$$I = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad X = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad Y = \begin{bmatrix} 0 & i \\ -i & 0 \end{bmatrix}, \quad \text{and} \quad Z = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}.$$

The following definition captures the notion of an “architecture” of a quantum circuit (see Figure 1 for an example):

► **Definition 3** (Circuit skeleton and light cone). *Let  $n \in 2\mathbb{N}$  and  $d \in \mathbb{N}$ , an  $n$ -qubit depth  $d$  circuit skeleton  $\mathcal{S}$  is a directed acyclic graph with  $d+2$  layers with the following structure. For convenience, we start the index of layers from 0.*

- *The  $0^{\text{th}}$  and the  $(d+1)^{\text{th}}$  layer has  $n$  nodes corresponding to the  $n$  input and output qubits. Each node in the first layer has exactly one out-going edge to the next layer while each node in the last layer has exactly one in-going edge from the previous layer.*
- *Each of the other layers has exactly  $n/2$  nodes and each node has exactly two in-going to the next layer and two out-going edges from the previous layer. Specifically, the first edge  $i^{\text{th}}$  gate is indexed by  $2i-1$  while the second edge is indexed by  $2i$  for each  $i = 1, 2, \dots, n/2$ .*
- *For each  $i = 1, 2, \dots, n$ , the  $i^{\text{th}}$  input node connects to the  $i^{\text{th}}$  edge of the second layer while the  $i^{\text{th}}$  edge of the  $(d+1)^{\text{th}}$  layer connects to the  $i^{\text{th}}$  output node.*

*Note that with the above definition, a circuit skeleton  $\mathcal{S}$  can be specified by  $d+1$  many permutations  $\pi^{(0)}, \pi^{(1)}, \dots, \pi^{(d)} \in S_n$ . Namely, for each  $t = 0, 1, 2, \dots, d-1$  and  $i = 1, 2, \dots, n$ , the  $i^{\text{th}}$  edge of the  $t^{\text{th}}$  layer connects to the  $\pi^{(t)}(i)^{\text{th}}$  edge of the  $(t+1)^{\text{th}}$  layer.*

*For every circuit skeleton  $G$ , the light cone size of  $G$  is the maximum over all output qubits  $i$  of the size of the set  $\{j : j \text{ is input qubit connected to } i \text{ in } G\}$ .*

■ **Figure 1** An example of 1D circuit skeleton with  $n = 8$  and  $d = 3$ . In this example the permutations are  $\pi^{(0)} = \pi^{(4)} = \text{id}$ ,  $\pi^{(1)} = \pi^{(3)} = (18765432)$ ,  $\pi^{(2)} = (81234567)$ .

Next, we define the light cone for an output qubit and the light cone size for a circuit skeleton.

► **Definition 4** (Light cone). *Let  $\mathcal{S}$  be a circuit skeleton and  $i$  be an output qubit. The light cone of  $i$  is the set of all input vertices in  $\mathcal{S}$  that has a path from left to right that ends at  $i$ . The light cone size of  $\mathcal{S}$  is then defined as the largest light cone size of an output qubit in  $\mathcal{S}$ .*

Note that the light cone size of the 1D circuit in Figure 1 is 6, which is less than the number of qubits. Also, it turns out that computing the marginal of an output qubit only requires the information from the light cone.

► **Lemma 5** (Marginal probability and light cone). *Let  $\mathcal{S}$  be a circuit skeleton with light cone size  $L$  and  $C$  be a circuit using skeleton  $\mathcal{S}$ . For each output qubit of  $C$ , the marginal probability can be computed in time  $O(2^L)$ .*

**Proof of Lemma 5.** We use the circuit skeleton in Figure 1 as an illustrating example. For an output qubit in  $C$ , to compute its marginal probability it suffices to compute the input state to the gate it connects to. For example, for output qubit  $y_3$ , it suffices to compute the input state to gate (a).

Similarly, to compute the input state of a gate, it suffices to compute the input states of the gate it connects to from the previous layer. Namely, to compute the input state of gate (a), it suffices to compute that of gate (b) and (c). If we continue this process inductively, the only input state needed to compute the marginal probability of an output bit is then the one lies in its light cone. In this example, to compute the marginal probability of  $y_3$ , it suffices to consider only  $x_1, x_2, \dots, x_6$ .

Finally, to compute the input states of all the intermediate gates, it suffices to perform  $2^L \times 2^L$  matrix vector multiplication because each intermediate state is of size at most  $L$ . While all the above operations can be done in  $O(2^L)$  times, computing the marginal probability of an output qubits in  $C$  only requires  $O(2^L)$  time. ◀

Now, we are able to formally define random quantum circuits.

► **Definition 6** (Random quantum circuits). *Let  $n \in 2\mathbb{N}$ ,  $d \in \mathbb{N}$ . A distribution  $\mathcal{D}$  of  $n$ -qubit depth  $d$  random circuits consists of an  $n$ -qubit depth  $d$  circuit skeleton  $\mathcal{S}$  and ensembles  $\{\mathcal{E}_{i,j}\}$  over  $4 \times 4$  unitary matrices for each  $i = 1, \dots, d$  and  $j = 1, \dots, n/2$ .*

*A random quantum circuit  $C$  sampled from  $\mathcal{D}$  by sampling a  $4 \times 4$  unitary matrix  $U_i^{(t)}$  from  $\mathcal{E}_i^{(t)}$  and assigning  $U_i^{(t)}$  to the  $i^{\text{th}}$  node of the  $t^{\text{th}}$  layer for each  $t = 1, \dots, d$  and  $i = 1, \dots, n/2$ .*

*Specifically, if each  $\mathcal{E}_i^{(t)}$  is Haar random, then we say  $\mathcal{D}$  is Haar random 2-qubit circuits over  $\mathcal{S}$ .*

## 2.1 Tensor networks

Tensor network is an intuitive graphical language that can be rigorously used in reasoning about multilinear maps. Especially, it finds many applications in quantum computing since the basic operations such as partial measurement are all multilinear maps. In this paper, we restrict our attention to *qubits* (as opposed to the general case of *qudits*) and only to gates that act on two qubits.

■ **Figure 2** Three basic elements in tensor networks. (a) Gate: the figure represents  $\sum_{b_i, b_j \in \{0,1\}} A_{b_i, b_j} |b_i\rangle \langle b_j|$ . (b) State: the figure represents  $\langle b_i|$ . (c) Line: the figure represents  $\delta_{b_i, b_j}$ .

In a tensor network, we represent a unitary matrix (e.g., a gate) as a box with lines on the sides (see Figure 2a). Each line represents a coordinate of the gate and in this paper each coordinate has dimension 2 and is indexed by  $\{0, 1\}$ . Specifically, a line on the left represents a column vector (i.e.,  $|\cdot\rangle$ ) while a line on the right represents a row vector (i.e.,  $\langle \cdot|$ ).<sup>7</sup> For example, Figure 2a represents  $\sum_{b_i, b_j \in \{0,1\}} A_{b_i, b_j} |b_i\rangle \langle b_j|$ .

<sup>7</sup> This is when the tensor network is written left to right - sometimes it is written top to bottom, in which case a line on the top represents a column vector and a line on the bottom represents a row vector.

Similarly, a state (e.g., a qubit) is represented by a triangle with line only on one side and it is a  $|\cdot\rangle$  (resp.  $\langle\cdot|$ ) if the free-end of the line is left (resp. right). For example, Figure 2b represents  $\langle b_i|$ .

Semantically, a pure line refers to an indicator function<sup>8</sup> for its two ends. For example, the line in Figure 2c reads as  $\sum_{b_i, b_j \in \{0,1\}} \delta_{b_i, b_j} \langle b_i|b_j\rangle$  where  $\delta_{b_i, b_j} = 1$  if  $b_i = b_j$ ; otherwise it is 0.

### 3 Our Algorithm

We now describe our classical algorithm that spoofs the linear cross-entropy benchmark in shallow quantum circuits. The key idea is that rather than directly simulating the whole quantum circuit, our algorithm only computes the marginal distributions of few output qubits and then samples substrings for those qubit accordingly. We sample the remaining subits uniformly at random. Intuitively, due to the correlation on those output qubits, one can expect that the linear cross-entropy of our algorithm could be better than uniform distribution, but the analysis is somewhat delicate. Because consider shallow quantum circuits (of at most logarithmic light cone size), the marginal of few output qubits can be efficiently computed.

■ **Algorithm 1** Classical algorithm for spoofing linear XEB in shallow quantum circuits.

**Input:** A quantum circuit  $C$  sampled from  $\mathcal{D}_{\mathcal{S}}$ , a Haar random distribution over an  $n$ -qubit circuit skeleton  $\mathcal{S}$  with light cone size at most  $L$ .

- 1: We set  $m$  be some parameter in  $\{1, \dots, \lfloor n/L \rfloor\}$ . (We set  $m = \lfloor n/L \rfloor$  to obtain the result of Theorem 1 as stated.)
- 2: Find  $m$  output qubits  $i_1, \dots, i_m$  such that their light cones are disjoint.
- 3: Calculate the marginal probability of each output qubits  $i_1, \dots, i_m$ .
- 4: Sample  $x_{i_1}, \dots, x_{i_m}$  according to the marginal probabilities calculated in the previous step. For any  $i \notin \{i_1, \dots, i_m\}$ , sample  $x_i$  uniformly random from  $\{0, 1\}$ .

**Output:**  $x$ .

#### Running time of the algorithm

The total running time of Algorithm 1 is at most  $\text{poly}(n, 2^L)$ . Finding  $m$  outputs with disjoint light cones takes  $\text{poly}(n)$  time by a greedy algorithm. The second step takes  $\text{poly}(n, 2^L)$  time because it suffices to keep track of the  $2^L \times 2^L$  density matrix recording the marginal probability of every qubit in the light cone of  $i_j$  for each  $j \in [m]$  (see Lemma 5). The final step of sampling uniform bits for the remaining outputs can be done in polynomial time.

### 3.1 Analysis

The following theorem implies Theorem 1 by setting  $m = \lfloor n/L \rfloor$ :

► **Theorem 7** (Linear XEB for circuits with small light cones.). *Let  $n, d, L \in \mathbb{N}$  and let  $\mathcal{D}$  be a distribution over  $n$ -qubit quantum circuits with (i) light cone size at most  $L$ , (ii) depth at most  $d$ , and (iii) Haar random 2-qubit gates. Then, letting  $A_C$  be the distribution output by Algorithm 1 on input  $C$ ,*

$$\mathbb{E}_{C \sim \mathcal{D}} [\mathcal{F}_C(A_C)] \geq (1 + 15^{-d})^m - 1,$$

where  $m$  is the parameter chosen in step 1 of the algorithm.

<sup>8</sup> Also known as *contraction*.

The proof of Theorem 7 consists of three steps:

1. We reduce analyzing the expectation when the algorithm samples the marginals of  $m$  output qubits into analyzing it for a single output qubit.
2. We apply the integration formula for Haar measure and rewrite the expected linear XEB of a single qubit into a tensor network.
3. We then perform a change of basis on the tensor network and turn the single qubit analysis into a Markov chain problem where the expected linear XEB of a single qubit can be easily lower bounded.

Since the heart of the proof is the single output qubit analysis, we will describe it first.

#### 4 Single qubit analysis

In this section, we prove the  $m = 1$  case of our algorithm. That is, we prove that for a single output qubit, the expected contribution to linear XEB is of the order of  $15^{-d}$ .

► **Theorem 8** (Linear XEB of a single output qubit). *Let  $n, d \in \mathbb{N}$  and  $\mathcal{D}$  be distribution over  $n$ -qubit quantum circuits with depth at most  $d$  and with Haar random 2-qubit gates. For  $C \sim \mathcal{D}$ , let  $U$  denote the unitary matrix computed by  $C$ . For each  $i \in [n]$ , we have*

$$\mathbb{E}_{C \sim \mathcal{D}} [q_{C,i,0}^2 + q_{C,i,1}^2] \geq \frac{1 + 15^{-d}}{2},$$

where  $q_{C,i,b} = \Pr_{x \sim q_C} [x_i = b]$ .

We prove Theorem 8 by reducing to a Markov chain problem using tensor networks. Without loss of generality we can assume  $i = 1$ . Observe that

$$q_{C,1,0}^2 + q_{C,1,1}^2 = \frac{1 + \text{tr} (Z \otimes I^{\otimes n-1} U^\dagger |0^n\rangle \langle 0^n| U)^2}{2} \quad (1)$$

So our goal is to show that

$$\mathbb{E}_{C \sim \mathcal{D}} \left[ \text{tr} (Z \otimes I^{\otimes n-1} U^\dagger |0^n\rangle \langle 0^n| U)^2 \right] \geq 15^{-d}. \quad (2)$$

Let us start with rewriting the trace term of Equation 2 into an equivalent tensor network expression as follows.

$$\text{tr} (Z \otimes I^{\otimes n-1} U^\dagger |0^n\rangle \langle 0^n| U)^2 = \begin{array}{c} \begin{array}{c} \langle 0^n | \pi^{(0)} \end{array} \begin{array}{c} U_1 \end{array} \begin{array}{c} \pi^{(1)} \end{array} \begin{array}{c} U_2 \end{array} \cdots \begin{array}{c} U_d \end{array} \begin{array}{c} Z \otimes I^{\otimes n-1} \end{array} \\ \begin{array}{c} \langle 0^n | \pi^{(0)} \end{array} \begin{array}{c} U_1^\dagger \end{array} \begin{array}{c} \pi^{(1)} \end{array} \begin{array}{c} U_2^\dagger \end{array} \cdots \begin{array}{c} U_d^\dagger \end{array} \begin{array}{c} Z \otimes I^{\otimes n-1} \end{array} \\ \begin{array}{c} \langle 0^n | \pi^{(0)} \end{array} \begin{array}{c} U_1 \end{array} \begin{array}{c} \pi^{(1)} \end{array} \begin{array}{c} U_2 \end{array} \cdots \begin{array}{c} U_d \end{array} \begin{array}{c} Z \otimes I^{\otimes n-1} \end{array} \\ \begin{array}{c} \langle 0^n | \pi^{(0)} \end{array} \begin{array}{c} U_1^\dagger \end{array} \begin{array}{c} \pi^{(1)} \end{array} \begin{array}{c} U_2^\dagger \end{array} \cdots \begin{array}{c} U_d^\dagger \end{array} \begin{array}{c} Z \otimes I^{\otimes n-1} \end{array} \end{array}.$$

Next, for a single gate  $g$  in a quantum circuit, its expected behavior over the choice of 2-qubit Haar random gates can be characterized in the following lemma.

► **Lemma 9.** *Let  $U_g$  be Haar random 2-qubit gate, then the following holds.*

$$\mathbb{E}_{U_g} \left[ \begin{array}{c} \begin{array}{c} 1_a \\ 2_a \end{array} \begin{array}{c} U_g \end{array} \begin{array}{c} \tilde{1}_a \\ \tilde{2}_a \end{array} \\ \begin{array}{c} 1_b \\ 2_b \end{array} \begin{array}{c} U_g^\dagger \end{array} \begin{array}{c} \tilde{1}_b \\ \tilde{2}_b \end{array} \\ \begin{array}{c} 1_c \\ 2_c \end{array} \begin{array}{c} U_g \end{array} \begin{array}{c} \tilde{1}_c \\ \tilde{2}_c \end{array} \\ \begin{array}{c} 1_d \\ 2_d \end{array} \begin{array}{c} U_g^\dagger \end{array} \begin{array}{c} \tilde{1}_d \\ \tilde{2}_d \end{array} \end{array} \right] = \sum_{\sigma_1, \sigma_2, \sigma'_1, \sigma'_2 \in \{I, X, Y, Z\}} M_{\sigma_1, \sigma_2, \sigma'_1, \sigma'_2} \begin{array}{c} \begin{array}{c} 1_a \\ 1_b \\ 1_c \\ 1_d \end{array} \begin{array}{c} \sigma_1 \end{array} \begin{array}{c} \frac{1}{\sqrt{2}} \end{array} \\ \begin{array}{c} 2_a \\ 2_b \\ 2_c \\ 2_d \end{array} \begin{array}{c} \sigma_2 \end{array} \begin{array}{c} \frac{1}{\sqrt{2}} \end{array} \\ \begin{array}{c} \frac{1}{\sqrt{2}} \end{array} \begin{array}{c} \sigma'_1 \end{array} \begin{array}{c} \tilde{1}_a \\ \tilde{1}_b \\ \tilde{1}_c \\ \tilde{1}_d \end{array} \\ \begin{array}{c} \frac{1}{\sqrt{2}} \end{array} \begin{array}{c} \sigma'_2 \end{array} \begin{array}{c} \tilde{2}_a \\ \tilde{2}_b \\ \tilde{2}_c \\ \tilde{2}_d \end{array} \end{array}.$$

where

$$M_{\sigma_1, \sigma_2, \sigma'_1, \sigma'_2} = \begin{pmatrix} II & IX & IY & \cdots & ZZ \\ 1 & 0 & 0 & 0 & 0 \\ 0 & \frac{1}{15} & \frac{1}{15} & \cdots & \frac{1}{15} \\ 0 & \frac{1}{15} & \frac{1}{15} & \cdots & \frac{1}{15} \\ 0 & \vdots & \vdots & \ddots & \vdots \\ 0 & \frac{1}{15} & \frac{1}{15} & \cdots & \frac{1}{15} \end{pmatrix} \begin{matrix} II \\ IX \\ IY \\ \vdots \\ ZZ \end{matrix}.$$

The proof of Lemma 9 is based on the integration formula [5] for Haar measure. We postpone the proof of Lemma 9 to Subsection 4.1. Intuitively, the lemma says that by a change a basis, the expected behavior of a single Haar random 2-qubit gate can be exactly understood by an explicit transition matrix  $M$ . By the linearity of taking expectation, we can apply Lemma 9 on every gates in the circuit  $C$  and thus the whole tensor network is simplified to a *Markov chain*. Concretely, we have the following lemma.

