frac{\log\left(\frac{1-\varphi}{\lambda+\varphi}\right)}{\log\left(\frac{1-\varphi}{\varphi}\right)}} \leq n^{f(\lambda)} \tag{3}$$

switches, with an equation only if $\varphi = \varphi^*(\lambda)$. Having $\widetilde{\Theta}(n)$ nodes in the last level, this sums up to about $n^{1+f(\lambda)}$ switches altogether.

4.1 Conflict propagation systems

The upper bound on stabilization time is easiest to present in a general form that only focuses on this flow of conflicts in the graph. We define a simpler representation of the processes which only keeps a few necessary concepts to describe the flow of conflicts, and ignores e.g. the color of nodes or the timing of the switches at each node. In fact, we only require the number of times $s(v)$ each $v \in V$ switches, and the number $c(u, v)$ of conflicts that were created by node u and then removed by node v, for each $(u, v) \in \widehat{E}$.

For simplicity, given a function $c : \widehat{E} \to \mathbb{N}$, let us introduce the notation $c_{in}(v) := \sum_{u \in N(v)} c(u, v)$ and $c_{out}(v) := \sum_{u \in N(v)} c(v, u)$.

▶ **Definition 1** (Conflict Propagation System, CPS). *Given an undirected graph G, a conflict propagation system is an assignment $s : V \to \mathbb{N}$ and $c : \widehat{E} \to \mathbb{N}$ such that*

1. *for each $v \in V$, we have $c_{in}(v) + deg(v) \geq \lambda \cdot deg(v) \cdot s(v) + c_{out}(v)$,*
2. *for each $v \in V$, we have $c_{out}(v) \leq \frac{1-\lambda}{2} \cdot deg(v) \cdot s(v)$, and*
3. *for each $(u, v) \in \widehat{E}$, we have $c(u, v) \leq s(u)$.*

With the choice of $s(v)$ and $c(u, v)$ described above, any proportional majority or minority process indeed satisfies these properties, and thus provides a CPS. Hence if we upper bound the stabilization time (i.e. the total number of switches $\sum_{v \in V} s(v)$) of any CPS, this establishes the same bound on the stabilization time of any majority/minority process.

Condition 1 is the most complex of the three; it expresses the amount of "input conflicts" $c_{in}(v)$ required to switch v an $s(v)$ times altogether. Every time after v switches, it has at most $\frac{1-\lambda}{2} \cdot \deg(v)$ conflicts on the incident edges, so it needs to acquire $\lambda \cdot \deg(v)$ new conflicts to reach the threshold of $\frac{1+\lambda}{2} \cdot \deg(v)$ and be switchable again; this results in the

$\lambda \cdot \deg(v) \cdot s(v)$ term. Moreover, if in the meantime, the neighboring nodes remove some of the conflicts from the incident edges (expressed by $c_{out}(v)$), then this also has to be compensated for by extra input conflicts. Finally, the extra $\deg(v)$ term comes from the (at most) $\deg(v)$ conflicts that are already on the incident edges in the initial coloring. For a detailed discussion of this condition, see the full version of the paper.

Condition 2 also holds, since each time when v switches, it creates at most $\frac{1-\lambda}{2} \cdot \deg(v)$ conflicts on the incident edges. Each time u switches, it can only create one conflict on a specific edge, so condition 3 also follows. Hence any majority/minority process indeed provides a CPS.

Finally, we need a technical step to get rid of the extra $\deg(v)$ term in condition 1. Note that this term becomes asymptotically irrelevant as $s(v)$ grows; hence, our approach is to handle fewer-switching nodes separately, and require condition 1 only for nodes with large $s(v)$. More formally, we select a constant s_0, and we refer to nodes v with $s(v) < s_0$ as *base nodes*. We then consider *Relaxed CPSs*, where, given this extra parameter s_0, condition 1 is replaced by:

1R. *for each $v \in V$ with $s(v) \geq s_0$, we have $c_{in}(v) \geq \lambda \cdot deg(v) \cdot s(v) + c_{out}(v)$,*

This relaxation comes at the cost of an extra ϵ additive term in the exponent of our upper bound.

5 Upper bound proof

We now outline the proof of the upper bound on the number of switches. A more detailed discussion of this proof is available in the full version of the paper.

5.1 Properties of an optimal construction

We start by noting that since moving a conflict through a node is wasteful, it is suboptimal to have two neighboring nodes that both transfer a conflict to each other, or more generally, to move a conflict along any directed cycle. Therefore, in a CPS with maximal stabilization time, the conflicts are essentially moved along the edges of a DAG. To formalize this, given a CPS, let us say that a directed edge $(u, v) \in \widehat{E}$ is a *real edge* if $c(u, v) > 0$.

▶ **Lemma 2.** *There exists a CPS with maximal stabilization time where the real edges form a DAG.*

Proof. Among the CPSs on n nodes with maximal stabilization time, let us take the CPS P where the sum $\sum_{e \in \widehat{E}} c(e)$ is minimal. Assume that there is a directed cycle along the real edges of this CPS, and let $c(e_0)$ denote the minimal value of function c along this cycle.

Now consider the CPS P' where the value of c on each edge of this directed cycle is decreased by $c(e_0)$. Since in each affected node, the inputs and outputs have been decreased by the same value, P' still satisfies all three conditions, and thus it is also a valid CPS. Moreover, P' has the same amount of total switches as P. However, since $c(e_0) > 0$, the sum of $c(e)$ values in P' is less than in P, which contradicts the minimality of P. ◀

Hence for the upper bound proof, we can assume that the real edges of the CPS form a DAG. In the rest of the section, we focus on this DAG composed of the real edges of the CPS. We first show that for convenience, we can also assume that each base node is a source in this DAG.

▶ **Lemma 3.** *There exists a CPS with maximal stabilization time where each base node is a source node of the DAG.*

Proof. Note that by removing an input edge (u, v) of a base node v (that is, setting $c(u, v)$ to 0), the remaining CPS is still valid, since node v does not have to satisfy condition 1R, and in node u, only the sum of outputs was decreased. Therefore, we can remove all the input edges of each base node, and hence base nodes will all become source nodes of the DAG. ◀

▶ **Lemma 4.** *For each directed edge (u, v) in the DAG where u is a source node, $c(u, v) = O(1)$. More specifically, $c(u, v) \leq s_0$.*

Proof. If u is a base node, then $s(u) \leq s_0$, so $c(u, v) \leq s_0$ due to condition 3. Otherwise, condition 1R must hold, and since u has no input nodes, we get $0 \geq c_{out}(u) + \lambda \cdot \deg(u) \cdot s(u)$, hence $c_{out}(u) = 0$, so $c(u, v) = 0$ for every v. Thus $c(u, v) \leq s_0$. ◀

5.2 Edge potential

As a main ingredient of the proof, we define a way to measure how close we are to propagating conflicts optimally.

▶ **Definition 5** (Potential). *Given a real edge $e \in \widehat{E}$, the potential of e is defined as $P(e) = c(e)^{1/f(\lambda)}$.*

For simplicity of notation, we also use P to denote the function $x \to x^{1/f(\lambda)}$ on real numbers instead of edges.

Intuitively speaking, the potential function describes the cost of sending a specific number of conflicts through a single edge, in terms of the number of initial conflicts used up for this. Note that since $f(\lambda) < 1$, the function P is always convex. This shows that sending a high number of conflicts through a single edge is more costly than sending the same amount of conflicts through multiple edges.

As the following lemma shows, the potential is defined in such a way that the total potential can never increase when passing through a node in the DAG; the best that a node can do is to preserve the input potential if it relays conflicts optimally.

▶ **Lemma 6.** *For any non-source node v of the DAG, with input edges from $N_{in}(v)$ and output edges to $N_{out}(v)$, we have*

$$\sum_{u \in N_{in}(v)} P(u, v) \geq \sum_{u \in N_{out}(v)} P(v, u).$$

Proof. If v is not a source, then by Lemma 3 it is not a base node, and thus has to satisfy condition 1R. In our DAG, c_{in} and c_{out} correspond to $\sum_{u \in N_{in}(v)} c(u, v)$ and $\sum_{u \in N_{out}(v)} c(v, u)$, respectively. Assume that we fix the value of c_{in} and c_{out}. Since the potential function P is convex, the incoming potential (left side) is minimized if c_{in} is split as equally among the input neighbors as possible. On the other hand, the outgoing potential (right side) is maximized if c_{out} is split as unequally among outputs as possible, so all output edges present in the DAG have the maximal possible number of switches, meaning $c(v, u) = s(v)$ for every $u \in N_{out}(v)$.

Assume that a fraction φ of v's incident edges are outgoing, i.e. $|N_{out}(v)| = \varphi \cdot \deg(v)$ and $|N_{in}(v)| = (1 - \varphi) \cdot \deg(v)$. By condition 1R, we have $c_{in} \geq \lambda \cdot \deg(v) \cdot s(v) + c_{out}$; with $c_{out} = \varphi \cdot \deg(v) \cdot s(v)$, this gives $c_{in} \geq (\lambda + \varphi) \cdot \deg(v) \cdot s(v)$. If split evenly among the $(1 - \varphi) \cdot \deg(v)$ inputs, this means

$$\frac{c_{in}}{|N_{in}(v)|} \geq \frac{(\lambda + \varphi) \cdot \deg(v) \cdot s(v)}{(1 - \varphi) \cdot \deg(v)} = \left(\frac{\lambda + \varphi}{1 - \varphi}\right) \cdot s(v)$$

switches for each input node. The inequality on the potential then comes down to

$$\sum_{u \in N_{in}(v)} P(u,v) \geq (1-\varphi) \cdot \deg(v) \cdot \left(\frac{\lambda+\varphi}{1-\varphi} \cdot s(v) \right)^{1/f(\lambda)} \geq$$
$$\geq \varphi \cdot \deg(v) \cdot s(v)^{1/f(\lambda)} \geq \sum_{u \in N_{out}(v)} P(v,u).$$

To show that the inequality in the middle holds, we only require

$$\left(\frac{\lambda+\varphi}{1-\varphi} \right)^{1/f(\lambda)} \geq \frac{\varphi}{1-\varphi},$$

or, put otherwise,

$$\frac{1}{f(\lambda)} \log \left(\frac{\lambda+\varphi}{1-\varphi} \right) \geq \log \left(\frac{\varphi}{1-\varphi} \right).$$

Since $\frac{\varphi}{1-\varphi} < 1$ (thus its logarithm is negative), we get

$$\frac{\log\left(\frac{\lambda+\varphi}{1-\varphi}\right)}{\log\left(\frac{\varphi}{1-\varphi}\right)} = \frac{\log\left(\frac{1-\varphi}{\lambda+\varphi}\right)}{\log\left(\frac{1-\varphi}{\varphi}\right)} \leq f(\lambda).$$

This holds by the definition of $f(\lambda)$. Note that this also shows that equality can only be achieved if the output rate φ is indeed chosen as the argmax value $\varphi^*(\lambda)$. ◀

Lemma 6 provides the key insight to the main idea of our proof: if we process the nodes of a DAG according to a topological ordering, always maintaining a dicut of outgoing edges from the already processed part of the DAG, then this potential cannot ever increase when adding a new node.

▶ **Lemma 7.** *Given a dicut S of a dipartitioning in the DAG, we have*

$$\sum_{e \in S} P(e) = O(n^2).$$

Proof (Sketch). Each dipartitioning can be obtained by starting from the trivial dipartitioning where V_1 only contains the source nodes of the DAG, and then iteratively adding nodes one by one to this initial V_1. The number of outgoing edges from this initial V_1 (the set of source nodes) is upper bounded by $|E| = O(n^2)$. According to Lemma 4, the number of switches (and hence the potential) on each edge of the dicut is at most constant, so the sum of potential in this initial dicut is also $O(n^2)$.

Now consider the process of iteratively adding nodes to this initial V_1 to obtain a specific dipartitioning. Whenever we add a new node v to V_1, the incoming edges of v are removed from the dicut, and the outgoing edges of v are added to the dicut. According to Lemma 6, the potential on the outgoing edges of v is at most as much as the potential on the incoming edges, so the sum of potential can not increase in any of these steps. Therefore, when arriving at the final V_1, the sum of potential on the cut edges is still at most $O(n^2)$. ◀

5.3 Upper bounding switches

Finally, we present our main lemma that uses the previous upper bound on potential in order to upper bound the number of switches in the CPS.

▶ **Lemma 8.** *Given a CPS and an integer $a \in \{1, ..., n\}$, let $A = \{v \in V \mid a \leq deg(v) < 2a\}$. For the total number of switches $s(A) = \sum_{v \in A} s(v)$, we have*

$$s(A) = O\left(n^{1+f(\lambda)} \cdot a^{-f(\lambda)}\right).$$

Proof (Sketch). If the input edges of the nodes in A would form the dicut of a dipartitioning, then we could directly use Lemma 7 to upper bound the number of switches in A through the potential of the input edges. However, the nodes of A might be scattered arbitrarily in the DAG, and if there is a directed path from one node in A to another, then the "same" potential might be used to switch more than one node in A. Thus we cannot apply Lemma 7 directly. Instead, our proof consists of two parts.

1. First, we define so-called responsibilities for the nodes in A. Given a node $v_0 \in A$, the idea is to devise two different functions: (i) a function $\Delta c(e)$, defined on each edge e which is contained in any directed path starting from v_0, and (ii) a function $\Delta s(v)$, which is defined on any node v that is reachable from v_0 on a directed path. Intuitively, we will consider the conflicts $\Delta c(e)$ and the switches $\Delta s(v)$ to be those that are indirectly "the effects of the switches of v_0". More specifically, Δc and Δs are chosen such that if they are removed (subtracted from the CPS), then v_0 has no output edges in the DAG anymore, and the resulting assignment $s'(v) = s(v) - \Delta s(v)$ and $c'(e) = c(e) - \Delta c(e)$ still remains a valid CPS. Hence the subtraction results in a CPS where v_0 has no directed path to other nodes in A anymore. This shows that we can keep on executing this step for each $v_0 \in A$ until no two nodes in A are connected by a directed path, at which point we can apply Lemma 7 to the resulting graph.

Whenever we process such a node $v_0 \in A$, we define the *responsibility* of v_0 as $R(v_0) := s(v_0) + \sum \Delta s(v)$, where the sum is understood over all the nodes $v \in A$ that are reachable from v_0. The main idea is that we "reassign" these switches to v_0 from other nodes in A. This method is essentially a redistribution of switches in the CPS, so we have $\sum_{v \in A} s(v) = \sum_{v \in A} R(v)$ altogether.

Furthermore, our definition of $\Delta s(v)$ will ensure that $R(v_0) = O(1) \cdot s(v_0)$. Intuitively, this can be explained as follows. Recall that with Rule II, the ratio of output to input conflicts is always upper bounded by a constant factor (below 1) at every node, since switching always wastes a specific proportion of conflicts. Hence, over any path starting from v_0, the number of outputs that can be attributed to v_0 forms a geometric series. As the ratio of the geometric series is below 1, the total amount of conflicts caused by v_0 this way is still within the magnitude of the input conflicts of v_0. Since each node in A has similar degree (and thus requires similar number of input conflicts for one switching), these conflicts can only switch nodes in A approximately the same number of times as v_0 can be switched by its own inputs. A detailed discussion of this responsibility technique is available in the full version of the paper.

2. For the second part of the proof, we show the claim in this modified CPS with no directed path between nodes in A. This implies that there exists a dipartitioning where the nodes of A are in V_2, but all their input nodes are in V_1. This means that all the input edges of each node in A are included in the dicut S of the partitioning.

Consider a node $v \in A$. Due to condition 1R, v has at least $\lambda \cdot \deg(v) \cdot s(v)$ input conflicts. Even if these are distributed equally on all incident edges of v (this is the case that amounts to the lowest total potential, since P is convex), this requires a total input potential of

$$\deg(v) \cdot P(\lambda \cdot s(v)) = \deg(v) \cdot s(v)^{1/f(\lambda)} \cdot \lambda^{1/f(\lambda)}$$

at least. Recall that Lemma 7 shows that the total potential on all edges in S is $O(n^2)$. Our task is hence to find an upper bound on $\sum_{v \in A} s(v)$, subject to

$$\sum_{v \in A} \deg(v) \cdot s(v)^{1/f(\lambda)} \cdot \lambda^{1/f(\lambda)} = O(n^2).$$

Since the last factor on the left side is a constant, we can simply remove it and include it in the $O(n^2)$ term. Furthermore, the degree of each node in A is at least a, so by lower bounding each degree by a, we get

$$\sum_{v \in A} s(v)^{1/f(\lambda)} = O(n^2) \cdot \frac{1}{a}.$$

Given this upper bound on $\sum_{v \in A} P(s(v))$, since the function P is convex, the sum of switches $\sum_{v \in A} s(v)$ is maximal when each node in A switches the same amount of times (i.e. there is an s such that $s(v) = s$ for every $v \in A$), giving

$$|A| \cdot s^{1/f(\lambda)} = O(n^2) \cdot \frac{1}{a}.$$

With this upper bound, $|A| \cdot s$ is maximal if $|A|$ is as large as possible and s as small as possible (again because P grows faster than linearly). Clearly $|A| \leq n$, so assuming $|A| = n$, we get

$$s^{1/f(\lambda)} = O(n) \cdot \frac{1}{a},$$

which means that

$$s = O(n^{f(\lambda)}) \cdot a^{-f(\lambda)},$$

and thus for the total number of switches in A, we get

$$|A| \cdot s = O(n^{1+f(\lambda)}) \cdot a^{-f(\lambda)}. \quad ◀$$

It only remains to sum up this bound for the appropriate intervals to obtain our final bound. Let us consider the intervals $[1, 2)$, $[2, 4)$, $[4, 8)$, ..., i.e. $a = 2^k$ for each factor of 2 up to n, which is a disjoint partitioning of the possible degrees. Note that for these specific values of a, the sum $\sum_{k=0}^{\infty} (2^k)^{-f(\lambda)}$ converges to a constant according to the ratio test. In other words, the sum is dominated by the number of switches of the lowest (constant) degree nodes, and hence, the total number of switches in the graph can be upper bounded by $O(1) \cdot n^{1+f(\lambda)}$.

Recall that since we work with Relaxed CPSs, we lose an ϵ in the exponent of this upper bound when we carry the result over to an original CPS.

▶ **Theorem 9.** *In any CPS with parameter λ, we have $\sum_{v \in V} s(v) = O(n^{1+f(\lambda)+\epsilon})$ for any $\epsilon > 0$.*

Since we have established that every majority/minority process provides a CPS, the upper bound on their stabilization time also follows.

▶ **Corollary 10.** *Under Rule II with any $\lambda \in (0, 1)$, every majority/minority process stabilizes in time $O(n^{1+f(\lambda)+\epsilon})$ for any $\epsilon > 0$.*

6 Lower bound construction

Having established the most efficient way to relay conflicts, the high-level design of the matching lower bound construction is rather straightforward, following the level-based idea described in Section 4.

Given λ, we first determine the optimal output rate $\varphi = \varphi^*(\lambda)$. We then create a construction consisting of distinct levels, where each level has the same size, and each consists of a set of nodes that have the same degree. Since the degree should decrease by a factor of $\frac{\varphi}{1-\varphi}$ in each new level from top to bottom, we can add $L = \log_{\frac{1-\varphi}{\varphi}}(n)$ such levels to the graph. If each of these level has $\Theta(\frac{n}{\log n})$ nodes, then with the appropriate choice of constants, the total number of nodes is below n.

Each node in the construction is only connected to other nodes on the levels immediately above or below its own. All conflicts are propagated down in the graph, from upper to lower levels, so the upper neighbors of a node are always used as inputs, while the lower neighbors are always used as outputs. For the optimal propagation of conflicts, each node v must have the optimal input-output rate, i.e. an up-degree of $(1-\varphi) \cdot \deg(v)$ and a down-degree of $\varphi \cdot \deg(v)$. Thus each consecutive level pair forms a regular bipartite graph, with $\frac{\varphi}{1-\varphi}$ of the degree of the level pair above. The construction is illustrated in Figure 2.

Our parameters λ and φ also determine that the number of switches should increase by a factor $\frac{1-\varphi}{\lambda+\varphi}$ on each new level. If we can always increase the switches at this rate, then each node on the lowermost level will switch

$$\left(\frac{1-\varphi}{\lambda+\varphi}\right)^{\log_{\frac{1-\varphi}{\varphi}}(n)} = n^{\frac{\log\left(\frac{1-\varphi}{\lambda+\varphi}\right)}{\log\left(\frac{1-\varphi}{\varphi}\right)}} = n^{f(\lambda)},$$

times, where the last equation holds because we are using $\varphi = \varphi^*(\lambda)$. Since there are $\widetilde{\Theta}(n)$ nodes on the lowermost level, the switches in this level already amount to a total of $\widetilde{\Theta}(n^{1+f(\lambda)})$, matching the upper bound.

However, note that when $\varphi^*(\lambda)$ or $\frac{1-\varphi}{\lambda+\varphi}$ is irrational, we can only use close enough rational approximations of these values. This comes at the cost of losing a small ϵ in the exponent.

▶ **Theorem 11.** *Under Rule II with a wide range of λ values, there is a graph construction and initial coloring where majority/minority processes stabilize in time $\Omega(n^{1+f(\lambda)-\epsilon})$ for any $\epsilon > 0$.*

This level-based structure describes the general idea behind our lower bound construction. However, the main challenge of the construction is in fact designing the connection between subsequent levels. In particular, this connection has to make sure that conflicts are indeed always relayed optimally, i.e. no potential is wasted between any two levels.

Recall from the proof of Lemma 6 that this is only possible if between any two consecutive switches of a node v, it is exactly a $\frac{\lambda+\varphi}{1-\varphi}$ fraction of v's upper neighbors that switch. Moreover, these switching $\frac{\lambda+\varphi}{1-\varphi} \cdot \deg(v)$ upper neighbors always have to be of the right color, i.e. they need to switch to the opposite of v's current color in case of majority processes, and to the same color in case of minority processes. Since the upper neighbors of v are in the same level, we also have to ensure that throughout the entire process, each upper neighbor switches the same number of times altogether.

These conditions impose heavy restrictions on the possible ways to connect two subsequent levels. If the conditions hold for a node v (i.e. the sequence of switches of v's upper neighbors can be split into $\frac{\lambda+\varphi}{1-\varphi} \cdot \deg(v)$-size consecutive appropriate-colored subsets, in an altogether balanced way), then we say that v's upper neighbors follow a valid *control sequence*.

On the other hand, in order to argue about levels in general, we want each level to behave in a similar way. The easiest way to achieve this is to have a one-to-one correspondence between the nodes of different levels, and ensure that each level repeats the same sequence of steps periodically, but in a different pace. That is, we want to connect the levels in such a way that when a level exhibits a specific pattern of switches, then this allows the nodes of the next level to replicate the exact same pattern of switches, but more times.

Thus the key task in our lower bound constructions is to develop a so-called *control gadget*, which is essentially a bipartite graph that fulfills these two requirements: it admits a scheduling of switches such that (i) the upper neighborhood of each lower node follows a valid control sequence, and (ii) while the upper level executes a sequence s times, the lower level executes the same sequence $\frac{1-\varphi}{\lambda+\varphi} \cdot s$ times. Given such a control gadget, we can connect the subsequent level pairs of our construction using this gadgets. This allows us to indeed increase the number of switches by a $\frac{1-\varphi}{\lambda+\varphi}$ factor in each new level, resulting in a total of $\widetilde{\Theta}(n^{1+f(\lambda)})$ switches as described above.

However, developing a control gadget is a difficult combinatorial task in general: it depends on many factors including divisibility questions, and whether our parameters can be expressed as a fraction of small integers. A detailed discussion of control gadget design and the λ values covered by Theorem 11 is available in the full version of the paper. In particular, we present a method which allows us to develop a control gadget for every small λ value below a threshold of approximately 0.476 (more specifically, as long as $\frac{\lambda+\varphi}{1-\varphi} \leq \frac{3}{5}$). The same technique also provides a control gadget for some larger λ values above the threshold, but only when the corresponding switch increase ratio $\frac{1-\varphi}{\lambda+\varphi}$ can be expressed as a fraction of relatively small integers. Furthermore, the full version also describes a simpler solution technique to the control gadget problem; this leaves a slightly larger gap to the upper bound, but it works for any λ without much difficulty.

Abstract

We study the incentives of banks in a financial network, where the network consists of debt contracts and credit default swaps (CDSs) between banks. One of the most important questions in such a system is the problem of deciding which of the banks are in default, and how much of their liabilities these banks can pay. We study the payoff and preferences of the banks in the different solutions to this problem. We also introduce a more refined model which allows assigning priorities to payment obligations; this provides a more expressive and realistic model of real-life financial systems, while it always ensures the existence of a solution.

The main focus of the paper is an analysis of the actions that a single bank can execute in a financial system in order to influence the outcome to its advantage. We show that removing an incoming debt, or donating funds to another bank can result in a single new solution that is strictly more favorable to the acting bank. We also show that increasing the bank's external funds or modifying the priorities of outgoing payments cannot introduce a more favorable new solution into the system, but may allow the bank to remove some unfavorable solutions, or to increase its recovery rate. Finally, we show how the actions of two banks in a simple financial system can result in classical game theoretic situations like the prisoner's dilemma or the dollar auction, demonstrating the wide expressive capability of the financial system model.

1 Introduction

The world's financial system is a complex network where financial institutions such as banks are connected via various kinds of financial contracts. If some financial institutions go bankrupt, then others might suffer as well; the financial network might experience a ripple effect. Two of the most common financial contracts are (i) debt contracts (some bank owes a specific amount of money to another bank) and (ii) Credit Default Swaps (CDSs). A CDS is a simple financial derivative where the payment obligation depends on the defaulting of another bank in the system. The combination of debt contracts and CDSs turns out to provide a simple and yet expressive model, which is able to capture a wide range of interesting phenomena in real-life financial markets [10, 22, 18, 17].

Given a set of banks and a set of payment obligations between these banks, one of the most natural questions is to decide which of the banks can fulfill these obligations, and which of them cannot, and hence are in default. The problem of deciding what portion of obligations banks can fulfill is known as the *clearing problem.* One can easily encounter

a situation when this problem has multiple different solutions in a financial system. It is natural to study how much the individual banks prefer these solutions, i.e. what is their payoff in specific solutions of the system.

In this paper we study the problem from the point of view of a single bank v. We analyze whether some simple actions of v can improve its situation in the network. In a financial system, the complex interconnection between the banks can easily result in situations where banks can achieve a better outcome in surprising and somewhat counterintuitive ways. For example, being on the receiving end of a debt contract is generally considered beneficial, because the bank obtains payment from this contract. However, in a system with debts and CDSs, it is also possible that if a bank v nullifies a debt contract as a creditor, then (through a number of intermediate steps in the network) this results in an even higher total payoff for v. Such phenomena are crucial to understand, since if banks indeed execute these actions to obtain a better outcome, then these opportunities will determine how the financial system changes and evolves in the future.

We begin with a description of the financial system model recently developed by Schuldenzucker *et. al.* [22], which serves as the base model for our findings. We then introduce a more refined version of this model which also assigns *priorities* to each contract, and assumes that banks have to fulfill their payment obligations in the order defined by these priorities. We show that besides being more expressive and realistic, this augmented model still ensures the existence of a solution.

Our main contribution is an analysis of various different actions that banks in the system can execute in order to increase their final payoff when the system is cleared. We first show that by removing an incoming debt (partially or entirely) or by donating extra funds to another bank, a bank might be able to increase its payoff. We then show that investing more external assets or reprioritizing its outgoing payments can also allow a bank to influence the system. However, these actions do not allow a bank to introduce more favorable new solutions, but they can allow the bank to remove unfavorable solutions from the system, or increase its own recovery rate.

Finally, we present some simple examples where two banks try to influence the financial system simultaneously, resulting in situations that are identical to the classical prisoner's dilemma or dollar auction game. This suggests that financial systems in this model can exhibit very rich behavior, and if two or more banks execute these actions simultaneously, this can easily lead to complex game-theoretic settings.

2 Related Work

Numerous studies on the properties of financial systems are directly or indirectly based on the financial system model introduced by Eisenberg and Noe in [11]. This model only assumes simple debt contracts between banks. Different studies have later also extended this model with default costs [21], cross-ownership relations [25, 12] or so-called covered CDSs [17]. The related literature has studied the propagation of shocks in many different variants of these models [2, 8, 5, 4, 1, 13].

One disadvantage of these models is that they can only describe *long positions* of banks on each other, meaning that a worse situation for one bank is always worse (or the same) for any other bank. For example, if a bank is unable to pay its debt, then its creditor receives less money, and it might not be able to pay its debts either. This already enables the model to capture many interesting phenomena, e.g. how a small shock causes a ripple effect in the network. However, long positions imply that there is a solution in these systems which is simultaneously the best for all banks. As such, the models cannot represent the opposing interests of banks in many real-world situations, and thus these models are not so interesting from a game-theoretic point of view.

On the other hand, a more realistic model was recently introduced by Schuldenzucker, Seuken and Battiston [22]; we assume this model of financial systems in our paper. Besides debt contracts, this new model also allows credit default swaps between banks, which are essentially financial derivatives where banks are betting on the default of another bank. CDSs are a prominent kind of derivative that played a significant role in the 2008 financial crisis [14]; as such, they have been studied in various works in the financial literature [9, 18, 10]. While the model still remains relatively simple with these two kind of contracts, it now also allows us to model *short positions*, when it is more favorable for a bank if another bank is worse off. This increases the expressive power of the model dramatically, allowing us to capture a wide range of properties of practical financial systems.

The work of Schuldenzucker *et. al.* analyzes their model from a complexity-theoretic perspective. The authors show that in the base variant of this model, each system has at least one solution; however, if we also assume so-called default costs, then some systems might not have a solution at all. In case of default costs, they also describe sufficient conditions for the existence of a solution. Their follow-up work shows that it is computationally hard to decide if a solution exists, and also to find or approximate a solution of the system [23].

However, to our knowledge, the model has not been analyzed from a game-theoretic perspective before. Our paper aims to lay the foundations of such an analysis, by evaluating a variety of simple (and yet realistic) actions that allow nodes to influence the network due to the presence of short positions. Since banks often have conflicting interests in these systems, these actions can easily lead to interesting game-theoretical dilemmas.

The only similar game-theoretic analysis we are aware of is the recent work of Bertschinger *et. al.* [6], set in the original model of Eisenberg and Noe. Instead of having institutional rules for payment obligations in case of default, [6] assumes that banks can freely select the order of paying their outgoing debts, or even decide to make partial payments in some contracts. The paper discusses the properties of Nash-Equilibria and Social Optima in this setting. While this has a connection to our observations in Section 5.3, we analyze the results of such actions in a significantly more complex model with CDSs.

In general, measuring the sensitivity or complexity of a financial network has also been exhaustively studied [15, 3, 5, 4]. The topic also has a major importance for financial authorities in practice, who regularly conduct stress tests to analyze real-world financial systems. The clearing problem, in particular, also plays an important role in the European Central Bank's stress test framework [7], for example.

3 Financial system model

The model introduced by [22] describes a financial network as a set of *banks* (i.e. nodes), denoted by V, with different kinds of financial contracts (i.e. directed edges) between specific pairs of banks. Banks in our examples are usually denoted by u, v or w. Every bank in the system has a predefined amount of *external assets*, denoted by e_v for bank v.

3.1 Debt and CDS contracts

We assume that each contract in the system is between two specific banks u and v. A contract obliges u (the debtor) to pay a specific amount of money to bank v (the creditor), either unconditionally or based on a specific event. The amount of payment obligation in the contract is the *weight* (in financial terms: the notional) of the contract.

While these contracts might be connected to earlier transactions between the banks (e.g. a loan offered by v to u in the past which results in a debt contract from u to v in the present), we assume that these initial payments are implicitly represented in the external assets of banks, and thus the external assets and the contracts together provide all the necessary information to describe the current state of the system.

The outgoing contracts of bank v altogether specify a given amount of total payment obligations for v. If v is unable to fulfill all these obligations, then we say that v is *in default*. In this case, we are interested in the portion of liabilities that v is still able to pay, known as the *recovery rate* of v and denoted by r_v. The definition implies that we always have $r_v \in [0, 1]$, and v is in default exactly if $r_v < 1$. The recovery rates of all banks is represented together in a recovery rate vector $r \in [0, 1]^V$.

The model allows two kinds of contracts between banks in the system. In case of a simple *debt* contract, u has to pay a specific amount to v unconditionally, i.e. in any case. On the other hand, *credit default swaps* (*CDSs*) are ternary financial contracts, made in reference to a third bank w known as the *reference entity*. A CDS describes a conditional debt which only requires u to pay a specific amount to v if w is in default. In particular, if the weight of the CDS is δ and the recovery rate of w is r_w, then the CDS incurs a payment obligation of $\delta \cdot (1 - r_w)$ from u to v.

In practice, CDSs often describe an insurance policy on debt contracts for the creditor bank. If v is the creditor of a debt coming from w, and v suspects that w might go into default and thus will be unable to pay some of its debt, then v can enter into a CDS as a creditor with some other bank u in the system, in reference to w. If w indeed defaults and cannot pay its liabilities to v, then v instead receives some payment from u. Nonetheless, there could be other reasons for banks to enter CDS contracts, e.g. speculative bets about future developments in the market.

3.2 Assets and liabilities

Since payment obligations in CDSs depend on the recovery rate of other banks, the assets and liabilities of a bank are defined as a function of the vector r. The *liability* of u towards v is the sum of payment obligations from all simple debt contracts and CDSs, i.e.

$$l_{u,v}(r) = c_{u,v} + \sum_{w \in V} c_{u,v}^{w} \cdot (1 - r_w),$$

where $c_{u,v}$ denotes the weight of the simple debt from u to v, and $c_{u,v}^{w}$ denotes the weight of the CDS from u to v with reference to w (understood as 0 if the contracts do not exist). The total liabilities of u is then the sum of liabilities to all other banks, i.e.

$$l_u(r) = \sum_{v \in V} l_{u,v}(r).$$

In contrast to this, the actual *payment* from u to v can be lower than $l_{u,v}(r)$ if u is in default. In this case, the model assumes that u makes payments based on the *principle of proportionality*, i.e. it uses all of its assets to make payments to creditors, in proportion to the respective liabilities. In practice, this means that u can pay an r_u portion of each liability, and thus its payment to v is defined as $p_{u,v}(r) = r_u \cdot l_{u,v}(r)$.

On the other hand, the *assets* of v is the sum of its external assets and its incoming payments, i.e.

$$a_v(r) = e_v + \sum_{u \in V} p_{u,v}(r).$$

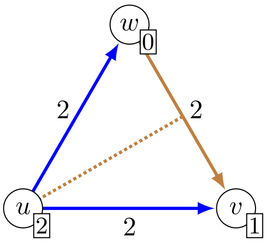

Figure 1 Example financial system with three banks. External assets are shown in rectangles besides the nodes, simple debt contracts are shown as blue arrows from debtor to creditor, and CDSs are shown as brown arrows from debtor to creditor, with a dotted line specifying the reference entity.

Recall that a recovery rate describes the portion of liabilities that a bank can pay. Hence given the assets and liabilities of each bank v, the recovery rate r_v must satisfy $r_v = 1$ if $a_v(r) \geq l_v(r)$, and $r_v = \frac{a_v(r)}{l_v(r)}$ otherwise. A vector r is called a *solution* (in financial terms: a clearing vector) if it describes an equilibrium point for these equalities, i.e. if for each bank v, r_v satisfies this constraint for the assets and liabilities defined by r. Previous work has expressed this by defining the *update function* $f : [0,1]^V \to [0,1]^V$ as

$$f_v(r) = \begin{cases} 1, & \text{if } a_v(r) \geq l_v(r) \\ \frac{a_v(r)}{l_v(r)}, & \text{if } a_v(r) < l_v(r) \end{cases},$$

and defining a solution as a fixed point of the update function.

In order to model the utility function of nodes in the system, we define the *payoff* (in financial terms: equity) of a bank v as the amount of remaining assets after payments if a node is not in default, and 0 otherwise, i.e. $q_v(r) = \max(a_v(r) - l_v(r), 0)$. We assume that the aim of each bank is to maximize its own payoff.

Note that assets, liabilities and payoffs are always defined with regard to a certain recovery rate vector r. However, in order to simplify notation, we do not show r explicitly when it is clear from the context, and instead we simply write e.g. a_v or q_v.

Figure 1 shows an example financial system with three banks u, v and w, with a consistent notation to that of [22, 23]. The system has $e_u = 2$, $e_v = 1$ and $e_w = 0$. There are two debts of weight 2 in the system: one from u to v, the other from u to w. Finally, the system contains a CDS from w to v (also of weight 2), which is in reference to bank u.

Regardless of recovery rates, bank u has liabilities $l_u = 4$ and assets $a_u = 2$, so $r_u = \frac{1}{2}$ in any case. This implies that u can only make payments of $r_u \cdot 2 = 1$ to both v and w. Given $r_u = \frac{1}{2}$, the CDS induces a liability of $2 \cdot (1 - r_u) = 1$ from w to v. Since w receives an incoming payment of $p_{u,w} = 1$ from u, we have $a_w = l_w = 1$, so w can still pay its liability and has a recovery rate of $r_w = 1$. Finally, v has incoming payments $p_{u,v} = 1$ and $p_{w,v} = 1$, external assets $e_w = 1$, and no liabilities. This implies $a_v = 3$ and $l_v = 0$, and thus $r_v = 1$. Hence $(r_u, r_v, r_w) = (\frac{1}{2}, 1, 1)$ is the only solution of the system, providing a payoff of $q_u = 0$, $q_w = 0$ and $q_v = 3$ to the banks.

We also use two sanity assumptions introduced by previous work to exclude degenerate cases [22]. First, we assume that no bank enters into a contract with itself or in reference to itself. Furthermore, since CDSs are regarded as an insurance on debt, we require that if a bank w is a reference entity of some CDS, then w is the debtor of at least one debt contract of positive weight.

4 Payments with priorities

While the principle of proportionality is a simple and natural assumption, financial systems often have more complex payment rules in practice. Thus we also introduce a more general model of *payments with priorities.*

That is, we assume that there is a constant number of priority classes P, and each contract belongs to one of these priority classes. If a node v is in default, then it first spends all its assets to fulfill its liabilities in the highest priority class. If v does not have enough assets to fulfill all such obligations, it spends all its assets on the payments for these edges, proportionally to the amount of liabilities. On the other hand, if v has more assets than highest-priority liabilities, then v pays for all the liabilities in this highest priority level, and continues using the rest of its assets for the lower-priority liabilities in a similar fashion.

More formally, in our modified model, each contract in the network receives another *priority* parameter (besides its weight), which is an integer in $\{1, ..., P\}$. The value 1 denotes the highest priority (i.e. liabilities that have to be paid first), while class P denotes the lowermost priority level.

Given a clearing vector r, for each node v, let $l_v^{(\rho)}$ denote the total amount of liabilities of v due to edges on priority level ρ. Let us also introduce the notation $l_v^{(\leq\rho)} = \sum_{i=1}^{\rho} l_v^{(i)}$. Assume that v has total assets of a_v, and a liability of $l_{v,u}$ on priority level ρ towards another node u. Then the payment of v to u is defined as

$$p_{v,u} = \begin{cases} 0, & \text{if } a_v \leq l_v^{(\leq\rho-1)} \\ \frac{a_v - l_v^{(\leq\rho-1)}}{l_v^{(\rho)}} \cdot l_{v,u}, & \text{if } a_v \in \left(l_v^{(\leq\rho-1)}, l_v^{(\leq\rho)}\right) \\ l_{v,u}, & \text{if } a_v \geq l_v^{(\leq\rho)}. \end{cases}$$

For an example, consider a modified version of the network in Figure 1. Assume we now have 2 priority levels: the debt from u to w is on the higher level, while the other two contracts are on the lower level. For the case of u, this still means $l_u = 4$, $a_u = 2$ and $r_u = \frac{1}{2}$ as before. However, now u uses its 2 units of assets to pay its full liability to w, since this contract has higher priority than the debt to v. Hence $p_{u,v} = 0$ and $p_{u,w} = 2$, resulting in $a_w = 2$. Since $r_u = \frac{1}{2}$ still implies $l_w = 1$ for the CDS, the rest of the payments and recovery rates remain unchanged: we still have $p_{w,v} = 1$ and $r_w = r_v = 1$. However, the payoffs of the banks in the system are now $q_u = 0$, $q_w = 1$ and $q_v = 2$.

The main motivation for introducing payment priorities is that in many cases, it is very close to what happens in real-world financial systems. In many countries, economic laws provide a specific priority list for companies to follow when paying their debts in case of a default. This might start with salaries and other payments to the employees of the company first, then specific kind of debt contracts, and so on.

Another advantage of priorities is that we can often use them to replace so-called *default costs*. Default costs (also studied in [22, 23]) are an extension of the original model, assuming that when banks go into default, they immediately lose a specific portion of their assets. This represents the fact that in practice, once a company goes into default, it has a range of immediate payment obligations (e.g. employees' wages) before it can make payments to other banks. If we instead represent the bank's employees as a separate node in the network, and model this payment obligation with a high-priority edge, then this might allow us to model some of these obligations *without* the use of default costs.

This observation is crucial because the introduction of default costs comes at a significant price: intuitively speaking, default costs introduce a point of discontinuity into the update function, and as a result, some financial systems do not have a solution at all [22]. In contrast to this, without default costs, systems always have at least one solution, as shown by a fixed-point argument in [22]. We point out that the same fixed-point theorem proof also applies in our model with payment priorities: even though the functions $p_{u,v}(r)$ and $a_v(r)$ become significantly more complicated, they are still continuous.

This shows that by introducing priorities, we obtain a model that is significantly more realistic on one hand, but also ensures the existence of a solution at the same time.

▶ **Theorem 1.** *Every financial system with payment priorities has at least one solution.*

Proof (sketch). The proof of this claim is identical to the same proof in the original financial system model, described in the results of [22]. The main idea of the proof is to apply the fixed-point theorem of Kakutani [16], which ensures the existence of a fixed point of the update function f, and thus a solution. This proof can still be applied after the introduction of priorities, since both $a_v(r)$ and $l_v(r)$ still remain a continuous function of r, and so does the update function $f_v(r) = \min(\frac{a_v(r)}{l_v(r)}, 1)$, at least in the domain where $l_v(r) > 0$. The technical part of the proof is slightly more complicated, since one has to consider the $l_v(r) = 0$ case separately. For more details on this proof, we refer the reader to the work of [22]. ◀

5 Influencing the financial system

We now discuss a wide range of actions that a bank can execute in order to obtain a more favorable outcome in the system. Note that except for Section 5.3 which explicitly studies readjusting priorities, all the results also hold in the base model without priorities.

5.1 Removing an incoming debt

One of the most natural actions for a bank v would be to simply cancel a debt contract in which v is a creditor. Since the creditor is considered the beneficiary of a debt, in some financial/legal frameworks, the regulations may indeed allow a bank to nullify an incoming debt contract. However, in case of a financial system with short positions, it is actually possible that in the end, this indirectly increases the payoff of v.

▶ **Theorem 2.** *Removing an incoming debt of v can increase the payoff of v.*

More precisely, our claim is as follows: there exists a financial system S such that (i) S has only one solution r, in which v has payoff q_v and an incoming debt contract, and (ii) in the modified financial system S' obtained by removing this debt, there is again only one solution r', in which the payoff q'_v satisfies $q'_v > q_v$.

Proof. Consider the network in Figure 2. Note that the unlabeled nodes in this system can always pay all their liabilities, so their recovery rate is always 1. Originally, the system has $a_u = 1$ and $l_u = 2$, thus $r_u = \frac{1}{2}$ in any case. This implies $a_w = 2 \cdot (1 - \frac{1}{2}) = 1$, and thus $r_w = 1$. With $r_w = 1$, v obtains no payment from its incoming CDS at all, so the payoff of v in this only solution is $q_v = p_{u,v} = r_u \cdot 1 = \frac{1}{2}$.

One the other hand, consider the system obtained by removing the debt contract from u to v. In this case, $a_u = l_u = 1$, and thus $r_u = 1$. This means that w receives no incoming payments at all, and with $a_w = 0$, we have $r_w = 0$. As a result, v obtains a payment of $2 \cdot (1 - r_w) = 2$ from its incoming CDS, so we have $q_v = 2$. ◀

The proof shows that releasing an outgoing debt increases the recovery rate of u, which indirectly yields an extra payoff for v. Note that v could also achieve this result by donating funds to u, i.e. by increasing e_u by 1. This is even more realistic in a legal framework: the

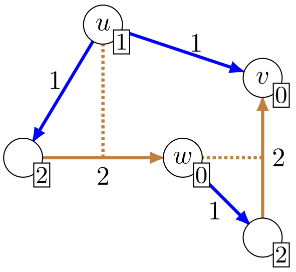

Figure 2 A bank v removing one of its incoming debts.

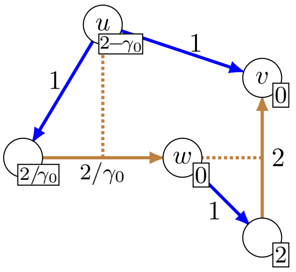

Figure 3 A bank v removing a γ_0 portion of an incoming debt.

owner(s) of bank v can simply donate a specific amount to bank u, who would accept it in hope of avoiding default. Naturally, this is only a favorable step to v if by donating x units of money, it can increase its own payoff by more than x.

▶ **Theorem 3.** *Donating external assets to another node u can be a favorable step.*

More precisely, there is a system S such that (i) S has only one solution r, in which node v has payoff q_v, and (ii) in the system S' obtained by replacing external funds of u by $e'_u := e_u + x$, there is again only one solution r' which satisfies $q'_v > q_v + x$.

The proof of the theorem is identical to that of Theorem 2: if v increases e_u by $x = 1$ in Figure 2, then again $r_u = 1$, which ultimately provides a payoff of $q_v = 3$ (as opposed to the original $\frac{1}{2}$). Note that in general, this action may allow banks to improve their position by affecting a bank that is arbitrarily far in the topology of the network.

While our main focus in the paper is a theoretical analysis of these improvement techniques, we point out that these operations are not only theoretical anomalies in the model; there are known examples when some institutions indeed applied similar techniques in real-world financial networks [19].

We also note that one could prove Theorems 2 and 3 on a smaller example system, where v only has an incoming debt from u and a larger outgoing CDS in reference to u. We have chosen this slightly larger example since it allows us to use a similar proof structure for all our claims in this section.

Finally, if v can increase its payoff by releasing an incoming debt, it is natural to wonder if it is always optimal for v to erase the entire debt, or whether it could be beneficial to only reduce the amount in some cases. We show that reducing a debt to a given portion γ_0 of its original weight can also be an optimal strategy.

▶ **Theorem 4.** *For each constant $\gamma_0 \in [0, 1]$, there is a financial system where bank v achieves its maximal payoff by reducing an incoming debt by a γ_0 portion of its original weight.*

Proof. Consider a modified version of our previous systems, as shown in Figure 3. We show that for any γ_0 parameter, the optimal action of v in this system is to let go of γ_0 portion of the incoming debt from u, i.e. to reduce its weight to $1 - \gamma_0$.

Assume that v reduces the incoming debt by a γ portion for some $\gamma \in [0, 1]$, and let us analyze the final payoff of v as a function of γ. Note that a choice of $\gamma = \gamma_0$ implies that $a_u = l_u$ exactly, and thus $r_u = 1$, $r_w = 0$ and $q_v = (1 - \gamma_0) + 2 = 3 - \gamma_0$ as a result. Hence we have to show that $q_v < 3 - \gamma_0$ in any other case.

First consider the case when $\gamma < \gamma_0$. Since u has $l_u = 1 + (1-\gamma) = 2-\gamma > 2-\gamma_0$, u is in default. Then $r_u = \frac{2-\gamma_0}{2-\gamma}$, and thus w receives an incoming payment of

$$a_w = \frac{2}{\gamma_0} \cdot \left(1 - \frac{2-\gamma_0}{2-\gamma}\right) = \frac{2 \cdot (\gamma_0 - \gamma)}{\gamma_0 \cdot (2-\gamma)}.$$

This is a decreasing function in γ, and it equals 1 exactly for $\gamma = 0$, so $a_w < 1$ for any $\gamma > 0$, and thus w is in default with $r_w = a_w$. Then the amount v receives from the CDS is

$$2 \cdot (1 - r_w) = 2 \cdot \left(1 - \frac{2 \cdot (\gamma_0 - \gamma)}{\gamma_0 \cdot (2-\gamma)}\right) = 2 \cdot \frac{\gamma \cdot (2-\gamma_0)}{\gamma_0 \cdot (2-\gamma)}.$$

Since $q_v = (1-\gamma) \cdot r_u + 2 \cdot (1-r_w)$, we need to show that

$$3 - \gamma_0 > (1-\gamma) \cdot \frac{2-\gamma_0}{2-\gamma} + 2 \cdot \frac{\gamma \cdot (2-\gamma_0)}{\gamma_0 \cdot (2-\gamma)}.$$

After multiplying this by $\gamma_0 \cdot (2-\gamma)$, expanding the brackets and removing terms that cancel out, we are left with $\gamma_0 \cdot (4-\gamma_0) > \gamma \cdot (4-\gamma_0)$, which naturally holds since $\gamma < \gamma_0$.

On the other hand, if $\gamma > \gamma_0$, then $a_u > l_u$, and thus $r_u = 1$. This means $r_w = 0$, so v receives an amount of 2 from the CDS, and has a total payoff of $(1-\gamma) + 2 = 3 - \gamma$, which is again less than $3 - \gamma_0$. Thus selecting $\gamma = \gamma_0$ is indeed the best option for v. ◀

5.2 Investing more external assets

In light of Theorem 3, it is natural to ask if v can also increase its payoff by increasing *its own* external assets. In practice, this could easily happen in multiple ways, e.g. by creating more shares to raise capital for the bank, or by the owners of the bank investing further funds into the bank. If increasing e_v by x would allow v to increase its payoff by more than x in the only solution, then the owners of v would indeed be motivated to invest these extra funds into the bank.

However, somewhat surprisingly, it turns out that this is not possible in the same way as in previous cases: we cannot increase the payoff of v by more than x in the only solution of the system. More specifically, if a vector r' is a solution to the new system and provides a payoff of q'_v, then r' was already a solution of the original system with a payoff of $q'_v - x$.

▶ **Theorem 5.** *Assume that every solution of system S provides a payoff of at most q_v for v. Then setting $e'_v = e_v + x$ cannot introduce a new solution r' with $q'_v > q_v + x$.*

Proof. Assume that such a new solution r' is introduced. Since payoff is always nonnegative, $q_v \geq 0$, and thus $q'_v > x$ in r'. This means that we have $a'_v > x + l'_v$ in r'. Hence, even if e'_v was reduced by x (back to its original value e_v), then v could still pay all of its liabilities; thus the same recovery vector r' and the same payments on each edge also provide a solution in the original system S. The payoff of v in this solution is $q'_v - x$, which is larger than q_v by assumption. This contradicts the fact that q_v was the maximal payoff for v in S. ◀

Naturally, if v is in default, the *recovery rate* of v can indeed be increased in the only solution by injecting extra funds. However, an increase of r_v does not translate to an increase in payoff, so it is a waste for the owners of v to invest resources for this.

On the other hand, while it is not possible to produce a new, more favorable solution for v, it is possible to invalidate solutions that are unfavorable to v. That is, if the original financial system had multiple solutions with different payoffs for v, and v is unsure which

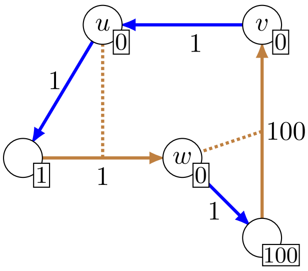

Figure 4 A bank v increasing its own external assets.

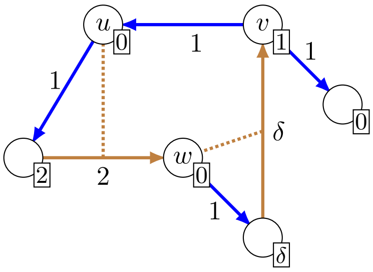

Figure 5 A bank v readjusting the priority of its outgoing contracts.

of these solutions will be implemented by a financial authority, then it is possible that v can inject extra funds to remove a solution where its payoff is much smaller than in other solutions. This may allow v to increase its worst-case payoff, or its payoff in expectation (in case of a randomized choice of solution).

▶ **Theorem 6.** *Given a financial system S with two solutions, it is possible that setting $e'_v = e_v + x$ removes a solution which is unfavorable to v.*

More precisely, there is a system S such that (i) S has two solutions r_1 and r_2, with solution r_2 satisfying $q_v = 0$, and (ii) in the system S' obtained by setting $e'_v := e_v + x$, the only solution is $r' = r_1$, satisfying $q'_v > x$.

Proof. Consider the system in Figure 4, which has two solutions. The design of the system ensures $r_u = r_v$ and $r_w = 1 - r_u$. If $r_v = 1$, then this implies $r_u = 1$ and $r_w = 0$, in which case v has $a_v = 100$, giving a solution with $q_v = 99$. On the other hand, if $r_v < 1$, then it has to satisfy

$$r_v = \frac{100 \cdot (1 - r_w)}{1} = 100 \cdot r_u = 100 \cdot r_v .$$

This is only satisfied if $r_v = 0$, so this is the only other solution, providing $q_v = 0$.

Now assume that v invests $x = 1$ extra funds to have $e_v = 1$. In this case, the system always has $r_v = 1$, hence $r_u = 1$ and $r_w = 0$. This implies that v obtains a payment of 100 in the CDS, resulting in a payoff of $q_v = 100$. Even if we subtract the extra $x = 1$ investment, v has an extra payoff of 99, and thus it has indeed increased its worst-case payoff significantly. ◀

5.3 Readjusting priorities

Assuming payments with priorities as discussed in Section 4, it is also interesting to know if a node can improve its situation by readjusting the priorities of its outgoing edges. That is, in a more flexible regulation framework, banks may be allowed to choose to some extent the order in which they fulfill their payment obligations. However, we show that similarly to the previous case, readjusting the priorities of outgoing edges cannot introduce a better solution.

▶ **Theorem 7.** *Assume that every solution of system S provides a payoff of at most q_v for v. Then redefining v's outgoing priorities cannot introduce a new solution r' with $q'_v > q_v$.*

Proof. Assume that such a new solution r' is introduced. Payoff is nonnegative, so $q_v \geq 0$, and thus $q'_v > 0$. This implies that $a'_v > l'_v$ in r', i.e. v is able to pay all of its liabilities in every outgoing contract. However, in this case, the priorities on the outgoing edges do not matter; hence r' is a solution of S' regardless of how the priorities of outgoing contracts are chosen. In particular, r' is already a solution of the initial system S before the priorities were reorganized, giving the same payoff q'_v in S. This contradicts the fact that q_v was the maximal payoff for v in S. ◀

However, it is again possible that v can increase its recovery rate by readjusting priorities. Recall that in the previous case of increasing the bank's own external assets, we did not explore this possibility, since it required the bank v to invest extra funds while not yielding (the same amount of) extra payoff. However, readjusting priorities is an action that v might be able to execute free of charge. Thus if we define the recovery rate as the secondary objective function of a bank (i.e. even if v is in default and thus has 0 payoff, it is not oblivious to the outcome, and prefers a higher recovery rate), then redefining priorities may allow v to achieve a more preferred outcome without having to invest any extra funds.

▶ **Theorem 8.** *Redefining v's outgoing priorities can increase the recovery rate of v.*

Proof. Consider the system in Figure 5 with a choice of $\delta = \frac{1}{2}$. Originally, each contract is in the same (lower) priority class. Bank v never has enough assets to pay its liabilities, hence u is also in default. In this case, we have $r_u = r_v$ and $r_w = 2 - 2 \cdot r_u$, so v receives $\delta \cdot (1 - r_w) = \delta \cdot (2 \cdot r_v - 1)$ funds from the CDS. This means that

$$r_v = \frac{\delta \cdot (2 \cdot r_v - 1) + 1}{2},$$

which, after reorganization, gives $\delta - 1 = 2 \cdot (\delta - 1) \cdot r_v$, and thus $r_v = \frac{1}{2}$. This is the only solution of the system if $\delta \neq 1$.

Now assume that v is able to raise the debt towards u to the higher priority level. In this new system, v first fulfills its payment obligation to u, which is always possible from its external assets. Hence $r_u = 1$ in this case, implying $r_w = 0$ and thus a payment of $\frac{1}{2}$ to v in the CDS. This implies $r_v = \frac{3}{4}$ in the only solution of the new system. ◀

We again point out that the previous work of Bertschinger *et. al.* [6] discusses a similar phenomenon in debt-only networks, i.e. how redefining the priorities of v's outgoing payments can result in an increased recovery rate for v.

Finally, we show that redefining priorities can allow v to remove an unfavorable solution, and thus increase its worst-case or expected payoff as in the previous subsection.

▶ **Theorem 9.** *Given a financial system S with two solutions, redefining v's outgoing priorities can remove a solution which is unfavorable to v.*

Proof. Consider the system in Figure 5 with a choice of $\delta = 100$. As discussed in the proof of Theorem 8, if $r_v < 1$, then the only solution is $r_v = \frac{1}{2}$. However, the large δ value now allows another solution in the original system: if $r_v = 1$, then $r_u = 1$ and $r_w = 0$, ensuring that v indeed has enough funds to pay its liabilities. The two solutions come with payoffs of $q_v = 0$ and $q_v = 98$, respectively.

Now if v raises its debt towards u to the higher priority level, then $r_u = 1$ is always guaranteed, so $r_w = 0$ and thus v indeed has a payoff of 98 in the only solution. ◀

6 Game-theoretic dilemmas in financial systems

Finally, we briefly show that the attempts of banks to influence the system can also easily lead to situations that can be described by classical game-theoretic settings.

We first show an example where if two nodes simultaneously try to influence the system to their advantage, then the resulting situation is essentially identical to the well-known prisoner's dilemma [20]. We then show that with some modifications to this network, we can also obtain financial systems that represent other well-known two-player-two-strategy games, e.g. the chicken or stag hunt game [20]. Finally, we show a different network design that allows us to model the multiple-round setting of a dollar auction [24].

6.1 Prisoner's dilemma

For an example of the prisoner's dilemma, consider the financial system in Figure 6, where banks v_1 and v_2 want to influence the system to achieve a better outcome. Assume that in the current legal framework, the only step available to these banks is to completely remove their incoming debt contract from u (as in Theorem 2); both banks can decide whether to execute this step or not. Note that canceling a debt increases the recovery rate of u, which indirectly implies a larger payment on the CDS for both v_1 and v_2, and thus can be beneficial for both banks. Applying prisoner's dilemma terminology, we also refer to the step of canceling the debt as *cooperation*, and the step of not canceling the debt as *defection*.

Now let us analyze the payoff of v_1 and v_2 in each strategy profile. Note that $r_w = 1 - r_u$, so the payment on the CDSs for both v_1 and v_2 is $3 \cdot (1 - r_w) = 3 \cdot r_u$ in any case.

If both of the nodes cooperate (i.e. both debts are removed), then u can pay its remaining liabilities, thus $r_u = 1$. This implies a payment of 3 on the CDS, which is the only asset of the acting nodes in this case; hence $q_{v_1} = q_{v_2} = 3$.

If both of the nodes defect (no debt is removed), then we only have $r_u = \frac{1}{3}$, resulting in a payment of 1 from the CDS. However, in this case, both v_1 and v_2 also get a direct payment of $5 \cdot r_u = \frac{5}{3}$ from the defaulting u, which adds up to a total payoff of $\frac{8}{3} = 2.\dot{6}$.

Finally, assume that only one of the nodes cooperate (say, v_1). With only one of the outgoing debts removed, u will have a recovery rate of $r_u = \frac{1}{2}$. This results in a payment of $\frac{3}{2}$ on the CDS for both nodes. However, note that v_2 still has an incoming debt contract from u, and receives a payment of $5 \cdot r_u = \frac{5}{2}$ on this contract. This implies $q_{v_1} = \frac{3}{2} = 1.5$, while $q_{v_2} = 4$ for the strategy profile. The symmetric case yields $q_{v_1} = 4$ and $q_{v_2} = 1.5$.

Since the payoffs are ordered exactly as in a prisoner's dilemma, we obtain an essentially equivalent situation if the two banks are not allowed to coordinate. For both players, defection is always a dominant strategy. E.g. for v_2, defection yields a payoff of 4 (instead of only 3) if v_1 cooperates, and it yields a payoff of $2.\dot{6}$ (instead of only 1.5) if v_1 defects. Thus the Nash-Equilibrium is obtained when both players defect, with $q_{v_1} = q_{v_2} = 2.\dot{6}$. However, both players would be better off with mutual cooperation, which gives $q_{v_1} = q_{v_2} = 3$.

Note that we only assumed for convenience that banks can only remove their entire debt; the behavior is similar if v_1 and v_2 can freely select the portions γ_1 and γ_2 of incoming debt that they keep. In particular, by differentiating the payoff $q_{v_1} = \frac{3+5\cdot\gamma_1}{1+\gamma_1+\gamma_2}$, one can show that defection is indeed the best response of v_1 for any choice of γ_2, and vice versa.

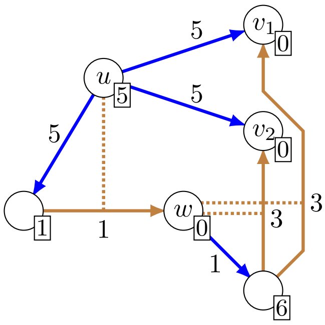

Figure 6 Representation of a prisoner's dilemma in a financial system.

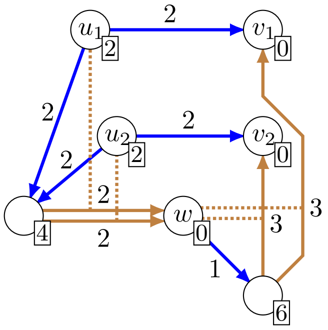

Figure 7 Representation of a stag hunt game in a financial system.

6.2 Stag Hunt

Next, we analyze the financial system in Figure 7, which represents the coordination game known as stag hunt [20]. We again assume that the two acting nodes v_1 and v_2 can only execute the action of completely removing their incoming debt contract from u_1 and u_2, respectively. As before, we refer to the decisions of removing and not removing the debt as cooperation and defection, respectively.

Recall that canceling an incoming debt and donating funds to another bank are very similar operations in some sense. With a slight modification to our system, we could also present the same example game in a setting where the acting banks must decide to donate or not donate a specific amount of funds to a bank. For our example systems, we select the action that allows a simpler presentation.

Let us analyze the payoffs in the different strategy profiles. If both players cooperate, then both u_1 and u_2 will only have a liability of 2, which implies $r_{u_1} = r_{u_2} = 1$. In this case, w receives no payment from either of the CDSs, resulting in $r_w = 0$. This means that both v_1 and v_2 get a payment of 3 from their incoming CDSs. With their debt contracts canceled, we get $q_{v_1} = q_{v_2} = 3$.

If both players defect and keep their debt contract, then both u_1 and u_2 will have a recovery rate of only $\frac{1}{2}$. This implies a payment of 1 to w on both CDSs, so w avoids default with $r_w = 1$. This means that the acting nodes will not receive any payment on the CDS. On their debt contracts, they both receive $\frac{1}{2} \cdot 2$, i.e. $q_{v_1} = q_{v_2} = 1$.

Finally, assume that v_1 cooperates but v_2 defects. In this case, we end up with recovery rates of $r_{u_1} = 1$ and $r_{u_2} = \frac{1}{2}$. Thus w only receives payment on the CDS that is in reference to u_2. However, this payment of $\frac{1}{2} \cdot 2$ is already enough for w to fulfill its liabilities, and hence $r_w = 1$. Again, v_1 and v_2 do not receive any payment on the CDS. However, v_2 still has an incoming debt contract that ensures a payment of $\frac{1}{2} \cdot 2 = 1$, while v_1 has no assets at all. Thus the solution provides $q_{v_1} = 0$ and $q_{v_2} = 1$. In a symmetric manner, the case when v_2 cooperates and v_1 defects incurs $q_{v_1} = 1$, $q_{v_2} = 0$.

Thus the system represents a game where the players are incentivized to coordinate their strategies. Both the case when both banks cooperate and when both banks defect is a pure Nash-Equilibrium, with mutual cooperation being the social optimum. However, if a bank is unsure whether the other bank will cooperate, it might be motivated to defect in order to avoid the risk of getting no payoff at all.

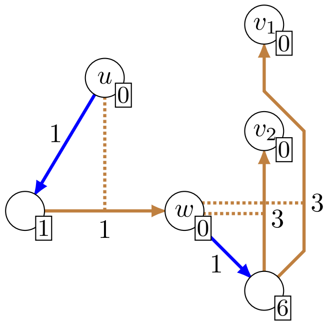

Figure 8 Representation of a chicken game in a financial system.

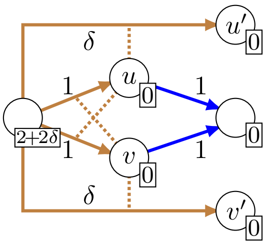

Figure 9 Representation of a dollar auction in a financial system.

6.3 Chicken game

We also provide an example of the chicken game (also known as the hawk-dove game [20]), when the pure Nash-Equilibria are obtained in the asymmetric strategy profiles.

Consider the financial system in Figure 8, and assume the acting banks v_1 and v_2 now have the options to either donate 1 unit or money to another bank, or do not donate money at all. Due to the structure of the network, the nodes are motivated to donate this 1 unit of money to u, since this results in a payment on their incoming CDS contract. We again refer to donating a unit of money to u as cooperation, and not donating as defection.

If both nodes defect, then u still has no assets at all, implying $r_u = 0$. This results in $r_w = 1$, and hence the acting nodes receive no incoming payment, so $q_{v_1} = q_{v_2} = 0$.

If both nodes cooperate, then u has more than enough assets to pay its liabilities, resulting in $r_u = 1$ and $r_w = 0$. This means that both nodes get a payment of 3 in the CDS. After subtracting the amount they have donated, we get $q_{v_1} = q_{v_2} = 2$.

However, to ensure that u does not go into default, it is enough if only one of the two nodes make a donation. I.e. if v_1 cooperates but v_2 defects, then u still has 1 asset, which already implies $r_u = 1$, $r_w = 0$ and a payment of 3 to both v_1 and v_2 on their incoming CDS. After subtracting the donated funds, this gives $q_{v_1} = 2$ and $q_{v_2} = 3$. Similarly, if v_2 cooperates and v_1 defects, we obtain $q_{v_1} = 3$, $q_{v_2} = 2$.

The payoffs show that there is no dominant strategy in the game: if v_1 cooperates, then the best response of v_2 is to defect, while if v_1 defects, then the best response of v_2 is to cooperate. This implies that the two pure Nash-Equilibria are obtained in the strategy profiles when the banks choose the opposite strategies.

Note that we can easily generalize this setting to the case of more than 2 acting nodes, resulting in the so-called volunteer's dilemma. For any k, we can add distinct banks $v_1, v_2, ..., v_k$ that are all connected to the financial network in the same way (through an incoming CDS of weight 3 in reference to w), and all have the same two options of either donating 1 unit of money to u or not acting at all. Note that we also have to ensure that the (currently unlabeled) debtor of the CDSs to these acting nodes has enough resources to make payments on these CDSs in any case, i.e. it must have external assets of at least $3 \cdot k$.

In this case, we obtain a game where again only one volunteer bank v_i is required to make a donation to u, and this already ensures a payoff of 3 for every other bank (and a payoff of 2 for v_i). In this game, the pure Nash-Equilibria are the strategy profiles where exactly one bank cooperates, and the remaining banks all defect.

6.4 Dollar auction

Finally, we show a representation of the dollar auction game [24] in financial systems. We find this example network even more interesting because it builds on a threshold behavior in the financial system model, i.e. that a minor difference in assets can lead to a completely different outcome.

Consider the system in Figure 9, and assume that banks u' and v' want to influence this system by donating extra funds to banks u or v (as in Theorem 3). Note that the payoff of u' and v' depends on the recovery rates of u and v, respectively, which in turn have a recovery rate depending on each other. Due to the design of the system, u' prefers bank u to be in default, and thus it wants to increase e_v; similarly, v' prefers bank v to be in default, so it wants to increase e_u. We assume that 1 unit of money is a very high amount in our context, and thus u' and v' cannot donate enough to ensure that u or v pays its debt entirely from external assets; i.e. we assume that $e_u, e_v < 1$ even after the donation of extra funds.

For a convenient analysis, we assume that there is a small minimum amount ϵ of funds that u' or v' can donate in one step. In our example, we choose a δ value in the magnitude of this ϵ, e.g. $\delta = 6\epsilon$.

Let us now analyze the recovery rates of u and v in the solutions of the system.

- The vector $r_u = r_v = 1$ cannot be a solution, since it would imply no payment on the incoming CDSs, and thus these recovery rates would only be possible if $e_u, e_v \geq 1$.
- If a vector $r_u = 1$, $r_v < 1$ is a solution, then since v receives no incoming payments, we must have $r_v = \frac{e_v}{1} = e_v$. Thus bank u has assets of $e_u + 1 - e_v$, which has to be at least 1 for $r_u = 1$ to hold. Hence this is only a solution if $e_u + 1 - e_v \geq 1$, i.e. $e_u \geq e_v$. In a symmetric manner, $r_v = 1$, $r_u = e_u$ is only a solution if $e_v \geq e_u$.
- If $r_u < 1$, $r_v < 1$ in a solution, then $r_u = e_u + 1 - r_v$ and $r_v = e_v + 1 - r_u$ must hold. This implies $e_u = e_v$, and $r_u + r_v = 1 + e_u$. Hence if $e_u = e_v$, then any r_u, r_v with $r_u + r_v = 1 + e_u$ provides a solution.

Thus as long as $e_u, e_v < 1$, the behavior of the system is as follows:

- If $e_u < e_v$, then the only solution is $r_u = e_u$, $r_v = 1$. This means $q_{u'} = \delta \cdot (1 - e_u)$ and $q_{v'} = 0$.
- If $e_u > e_v$, then the only solution is $r_u = 1$, $r_v = e_v$. This implies $q_{u'} = 0$ and $q_{v'} = \delta \cdot (1 - e_v)$.
- If $e_u = e_v$, then any $r_u, r_v \leq 1$ with $r_u + r_v = 1 + e_u$ is a solution of the system. In the general case, $q_{u'} = \delta \cdot (1 - r_u)$ and $q_{v'} = \delta \cdot (1 - r_v)$.