► **Lemma 10** (Rewrite Equation 2 as a Markov chain). *Let  $n, d \in \mathbb{N}$  and  $\mathcal{D}$  be a Haar random distribution over an  $n$ -qubit depth  $d$  circuit skeleton  $\mathcal{S}$  with permutations  $\pi^{(0)}, \pi^{(1)}, \dots, \pi^{(d)}$ . For  $C \sim \mathcal{D}$ , let  $U$  denote the unitary matrix computed by  $C$ .*

$$\mathbb{E}_{C \sim \mathcal{D}} \left[ \text{tr} \left( Z \otimes I^{\otimes n-1} U^\dagger |0^n\rangle \langle 0^n| U \right)^2 \right] = \sum_{\substack{\sigma_{i'}^{(t')} \in \{I, X, Y, Z\} \\ i'=1,2,\dots,n \\ t'=1,2,\dots,d+1}} \prod_{t=0}^{d+1} V^{(t)} \left( \left\{ \sigma_{i'}^{(t')} \right\} \right) \quad (3)$$

where

$$V^{(t)} \left( \left\{ \sigma_{i'}^{(t')} \right\} \right) = \begin{cases} \prod_{i=1}^n \text{tr} \left( \frac{I+Z}{2} \frac{\sigma_i^{(1)}}{\sqrt{2}} \right)^2 & , \text{ if } t = 0 \\ \prod_{i=1}^{n/2} M_{\sigma_{2i-1}^{(t)}, \sigma_{2i}^{(t)}, \sigma_{\pi^{(t)}(2i-1)}^{(t+1)}, \sigma_{\pi^{(t)}(2i)}^{(t+1)}} & , \text{ if } t = 1, 2, \dots, d \\ \text{tr} \left( \frac{\sigma_1^{(d+1)}}{\sqrt{2}} Z \right)^2 \cdot \prod_{i=2}^n \text{tr} \left( \frac{\sigma_i^{(d+1)}}{\sqrt{2}} I \right)^2 & , \text{ if } t = d+1. \end{cases}$$

The proof of Lemma 10 is based on a careful composition of applying Lemma 9 on each of the gates. We postpone the proof of Lemma 10 to Subsection 4.2. Now, we are ready to prove Theorem 8 and complete the analysis for the expected linear XEB of single output qubit.

**Proof of Theorem 8.** Lemma 10 rewrites the desiring quantity into the form of a Markov chain so now it suffices to show that the right hand side of Equation 3 is at least  $15^{-d}$ .

Notice that for every possible assignment to  $\{\sigma_{i'}^{(t')}\}$ ,  $V(\{\sigma_{i'}^{(t')}\}) \geq 0$ . That is, it suffices to find an assignment such that  $\prod_{t=0}^{d+1} V^{(t)}(\{\sigma_{i'}^{(t')}\}) \geq 15^{-d}$ . Specifically, let us consider the following assignment. For all  $i = 1, 2, \dots, n$  and  $t = 1, 2, \dots, d+1$ , let

$$\sigma_i^{(t)} = \begin{cases} Z & , \text{ if } \pi^{(d)} \circ \pi^{(d-1)} \circ \dots \circ \pi^{(t)}(i) = 1 \\ I & , \text{ else.} \end{cases}$$

## 30:10 Spoofing Linear Cross-Entropy Benchmarking in Shallow Quantum Circuits

To analyze this assignment, let us start with the last layer. There we have  $\sigma_1^{(d+1)} = Z$  and  $\sigma_i^{(d+1)} = I$  for each  $i = 2, 3, \dots, n$  and thus

$$\begin{aligned} V^{(d+1)}(\{\sigma_{i'}^{(t')}\}) &= \text{tr} \left( \frac{\sigma_1^{(d+1)}}{\sqrt{2}} Z \right)^2 \cdot \prod_{i=2}^n \text{tr} \left( \frac{\sigma_i^{(d+1)}}{\sqrt{2}} I \right)^2 \\ &= \text{tr} \left( \frac{ZZ}{\sqrt{2}} \right)^2 \cdot \text{tr} \left( \frac{II}{\sqrt{2}} \right)^{2(n-1)} = 2^n. \end{aligned}$$

Next, for each  $t = 1, 2, \dots, d$  and  $i = 1, 2, \dots, n$ , observe that  $\sigma_i^{(t)} = \sigma_{\pi^{(t+1)}(i)}^{(t)}$  due to the choice of the assignment. As a result, all the  $M_{\sigma_{2i-1}^{(t)}, \sigma_{2i}^{(t)}, \sigma_{\pi^{(t)}(2i-1)}^{(t+1)}, \sigma_{\pi^{(t)}(2i)}^{(t+1)}}$  will be either  $M_{I,I,I,I}$  or  $M_{I,Z,I,Z}$ . Specifically, for each  $t = 1, 2, \dots, d$ , since there is exactly one  $Z$  appears among  $\{\sigma_i^{(t)}\}_{i=1,\dots,n}$  while the rest are  $I$ s, there is also exactly one  $M_{I,Z,I,Z}$  term contributes in  $V^{(t)}(\{\sigma_{i'}^{(t')}\})$  while the other terms are  $M_{I,I,I,I}$ . Namely, we have

$$V^{(t)}(\{\sigma_{i'}^{(t')}\}) = M_{I,Z,I,Z} \cdot (M_{I,I,I,I})^{n/2-1} = \frac{1}{15}$$

for each  $t = 1, 2, \dots, d$ .

Finally, since there is exactly one  $Z$  appears in  $\{\sigma_i^{(0)}\}_{i=1,\dots,n}$  while the rest are  $I$ s, we have

$$\begin{aligned} V^{(0)}(\{\sigma_{i'}^{(t')}\}) &= \prod_{i=1}^n \text{tr} \left( \frac{I + Z \sigma_i^{(0)}}{2 \sqrt{2}} \right)^2 = \text{tr} \left( \frac{I + Z}{2} \frac{Z}{\sqrt{2}} \right)^2 \cdot \text{tr} \left( \frac{I + Z}{2} \frac{I}{\sqrt{2}} \right)^{2(n-1)} \\ &= \left( \frac{1}{\sqrt{2}} \right) \cdot \left( \frac{1}{\sqrt{2}} \right)^{2(n-1)} = \frac{1}{2^n}. \end{aligned}$$

To sum up, we conclude that  $V(\{\sigma_{i'}^{(t')}\}) = \prod_{t=0}^{d+1} V^{(t)}(\{\sigma_{i'}^{(t')}\}) = 15^{-d}$  as desired. Specifically, this implies Equation 2, i.e.,  $\mathbb{E}_{C \sim \mathcal{D}} \left[ \text{tr} (Z \otimes I^{\otimes n-1} U^\dagger |0^n\rangle \langle 0^n| U)^2 \right] \geq 15^{-d}$ . Combine with Equation 1, this completes the proof of Theorem 8.  $\blacktriangleleft$

### 4.1 Proof of Lemma 9

We start with applying the integration formula for Haar random matrix and considering its tensor network representation.

► **Lemma 11** ([5, Equation 2.4]). *Let  $U$  be a Haar random 2-qubit gate, then we have the following. For each  $x_a, x_b, x_c, x_d, y_a, y_b, y_c, y_d \in \{0, 1\}^2$ ,*

$$\begin{aligned} \mathbb{E}_U [U_{x_a y_a} U_{x_b y_b}^\dagger U_{x_c y_c} U_{x_d y_d}^\dagger] &= \frac{1}{15} \cdot \left[ \delta_{x_a x_b} \delta_{x_c x_d} \delta_{y_a y_b} \delta_{y_c y_d} + \delta_{x_a x_d} \delta_{x_b x_c} \delta_{y_a y_d} \delta_{y_b y_c} \right] \\ &\quad - \frac{1}{60} \cdot \left[ \delta_{x_a x_b} \delta_{x_c x_d} \delta_{y_a y_d} \delta_{y_b y_c} + \delta_{x_a x_d} \delta_{x_b x_c} \delta_{y_a y_b} \delta_{y_c y_d} \right]. \end{aligned}$$

The above equation can be represented as the following tensor network.

$$\mathbb{E}_{U_g} \left[ \begin{array}{c} \text{1}_a \text{---} \boxed{U_g} \text{---} \widetilde{\text{1}}_a \\ \text{2}_a \text{---} \boxed{U_g} \text{---} \widetilde{\text{2}}_a \\ \text{1}_b \text{---} \boxed{U_g^\dagger} \text{---} \widetilde{\text{1}}_b \\ \text{2}_b \text{---} \boxed{U_g^\dagger} \text{---} \widetilde{\text{2}}_b \\ \text{1}_c \text{---} \boxed{U_g} \text{---} \widetilde{\text{1}}_c \\ \text{2}_c \text{---} \boxed{U_g} \text{---} \widetilde{\text{2}}_c \\ \text{1}_d \text{---} \boxed{U_g^\dagger} \text{---} \widetilde{\text{1}}_d \\ \text{2}_d \text{---} \boxed{U_g^\dagger} \text{---} \widetilde{\text{2}}_d \end{array} \right] = \frac{1}{15} \cdot \left[ \begin{array}{c} \text{1}_a \text{---} \text{---} \widetilde{\text{1}}_a \\ \text{1}_b \text{---} \text{---} \widetilde{\text{1}}_b \\ \text{1}_c \text{---} \text{---} \widetilde{\text{1}}_c \\ \text{1}_d \text{---} \text{---} \widetilde{\text{1}}_d \\ \text{2}_a \text{---} \text{---} \widetilde{\text{2}}_a \\ \text{2}_b \text{---} \text{---} \widetilde{\text{2}}_b \\ \text{2}_c \text{---} \text{---} \widetilde{\text{2}}_c \\ \text{2}_d \text{---} \text{---} \widetilde{\text{2}}_d \end{array} \right] - \frac{1}{60} \cdot \left[ \begin{array}{c} \text{1}_a \text{---} \text{---} \widetilde{\text{1}}_a \\ \text{1}_b \text{---} \text{---} \widetilde{\text{1}}_b \\ \text{1}_c \text{---} \text{---} \widetilde{\text{1}}_c \\ \text{1}_d \text{---} \text{---} \widetilde{\text{1}}_d \\ \text{2}_a \text{---} \text{---} \widetilde{\text{2}}_a \\ \text{2}_b \text{---} \text{---} \widetilde{\text{2}}_b \\ \text{2}_c \text{---} \text{---} \widetilde{\text{2}}_c \\ \text{2}_d \text{---} \text{---} \widetilde{\text{2}}_d \end{array} \right].$$

Next, the idea is to apply the Pauli identity (i.e., on each pair of  $(1_a, 1_b), (1_c, 1_d), (2_a, 2_b), (2_c, 2_d), (1'_a, 1'_b), (1'_c, 1'_d), (2'_a, 2'_b)$ , and  $(2'_c, 2'_d)$ ). Intuitively, this is doing a change of basis from the standard basis to Pauli basis.

Let us first apply the Pauli identity on  $(1_a, 1_b)$  and  $(1_c, 1_d)$  note that we have

$$\left( \begin{array}{c} 1a \\ 1b \\ 1c \\ 1d \end{array} \right) \left( \begin{array}{c} \sigma \\ \sigma' \end{array} \right) = \begin{cases} 2 \begin{array}{c} 1a \\ 1b \\ 1c \\ 1d \end{array} \left( \begin{array}{c} \sigma \\ \sigma' \end{array} \right), & \sigma = \sigma' \\ 0, & \text{else} \end{cases} \quad (4)$$

and

$$\left( \begin{array}{c} 1a \\ 1b \\ 1c \\ 1d \end{array} \right) \left( \begin{array}{c} \sigma \\ \sigma' \end{array} \right) = \begin{cases} 4 \begin{array}{c} 1a \\ 1b \\ 1c \\ 1d \end{array} \left( \begin{array}{c} \sigma \\ \sigma' \end{array} \right), & \sigma = \sigma' = I \\ 0, & \text{else.} \end{cases} \quad (5)$$

That is, the tensor network is non-zero only if  $\sigma = \sigma'$ . Thus, we only need one variable  $\sigma_1 \in \{I, X, Y, Z\}$  to handle  $(1_a, 1_b)$  and  $(1_c, 1_d)$ . Similarly, we can use  $\sigma_2, \widetilde{\sigma}_1, \widetilde{\sigma}_2 \in \{I, X, Y, Z\}$  to handle other pairs respectively. The equation becomes the following.

$$\mathbb{E}_{U_g} \left[ \begin{array}{c} 1a \\ 2a \\ 1b \\ 2b \\ 1c \\ 2c \\ 1d \\ 2d \end{array} \right] = \frac{1}{2^8} \sum_{\substack{\sigma'_1, \sigma'_2, \sigma''_1, \sigma''_2 \\ \in \{I, X, Y, Z\}}} \left( \frac{1}{15} \cdot \left[ \begin{array}{c} 1a \\ 1b \\ 1c \\ 1d \\ 2a \\ 2b \\ 2c \\ 2d \end{array} \right] + \left[ \begin{array}{c} 1a \\ 1b \\ 1c \\ 1d \\ 2a \\ 2b \\ 2c \\ 2d \end{array} \right] \right) - \frac{1}{60} \cdot \left[ \begin{array}{c} 1a \\ 1b \\ 1c \\ 1d \\ 2a \\ 2b \\ 2c \\ 2d \end{array} \right].$$

To finish the proof of Lemma 9, we have to explicitly calculate the value of the tensor network for each choice of  $\sigma_1, \sigma_2, \sigma_1', \sigma_2' \in \{I, X, Y, Z\}$ . Again, by Equation 4 and Equation 5, we have the following observations.

- If  $\sigma_1 = \sigma_2 = \sigma_1' = \sigma_2' = I$ , then the value is  $2^{-8} \cdot (15^{-1} \cdot (2^8 + 2^4) - 60^{-1} \cdot (2^6 + 2^6)) = 2^{-4}$ .
  - If  $\sigma_1 = \sigma_2 = I$  and at least one of  $\sigma_1', \sigma_2'$  is not  $I$ , or at least one of  $\sigma_1, \sigma_2$  is not  $I$  and  $\sigma_1' = \sigma_2' = I$ , then the value is  $2^{-4} \cdot (15^{-1} \cdot (0 + 2^4) + 60^{-1} \cdot (2^6 + 0)) = 0$ .
  - For all the other cases, the value is  $2^{-4} \cdot (15^{-1} \cdot (0 + 2^4) + 60^{-1} \cdot (0 + 0)) = 2^{-4} \cdot 15^{-1}$ .
- Finally, we take out the  $2^{-4}$  and evenly distribute it to the Pauli gates outside. Namely, each of them gets an extra  $1/\sqrt{2}$  factor as shown in the equation. This completes the proof of Lemma 9.

## 4.2 Proof of Lemma 10

Let us do a change of basis from the standard basis to the Pauli basis. Concretely, we apply Lemma 9 on every gate. Note that by the independence of each gate and the linearity of expectation, the  $t^{\text{th}}$  layer of the circuit becomes the following for each  $t = 1, 2, \dots, d$ .

$$\mathbb{E}_{U_t} \left( \begin{array}{c} 1a \\ n_a \\ 1b \\ n_b \\ 1c \\ n_c \\ 1d \\ n_d \end{array} \right) U_t = \sum_{\substack{\sigma_i^{(t)}, \widetilde{\sigma}_i^{(t)} \in \{I, X, Y, Z\} \\ \forall i=1, 2, \dots, n}} \prod_{i=1}^{n/2} M_{\sigma_{2i-1}^{(t)}, \sigma_{2i}^{(t)}, \widetilde{\sigma}_{2i-1}^{(t)}, \widetilde{\sigma}_{2i}^{(t)}} \left( \begin{array}{c} 1a \\ 1b \\ 1c \\ 1d \\ n_a \\ n_b \\ n_c \\ n_d \end{array} \right) \left( \begin{array}{c} \sigma_1^{(t)} \\ \sigma_2^{(t)} \\ \vdots \\ \sigma_n^{(t)} \end{array} \right) \left( \begin{array}{c} \widetilde{\sigma}_1^{(t)} \\ \widetilde{\sigma}_2^{(t)} \\ \vdots \\ \widetilde{\sigma}_n^{(t)} \end{array} \right).$$

### 30:12 Spoofing Linear Cross-Entropy Benchmarking in Shallow Quantum Circuits

Next, the  $i^{\text{th}}$  output wire at the  $t^{\text{th}}$  layer, i.e., the wires indexed by  $\tilde{i}_a, \tilde{i}_b, \tilde{i}_c, \tilde{i}_d$ , connects to the  $(\pi^{(t)}(i))^{\text{th}}$  input wire at the  $(t+1)^{\text{th}}$  layer, i.e., the wires indexed by  $\pi^{(t)}(i)_a, \pi^{(t)}(i)_b, \pi^{(t)}(i)_c, \pi^{(t)}(i)_d$ . By the orthogonality of Pauli gates (i.e., we have  $\text{tr}\left(\frac{\tilde{\sigma}_i^{(t)}}{\sqrt{2}} \frac{\sigma_{\pi^{(t)}(i)}^{(t+1)}}{\sqrt{2}}\right) = \delta_{\tilde{\sigma}_i^{(t)}, \sigma_{\pi^{(t)}(i)}^{(t+1)}}$  for all  $i = 1, 2, \dots, n$ . To sum up, the  $1^{\text{st}}$  to  $d^{\text{th}}$  layer is equivalent to following.

$$\begin{aligned}
 \mathbb{E}_{U_1, U_2, \dots, U_d} & \left[ \begin{array}{c} \begin{array}{cccc} \pi^{(0)} & \pi^{(1)} & \dots & \pi^{(d+1)} \\ \begin{array}{c} 1_a \\ n_a \\ \vdots \\ 1_b \\ n_b \\ \vdots \\ 1_c \\ n_c \\ \vdots \\ 1_d \\ n_d \end{array} & \begin{array}{c} U_1 \\ U_1^1 \\ \vdots \\ U_1^1 \\ U_1^1 \end{array} & \begin{array}{c} U_2 \\ U_2^1 \\ \vdots \\ U_2^1 \\ U_2^1 \end{array} & \begin{array}{c} U_d \\ U_d^1 \\ \vdots \\ U_d^1 \\ U_d^1 \end{array} \\ \end{array} \end{array} \right] = \\
 & \sum_{\substack{\sigma_i^{(t)} \in \{I, X, Y, Z\} \\ \forall i=1, 2, \dots, n \\ t=1, 2, \dots, t+1}} \prod_{t=1}^d \left( \prod_{i=1}^{n/2} M_{\sigma_{2i-1}^{(t)}, \sigma_{2i}^{(t)}, \sigma_{\pi^{(t)}(2i-1)}^{(t+1)}, \sigma_{\pi^{(t)}(2i)}^{(t+1)}} \right) \cdot \\
 & \begin{array}{c} \begin{array}{c} \sigma_1^{(1)} \\ \vdots \\ \sigma_n^{(1)} \end{array} \rightarrow \begin{array}{c} \sigma_1^{(d+1)} \\ \vdots \\ \sigma_n^{(d+1)} \end{array} \end{array}
 \end{aligned}$$

Finally, let us plug in the input and output layer. Recall that the input layer contains 4 copies of  $|0^n\rangle$  and the output layer contains 2 copies of  $Z \otimes I^{\otimes n-1}$ . Concretely, the contribution from the input layer would be

$$\prod_{i=1}^n \left( \langle 0 | \frac{\sigma_i^{(1)}}{\sqrt{2}} | 1 \rangle \right)^2 = \prod_{i=1}^n \text{tr} \left( \frac{I + Z}{2} \frac{\sigma_i^{(1)}}{\sqrt{2}} \right)^2$$

while the contribution from the output layer would be

$$\text{tr} \left( \frac{\sigma_1^{(d+1)}}{\sqrt{2}} Z \right)^2 \cdot \prod_{i=2}^n \text{tr} \left( \frac{\sigma_i^{(d+1)}}{\sqrt{2}} I \right)^2.$$

This completes the proof of Lemma 10.

## 5 Wrapping up: from single output bit to many bits

In this section we complete the proof of Theorem 1.

We will use the following notation. Let  $q(x)$  be a pdf over  $x \in \{0, 1\}^n$ . For any  $I \subset [n]$  and  $x_I \in \{0, 1\}^I$ , let  $q(I, x_I)$  denote the marginal probability of the output qubit at location  $I$  being  $x_I$ . Formally,  $q(I, x_I) = \sum_{y_{I^c} \in \{0, 1\}^{n-I}} q(y)$ . For a fixed input  $C$ , let  $I = \{i_1, \dots, i_m\}$  be the output qubits selected by Algorithm 1. Note that Algorithm 1 will choose the same  $I$  for each  $C$  sampled from  $\mathcal{D}$ . By the design of Algorithm 1,  $A_C(x) = \frac{1}{2^{n-m}} q_C(I, x_I)$  for every  $x \in \{0, 1\}^n$ . Thus, the linear XEB of  $A_C$  is the following.

$$\begin{aligned}
 \mathcal{F}_C(A_C) &= 2^n \sum_{x \in \{0, 1\}^n} q_C(x) A_C(x) - 1 = 2^n \sum_{x \in \{0, 1\}^n} q_C(x) \frac{q_C(I, x_I)}{2^{n-m}} - 1 \\
 &= 2^m \sum_{x_I \in \{0, 1\}^I} q_C(I, x_I)^2 - 1.
 \end{aligned} \tag{6}$$

Note that because their light cones are disjoint, we have  $q_C(I, x_I) = \prod_{j=1}^m q_C(\{i_j\}, x_{i_j})$ . Thus, the equation becomes

$$= \sum_{x_I \in \{0,1\}^I} \prod_{j=1}^m 2q_C(\{x_{i_j}\}, x_{i_j})^2 - 1. \quad (7)$$

Now, let us take expectation on the linear XEB over  $\mathcal{D}$ . Since  $\mathcal{D}$  fixes the structure of the circuit and the randomness only lies in the choice of gates,  $q_C(\{i_j\}, x_{i_j})$  is independent to each other. Namely,

$$\begin{aligned} \mathbb{E}_{C \sim \mathcal{D}} [\mathcal{F}_C(A_C)] &= \sum_{x_I \in \{0,1\}^I} \prod_{j=1}^m 2 \mathbb{E}_{C \sim \mathcal{D}} [q_C(\{x_{i_j}\}, x_{i_j})^2] - 1 \\ &= \prod_{j=1}^m 2 \mathbb{E}_{C \sim \mathcal{D}} [q_C(\{x_{i_j}\}, 0)^2 + q_C(\{x_{i_j}\}, 1)^2] - 1. \end{aligned} \quad (8)$$

Using the single qubit analysis (Theorem 8), we can complete the proof of Theorem 1 as follows.

**Proof of Theorem 1.** Apply Theorem 8 on Equation 8, we have

$$\mathbb{E}_{C \sim \mathcal{D}} [\mathcal{F}_C(A_C)] \geq (1 + 15^{-d})^m - 1$$

as desired. ◀

## 5.1 Probability over circuits

Using Theorem 1, we can obtain the following lower bound on the probability over the choice of the circuit  $C$  of obtaining non-trivial fidelity:

► **Corollary 12** (Lower bounding for the probability of success). *Let  $n, d, \mathcal{D}, L$  be as in Theorem 1. Then there is a randomized  $\text{poly}(n, 2^L)$  time algorithm such that for every  $1 \leq n \leq \lfloor \frac{n}{L} \rfloor$  and  $0 < \epsilon < 1$ ,*

$$\Pr_{C \sim \mathcal{D}} [\mathcal{F}_C(A_C) \geq ((1 + 15^{-d})^m - 1)] \geq \frac{(1 - \epsilon) \cdot ((1 + 15^{-d})^m - 1)}{2^m - 1} \geq \Omega\left(\frac{m \cdot 15^{-d}}{2^m}\right).$$

**Proof of Corollary 12.** The idea is simple - since our algorithm picks  $n - m$  bits uniformly at random, for every circuit  $C$ , by Equation 7,  $\mathcal{F}_C(A_C) \leq 2^m$ . Now, for any  $0 < \epsilon < 1$ , let  $\delta = \Pr_{C \sim \mathcal{D}} [\mathcal{F}_C(A_C) > \epsilon \cdot ((1 + 15^{-d})^m - 1)]$ , we have

$$(1 + 15^{-d})^m - 1 \leq \mathbb{E}_{C \sim \mathcal{D}} [\mathcal{F}_C(A_C)] \leq \delta \cdot 2^m + \epsilon \cdot ((1 + 15^{-d})^m - 1).$$

Thus,

$$\delta \geq \frac{(1 - \epsilon) \cdot ((1 + 15^{-d})^m - 1)}{2^m}. \quad \blacktriangleleft$$

## 6 Sample complexity analysis

In this section, we discuss the empirical linear XEB of our algorithm. Namely, how many samples are required so that the empirical average of the linear XEB can be non-trivially lower bounded. Specifically, the goal would be the following. For some  $T = \text{poly}(n)$ ,

$$\Pr_{\substack{C \sim \mathcal{D} \\ x_1, \dots, x_T \sim A_C}} \left[ \frac{1}{T} \sum_{i=1}^T \mathcal{F}_C(x_i) = \Omega(1) \right] \geq \frac{1}{\text{poly}(n)}. \quad (9)$$

In Section 5, we have shown that the expectation of the linear XEB of our algorithm is at least  $(1 + 15^{-d})^m$  for  $1 \leq m \leq \lfloor n/L \rfloor$  with probability  $1/\text{poly}(n)$  over the choice of random circuits. Thus, to achieve Equation 9, it suffices to show that the probability of the empirical average of the linear XEB deviating from  $\mathcal{F}_C(x)$  is small.

In general, it is a difficult task to rigorously upper bound the sample complexity of linear XEB. The reason is that such analysis needs to handle higher moment of  $q_C$  which is highly non-trivial for even 2D circuits. In this work we stick with the simpler case of analyzing the variance of linear XEB in Lemma 13. We further show in Lemma 14 that an inverse exponential bound on the collision probability of  $q_C$  would be sufficient for giving  $\text{poly}(n)$  upper bound for the sample complexity.

### 6.1 A variance/collision probability approach

The variance of  $\mathcal{F}_C(x)$  is sufficient for upper bounding the number of samples required for the empirical linear XEB to converge. Specifically, Chebyshev's inequality implies that with  $\text{Var}_{x \sim p}[\mathcal{F}_C(x)]/(\epsilon^2 \delta)$  many samples, the empirical XEB is at least  $\mathcal{F}_C(p) - \epsilon$  with probability  $\delta$  over the randomness of  $p$ . Note that here the circuit  $C$  is fixed.

► **Lemma 13.** *Let  $C$  be an  $n$ -qubit quantum circuit and  $q_C$  be the pdf of the distribution obtained from  $C |0^n\rangle$ . For any pdf  $p : \{0, 1\}^n \rightarrow [0, 1]$  and  $\epsilon, \delta \in (0, 1)$ , we have*

$$\Pr_{x_1, \dots, x_T \sim p} \left[ \frac{1}{T} \sum_{i=1}^T \mathcal{F}_C(x_i) \leq \mathcal{F}_C(p) - \epsilon \right] \leq \delta$$

when  $T \geq \frac{\text{Var}_{x \sim p}[\mathcal{F}_C(x)]}{\epsilon^2 \delta}$ .

**Proof.** Since  $\{\mathcal{F}_C(x_i)\}$  are i.i.d. random variables with mean  $\mathcal{F}_C(p)$  and variance  $\text{Var}_{x \sim p}[\mathcal{F}_C(x)]$ , by Chebyshev's inequality, we have

$$\Pr_{x_1, \dots, x_T \sim p} \left[ \frac{1}{T} \sum_{i=1}^T \mathcal{F}_C(x_i) < \mathcal{F}_C(p) - \epsilon \right] \leq \frac{\text{Var}_{x \sim p}[\mathcal{F}_C(x)]}{T \cdot \epsilon^2}.$$

As we pick  $T \geq \frac{\text{Var}_{x \sim p}[\mathcal{F}_C(x)]}{\epsilon^2 \delta}$ , the above error is at most  $\delta$  desired. ◀

The following lemma further shows that to upper bound the variance of our algorithm, it suffices to bound the *collision probability* of the ideal distribution.

► **Lemma 14.** *Let  $n, d, L \in \mathbb{N}$  and  $\mathcal{D}$  be distribution over  $n$ -qubit quantum circuits with (i) light cone size at most  $L$ , (ii) depth at most  $d$ , and (iii) with Haar random 2-qubit gates. Let  $1 \leq m \leq \lfloor n/L \rfloor$  and  $A$  be the algorithm from Algorithm 1, we have*

$$\text{Var}_{x \sim A_C} [\mathcal{F}_C(x)] \leq 2^{m+n} \sum_{x \in \{0, 1\}^n} q_C(x)^2$$

where  $\sum_{x \in \{0, 1\}^n} q_C(x)^2$  is also known as the collision probability of  $q_C$ .

**Proof of Lemma 14.** Consider the variance of the linear XEB of our algorithm  $A_C$  as follows.

$$\text{Var}_{x \sim A_C} [\mathcal{F}_C(x)] \leq \mathbb{E}_{x \sim A_C} [2^{2n} q_C(x)^2] = 2^{2n} \sum_{x \in \{0,1\}^n} A_C(x) q_C(x)^2.$$

Recall that  $A_C(x) \leq 2^{m-n}$  for all  $x$ , thus the equation becomes

$$\leq 2^{m+n} \sum_{x \in \{0,1\}^n} q_C(x)^2. \quad \blacktriangleleft$$

To have some intuition on Lemma 14, the right hand side is minimized when  $q_C$  is the uniform distribution over  $\{0,1\}^n$  where the collision probability is  $2^{-n}$ . In such case, the variance of our algorithm is  $O(2^m)$ . When choosing  $m = O(\log n)$ , the sample complexity of our algorithm would be  $\text{poly}(n)$  as desired.

In general, using the variance/collision probability to upper bound the sample complexity might not be tight. For example, consider the distribution of a sequence of independent biased coins, i.e.,  $q(x) = (1/2 + \epsilon)^{\|x\|_1} \cdot (1/2 - \epsilon)^{n - \|x\|_1}$  for each  $x \in \{0,1\}^n$ . Then the variance  $\text{Var}_{x \sim q}[q(x)]$  is exponentially large, however, the sample complexity of having the empirical average of  $q(x)$  being of the order of  $\mathbb{E}_{x \sim q}[q(x)]$  is  $O(1)$  with high probability. Specifically, when the depth of the random circuit is 1, then the marginal distribution looks like the above biased coins distribution with high probability and thus undesirable.

On the other extreme where the random circuit is very deep, it is known that the marginal distribution will converge to the *Porter Thomas distribution* and its collision probability is  $O(2^{-n})$  [2].

In Subsection 6.2, we further show that the collision probability of  $q_C$  is  $O(2^{-n})$  in expectation for 1D circuit of depth at least  $(\log n)/\log(5/4)$ . While the proof could potentially be extended to 2D circuit and beyond, we leave it as a future direction and state the following conjecture.

► **Conjecture 10.** Let  $n, d \in \mathbb{N}$  and  $\mathcal{D}$  be a distribution of  $n$ -qubit. For a circuit  $C$ , denote  $q_C$  as the pdf of  $C|0^n\rangle$ . We conjecture that there exists a constant  $c > 0$  such that when  $\mathcal{D}$  is the distribution over 2D random circuits of depth  $d \geq c\sqrt{\log n}$ ,

$$\mathbb{E}_{C \sim \mathcal{D}} \left[ \sum_{x \in \{0,1\}^n} q_C(x)^2 \right] = O\left(\frac{1}{2^n}\right).$$

## 6.2 The sample complexity of 1D random circuits of logarithmic depth

In this subsection, we formally prove that the sample complexity of our algorithm is  $O(2^m)$  for random 1D circuits with high probability.

► **Theorem 15.** Let  $n \in \mathbb{N}$  and  $\mathcal{D}$  be the distribution over  $n$ -qubit 1D quantum circuits with depth  $d = \Omega(\log n)$  and with Haar random 2-qudit gates where the dimension of the qudit is at least 4. Let  $1 \leq m \leq \lfloor n/2d \rfloor$  be the number of output qubits used by our algorithm. Then for any  $\delta \in (0, 1)$ , we have

$$\Pr_{C \sim \mathcal{D}} \left[ \text{Var}_{x \sim A_C} [\mathcal{F}_C(x)] = O\left(\frac{2^m}{\delta}\right) \right] \geq 1 - \delta.$$

Specifically, combine with Theorem 1, we have

$$\Pr_{\substack{C \sim \mathcal{D} \\ x_1, \dots, x_T \sim A_C}} \left[ \sum_{i=1}^T \mathcal{F}_C(x_i) = \Omega\left(\frac{1}{\text{poly}(n)}\right) \right] \geq \frac{1}{\text{poly}(n)}$$

when  $T = \Omega(1)$ .

### 30:16 Spoofing Linear Cross-Entropy Benchmarking in Shallow Quantum Circuits

**Proof of Theorem 15.** Let us first show that upper bounding the second moment of  $q_C$  is sufficient for proving Theorem 15. Consider the variance of the linear XEB of our algorithm  $A_C$  as follows.

$$\text{Var}_{x \sim A_C} [\mathcal{F}_C(x)] \leq \mathbb{E}_{x \sim A_C} [2^{2n} q_C(x)^2] = 2^{2n} \sum_{x \in \{0,1\}^n} A_C(x) q_C(x)^2.$$

Recall that  $A_C(x) \leq 2^{m-n}$  for all  $x$ , thus the equation becomes

$$\leq 2^{m+n} \sum_{x \in \{0,1\}^n} q_C(x)^2.$$

Next, the lemma below shows that the second moment term  $\sum_{x \in \{0,1\}^n} q_C(x)^2$  is exponentially small with high probability over the choice of  $C$ .

► **Lemma 16.** *Let  $n \in \mathbb{N}$  and  $\mathcal{D}$  be the distribution over  $n$ -qubit 1D quantum circuits with depth at least  $\frac{\log n}{\log(5/4)}$  and with Haar random 2-qubit gates. Then we have*

$$\mathbb{E}_{C \sim \mathcal{D}} \left[ \sum_{x \in \{0,1\}^n} q_C(x)^2 \right] = O\left(\frac{1}{2^n}\right).$$

The proof of Lemma 16 is based on the Ising model analysis by [7]. We postpone it to Subsection 6.3. Now, let us complete the proof of Theorem 15. By Lemma 16, we have

$$\mathbb{E}_{C \sim \mathcal{D}} \left[ \text{Var}_{x \sim A_C} [\mathcal{F}_C(x)] \right] \leq 2^{m+n} \mathbb{E}_{C \sim \mathcal{D}} [q_C(x)^2] \leq O(2^m).$$

Thus, for any  $\delta > 0$ , by Markov's inequality, we have  $\Pr_{C \sim \mathcal{D}} [\text{Var}_{x \sim A_C} [\mathcal{F}_C(x)] = O(2^m/\delta)] \geq 1 - \delta$  as desired. ◀

## 6.3 Proof of Lemma 16

It turns out that the previous Markov chain approach in analysis the expected linear XEB of our algorithm is not sufficient for upper bounding the expectation of  $\sum_{x \in \{0,1\}^n} q_C(x)^2$ . We thus consider a different approach by reducing the quantity to a combinatorial problem in a spin system on lattice. The proof is highly inspired by a recent paper of Hunter [7].