This describes a setting that is very similar to a dollar auction. In the beginning, with $e_u = e_v = 0$, we have a range of different solutions, and a choice among these depends on a financial authority. One of the banks (say, bank u') decides to donate a small ϵ amount of funds to v; then with $e_v = \epsilon > e_u = 0$, bank u' receives a payment of $\delta \cdot (1 - 0)$ in the only resulting solution. At this point, the payoff of v' is 0; however, at the cost of donating $2 \cdot \epsilon$ funds to u, it could achieve $e_u = 2\epsilon > e_v = \epsilon$, thus resulting in a single solution with a payoff of $q_{v'} = \delta \cdot (1 - \epsilon)$. Since this increases the payoff of v' by $\delta \cdot (1 - \epsilon)$ at the cost of only 2ϵ, this is indeed a rational step for the appropriate δ and ϵ values. However, then u' is again motivated to donate 2ϵ more funds to increase e_v over e_u again, and so on.

Assuming that both u' and v' has at most $\frac{1}{2}$ funds to donate, we always have $e_u, e_v \in [0, \frac{1}{2}]$. This shows that e.g. if we have $e_u > e_v$, then the payoff of bank v' is always within

$$q_{v'} = \delta \cdot (1 - e_v) \; \in \; [\delta/2 \, , \, \delta] = [3\epsilon \, , \, 6\epsilon].$$

Hence in every step, it is indeed rational for v' to donate another 2ϵ funds, since it increases its payoff from 0 to at least 3ϵ. After a couple of rounds, u' and v' will have both donated significantly more money than their payoff of at most 6ϵ. However, the banks are still always tempted to execute the next donation step to mitigate their losses.

Abstract

We investigate the power of randomness in two-party communication complexity. In particular, we study the model where the parties can make a constant number of queries to a function with an efficient one-sided-error randomized protocol. The complexity classes defined by this model comprise the Randomized Boolean Hierarchy, which is analogous to the Boolean Hierarchy but defined with one-sided-error randomness instead of nondeterminism. Our techniques connect the Nondeterministic and Randomized Boolean Hierarchies, and we provide a complete picture of the relationships among complexity classes within and across these two hierarchies. In particular, we prove that the Randomized Boolean Hierarchy does not collapse, and we prove a query-to-communication lifting theorem for all levels of the Nondeterministic Boolean Hierarchy and use it to resolve an open problem stated in the paper by Halstenberg and Reischuk (CCC 1988) which initiated the study of this hierarchy.

1 Introduction

A classic example of the power of randomness in communication is the Equality function: Alice gets an n-bit string x, Bob gets an n-bit string y, and they want to know whether x equals y. Though Equality is maximally hard for deterministic communication [35], it can be solved by a randomized protocol using $O(1)$ bits of communication (in the public-coin model) using the fingerprinting technique. Although this example (known for over 40 years) demonstrates the power of randomized communication in the standard two-party setting, many questions remain about the exact power of randomness in communication.

Much is still not understood about the power of randomness in other important communication settings beyond the standard two-party model. For example, in the Number-on-Forehead (NOF) model, even for three parties, no explicit function is known to exhibit a superpolylogarithmic separation between randomized and deterministic communication [25] (despite the fact that linear lower bounds for randomized NOF protocols were proven over 30 years ago in the seminal paper [3]). Another example concerns randomness in the context of *nondeterministic* two-party protocols (so-called Arthur–Merlin and Merlin–Arthur models). While strong lower bounds are known for Merlin–Arthur protocols [22] (though even here, explicit linear lower bounds remain elusive), no strong lower bounds are known for Arthur–Merlin protocols computing any explicit function – such bounds are necessary for making progress on rigidity bounds and circuit lower bounds, and also important for delegation [29, 12, 1].

We wish to highlight that even in the standard setting of plain randomized two-party communication protocols, many fundamental questions remain poorly understood. Our goal in this paper is to make progress on some of these questions. Much is known about the *limitations* of randomness – e.g., strong (indeed, linear) lower bounds are known for the classic SET-DISJOINTNESS function [2, 21, 30, 4], which can be viewed as showing that $\mathsf{coNP}^{\mathsf{cc}} \not\subseteq \mathsf{BPP}^{\mathsf{cc}}$ (where we use $^{\mathsf{cc}}$ superscripts to indicate the communication analogues of classical complexity classes). However, surprisingly little is known about the *power* of randomness. Most known efficient randomized protocols for other functions, such as GREATER-THAN, can be viewed as oracle reductions to the aforementioned EQUALITY upper bound: GREATER-THAN $\in \mathsf{P}^{\textsc{Equality}}$. Until recently, it was not even known whether $\mathsf{BPP}^{\mathsf{cc}} = \mathsf{P}^{\textsc{Equality}}$ (assuming the classes are defined to contain only total two-party functions), i.e., whether EQUALITY is the "only" thing randomness is good for. Chattopadhyay, Lovett, and Vinyals [8] answered this question in the negative by exhibiting a total function that is in $\mathsf{BPP}^{\mathsf{cc}}$ (indeed, in $\mathsf{coRP}^{\mathsf{cc}}$) but not in $\mathsf{P}^{\textsc{Equality}}$ (though the upper bound is still a form of fingerprinting). Since EQUALITY $\in \mathsf{coRP}^{\mathsf{cc}}$, we have $\mathsf{P}^{\textsc{Equality}} \subseteq \mathsf{P}^{\mathsf{RP}^{\mathsf{cc}}}$ where the latter class contains functions with efficient deterministic protocols that can make (adaptive) oracle queries to any function in $\mathsf{RP}^{\mathsf{cc}}$. In fact, [8] exhibited a strict infinite hierarchy of classes within $\mathsf{P}^{\mathsf{RP}^{\mathsf{cc}}}$, with $\mathsf{P}^{\textsc{Equality}}$ at the bottom, and with subsequent levels having increasingly powerful specific oracle functions.

However, it remains open whether $\mathsf{BPP}^{\mathsf{cc}} = \mathsf{P}^{\mathsf{RP}^{\mathsf{cc}}}$ for total functions (intuitively, whether two-sided error can be efficiently converted to oracle queries to one-sided error). It is even open whether $\mathsf{BPP}^{\mathsf{cc}} \subseteq \mathsf{P}^{\mathsf{NP}^{\mathsf{cc}}}$ for total functions [15], although this is known to be false if the classes are defined to allow partial functions [26]. We obtain a more detailed understanding of the structure of $\mathsf{P}^{\mathsf{RP}^{\mathsf{cc}}}$ by focusing on *restricting the number of oracle queries* (rather than restricting the $\mathsf{RP}^{\mathsf{cc}}$ function as in [8]). For constants $q = 0, 1, 2, 3, \ldots$, the class $\mathsf{P}_{\parallel}^{\mathsf{RP}[q]^{\mathsf{cc}}}$ consists of all two-party functions with an efficient (polylogarithmic communication cost) deterministic protocol that can make q many nonadaptive queries to an oracle for a function in $\mathsf{RP}^{\mathsf{cc}}$. Even if partial functions are allowed, it was not known whether these classes form a strict infinite hierarchy, i.e., whether $\mathsf{P}_{\parallel}^{\mathsf{RP}[q]^{\mathsf{cc}}} \subsetneq \mathsf{P}_{\parallel}^{\mathsf{RP}[q+1]^{\mathsf{cc}}}$ for all q. One of our main contributions (Theorem 1) implies that this is indeed the case, even for total functions. Our proof introduces new lower bound techniques.

With $\mathsf{NP}^{\mathsf{cc}}$ in place of $\mathsf{RP}^{\mathsf{cc}}$, $\bigcup_q \mathsf{P}_{\parallel}^{\mathsf{NP}[q]^{\mathsf{cc}}}$ forms the communication version of the Boolean Hierarchy from classical complexity, which was previously studied by Halstenberg and Reischuk [16, 17, 18]. We also prove results (Theorem 2 and Theorem 3) that resolve a 31-year-old open question posed in their work. $\bigcup_q \mathsf{P}_{\parallel}^{\mathsf{RP}[q]^{\mathsf{cc}}}$ can be viewed as the communication version of the Randomized Boolean Hierarchy, which has not been studied explicitly in previous works. Overall, we obtain a complete understanding of the relationships among the classes within and across the Nondeterministic and Randomized Boolean Hierarchies in communication complexity. In the following subsection we discuss the relevant communication complexity classes and describe our theorems in detail.

1.1 Background and our contributions

Forgetting about communication complexity for a moment, the Boolean Hierarchy in classical complexity theory consists of problems that have a polynomial-time algorithm making a constant number of queries to an NP oracle. This hierarchy has an intricate relationship with other complexity classes, and its second level (DP) captures the complexity of certain "exact" versions of optimization problems. It consists of an infinite sequence of complexity classes $\mathsf{NP}(q)$ for $q = 1, 2, 3, \ldots$ (where $\mathsf{NP}(1) = \mathsf{NP}$ and $\mathsf{NP}(2) = \mathsf{DP}$). Among the several equivalent ways of defining these classes [34, 7, 23, 32], perhaps the simplest is that $\mathsf{NP}(q)$ consists of all decision problems that can be computed by taking the parity of the answers to a sequence of q NP problems on the given input. As illustrated in Figure 1, it is known that these levels are intertwined with the classes $\mathsf{P}_{\parallel}^{\mathsf{NP}[q]}$ of all decision problems solvable in polynomial time using q nonadaptive NP queries (for constant q) [23, 32, 5]:

$$\mathsf{NP}(q) \subseteq \mathsf{P}_{\parallel}^{\mathsf{NP}[q]} \subseteq \mathsf{NP}(q+1) \qquad \text{and} \qquad \mathsf{coNP}(q) \subseteq \mathsf{P}_{\parallel}^{\mathsf{NP}[q]} \subseteq \mathsf{coNP}(q+1)$$

(by closure of $\mathsf{P}_{\parallel}^{\mathsf{NP}[q]}$ under complementation). Here, $\mathsf{coNP}(q)$ means $\mathsf{co}(\mathsf{NP}(q))$ rather than $(\mathsf{coNP})(q)$.

Analogous to the above *Nondeterministic* Boolean Hierarchy, one can define the *Randomized* Boolean Hierarchy by using RP (one-sided error randomized polynomial time) instead of NP in the definitions [6]. The analogous inclusions like in Figure 1 hold among all the classes $\mathsf{RP}(q)$, $\mathsf{coRP}(q)$, and $\mathsf{P}_{\parallel}^{\mathsf{RP}[q]}$, by similar arguments. Although the (suitably defined) *Polynomial* Hierarchy over RP is known to collapse to its second level, which equals BPP [36], the *Boolean* Hierarchy over RP has not been widely studied.

Recall the basic (deterministic) model of communication [35, 24], where Alice is given an input x and Bob is given an input y, and they wish to collaboratively evaluate some function $F(x, y)$ of their joint input by engaging in a protocol that specifies how they exchange bits of information about their inputs. Many classical complexity classes (P, RP, NP, and so on) have natural two-party communication analogues [2] (including the classes in the Nondeterministic and Randomized Boolean Hierarchies). The area of structural communication complexity, which concerns the properties of and relationships among these classes, is undergoing a renaissance and has turned out to yield new techniques and perspectives for understanding questions in a variety of other areas (circuit complexity, proof complexity, data structures, learning theory, delegation, fine-grained complexity, property testing, cryptography, extended formulations, etc.) [15]. For any classical time-bounded complexity class $\mathcal{C}$, we use $\mathcal{C}^{\mathsf{cc}}$ to denote its communication complexity analogue – the class of all two-party functions on n bits that admit a protocol communicating at most polylog(n) bits, in a model defined by analogy with the classical $\mathcal{C}$.

Halstenberg and Reischuk [16, 17] initiated the study of the Nondeterministic Boolean Hierarchy in two-party communication complexity. They observed that the inclusions shown in Figure 1 hold for the communication versions of the classes, by essentially the same proofs as in the time-bounded setting. They also proved that $\mathsf{NP}(q)^{\mathsf{cc}} \neq \mathsf{coNP}(q)^{\mathsf{cc}}$, which simultaneously implies that each of the inclusions is strict: $\mathsf{NP}(q)^{\mathsf{cc}} \subsetneq \mathsf{P}_{\parallel}^{\mathsf{NP}[q]\mathsf{cc}} \subsetneq \mathsf{NP}(q+1)^{\mathsf{cc}}$.

The communication version of the Randomized Boolean Hierarchy has not been explicitly studied as far as we know, but as mentioned earlier it is interesting since Equality $\in \mathsf{coRP}^{\mathsf{cc}}$ and many randomized protocols have been designed by reduction to this fact (such as

$$\begin{tikzcd}
 & \begin{array}{c}\mathsf{NP} =\\ \mathsf{NP}(1)\end{array} \arrow[dr] & & \begin{array}{c}\mathsf{DP} =\\ \mathsf{NP}(2)\end{array} \arrow[dr] & & \mathsf{NP}(3) \arrow[dr] & & \mathsf{NP}(4) \arrow[dr] & & & & \\
\mathsf{P} \arrow[ur] \arrow[dr] & & \mathsf{P}^{\mathsf{NP}[1]} \arrow[ur] \arrow[dr] & & \mathsf{P}_{\|}^{\mathsf{NP}[2]} \arrow[ur] \arrow[dr] & & \mathsf{P}_{\|}^{\mathsf{NP}[3]} \arrow[ur] \arrow[dr] & & \mathsf{P}_{\|}^{\mathsf{NP}[4]} & \cdots & \mathsf{P}_{\|}^{\mathsf{NP}} \arrow[r] & \mathsf{P}^{\mathsf{NP}} \\
 & \begin{array}{c}\mathsf{coNP}(1)\\ = \mathsf{coNP}\end{array} \arrow[ur] & & \begin{array}{c}\mathsf{coNP}(2)\\ = \mathsf{coDP}\end{array} \arrow[ur] & & \mathsf{coNP}(3) \arrow[ur] & & \mathsf{coNP}(4) \arrow[ur] & & & &
\end{tikzcd}$$

Figure 1 Relations between classes in the Boolean Hierarchy. Here, $\mathcal{C}_1 \to \mathcal{C}_2$ represents $\mathcal{C}_1 \subseteq \mathcal{C}_2$.

Greater-Than $\in \mathsf{P}^{\mathsf{RP}^{\mathsf{cc}}}$). What can we say about the power of a fixed number of queries to an $\mathsf{RP}^{\mathsf{cc}}$ oracle? Our first contribution strengthens the aforementioned separation due to Halstenberg and Reischuk.

▶ **Theorem 1.** *For total functions,* $\mathsf{coRP}(q)^{\mathsf{cc}} \not\subseteq \mathsf{NP}(q)^{\mathsf{cc}}$ *for every constant* q.

Since $\mathsf{RP}^{\mathsf{cc}} \subseteq \mathsf{NP}^{\mathsf{cc}}$, Theorem 1 simultaneously implies that each of the inclusions in the Randomized Boolean Hierarchy is strict: $\mathsf{RP}(q)^{\mathsf{cc}} \subsetneq \mathsf{P}_{\|}^{\mathsf{RP}[q]\mathsf{cc}} \subsetneq \mathsf{RP}(q+1)^{\mathsf{cc}}$, and thus the hierarchy does not collapse. Previously, no separation beyond the first level seemed to be known in the literature. Our proof of Theorem 1 is completely different from (and more involved than) Halstenberg and Reischuk's proof of $\mathsf{coNP}(q)^{\mathsf{cc}} \not\subseteq \mathsf{NP}(q)^{\mathsf{cc}}$, which used the "easy-hard argument" of [20].

In [16, 17], Halstenberg and Reischuk asked whether the inclusion $\mathsf{P}_{\|}^{\mathsf{NP}[q]\mathsf{cc}} \subseteq \mathsf{NP}(q+1)^{\mathsf{cc}} \cap \mathsf{coNP}(q+1)^{\mathsf{cc}}$ is strict. When $q = 0$, this is answered by the familiar results that $\mathsf{P}^{\mathsf{cc}} = \mathsf{NP}^{\mathsf{cc}} \cap \mathsf{coNP}^{\mathsf{cc}}$ when the classes are defined to contain only total functions [18], whereas $\mathsf{P}^{\mathsf{cc}} \subsetneq \mathsf{NP}^{\mathsf{cc}} \cap \mathsf{coNP}^{\mathsf{cc}}$ (indeed, $\mathsf{P}^{\mathsf{cc}} \subsetneq \mathsf{ZPP}^{\mathsf{cc}}$) holds when partial functions (promise problems) are allowed. For $q > 0$, we resolve this 31-year-old open question by proving that the situation is analogous to the $q = 0$ case.

▶ **Theorem 2.** *For total functions,*

$$\mathsf{P}_{\|}^{\mathsf{NP}[q]\mathsf{cc}} = \mathsf{NP}(q+1)^{\mathsf{cc}} \cap \mathsf{coNP}(q+1)^{\mathsf{cc}} \qquad \textit{and} \qquad \mathsf{P}_{\|}^{\mathsf{RP}[q]\mathsf{cc}} = \mathsf{RP}(q+1)^{\mathsf{cc}} \cap \mathsf{coRP}(q+1)^{\mathsf{cc}}$$

for every constant q.

▶ **Theorem 3.** *For partial functions,* $\mathsf{RP}(q+1)^{\mathsf{cc}} \cap \mathsf{coRP}(q+1)^{\mathsf{cc}} \not\subseteq \mathsf{P}_{\|}^{\mathsf{NP}[q]\mathsf{cc}}$ *for every constant* q.

Since $\mathsf{RP}^{\mathsf{cc}} \subseteq \mathsf{NP}^{\mathsf{cc}}$, Theorem 3 implies that

$$\mathsf{P}_{\|}^{\mathsf{NP}[q]\mathsf{cc}} \subsetneq \mathsf{NP}(q+1)^{\mathsf{cc}} \cap \mathsf{coNP}(q+1)^{\mathsf{cc}} \qquad \text{and} \qquad \mathsf{P}_{\|}^{\mathsf{RP}[q]\mathsf{cc}} \subsetneq \mathsf{RP}(q+1)^{\mathsf{cc}} \cap \mathsf{coRP}(q+1)^{\mathsf{cc}}$$

for partial functions. Taken together, Theorem 1, Theorem 2, and Theorem 3 complete the picture of the relationships among the classes within and across both hierarchies, for both total and partial functions.

1.2 Query-to-communication lifting

Our proof of Theorem 3 uses the paradigm of *query-to-communication lifting* [28, 11, 9, 14, 10, 13, 33]. This approach to proving communication lower bounds has led to breakthroughs on fundamental questions in communication complexity and many of its application areas. The idea consists of two steps:

(1) First prove an analogous lower bound in the simpler setting of decision tree depth complexity (a.k.a. query complexity). This step captures the combinatorial core of the lower bound argument without the burden of dealing with the full power of communication protocols.
(2) Then apply a *lifting theorem*, which translates the query lower bound into a communication lower bound for a related two-party function. This step encapsulates the general-purpose machinery for dealing with protocols, and can be reused from one argument to the next.

The availability of a lifting theorem greatly simplifies the task of proving certain communication lower bounds, because it divorces the problem-specific aspects from the generic aspects. The format of a lifting theorem is that if $f\colon \{0,1\}^n \to \{0,1\}$ is any partial function and $g\colon \mathcal{X} \times \mathcal{Y} \to \{0,1\}$ is a certain "small" two-party function called a gadget, then the communication complexity of the two-party composed function $f \circ g^n\colon \mathcal{X}^n \times \mathcal{Y}^n \to \{0,1\}$ – in which Alice gets $x = (x_1, \dots, x_n)$, Bob gets $y = (y_1, \dots, y_n)$, and their goal is to evaluate $(f \circ g^n)(x, y) := f(g(x_1, y_1), \dots, g(x_n, y_n))$ – should be approximately the query complexity of the outer function f. One direction is generally straightforward: given a query upper bound for f, a communication upper bound for $f \circ g^n$ is witnessed by a protocol that simulates the decision tree for f and evaluates $g(x_i, y_i)$ whenever it queries the i^{th} bit of the input to f; the number of bits of communication is at most the number of queries made by the decision tree times the (small) cost of evaluating a copy of g. The other direction is the challenging part: despite Alice and Bob's ability to send messages that depend in arbitrary ways on all n coordinates, they nevertheless cannot do much better than just simulating a decision tree, which involves "talking about" one coordinate at a time.

A lifting theorem must be stated with respect to a particular model of computation, such as deterministic, one-sided error randomized, nondeterministic, etc., which we associate with the corresponding complexity classes. Indeed, lifting theorems are known for P [28, 14], RP [13], NP [11, 9], and many other classes. It is convenient to recycle complexity class names to denote the complexity of a given function in the corresponding model, e.g., $\mathsf{P}^{\mathsf{dt}}(f)$ is the minimum worst-case number of queries made by any decision tree that computes f, and $\mathsf{P}^{\mathsf{cc}}(F)$ is the minimum worst-case communication cost of any protocol that computes F. With this notation, the deterministic lifting theorem from [28, 14] can be stated as: for all f, $\mathsf{P}^{\mathsf{cc}}(f \circ g^n) = \mathsf{P}^{\mathsf{dt}}(f) \cdot \Theta(\log n)$ where $g\colon [m] \times \{0,1\}^m \to \{0,1\}$ is the "index" gadget defined by $g(x, y) = y_x$ with $m := n^{20}$. (Note that $\mathsf{P}^{\mathsf{cc}}(g) = O(\log n)$ since Alice can send her $\log m$-bit "pointer" to Bob, who responds with the pointed-to bit from his string.) The index gadget has also been used in lifting theorems for several other complexity classes.

We prove lifting theorems for all classes in the Nondeterministic Boolean Hierarchy, with the index gadget.

▶ **Theorem 4.** *For every partial function* $f\colon \{0,1\}^n \to \{0,1\}$ *and every constant* q*,*
(i) $\mathsf{NP}(q)^{\mathsf{cc}}(f \circ g^n) \;=\; \mathsf{NP}(q)^{\mathsf{dt}}(f) \cdot \Theta(\log n)$
(ii) $\mathsf{P}_{\parallel}^{\mathsf{NP}[q]\mathsf{cc}}(f \circ g^n) \;=\; \mathsf{P}_{\parallel}^{\mathsf{NP}[q]\mathsf{dt}}(f) \cdot \Theta(\log n)$
where $g\colon [m] \times \{0,1\}^m \to \{0,1\}$ *is the index gadget defined by* $g(x, y) = y_x$ *with* $m := n^{20}$*.*

Only part *(ii)* is needed for proving Theorem 3, but part *(i)* forms an ingredient in the proof of *(ii)* and is of independent interest.

The most closely related lifting theorem to Theorem 4 is the one for P^{NP} [10], corresponding to computations that make an unbounded number of adaptive queries to an NP oracle. In that paper, the overall idea was to approximately characterize P^{NP} complexity in terms of *decision lists* (DL), and then prove a lifting theorem directly for DLs. Briefly, a conjunction

DL (introduced by [31]) is a sequence of small-width conjunctions each with an associated output bit, and the output is determined by finding the first conjunction in the list that accepts the given input. A rectangle DL is similar but with combinatorial rectangles instead of conjunctions. The proof from [10] shows how to convert a rectangle DL for $f \circ g^n$ into a conjunction DL for f.

The gist of our arguments for both parts of Theorem 4 is to approximately characterize (via different techniques than for P^{NP}) these classes in terms of DLs with a bounded number of *alternations* (how many times the associated output bit flips as we walk down the entire DL). The DL lifting argument from [10] does not preserve the number of alternations, but we show how it can be adapted to do this. Our techniques also yield an approximate lifting theorem for $\mathsf{P}_{\|}^{\mathsf{NP}}$ (corresponding to computations that make an unbounded number of nonadaptive NP oracle queries), but we omit the details.

2 Preliminaries

We assume familiarity with deterministic computation in query and communication complexity [19, 24]. Recall the following standard definitions of nondeterministic and one-sided error randomized models:

- An $\mathsf{NP}^{\mathsf{dt}}$ decision tree is a DNF formula Φ. Given an input z, the output of such a decision tree is Φ evaluated on z. A function f is computed by Φ if $f(z) = \Phi(z)$ on all inputs z for which $f(z)$ is defined. The cost of Φ is the maximum width (number of literals) in any conjunction in Φ.
- An $\mathsf{NP}^{\mathsf{cc}}$ protocol is a set $\mathcal{R}$ of combinatorial rectangles. Given an input (x, y), the output of such a protocol is $\mathcal{R}(x, y) \coloneqq 1$ iff there exists an $R \in \mathcal{R}$ containing (x, y). A two-party function F is computed by $\mathcal{R}$ if $F(x, y) = \mathcal{R}(x, y)$ on all inputs (x, y) for which $F(x, y)$ is defined. The cost of $\mathcal{R}$ is $\lceil \log(|\mathcal{R}| + 1) \rceil$, which intuitively represents the number of bits required to specify a rectangle in $\mathcal{R}$ or indicate that the input is in no such rectangle.
- An $\mathsf{RP}^{\mathsf{dt}}$ decision tree is a distribution $\boldsymbol{T}$ over deterministic decision trees. Given an input z, the output of such a decision tree is computed by sampling a deterministic decision tree T from $\boldsymbol{T}$ and evaluating $T(z)$. A function f is computed by $\boldsymbol{T}$ if for all $z \in f^{-1}(0)$, $\Pr_{T \sim \boldsymbol{T}}[T(z) = 1] = 0$ and for all $z \in f^{-1}(1)$, $\Pr_{T \sim \boldsymbol{T}}[T(z) = 1] \geq 1/2$. The cost of $\boldsymbol{T}$ is the maximum number of bits queried in any T in its support.
- An $\mathsf{RP}^{\mathsf{cc}}$ protocol is a distribution $\boldsymbol{\Pi}$ over deterministic communication protocols. Given an input (x, y), the output of such a protocol is computed by sampling a deterministic protocol Π from $\boldsymbol{\Pi}$ and evaluating $\Pi(x, y)$. A function F is computed by $\boldsymbol{\Pi}$ if for all $(x, y) \in F^{-1}(0)$, $\Pr_{\Pi \sim \boldsymbol{\Pi}}[\Pi(x, y) = 1] = 0$ and for all $(x, y) \in F^{-1}(1)$, $\Pr_{\Pi \sim \boldsymbol{\Pi}}[\Pi(x, y) = 1] \geq 1/2$. The cost of $\boldsymbol{\Pi}$ is the maximum number of bits exchanged in any Π in its support.

Let $\mathcal{C}$ be an arbitrary complexity class name representing a model of computation (such as NP or RP). We let $\mathcal{C}^{\mathsf{cc}}(F)$ denote the communication complexity of a two-party function F in the corresponding model: the minimum cost of any $\mathcal{C}^{\mathsf{cc}}$ protocol computing F. We let $\mathcal{C}^{\mathsf{dt}}(f)$ denote the query complexity of a Boolean function f in the corresponding model: the minimum cost of any $\mathcal{C}^{\mathsf{dt}}$ decision tree computing f. Often we will abuse notation by having F or f refer to an infinite *family* of functions, where there is at most one function in the family for each possible input length. In this case, $\mathcal{C}^{\mathsf{cc}}(F)$ or $\mathcal{C}^{\mathsf{dt}}(f)$ will be the complexity parameterized by the input length n; we typically express this with asymptotic notation. When written by itself, $\mathcal{C}^{\mathsf{cc}}$ or $\mathcal{C}^{\mathsf{dt}}$ denotes the class of all families of functions with complexity at most polylogarithmic in n, in the corresponding model. We will always clarify whether a class $\mathcal{C}^{\mathsf{cc}}$ or $\mathcal{C}^{\mathsf{dt}}$ is meant to contain partial functions or just total functions, since this is not explicit in the notation.

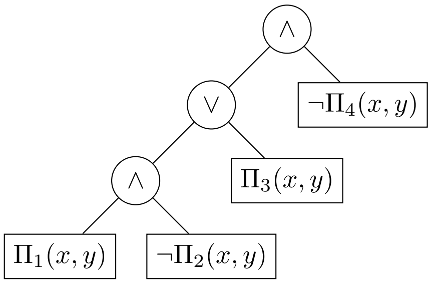

Figure 2 A visualization of a $\mathcal{C}(4)^{\mathsf{cc}}$ protocol, where each Π_i is a $\mathcal{C}^{\mathsf{cc}}$ protocol.

For $\mathsf{RP}^{\mathsf{cc}}$ and $\mathsf{RP}^{\mathsf{dt}}$, the constant $1/2$ in the success probability is arbitrary: by amplification, choosing a different positive constant in the definition would only affect the complexity of any function by a constant factor. Also note that $\mathsf{NP}^{\mathsf{dt}}(f) \leq \mathsf{RP}^{\mathsf{dt}}(f)$ for all f, and since we defined $\mathsf{RP}^{\mathsf{cc}}$ using the public-coin model, we have $\mathsf{NP}^{\mathsf{cc}}(F) \leq \mathsf{RP}^{\mathsf{cc}}(F) + O(\log n)$ for all F (by decreasing the number of random bits for sampling a protocol to $O(\log n)$ and using nondeterminism to guess an outcome that results in output 1).

2.1 Nondeterministic and Randomized Boolean Hierarchies

In the following definitions, restrict $\mathcal{C}$ to be either NP or RP. We will use two different but equivalent definitions of the constituent levels of the Nondeterministic and Randomized Boolean Hierarchies. Our "official" definition is in terms of the following "decision list functions" (also known as "odd-max-bit"):

▶ **Definition 5.** $\Delta_q \colon \{0,1\}^q \to \{0,1\}$ *is defined inductively as follows:*
- $\Delta_1(z_1) \coloneqq z_1$.
- *If q is odd,* $\Delta_q(z_1,\ldots,z_{q-1},z_q) \coloneqq \Delta_{q-1}(z_1,\ldots,z_{q-1}) \vee z_q$.
- *If q is even,* $\Delta_q(z_1,\ldots,z_{q-1},z_q) \coloneqq \Delta_{q-1}(z_1,\ldots,z_{q-1}) \wedge (\neg z_q)$.

In other words, letting $\oplus \colon \mathbb{N} \to \{0,1\}$ denote the parity function, we have $\Delta_q(z) \coloneqq \oplus(i)$ where i is the greatest index such that $z_i = 1$ (or $i = 0$ if z is all zeros).

▶ **Definition 6.** *A $\mathcal{C}(q)^{\mathsf{cc}}$ protocol is an ordered list of q many $\mathcal{C}^{\mathsf{cc}}$ protocols $\Pi = (\Pi_1,\ldots,\Pi_q)$. Given an input (x,y), the output of the protocol is $\Pi(x,y) \coloneqq \Delta_q(\Pi_1(x,y),\ldots,\Pi_q(x,y))$. The cost of a $\mathcal{C}(q)^{\mathsf{cc}}$ protocol is the sum of the costs of the component $\mathcal{C}^{\mathsf{cc}}$ protocols.*

See Figure 2 for an example of such a protocol. The Nondeterministic Boolean Hierarchy is $\bigcup_{\text{constant } q} \mathsf{NP}(q)^{\mathsf{cc}}$ and the Randomized Boolean Hierarchy is $\bigcup_{\text{constant } q} \mathsf{RP}(q)^{\mathsf{cc}}$. We are also interested in the complement classes $\mathsf{coNP}(q)^{\mathsf{cc}}$ and $\mathsf{coRP}(q)^{\mathsf{cc}}$. As is standard, when we write $\mathsf{co}\mathcal{C}(q)^{\mathsf{cc}}$ we refer to the class $\mathsf{co}(\mathcal{C}(q)^{\mathsf{cc}})$ (that is, functions that are the negations of functions in $\mathcal{C}(q)^{\mathsf{cc}}$) as opposed to $(\mathsf{co}\mathcal{C})(q)^{\mathsf{cc}}$ (that is, where the component protocols are $\mathsf{co}\mathcal{C}^{\mathsf{cc}}$ protocols).

There are analogous definitions in query complexity:

▶ **Definition 7.** *A $\mathcal{C}(q)^{\mathsf{dt}}$ decision tree is an ordered list of q many $\mathcal{C}^{\mathsf{dt}}$ decision trees $T = (T_1,\ldots,T_q)$. Given an input z, define the output as $T(z) \coloneqq \Delta_q(T_1(z),\ldots,T_q(z))$. The cost of a $\mathcal{C}(q)^{\mathsf{dt}}$ decision tree is the sum of the costs of the component $\mathcal{C}^{\mathsf{dt}}$ decision trees.*

Our alternative definition of the Nondeterministic and Randomized Boolean Hierarchies simply replaces Δ_q with the parity function $\oplus_q \colon \{0,1\}^q \to \{0,1\}$.

▶ **Lemma 8.** *For $\mathcal{C} \in \{\mathsf{NP}, \mathsf{RP}\}$, if the definitions of $\mathcal{C}(q)^{\mathsf{cc}}$ and $\mathcal{C}(q)^{\mathsf{dt}}$ are changed to use $\oplus_q$ in place of Δ_q, it only affects the complexity measures $\mathcal{C}(q)^{\mathsf{cc}}(F)$ and $\mathcal{C}(q)^{\mathsf{dt}}(f)$ by a constant factor (depending on q).*

Wagner [32] showed that these alternative characterizations are equivalent for the classical Nondeterministic Boolean Hierarchy, and Halstenberg and Reischuk [17] observed the same (up to a constant factor) in communication complexity. This latter proof uses only the property that $\mathsf{NP}^{\mathsf{cc}}$ is closed under intersection and union; that is, if $\mathsf{NP}^{\mathsf{cc}}(F_1), \mathsf{NP}^{\mathsf{cc}}(F_2) \leq k$, then $\mathsf{NP}^{\mathsf{cc}}(F_1 \wedge F_2)$ and $\mathsf{NP}^{\mathsf{cc}}(F_1 \vee F_2)$ are both $O(k)$. Observe that since this property also holds for $\mathsf{RP}^{\mathsf{cc}}$, $\mathsf{NP}^{\mathsf{dt}}$, and $\mathsf{RP}^{\mathsf{dt}}$, their proof works for these models of computation as well. In fact, in all of these models, the cost of the intersection or union of i cost-k computations is at most ik.

We use both definitions in this paper. We found that the Δ_q definition makes it easier to prove the lifting theorems, and the $\oplus_q$ definition makes it easier to prove concrete upper and lower bounds.

2.2 Parallel queries

In the following definitions, restrict $\mathcal{C}$ to be either NP or RP.

▶ **Definition 9.** *A $\mathsf{P}_{\|}^{\mathcal{C}[q]\mathsf{cc}}$ protocol consists of a deterministic protocol Π_{det} that maps an input (x, y) to two things: a function $\mathsf{out}\colon \{0,1\}^q \to \{0,1\}$ and an ordered list of q many $\mathcal{C}^{\mathsf{cc}}$ protocols $(\Pi_1, \ldots, \Pi_q)$. The output is then $\mathsf{out}(\Pi_1(x,y), \ldots, \Pi_q(x,y))$. The cost of a $\mathsf{P}_{\|}^{\mathcal{C}[q]\mathsf{cc}}$ protocol is the communication cost (depth) of Π_{det} plus the maximum over (x,y) of the sum of the costs of the $\mathcal{C}^{\mathsf{cc}}$ protocols produced by $\Pi_{\text{det}}(x,y)$.*

▶ **Definition 10.** *A $\mathsf{P}_{\|}^{\mathcal{C}[q]\mathsf{dt}}$ decision tree consists of a deterministic decision tree T_{det} that maps an input z to two things: a function $\mathsf{out}\colon \{0,1\}^q \to \{0,1\}$ and an ordered list of q many $\mathcal{C}^{\mathsf{dt}}$ decision trees $(T_1, \ldots, T_q)$. The output is then $\mathsf{out}(T_1(z), \ldots, T_q(z))$. The cost of a $\mathsf{P}_{\|}^{\mathcal{C}[q]\mathsf{dt}}$ decision tree is the query cost (depth) of T_{det} plus the maximum over z of the sum of the costs of the $\mathcal{C}^{\mathsf{dt}}$ decision trees produced by $T_{\text{det}}(z)$.*

The following lemma states that at each leaf of Π_{det} or T_{det}, we can replace the q "$\mathcal{C}$ oracle queries" with one "$\mathcal{C}(q)$ oracle query" (where some leaves may output the oracle's answer, while other leaves output the negation of it). This was shown in classical time-bounded complexity using the so-called "mind-change argument" [5], and this argument can be translated directly to communication and query complexity. For example, [17] used this method to show that $\mathsf{P}_{\|}^{\mathsf{NP}[q]\mathsf{cc}} \subseteq \mathsf{NP}(q+1)^{\mathsf{cc}} \cap \mathsf{coNP}(q+1)^{\mathsf{cc}}$. We will only need to use the result for $\mathcal{C} = \mathsf{NP}$.

▶ **Lemma 11.** *For $\mathcal{C} \in \{\mathsf{NP}, \mathsf{RP}\}$, we have $\mathsf{P}_{\|}^{\mathcal{C}[q]\mathsf{cc}}(F) = \Theta(\mathsf{P}^{\mathcal{C}(q)[1]\mathsf{cc}}(F))$ and $\mathsf{P}_{\|}^{\mathcal{C}[q]\mathsf{dt}}(f) = \Theta(\mathsf{P}^{\mathcal{C}(q)[1]\mathsf{dt}}(f))$ for every constant q.*

3 Separations

In this section we prove our separation results (Theorem 1 and Theorem 3).

3.1 Proof of Theorem 1

▶ **Theorem** (Restatement of Theorem 1). *For total functions, $\mathsf{coRP}(q)^{\mathsf{cc}} \not\subseteq \mathsf{NP}(q)^{\mathsf{cc}}$ for every constant q.*

Fix any constant q. Let $\oplus_q\textsc{NonEq}\colon (\{0,1\}^n)^q \times (\{0,1\}^n)^q \to \{0,1\}$ be the two-party total function where Alice's and Bob's inputs are divided into q blocks $x = (x_1,\dots,x_q)$ and $y = (y_1,\dots,y_q)$ with each $x_i, y_i \in \{0,1\}^n$, and which is defined by $\oplus_q\textsc{NonEq}(x,y) \coloneqq 1$ iff there are an odd number of blocks i such that $x_i \neq y_i$. Note that $\mathsf{RP}(q)^{\mathsf{cc}}(\oplus_q\textsc{NonEq}) = O(1)$ by Lemma 8 and the standard fact that $\mathsf{RP}^{\mathsf{cc}}(\textsc{NonEq}) = O(1)$. Thus $\overline{\oplus_q\textsc{NonEq}} \in \mathsf{coRP}(q)^{\mathsf{cc}}$. We will now prove that $\mathsf{NP}(q)^{\mathsf{cc}}(\overline{\oplus_q\textsc{NonEq}}) = \Omega(n)$.

Suppose for contradiction $\overline{\oplus_q\textsc{NonEq}}$ has an $\mathsf{NP}(q)^{\mathsf{cc}}$ protocol of cost $k \le n/2^q$, say $\Pi = (\mathcal{R}_1,\dots,\mathcal{R}_q)$ where each $\mathcal{R}_i$ is a nonempty set of rectangles. By Lemma 8 we may assume the protocol outputs 1 iff the input is contained in an odd number of the rectangle unions $\bigcup_{R\in\mathcal{R}_i} R$ for $i \in [q]$, in other words, $\Pi(x,y) \coloneqq \oplus_q(\mathcal{R}_1(x,y),\dots,\mathcal{R}_q(x,y))$. Note that, assuming $\mathcal{R}_i$ has cost k_i, the total number of rectangles in these unions is at most $\sum_i |\mathcal{R}_i| \le \prod_i(|\mathcal{R}_i|+1) \le \prod_i 2^{k_i} = 2^k$.

We will iteratively construct a sequence of rectangles Q^j for $j = 0,\dots,q$ such that *(i)* there are at least j many values of i for which $Q^j \subseteq \bigcup_{R\in\mathcal{R}_i} R$, and *(ii)* Q^j contains an input where exactly j blocks are unequal. We obtain the contradiction when $j = q$: by *(ii)* some input $(x,y) \in Q^q$ has $x_i \neq y_i$ for all i and thus $\overline{\oplus_q\textsc{NonEq}}(x,y) = 1 - \oplus(q)$, yet by *(i)* we have $\mathcal{R}_i(x,y) = 1$ for all i and thus $\Pi(x,y) = \oplus(q)$, contradicting the supposed correctness of Π.

We will actually maintain stronger invariants than the above *(i)* and *(ii)*: For *(i)*, we will actually have for some j values of i – we assume they are $1,\dots,j$ for notational convenience – some individual rectangle $R_i \in \mathcal{R}_i$ contains Q^j. For *(ii)*, Q^j will actually have the following form: for some fixed strings $a^j = (a_1,\dots,a_j) \in (\{0,1\}^n)^j$ and $b^j = (b_1,\dots,b_j) \in (\{0,1\}^n)^j$ such that $a_i \neq b_i$ for all $i \in [j]$, and for some nonempty set $S^j \subseteq (\{0,1\}^n)^{q-j}$, we have $Q^j \coloneqq \{a^j s : s \in S^j\} \times \{b^j s : s \in S^j\}$, which we abbreviate as $a^jS^j \times b^jS^j$. Defining a *diagonal* input in Q^j to be one of the form (a^js, b^js) for any particular $s \in S^j$, we see that each diagonal input has exactly j unequal blocks, as needed for *(ii)*.

In fact, we will maintain not just that S^j is nonempty, but that it is sufficiently large. Specifically, the *deficiency* of S^j, defined as $\mathbf{D}_\infty(S^j) \coloneqq n(q-j) - \log|S^j|$, will be at most $(2^j-1)(2k+1)$. At the end, since $(2^q-1)(2k+1) < \infty$, this guarantees that S^q will contain at least one element from $(\{0,1\}^n)^{q-q}$. The latter set only has one element, namely the empty tuple, so this means Q^q will contain the single input (a^q, b^q), which has all blocks unequal.

We start with $S^0 = (\{0,1\}^n)^q$, which indeed has $\mathbf{D}_\infty(S^0) = 0 = (2^0-1)(2k+1)$, and thus Q^0 is the rectangle of all possible inputs. Now supposing we already have a^j, b^j, and S^j satisfying all the properties from the previous two paragraphs, we explain how to obtain $a_{j+1}, b_{j+1} \in \{0,1\}^n$ and $S^{j+1} \subseteq (\{0,1\}^n)^{q-(j+1)}$ so these properties again hold (with $a^{j+1} \coloneqq a^ja_{j+1}$ and $b^{j+1} \coloneqq b^jb_{j+1}$).

We first observe that each diagonal input in Q^j must be contained in at least one rectangle from $\mathcal{R}_{j+1} \cup \dots \cup \mathcal{R}_q$. This is because such an input (x,y) is already contained in the rectangles $R_1 \in \mathcal{R}_1,\dots,R_j \in \mathcal{R}_j$, and these cannot be the only values of i such that $\mathcal{R}_i(x,y) = 1$ since otherwise we would have $\Pi(x,y) = \oplus(j)$ while $\overline{\oplus_q\textsc{NonEq}}(x,y) = 1 - \oplus(j)$, contradicting the supposed correctness of Π. Now pick one of the (at most 2^k) rectangles from $\mathcal{R}_{j+1} \cup \dots \cup \mathcal{R}_q$ that contains the largest fraction (at least $1/2^k$) of diagonal inputs from Q^j, and assume this rectangle is $R_{j+1} \in \mathcal{R}_{j+1}$ for notational convenience. Defining $\tilde{S}^j \coloneqq \{s \in S^j : (a^js, b^js) \in R_{j+1}\}$, we see that $\mathbf{D}_\infty(\tilde{S}^j) \le \mathbf{D}_\infty(S^j) + k \le (2^j-1)(2k+1) + k$.

Since R_{j+1} is a rectangle, it must in fact contain the entire rectangle $a^j\tilde{S}^j \times b^j\tilde{S}^j$. Since $a^j\tilde{S}^j \times b^j\tilde{S}^j \subseteq a^jS^j \times b^jS^j = Q^j$, by assumption it is also contained in each of $R_1,\dots,R_j$. In the end, we will ensure Q^{j+1} is a subrectangle of $a^j\tilde{S}^j \times b^j\tilde{S}^j$, which will maintain property *(i)*: Q^{j+1} is contained in each of $R_1,\dots,R_{j+1}$.

To maintain *(ii)*, we will find some $a_{j+1} \neq b_{j+1}$ and then define $S^{j+1} \coloneqq \{s : a_{j+1}s \in \tilde{S}^j \text{ and } b_{j+1}s \in \tilde{S}^j\}$. Then $a_{j+1}S^{j+1} \subseteq \tilde{S}^j$ and $b_{j+1}S^{j+1} \subseteq \tilde{S}^j$ ensure that $Q^{j+1} \coloneqq a^{j+1}S^{j+1} \times b^{j+1}S^{j+1}$ is indeed a subrectangle of $a^j\tilde{S}^j \times b^j\tilde{S}^j$, as we needed for *(i)*. The fact that this can be done with a not-too-small S^{j+1} is encapsulated in the following technical lemma, which we prove shortly:

▶ **Lemma 12.** *Consider any bipartite graph with left nodes U and right nodes V, and suppose $1 \geq \varepsilon \geq 2/|U|$. If an ε fraction of all possible edges are present in the graph, then there exist distinct nodes $u, u' \in U$ that have at least $(\varepsilon^2/2) \cdot |V|$ common neighbors.*

Specifically, take $U \coloneqq \{0,1\}^n$ and $V \coloneqq (\{0,1\}^n)^{q-(j+1)}$ (so $|V| = 1$ if $j = q-1$, but that is fine), put an edge between $u \in U$ and $v \in V$ iff $uv \in \tilde{S}^j$, and let $\varepsilon \coloneqq |\tilde{S}^j|/2^{n(q-j)} = 1/2^{\mathbf{D}_\infty(\tilde{S}^j)}$. Notice that $\varepsilon \geq 2/|U|$ holds since $\mathbf{D}_\infty(\tilde{S}^j) \leq (2^j - 1)(2k+1) + k \leq 2^{j+1}k - 1 \leq n - 1$ follows from our assumption that $k \leq n/2^q$. Thus Lemma 12 guarantees we can pick strings $a_{j+1} \neq b_{j+1}$ (corresponding to the nodes u, u') such that S^{j+1} (the set of common neighbors) has size at least $(\varepsilon^2/2) \cdot 2^{n(q-(j+1))}$. Thus

$$\begin{aligned}\mathbf{D}_\infty(S^{j+1}) \;&\coloneqq\; n(q-(j+1)) - \log|S^{j+1}| \;\leq\; \log(2/\varepsilon^2) \;=\; 2\mathbf{D}_\infty(\tilde{S}^j) + 1 \\ &\leq\; 2\big((2^j - 1)(2k+1) + k\big) + 1 \;=\; \big(2(2^j-1)+1\big)(2k+1) \\ &=\; (2^{j+1} - 1)(2k+1)\end{aligned}$$

as we needed for *(ii)*. This finishes the proof of Theorem 1.

Proof of Lemma 12. Let d_u and d_v denote the degrees of nodes $u \in U$ and $v \in V$, and let $d_{u,u'}$ denote the number of common neighbors of $u, u' \in U$. Summing over ordered pairs u, u' of not-necessarily-distinct left nodes, we have

$$\sum_{u,u' \in U} d_{u,u'} \;=\; \sum_{v \in V} d_v^2 \;\geq\; \Big(\sum_{v \in V} d_v\Big)^2 / |V| \;=\; \varepsilon^2 \cdot |U|^2 \cdot |V|$$

by Cauchy–Schwarz and the assumption $\sum_{v \in V} d_v = \varepsilon \cdot |U| \cdot |V|$. Now sampling u, u' independently uniformly at random from U, we have

$$\varepsilon^2 \cdot |V| \;\leq\; \mathop{\mathrm{E}}_{u,u'}[d_{u,u'}] \;\leq\; \mathop{\mathrm{E}}_{u,u'}[d_{u,u'} \mid u \neq u'] + \mathop{\mathrm{E}}_{u}[d_u] \cdot \Pr_{u,u'}[u = u']$$

(the conditioning is valid by the assumption $|U| \geq 2$). Since $\mathrm{E}_u[d_u] = \varepsilon \cdot |V|$ and $\Pr_{u,u'}[u = u'] = 1/|U|$, rearranging gives

$$\mathop{\mathrm{E}}_{u,u'}[d_{u,u'} \mid u \neq u'] \;\geq\; \varepsilon^2 \cdot |V| - \varepsilon \cdot |V|/|U| \;\geq\; (\varepsilon^2/2) \cdot |V|$$

where the last inequality holds by the assumption $1/|U| \leq \varepsilon/2$. Thus there must be some $u \neq u'$ such that $d_{u,u'}$ is at least this large. ◀

3.2 Proof of Theorem 3

▶ **Theorem** (Restatement of Theorem 3). *For partial functions,* $\mathsf{RP}(q+1)^{\mathsf{cc}} \cap \mathsf{coRP}(q+1)^{\mathsf{cc}} \not\subseteq \mathsf{P}_{\|}^{\mathsf{NP}[q]\mathsf{cc}}$ *for every constant q.*

To prove this result, we require the query complexity separation $\mathsf{coRP}(q)^{\mathsf{dt}} \not\subseteq \mathsf{NP}(q)^{\mathsf{dt}}$.

▶ **Definition 13.** *Fix any constant q. Let $\oplus_q\textsc{GapOr}\colon (\{0,1\}^n)^q \to \{0,1\}$ be the partial function where the input is divided into q blocks $z = (z_1, \ldots, z_q)$ having the promise that each $z_i \in \{0,1\}^n$ is either all zeros or at least half ones (call such an input* valid*), and which is defined by $\oplus_q\textsc{GapOr}(z) \coloneqq 1$ iff an odd number of blocks i are such that z_i is nonzero.*

Note that $\mathsf{RP}(q)^{\mathsf{dt}}(\oplus_q\textsc{GapOr}) = O(1)$ by Lemma 8 and the fact that $\mathsf{RP}^{\mathsf{dt}}(\textsc{GapOr}) = 1$. The full version of this paper [27] contains a proof of the following lemma:

▶ **Lemma 14.** $\mathsf{NP}(q)^{\mathsf{dt}}(\overline{\oplus_q\textsc{GapOr}}) = \Omega(n)$.

We now proceed to the proof of Theorem 3.

Fix any constant q. Let $\textsc{Which}\oplus_{q+1}\textsc{GapOr}\colon (\{0,1\}^{2n})^{2(q+1)} \to \{0,1\}$ be the following partial function: The input is divided into two halves $z = (z^0, z^1)$, and each half is divided into $q+1$ blocks $z^h = (z^h_1, \dots, z^h_{q+1})$ having the promise that each $z^h_i \in \{0,1\}^{2n}$ is either all zeros or at least a *quarter* ones, and moreover it is promised that the number of nonzero blocks in z^0 has the opposite parity as the number of nonzero blocks in z^1 (call such an input *valid*). The partial function is defined by

$$\textsc{Which}\oplus_{q+1}\textsc{GapOr}(z) = \begin{cases} 1 & \text{if the number of nonzero blocks is odd in } z^0 \text{ and even in } z^1 \\ 0 & \text{if the number of nonzero blocks is even in } z^0 \text{ and odd in } z^1 \end{cases}$$

We henceforth abbreviate $\textsc{Which}\oplus_{q+1}\textsc{GapOr}$ as f. Note that $\mathsf{RP}(q+1)^{\mathsf{dt}}(f) = O(1)$ by applying the $\mathsf{RP}(q+1)^{\mathsf{dt}}$ decision tree for $\oplus_{q+1}\textsc{GapOr}$ on z^0 (adapted for the different block length and different threshold for fraction of ones in a block). By symmetry (focusing on z^1), we also have $\mathsf{RP}(q+1)^{\mathsf{dt}}(\overline{f}) = O(1)$. Letting $g\colon [m] \times \{0,1\}^m \to \{0,1\}$ be the index gadget with $m := N^{20}$ where $N := 4(q+1)n$, this implies that

$$\mathsf{RP}(q+1)^{\mathsf{cc}}(f \circ g^N) = O(\log n) \qquad \text{and} \qquad \mathsf{coRP}(q+1)^{\mathsf{cc}}(f \circ g^N) = O(\log n)$$

(by the "easy direction" of $\mathsf{RP}(q+1)$ lifting) and thus $f \circ g^N \in \mathsf{RP}(q+1)^{\mathsf{cc}} \cap \mathsf{coRP}(q+1)^{\mathsf{cc}}$. We will now prove that $\mathsf{P}_{\parallel}^{\mathsf{NP}[q]\mathsf{dt}}(f) = \Omega(n)$, which by Theorem 4.*(ii)* implies that $\mathsf{P}_{\parallel}^{\mathsf{NP}[q]\mathsf{cc}}(f \circ g^N) = \Omega(n \log n)$.

We show this by reduction from Lemma 14. We henceforth abbreviate $\overline{\oplus_q\textsc{GapOr}}$ as f'. Supposing f has a $\mathsf{P}_{\parallel}^{\mathsf{NP}[q]\mathsf{dt}}$ decision tree T of cost $k \le n/2$, say with deterministic phase T_{det}, we will use it to construct an $\mathsf{NP}(q)^{\mathsf{dt}}$ decision tree T' of cost at most k for f'.

By Lemma 11 we may assume that each leaf of T_{det} produces a single $\mathsf{NP}(q)^{\mathsf{dt}}$ decision tree and chooses whether to output the same or opposite answer as that decision tree. Follow the root-to-leaf path in T_{det} where all queries are answered with zero. Let $\rho \in (\{0,*\}^{2n})^{2(q+1)}$ be the partial assignment with at most $k \le n/2$ zeros that records these queries (so an input leads to this leaf iff it is consistent with ρ). Let $T_{\text{leaf}} = (\Phi_1, \dots, \Phi_q)$ be the $\mathsf{NP}(q)^{\mathsf{dt}}$ decision tree of cost at most k produced at this leaf, where each Φ_i is a DNF. By symmetry, we assume (without loss of generality) that this leaf chooses to output the same answer as T_{leaf}.

Given any valid input z' to f', we show how to map it to a valid input z to f such that *(i)* $f'(z') = f(z)$, *(ii)* z is consistent with ρ, and *(iii)* each bit of z either is fixed or is some preselected bit of z'. Since *(iii)* implies that $T_{\text{leaf}}(z)$ can be viewed as an $\mathsf{NP}(q)^{\mathsf{dt}}$ decision tree $T'(z')$ by substituting a constant or variable of z' in for each variable of z (which does not increase the width of any conjunction), and T' would correctly compute f' since

$$f'(z') \;=\; f(z) \;=\; T(z) \;=\; T_{\text{leaf}}(z) \;=\; T'(z')$$

by *(i)*, correctness of T, *(ii)*, and *(iii)* respectively, this would show that $\mathsf{NP}(q)^{\mathsf{dt}}(f') \le k \le n/2$, which we know is false from Lemma 14.

To define z, we start with ρ (that is, we place zeros everywhere ρ requires, thus ensuring *(ii)*). Since ρ has at most n zeros in each block (indeed, at most $n/2$ zeros total), we can then place more zeros in such a way that each block now has exactly n zeros and n stars.

Next we replace the stars in z^0_{q+1} with ones and replace the stars in z^1_{q+1} with zeros. Finally, for each $i \in [q]$, we fill in the stars of z^0_i with a copy of z'_i and fill in the stars of z^1_i with another copy of z'_i. This construction satisfies *(iii)*.

To verify *(i)*, first observe that since each block of z' is either all zeros or at least half $(n/2)$ ones, this ensures each block of z is either all zeros or at least a quarter $(2n/4)$ ones. Furthermore, if z' has exactly ℓ nonzero blocks then the number of nonzero blocks is $\ell + 1$ in z^0 (since z^0_{q+1} is nonzero) and ℓ in z^1 (since z^1_{q+1} is all zeros). Hence if $f'(z') = 1$ (ℓ is even) then $f(z) = 1$ (since $\ell + 1$ is odd and ℓ is even), and if $f'(z') = 0$ (ℓ is odd) then $f(z) = 0$ (since $\ell + 1$ is even and ℓ is odd). Thus $f'(z') = f(z)$, and this finishes the proof of Theorem 3.

4 Total function collapse

▶ **Theorem** (Restatement of Theorem 2). *For total functions,*

$$\mathsf{P}_{\|}^{\mathsf{NP}[q]\mathsf{cc}} = \mathsf{NP}(q+1)^{\mathsf{cc}} \cap \mathsf{coNP}(q+1)^{\mathsf{cc}} \qquad \textit{and} \qquad \mathsf{P}_{\|}^{\mathsf{RP}[q]\mathsf{cc}} = \mathsf{RP}(q+1)^{\mathsf{cc}} \cap \mathsf{coRP}(q+1)^{\mathsf{cc}}$$

for every constant q.

In this section we will present intuition for the proof of the nondeterministic case of Theorem 2. For the complete proof, see the full version of this paper [27].

This proof is similar to the argument for the $q = 0$ case (that is, for total functions, $\mathsf{P}^{\mathsf{cc}} = \mathsf{NP}^{\mathsf{cc}} \cap \mathsf{coNP}^{\mathsf{cc}}$). In that proof, Alice and Bob can use the fact that the rectangles in the $\mathsf{NP}^{\mathsf{cc}}$ protocol's 1-monochromatic covering of F are disjoint from the rectangles in the $\mathsf{coNP}^{\mathsf{cc}}$ protocol's 0-monochromatic covering. Specifically, if $F(x, y) = 1$, then (x, y) is in some 1-rectangle, which is row-disjoint or column-disjoint from each 0-rectangle. (If a 1-rectangle and 0-rectangle shared a row and a column, they would intersect, which is not possible for a total function.) Therefore, Alice and Bob can repeatedly eliminate from consideration at least half of the remaining 0-rectangles, by identifying a 1-rectangle that either has x in its row set but is row-disjoint from at least half the remaining 0-rectangles, or has y in its column set but is column-disjoint from at least half the remaining 0-rectangles. If (x, y) is indeed in a 1-rectangle, then this process can always continue until there are no 0-rectangles left. If (x, y) is in a 0-rectangle, then this process will never eliminate that rectangle, so the process will halt with a nonempty set of 0-rectangles.

We repeat a similar argument, but using the "top level" of the $\mathsf{NP}(q+1)^{\mathsf{cc}}$ and the $\mathsf{coNP}(q+1)^{\mathsf{cc}}$ protocols for F as our monochromatic rectangle sets. Here we think of a $\mathsf{coNP}(q+1)^{\mathsf{cc}}$ protocol as computing F by applying $\overline{\Delta}_{q+1}$ (with negations pushed to the leaves) to the indicators for $q + 1$ rectangle unions. Depending on the parity of q, the rectangle union $\mathcal{R}_{q+1}$ queried at depth 1 of the $\mathsf{NP}(q+1)^{\mathsf{cc}}$ protocol will correspond to either 1-monochromatic rectangles or 0-monochromatic rectangles for F. The rectangle union $\mathcal{R}'_{q+1}$ queried at depth 1 of the $\mathsf{coNP}(q+1)^{\mathsf{cc}}$ protocol will be the opposite color of monochromatic rectangles. Crucially, this means that no input is in a rectangle from both of these sets (as we are assuming F is total). See Figure 3 for an illustration.

A key observation is that a deterministic protocol similar to the one used in the $q = 0$ case, ran using these top-level rectangle sets, will return the correct answer *under the promise that (x, y) is in one of these rectangles.* Say, for example, that (x, y) is in some rectangle in the 1-monochromatic top-level set. Then the deterministic protocol will successfully eliminate all 0-rectangles from the other top-level set, and will announce that the answer is 1. If (x, y) was in one of the 0-rectangles, then that rectangle will never be eliminated, and so the protocol would announce that the answer is 0.

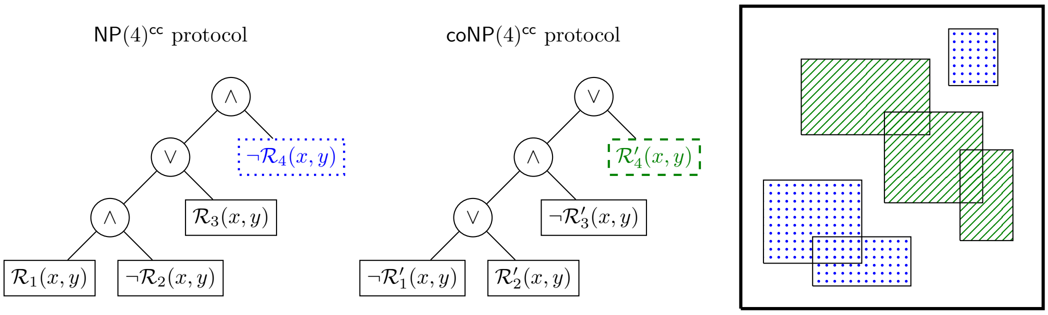

Figure 3 If a total function has an $\mathsf{NP}(4)^{\mathsf{cc}}$ protocol and a $\mathsf{coNP}(4)^{\mathsf{cc}}$ protocol, then the rectangle unions from the $\mathsf{NP}^{\mathsf{cc}}$ functions at depth one of each protocol are disjoint.

If (x, y) is in the top-level rectangle union for one of the protocols, then (x, y) is not in the top-level rectangle union of the *other* protocol, so $F(x, y)$ can be computed by the other protocol but where the top level is skipped (resulting in only q many $\mathsf{NP}^{\mathsf{cc}}$ oracle queries). This boils down to the observation that $\Delta_{q+1}(z_1, \ldots, z_q, 0) = \Delta_q(z_1, \ldots, z_q)$.

What if (x, y) is in neither top-level rectangle union? Then we can make no guarantees about the behavior of the deterministic protocol – it might answer 0 or 1 (which we interpret as merely a "guess" for $F(x, y)$). However, in this case *both* protocols correctly compute $F(x, y)$ even if the top level is skipped. Therefore, we will still get the correct answer no matter which guess is produced by the deterministic protocol.

5 Query-to-communication lifting theorems

▶ **Theorem** (Restatement of Theorem 4.). *For every partial function $f\colon \{0,1\}^n \to \{0,1\}$ and every constant q,*

(i) $\mathsf{NP}(q)^{\mathsf{cc}}(f \circ g^n) = \mathsf{NP}(q)^{\mathsf{dt}}(f) \cdot \Theta(\log n)$

(ii) $\mathsf{P}_{\parallel}^{\mathsf{NP}[q]\mathsf{cc}}(f \circ g^n) = \mathsf{P}_{\parallel}^{\mathsf{NP}[q]\mathsf{dt}}(f) \cdot \Theta(\log n)$

where $g\colon [m] \times \{0,1\}^m \to \{0,1\}$ is the index gadget defined by $g(x, y) = y_x$ with $m := n^{20}$.

In this section we present the proof for Theorem 4.*(i)*, as well as the necessary background. The full version of this paper [27] contains the proof of Theorem 4.*(ii)*. The high-level idea of the latter proof is to convert a $\mathsf{P}^{\mathsf{NP}(q)[1]\mathsf{cc}}$ protocol for $f \circ g^n$ into a $\mathsf{P}^{\mathsf{NP}(q)[1]\mathsf{dt}}$ decision tree for f by using the P lifting theorem of Raz and McKenzie [28, 14] to handle the deterministic phase, followed by our $\mathsf{NP}(q)$ lifting theorem to handle the single $\mathsf{NP}(q)$ oracle query.

5.1 Decision lists

The reason we call Δ_q a "decision list function" is that it highlights the connection between the Boolean Hierarchy classes and the *decision list* models of computation:

▶ **Definition 15.** *A rectangle decision list $\mathcal{L}_{\mathrm{R}}$ is an ordered list of pairs $(R_1, \ell_1), (R_2, \ell_2), \ldots$ where each R_i is a combinatorial rectangle, $\ell_i \in \{0,1\}$ is a label, and the final rectangle in the list contains all inputs in the domain. For an input (x, y), the output $\mathcal{L}_{\mathrm{R}}(x, y)$ is ℓ_i where i is the first index for which $(x, y) \in R_i$. The cost of $\mathcal{L}_{\mathrm{R}}$ is the* log *of the length of the list.*

▶ **Definition 16.** *A conjunction decision list $\mathcal{L}_{\mathrm{C}}$ is an ordered list of pairs $(C_1, \ell_1), (C_2, \ell_2), \ldots$ where each C_i is a conjunction, $\ell_i \in \{0,1\}$ is a label, and the final conjunction in the list accepts all inputs in the domain. For an input z, the output $\mathcal{L}_{\mathrm{C}}(z)$ is ℓ_i where i is the first index for which $C_i(z) = 1$. The cost of $\mathcal{L}_{\mathrm{C}}$ is the maximum width of any conjunction in the list.*

Note that the restriction on the final rectangle/conjunction is without loss of generality. The complexity measures $\mathsf{DL}^{\mathsf{cc}}(F)$ and $\mathsf{DL}^{\mathsf{dt}}(f)$ are the minimum cost of any rectangle/conjunction decision list computing F or f, and the classes $\mathsf{DL}^{\mathsf{cc}}$ and $\mathsf{DL}^{\mathsf{dt}}$ contain those functions with complexity at most $\text{polylog}(n)$.

We now define *q-alternating decision lists* to have the additional restriction that the sequence of output labels $\ell_1, \ell_2, \ldots$ only flips between 0 and 1 at most q times, and furthermore the last label is 0. This restriction partitions the list into contiguous *levels* where all labels in the same level are equal; without loss of generality the last level consists only of the final "catch-all" entry. For convenience, in the list entries we replace the labels with the level numbers themselves.

▶ **Definition 17.** *A q-alternating rectangle decision list $\mathcal{L}_{\mathrm{R}}$ is an ordered list of pairs $(R_1, \ell_1), (R_2, \ell_2), \ldots$ where each R_i is a combinatorial rectangle, $\ell_i \in \{0, 1, \ldots, q\}$ is a level such that $\ell_i \geq \ell_{i+1}$ for all i, and the final rectangle in the list contains all inputs in the domain and is the only rectangle at level 0. For an input (x, y), the output $\mathcal{L}_{\mathrm{R}}(x, y)$ is $\oplus(\ell_i)$ where i is the first index for which $(x, y) \in R_i$. The cost of $\mathcal{L}_{\mathrm{R}}$ is the* log *of the length of the list.*

▶ **Definition 18.** *A q-alternating conjunction decision list $\mathcal{L}_{\mathrm{C}}$ is an ordered list of pairs $(C_1, \ell_1), (C_2, \ell_2), \ldots$ where each C_i is a conjunction, $\ell_i \in \{0, 1, \ldots, q\}$ is a level such that $\ell_i \geq \ell_{i+1}$ for all i, and the final conjunction in the list accepts all inputs in the domain and is the only conjunction at level 0. For an input z, the output $\mathcal{L}_{\mathrm{C}}(z)$ is $\oplus(\ell_i)$ where i is the first index for which $C_i(z) = 1$. The cost of $\mathcal{L}_{\mathrm{C}}$ is the maximum width of any conjunction in the list.*

The complexity measures $\mathsf{DL}(q)^{\mathsf{cc}}(F)$ and $\mathsf{DL}(q)^{\mathsf{dt}}(f)$ are the minimum cost of any q-alternating rectangle/conjunction decision list computing F or f, and the classes $\mathsf{DL}(q)^{\mathsf{cc}}$ and $\mathsf{DL}(q)^{\mathsf{dt}}$ contain those functions with complexity at most $\text{polylog}(n)$.

It turns out that q-alternating decision lists are equivalent to $\mathsf{NP}(q)$ in both communication and query complexity. As this follows almost immediately from the definition of Δ_q, we omit the proof here.

▶ **Lemma 19.** $\mathsf{DL}(q)^{\mathsf{cc}}(F) = \Theta(\mathsf{NP}(q)^{\mathsf{cc}}(F))$ *and* $\mathsf{DL}(q)^{\mathsf{dt}}(f) = \Theta(\mathsf{NP}(q)^{\mathsf{dt}}(f))$ *for every constant q. Thus,* $\mathsf{DL}(q)^{\mathsf{cc}} = \mathsf{NP}(q)^{\mathsf{cc}}$ *and* $\mathsf{DL}(q)^{\mathsf{dt}} = \mathsf{NP}(q)^{\mathsf{dt}}$ *for partial functions.*

This can be contrasted with the lemma from [10] stating that $\mathsf{DL}^{\mathsf{cc}} = \mathsf{P}^{\mathsf{NPcc}}$ and $\mathsf{DL}^{\mathsf{dt}} = \mathsf{P}^{\mathsf{NPdt}}$ for partial functions.

5.2 Query-to-communication lifting for $\mathsf{NP}(q)$

The big-O direction of Theorem 4.*(i)* follows immediately from the same fact for NP: for every f, $\mathsf{NP}^{\mathsf{cc}}(f \circ g^n) = \mathsf{NP}^{\mathsf{dt}}(f) \cdot O(\log n)$ holds by replacing each of the $n^{O(k)}$ conjunctions in a width-k DNF with m^k rectangles (each of which contains inputs where the gadget outputs satisfy the conjunction), for a total of $n^{O(k)} m^k = 2^{k \cdot O(\log n)}$ rectangles. In the rest of this section we prove the big-Ω direction. By Lemma 19 it suffices to show

$$\mathsf{DL}(q)^{\mathsf{cc}}(f \circ g^n) = \mathsf{DL}(q)^{\mathsf{dt}}(f) \cdot \Omega(\log n).$$

5.2.1 Technical preliminaries

Our proof is closely related to the P^{NP} lifting theorem of Göös, Kamath, Pitassi, and Watson [10], so we start by recalling some definitions and lemmas that were used in that work. We will need to tweak some of the statements and parameters, though.

Define $G\colon [m]^n \times (\{0,1\}^m)^n \to \{0,1\}^n$ as $G \coloneqq g^n$. This partitions the input domain into 2^n slices $G^{-1}(z) = \{(x,y) : g(x_i,y_i) = z_i \text{ for all } i \in [n]\}$, one for each $z \in \{0,1\}^n$. For a set $Z \subseteq \{0,1\}^n$, let $G^{-1}(Z) \coloneqq \bigcup_{z\in Z} G^{-1}(z)$. Consider sets $A \subseteq [m]^n$ and $B \subseteq (\{0,1\}^m)^n$. For $I \subseteq [n]$, we let $A_I \coloneqq \{x_I : x \in A\}$ and $B_I \coloneqq \{y_I : y \in B\}$ be the *projections* onto the coordinates of I. The *min-entropy* of a random variable $\boldsymbol{x}$ is $\mathbf{H}_\infty(\boldsymbol{x}) \coloneqq \min_x \log(1/\Pr[\boldsymbol{x} = x])$. We say A is *δ-dense* if the uniform random variable $\boldsymbol{x}$ over A satisfies the following: for every nonempty $I \subseteq [n]$, $\mathbf{H}_\infty(\boldsymbol{x}_I) \geq \delta|I|\log m$ (that is, the min-entropy of the marginal distribution of $\boldsymbol{x}$ on coordinates I is at least a δ fraction of the maximum possible for a distribution over $[m]^I$). The *deficiency* of B is $\mathbf{D}_\infty(B) \coloneqq mn - \log|B|$.

▶ **Lemma 20** ([10, Lemma 11]). *If $A \subseteq [m]^n$ is 0.8-dense and $B \subseteq (\{0,1\}^m)^n$ has deficiency at most n^4, then $G(A \times B) = \{0,1\}^n$, that is, for every $z \in \{0,1\}^n$ there are $x \in A$ and $y \in B$ with $G(x,y) = z$.*

Here the density parameter is $\delta = 0.8$ and the deficiency is $\mathbf{D}_\infty(B) \leq n^4$, instead of $\delta = 0.9$ and $\mathbf{D}_\infty(B) \leq n^2$ as in the original. Lemma 20 still holds because our gadget size has increased: we use $m \coloneqq n^{20}$, whereas [10] used $m \coloneqq n^4$. This can be verified by a simple substitution in the proof.

The next lemma is altered somewhat from the original. For a proof, see the full version [27].

▶ **Lemma 21** (A more general version of [10, Claim 12]). *Let $\mathcal{X} \subseteq [m]^n$ be 0.85-dense. If $A' \subseteq \mathcal{X}$ satisfies $|A'| \geq |\mathcal{X}|/2^{k+1}$ then there exist an $I \subseteq [n]$ of size $|I| < 20(k+1)/\log m$ and an $A \subseteq A'$ such that A is fixed on coordinates I and 0.8-dense on all other coordinates.*

5.2.2 The simulation

We exhibit an algorithm that takes a q-alternating rectangle decision list $\mathcal{L}_{\mathrm{R}}$ for $f \circ g^n$ of cost k, and converts it to a q-alternating conjunction decision list $\mathcal{L}_{\mathrm{C}}$ for f of cost $O(k/\log n)$. The argument from [10] does exactly this except without preserving the bound on the number of alternations. In [10] the argument is formulated using a "dual" characterization of $\mathsf{DL}^{\mathsf{dt}}$, but it has the effect of building $\mathcal{L}_{\mathrm{C}}$ in order, obtaining each conjunction by "extracting" it from one of the rectangles in $\mathcal{L}_{\mathrm{R}}$. The trouble is that the rectangles are not necessarily "extracted from" in order: after extracting a conjunction from some rectangle, the *next* conjunction that gets put in $\mathcal{L}_{\mathrm{C}}$ may be extracted from a rectangle that is *earlier* in $\mathcal{L}_{\mathrm{R}}$. Thus $\mathcal{L}_{\mathrm{C}}$ may end up with more alternations than $\mathcal{L}_{\mathrm{R}}$.

To fix this, we convert the argument to a "primal" form and argue that it still works when we force the rectangles to be extracted from in order. The high-level view is that we iterate through the rectangles of $\mathcal{L}_{\mathrm{R}}$ in order, and for each we extract as many conjunctions as we can until the rectangle becomes "exhausted", at which time we remove the remaining "error" portion of the rectangle (by deleting few rows and columns) and move on to the next rectangle. With this modification, the rest of the technical details from [10] continue to work, and it now preserves the number of alternations.

At any step of this process, we let $X \times Y$ be the remaining rows and columns (after having removed the error portion of all previous rectangles in $\mathcal{L}_{\mathrm{R}}$), and we let $Z \subseteq \{0,1\}^n$ be the remaining inputs to f (which have not been accepted by any previous conjunctions we put in $\mathcal{L}_{\mathrm{C}}$). Suppose (R_i, ℓ_i) is our current entry in $\mathcal{L}_{\mathrm{R}}$. The goal is to find a subrectangle $A \times B \subseteq R_i \cap (X \times Y)$ that is "conjunction-like" in the sense that $G(A \times B)$ is exactly the inputs accepted by some small-width conjunction C, and such that among all remaining inputs $z \in Z$, C only accepts those with $f(z) = \oplus(\ell_i)$. These properties would ensure it is safe to put (C, ℓ_i) next in $\mathcal{L}_{\mathrm{C}}$.

Algorithm 1 Simulation algorithm.

```
     In: $\mathcal{L}_{\mathrm{R}} = (R_1, \ell_1), \ldots, (R_{2^k}, \ell_{2^k})$ and $\mathcal{X} \subseteq [m]^n$, $\mathcal{Y} \subseteq (\{0,1\}^m)^n$
     Out: $\mathcal{L}_{\mathrm{C}}$
 1:  initialize $X \leftarrow \mathcal{X}$, $Y \leftarrow \mathcal{Y}$, $Z \leftarrow$ domain of $f$, $\mathcal{L}_{\mathrm{C}} \leftarrow$ empty list
 2:  for $i = 1$ to $2^k$ do
 3:      while $Z \neq \emptyset$ do
 4:          for each $x \in X$, let $Y_x := \{y \in Y : (x,y) \in R_i \cap G^{-1}(Z)\}$
 5:          let $A' := \{x \in X : |Y_x| \geq 2^{mn-n^4}\}$
 6:          if $|A'| \leq |\mathcal{X}|/2^{k+1}$ then
 7:              update $X \leftarrow X \smallsetminus A'$
 8:              update $Y \leftarrow Y \smallsetminus \bigcup_{x \in X \smallsetminus A'} Y_x$
 9:              break out of inner loop
10:          else $|A'| > |\mathcal{X}|/2^{k+1}$
11:              let $A \subseteq A'$, $I \subseteq [n]$, $\alpha \in [m]^I$ be such that:
12:                  $|I| = O(k/\log n)$, $A_I$ is fixed to $\alpha$, and $A_{[n] \smallsetminus I}$ is 0.8-dense
13:              pick any $x' \in A$ and choose $\beta \in (\{0,1\}^m)^I$ to maximize $|\{y \in Y_{x'} : y_I = \beta\}|$
14:              let $C$ be the conjunction "$z_I = g^I(\alpha, \beta)$"
15:              update $\mathcal{L}_{\mathrm{C}}$ by appending $(C, \ell_i)$ to it
16:              update $Z \leftarrow Z \smallsetminus C^{-1}(1)$
```

Combining Lemma 20 and Lemma 21 (using $\mathcal{X} = [m]^n$) suggests an approach for finding a conjunction-like subrectangle: If A' is not too small, we can restrict it to A that is fixed on few coordinates I and dense on the rest (by Lemma 21). If B is also not too small (low deficiency) and fixed on coordinates I, then $G(A \times B)$ is fixed on I and takes on all possible values on the remaining coordinates (by Lemma 20, which still works with $[n] \smallsetminus I$ in place of $[n]$). In other words, $G(A \times B) = C^{-1}(1)$ for a small-width conjunction C, as desired.

The other property we needed to ensure is that if this C is the first conjunction in $\mathcal{L}_{\mathrm{C}}$ to accept a particular z, then $f(z) = \oplus(\ell_i)$ (so $\mathcal{L}_{\mathrm{C}}$ is correct). This will follow if we know there is some $(x,y) \in G^{-1}(z)$ such that R_i is the first rectangle in $\mathcal{L}_{\mathrm{R}}$ to contain (x,y), as that guarantees $f(z) = f(G(x,y)) = (f \circ g^n)(x,y) = \oplus(\ell_i)$. It turns out this will hold automatically if $A \times B \subseteq R_i \cap (X \times Y)$, because $A \times B$ touches the slice of every z that is accepted by C, and all inputs $(x,y) \in G^{-1}(Z)$ that were in some R_j with $j < i$ have already been removed from $X \times Y$.

Our algorithm for building $\mathcal{L}_{\mathrm{C}}$ from $\mathcal{L}_{\mathrm{R}}$ is shown in Algorithm 1. It is described as starting from some arbitrary initial rectangle $\mathcal{X} \times \mathcal{Y}$. For the purpose of proving Theorem 4.*(i)* we only need to take $\mathcal{X} = [m]^n$ and $\mathcal{Y} = (\{0,1\}^m)^n$, but when we invoke this as a component in the proof of Theorem 4.*(ii)* we will need to start from some $\mathcal{X} \times \mathcal{Y}$ that is merely "dense × large" rather than the full input domain, so we state this more general version now.

▶ **Lemma 22.** *If $\mathcal{L}_{\mathrm{R}}$ computes $f \circ g^n$ on $\mathcal{X} \times \mathcal{Y}$ and has cost k, and if $\mathcal{X}$ is 0.85-dense and $\mathbf{D}_\infty(\mathcal{Y}) \leq n^3$, then $\mathcal{L}_{\mathrm{C}}$ produced by Algorithm 1 computes f and has cost $O(k/\log n)$. Moreover, if $\mathcal{L}_{\mathrm{R}}$ is q-alternating then so is $\mathcal{L}_{\mathrm{C}}$.*

Proof. To verify the cost, just note that lines 11 and 12 always succeed by Lemma 21 (since $\mathcal{X}$ is 0.85-dense and $|A'| \geq |\mathcal{X}|/2^{k+1}$), so when a conjunction is added to $\mathcal{L}_{\mathrm{C}}$ on lines 14 and 15, it has width $|I| < 20(k+1)/\log m = O(k/\log n)$. On line 13, defining $B := \{y \in Y_{x'} : y_I = \beta\}$ we have $|B| \geq |Y_{x'}|/2^{m|I|} \geq 2^{mn-n^4-m|I|} = 2^{m(n-|I|)-n^4}$ (since $x' \in A \subseteq A'$) and therefore

$\mathbf{D}_\infty(B_{[n]\smallsetminus I}) \le n^4$ (relative to $(\{0,1\}^m)^{[n]\smallsetminus I}$). Thus by applying Lemma 20 to $A_{[n]\smallsetminus I}$ (which is 0.8-dense) and $B_{[n]\smallsetminus I}$ we have $g^{[n]\smallsetminus I}(A_{[n]\smallsetminus I} \times B_{[n]\smallsetminus I}) = \{0,1\}^{n-|I|}$ and therefore $G(A \times B) = C^{-1}(1)$. (Lemma 20 works with the same parameters even though the sets are now on fewer than n coordinates.)

The algorithm terminates because Z always shrinks on line 16: for any $y \in B$ we have $G(x', y) \in Z$ (from the definition of $Y_{x'}$) and $C(G(x', y)) = 1$ (since $x'_I = \alpha$ and $y_I = \beta$ and thus $G(x', y)_I = g^I(\alpha, \beta)$).

The algorithm maintains the invariant that for all $j < i$, $R_j \cap (X \times Y) \cap G^{-1}(Z) = \emptyset$. This vacuously holds at the beginning, and is clearly maintained in the **else** case because i stays the same and nothing gets added to X, Y, or Z. Lines 7 and 8 maintain the invariant in the **if** case because the removed rows and columns cover all of $R_i \cap (X \times Y) \cap G^{-1}(Z)$ and i goes up by 1.

Next we argue that when the algorithm terminates, Z must be empty. In each iteration of the outer loop, we throw out at most $|\mathcal{X}|/2^{k+1}$ rows and at most $|\mathcal{X}| \cdot 2^{mn-n^4} \le m^n \cdot 2^{mn-n^4} \le 2^{mn-n^3}/2^{k+1} \le |\mathcal{Y}|/2^{k+1}$ columns. (We throw out columns in Y_x for $x \notin A'$, all of these Y_x had the property $|Y_x| < 2^{mn-n^4}$, we do this for at most $|\mathcal{X}|$ values of x, and $n^4 - n \log m \ge n^3 + k + 1$.) Since the outer loop executes 2^k times, by the end at most half the rows of $\mathcal{X}$ and half the columns of $\mathcal{Y}$ have been discarded, so $|X| \ge |\mathcal{X}|/2$ and $|Y| \ge |\mathcal{Y}|/2$. This means X is essentially as dense as $\mathcal{X}$ (only a -1 loss in any $\mathbf{H}_\infty(\boldsymbol{x}_I)$) and Y is essentially as low-deficiency as $\mathcal{Y}$ (only a $+1$ loss in $\mathbf{D}_\infty$). Thus Lemma 20 (with a tiny perturbation of the parameters, which does not affect the result) shows that $G(X \times Y) = \{0,1\}^n$. However, the last rectangle that is processed, R_{2^k}, contains all of $\mathcal{X} \times \mathcal{Y}$ by definition (since we assume $\mathcal{L}_\mathrm{R}$ is correct on $\mathcal{X} \times \mathcal{Y}$). So, the invariant guarantees $(X \times Y) \cap G^{-1}(Z) = \emptyset$ at termination. This can only happen if $G^{-1}(Z) = \emptyset$ and thus $Z = \emptyset$ (since $G(X \times Y) = \{0,1\}^n$).

We now argue that $\mathcal{L}_\mathrm{C}$ is correct. Consider any z in the domain of f. Since Z is empty at termination, z must be accepted by some conjunction in $\mathcal{L}_\mathrm{C}$. Let (C, ℓ_i) be the first entry such that $C(z) = 1$, so $z \in Z$ during the iteration of the inner loop when this entry was added. Since in this iteration we have $G(A \times B) = C^{-1}(1)$ and $z \in C^{-1}(1)$, there is some $(x, y) \in A \times B$ with $G(x, y) = z$. Since $A \times B \subseteq R_i$ we have $(x, y) \in R_i$. Since $A \times B \subseteq X \times Y$, we have $(x, y) \in (X \times Y) \cap G^{-1}(Z)$ and thus (x, y) cannot be in R_j for any $j < i$ since $R_j \cap (X \times Y) \cap G^{-1}(Z) = \emptyset$ by the invariant. In summary, R_i is the first rectangle in $\mathcal{L}_\mathrm{R}$ that contains (x, y). By correctness of $\mathcal{L}_\mathrm{R}$ on $\mathcal{X} \times \mathcal{Y}$, we have $\oplus(\ell_i) = (f \circ g^n)(x, y) = f(G(x, y)) = f(z)$. Thus $\mathcal{L}_\mathrm{C}$ also correctly outputs $\oplus(\ell_i)$ on input z.

The "moreover" part is straightforward to verify: the levels assigned to conjunctions in $\mathcal{L}_\mathrm{C}$ come from the levels assigned to rectangles in $\mathcal{L}_\mathrm{R}$ (namely $\{0, \ldots, q\}$), in the same order (which is non-increasing). ◀

A Spectral Bound on Hypergraph Discrepancy

Aditya Potukuchi

Abstract

Let $\mathcal{H}$ be a t-regular hypergraph on n vertices and m edges. Let M be the $m \times n$ incidence matrix of $\mathcal{H}$ and let us denote $\lambda = \max_{v \in \mathbf{1}^\perp} \frac{1}{\|v\|}\|Mv\|$. We show that the discrepancy of $\mathcal{H}$ is $O(\sqrt{t} + \lambda)$. As a corollary, this gives us that for every t, the discrepancy of a random t-regular hypergraph with n vertices and $m \geq n$ edges is almost surely $O(\sqrt{t})$ as n grows. The proof also gives a polynomial time algorithm that takes a hypergraph as input and outputs a coloring with the above guarantee.

1 Introduction

The main aim of this paper is to give a spectral condition that is sufficient for the discrepancy of a regular hypergraph to be small. This is proved via the partial coloring approach while using some combinatorial properties of the hypergraph that are given by this spectral condition. This immediately implies, via an old proof technique of Kahn and Szemerédi, that for every t, the discrepancy of a random t-regular hypergraph on n vertices and $m \geq n$ edges is almost surely $O\left(\sqrt{t}\right)$. Previously, a result of this form was proved by Ezra and Lovett [11] who show that the discrepancy of a random t-regular hypergraph on n vertices and $m \geq n$ edges is $O(\sqrt{t \log t})$ almost surely as t grows. More recently, Bansal and Meka [3] showed that for random t-regular hypergraphs on n vertices and m edges, the discrepancy is $O\left(\sqrt{t}\right)$ almost surely provided $t = \Omega\left((\log\log m)^2\right)$. To state our result formally, we make some definitions.

Let $\mathcal{H} = (V, E)$ be a hypergraph, with V as the set of vertices, and $E \subseteq 2^V$ as the set of (hyper)edges. Let $\mathcal{X} = \{\chi : V \to \{\pm 1\}\}$, be the set of ± 1 colorings of V, and for $\chi \in \mathcal{X}$, and $e \in E$, denote $\chi(e) := \sum_{v \in e} \chi(v)$. The discrepancy of $\mathcal{H}$, denoted by $\text{disc}(\mathcal{H})$ is defined as:

$$\text{disc}(\mathcal{H}) := \min_{\chi \in \mathcal{X}} \max_{e \in E} |\chi(e)|.$$

We call a hypergraph t-*regular* if every vertex is present in exactly t hyperedges. These will be the main focus of this paper. For a hypergraph $\mathcal{H}$, let $M = M(\mathcal{H})$ be the $|E| \times |V|$ incidence matrix of $\mathcal{H}$, i.e., M has rows indexed by E, columns indexed by V, and entries are $M(e, v) = 1$ if $v \in e$ and 0 otherwise. We will use $\|\cdot\|$ to denote the Euclidean norm throughout the paper. Our main result is the following:

▶ **Theorem 1.** *Let $\mathcal{H}$ be a t-regular hypergraph on n vertices and m edges with M as its incidence and let $\lambda = \max_{v \perp \bar{1}, \|v\|=1} \|Mv\|$. Then*

$$\operatorname{disc}(\mathcal{H}) = O\left(\sqrt{t} + \lambda\right).$$

Moreover, there is an $\tilde{O}((\max\{n, m\})^7)$ time algorithm that takes the hypergraph $\mathcal{H}$ as input and outputs the coloring with the above guarantee.

1.1 Background

The study of hypergraph discrepancy, which seems to have been first defined in a paper of Beck [4], has led to some very interesting results with diverse applications (see, for example [18, 9]). One of the most interesting open problems in discrepancy theory is what is commonly known as the Beck-Fiala conjecture, regarding the discrepancy of general t-regular hypergraphs.

▶ **Conjecture 2** (Beck-Fiala conjecture). *For a t-regular hypergraph $\mathcal{H}$, we have*

$$\operatorname{disc}(\mathcal{H}) = O(\sqrt{t}).$$

Although this conjecture is usually stated for *bounded degree* hypergraphs (as opposed to regular ones), this is not really an issue. One can always add hyperedges containing just a single vertex and make it regular, which increases the discrepancy of the original hypergraph by at most one. Beck and Fiala [5] also proved that for any t-regular hypergraph $\mathcal{H}$,

$$\operatorname{disc}(\mathcal{H}) \leq 2t - 1.$$

This is more commonly known as the Beck-Fiala theorem. Essentially the same proof can be done a bit more carefully to get a bound of $2t - 3$ (see [6]). Given Conjecture 2, it is perhaps surprising that the best upper bound, due to Bukh [8], is "stuck at" $2t - \log^* t$ for large enough t.

It is possible that one of the reasons that the discrepancy upper bounds are so far away from the conjectured bound (assuming it's true) is our inability to handle many "large" hyperedges. Indeed, if one is offered the restriction that each hyperedge is also of size $O(t)$ (regular and "almost uniform"), then a folklore argument using the Lovász Local Lemma shows that the discrepancy is bounded by $O(\sqrt{t \log t})$. The proof of Theorem 1 also relies on being able to avoid dealing with large edges (which are few, if any, in number).

1.2 Discrepancy in random settings

Motivated by the long-standing open problem of bounding discrepancy of general t-regular hypergraphs, Ezra and Lovett [11] initiated the study of discrepancy of *random* t-regular hypergraphs. By random t-regular hypergraph, we mean the hypergraph sampled by the following procedure: We fix n vertices V and m (initially empty) hyperedges E. Each vertex in V chooses t (distinct) hyperedges in E uniformly and independently to be a part of. They showed that if $m \geq n$, then the discrepancy of such a hypergraph is almost surely $O(\sqrt{t \log t})$ as t grows. The proof idea is the following: First observe that most of the hyperedges have size $O(t)$. For the remaining large edges, one can delete one vertex from every hyperedge and make them pairwise disjoint. This allows one to apply a folklore Lovász Local Lemma based argument, but with a slight modification which makes sure that the large edges have discrepancy at most 2. More recently, Bansal and Meka [3] reduced the discrepancy bound to

$O(\sqrt{t})$ almost surely as long as $t = \Omega\left((\log\log n)^2\right)$ for all m and n. A corollary of Theorem 1 states that one can get the bound of $O(\sqrt{t})$ for every (not necessarily growing) $t = t(n)$ as n grows and $m \geq n$. More formally,

▶ **Corollary 3.** *There is an absolute constant $C > 0$ such that the following holds: Let $\mathcal{H}_t$ be a random t-regular hypergraph on n vertices and $m \geq n$ hyperedges where $t = o(\sqrt{m})$. Then,*

$$\mathbb{P}\left(\operatorname{disc}(\mathcal{H}_t) \leq C\sqrt{t}\right) \geq 1 - o(1)$$

The theorem that implies Corollary 3 from Theorem 1 is the following:

▶ **Theorem 4.** *Let M be the incidence matrix of a random t-regular set system on n vertices, where $t = o(\sqrt{m})$, and $m \geq n$ edges. Then with probability at least $1 - n^{\Omega(1)}$,*

$$\max_{v \perp \bar{1}, \|v\|=1} \|Mv\| = O\left(\sqrt{t}\right).$$

A couple of remarks here: First, observe that it suffices to prove Theorem 4 for $m = n$. Indeed, let M and N be random $m \times m$ and $m \times n$ random matrices (m > n) respectively distributed by choosing t random 1's in each column independently. Notice that the distribution of N is exactly the same as that of the first n columns of M. Then, setting M_n to be the matrix consisting of the first n columns of M, we observe that $\lambda(M_n) \leq \lambda(M)$. Second, we point out that $t = o(\sqrt{m})$ is just a limitation of the proof technique in [13] (also see [7]) that we use to prove this theorem. Although we believe that Theorem 4 should hold for all $t < m$, we do not make any attempt to verify this, especially since the result of Bansal and Meka [3] already takes care of the discrepancy of random hypergraphs in this case. Although many variations of Theorem 4 are known and standard, one needs to verify it for our setting too. It should come as no surprise that the proof follows that of Kahn and Szemerédi's [1] in [13], which is postponed to Section 3.2.

1.3 The partial coloring approach

Most of the bounds and algorithms on hypergraph discrepancy proceed via a *partial coloring approach*. In general, a partial coloring approach [4] works by coloring a fraction of the (still uncolored) vertices in each step, while ensuring that no edge has discrepancy more than the desired bound. Perhaps the most famous successful application of this is Spencer's celebrated "six standard deviations" result [22], which gives a bound of $6\sqrt{n}$ for any hypergraph on n vertices and n edges. The original proof of Spencer was not algorithmic, i.e., it did not give an obvious way to take as input a hypergraph on n vertices and n edges, and efficiently output a coloring that achieves discrepancy $O(\sqrt{n})$. In fact, Alon and Spencer([1], §14.5) suggested that such an algorithm is not possible. However, this was shown to be incorrect by Bansal [2] who showed an efficient algorithm to do the same task. However, the analysis of this algorithm still relied on the (non-algorithmic) discrepancy bound of $6\sqrt{n}$. Later, Lovett and Meka [17] gave a "truly constructive" proof of the fact that the discrepancy is $O(\sqrt{n})$. This proof did not rely on any existing discrepancy bounds and the novel and simple analysis proved to be extremely influential. The proof of Theorem 1 will rely on a somewhat technical feature of the main partial coloring from this work. More recently, a result due to Rothvoss [21] gives a simpler proof of the same $O(\sqrt{n})$ bound, which is also constructive, and more general.

[1] [13] is combination of two papers that prove the same result upto a constant factor: one by Friedman using the so-called trace method, and the other by Kahn and Szemerédi using a more combinatorial approach which is flexible enough to be easily adapted here.

1.4 Proof sketch

The proof of Theorem 1 is proved via the aforementioned partial coloring approach. The main source of inspiration is a later paper of Spencer [23], which computes the discrepancy of the projective plane (i.e., the hypergraph where the vertices are the points and the hyperedges are the lines of $\mathrm{PG}(2,q)$) upto a constant factor. A more general bound was also obtained by Matoušek [19], who upper bounds the discrepancy of set systems of bounded VC-dimension (note that the projective plane has VC-dimension 2).

We also use the aforementioned result of Lovett and Meka [17] heavily, in particular, the partial coloring theorem. Informally, this says that one can "color" roughly an α fraction of the hypergraph with real numbers in $[-1,1]$ so that (1) at least half the vertices get colors 1 or -1 and (2) every edge e has discrepancy $O(\sqrt{e})$. We now sketch the proof.

Consider the following "dream approach" using partial coloring: In every step, one colors an α fraction of vertices. Suppose that at the start, every edge has size $O(t)$ and that each step of partial coloring colors exactly an α fraction of the remaining uncolored vertices (i.e., these vertices are colored from $\{-1,1\}$). Then the discrepancy of an edge e is at most $O\left(\sum_i \sqrt{\alpha^i|e|}\right) = O(\sqrt{t})$. Of course, this is too much to hope for, since some edges can potentially be large, and more importantly, there is no guarantee on how much of each edge gets colored in this partial coloring procedure.

This is precisely where the spectral condition on M saves us. One can establish standard combinatorial "pseudorandomness" properties of $\mathcal{H}$ in terms of λ. In particular, if λ is small, then an α fraction of $V(\mathcal{H})$ take up an α fraction of most edges. This means, intuitively, that in the partial coloring approach, if one colors an α fraction of the vertices, then most of the edge sizes will have also reduced by an α fraction. The partial coloring method of Lovett and Meka (and, curiously, none of the older ones) also allows one to color in such a way that $\Omega(n)$ edges can be made to have discrepancy zero in each step. This allows one to maintain that in every round of the partial coloring, the edges that don't behave according to the "dream approach", i.e., those that are too large (i.e., $\Omega(t)$) or don't reduce by an α fraction can be made to have discrepancy *zero* in the next step. Thus, most other edges reduce in size by an α fraction. This lets one not have to deal with the discrepancy of these "bad" edges until they become small.

2 Proof of Theorem 1

2.1 Preliminaries and notation

We will need the aforementioned partial coloring theorem due to Lovett and Meka:

▶ **Theorem 5** ([17]). *Given a family of sets $M_1,\dots,M_m \subseteq [n]$, a vector $x_0 \in [-1,1]^n$, positive real numbers $c_1,\dots,c_m$ such that $\sum_{i\in[m]} \exp\left(-c_i^2/16\right) \le n/16$, and a real number $\delta \in [0,1]$, there is a vector $x \in [-1,1]^n$ such that:*

1. *For all $i \in [m]$, $\langle x - x_0, \mathbb{1}_{M_i}\rangle \le c_i\sqrt{|M_i|}$.*
2. *$|x_i| \ge 1-\delta$ for at least $n/2$ values of i.*

Moreover, this vector x can be found in $\tilde{O}((m+n)^3\delta^{-2})$ time.

Lovett and Meka initially gave a randomized algorithm for the above. It has since been made deterministic [16].

2.1.1 A technical remark

The reason we use the Lovett-Meka partial coloring, as opposed to Beck's partial coloring is not just the algorithmic aspect that the former offers, but also because it also offers the technical condition:

$$\sum_{i\in[m]} \exp\left(-c_i^2/16\right) \leq n/16.$$

This means one can set $\Omega(n)$ edges to have discrepancy 0. To compare, we first state Beck's partial coloring lemma (for reference, see [18]):

▶ **Theorem 6** (Beck's partial coloring lemma). *Given a family of sets $M_1, \ldots, M_m \subseteq [n]$, and positive real numbers $c_1, \ldots, c_m$ such that $\sum_{i\in[m]} g(c_i) \leq n/5$, where*

$$g(x) = \begin{cases} e^{-x^2/9} & x > 0.1 \\ \ln(1/x) & x \leq 0.1 \end{cases}$$

there is a vector $x \in \{-1, 0, 1\}^n$ such that:

1. *For all $i \in [m]$, $\langle x, \mathbb{1}_{M_i}\rangle \leq c_i\sqrt{|M_i|}$.*
2. *$|x_i| = 1$ for at least $n/2$ values of i.*

If one ignores the algorithmic aspect, Beck's partial coloring, while assigning vertices to $\{-1, 1, 0\}$ (instead of $[-1, 1]$, thus making it a "partial coloring" in the true sense) only guarantees that $\Omega\left(\frac{n}{\log t}\right)$ edges can be made to have discrepancy 0. Although [17] did not really need this particular advantage, they do mention that this feature could potentially be useful elsewhere. This seemingly subtle advantage turns out to be crucial in the proof of Theorem 1, where we set $\Omega(n)$ edges (that will be called "bad" and "dormant" edges) to have discrepancy 0.

Henceforth, let V and E denote the vertices and edges of our hypergraph respectively. We will need a "pseudorandomness" lemma that informally states that an α fraction of vertices takes up around an α fraction of most edges:

▶ **Lemma 7.** *For any $S \subseteq V$ with $|S| = \alpha n$ where $\alpha \in (0, 1)$ and a positive real number K, there is a subset $E' \subset E$ of size at most $K^{-2} \cdot \alpha n$ such that for every $e \notin E'$, we have $||e \cap S| - \alpha|e|| \leq K\lambda$, where $\lambda = \max_{v\perp\bar{\mathbf{1}}, \|v\|=1} \|Mv\|$.*

Proof. Consider a vector $v \in \mathbb{R}^n$ where $v(i) = 1 - \alpha$ for $i \in S$ and $-\alpha$ otherwise. Clearly, $v \in \mathbf{1}^\perp$ and so

$$\|Mv\|^2 \leq \lambda^2 \cdot \|v\|^2 = \lambda^2\alpha(1-\alpha)n. \tag{1}$$

On the other hand, $Mv(e) = (1-\alpha)|e \cap S| - \alpha|e \setminus S| = |e \cap S| - \alpha|e|$, and so

$$\|Mv\|^2 = \sum_e (|e \cap S| - \alpha|e|)^2. \tag{2}$$

Putting (1) and (2) together, we get that there at most $K^{-2} \cdot \alpha n$ edges e such that $||e \cap S| - \alpha|e|| \geq K\lambda$. ◀

Since this proof is via partial coloring, let us use i to index the steps of the partial coloring. For a partial coloring $\chi : V \to [-1,1]$, we call the set of vertices u for which $|\chi(u)| < 1$ as *uncolored.* Let us use V^i to denote the still uncolored vertices at step i and for an edge $e \in E$, let us denote $e^i := e \cap V^i$. In every step, we invoke Theorem 5 setting $\delta = \frac{1}{n}$ to get the partial coloring, so will have $|V^i| \leq 2^{-i}n$. Let $t' := \max\{t, \lambda\}$ [2].

We call an edge *dormant* at step i if $|e^i| > 100t'$. Let us call an edge *bad* in step i if $\big||e^i| - 2^{-i}|e|\big| \geq 10\lambda$. Edges that are neither dormant not bad are called *good.* Finally, we say that e is *dead* in step i if $|e^i| \leq 100\lambda$.

Informally, the roles of these sets are as follows: In the partial coloring step i, we ensure that an edge e edges only get nonzero discrepancy if it is good, i.e., if $|e^i|$ is close to what is expected and is not too large. Even dead edges can be good or bad, and we will not distinguish them while coloring the vertices. However, in the analysis we will break the total discrepancy accumulated by e into two parts: Before it is dead and after. The main point is to bound the discrepancy gained before it becomes dead. After it becomes dead, we simply bound the discrepancy incurred since by its remaining size, i.e., at most 100λ.

First, we make two easy observations:

▷ Claim 8. If $|V^i| = 2^{-i}n$, then at step i, the number of dormant edges is at most $\frac{1}{100}2^{-i}n$.

Proof. This is just Markov's inequality, using the fact that the average edge size is $\frac{|V^i|t}{m} \leq \frac{|V^i|t'}{m}$. ◁

▷ Claim 9. If $|V^i| = 2^{-i}n$, then at step i, the number of bad edges is at most $\frac{1}{100}2^{-i}n$.

Proof. This is by setting $K = 10$ and $\alpha = 2^{-i}$ in Lemma 7. ◁

2.2 Partial coloring using Lemma 7

Proof of Theorem 1. Setting $V^0 = V$, we proceed by partial coloring that colors exactly half the remaining uncolored vertices at each stage. For a step $i \geq 0$, suppose that $|V^i| = 2^{-i}n$. We will describe a partial coloring given by $\chi_i : V^i \to [-1,1]$ that colors half the vertices of V^i.

For $\ell \geq 1$, let $A_\ell := \{e \in E \mid |e| \in [100 \cdot 2^\ell t', 100 \cdot 2^{\ell+1}t')\}$, and $A_0 := \{e \in E \mid |e| < 200t'\}$. Observe that the edges in A_ℓ for $\ell \geq 1$ are either bad or dormant in steps $i < \ell$. Also observe that $|A_\ell| \leq \frac{2^{-\ell}}{100}n$ for $\ell \geq 1$, Define constants $\{c_e\}_{e \in E}$ as follows:

$$c_e = \begin{cases} 4\sqrt{2\ln\left(\frac{1}{2^{\ell-i}}\right)} & \text{if } e \in A_\ell \text{ for } \ell \geq 1 \text{ is good} \\ 4\sqrt{\ln\left(\frac{200t'}{2^{-i}|e|}\right)} & \text{if } e \in A_0 \text{ is good} \\ 0 & \text{otherwise.} \end{cases}$$

[2] In fact, we may assume w.l.o.g. that $\lambda \leq t$ and so $t' = t$ since in the other case, the Beck-Fiala Theorem gives us that the discrepancy is $O(t) = O(\lambda)$. However, this is not needed and the techniques here also handle this case with this minor change.

Let $\mathcal{B} = \mathcal{B}^i$ and $\mathcal{D} = \mathcal{D}^i$ denote the bad and dormant edges respectively. We handle the edges in A_0 and $E \setminus A_0$ separately. For edges in $E \setminus A_0$, we have:

$$\begin{aligned}\sum_{e \in E \setminus A_0} e^{-\frac{c_e^2}{16}} &\leq \sum_{e \in E \setminus (\mathcal{B} \cup \mathcal{D} \cup A_0)} e^{-\frac{c_e^2}{16}} + |\mathcal{B}| + |\mathcal{D}| \\ &\leq \sum_{1 \leq \ell \leq i} \sum_{e \in A_\ell} e^{2 \ln(2^{\ell - i})} + \frac{2^{-i} n}{50} \\ &= \sum_{1 \leq \ell \leq i} |A_\ell| 2^{2(\ell - i)} + \frac{2^{-i} n}{50} \\ &\leq \frac{n}{100} \sum_{\ell \leq i} 2^{-\ell} \cdot 2^{2\ell - 2i} + \frac{2^{-i} n}{50} \\ &= \frac{2^{-i} n}{100} \sum_{\ell \leq i} 2^{\ell - i} + \frac{2^{-i} n}{50} \\ &\leq \frac{2^{-i} n}{25}.\end{aligned}$$

The second inequality above follows from Claim 8 and Claim 9. For the other case, we have

$$\sum_{e \in A_0} e^{-\frac{c_e^2}{16}} \leq \sum_{e \in A_0} e^{\ln\left(\frac{2^{-i}|e|}{200t}\right)} = \frac{2^{-i}}{200} \sum_{e \in E} \frac{|e|}{t'} = \frac{2^{-i} n}{200}.$$

Here we have used the fact that since the hypergraph is t-regular, we have $\sum_{e \in E} |e| = nt \leq nt'$. Putting these together, we have

$$\sum_{e \in E} e^{-\frac{c_e^2}{16}} \leq \frac{2^{-i} n}{200} + \frac{2^{-i} n}{50} \leq \frac{|V^i|}{20}.$$

Therefore, Theorem 5 guarantees that there is a fractional coloring $\chi_i : V^i \to [-1, 1]$ such that

1. $|\chi_i(v)| \geq 1 - \frac{1}{n}$ for at least half of V^i.
2. All the bad and dormant edges get discrepancy 0.
3. A good and live edge e gets discrepancy at most $c_e \sqrt{|e^i|}$.

Finally, we pick an arbitrary subset of all the vertices v such that $|\chi_i(v)| \geq 1 - \frac{1}{n}$ of size exactly $(1/2) \cdot |V^i|$ and round them to the nearest integer. It is easy to see that since every edge has size at most n, this rounding, over all the steps of the partial coloring adds discrepancy of at most 1 for every edge. This completes step i of the partial coloring and we are left with $2^{-(i+1)} n$ uncolored vertices for the next step.

For an edge e, let i be a round where e had incurred non-zero discrepancy and e^i was not dead. Since only good edges incur nonzero discrepancy, $|e^i| = 2^{-i}|e| \pm 10\lambda$. Since e is also not dead at step i, we must have that $|e^i| \geq 100\lambda$. This gives us that $2^{-i}|e| \geq 90\lambda$ and therefore $(1/2) \cdot 2^{-i}|e| \leq |e_i| \leq 2 \cdot 2^{-i}|e|$. So, if $e \in A_\ell$ where $\ell \geq 1$, the total discrepancy incurred by e at step i without the rounding step is at most

$$4\sqrt{2 \ln(1/2^{j-i}) e^i} \leq 8\sqrt{200 \ln(1/2^{\ell - i}) \cdot (2^{\ell - i}) \cdot t'}.$$

Here, we have used the fact that $|e| \leq 100 \cdot 2^{\ell+1} t'$. If $e \in A_0$, the discrepancy incurred by e at step i without the rounding is at most

$$4\sqrt{2\ln\left(\frac{200t'}{2^{-i}|e|}\right)e^i} \leq 8\sqrt{200\ln(1/2^{-i})\cdot(2^{-i})\cdot t'}.$$

Therefore, the discrepancy of an edge $e \in A_\ell$ for $\ell \geq 0$ until it becomes dead is at most

$$\sum_{i\geq\ell} 8\sqrt{200\ln(1/2^{\ell-i})\cdot(2^{\ell-i})\cdot t'} = O(\sqrt{t'}) = O(\sqrt{t}+\lambda).$$

Here we have used the fact that $t' = \max\{t,\lambda\}$. Finally, rounding the color of every vertex to its nearest integer increases the discrepancy by at most 1. When the edge becomes dead, we simply bound its discrepancy by its size $O(\lambda)$.

It remains to check that each of the $O(\log n)$ stages of partial coloring can be done in time $\tilde{O}((m+n)^3 n^2)$, and the constants $\{c_e\}_{e\in E}$ take $\tilde{O}(mn)$ time to compute at each stage, thus establishing the algorithmic part. ◀

3 Proof of Theorem 4

3.1 A martingale inequality

We will state a martingale inequality that we will use in the proof of Theorem 4. A sequence of random variables $X_0, X_1, \ldots, X_n$ martingale with respect to another sequence of random variables $Z_0, Z_1, \ldots, Z_n$ such that for all $i \in [n-1]$, we have $X_i = f_i(Z_1, \ldots Z_i)$ for some function f_i, and $\mathbf{E}[X_{i+1}|Z_i, \ldots, Z_1] = X_i$.

A martingale is said to have the C-bounded difference property if $|X_{i+1} - X_i| \leq C$.

The variance of a martingale is the quantity:

$$\sigma^2 = \sum_{i\in[n-1]} \sup_{(Z_1,\ldots,Z_i)} \mathbf{E}[(X_{i+1}-X_i)^2|Z_1,\ldots,Z_i].$$

We get good large deviation inequalities for martingales with bounded differences and variances (see, for example, [10], Theorem 6.3 and Theorem 6.5). For a martingale $X_0, X_1, \ldots, X_n$ with respect to $Z_0, Z_1, \ldots, Z_n$, with the C-bounded difference property and variance σ^2, we have

$$\mathbb{P}(|X_n - X_0| \geq \lambda) \leq e^{-\frac{t^2}{2(\sigma^2+C\lambda/3)}}. \tag{3}$$

3.2 Proof of Theorem 4

We shall now prove Theorem 4. Recall that we only need to prove the case where $m = n$, As mentioned before, we adapt the proof technique of Kahn and Szemerédi for our random model (also see [7]). We have that the regularity is $t \ll m^{1/2}$.

We shall prove that for every x, and y such that $\|x\| = \|y\| = 1$ and $x \perp \bar{1}$, we have that $|y^t M x| \leq O(\sqrt{t})$. First, we "discretize" our problem by restricting x to belong to the ϵ-net

$$T := \left\{x \in \left(\frac{\epsilon}{\sqrt{m}}\mathbb{Z}\right)^m \mid \|x\| \leq 1 \text{ and } x \perp \bar{1}\right\}$$

and y belonging to

$$T' := \left\{y \in \left(\frac{\epsilon}{\sqrt{m}}\mathbb{Z}\right)^m \mid \|y\| \leq 1\right\}$$

for a small enough constant ϵ.

▷ Claim 10 ([13], Proposition 2.1). If for every $x \in T$, and $y \in T'$, we have that $\|y^t Mx\| \le \alpha$, then we have that for every $z \in \mathbb{R}^m$ such that $\|z\| = 1$, we have that $\|Mz\| \le (1-3\epsilon)^{-1}\alpha$.

Proof. Let $z = \operatorname{argmax}_{\|z\|=1} \|Mz\|$. We shall use the fact that there are $x \in T$, and $y \in T'$ such that $\|x - z\| \le \epsilon$, and $\left\| y - \frac{Mz}{\|Mz\|} \right\| \le \epsilon$. With this in mind, we have:

$$\begin{aligned}\|Mz\| &= \left\langle \frac{Mz}{\|Mz\|}, Mz \right\rangle = \langle y + w_1, M(x + w_2)\rangle \\ &= y^t Mx + \langle w_1, Mx\rangle + \langle y, Mw_2\rangle + \langle w_1, Mw_2\rangle.\end{aligned}$$

Where $|w_1|, |w_2| \le \epsilon$. We note that each of the terms $\langle w_1, Mx\rangle$ and $\langle y, Mw_2\rangle$, and $\langle w_1, Mw_2\rangle$ are upper bounded by $\epsilon\|Mz\|$, and $\langle w_1, Mw_2\rangle \le \epsilon^2\|Mz\|$. Combining this, and using the fact that $\epsilon^2 \le \epsilon$, we have

$$\|Mz\| \le (1-3\epsilon)^{-1} y^t Mx \le (1-3\epsilon)^{-1}\alpha. \qquad \triangleleft$$

So now, will need to only union bound over $T \cup T'$. It is not hard to see that each of these has size at most $|T|, |T'| \le \left(\frac{C_v}{\epsilon}\right)^m$ for some absolute constant C_v.

Indeed, we have:

$$\begin{aligned}|T| &\le \left(\frac{\sqrt{m}}{\epsilon}\right)^m \mathrm{Vol}\,\{x \in \mathbb{R}^m \mid \|x\| \le 1 + \epsilon\} \\ &\le \left(\frac{\sqrt{m}}{\epsilon}\right)^m \cdot \frac{1}{\sqrt{\pi m}} \left(\frac{2\pi e}{m}\right)^{m/2} (1+\epsilon)^m \\ &\le \left(\frac{C_v}{\epsilon}\right)^m\end{aligned}$$

for some constant C_v.

We split the pairs $[m] \times [m] = L \cup \overline{L}$ where $L := \{(u, v) \mid |x_u y_v| \ge \sqrt{t}/m\}$, which we will call "large entries" and write our quantity of interest:

$$\sum_{(u,v)\in[m]\times[m]} x_u M_{u,v} y_v = \sum_{(u,v)\in L} x_u M_{u,v} y_v + \sum_{(u,v)\in\overline{L}} x_u M_{u,v} y_v.$$

For the large entries: For a set of vertices $A \subset [m]$ and a set of edges $B \subset [m]$, let us denote $I(A, B)$ to be the number of vertex-edge incidences in A and B. Let us use $\mu(A, B) := \mathbf{E}[|I(A, B)|]$.

▶ **Lemma 11.** *There is a constant C such that, for every set A of vertices and every set B of hyperedges where $|A| \le |B|$, we have that with probability at least $1 - m^{-\Omega(1)}$, $I := |I(A, B)|$ and $\mu := \mu(A, B)$ satisfy at least one of the following:*

1. $I \le C\mu$
2. $I \log(I/\mu) \le C|B| \log(m/|B|)$.

This lemma is sufficient to show that the large pairs do not contribute too much, as shown by the following lemma, which is the main part of the proof of Kahn and Szemerédi.

▶ **Lemma 12** ([13], Lemma 2.6, [7], Lemma 17). *If the conditions given in Lemma 11 are satisfied, then $\sum_{(u,v)\in L} |x_u M_{u,v} y_v| = O(\sqrt{t})$ for all $x, y \in T$.*

Notice that since we are bounding $\sum_{(u,v)\in L} |x_u M_{u,v} y_v| = O(\sqrt{t})$, which is much stronger than what we really need, it is okay to consider both x and y from T.

Proof of Lemma 11. First, we observe that it is enough to consider $|B| \le m/2$, since otherwise, $|I(A,B)| \le d|A| \le 2\mu(A,B)$. Let $\mathcal{B}_i(a,b)$ denote the event that there is an A of size a and a B of size b which do not satisfy either of the conditions (with a fixd constant C to be specified later) and $|I(A,B)| = i$. Before, we prove the lemma, let us make some observations, which (in hindsight) help us compute the probabilities much easier. Let A be a set of a vertices and B be a collection of b edges, such that $a \le b \le m/2$.

The point here is that we basically want to evaluate the sum:

$$\begin{aligned}\mathbb{P}\left(\bigcup_{a,b,i}\mathcal{B}_i(a,b)\right) &\le \sum_i \mathbb{P}\left(\bigcup_{a,b}\mathcal{B}_i(a,b)\right)\\ &= \sum_{i\le\log^2 m}\mathbb{P}\left(\bigcup_{a,b}\mathcal{B}_i(a,b)\right) + \sum_{i\ge\log^2 m}\mathbb{P}\left(\bigcup_{a,b}\mathcal{B}_i(a,b)\right).\end{aligned}$$

The first observation is that every term in the second sum is small. Towards this, we have the straightforward claim.

▷ Claim 13. For a set of vertices A and edges B and a set of possible incidences $J \subset A \times B$, we have that $\mathbb{P}(I(A,B) = J) \le \left(\frac{2t}{m}\right)^{|J|}$.

Proof. W.L.O.G, let $A = \{1,\dots,a\}$, and for $i \in A$, let $t_i = I(\{i\},B)$. We have that:

$$\mathbb{P}(I(A,B)=J) = \prod_{i\in A}\frac{\binom{m-b}{t-t_i}}{\binom{m}{t}} \le \prod_{i\in A} 2\frac{(m-b)^{t-t_i}}{(t-t_i)!}\frac{t!}{m^t} \le \prod_{i\in A}\left(\frac{2t}{m}\right)^{t_i} \le \left(\frac{2t}{m}\right)^{|J|}. \qquad \triangleleft$$

Here, the first inequality uses the fact that $t = o(\sqrt{m})$. Therefore, we have:

$$\mathbb{P}\left(\mathcal{B}_i(a,b)\right) \le \binom{m}{a}\binom{m}{b}\binom{ab}{i}\left(\frac{2t}{m}\right)^i \le \binom{m}{b}^2\left(e\frac{abt}{mi}\right)^i \le \binom{m}{b}^2\left(\frac{\mu}{i}\right)^i (e)^i.$$

If $i \ge 2e\mu$ and $i \ge \log^2 m$, this probability is at most $2^{2m} \cdot 2^{-\log^2 m} \ll m^{-\Omega(\log m)}$. Thus

$$\sum_{i\ge\log^2 m}\mathbb{P}\left(\bigcup_{a,b}\mathcal{B}_i(a,b)\right) \le \sum_{a,b}\sum_{i\ge\log^2 m}\mathbb{P}\left(\mathcal{B}_i(a,b)\right) \le m^{-\Omega(\log m)}.$$

It remains to deal with the sum $\sum_{i\le\log^2 m}\Pr\left(\bigcup_{a,b}\mathcal{B}_i(a,b)\right)$. For these summands, we have that if $|I(A,B)| \le \log^2 m$ and $I\log(I/\mu) > Cb\log(m/b)$, then

$$I\log m \ge I\log(I/\mu) > Cb\log(m/b) \ge Cb.$$

and so $Cb \le \log^3 m$. The first inequality above comes from the observation that $I \le ab$ and so $I/\mu \le m/t \le m$. Now, using that $I\log m \ge Cb\log(m/\log^3 m)$, we have that $I \ge Cb/2$.

Therefore, we only need to evaluate the sum:

$$\begin{aligned}\sum_{i=Cb/2}^{\log^2 m}\mathbb{P}\left(\mathcal{B}_i(a,b)\right) &\le \binom{m}{a}\binom{m}{b}\sum_{i=Cb/2}^{\log^2 m}\binom{ab}{i}\left(\frac{10et}{m}\right)^i \le \binom{m}{b}^2\sum_{i=Cb/2}^{\log^2 m}\left(\frac{10e^2abt}{im}\right)^i\\ &\le \log^2 m\left(\frac{em}{b}\right)^{2b}\left(\frac{20e^2at}{Cm}\right)^{Cb/2}\\ &= m^{2b-Cb/2}b^{-2b}a^{Cb/2}t^{Cb/2}(20e^2)^{2b}\\ &\le m^{2b-Cb/4}b^{Cb/2-2b}(20e^2)^{2b}\\ &= m^{-\Omega(b)}.\end{aligned}$$

We have used the fact that $t = o(\sqrt{m})$, $b \ge a$ and $b \le \log^3 m$. Thus union bounding over $\log^3 m$ many values of a and b, we have $\sum_{a,b\le\log^3 m}\sum_{i\le\log^2 m}\mathbb{P}\left(\bigcup_{a,b}\mathcal{B}_i(a,b)\right) = m^{-\Omega(1)}$. ◀

For the small entries: Bounding the contribution from the small entries is much easier. The analysis given here is slightly different to the one given in [13] and [7]. However, it does not make much of a difference, and is still, essentially, the same large deviation inequality. We will first compute the expected value of the quantity of interest using the following claim:

▷ Claim 14. We have that:

$$\left|\sum_{(u,v)\in\overline{L}} x_u y_v\right| \leq \frac{m}{\sqrt{t}}.$$

Proof. Since $\sum x_i = 0$, we have $\left(\sum x_i\right)\left(\sum y_i\right) = \sum_{(u,v)\in L} x_u y_v + \sum_{(u,v)\in\overline{L}} x_u y_v = 0$ or

$$\left|\sum_{(u,v)\in\overline{L}} x_u y_v\right| = \left|\sum_{(u,v)\in L} x_u y_v\right|.$$

To bound this, we note that

$$1 = \left(\sum x_u^2\right)\left(\sum y_u^2\right) \geq \sum_{(u,v)\in L} x_u^2 y_v^2 \geq \frac{\sqrt{t}}{m}\left|\sum_{(u,v)\in L} x_u y_v\right| = \frac{\sqrt{t}}{m}\left|\sum_{(u,v)\in\overline{L}} x_u y_v\right|.$$

which gives us what we want. ◁

Given Claim 14 above, we can easily compute the expectation:

$$\mathbf{E}\left[\sum_{(u,v)\in\overline{L}} x_u M_{u,v} y_v\right] = \frac{t}{m}\sum_{(u,v)\in\overline{L}} x_u y_v \in [-\sqrt{t}, \sqrt{t}].$$

▷ Claim 15. We have that with high probability, $\sum_{(u,v)\in\overline{L}} x_u M_{u,v} y_v = O(\sqrt{t})$.

Proof. We set up a martingale and use the method of bounded variances. Let us write the quantity that we wish to estimate as

$$X := \sum_{(u,v)\in B} x_u M_{u,v} y_v.$$

We imagine M being sampled one column at a time, and in each column, t entries are sampled. For column i, let us denote these by $e_{i,1},\ldots,e_{i,t}$. Clearly, $X = X(e_{1,1},\ldots,e_{m,t})$. Denote $X_{i,j} := \mathbf{E}[X|e_{1,1},\ldots,e_{i,j}]$. For distinct $k,k'\in[m]$, it is easy to see that we have the "Lipschitz property":

$$|\mathbf{E}[X|e_{1,1},\ldots,e_{i,j-1},e_{i,j}=k] - \mathbf{E}[X|e_{1,1},\ldots,e_{i,j-1},e_{i,j}=k']| \leq |x_i y_k| + |x_i y_{k'}|.$$

Therefore, we have a bounded difference property on $|X_{i,j} - X_{i,j-1}|$ as follows:

$$\begin{aligned}|X_{i,j} - X_{i,j-1}| = \Bigg|&\mathbf{E}[X|e_{1,1},\ldots,e_{i,j-1},e_{i,j}] \\ &- \frac{1}{m-j+1}\sum_{k'\in[m]\setminus\{e_{i,1},\ldots,e_{i,j-1}\}} \mathbf{E}[X|e_{1,1},\ldots,e_{i,j-1},e_{i,j}=k']\Bigg| \\ \leq |x_{e_j}||y_i| &+ \frac{1}{m-j+1}\sum_{k'\in[m]\setminus\{e_{i,1},\ldots,e_{i,j-1}\}} \mathbb{1}[(k',i)\in\overline{L}]|x_{k'}y_i|\end{aligned}$$

We will use that the above quantity is bounded by $\frac{2\sqrt{t}}{m}$ since we only consider $|x_{e_j} y_i|$ where $(e_j, i) \in \overline{L}$. However, another way to upper bound the above is by using

$$\begin{aligned}
&\frac{1}{m-j+1} \sum_{k' \in [m] \setminus \{e_{i,1}, \ldots, e_{i,j-1}\}} \mathbb{1}[(k', i) \in \overline{L}] |x_{k'} y_i| \\
&\leq \frac{1}{m-j+1} \sum_{k' \in [m] \setminus \{e_{i,1}, \ldots, e_{i,j-1}\}} |x_{k'} y_i| \\
&\leq \frac{|y_i|}{n-j+1} \sum_{k' \in [m]} |x_{k'}| \\
&\leq \frac{2|y_i|}{\sqrt{m}}.
\end{aligned}$$

Using this, we now compute the variance of the martingale:

$$\begin{aligned}
\operatorname{Var}(X_{i,j} - X_{i,j-1} | e_{1,1}, \ldots, e_{i,j-1}) &\leq \frac{1}{m-j+1} \sum_{k \in [m]} \left(|x_k y_i| + \frac{2|y_i|}{\sqrt{m}} \right)^2 \\
&\leq \frac{2}{m-j+1} \sum_{k \in [m]} \left(|x_k y_i|^2 + \frac{4y_i^2}{m} \right) \\
&\leq \frac{10 y_i^2}{m-j+1}.
\end{aligned}$$

Where the last inequality uses that $\sum_k x_k^2 \leq 1$. Therefore, the variance of the martingale is at most$t \cdot \frac{10}{m-t} \sum_i y_i^2 \leq \frac{20t}{m} =: \sigma^2$. This is because $\sum_i y_i^2 \leq 1$. Therefore, by the bounded variance martingale inequality (3), using $|X_i - X_{i-1}| \leq \frac{2\sqrt{t}}{m} =: C$:

$$\mathbb{P}(X \geq (D+1)\sqrt{t}) \leq \exp\left\{ -\frac{D^2 t}{2\sigma^2 + tC/3} \right\} \leq \exp\left\{ -\frac{D^2 t}{\frac{40t}{m} + \frac{2t}{3m}} \right\} \leq \exp\left\{ -\Omega(D^2 m) \right\}.$$

For a large enough constant D, this lets us union bound over all $x, y \in T$, whose number can be bounded by $\left(\frac{C_v}{\epsilon}\right)^m$. ◁

4 Conclusion

We have given an upper bound on t-regular hypergraph discrepancy in terms of t and a spectral property of the incidence matrix. However, when one restricts attention to random t-regular hypergraphs, the $O(\sqrt{t})$ bound is achieved only when $m = \Omega(n)$. In the case where $m = o(n)$, one can replace λ in Theorem 1 by λ' where

$$\lambda'(\mathcal{H}) := \max_{\substack{U \subset V \\ |U| = 16m}} \max_{\substack{v \perp \overline{1}, \\ \|v\|=1, \\ \operatorname{supp}(v) \subseteq U}} \|Mv\|$$

and the proof would remain the same. This is because using the partial coloring theorem (Theorem 5), one may assign colors to all but at most $16m$ vertices while maintaining that the discrepancy of *every* edge is 0. However, when $\mathcal{H}$ is a random t regular hypergraph with n vertices and $m = o(n)$ edges, we need not have $\lambda'(\mathcal{H}) = O\left(\sqrt{t}\right)$ (in fact, the guess would be $O(\sqrt{tn/m})$). The problem is that Claim 15 (In Section 3.2) does not extend. However, in this regime, we believe that with high probability, the discrepancy is much *lower* than $\sqrt{t}$ (in contrast to λ growing).

Recently, Franks and Saks [12] showed that for $n = \tilde{\Omega}(m^3)$, the discrepancy is $O(1)$ almost surely. Independently, Hoberg and Rothvoss [14] considered a different model of random hypergraphs with n vertices and m edges and each vertex-edge-incidence is an i.i.d. $\mathrm{Ber}(p)$ random variable. They show that if $n = \tilde{\Omega}(m^2)$, the discrepancy is $O(1)$ almost surely. Both [12] and [14] used similar Fourier analytic techniques inspired by [15]. Moreover, it was an open question in [14] whether the hypergraph with i.i.d $\mathrm{Ber}(1/2)$ incidences where $n = O(m \log m)$ almost surely has discrepancy $O(1)$. This was shown to be true by the author [20].

We argue that this is an interesting regime for random regular hypergraphs, as this kind of discrepancy bound is not implied by the Beck-Fiala conjecture. The case where $n = \Omega(m \log m)$, is of particular interest, since we believe there is a phase transition for constant discrepancy at this point. On the one hand, we do not know if the discrepancy bound given by Corollary 3 is the truth, and on the other hand, we do not know if random regular hypergraphs with, for example, $n = \Theta(m^{1.5})$ almost surely has discrepancy $O(1)$. We conclude with a conjecture, building on an open problem (open problem 1) in [12]:

▶ **Conjecture 16.** *There is an absolute constant $K > 0$ such that the following holds. Let $t > 0$ be any integer and $\mathcal{H}$ be a random t-regular hypergraph on n vertices and $K\frac{n}{\log n}$ edges. Then with high probability,*

$$\mathrm{disc}(\mathcal{H}) = O(1).$$

Abstract

In the dynamic range mode problem, we are given a sequence a of length bounded by N and asked to support element insertion, deletion, and queries for the most frequent element of a contiguous subsequence of a. In this work, we devise a deterministic data structure that handles each operation in worst-case $\tilde{O}(N^{0.655994})$ time, thus breaking the $O(N^{2/3})$ per-operation time barrier for this problem. The data structure is achieved by combining the ideas in Williams and Xu (SODA 2020) for batch range mode with a novel data structure variant of the Min-Plus product.

1 Introduction

Given a sequence of elements $a_1, a_2, \dots, a_n$, the dynamic range mode problem asks to support queries for the most frequent element in a specified subsequence $a_l, a_{l+1}, \dots, a_r$ while also supporting insertion or deletion of an element at a given index i. The mode of a sequence of elements is one of the most basic data statistics, along with the median and the mean. It is frequently computed in data mining, information retrieval, and data analytics.

The range mode problem seeks to answer multiple queries on distinct intervals of the data sequence without having to recompute each answer from scratch. Its study in the data structure community has shown that the mode is a much more challenging data statistic to maintain than other natural range queries: while range sum, min or max, median, and majority all support linear space dynamic data structures with poly-logarithmic or better time per operation [22, 7, 16, 12, 10], the current fastest dynamic range mode data structure prior to this paper requires a stubborn $O(n^{2/3})$ time per operation [9]. Indeed, range mode is one of few remaining classical range queries to which our currently known algorithms may be far from optimal. As originally stated by Brodal et al. [4] and mentioned by Chan et al. [6] in 2011 and 2014, respectively, "The problem of finding the most frequent element within a given array range is still rather open."

The current best conditional lower bound, by Chan et al. [6], reduces multiplication of two $\sqrt{n} \times \sqrt{n}$ boolean matrices to n range mode queries on a fixed array of size $O(n)$. This indicates that if the current algorithm for boolean matrix multiplication is optimal, then answering n range mode queries on an array of size $O(n)$ cannot be performed in time better than $O(n^{3/2-\epsilon})$ time for $\epsilon > 0$ with combinatorial techniques, or $O(n^{\omega/2-\epsilon})$ time for $\epsilon > 0$ in general, where $\omega < 2.373$ [25, 13] is the square matrix multiplication exponent. This reduction can be strengthened for dynamic range mode by reducing from the online

matrix-vector multiplication problem [17]. Using $O(n)$ dynamic range mode operations on a sequence of length $O(n)$, we can multiply a $\sqrt{n} \times \sqrt{n}$ boolean matrix with $\sqrt{n}$ boolean vectors given one at a time. This indicates that a dynamic range mode data structure taking $O(n^{1/2-\epsilon})$ time per operation for $\epsilon > 0$ is not possible with current knowledge.

Previous attempts indicate the higher $O(n^{2/3})$ per operation cost as the bound to beat [6, 9]. Indeed, $\tilde{O}(n^{2/3})$ time per operation[1] can be achieved with a variety of techniques, but crossing the $O(n^{2/3})$ barrier appears much harder.

Progress towards this goal has been established with the recent work of Williams and Xu [26]. They show that by appealing to Min-Plus product of structured matrices, n range mode queries on an array of size n can be answered in $\tilde{O}(n^{1.4854})$ time, thus beating the combinatorial lower bound for batch range mode. This result also shows a separation between batch range mode and dynamic range mode: while batch range mode can be completed in $O(n^{1/2-\epsilon})$ time per operation, such a result for dynamic range mode would imply a breakthrough in the online matrix-vector multiplication problem.

Range mode is not the first problem shown to be closely related to the Min-Plus product problem. It is well-known that the all-pairs shortest paths (APSP) problem is asymptotically equivalent to Min-Plus product [11], in the sense that a $T(n)$ time algorithm to compute the Min-Plus product of two $n \times n$ matrices implies an $O(T(n))$ time algorithm for APSP in n-node graphs and vice versa. Although it is not known how to perform Min-Plus product of two arbitrary $n \times n$ matrices in time $O(n^{3-\epsilon})$ for $\epsilon > 0$, several problems reduce to Min-Plus products of matrices A and B which have nice structures that can be exploited. The simplest examples result by restricting edge weights in APSP problems [23, 24, 28, 5, 27]. Bringmann et al. [3] show Language Edit Distance, RNA-folding, and Optimum Stack Generation can be reduced to Min-Plus product where matrix A has small difference between adjacent entries in each row and column. Finally, the recent work of Williams and Xu [26] reduces APSP in certain geometric graphs, batch range mode, and the maximum subarray problem with entries bounded by $O(n^{0.62})$ to a more general structured Min-Plus product, extending the result of Bringmann et al. All of the above structured Min-Plus products are solvable in truly subcubic $O(n^{3-\epsilon})$ time for $\epsilon > 0$, improving algorithms in the problems reduced to said product.

The connection and upper bound established by Williams and Xu [26] of batch range mode to Min-Plus product suggest other versions of the range mode problem may be amenable to similar improvements. In particular, the ability to efficiently compute a batch of range mode queries via reducing to a structured Min-Plus product suggests that one might be able to improve the update time of dynamic range mode in a similar way.

1.1 Our Results

In this paper, we break the $O(n^{2/3})$ time per operation barrier for dynamic range mode. We do so by adapting the result of Williams and Xu [26]. Specifically, we define the following new type of data structure problem on the Min-Plus product that can be applied to dynamic range mode, which may be of independent interest. Then we combine this data structure problem with the algorithm of Williams and Xu.

▶ **Problem 1** (*Min-Plus-Query* problem)**.** *During initialization, we are given two matrices A, B. For each query, we are given three parameters i, j, S, where i, j are two integers, and S is a set of integers. The query asks* $\min_{k \notin S}\{A_{i,k} + B_{k,j}\}$.

[1] We use the $\tilde{O}(\cdot)$ notation to hide poly-logarithmic factors.

Our performance theorem is the following.

▶ **Theorem 2.** *There exists a deterministic data structure for dynamic range mode on a sequence $a_1, \ldots, a_n$ that supports query, insertion, and deletion in worst-case $\tilde{O}(N^{0.655994})$ time per operation, where N is the maximum size of the sequence at any point in time. The space complexity of the data structure is $\tilde{O}(N^{1.327997})$.*

Our result shows yet another application of the Min-Plus product to an independently-studied problem, ultimately showing a dependence of the complexity of dynamic range mode on the complexity of fast matrix multiplication. Further, in contrast to many other reductions to Min-Plus in which we must assume a structured input on the original problem [23, 24, 28, 5, 27, 26], our algorithm works on the fully general dynamic range mode problem. In this sense, our result is perhaps most directly comparable to the batch range mode reduction of Williams and Xu [26] and the Language Edit Distance, RNA-folding, and Optimum Stack Generation reductions of Bringmann et al. [3].

1.2 Discussion of Technical Difficulty

Despite the new $\tilde{O}(n^{1.4854})$ time algorithm for batch range mode [26], we cannot directly apply the result to dynamic range mode. The main issue is the element deletion operation. In the range mode algorithm of Williams and Xu (and in many other range mode algorithms), critical points are chosen evenly distributed in the array, and the algorithm precomputes the range mode of intervals between every pair of critical points. In [26], the improvement is achieved via a faster precomputation algorithm, which uses a Min-Plus product algorithm for structured matrices. However, if element deletion is allowed, the results stored in the precomputation will not be applicable. For example, an interval between two critical points could contain x copies of element a, $x-1$ copies of element b, and many other elements with frequencies less than $x-1$. During precomputation, the range mode of this interval would be a. However, if we delete two copies of a, there is no easy way to determine that the mode of this interval has now changed to b.

We overcome this difficulty by introducing the Min-Plus-Query problem, as defined in Section 1.1. Intuitively, in the Min-Plus-Query problem, a large portion of the work of the Min-Plus product is put off until the query. It also supports more flexible queries. Using the Min-Plus-Query problem as a subroutine, we will be able to query the most frequent element excluding a set S of forbidden elements. For instance, in the preceding example, we would be able to query the most frequent element that is not a. This is the main technical contribution of the paper.

Another major difference between our algorithm for dynamic range mode and the batch range mode algorithm of Williams and Xu [26] is the need for rectangular matrix multiplication. In our algorithm, we treat elements that appear more than about $N^{2/3}$ times differently from the rest (a similar treatment is given in the dynamic range mode algorithm of Hicham et al. [9]). However, the number of critical points we use is about $N^{1/3}$; thus the number of critical points and frequent elements differ. This contrasts with batch range mode, where elements that appear more than about $\sqrt{n}$ times are considered frequent and the number of critical points used coincides with the number of frequent elements. The consequence of this difference is that a rectangular matrix product is required for dynamic range mode, while a square matrix product sufficed in [26].

2 Related Work

The range mode problem was first studied formally by Krizanc et al. [18]. They study space-efficient data structures for static range mode, achieving a time-space tradeoff of $O(n^{2-2\epsilon})$ space and $O(n^\epsilon \log n)$ query time for any $0 < \epsilon \leq 1/2$. They also give a solution occupying $O(n^2 \log\log n / \log n)$ space with $O(1)$ time per query.

Chan et al. [6] also study static range mode, focusing on linear space solutions. They achieve a linear space data structure supporting queries in $O(\sqrt{n})$ time via clever use of arrays, which can be improved to $O(\sqrt{n/\log n})$ time via bit-packing tricks. Their paper also introduces the conditional lower bound which reduces multiplication of two $\sqrt{n} \times \sqrt{n}$ boolean matrices to n range mode queries on an array of size $O(n)$. As mentioned, combined with the presumed hardness of the online matrix vector problem [17], this result indicates a dynamic range mode data structure must take greater than $O(n^{1/2-\epsilon})$ for $\epsilon > 0$ time per operation. Finally, Chan et al. [6] also give the first data structure for dynamic range mode. At linear space, their solution achieves $O(n^{3/4} \log n / \log\log n)$ worst-case time per query and $O(n^{3/4} \log\log n)$ amortized expected time update, and at $O(n^{4/3})$ space, their solution achieves $O(n^{2/3} \log n / \log\log n)$ worst-case time query and amortized expected update time.

Recently, Hicham et al. [9] improved the runtime of dynamic range mode to worst-case $O(n^{2/3})$ time per operation while simultaneously improving the space usage to linear. Prior to this paper, this result was the fastest data structure for dynamic range mode.

A cell-probe lower bound for static range mode has been devised by Greve et al. [15]. Their result states that any range mode data structure that uses S memory cells of w-bit words needs $\Omega(\frac{\log n}{\log(Sw/n)})$ time to answer a query.

Via reduction to a structured Min-Plus product, Williams and Xu [26] recently showed that n range mode queries on a fixed array of size n can be answered in $\tilde{O}(n^{1.4854})$ time. Williams and Xu actually show how to compute the *frequency* of the mode for each query. We can adapt this method to find the element that is mode using the following binary search. For query $[l, r]$, we ask the frequency of the mode in range $[l, (l + r)/2]$. If it is the same, we repeat the search with right endpoint in range $[(l + r)/2, r]$; if it is not, we repeat the search with right endpoint in range $[l, (l + r)/2]$. Using this method, we can binary search until we determine when the frequency of the mode changes, thus finding the element that is mode in an additional $O(\log n)$ queries. The algorithm of Williams and Xu can also be used to speed up the preprocessing time of the $O(n)$ space, $O(\sqrt{n})$ query time static range mode data structure to $\tilde{O}(n^{1.4854})$ time.