For the convenience of the analysis, here we fix the following skeleton for 1D circuit while the result can be easily extended to other variants.

$$(11)$$

### Step 1: Reducing to counting spin configurations on a hexagonal lattice

First, let us rewrite  $\sum_{x \in \{0,1\}^n} q_C(x)^2$  into an equivalent tensor network.

$$\begin{aligned} \sum_{x \in \{0,1\}^n} q_C(x)^2 &= \sum_{x \in \{0,1\}^n} \text{tr} (\langle 0^n | U | x \rangle \langle x | U^\dagger | 0^n \rangle)^2 \\ &= \sum_{x \in \{0,1\}^n} \begin{array}{c} \begin{array}{c} \leftarrow 0^n \pi^{(0)} U_1 \pi^{(1)} U_2 \cdots U_d \pi^{(d+1)} x \\ \leftarrow 0^n \pi^{(0)} U_1^\dagger \pi^{(1)} U_2^\dagger \cdots U_d^\dagger \pi^{(d+1)} x \\ \leftarrow 0^n \pi^{(0)} U_1 \pi^{(1)} U_2 \cdots U_d \pi^{(d+1)} x \\ \leftarrow 0^n \pi^{(0)} U_1^\dagger \pi^{(1)} U_2^\dagger \cdots U_d^\dagger \pi^{(d+1)} x \end{array} \end{array} \end{aligned}$$

In Lemma 9, we change the basis to the Pauli basis and replace the expectation of a single gate with a transition matrix. Here, we instead stick to the permutation basis in the integration formula and represent a single gate as an *effective vertex* [5].

► **Lemma 17** ([5]). *Let  $U_g$  be a Haar-random 2-qubit gate. We have the following.*

$$\mathbb{E}_{U_g} \left[ \begin{array}{c} 1_a \\ 2_a \\ 1_b \\ 2_b \\ 1_c \\ 2_c \\ 1_d \\ 2_d \end{array} \begin{array}{c} U_g \\ U_g^\dagger \\ U_g \\ U_g^\dagger \end{array} \begin{array}{c} \tilde{1}_a \\ \tilde{2}_a \\ \tilde{1}_b \\ \tilde{2}_b \\ \tilde{1}_c \\ \tilde{2}_c \\ \tilde{1}_d \\ \tilde{2}_d \end{array} \right] = \sum_{\sigma, \tau \in S_2} \begin{array}{c} 1_a, \dots, 1_d \quad 1'_a, \dots, 1'_d \\ \sigma \quad \tau \\ 2_a, \dots, 2_d \quad 2'_a, \dots, 2'_d \end{array}.$$

Here  $S_2 = \{\mathbb{I}, \mathbb{S}\}$  is the permutation group of two elements and an edge on the left represents four edges on the right. Specifically, the edge with  $\sigma$  and  $\tau$  on the two ends has weight  $\langle \sigma | \tau \rangle$  where

$$\langle \sigma | \tau \rangle = \begin{cases} \frac{1}{15} & , \sigma = \tau \\ \frac{-1}{60} & , \sigma \neq \tau. \end{cases}$$

for all  $\sigma, \tau \in S_2$ . As for the boundary condition, for each  $b_i \in \{0, 1\}$ , we have

$$\begin{array}{c} \begin{array}{c} b_i \\ b_i \\ b_i \\ b_i \\ b_i \\ b_i \\ b_i \\ b_i \end{array} \end{array} \begin{array}{c} \text{red circle} \\ \text{blue circle} \end{array} = \begin{array}{c} \text{red circle} \end{array}, \quad \begin{array}{c} \begin{array}{c} b_i \\ b_i \\ b_i \\ b_i \\ b_i \\ b_i \\ b_i \\ b_i \end{array} \end{array} \begin{array}{c} \text{blue circle} \\ \text{red circle} \end{array} = \begin{array}{c} \text{blue circle} \end{array}, \quad \text{and} \quad \sum_{\circ \in S_2} \begin{array}{c} \text{red circle} \end{array} \begin{array}{c} \text{blue circle} \end{array} = \frac{1}{20} \begin{array}{c} \text{red circle} \end{array}.$$

Apply Lemma 17 on a 1D circuit, the expectation of  $\sum_{x \in \{0,1\}^n} q_C(x)^2$  is then exactly the sum over spin configurations on the hexagonal lattice. For example, Equation 11 becomes the following. Note that each circle represents a distinct choices of elements from  $S_2$ .

$$\mathbb{E}_{C \sim \mathcal{D}} \left[ \sum_{x \in \{0,1\}^n} q_C(x)^2 \right] = 2^n \cdot \sum_{\circ, \circ \in S_2} \begin{array}{c} \begin{array}{c} \text{hexagonal lattice diagram} \end{array} \end{array}. \quad (12)$$

### Step 2: Reducing to counting domain wall configurations on a triangular lattice

The second idea in [7] is doing local summation on the blue vertices. Specifically, he showed that the local behavior of a blue vertex and its three red neighboring vertices can be fully described only by the spin of these three red vertices.

► **Lemma 18** ([7, Equation 18]). *Let  $U_g$  be a Haar-random 2-qubit gate. We have the following.*

$$\sum_{\tau \in S_2} \begin{array}{c} \text{red circle } \sigma_2 \\ \diagup \quad \diagdown \\ \text{blue circle } \tau \quad \text{red circle } \sigma_3 \\ \diagdown \quad \diagup \\ \text{red circle } \sigma_1 \end{array} = \begin{array}{c} \text{red circle } \sigma_2 \\ \diagup \quad \diagdown \\ \text{blue triangle} \\ \diagdown \quad \diagup \\ \text{red circle } \sigma_1 \end{array} = \begin{cases} 1 & , \sigma_1 = \sigma_2 = \sigma_3 \\ 0 & , \sigma_1 \neq \sigma_2 = \sigma_3 \\ \frac{2}{5} & , \text{else.} \end{cases}$$

An immediate corollary of Lemma 18 is that now we can instead summing over the spin configurations over a triangular lattice. That is, Equation 12 becomes the following

$$\mathbb{E}_{C \sim \mathcal{D}} \left[ \sum_{x \in \{0,1\}^n} q_C(x)^2 \right] = 2^n \cdot \left( \frac{1}{20} \right)^{n/2} \cdot \sum_{\sigma \in S_2} \begin{array}{c} \text{triangular lattice with red circles at vertices} \\ \text{and blue triangles at edges} \end{array} \quad (13)$$

The advantage of working on this triangular lattice is that the non-zero term on the right hand side of Equation 13 corresponds to a *domain wall* in the triangular lattice.

► **Definition 19** (Domain wall). *Consider the right hand side of Equation 13 and a configuration to all the red circles. The domain wall for this configuration is a collection of disjoint horizontal lines that separate the circles that are configured to  $\mathbb{I}$  from the circles that are configured to  $\mathbb{S}$ .*

Note that the domain wall configuration is in 1-to-1 correspondence with the spin configurations. Let  $\text{dw}$  denote a domain wall, let  $w(\text{dw})$  be the weight of the corresponding spin configuration. Thus, Equation 13 becomes the following.

$$\mathbb{E}_{C \sim \mathcal{D}} \left[ \sum_{x \in \{0,1\}^n} q_C(x)^2 \right] = \left( \frac{1}{5} \right)^{n/2} \cdot \sum_{\text{dw} \in \begin{array}{c} \text{triangular lattice} \\ \text{with domain walls} \end{array}} w(\text{dw}). \quad (14)$$

Note that a domain wall could contain two types of paths: (i) a path that goes from left boundary to the right boundary and (ii) a path that starts from and ends at both the right boundary. Furthermore, as the domain wall configuration is in 1-to-1 correspondence with subset of disjoint paths, Equation 14 becomes the following.

$$\mathbb{E}_{C \sim \mathcal{D}} \left[ \sum_{x \in \{0,1\}^n} q_C(x)^2 \right] \leq \left( \frac{1}{5} \right)^{n/2} \cdot \left( 1 + \sum_{\substack{\text{disjoint path of type (i)} \\ \in \begin{array}{c} \text{triangular lattice} \\ \text{with domain walls} \end{array}}} w(\text{path}) \right) \cdot \left( 1 + \sum_{\substack{\text{disjoint path of type (ii)} \\ \in \begin{array}{c} \text{triangular lattice} \\ \text{with domain walls} \end{array}}} w(\text{path}) \right). \quad (15)$$

### Step 3: Upper bound the sum of possible path configurations of type (i)

For a set of disjoint path of type (i), it contains at most  $\lfloor n/2 \rfloor$  paths. Also, a path of type (i) contributes  $\left(\frac{q}{q^2+1}\right)^d$  in the weight of a domain wall.

Now, for each  $1 \leq t \leq \lfloor n/2 \rfloor$  let us first estimate the number of domain walls having at most  $t$  paths of type (i). Specifically, for every  $i \in [\lfloor n/2 \rfloor]$ , the number of paths starting from  $i$  is at most  $2^d$  because at each layer it either moves up or down. Next, for each  $1 \leq t \leq \lfloor n/2 \rfloor$ , the number of possible  $t$  paths is then at most  $\binom{n/2}{t} \cdot 2^{dt}$ . This gives the following upper bound for the weight contributing from domain wall of type (i).

$$\begin{aligned} \left( \sum_{\substack{\text{disjoint path of type (i)} \\ \in \text{domain wall}}} w(\text{path}) \right) &\leq \sum_{t=1}^{\lfloor n/2 \rfloor} \left(\frac{2}{5}\right)^{dt} \cdot \binom{\lfloor n/2 \rfloor}{t} \cdot 2^{dt} \\ &\leq \sum_{t=1}^{\lfloor n/2 \rfloor} \left(\frac{4}{5}\right)^{dt} \cdot \binom{\lfloor n/2 \rfloor}{t} \\ &\leq \left(1 + \left(\frac{4}{5}\right)^d\right)^{\lfloor n/2 \rfloor}. \end{aligned}$$

Consider  $d \geq \frac{\log n}{\log(5/4)}$ , the equation becomes

$$\leq \exp\left(\left(\frac{4}{5}\right)^{\frac{\log n}{\log(5/4)}} \frac{n}{2}\right) = O(1).$$

### Step 4: Upper bound the sum of possible path configurations of type (ii)

Let us consider the 1D circuit with infinite depth and denote the distribution as  $\mathcal{D}_\infty$ . Also, since the depth is infinity, the sum of the weight of domain wall with paths of type (i) is negligible. Namely, only paths of type (ii) contribute in the infinite depth circuit. Thus, we have the following upper bound.

$$\begin{aligned} \left( 1 + \sum_{\substack{\text{disjoint path of type (ii)} \\ \in \text{domain wall}}} w(\text{path}) \right) &\leq \left( 1 + \sum_{\substack{\text{disjoint path of type (ii)} \\ \in \text{domain wall}}} w(\text{path}) \right) \\ &= 5^{n/2} \cdot \mathbb{E}_{C \sim \mathcal{D}_\infty} \left[ \sum_{x \in \{0,1\}^n} q_C(x)^2 \right]. \end{aligned}$$

Finally, it is a well known fact that the expectation of the sum of squares of marginal probabilities is  $O(2^{-n})$  for infinite depth 1D circuit. So the above equation becomes

$$= O\left(\left(\frac{5}{4}\right)^{n/2}\right).$$

**Wrap up**

To conclude the proof of Lemma 16, let us plug in the calculations from step 3 and step 4 into Equation 15, this gives us

$$\mathbb{E}_{C \sim \mathcal{D}} \left[ \sum_{x \in \{0,1\}^n} q_C(x)^2 \right] \leq \left( \frac{1}{5} \right)^{n/2} \cdot O(1) \cdot O \left( \left( \frac{5}{4} \right)^{n/2} \right) = O \left( \frac{1}{2^n} \right)$$

as desired.

## Abstract

We study the complexity of isomorphism problems for tensors, groups, and polynomials. These problems have been studied in multivariate cryptography, machine learning, quantum information, and computational group theory. We show that these problems are all polynomial-time equivalent, creating bridges between problems traditionally studied in myriad research areas. This prompts us to define the complexity class  $TI$ , namely problems that reduce to the Tensor Isomorphism ( $TI$ ) problem in polynomial time. Our main technical result is a polynomial-time reduction from  $d$ -tensor isomorphism to 3-tensor isomorphism. In the context of quantum information, this result gives multipartite-to-tripartite entanglement transformation procedure, that preserves equivalence under stochastic local operations and classical communication (SLOCC).

## 1 Introduction

Although GRAPH ISOMORPHISM ( $GI$ ) is perhaps the most well-studied isomorphism problem in computational complexity – even going back to Cook’s and Levin’s initial investigations into NP (see [3, Sec. 1]) – it has long been considered to be solvable in practice [51, 52], and Babai’s recent quasi-polynomial-time breakthrough is one of the theoretical gems of the last several decades [5].

However, several isomorphism problems for tensors, groups, and polynomials seem to be much harder to solve, both in practice – they’ve been suggested as difficult enough to support cryptography [39, 57] – and in theory: the best known worst-case upper bounds are barely improved from brute force (e.g., [46, 63]). As these problems arise in a variety of areas, from

multivariate cryptography and machine learning, to quantum information and computational algebra, getting a better understanding of their complexity is an important goal with many potential applications. These isomorphism problems are the focus of this paper.

Our first set of results shows that all these isomorphism problems from many research areas are equivalent under polynomial-time reductions, creating bridges between different disciplines. The TENSOR ISOMORPHISM (TI) problem turns out to occupy a central position among these problems, leading us to define the complexity class TI, consisting of those problems polynomial-time reducible to the TENSOR ISOMORPHISM problem.

More specifically, we first present a polynomial-time reduction from  $d$ -TENSOR ISOMORPHISM to 3-TENSOR ISOMORPHISM. This result may be viewed as corresponding to the  $k$ -SAT to 3-SAT reduction in the setting of TENSOR ISOMORPHISM, but the proof is much more involved. This result also has a natural application to quantum information: it gives a procedure that turns multipartite entanglements to tripartite entanglements while preserving equivalence under stochastic local operations and classical communication (SLOCC).

We then demonstrate that various isomorphism problems for polynomials, general algebras, groups, and tensors all turn out to be TI-complete. One important reference here is the recent work [26], in which they showed that several such problems reduce to 3TI. Our contribution is to show that these problems are also 3TI-hard. Another set of related works are [1, 2, 42] by Agrawal, Kayal, and Saxena, who showed some equivalences and reductions between RING ISOMORPHISM (commutative with unit), CUBIC FORM EQUIVALENCE, and isomorphism of commutative, unital, associative algebras [1, 2, 42]. Here we greatly expand these and show a much wider class of problems are equivalent (see Thm. 4=Thm. B and Fig. 1).

In a follow-up paper [33], we study search and counting to decision reductions, apply these results to GROUP ISOMORPHISM in the matrix group model, and obtain a nilpotency class reduction for GROUP ISOMORPHISM.

All these results together lay the foundation for an emerging theory of the complexity class TI that in some cases parallels, and in some cases deviates from, the complexity theory of the class GI, namely the set of problems that are polynomial-time reducible to GRAPH ISOMORPHISM [43]. From the theory perspective, this theory reveals a family of algorithmic problems demonstrating highly interesting complexity-theoretic properties. From the practical perspective, this theory could serve as guidance for, and facilitate dialogue among, researchers from diverse research areas including cryptography, machine learning, quantum information, and computational algebra. Indeed, some of our results already have natural applications to quantum information and computational group theory.

**Organization.** Due to page constraints and the nature of this work, we are only able to present the main results and the related implications and discussions. For detailed proofs, we refer the reader to the full version [32]. In the remainder of this paper, we first present the origins of those isomorphism problems we consider (Sec. 2). We then state our main results in Sec. 3, and briefly indicate the main techniques in Sec. 4. In Sec. 5, we present formal statements of the various problems involved and a detailed statement of one main result. Finally in Sec. 6 we present the implication to quantum information and discuss on some further related works and the outlook of this research direction.

## 2 Isomorphism testing problems from several areas

Let  $\mathbb{F}$  be a field. Let  $\text{GL}(n, \mathbb{F})$  denote the general linear group of degree  $n$  over  $\mathbb{F}$ , and  $\text{M}(n, \mathbb{F})$  the linear space of  $n \times n$  matrices. For a finite field  $\mathbb{F}_q$ , we may also write  $\text{GL}(n, \mathbb{F}_q)$  and  $\text{M}(n, \mathbb{F}_q)$  as  $\text{GL}(n, q)$  and  $\text{M}(n, q)$ , respectively.

**Multivariate cryptography.** In 1996, Patarin [57] proposed identification and signature schemes based on a family of problems called “isomorphism of polynomials.” A specific problem, called *isomorphism of (quadratic) polynomials with two secrets* (IP2S), asks the following. Let  $\vec{f} = (f_1, \dots, f_m)$  and  $\vec{g} = (g_1, \dots, g_m)$  be two  $m$ -tuples of homogeneous quadratic polynomials, where  $f_i, g_j \in \mathbb{F}[x_1, \dots, x_n]$ . Recall an  $m$ -tuple of polynomials in  $n$  variables can be viewed as a polynomial map from  $\mathbb{F}^n$  to  $\mathbb{F}^m$ . It is natural to ask whether  $\vec{f}$  and  $\vec{g}$  represent the same polynomial map up to change of basis, or more specifically, whether there exists  $P \in \text{GL}(n, \mathbb{F})$  and  $Q \in \text{GL}(m, \mathbb{F})$ , such that  $Q \circ \vec{f} \circ P = \vec{g}$ . Since then, the IP2S problem, and its variant isomorphism of (quadratic) polynomials with one secret (IP1S), have been intensively studied in multivariate cryptography (see [11, 38] and references therein).

**Machine learning.** In machine learning, it is natural to view a sequential data stream as a path. This leads to the use of the *signature* tensor of a path  $\phi : [0, 1] \rightarrow \mathbb{R}^n$ , first introduced by Chen [20] to extract features of data. This is the basic idea of the signature tensor method, which has been pursued by in a series of works; see [21, 49, 54] and references therein. The algorithmic problem of reconstructing the path from the signature tensor is of considerable interest; see e.g. [50, 59]. In this context, the following problem was recently studied by Pfeffer, Seigal, and Sturmfels [59], called the TENSOR CONGRUENCE problem: given two 3-tensors  $\mathbf{A} = (a_{ijk}), \mathbf{B} = (b_{ijk}) \in \mathbb{F}^{n \times n \times n}$ , decide whether there exists  $P \in \text{GL}(n, \mathbb{F})$ , such that the congruence action of  $P$  sends  $\mathbf{A}$  to  $\mathbf{B}$ . More specifically, this action of  $P = (p_{ij})$  sends  $\mathbf{A} = (a_{ijk})$  to  $\mathbf{A}' = (a'_{ijk})$ , where  $a'_{ijk} = \sum_{i', j', k'} a_{i'j'k'} p_{i,i'} p_{j,j'} p_{k,k'}$ .

**Quantum information.** Let  $\mathcal{H} = \mathcal{H}_1 \otimes \dots \otimes \mathcal{H}_d$ , where  $\mathcal{H}_i = \mathbb{C}^{n_i}$ . Let  $\rho = |\phi\rangle\langle\phi|$  and  $\tau = |\psi\rangle\langle\psi|$  be two pure quantum states, where  $|\phi\rangle, |\psi\rangle \in \mathcal{H}$ . In quantum information, a natural question is to decide whether  $\rho$  can be converted to  $\tau$  using local operations and classical communication statistically (SLOCC), i.e. with non-zero probability [10, 23]. It is well-known by [23] that  $\rho$  and  $\tau$  are interconvertible via SLOCC, if and only if there exist  $T_i \in \text{GL}(\mathcal{H}_i)$ , such that  $(T_1 \otimes \dots \otimes T_m)|\phi\rangle = |\psi\rangle$ . Therefore, given pure quantum states  $\rho$  and  $\tau$ , whether  $\rho$  and  $\tau$  are interconvertible via SLOCC can be cast as an isomorphism testing problem, called the  $d$ -TENSOR ISOMORPHISM problem (see Definition 1).

**Computational group theory.** In computational group theory, a notoriously difficult problem is to test isomorphism of finite  $p$ -groups, namely groups of prime power order (see, e.g., [55]). Here, the groups are represented succinctly, e.g., by generating sets of permutations or matrices over finite fields. Testing isomorphism of  $p$ -groups is considered to be a bottleneck to testing isomorphism of general groups [7, 19, 31]. Even for  $p$ -groups of class 2 and exponent  $p$ , current methods are still limited to instances of quite small size.

**Theoretical computer science.** As already mentioned, Agrawal, Kayal, and Saxena studied isomorphism and automorphism problems of rings, algebras, and polynomials [1, 2, 42], motivated by several problems including PRIMALITY TESTING, POLYNOMIAL FACTORIZATION, and GRAPH ISOMORPHISM. Later, motivated by cryptographic applications and algebraic complexity, Kayal studied the POLYNOMIAL EQUIVALENCE problems (possibly under affine projections) and solved certain important special cases [40, 41] (see also [30]). Among these problems, we will be mostly concerned with the following two. First, the ALGEBRA ISOMORPHISM problem for commutative, unital, associative algebras over a field  $\mathbb{F}$ , asks whether two such algebras, given by structure constants, are isomorphic. Second, the CUBIC FORM EQUIVALENCE problem asks whether two homogeneous cubic polynomials over  $\mathbb{F}$  are equivalent under the natural action of the general linear group by change of basis on the variables.

**Practical complexity of these problems.** The preceding isomorphism testing problems are of great interest to researchers from seemingly unrelated areas. Furthermore, they pose considerable challenges for practical computations at the present stage. The latter is in sharp contrast to GRAPH ISOMORPHISM, for which very effective practical algorithms have existed for some time [51, 52]. Indeed, the problems we consider have been proposed to be difficult enough for cryptographic purposes [39, 57]. As further evidence of their practical difficulty, current algorithms implemented for testing isomorphism of  $p$ -groups of class 2 and exponent  $p$  can handle groups of dimension 20 over  $\mathbb{F}_{13}$ , but absolutely not for groups of dimension 200 over  $\mathbb{F}_{13}$ , even though in this case the input can still be stored in only a few megabytes.<sup>1</sup> In [59, arXiv version 1], computations on special cases of the TENSOR CONGRUENCE problem were performed in Macaulay2 [28], but these could not go beyond small examples either.

**A note on terminology.** Before introducing our results formally, a terminological note is in order: we shall call valence- $d$  tensors  $d$ -way arrays, and tensors will be understood to be  $d$ -way arrays considered under a specific group action. The reason for this change of terminology will be clearer in the following. We remark that it is not uncommon to see such differences in the terminologies around tensors, see, e.g., the preface of [45].

We follow a natural convention: when  $\mathbb{F}$  is finite, a fixed algebraic extension of a finite field such as  $\overline{\mathbb{F}}_p$ , the rationals, or a fixed algebraic extension of the rationals such as  $\overline{\mathbb{Q}}$ , we consider the usual model of Turing machines; when  $\mathbb{F}$  is  $\mathbb{R}$ ,  $\mathbb{C}$ , the  $p$ -adic rationals  $\mathbb{Q}_p$ , or other more “exotic” fields, we work in the Blum–Shub–Smale model over  $\mathbb{F}$ .

### 3 Main results

#### 3.1 Defining the TENSOR ISOMORPHISM complexity class

Given the diversity of the isomorphism problems from Sec. 2, the first main question addressed in this paper is

Is there a unifying framework that accommodates the many difficult isomorphism testing problems arising in practice?

Such a framework would help to explain the difficulties from various areas when dealing with these isomorphism problems, and facilitate dialogue among researchers from different fields.

At first sight, this seems quite difficult: these problems concern very different mathematical objects, ranging from sets of quadratic equations, to algebras, to finite groups, to tensors, and each of them has its own rich theory.

Despite these obstacles, our first main result shows that those problems in Sec. 2 arising in many fields – from computational group theory to cryptography to machine learning – are equivalent under polynomial-time reductions. In proving the first main result, the  $d$ -TENSOR ISOMORPHISM problem occupies a central position. This leads us to define the complexity class TI, consisting of problems reducible to TI, much in vein of the introduction of the GRAPH ISOMORPHISM complexity class GI [43].

---

<sup>1</sup> We thank James B. Wilson, who maintains a suite of algorithms for  $p$ -group isomorphism testing [16], for communicating this insight to us from his hands-on experience. We of course maintain responsibility for any possible misunderstanding, or lack of knowledge regarding the performance of other implemented algorithms.

► **Definition 1** (The  $d$ -TENSOR ISOMORPHISM problem).  $d$ -TENSOR ISOMORPHISM over a field  $\mathbb{F}$  is the problem: given two  $d$ -way arrays  $\mathbf{A} = (a_{i_1, \dots, i_d})$  and  $\mathbf{B} = (b_{i_1, \dots, i_d})$ , where  $i_k \in [n_k]$  for  $k \in [d]$ , and  $a_{i_1, \dots, i_d}, b_{i_1, \dots, i_d} \in \mathbb{F}$ , decide whether there are  $P_k \in \text{GL}(n_k, \mathbb{F})$  for  $k \in [d]$ , such that for all  $i_1, \dots, i_d$ ,

$$a_{i_1, \dots, i_d} = \sum_{j_1, \dots, j_d} b_{j_1, \dots, j_d} (P_1)_{i_1, j_1} (P_2)_{i_2, j_2} \cdots (P_d)_{i_d, j_d}. \quad (1)$$

Our first main result resolves an open question well-known to the experts:<sup>2</sup>

► **Theorem 2** (=Cor. A).  $d$ -TENSOR ISOMORPHISM reduces to 3-TENSOR ISOMORPHISM in time  $O(n^d)$ .

Thm. 2 is also key to the application to quantum information in Sec. 6.1.

Thus, while the 2TI problem is easy (it's just matrix rank), 3TI already captures the complexity of  $d$ TI for any  $d$ . This phenomenon is reminiscent of the transition in hardness from 2 to 3 in  $k$ -SAT,  $k$ -COLORING,  $k$ -MATCHING, and many other NP-complete problems. It is interesting that an analogous phenomenon – a transition to some sort of “universality” from 2 to 3 – occurs in the setting of isomorphism problems, which we believe are not NP-complete over finite fields (indeed, they cannot be unless PH collapses).

► **Definition 3** (TI). For any field  $\mathbb{F}$ ,  $\text{TI}_{\mathbb{F}}$  denotes the class of problems that are polynomial-time Turing (Cook) reducible to  $d$ -TENSOR ISOMORPHISM over  $\mathbb{F}$ , for some  $d$ . A problem is  $\text{TI}_{\mathbb{F}}$ -complete, if it is in  $\text{TI}_{\mathbb{F}}$ , and  $d$ -TENSOR ISOMORPHISM over  $\mathbb{F}$  for any  $d$  reduces to this problem.

By Thm. 2, we may take  $d = 3$  without loss of generality. When we write TI without mentioning the field, the result holds for any field.

## 3.2 TI-complete problems

Our second main result shows the wide applicability and robustness of the TI class.

► **Theorem 4** (Informal statement of part of Theorem B). All the problems mentioned in Sec. 2 are TI-hard: IP2S, TENSOR CONGRUENCE, CUBIC FORM EQUIVALENCE (over fields of characteristic not 2 or 3), ALGEBRA ISOMORPHISM for commutative, unital, associative algebras, and GROUP ISOMORPHISM for  $p$ -groups of class 2 and exponent  $p$  given by matrix generators over  $\mathbb{F}_{p^e}$ .

In combination with the results of [26], we conclude that they are in fact TI-complete.

► **Remark 5.** Our results allow us to mostly answer a question from Saxena's thesis [64, p. 86]. Namely, Agrawal & Saxena [1] gave a reduction from CUBIC FORM EQUIVALENCE to RING ISOMORPHISM for commutative, unital, associative algebras over  $\mathbb{F}$ , under the assumption that every element of  $\mathbb{F}$  has a cube root in  $\mathbb{F}$ . For finite fields  $\mathbb{F}_q$ , the only such fields are those for which  $q = p^{2e+1}$  and  $p \equiv 2 \pmod{3}$ , which is asymptotically half of all primes. As explained after the proof of [1, Thm. 5], the use of cube roots seems inherent in their reduction, and Saxena asked whether such a reduction could be done over arbitrary fields. Using our results in conjunction with [26], we get a new such reduction – very different from the previous one [1] – which works over any field of characteristic not 2 or 3.

<sup>2</sup> We asked several experts who knew of the question, but we were unable to find a written reference. Interestingly, Oldenburger [56] worked on what we would call  $d$ -TENSOR ISOMORPHISM as far back as the 1930s. We would be grateful for any prior written reference to the question of whether  $d$ TI reduces to 3TI.

Here, we would also like to point out that some of the polynomial-time equivalences in Thm. 4, though perhaps expected by some experts, were not *a priori* clear. To get a sense for the non-obviousness of the equivalences of problems in Theorem 4, let us postulate the following hypothetical question. Recall that two matrices  $A, B \in M(n, \mathbb{F})$  are called *equivalent* if there exist  $P, Q \in GL(n, \mathbb{F})$  such that  $P^{-1}AQ = B$ , and they are *conjugate* if there exists  $P \in GL(n, \mathbb{F})$  such that  $P^{-1}AP = B$ . Can we reduce testing MATRIX CONJUGACY to testing MATRIX EQUIVALENCE? Of course since they are both in P there is a trivial reduction; to avoid this, let us consider only reductions  $r$  which send a matrix  $A$  to a matrix  $r(A)$  such that  $A$  and  $B$  are conjugate iff  $r(A)$  and  $r(B)$  are equivalent. Nearly all reductions between isomorphism problems that we are aware of have this form (so-called “kernel reductions” [25]; cf. functorial reductions [4]). This turns out to be essentially impossible. The reason is that the equivalence class of a matrix is completely determined by its rank, while the conjugacy class of a matrix is determined by its rational canonical form. Among  $n \times n$  matrices there are only  $n + 1$  equivalence classes, but there are at least  $|\mathbb{F}|^n$  rational canonical forms, coming from the choice of minimal polynomial/companion matrix. Even when  $\mathbb{F}$  is a finite field, such a reduction would thus require an exponential increase in dimension, and when  $\mathbb{F}$  is infinite, such a reduction is impossible regardless of running time.

Nonetheless, one of our results is that for *linear spaces* of matrices (one form of 3-way arrays; see Sec. 5.1), conjugacy testing and equivalence testing are polynomial-time equivalent. We say two subspaces  $\mathcal{A}, \mathcal{B} \subseteq M(n, \mathbb{F})$  are *conjugate* if there exists  $P \in GL(n, \mathbb{F})$  such that  $P\mathcal{A}P^{-1} = \{PAP^{-1} : A \in \mathcal{A}\} = \mathcal{B}$ , and analogously for equivalence. This is in sharp contrast to the case of single matrices. In the above setting, it means that there exists a polynomial-time computable map  $\phi$  from  $M(n, \mathbb{F})$  to *subspaces of*  $M(s, \mathbb{F})$ , such that  $A, B$  are conjugate up to a scalar if and only if  $\phi(A), \phi(B) \leq M(s, \mathbb{F})$  are equivalent as matrix spaces. Such a reduction may not be clear at first sight.

### 3.3 The relation between TENSOR ISOMORPHISM and GRAPH ISOMORPHISM

After introducing the TI class, it is natural to compare this class with the corresponding class for GRAPH ISOMORPHISM, GI.

Already by using known reductions [26, 30, 34, 48, 58], GRAPH ISOMORPHISM and PERMUTATIONAL CODE EQUIVALENCE reduce to 3-TENSOR ISOMORPHISM. For the inverse direction, we have the following connection.

► **Corollary 6.** *Let  $\mathbf{A}$  and  $\mathbf{B}$  be two 3-tensors over  $\mathbb{F}_q$ , and let  $n$  be the sum of the lengths of all three sides. To decide whether  $\mathbf{A}$  and  $\mathbf{B}$  are isomorphic reduces to solving GI for graphs of size  $q^{O(n)}$ .*

Therefore, if GI is in P, then  $3TI_{\mathbb{F}_q}$  can be solved in  $q^{O(n)}$  time, where  $n$  is the sum of the lengths of all three sides. More generally, if  $GI \in \text{TIME}(2^{O(\log n)^c})$  then  $3TI_{\mathbb{F}_q} \in \text{TIME}(q^{O(n^c)})$ . The current value of  $c$  for GI is 3 [5] (see [35] for the analysis of  $c$ ); improving  $c$  to be less than 2 would improve over the current state of the art for both GPI and 3TI.

In Fig. 1 we summarize the relationships between GI, TI, and many more isomorphism testing problems.

## 4 An overview of proof strategies and techniques

### 4.1 The main new technique

Our main new technique, used to show the reduction from  $d$ TI to 3TI (Thm. 2=Thm. A), is a simultaneous generalization of our reduction from 3TI to ALGEBRA ISOMORPHISM and the technique Grigoriev used [29] to show that isomorphism in a certain restricted class of algebras is equivalent to GI. In brief outline: a 3-way array  $\mathbf{A}$  specifies the structure constants of an algebra with basis  $x_1, \dots, x_n$  via  $x_i \cdot x_j := \sum_k \mathbf{A}(i, j, k)x_k$ , and this is essentially how we use it in the reduction from 3TI to ALGEBRA ISOMORPHISM. For arbitrary  $d \geq 3$ , we would like to similarly use a  $d$ -way array  $\mathbf{A}$  to specify how  $d$ -tuples of elements in some algebra  $\mathcal{A}$  multiply. The issue is that for  $\mathcal{A}$  to be an algebra, our construction must still specify how *pairs* of elements multiply. The basic idea is to let pairs (and triples, and so on, up to  $(d-2)$ -tuples) multiply “freely” (that is, without additional relations), and then to use  $\mathbf{A}$  to rewrite any product of  $d-1$  generators as a linear combination of the original generators. While this construction as described already gives one direction of the reduction (if  $\mathbf{A} \cong \mathbf{B}$ , then  $\mathcal{A} \cong \mathcal{B}$ ), the other direction is trickier. For that, we modify the construction to an algebra in which short products (less than  $d-2$  generators) do not quite multiply freely, but almost. After the fact, we found out that this construction generalizes the one used by Grigoriev [29] to show that GI was equivalent ALGEBRA ISOMORPHISM for a certain restricted class of algebras (see Sec. 6 for a comparison).

### 4.2 The proof strategy for Theorem 4=B

Let us now explain briefly on the proof of Thm. B=Thm. 4. The first step is to realize all of these problems in a single unifying viewpoint. That is, all these equivalence relations underlying these isomorphism testing problems can be realized as the orbits of certain natural group actions by direct products of general linear groups on 3-way arrays. We shall explain this in detail in Sec. 5. Here, we only demonstrate five group actions on 3-way arrays, and indicate how those practical problems correspond to some of these actions.

To introduce these five group actions, it is instructive to first examine the more familiar cases of matrices. There are three natural group actions on  $M(n, \mathbb{F})$ : for  $A \in M(n, \mathbb{F})$ , (1)  $(P, Q) \in GL(n, \mathbb{F}) \times GL(n, \mathbb{F})$  sends  $A$  to  $P^t A Q$ , (2)  $P \in GL(n, \mathbb{F})$  sends  $A$  to  $P^{-1} A P$ , and (3)  $P \in GL(n, \mathbb{F})$  sends  $A$  to  $P^t A P$ . These three actions endow  $A$  with different algebraic/geometric interpretations: (1) a linear map from a vector space  $V$  to another vector space  $W$ , (2) a linear map from  $V$  to itself, and (3) a bilinear map from  $V \times V$  to  $\mathbb{F}$ .