Both static and dynamic range mode have been studied in approximate settings [2, 15, 8].

3 Preliminaries

We formally define the Min-Plus product problem and the dynamic range mode problem.

▶ **Problem 3** (Min-Plus product). *The Min-Plus product of an $m \times n$ matrix A and an $n \times p$ matrix B is the $m \times p$ matrix $C = A \star B$ such that $C_{i,j} = \min_k\{A[i, k] + B[k, j]\}$.*

▶ **Problem 4** (Dynamic Range Mode). *In the dynamic range mode problem, we are given an initially empty sequence and must support the following operations:*

- *Insert an element at a given position of the sequence.*
- *Delete one element of the sequence.*
- *Query the most frequent element of any contiguous subsequence. If there are multiple answers, output any.*

It is guaranteed that the size of the array does not exceed N at any point in time.

We use ω to denote the square matrix multiplication exponent, i.e. the smallest real number such that two $n \times n$ matrices can be multiplied in $n^{\omega+o(1)}$ time. The current bound on ω is $2 \leq \omega < 2.373$ [13, 25]. In this work, we will use fast rectangular matrix multiplication. Analogous to the square case, we use $\omega(k)$ to denote the exponent of rectangular matrix multiplication, i.e., the smallest real number such that an $n \times n^k$ matrix and an $n^k \times n$ matrix can be multiplied in $n^{\omega(k)+o(1)}$ time. Le Gall and Urrutia [14] computed smallest upper bounds to date for various values of k. In this work, we are mostly interested in values of $\omega(k)$ listed in Figure 1.

k	Upper Bound on $\omega(k)$
1.75	3.021591
2	3.251640

Figure 1 Upper bounds for the exponent of multiplying an $n \times n^k$ matrix and an $n^k \times n$ matrix [14].

It is known that the function $\omega(k)$ is convex for $k > 0$ (see e.g. [19], [20]), so we can use values of $\omega(p)$ and $\omega(q)$ to give upper bounds for $\omega(k)$ as long as $p \leq k \leq q$.

▶ **Fact 5.** *When $0 < p \leq k \leq q$, $\omega(k) \leq \frac{k-p}{q-p}\omega(q) + \frac{q-k}{q-p}\omega(p)$.*

Combining Figure 1 and Fact 5, we obtain the following bound on $\omega(k)$ when $k \in [1.75, 2]$.

▶ **Corollary 6.** *When $1.75 \leq k \leq 2$, $\omega(k) \leq 0.920196k + 1.41125$.*

4 Main Algorithm

A main technical component for our dynamic range mode algorithm is the use of the *Min-Plus-Query* problem, which is formally defined in Section 1. We are given two matrices A, B. For each query, we are given three parameters i, j, S, and we need to compute $\min_{k \notin S}\{A_{i,k} + B_{k,j}\}$.

If we just use the Min-Plus-Query problem, we can only compute the frequency of the range mode. Although we can binary search for the most frequent element as described in Section 2, we are also able to return the witness from the Min-Plus-Query problem organically. This construction may be of independent interest.

▶ **Problem 7** (*Min-Plus-Query-Witness* **problem**)**.** *During initialization, we are given two matrices A, B. For each query, we are given three parameters i, j, S, where i, j are two integers, and S is a set of integers. We must output an index $k^* \notin S$ such that $A_{i,k^*} + B_{k^*,j} = \min_{k \notin S}\{A_{i,k} + B_{k,j}\}$.*

If A is an $n \times n^s$ matrix and B is an $n^s \times n$ matrix, then the naive algorithm for Min-Plus-Query just enumerates all possible indices k for each query, which takes $O(n^s)$ time per query. In order to get a faster algorithm for dynamic range mode, we need to achieve $\tilde{O}(n^{2+s-\epsilon})$ preprocessing time and $\tilde{O}(n^{s-\epsilon} + |S|)$ query time, for some $\epsilon > 0$, where A, B are some special matrices generated by the range mode instance. Specifically, matrix B meets the following two properties:

1. Each row of B is non-increasing;
2. The difference between the sum of elements in the j-th column and the sum of elements in the $(j+1)$-th column is at most n^s, for any j.

Williams and Xu [26] give a faster algorithm for multiplying an arbitrary matrix A with such matrix B, which leads to a faster algorithm for static range mode. We will show that nontrivial data structures exist for the Min-Plus-Query problem for such input matrices A and B. Such a data structure will lead to a faster algorithm for dynamic range mode.

In the following lemma, we show a data structure for the Min-Plus-Query problem when both input matrices have integer weights small in absolute value.

▶ **Lemma 8.** *Let $s \geq 1$ be a constant. Let A and B be two integer matrices of dimension $n \times n^s$ and $n^s \times n$, respectively, with entries in $\{-W, \ldots, W\} \cup \{\infty\}$ for some $W \geq 1$. Then we can solve the Min-Plus-Query problem of A and B in $\tilde{O}(Wn^{\omega(s)})$ preprocessing time and $\tilde{O}(|S|)$ query time. The space complexity is $\tilde{O}(Wn^2 + n^{1+s})$.*

Proof. The algorithm uses the idea by Alon, Galil and Margalit in [1], which computes the Min-Plus product of A, B in $\tilde{O}(Wn^{\omega(s)})$ time.

In their algorithm, they first construct matrix A' defined by

$$A'_{i,k} = \begin{cases} (n^s+1)^{A_{i,k}+W} & \text{if } A_{i,k} \neq \infty, \\ 0 & \text{otherwise.} \end{cases}$$

We can define B' similarly. Then the product $A'B'$ captures some useful information about the Min-Plus product of A and B. Namely, for each entry $(A'B')_{i,j}$, we can uniquely write it as $\sum_{t \geq 0} r_t^{i,j}(n^s+1)^t$ for integers $0 \leq r_t^{i,j} \leq n^s$. Note that $r_t^{i,j}$ exactly equals the number of k such that $A_{i,k} + B_{k,j} = t - 2W$. Thus, we can use $A'B'$ to compute the Min-Plus Product of A and B.

In our algorithm, we use a range tree to maintain the sequence $r_t^{i,j}$ for each pair of i, j. The preprocessing takes $\tilde{O}(Wn^{\omega(s)})$ time, which is the time to compute $A'B'$ and the sequences $r_t^{i,j}$.

During each query, we are given i, j, S. We enumerate each $k \in S$, and decrement $r^{i,j}_{A_{i,k}+B_{k,j}+2W}$ in the range tree if $A_{i,j} + B_{k,j} < \infty$. After we do this for every $k \in S$, we query the range tree for the smallest t such that $r_t^{i,j} \neq 0$, so $t - 2W$ is the answer to the Min-Plus-Query query. After each query, we need to restore the values of $r^{i,j}$, which can also be done efficiently. The query time is $\tilde{O}(|S|)$, since each update and each query of range tree takes $\tilde{O}(1)$ time. The space complexity should be clear from the algorithm. ◀

In the previous lemma, the data structure only answers the Min-Plus-Query problem. In all subsequent lemmas, the data structure will be able to handle the Min-Plus-Query-Witness problem.

In the next lemma, we use Lemma 8 as a subroutine to show a data structure for the Min-Plus-Query-Witness problem when only matrix A has small integer weights in absolute value.

▶ **Lemma 9.** *Let $s \geq 1$ be a constant. Let A and B be two integer matrices of dimension $n \times n^s$ and $n^s \times n$, respectively, where A has entries in $\{-W, \ldots, W\} \cup \{\infty\}$ for some $W \geq 1$, and B has arbitrary integer entries represented by* polylog n *bit numbers. Then for every integer $1 \leq P \leq n^s$, we can solve the Min-Plus-Query-Witness problem of A and B in $O(\frac{n^s}{P}Wn^{\omega(s)})$ preprocessing time and $O(|S| + P)$ query time. The space complexity is $\tilde{O}(\frac{Wn^{2+s}}{P} + \frac{n^{1+2s}}{P})$.*

Proof. For simplicity, assume P is a factor of n^s. We sort each column of matrix B and put entries whose rank is between $(\ell - 1)P + 1$ and ℓP into the ℓ-th bucket. We use $K_{j,\ell}$ to denote the set of row indices of entries in the ℓ-th bucket of the column j. We use $L_{j,\ell}$ to denote the smallest entry value of the bucket $K_{j,\ell}$, and use $H_{j,\ell}$ to denote the largest entry value. Formally,

$$L_{j,\ell} = \min_{k \in K_{j,\ell}} B_{k,j} \quad \text{and} \quad H_{j,\ell} = \max_{k \in K_{j,\ell}} B_{k,j}.$$

For each $\ell \in [n^s/P]$, we do the following[2]. We create an $n^s \times n$ matrix B^ℓ and initialize all its entries to ∞. Then for each column j, if $H_{j,\ell} - L_{j,\ell} \leq 2W$ (we will call it a small bucket), we set $B^\ell_{k,j} := B_{k,j} - L_{j,\ell} - W$ for all $k \in K_{j,\ell}$. We will handle the case $H_{j,\ell} - L_{j,\ell} > 2W$ (large bucket) later. Clearly, all entries in B^ℓ have values in $\{-W, \dots, W\} \cup \{\infty\}$, so we can use the algorithm in Lemma 8 to preprocess A and B^ℓ and store the data structure in D^ℓ. Also, for each pair (i,j), we create a range tree $\mathcal{T}^{i,j}_{\text{small}}$ on the sequence $(A \star B^1)_{i,j}, (A \star B^2)_{i,j}, (A \star B^3)_{i,j}, \dots, (A \star B^{n^s/P})_{i,j}$, which stores the optimal Min-Plus values when k is from a specific small bucket. This part takes $\tilde{O}(\frac{n^s}{P} W n^{\omega(s)})$ time. The space complexity is $\frac{n^s}{P}$ times more than the space complexity of Lemma 8, so space complexity of this part is $\tilde{O}(\frac{Wn^{2+s}}{P} + \frac{n^{1+2s}}{P})$.

We also do the following preprocessing for buckets where $H_{j,\ell} - L_{j,\ell} > 2W$. We first create a 0/1 matrix $\bar{A}$ where $\bar{A}_{i,k} = 1$ if and only if $A_{i,k} \neq \infty$. Then for each $\ell \in [n^s/P]$, we create a 0/1 matrix $\bar{B}^\ell$ such that $\bar{B}^\ell_{k,j} = 1$ if and only if $k \in K_{j,\ell}$ and $H_{j,\ell} - L_{j,\ell} > 2W$. Then we use fast matrix multiplication to compute the product $\bar{A}\bar{B}^\ell$. If $K_{j,\ell}$ is a large bucket, the (i,j)-th entry of $\bar{A}\bar{B}^\ell$ is the number of $k \in K_{j,\ell}$ such that $A_{i,k} < \infty$; if $K_{j,\ell}$ is a small bucket, the (i,j)-th entry is 0. For each pair (i,j), we create a range tree $\mathcal{T}^{i,j}_{\text{large}}$ on the sequence $(\bar{A}\bar{B}^1)_{i,j}, (\bar{A}\bar{B}^2)_{i,j}, (\bar{A}\bar{B}^3)_{i,j}, \dots, (\bar{A}\bar{B}^{n^s/P})_{i,j}$. This part takes $\tilde{O}(\frac{n^s}{P} n^{\omega(s)})$ time, which is dominated by the time for small buckets. The space complexity is also dominated by the data structures for small buckets.

Now we describe how to handle a query (i,j,S). First consider small buckets. In $O(|S|)$ time, we can compute the set of small buckets $K_{j,\ell}$ that intersect with S. For each such $K_{j,\ell}$, we can query the data structure D^ℓ with input $(i, j, S \cap K_{j,\ell})$ to get the optimum value when $k \in K_{j,\ell}$. For each small bucket that intersects with S, we can set its corresponding value in the range tree $\mathcal{T}^{i,j}_{\text{small}}$ to ∞, then we can compute the optimum value of all small buckets that do not intersect with S by querying the minimum value of the range tree $\mathcal{T}^{i,j}_{\text{small}}$. After this query, we need to restore all values in the range tree. It takes $\tilde{O}(|S|)$ time to handle small buckets on query.

Now consider large buckets. Intuitively, we want to enumerate indices in all large buckets $K_{j,\ell}$ such that there exists an index $k \in K_{j,\ell} \cap ([n^s] \setminus S)$ where $A_{i,k} < \infty$. However, doing so would be prohibitively expensive. We will show that we only need two such buckets. Consider three large buckets $l_1 < l_2 < l_3$. Pick any $k_1 \in T_{j,l_1}, k_3 \in T_{j,l_3}$ such that $A_{i,k_1} < \infty$. Since

$$A_{i,k_1} + B_{k_1,j} \leq W + L_{j,l_2} < W + H_{j,l_2} - 2W < A_{i,k_3} + B_{k_3,j},$$

k_3 can never be the optimum. Thus, it suffices to find the smallest two buckets such that there exists an index $k \in K_{j,\ell} \cap ([n^s] \setminus S)$ where $A_{i,k} < \infty$, and then enumerate all indices in these two buckets. To find such two buckets, we can enumerate over all indices $k \in S$, and if $A_{i,k} < \infty$ we can decrement the corresponding value in the range tree $\mathcal{T}^{i,j}_{\text{large}}$. Thus, we can compute the two smallest buckets by querying the two earliest nonzero values in the range tree. We also need to restore the range tree after the query. The range tree part takes $\tilde{O}(|S|)$ time and scanning the two large buckets requires $O(P)$ time. Thus, this step takes $\tilde{O}(|S| + P)$ time.

At this point, we will know the bucket that contains the optimum index k^*. Thus, we can iterate all indices in this bucket to actually get the witness for the Min-Plus-Query-Witness query. It takes $O(P)$ time to do so.

In summary, the preprocessing time, query time, and space complexity meet the promise in the lemma statement. ◀

[2] We use $[n]$, with n integer, to denote the set $\{1, 2, \dots, n\}$.

In the following lemma, we show a data structure for the Min-Plus-Query-Witness problem when the matrix B has the *bounded difference* property, which means that nearby entries in each row have close values. The proof adapts the strategy of [26].

▶ **Lemma 10.** *Let $s \geq 1$ be a constant. Let A be an $n \times n^s$ integer matrix, and let B be an $n^s \times n$ integer matrix. It is guaranteed that there exists $1 \leq \Delta \leq \min\{n, W\}$, such that for every k, $|B_{k,j_1} - B_{k,j_2}| \leq W$ as long as $\lceil j_1/\Delta \rceil = \lceil j_2/\Delta \rceil$. Then for every $L = \Omega(\Delta)$, we can solve the Min-Plus-Query-Witness problem of A and B in $\tilde{O}(\Delta^2 \frac{n^s}{L} W n^{\omega(s)} + \frac{n^{2+s}}{\Delta})$ preprocessing time and $\tilde{O}(L)$ query time, when $|S| < L$. The space complexity is $\tilde{O}(\frac{\Delta^2 W n^{2+s}}{L} + \frac{\Delta^2 n^{1+2s}}{L} + \frac{n^{2+s}}{\Delta})$.*

Proof. Preprocessing Step 1: Create an Estimation Matrix

First, we create a matrix $\hat{B}$, where $\hat{B}_{k,j} = B_{k,\lceil j/\Delta \rceil \Delta}$. By the property of matrix B, $|\hat{B}_{k,j} - B_{k,j}| \leq W$ for every k, j. For each pair (i,j), we compute the L-th smallest value of $A_{i,k} + \hat{B}_{k,j}$ among all $1 \leq k \leq n^s$, and denote this value by $\hat{C}^L_{i,j}$. Notice that $\hat{C}^L_{i,j} = \hat{C}^L_{i,\lceil j/\Delta \rceil \Delta}$, so it suffices to compute $\hat{C}^L_{i,j}$ when j is a multiple of Δ, and we can infer other values correctly. It takes $O(n^s)$ time to compute each $\hat{C}^L_{i,j}$, so this step takes $O(n^{2+s}/\Delta)$ time.

If we similarly define $C^L_{i,j}$ as the L-th smallest value of $A_{i,k} + B_{k,j}$ among all $1 \leq k \leq n^s$, then $|C^L_{i,j} - \hat{C}^L_{i,j}| \leq W$ by the following claim, whose proof is omitted for space constraint.

▷ Claim. Given two sequences $(a_k)_{k=1}^m$ and $(b_k)_{k=1}^m$ such that $|a_k - b_k| \leq W$, then the L-th smallest element of a and the the L-th smallest element of b differ by at most W.

Also, in $\tilde{O}(n^{2+s}/\Delta)$ time, we can compute a sorted list $\mathcal{L}^{i,j}_{\text{small}}$ of indices k sorted by the value $A_{i,k} + \hat{B}_{k,j} - \hat{C}^L_{k,j}$, for every i, and every j that is a multiple of Δ.

The space complexity in this step is not dominating.

Preprocessing Step 2: Perform Calls to Lemma 9

For some integer $\rho \geq 1$, we will perform ρ rounds of the following algorithm. At the r-th round for some $1 \leq r \leq \rho$, we randomly sample $j^r \in [n]$, and let $A^r_{i,k} := A_{i,k} + B_{k,j^r} - \hat{C}^L_{i,j^r}$ and $B^r_{k,j} := B_{k,j} - B_{k,j^r}$. Clearly, $A^r_{i,k} + B^r_{k,j} = A_{i,k} + B_{k,j} - \hat{C}^L_{i,j^r}$. For each pair (i,k), we find the smallest r such that $|A^r_{i,k}| \leq 3W$. We keep these entries as they are and replace all other entries by ∞. For every (i,k), there exists at most one r such that $A^r_{i,k} \neq \infty$. Then we use Lemma 9 to preprocess A^r and B^r for every $1 \leq r \leq \rho$. Thus, this part takes $O(\rho \frac{n^s}{P} W n^{\omega(s)})$ time, for some integer P to be determined later. Note that this parameter also affects the query time. This step stores ρ copies of the data structure from Lemma 9, so the space complexity is $\tilde{O}(\rho \frac{W n^{2+s}}{P} + \rho \frac{n^{1+2s}}{P})$.

Note that this step is the only step that uses randomization. We can use the method of [26], Appendix A, to derandomize it. We omit the details for simplicity.

Preprocessing Step 3: Handling Uncovered Pairs

For a pair (i,k), if $A^r_{i,k} \neq \infty$ for any r, we call (i,k) *covered*; otherwise, we call the pair (i,k) *uncovered.* For each pair (i,j), we enumerate all k such that $|A_{i,k} + \hat{B}_{k,j} - \hat{C}^L_{i,j}| \leq 2W$ and (i,k) is uncovered. Notice that since $A_{i,k} + \hat{B}_{k,j} - \hat{C}^L_{i,j} = A_{i,k} + \hat{B}_{k,\lceil j/\Delta \rceil \Delta} - \hat{C}^L_{i,\lceil j/\Delta \rceil \Delta}$, we only need to exhaustively enumerate all $k \in [n^s]$ when j is a multiple of Δ. Thus, if the total number of (i,k,j) where $|A_{i,k} + \hat{B}_{k,j} - \hat{C}^L_{i,j}| \leq 2W$ and (i,k) is uncovered is X, then we can enumerate all such triples (i,k,j) in $O(X + n^{2+s}/\Delta)$ time.

It remains to bound the total number of triples that satisfy the condition. Fix an arbitrary pair (i,k), and suppose the number of j such that $|A_{i,k} + \hat{B}_{k,j} - \hat{C}^L_{i,j}| \leq 2W$ is at least $(10+s)n \ln n/\rho$. Then with probability at least $1 - (1 - \frac{(10+s)\ln n}{\rho})^\rho \geq 1 - \frac{1}{n^{10+s}}$, we pick a j^r where $|A_{i,k} + \hat{B}_{k,j^r} - \hat{C}^L_{i,j^r}| \leq 2W$. Therefore,

$$|A^r_{i,k}| = \left|A_{i,k} + B_{k,j^r} - \hat{C}^L_{i,j^r}\right| \le \left|A_{i,k} + \hat{B}_{k,j^r} - \hat{C}^L_{i,j^r}\right| + \left|\hat{B}_{k,j^r} - B_{k,j^r}\right| \le 3W,$$

which means (i,k) is covered. Therefore, with high probability, all pairs of (i,k) where the number of j such that $|A_{i,k} + \hat{B}_{k,j} - \hat{C}^L_{i,j}| \le 2W$ is at least $(10+s)n \ln n/\rho$ will be covered. In other words, $X = O(n^{1+s} \cdot n \ln n/\rho) = \tilde{O}(n^{2+s}/\rho)$.

For each pair (i,j), if we enumerate more than L indices k, we only keep the L values of k that give the smallest values of $A_{i,k} + B_{k,j}$. We call this list $\mathcal{L}^{i,j}_{\text{triple}}$. From previous discussion, the time cost in this step is $\tilde{O}(n^{2+s}/\rho + n^{2+s}/\Delta)$. Since we need to store all the triples, the space complexity is $O(n^{2+s}/\rho)$.

Handling Queries

Now we discuss how to handle queries. For each query (S,i,j), let $k^* = \arg\min_{k \notin S} A_{i,k} + B_{k,j}$ be the optimum index. Consider two cases:

- (i,k^*) is covered. By definition of being covered, there exists a round r such that $A^r_{i,k^*} = A_{i,k^*} + B_{k^*,j^r} - \hat{C}^L_{i,j^r}$, so $A^r_{i,k^*} + B^r_{k^*,j} = A_{i,k^*} + B_{k^*,j} - \hat{C}^L_{i,j^r}$. Therefore, we can query the data structure in Lemma 9 for every A^r and B^r and denote b^r as the result. The answer is given by the smallest value of $b^r + \hat{C}^L_{i,j^r}$ over all r. The witness is given by the data structure of Lemma 9.

  Note that when querying A^r and B^r, we only need to pass the set $\{k \in S : A^r_{i,k} \ne \infty\}$. For every $k \in S$, there is at most one r such that $A^r_{i,k} \ne \infty$, so the total size of the sets passing to the data structure of Lemma 9 is $|S|$. Thus, this case takes $O(|S| + \rho P)$ time.
- (i,k^*) is uncovered. There are still two possibilities to consider in this case.
  - **Possibility I**: $A_{i,k^*} + \hat{B}_{k^*,j} - \hat{C}^L_{i,j} < -2W$. In this case,

    $$A_{i,k^*} + B_{k^*,j} \le A_{i,k^*} + \hat{B}_{k^*,j} + W < \hat{C}^L_{i,j} - W,$$

    so the optimum value is smaller than $\hat{C}^L_{i,j}$. By reading the list $\mathcal{L}^{i,\lceil j/\Delta\rceil\Delta}_{\text{small}}$, we can effectively find all such k where $A_{i,k} + \hat{B}_{k,j} - \hat{C}^L_{i,j} < -2W$ in time linear to the number of such k. The number of such k is at most L, by the definition of $\hat{C}^L_{i,j}$. Thus, this part takes $O(L)$ time.
  - **Possibility II**: $A_{i,k^*} + \hat{B}_{k^*,j} - \hat{C}^L_{i,j} \ge -2W$. In fact, in this case, we further have

    $$A_{i,k^*} + \hat{B}_{k^*,j} - \hat{C}^L_{i,j} \le A_{i,k^*} + B_{k^*,j} - C^L_{i,j} + 2W \le 2W,$$

    where $A_{i,k^*} + B_{k^*,j} - C^L_{i,j} \le 0$ because $|S| < L$. Therefore, in this case, we have $|A_{i,k^*} + \hat{B}_{k^*,j} - \hat{C}^L_{i,j}| \le 2W$, so we can enumerate all indices in $\mathcal{L}^{i,j}_{\text{triple}}$ and take the best choice. This takes $O(L)$ time.

Time and Space Complexity

In summary, the preprocessing time is

$$\tilde{O}\left(\rho \frac{n^s}{P} W n^{\omega(s)} + n^{2+s}/\Delta + n^{2+s}/\rho\right),$$

and the query time is $\tilde{O}(L + \rho P)$. To balance the terms, we can set $\rho = \Delta$ and $P = \frac{L}{\Delta}$ to achieve a $\tilde{O}(\Delta^2 \frac{n^s}{L} W n^{\omega(s)} + \frac{n^{2+s}}{\Delta})$ preprocess time and a $\tilde{O}(L)$ query time. Note that since we need $P \ge 1$, we must have $L = \Omega(\Delta)$.

From the preprocessing steps, the space complexity is $\tilde{O}(\rho\frac{Wn^{2+s}}{P}+\rho\frac{n^{1+2s}}{P}+n^{2+s}/\rho)$. Plugging in $\rho=\Delta$ and $P=\frac{L}{\Delta}$ reduces this to

$$\tilde{O}\left(\frac{\Delta^2 W n^{2+s}}{L}+\frac{\Delta^2 n^{1+2s}}{L}+\frac{n^{2+s}}{\Delta}\right),$$

as given in the statement of the lemma. ◀

The next lemma is our last data structure for Min-Plus-Query-Witness problems.

▶ **Lemma 11.** *Let $s \geq 1$ be a constant. Let A be an $n \times n^s$ integer matrix and B be an $n^s \times n$ integer matrix. Suppose matrix B satisfies*

1. *Each row of B is non-increasing;*
2. *The difference between the sum of elements in the j-th column and the sum of elements in the $(j+1)$-th column is at most n^s, for any j.*

Then for every positive integer $L=\Omega(n^{\omega(s)-2})$, we can solve the Min-Plus-Query-Witness problem of A and B in $\tilde{O}(n^{\frac{8}{5}+s+\frac{1}{5}\omega(s)}L^{-\frac{1}{5}})$ preprocessing time and $\tilde{O}(L)$ query time, when $|S|<L$. The space complexity is $\tilde{O}(L^{-\frac{1}{5}}n^{\frac{18}{5}+s-\frac{4}{5}\omega(s)}+L^{-\frac{3}{5}}n^{\frac{9}{5}+2s-\frac{2}{5}\omega(s)}+L^{-\frac{1}{5}}n^{\frac{8}{5}+s+\frac{1}{5}\omega(s)})$.

Proof. Let $\Delta, W \geq 1$ be small polynomials in n to be fixed later. Define $I(j)$ to be the interval $[j-\Delta+1, j]$.

Let j' be any multiple of Δ. By property **2** of matrix B, $\sum_{k=1}^{n^s} B_{k,j}-\sum_{k=1}^{n^s} B_{k,j+1} \leq n^s$ for any $j \in I(j')$. Thus, we have

$$\sum_{k=1}^{n^s} B_{k,j'-\Delta+1}-\sum_{k=1}^{n^s} B_{k,j'} \leq \Delta n^s.$$

By averaging, there are at most $\Delta n^s/W$ indices $k \in [n^s]$ such that $B_{k,j'-\Delta+1}-B_{k,j'}>W$. We create a new matrix $\hat{B}$, initially the same as matrix B. For each k such that $B_{k,j'-\Delta+1}-B_{k,j'}>W$, and for each $j \in I(j')$, we set $\hat{B}_{k,j}$ as M, where M is some large enough integer. After this replacement, $\hat{B}_{k,j'-\Delta+1}-\hat{B}_{k,j'} \leq W$ for any k and any j' multiple of Δ. Also, since $\hat{B}_{k,j'-\Delta+1} \geq \hat{B}_{k,j} \geq \hat{B}_{k,j'}$ for any $j \in I(j')$, we have that $|\hat{B}_{k,j_1}-\hat{B}_{k,j_2}| \leq W$ as long as $\lceil j_1/\Delta\rceil=\lceil j_2/\Delta\rceil$. Therefore, we can use Lemma 10 to preprocess A and $\hat{B}$ in $O(\Delta^2\frac{n^s}{L}Wn^{\omega(s)}+\frac{n^{2+s}}{\Delta})$ time. The space complexity is $\tilde{O}(\frac{\Delta^2 W n^{2+s}}{L}+\frac{\Delta^2 n^{1+2s}}{L}+\frac{n^{2+s}}{\Delta})$.

On the other hand, note that $\hat{B}$ differs with B on at most $n^{1+s}\Delta/W$ entries, so we need to do some extra preprocessing to handle those entries. For each pair (i,j), we initialize a range tree $\mathcal{T}^{(i,j)}$ whose elements are all ∞ (it takes $\tilde{O}(1)$ time to initialize each range tree if we implement it carefully). Then for every k such that $B_{k,j} \neq \hat{B}_{k,j}$, we set the k-th element in $\mathcal{T}^{(i,j)}$ as $A_{i,k}+B_{k,j}$. The total number of operations we perform in all the range trees are $O(n^{2+s}\Delta/W)$, so this part takes $\tilde{O}(n^{2+s}\Delta/W)$ time. The space complexity is also $\tilde{O}(n^{2+s}\Delta/W)$.

During a query (S,i,j), we first query the data structure in Lemma 10 on matrix A and $\hat{B}$ with parameters (S,i,j). Then we query the minimum value from the range tree $\mathcal{T}^{(i,j)}$ after setting all $A_{i,k}+B_{k,j}$ as ∞ for $k \in S$. Taking the minimum of these two queries gives the answer. The optimum index k^* is either given by the data structure of Lemma 10 or can be obtained from the range tree.

Thus, the preprocessing time of the algorithm is

$$\tilde{O}(\Delta^2\frac{n^s}{L}Wn^{\omega(s)}+\frac{n^{2+s}}{\Delta}+n^{2+s}\Delta/W),$$

and the query time is $\tilde{O}(L)$. We get the desired preprocessing time by setting $\Delta = L^{1/5}n^{\frac{2}{5}-\frac{1}{5}\omega(s)}$ and $W = \Delta^2$. Since we need $\Delta \geq 1$, we require that $L = \Omega(n^{\omega(s)-2})$. In Lemma 10, we also requires that $L = \Omega(\Delta)$, but this is always true when $L = \Omega(n^{\omega(s)-2})$.

By previous discussion, the space complexity is $\tilde{O}(\frac{\Delta^2 W n^{2+s}}{L} + \frac{\Delta^2 n^{1+2s}}{L} + \frac{n^{2+s}}{\Delta} + n^{2+s}\Delta/W)$. Plugging in the value for Δ and W simplifies the complexity to

$$\tilde{O}(L^{-1/5}n^{18/5+s-4\omega(s)/5} + L^{-3/5}n^{9/5+2s-2\omega(s)/5} + L^{-1/5}n^{8/5+s+\omega(s)/5}). \qquad ◀$$

Finally, we can apply the data structure of Lemma 11 to prove Theorem 2.

Proof of Theorem 2. For clarity, we will use *element* to refer to a specific item a_i of the sequence and use *value* to refer to all elements of a given type. Given a pointer to an element of the sequence a_i, we assume the ability to look up its index i in the sequence in $\tilde{O}(1)$ time by storing all elements of the sequence in a balanced binary search tree with worst-case time guarantees (e.g. a red-black tree). Thus we can go from index i to element a_i and back via appropriate rank and select queries on the balanced binary search tree. We may also add or remove an element a_i from the sequence, and thus the binary search tree, in $\tilde{O}(1)$ time.

Let T_1, T_2, T_3 be three parameters of the algorithm. Parameter T_1 is a threshold that controls the number of "frequent" colors, T_2 controls how frequently the data structure is rebuilt, and T_3 represents the size of blocks in the algorithm.

We call values that appear more than N/T_1 times *frequent* and all other values *infrequent*. Thus, there are at most T_1 frequent values at any point in time. Note that a fixed value can change from frequent to infrequent, or from infrequent to frequent, via a deletion or insertion.

Infrequent Values

First, we discuss how to handle infrequent values. We maintain $\frac{N}{T_1}$ balanced search trees $\mathcal{BST}_1, \ldots, \mathcal{BST}_{\frac{N}{T_1}}$. For balanced search tree $\mathcal{BST}_k$, we prepare the key/value pairs in the following way. Fix a given value of the sequence. Say all its occurrences are at indices $i_1, i_2, \ldots, i_t$. Then we insert the key/value pairs (i_x, i_{x+k-1}) to $\mathcal{BST}_k$ for every $1 \leq x \leq t-k+1$. However, the indices themselves would need updating when sequence a is updated. Instead of inserting the indices themselves, we insert corresponding pointers to the nodes of the binary search tree that holds sequence a. That way we can perform all comparisons using binary search tree operations in $\tilde{O}(1)$ time, without needing to update indices when sequence a changes. We also augment each balanced search tree $\mathcal{BST}_i$ so that every subtree stores the smallest value y of any pair (x, y) in the subtree. After an insertion or deletion, we need to update a total of $O((\frac{N}{T_1})^2)$ pairs. Thus, we can maintain these balanced search trees in $\tilde{O}((\frac{N}{T_1})^2)$ time per operation.

During a query $[l, r]$, we iterate through all the balanced search trees $\mathcal{BST}_1, \ldots, \mathcal{BST}_{\frac{N}{T_1}}$. If there exists a pair $(i_1, i_2) \in \mathcal{BST}_k$ such that $l \leq i_1 \leq i_2 \leq r$, then the range mode is at least k. Thus, if the range mode is an infrequent value, we can find its frequency and corresponding value by querying the balanced search trees. The query time is $\tilde{O}(\frac{N}{T_1})$, which is not the dominating term.

Newly Modified Values

We now consider how to handle frequent values. We handle newly modified values and unmodified values differently. We will rebuild our data structure after every T_2 operations, and call values that are inserted or deleted after the last rebuild *newly modified values.*

For every value, we maintain a balanced search tree of occurrences of this value in the sequence. It takes $\tilde{O}(1)$ time per operation to maintain such balanced search trees. Thus, given an interval $[l, r]$, it takes $\tilde{O}(1)$ time to query the number of occurrences of a particular value in the interval. We use this method to query the number of occurrences of each newly modified value. Since there can be at most T_2 such values, this part takes $\tilde{O}(T_2)$ time per operation.

Data Structure Rebuild

It remains to handle the frequent, not newly modified values during each rebuild. In this case, we will assume we can split the whole array roughly equally into a left half and right half. We can recursively build the data structure on these two halves so that we may assume a range mode query interval has left endpoint in the left half and right endpoint in the right half. The recursive construction adds only a poly-logarithmic factor to the complexity.

We split the left half and the right half into consecutive segments of length at most T_3, so that there are $O(N/T_3)$ segments. We call the segments $P_1, P_2, \ldots, P_m$ in the left half and $Q_1, Q_2, \ldots, Q_m$ in the right half, where segments with a smaller index are closer to the middle of the sequence.

Let $v_1, v_2, \ldots, v_l$ be the frequent values during the rebuild. We create a matrix A such that $A_{i,k}$ equals the negation of the number of occurrences of v_k in segments $P_1, \ldots, P_i$; similarly, we create a matrix B such that $B_{k,j}$ equals the negation of the number of occurrences of v_k in segments $Q_1, \ldots, Q_j$. Note that the negation of the value $A_{i,k} + B_{k,j}$ is the frequency of value v_k in the interval from P_i to Q_j. It is not hard to verify that matrix B satisfies the requirement of Lemma 11. We take the negation here since Lemma 11 handles $(\min, +)$-product instead of $(\max, +)$-product. Then we use the preprocessing part of Lemma 11 with matrices A, B, and $L = T_2$. If we let $T_1 = N^{t_1}, T_2 = N^{t_2}, T_3 = N^{t_3}$, then in the notation of Lemma 11, $n = m = O(N/T_3) = O(N^{1-t_3})$ and $n^s = O(T_1) = O(N^{t_1})$, so $s = \frac{t_1}{1-t_3}$ and $L = N^{t_2}$. Thus, by Lemma 11 the rebuild takes

$$\tilde{O}(N^{(1-t_3)(\frac{8}{5}+\frac{t_1}{1-t_3}+\frac{1}{5}\omega(\frac{t_1}{1-t_3}))-\frac{1}{5}t_2})$$

time. Since we perform the rebuild every T_2 operations, the amortized cost of rebuild is

$$\tilde{O}(N^{(1-t_3)(\frac{8}{5}+\frac{t_1}{1-t_3}+\frac{1}{5}\omega(\frac{t_1}{1-t_3}))-\frac{6}{5}t_2})$$

per operation.

Now we discuss how to handle queries for frequent, unmodified elements. For a query interval $[l, r]$, we find all the segments inside the interval $[l, r]$. The set of such segments must have the form $P_1, \cup \cdots \cup P_i \cup Q_1 \cup \cdots \cup Q_j$ for some i, j. We scan through all elements in $[l, r] \setminus (P_1 \cup \cdots \cup P_i \cup Q_1 \cup \cdots \cup Q_j)$, and use their frequency to update the answer. Since the size of segments is $O(T_3)$, the time complexity to do so is $\tilde{O}(T_3)$.

For the segments $P_1, \ldots, P_i, Q_1, \ldots, Q_j$, we query the data structure in Lemma 11 with S being the set of newly modified elements. The answer will be the most frequent element in the interval from P_i to Q_j that is not newly modified. By Lemma 11 this takes $O(L) = O(N^{t2})$ time per operation.

Time and Space Complexity

In summary, the amortized cost per operation is

$$\tilde{O}(N^{2-2t_1} + N^{t_2} + N^{t_3} + N^{(1-t_3)(\frac{8}{5}+\frac{t_1}{1-t_3}+\frac{1}{5}\omega(\frac{t_1}{1-t_3}))-\frac{6}{5}t_2}).$$

To balance the terms, we set $t_1 = 1 - \frac{1}{2}t_2$, and $t_3 = t_2$. The time complexity thus becomes

$$\tilde{O}(N^{t_2} + N^{(1-t_2)(\frac{8}{5}+\frac{1-0.5t_2}{1-t_2}+\frac{1}{5}\omega(\frac{1-0.5t_2}{1-t_2}))-\frac{6}{5}t_2}).$$

By observation, we can note that the optimum value of $\frac{1-0.5t_2}{1-t_2}$ lies in $[1.75, 2]$. Thus, we can plug in Corollary 6 and use $t_2 = 0.655994$ to balance the two terms. This gives an $\tilde{O}(N^{0.655994})$ *amortized* time per operation algorithm.

The space usage has two potential bottlenecks. The first is the space to store $\mathcal{BST}_1, \ldots, \mathcal{BST}_{\frac{N}{T_1}}$ for handling infrequent elements, which is $\tilde{O}(\frac{N^2}{T_1})$. The second is the space used by Lemma 11, which is

$$\tilde{O}(N^{-t_2/5}N^{(1-t_3)(18/5+s-4\omega(s)/5)}+N^{-3t_2/5}N^{(1-t_3)(9/5+2s-2\omega(s)/5)}+N^{-t_2/5}N^{(1-t_3)(8/5+s+\omega(s)/5)}).$$

By plugging in the values for t_2, t_3 and s, the space complexity becomes $\tilde{O}(N^{1.327997})$, with the $\tilde{O}(\frac{N^2}{T_1})$ term being the dominating term.

Worst-Case Time Complexity

By applying the *global rebuilding* of Overmars [21], we can achieve a worst-case time bound. The basic idea is that after T_2 operations, we don't immediately rebuild the Min-Plus-Query-Witness data structure. Instead, we rebuild the data structure during the next T_2 operations, spreading the work evenly over each operation. To answer queries during these T_2 operations, we use the previous build of the Min-Plus-Query-Witness data structure. By this technique, the per-operation runtime can be made worst-case. ◀

Abstract

Let $\mathcal{G}$ be a graph class. We say that a graph G is a k-*apex* of $\mathcal{G}$ if G contains a set S of at most k vertices such that $G \setminus S$ belongs to $\mathcal{G}$. We prove that if $\mathcal{G}$ is minor-closed, then there is an algorithm that either returns a set S certifying that G is a k-apex of $\mathcal{G}$ or reports that such a set does not exist, in $2^{\mathsf{poly}(k)}n^3$ time. Here poly is a polynomial function whose degree depends on the maximum size of a minor-obstruction of $\mathcal{G}$, i.e., the minor-minimal set of graphs not belonging to $\mathcal{G}$. In the special case where $\mathcal{G}$ excludes some apex graph as a minor, we give an alternative algorithm running in $2^{\mathsf{poly}(k)}n^2$ time.

1 Introduction

Graph modification problems are fundamental in algorithmic graph theory. Typically, such a problem is determined by a graph class $\mathcal{G}$ and some prespecified set $\mathcal{M}$ of *local* modifications, and the question is, given a graph G and an integer k, whether it is possible to transform G to a graph in $\mathcal{G}$ by applying k modification operations from $\mathcal{M}$. A plethora of graph

problems can be formulated for different instantiations of $\mathcal{G}$ and $\mathcal{M}$. Applications span diverse topics such as computational biology, computer vision, machine learning, networking, and sociology [24]. As reported by Roded Sharan in [48], already in 1979, Garey and Johnson mentioned 18 different types of modification problems [25, Section A1.2]. For more on graph modification problems, see [9, 24], as well as the running survey in [13]. In this paper we focus our attention on the vertex deletion operation. We say that a graph G is a *k-apex* of a graph class $\mathcal{G}$ if there is a set $S \subseteq V(G)$ of size at most k such that the removal of S from G results in a graph in $\mathcal{G}$. In other words, we consider the following meta-problem.

Vertex Deletion to $\mathcal{G}$
Input: A graph G and a non-negative integer k.
Question: Find, if exists, a set $S \subseteq V(G)$ certifying that G is a k-apex of $\mathcal{G}$.

To illustrate the expressive power of Vertex Deletion to $\mathcal{G}$, if $\mathcal{G}$ is the class of edgeless (resp. acyclic, planar, bipartite, (proper) interval, chordal) graphs, we obtain the Vertex Cover (resp. Feedback Vertex Set, Vertex Planarization, Odd Cycle Transversal, (proper) Interval Vertex Deletion, Chordal Vertex Deletion) problem.

By the classical result of Lewis and Yannakakis [39], Vertex Deletion to $\mathcal{G}$ is NP-hard for every non-trivial graph class $\mathcal{G}$. To circumvent its intractability, we study it from the parameterized complexity point of view and we parameterize it by the number k of vertex deletions. In this setting, the most desirable behavior is the existence of an algorithm running in time $f(k) \cdot n^{\mathcal{O}(1)}$, where f is a function depending only on k. Such an algorithm is called *fixed-parameter tractable*, or FPT-algorithm for short, and a parameterized problem admitting an FPT-algorithm is said to belong to the parameterized complexity class FPT. Also, the function f is called *parametric dependence* of the corresponding FPT-algorithm, and the challenge is to design FPT-algorithms with small parametric dependencies [14, 17, 20, 42].

Unfortunately, we cannot hope for the existence of FPT-algorithms for every graph class $\mathcal{G}$. Indeed, the problem is W-hard[1] for some classes $\mathcal{G}$ that are closed under induced subgraphs [40] or, even worse, NP-hard, for $k = 0$, for every class $\mathcal{G}$ whose recognition problem is NP-hard, such as some classes closed under subgraphs or induced subgraphs (for instance 3-colorable graphs), edge contractions [11], or induced minors [18].

On the positive side, a very relevant subset of classes of graphs *does* allow for FPT-algorithms. These are classes $\mathcal{G}$ that are closed under minors[2], or *minor-closed*. To see this, we define $\mathcal{G}_k$ as the class of the k-apices of $\mathcal{G}$, i.e., the yes-instances of Vertex Deletion to $\mathcal{G}$, and observe that if $\mathcal{G}$ is minor-closed then the same holds for $\mathcal{G}_k$, for every k. This, in turn, implies that for every k, $\mathcal{G}_k$ can be characterized by a set $\mathcal{F}_k$ of minor-minimal graphs not in $\mathcal{G}_k$; we call these graphs the *obstructions* of $\mathcal{G}_k$ and we know that they are finite because of the Robertson and Seymour theorem [46]. In other words, we know that the obstruction set of $\mathcal{G}_k$ is bounded by some function of k. Then one can decide whether a graph G belongs to $\mathcal{G}_k$ by checking whether G excludes all members of the obstruction set of $\mathcal{G}_k$, and this can be checked by using the FPT-algorithm in [45] (see also [19]).

As the Robertson and Seymour theorem [46] does not construct $\mathcal{F}_k$, the aforementioned argument is not constructive, i.e., it is not able to construct the claimed FPT-algorithm. An important step towards the constructibility of such an FPT-algorithm was done by Adler et al. [2], who proved that the parametric dependence of the above FPT-algorithm is indeed a constructible function.

[1] Implying that an FPT-algorithm would result in an unexpected complexity collapse; see [17].
[2] A graph H is a *minor* of a graph G if it can be obtained from a subgraph of G by contracting edges.

The task of specifying (or even optimizing) this parametric dependence for different instantiations of $\mathcal{G}$ occupied a considerable part of research in parameterized algorithms. The most general result in this direction says that, for every t, there is some c such that if the graphs in $\mathcal{G}$ have treewidth at most t, then Vertex Deletion to $\mathcal{G}$ admits an FPT-algorithm that runs in $c^k \cdot n^{\mathcal{O}(1)}$ time [22,34]. Reducing the constant c in this running time has attracted research on particular problems such as Vertex Cover [12] (with $c = 1.2738$), Freedback Vertex Set [36] (with $c = 3.619$), Apex-Pseudoforest [10] (with $c = 3$), Pathwidth 1 Vertex Deletion (with $c = 4.65$) [15] (see also [29] for further related results). The first step towards a parameterized algorithm for Vertex Deletion to $\mathcal{G}$ for cases where $\mathcal{G}$ has unbounded treewidth was done in [41] and later in [30] for the Planarization problem, and the best parameterized dependence for this problem is $2^{\mathcal{O}(k \cdot \log k)} \cdot n$, achieved by Jansen et al. [28]. These results were later extended by Kociumaka and Marcin Pilipczuk [37], who proved that if $\mathcal{G}_g$ is the class of graphs of Euler genus at most g, then Vertex Deletion to $\mathcal{G}_g$ admits a $2^{\mathcal{O}_g(k^2 \log k)} \cdot n^{\mathcal{O}(1)}$ step[3] algorithm.

Our results. In this paper we give an explicit FPT-algorithm for Vertex Deletion to $\mathcal{G}$ for *every* minor-closed graph class $\mathcal{G}$. In particular, our main results are the following:

▶ **Theorem 1.** *If $\mathcal{G}$ is a minor-closed graph class, then Vertex Deletion to $\mathcal{G}$ admits an algorithm of time $2^{\mathsf{poly}(k)} \cdot n^3$, for some polynomial* poly *whose degree depends on $\mathcal{G}$.*

We say that a graph H is an *apex* graph if it is a 1-apex of the class of planar graphs.

▶ **Theorem 2.** *If $\mathcal{G}$ is a minor-closed graph class excluding some apex graph, then Vertex Deletion to $\mathcal{G}$ admits an algorithm of time $2^{\mathsf{poly}(k)} \cdot n^2$, for some polynomial* poly *whose degree depends on $\mathcal{G}$.*

Very recently, Fomin et al. [23] gave an FPT-algorithm of $\mathcal{O}_{s,k}(n^4)$ time for the following problem: for a fixed finite family of graphs $\mathcal{F}$, each on at most s vertices, decide whether an n-vertex input graph G contains a k-apex of the class of graphs that exclude the graphs in $\mathcal{F}$ as *topological minors*[4]. For every graph H, there is a finite set $\mathcal{H}$ of graphs such that a graph G contains H as a minor if and only if G contains a graph in $\mathcal{H}$ as a topological minor. Based on this observation, the result of Fomin et al. [23] implies that for every minor-closed graph class $\mathcal{G}$, Vertex Deletion to $\mathcal{G}$ admits an $\mathcal{O}(h(k,s) \cdot n^4)$ time FPT-algorithm,where s is the maximum size of an obstruction of $\mathcal{G}$. Notice that this implication is a solid improvement on Vertex Deletion to $\mathcal{G}$ with respect to the result of [2], where only the computability of h is proved. However, as mentioned in [23], even for fixed values of s, the dependence of h on k is humongous. Therefore, Theorem 1 can be seen as orthogonal to the result of [23].

Our techniques. We provide here just a very succinct enumeration of the techniques that we use in order to achieve Theorem 1 and Theorem 2; a more detailed description with the corresponding definitions is provided, along with the algorithms, in the next sections.

Our starting point to prove Theorem 1 is to use the standard iterative compression technique of Reed et al. [44]. This allows us to assume that we have at hand a slightly too large set $S \subseteq V(G)$ such that $G \setminus S \in \mathcal{G}$. We then run the algorithm of Lemma 11 (whose proof uses [1,3,31,43]) that either reports that we have a no-instance, or concludes that the

[3] Given a tuple $\mathbf{t} = (x_1, \ldots, x_\ell) \in \mathbb{N}^\ell$ and two functions $\chi, \psi : \mathbb{N} \to \mathbb{N}$. We write $\chi(n) = \mathcal{O}_{\mathbf{t}}(\psi(n))$ in order to denote that there exists a computable function $\phi : \mathbb{N}^\ell \to \mathbb{N}$ such that $\chi(n) = \mathcal{O}(\phi(\mathbf{t}) \cdot \psi(n))$.

[4] The definition is as minors, except that only edges incident to degree-two vertices are contracted.

treewidth of G is polynomially bounded by k, or finds a large wall R in G. In the second case, we use the main algorithmic result of Baste et al. [5] (Proposition 3) to solve the problem parameterized by treewidth, achieving the claimed running time. In the latter case, we apply Proposition 12 (whose proof uses [8, 32, 33]) to find in R a large *flat* wall W together with an apex set A. We find in W a packing of an appropriate number of pairwise disjoint large enough subwalls. Two possible scenarios may occur. If the "interior" of each of these subwalls has enough neighbors in the set apex $S \cup A$, we apply a combinatorial result (Lemma 15) that guarantees that every possible solution should intersect $S \cup A$, and we can branch on it. On the other hand, if there exists a subwall whose interior W has few neighbors in $S \cup A$, we argue that we can define from it a *flat* wall in which we can apply the irrelevant vertex technique of Robertson and Seymour [45] (Lemma 14). We stress that this flat subwall is not precisely a subwall of W but a tiny "tilt" of a subwall of W, a new concept that is necessary for our proofs. The application of the irrelevant vertex technique requires a lot of technical care. For this, we use and enhance some of the ingredients introduced by Baste et al. [5].

In order to achieve the improved running time claimed in Theorem 2, we do *not* use iterative compression. Instead, we directly invoke Lemma 11. If the treewidth is small, we proceed as above. If a large wall is found, we apply Proposition 12 and we now distinguish two cases. If a large flat wall whose flaps have bounded treewidth is found, we find an irrelevant vertex using Lemma 14. Otherwise, inspired by an idea of Marx and Schlotter [41], we exploit the fact that $\mathcal{G}$ excludes an apex graph, and we use flow techniques to either find a vertex that should belong to the solution, or to conclude that we are dealing with a no-instance.

Organization. We provide in Section 2 some definitions and preliminary results. In Section 3 we state several algorithmic and combinatorial results that will be used when finding an irrelevant vertex and when applying the branching argument discussed above. In Section 4 we present the algorithms claimed in Theorem 1 and Theorem 2. We conclude in Section 5 with some directions for further research. All the missing proofs are available in the full version of the paper [47].

2 Definitions and preliminary results

Before we explain our techniques, we give some necessary definitions. They concern fundamental tools from the Graph Minors series of Robertson and Seymour that are heavily used in our algorithms and proofs. But first, we restate the problem in a more convenient way.

2.1 Restating the problem

Let $\mathcal{F}$ be a finite non-empty collection of non-empty graphs. We use $\mathcal{F} \leq_{\mathsf{m}} G$ to denote that some graph in $\mathcal{F}$ is a minor of G.

Let $\mathcal{G}$ be a minor-closed graph class and $\mathcal{F}$ be the set of its minor-obstructions. Clearly, Vertex Deletion to $\mathcal{G}$ is the same problem as asking, given a graph G and some $k \in \mathbb{N}$, whether G contains a vertex set S of at most k vertices such that $\mathcal{F} \not\leq_{\mathsf{m}} G \setminus S$. Following the terminology of [4–7, 22, 23, 34, 35], we call this problem $\mathcal{F}$-M-Deletion. In order to prove Theorem 1, we apply the iterative compression technique (introduced in [44]; see also [14]) and we give a $2^{\mathsf{poly}(k)} \cdot n^2$ time algorithm for the following problem.

$\mathcal{F}$-M-Deletion-Compression
Input: A graph G, a $k \in \mathbb{N}$, and a set S of size $k+1$ such that $\mathcal{F} \not\leq_{\mathsf{m}} G \setminus S$.
Objective: Find, if exists, a set $S' \subseteq V(G)$ of size at most k such that $\mathcal{F} \not\leq_{\mathsf{m}} G \setminus S'$.

Some conventions. In what follows we always denote by $\mathcal{F}$ the obstruction set of the minor-closed class $\mathcal{G}$ of the instantiation of VERTEX DELETION TO $\mathcal{G}$ that we consider. Also, given a graph G, we define its *apex number* to be the smallest integer a for which G is an a-apex of the class of planar graphs. We define three constants depending on $\mathcal{F}$ that will be used throughout the paper whenever we consider such a collection $\mathcal{F}$. We define $a_{\mathcal{F}}$ as the minimum apex number of a graph in $\mathcal{F}$, we set $s_{\mathcal{F}} = \max\{|V(H)| \mid H \in \mathcal{F}\}$, and we set $\ell_{\mathcal{F}} = \max\{|E(H)| + |V(H)| \mid H \in \mathcal{F}\}$. We also agree that n is the size of the input graph G. We can always assume that G has $\mathcal{O}_{s_{\mathcal{F}}}(k \cdot n)$ edges, otherwise we can directly conclude that (G, k) is a no-instance (for this, use the fact that $\mathcal{F}$-minor free graphs are sparse [38, 50]).

We present here the main result of [5]. We will use this in order to solve $\mathcal{F}$-M-DELETION on instances of bounded treewidth.

▶ **Proposition 3.** *Let $\mathcal{F}$ be a finite collection of graphs. There exists an algorithm that given a triple (G, tw, k) where G is a graph on n vertices and of treewidth at most tw, and k is a non-negative integer, it outputs, if it exists, a vertex set S of G of size at most k such that $\mathcal{F} \not\leq_m G \setminus S$. This algorithm runs in $2^{\mathcal{O}_{s_{\mathcal{F}}}(\mathsf{tw} \log \mathsf{tw})} \cdot n$ time.*

2.2 Definitions

We give here a minimal set of definitions and concepts that are necessary to support the description of our results. Some of them are given precisely, and for some of them we just provide enough intuition.

Renditions. Let Δ be a closed disk, i.e., a set homeomorphic to the set $\{(x, y) \in \mathbb{R}^2 \mid x^2 + y^2 \leq 1\}$. Given a subset X of Δ, we denote its closure by $\bar{X}$ and its boundary by $\mathbf{bor}(X)$. A Δ-*painting* is a pair $\Gamma = (U, N)$ where N is a finite set of points of Δ, $N \subseteq U \subseteq \Delta$, $U \setminus N$ has finitely many arcwise-connected components, called *cells*, such that, for every cell c, $\bar{c}$ is a closed disk, $\mathbf{bor}(c) \cap \Delta \subseteq N$, and $|\mathbf{bor}(c) \cap N| \leq 3$. We use the notation $U(\Gamma) := U$, $N(\Gamma) := N$ and denote the set of cells of Γ by $C(\Gamma)$. Notice that, given a Δ-painting Γ, the pair $(N(\Gamma), \{c \cap N \mid c \in C(\Gamma)\})$ is a hypergraph whose hyperedges have cardinality at most three, and Γ can be seen as a plane embedding of this hypergraph in Δ. Let G be a graph, and let Ω be a cyclic permutation of a subset of $V(G)$ that we denote by $V(\Omega)$. By an Ω-*rendition* of G we mean a triple (Γ, σ, π), where (a) Γ is a Δ-painting for some closed disk Δ, (b) $\pi : N(\Gamma) \to V(G)$ is an injection, and (c) σ assigns to each cell $c \in C(\Gamma)$ a subgraph $\sigma(c)$ of G, such that

(1) $G = \bigcup_{c \in C(\Gamma)} \sigma(c)$,
(2) for distinct $c, c' \in C(\Gamma)$, $\sigma(c)$ and $\sigma(c')$ are edge-disjoint,
(3) for every cell $c \in C(\Gamma)$, $\pi(c \cap N) \subseteq V(\sigma(c))$,
(4) for every cell $c \in C(\Gamma)$, $V(\sigma(c)) \cap \bigcup_{c' \in C(\Gamma) \setminus \{c\}} V(\sigma(c')) \subseteq \pi(c \cap N)$, and
(5) $\pi(N(\Gamma) \cap \mathbf{bor}(\Delta)) = V(\Omega)$, such that the points in $N(\Gamma) \cap \mathbf{bor}(\Delta)$ appear in $\mathbf{bor}(\Delta)$ in the same ordering as their images, via π, in Ω.

We say that an Ω-rendition (Γ, σ, π) of G is *tight* if the following conditions are satisfied:

(1) For every $c \in C(\Gamma)$, the graph $\sigma(c) \setminus \pi(c \cap N)$, when non-null, is connected and the neighborhood of its vertex set in G is $\pi(c \cap N)$.
(2) For every $c \in C(\Gamma)$ there are $|c \cap N|$ vertex-disjoint paths in G from $\pi(c \cap N)$ to the set $V(\Omega)$.
(3) If there are two points x, y of N such that $e = \{\pi(x), \pi(y)\} \in E(G)$, then there is a $c \in C(\Gamma)$ such that $\sigma(c)$ is the two-vertex connected graph $(e, \{e\})$.

It is easy to see that given an Ω-rendition of a graph G where $V(\Omega)$ contains at least three vertices that are in a cycle of G, a tight Ω-rendition of G can be constructed in $\mathcal{O}(n + m)$ steps.

Walls. We avoid here the detailed definition of an r-wall. As an intuitive alternative we provide the graph G in Figure 1 where an *elementary* 7*-wall* $\hat{W}$ is the graph with red and green vertices that has as edges the vertical and horizontal segments between a red and a green vertex. The 7*-wall* W is the spanning subgraph of G that is a subdivision of $\hat{W}$ with the black vertices as subdivision vertices. The *pegs* of $\hat{W}$ are depicted by the squared vertices, while the *corners* of $\hat{W}$ are the endpoints of the highest and the lowest horizontal path of $\hat{W}$, depicted by the fat squared vertices (the corners are also pegs). Notice that a wall W can occur in several ways from the elementary wall $\hat{W}$, depending on the way the vertices in the perimeter of $\hat{W}$ are subdivided. Each of them gives a different selection (P, C) of pegs and corners of W. We insist that, for every r-wall, the number r is always odd: for this, whenever an r-wall appears with r even, we agree to round it up to the next odd $r + 1$.

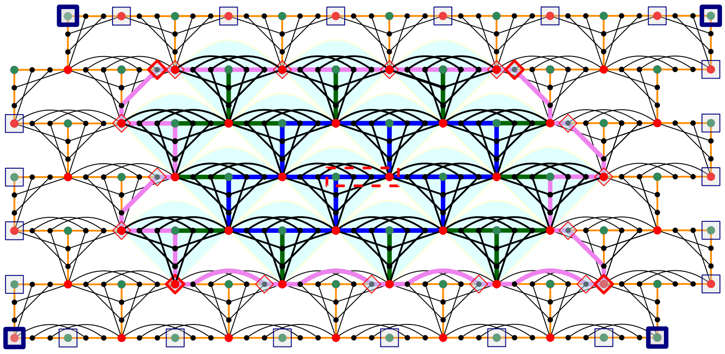

Figure 1 A graph G with a 7-wall and a flat 5-wall in it.

Flat walls. Given a graph G, we say that a pair $(L, R) \in 2^{V(G)} \times 2^{V(G)}$ is a *separation* of G if $L \cup R = V(G)$ and there is no edge in G between $L \setminus R$ and $R \setminus L$. An r-wall has a planar embedding where the boundary/ies of its external/internal face/es define its *perimeter* and its *bricks*. The *center* of the wall W is the path between a red and a green vertex depicted in the dashed red rectangle in Figure 1. Let G be a graph and let W be an r-wall of G. We say that W is a *flat* r*-wall* of G if there is a separation (X, Y) of G and a choice (P, C) of pegs and corners for W such that:

- $V(W) \subseteq Y$,
- $P \subseteq X \cap Y \subseteq V(D(W))$, and
- if Ω is the cyclic ordering of the vertices $X \cap Y$ as they appear in $D(W)$, then there exists an Ω-rendition (Γ, σ, π) of $G[Y]$.

A subwall of W is every subgraph W' of W that is located "orthocanonically" in W and the wall $W^{(r)}$ is the unique r-subwall of W with the same center as W. A subwall is called *internal* if it does not intersect the perimeter of W. In Figure 1, W contains only one internal 5-subwall $W' = W^{(5)}$ and many internal 3-subwalls, among them the wall $W''' = W^{(3)}$ (depicted in blue). Of course, the graph G in Figure 1 contains also other walls as subgraphs such as the wall W'' consisting of the purple, green, and blue edges.

Compass and flaps. Given a flat wall W of a graph G as above, we call $G[Y]$ *the compass* of W in G, denoted by $\mathsf{compass}(W)$. We call (X, Y) the *separation certifying the flat wall* W and $X \cap Y$ is called the *frontier* of W. The *ground set* of W is $\mathsf{ground}(W) := \pi(N(\Gamma))$. We clarify that $\mathsf{ground}(W)$ may consist of vertices of the compass of W that are not necessarily vertices of W (this is not the case in the simple example of Figure 1). We also call the

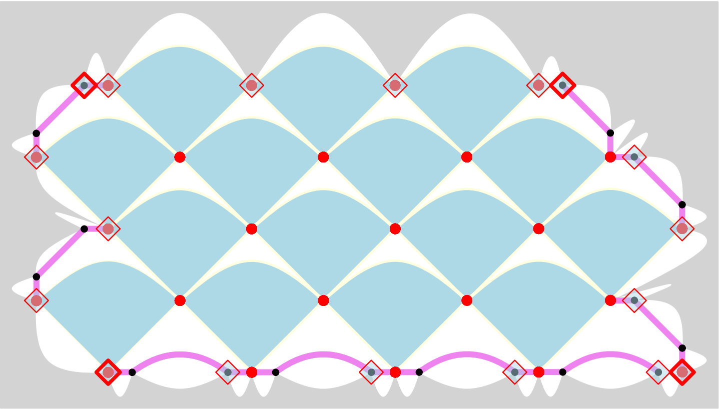

Figure 2 The rendition of the compass of the flat 5-wall W'' of Figure 1. Trivial flaps are depicted in purple.

graphs in $\mathsf{flaps}(W) := \{\sigma(c) \mid c \in C(\Gamma)\}$ *flaps* of the wall W. For each flap $F \in \mathsf{flaps}(W)$ we define its *base* as the set $\partial F := V(F) \cap \mathsf{ground}(W)$. A flap $F \in \mathsf{flaps}(W)$ is *trivial* if $|\partial F| = 2$ and it consists of one edge between the two vertices in ∂F. As an example, the wall W'' in Figure 1, formed by all the fat edges (purple, green, and blue), is a flat wall. The pegs are the diamond vertices, the corners are the fat diamond vertices, and the rendition has two types of flaps: those whose base has three vertices, that are inside the light-blue disks, and those that are trivial flaps and are the purple fat edges that are outside of the light-blue disks (see also Figure 2 for the rendition of W''). Notice that *none* of the internal subwalls of W is a flat wall.

Tilts. Given a wall W', we define its *inpegs* as the vertices of its perimeter that are incident to edges of W that are not in its perimeter. The *interior* of W' is the subgraph of W' induced by the union $V(W' \setminus V(P))$ and its inpegs. We say that a wall W'' is a *tilt* of a wall W' if W'' and W' have identical interiors. For instance, in Figure 1 the wall W'' is a tilt of $W' = W^{(5)}$.

Partially disk-embedded graphs. We say that a graph G is *partially disk-embedded in some closed disk* Δ, if there is some subgraph K of G that is embedded in Δ such that $(V(G) \cap \Delta, V(G) \setminus \mathsf{int}(\Delta))$ is a separation of G, where int is used to denote the interior of a subset of the plane. From now on, we use the term *partially* Δ*-embedded graph* G to denote that a graph G is partially disk-embedded in some closed disk Δ. We call the graph $K = G \cap \Delta$ *compass* of the Δ-embedded graph G and we assume that G is accompanied by an embedding of its compass in Δ, that is the set $G \cap \Delta$. We say that G is a Δ-embedded graph if it is partially Δ-embedded graph and $G \subseteq \Delta$ (the whole G is embedded in Δ).

Levelings. Let W be a flat wall of a graph G. Following [5], we define the *leveling* of W in G, denoted by $\tilde{W}$, as the bipartite graph where one part is the ground set of W, the other part is the set of flaps of W, and, given a pair $(v, F) \in \mathsf{ground}(W) \times \mathsf{flaps}(W)$, the set $\{v, F\}$ is an edge of $\tilde{W}$ if and only if $v \in \partial F$. Again, keep in mind that $\tilde{W}$ may contain (many) vertices that are not in W. Notice that the incidence graph of the plane hypergraph $(N(\Gamma), \{c \cap N \mid c \in C(\Gamma)\})$ is isomorphic to $\tilde{W}$ via an isomorphism that extends π and, moreover, bijectively corresponds cells to flaps. This permits us to treat $\tilde{W}$ as a Δ-embedded graph where $\mathbf{bor}(\Delta) \cap \tilde{W}$ is the frontier of W. We call the vertices of $\mathsf{ground}(W)$ (resp. $\mathsf{flaps}(W)$) *ground-vertices* (resp. *flap-vertices*) of $\tilde{W}$. See Figure 3 for an example of a leveling.

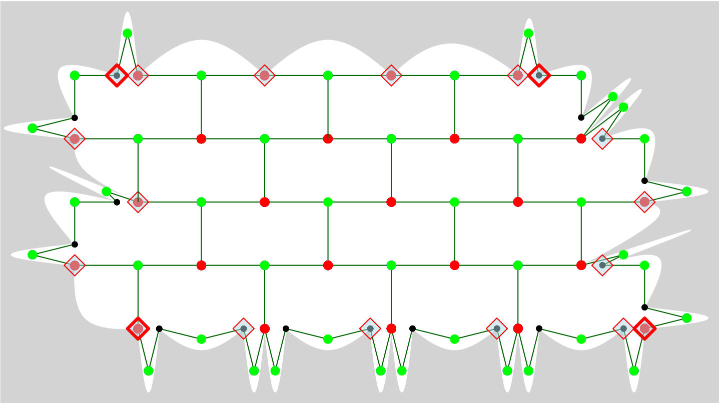

Figure 3 The leveling of the flat 5-wall W'' of Figure 1. The green vertices are the flap-vertices and the non-green vertices are the ground-vertices.

Recall that each edge e of $\mathsf{compass}(W)$ belongs to exactly one flap of W. If both of the endpoints of e are in the boundary of this flap, then this flap should be a trivial one and we say that e is a *short* edge of $\mathsf{compass}(W)$. We define the graph $W^\bullet$ as the graph obtained from W if we subdivide once every short edge in W. The next observation is a consequence of the following three facts: flap-vertices of $\tilde{W}$ have degree at most three, all the vertices of a wall have degree at most three, and every separation (A, B) of order at most three of a wall is trivial.

▶ **Observation 4.** *If W is a flat wall of a graph G, then the leveling $\tilde{W}$ of W in G contains a subgraph W^R that is isomorphic to some subdivision of $W^\bullet$ via an isomorphism that maps each ground vertex to itself.*

We call the graph W^R as in Observation 4 *representation* of the flat wall W in the Δ-embedded graph $\tilde{W}$, and therefore we can see it as a Δ-embedded subgraph of $\tilde{W}$. Notice that the above observation permits to bijectively map each cycle of W to a cycle of W^R that is also a cycle of $\tilde{W}$. That way, each cycle C of W corresponds to a cycle C of W^R denoted by C^R and we call C^R the *representation* of C in $\tilde{W}$. From now on, we reserve the superscript "^{R}"-notation to denote the correspondence between W (resp. C) and W^R (resp. C^R).

We define the function $\mathsf{flaps} : \mathcal{C}(W) \to 2^{\mathsf{flaps}(W)}$ so that, for each cycle C of W, $\mathsf{flaps}(C)$ contains each flap F of W that, when seen as a flap-vertex of the Δ-embedded graph $\tilde{W}$, belongs to the closed disk bounded by C^R. The following result is very similar to [33, Lemma 6.1]. The proof is strongly based on the notion of levelings.

▶ **Lemma 5.** *Let $a, r, r' \in \mathbb{N}$, where $r > r' \geq 3$. Also, let G be a graph, let (A, W) be an (a, r)-apex wall pair of G, and let W' be an internal r'-subwall of W. Then W' has a tilt W'' such that (A, W'') is an (a, r')-apex wall pair of G. Moreover,*

1. *the compass of W'' in $G \setminus A$ is a subgraph of the compass of W in $G \setminus A$ and*
2. *if P' is the perimeter of W', then the vertex set of the compass of W'' in $G \setminus A$ is a subset of $\bigcup \mathsf{flaps}(P')$.*

Morever, given G, (A, W), and W', the (a, r')-apex wall pair (A, W'') can be constructed in $\mathcal{O}(n)$ time.

From now on we refer to an (A, W'') as in Lemma 5 as *an* (a, r')-apex wall pair *generated by* the internal r'-subwall W' of W and we keep in mind that the compasses of all such flat walls W'' may differ *only* on their perimeter. The proof of Lemma 5 also implies the following.

▶ **Observation 6.** *Let W be a flat wall of a graph G, and W^R be the representation of W in the leveling $\tilde{W}$ of W in G. Then for every internal subwall $\bar{W}$ of W^R there exist an internal subwall W' of W and a tilt W'' of W' such that*

- *$\bar{W}$ is the representation of W' in the leveling $\tilde{W}$ of W,*
- *W'' is a flat wall, and*
- *the vertex set of the compass of W'' in G is a subset of $\bigcup \mathsf{flaps}(P')$, where P' is the perimeter of W'.*

Moreover, given G, W, and $\bar{W}$, the flat wall W'' can be constructed in $\mathcal{O}(n)$ steps.

Boundaried graphs. Let $t \in \mathbb{N}$. A *t-boundaried graph* is a triple $\mathbf{G} = (G, B, \rho)$ where G is a graph, $B \subseteq V(G)$, $|B| = t$, and $\rho : B \to [t]$ is a bijection. We say that $\mathbf{G}_1 = (G_1, B_1, \rho_1)$ and $\mathbf{G}_2 = (G_2, B_2, \rho_2)$ are *isomorphic* if there is an isomorphism from G_1 to G_2 that extends the bijection $\rho_2^{-1} \circ \rho_1$. The triple (G, B, ρ) is a *boundaried graph* if it is a t-boundaried graph for some $t \in \mathbb{N}$. As in [45], we define the *detail* of a boundaried graph $\mathbf{G} = (G, B, \rho)$ as $\mathsf{detail}(\mathbf{G}) := \max\{|E(G)|, |V(G) \setminus B|\}$. We denote by $\mathcal{B}^{(t)}$ the set of all (pairwise non-isomorphic) t-boundaried graphs. We also set $\mathcal{B} = \bigcup_{t \in \mathbb{N}} \mathcal{B}^{(t)}$.

Folios. We say that a t-boundaried graph $\mathbf{G}_1 = (G_1, B_1, \rho_1)$ is a *minor* of a t-boundaried graph $\mathbf{G}_2 = (G_2, B_2, \rho_2)$, denoted by $\mathbf{G}_1 \preceq_{\mathsf{m}} \mathbf{G}_2$, if there is a sequence of removals of non-boundary vertices, edge removals, and edge contractions in G_2, disallowing contractions of edges with both endpoints in B_2, that transforms $\mathbf{G}_2$ to a boundaried graph that is isomorphic to $\mathbf{G}_1$ (during edge contractions, boundary vertices prevail). Note that this extends the usual definition of minors in graphs without boundary.

We say that (M, T) is a *tm-pair* if M is a graph, $T \subseteq V(M)$, and all vertices in $V(M) \setminus T$ have degree two. We denote by $\mathsf{diss}(M, T)$ the graph obtained from M by dissolving all vertices in $V(M) \setminus T$. A *tm-pair* of a graph G is a *tm-pair* (M, T) where if M is a subgraph of G. We call the vertices in T *branch* vertices of (M, T).

If $\mathbf{M} = (M, B, \rho) \in \mathcal{B}$ and $T \subseteq V(M)$ with $B \subseteq T$, we call $(\mathbf{M}, T)$ a *btm-pair* and we define $\mathsf{diss}(\mathbf{M}, T) = (\mathsf{diss}(M, T), B, \rho)$. Note that we do not permit dissolution of boundary vertices, as we consider all of them to be branch vertices. If $\mathbf{G} = (G, B, \rho)$ is a boundaried graph and (M, T) is a tm-pair of G where $B \subseteq T$, then we say that $(\mathbf{M}, T)$, where $\mathbf{M} = (M, B, \rho)$, is a *$\mathsf{btm}$-pair* of $\mathbf{G} = (G, B, \rho)$. Let $\mathbf{G}_i = (G_i, B_i, \rho_i), i \in [2]$. We say that $\mathbf{G}_1$ is a *topological minor* of $\mathbf{G}_2$, denoted by $\mathbf{G}_1 \preceq_{\mathsf{tm}} \mathbf{G}_2$, if $\mathbf{G}_2$ has a btm-pair $(\mathbf{M}, T)$ such that $\mathsf{diss}(\mathbf{M}, T)$ is isomorphic to $\mathbf{G}_1$. We define the *ℓ-folio* of $\mathbf{G} = (G, B, \rho) \in \mathcal{B}$ as $\ell\text{-}\mathsf{folio}(\mathbf{G}) = \{\mathbf{G}' \in \mathcal{B} \mid \mathbf{G}' \preceq_{\mathsf{tm}} \mathbf{G}$ and $\mathbf{G}'$ has detail at most $\ell\}$.

Homogeneous walls. Let G be a graph and W be a flat wall of G. Let also (Γ, σ, π) be a rendition of the compass of W in G. Recall that $\Gamma = (U, N)$ is a Δ-painting for some closed disk Δ. Given a flap F, we denote by $\Omega(F)$ the counter-clockwise ordering of the vertices of ∂F as they appear in the corresponding cell of $C(\Gamma)$. Notice that as $|\partial F| \leq 3$, this cyclic ordering is significant only when $|\partial F| = 3$, in the sense that (x_1, x_2, x_3) remains invariant under shifting, i.e., $(v_1, v_2, v_3) \equiv (v_2, v_3, v_1)$ but not under inversion, i.e., $(v_1, v_2, v_3) \not\equiv (v_3, v_2, v_1)$.

Given a graph G, we say that the pair (A, W) is an *(r, a)-apex wall pair* of G if A is a subset of a vertices from G and W is a flat r-wall of $G \setminus A$. Let G be a graph and let (A, W) be an (a, r)-apex wall pair of G. For each cell $F \in \mathsf{flaps}(W)$ with $t_F = |\partial F|$, we fix $\rho_F : \partial F \to [a + 1, a + t_F]$ such that $(\rho_F^{-1}(a + 1), \ldots, \rho_F^{-1}(a + t_F)) \equiv \Omega(c)$. We also fix a bijection $\rho_A : A \to [a]$. For each flap $F \in \mathsf{flaps}(W)$, we define the boundaried graph $\mathbf{F}^A := (G[A \cup F], A \cup \partial F, \rho_A \cup \rho_F)$ and we denote by F^A the underlying graph of $\mathbf{F}^A$. We call $\mathbf{F}^A$ *augmented flap* of (A, W). Notice that $G[V(\mathsf{compass}(W)) \cup A] = \bigcup_{F \in \mathsf{flaps}(W)} F^A$.

Given some $\ell \in \mathbb{N}$, we say that two flaps $F_1, F_2 \in \mathsf{flaps}(W)$ are *(A,ℓ)-equivalent*, denoted by $F_1 \sim_{A,\ell} F_2$, if $\ell\text{-}\mathsf{folio}(\mathbf{F}_1^A) = \ell\text{-}\mathsf{folio}(\mathbf{F}_2^A)$. For each $F \in \mathsf{flaps}(W)$, we define the *(a,ℓ)-color* of F, denoted by $(a,\ell)\text{-}\mathsf{color}(F)$, as the equivalence class of $\sim_{A,\ell}$ to which $\mathbf{F}^A$ belongs.

Let $\tilde{W}$ be the leveling of W in $G \setminus A$ and let W^R be the representation of W in $\tilde{W}$. Recall that $\tilde{W}$ is a Δ-embedded graph. For each cycle C of W, we define the *(a,ℓ)-palette* of C, denoted by $(a,\ell)\text{-}\mathsf{palette}(C)$, as the set of all the (a,ℓ)-colors of the flaps that appear as vertices of $\tilde{W}$ in the closed disk bounded by C^R in Δ (recall that by C^R we denote the representation of C in $\tilde{W}$).

Let $a, \ell, r, q \in \mathbb{N}$, where $r > q \geq 3$ and let (A, W) be an (a,r)-apex wall pair of a graph G. We say that (A, W) is an *(ℓ, q)-homogeneous* (a,r)-apex wall pair of G if every internal brick B of W that is not a brick of $W^{(q)}$ has the same (a,ℓ)-palette (seen as a cycle of W). If we drop the demand that "B is not a brick of $W^{(q)}$" then we simply say that (A, W) is an *ℓ-homogeneous* (a,r)-apex wall pair of G.

The following observation is a consequence of the fact that, given a wall W and an internal subwall W' of W, every internal brick of a tilt W'' of W' is also an internal brick of W.

▶ **Observation 7.** *Let $a, r, r' \in \mathbb{N}$, where $r > r' \geq 3$. Also, let G be a graph, let (A, W) be an (a,r)-apex wall pair of G, and let W' be an internal r'-subwall of W. If (A, W) is (ℓ, q)-homogeneous for some $\ell, q \in \mathbb{N}$ where $r > q \geq 3$, then every (a, r')-apex wall pair (A, W'') generated by W' is (ℓ, q)-homogeneous.*

The following result is from [5, Lemma 4.3] and implies that if the wall of an apex wall pair is polynomially large on r, then its compass contains a homogeneous flat r-wall.

▶ **Proposition 8.** *There is a function $f_1 : \mathbb{N}^3 \to \mathbb{N}$ such that if $\ell, r, a \in \mathbb{N}$, where $r \geq 3$, G is a graph, and (A, W) is an $(a, f_1(\ell, r, a))$-apex wall pair of G, then W has a r-subwall W' such that every (a,r)-apex wall pair of G that is generated by W' is ℓ-homogeneous. Moreover, it holds that $f_1(\ell, r, a) = \mathcal{O}(r^{c_{a,\ell}})$, for some constant $c_{a,\ell}$ depending on a and ℓ.*

We refer to the constant $c_{a,\ell}$ of Proposition 8, when $a = a_{\mathcal{F}}$ and $\ell = \ell_{\mathcal{G}}$ as the *palette-variety* of $\mathcal{F}$. This constant reflects the *price of homogeneity*: the degree of the polynomial overhead that we need to pay in order to force homogeneity in a flat wall.

Treewidth. A *tree decomposition* of a graph G is a pair (T, χ) where T is a tree and $\chi : V(T) \to 2^{V(G)}$ such that (1) $\bigcup_{t \in V(T)} \chi(t) = V(G)$, (2) for every edge e of G there is a $t \in V(T)$ such that $\chi(t)$ contains both endpoints of e, and (3) for every $v \in V(G)$, the subgraph of T induced by $\{t \in V(T) \mid v \in \chi(t)\}$ is connected. The *width* of (T, χ) is defined as $\mathbf{w}(T, \chi) := \max\big\{\, |\chi(t)| - 1 \;\big|\; t \in V(T)\big\}$. The *treewidth of G* is defined as $\mathsf{tw}(G) := \min\big\{\, \mathbf{w}(T, \chi) \;\big|\; (T, \chi) \text{ is a tree decomposition of } G\big\}$.

The following is the main result of [8]. We will use it to compute a tree decomposition of a graph of bounded treewidth.

▶ **Proposition 9.** *There is an algorithm that, given an graph G on n vertices and an integer k, it outputs either a report that $\mathsf{tw}(G) > k$, or a tree decomposition of G of width at most $5k + 4$. Moreover, this algorithm runs in $2^{\mathcal{O}(k)} \cdot n$ steps.*

The following result is derived from [1]. We will use it in order to find a wall in a bounded treewidth graph, given a tree decomposition of it.

▶ **Proposition 10.** *There is an algorithm that, given a graph G on m edges, a graph H on h edges without isolated vertices, and a tree decomposition of G of width at most k, it outputs, if it exists, a minor of G isomorphic to H. Moreover, this algorithm runs in $2^{\mathcal{O}(k \log k)} \cdot h^{\mathcal{O}(k)} \cdot 2^{\mathcal{O}(h)} \cdot m$ steps.*

3 Auxiliary algorithmic and combinatorial results

3.1 Two algorithmic results

We are now in position to state some results that will support our algorithms.

▶ **Lemma 11.** *There exist a function $f_2 : \mathbb{N} \to \mathbb{N}$ and an algorithm as follows:*
`Find-Wall`(G, r, k)
Input: *A graph G, an odd $r \in \mathbb{N}_{\geq 3}$, and a $k \in \mathbb{N}$.*
Output: *One of the following:*

- *Either a report that G has treewidth at most $f_2(s_{\mathcal{F}}) \cdot r + k$, or*
- *an r-wall W of G, or*
- *a report that (G, k) is a* no*-instance of $\mathcal{F}$-M-Deletion.*

Moreover, this algorithm runs in $2^{\mathcal{O}_{s_{\mathcal{F}}}(r^2+(k+r)\log(k+r))} \cdot n$ steps.

The proof of Lemma 11 combines the algorithm of Perkovič and Reed in [43] for computing the treewidth of a graph, as well as the excellent analysis of the algorithm provided in [3]. We also use the upper bound for the treewidth of an K_h-minor free graph without an r-wall by [31], the dynamic programming algorithm of [1] for finding a wall in a graph of bounded treewidth, and the single-exponential FPT-approximation algorithm for treewidth in [8].

The next result follows from [33, Theorem 1.9] and the proof of [32, Theorem 5.2].

▶ **Proposition 12.** *There are functions $f_3 : \mathbb{N} \to \mathbb{N}$, $f_4 : \mathbb{N} \to \mathbb{N}$ and an algorithm as follows:*
`Clique-Or-Flat-Wall`(G, r, t, W)
Input: *A graph G on n vertices and m edges, an odd integer $r \geq 3$, a $t \in \mathbb{N}_{\geq 1}$, and an R-wall W in G, where $R = f_3(t) \cdot r$.*
Output: *Either a minor of G isomorphic to K_t, or*

(1) *a set $A \subseteq V(G)$ of size at most $12288t^{24}$,*
(2) *a flat r-wall $\bar{W}$ of $G \setminus A$ such that $V(\bar{W}) \cap A = \emptyset$, and*
(3) *a separation (X, Y) of $G \setminus A$ that certifies that $\bar{W}$ is a flat wall and an Ω-rendition of $G[Y]$ with flaps of treewidth at most $f_4(t) \cdot r$, where Ω is a cyclic ordering of $X \cap Y$ determined by the order on the perimeter of $\bar{W}$.*

Moreover, this algorithm runs in $2^{\mathcal{O}_t(r)}(m + n)$ time.

Proposition 12, without the bound on the treewidth of the flaps, has been proven in [33, Theorem 1.9]. However, in [33, Theorem 1.9] $\bar{W}$ is a tilt of some r-subwall of W with a different function $f_3{}'$ for the relation between R and r and has running time $\mathcal{O}(t^{24}(n+m))$.

In Proposition 12 the bound on the treewidth of the flaps is obtained if we plug [33, Theorem 1.9] in the proof of [32, Theorem 5.2], taking into account the linear dependence between R and r. The parameterized dependence $2^{\mathcal{O}_t(r)}$ of the algorithm follows because of the use of the linear FPT-approximation algorithm for treewidth in [8] so as to compute the tree decompositions of the flaps. Another stronger version of Proposition 12, where no R-wall W is given in the input, appears in [23, Lemma 3.2], running in $2^{\mathcal{O}_t(r^{58})} \cdot n \log^2 n$ time. We do not need this stronger version as, for our problem, the R-wall W will be found by the algorithm of Lemma 11.

3.2 Finding an irrelevant vertex

The *irrelevant vertex technique* was introduced in [45] for providing an FPT-algorithm for the Disjoint Paths problem. Moreover, this technique has appeared to by quite versatile and is now a standard tool of parameterized algorithm design (see e.g., [14, 49]). The applicability of this technique for $\mathcal{F}$-M-Deletion is materialized by the algorithm of Lemma 14.

Given a graph G, a set $A \subseteq V(G), |A| = a$, and an r-wall W of G, we say that (A, W) is an (a, r)-*apex-wall* pair if W is a flat r-wall of $G \setminus A$.

▶ **Lemma 13.** *There is a function $f_5 : \mathbb{N}^4 \to \mathbb{N}$ such that if $a, \ell, q, k \in \mathbb{N}$, $q \geq 3$, G is a graph, and (A, W) is an ℓ-homogeneous $(a, f_5(a, \ell, q, k))$-apex wall pair of G, then for every (a, q)-apex wall pair $(A, \hat{W})$ generated by $W^{(q)}$, it holds that (G, k) and $(G \setminus V(\mathsf{compass}(\hat{W})), k)$ are equivalent instances of $\mathcal{F}$-M-Deletion. Moreover, $f_6(a, \ell, q, k) = O_{a,\ell,q}(k)$.*

Sketch of the proof. The proof considers $k + 1$ subwalls of W which, in turn, generate $k + 1$ flat walls (by taking their tilts) whose compasses are all disjoint except at some territory T of constant size containing the center of W that is common for all these walls. If now S is a solution to $\mathcal{F}$-M-Deletion for the instance (G, k) then one, say W_i, of these $k + 1$ flat walls will have a compass that does not intersect S (except from some constant size territory $T_i$around the center of W_i that contains T). We then claim that $S' = S \setminus T_i$ is a new solution of $\mathcal{F}$-M-Deletion that avoids the center of W. To prove that this is the case, we assume to the contrary that some graph L in $\mathcal{F}$ appears as a minor in $G' = G \setminus S'$. But this means that part of the realization of H in G' meets some vertex in the center of W and therefore it traverses $\mathsf{compass}(W_i)$. We arrive to a contradiction by providing an alternative realization of L that is routed away from T_i. For this rerouting we use the main combinatorial result of [5] that guarantees that there is a function $f_6 : \mathbb{N}^3 \to \mathbb{N}$ such that, for every $a, \ell, q \in \mathbb{N}$ and every graph G, if (A, W) is an (ℓ, q)-homogeneous $(a, f_6(a, \ell, q))$-apex wall pair of G, there is an (a, q)-apex wall pair of G generated by $W^{(q)}$ whose compass is irrelevant. For this it is enough to pick $f_5(a, \ell, q, k) = \mathcal{O}(k \cdot f_6(a, \ell, q) + q)$. ◀

▶ **Lemma 14.** *There exist a function $f_7 : \mathbb{N}^4 \to \mathbb{N}$ and an algorithm with the following specifications:*

`Find-Irrelevant-Wall`(G, q, k, b, A, W)

***Input:** A graph G on n vertices, two integers $k, q \in \mathbb{N}$, a $b \in \mathbb{N}_{\geq 3}$, and an $(a, f_7(a, \ell_{\mathcal{F}}, b, k))$-apex wall pair (A, W) of G whose all flaps have treewidth at most q.*

***Output:** A flat b-wall $\hat{W}$ of $G \setminus A$ such that (G, k) and $(G \setminus V(\mathsf{compass}(\hat{W})), k)$ are equivalent instances of $\mathcal{F}$-M-Deletion.*

Moreover, $f_7(a, \ell_{\mathcal{F}}, b, k) = \mathcal{O}_{a,\ell_{\mathcal{F}}}((k + b)^{c_{a,\ell_{\mathcal{F}}}})$ for some constant $c_{a,\ell_{\mathcal{F}}}$ depending on a and $\ell_{\mathcal{F}}$. This algorithm runs in $2^{\mathcal{O}_{a,\ell_{\mathcal{F}}}(q \log q + (k+b) \log(k+b))} \cdot n$ time.

Proof. We set $f_7(a, \ell_{\mathcal{F}}, b, k) := f_1(\ell_{\mathcal{F}}, r, a)$, where $r = f_5(a, \ell, b, k)$. The algorithm considers each one of the $\binom{f_7(a,\ell_{\mathcal{F}},b,k)}{r}$ internal r-subwalls W' of W and constructs an (a, r)-wall pair (A, W'') generated by W'. This can be done in $\mathcal{O}(n)$ time because of Lemma 5.

From Proposition 8 there is a choice of W' such that (A, W'') is $\ell_{\mathcal{F}}$-homogeneous. To check whether (A, W'') is $\ell_{\mathcal{F}}$-homogeneous we do the following. Let $\mathcal{B}$ be the set of all flaps of W'' that, when seen as flap vertices of $\tilde{W}$, appear in the closed disk bounded by the representation of B in $\tilde{W}$, where B is an internal brick of W'' that is not a brick of $W''^{(b)}$. For every flap $F \in \mathcal{B}$, we consider the boundaried graph $\mathbf{F}^A$. Using the fact that $\mathsf{tw}(F^A) \leq q + a$, we apply the algorithm of Proposition 9 which outputs a tree decomposition of F^A of width at most $5(q + a) + 4$. Then by applying the algorithm of Proposition 10, we compute $\ell_{\mathcal{F}}$-$\mathsf{folio}(\mathbf{F}^A)$ in $2^{\mathcal{O}_{a,\ell_{\mathcal{F}}}(q \log q)}$ time. Then, it is easy to check in linear time whether (A, W'') is $\ell_{\mathcal{F}}$-homogeneous.

After we find W', we again use Lemma 5 in order to construct a flat b-wall $\hat{W}$ of $G \setminus A$ generated by $W'^{(b)}$. The algorithm outputs $\hat{W}$, and this is correct because of Lemma 13. ◀

3.3 Combinatorial results for branching

We now give a combinatorial result that will justify a branching step of our algorithm, i.e., its recursive application on a set of $\mathcal{O}_s(k)$ vertices. Given a graph G and a set $A \subseteq V(G)$, we say that a graph H is an *A-fixed minor of G* if H can be obtained from a subgraph G' of G where $A \subseteq V(G')$, after contracting edges without endpoints in A (see Figure 4 for the definition of an r-grid and its central subgrids that we will need later). A graph H is an *A-apex r-grid* if it can be obtained by an r-grid Γ after adding a set A of new vertices and some edges between the vertices of A and $V(\Gamma)$. We call Γ *underlying grid* of H.

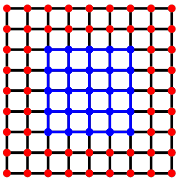

Figure 4 A 9-grid and its central 5-subgrid.

Next we identify a combinatorial structure that guarantees the existence of a set of $q = \mathcal{O}_s(k)$ vertices that intersects every solution S of $\mathcal{F}$-M-Deletion on imput (G, k). This will permit branching on q simpler instances of the form $(G', k-1)$.

▶ **Lemma 15.** *There exist three functions $f_8, f_9, f_{10} : \mathbb{N}^2 \to \mathbb{N}$, such that if $\mathcal{F}$ is a finite set of graphs, G is a graph, $k \in \mathbb{N}$, and $A \subseteq V(G)$, $|A| = a_{\mathcal{F}}$, such that G contains as an A-fixed minor an A-apex $f_8(s_{\mathcal{F}}, k)$-grid H where each vertex $v \in A$ has at least $f_9(s_{\mathcal{F}}, k)$ neighbors in the central $(f_8(s_{\mathcal{F}}, k) - f_{10}(s_{\mathcal{F}}, k))$-grid of $H \setminus A$, then for every solution S of $\mathcal{F}$-M-Deletion for the instance (G, k), it holds that $S \cap A \neq \emptyset$. Moreover, $f_8(s_{\mathcal{F}}, k) = \mathcal{O}_{s_{\mathcal{F}}}(k^{3/2})$, $f_9(s_{\mathcal{F}}, k) = \mathcal{O}_{s_{\mathcal{F}}}(k^3)$, and $f_{10}(s_{\mathcal{F}}, k) = \mathcal{O}_{s_{\mathcal{F}}}(k)$.*

We conjecture that Lemma 15 is tight, in the sense that it cannot be proved for some $f_9(s_{\mathcal{F}}, k) = \mathcal{O}_{s_{\mathcal{F}}}(k^{3-\epsilon})$.

Notice that in the special case where $a_{\mathcal{F}} = 1$, then Lemma 15 can be improved by using the main combinatorial result of [16]. In particular [16, Lemma 3.1] easily implies that, in this case, $f_8(s_{\mathcal{F}}, k) = \mathcal{O}_{s_{\mathcal{F}}}(k)$, $f_9(s_{\mathcal{F}}, k) = \mathcal{O}_{s_{\mathcal{F}}}(k^2)$, and $f_{10}(s_{\mathcal{F}}, k) = \mathcal{O}_{s_{\mathcal{F}}}(\sqrt{k})$. In [47], we prove that these bounds can be improved to $f_8(s_{\mathcal{F}}, k) = \mathcal{O}_{s_{\mathcal{F}}}(\sqrt{k})$, $f_9(s_{\mathcal{F}}, k) = \mathcal{O}_{s_{\mathcal{F}}}(k)$, and $f_{10}(s_{\mathcal{F}}, k) = \mathcal{O}_{s_{\mathcal{F}}}(1)$. We will use these improved bounds for the proof of Theorem 2.

We conclude this subsection with one additional definition that will be useful for the application of Lemma 15 in our main algorithm.

Canonical partitions. We define the *canonical partition* of an r-wall W to be a collection $\mathcal{Q} = \{Q_{\text{ext}}, Q_1, \ldots, Q_q\}$ of $(r-2)^2 + 1$ connected subgraphs of W such that their vertex sets form a partition of $V(W)$ as indicated in Figure 5.

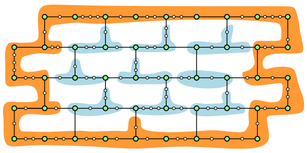

Figure 5 A 5-wall and its canonical partition $\mathcal{Q}$. The orange bag is the external bag Q_{ext}.

Let (A, W) be an (a, r)-apex wall pair of a graph G and let $\tilde{W}$ be the Δ-embedded graph that is the leveling $\tilde{W}$ of W in $G \setminus A$. Let also W^R be the representation of W in $\tilde{W}$. Consider a canonical partition $\mathcal{Q}$ of W^R. We enhance the graphs of $\mathcal{Q}$ so to include in them all the vertices of $\tilde{W}$ by applying the following procedure. We set $\tilde{\mathcal{Q}} := \mathcal{Q}$ and, as long as there is a vertex $x \in V(\tilde{W}) \setminus V(\bigcup \tilde{\mathcal{Q}})$[5] that is adjacent to a vertex of a graph $Q \in \tilde{\mathcal{Q}}$, update $\tilde{\mathcal{Q}} := \tilde{\mathcal{Q}} \setminus \{Q\} \cup \{\tilde{Q}\}$, where $\tilde{Q} = \tilde{W}[\{x\} \cup V(Q)]$. We just defined a partition of the vertices of $\tilde{W}$ into subsets inducing connected graphs. We call such a partition *canonical partition* of $\tilde{W}$. Notice that a canonical partition of $\tilde{W}$ is not unique (since the sets in $\mathcal{Q}$ can be "expanded" arbitrarily when introducing the vertex x).

4 The algorithms

4.1 The general algorithm

▶ **Lemma 16.** *Let $\mathcal{F}$ be a finite collection of graphs. There is an algorithm solving $\mathcal{F}$-*M-Deletion-Compression *in $2^{\mathcal{O}_s(k^{2(c_{\mathcal{F}}+2)}\log k)} \cdot n^2$ time.*

Proof. For simplicity, in this proof, we use c instead of $c_{\mathcal{F}}$, s instead of $s_{\mathcal{F}}$, ℓ instead of $\ell_{\mathcal{F}}$, a instead of $a_{\mathcal{F}}$, and remember that $\ell = \mathcal{O}_s(1)$ and $a = \mathcal{O}_s(1)$. We set

$$\begin{array}{lll} b = f_7(k, a, \ell) = \mathcal{O}(k^c), & x = f_9(s, k), & l = (12288 s^{24} + k + 1) \cdot x, \\ m = f_8(s, k), & p = f_{10}(s, k), & h = \max\{m - p, \lceil \sqrt{l+1} \cdot b \rceil\}, \\ r = h + p + 2, & R = f_3(s) \cdot r, & \text{and notice that } R = \mathcal{O}_s(k^{c+2}). \end{array}$$

Recall that, in the definition of R, the constant c is the palette-variety of $\mathcal{F}$. We present the algorithm `Solve-Compression`, whose input is a quadruple (G, k', k, S) where G is a graph, k' and k are non-negative integers where $k' \leq k$, and S is a subset of $V(G)$ such that $|S| = k$ and $\mathcal{F} \not\leq_{\mathsf{m}} G \setminus S$. The algorithm returns, if it exists, a solution for $\mathcal{F}$-M-Deletion on (G, k'). Certainly, we may assume that $k' < k$, otherwise S is already a solution and we are done. The steps of the algorithm are the following:

Step 1. Run the algorithm `Find-Wall` of Lemma 11 with input $(G \setminus S, R, 0)$. This outputs, in $2^{\mathcal{O}_s(k^{2(c+2)})} \cdot n$ time, either a report that $\mathsf{tw}(G \setminus S) \leq f_2(s) \cdot R$, or an R-wall W_0 of $G \setminus S$. Notice that `Find-Wall`$(G \setminus S, R, s)$ never outputs the third case, since $(G \setminus S, 0)$ is a yes-instance of $\mathcal{F}$-M-Deletion. In the first possible output, we know that $\mathsf{tw}(G) \leq f_2(s) \cdot R + k = \mathcal{O}_s(k^{c+2})$, and we call the algorithm of Proposition 3 with input $(G, f_2(s) \cdot R + k, k')$ and return a correct answer in $2^{\mathcal{O}_s(k^{c+2}\log k)} \cdot n$ steps. In the second possible output, the algorithm moves to the second step.

Step 2. Call `Clique-Or-Flat-Wall` of Proposition 12 on $(G \setminus S, r, s, W_0)$. Since $\mathcal{F} \not\leq_{\mathsf{m}} G \setminus S$ and $\mathcal{F} \leq_{\mathsf{m}} K_s$, the algorithm outputs, in time $2^{\mathcal{O}_s(r)} \cdot (m + n) = 2^{\mathcal{O}_s(k^{c+2})} \cdot n$, the following:

- A set $A \subseteq V(G) \setminus S$ of size at most $12288 s^{24}$,
- a flat r-wall W of $G \setminus (S \cup A)$ such that $V(W) \cap A = \emptyset$, and
- a separation (X, Y) of $G \setminus A$ that certifies that W is a flat wall, and an Ω-rendition of $G[Y]$ with flaps of treewidth at most $q = f_4(s) \cdot r$, where Ω is a cyclic ordering of $X \cap Y$ determined by the order on the outer cycle of W.

Let $\tilde{W}$ be the leveling of W and let W^R be the representation of W in the Δ-embedded graph $\tilde{W}$ ($\tilde{W}$ and W^R can straighforwardly be constructed in $\mathcal{O}(n)$ steps using the Ω-rendition of $G[Y]$). Let also $\bar{W} = (W^R)^{(r-p)}$, i.e., $\bar{W}$ is the central $(r-p)$-subwall of W^R.

[5] If $\mathcal{S}$ is a collection of objects where the operation $\cup$ is defined, then we denote $\bigcup \mathcal{S} = \bigcup_{X \in \mathcal{S}} X$.

Consider a family $\bar{\mathcal{W}} = \{\bar{W}_1, \ldots, \bar{W}_{l+1}\}$ of $l+1$ internal b-subwalls of $\bar{W}$, such that if D_i is the closed disk in Δ bounded by the perimeter, denoted by $\bar{P}_i$, of $\bar{W}_i$, then $D_i \cap D_j = \emptyset$, for $i \neq j$. We are allowed to do this since $r - p - 2 \geq \lceil \sqrt{l+1} \cdot b \rceil$. By $\mathsf{flaps}(D_i)$ we denote all the flaps corresponding to flap-vertices of $\tilde{W}$ that are inside D_i in the embedding of $\tilde{W}$ in Δ. For every $i \in [l+1]$, we compute, in $\mathcal{O}(n)$ time, the set $A_i = \big\{v \in S \cup A \mid v \text{ is adjacent in } G \text{ to a vertex of } \bigcup \mathsf{flaps}(D_i)\big\}$ and we proceed to the last step.

Step 3. The algorithm examines two cases:

Case A: For every $i \in [l+1]$, it holds that $|A_i| > a$. In this case the algorithm recursively calls `Solve-Compression` with input $(G \setminus x, k' - 1, |S \setminus x|, S \setminus x)$, for every $x \in S \cup A$, and if one of these new instances is a yes-instance, certified by a set $\bar{S}$, then return $\bar{S} \cup \{x\}$, otherwise return that (G, k') is a no-instance.

We now prove that the above branching step of the algorithm is correct. Let $\tilde{W}$ be the leveling of W in $G \setminus (S \cup A)$. We define $\tilde{G}$ as the graph obtained from $G \setminus (S \cup A)$ if we remove all the vertices of the compass of W and take the union of the resulting graph with $\tilde{W}$. Notice that $\tilde{G}$ is *partially* Δ*-embedded* in the sense that the part of G that is embedded in Δ is $\tilde{W}$. Notice that $\tilde{G}$ is not necessarily a contraction of $G \setminus (S \cup A)$, and this is because the trivial flaps appear in $\tilde{W}$ as induced paths of length two instead of edges. Therefore, if $\breve{G}$ is the graph obtained from $\tilde{G}$ after dissolving each flap-vertex corresponding to a trivial flap, then

- $\breve{G}$ is a contraction of $G \setminus (S \cup A)$,
- $\breve{G}$ is a partially Δ-embedded graph whose compass is a dissolution of $\tilde{W}$, and
- $\breve{G}$ contains an r-wall $\breve{W}$ that is a dissolution of W^R and $\breve{W}$ is embedded in Δ so that its perimeter is a dissolution of the perimeter of W^R.

Consider a canonical partition $\tilde{\mathcal{Q}}$ of $\tilde{W}$. Let $\breve{\mathcal{Q}}$ be the collection of connected subgraphs of $\breve{G}$ that are obtained if we apply to the graphs in $\tilde{\mathcal{Q}}$ the same dissolutions that we used to transform $\tilde{G}$ to $\breve{G}$ (we just take care that the edge contracted during each dissolution has both endpoints in some bag). Moreover, we enhance $\breve{\mathcal{Q}}$ by adding in its external bag all the vertices of $\breve{G}$ that are not points of Δ. Notice that the vertex sets of the graphs in this new $\breve{\mathcal{Q}}$ define a partition of $V(\breve{G})$. Let now $\breve{G}^+$ be the graph obtained if we apply in G the same contractions that transform $G \setminus (S \cup A)$ to its contraction $\breve{G}$. Let $a^* = |S \cup A| \leq 12288 s^{24} + k + 1$. We now construct a minor of $\breve{G}^+$ by contracting all edges of each member of $\breve{\mathcal{Q}}$ to a single vertex and removing the vertex to which the external bag was contracted. We denote the resulting graph by $\bar{G}$ and we observe that $\bar{G}$ contains as a spanning subgraph an $S \cup A$-apex $(r-2)$-grid Γ. Recall that Γ is a $S \cup A$-fixed minor of G. Let $\bar{\Gamma}$ be the underlying grid of Γ and let $\bar{\Gamma}_1, \ldots, \bar{\Gamma}_{l+1}$ be the "packing" of the h-central grid $\bar{\Gamma}'$ of $\bar{\Gamma}$, corresponding to the walls in $\bar{\mathcal{W}}$, where each $\bar{\Gamma}_i$ is a b-grid. We can assume the existence of this packing because $h \geq \lceil \sqrt{l+1} \cdot b \rceil$. The initial assumption that $|A_i| > a$, for $i \in [l+1]$, implies that $\forall i \in [l+1]$, there are more than a apices of Γ that are adjacent to vertices of $\bar{\Gamma}_i$.

For every $v \in S \cup A$, let N_v be the set of neighbors of v in $\bar{\Gamma}'$ and let $\bar{N} = \bigcup_{v \in S \cup A} N_v$. Let A^* be the set of vertices of $S \cup A$ with $|N_v| \geq x$. We claim that $|A^*| \geq a$. Suppose to the contrary that $|A^*| < a$. This implies that the vertices in $(S \cup A) \setminus A^*$ are adjacent to at most $x \cdot |(S \cup A) \setminus A^*| \leq l$ vertices in $\bar{N}$. This, in turn implies that there is an $i \in [l+1]$ such that there are no vertices in $(S \cup A) \setminus A^*$ adjacent to vertices of $\bar{\Gamma}_i$. Thus, for this i, there are at most a apex vertices of $\bar{G}$ that are adjacent to vertices of $\bar{\Gamma}_i$, a contradiction to the conclusion of the previous paragraph. We arbitrarily remove vertices from A^* so that $|A^*| = a$.

Consider now the A^*-apex $(r-2)$-grid $H = \Gamma \setminus ((S \cup A) \setminus A^*)$, and as each vertex in A^* has at least x neighbors in $V(\bar{\Gamma}')$ and $r - 2 \geq m$, Lemma 15 can be applied for k', A^*, H. This implies that (G, k') is a yes-instance of $\mathcal{F}$-M-Deletion if and only if there is some

$v \in A^*$ such that $(G \setminus v, k' - 1)$ is a yes-instance of $\mathcal{F}$-M-Deletion. This completes the correctness of the branching step in Case A.

Case B: there is an $i \in [l+1]$ such that $|A_i| \leq a$. Since $\bar{W}_i$ is an internal b-subwall of W^R, there is a subgraph of $\mathsf{compass}(W)$ that is a flat b-wall W_i'' of $G \setminus (S \cup A)$ such that the set of vertices of the compass of W_i'' is a subset of $\bigcup \mathsf{flaps}(D_i)$ (as we argued in Subsection 3.2, W_i'' is a tilt of the subwall of W represented by $\bar{W}_i$ and can be found in $\mathcal{O}(n)$ time). This implies that if A_i'' is the set of vertices from $S \cup A$ that are adjacent with vertices of the compass of W_i'' in $G \setminus (S \cup A)$, then $A_i'' \subseteq A_i$. Thus (A'', W_i'') is an $(|A_i''|, b)$-apex wall pair in G.

We now apply `Find-Irrelevant-Wall` of Lemma 14 for $(G, k, q, 3, A_i'', W_i'')$ and pick a vertex v in the center of the obtained 3-wall. According to Lemma 14, it holds that (G, k) and $(G \setminus v, k)$ are equivalent instances of $\mathcal{F}$-M-Deletion, v can be detected in $2^{\mathcal{O}_{a,\ell}(k \log k)} \cdot n$ time, and the algorithm correctly calls recursively `Solve-Compression` with input $(G \setminus v, k', k, S)$.

Recall that $|S \cup A| \leq k + 1 + 12288 s^{24} = \mathcal{O}_s(k)$. Therefore, if $T(n, k', k)$ is the running time of the above algorithm, then $T(n, k', k) \leq 2^{\mathcal{O}_s(k^{2(c+2)})} n + \max\{T(n-1, k', k), \mathcal{O}_s(k) \cdot T(n, k-1, k)\}$ which, given that $k' \leq k$, implies that $T(n, k', k) = 2^{\mathcal{O}_s(k^{2(c+2)})} n^2$.

Notice now that the output of `Solve-Compression` on $(G, k, k+1, S)$ gives a solution for $\mathcal{F}$-M-Deletion-Compression on this instance. ◀

4.2 The apex-minor free case

In this subsection we prove that, in the case where $a_{\mathcal{F}} = 1$, there is an algorithm that solves $\mathcal{F}$-M-Deletion in time $2^{\mathcal{O}_{s_{\mathcal{F}}}(k^{2(c+1)})} \cdot n^2$, where $c = c_{a, \ell_{\mathcal{F}}}$ and $a = 12288 (s_{\mathcal{F}})^{24}$. The existence of such an algorithm implies Theorem 2.

Let G be graph and let W be an r-wall in G. The *drop*, denoted by $D_{W'}$, of a q-subwall W' of W, where $q \leq r$, is defined as follows: Contract in G the perimeter of W to a single vertex v. $D_{W'}$ is the unique biconnected component of the resulting graph that contains the interior of W'. We call the vertex v the *pole* of the drop $D_{W'}$.

The algorithm. Our algorithm avoids iterative compression in the fashion that this is done by Marx and Schlotter in [41] for the Planarization problem. The algorithm has three main steps. We first set $s = s_{\mathcal{F}}$, $a = 12288 s^{24}$, $b' = f_7(a, k, \ell_{\mathcal{F}}) = \mathcal{O}_s(k^{c_{a,\ell_{\mathcal{F}}}})$, and we define

$$b = f_3(s) \cdot 2b' + 2 \qquad l = f_9(s,k) \cdot k \qquad p = f_{10}(s,k)$$
$$h = \max\{f_8(s,k) - p, b \cdot \sqrt{l+1}\} \qquad r = h + p + 2 \qquad R = f_3{}'(s) \cdot r + k = \mathcal{O}_s(k^{c+1}).$$

Step 1. Run the algorithm `Find-Wall` of Lemma 11 with input (G, R, k) and, in $2^{\mathcal{O}_s(k^{2(c+1)})} \cdot n$ time, either report a no-answer, or conclude that $\mathsf{tw}(G) \leq f_2(s) \cdot R + k$ and solve $\mathcal{F}$-M-Deletion in $\mathcal{O}(2^{\mathcal{O}_s(k^{c+1}) \log k} \cdot n)$ time using the algorithm of Proposition 3, or obtain an R-wall $W^\bullet$ of G. In the third case, consider all the $\binom{R}{b} = 2^{\mathcal{O}_s(k^c \log k)}$ b-subwalls of W and for each one of them, say W', construct its drop $D_{W'}$, consider in $D_{W'}$ the central $(b-2)$-subwall $\bar{W}$ of W', and run the algorithm `Clique-Or-Flat-Wall` of Proposition 12 with input $D_{W'}$, $2b'$, s, and $\bar{W}$. This takes time $2^{\mathcal{O}_s(k^c)} \cdot n$. If for some of these drops the result is an $(|A'|, 2b')$-apex wall pair (W'', A') where $|A'| \leq a$ and its flaps have treewidth at most $q = f_4(2b') \cdot r$, then apply Step 2, otherwise apply Step 3.

Step 2. Consider the leveling $\tilde{W}$ of W'' and, in the representation W^R of W'' in $\tilde{W}$, pick a b'-wall $\bar{W}$ whose flap vertices do not correspond to a flap containing the pole of $D_{W'}$. Then use $\bar{W}$ in order to find an $(|A'|, b')$-apex wall pair (W''', A') of $D_{W'}$ whose compass does not contain the pole of $D_{W'}$. Notice that (A', W''') is also an $(|A'|, b')$-apex wall pair of G, therefore the algorithm can apply `Find-Irrelevant-Vertex` of Lemma 14 for $(G, k, q, 3, A', W''')$ and obtain, in $2^{\mathcal{O}_s(k \log k)} \cdot n$ time, an "irrelevant" flat 3-wall and a vertex v in its center such that (G, k) and $(G \setminus v, k)$ are equivalent instances of $\mathcal{F}$-M-Deletion. Then the algorithm runs recursively on the equivalent instance $(G \setminus v, k)$.

Step 3. Consider all the $\binom{R}{r} = 2^{\mathcal{O}_s(k^c \log k)}$ r-subwalls of $W^\bullet$, and for each one W' of them, consider its central h-subwall $\bar{W}$ and compute the canonical partition $\mathcal{Q}$ of $\bar{W}$. Then for each internal bag Q of $\mathcal{Q}$ add a new vertex v_Q and make it adjacent with all vertices in Q, then add a new vertex x_{all} and make it adjacent with all x_Q's, and in the resulting graph, for every vertex y of G that is not in the union of the internal bags of $\mathcal{Q}$, check, in time $\mathcal{O}(k \cdot m) = \mathcal{O}_s(k \cdot n)$ (using standard flow techniques), if there there are $f_9(s, k)$ internally vertex-disjoint paths from x_{all} to y. If this is indeed the case for some y, then y should belong to every solution of $\mathcal{F}$-M-Deletion for the instance (G, k) and the algorithm runs recursively on the equivalent instance $(G \setminus y, k - 1)$. If no such y exists, then report that (G, k) is a no-instance of $\mathcal{F}$-M-Deletion.

Notice that the third step of the algorithm, when applied takes time $2^{\mathcal{O}_s(k^c \log k)} \cdot n^2$. However, it cannot be applied more than k times during the course of the algorithm. As the first step runs in time $2^{\mathcal{O}_s(k^{2(c+1)}) \log k} \cdot n$, and the second step runs in time $2^{\mathcal{O}_s(k \log k)} \cdot n$, they may be applied at most n times, and the claimed time complexity follows.

5 Concluding remarks

Limitations of the irrelevant vertex technique. An intriguing open question is whether Vertex Deletion to $\mathcal{G}$ admits an algorithm in time $2^{\mathcal{O}_{s_\mathcal{F}}(k^c)} \cdot n^{\mathcal{O}(1)}$ for some universal constant c (i.e., not depending on the class $\mathcal{G}$). Clearly, this is not the case of the algorithms of Theorem 1 and Theorem 2, running in time $2^{\mathcal{O}_{s_\mathcal{F}}(k^{2(c+2)} \log k)} \cdot n^3$ and $2^{\mathcal{O}_{s_\mathcal{F}}(k^{2(c+1)} \log k)} \cdot n^2$, respectively, where c is the *the palette-variety* of the minor-obstruction set $\mathcal{F}$ of $\mathcal{G}$ which, from the corresponding proofs, is estimated to be $c = 2^{\mathcal{O}({s_\mathcal{F}}^2 \cdot \log s_\mathcal{F})}$ and $c = 2^{\mathcal{O}({s_\mathcal{F}}^{24} \cdot \log s_\mathcal{F})}$, respectively (recall that $s_\mathcal{F}$ is the maximum size of a minor-obstruction of $\mathcal{G}$). We tend to believe that this dependence is unavoidable if we want to use the *irrelevant vertex technique*, as it reflects the *price of homogeneity*, as we mentioned in the end of Subsection 2.2. Having homogeneous walls is critical for the application of this technique when $\mathcal{G}$ is more general than surface embeddable graphs (in the bounded genus case, all subwalls are already homogeneous). Is there a way to prove that this behavior is unavoidable subject to some complexity assumption? An interesting result of this flavor concerning the existence of polynomial kernels for Vertex Deletion to $\mathcal{G}$ was given by Giannopoulou et al. [26] who proved that, even for minor-closed families $\mathcal{G}$ that exclude a planar graph, the dependence on $\mathcal{G}$ on the degree of the polynomial kernel, which exists because of [22], is unavoidable subject to reasonable complexity assumptions.

Variants. Our approach can be easily modified so to deal with several variants of the Vertex Deletion to $\mathcal{G}$ problem such as the *annotated version* of the problem where the input comes with a set of vertices that we are permitted to remove, the *weighted version* where the vertices carry positive weights, the *counting version* where we are asked to count the number of (minimal) solutions, or the *colored version* where the vertices of the input graph are partitioned into k parts and we are requested to pick one vertex from each part. The details can be found in the full version of the paper [47].

Other modification operations. Another direction is to consider graph modification to a minor-closed graph class for different modification operations. Our approach becomes just simpler in the case where the modification operation is edge removal or edge contraction. In these two cases, we immediately get rid of the branching part of our algorithms, and only the irrelevant vertex part needs to be applied. Another challenge is to combine all aforementioned modifications. This is more complicated (and tedious) but not more complex. What is really more complex is to additionally consider edge additions. We leave it as an open research challenge (a first step was done for the case of planar graphs [21]).

Lower bounds. Concerning lower bounds for VERTEX DELETION TO $\mathcal{G}$ under the Exponential Time Hypothesis [27], we are not aware of any lower bound stronger than $2^{o(k)} \cdot n^{\mathcal{O}(1)}$ for *any* minor-closed class $\mathcal{G}$. This lower bound already applies when $\mathcal{F} = \{K_2\}$, i.e., for the VERTEX COVER problem [7, 27].

Abstract

We study complex zeros of the partition function of 2-spin systems, viewed as a multivariate polynomial in terms of the edge interaction parameters and the uniform external field. We obtain new zero-free regions in which all these parameters are complex-valued. Crucially based on the zero-freeness, we are able to extend the existence of correlation decay to these complex regions from real parameters. As a consequence, we obtain an FPTAS for computing the partition function of 2-spin systems on graphs of bounded degree for these parameter settings. We introduce the *contraction* property as a *unified* sufficient condition to devise FPTAS via either Weitz's algorithm or Barvinok's algorithm. Our main technical contribution is a very simple but general approach to extend any *real* parameter of which the 2-spin system exhibits correlation decay to its *complex* neighborhood where the partition function is zero-free and correlation decay still exists. This result formally establishes the inherent connection between two distinct notions of phase transition for 2-spin systems: the existence of correlation decay and the zero-freeness of the partition function via a unified perspective, contraction.

Acknowledgements We want to thank Professor Jin-Yi Cai, the advisor of the first author, for many inspiring discussions and valuable comments on a preliminary version of this paper. Despite his support, he generously declined our invitation for co-authorship. We also want to thank Professor Alex Scott, Dr. Jingcheng Liu and anonymous reviewers for their helpful comments.

1 Introduction

Spin systems originated from statistical physics to model interactions between neighbors on graphs. In this paper, we focus on 2-state spin (2-spin) systems. Such a system is specified by two edge interaction parameters β and γ, and a uniform external field λ. An instance is a graph $G = (V, E)$. A configuration σ is a mapping $\sigma : V \to \{+, -\}$ which assigns one of the two spins $+$ and $-$ to each vertex in V. The weight $w(\sigma)$ of a configuration σ is given by $w(\sigma) = \beta^{m_+(\sigma)}\gamma^{m_-(\sigma)}\lambda^{n_+(\sigma)}$, where $m_+(\sigma)$ denotes the number of $(+, +)$ edges under the configuration σ, $m_-(\sigma)$ denotes the number of $(-, -)$ edges, and $n_+(\sigma)$ denotes the number of vertices assigned to spin $+$. The partition function $Z_G(\beta, \gamma, \lambda)$ of the system parameterized by (β, γ, λ) is defined to be the sum of weights over all configurations, i.e.,

$$Z_G(\beta,\gamma,\lambda) = \sum_{\sigma:V\to\{+,-\}} w(\sigma).$$

It is a sum-of-product computation. If a 2-spin system is restricted to graphs of degree bounded by Δ, we say such a system is Δ-bounded.

In classical statistical mechanics the parameters (β,γ,λ) are usually non-negative real numbers, and such 2-spin systems are divided into the *ferromagnetic* case ($\beta\gamma > 1$) and the *antiferromagnetic* case ($\beta\gamma < 1$). The case $\beta\gamma = 1$ is degenerate. When (β,γ,λ) are non-negative numbers and they are not all zero, the partition function can be viewed as the normalizing factor of the Gibbs distribution, which is the distribution where a configuration σ is drawn with probability $\Pr_{G;\beta,\gamma,\lambda}(\sigma) = \frac{w(\sigma)}{Z_G(\beta,\gamma,\lambda)}$. However, it is meaningful to consider parameters of complex values. By analyzing the location of *complex* zeros of the partition function, the phenomenon of *phase transitions* was discovered by statistical physicists. One of the first and also the best known result is the Lee-Yang theorem [21] for the *Ising model*, a special case of 2-spin systems. This result was later extended to more general models by several people [1, 34, 37, 29, 24]. In this paper, we view the partition function $Z_G(\beta,\gamma,\lambda)$ as a *multivariate* polynomial over these three *complex* parameters (β,γ,λ). We study the zeros of this polynomial and the relation to the approximation of the partition function.

Partition functions encode rich information about the macroscopic properties of 2-spin systems. They are not only of significance in statistical physics, but also are well-studied in computer science. Computing the partition function of 2-spin systems given an input graph G can be viewed as the most basic case of Counting Graph Homomorphisms (#GH) [11, 5, 14, 8] and Counting Constraint Satisfaction Problems (#CSP) [10, 9, 6, 12, 7], which are two very well studied frameworks for counting problems. Many natural combinatorial problems can be formulated as 2-spin systems. For example, when $\beta = \gamma$, such a system is the famous *Ising model.* And when $\beta = 0$ and $\gamma = 1$, $Z_G(0,1,\lambda)$ is the independence polynomial of the graph G (also known as the *hard-core model* in statistical physics); it counts the number of independent sets of the graph G when $\lambda = 1$.

Related work

For exact computation of $Z_G(\beta,\gamma,\lambda)$, the problem is proved to be #P-hard for all complex valued parameters but a few very restricted trivial settings [2, 8, 9]. So the main focus is to approximate $Z_G(\beta,\gamma,\lambda)$. This is an area of active research, and many inspiring algorithms are developed. The pioneering algorithm developed by Jerrum and Sinclair gives a *fully polynomial-time randomized approximation scheme* (FPRAS) for the ferromagnetic Ising model [19]. This FPRAS is based on the *Markov Chain Monte Carlo* (MCMC) method which devises approximation counting algorithms via random sampling. Later, it was extended to general ferromagnetic 2-spin systems [15, 26]. The MCMC method can only handle non-negative parameters as it is based on probabilistic sampling.

The *correlation decay* method developed by Weitz [43] was originally used to devise *deterministic fully polynomial-time approximation schemes* (FPTAS) for the hardcore model up to the uniqueness threshold of the infinite regular tree. It turns out to be a very powerful tool for devising FPTAS for antiferromagnetic 2-spin systems [44, 22, 23, 39]. Combining with hardness results [40, 13], an exact threshold of computational complexity transition of antiferromagnetic 2-spin systems is identified and the only remaining case is at the critical point. On the other hand, for ferromagnetic 2-spin systems, limited results [44, 17] have been obtained via the correlation decay method. Although correlation decay is usually analyzed in 2-spin systems of non-negative parameters, it can be adapted to complex parameters. An FPTAS was obtained for the hard-core model in the Shearer's region (a disc in the complex plane) via correlation decay in [18].

Recently, a new method developed by Barvinok [3], and extended by Patel and Regts [30] is the *Taylor polynomial interpolation* method that turns complex zero-free regions of the partition function into FPTAS of corresponding complex parameters. Suppose that the partition function $Z_G(\beta,\gamma,\lambda)$ has no zero in a complex region containing an easy computing point, e.g., $\lambda = 0$. It turns out that, probably after a change of coordinates, $\log Z_G(\beta,\gamma,\lambda)$ is well approximated in a slightly smaller region by a low degree Taylor polynomials which can be efficiently computed. This method connects the long-standing study of complex zeros to algorithmic studies of the partition function of physical systems. Motivated by this, more recently some complex zero-free regions have been obtained for hard-core models [4, 32], Ising models [27, 31], and general 2-spin systems [16].

Our contribution

In this paper, we obtain new zero-free regions of the partition function of 2-spin systems. Crucially based on the zero-freeness, we are able to extend the existence of correlation decay to these *complex* regions from real parameters. As a consequence, we obtain an FPTAS for computing the partition function of bounded 2-spin systems for these parameter settings. Our result gives the first zero-free regions in which all three parameters (β,γ,λ) are complex-valued and new correlation decay results for bounded ferromagnetic 2-spin systems. Our main technical contribution is a very simple but general approach to extend any real parameter of which the bounded 2-spin system exhibits correlation decay to its complex neighborhood where the partition function is zero-free and correlation decay still exists. We show that for bounded 2-spin systems, the *real contraction*[1] property that ensures correlation decay exists for certain real parameters directly implies the zero-freeness and the existence of correlation decay of corresponding complex neighborhoods.

We formally describe our main result. We use $\boldsymbol{\zeta} \in \mathbb{C}^3$ to denote the parameter vector (β,γ,λ). Since the case $\beta = \gamma = 0$ is trivial, by symmetry we always assume $\gamma \neq 0$.

▶ **Theorem 1.** *Fix $\Delta \in \mathbb{N}$. If $\boldsymbol{\zeta}_0 \in \mathbb{R}^3$ satisfies real contraction for Δ, then there exists a $\delta > 0$ such that for any $\boldsymbol{\zeta} \in \mathbb{C}^3$ where $\|\boldsymbol{\zeta} - \boldsymbol{\zeta}_0\|_\infty < \delta$, we have*

- *$Z_G(\boldsymbol{\zeta}) \neq 0$ for every graph[2] G of degree at most Δ;*
- *the Δ-bounded 2-spin system specified by $\boldsymbol{\zeta}$ exhibits correlation decay.*

As a consequence, there is an FPTAS for computing $Z_G(\boldsymbol{\zeta})$.

This result formally establishes the inherent connection between two distinct notions of phase transition for bounded 2-spin systems: the existence of correlation decay and the zero-freeness of the partition function, via a unified perspective, *contraction*. The connection from the existence of correlation decay of real parameters to the zero-freeness of corresponding complex neighborhoods was already observed for the hard-core model [32] and the Ising model without external field [27]. In this paper, we extend it to general 2-spin systems, and furthermore we establish the connection from the zero-freeness of complex neighborhoods back to the existence of correlation decay of such complex regions.

Now, we give our zero-free regions. We first identify the sets of real parameters of which bounded 2-spin systems exhibit correlation decay.

[1] See Definition 11. In many cases, the existence of correlation decay boils down to this property.

[2] This is true even if G contains some vertices pinned by a *feasible configuration* (Definition 7).

▶ **Definition 2.** *Fix integer $\Delta \geq 3$. We define the following four real correlation decay sets.*

1. $\mathcal{S}_1^\Delta = \{\boldsymbol{\zeta} \in \mathbb{R}^3 \mid \frac{\Delta-2}{\Delta} < \sqrt{\beta\gamma} < \frac{\Delta}{\Delta-2}, \beta, \gamma > 0$ *and* $\lambda \geq 0\}$*,*
2. $\mathcal{S}_2^\Delta = \{\boldsymbol{\zeta} \in \mathbb{R}^3 \mid \beta\gamma < 1, \beta \geq 0, \gamma > 0, \lambda \geq 0,$ *and* $\boldsymbol{\zeta}$ *is up-to-*Δ *unique (Definition 14)*$\}$*,*
3. $\mathcal{S}_3^\Delta = \{\boldsymbol{\zeta} \in \mathbb{R}^3 \mid \beta\gamma > \frac{\Delta}{\Delta-2}, \beta, \gamma > 0$ *and* $0 \leq \lambda < \frac{\gamma}{t^{\Delta-1}[(\Delta-2)\beta\gamma-\Delta]}\}$ *where* $t = \max\{1, \beta\}$*,*
4. *and* $\mathcal{S}_4^\Delta = \{\boldsymbol{\zeta} \in \mathbb{R}^3 \mid \beta\gamma > \frac{\Delta}{\Delta-2}, \beta, \gamma > 0$ *and* $\lambda > \frac{(\Delta-2)\beta\gamma-\Delta}{\beta r^{\Delta-1}}\}$ *where* $r = \min\{1, 1/\gamma\}$*.*

When context is clear, we omit the superscript Δ*.*

The set $\mathcal{S}_1^\Delta$ was given in [44] and $\mathcal{S}_2^\Delta$ was given in [23]. To our best knowledge, $\mathcal{S}_1^\Delta$ and $\mathcal{S}_2^\Delta$ cover all *non-negative* parameters of which *bounded* 2-spin systems are known to exhibit correlation decay. The sets $\mathcal{S}_3^\Delta$ and $\mathcal{S}_4^\Delta$ are obtained in this paper[3]. They give new correlation decay results and hence FPTAS for bounded ferromagnetic 2-spin systems. When $\beta < \gamma$ and λ is sufficiently large, it is known that approximating the partition function of ferromagnetic 2-spin systems over general graphs is #BIS-hard [26]. Our result $\mathcal{S}_4^\Delta$ shows that there is an FPTAS for such a problem when restricted to graphs of bounded degree. When $\beta < 1 < \gamma$, the FPTAS obtained from $\mathcal{S}_3^\Delta$ is covered by [17].

▶ **Theorem 3.** *Fix integer $\Delta \geq 3$. For every $\boldsymbol{\zeta}_0 \in \mathcal{S}_i^\Delta$ $(i \in [4])$, there exists a $\delta > 0$ such that for any $\boldsymbol{\zeta} \in \mathbb{C}^3$ where $\|\boldsymbol{\zeta} - \boldsymbol{\zeta}_0\|_\infty < \delta$, we have*

- $Z_G(\boldsymbol{\zeta}) \neq 0$ *for every graph G of degree at most Δ; (G may contain a feasible configuration.)*
- *the Δ-bounded 2-spin system specified by $\boldsymbol{\zeta}$ exhibits correlation decay.*

Then via either Weitz's algorithm or Barvinok's algorithm, there is an FPTAS for computing the partition function $Z_G(\boldsymbol{\zeta})$.

▶ Remark 4. The choice of δ does not depend on the size of the graph, only on Δ and $\boldsymbol{\zeta}_0$.

Organization

This paper is organized as follows. In Section 2, we briefly describe Weitz's algorithm [43]. We introduce real contraction as a sufficient condition for the existence of correlation decay of real parameters, and we show that sets $\mathcal{S}_i^\Delta (i \in [4])$ satisfy it. In Section 3, we briefly describe Barvinok's algorithm [3]. We introduce complex contraction as a generalization of real contraction, and we show that it gives a unified sufficient condition for both the zero-freeness of the partition function and the existence of correlation decay of complex parameters. Finally, in Section 4, we prove our main result that real contraction implies complex contraction. This finishes the proof of Theorem 3. We use the following diagram (Figure 1) to summarize our approach to establish the connection between correlation decay and zero-freeness. We expect it to be further explored for other models.

Independent work

After a preliminary version [36] of this manuscript was posted, we learned that based on similar ideas, Liu simplified the proofs of [32] and [27], and generalized them to antiferromagnetic Ising models ($\beta = \gamma < 1$) in chapter 3 of his Ph.D. thesis [25], where similar zero-freeness results (a complex neighborhood of $\mathcal{S}_2^\Delta$ restricted to $\beta = \gamma$) were obtained. We mention that by using the unique analytic continuation and the inverse function theorem, our main technical result (Theorem 24) is generic; it does not rely on a particularly chosen potential function. Thus, in our approach we can work with *any* existing potential function based

[3] Since we do *not* assume $\beta \leqslant \gamma$ or $\beta \geqslant \gamma$, $\mathcal{S}_3^\Delta$ and $\mathcal{S}_4^\Delta$ are essentially the same by swapping β and γ and replacing λ with $1/\lambda$. However, if one restrict to $\beta \leqslant \gamma$, then $\mathcal{S}_3^\Delta$ is no longer the same as $\mathcal{S}_4^\Delta$.

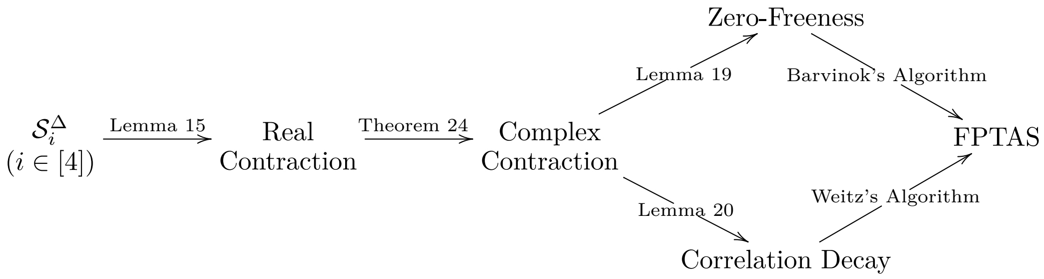

Figure 1 The structure of our approach.

argument for correlation decay even if the potential function does not have an explicit expression, for instance, the one used in [23] when $\beta \neq \gamma$. Furthermore, we mention also that based on the zero-freeness, we obtain new correlation decay results for complex parameters (Lemma 20). Note that Barvinok's algorithm requires an entire region in which the partition function is zero-free and there is an easy computing point in this region. However, our correlation decay results show that one can always devise an FPTAS for these parameter settings via Weitz's algorithm, even if Barvinok's algorithm fails.

2 Weitz's Algorithm

In this section, we describe Weitz's algorithm and introduce real contraction. We first consider positive parameters $\boldsymbol{\zeta} \in \mathbb{R}_+^3$. An obvious but important fact about $\boldsymbol{\zeta}$ being positive is that $Z_G(\boldsymbol{\zeta}) \neq 0$ for any graph G. This is true even if G contains arbitrary number of vertices pinned to spin $+$ or $-$. Then, the partition function can be viewed as the normalizing factor of the Gibbs distribution.

2.1 Notations and definitions

Let $\boldsymbol{\zeta} \in \mathbb{R}_+^3$. We use $p_v(\boldsymbol{\zeta})$ to denote the marginal probability of v being assigned to spin $+$ in the Gibbs distribution, i.e., $p_v(\boldsymbol{\zeta}) = \frac{Z^+_{G,v}(\boldsymbol{\zeta})}{Z_G(\boldsymbol{\zeta})}$, where $Z^+_{G,v}(\boldsymbol{\zeta})$ is the contribution to $Z_G(\boldsymbol{\zeta})$ over all configurations with v being assigned to spin $+$. We know that $p_v(\boldsymbol{\zeta})$ is well-defined since $Z_G(\boldsymbol{\zeta}) \neq 0$. (Later, we will extend the definition of $p_v(\boldsymbol{\zeta})$ to complex parameters $\boldsymbol{\zeta}$.)

Let $\sigma_\Lambda \in \{0,1\}^\Lambda$ be a configuration of some subset $\Lambda \subseteq V$. We allow Λ to be the empty set. We call vertices in Λ *pinned* and other vertices *free*. We use $p_v^{\sigma_\Lambda}(\boldsymbol{\zeta})$ to denote the marginal probability of a free vertex v ($v \notin \Lambda$) being assigned to spin $+$ conditioning on the configuration σ_Λ of Λ, i.e., $p_v^{\sigma_\Lambda}(\boldsymbol{\zeta}) = \frac{Z^{\sigma_\Lambda,+}_{G,v}(\boldsymbol{\zeta})}{Z^{\sigma_\Lambda}_G(\boldsymbol{\zeta})}$, where $Z^{\sigma_\Lambda}_G(\boldsymbol{\zeta})$ is the weight over all configurations where vertices in Λ are pinned by the configuration σ_Λ, and $Z^{\sigma_\Lambda,+}_{G,v}(\boldsymbol{\zeta})$ is the contribution to $Z^{\sigma_\Lambda}_G(\boldsymbol{\zeta})$ with v being assigned to spin $+$. Correspondingly, we can define $Z^{\sigma_\Lambda,-}_{G,v}(\boldsymbol{\zeta})$. Let $R^{\sigma_\Lambda}_{G,v}(\boldsymbol{\zeta}) := \frac{Z^{\sigma_\Lambda,+}_{G,v}(\boldsymbol{\zeta})}{Z^{\sigma_\Lambda,-}_{G,v}(\boldsymbol{\zeta})} = \frac{p_v^{\sigma_\Lambda}(\boldsymbol{\zeta})}{1-p_v^{\sigma_\Lambda}(\boldsymbol{\zeta})}$ be the ratio between the two probabilities that the free vertex v is assigned to spin $+$ and $-$, while imposing some condition σ_Λ. Since $Z_G(\boldsymbol{\zeta}) \neq 0$ for any graph G with arbitrary number of pinned vertices, both $p_v^{\sigma_\Lambda}(\boldsymbol{\zeta})$ and $R^{\sigma_\Lambda}_{G,v}(\boldsymbol{\zeta})$ are well-defined. When context is clear, we write $p_v(\boldsymbol{\zeta})$, $p_v^{\sigma_\Lambda}(\boldsymbol{\zeta})$ and $R^{\sigma_\Lambda}_{G,v}(\boldsymbol{\zeta})$ as p_v, $p_v^{\sigma_\Lambda}$ and $R^{\sigma_\Lambda}_{G,v}$ for convenience.

Since computing the partition function of 2-spin systems is self-reducible, if one can compute p_v for any vertex v, then the partition function can be computed via telescoping [20]. The goal of Weitz's algorithm is to estimate $p_v^{\sigma_\Lambda}$, which is equivalent to estimating $R_{G,v}^{\sigma_\Lambda}$. For the case that the graph is a tree T, $R_{T,v}^{\sigma_\Lambda}$ can be computed by recursion. Suppose that a free vertex v has d children, and s_1 of them are pinned to $+$, s_2 are pinned to $-$, and k are free ($s_1 + s_2 + k = d$). We denote these k free vertices by $v_i (i \in [k])$ and let T_i be the corresponding subtree rooted at v_i. We use σ_Λ^i to denote the configuration σ_Λ restricted to T_i. Since all subtrees are independent, it is easy to get the following recurrence relation,

$$R_{T,v}^{\sigma_\Lambda} = \frac{Z_{T,v}^{\sigma_\Lambda,+}(\boldsymbol{\zeta})}{Z_{T,v}^{\sigma_\Lambda,-}(\boldsymbol{\zeta})} = \frac{\lambda^{1+s_1}\beta^{s_1}\prod_{i=1}^{k}\left(\beta Z_{T_i,v_i}^{\sigma_\Lambda^i,+}(\boldsymbol{\zeta}) + Z_{T_i,v_i}^{\sigma_\Lambda^i,-}(\boldsymbol{\zeta})\right)}{\lambda^{s_1}\gamma^{s_2}\prod_{i=1}^{k}\left(Z_{T_i,v_i}^{\sigma_\Lambda^i,+}(\boldsymbol{\zeta}) + \gamma Z_{T_i,v_i}^{\sigma_\Lambda^i,-}(\boldsymbol{\zeta})\right)} = \frac{\lambda\beta^{s_1}}{\gamma^{s_2}}\prod_{i=1}^{k}\left(\frac{\beta R_{T_i,v_i}^{\sigma_\Lambda^i} + 1}{R_{T_i,v_i}^{\sigma_\Lambda^i} + \gamma}\right).$$

▶ **Definition 5** (Recursion function). *Let* $\mathbf{s} = (s_1, s_2, k) \in \mathbb{N}^3$ *(including 0). A recursion function* $F_{\mathbf{s}}$ *for 2-spin systems is defined to be*

$$F_{\mathbf{s}}(\boldsymbol{\zeta}, \mathbf{x}) := \lambda\beta^{s_1}\gamma^{-s_2}\prod_{i=1}^{k}\left(\frac{\beta x_i + 1}{x_i + \gamma}\right),$$

where $\boldsymbol{\zeta} = (\beta, \gamma, \lambda) \in \mathbb{C} \times (\mathbb{C}\backslash\{0\}) \times \mathbb{C}$ *and* $\mathbf{x} = (x_1, \ldots, x_k) \in (\mathbb{C}\backslash\{-\gamma\})^k$*. We define* $F_{\boldsymbol{\zeta},\mathbf{s}}(\mathbf{x}) := F_{\mathbf{s}}(\boldsymbol{\zeta}, \mathbf{x})$ *for fixed* $\boldsymbol{\zeta}$ *with* $\gamma \neq 0$*, and* $F_{\mathbf{x},\mathbf{s}}(\boldsymbol{\zeta}) := F_{\mathbf{s}}(\boldsymbol{\zeta}, \mathbf{x})$ *for fixed* $\mathbf{x}$*.*

▶ Remark 6. Every recursion function is analytic on its domain.