The five group actions on 3-way arrays referred to above are precisely analogous to the matrix setting. For a 3-way array  $\mathbf{A} = (a_{i,j,k})$ ,  $i, j, k \in [n]$ ,  $a_{i,j,k} \in \mathbb{F}$ , these actions are (1)  $(P_1, P_2, P_3) \in GL(n, \mathbb{F}) \times GL(n, \mathbb{F}) \times GL(n, \mathbb{F})$  acts on  $\mathbf{A}$  according to Equation 1 with  $d=3$ ; (2)  $(P_1, P_2) \in GL(n, \mathbb{F}) \times GL(n, \mathbb{F})$  acts on  $\mathbf{A}$  as  $(P_1^{-t}, P_1, P_2)$  in (1), where  $P^{-t}$  denotes the transpose of the inverse of  $P$ ; (3)  $(P_1, P_2) \in GL(n, \mathbb{F}) \times GL(n, \mathbb{F})$  acts on  $\mathbf{A}$  as  $(P_1, P_1, P_2)$  in (1); (4)  $P \in GL(n, \mathbb{F})$  acts on  $\mathbf{A}$  as  $(P, P, P)$  in (1); and (5)  $P \in GL(n, \mathbb{F})$  acts on  $\mathbf{A}$  as  $(P, P, P^{-t})$  in (1).

These five actions endow various families of 3-way arrays with different algebraic/geometric meanings, including 3-tensors, bilinear maps, matrix (associative or Lie) algebras, and trilinear forms, a.k.a. non-commutative cubic forms. It is then not difficult to cast each of the problems in Thm. 4 as (a special case of) the problem of deciding whether two 3-way arrays are in the same orbit under one of the five group actions; see Sec. 5.1 for detailed explanations.<sup>3</sup>

The first step only provides the context for proving Thm. 4. After the first step, we need to devise polynomial-time reductions among those isomorphism testing problems for 3-way arrays under these five group actions, often with certain restrictions on the 3-way array structures. The two basic ideas for these reductions are a gadget construction from [26], and the “embedding” technique from [27]. To implement these ideas, however, usually involves detailed and complicated computations.

For example, in the proof of Theorem 4, we use a gadget construction from [26] for the reduction from TENSOR ISOMORPHISM to IP2S. To show that this gadget works in our setting, we need a proof strategy that is different from that in [26]. Furthermore, the gadget from [26] introduces a quadratic blow-up in the input parameters. We then devise a new gadget, which achieves the same function with only linear blow-up, and enables Corollary 6. Having only linear blow-up is important in applications, e.g., to GROUP ISOMORPHISM in the Cayley table model (see [33]).

## 5 More details and more results on TI-completeness

### 5.1 Five group actions on 3-way arrays and the corresponding mathematical objects

In Section 3, we briefly defined five group actions on 3-way arrays with the help of Equation 1. However, the formulas for these group actions on 3-way arrays are somewhat unwieldy; our experience suggests that they are more easily digested when presented in the context of some of the natural interpretations of 3-way arrays as mathematical objects, which will also allow us to connect them back to the problems of Section 2. To connect the interpretations with the formulas themselves, one technical tool is very useful, namely, given a 3-way array  $\mathbf{A}(i, j, k)$ , we define its *frontal slices* to be the matrices  $A_k$  defined by  $A_k(i, j) := \mathbf{A}(i, j, k)$ ; that is, we think of the box of  $\mathbf{A}$  as arranged so that the  $i$  and  $j$  axes lie in the page, while the  $k$ -axis is perpendicular to the page. Similarly, its *lateral slices* (viewing the 3D box of  $\mathbf{A}$  “from the side”) are defined by  $L_j(i, k) := \mathbf{A}(i, j, k)$ . An  $\ell \times n \times m$  3-way array thus has  $m$  frontal slices and  $n$  lateral slices.

A natural action on arrays of size  $\ell \times n \times m$  is that of  $\text{GL}(\ell, \mathbb{F}) \times \text{GL}(n, \mathbb{F}) \times \text{GL}(m, \mathbb{F})$  by change of basis in each of the 3 directions, namely

$$((P, Q, R) \cdot \mathbf{A})(i', j', k') = \sum_{i, j, k} \mathbf{A}(i, j, k) P_{ii'} Q_{jj'} R_{kk'}.$$

We will see several interpretations of this action below.

**3-tensors.** A 3-way array  $\mathbf{A}(i, j, k)$ , where  $i \in [\ell]$ ,  $j \in [n]$ , and  $k \in [m]$ , is naturally identified as a vector in  $\mathbb{F}^\ell \otimes \mathbb{F}^n \otimes \mathbb{F}^m$ . Letting  $\vec{e}_i$  denote the  $i$ th standard basis vector of  $\mathbb{F}^n$ , a standard basis of  $\mathbb{F}^\ell \otimes \mathbb{F}^n \otimes \mathbb{F}^m$  is  $\{\vec{e}_i \otimes \vec{e}_j \otimes \vec{e}_k\}$ . Then  $\mathbf{A}$  represents the vector  $\sum_{i, j, k} \mathbf{A}(i, j, k) \vec{e}_i \otimes \vec{e}_j \otimes \vec{e}_k$ .

<sup>3</sup> While problems in Thm. 4 only use three out of those five actions, the other two actions also lead to problems that arise naturally, including MATRIX ALGEBRA CONJUGACY from [18], MATRIX LIE ALGEBRA CONJUGACY from [30], and BILINEAR MAP ISOTOPIISM from [13]; see Sec. 5.1 and Sec. 6.

in  $\mathbb{F}^\ell \otimes \mathbb{F}^n \otimes \mathbb{F}^m$ . The natural action by  $\text{GL}(\ell, \mathbb{F}) \times \text{GL}(n, \mathbb{F}) \times \text{GL}(m, \mathbb{F})$  above corresponds to changes of basis of the three vector spaces in the tensor product. The problem of deciding whether two 3-way arrays are the same under this action is called 3-TENSOR ISOMORPHISM.<sup>4</sup> This problem has been studied as far back as the 1930s [56].

**Cubic forms, trilinear forms, and tensor congruence.** From a 3-way array  $\mathbf{A}$  we can also construct a cubic form (=homogeneous degree 3 polynomial)  $\sum_{i,j,k} \mathbf{A}(i,j,k)x_i x_j x_k$ , where  $x_i$  are formal variables. If we consider the variables as commuting – or, equivalently, if  $\mathbf{A}$  is symmetric, meaning it is unchanged by permuting its three indices – we get an ordinary cubic form; if we consider them as non-commuting, we get a trilinear form (or “non-commutative cubic form”). In either case, the natural notion of isomorphism here comes from the action of  $\text{GL}(n, \mathbb{F})$  on the  $n$  variables  $x_i$ , in which  $P \in \text{GL}(n, \mathbb{F})$  transforms the preceding form into  $\sum_{i,j,k} \mathbf{A}(i,j,k)(\sum_{i'} P_{ii'} x_{i'}) (\sum_{j'} P_{jj'} x_{j'}) (\sum_{k'} P_{kk'} x_{k'})$ . In terms of 3-way arrays, we get  $(P \cdot \mathbf{A})(i', j', k') = \sum_{i,j,k} \mathbf{A}(i,j,k) P_{ii'} P_{jj'} P_{kk'}$ . The corresponding isomorphism problems are called CUBIC FORM EQUIVALENCE (in the commutative case) and TRILINEAR FORM EQUIVALENCE. This is identical to the TENSOR CONGRUENCE problem from [59] (where they worked over  $\mathbb{R}$ ).

**Matrix spaces.** Given a 3-way array  $\mathbf{A}$ , it is natural to consider the linear span of its frontal slices,  $\mathcal{A} = \langle A_1, \dots, A_m \rangle$ , also called a *matrix space*. One convenience of this viewpoint is that the action of  $\text{GL}(m, \mathbb{F})$  becomes implicit: it corresponds to change of basis *within* the matrix space  $\mathcal{A}$ . This allows us to generalize the three natural equivalence relations on matrices to matrix spaces: (1) two  $\ell \times n$  matrix spaces  $\mathcal{A}$  and  $\mathcal{B}$  are *equivalent* if there exists  $(P, Q) \in \text{GL}(\ell, \mathbb{F}) \times \text{GL}(n, \mathbb{F})$  such that  $PAQ = \mathcal{B}$ , where  $PAQ := \{PAQ : A \in \mathcal{A}\}$ ; (2) two  $n \times n$  matrix spaces  $\mathcal{A}, \mathcal{B}$  are *conjugate* if there exists  $P \in \text{GL}(n, \mathbb{F})$  such that  $PAP^{-1} = \mathcal{B}$ ; and (3) they are *isometric* if  $PAP^t = \mathcal{B}$ . The corresponding decision problems, when  $\mathcal{A}$  is given by a basis  $A_1, \dots, A_d$ , are MATRIX SPACE EQUIVALENCE, MATRIX SPACE CONJUGACY, and MATRIX SPACE ISOMETRY, respectively.

**Isomorphism of quadratic polynomials with 2 secrets.** For a tuple of homogeneous quadratic polynomials (over a field of characteristic not 2)  $\vec{f} = (f_1, \dots, f_m)$ , we may encode  $f_i$  by a symmetric matrix  $F_i$  in the usual way – where  $f_i(x) = x^t F_i x$  – and thus obtain a tuple of (symmetric) matrices  $(F_1, \dots, F_m)$ . Since, in the IP2S problem, we are also allowed to take linear combinations of the  $f_i$  themselves, we see that the IP2S problem is equivalent to the MATRIX SPACE ISOMETRY problem for  $\langle F_1, \dots, F_m \rangle$ . Equivalently, the action of  $(P, Q) \in \text{GL}(m, \mathbb{F}) \times \text{GL}(n, \mathbb{F})$  is by  $F_i \mapsto \sum_j P_{ij} Q^t F_j Q$ .

**Finite  $p$ -groups.** If we consider the quadratic polynomials  $f_i$  as defining a (symmetric) bilinear map  $\mathbb{F}^n \times \mathbb{F}^n \rightarrow \mathbb{F}^m$ , we may generalize to see that (not necessarily symmetric) bilinear maps arise naturally in other areas, notably in group theory. For matrices  $A_k$  over  $\mathbb{F}_p$ ,  $p$  an odd prime, we may consider MATRIX SPACE ISOMETRY for the matrix space  $\langle A_1, \dots, A_m \rangle$ . Two bilinear maps that are essentially the same up to such basis changes are sometimes called pseudo-isometric [17].

<sup>4</sup> Some authors call this TENSOR EQUIVALENCE; we use “ISOMORPHISM” both because this is the natural notion of isomorphism for such objects, and because we will be considering many different equivalence relations on essentially the same underlying objects.

When the  $A_k$  are skew-symmetric, Baer's correspondence [9] gives a bijection between finite  $p$ -groups of class 2 and exponent  $p$ , that is, in which  $g^p = 1$  for all  $g$  and in which  $[G, G] \leq Z(G)$ , and their corresponding skew-symmetric bilinear maps  $G/Z(G) \times G/Z(G) \rightarrow [G, G]$ , given by  $(gZ(G), hZ(G)) \mapsto [g, h] = ghg^{-1}h^{-1}$ . Two such groups are isomorphic if and only if their corresponding bilinear maps are pseudo-isometric, if and only if, using the matrix space terminology, the matrix spaces they span are isometric.

**Bilinear maps.** If we generalize even further to bilinear maps  $U \times V \rightarrow W$ , we find that from an  $\ell \times n \times m$  3-way array  $\mathbf{A}$ , we can construct such a bilinear map (=system of  $m$  bilinear forms)  $f_{\mathbf{A}} : \mathbb{F}^{\ell} \times \mathbb{F}^n \rightarrow \mathbb{F}^m$ , sending  $(u, v) \in \mathbb{F}^{\ell} \times \mathbb{F}^n$  to  $(u^t A_1 v, \dots, u^t A_m v)^t$ , where the  $A_k$  are the frontal slices of  $\mathbf{A}$ . The group action defining MATRIX SPACE EQUIVALENCE is equivalent to the action of  $\text{GL}(\ell, \mathbb{F}) \times \text{GL}(n, \mathbb{F}) \times \text{GL}(m, \mathbb{F})$  on such bilinear maps. This problem was recently studied under the name “testing isotopism of bilinear maps” in [13], in the context of testing isomorphism of graded algebras.

**Algebras.** We may also consider a 3-way array  $\mathbf{A}(i, j, k)$ ,  $i, j, k \in [n]$ , as the structure constants of an algebra (which need not be associative, commutative, nor unital), say with basis  $x_1, \dots, x_n$ , and with multiplication given by  $x_i \cdot x_j = \sum_k \mathbf{A}(i, j, k)x_k$ , and then extended (bi)linearly. Here the natural notion equivalence comes from the action of  $\text{GL}(n, \mathbb{F})$  by change of basis on the  $x_i$ . Despite the seeming similarity of this action to that on cubic forms, it turns out to be quite different: given  $P \in \text{GL}(n, \mathbb{F})$ , let  $\tilde{x}' = P\tilde{x}$ ; then we have  $x'_i \cdot x'_j = (\sum_i P_{i'i}x_i) \cdot (\sum_j P_{j'j}x_j) = \sum_{i,j} P_{i'i}P_{j'j}x_i \cdot x_j = \sum_{i,j,k} P_{i'i}P_{j'j}\mathbf{A}(i, j, k)x_k = \sum_{i,j,k} P_{i'i}P_{j'j}\mathbf{A}(i, j, k) \sum_{k'} (P^{-1})_{kk'}x_{k'}$ . Thus  $\mathbf{A}$  becomes  $(P \cdot \mathbf{A})(i', j', k') = \sum_{i,j,k} \mathbf{A}(i, j, k) P_{i'i}P_{j'j}(P^{-1})_{kk'}$ . The inverse in the third factor here is the crucial difference between this case and that of cubic or trilinear forms above, similar to the difference between matrix conjugacy and matrix isometry. The corresponding isomorphism problem is called ALGEBRA ISOMORPHISM.

**Summary.** The isomorphism problems of the above structures all have 3-way arrays as the underlying object, but are determined by different group actions. It is not hard to see that there are essentially five group actions in total: 3-TENSOR ISOMORPHISM, MATRIX SPACE CONJUGACY, MATRIX SPACE ISOMETRY, TRILINEAR FORM EQUIVALENCE, and ALGEBRA ISOMORPHISM. It turns out that these cover all the natural isomorphism problems on 3-way arrays in which the group acting is a product of  $\text{GL}(n, \mathbb{F})$  (where  $n$  is the side length of the arrays); see the full version [32] for a detailed discussion.

## 5.2 Full statement of main results

► **Theorem A.** *For any fixed  $d \geq 1$ ,  $d$ -TENSOR ISOMORPHISM reduces to ALGEBRA ISOMORPHISM.*

Combined with the results of [26], this immediately gives:

► **Corollary A.** *For any fixed  $d \geq 1$ ,  $d$ -TENSOR ISOMORPHISM reduces to 3-TENSOR ISOMORPHISM.*

Given the viewpoint of Section 5.1 on the problems from Section 2, to show that they are equivalent, it is enough to show that the isomorphism problems for 3-way arrays corresponding to the five group actions are equivalent, where 3-way arrays may also need to satisfy certain structural constraints (e.g., the frontal slices are symmetric or skew-symmetric). This is the content of our second main result.

► **Theorem B.** 3-TENSOR ISOMORPHISM reduces to each of the following problems in polynomial time.

1. GROUP ISOMORPHISM for  $p$ -groups exponent  $p$  ( $g^p = 1$  for all  $g$ ) and class 2 ( $G/Z(G)$  is abelian) given by generating matrices over  $\mathbb{F}_{p^e}$ . Here we consider only  $3\text{TI}_{\mathbb{F}_{p^e}}$  where  $p$  is an odd prime.
2. MATRIX SPACE ISOMETRY, even for alternating or symmetric matrix spaces.
3. MATRIX SPACE CONJUGACY, and even the special cases:
  - a. MATRIX LIE ALGEBRA CONJUGACY, for solvable Lie algebras  $L$  of derived length 2.<sup>5</sup>
  - b. ASSOCIATIVE MATRIX ALGEBRA CONJUGACY.<sup>6</sup>
4. ALGEBRA ISOMORPHISM, and even the special cases:
  - a. ASSOCIATIVE ALGEBRA ISOMORPHISM, for algebras that are commutative and unital, or for algebras that are commutative and 3-nilpotent ( $abc = 0$  for all  $a, b, c \in A$ )
  - b. LIE ALGEBRA ISOMORPHISM, for 2-step nilpotent Lie algebras ( $[u, [v, w]] = 0 \forall u, v, w$ )
5. CUBIC FORM EQUIVALENCE and TRILINEAR FORM EQUIVALENCE.

The algebras in (3) are given by a set of matrices which linearly span the algebra, while in (4) they are given by structure constants (see “Algebras” in Sec. 5.1).

Since the main result of [26] reduces the problems in Theorem B to 3-TENSOR ISOMORPHISM (cf. [26, Rmk. 1.1]), we have:

► **Corollary B.** Each of the problems listed in Theorem B is TI-complete.<sup>7</sup>

► **Remark 7.** Here is a brief summary of what is known about the complexity of some of these problems. Over a finite field  $\mathbb{F}_q$ , these problems are in  $\text{NP} \cap \text{coAM}$ . For  $\ell \times n \times m$  3-way arrays, the brute-force algorithms run in time  $q^{O(\ell^2 + n^2 + m^2)}$ , as  $\text{GL}(n, \mathbb{F}_q)$  can be enumerated in time  $q^{\Theta(n^2)}$ . Note that polynomial-time in the input size here would be  $\text{poly}(\ell, n, m, \log q)$ . Over any field  $\mathbb{F}$ , these problems are in  $\text{NP}_{\mathbb{F}}$  in the Blum–Shub–Smale model. When the input arrays are over  $\mathbb{Q}$  and we ask for isomorphism over  $\mathbb{C}$  or  $\mathbb{R}$ , these problems are in PSPACE using quantifier elimination. By Koiran’s celebrated result on Hilbert’s Nullstellensatz, for equivalence over  $\mathbb{C}$  they are in AM assuming the Generalized Riemann Hypothesis [44]. When the input is over  $\mathbb{Q}$  and we ask for equivalence over  $\mathbb{Q}$ , it is unknown whether these problems are even decidable; classically this is studied under ALGEBRA ISOMORPHISM for associative, unital algebras over  $\mathbb{Q}$  (see, e. g., [2, 60]), but by Cor. B, the question of decidability is open for all of these problems.

Over finite fields, several of these problems can be solved efficiently when one of the side lengths of the array is small. For  $d$ -dimensional spaces of  $n \times n$  matrices, MATRIX SPACE CONJUGACY and ISOMETRY can be solved in  $q^{O(n^2)} \cdot \text{poly}(d, n, \log q)$  time: once we fix an element of  $\text{GL}(n, \mathbb{F}_q)$ , the isomorphism problem reduces to solving linear systems of equations. Less trivially, MATRIX SPACE CONJUGACY can be solved in time  $q^{O(d^2)} \cdot \text{poly}(d, n, \log q)$  and 3TI for  $n \times m \times d$  tensors in time  $q^{O(d^2)} \cdot \text{poly}(d, n, m, \log q)$ , since once we fix an element of  $\text{GL}(d, \mathbb{F}_q)$ , the isomorphism problem either becomes an instance of, or reduces to [38], MODULE ISOMORPHISM, which admits several polynomial-time algorithms [15, 22, 37, 67]. Finally, one can solve MATRIX SPACE ISOMETRY in time  $q^{O(d^2)} \cdot \text{poly}(d, n, \log q)$ : once one fixes an element of  $\text{GL}(d, \mathbb{F}_q)$ , there is a rather involved algorithm [38], which uses the  $*$ -algebra technique originated from the study of computing with  $p$ -groups [17, 69].

<sup>5</sup> And even further, where  $L/[L, L] \cong \mathbb{F}$ .

<sup>6</sup> Even for algebras  $A$  whose Jacobson radical  $J(A)$  squares to zero and  $A/J(A) \cong \mathbb{F}$ .

<sup>7</sup> For CUBIC FORM EQUIVALENCE, we only show that it is in  $\text{TI}_{\mathbb{F}}$  when  $\text{char } \mathbb{F} > 3$  or  $\text{char } \mathbb{F} = 0$ .

## 6 Implications, more related works, and further discussions

### 6.1 An implication to quantum information

Quantum information is the study of information-theoretic properties of quantum states and channels, such as entanglement, non-classical correlations, and the uses of quantum states and channels for various computational tasks. A pure quantum particle takes states in a Hilbert space (=complex vector space, along with an inner product)  $V$ ; a pure multi-particle system takes states in the tensor product of the corresponding Hilbert spaces  $V_1 \otimes V_2 \otimes \cdots \otimes V_k$ .

A fundamental relation between  $k$ -partite quantum states is that of equivalence under *stochastic local operations and classical communication* (SLOCC) [10, 23]. If we imagine each particle is held by a different party, a “local operation” is an operation that a single party  $i$  can perform on its state in  $V_i$ . Although the definition of SLOCC involves combining this with classical communication, an equivalent definition is that two  $k$ -particle states  $\psi, \phi \in V_1 \otimes \cdots \otimes V_k$  are SLOCC-equivalent if they are in the same orbit under the action of the product of general linear groups  $\text{GL}(V_1) \times \text{GL}(V_2) \times \cdots \times \text{GL}(V_k)$  [23].<sup>8</sup> Deciding SLOCC equivalence (of un-normalized quantum states) is thus precisely the same as TI.

In this light, we may interpret our Thm. A as saying that SLOCC equivalence classes for  $k$ -partite entanglement can be simulated by SLOCC equivalence classes of tripartite entanglement. This might at first seem surprising, since bipartite entanglement is much better understood than tripartite or higher entanglement, so one might naively expect that 4-partite entanglement should be more complicated than tripartite, and so on. Our results show that in fact the tripartite case is already universal. This may be compared with a recent result in [72], which gives a transformation of multipartite states to a *set* of tripartite or bipartite states, interrelated by a *tensor network*, whereas our reduction produces a single tripartite state.

### 6.2 Further related works

While most of the related works have already been introduced before, we collect some of the key ones here for further discussions and comparisons.

The most closely related work is that of Futorny, Grochow, and Sergeichuk [26]. They show that a large family of isomorphism problems on 3-way arrays – including those involving multiple 3-way arrays simultaneously, or 3-way arrays that are partitioned into blocks, or 3-way arrays where some of the blocks or sides are acted on by the same group (e. g., MATRIX SPACE ISOMETRY) – all reduce to 3TI. Our work complements theirs in that all our reductions for Thm. B go in the opposite direction, reducing 3TI to other problems. Furthermore, the resulting 3-way arrays from our reductions for Thm. B usually satisfy certain structural constraints, which allows for versatile mathematical interpretations. Some of our other results relate GI and CODE EQUIVALENCE to 3TI; the latter problems were not considered in [26]. Thm. A considers  $d$ -tensors for any  $d \geq 3$ , which were not considered in [26].

In [1, 2], Agrawal and Saxena considered CUBIC FORM EQUIVALENCE and testing isomorphism of commutative, associative, unital algebras. They showed that GI reduces to ALGEBRA ISOMORPHISM; COMMUTATIVE ALGEBRA ISOMORPHISM reduces to CUBIC FORM

---

<sup>8</sup> Some authors use the action by the product of *special* linear groups  $\text{SL}(V_i)$  instead, but the difference is actually that physicists typically consider *normalized* quantum states, which are elements in the corresponding projective space  $\mathbb{P}(V_1 \otimes \cdots \otimes V_k)$ . Because the difference between  $\text{SL}(V_i)$  and  $\text{GL}(V_i)$  is merely scalar matrices, and scalar matrices act trivially on projective space, the equivalence relation is the same.

EQUIVALENCE; and HOMOGENEOUS DEGREE- $d$  FORM EQUIVALENCE reduces to ALGEBRA ISOMORPHISM assuming that the underlying field has  $d$ th root for every field element. By combining a reduction from [26] and our main Theorem B, we get a new reduction from CUBIC FORM EQUIVALENCE to ALGEBRA ISOMORPHISM that works over any field in which  $3!$  is a unit, which is fields of characteristic 0 or  $p > 3$ .

There are several other works which consider related isomorphism problems. Grigoriev [29] showed that GI is equivalent to isomorphism of unital, associative algebras  $A$  such that the radical  $R(A)$  squares to zero and  $A/R(A)$  is abelian. Interestingly, we show TI-completeness for *conjugacy* of *matrix* algebras with the same abstract structure (even when  $A/R(A)$  is only 1-dimensional). Note the latter problem is equivalent to asking whether two representations of  $A$  are equivalent up to automorphisms of  $A$ . The proof of Thm. A uses algebras in which  $R(A)^d = 0$  when reducing from  $d$ TI; it also uses Grigoriev’s result in one step.

Brooksbank and Wilson [18] showed a reduction from ASSOCIATIVE ALGEBRA ISOMORPHISM (when given by structure constants) to MATRIX ALGEBRA CONJUGACY. Grochow [30], among other things, showed that GI and CODEEQ reduce to MATRIX LIE ALGEBRA CONJUGACY, which is a special case of MATRIX SPACE CONJUGACY.

In [42], Kayal and Saxena considered testing isomorphism of finite rings when the rings are given by structure constants. This problem generalizes testing isomorphism of algebras over finite fields. They put this problem in  $\text{NP} \cap \text{coAM}$  [42, Thm. 4.1], reduce GI to this problem [42, Thm. 4.4], and prove that counting the number of ring automorphism ( $\#RA$ ) is in  $\text{FP}^{\text{AM} \cap \text{coAM}}$  [42, Thm. 5.1]. They also present a ZPP reduction from GI to  $\#RA$ , and show that the decision version of the ring automorphism problem is in P.

### 6.3 Combinatorial and group-theoretic techniques for GI and TI

Comparing with GRAPH ISOMORPHISM also offers one way to see why isomorphism problems for 3-way arrays are difficult. Indeed, the techniques for GI face great difficulty when dealing with isomorphism problems for multi-way arrays. Recall that most algorithms for GI, including Babai’s [5], are built on two families of techniques: group-theoretic, and combinatorial. One of the main differences is that the underlying group action for GI is a permutation group acting on a combinatorial structure, whereas the underlying group actions for isomorphism problems for 3-way arrays are matrix groups acting on (multi)linear structures.

Already in moving from permutation groups to matrix groups, we find many new computational difficulties that arise naturally in basic subroutines used in isomorphism testing. For example, the membership problem for permutation groups is well-known to be efficiently solvable by Sims’s algorithm [68] (see, e.g., [65] for a textbook treatment), while for matrix groups this was only recently shown to be solvable with a number-theoretic oracle over finite fields of odd characteristic [6]. Correspondingly, when moving from combinatorial structures to (multi)linear algebraic structures, we also find severe limitation on the use of most combinatorial techniques, like individualizing a vertex. For example, it is quite expensive to enumerate all vectors in a vector space, while it is usually considered efficient to go through all elements in a set. Similarly, within a set, any subset has a unique complement, whereas within  $\mathbb{F}_q^n$ , a subspace can have up to  $q^{\Theta(n^2)}$  complements.

Given all the differences between the combinatorial and linear-algebraic worlds, it may be surprising that combinatorial techniques for GRAPH ISOMORPHISM can nonetheless be useful for GROUP ISOMORPHISM. Indeed, Li and Qiao [46] adapted the individualisation and refinement technique, as used by Babai, Erdős and Selkow [8], to tackle ALTERNATING

MATRIX SPACE ISOMETRY over  $\mathbb{F}_q$ . This algorithm was recently shown [14] to practically improve over the default algorithms in Magma [12]. However, this technique, though helpful to improve from the brute-force  $q^{n^2} \cdot \text{poly}(n, \log q)$  time, seems still limited to getting *average-case*  $q^{O(n)}$ -time algorithms.

## 6.4 Outlook

In light of Babai’s breakthrough on GI [5], it is natural to consider “what’s next?” for isomorphism problems. That is, what isomorphism problems stand as crucial bottlenecks to further improvements on GI, and what isomorphism problems should naturally draw our attention for further exploration? Of course, one of the main open questions in the area remains whether or not GI is in P. Babai [5, arXiv ver., Sec. 13.2 & 13.4] already lists several isomorphism problems for further study, including GROUP ISOMORPHISM, PERMUTATIONAL CODE EQUIVALENCE (of linear codes), and PERMUTATION GROUP CONJUGACY. The reader may see where these sit in Fig. 1.

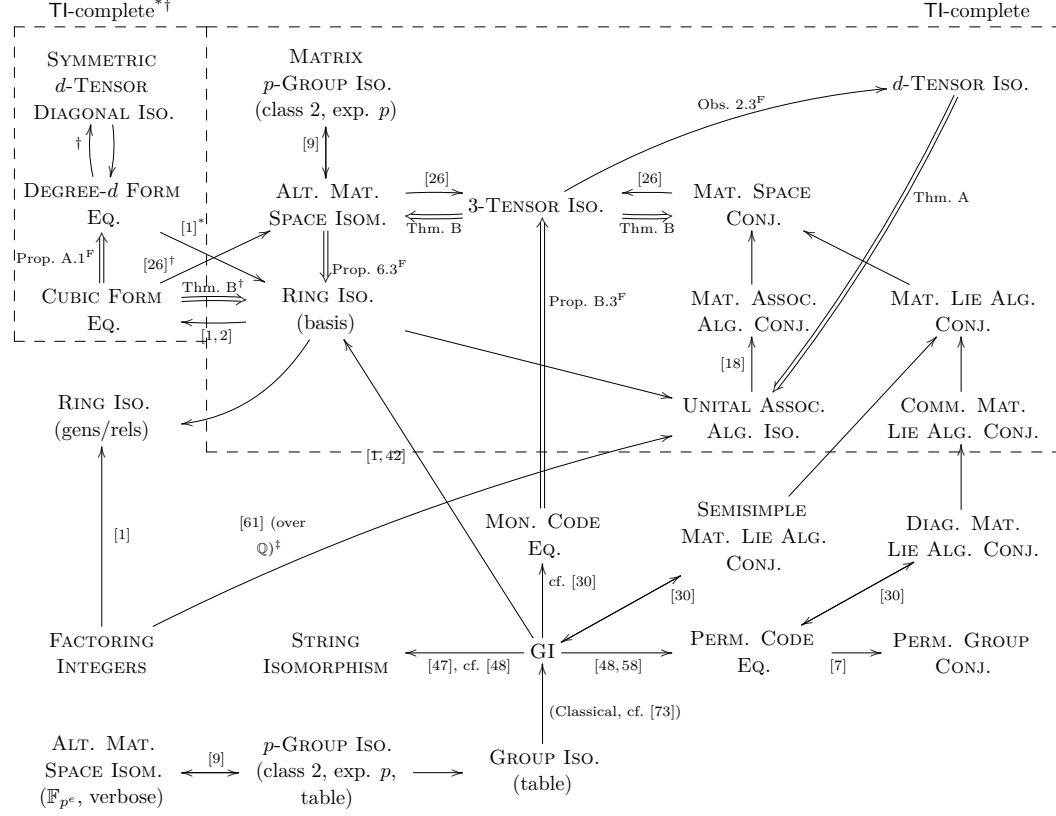

Based on the results above, we propose TI as a natural problem to study, both “after” GI, and to make further progress on GI itself. In particular, TI stands as a key bottleneck to put GI in P, because of the following. First, Babai suggested [5] that GROUP ISOMORPHISM (GPI) in the Cayley table model is a key bottleneck<sup>9</sup> to putting GI into P. Second, it has been long believed that  $p$ -groups of class 2 and exponent  $p$  are the hardest cases of GPI (for a number of reasons, see, e. g., [9, 36, 66, 71]). Third, by Baer’s correspondence [9], isomorphism for such groups is equivalent<sup>10</sup> to ALTERNATING MATRIX SPACE ISOMETRY (see Section 5.1). Finally, by our main Thm. B, ALTERNATING MATRIX SPACE ISOMETRY over  $\mathbb{F}_{p^e}$  is  $\text{TI}_{\mathbb{F}_{p^e}}$ -complete.

This then relates TI over finite fields to the believed-to-be-hardest instances of GPI, which in turn, as Babai suggested, is a key bottleneck for further progress on GI. We thus view the study of TI as a natural continuation of the study of GI. Furthermore, the main techniques for GI, namely the group-theoretic techniques and the combinatorial ones, also have corresponding techniques in the TI setting, although they are perhaps more complicated and less efficient than in the setting of GI. We explain this in detail in Sec. 6.

This theory for TI is far from complete, and many questions remain, largely inspired by the study of GI. In the full version [32, Section 10.1], we discuss a possible theory of universality for basis-explicit linear structures, in analogy with the universality of GI for explicit combinatorial structures [73, Section 15]. While not yet complete, this is another exciting reason to study TENSOR ISOMORPHISM and related problems, and it motivates some interesting open questions. Then we pose several natural open problems.

<sup>9</sup> Indeed, the current-best upper bounds on these two problems are now quite close:  $n^{O(\log n)}$  for GPI (originally due to [24, 53] – Miller attributes this to Tarjan – with improved constants [62, 63, 70]), and  $n^{O(\log^2 n)}$  for GI [5] (see [35] for calculation of the exponent).

<sup>10</sup> Specifically, solving ALTERNATING MATRIX SPACE ISOMETRY over  $\mathbb{F}_p$  in time  $p^{O(n+m)}$  is equivalent to testing isomorphism for  $p$ -groups of class 2 and exponent  $p$  in time polynomial in the group order, i.e. polynomial time in the Cayley table model.

■ **Figure 1** Summary of key isomorphism problems.  $A \rightarrow B$  indicates that  $A$  reduces to  $B$ , i. e.,  $A \leq_m^p B$ .  $A \Rightarrow B$  indicates a new result. Unattributed arrows indicate  $A$  is clearly a special case of  $B$ . Note that the definition of ring used in [1] is commutative, finite, and unital; by “algebra” we mean an algebra (not necessarily associative, let alone commutative nor unital) over a field. The reductions between RING ISO. (in the basis representation) and DEGREE- $d$  FORM EQ. and UNITAL ASSOCIATIVE ALGEBRA ISOMORPHISM are for rings over a field. The equivalences between ALTERNATING MATRIX SPACE ISOMETRY and  $p$ -GROUP ISOMORPHISM are for matrix spaces over  $\mathbb{F}_{p^e}$ . Some TI-complete problems from Thm. B are left out for clarity.

\* These results only hold over fields where every element has a  $d$ th root. In particular, DEGREE  $d$  FORM EQUIVALENCE and SYMMETRIC  $d$ -TENSOR ISOMORPHISM are TI-complete over fields with  $d$ -th roots. A finite field  $\mathbb{F}_q$  has this property if and only if  $d$  is coprime to  $q - 1$ .

† These results only hold over rings where  $d!$  is a unit.

‡ Assuming the Generalized Riemann Hypothesis, Rónyai [61] shows a Las Vegas randomized polynomial-time reduction from factoring square-free integers – probably not much easier than the general case – to isomorphism of 4-dimensional algebras over  $\mathbb{Q}$ . Despite the additional hypotheses, this is notable as the target of the reduction is algebras of *constant* dimension, in contrast to all other reductions in this figure.