For a general graph G, Weitz reduced computing $R_{G,v}^{\sigma_\Lambda}$ to that in a tree T, called the self-avoiding walk (SAW) tree, and Weitz's theorem [43] states that $R_{G,v}^{\sigma_\Lambda} = R_{T,v}^{\sigma_\Lambda}$. (Please see [43], [17] or the full paper for more details.) We want to generalize Weitz's theorem to complex parameters $\boldsymbol{\zeta} \in \mathbb{C}^3$. First, we need to make sure that $R_{G,v}^{\sigma_\Lambda}$ and $p_v^{\sigma_\Lambda}$ are well-defined for any vertex $v \notin \Lambda$. This requires that $Z_G^{\sigma_\Lambda}(\boldsymbol{\zeta}) \neq 0$ for any graph G and any configuration σ_Λ. Now, $p_v^{\sigma_\Lambda}$ no longer has a probabilistic meaning. It is just a ratio of two complex numbers. However, one can easily observe that for some special parameters, there are trivial configurations such that $Z_{G,v}^{\sigma_\Lambda}(\boldsymbol{\zeta}) = 0$. We will rule these cases out as they are *infeasible.*

▶ **Definition 7** (Feasible configuration). *Let* $\boldsymbol{\zeta} \in \mathbb{C}^3$*. Given a graph* $G = (V, E)$ *of the 2-spin system specified by* $\boldsymbol{\zeta}$*, a configuration* σ_Λ *on some vertices* $\Lambda \subseteq V$ *is feasible if*

- σ_Λ *does not assign any vertex in* G *to spin* $+$ *when* $\lambda = 0$*, and*
- σ_Λ *does not assign any two adjacent vertices in* G *both to spin* $+$ *when* $\beta = 0$*.*

▶ Remark 8. Let σ_Λ be a feasible configuration. If we further pin one vertex $v \notin \Lambda$ to spin $-$, and get the configuration $\sigma_{\Lambda'}$ on $\Lambda' = \Lambda \cup \{v\}$, then $\sigma_{\Lambda'}$ is still a feasible configuration. Thus, given $\boldsymbol{\zeta} \in \mathbb{C}^3$, if $Z_G^{\sigma_\Lambda}(\boldsymbol{\zeta}) \neq 0$ for any graph G and any arbitrary feasible configuration σ_Λ on G, then both $p_v^{\sigma_\Lambda}$ and $R_{G,v}^{\sigma_\Lambda}$ are well-defined.

Given $R_{G,v}^{\sigma_\Lambda}$ is well-defined for some $\boldsymbol{\zeta} \in \mathbb{C}^3$, we can still compute it by recursion via SAW tree. We first consider the case that $\lambda \neq 0$. Let σ_Λ be a feasible configuration. It is easy to verify that the corresponding configuration on the SAW tree is also feasible and Weitz's theorem still holds. For the case that $\lambda = 0$, it is obvious that $R_{G,v}^{\sigma_\Lambda} \equiv 0$ for any graph G, any free vertex v and any feasible configuration σ_Λ. This is equal to the value of recursion functions $F_{\mathbf{s}}(\boldsymbol{\zeta}, \mathbf{x})$ at $\lambda = 0$. We agree that $R_{G,v}^{\sigma_\Lambda}$ can be computed by recursion functions when $\lambda = 0$, although Weitz's theorem does not hold for this case. For the case that $\beta = 0$, we have $R_{G,v}^{\sigma_\Lambda} = 0$ if one of the children of v is pinned to $+$. Then, we may view v as it is pinned to $-$. Thus, for $\beta = 0$, we only consider recursion functions $F_{\mathbf{s}}$ where $s_1 = 0$.

$$\begin{tikzcd}
\mathbf{y} \arrow[r, shift left, "\varphi"] \arrow[d, "F"] & \mathbf{x} \arrow[l, shift left, "\varphi^{-1}"] \arrow[d, "F^{\varphi}"] \\
F(\mathbf{y}) \arrow[r, shift left, "\varphi"] & F^{\varphi}(\mathbf{x}) \arrow[l, shift left, "\varphi^{-1}"]
\end{tikzcd}$$

Figure 2 Commutative diagram between F and F^{φ}.

2.2 Correlation decay and real contraction

The SAW tree may be exponentially large in size of G. In order to get a polynomial time approximation algorithm, we may run the tree recursion at logarithmic depth and hence in polynomial time, and plug in some arbitrary values at the truncated boundary. We have the following notion of *strong spatial mixing* (SSM) to bound the error caused by arbitrary guesses. It was originally introduced for non-negative parameters. Here, we extend it to complex parameters.

▶ **Definition 9** (Strong spatial mixing). *A 2-spin system specified by $\boldsymbol{\zeta} \in \mathbb{C}^3$ on a family $\mathcal{G}$ of graphs is said to exhibit strong spatial mixing if for any graph $G = (V, E) \in \mathcal{G}$, any $v \in V$, and any feasible configurations $\sigma_{\Lambda_1} \in \{0,1\}^{\Lambda_1}$ and $\tau_{\Lambda_2} \in \{0,1\}^{\Lambda_2}$ where $v \notin \Lambda_1 \cup \Lambda_2$, we have*

1. $Z_G^{\sigma_{\Lambda_1}}(\boldsymbol{\zeta}) \neq 0$ *and* $Z_G^{\tau_{\Lambda_2}}(\boldsymbol{\zeta}) \neq 0$*, and*
2. $\left|p_v^{\sigma_{\Lambda_1}} - p_v^{\tau_{\Lambda_2}}\right| \leq \exp(-\Omega(\mathrm{dist}(v, S)))$.

Here, $S \subseteq \Lambda_1 \cup \Lambda_2$ is the subset on which σ_{Λ_1} and τ_{Λ_2} differ (If a vertex v is free in one configuration but pinned in the other, we say that these two configurations differ at v), and $\mathrm{dist}_G(v, S)$ is the shortest distance from v to any vertex in S.

▶ Remark 10. When $\boldsymbol{\zeta} \in \mathbb{R}_+^3$, condition 1 is always satisfied. Condition 2 is a stronger form of SSM of real parameters (see Definition 5 of [23]). For real values, by monotonicity one need to consider only the case that $\Lambda_1 = \Lambda_2$ (the two configurations are on the same set of vertices). Here, we need to consider the case that $\Lambda_1 \neq \Lambda_2$. This is *necessary* to extend Weitz's algorithm to complex parameters.

In statistical physics, SSM implies correlation decay. If SSM holds, then the error caused by arbitrary boundary guesses at logarithmic depth of the SAW tree is polynomially small. Hence, Weitz's algorithm gives an FPTAS. A main technique that has been widely used to establish SSM is the *potential method* [33, 22, 23, 38, 17]. Instead of bounding the rate of decay of recursion functions directly, we use a potential function $\varphi(x)$ to map the original recursion to a new domain (See Figure 2 for the commutative diagram).

Let $F_{\mathbf{s}}(\boldsymbol{\zeta}, \mathbf{y})$ be a recursion function ($\mathbf{s} = (s_1, s_2, k) \in \mathbb{N}^3$). We use $F_{\mathbf{s}}^{\varphi}(\boldsymbol{\zeta}, \mathbf{x})$ to denote the composition $\varphi(F_{\mathbf{s}}(\boldsymbol{\zeta}, \boldsymbol{\varphi}^{-1}(\mathbf{x})))$ where $\mathbf{y} = \boldsymbol{\varphi}^{-1}(\mathbf{x})$ denotes the vector $(\varphi^{-1}(x_1), \ldots, \varphi^{-1}(x_k))$. Correspondingly, we define $F_{\boldsymbol{\zeta},\mathbf{s}}^{\varphi}(\mathbf{x})$ for fixed $\boldsymbol{\zeta}$, and $F_{\mathbf{x},\mathbf{s}}^{\varphi}(\boldsymbol{\zeta})$ for fixed $\mathbf{x}$. We will specify the domain on which $F_{\mathbf{s}}^{\varphi}$ is well-defined per each φ that will be used. For positive $\boldsymbol{\zeta}$, a sufficient condition for the bounded 2-spin system of $\boldsymbol{\zeta}$ exhibiting SSM is that there exists a "good" potential function φ such that $F_{\boldsymbol{\zeta},\mathbf{s}}^{\varphi}$ satisfies the following contraction property.

▶ **Definition 11** (Real contraction). *Fix $\Delta \in \mathbb{N}$. We say that $\boldsymbol{\zeta} \in \mathbb{R}^3$ satisfies real contraction for Δ if there is a real compact interval $J \subseteq \mathbb{R}$ where $\lambda \in J$, $-\gamma \notin J$ and $-1 \notin J$, and a real analytic function $\varphi : J \to I$ where $\varphi'(x) \neq 0$ for all $x \in J$, such that*

1. *$F_{\boldsymbol{\zeta},\mathbf{s}}(J^k) \subseteq J$ for every $\mathbf{s}$ with $\|\mathbf{s}\|_1 \leq \Delta - 1$ and $-1 \notin F_{\boldsymbol{\zeta},\mathbf{s}}(J^k)$ for every $\mathbf{s}$ with $\|\mathbf{s}\|_1 = \Delta$;*
2. *there exists $\eta > 0$ s.t. $\left\|\nabla F^{\varphi}_{\boldsymbol{\zeta},\mathbf{s}}(\mathbf{x})\right\|_1 \leq 1 - \eta$ for every $\mathbf{s}$ with $\|\mathbf{s}\|_1 \leq \Delta - 1$ and all $\mathbf{x} \in I^k$.*

We say φ defined on J is a good potential function for $\boldsymbol{\zeta}$.

▶ Remark 12. Since φ is analytic and $\varphi'(x) \neq 0$ for all $x \in J$, the function φ is invertible and the inverse $\varphi^{-1} : I \to J$ is also analytic by the inverse function theorem (Theorem 22). Also for every $\mathbf{s}$ with $\|\mathbf{s}\|_1 \leq \Delta - 1$, since $F_{\boldsymbol{\zeta},\mathbf{s}}(J^k) \subseteq J$ and $-\gamma \notin J$, the function $F_{\boldsymbol{\zeta},\mathbf{s}}(\mathbf{x})$ is analytic on J^k. Thus, $F^{\varphi}_{\boldsymbol{\zeta},\mathbf{s}}(\mathbf{x})$ is well-defined and analytic on I^k, and then $\nabla F^{\varphi}_{\boldsymbol{\zeta},\mathbf{s}}(\mathbf{x})$ is well-defined on I^k. Note that I is also a real compact interval since J is a real compact interval and φ is a real analytic function.

Since $-1 \notin J$, $F_{\boldsymbol{\zeta},\mathbf{s}}(J^k) \subseteq J$ implies that $-1 \notin F_{\boldsymbol{\zeta},\mathbf{s}}(J^k)$. Thus, real contraction implies that $-1 \notin F_{\boldsymbol{\zeta},\mathbf{s}}(J^k)$ for all $\|\mathbf{s}\|_1 \leq \Delta$. The reason why we require $F_{\boldsymbol{\zeta},\mathbf{s}}(J^k) \subseteq J$ for $\|\mathbf{s}\|_1 \leq \Delta - 1$, but only require $-1 \notin F_{\boldsymbol{\zeta},\mathbf{s}}(J^k)$ for $\|\mathbf{s}\|_1 = \Delta$ is that in a tree of degree at most Δ, only the root node may have Δ many children, while other nodes have at most $\Delta - 1$ many children.

▶ **Lemma 13.** *If $\boldsymbol{\zeta} \in \mathbb{R}^3_+$ satisfies real contraction for Δ, then the Δ-bounded 2-spin system of $\boldsymbol{\zeta}$ exhibits SSM. Thus there is an FPTAS for computing the partition function $Z_G(\boldsymbol{\zeta})$.*

Proof. The proof directly follows from the argument of the potential method, see [23, 17]. The FPTAS follows from Weitz's algorithm. ◀

Now, we give the sets of non-negative parameters that satisfy real contraction.

▶ **Definition 14** (Uniqueness condition [23]). *Let $\boldsymbol{\zeta} \in \mathbb{R}^3$ be antiferromagnetic ($\beta\gamma < 1$) with $\beta \geq 0$, $\gamma > 0$ and $\lambda \geq 0$, and $f_d(x) = \lambda \left(\frac{\beta x + 1}{x + \gamma}\right)^d$. We say $\boldsymbol{\zeta}$ is up-to-Δ unique, if $\lambda = 0$ or $\lambda > 0$ and there exists a constant $0 < c < 1$ such that for every integer $1 \leq d \leq \Delta - 1$,*

$$|f'_d(\hat{x}_d)| = \frac{d(1 - \beta\gamma)\hat{x}_d}{(\beta\hat{x}_d + 1)(\hat{x}_d + \gamma)} \leq c,$$

where $\hat{x}_d$ is the unique positive fixed point of the function $f_d(x)$.

Let $\mathcal{S}^{\Delta}_i (i \in [4])$ be the correlation decay sets defined in Definition 2. The set $\mathcal{S}^{\Delta}_1$ was given in [44] and $\mathcal{S}^{\Delta}_2$ was given in [23]. Directly following their proofs, it is easy to verify that both sets satisfy real contraction . The sets $\mathcal{S}^{\Delta}_3$ and $\mathcal{S}^{\Delta}_4$ are obtained in this paper, and we show that they also satisfy real contraction.

▶ **Lemma 15.** *Fix $\Delta \geq 3$. For every $\boldsymbol{\zeta} \in \mathcal{S}^{\Delta}_i (i \in [4])$, it satisfies real contraction for Δ.*

Proof. We only give a proof for sets $\mathcal{S}^{\Delta}_3$ and $\mathcal{S}^{\Delta}_4$. For a proof of sets $\mathcal{S}^{\Delta}_1$ and $\mathcal{S}^{\Delta}_2$, please refer to the full paper. The case that $\lambda = 0$ is easy to check. We only consider that $\lambda \neq 0$.

Since $\beta\gamma > \frac{\Delta}{\Delta - 2} > 1$, we have $1/\gamma < \beta$. We pick the interval $J = [\lambda r^{\Delta-1}, \lambda t^{\Delta-1}]$ where $r = \min\{1, 1/\gamma\}$ and $t = \max\{1, \beta\}$, and the potential function $\varphi = \log(x)$. Clearly, φ is analytic on J and $\varphi'(x) \neq 0$ for all $x \in J$. Also, we know that $\lambda \in J$, $-\gamma \notin J$ and $-1 \notin J$, and $-1 \notin F_{\boldsymbol{\zeta},\mathbf{s}}(J^k)$ for every $\|\mathbf{s}\|_1 = \Delta$. Since $\beta > 0$ and $\gamma > 0$, for all $x > 0$,

$$r \leq \min\{\beta, 1/\gamma\} \leq \frac{\beta x + 1}{x + \gamma} \leq \max\{\beta, 1/\gamma\} \leq t.$$

Thus, for all $\mathbf{x} \in J^k$,

$$F_{\boldsymbol{\zeta},\mathbf{s}}(\mathbf{x}) = \lambda\beta^{s_1}\gamma^{-s_2}\prod_{i=1}^{k}\left(\frac{\beta x_i+1}{x_i+\gamma}\right) \in \left[\lambda r^{\|\mathbf{s}\|_1}, \lambda t^{\|\mathbf{s}\|_1}\right] \subseteq \left[\lambda r^{\Delta-1}, \lambda t^{\Delta-1}\right].$$

Hence, $F_{\boldsymbol{\zeta},\mathbf{s}}(J^k) \subseteq J$ for every $\|\mathbf{s}\|_1 \leq \Delta - 1$. Condition 1 of real contraction is satisfied.

Let $I = \varphi(J)$. Consider the gradient $\nabla F^{\varphi}_{\boldsymbol{\zeta},\mathbf{s}}(\mathbf{x})$ for every $\|\mathbf{s}\|_1 \leq \Delta - 1$ and all $\mathbf{x} \in I^k$. Note that $F^{\varphi}_{\boldsymbol{\zeta},\mathbf{s}}(\mathbf{x}) = \log\lambda + s_1\log\beta - s_2\log\gamma + \sum_{i=1}^{k}\log\left(\frac{\beta e^{x_i}+1}{e^{x_i}+\gamma}\right)$, and $e^{x_i} = \varphi^{-1}(x_i) \in J$ and $e^{-x_i} \in [\frac{1}{\lambda t^{\Delta-1}}, \frac{1}{\lambda r^{\Delta-1}}]$ when $x_i \in I$.

If $\boldsymbol{\zeta} \in \mathcal{S}_3^{\Delta}$, then $(\Delta-2)\beta\gamma - \Delta < \frac{\gamma}{\lambda t^{\Delta-1}}$. Thus,

$$\left|\frac{\partial F^{\varphi}_{\boldsymbol{\zeta},\mathbf{s}}}{\partial x_i}\right| = \frac{\beta\gamma-1}{\beta e^{x_i}+\gamma e^{-x_i}+1+\beta\gamma} \leq \frac{\beta\gamma-1}{\frac{\gamma}{\lambda t^{\Delta-1}}+1+\beta\gamma} < \frac{\beta\gamma-1}{(\Delta-2)\beta\gamma-\Delta+1+\beta\gamma} = \frac{1}{\Delta-1}.$$

Otherwise, $\boldsymbol{\zeta} \in \mathcal{S}_4^{\Delta}$ and then $\lambda\beta r^{\Delta-1} > (\Delta-2)\beta\gamma - \Delta$. Thus,

$$\left|\frac{\partial F^{\varphi}_{\boldsymbol{\zeta},\mathbf{s}}}{\partial x_i}\right| = \frac{\beta\gamma-1}{\beta e^{x_i}+\gamma e^{-x_i}+1+\beta\gamma} \leq \frac{\beta\gamma-1}{\beta\lambda r^{\Delta-1}+1+\beta\gamma} < \frac{\beta\gamma-1}{(\Delta-2)\beta\gamma-\Delta+1+\beta\gamma} = \frac{1}{\Delta-1}.$$

Thus, in both cases, there exists some $\eta > 0$ such that $\left\|\nabla F^{\varphi}_{\boldsymbol{\zeta},\mathbf{s}}(\mathbf{x})\right\|_1 \leq 1 - \eta$ for every $\|\mathbf{s}\|_1 \leq \Delta - 1$ and all $\mathbf{x} \in I^k$. Condition 2 of real contraction is satisfied. ◀

In order to generalize the correlation decay technique to complex parameters, we need to ensure that the partition function is zero-free. Now, let us first take a detour to Barvinok's algorithm which crucially relies on the zero-free regions of the partition function. After we carve out our new zero-free regions, we will come back to the existence of correlation decay of complex parameters.

3 Barvinok's Algorithm

In this section, we describe Barvinok's algorithm and introduce complex contraction. Let $I = [0, t]$ be a closed real interval. We define the δ-strip of I to be $\{z \in \mathbb{C} \mid |z - z_0| < \delta, z_0 \in I\}$, denoted by I_δ. It is a complex neighborhood of I. Suppose a graph polynomial $P(z) = \sum_{i=0}^{n} a_i z^i$ of degree n is zero-free in I_δ. Barvinok's method [3] roughly states that for any $z \in I_\delta$, $P(z)$ can be $(1 \pm \varepsilon)$-approximated using coefficients $a_0, \ldots, a_k$ for some $k = O(e^{\Theta(1/\delta)}\log(n/\varepsilon))$, via truncating the Taylor expansion of the logarithm of the polynomial. For the partition function of 2-spin systems, these coefficients can be computed in polynomial time [30, 28]. For the purpose of obtaining an FPTAS, we will view the partition function as a univariate polynomial $Z_{G;\beta,\gamma}(\lambda)$ in λ and fix β and γ. The following result is known.

▶ **Lemma 16.** *Fix $\beta, \gamma \in \mathbb{C}$ and $\Delta \in \mathbb{N}$. Let G be a graph of degree at most Δ. If $Z_{G;\beta,\gamma}(\lambda) \neq 0$ lies in a δ-strip I_δ of $I = [0, t]$, then there is an FPTAS for computing $Z_{G;\beta,\gamma}(\lambda)$ for $\lambda \in I_\delta$.*

Proof. This lemma is a generalization of Lemma 4 in [16], where β and γ are both real. The generalization to complex valued parameters directly follows from the argument in [28]. ◀

3.1 Zero-freeness and complex contraction

With Lemma 16 in hand, the main effort is to obtain zero-free regions of the partition function. For this purpose, we will still view $Z_G(\boldsymbol{\zeta})$ as a multivariate polynomial in (β, γ, λ). A main and widely used approach to obtain zero-free regions is the *recursion* method [41, 35, 4, 32, 27]. This method is related to the correlation decay method.

Assuming $Z^-_{G,v}(\boldsymbol{\zeta}) \neq 0$ for some vertex v, then $Z_G(\boldsymbol{\zeta}) \neq 0$ is equivalent to $R_{G,v} = \frac{Z^+_{G,v}(\boldsymbol{\zeta})}{Z^-_{G,v}(\boldsymbol{\zeta})} \neq -1$. As pointed above, the ratio $R_{G,v}$ can be computed by recursion via the SAW tree in which v is the root. Roughly speaking, the key idea of the recursion method is to construct a *contraction* region $Q \subseteq \mathbb{C}$ where $\lambda \in Q$ and $-1 \notin Q$ such that for all recursion functions $F_{\boldsymbol{\zeta},\mathbf{s}}$ with $\|\mathbf{s}\|_1 \leq \Delta - 1$, $F_{\boldsymbol{\zeta},\mathbf{s}}(Q^k) \subseteq Q$, and for all $F_{\boldsymbol{\zeta},\mathbf{s}}$ with $\|\mathbf{s}\|_1 = \Delta$, $-1 \notin F_{\boldsymbol{\zeta},\mathbf{s}}(Q^k)$. This condition guarantees that with the initial value $R_{G,v_\ell} = \lambda$ where v_ℓ is a free leaf node in the SAW tree of which the degree is bounded by Δ, the recursion will never achieve -1. Hence, we have $Z_G(\boldsymbol{\zeta}) \neq 0$ by induction. Again, we may use a potential function $\varphi : Q \to P$ to change the domain, and we prove $F^{\varphi}_{\boldsymbol{\zeta},\mathbf{s}}(P^k) \subseteq P$.

Now, we introduce the following *complex* contraction property as a generalization of real contraction. This property gives a sufficient condition for the zero-freeness of the partition function.

▶ **Definition 17** (Complex contraction). *Fix $\Delta \in \mathbb{N}$. We say that $\boldsymbol{\zeta} \in \mathbb{C}^3$ satisfies complex contraction for Δ if there is a closed and bounded complex region $Q \subseteq \mathbb{C}$ where $\lambda \in Q$, $-\gamma \notin Q$ and $-1 \notin Q$, and an analytic and invertible function $\varphi : Q \to P$ where the inverse $\varphi^{-1} : P \to Q$ is also analytic and P is convex, such that*

1. *$F_{\boldsymbol{\zeta},\mathbf{s}}(Q^k) \subseteq Q$ for every $\mathbf{s}$ with $\|\mathbf{s}\|_1 \leq \Delta - 1$ and $-1 \notin F_{\boldsymbol{\zeta},\mathbf{s}}(Q^k)$ for every $\mathbf{s}$ with $\|\mathbf{s}\|_1 = \Delta$;*
2. *there exists $\eta > 0$ s.t. $\left\|\nabla F^{\varphi}_{\boldsymbol{\zeta},\mathbf{s}}(\mathbf{x})\right\|_1 \leq 1 - \eta$ for every $\mathbf{s}$ with $\|\mathbf{s}\|_1 \leq \Delta - 1$ and all $\mathbf{x} \in P^k$.*

▶ Remark 18. Similar to the remark of Definition 11, the function $F^{\varphi}_{\boldsymbol{\zeta},\mathbf{s}}(\mathbf{x})$ is well-defined and analytic on P^k. Here, we directly assume that the inverse φ^{-1} is analytic instead of $\varphi'(x) \neq 0$ for the sake of simplicity of our proof.

▶ **Lemma 19.** *If $\boldsymbol{\zeta} \in \mathbb{C}^3$ satisfies complex contraction for Δ, then $Z^{\sigma_\Lambda}_G(\boldsymbol{\zeta}) \neq 0$ for any graph G of degree at most Δ and any feasible configuration σ_Λ.*

Please refer to the full paper for a proof of Lemma 19. Such a proof only uses condition 1 of complex contraction. However, condition 2 combining with the zero-freeness result of Lemma 19 gives a sufficient condition for bounded 2-spin systems of *complex* parameters exhibiting correlation decay. This is a generalization of Lemma 13. Also, please refer to the full paper for a proof.

▶ **Lemma 20.** *If $\boldsymbol{\zeta} \in \mathbb{C}^3$ satisfies complex contraction for Δ, then the Δ-bounded 2-spin system of $\boldsymbol{\zeta}$ exhibits SSM. Thus, there is an FPTAS for computing $Z_G(\boldsymbol{\zeta})$ via Weitz's algorithm.*

4 From Real Contraction to Complex Contraction

In this section, we prove our main result. We first give some preliminaries in complex analysis. The main tools are the unique analytic continuation and the inverse function theorem. Here, we slightly modify the statements to fit for our settings. Please refer to [42] for the proofs.

▶ **Theorem 21** (Unique analytic continuation). *Let $f(x)$ be a (real) analytic function defined on a compact real interval $I \subseteq \mathbb{R}$. Then, there exists a complex neighborhood $\widetilde{I} \subseteq \mathbb{C}$ of I, and a (complex) analytic function $\widetilde{f}(x)$ defined on $\widetilde{I}$ such that $\widetilde{f}(x) \equiv f(x)$ for all $x \in I$. Moreover, if there is another (complex) analytic function $\widetilde{g}(x)$ also defined on $\widetilde{I}$ such that $\widetilde{g}(x) \equiv \widetilde{f}(x)$ for all $x \in I$ and the measure $\mathfrak{m}(I) \neq 0$, then $\widetilde{g}(x) \equiv \widetilde{f}(x)$ for all $x \in \widetilde{I}$. We call $\widetilde{f}(x)$ the unique analytic continuation of $f(x)$ on $\widetilde{I}$.*

▶ **Theorem 22** (Inverse function theorem). *For a real analytic function φ defined on a real interval $J \subseteq \mathbb{R}$, if $\varphi'(x) \neq 0$ for all $x \in J$, then φ is invertible on J and the inverse φ^{-1} is also analytic on $\varphi(J)$. For a complex analytic function ψ defined on $U \subseteq \mathbb{C}$, if $\psi'(z) \neq 0$ for some $z \in U$, then there exists a complex neighborhood D of z such that ψ is invertible on D and the inverse is also analytic.*

Combining the above theorems, we have the following result.

▶ **Lemma 23.** *Let $\varphi : J \to I$ be a real analytic function, and $\varphi'(x) \neq 0$ for all $x \in J$ where J and I are real compact intervals. Then, there exists an analytic continuation $\widetilde{\varphi}$ on a complex neighborhood $\widetilde{J}$ of J such that $\widetilde{\varphi}$ is invertible on $\widetilde{J}$ and the inverse $\widetilde{\varphi}^{-1}$ is also analytic.*

Proof. If $\mathfrak{m}(J) = 0$, i.e., $J = \{x\}$, then by Theorem 21 there exists an analytic continuation $\widetilde{\varphi}$ of φ. Since $\widetilde{\varphi}'(x) = \varphi'(x) \neq 0$, by Theorem 22, there is a neighborhood of x on which $\widetilde{\varphi}$ is invertible and the inverse $\widetilde{\varphi}^{-1}$ is analytic.

Otherwise, $\mathfrak{m}(J) \neq 0$. Since $\varphi(x)$ is analytic and $\varphi'(x) \neq 0$ for all $x \in J$, the function φ is invertible and by Theorem 22, the inverse $\varphi^{-1} : I \to J$ is analytic on I. By Theorem 21, there exists an analytic continuation $\widetilde{\varphi^{-1}}$ of φ^{-1} defined on a neighborhood $\widetilde{I_1}$ of I. Similarly, there exists an analytic continuation $\widetilde{\varphi}$ of φ defined on a neighborhood $\widetilde{J}$ of J. We use $\widetilde{I}$ to denote the image $\widetilde{\varphi}(\widetilde{J})$. Since $\widetilde{\varphi}$ is analytic, by the open mapping theorem $\widetilde{I}$ is an open set in the complex plane. Clearly, we have $\varphi(J) = I \subseteq \widetilde{I}$. We can pick $\widetilde{J}$ small enough while still keeping $J \subseteq \widetilde{J}$ such that the image $\widetilde{I} = \widetilde{\varphi}(\widetilde{J}) \subseteq \widetilde{I_1}$ and still $I \subseteq \widetilde{I}$. Thus, the composition $\widetilde{\varphi^{-1}} \circ \widetilde{\varphi}$ is a well-defined analytic function on $\widetilde{J}$. Clearly, we have that

$$\widetilde{\varphi^{-1}} \circ \widetilde{\varphi}(x) = \varphi^{-1} \circ \varphi(x) \equiv x \text{ for all } x \in J.$$

Since $\mathfrak{m}(J) \neq 0$, by Theorem 21, we have that $\widetilde{\varphi^{-1}} \circ \widetilde{\varphi}(x) \equiv x$ for all $x \in \widetilde{J}$.

Thus, $\widetilde{\varphi}$ is invertible on $\widetilde{J}$ and the inverse $\widetilde{\varphi}^{-1} = \widetilde{\varphi^{-1}}$ is analytic. ◀

Now, we are ready to prove our main result.

▶ **Theorem 24.** *If $\boldsymbol{\zeta}_0$ satisfies real contraction for Δ, then there exists a $\delta > 0$ such that for every $\boldsymbol{\zeta} \in \mathbb{C}^3$ with $\|\boldsymbol{\zeta} - \boldsymbol{\zeta}_0\|_\infty < \delta$, $\boldsymbol{\zeta}$ satisfies complex contraction for Δ.*

Proof. Let $\varphi : J \to I$ be a good potential function for $\boldsymbol{\zeta}_0$. By Definition 11 and Lemma 23, there exists a neighborhood $\widetilde{J}$ of J such that the analytic continuation $\widetilde{\varphi} : \widetilde{J} \to \widetilde{I}$ of φ on $\widetilde{J}$ is invertible. Here $\widetilde{I} = \widetilde{\varphi}(\widetilde{J})$ is a neighborhood of I, and the inverse $\widetilde{\varphi}^{-1}$ is also analytic on $\widetilde{I}$. We use $\mathcal{B}_\delta := \{\mathbf{z} \in \mathbb{C}^3 \mid \|\mathbf{z} - \boldsymbol{\zeta}_0\|_\infty < \delta\}$ to denote the 3-dimensional complex ball around $\boldsymbol{\zeta}_0$ of radius δ in terms of the infinity norm. Recall that we define $I_\varepsilon = \{z \in \mathbb{C} \mid |z - z_0| < \varepsilon, z_0 \in I\}$. Given a set $U \subseteq \mathbb{C}^k$, we use $\overline{U}$ to denote its closure.

We first show that we can pick a pair of $(\delta_1, \varepsilon_1)$ such that for every $\mathbf{s}$ with $\|\mathbf{s}\|_1 \leq \Delta - 1$, the composition

$$F_{\mathbf{s}}^{\widetilde{\varphi}}(\boldsymbol{\zeta}, \mathbf{x}) = \widetilde{\varphi}(F_{\mathbf{s}}(\boldsymbol{\zeta}, \widetilde{\boldsymbol{\varphi}}^{-1}(\mathbf{x}))) \text{ is well-defined and analytic on } \mathcal{B}_{\delta_1} \times I_{\varepsilon_1}^k.$$

Given some $\mathbf{s}$ with $\|\mathbf{s}\|_1 \leq \Delta - 1$, we consider the function $F_{\mathbf{s}}(\boldsymbol{\zeta}, \mathbf{x})$. We know that it is analytic on a neighborhood of $\{\boldsymbol{\zeta}_0\} \times J^k$ and by real contraction we have $F_{\mathbf{s}}(\boldsymbol{\zeta}_0, J^k) \subseteq J$. Then, we can pick some $\delta_{\mathbf{s}}$ and a neighborhood $\widetilde{J_{\mathbf{s}}}$ of J that are small enough such that $F_{\mathbf{s}}(\boldsymbol{\zeta}, \mathbf{x})$ is analytic on $\mathcal{B}_{\delta_{\mathbf{s}}} \times \widetilde{J}_{\mathbf{s}}^k$, and $F_{\mathbf{s}}(\mathcal{B}_{\delta_{\mathbf{s}}}, \widetilde{J}_{\mathbf{s}}^k) \subseteq \widetilde{J}$. Let

$$\delta_1 = \min_{\|\mathbf{s}\|_1 \leq \Delta - 1} \{\delta_{\mathbf{s}}\} \quad \text{and} \quad \widetilde{J_1} = \bigcap_{\|\mathbf{s}\|_1 \leq \Delta - 1} \widetilde{J_{\mathbf{s}}}.$$

Since there is only a finite number of $\mathbf{s}$ with $\|\mathbf{s}\|_1 \leq \Delta - 1$, we have that $\delta_1 > 0$, and $\widetilde{J_1}$ is open and it is a neighborhood of J. Then, $F_{\mathbf{s}}(\mathcal{B}_{\delta_1}, \widetilde{J_1}) \subseteq \widetilde{J}$ for every $\mathbf{s}$ with $\|\mathbf{s}\|_1 \leq \Delta - 1$. Since $\widetilde{\varphi}^{-1}$ is analytic on $\widetilde{I}$ and $\widetilde{\varphi}^{-1}(I) = J$, similarly we can pick a small enough neighborhood $\widetilde{I_1}$ of I where $\widetilde{I_1} \subseteq \widetilde{I}$ such that $\widetilde{\varphi}^{-1}(\widetilde{I_1}) \subseteq \widetilde{J_1}$. For every $z_0 \in I$, we can pick an ε_{z_0} such that the disc $B_{z_0,\varepsilon_{z_0}} := \{z \in \mathbb{C} \mid |z - z_0| < \varepsilon_{z_0}\}$ is in $\widetilde{I_1}$. Recall that I is a compact real interval, by the finite cover theorem, we can uniformly pick an ε_1 such that $I \subseteq I_{\varepsilon_1} \subseteq \widetilde{I_1}$. Thus, $F^{\widetilde{\varphi}}_{\mathbf{s}}(\boldsymbol{\zeta}, \mathbf{x})$ is well-defined and analytic on $\mathcal{B}_{\delta_1} \times I^k_{\varepsilon_1}$ for every $\mathbf{s}$ with $\|\mathbf{s}\|_1 \leq \Delta - 1$. In fact, $F^{\widetilde{\varphi}}_{\mathbf{s}}$ is a (multivariate) analytic continuation of $F^{\varphi}_{\mathbf{s}}$. Since I is a compact interval, in the following when we pick a neighborhood $\widetilde{I}$ of I, without loss of generality, we may always pick $\widetilde{I}$ as an ε-strip I_ε of I.

Then, we show that we can pick a pair of $(\delta_2, \varepsilon_2)$ where $\delta_2 < \delta_1$ and $\varepsilon_2 < \varepsilon_1$, a constant $M > 0$ and a constant $\eta > 0$ such that for every $\mathbf{s}$ with $\|\mathbf{s}\|_1 \leq \Delta - 1$,

$$\left\|\nabla F^{\widetilde{\varphi}}_{\boldsymbol{\zeta},\mathbf{s}}(\mathbf{x})\right\|_1 \leq 1 - \eta \qquad \text{and} \qquad \left\|\nabla F^{\widetilde{\varphi}}_{\mathbf{x},\mathbf{s}}(\boldsymbol{\zeta})\right\|_1 \leq M$$

for all $\boldsymbol{\zeta} \in \overline{\mathcal{B}_{\delta_2}}$ and all $\mathbf{x} \in \overline{I^k_{\varepsilon_2}}$. By real contraction, there is an $\eta' > 0$ such that $\left\|\nabla F^{\widetilde{\varphi}}_{\boldsymbol{\zeta}_0,\mathbf{s}}(\mathbf{x})\right\|_1 \leq 1 - \eta'$ for every $\mathbf{s}$ with $\|\mathbf{s}\|_1 \leq \Delta - 1$ and all $\mathbf{x} \in I^k$. Given some $\mathbf{s}$ with $\|\mathbf{s}\|_1 \leq \Delta - 1$, since $F^{\widetilde{\varphi}}_{\mathbf{s}}(\boldsymbol{\zeta}, \mathbf{x})$ is analytic on $\mathcal{B}_{\delta_1} \times I^k_{\varepsilon_1}$, by continuity we can pick some $\delta_{\mathbf{s}} < \delta_1$ and $\varepsilon_{\mathbf{s}} < \varepsilon_1$ such that $\left\|\nabla F^{\widetilde{\varphi}}_{\boldsymbol{\zeta},\mathbf{s}}(\mathbf{x})\right\|_1 \leq 1 - \frac{\eta'}{2}$ for all $\boldsymbol{\zeta} \in \overline{\mathcal{B}_{\delta_{\mathbf{s}}}}$ and all $\mathbf{x} \in \overline{I^k_{\varepsilon_{\mathbf{s}}}}$. In addition, let

$$M_{\mathbf{s}} = \sup_{\boldsymbol{\zeta} \in \overline{\mathcal{B}_{\delta_{\mathbf{s}}}}, \mathbf{x} \in \overline{I^k_{\varepsilon_{\mathbf{s}}}}} \left\|\nabla F^{\widetilde{\varphi}}_{\mathbf{x},\mathbf{s}}(\boldsymbol{\zeta})\right\|_1,$$

and we know that $M_{\mathbf{s}} < +\infty$ since $F^{\widetilde{\varphi}}$ is analytic on $\overline{\mathcal{B}_{\delta_{\mathbf{s}}}} \times \overline{I^k_{\varepsilon_{\mathbf{s}}}}$ which is closed and bounded. Finally, let

$$\eta = \frac{\eta'}{2}, \quad \delta_2 = \min_{\|\mathbf{s}\|_1 \leq \Delta - 1}\{\delta_{\mathbf{s}}\}, \quad \varepsilon_2 = \min_{\|\mathbf{s}\|_1 \leq \Delta - 1}\{\varepsilon_{\mathbf{s}}\}, \quad \text{and} \quad M = \max_{\|\mathbf{s}\|_1 \leq \Delta - 1}\{M_{\mathbf{s}}\}.$$

These choices will satisfy our requirement.

For the case that $\|\mathbf{s}\|_1 = \Delta$, we show that we can pick a pair of $(\delta_3, \varepsilon_3)$ where $\delta_3 < \delta_1$ and $\varepsilon_3 < \varepsilon_1$ such that for every $\mathbf{s}$ with $\|\mathbf{s}\|_1 = \Delta$, we have $-1 \notin F_{\mathbf{s}}(\overline{\mathcal{B}_{\delta_3}}, \widetilde{J}^k_2)$ where $\widetilde{J_2} = \widetilde{\varphi}^{-1}(\overline{I_{\varepsilon_3}})$ is a closed neighborhood of J. Since $F_{\mathbf{s}}$ is analytic, by real contraction, $-1 \notin F_{\boldsymbol{\zeta}_0,\mathbf{s}}(J^k)$ which is closed. Again by continuity we can pick some $(\delta_3, \varepsilon_3)$ that satisfy our requirement.

Since $\boldsymbol{\zeta}_0 = (\beta_0, \gamma_0, \lambda_0)$ satisfies real contraction, we have $\lambda_0 \in J$, $-\gamma_0 \notin J$ and $-1 \notin J$. Recall that $J = \widetilde{\varphi}^{-1}(I)$. Again, since $\widetilde{\varphi}^{-1}$ is analytic, by continuity we can pick some $\varepsilon \leq \min\{\varepsilon_2, \varepsilon_3\}$ such that $\lambda_0 \in \widetilde{\varphi}^{-1}(I_\varepsilon)$ (an open set), $-\gamma_0 \notin \widetilde{\varphi}^{-1}(\overline{I_\varepsilon})$ (a closed set) and $-1 \notin \widetilde{\varphi}^{-1}(\overline{I_\varepsilon})$. Moreover, we can pick some δ_4 small enough such that the disc $B_{\lambda_0,\delta_4} := \{z \in \mathbb{C} \mid |z - \lambda_0| < \delta_4\}$ is in $\widetilde{\varphi}^{-1}(I_\varepsilon)$, and the disc $B_{-\gamma_0,\delta_4} := \{z \in \mathbb{C} \mid |z - (-\gamma_0)| < \delta_4\}$ is disjoint with $\widetilde{\varphi}^{-1}(\overline{I_\varepsilon})$. Let $P = \overline{I_\varepsilon}$ and $Q = \widetilde{\varphi}^{-1}(\overline{I_\varepsilon})$. Clearly, P is convex. For every $\boldsymbol{\zeta}$ with $\|\boldsymbol{\zeta} - \boldsymbol{\zeta}_0\|_\infty < \delta$, we have $\lambda \in Q$, $-\gamma \notin Q$ and $-1 \notin Q$. In addition, we know that Q is closed and bounded since P is closed and bounded and $\widetilde{\varphi}^{-1}$ is analytic on P. Finally, let $\delta = \min\{\delta_2, \delta_3, \delta_4, \frac{\varepsilon\eta}{M}\}$. We show that for every $\mathbf{s}$ with $\|\mathbf{s}\|_1 \leq \Delta - 1$, $F^{\widetilde{\varphi}}_{\mathbf{s}}(\mathcal{B}_\delta, P^k) \subseteq P$, which implies that $F_{\mathbf{s}}(\mathcal{B}_\delta, Q^k) \subseteq Q$.

Consider some $\mathbf{x} \in P^k$. By the definition of P, there exists an $\mathbf{x}_0 \in I^k$ such that $\|\mathbf{x} - \mathbf{x}_0\|_\infty \le \varepsilon$. Also, consider some $\boldsymbol{\zeta} \in \mathcal{B}_\delta$, and we have $\|\boldsymbol{\zeta} - \boldsymbol{\zeta}_0\|_\infty < \delta$. Then, for every $\mathbf{s}$ with $\|\mathbf{s}\|_1 \le \Delta - 1$, consider $F_{\mathbf{s}}^{\widetilde{\varphi}}(\boldsymbol{\zeta}, \mathbf{x}) - F_{\mathbf{s}}^{\widetilde{\varphi}}(\boldsymbol{\zeta}_0, \mathbf{x}_0)$. We have

$$\begin{aligned}
&\left|F_{\mathbf{s}}^{\widetilde{\varphi}}(\boldsymbol{\zeta}, \mathbf{x}) - F_{\mathbf{s}}^{\widetilde{\varphi}}(\boldsymbol{\zeta}_0, \mathbf{x}_0)\right| \\
\le &\left|F_{\mathbf{s}}^{\widetilde{\varphi}}(\boldsymbol{\zeta}, \mathbf{x}) - F_{\mathbf{s}}^{\widetilde{\varphi}}(\boldsymbol{\zeta}_0, \mathbf{x})\right| + \left|F_{\mathbf{s}}^{\widetilde{\varphi}}(\boldsymbol{\zeta}_0, \mathbf{x}) - F_{\mathbf{s}}^{\widetilde{\varphi}}(\boldsymbol{\zeta}_0, \mathbf{x}_0)\right| \\
\le &\sup_{\boldsymbol{\zeta}' \in \mathcal{B}_\delta} \left\|\nabla F_{\mathbf{x},\mathbf{s}}^{\widetilde{\varphi}}(\boldsymbol{\zeta}')\right\|_1 \cdot \|\boldsymbol{\zeta} - \boldsymbol{\zeta}_0\|_\infty + \sup_{\mathbf{x}' \in P^k} \left\|\nabla F_{\boldsymbol{\zeta}_0,\mathbf{s}}^{\widetilde{\varphi}}(\mathbf{x}')\right\|_1 \cdot \|\mathbf{x} - \mathbf{x}_0\|_\infty \\
\le &M\delta + (1 - \eta) \cdot \varepsilon \le \varepsilon.
\end{aligned}$$

The second inequality above uses the fact that both $\mathcal{B}_\delta$ and P^k are convex, which ensures that the line between $\boldsymbol{\zeta}_0$ and $\boldsymbol{\zeta}$ is in $\mathcal{B}_\delta$ and the line between $\mathbf{x}_0$ and $\mathbf{x}$ is in P^k. By real contraction, we know that $F_{\mathbf{s}}^{\widetilde{\varphi}}(\boldsymbol{\zeta}_0, \mathbf{x}_0) \in I$ since $\mathbf{x}_0 \in I^k$. Thus, we have $F_{\mathbf{s}}^{\widetilde{\varphi}}(\boldsymbol{\zeta}, \mathbf{x}) \in P$. Thus, for every $\boldsymbol{\zeta}$ with $\|\boldsymbol{\zeta} - \boldsymbol{\zeta}_0\|_\infty < \delta$, we have that $\lambda \in Q$, $-\gamma \notin Q$ and $-1 \notin Q$, and

1. $F_{\boldsymbol{\zeta},\mathbf{s}}(Q^k) \subseteq Q$ for every $\mathbf{s}$ with $\|\mathbf{s}\|_1 \le \Delta - 1$ and $-1 \notin F_{\boldsymbol{\zeta},\mathbf{s}}(Q^k)$ for every $\mathbf{s}$ with $\|\mathbf{s}\|_1 = \Delta$;
2. there exists $\eta > 0$ s.t. $\left\|\nabla F_{\boldsymbol{\zeta},\mathbf{s}}^{\varphi}(\mathbf{x})\right\|_1 \le 1 - \eta$ for every $\mathbf{s}$ with $\|\mathbf{s}\|_1 \le \Delta - 1$ and all $\mathbf{x} \in P^k$.

The function $\widetilde{\varphi} : Q \to P$ is a good potential function for $\boldsymbol{\zeta}$. ◀

Combining Lemmas 15, 19, 20 and Theorem 24, we have the following result.

▶ **Theorem 25.** *Fix $\Delta \ge 3$. For every $\boldsymbol{\zeta}_0 \in \mathcal{S}_i^\Delta$ ($i \in [4]$), there exists a $\delta > 0$ such that for any $\boldsymbol{\zeta} \in \mathbb{C}^3$ where $\|\boldsymbol{\zeta} - \boldsymbol{\zeta}_0\|_\infty < \delta$, we have*

- *$Z_G^{\sigma_\Lambda}(\boldsymbol{\zeta}) \ne 0$ for every graph G of degree at most Δ and every feasible configuration σ_Λ;*
- *the Δ-bounded 2-spin system specified by $\boldsymbol{\zeta}$ exhibits correlation decay.*

Then via either Weitz's or Barvinok's algorithm, there is an FPTAS for computing $Z_G(\boldsymbol{\zeta})$.

▶ Remark 26. The choice of δ does not depend on the size of the graph, only on Δ and $\boldsymbol{\zeta}_0$. In particular, let D be a compact set in $\mathcal{S}_i^\Delta$ for some $i \in [4]$. Then there is a uniform δ such that for all $\boldsymbol{\zeta}$ in a complex neighborhood D_δ of radius δ around D, i.e., $\boldsymbol{\zeta} \in D_\delta := \{\mathbf{z} \in \mathbb{C}^3 \mid \|\mathbf{z} - \mathbf{z}_0\|_\infty < \delta, \mathbf{z}_0 \in D\}$, $Z_G(\boldsymbol{\zeta}) \ne 0$ for every graph G of degree at most Δ. In addition, in order to apply Barvinok's algorithm, by Lemma 16, we need to make sure that the zero-free regions contain $\lambda = 0$ (an easy computing point). This is true for $\mathcal{S}_1^\Delta$, $\mathcal{S}_2^\Delta$ and $\mathcal{S}_3^\Delta$. For parameters in $\mathcal{S}_4^\Delta$, we will reduce the problem to a case in $\mathcal{S}_3^\Delta$ by swapping β and γ and replacing λ by $1/\lambda$. Then, one can apply Barvinok's algorithm.

Abstract

Consider a distributed graph where each vertex holds one of two distinct opinions. In this paper, we are interested in synchronous *voting processes* where each vertex updates its opinion according to a predefined common local updating rule. For example, each vertex adopts the majority opinion among 1) itself and two randomly picked neighbors in *best-of-two* or 2) three randomly picked neighbors in *best-of-three*. Previous works intensively studied specific rules including best-of-two and best-of-three individually.

In this paper, we generalize and extend previous works of best-of-two and best-of-three on expander graphs by proposing a new model, *quasi-majority functional voting*. This new model contains best-of-two and best-of-three as special cases. We show that, on expander graphs with sufficiently large initial bias, any quasi-majority functional voting reaches consensus within $O(\log n)$ steps with high probability. Moreover, we show that, for any initial opinion configuration, any quasi-majority functional voting on expander graphs with higher expansion (e.g., Erdős-Rényi graph $G(n,p)$ with $p = \Omega(1/\sqrt{n})$) reaches consensus within $O(\log n)$ with high probability. Furthermore, we show that the consensus time is $O(\log n/\log k)$ of best-of-$(2k+1)$ for $k = o(n/\log n)$.

1 Introduction

Consider an undirected graph $G = (V, E)$ where each vertex $v \in V$ initially holds an opinion $\sigma \in \Sigma$ from a finite set Σ. In *synchronous voting process* (or simply, *voting process*), in each round, every vertex communicates with its neighbors and then all vertices simultaneously update their opinions according to a predefined protocol. The aim of the protocol is to reach a *consensus configuration*, i.e., a configuration where all vertices have the same opinion. Voting process has been extensively studied in several areas including biology, network analysis, physics and distributed computing [10, 32, 30, 22, 26, 2]. For example, in distributed computing, voting process plays an important role in the consensus problem [22, 26].

This paper is concerned with the *consensus time* of voting processes over *binary* opinions $\Sigma = \{0, 1\}$. Then voting processes have state space 2^V. A state of 2^V is called a *configuration*. The *consensus time* is the number of steps needed to reach a consensus configuration. Henceforth, we are concerned with connected and nonbipartite graphs.

1.1 Previous works of specific updating rules

In *pull voting*, in each round, every vertex adopts the opinion of a randomly selected neighbor. This is one of the most basic voting process, which has been well explored in the past [33, 27, 14, 18, 8]. In particular, the expected consensus time of this process has been extensively studied in the literature. For example, Hassin and Peleg [27] showed that the expected consensus time is $O(n^3 \log n)$ for all non-bipartite graphs and all initial opinion configurations, where n is the number of vertices. From the result of Cooper, Elsässer, Ono, and Radzik [14], it is known that on the complete graph K_n, the expected consensus time is $O(n)$ for any initial opinion configuration.

In *best-of-two* (a.k.a. *2-Choices*), each vertex v samples two random neighbors (with replacement) and, if both hold the same opinion, v adopts the opinion. Otherwise, v keeps its own opinion. Doerr, Goldberg, Minder, Sauerwald, and Scheideler [21] showed that, on the complete graph K_n, the consensus time of best-of-two is $O(\log n)$ with high probability[1] for an arbitrary initial opinion configuration. Since best-of-two is simple and is faster than pull voting on the complete graphs, this model gathers special attention in distributed computing and related area [25, 15, 16, 17, 19, 20, 37]. There is a line of works that study best-of-two on expander graphs [15, 16, 17], which we discuss later.

In *best-of-three* (a.k.a. *3-Majority*), each vertex v randomly selects three random neighbors (with replacement). Then, v updates its opinion to match the majority among the three. It follows directly from Ghaffari and Lengler [25] that, on K_n with any initial opinion configuration, the consensus time of best-of-three is $O(\log n)$ w.h.p. Kang and Rivera [28] considered the consensus time of best-of-three on graphs with large minimum degree starting from a random initial configuration. Shimizu and Shiraga [37] showed that, for any initial configurations, best-of-two and best-of-three reach consensus in $O(\log n)$ steps w.h.p. if the graph is an Erdős-Rényi graph $G(n,p)$[2] of $p = \Omega(1)$.

Best-of-k ($k \geq 1$) is a generalization of pull voting, best-of-two and best-of-three. In each round, every vertex v randomly selects k neighbors (with replacement) and then if at least $\lfloor k/2 \rfloor + 1$ of them have the same opinion, the vertex v adopts it. Note that the best-of-1 is equivalent to pull voting. Abdullah and Draief [1] studied a variant of best-of-k ($k \geq 5$ is odd) on a specific class of sparse graphs that includes n-vertex random d-regular graphs[3] $G_{n,d}$ of $d = o(\sqrt{\log n})$ with a random initial configuration. To the best of our knowledge, best-of-k has not been studied explicitly so far.

In *Majority* (a.k.a. *local majority*), each vertex v updates its opinion to match the majority opinion among the neighbors. This simple model has been extensively studied in previous works [6, 9, 24, 34, 35, 40]. For example, Majority on certain families of graphs including the Erdős-Rényi random graph [6, 40], random regular graphs [24] have been investigated. See [35] for further details.

Voting process on expander graphs

Expander graph gathers special attention in the context of Markov chains on graphs, yielding a wide range of theoretical applications. A graph G is λ-*expander* if $\max\{|\lambda_2|, |\lambda_n|\} \leq \lambda$, where $1 = \lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_n \geq -1$ are the eigenvalues of the transition matrix P of the

[1] In this paper "with high probability" (w.h.p.) means probability at least $1 - n^{-c}$ for a constant $c > 0$.

[2] Recall that the Erdős-Rényi random graph $G(n,p)$ is a graph on n vertices where each of possible $\binom{n}{2}$ vertex pairs forms an edge with probability p independently.

[3] An n-vertex random d-regular graph $G_{n,d}$ is a graph selected uniformly at random from the set of all labelled n-vertex d-regular graphs.

simple random walk on G. For example, an Erdős-Rényi graph $G(n,p)$ of $p \geq (1+\epsilon)\frac{\log n}{n}$ for an arbitrary constant $\epsilon > 0$ is $O(1/\sqrt{np})$-expander w.h.p. [12]. An n-vertex random d-regular graph $G_{n,d}$ of $3 \leq d \leq n/2$ is $O(1/\sqrt{d})$-expander w.h.p. [13, 39].

Cooper et al. [14] showed that the expected consensus time of pull voting is $O(n/(1-\lambda))$ on λ-expander regular graphs for any initial configuration. Compared to pull voting, the study of best-of-two on general graphs seems much harder. Most of the previous works concerning best-of-two on expander graphs put some assumptions on the initial configuration. Let A denote the set of vertices of opinion 0 and $B = V \setminus A$. Cooper, Elsässer, and Radzik [15] showed that, for any regular λ-expander graph, the consensus time is $O(\log n)$ w.h.p. if $\big||A| - |B|\big| = \Omega(\lambda n)$. This result was improved by Cooper, Elsässer, Radzik, Rivera, and Shiraga [16]. Roughly speaking, they proved that, on λ-expander graphs, the consensus time is $O(\log n)$ if $|d(A) - d(B)| = \Omega(\lambda^2 d(V))$, where $d(S) = \sum_{v \in S} \deg(v)$ denotes the volume of $S \subseteq V$. To the best of our knowledge, the worst case consensus time of best-of-k on expander graphs has not been studied.

1.2 Our model

In this paper, we propose a new class *functional voting* of voting process, which contains many known voting processes as a special case. Let $A \subseteq V$ be the set of vertices of opinion 0 and A' be the set in the next round. Let $B = V \setminus A$ and $B' = V \setminus A'$. For $v \in V$ and $S \subseteq V$, let $N(v) = \{w \in V : \{v,w\} \in E\}$ and $\deg_S(v) = |N(v) \cap S|$.

▶ **Definition 1.1** (Functional voting). *Let $f : \mathbb{R} \to \mathbb{R}$ be a function satisfying $f([0,1]) = [0,1]$ and $f(0) = 0$. A* functional voting with respect to f *is a synchronous voting process defined as*

$$\mathbf{Pr}[v \in A'] = f\left(\frac{\deg_A(v)}{\deg(v)}\right) \quad \text{if } v \in B,$$
$$\mathbf{Pr}[v \in B'] = f\left(\frac{\deg_B(v)}{\deg(v)}\right) \quad \text{if } v \in A.$$

We call the function f a betrayal function *and the function*

$$H_f(x) := x\big(1 - f(1-x)\big) + (1-x)f(x)$$

an updating function.

Since $f(0) = 0$, consensus configurations are absorbing states. The intuition behind the updating function H_f is that, letting $\alpha = |A|/n$ and $\alpha' = |A'|/n$, on a complete graph K_n (with self-loop), the functional voting with respect to f satisfies $\mathbf{E}[\alpha'] = \frac{|A|}{n}\left(1 - f\left(\frac{|B|}{n}\right)\right) + \frac{|B|}{n} f\left(\frac{|A|}{n}\right) = H_f(\alpha)$.

Functional voting contains many existing models as special cases. For example, pull voting, best-of-two, and best-of-three are functional votings with respect to x, x^2 and $3x^2 - 2x^3$, respectively. In general, best-of-k is a functional voting with respect to

$$f_k(x) = \sum_{i=\lfloor k/2 \rfloor + 1}^{k} \binom{k}{i} x^i (1-x)^{k-i}. \qquad (1)$$

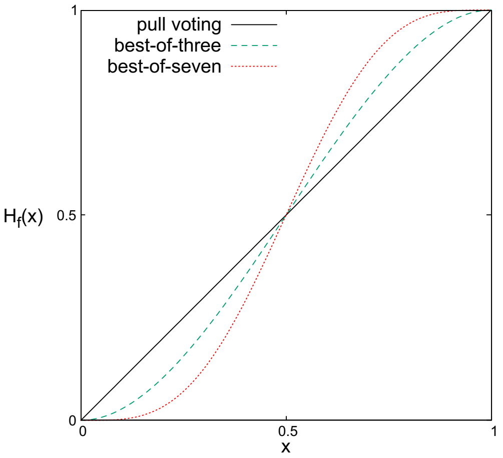

Figure 1 The updating functions $H_f(x)$ of pull voting (solid line), best-of-three (dashed line) and best-of-seven (dotted line). One can easily observe that best-of-three and best-of-seven are quasi-majority functional voting. Intuitively speaking, quasi-majority functional voting has an updating function H_f with the property so-called "the rich get richer", which coincides with Definition 1.2.

It is straightforward to check that $H_{f_k}(x) = f_k(x)$ if k is odd and $H_{f_k}(x) = f_{k+1}(x)$ if k is even. Majority is a functional voting with respect to

$$f(x) = \begin{cases} 0 & \text{if } x < \frac{1}{2}, \\ \frac{1}{2} & \text{if } x = \frac{1}{2}, \\ 1 & \text{if } x > \frac{1}{2} \end{cases} \tag{2}$$

if a vertex adopts the random opinion when it meets the tie.

Quasi-majority functional voting

In this paper, we focus on functional voting with respect to f satisfying the following property.

▶ **Definition 1.2** (Quasi-majority). *A function f is* quasi-majority *if f satisfies the following conditions.*

(i) *f is C^2 (i.e., the derivatives f' and f'' exist and they are continuous).*
(ii) $0 < f(1/2) < 1$,
(iii) *$H_f(x) < x$ whenever $x \in (0, 1/2)$.*
(iv) $H'_f(1/2) > 1$,
(v) $H'_f(0) < 1$.

A voting process is a quasi-majority functional voting *if it is a functional voting with respect to a quasi-majority function f.*

Note that $H_f(x)$ is symmetric (i.e., $H_f(1-x) = 1 - H_f(x)$) and thus the condition (iii) implies $H_f(x) > x$ for every $x \in (1/2, 1)$. Intuitively, the conditions (iii) to (v) ensure the drift towards consensus. The conditions (i) and (ii) are due to a technical reasons.

For each constant $k \geq 2$, best-of-k is quasi-majority functional voting but pull voting and Majority are not. Indeed, if H_{f_k} is the updating function of best-of-k, then $H'_{f_{2\ell}}(x) = H'_{f_{2\ell+1}}(x) = (2\ell+1)\binom{2\ell}{\ell}x^\ell(1-x)^\ell$. It is straightforward to check that this function satisfies the conditions (iii) to (v) if $\ell \neq 0$ (pull-voting). See Figure 1 for depiction of the updating functions of pull voting, best-of-three and best-of-seven.

1.3 Our result

In this paper, we study the consensus time of quasi-majority functional voting on expander graphs[4]. Let $T_{\mathrm{cons}}(A)$ denote the consensus time starting from the initial configuration $A \subseteq V$. For a graph $G = (V, E)$, let $\pi = (\pi(v))_{v\in V}$ denote the *degree distribution* defined as

$$\pi(v) = \frac{\deg(v)}{2|E|}. \tag{3}$$

Note that $\sum_{v\in V} \pi(v) = 1$ holds. We denote by $\|x\|_p := \left(\sum_{v\in V} |x_v|^p\right)^{1/p}$ the ℓ^p norm of $x \in \mathbb{R}^V$. For $\pi \in [0,1]^V$ and $A \subseteq V$, let $\pi(A) := \sum_{v\in A} \pi(v)$. Let

$$\delta(A) := \pi(A) - \pi(V \setminus A) = 2\pi(A) - 1$$

denote the *bias* between A and $V \setminus A$.

▶ **Theorem 1.3** (Main theorem). *Consider a quasi-majority functional voting with respect to f on an n-vertex λ-expander graph with degree distribution π. Then, the following holds:*

(i) *Let $C_1 > 0$ be an arbitrary constant and $\varepsilon : \mathbb{N} \to \mathbb{R}$ be an arbitrary function satisfying $\varepsilon(n) \to 0$ as $n \to \infty$. Suppose that $\lambda \le C_1 n^{-1/4}$, $\|\pi\|_2 \le C_1/\sqrt{n}$ and $\|\pi\|_3 \le \varepsilon/\sqrt{n}$. Then, for any $A \subseteq V$, $T_{\mathrm{cons}}(A) = O(\log n)$ w.h.p.*

(ii) *Let C_2 be a positive constant depending only on f. Suppose that $\lambda \le C_2$ and $\|\pi\|_2 \le C_2/\sqrt{\log n}$. Then, for any $A \subseteq V$ satisfying $|\delta(A)| \ge C_2 \max\{\lambda^2, \|\pi\|_2\sqrt{\log n}\}$, $T_{\mathrm{cons}}(A) = O(\log n)$ w.h.p.*

The following result indicates that the consensus time of Theorem 1.3(i) is optimal up to a constant factor.

▶ **Theorem 1.4** (Lower bound). *Under the same assumption of Theorem 1.3(i), $T_{\mathrm{cons}}(A) = \Omega(\log n)$ w.h.p. for some $A \subseteq V$.*

See the full version [38] for the proof of Theorem 1.4.

▶ **Theorem 1.5** (Fast consensus for $H'_f(0) = 0$). *Consider a quasi-majority functional voting with respect to f on an n-vertex λ-expander graph with degree distribution π. Let $C > 0$ be a constant depending only on f. Suppose that $H'_f(0) = 0$, $\lambda \le C$ and $\|\pi\|_2 \le C/\sqrt{\log n}$. Then, for any $A \subseteq V$ satisfying $|\delta(A)| \ge C \max\{\lambda^2, \|\pi\|_2\sqrt{\log n}\}$, it holds w.h.p. that*

$$T_{\mathrm{cons}}(A) = O\left(\log\log n + \log|\delta(A)|^{-1} + \frac{\log n}{\log \lambda^{-1}} + \frac{\log n}{\log(|\pi\|_2\sqrt{\log n})^{-1}}\right).$$

For example, for each constant $k \ge 2$, best-of-k is quasi-majority with $H'_f(0) = 0$.

▶ Remark 1.6. Roughly speaking, for $p \ge 2$, $\|\pi\|_p$ measures the imbalance of the degrees. For any graphs, $\|\pi\|_p \ge n^{-1+1/p}$ and the equality holds if and only if the graph is regular. For star graphs, we have $\|\pi\|_p \approx 1$.

Results of best-of-k

Our results above do not explore Majority since it is not quasi-majority. A plausible approach is to consider best-of-k for $k = k(n) = \omega(1)$ since each vertex is likely to choose the majority opinion if the number of neighbor sampling increases. Also, note that the betrayal function f_k

[4] Throughout the paper, we consider sufficiently large $n = |V|$.

of best-of-k given in (1) converges to that of Majority (i.e., $f_k(x) \to f(x)$ as $k \to \infty$ for each $x \in [0,1]$, where f is the betrayal function (2) of Majority). On the other hand, if $k = O(1)$, there is a tremendous gap between best-of-k and Majority: For any functional voting on the complete graph K_n, $T_{\mathrm{cons}}(A) = \Omega(\log n)$ for some $A \subseteq V$ from Theorem 1.4. Majority on K_n reaches the consensus in a single step if $|A| < |V \setminus A| - 1$. This motivates us to consider best-of-k for $k = k(n) \to \infty$ as $n \to \infty$. For simplicity, we focus on best-of-$(2k+1)$ and prove the following result (see the full version [38] for the proof).

▶ **Theorem 1.7.** *Let $k = k(n)$ be such that $k = \omega(1)$ and $k = o(n/\log n)$. Let C be an arbitrary positive constant. Consider best-of-$(2k+1)$ on an n-vertex λ-expander graph with degree distribution π such that $\lambda \le Ck^{-1/2}n^{-1/4}$, $\|\pi\|_2 \le Cn^{-1/2}$ and $\|\pi\|_3 \le Ck^{-1/6}n^{-1/2}$. Then, $T_{\mathrm{cons}}(A) = O\left(\frac{\log n}{\log k}\right)$ holds w.h.p. for any $A \subseteq V$.*

1.4 Application

Here, we apply our main theorem to specific graphs and derive some useful results.

For any $p \ge (1+\epsilon)\frac{\log n}{n}$ for an arbitrary constant $\epsilon > 0$, $G(n,p)$ is connected and $O(1/\sqrt{np})$-expander w.h.p [12, 23].

▶ **Corollary 1.8.** *Consider a best-of-k on an Erdős-Rényi graph $G(n,p)$ for an arbitrary constant $k \ge 2$. Then, $G(n,p)$ w.h.p. satisfies the following:*

(i) *Suppose that $p = \Omega(n^{-1/2})$. Then*
  - **(a)** *for any $A \subseteq V$, $T_{\mathrm{cons}}(A) = O(\log n)$ w.h.p.*
  - **(b)** *for some $A \subseteq V$, $T_{\mathrm{cons}}(A) = \Omega(\log n)$ w.h.p.*

(ii) *Suppose that $p \ge (1+\epsilon)\frac{\log n}{n}$ for an arbitrary constant $\epsilon > 0$. Then, for any $A \subseteq V$ satisfying $|\delta(A)| \ge C\max\left\{\frac{1}{np}, \sqrt{\frac{\log n}{n}}\right\}$, $T_{\mathrm{cons}}(A) = O\left(\log\log n + \log|\delta(A)|^{-1} + \frac{\log n}{\log(np)}\right)$ w.h.p., where $C > 0$ is a constant depending only on f.*

In Corollary 1.8(i), we stress that the worst-case consensus time on $G(n,p)$ was known for $p = \Omega(1)$ [37]. If $\frac{\log n}{\log(np)} = O(\log\log n)$ (or equivalently, $np = n^{\Omega(1/\log\log n)}$), Corollary 1.8(ii) implies $T_{\mathrm{cons}}(A) = O(\log\log n + \log|\delta(A)|^{-1})$ w.h.p.

▶ **Corollary 1.9.** *Let $k = k(n)$ be such that $k = \omega(1)$ and $k = O(\sqrt{n})$. Consider best-of-$(2k+1)$ on $G(n,p)$ for $p = \Omega(k/\sqrt{n})$. Then, for any $A \subseteq V$, $T_{\mathrm{cons}}(A) = O\left(\frac{\log n}{\log k}\right)$ holds w.h.p.*

From Corollary 1.9, best-of-n^ϵ on $G(n, n^{-1/2+\epsilon})$ for any constant $\epsilon \in (0, 1/2)$ reaches consensus in $O(1)$ steps. It is known that Majority on $G(n, Cn^{-1/2})$ satisfies $T_{\mathrm{cons}}(A) \le 4$ for large constant C and random $A \subseteq V$ with constant probability [6].

For $3 \le d \le n/2$, n-vertex random d-regular graph $G_{n,d}$ is connected and $O(1/\sqrt{d})$-expander w.h.p. [13, 39].

▶ **Corollary 1.10.** *Consider a best-of-k on an n-vertex random d-regular graph $G_{n,d}$ for an arbitrary constant $k \ge 2$. Then, $G_{n,d}$ w.h.p. satisfies the following:*

(i) *Suppose that $d = \Omega(n^{1/2})$ and $d \le n/2$. Then,*
  - **(a)** *for any $A \subseteq V$, $T_{\mathrm{cons}}(A) = O(\log n)$ w.h.p.*
  - **(b)** *for some $A \subseteq V$, $T_{\mathrm{cons}}(A) = \Omega(\log n)$ w.h.p.*

(ii) *Suppose that $d \ge C$ and $d \le n/2$ for a constant $C > 0$ depending only on f. Then, for any $A \subseteq V$ satisfying $|\delta(A)| \ge C\max\left\{\frac{1}{d}, \sqrt{\frac{\log n}{n}}\right\}$, it holds w.h.p. that $T_{\mathrm{cons}}(A) = O\left(\log\log n + \log|\delta(A)|^{-1} + \frac{\log n}{\log d}\right)$.*

▶ **Corollary 1.11.** *Let $k = k(n)$ be such that $k = \omega(1)$ and $k = O(\sqrt{n})$. Consider best-of-$(2k+1)$ on an n-vertex random d-regular graph $G_{n,d}$ such that $d = \Omega(k\sqrt{n})$ and $d \le n/2$. Then, for any $A \subseteq V$, $T_{\mathrm{cons}}(A) = O\left(\frac{\log n}{\log k}\right)$ holds w.h.p.*

See the full version [38] for other specific results and examples of quasi-majority functional voting.

1.5 Related work

In asynchronous voting process, in each round, a vertex is selected uniformly at random and only the selected vertex updates its opinion. Cooper and Rivera [18] introduced *linear voting model*. In this model, an opinion configuration is represented as a vector $v \in \Sigma^V$ and the vector v updates according to the rule $v \leftarrow Mv$, where M is a random matrix sampled from some probability space. This model captures a wide variety model including asynchronous push/pull voting and synchronous pull voting. Note that best-of-two and best-of-three are not included in linear voting model. Schoenebeck and Yu [36] proposed an asynchronous variant of our functional voting. The authors of [36] proved that, if the function f is symmetric (i.e., $f(1-x) = 1 - f(x)$), smooth and has "majority-like" property (i.e., $f(x) > x$ whenever $1/2 < x < 1$), then the expected consensus time is $O(n \log n)$ w.h.p. on $G(n,p)$ with $p = \Omega(1)$. This perspective has also been investigated in physics (see, e.g., [10]).

Several researchers have studied best-of-two and best-of-three on complete graphs initially involving $k \ge 2$ opinions [5, 4, 7, 25]. For example, the consensus time of best-of-three is $O(k \log n)$ if $k = O(n^{1/3}/\sqrt{\log n})$ [25]. Cooper, Radzik, Rivera, and Shiraga [17] considered best-of-two and best-of-three on regular expander graphs that hold more than two opinions.

Recently, Cruciani, Natale, and Scornavacca [20] studied best-of-two with a random initial configuration on a clustered regular graph. Shimizu and Shiraga [37] obtained phase-transition results of best-of-two and best-of-three on stochastic block models.

2 Preliminary and technical result

2.1 Formal definition

Let $G = (V, E)$ be an undirected and connected graph. Let $P \in [0,1]^{V \times V}$ be the matrix defined as

$$P(u,v) := \frac{\mathbb{1}_{\{u,v\} \in E}}{\deg(u)} \quad \forall (u,v) \in V \times V \tag{4}$$

where $\mathbb{1}_Z$ denotes the indicator of an event Z. For $v \in V$ and $S \subseteq V$, we write $P(v,S) = \sum_{s \in S} P(v,s)$.

Now, let us describe the formal definition of functional voting. For a given $A \subseteq V$, let $(X_v)_{v \in V}$ be independent binary random variables defined as

$$\begin{aligned} \mathbf{Pr}[X_v = 1] &= f\big(P(v,A)\big) \quad \text{if } v \in B, \\ \mathbf{Pr}[X_v = 0] &= f\big(P(v,B)\big) \quad \text{if } v \in A, \end{aligned} \tag{5}$$

where $B = V \setminus A$. For $A \subseteq V$ and (X_v) above, define $A' = \{v \in V : X_v = 1\}$. Note that this definition coincides with Definition 1.1 since $P(v,A) = \frac{\deg_A(v)}{\deg(v)}$. Then, a functional voting is a Markov chain $A_0, A_1, \ldots$ where $A_{t+1} = (A_t)'$.

For $A \subseteq V$, let $T_{\mathrm{cons}}(A)$ denote the consensus time of the functional voting starting from the initial configuration A. Formally, $T_{\mathrm{cons}}(A)$ is the stopping time defined as

$$T_{\mathrm{cons}}(A) := \min\{t \ge 0 : A_t \in \{\emptyset, V\}, A_0 = A\}.$$

2.2 Technical background

Consider best-of-two on a complete graph K_n (with self loop on each vertex) with a current configuration $A \subseteq V$. Let $\alpha = |A|/n$. We have $P(v, A) = \alpha$ for any $v \in V$ and $A \subseteq V$. Then, for any $A \subseteq V$, $\mathbf{E}[\alpha'] = H_f(\alpha) = 3\alpha^2 - 2\alpha^3$. Thus, in each round, $\alpha' = 3\alpha^2 - 2\alpha^3 \pm O(\sqrt{\log n/n})$ holds w.h.p. from the Hoeffding bound. Therefore, the behavior of α can be written as the iteration of applying H_f.

The most technical part is the symmetry breaking at $\alpha = 1/2$. Note that $H_f(1/2) = 1/2$ and thus, the argument above does not work in the case of $|\alpha - 1/2| = o(\sqrt{\log n/n})$. To analyze this case, the authors of [21, 11] proved the following technical lemma asserting that α w.h.p. escapes from the area in $O(\log n)$ rounds.

▶ **Lemma 2.1** (Lemma 4.5 of [11] (informal)). *For any constant C, it holds w.h.p. that $|\alpha - 1/2| \geq C\sqrt{\log n/n}$ in $O(\log n)$ rounds (the hidden constant factor depends on C) if*

(i) *For any constant h, there is a constant $C_0 > 0$ such that, if $|\alpha - 1/2| = O(\sqrt{\log n/n})$ then $\mathbf{Pr}[|\alpha' - 1/2| > h/\sqrt{n}] > C_0$.*

(ii) *If $|\alpha - 1/2| = O(\sqrt{\log n/n})$ and $|\alpha - 1/2| = \Omega(1/\sqrt{n})$, $\mathbf{Pr}[|\alpha' - 1/2| \leq (1+\epsilon)|\alpha - 1/2|] \leq \exp(-\Theta((\alpha - 1/2)^2 n))$ for some constant $\epsilon > 0$.*

Intuitively speaking, the condition (ii) means that the bias $|\alpha' - 1/2|$ is likely to be at least $(1 + \epsilon)|\alpha - 1/2|$ for some constant $\epsilon > 0$. The condition (ii) is easy to check using the Hoeffding bound. The condition (i) means that α' has a fluctuation of size $\Omega(1/\sqrt{n})$ with a constant probability. We can check condition (i) using the Central Limit Theorem (the Berry-Esseen bound). The Central Limit Theorem implies that the normalized random variable $(\alpha' - \mathbf{E}[\alpha'])/\sqrt{\mathbf{Var}[\alpha']}$ converges to the standard normal distribution as $n \to \infty$. In other words, α' has a fluctuation of size $\Theta(\sqrt{\mathbf{Var}[\alpha']})$ with constant probability. Now, to verify the condition (i), we evaluate $\mathbf{Var}[\alpha']$. On K_n, it is easy to show that $\mathbf{Var}[\alpha'] = \Theta(1/n)$, which implies the condition (i).

The authors of [16, 17] considered best-of-two on expander graphs. They focused on the behavior of $\pi(A)$ instead of α. Roughly speaking, they proved that $\mathbf{E}[\pi(A') - 1/2] \geq (1 + \epsilon)(\pi(A) - 1/2) - O(\lambda^2)$. At the heart of the proof, they showed the following result.

▶ **Lemma 2.2** (Special case of Lemma 3 of [17]). *Consider a λ-expander graph with degree distribution π. Then, for any $S \subseteq V$, $\left|\sum_{v\in V} \pi(v)P(v, S)^2 - \pi(S)^2\right| \leq \lambda^2\pi(S)\big(1 - \pi(S)\big)$.*

Then, from the Hoeffding bound, we have $\mathbf{E}[\pi(A') - 1/2] \geq (1 + \epsilon)(\pi(A) - 1/2) - O(\lambda^2 + \|\pi\|_2\sqrt{\log n}))$. Thus, if the initial bias $|\pi(A) - 1/2|$ is $\Omega(\max\{\lambda^2, \sqrt{\log n/n}\})$, we can show that the consensus time is $O(\log n)$.

Unfortunately, we can not apply the same technique to estimate $\mathbf{Var}[\pi(A')]$ on expander graphs, and due to this reason, it seems difficult to estimate the worst-case consensus time on expander graphs. Actually, any previous works put assumptions on the initial bias due to the same reason. It should be noted that Lemma 2.1 is well-known in the literature. For example, Cruciani et al. [20] used Lemma 2.1 from random initial configurations.

The technique of estimating $\mathbf{E}[\pi(A')]$ by Cooper et al. [16, 17] is specialized in best-of-two. Thus, it is not straightforward to prove the estimation of $\mathbf{E}[\pi(A')]$ for voting processes other than best-of-two.

2.3 Our technical contribution

For simplicity, in this part, we focus on a quasi-majority functional voting with respect to a *symmetric* function f (i.e., $f(1 - x) = 1 - f(x)$ for every $x \in [0, 1]$) on a λ-expander graph with degree distribution π. For example, $f(x) = 3x^2 - 2x^3$ of best-of-three is a symmetric function. Note that $f = H_f$ if f is symmetric. Similar results mentioned in this subsection holds for non-symmetric f (see Lemma 3.5 and 3.6 of the full version [38]). For a C^2 function $h : \mathbb{R} \to \mathbb{R}$, let

$$K_1(h) := \max_{x\in[0,1]} |h'(x)|\,, \quad K_2(h) := \max_{x\in[0,1]} |h''(x)|$$

be constants[5] The following technical result enables us to estimate $\mathbf{E}[\pi(A')]$ and $\mathbf{Var}[\pi(A')]$ of functional voting.

▶ **Lemma 2.3.** *Consider a functional voting with respect to a symmetric C^2 function f on a λ-expander graph with degree distribution π. Let $g(x) := f(x)(1-f(x))$. Then, for all $A \subseteq V$,*

$$\left|\mathbf{E}[\pi(A')] - H_f(\pi(A))\right| \le \frac{K_2(f)}{2}\lambda^2\pi(A)\bigl(1-\pi(A)\bigr),$$
$$\left|\mathbf{Var}[\pi(A')] - \|\pi\|_2^2 g\bigl(\pi(A)\bigr)\right| \le K_1(g)\lambda\sqrt{\pi(A)\bigl(1-\pi(A)\bigr)}\|\pi\|_3^{3/2}.$$

Note that, if f is symmetric, the corresponding functional voting satisfies that $\mathbf{Pr}[v \in A'] = f(P(v,A))$ for any $v \in V$. Thus we have

$$\mathbf{E}[\pi(A')] = \sum_{v\in V}\pi(v)f\bigl(P(v,A)\bigr), \quad \mathbf{Var}[\pi(A')] = \sum_{v\in V}\pi(v)^2 g\bigl(P(v,A)\bigr).$$

To evaluate $\mathbf{E}[\pi(A')]$ and $\mathbf{Var}[\pi(A')]$ above, we prove the following key lemma that is a generalization of Lemma 2.2 and implies Lemma 2.3.

▶ **Lemma 2.4** (Special case of Lemmas 3.2 and 3.3)**.** *Consider a λ-expander graph with degree distribution π. Then, for any $S \subseteq V$ and any C^2 function $h : \mathbb{R} \to \mathbb{R}$,*

$$\left|\sum_{v\in V}\pi(v)h\bigl(P(v,S)\bigr) - h\bigl(\pi(S)\bigr)\right| \le \frac{K_2(h)}{2}\lambda^2\pi(S)\bigl(1-\pi(S)\bigr),$$
$$\left|\sum_{v\in V}\pi(v)^2 h\bigl(P(v,S)\bigr) - \|\pi\|_2^2 h\bigl(\pi(S)\bigr)\right| \le K_1(h)\lambda\sqrt{\pi(S)\bigl(1-\pi(S)\bigr)}\|\pi\|_3^{3/2}.$$

Non-symmetric functions

For general f, we prove the following.

▶ **Lemma 2.5.** *Consider a functional voting with respect to a C^2 function f on a λ-expander graph. Let $g(x) := f(x)(1-f(x))$. Then, for all $A \subseteq V$,*

$$\left|\mathbf{E}[\pi(A')] - H_f\bigl(\pi(A)\bigr)\right| \le K_2(f)\lambda\bigl(|2\pi(A)-1| + \lambda\bigr)\pi(A)\bigl(1-\pi(A)\bigr),$$
$$\left|\mathbf{Var}[\pi(A')] - \|\pi\|_2^2 g\left(\frac{1}{2}\right)\right| \le K_1(g)\left(\frac{1}{2}\|\pi\|_2^2\,|2\pi(A)-1| + 2\|\pi\|_3^{3/2}\lambda\sqrt{\pi(A)\bigl(1-\pi(A)\bigr)}\right).$$

We refer the proof of Lemma 2.5 to the full-version [38] due to the page limitation.

[5] For example, for $f(x) = 3x^2 - 2x^3$ of best-of-three, $f''(x) = 6 - 12x$ and $K_2(f) = 6$. It should be noted that we deal with f not depending on G except for best-of-k with $k = \omega(1)$.

2.4 Proof sketch of Theorem 1.3

We present proof sketch of Theorem 1.3(i). From the assumption of Theorem 1.3(i) and Lemma 2.3, if $|\pi(A) - 1/2| = o(1)$, we have $\mathbf{Var}[\pi(A')] = \Theta(\|\pi\|_2^2 g(\pi(A))) = \Theta(\|\pi\|_2^2 g(1/2 + o(1))) = \Theta(1/n)$. Moreover, $\mathbf{E}[\pi(A')] = H_f(\pi(A)) \pm O(\pi(A)/\sqrt{n})$ holds for any $A \subseteq V$. Hence, from the Hoeffding bound, $\pi(A') = H_f(\pi(A)) + O(\sqrt{\log n/n})$ holds w.h.p. for any $A \subseteq V$.

- If $|\pi(A) - 1/2| = O(\sqrt{\log n/n})$, we use Lemma 2.1 to obtain an $O(\log n)$ round symmetry breaking. In this phase, since $|\pi(A) - 1/2| = o(1)$, $\mathbf{Var}[\pi(A') - 1/2] = \Theta(1/n)$. Then, from the Berry-Esseen bound, we can check the condition (i). To check the condition (ii), we invoke the condition $H_f'(1/2) > 1$ of the quasi-majority function. From Taylor's theorem and the assumption of Lemma 2.1(ii) ($\pi(A) - 1/2 = \Omega(1/\sqrt{n})$), $\mathbf{E}[\pi(A') - 1/2] = H_f(\pi(A)) - H_f(1/2) - O(1/\sqrt{n}) \approx (1 + \epsilon_1)(\pi(A) - 1/2)$ for some positive constant $\epsilon_1 > 0$. Note that $H_f(1/2) = 1/2$.
- If $C_1\sqrt{\log n/n} \leq |\pi(A) - 1/2| \leq C_2$ for sufficiently large constant C_1 and some constant $C_2 > 0$, we use the Hoeffding bound and then obtain $\pi(A') - 1/2 \approx (1 + \epsilon_1)(\pi(A) - 1/2) - O(\sqrt{\log n/n}) \geq (1 + (\epsilon_1/2))(\pi(A) - 1/2)$ w.h.p. Hence, $O(\log n)$ rounds suffice to yield a constant bias. (Note that this argument holds when $|\pi(A) - 1/2| \leq C_2$ due to the remainder term of Taylor's theorem.)
- If $C_3 \leq \pi(A) < 1/2$, it is straightforward to see that $\pi(A') = H_f(\pi(A)) + O(\sqrt{\log n/n}) \leq \pi(A) - \epsilon_2$ w.h.p. for some constant $\epsilon_2 > 0$. Note that we invoke the property that $H_f(x) < x$ whenever $0 < x < 1/2$.
- If $\pi(A) \leq C_3$ for sufficiently small constant C_3, we use the Markov inequality to show $\pi(A_t) = O(n^{-3})$ w.h.p. for some $t = O(\log n)$. Since $\pi(A) \geq 1/n^2$ whenever $A \neq \emptyset$, this implies that the consensus time is $O(\log n)$ w.h.p. Note that, since $H_f'(0) < 1$, we have $\mathbf{E}[\pi(A')] \leq H_f(\pi(A)) + O(\pi(A)/\sqrt{n}) \approx H_f'(0)\pi(A) + O(\pi(A)/\sqrt{n}) \leq (1 - \epsilon_3)\pi(A)$ for some constant $\epsilon_3 > 0$.

In the proof of Theorem 1.7, we modify Lemma 2.1 and apply the same argument.

3 Reversible Markov chains and Proof of Lemma 2.4

In this section, we prove Lemma 2.4 by showing Lemmas 3.2 and 3.3, which are generalizations of Lemma 2.4 in terms of *reversible Markov chain*. This enables us to evaluate $\mathbf{E}[\pi(A')]$ and $\mathbf{Var}[\pi(A')]$ for functional voting with respect to a C^2 function f (see the full version [38] for functional voting with respect to non-symmetric f).

3.1 Technical tools for reversible Markov chains

To begin with, we briefly summarize the notation of Markov chain, which we will use in this section[6]. Let V be a set of size n. A *transition matrix* P over V is a matrix $P \in [0,1]^{V \times V}$ satisfying $\sum_{v \in V} P(u,v) = 1$ for any $u \in V$. Let $\pi \in [0,1]^V$ denote the *stationary distribution* of P, i.e., a probability distribution satisfying $\pi P = \pi$. A transition matrix P is *reversible* if $\pi(u)P(u,v) = \pi(v)P(v,u)$ for any $u, v \in V$. It is easy to check that the matrix (4) is

[6] For further detailed arguments about reversible Markov chains, see e.g., [29].

a reversible transition matrix and its stationary distribution is (3). Let $\lambda_1 \geq \cdots \geq \lambda_n$ denote the eigenvalues of P. If P is reversible, it is known that $\lambda_i \in \mathbb{R}$ for all i. Let $\lambda = \max\{|\lambda_2|, |\lambda_n|\}$ be the second largest eigenvalue in absolute value[7].

For a function $h : \mathbb{R} \to \mathbb{R}$ and subsets $S, T \subseteq V$, consider the quantity $Q_h(S,T)$ defined as

$$Q_h(S,T) := \sum_{v \in S} \pi(v) h\bigl(P(v,T)\bigr). \tag{6}$$

The special case of $h(x) = x$, that is, $Q(S,T) := \sum_{v \in S} \pi(v) P(v,T)$, is well known as *edge measure* [29] or *ergodic flow* [3, 31]. Note that, for any reversible P and subsets $S, T \subseteq V$, $Q(S,T) = Q(T,S)$ holds. The following result is well known as a version of the *expander mixing lemma*.

▶ **Lemma 3.1** (See, e.g., p.163 of [29]). *Suppose P is reversible. Then, for any $S, T \subseteq V$,*

$$|Q(S,T) - \pi(S)\pi(T)| \leq \lambda \sqrt{\pi(S)\pi(T)\bigl(1 - \pi(S)\bigr)\bigl(1 - \pi(T)\bigr)}.$$

We show the following lemma which gives a useful estimation of $Q_h(S,T)$.

▶ **Lemma 3.2.** *Suppose P is reversible. Then, for any $S, T \subseteq V$ and any C^2 function $h : \mathbb{R} \to \mathbb{R}$,*

$$\Bigl| Q_h(S,T) - \pi(S) h\bigl(\pi(T)\bigr) - h'\bigl(\pi(T)\bigr)\bigl(Q(S,T) - \pi(S)\pi(T)\bigr) \Bigr| \leq \frac{K_2(h)}{2} \lambda^2 \pi(T)\bigl(1 - \pi(T)\bigr).$$

Proof of Lemma 3.2. From Taylor's theorem, it holds for any $x, y \in [0,1]$ that

$$|h(x) - h(y) - h'(y)(x-y)| \leq \frac{K_2(h)}{2}(x-y)^2.$$

Hence

$$\begin{aligned}
&\Bigl| Q_h(S,T) - \pi(S) h\bigl(\pi(T)\bigr) - h'\bigl(\pi(T)\bigr)\bigl(Q(S,T) - \pi(S)\pi(T)\bigr) \Bigr| \\
&= \left| \sum_{v \in S} \pi(v) \Bigl(h\bigl(P(v,T)\bigr) - h\bigl(\pi(T)\bigr) - h'\bigl(\pi(T)\bigr)\bigl(P(v,T) - \pi(T)\bigr) \Bigr) \right| \\
&\leq \sum_{v \in S} \pi(v) \Bigl| h\bigl(P(v,T)\bigr) - h\bigl(\pi(T)\bigr) - h'\bigl(\pi(T)\bigr)\bigl(P(v,T) - \pi(T)\bigr) \Bigr| \\
&\leq \sum_{v \in S} \pi(v) \frac{K_2(h)}{2} \bigl(P(v,T) - \pi(T)\bigr)^2 \leq \frac{K_2(h)}{2} \sum_{v \in V} \pi(v) \bigl(P(v,T) - \pi(T)\bigr)^2 \\
&\leq \frac{K_2(h)}{2} \lambda^2 \pi(T)\bigl(1 - \pi(T)\bigr).
\end{aligned}$$

The last inequality follows from Corollary A.2 of the full version [38]. ◀

Next, consider

$$R_h(S,T) := \sum_{v \in S} \pi(v)^2 h\bigl(P(v,T)\bigr) \tag{7}$$

for a function $h : \mathbb{R} \to \mathbb{R}$ and $S, T \subseteq V$. For notational convenience, for $S \subseteq V$, let $\pi_2(S) := \sum_{v \in S} \pi(v)^2$. We show the following lemma that evaluates $R_h(S,T)$.

[7] If P is *ergodic*, i.e., for any $u, v \in V$, there exists a $t > 0$ such that $P^t(u,v) > 0$ and $\mathrm{GCD}\{t > 0 : P^t(x,x) > 0\} = 1$, $1 > \lambda_2$ and $\lambda_n > -1$. For example, the transition matrix of the simple random walk on a connected and non-bipartite graph is ergodic.

▶ **Lemma 3.3.** *Suppose that P is reversible. Then, for any $S, T \subseteq V$ and any C^2 function $h : \mathbb{R} \to \mathbb{R}$,*

$$\left|R_h(S,T) - \pi_2(S)h\bigl(\pi(T)\bigr)\right| \le K_1(h)\|\pi\|_3^{3/2}\lambda\sqrt{\pi(T)\bigl(1-\pi(T)\bigr)}.$$

Proof. We first observe that

$$\bigl|h(x) - h(y)\bigr| \le K_1(h)|x-y| \tag{8}$$

holds for any $x, y \in [0,1]$ from Taylor's theorem. Hence,

$$\begin{aligned}&\left|R_h(S,T) - \pi_2(S)h\bigl(\pi(T)\bigr)\right|\\ &= \left|\sum_{v\in S}\pi(v)^2\Bigl(h\bigl(P(v,T)\bigr) - h\bigl(\pi(T)\bigr)\Bigr)\right| \le \sum_{v\in S}\pi(v)^2\left|h\bigl(P(v,T)\bigr) - h\bigl(\pi(T)\bigr)\right|\\ &\le \sum_{v\in S}\pi(v)^2K_1(h)\bigl|P(v,T)-\pi(T)\bigr| \le K_1(h)\sum_{v\in V}\pi(v)^2\bigl|P(v,T)-\pi(T)\bigr|.\end{aligned}$$

Then, applying the Cauchy-Schwarz inequality and Corollary A.2 of the full version [38],

$$\begin{aligned}\sum_{v\in V}\pi(v)^2\bigl|P(v,T)-\pi(T)\bigr| &\le \sqrt{\left(\sum_{v\in V}\pi(v)^3\right)\left(\sum_{v\in V}\pi(v)\bigl(P(v,T)-\pi(T)\bigr)^2\right)}\\ &\le \|\pi\|_3^{3/2}\lambda\sqrt{\pi(T)\bigl(1-\pi(T)\bigr)}\end{aligned}$$

and we obtain the claim. ◀

▶ Remark 3.4. The results of this paper can be extended to voting processes where the sampling probability is determined by a reversible transition matrix P. This includes voting processes on edge-weighted graphs $G = (V, E, w)$, where $w : E \to \mathbb{R}$ denotes an edge weight function. Consider the transition matrix P defined as follows: $P(u,v) = w(\{u,v\})/\sum_{x:\{u,x\}\in E} w(\{u,x\})$ for $\{u,v\} \in E$ and $P(u,v) = 0$ for $\{u,v\} \notin E$. A *weighted* functional voting with respect to f is determined by $\mathbf{Pr}[v \in A'|v \in B] = f(P(v,B))$ and $\mathbf{Pr}[v \in B'|v \in A] = f(P(v,A))$. For simplicity, in this paper, we do not explore the weighted variant and focus on the usual setting where P is the matrix (4) and its stationary distribution π is (3).

3.2 Proof of Lemma 2.4

For the first inequality, by substituting V to S of Lemma 3.2, we obtain $\Bigl|Q_h(V,T) - h\bigl(\pi(T)\bigr)\Bigr| \le \frac{K_2(h)}{2}\lambda^2\pi(T)\bigl(1-\pi(T)\bigr)$. Note that $Q(V,T) = Q(T,V) = \pi(T)$ from the reversibility of P. Similarly, we obtain the second inequality by substituting V to S of Lemma 3.3. ◀

4 Proofs of Theorems 1.3 and 1.5

Consider a quasi-majority functional voting with respect to f on an n-vertex λ-expander graph with degree distribution π. Let $A_0, A_1, \ldots,$ be the sequence given by the functional voting with initial configuration $A_0 \subseteq V$. Theorems 1.3 and 1.5 follow from the following lemma.

▶ **Lemma 4.1.** *Consider a quasi-majority functional voting with respect to f on an n-vertex λ-expander graph with degree distribution π. Let $\epsilon_h(f) := H_f'(1/2) - 1$, $\epsilon_c(f) := 1 - H_f'(0)$ and $K(f) := \max\{K_2(f), K_2(H_f)\}$ be three positive constants depending only on f. Then, the following holds:*

- **(I)** *Let $C_1 > 0$ be an arbitrary constant and $\varepsilon : \mathbb{N} \to \mathbb{R}$ be an arbitrary function satisfying $\varepsilon(n) \to 0$ as $n \to \infty$. Suppose that $\lambda \le C_1 n^{-1/4}$, $\|\pi\|_2 \le C_1/\sqrt{n}$ and $\|\pi\|_3 \le \varepsilon/\sqrt{n}$. Then, for any $A_0 \subseteq V$ such that $|\delta(A_0)| \le c_1 \log n/\sqrt{n}$ for an arbitrary constant $c_1 > 0$, $|\delta(A_t)| \ge c_1 \log n/\sqrt{n}$ within $t = O(\log n)$ steps w.h.p.*
- **(II)** *Suppose that $\lambda \le \frac{\epsilon_h(f)}{2K(f)}$. Then, for any $A_0 \subseteq V$ s.t. $\frac{2\max\{K(f),8\}}{\epsilon_h(f)} \max\{\lambda^2, \|\pi\|_2\sqrt{\log n}\} \le |\delta(A_0)| \le \frac{\epsilon_h(f)}{K(f)}$, $|\delta(A_t)| \ge \frac{\epsilon_h(f)}{K(f)}$ within $t = O(\log|\delta(A_0)|^{-1})$ steps w.h.p.*
- **(III)** *Let c_2, c_3 be two arbitrary constants satisfying $0 < c_2 < c_3 < 1/2$ and $\epsilon(f) := \min_{x\in[c_2,c_3]}\big(x - H_f(x)\big)$ be a positive constant depending f, c_2, c_3. Suppose that $\lambda \le \frac{\epsilon(f)}{2K(f)}$ and $\|\pi\|_2 \le \frac{\epsilon(f)}{4\sqrt{\log n}}$. Then, for any $A_0 \subseteq V$ satisfying $c_2 \le \pi(A_0) \le c_3$, $\pi(A_t) \le c_2$ within constant steps w.h.p.*
- **(IV)** *Suppose that $\lambda \le \frac{\epsilon_c(f)}{2K(f)}$ and $\|\pi\|_2 \le \frac{\epsilon_c(f)^2}{32K(f)\sqrt{\log n}}$. Then, for any $A_0 \subseteq V$ satisfying $\pi(A_0) \le \frac{\epsilon_c(f)}{8K(f)}$, $\pi(A_t) = 0$ within $t = O(\log n)$ steps w.h.p.*
- **(V)** *Suppose that $H_f'(0) = 0$, $\lambda \le \frac{1}{10K(f)}$ and $\|\pi\|_2 \le \frac{1}{64K(f)\sqrt{\log n}}$. Then, for any $A_0 \subseteq V$ satisfying $\pi(A_0) \le \frac{1}{7K(f)}$, it holds w.h.p. that $\pi(A_t) = 0$ within*

$$t = O\left(\log\log n + \frac{\log n}{\log \lambda^{-1}} + \frac{\log n}{\log(\|\pi\|_2\sqrt{\log n})^{-1}}\right) \textit{ steps.}$$

Proof of Theorem 1.3(ii). Since $\|\pi\|_2 \ge 1/\sqrt{n}$, we have $|\delta(A_0)| = \Omega(\sqrt{\log n/n})$. This implies that Phase (II) takes at most $O(\log n)$. Thus, we obtain the claim since we can merge Phases (II) to (IV) by taking appropriate constants c_2, c_3 in Phase (III). ◀

Proof of Theorem 1.3(i). Under the assumption of Theorem 1.3(i), for any positive constant C, a positive constant C' exists such that $C(\lambda^2 + \|\pi\|_2\sqrt{\log n}) \le C'\frac{\log n}{\sqrt{n}}$. Thus, we can combine Phase (I) and Theorem 1.3(ii), and we obtain the claim. ◀

Proof of Theorem 1.5. Combining Phases (II), (III) and (V), we obtain the claim. ◀

In the rest of this section, we show Phases (I) to (V) of Lemma 4.1. For notational convenience, let

$$\alpha := \pi(A),\ \alpha' := \pi(A'),\ \alpha_t := \pi(A_t), \delta := \delta(A) = 2\alpha - 1,\ \delta' := \delta(A'),\ \delta_t := \delta(A_t).$$

4.1 Phase (I): $0 \le |\delta| \le c_1 \log n/\sqrt{n}$

We use the following lemma to show Lemma 4.1(I).

▶ **Lemma 4.2** (Lemma 4.5 of [11]). *Consider a Markov chain $(X_t)_{t=1}^{\infty}$ with finite state space Ω and a function $\Psi : \Omega \to \{0, \dots, n\}$. Let C_3 be arbitrary constant and $m = C_3\sqrt{n}\log n$. Suppose that Ω, Ψ and m satisfies the following conditions:*

- **(i)** *For any positive constant h, there exists a positive constant $C_1 < 1$ such that*

$$\mathbf{Pr}\left[\Psi(X_{t+1}) < h\sqrt{n} \,\middle|\, \Psi(X_t) \le m\right] < C_1.$$

(ii) *Three positive constants γ, C_2 and h exist such that, for any $x \in \Omega$ satisfying $h\sqrt{n} \leq \Psi(x) < m$,*

$$\mathbf{Pr}\left[\Psi(X_{t+1}) < (1+\gamma)\Psi(X_t) \mid X_t = x\right] < \exp\left(-C_2\frac{\Psi(x)^2}{n}\right).$$

Then, $\Psi(X_t) \geq m$ holds w.h.p. for some $t = O(\log n)$.

Let us first prove the following lemma concerning the growth rate of $|\delta|$, which we will use in the proofs of (I) and (II) of Lemma 4.1.

▶ **Lemma 4.3.** *Consider a quasi-majority functional voting with respect to f on an n-vertex λ-expander graph with degree distribution π. Let $\epsilon_h(f) := H_f'(1/2) - 1$ and $K(f) := \max\{K_2(f), K_2(H_f)\}$ be positive constants depending only on f. Suppose that $\lambda \leq \frac{\epsilon_h(f)}{2K(f)}$. Then, for any $A \subseteq V$ satisfying $\frac{2K(f)}{\epsilon_h(f)}\lambda^2 \leq |\delta| \leq \frac{\epsilon_h(f)}{K(f)}$,*

$$\mathbf{Pr}\left[|\delta'| \leq \left(1 + \frac{\epsilon_h(f)}{8}\right)|\delta|\right] \leq 2\exp\left(-\frac{\epsilon_h(f)^2\delta^2}{128\|\pi\|_2^2}\right).$$

Proof. Combining Lemma 2.5 and Taylor's theorem, we have

$$\begin{aligned}\left|\mathbf{E}[\delta'] - H_f'\left(\frac{1}{2}\right)\delta\right| &= 2\left|\mathbf{E}[\alpha'] - \frac{1}{2} - H_f'\left(\frac{1}{2}\right)\left(\alpha - \frac{1}{2}\right)\right| \\ &= 2\left|\mathbf{E}\left[\alpha'\right] - H_f\left(\alpha\right) + H_f\left(\alpha\right) - H_f\left(\frac{1}{2}\right) - H_f'\left(\frac{1}{2}\right)\left(\alpha - \frac{1}{2}\right)\right| \\ &\leq 2K_2(f)\lambda\left(|\delta| + \lambda\right)\alpha(1-\alpha) + K_2(H_f)\left(\alpha - \frac{1}{2}\right)^2 \\ &\leq \left(\frac{K(f)}{2}\lambda + \frac{K(f)}{4}|\delta|\right)|\delta| + \frac{K(f)}{2}\lambda^2 \end{aligned} \tag{9}$$

Note that $H_f(1/2) = 1/2$ from the definition. From assumptions of $\lambda \leq \frac{\epsilon_h(f)}{2K(f)}$, $|\delta| \leq \frac{\epsilon_h(f)}{K(f)}$ and $\lambda^2 \leq \frac{\epsilon_h(f)}{2K(f)}|\delta|$, we have $\left|H_f'\left(\frac{1}{2}\right)\delta\right| - |\mathbf{E}[\delta']| \leq \left|H_f'\left(\frac{1}{2}\right)\delta - \mathbf{E}[\delta']\right| \leq \frac{3}{4}\epsilon_h(f)|\delta|$. Hence, it holds that

$$\left|\mathbf{E}[\delta']\right| \geq \left|H_f'\left(\frac{1}{2}\right)\delta\right| - \frac{3}{4}\epsilon_h(f)|\delta| = (1+\epsilon_h(f))|\delta| - \frac{3}{4}\epsilon_h(f)|\delta| = \left(1 + \frac{\epsilon_h(f)}{4}\right)|\delta|.$$

We observe that, for any $\kappa > 0$,

$$\mathbf{Pr}\left[|\delta'| \leq \left|\mathbf{E}[\delta']\right| - \kappa\right] \leq 2\exp\left(-\frac{\kappa^2}{2\|\pi\|_2^2}\right) \tag{10}$$

from Corollary A.4 of the full version [38]. Note that $\delta' = \sum_{v\in V}\pi(v)(2X_v - 1)$ for independent indicator random variables $(X_v)_{v\in V}$ (see (5) for the definition of X_v). Thus,

$$\begin{aligned}\mathbf{Pr}\left[|\delta'| \leq \left(1 + \frac{\epsilon_h(f)}{8}\right)|\delta|\right] &= \mathbf{Pr}\left[|\delta'| \leq \left(1 + \frac{\epsilon_h(f)}{4}\right)|\delta| - \frac{\epsilon_h(f)}{8}|\delta|\right] \\ &\leq \mathbf{Pr}\left[|\delta'| \leq \left|\mathbf{E}[\delta']\right| - \frac{\epsilon_h(f)}{8}|\delta|\right] \leq 2\exp\left(-\frac{\epsilon_h(f)^2\delta^2}{128\|\pi\|_2^2}\right)\end{aligned}$$

and we obtain the claim. ◀

Proof of Lemma 4.1(I). We check the conditions (i) and (ii) of Lemma 4.2 with letting $\Psi(A) = \lfloor n|\delta(A)|\rfloor$ and $m = c_1\sqrt{n}\log n$.

Condition (i). First, we show the following claim that evaluates $\mathbf{Var}[\delta']$.

▷ Claim 4.4. Under the same assumption as Lemma 4.1(I),

$$\frac{\epsilon_{\mathrm{var}}(f)}{n} \le \mathbf{Var}[\delta'] \le \frac{5C_1^2}{n}$$

holds, where $\epsilon_{\mathrm{var}}(f) := f(1/2)(1-f(1/2))$ is a positive constant depending only on f.

Proof of the claim. From Lemma 2.5 and assumptions, we have

$$\left|\frac{\mathbf{Var}[\delta']}{4} - \|\pi\|_2^2 g\left(\frac{1}{2}\right)\right| = \left|\mathbf{Var}[\alpha'] - \|\pi\|_2^2 g\left(\frac{1}{2}\right)\right| \le K_1(g)\left(\|\pi\|_2^2\frac{|\delta|}{2} + \|\pi\|_3^{3/2}\lambda\right)$$
$$\le \frac{K_1(g)}{n}\left(C_1^2 c_1\frac{\log n}{\sqrt{n}} + C_1\epsilon^{3/2}\right) = \frac{1}{n}\cdot o(1).$$

Note that $\mathbf{Var}[\delta'] = \mathbf{Var}[2\alpha' - 1] = 4\,\mathbf{Var}[\alpha']$. Since $\|\pi\|_2^2 \ge 1/n$, we have

$$\frac{\epsilon_{\mathrm{var}}(f)}{n} \le \frac{4\epsilon_{\mathrm{var}}(f) - o(1)}{n} \le \mathbf{Var}[\delta'] \le \frac{4C_1^2 + o(1)}{n} \le \frac{5C_1^2}{n}. \qquad \triangleleft$$

From Corollary A.6 of the full version [38] with letting $Y_v = \pi(v)(2X_v - 1)$, we have

$$\mathbf{Pr}\left[|\delta'| \le x\sqrt{\frac{\epsilon_{\mathrm{var}}(f)}{n}}\right] \le \mathbf{Pr}\left[|\delta'| \le x\sqrt{\mathbf{Var}[\delta']}\right] \le \Phi(x) + \frac{5.6\|\pi\|_3^3}{\mathbf{Var}[\delta']^{3/2}}$$
$$\le \Phi(x) + 5.6\frac{\epsilon^3}{n^{3/2}}\cdot\frac{n^{3/2}}{\epsilon_{\mathrm{var}}(f)^{3/2}} = \Phi(x) + o(1) \tag{11}$$

for any $x \in \mathbb{R}$, where $\Phi(x) = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{x} \mathrm{e}^{-y^2/2}\mathrm{d}y$. Thus, for any constant $h > 0$, there exists some constant $C > 0$ such that $\mathbf{Pr}[\Psi(A') < h\sqrt{n} \mid \Psi(A) \le m] < C$, which verifies the condition (i).

Condition (ii). Set $h = \frac{2K(f)}{\epsilon_h(f)}C_1^2$ and assume $h\sqrt{n} \le \Psi(A) < m$. Then

$$\frac{2K(f)}{\epsilon_h(f)}\lambda^2 n \le \frac{2K(f)}{\epsilon_h(f)}C_1^2\sqrt{n} = h\sqrt{n} \le \Psi(A) \le |\delta|n = o(n).$$

Thus, we can apply Lemma 4.3 and positive constants γ, C exist such that, for any $h\sqrt{n} \le \Psi(A) \le c_1\sqrt{n}\log n$, $\mathbf{Pr}[\Psi(A') < (1+\gamma)\Psi(A)] < \exp\left(-C\frac{\Psi(A)^2}{n}\right)$. Note that $\|\pi\|_2^2 = \Theta(1/n)$ from the assumption. Thus the condition (ii) holds and we can apply Lemma 4.2. ◀

4.2 Phase (II): $\frac{2\max\{K(f),8\}}{\epsilon_h(f)}\max\{\lambda^2, \|\pi\|_2\sqrt{\log n}\} \le |\delta| \le \frac{\epsilon_h(f)}{K(f)}$

Proof of Lemma 4.1(II). Since $|\delta| \ge \frac{16}{\epsilon_h(f)}\|\pi\|_2\sqrt{\log n}$ from assumptions, applying Lemma 4.3 yields $\mathbf{Pr}\left[|\delta'| \le \left(1 + \frac{\epsilon_h(f)}{8}\right)|\delta|\right] \le \frac{2}{n^2}$. Thus, it holds with probability larger than $(1 - 2/n^2)^t$ that $|\delta_t| \ge \left(1 + \frac{\epsilon_h(f)}{8}\right)^t |\delta_0|$ and we obtain the claim by substituting $t = O(\log|\delta_0|^{-1})$. ◀

4.3 Phase (III): $0 < c_2 \le \alpha \le c_3 < 1/2$

Proof of Lemma 4.1(III). We first observe that, for any $\kappa > 0$,

$$\mathbf{Pr}\left[|\alpha' - \mathbf{E}[\alpha']| \ge \kappa\|\pi\|_2\sqrt{\log n}\right] \le 2n^{-2\kappa} \tag{12}$$

from the Hoeffding theorem. Note that $\alpha' = \sum_{v\in V}\pi(v)X_v$ for independent indicator random variables $(X_v)_{v\in V}$. Hence, applying Lemma 2.5 yields

$$|\alpha' - H_f(\alpha)| \le |\alpha' - \mathbf{E}[\alpha']| + |\mathbf{E}[\alpha'] - H_f(\alpha)| \le \|\pi\|_2\sqrt{\log n} + \frac{K_2(f)}{4}(|\delta| + \lambda)\lambda \tag{13}$$

with probability larger than $1 - 2/n^2$. Then, for any $\alpha \in [c_2, c_3]$, it holds with probability larger than $1 - 2/n^2$ that

$$\alpha' \le H_f(\alpha) + \frac{K(f)}{2}\lambda + \|\pi\|_2\sqrt{\log n} \le \alpha - \epsilon(f) + \frac{\epsilon(f)}{4} + \frac{\epsilon(f)}{4} \le \alpha - \frac{\epsilon(f)}{2}.$$

Thus, for $\alpha_0 \in [c_2, c_3]$, $\alpha_t \le c_2$ within $t = 2(c_3 - c_2)/\epsilon(f) = O(1)$ steps w.h.p. ◀

4.4 Phase (IV): $0 \le \alpha \le \frac{\epsilon_c(f)}{8K(f)}$

We show the following lemma which is useful for proving (IV) and (V) of Lemma 4.1.

▶ **Lemma 4.5.** *Let $\epsilon \in (0, 1]$ be an arbitrary constant. Consider functional voting on an n-vertex connected graph with degree distribution π. Suppose that, for some $\alpha_* \in [0, 1]$ and $K \in [0, 1 - \epsilon]$, $\mathbf{E}[\alpha'] \le K\alpha$ holds for any $A \subseteq V$ satisfying $\alpha \le \alpha_*$ and $\|\pi\|_2 \le \frac{\epsilon\alpha_*}{2\sqrt{\log n}}$. Then, for any $A_0 \subseteq V$ satisfying $\alpha_0 \le \alpha_*$, $\alpha_t = 0$ w.h.p. within $O\left(\frac{\log n}{\log K^{-1}}\right)$ steps.*

Proof. For any $\alpha \le \alpha_*$, from (12) and assumptions of $\mathbf{E}[\alpha'] \le \alpha$ and $\|\pi\|_2 \le \frac{\epsilon\alpha_*}{2\sqrt{\log n}}$, it holds with probability larger than $1 - 2/n^4$ that

$$\alpha' \le \mathbf{E}[\alpha'] + 2\|\pi\|_2\sqrt{\log n} \le K\alpha + \epsilon\alpha_* \le (1 - \epsilon)\alpha_* + \epsilon\alpha_* = \alpha_*.$$

Thus, for any $\alpha_0 \le \alpha_*$, we have

$$\begin{aligned}\mathbf{E}[\alpha_t] &= \sum_{x \le a_*}\mathbf{E}\left[\alpha_t | \alpha_{t-1} = x\right]\mathbf{Pr}\left[\alpha_{t-1} = x\right] + \sum_{x > a_*}\mathbf{E}\left[\alpha_t | \alpha_{t-1} = x\right]\mathbf{Pr}\left[\alpha_{t-1} = x\right] \\ &\le \sum_{x \le a_*} Kx\,\mathbf{Pr}\left[\alpha_{t-1} = x\right] + \mathbf{Pr}\left[\alpha_{t-1} > a_*\right] \le K\,\mathbf{E}[\alpha_{t-1}] + \frac{2t}{n^4} \\ &\le \cdots \le K^t\alpha_0 + \frac{2t^2}{n^4} \le K^t + \frac{2t^2}{n^4}.\end{aligned}$$

This implies that, $\mathbf{E}[\alpha_t] = O(n^{-3})$ within $t = O\left(\frac{\log n}{\log K^{-1}}\right)$ steps. Let $\pi_{\min} := \min_{v\in V}\pi(v) \ge 1/(2|E|) \ge 1/n^2$. We obtain the claim from the Markov inequality, which yields $\mathbf{Pr}[\alpha_t = 0] = 1 - \mathbf{Pr}[\alpha_t \ge \pi_{\min}] \ge 1 - \frac{\mathbf{E}[\alpha_t]}{\pi_{\min}} = 1 - O(1/n)$. ◀

Proof of Lemma 4.1 of (IV). Combining Lemma 2.5 and Taylor's theorem,

$$\begin{aligned}\left|\mathbf{E}[\alpha'] - H_f'(0)\alpha\right| &= \left|\mathbf{E}[\alpha'] - H_f(\alpha) + H_f(\alpha) - H_f(0) - H_f'(0)(\alpha - 0)\right| \\ &\le K_2(f)\lambda\left(|\delta| + \lambda\right)\alpha(1 - \alpha) + \frac{K_2(H_f)}{2}\alpha^2 \\ &\le 2K(f)\lambda\alpha + \frac{K(f)}{2}\alpha^2. \end{aligned}\tag{14}$$

Hence, for any $\alpha \le \frac{\epsilon_c(f)}{8K(f)}$, we have $\mathbf{E}[\alpha'] \le \left(H'_f(0) + 2K(f)\lambda + \frac{K(f)}{2}\alpha\right)\alpha \le \left(1 - \frac{\epsilon_c(f)}{2}\right)\alpha$. Letting $\epsilon = \epsilon_c(f)/2$, $K = 1 - \epsilon_c(f)/2$ and $\alpha_* = \frac{\epsilon_c(f)}{8K(f)}$, from the assumption, $\|\pi\|_2 \le \frac{\epsilon_c(f)^2}{32K(f)\sqrt{\log n}} = \frac{\epsilon\alpha_*}{2\sqrt{\log n}}$. Thus, we can apply Lemma 4.5 and we obtain the claim. ◀

4.5 Phase (V): $H'_f(0) = 0$ and $0 \le \alpha \le \frac{1}{7K(f)}$

Proof of Lemma 4.1(V). In this case, from (14),

$$\mathbf{E}[\alpha'] \le 2K(f)\lambda\alpha + \frac{K(f)}{2}\alpha^2. \tag{15}$$

We consider the following two cases.

Case 1. $\max\left\{\lambda, \sqrt{\frac{\|\pi\|_2\sqrt{\log n}}{K(f)}}\right\} \le \alpha \le \frac{1}{7K(f)}$: In this case, combining (12) and (15), it holds with probability larger than $1 - 2/n^2$ that

$$\alpha' \le \left(\frac{2K(f)\lambda}{\alpha} + \frac{K(f)}{2} + \frac{\|\pi\|_2\sqrt{\log n}}{\alpha^2}\right)\alpha^2 \le \frac{7K(f)}{2}\alpha^2.$$

Applying this inequality iteratively, for any $\alpha_0 \le 7K(f)^{-1}$,

$$\alpha_t \le \frac{7K(f)}{2}\alpha_{t-1}^2 \le \cdots \le \frac{2}{7K(f)}\left(\frac{7K(f)}{2}\alpha_0\right)^{2^t} \le \frac{2}{7K(f)2^{2^t}}.$$

holds with probability larger than $(1 - 2/n^2)^t$. This implies that, within $t = O(\log\log n)$ steps, $\alpha_t \le \max\left\{\lambda, \sqrt{\frac{\|\pi\|_2\sqrt{\log n}}{K(f)}}\right\}$ w.h.p. Note that $\max\left\{\lambda, \sqrt{\frac{\|\pi\|_2\sqrt{\log n}}{K(f)}}\right\} \ge \sqrt{\frac{\|\pi\|_2\sqrt{\log n}}{K(f)}} \ge \sqrt{\frac{\sqrt{\log n/n}}{K(f)}}$ since $\|\pi\|_2^2 \ge 1/n$.

Case 2. $\alpha \le \max\left\{\lambda, \sqrt{\frac{\|\pi\|_2\sqrt{\log n}}{K(f)}}\right\}$: Set $\alpha_* = \max\left\{\lambda, \sqrt{\frac{\|\pi\|_2\sqrt{\log n}}{K(f)}}\right\} \ge \sqrt{\frac{\|\pi\|_2\sqrt{\log n}}{K(f)}}$, $K = \frac{5K(f)}{2}\lambda + \frac{1}{2}\sqrt{K(f)\|\pi\|_2\sqrt{\log n}}$ and $\epsilon = 1/4$. Then, from $\lambda \le \frac{1}{10K(f)}$ and $\|\pi\|_2 \le \frac{1}{64K(f)\sqrt{\log n}}$, we have $K \le 1 - \epsilon$,

$$\|\pi\|_2 = (\sqrt{\|\pi\|_2})^2 \le \frac{\sqrt{\|\pi\|_2}}{8\sqrt{K(f)\sqrt{\log n}}} = \sqrt{\frac{\|\pi\|_2\sqrt{\log n}}{K(f)}}\frac{\epsilon}{2\sqrt{\log n}} \le \frac{\epsilon\alpha_*}{2\sqrt{\log n}},$$

$$\mathbf{E}[\alpha'] \le \left(2K(f)\lambda + \frac{K(f)}{2}\alpha\right)\alpha \le \left(2K(f)\lambda + \frac{K(f)}{2}\lambda + \frac{1}{2}\sqrt{K(f)\|\pi\|_2\sqrt{\log n}}\right)\alpha = K\alpha.$$

Thus, applying Lemma 4.5, we obtain the claim. ◀

5 Conclusion

In this paper we propose functional voting as a generalization of several known voting processes. We show that the consensus time is $O(\log n)$ for any quasi-majority functional voting on $O(n^{-1/2})$-expander graphs with balanced degree distributions. This result extends previous works concerning voting processes on expander graphs. Possible future direction of this work includes

1. Does $O(\log n)$ worst-case consensus time holds for quasi-majority functional voting on graphs with less expansion (i.e., $\lambda = \omega(n^{-1/2})$)?
2. Is there some relationship between best-of-k and Majority?

Abstract

Given query access to a set of constraints S, we wish to quickly check if some objective function φ subject to these constraints is at most a given value k. We approach this problem using the framework of property testing where our goal is to distinguish the case $\varphi(S) \leq k$ from the case that at least an ϵ fraction of the constraints in S need to be removed for $\varphi(S) \leq k$ to hold. We restrict our attention to the case where (S, φ) are LP-Type problems which is a rich family of combinatorial optimization problems with an inherent geometric structure. By utilizing a simple sampling procedure which has been used previously to study these problems, we are able to create property testers for any LP-Type problem whose query complexities are independent of the number of constraints. To the best of our knowledge, this is the first work that connects the area of LP-Type problems and property testing in a systematic way. Among our results are property testers for a variety of LP-Type problems that are new and also problems that have been studied previously such as a tight upper bound on the query complexity of testing clusterability with one cluster considered by Alon, Dar, Parnas, and Ron (FOCS 2000). We also supply a corresponding tight lower bound for this problem and other LP-Type problems using geometric constructions.

1 Introduction

Many problems in combinatorial optimization can be represented as a pair (S, φ) where S is a set of constraints and φ is a function of the constraints that we would like to minimize. This class includes many problems that are NP-hard, even for the decision version of some problems where we would like to determine if $\varphi(S)$ is at most some constant k. For instance, let S be constraints that say two nodes in a graph are connected by an edge (so S can be thought of as a set of edges) and φ be the chromatic number of a graph with those edges. Then it is NP-complete to determine if $\varphi(S) \leq 3$.

In this work, we consider a relaxation of the above hard class of problems by using the framework of *property testing*. Specifically, given a value parameter k and distance parameter ϵ, we wish to determine if $\varphi(S) \leq k$ or if (S, φ) is ϵ-far from $\varphi(S) \leq k$, where ϵ-far means that at least $\epsilon|S|$ many of the constraints of S need to be removed for $\varphi(S) \leq k$ to hold. We assume we have query access to the constraints and knowledge of φ and our goal is to perform property testing while minimizing the number of constraints of S we access.

Even under the property testing setting, this question is too broad. Therefore, we focus our attention to *LP-Type Problems*, formally described in Definition 1. Informally, these problems have an underlying geometrical structure, much like that of linear programs, which can be used to create efficient testing algorithms.

Our main result is a general algorithm that is able to perform property testing for *any* LP-Type problem with $O(\delta/\epsilon)$ queries where δ is the dimension of the LP-Type problem, formally defined in Section 2. In many cases, this bound is tight such as testing clusterability using one cluster considered in [1]. To the best of our knowledge, this is the first work that connects the area of LP-Type problems and property testing in a systematic way. The class of these problems is quite general and includes problems which have been previously studied individually in property testing, such as testing clusterability of points in [1], and newer testing problems, such as determining if a set of linear constraints is feasible or "far" from feasible. We also give a matching lower bound for many of these problems using geometric constructions. For a comprehensive overview of our contributions, see Section 2.2.

1.1 Related Work

Many problems in property testing can be modeled as a set of constraints and some optimization function over these constraints. These include well studied graph problems such as bipartiteness, expansion, k-colorability, and many other problems [14, 15, 16, 23]. This line of work was initiated by Goldreich and Ron and there are many results in the area of graph property testing. For more information about graph property testing, see [13] and the references within. Overall, these testing problems differ from our setting where our queries are essentially access to random constraints.

This model where queries are accesses to constraints have also been studied in the case where we wish to test properties of a metric space and queries are access to points (see [19, 1, 21]). There are instances of these problems that are also examples of LP-Type problems that we consider. For more information, see Section 2.2.

LP-Type problems have a rich literature and there have been many previous work on them, including general algorithms to solve LP-Type problems [25, 6, 26, 18]. The algorithms for these problems have runtimes that are generally linear in the number of constraints, but exponential in the dimension of the LP-Type problem (see Definition 3). This is in contrast to our testing algorithms that have no dependence on the number of constraints.

Furthermore, many properties of LP-Type problems have been generalized to a larger class of problems called violator spaces [11, 4]. We do not explicitly consider them here since these problems do not yield any additional interesting property testing applications but our results carry over to this setting in a straightforward manner.

There are previous works on geometric property testing, for example, testing convexity of point sets [7, 20], testing disjointness of geometric bodies [9], and testing properties of two dimensional images [22, 24, 2, 3]. While many of these work share the paradigm of "sample few objects and test" that is common among many property testers, including ours, the problems considered in these works are very different than the problems we focus on (see 2.2).

There is also existing work on property testing for constraint satisfaction problems (CSPs) where given an instance of a CSP, one is given query access to an assignment of the variables and the task is to determine if the assignment is "close" or "far" from satisfying the instance [5]. This is different than our setting where we wish to check if $\varphi(S) \leq k$ where φ is a function of the constraints in S.

The paper of Czumaj and Sohler cited in [8] is closest in spirit to our work, as it also introduces a framework for property testing for a general class of problems which they refer to as *abstract combinatorial problems* (ACPs). This class of problems are similar to LP-type problems as they both include a set of constraints and consider a restricted set of subsets called a basis (see Section 2 for a formal definition of LP-Type problems). Furthermore, [8] exploit the combinatorial structure of ACPs to develop testing algorithms, just as we do for LP-Type problems. However, there are some key differences between ACPs and LP-Type problems, such as the fact that LP-Type problems are equipped with a function ϕ that is optimized over a set of constraints. LP-Type problems also have a clean correspondence between dimension and the number of "violators" for a particular basis as formulated in Lemma 11 and Corollary 13, which lets us automatically translate between the dimension and the property testing query complexity.

In terms of concrete property testing problems, [8] also consider the smallest enclosing ball problem (see Section 2.2). We achieve a better query complexity bound than [8] for this problem, but it is important to note that the results of [8] also hold for the general problem of clustering with multiple balls while we only consider one ball. However, the rest of the problems considered in [8] do not overlap with the problems we present in this paper and furthermore, the problems we study are inherently geometric in nature. Lastly, while ACPs are the invention of the authors in [8], there exists rich literature for LP-Type problems outside of the domain of property testing.

Lastly, we note that using a few samples to determine information about your underlying data has also been studied in the PAC-learning literature. In that setting, the goal is to learn a classifier of your dataset and recently, the question of optimal sample complexity for PAC learning has been settled, see for instance [17]. The key differences between the PAC learning setting and our work is that our "datapoints" do not necessarily come with a label. For instance, the PAC learning framework would be valid in the example where we have labeled points in $\mathbb{R}^d$ and we wish to learn a separator from a family class such as balls. However, this framework would not apply if we wished to compute the smallest enclosing ball of the points. We do consider one instance where a PAC learning framework would apply and that is problem of property testing if a set of labeled points are linearly separable or far from it (for more information, see Section 2.2). In this example, a valid approach would be to use the PAC learning framework and learn a linear classifier. Instead of pursuing this route, we are able to cast this problem as an example of a LP-Type problem and achieve the optimal sample complexity using the theory we develop.

1.2 Organization

In Section 2, we formally define the class of LP-Type problems. In Section 2.2 we outline our contributions. In Section 3, we present our algorithms and prove their correctness and in Section 4, we apply our algorithm to specific LP-Type problems. Finally, we complement some of these problems with lower bounds in Section 5.

2 Preliminaries

2.1 Notation and Definitions

We define LP-Type problems as well as some related concepts. These definitions are standard in the literature for LP-Type problems but we reproduce them below for the sake of completeness. For more information, see [26, 18, 12].

▶ **Definition 1** (LP-Type Problem). *Let S be a finite set and φ be a function that maps subsets of S to some value. We say (S, φ) is a LP-Type problem if φ satisfies the following two properties:*

- *Monotonicity: if $A \subseteq B \subseteq S$ then $\varphi(A) \leq \varphi(B)$*
- *Locality: For all $A \subseteq B \subseteq S$ and elements $x \in S$, if $\varphi(A) = \varphi(B) = \varphi(A \cup \{x\})$, then $\varphi(A) = \varphi(B \cup \{x\})$.*

In general, one should think of S as a set of constraints, and φ as some objective function we wish to minimize (or equivalently, maximize) over these constraints. The canonical example of a LP-Type problem is a linear program where S is a set of linear constraints and φ is a linear functional.

Just as linear programs can be associated with a dimension, which is the number of variables, LP-Type problems in general also have a natural definition of dimension which influences the runtime of many algorithms for LP-Type problems as well as our algorithm for property testing. First, we must define the notion of a basis.

▶ **Definition 2** (Basis of LP-Type problems). *Given an LP-Type problem, a* basis *$B \subseteq S$ is a set such that for all proper subsets $B' \subset B$, we have $\varphi(B') < \varphi(B)$.*

Given the above definitions, we can now define the dimension of a LP-Type problem.

▶ **Definition 3** (Dimension of LP-Type problem). *The* dimension *δ of an LP-Type problem is the largest possible size of a basis $B \subseteq S$. This is sometimes also called the* combinatorial dimension*.*

There are many examples of well-studied LP-Type problems and in many of these cases explicit bounds, if not exact values, are known regarding their dimensions. For more information, see our contributions in Section 2.2. In general, the dimension of the problem tends to grow with the "difficulty" of solving it and for property testing, our query complexity bound is also a function of the dimension. We now formally define property testing for LP-Type problems.

▶ **Definition 4** (Property Testing of LP-Type problems). *Given an LP-Type problem (S, φ), a parameter k, a distance parameter ϵ, and query access to the constraints in S, we wish to distinguish the following two cases:*

- *Output accept with probability at least $2/3$ if $\varphi(S) \leq k$ (Completeness Case)*
- *Output reject with probability at least $2/3$ if at least $\epsilon|S|$ constraints need to be removed from S for $\varphi(S) \leq k$ to hold (Soundness Case).*

▶ Remark 5. We say that S is ϵ-far if it falls in the soundness case.

2.2 Our Contributions

The main contribution of this paper is a comprehensive algorithm for property testing of LP-Type problems with query complexity $O(\delta/\epsilon)$ where δ is the dimension of the LP-Type problem. Note that this bound is independent of the number of constraints which is $|S|$. Our algorithm is simple and proceeds by first sampling a small set of random constraints in S, constructing a partial solution, and "testing" this partial solution against few other randomly chosen constraints. The analysis that we reject in the ϵ-far case (soundness) is straightforward. However, the main technical challenge lies in showing that our algorithm accepts in the completeness case. To do so, we use a "sampling" lemma which roughly says that for a randomly chosen subset R of S of a particular size (depending on the dimension δ) and x a randomly chosen element of $S \setminus R$, we have $\varphi(R) = \varphi(R \cup \{x\})$. Using this result, we show that we are likely to accept in the completeness case. For the full detailed analysis, see Section 3. All of our algorithms have two-sided error.

We highlight the power of our approach by considering the query complexity bounds that we get for a few selected problems. In many cases, we are also able to get matching lower bounds. More specifically, we obtain the following results as an application of our framework:

1. We consider the problem of determining if a set of linear inequalities in d variables is feasible (there exists a satisfying assignment) or if at least ϵ-fraction of the constraints need to be removed for the set of constraints to be feasible. While this problem does not exactly fall under the LP-Type definition (since there is no optimization function), we modify our general algorithm slightly to given an algorithm with query complexity is $O(d/\epsilon)$. We also modify our approach for this problem to give a *tolerant* tester for linear program feasibility. This passes programs which are ϵ/c-close to feasible for some fixed constant $c > 1$, and rejects those which are ϵ-far from feasible. This tester also has query complexity $O(d/\epsilon)$
2. We study the problem of determining if a set of points in d dimensions labeled $\{+1, -1\}$ is linearly separable or if at least ϵ-fraction of the points need to be relabeled or removed for the points to be linearly separable. Using result 1 above, we directly get a query complexity bound of $O(d/\epsilon)$. We also give a matching lower bound for this problem which implies a lower bound for result 1.
3. We obtain a result for property testing of many classical LP-Type problems. In particular, we consider the following problems:
   - *Smallest enclosing ball*: Accept if a set of points in $\mathbb{R}^d$ can be covered by a ball of radius r and reject if at least ϵ-fraction of the points need to be removed to be able to be covered by a ball of radius r. This problem has been previously studied in [1]. We improve upon the upper bound obtained in this paper in the case of two-sided error by getting a tight query complexity of $O(d/\epsilon)$ queries (also see point 4 below). Note that the algorithm in [1] has one sided error but has slightly worse query complexity.
   - *Smallest intersecting ball*: Accept if a set of closed convex bodies in $\mathbb{R}^d$ can all be intersected by a ball of radius r and reject if at least ϵ-fraction of the convex bodies need to be removed to be able to be intersected by a ball of radius r.
   - *Smallest volume annulus*: Accept if a set of points in $\mathbb{R}^d$ can be enclosed in an annulus of volume V and reject if at least ϵ-fraction of the points need to be removed to be encloseable by an annulus of volume V.

   In all these cases, it is known that the dimension of the LP-Type problem is linearly related to the dimension of the points in S, so we get an upper bound of $O(d/\epsilon)$ queries.
4. We get a matching lower bound of $\Omega(d/\epsilon)$ queries for the smallest enclosing ball problem and the smallest intersecting ball problem. This provides a lower bound for the radius cost of clustering considered by Alon et al. in [1] in the case of 1 cluster.

▶ Remark 6. Note that there are also many examples of LP-Type problems where the constraints in S describe points in dimension d but the dimension of the LP-Type problem is not a linear function of d. For example, if $\varphi(S)$ is the smallest ellipsoid that encloses the set of points in S which are in $\mathbb{R}^d$, then (S, φ) has dimension $O(d^2)$ as a LP-Type problem [12]. We did not explicitly highlight these problems but our approach also gives an upper bound on the query complexity for the property testing versions of these problems.

3 General Algorithm for Property Testing of LP-Type problems

We now present our general algorithm, LP-Type Tester, for property testing of LP-Type problems as defined in Definition 4. Given a LP-Type problem (S, φ), Our algorithm first samples a subset R of $O(\delta/\epsilon)$ constraints from S where δ is the dimension of the LP-Type problem. It then calculates the value of φ on the sampled subset. After this step, an additional $O(1/\epsilon)$ constraints are sampled randomly from S. If $\varphi(R \cup \{x\})$ differs from $\varphi(R)$ where x is any of the additional random constraints, then our algorithm outputs reject. Otherwise, the algorithm outputs accept. We present our approach in Algorithm 1 along with our main theorem, Theorem 7 which proves the correctness of Algorithm 1.

Algorithm 1 LP-Type Tester.

```
Input  : $\delta, \epsilon, k$, query access to constraints in $S$
Output : accept or reject
$r \leftarrow \lceil 10\delta/\epsilon \rceil$
$R \leftarrow$ random sample of size $r$ of constraints from $S$.
if $\varphi(R) > k$ then
    Output reject and abort.
for $2/\epsilon$ rounds do
    $x \leftarrow$ uniformly random constraint of $S \setminus R$
    if $\varphi(R \cup \{x\}) \neq \varphi(R)$ then
        Output reject and abort.
Output accept.
```

▶ **Theorem 7** (Correctness of LP-Type Tester). *Given an LP-Type problem (S, φ) of dimension δ and parameters k and ϵ, the following statements hold with probability at least $2/3$:*

- ***Completeness case:*** *LP-Type Tester outputs accept $\varphi(S) \leq k$.*
- ***Soundness Case:*** *LP-Type Tester outputs reject if at least $\epsilon|S|$ constraints need to be removed from S for $\varphi(S) \leq k$ to hold.*

▶ Remark 8. Note that the query complexity of Algorithm 1 is $O(\delta/\epsilon)$ which is independent of $|S|$, the number of constraints.

3.1 Overview of the proof

To prove the correctness of LP-Type Tester, we analyze the completeness case and the soundness case separately. For the soundness case, we show that with sufficiently large probability, either $\varphi(R) > k$ or LP-Type Tester outputs reject during the second sampling phase where we sample an additional $O(1/\epsilon)$ constraints. To show this, we use the locality property of LP-Type problems (see Definition 1) to show that there must be "many" x such that $\varphi(R \cup \{x\}) \neq \varphi(R)$. To analyze the completeness case, we use the *Sampling Lemma*, Lemma 11, to show that there are "few" x such that $\varphi(R \cup \{x\}) \neq \varphi(R)$ so that Algorithm 1 outputs accept with sufficiently large probability.

Before we present the proof of Theorem 7, we present the Sampling Lemma as described above. This lemma has previously been used to study LP-Type problems. For completeness, we present a proof. For more information, see [26, 18, 11, 10]. Before we present the lemma, we introduce two new definitions.

▶ **Definition 9** (Violators and Extreme Elements). *For a subset $R \subseteq S$, define the violators and extreme elements of R as the following:*

- *Define the* ***violators*** *of R as the set $V(R) = \{s \in S \backslash R \mid \varphi(R \cup \{s\}) \neq \varphi(R)\}$.*
- *Define the* ***extreme elements*** *of R as the set $X(R) = \{s \in R \mid \varphi(R) \neq \varphi(R \backslash \{s\}\}$.*

▶ Remark 10. Note that s is a violator of R if and only if s is an extreme element of in $R \cup \{s\}$.

We now present the Sampling Lemma.

▶ **Lemma 11** (Sampling Lemma). *Let $v_r = \mathbb{E}[|V(R)|]$ and $x_r = \mathbb{E}[|X(R)|]$ where both expectations are taken over the random subsets R of S which have size r. Suppose $|S| = n$. Then for $0 \le r \le n$, we have*

$$\frac{v_r}{n-r} = \frac{x_{r+1}}{r+1}.$$

Proof. Let $\mathbf{1}\{\cdot\}$ denote an indicator variable. Note that

$$\begin{aligned}\binom{n}{r} v_r &= \sum_{R \in \binom{S}{r}} \sum_{s \in S \setminus R} \mathbf{1}\{s \text{ is a violator of } R\} = \sum_{R \in \binom{S}{r}} \sum_{s \in S \setminus R} \mathbf{1}\{s \text{ is extreme for } R \cup \{s\}\} \\ &= \sum_{Q \in \binom{S}{r+1}} \sum_{s \in Q} \mathbf{1}\{s \text{ is extreme for } Q\} = \binom{n}{r+1} x_{r+1}.\end{aligned}$$

The proof follows from the following calculation.

$$\frac{\binom{n}{r+1}}{\binom{n}{r}} = \frac{r!(n-r)!}{(r+1)!(n-r-1)!} = \frac{n-r}{r+1}. \qquad ◀$$

▶ Remark 12. Note that (S, φ) does not need to be a LP-Type problem for the Sampling Lemma to hold true.

If (S, φ) is a LP-Type problem, there is a direct relationship between the expected number of violators and the dimension of (S, φ) as defined in 3. The following corollary also appears in many forms in literature (for instance [26, 18, 11, 4]) but we present its proof for completeness.

▶ **Corollary 13.** *Let (S, φ) be a LP-Type problem of dimension δ and let $|S| = n$. If $R \subseteq S$ is subset of size r chosen uniformly at random, then $v_r = \mathbb{E}[|V(R)|]$ satisfies*

$$v_r \le \frac{\delta(n-r)}{r+1}.$$

Proof. We show that for any set $R \subseteq S$, we have $|X(R)| \le \delta$. Then the corollary follows from Lemma 11. Let R' be the smallest subset of R such that $\varphi(R') = \varphi(R)$. We first claim that $V(R') = V(R)$. It is clear that $V(R) \subseteq V(R')$ by monotonicity (see Definition 1). For the other inclusion, consider $x \in V(R')$. If $x \notin V(R)$, we have $\varphi(R \cup \{x\}) = \varphi(R) = \varphi(R')$ so by locality, we have $\varphi(R') = \varphi(R' \cup \{x\})$ which contradicts the fact that $x \in V(R')$. Therefore, our claim holds true.

We now claim that R' is a basis as defined in Definition 2. Suppose for the sake of contradiction that R' is not a basis. Then there exists a $F \subset R'$ such that $\varphi(F) = \varphi(R')$. We now claim that $V(R') = V(F)$. It is clear that $V(R') \subseteq V(F)$. To show the other inclusion, let $x \in V(F)$. Then if x was not a violator of R', then $\varphi(R' \cup \{x\}) = \varphi(R') = \varphi(F)$ which would imply that $\varphi(F \cup \{x\}) = \varphi(F)$ by the locality property in Definition 1 which is false by definition. Hence, $V(F) = V(R') = V(R)$ which contradicts the minimality of R'. Therefore, R' is a basis.

Finally, we claim that if $x \in X(R)$ then $x \in R'$. This must be true because otherwise, we have $R' \subseteq R \setminus \{x\} \subseteq R$ which results in a contradiction by monotonicity. Finally, since $X(R) \subseteq R'$ and R' is a basis, it follows that $|X(R)| \le \delta$, as desired. ◀

▶ Remark 14. Corollary 13 holds for a larger class of problems than LP-Type problems called *violator spaces* ([11, 4]. However, we omitted this extra layer of abstraction since there are no additional natural property testing consequences from considering violator spaces over LP-Type problems.

Proof of Theorem 7. We first prove the soundness case. Consider the set R that was randomly sampled in step 2 of LP-Type Tester. Assume that $\varphi(R) \le k$ since this can only decrease the probability that our algorithm outputs reject. Now we claim that there must be at least $\epsilon|S|$ choices of x in step 6 of LP-Type Tester that results in $\varphi(R \cup \{x\}) > \varphi(R)$ (so that we correctly output reject). To show this, note that if $\varphi(R) = \varphi(R \cup \{x\}) = \varphi(R \cup \{y\})$ for $x \neq y$ then by locality, it follows that $\varphi(R) = \varphi(R \cup \{x, y\})$. Therefore, if there are less than $\epsilon|S|$ choices of x in step 6 of LP-Type Tester for some R such that $\varphi(R \cup \{x\}) > \varphi(R)$, then we would have $\varphi(R \cup R') = \varphi(R) \le k$ where $|R \cup R'| \ge (1-\epsilon)|S|$ which would contradict our assumption that at least $\epsilon|S|$ constraints need to be removed from S for $\varphi(S) \le k$ to hold true. Therefore, the probability our algorithm does not output reject in any of the $2/\epsilon$ rounds is at most

$$(1-\epsilon)^{2/\epsilon} \le e^{-2} < \frac{1}{3} \tag{1}$$

which means that we output reject with probability at least 2/3, as desired.

We now prove Theorem 7 for the completeness case. Let $v_r = \mathbb{E}[|V(R)|]$. Since $r = |R| = 10\delta/\epsilon$, Corollary 13 gives us

$$v_r \le \frac{\delta(|S| - r)}{r+1} \le \frac{\epsilon|S|}{10}.$$

Therefore in the completeness case, the probability that a randomly chosen x satisfies $\varphi(R \cup \{x\}) \neq \varphi(R)$ is at most $\epsilon/10$. Since we choose $2/\epsilon$ random constraints, the probability we don't find such a x is at least

$$(1-\epsilon/10)^{2/\epsilon} \ge 1 - \frac{2}{10} > \frac{2}{3}. \tag{2}$$

Therefore, LP-Type Tester outputs accept with probability at least 2/3, as desired. ◀

4 Property Testing Applications of LP-Type Tester

We now give applications of the framework we build in Section 3. We first consider the problem of testing feasibility of a set of linear inequalities. As a direct consequence, we can test if a set of labeled points can be linearly sepearable (either by linear hyperplanes or by functions that have a finite basis). These two applications will not be an immediate corollary of Theorem 7 since there is no objective function that we want to optimize, but our results follow from Theorem 7 with some slight modificatons.

We then consider direct applications of Algorithm 1 to some cannonical LP-Type problems such as the smallest enclosing ball. Theorem 7 gives direct upper bounds for property testing for these problems.

4.1 Testing Feasibility of a System of Linear Equations

We first begin by considering testing feasibility of a set of linear inequalities. Recall that in this problem, we have n linear constraints in $\mathbb{R}^d$ (such as $x_1 + \cdots + x_d \le 1$) and we want to distinguish the following two cases with probability at least 2/3:

- The system of linear inequalities can all be mutually satisfied, i.e., the system is feasible (Completeness Case)
- At least $\epsilon|S|$ many of the constraints need to be removed (or flipped) for the system to be feasible (Soundness Case).

This is not exactly a LP-Type problem since we do not have an optimization function φ. We note that if φ was an indicator function for a subset of constraints being feasible then φ would break the locality condition in Definition 1. One way to see this is consider the case when A is the single constraint that $y \geq 0$, B is the set of two constraints $0 \leq y$ and $y \leq 1$, and x is the additional constraint that $y \geq 2$. We can see that A, B, and $A \cup \{x\}$ are all feasible, but $B \cup \{x\}$ is not, contradicting locality. However, we perform a slight modification of Algorithm 1 to create a new algorithm for this problem.

Our algorithm for this testing problem, Linear Feasibility Tester, uses the fact that if we pick any arbitrary $x \in \mathbb{R}^d$, then x will violate "many" of the linear constraints in S in the completeness case. In the soundness case, we use ideas from LP-Type Tester and show that if we introduce an arbitrary linear optimization function (thus turning our problem into an instance of linear programming), then a solution that optimizes a small subset of the constraints will not violate "too many" of the other constraints. We present our algorithm below along with Theorem 15 that proves its correctness.

Algorithm 2 Linear Feasibility Tester.

```
Input   : $d, \epsilon$, query access to constraints of $S$
Output : Accept or Reject
$r \leftarrow \lceil 10d/\epsilon \rceil$
$R \leftarrow$ random sample of size $r$ of constraints from $S$
Create the linear program $L$: $\max x_1$ subject to the constraints in $R$
$x \leftarrow$ solution of $L$
if $L$ is not feasible then
    Reject and abort
for $2/\epsilon$ rounds do
    $y \leftarrow$ uniformly random constraint of $S$
    if $x$ does not satisfy $y$ then
        Output reject and abort.
Output accept.
```

▶ **Theorem 15** (Correctness of Linear Feasibility Tester). *Given a set S of linear inequalities in $\mathbb{R}^d$, the following statements hold with probability at least $2/3$:*

- ***Completeness case:*** *Linear Feasibility Tester outputs accept if there exists $x \in \mathbb{R}^d$ that satisfies all of the constraints in S.*
- ***Soundness Case:*** *Linear Feasibility Tester outputs reject if at least $\epsilon|S|$ constraints need to be removed from S for S to be feasible.*

▶ Remark 16. Note that the query complexity of Algorithm 1 is $O(d/\epsilon)$ which is independent of $|S|$, the number of constraints. Furthermore, the runtime is polynomial in d/ϵ since we are solving a linear programs in d variables and $O(d/\epsilon)$ constraints.

Proof. The proof of the soundness case follows similarly to Theorem 7 using the fact that for any x, there are at least $\epsilon|S|$ constraints in x such that x violates these constraints. Then the probability that Linear Feasibility Tester outputs reject in this case can be calculated to be at least $2/3$ using the same bound as Eq. (1) in the proof of Theorem 7.

For the completeness case, we note that if we introduce the optimization function $\varphi(S) = \max x_1$ subject to the constraints in S, then (S, φ) is an LP-Type problem of dimension d (assuming that the constraints are non degenerate which can be assumed by perturbing the constraints and then taking the limit of the perturbation to 0. For more details, see [6, 25]). Now let x be the solution to the linear program that we solved in Step 4 of Linear Feasibility Tester. Using Corollary 13, we know that if $|R| = 10\lceil d/\epsilon \rceil$, then the number of constraints v_r in S that satisfy $\varphi(R \cup \{y\}) \neq \varphi(R)$ is at most $v_r \leq (d|S|)/(10d/\epsilon) = \epsilon|S|/10$ in expectation. Knowing that x not satisfying y implies that y is a violator of R, the probability that x does not satisfy a randomly chosen y is at most $\epsilon/10$. Thus, using the exact calculation as in Eq.(2) of Theorem 7, we have that Linear Feasibility Tester outputs accept in the completeness case with probability at least 2/3, as desired. ◀

In Section 6 we give a *tolerant* tester for testing linear feasibility. A tolerant tester accepts instances that are ϵ-close and rejects instances that are $c\epsilon$-far for some constant $c > 1$.

4.2 Testing if Labeled Points can be Linearly Separated

As a direct consequence of the Theorem 15, we can test if a set of points in d dimensions labeled $\{+1, -1\}$ can be linearly separated. More formally, we have the following corollary.

▶ **Corollary 17.** *Given a set S of points in $\mathbb{R}^d$ with labels in $\{+1, -1\}$, the following statements hold with probability at least $2/3$:*

- ***Completeness case:*** *Linear Feasibility Tester outputs accept if there exists a hyperplane that separates the two sets of labeled points.*
- ***Soundness Case:*** *Linear Feasibility Tester outputs reject if at least $\epsilon|S|$ points need to be removed (or relabeled) for S to be linearly sepearable.*

Proof. The proof follows directly from the fact that we can write a linear inequality that represents a separating hyperplane. For example, if $p \in S$ is labeled 1, we want to find x such that $p^T x \geq 1$ and if p is labeled -1, we want to find x such that $p^T x \leq -1$. ◀

We consider generalizations of this problem where we wish to separate labelled points by arbitrary functions, rather than just linear hyperplanes. In Section 7 we address the issue of separating using arbitrary functions when we know the basis of the functions, and the case of multiple labels.

4.3 Upper Bounds for Canonical LP-Type Problems

We now give direct applications of LP-Type Tester to some canonical LP-Type problems. The correctness of these applications follows directly from Theorem 7. Our list is not exhaustive and we only consider some of the more well known LP-Type problems. In all of the following problems, Theorem 7 tells us that the following statements hold with probability at least 2/3:

- LP-Type Tester outputs accept if $\varphi(S) \leq k$ (Completeness Case)
- LP-Type Tester outputs reject if at least $\epsilon|S|$ constraints need to be removed from S for $\varphi(S) \leq k$ to hold (Soundness Case).

Our results are the following:

- *Smallest enclosing ball*: In this problem, $\varphi(S)$ is the radius of the smallest enclosing ball of a set of points S in $\mathbb{R}^d$. It is known that the dimension of this LP-Type problem is $d + 1$ (see [12]) so we can test if $\varphi(S) \leq k$ with query complexity $O(d/\epsilon)$ queries.

- *Smallest intersecting ball*: In this problem, $\varphi(S)$ is the smallest radius ball that intersects a set of closed convex bodies S in $\mathbb{R}^d$. The dimension of this LP-Type problem is $O(d)$ ([12]) so we can test if $\varphi(S) \leq k$ with query complexity $O(d/\epsilon)$ queries.
- *Smallest volume annulus*: In this problem, $\varphi(S)$ is the volume of the smallest annulus that contains a set of points S in $\mathbb{R}^d$. Again, the dimension of this LP-Type problem is $O(d)$ ([12]) so we can test if $\varphi(S) \leq k$ with query complexity $O(d/\epsilon)$.

5 Lower Bounds

In this section, we give matching lower bounds for all the testing problems that we considered in Section 4.

5.1 Lower Bound for Testing Feasibility of Linear Constraints

Since linear separability is a special case of feasibility of linear constraints, we can lower bound the necessary query complexity of the latter by providing one for the former. In particular, we aim to show that $\Omega(d/\epsilon)$ queries are needed to determine if a set of points in d dimensions is linearly separable. By the reduction of linear separability to feasibility of linear constraints, this implies that $\Omega(d/\epsilon)$ constraint queries are needed to test feasibility of a system of linear constraints, which matches our upper bound.

Our overall approach is to first introduce a set of $O(d)$ points in $\mathbb{R}^d$ that have the property that if we do not look at a large enough collection of these points, they can be separated by a hyperplane even with arbitrary labels. However, there will exist a labeling of all of the points such that "many" of the points will have to be removed or relabeled for this labeling to be separated. The existence of these points is given in Lemma 18 (and is inspired by the moment curve).

Then, repeating these points with carefully chosen multiplicities allows us to construct our set S of points. Then a coupon collector argument gives us our desired lower bound on the query complexity. This argument is formalized in the proof of Theorem 19.

▶ **Lemma 18.** *There exists a set S of $3d+1$ points in $\mathbb{R}^d$ that satisfy the following conditions:*

1. *There exists a labeling of the points of S such that at least d points have to be relabeled for the points to be linearly separable.*
2. *Any subset of points of S of size $d+1$ with arbitrary labels in $\{-1, 1\}$ is linearly separable.*

Proof. We construct our set S as follows. Let x_i be the point $(i^1, \cdots, i^d) \in \mathbb{R}^d$ for $1 \leq i \leq 3d+1$ (note that this set of points is referred to as the moment curve). We prove the first claim using a standard relationship between the moment curve and polynomials. Assign the point x_i to the label $(-1)^i$. Let k be the number of relabeled points such that S is linearly separable. Then there exists $w \in \mathbb{R}^d$ and $w_0 \in \mathbb{R}$ such that $\text{Sign}(x_i^T w + w_0)$ matches the label of every point $x_i \in S$. In other words, there exists a polynomial $P(x) = \sum_{j=0}^{d} c_j x^j$ such that $\text{Sign}(P(i))$ matches the label of x_i. Now note that if there are two consecutive indices i and $i+1$ that have different labels, then P must have a root in the interval $(i, i+1)$. Originally, there are $3d$ such alternating intervals. Now note that the relabeling of any point can decrease the total number of such alternating intervals by at most 2. Hence after k relabelings, there must be at least $3d - 2k$ alternating intervals. However, since P is a d degree polynomial, it must have at most d roots which means $3d - 2k \leq d$ and therefore, $k \geq d$, as desired.

We now prove the second claim. Let $x_{a_1}, \cdots, x_{a_{d+1}}$ be a subset of $d+1$ points of S. Without loss of generality, suppose that $a_1 < \cdots < a_{d+1}$. We now show that for every labelings of these $d+1$ points, there exists a polynomial of degree d such that the sign of $P(a_i)$ matches the label of x_{a_i}. Towards this goal, pick t elements $b_1, \cdots, b_t$ of the set $\{a_2, \cdots, a_{d+1}\}$ where $t \le d$. Consider the $t+1$ intervals

$$[a_1, b_1), [b_1, b_2), \cdots, [b_{t-1}, b_t), [b_t, a_{d+1}+1).$$

We can then find a polynomial of degree d such that

- the sign of P is constant on $I \cap \{a_1, a_2, \cdots, a_{d+1}\}$ where I is any of the $t+1$ intervals above,
- the sign of P alternates between consecutive intervals.

This is possible since we are only specifying the value of P on $d+1$ locations. Now the total number of labelings described by all possible choices of P is given by $2\sum_{t=0}^{d}\binom{d}{t} = 2^{d+1}$ where the factor of 2 comes from specifying the sign of P on the first interval. Note that 2^{d+1} is exactly the total number of different ways to label $d+1$ points, which proves the second claim. ◀

With Lemma 18 on hand, we can prove our desired lower bound on the query complexity.

▶ **Theorem 19.** *Any algorithm that tests if a set S of labeled points in d dimensions can be linearly separated requires $\Omega(d/\epsilon)$ queries.*

Proof. Let $|S| = n$. We create two families of n points in $\mathbb{R}^d$ with a specific labeling such that any S from one family can be linearly separated while any S from the other family is ϵ-far from being linearly separable. First, consider the set of $3d+1$ points supplied by Lemma 18 and the labeling from part 1 of the lemma. The first family $\mathcal{F}_1$ consists of picking a subset of $d+1$ of these points (with the labeling above), repeating d of these points $n\epsilon/d$ times, and repeating the remaining point $(1-\epsilon)n$ times. The second family $\mathcal{F}_2$ (again with the same labeling) consists of picking all of the $3d+1$ points from Lemma 18, repeating some $3d$ of these points with multiplicity $n\epsilon/(3d)$, and repeating the last point with multiplicity $(1-\epsilon)n$.

By Lemma 18, we know that if S is from $\mathcal{F}_1$ then S is linearly separable while if S is from $\mathcal{F}_2$, then S is at least $\epsilon/(3d) \cdot d = O(\epsilon)$-far from separable. Any algorithm that queries points randomly must discover at least $d+1$ *unique* points out of the points that were repeated $n\epsilon/d$ time from any S in $\mathcal{F}_2$ to discover that this S is $O(\epsilon)$-far from separable (otherwise, the points look separable). Call points that are identical "groups". Now given a random point from S, the probability of hitting any one group is $\epsilon/(3d)$. Therefore by coupon collector, the expected number of queries required to hit at least $d+1$ of these $3d$ groups is at least

$$\frac{1}{\epsilon}\left(\frac{3d}{3d} + \frac{3d}{3d-1} + \cdots + \frac{3d}{3d-d}\right) = \frac{3d}{\epsilon}(H_{3d} - H_{2d-1}) = \Theta\left(\frac{d}{\epsilon}\right). \quad ◀$$

As a corollary, we have the following lower bound as well. This is due to the reduction from linear separability to linear program feasibility from the proof of Corollary 17.

▶ **Theorem 20.** *Any algorithm that tests if n linear inequalities in d dimensions are feasible requires $\Omega(d/\epsilon)$ queries.*

We now give matching query complexity lower bounds for the LP-Type problems that we considered in Section 4.

5.2 Lower bound for Testing Smallest Enclosing Ball

We first give a lower bound for property testing the radius of the smallest enclosing ball of a set of points. Our approach is to first construct a set of points in $\mathbb{R}^j$, for any j, whose smallest enclosing ball can be calculated exactly. This set of points will have the property that a small enough subset of the points will have a significantly smaller enclosing ball. Therefore, if an algorithm does not query enough points, it will incorrectly believe that this set of points can be covered by a ball of small radius. Our construction for this case will be a regular simplex and explained below. First we prove an auxiliary lemma.

▶ **Lemma 21.** *The radius of the circumcircle of a unit simplex in $\mathbb{R}^j$ is $\sqrt{j}/(\sqrt{2(j+1)})$.*

Proof. Note that we can embed a regular j-simplex in $\mathbb{R}^{j+1}$ using the coordinates $\{e_i\}_{i=1}^{j+1}$ where e_i is the all zero vector with a single 1 in the ith coordinate. This simplex has edge length $\sqrt{2}$ so we can scale appropriately to find the circumcircle of a unit simplex. Now the centroid of this simplex is easily seen to be located at $(1/(j+1), \cdots, 1/(j+1))$ which means that the circumcircle has radius

$$\sqrt{\left(1-\frac{1}{j+1}\right)^2+\frac{j}{(j+1)^2}}=\sqrt{\frac{j}{j+1}}.$$

Now scaling by $1/\sqrt{2}$ gives us the desired value. ◀

▶ **Theorem 22.** *Any algorithm that tests if a set of n points in $\mathbb{R}^d$ can be enclosed by a ball of radius k, where k is given, requires $\Omega(d/\epsilon)$ queries.*

Proof. Let k be fixed. We construct two families of points in $\mathbb{R}^{O(d)}$ such that any S from one family can be enclosed by a ball of radius k while any S from the second family is ϵ-far from being enclosed by a ball of radius k. Before constructing these families, we first pick ℓ such that the regular simplex of side length ℓ in $\mathbb{R}^{d+1}$ has circumradius k.

Now to create the first family $\mathcal{F}_1$, we first pick any $d+1$ points of the regular simplex with side length ℓ in $\mathbb{R}^{3d+1}$. Then we repeat one of these points with multiplicity $(1-\epsilon)n$ and we repeat the other d points with multiplicity $n\epsilon/d$ each. To create the second family $\mathcal{F}_2$, we pick a point of the regular simplex with side length ℓ in $\mathbb{R}^{3d+1}$, repeat it with multiplicity $(1-\epsilon)n$, and repeat the other $3d$ points with multiplicity $n\epsilon/(3d)$. Finally, let S be a set of n points from $\mathcal{F}_2$. From Lemma 21, we can check that the circumradius of a regular unit simplex is an increasing function of the dimension and that any subset of the vertices of a regular simplex is a regular simplex itself. Therefore, the smallest radius of the points in S is much larger than k and S is $O(\epsilon)$-far from being encloseable by a ball of radius k. However, similar to the argument in Theorem 19, any algorithm that rejects S must have discovered at least $d+1$ distinct "groups" of repeated points. By the same coupon collector argument as in the proof of Theorem 19, we have that this task takes at least $\Omega(d/\epsilon)$ queries in expectation. ◀

As a simple application of Theorem 22, we get the following lower bounds as well.

▶ **Corollary 23.** *Any algorithm for testing the smallest intersecting ball for n convex bodies in $\mathbb{R}^d$ requires $\Omega(d/\epsilon)$ queries.*

Proof. The proof follows from the fact that a set of singleton points is also a set of convex bodies. In this case, the smallest intersecting ball is equivalent to the smallest ball that encloses these points. Therefore, the same lower bound as in Theorem 22 holds. ◀

6 Tolerant Tester for Testing Feasibility of Linear Constraints

We generalize our argument in Section 4.1 by giving a *tolerant* tester for testing feasibility of a system of linear constraints. In the tolerant version, we output accept if there only "few" constraints need to be removed for a set of linear inequalities to be feasible. More formally, we wish to distinguish the following two cases with probability at least 2/3:

- At most $c\epsilon|S|$ many inequalities in S need to be removed for S (or flipped) for S to be feasible, i.e., S is $c\epsilon$-close to being feasible for some fixed positive $c < 1$ (Completeness Case).
- At least $\epsilon|S|$ many of the constraints need to be removed (or flipped) for the system to be feasible (Soundness Case).

Our approach is a slightly modified version of Linear Feasibility Tester, Algorithm 2, that we presented in Section 4.1. The challenge here is the completeness case where we must accept if we only have a "few" bad constraints. To accomplish this, we carefully select a solution to a small linear program that we run. For more details, see Algorithm 3. Our main theorem in this section, Theorem 24 shows that we can perform *tolerant* testing using the same query complexity we used for the non tolerant tester in Section 4.1, namely $O(d/\epsilon)$. However, as we will explain below, the *running time* of Algorithm 3, Tolerant Linear Feasibility Tester, is exponential in the running time of Algorithm 2. Our algorithm, Tolerant Linear Feasibility Tester, is presented below.

Algorithm 3 Tolerant Linear Feasibility Tester.

```
   Input   : $d, \epsilon$, query access to constraints of LP
   Output : Accept or Reject
1  $r \leftarrow \lceil 10d/\epsilon \rceil$
2  $R \leftarrow$ random sample of size $r$ of constraints from $S$
3  $x \leftarrow$ solution of the largest subset $R'$ of $R$ such that the linear program $L$: $\max x_1$
     subject to the constraints in $R'$ is feasible
4  if No $L$ is not feasible then
5      Reject and abort
6  for $2/\epsilon$ rounds do
7      $y \leftarrow$ uniformly random constraint of $S$
8      if $x$ does not satisfy $y$ then
9          Output reject and abort.
10 Output accept.
```

Unlike Linear Feasibility Tester where we run a linear program, we solve a slightly different program given in step 3 of Tolerant Linear Feasibility Tester. The step determines the largest feasible subset of these constraints. Note that this step is clearly exponential in the number of constraints (which is $O(d/\epsilon)$). Therefore, the overall *runtime* of Tolerant Linear Feasibility Tester will be exponential in the runtime of Linear Feasibility Tester. The correctness of Tolerant Linear Feasibility Tester is proven in Theorem 24.

▶ **Theorem 24** (Correctness of Tolerant Linear Feasibility Tester)**.** *Given a set S of linear inequalities in $\mathbb{R}^d$, there exists a constant $c < 1$ such that the following statements hold with probability at least $2/3$:*

- ***Completeness case:*** *Tolerant Linear Feasibility Tester outputs accept if there exists $x \in \mathbb{R}^d$ that satisfies $(1-c\epsilon)|S|$ of the constraints in S.*
- ***Soundness Case:*** *Tolerant Linear Feasibility Tester outputs reject if at least $\epsilon|S|$ constraints need to be removed from S for S to be feasible.*

▶ Remark 25. Note that the query complexity of Algorithm 3 is $O(d/\epsilon)$ which is independent of $|S|$, the number of constraints.

Proof. Note that the proof of the soundness case is identical to the proof of the soundness case in Theorem 15 since for any x we find in step 3 of Tolerant Linear Feasibility Tester, there exists at least $\epsilon|S|$ choices of y in step 7 such that x does not satisfy the constraint y. Then a similar calculation as in Eq. (1) implies that we reject with probability at least $2/3$.

We now focus on the completeness case where we know there is a subset of $(1-c\epsilon)|S|$ constraints that are feasible. We call this the *good* set, and the rest, the *bad* set. Consider the sample R from step 2 of Tolerant Linear Feasibility Tester. The expected number of constraints from the good set in R is $(1-c\epsilon)r$. This means at most $c\epsilon r$ constraints in R come from the bad set in expectation. Hence with probability at least $9/10$, we know that the number of constraints from the bad set is at most $10c\epsilon r$ by Markov's inequality, which means the number of constraints coming from the good set is at least $(1-10c\epsilon)r$. We condition on this event. Now note that one valid subset R' to use in step 3 of Tolerant Linear Feasibility Tester is to take all the constraints coming from the good set only. This results in $|R'| \geq (1-10c\epsilon)$. Since we are maximizing $|R'|$, this means that at most $10c\epsilon r$ of the constraints coming from the good set that are in R will not be included in R'. Thus, x satisfies at least $(1-20c\epsilon)r$ constraints in the good set with probability at least $9/10$. Now we proceed similarly as the proof of Theorem 15. By Corollary 13, the probability that x violates any other constraint in the good set is at most

$$\frac{d(n'-r+1)}{n'(r-d)} \leq \frac{dn'}{10dn'/\epsilon} = \frac{\epsilon}{10}$$

where n' is the size of the good set. Furthermore, x can possibly violate any constraint in the bad set which means that the probability x violates any other constraint is at most $\epsilon/10 + c\epsilon < \epsilon/6$ for sufficiently small c, i.e. $c < 1/15$. Then, the probability that we find such a constraint in $2/\epsilon$ rounds is at most

$$1 - \left(1 - \frac{\epsilon}{6}\right)^{2/\epsilon} \leq 1 - \left(1 - \frac{1}{3}\right) = \frac{1}{3}.$$

Therefore, we accept with probability at least $2/3$, as desired. Note that we can take any $c < 1/15$ in the statement of the Theorem for instance. ◀

7 Separating Points with Arbitrary Functions and Multiple Labels

7.1 Separating labeled points using arbitrary functions

We can generalize our result from Section 4.2 by separating labeled points using arbitrary *functions*: given a family of functions $\mathcal{F}$, we can ask if there is a $f \in \mathcal{F}$ such that $f(p) > 0$ for all points with a particular label and $f(p) < 0$ for all the points with the other label.

We now translate this problem to a setting with linear inequalities. Our approach is standard in machine learning and is known as feature maps. If the family $\mathcal{F}$ has a finite basis $f_1, \cdots, f_k$, meaning that every $f \in \mathcal{F}$ is a linear combination of $f_1, \cdots, f_k$, then we can create a system of linear inequalities as follows. For each point $p \in S$, we can make a new constraint which is $(f_1(p), \cdots, f_k(p))x \geq 1$ (note there that x is a column vector of variables) if p has one particular label or ≤ -1 if p has another label. Then this system of linear constraints is feasible iff there are scalars $a_1, \cdots, a_k$ such that $\sum_i a_i f_i(p) \geq 0$ for all p with one label and $\sum_i a_i f_i(p) \leq 0$ for all p with the other label. Then our separating function is precisely $f = \sum_i a_i f_i$. Note that in this formulation, we have k variables. Thus, the query complexity is $O(k/\epsilon)$.

As an example, we consider the case that $\mathcal{F}$ is the family of polynomials in d variables with degree $\leq t$. The basis of this family is all the possible terms of the form $x_1^{t_1} \cdots x_d^{t_d}$ where the t_i are non-negative and add to at most t. By a standard balls and bins argument, the number of these terms is $\binom{t+d}{d}$. For constant t, this is $O(d^t)$, which means that our system of linear constraints has $O(d^t)$ variables. Thus, the query complexity is $O(d^t/\epsilon)$.

7.2 Separating Points with Multiple Labels

Suppose that in Section 4.2, instead of assigning each point one of 2 labels, we instead chose to assign it one of $\ell \geq 2$ labels. One common interpretation of separability for this setup is to check if each of the $\binom{\ell}{2}$ pairs of label sets are separable. We modify our notion of ϵ-far to reflect this.

▶ **Definition 26.** *S is ϵ-far from linearly separable if at least $\epsilon|S|$ many labels in S have to be changed for S to be separable.*

If such a data set is ϵ-far from separable, then some subset with consisting of two labels must be $\epsilon/\binom{\ell}{2}$-far from separable. As such, we can consider an algorithm that runs Algorithm Linear Feasibility Tester on each pair of labels with $\epsilon' = \epsilon/\binom{\ell}{2}$ and outputs accept if all these tests output accept. We need to reduce the error probability for each pair such that the overall error probability of outputting the incorrect answer (acquired by a union bound) is still at most 1/3. This can be done by using a stronger version of the original algorithm where we run it $O(\log \ell)$ times and taking the majority answer. By a standard Chernoff bound argument, the probability this process gives the wrong answer is at most say $1/\ell^3$. Thus, we can distinguish separability in this case by running this stronger version over all pairs of distinct labels, resulting in $O(\ell^2 \log \ell)$ instances of Linear Feasibility Tester, using $\epsilon' = \epsilon/\binom{\ell}{2}$. So, the total query complexity will be $O(d\ell^4 \log \ell/\epsilon)$.

Additionally, the completeness case has error at most $\binom{\ell}{2} 1/\ell^3 = o(1)$ by a Union Bound argument. Clearly, the soundness case has error at most $1/\ell^3$, since there is one pair of distinct labels which is ϵ'-far from separable.

Lower Bounds for Dynamic Distributed Task Allocation

Hsin-Hao Su

Abstract

We study the problem of distributed task allocation in multi-agent systems. Suppose there is a collection of agents, a collection of tasks, and a *demand vector*, which specifies the number of agents required to perform each task. The goal of the agents is to cooperatively allocate themselves to the tasks to satisfy the demand vector. We study the *dynamic* version of the problem where the demand vector changes over time. Here, the goal is to minimize the *switching cost*, which is the number of agents that change tasks in response to a change in the demand vector. The switching cost is an important metric since changing tasks may incur significant overhead.
We study a mathematical formalization of the above problem introduced by Su, Su, Dornhaus, and Lynch [20], which can be reformulated as a question of finding a low distortion embedding from symmetric difference to Hamming distance. In this model it is trivial to prove that the switching cost is at least 2. We present the first non-trivial lower bounds for the switching cost, by giving lower bounds of 3 and 4 for different ranges of the parameters.

1 Introduction

Task allocation in multi-agent systems is a fundamental problem in distributed computing. Given a collection of tasks, a collection of task-performing agents, and a *demand vector* which specifies the number of agents required to perform each task, the agents must collectively allocate themselves to the tasks to satisfy the demand vector. This problem has been studied in a wide variety of settings. For example, agents may be identical or have differing abilities, agents may or may not be permitted to communicate with each other, agents may have limited memory or computational power, agents may be faulty, and agents may or may not have full information about the demand vector. See Georgiou and Shvartsman's book [7] for a survey of the distributed task allocation literature. See also the more recent line of work by Dornhaus, Lynch and others on algorithms for task allocation in ant colonies [4, 20, 5, 17].

We consider the setting where the demand vector *changes dynamically* over time and agents must redistribute themselves among the tasks accordingly. We aim to minimize the *switching cost*, which is the number of agents that change tasks in response to a change in the demand vector. The switching cost is an important metric since changing tasks may incur significant overhead. Dynamic task allocation has been extensively studied in practical, heuristic, and experimental domains. For example, in swarm robotics, there is much

experimental work on heuristics for dynamic task allocation (see e.g. [10, 19, 13, 14, 11, 12]). Additionally, in insect biology it has been empirically observed that demands for tasks in ant colonies change over time based on environmental factors such as climate, season, food availability, and predation pressure [15]. Accordingly, there is a large body of biological work on developing hypotheses about how insects collectively perform task allocation in response to a changing environment (see surveys [1, 18]).

Despite the rich experimental literature, to the best of our knowledge there are only two works on dynamic distributed task allocation from a theoretical algorithmic perspective. Su, Su, Dornhaus, and Lynch [20] present and analyze gossip-based algorithms for dynamic task allocation in ant colonies. Radeva, Dornhaus, Lynch, Nagpal, and Su [17] analyze dynamic task allocation in ant colonies when the ants behave randomly and have limited information about the demand vector.

1.1 Problem Statement

We study the formalization of dynamic distributed task allocation introduced by Su, Su, Dornhaus, and Lynch [20].

Objective. Our goal is to minimize the *switching cost*, which is the number of agents that change tasks in response to a change in the demand vector.

Properties of agents.

1. the agents have complete information about the changing demand vector
2. the agents are heterogeneous
3. the agents cannot communicate
4. the agents are memoryless

The first two properties specify *capabilities* of the agents while the third and fourth properties specify *restrictions* on the agents. Although the exclusion of communication and memory may appear overly restrictive, our setting captures well-studied models of both collective insect behavior and swarm robotics, as outlined in Section 1.1.3.

From a mathematical perspective, our model captures the *combinatorial* aspects of dynamic distributed task allocation. In particular, as we show in Section 2, the problem can be reformulated as finding a *low distortion embedding* from symmetric difference to Hamming distance.

1.1.1 Formal statement

Formally, the problem is defined as follows. There are three positive integer parameters: n is the number of agents, k is the number of tasks, and D is the target *maximum switching cost*, which we define later. The goal is to define a set of n deterministic functions $f_1^{n,k}, f_2^{n,k}, \dots, f_n^{n,k}$, one for each agent, with the following properties.

- **Input:** For each agent a, the function $f_a^{n,k}$ takes as input a *demand vector* $\vec{v} = \{v_1, v_2, \dots, v_k\}$ where each v_i is a non-negative integer and $\sum_i v_i = n$. Each v_i is the number of agents required for task i, and the total number of agents required for tasks is exactly the total number of agents.
- **Output:** For each agent a, the function $f_a^{n,k}$ outputs some $i \in [k]$. The output of $f_a^{n,k}(\vec{v})$ is the task that agent a is assigned when the demand vector is $\vec{v}$.

- **Demand satisfied:** For all demand vectors $\vec{v}$ and all tasks i, we require that the number of agents a for which $f_a^{n,k}(\vec{v}) = i$ is exactly v_i. That is, the allocation of agents to tasks defined by the set of functions $f_1^{n,k}, f_2^{n,k}, \dots, f_n^{n,k}$ exactly satisfies the demand vector.
- **Switching cost satisfied:** The *switching cost* of a pair $(\vec{v}, \vec{v'})$ of demand vectors is defined as the number of agents a for which $f_a^{n,k}(\vec{v}) \neq f_a^{n,k}(\vec{v'})$; that is, the number of agents that switch tasks if the demand vector changes from $\vec{v}$ to $\vec{v'}$ (or from $\vec{v'}$ to $\vec{v}$). We say that a pair of demand vectors $\vec{v}$, $\vec{v'}$ are *adjacent* if $|\vec{v} - \vec{v'}|_1 = 2$; that is, if we can get from $\vec{v}$ to $\vec{v'}$ by moving exactly one unit of demand from one task to another. The *maximum switching cost* of a set of functions $f_1^{n,k}, f_2^{n,k}, \dots, f_n^{n,k}$ is defined as the maximum switching cost over all pairs of adjacent demand vectors; that is, the maximum number of agents that switch tasks in response to the movement of a single unit of demand from one task to another. We require that the maximum switching cost of $f_1^{n,k}, f_2^{n,k}, \dots, f_n^{n,k}$ is at most D.

▶ **Question.** *Given n and k, what is the minimum possible maximum switching cost D over all sets of functions $f_1^{n,k}, \dots, f_n^{n,k}$?*

1.1.2 Remarks

▶ Remark 1. The problem statement only considers the switching cost of pairs of *adjacent* demand vectors. We observe that this also implies a bound on the switching cost of non-adjacent vectors: if every pair of adjacent demand vectors has switching cost at most D, then every pair of demand vectors with ℓ_1 distance d has switching cost at most $D(d/2)$.

▶ Remark 2. The problem statement is consistent with the properties of the agents listed above. In particular, the agents have complete information about the changing demand vector because for each agent, the function $f_a^{n,k}$ takes as input the current demand vector. The agents are heterogeneous because each agent a has a separate function $f_a^{n,k}$. The agents have no communication or memory because the *only* input to each function $f_a^{n,k}$ is the current demand vector.

▶ Remark 3. Forbidding communication among agents is crucial in the formulation of the problem, as otherwise the problem would be trivial. In particular, it would always be possible to achieve maximum switching cost 1: when the current demand vector changes to an adjacent demand vector, the agents simply reach consensus about which single agent will move.

1.1.3 Applications

1.1.3.1 Collective insect behavior

There are a number of hypotheses that attempt to explain the mechanism behind task allocation in ant colonies (see the survey [1]). One such hypothesis is the *response threshold model*, in which ants decide which task to perform based on individual preferences and environmental factors. Specifically, the model postulates that there is an environmental stimulus associated with each task, and each individual ant has an internal threshold for each task, whereby if the stimulus exceeds the threshold, then the ant performs that task. The response threshold model was introduced in the 70s and has been studied extensively since (for comprehensive background on this model see the survey [1] and the introduction of [6]).

Our setting captures the essence of the response threshold model since agents are permitted to behave based on individual preferences (property 2: agents are heterogeneous) and environmental factors (property 1: agents have complete information about the demand vector). We study whether models like the response threshold model can achieve low switching costs.

Inspired by collective insect behavior, researchers have also studied the response threshold model in the context of swarm robotics [2, 9, 22]. Our setting also relates more generally to swarm robotics:

1.1.3.2 Swarm robotics

There is a body of work in swarm robotics specifically concerned with property 3 of our setting: eliminating the need for communication (e.g. [21, 3, 8, 16]). In practice, communication among agents may be unfeasible or costly. In particular, it may be unfeasible to build a fast and reliable network infrastructure capable of dealing with delays and failures, especially in a remote location.

Regarding property 4 of our setting (the agents are memoryless), it may be desirable for robots in a swarm to not rely on memory. For example, if a robot fails and its memory is lost, we may wish to be able to introduce a new robot into the system to replace it.

Concretely, dynamic task allocation in swarm robotics may be applicable to disaster containment [16, 23], agricultural foraging, mining, drone package delivery, and environmental monitoring [19].

1.2 Past Work

Our problem was previously studied only by Su, Su, Dornhaus, and Lynch [20], who presented two upper bounds and a lower bound.

The first upper bound is a very simple set of functions $f_1^{n,k}, \ldots, f_n^{n,k}$ with maximum switching cost $k-1$. Each agent has a unique ID in $[n]$ and the tasks are numbered from 1 to k. The functions $f_1^{n,k}, \ldots, f_n^{n,k}$ are defined so that for all demand vectors, the agents populate the tasks in order from 1 to k in order of increasing agent ID. That is, for each agent a, $f_a^{n,k}$ is defined as the task j such that $\sum_{i=0}^{j-1} d_i < \mathrm{ID}(a)$ and $\sum_{i=0}^{j} d_i \geq \mathrm{ID}(a)$. Starting with any demand vector, if one unit of demand is moved from task i to task j, the switching cost is at most $|i-j|$ because at most one agent from each task numbered between i and j (including i but not including j) shifts to a new task. Thus, the maximum switching cost is $k-1$.

The lower bound of Su et al. is also very simple. It shows that there does not exist a set of functions $f_1^{n,k}, \ldots, f_n^{n,k}$ with maximum switching cost 1 for $n \geq 2$ and $k \geq 3$. Suppose for contradiction that there exists a set of functions $f_1^{n,k}, \ldots, f_n^{n,k}$ with maximum switching cost 1 for $n = 2$ and $k = 3$ (the argument can be easily generalized to higher n and k).

Suppose the current demand vector is $[1, 1, 0]$, that is, one agent is required for each of tasks 1 and 2 while no agent is required for task 3. Suppose agents a and b are assigned to tasks 1 and 2, respectively, which we denote $[a, b, \emptyset]$. Now suppose the demand vector changes from $[1, 1, 0]$ to the adjacent demand vector $[1, 0, 1]$. Since the maximum switching cost is 1, only one agent moves, so agent b moves to task 3, so we have $[a, \emptyset, b]$. Now suppose the demand vector changes from $[1, 0, 1]$ to the adjacent demand vector $[0, 1, 1]$. Again, since the maximum switching cost is 1, agent a moves from task 1 to task 2 resulting in $[\emptyset, a, b]$. Now suppose the demand vector changes from $[0, 1, 1]$ to the adjacent demand vector $[1, 1, 0]$, which was the initial demand vector. Since the maximum switching cost is 1, agent b moves from task 3 to task 1 resulting in $[b, a, \emptyset]$.

The problem statement requires that the allocation of agents depends *only* on the current demand vector, so the allocation of agents for any given demand vector must be the same regardless of the history of changes to the demand vector. However, we have shown that the allocation of agents for $[1,1,0]$ was initially $[a,b,\emptyset]$ and is now $[b,a,\emptyset]$, a contradiction. Thus, the maximum switching cost is at least 2.

The second upper bound of Su et al. states that there exists a set of functions $f_1^{n,k},\ldots,f_n^{n,k}$ with maximum switching cost 2 if $n \leq 6$ and $k = 4$. They prove this result by exhaustively listing all 84 demand vectors along with the allocation of agents for each vector.

1.3 Our results

We initiate the study of non-trivial lower bounds for the switching cost. In particular, with the current results it is completely plausible that the maximum switching cost can always be upper bounded by 2, regardless of the number of tasks and agents. Our results show that this is not true and provide further evidence that the maximum switching cost grows with the number of tasks.

One might expect that the limitations on n and k in the second upper bound of Su et al. is due to the fact the space of demand vectors grows exponentially with n and k so their method of proof by exhaustive listing becomes unfeasible. However, our first result is that the second upper bound of Su et al. is actually *tight* with respect to k. In particular, we show that achieving maximum switching cost 2 is impossible even for $k = 5$ (for *any* $n > 2$).

▶ **Theorem 4.** *For $n \geq 3$, $k \geq 5$, every set of functions $f_1^{n,k},\ldots,f_n^{n,k}$ has maximum switching cost at least 3.*

We then consider the next natural question: *For what values of n and k is it possible to achieve maximum switching cost 3?* Our second result is that maximum switching cost 3 is not always possible:

▶ **Theorem 5.** *There exist n and k such that every set of functions $f_1^{n,k},\ldots,f_n^{n,k}$ has maximum switching cost at least 4.*

The value of k for Theorem 5 is an extremely large constant derived from hypergraph Ramsey numbers. Specifically, there exists a constant c so that Theorem 5 holds for $n \geq 5$ and $k \geq t_{n-1}(cn)$ where the tower function $t_j(x)$ is defined by $t_1(x) = x$ and $t_{i+1}(x) = 2^{t_i(x)}$.

We remark that while our focus on small constant values of the switching cost may appear restrictive, functions with maximum switching cost 3 already have a highly non-trivial combinatorial structure.

1.4 Our techniques

We introduce two novel techniques, each tailored to a different parameter regime. One parameter regime is when $n \ll k$ and the demand for each task is either 0 or 1. This regime seems to be the most natural for the goal of proving the highest possible lower bounds on the switching cost.

1.4.1 The $n \ll k$ regime

We develop a proof framework for the $n \ll k$ regime and use it to prove Theorem 4 for $n = 3$, $k = 5$, and more importantly, to prove Theorem 5. We begin by supposing for contradiction that there exists a set of functions $f_1^{n,k},\ldots,f_n^{n,k}$ with switching cost 2 and 3, respectively, and then reason about the structure of these functions. The main challenge in proving Theorem 5 as compared to Theorem 4 is that functions with switching cost 3 can have a much more involved combinatorial structure than functions with switching cost 2. In principle, our proof framework could also apply to higher switching costs, but at present it is unclear how exactly to implement it for this setting.

The first step in our proofs is to reformulate the problem as that of finding a low distortion embedding from symmetric difference to Hamming distance, which we describe in Section 2. This provides a cleaner way to reason about the problem in the $n \ll k$ parameter regime. Our proofs are written in the language of the problem reformulation, but here we will briefly describe our proof framework in the language of the original problem statement.

The simple upper bound of $k-1$ described in Section 1.2 can be viewed as each agent having a "preference" for certain tasks. The main idea of our lower bound is to show that for *any* set of functions $f_1^{n,k}, \dots, f_n^{n,k}$ with low switching cost, many agents must have a "preference" for certain tasks. More formally, we introduce the idea of a task being *frozen* to an agent. A task t is frozen to agent a if for every demand vector in a particular large set of demand vectors, agent a is assigned to task t. Our framework has three steps:

- In step 1, we show roughly that in total, many tasks are frozen to some agent.
- In step 2, we show roughly that for many agents a, only few tasks are frozen to a.
- In step 3, we use a counting argument to derive a contradiction: we count a particular subset of frozen task/agent pairs in two different ways using steps 1 and 2, respectively.

The proof of Theorem 4 for $n = 3$ and $k = 5$ serves as a simple illustrative example of our proof framework, while the proof of Theorem 5 is more involved. In particular, in step 1 of the proof of Theorem 5, we derive *multiple* possible structures of frozen task/agent pairs. Then, we use Ramsey theory to show that there exists a collection of tasks that all obey only *one* of the possible structures. This allows us to reason about each of the possible structures independently in steps 2 and 3.

1.4.2 The remaining parameter regime

In the remaining parameter regime, we complete the proof of Theorem 4. In the previous parameter regime, we only addressed the $n = 3$, $k = 5$ case, and now we need to consider all larger values of n and k. Extending to larger k is trivial (we prove this formally in Section 4). However, it is not at all clear how to extend a lower bound to larger values of n. In particular, our proof framework from the $n \ll k$ regime immediately breaks down as n grows.

The main challenge of handling large n is that having an abundance of agents can actually allow *more* pairs of adjacent demand vectors to have switching cost 2, so it becomes more difficult to find a pair with switching cost greater than 2. To see this, consider the following example.

Consider the subset S_i of demand vectors in which a particular task i has an unconstrained amount of demand and each remaining task has demand at most $n/(k-1)$. We claim that there exists a set of functions $f_1^{n,k}, \dots, f_n^{n,k}$ so that every pair of adjacent demand vectors from S_i has switching cost 2. Divide the agents into $k-1$ groups of $n/(k-1)$ agents each, and associate each task except i to such a group of agents. We define the functions $f_1^{n,k}, \dots, f_n^{n,k}$ so that given any demand vector in S_i, the set of agents assigned to each task except i is simply a subset of the group of agents associated with that task (say, the subset of such agents with smallest ID). This is a valid assignment since the demand of each task except i is at most the size of the group of agents associated with that task. The remaining agents are assigned to task i. Then, given a pair $(\vec{v}, \vec{v'})$ of adjacent demand vectors in S_i, whose demands differ only for tasks s and t, their switching cost is 2 because the only agents assigned to different tasks between $\vec{v}$ and $\vec{v'}$ are: one agent from each of the groups associated with tasks s and t, respectively.

Because it is possible for many pairs of adjacent demand vectors to have switching cost 2, finding a pair of adjacent demand vectors with larger switching cost requires reasoning about a very precise set of demand vectors. To do this, we use roughly the following strategy. We identifying a task that serves the role of i in the above example and then successively move demand out of task i until task i is empty and can thus no longer fill this role. At this point, we argue that we have reached a pair of adjacent demand vectors with switching cost more than 2.

2 Problem reformulation

2.1 Notation

Let A and B be multisets. The intersection of A and B denoted $A \cap B$ is the maximal multiset of elements that appear in both A and B. For example, $\{a, a, b, b\} \cap \{a, b, b, c\} = \{a, b, b\}$. The symmetric difference between A and B, denoted $A \oplus B$, is the multiset of elements in either A or B but not in their intersection. For example, $\{a, a, b, b\} \oplus \{a, b, b, c\} = \{a, c\}$ since we are left with a after removing $\{a, b, b\}$ from $\{a, a, b, b\}$ and we are left with c after removing $\{a, b, b\}$ from a, b, b, c.

A permutation of a multiset A is simply a permutation of the elements of the multiset. For example, one permutation of $\{a, a, b\}$ is aba. We treat permutation as strings and perform string operations on them. For strings X and Y (which may be permutations), let $d(X, Y)$ denote the *Hamming distance* between X and Y. For example, $d(aba, bca) = 2$.

2.2 Problem statement

Given positive integers n, k, and D, the goal is to find a function $\pi_{n,k}$ with the following properties.

- Let $\mathcal{S}_{n,k}$ be the set of all size n multisets of $[k]$. The function $\pi_{n,k}$ takes as input a set $S \in \mathcal{S}_{n,k}$ and outputs a permutation of S.
- We say that a pair $S, S' \in \mathcal{S}_{n,k}$ has *distortion* D' with respect to $\pi_{n,k}$ if $|S \oplus S'| = 2$ and $d(\pi_{n,k}(S), \pi_{n,k}(S')) = D'$. In other words, a pair of multisets has distortion D' if they have the *smallest* possible symmetric distance but *large* Hamming distance (at least D'). We say that $\pi_{n,k}$ has *maximum distortion* D' if the maximum distortion over all pairs $S, S' \in \mathcal{S}_{n,k}$ with $|S \oplus S'| = 2$ is D'. We require that the function $\pi_{n,k}$ has maximum distortion at most D.

We are interested in the question of for which values of the parameters n, k, and D, there exists $\pi_{n,k}$ that satisfies the above properties. In particular, we aim to minimize the maximum distortion:

▶ **Question.** *Given n and k, what is the minimum possible maximum distortion over all functions $\pi_{n,k}$?*

In other words, the question is whether there exists a function $\pi_{n,k}$ such that *every* pair $S, S' \in \mathcal{S}_{n,k}$ has distortion at least D. Our theorems are lower bounds, so we show that for every function $\pi_{n,k}$ there *exists* a pair $S, S' \in \mathcal{S}_{n,k}$ with distortion at least D.

2.3 Equivalence to original problem statement

We claim that the new problem statement from Section 2.2 is equivalent to the original problem statement from Section 1.1.

▷ Claim 6. Given parameters n and k (the same for both problem statements) there exists a function $\pi_{n,k}$ with maximum distortion D if and only if there exists a set of functions $f_1^{n,k}, \ldots, f_n^{n,k}$ with maximum switching cost D.

We describe the correspondence between the two problem statements:

- **Demand vector.** $\mathcal{S}_{n,k}$ is the set of all possible demand vectors since a demand vector is simply a size n multiset of the k tasks. For example, the multiset $S = \{1, 1, 3\}$ is equivalent to the demand vector $\vec{v} = [2, 0, 1]$; both notations indicate that task 1 requires two units of demand, task 2 requires no demand, and task 3 requires one unit of demand.
- **Allocation of agents to tasks.** If $\vec{v}$ is the demand vector representing the multiset $S \in \mathcal{S}_{n,k}$, a permutation $\pi_{n,k}(S)$ is an allocation $f_1^{n,k}(\vec{v}), \ldots, f_n^{n,k}(\vec{v})$ of agents to tasks so that $\pi_{n,k}(S)[i] = f_i^{n,k}(\vec{v})$; that is, agent i performs the task that is the i^{th} element in the permutation $\pi_{n,k}(S)$. For example, $\pi_{3,3}(\{1, 1, 3\}) = 131$ is equivalent to the following: $f_1^{3,3}([2, 0, 1]) = 1$, $f_2^{3,3}([2, 0, 1]) = 3$, and $f_3^{3,3}([2, 0, 1]) = 1$; both notations indicate that agents 1 and 3 both performs task 1, while agent 2 performs task 2.
- **Switching cost.** If $\vec{v}, \vec{v'}$ are the demand vectors representing the multisets $S, S' \in \mathcal{S}_{n,k}$ respectively, the value $d(\pi_{n,k}(S), \pi_{n,k}(S'))$ is the switching cost because from the previous bullet point, $\pi_{n,k}(S)[i] \neq \pi_{n,k}(S')[i]$ if and only if $f_a^{n,k}(\vec{v}) \neq f_a^{n,k}(\vec{v'})$.
- **Adjacent demand vectors.** The set of all pairs $S, S' \in \mathcal{S}_{n,k}$ such that $|S \oplus S'| = 2$ is the set of all pairs of adjacent demand vectors. This is because $|S \oplus S'| = 2$ means that starting from S, one can reach S' by changing exactly one element in S from some $i \in [k]$ to some $j \in [k]$. Equivalently, starting from the demand vector represented by S and moving one unit of demand from task i to task j results in the demand vector represented by S'.
- **Maximum switching cost.** If $f_1^{n,k}, \ldots, f_n^{n,k}$ is the set of functions representing $\pi_{n,k}$, then $\pi_{n,k}$ has maximum distortion D if and only if $f_1^{n,k}, \ldots, f_n^{n,k}$ has maximum switching cost D. This is because $S, S' \in \mathcal{S}_{n,k}$ has distortion D if and only if $|S \oplus S'| = 2$ and $d(\pi_{n,k}(S), \pi_{n,k}(S')) = D$ which is equivalent to saying that the demand vectors $\vec{v}$ and $\vec{v'}$ that represent S and S' are adjacent and have switching cost D.

2.4 Restatement of results

We restate Theorems 4 and 5 in the language of the problem restatement.

▶ **Theorem 7** (Restatement of Theorem 4). *Let $n \geq 3$ and $k \geq 5$. Every function $\pi_{n,k}$ has maximum distortion at least 3.*

▶ **Theorem 8** (Restatement of Theorem 5). *There exist n and k so that every function $\pi_{n,k}$ has maximum distortion at least 4.*

2.5 Example instance

To build intuition about the problem restatement, we provide a concrete example of a small instance of the problem. Suppose $n = 3$ and $k = 2$. For notational clarity, instead of denoting $[k] = \{0, 1\}$ we denote $[k] = \{a, b\}$. Then $\mathcal{S}_{3,2}$ is the set of all size 3 multisets of $\{a, b\}$; that is, $\mathcal{S}_{3,2} = \{\{a, a, a\}, \{a, a, b\}, \{a, b, b\}, \{b, b, b\}\}$. $\pi_{3,2}$ is a function that maps each element of $\mathcal{S}_{3,2}$ to a permutation of itself. For example, $\pi_{3,2}$ could be defined as follows:

$$\pi_{3,2}(\{a,a,a\}) = aaa, \quad \pi_{3,2}(\{a,a,b\}) = aba \quad \pi_{3,2}(\{a,b,b\}) = bab, \quad \pi_{3,2}(\{b,b,b\}) = bbb.$$

We are concerned with all pairs $S, S' \in \mathcal{S}_{3,2}$ such that $|S \oplus S'| = 2$ (since the maximum distortion of $\pi_{3,2}$ is defined in terms of only these pairs). In this example, the only such pairs are as follows:

$$\{a,a,a\} \oplus \{a,a,b\} = 2, \quad \{a,a,b\} \oplus \{a,b,b\} = 2, \quad \{a,b,b\} \oplus \{b,b,b\} = 2.$$

For each such pair, we consider $d(\pi_{3,2}(S), \pi_{3,2}(S'))$:

$$d(aaa, aba) = 1, \quad d(aba, bab) = 3, \quad d(bab, bbb) = 1.$$

This particular choice of $\pi_{3,2}$ has maximum distortion 3 (since the largest value in the above row is 3), however we could have chosen $\pi_{3,2}$ with maximum distortion 1 (for example if $\pi_{3,2}(\{a,b,b\}) = bba$ instead of bab).

3 The $n \ll k$ regime

In this section we will prove Theorem 7 for $n = 3$, $k = 5$, and Theorem 8. The proofs are written in the language of the problem reformulation from Section 2. For these proofs it will suffice to consider only the elements of $\mathcal{S}_{n,k}$ that are *subsets* of $[k]$, rather than multisets. This corresponds to the set of demand vectors where each task has demand either 0 or 1. *For the rest of this section we consider only subsets of* $[k]$*, rather than multisets.*

We call each element of $[k]$ a *character* (e.g. in the above example instance, a and b are characters).

3.1 Proof framework

As described in Section 1.4, we develop a three-step proof framework for the $n \ll k$ regime. Suppose we are trying to prove that every function $\pi_{n,k}$ has maximum distortion at least D for a particular n and k. We begin by supposing for contradiction that there exists $\pi_{n,k}$ with maximum distortion less than D. That is, we suppose that every pair $S, S' \in \mathcal{S}_{n,k}$ with $|S \oplus S'| = 2$ has $d(\pi_{n,k}(S), \pi_{n,k}(S')) < D$. Under the assumption that such a $\pi_{n,k}$ exists, steps 1 and 2 of the framework show that $\pi_{n,k}$ must obey a particular structure. For the remainder of this section, we drop the subscript of π since n and k are fixed.

▶ **Notation.** *For any set $R \subseteq [k]$, let $\mathcal{U}_R$ be the set of all sets $S \subseteq [k]$ such that $R \subset S$ and $|S| = |R| + 1$.*

Step 1: Structure of size $n - 1$ sets

We begin by fixing a size $n - 1$ set $R \subseteq [k]$. Now, consider $\mathcal{U}_R$ (defined above). We note that all pairs $S, S' \in \mathcal{U}_R$ are by definition such that $|S \oplus S'| = 2$. Because we initially supposed that π has maximum distortion less than D, we know that for all pairs $S, S' \in \mathcal{U}_R$, we have $d(\pi(S), \pi(S')) < D$.

Then we prove a structural lemma which roughly says that many characters $r \in R$ have a "preference" to be in a particular position in the permutations $\pi(S)$ for $S \in \mathcal{U}_R$. We say that R *i-freezes* the character r if $\pi(S)[i] = r$ for many $S \in \mathcal{U}_R$. Our structural lemma roughly says that for many characters $r \in R$, there exists an index $i \in [n]$ such that R i-freezes r. In other words, for many $S \in \mathcal{U}_R$, the $\pi(S)$s agree on the position of many characters in the permutation.

Step 2: Structure of size $n-2$ sets

We begin by fixing a size $n-2$ set $Q \subseteq [k]$. Now, consider $\mathcal{U}_Q$. We note that each $R \in \mathcal{U}_Q$ obeys the structural lemma from step 1; that is, for many characters $r \in R$, there exists an index $i \in [n]$ such that R i-freezes r.

We prove a structural lemma which roughly says that the sets $P \in \mathcal{U}_Q$ are for the most part *consistent* about which characters they freeze to which index of the permutation. More specifically, for many characters $q \in Q$, for all pairs $P, P' \in \mathcal{U}_Q$, if R i-freezes r and R' j-freezes r, then $i = j$.

Step 3: Counting argument

In step 3, we use a counting argument to derive a contradiction. For the proof of Theorem 7, a simple argument suffices. The idea is that step 1 shows that many characters are frozen overall while step 2 shows that each character can only be frozen to a single index. Then, the pigeonhole principle implies that more than one character is frozen to a single index, which helps to derive a contradiction.

For the proof of Theorem 8, it no longer suffices to just show that more than one character is frozen to a single index. Instead, we require a more sophisticated counting argument and a careful choice of what quantity to count. We end up counting the number of pairs (Q, a) such that $R \in \mathcal{U}_Q$, where $Q \subset [k]$ is a size $n-2$ set and $a \in [n] \setminus Q$. To reach a contradiction, we count this quantity in two different ways, using steps 1 and 2 respectively.

Having reached a contradiction, we conclude that π has maximum distortion at least D.

3.2 Proof of Theorem 7 for $n = 3$, $k = 5$

In this section, we prove Theorem 7 for $n = 3$, $k = 5$, which serves as a simple illustrative example of our proof framework from Section 3.1.

▶ **Theorem 9** (Special case of Theorem 7). *Every function $\pi_{3,5}$ has maximum distortion at least 3.*

Proof. Suppose by way of contradiction that there is a function $\pi_{3,5}$ with maximum distortion at most 2. For the remainder of this section we omit the subscript of π since $n = 3$, $k = 5$ are fixed. For clarity of notation, we let $\{a, b, c, d, e\}$ be the characters in $[k]$ for $k = 5$. Thus, we are considering the set of all $\binom{5}{3} = 10$ size 3 subsets of $\{a, b, c, d, e\}$. (Recall that we are only concerned with subsets, not multisets.)

Step 1: Structure of size $n-1$ sets. We begin by fixing a set $\{x, y\} \subseteq \{a, b, c, d, e\}$ of size $n-1 = 2$. Recall that $\mathcal{U}_{\{x,y\}}$ is the set of all size 3 sets S such that $\{x, y\} \subseteq S \subseteq \{a, b, c, d, e\}$. For example, $\mathcal{U}_{\{a,b\}} = \{\{a, b, c\}, \{a, b, d\}, \{a, b, e\}\}$. We note that by definition all pairs $S, S' \in \mathcal{U}_{\{x,y\}}$ have $|S \oplus S'| = 2$. Thus, to find a pair with distortion 3 and thereby obtain a contradiction, it suffices to find a pair $S, S' \in \mathcal{U}_{\{x,y\}}$ with Hamming distance $d(\pi(S), \pi(S')) = 3$. Since $n = 3$, this means we are looking for permutations $\pi(S), \pi(S')$ that disagree about the position of *all* elements.

The following lemma says that π places one of x or y at the *same* position for *all* $\pi(S)$ with $S \in \mathcal{U}_{\{x,y\}}$. For ease of notation, we give this phenomenon a name:

▶ **Definition 10** (freeze). *We say that a pair $\{x, y\} \subseteq \{a, b, c, d, e\}$ i-*freezes *a character $p \in \{x, y\}$ if for all $S \in \mathcal{U}_{\{x,y\}}$, we have $\pi(S)[i] = p$. We simply say that $\{x, y\}$* freezes *p if i is unspecified. Equivalently, we say that a character p is i-*frozen *(or just* frozen*) by a pair.*

▶ **Lemma 11.** *For every $\{x, y\} \subseteq \{a, b, c, d, e\}$, there exists i so that $\{x, y\}$ i-freezes either x or y.*

For example, one way that the pair $\{a, b\}$ could satisfy Lemma 11 is if the permutations $\pi(\{a, b, c\})$, $\pi(\{a, b, d\})$, and $\pi(\{a, b, e\})$ *all* place the character a in the 0^{th} position. In this case, we would say that the pair $\{a, b\}$ 0-freezes a.

Proof of Lemma 11. Without loss of generality, consider $\{x, y\} = \{a, b\}$. In this case, $\mathcal{U}_{\{x,y\}} = \mathcal{U}_{\{a,b\}} = \{\{a, b, c\}, \{a, b, d\}, \{a, b, e\}\}$. Thus, we are trying to show that $\{a, b, c\}$, $\{a, b, d\}$, and $\{a, b, e\}$ *all* agree on the position of either a or b.

Suppose without loss of generality that $\pi(\{a, b, c\}) = abc$. We first note that $\pi(\{a, b, c\})$ and $\pi(\{a, b, d\})$ must agree on the position of either a or b because otherwise we would have $d(\pi(\{a, b, c\}), \pi(\{a, b, d\})) = 3$ which would mean that $\pi(\{a, b, c\})$ and $\pi(\{a, b, d\})$ would have distortion 3, and we would have proved Theorem 9. Without loss of generality, suppose $\pi(\{a, b, c\})$ and $\pi(\{a, b, d\})$ agree on the position of a; that is, $\pi(\{a, b, d\})$ is either abd or adb.

By the same reasoning, $\pi(\{a, b, c\})$ and $\pi(\{a, b, e\})$ agree on the position of either a or b, and $\pi(\{a, b, d\})$ and $\pi(\{a, b, e\})$ agree on the position of either a or b. If $\pi(\{a, b, e\})$ agrees with *either* $\pi(\{a, b, c\})$ or $\pi(\{a, b, d\})$ on the position of a, then it agrees with *both* (in which case we are done) since $\pi(\{a, b, c\})$ and $\pi(\{a, b, d\})$ agree on the position of a, by the previous paragraph. Thus, the only option is that $\pi(\{a, b, e\})$ agrees with *both* $\pi(\{a, b, c\})$ and $\pi(\{a, b, d\})$ on the position of b. This completes the proof. ◀

Step 2: Structure of size $n - 2$ sets. Since $n - 2 = 1$, we begin by fixing a single element $x \in \{a, b, c, d, e\}$. In the following lemma we prove that x cannot be frozen to two different indices.

▶ **Lemma 12.** *If a pair $\{x, y\} \subseteq \{a, b, c, d, e\}$ i-freezes x and a pair $\{x, z\} \subseteq \{a, b, c, d, e\}$ j-freezes x then $i = j$.*

Proof. Since $\{x, y\}$ i-freezes x, then in particular, $\pi(\{x, y, z\})[i] = x$. Since $\{x, z\}$ j-freezes x, then in particular, $\pi(\{x, y, z\})[j] = x$. A single character cannot be in multiple positions of the permutation $\pi(\{x, y, z\})$ so $i = j$. ◀

Step 3: Counting argument. Lemma 11 implies that for each character $x \in \{a, b, c, d, e\}$ except for at most one, *some* pair $\{x, y\}$ freezes x. That is, at least 4 characters are frozen by some pair. However $n = 3$ so by the pigeonhole principle, two characters $x, y \in \{a, b, c, d, e\}$ are frozen to the same index i.

Fix x, y, and i, and suppose x and y are each i-frozen. By Lemma 11, the pair $\{x, y\}$ freezes either x or y. Without loss of generality, say $\{x, y\}$ freezes x. By Lemma 12, since x is i-frozen by some pair, *all* pairs that freeze x must i-freeze x. Thus, the pair $\{x, y\}$ i-freezes x.

Let $\{y, z\} \subseteq \{a, b, c, d, e\}$ be a pair that i-freezes y. Thus we have $\pi(\{x, y, z\})[i] = y$. However, since $\{x, y\}$ i-freezes x, we also have $\pi(\{x, y, z\})[i] = x$. This is a contradiction since $\pi(\{x, y, z\})[i]$ cannot take on two different values. ◀

We defer the proof of Theorem 8, which is the remainder of Section 3, to the full version.

4 The remaining parameter regime

▶ **Theorem 13** (restatement of Theorem 4). *For $n \geq 3$, $k \geq 5$, every set of functions $f_1^{n,k}, \ldots, f_n^{n,k}$ has maximum switching cost at least 3.*

▶ Remark. We note that the proof framework from Section 3 immediately breaks down if we try to apply it to Theorem 13 for all n, k. For example, when $n > k$, there are no size n subsets of $[k]$ so we must instead consider size n *multisets* of $[k]$. Even if we have the same setting of parameters as Theorem 7 but we are considering multisets, in step 1 of the proof framework Lemma 11 is no longer true. That is, it is not true that for all size 2 multisets $\{x, y\}$ of $[k]$, we have that $\{x, y\}$ i-freezes either x or y for some i. In particular, suppose $\{x, y\} = \{a, a\}$. Then if is possible that $\pi(\{a, a, b\}) = aab$, $\pi(\{a, a, c\}) = aca$, and $\pi(\{a, a, d\}) = daa$, in which case a is not frozen to any index. Since the proof framework from Section 3 no longer applies, we develop entirely new techniques in this section. (However we do use this proof framework to prove Theorem 8.)

For the rest of this section we will use the language of the original problem statement rather than that of the problem reformulation.

4.1 Preliminaries

To prove the Theorem 13, we need to show that Theorem 9 extends to larger k and n. As noted in Section 1.4.2, extending to larger n is challenging, while extending to larger k is trivial, as shown in the following lemma.

▶ **Lemma 14.** *Fix n and k. If there exists a set of functions $f_1^{n,k}, \ldots, f_n^{n,k}$ with maximum switching cost D, then for all $k' < k$, there exists a set of functions $g_1^{n,k'}, \ldots, g_n^{n,k'}$ with maximum switching cost D.*

Proof. For each demand vector $\vec{v}$ with n agents and k tasks such that only the first k' entries of $\vec{v}$ are non-zero, let $\vec{v'}$ be the length k' vector consisting of only the first k' entries of $\vec{v}$. We note that the set of all such vectors $\vec{v'}$ is the set of all demand vectors for n agents and k' tasks. Set each $g_i^{n,k'}(\vec{v'}) = f_i^{n,k}(\vec{v})$. Then the switching cost for any adjacent pair $(\vec{v_1'}, \vec{v_2'})$ with respect to $g_1^{n,k'}, \ldots, g_n^{n,k'}$ is equal to the switching cost of the corresponding adjacent pair $(\vec{v_1}, \vec{v_2})$ with respect to $f_1^{n,k}, \ldots, f_n^{n,k}$. Thus, the maximum switching cost of $g_1^{n,k'}, \ldots, g_n^{n,k'}$ is equal to the maximum switching cost of $f_1^{n,k}, \ldots, f_n^{n,k}$. ◀

▶ **Notation.** *We say that an ordered pair of adjacent demand vectors $(\vec{v_1}, \vec{v_2})$ is (s, t)-adjacent if starting with $\vec{v_1}$ and moving exactly one unit of demand from task s to task t results in $\vec{v_2}$. We say that an agent a is (i, j)-*mobile *with respect to an ordered pair of adjacent demand vectors $(\vec{v_1}, \vec{v_2})$ if $f_a^{n,k}(\vec{v_1}) = i$, $f_a^{n,k}(\vec{v_2}) = j$, and $i \neq j$.*

We note that if $(\vec{v_1}, \vec{v_2})$ is (s, t)-adjacent and has switching cost 2, then for some task i, some agent a must be (s, i)-mobile and another agent b must be (i, t)-mobile. We say that i is the intermediate *task with respect to $(\vec{v_1}, \vec{v_2})$.*

4.2 Proof overview

We begin by supposing for contradiction that there exists a set of functions $f_1^{n,k}, \ldots, f_n^{n,k}$ with maximum switching cost 2, and then we prove a series of structural lemmas about such functions.

As previously mentioned, the main challenge of proving Lemma 13 is handling large n. To illustrate this challenge, we repeat the example from Section 1.4.2. This example shows that having large n can allow more pairs of adjacent demand vectors to have switching cost 2, making it more difficult to find a pair with switching cost greater than 2.

Consider the subset S_i of demand vectors in which a particular task i has an unconstrained amount of demand and each remaining task has demand at most $n/(k-1)$. We claim that there exists a set of functions $f_1^{n,k}, \ldots, f_n^{n,k}$ so that every pair of adjacent demand vectors from S_i has switching cost 2. Divide the agents into $k-1$ groups of $n/(k-1)$ agents each, and associate each task except i to such a group of agents. We define the functions $f_1^{n,k}, \ldots, f_n^{n,k}$ so that given any demand vector in S_i, the set of agents assigned to each task except i is simply a subset of the group of agents associated with that task (say, the subset of such agents with smallest ID). This is a valid assignment since the demand of each task except i is at most the size of the group of agents associated with that task. The remaining agents are assigned to task i. Then, given a pair $(\vec{v}, \vec{v'})$ of adjacent demand vectors in S_i, whose demands differ only for tasks s and t, their switching cost is 2 because the only agents assigned to different tasks between $\vec{v}$ and $\vec{v'}$ are: one agent from each of the groups associated with tasks s and t, respectively.

To overcome the challenge illustrated by the above example, our general method is to identify a task that serves the role of task i and then successively move demand out of task i until task i is empty, and thus can no longer serve its original role. We note that in the above example, the task i serves as the intermediate task for all pairs of adjacent demand vectors from S_i. Thus, we will choose i to be an intermediate task.

In particular, we show that there is a demand vector $\vec{v}$ so that we can identify tasks i and t with the following important property: if we start with $\vec{v}$ and move a unit of demand to task t from *any* other task except i, the switching cost is 2 and the intermediate task is i.

Furthermore, we prove that if we start with demand vector $\vec{v}$ and move a unit of demand from task i to task t resulting in demand vector $\vec{v_1}$, then t and i have the important property from the previous paragraph with respect to $\vec{v_1}$. Applying this argument inductively, we show that no matter how many units of demand we successively move from i to t, i and t still satisfy the important property with respect to the current demand vector.

We move demand from i to t until task i is empty. Then, the final contradiction comes from the fact that if we now move a unit of demand from any non-i task to t, then the important property implies that the switching cost is 2 and the intermediate task is i; however, i is empty and an empty task cannot serve as an intermediate task.

We defer the proof of Theorem 13, which is the remainder of Section 4 to the full version.