<sup>F</sup> Refers to numbers in the full version [32].

## Abstract

QAC circuits are quantum circuits with one-qubit gates and Toffoli gates of arbitrary arity. QAC<sup>0</sup> circuits are QAC circuits of constant depth, and are quantum analogues of AC<sup>0</sup> circuits. We prove the following:

- For all  $d \geq 7$  and  $\varepsilon > 0$  there is a depth- $d$  QAC circuit of size  $\exp(\text{poly}(n^{1/d}) \log(n/\varepsilon))$  that approximates the  $n$ -qubit parity function to within error  $\varepsilon$  on worst-case quantum inputs. Previously it was unknown whether QAC circuits of sublogarithmic depth could approximate parity regardless of size.
- We introduce a class of “mostly classical” QAC circuits, including a major component of our circuit from the above upper bound, and prove a tight lower bound on the size of low-depth, mostly classical QAC circuits that approximate this component.
- Arbitrary depth- $d$  QAC circuits require at least  $\Omega(n/d)$  multi-qubit gates to achieve a  $1/2 + \exp(-o(n/d))$  approximation of parity. When  $d = \Theta(\log n)$  this nearly matches an easy  $O(n)$  size upper bound for computing parity exactly.
- QAC circuits with at most two layers of multi-qubit gates cannot achieve a  $1/2 + \exp(-o(n))$  approximation of parity, even non-cleanly. Previously it was known only that such circuits could not cleanly compute parity exactly for sufficiently large  $n$ .

The proofs use a new normal form for quantum circuits which may be of independent interest, and are based on reductions to the problem of constructing certain generalizations of the cat state which we name “nekomata” after an analogous cat yōkai.

**2012 ACM Subject Classification** Theory of computation → Circuit complexity; Theory of computation → Quantum complexity theory; Theory of computation → Quantum complexity theory

**Keywords and phrases** quantum circuit complexity, QAC<sup>0</sup>, fanout, parity, nekomata

Thanks to Srinivasan Arunachalam, Daniel Grier, Ian Mertz, Eric Rosenthal, and Rahul Santhanam for helpful discussions as well. Part of this work was done while the author was visiting the Simons Institute for the Theory of Computing. Circuit diagrams were made using the Quantikz package [12].

## 1 Introduction

### 1.1 Background

A central problem in computational complexity theory is to prove lower bounds on the nonuniform circuit size required to compute explicit boolean functions. Since this appears to be out of reach given current techniques, research in circuit complexity has instead focused on

proving lower bounds in restricted circuit classes. There are now many known lower bounds in *classical* circuit complexity, as well as in quantum *query* complexity, but comparatively few lower bounds are known in quantum circuit complexity, which is the subject of the current paper.

The study of quantum circuit complexity was initiated in large part by Green, Homer, Moore and Pollett [8], who defined quantum analogues of a number of classical circuit classes. One of the seemingly most restrictive quantum circuit classes that they defined is the class of QAC<sup>0</sup> circuits, consisting of constant-depth QAC circuits, where QAC circuits are quantum circuits with arbitrary one-qubit gates and generalized Toffoli gates of arbitrary arity. (More precisely,  $(n + 1)$ -ary generalized Toffoli gates are defined by  $|x, b\rangle \mapsto |x, b \oplus \bigwedge_{j=1}^n x_j\rangle$  for  $x = (x_1, \dots, x_n) \in \{0, 1\}^n, b \in \{0, 1\}$ .) This is analogous to the classical circuit class of AC<sup>0</sup> circuits, consisting of constant-depth AC circuits, where AC circuits are boolean circuits with NOT gates and unbounded-fanin AND and OR gates. Low-depth circuits are a model of fast parallel computation, and this is especially important for quantum circuits, because quantum computations need to be fast relative to the decoherence time of the qubits in order to avoid error.

One difference between AC and QAC circuits is that AC circuits are allowed fanout “for free”, i.e. the input bits to the circuit and the outputs of gates may all be used as inputs to arbitrarily many gates. The quantum analogue of this would be to compute the unitary “fanout” transformation  $U_F$ , defined by  $U_F|b, x_1, \dots, x_{n-1}\rangle = |b, x_1 \oplus b, \dots, x_{n-1} \oplus b\rangle$  for  $b, x_1, \dots, x_{n-1} \in \{0, 1\}$ , or at least to compute this in the case that we call “restricted fanout” in which  $x_1 = \dots = x_{n-1} = 0$ . QAC<sup>0</sup> circuits with fanout gates are called QAC<sub>f</sub><sup>0</sup> circuits, and can simulate arbitrary AC<sup>0</sup> circuits by using ancillae and restricted fanout to make as many copies as needed of the input bits and of the outputs of gates. In fact, QAC<sub>f</sub><sup>0</sup> circuits are *strictly* more powerful than AC<sup>0</sup> circuits, because QAC<sub>f</sub><sup>0</sup> circuits (even without generalized Toffoli gates) of polynomial size can also compute threshold functions [11, 14] whereas AC<sup>0</sup> circuits require exponential size to do so [10]. In contrast, little is known about the power of QAC<sup>0</sup> circuits and how it compares with that of AC<sup>0</sup> circuits.

Green et al. [8] observed that fanout can be computed by QAC circuits of logarithmic depth and linear size. This raises the question of whether QAC circuits of *sublogarithmic* depth can compute fanout, or at least restricted fanout, even if allowed *arbitrary* size. The same question can be asked about parity, which is a famous example of a function that requires exponential size to compute in AC<sup>0</sup> [10], and which is defined for quantum circuits as the unitary transformation  $U_{\oplus}$  such that  $U_{\oplus}|b, x\rangle = |b \oplus \bigoplus_{j=1}^{n-1} x_j, x\rangle$  for  $b \in \{0, 1\}, x = (x_1, \dots, x_{n-1}) \in \{0, 1\}^{n-1}$ . In fact, all of these questions are equivalent: Green et al. [8] proved that parity and fanout are equivalent up to conjugation by Hadamard gates, and that they reduce to restricted fanout with negligible blowups in size and depth (see the full paper for illustrations).

Recent work [7, 9] suggests that QAC<sub>f</sub><sup>0</sup> may be a physically realistic model of constant depth computation in certain quantum computing architectures (such as ion traps). As for QAC lower bounds, Fang, Fenner, Green, Homer and Zhang [5] proved that QAC circuits with  $a$  ancillae require depth at least  $\Omega(\log(n/(a + 1)))$  to compute the  $n$ -qubit parity and fanout functions, which is a nontrivial lower bound when  $a$  is  $o(n)$ . Bera [3] used a different approach to prove something slightly weaker than the  $a = 0$  case of this result. Finally, Padé, Fenner, Grier and Thierauf [13] proved that QAC circuits with two layers of generalized Toffoli gates cannot cleanly<sup>1</sup> compute 4-qubit parity or fanout, regardless of the number of ancillae. A survey of Bera, Green and Homer [4] discusses some of the aforementioned QAC lower bounds and QAC<sub>f</sub> upper bounds in greater detail.

<sup>1</sup> A clean computation is one in which the ancillae end in the all-zeros state.

## 1.2 Results and Selected Proof Overviews

### 1.2.1 Definitions of Complexity Measures

Call  $|\langle\psi|\varphi\rangle|^2$  the *fidelity* of states  $|\varphi\rangle$  and  $|\psi\rangle$ . We define the *size* of a QAC circuit to be the number of multi-qubit gates in it, and the *depth* of a QAC circuit to be the number of layers of multi-qubit gates in it. One motivation for not counting single-qubit gates, besides mathematical convenience, is that size and depth can be interpreted as measures of the reliability and computation time of a quantum circuit respectively, and in practice multi-qubit gates tend to be less reliable and take more time to apply as compared to single-qubit gates.

### 1.2.2 Reductions to and from Constructing Nekomata

Recall that Green et al. [8] proved that parity, fanout, and restricted fanout are all equivalent up to low-complexity QAC reductions. In Section 3 we make the more general observation that clean approximate and non-clean approximate versions of these problems are all equivalent in this sense. For brevity's sake, here in Section 1.2 we will only state immediate corollaries of these reductions insofar as they relate to our other results.

We also introduce another problem equivalent to parity, which all of our results about parity and fanout are proved via reductions to. The state  $\frac{1}{\sqrt{2}} \sum_{b=0}^1 |b^n\rangle$  is commonly called the *cat state* on  $n$  qubits, and we denote it by  $|\mathbb{K}_n\rangle$ . More generally, call a state  $|\nu\rangle$  an *n-nekomata* if  $|\nu\rangle = \frac{1}{\sqrt{2}} \sum_{b=0}^1 |b^n, \psi_b\rangle$  for some states  $|\psi_0\rangle, |\psi_1\rangle$  on any number of qubits (the word “nekomata” is also the name of two-tailed cats from Chinese and Japanese folklore), or equivalently if a standard-basis measurement of some  $n$  qubits of  $|\nu\rangle$  outputs all-zeros and all-ones each with probability  $1/2$ .

Call a QAC circuit  $C$  acting on any number of qubits a solution to the “ $p$ -approximate  $n$ -nekomata problem” if there exists an  $n$ -nekomata  $|\nu\rangle$  such that  $C|0\dots 0\rangle$  and  $|\nu\rangle$  have fidelity at least  $p$ . (There is no need to allow “ancillae” in this problem, because if  $|\nu\rangle$  is an  $n$ -nekomata then so is  $|\nu, \psi\rangle$  for any state  $|\psi\rangle$ .) Note that the identity circuit on  $n$  or more qubits trivially solves the  $1/2$ -approximate  $n$ -nekomata problem. In informal discussions we will often say that a circuit “constructs an approximate  $n$ -nekomata” if it solves the  $p$ -approximate  $n$ -nekomata problem for some fixed  $p \in (1/2, 1)$ , say  $p = 3/4$ .

Constructing nekomata reduces to computing restricted fanout because  $|\mathbb{K}_n\rangle = U_F(H \otimes I)|0^n\rangle$ . Our reduction from parity to constructing nekomata is a variant of Green et al.’s [8] reduction from parity to restricted fanout.

### 1.2.3 Upper Bounds

► **Theorem 1.1.** *For all  $\varepsilon > 0$  there exists a depth-2 QAC circuit  $C$  such that for some  $n$ -nekomata  $|\nu\rangle$ , the fidelity of  $C|0\dots 0\rangle$  and  $|\nu\rangle$  is at least  $1 - \varepsilon$ . Furthermore, the size of  $C$  and the number of qubits acted on by  $C$  are both  $\exp(O(n \log(n/\varepsilon)))$ .*

To state a stronger upper bound for approximating unitary transformations than can conveniently be done in terms of fidelity, call  $1 - \|\varphi - \psi\|_2^2$  the *phase-dependent fidelity* of states  $|\varphi\rangle$  and  $|\psi\rangle$ . This quantity is at most the fidelity of  $|\varphi\rangle$  and  $|\psi\rangle$  (Equation (2)).

► **Corollary 1.2.** *For all  $d \geq 7$  and  $\varepsilon > 0$  there exist depth- $d$  QAC circuits  $C_\oplus, C_F, C_{\mathbb{K}}$  of size and number of ancillae  $\exp(\text{poly}(n^{1/d}) \log(n/\varepsilon))$ , where the  $\text{poly}(n^{1/d})$  term is at most  $O(n)$ , such that for all  $n$ -qubit states  $|\phi\rangle$ ,*

- *the phase-dependent fidelity of  $C_\oplus|\phi, 0\dots 0\rangle$  and  $U_\oplus|\phi\rangle \otimes |0\dots 0\rangle$  is at least  $1 - \varepsilon$ ;*
- *the phase-dependent fidelity of  $C_F|\phi, 0\dots 0\rangle$  and  $U_F|\phi\rangle \otimes |0\dots 0\rangle$  is at least  $1 - \varepsilon$ ;*
- *the phase-dependent fidelity of  $C_{\mathbb{K}}|0\dots 0\rangle$  and  $|\mathbb{K}_n, 0\dots 0\rangle$  is at least  $1 - \varepsilon$ .*

The  $d = 11$  case of Corollary 1.2 follows immediately from Theorem 1.1 and our reduction from parity to constructing nekomata. We decrease the minimum depth from 11 to 7 using an optimization specific to the circuit from our proof of Theorem 1.1. We prove Corollary 1.2 for higher depths using the fact that  $n$ -qubit restricted fanout can be computed by a circuit consisting of  $d$  layers of  $n^{1/d}$ -qubit restricted fanout gates.

If we were to also count one-qubit gates toward size and depth, then statements similar to Theorem 1.1 and Corollary 1.2 would still hold, because without loss of generality a depth- $d$  QAC circuit acting on  $m$  qubits has at most  $d + 1$  layers of one-qubit gates and at most  $(d + 1)m$  one-qubit gates.

### 1.2.4 Tight Lower Bounds for Constructing Approximate Nekomata in “Mostly Classical” Circuits

Call a QAC circuit *mostly classical* if it can be written as  $CLML^\dagger$  (i.e.  $C$  is applied last) such that  $C$  consists only of generalized Toffoli gates,  $L$  is a layer of one-qubit gates, and  $M$  is a layer of generalized Toffoli gates. The circuit  $C$  here is a close analogue of (classical) AC circuits with bounded fanout, since generalized Toffoli gates can simulate classical AND and NOT gates. The following is apparent from our proof of Theorem 1.1:

► **Remark 1.3.** Theorem 1.1 remains true even if “QAC circuit” is replaced by “mostly classical QAC circuit”.

Motivated by Remark 1.3, we prove the following lower bound for constructing approximate nekomata in mostly classical circuits:

► **Theorem 1.4.** *Let  $C$  be a mostly classical circuit of size  $s$  and depth  $o(\log n)$ , acting on any number of qubits. Then for all  $n$ -nekomata  $|\nu\rangle$ , the fidelity of  $C|0 \dots 0\rangle$  and  $|\nu\rangle$  is at most  $1/2 + \exp(-n^{1-o(1)}/\max(\log s, \sqrt{n}))$ .*

(See Theorem 4.2 for a more precise tradeoff between depth and fidelity.) In particular, Theorem 1.4 implies that mostly classical circuits of depth  $o(\log n)$  require size at least  $\exp(n^{1-o(1)})$  to construct approximate  $n$ -nekomata, essentially matching the  $\exp(\tilde{O}(n))$  size upper bound from Theorem 1.1 and Remark 1.3. This lower bound does not contradict the  $\exp(n^{o(1)})$  size upper bounds of depth  $\omega(1)$  from Corollary 1.2, because our reductions between parity, fanout, and constructing nekomata do not in general map mostly classical circuits to mostly classical circuits. Since the identity circuit is mostly classical, the upper bound on the fidelity of  $C|0 \dots 0\rangle$  and  $|\nu\rangle$  in Theorem 1.4 is tight up to the value being exponentiated. Finally, if we also allow  $r$ -qubit parity and fanout gates in mostly classical circuits – a natural model for small values of  $r$ , in light of the upper bounds from Corollary 1.2 – then a trivial generalization of our proof of Theorem 1.4 implies that an identical statement holds for circuits of depth  $o(\log_{\max(r,2)} n)$ .

To prove Theorem 1.4, it suffices to prove that the Hamming weight of a standard-basis measurement of any  $n$  qubits of  $C|0 \dots 0\rangle$  is concentrated around some value. We use the fact that standard-basis measurements commute with generalized Toffoli gates, and, after some preparation, apply a concentration inequality of Gavinsky, Lovett, Saks and Srinivasan [6].

### 1.2.5 Lower Bounds for Arbitrary QAC Circuits of Low Size and Depth

Call the first  $n$  qubits of an  $n$ -nekomata  $\frac{1}{\sqrt{2}} \sum_{b=0}^1 |b^n, \psi_b\rangle$  the *targets* of that nekomata.

► **Theorem 1.5.** *There is a universal constant  $c > 0$  such that the following holds. Let  $C$  be a depth- $d$  QAC circuit acting on any number of qubits, and let  $|\nu\rangle$  be an  $n$ -nekomata such that at most  $cn/(d + 1)$  multi-qubit gates in  $C$  act on the targets of  $|\nu\rangle$ . Then the fidelity of  $C|0 \dots 0\rangle$  and  $|\nu\rangle$  is at most  $1/2 + \exp(-\Omega(n/(d + 1)))$ .*

► **Corollary 1.6.** *Let  $c$  be the constant from Theorem 1.5. Let  $C$  be a depth- $d$  QAC circuit acting on any number of qubits, and assume that, collectively, the first  $n$  of these qubits are acted on by at most  $cn/(d+1)$  multi-qubit gates in  $C$ . Then for all states  $|\psi\rangle$ ,*

- *for  $|\phi_\oplus\rangle = |0, +^{n-1}\rangle$ , the fidelity of  $C|\phi_\oplus, 0 \dots 0\rangle$  and  $U_\oplus|\phi_\oplus\rangle \otimes |\psi\rangle$  is at most  $1/2 + \exp(-\Omega(n/(d+1)))$ ;*
- *for  $|\phi_F\rangle = |+, 0^{n-1}\rangle$ , the fidelity of  $C|\phi_F, 0 \dots 0\rangle$  and  $U_F|\phi_F\rangle \otimes |\psi\rangle$  is at most  $1/2 + \exp(-\Omega(n/(d+1)))$ ;*
- *the fidelity of  $C|0 \dots 0\rangle$  and  $|\otimes_n, \psi\rangle$  is at most  $1/2 + \exp(-\Omega(n/(d+1)))$ .*

(Perhaps surprisingly, a sharp “phase change” near the  $cn/(d+1)$  threshold is in fact inherent to our proof. The  $+1$  in  $\exp(-\Omega(n/(d+1)))$  is necessary when  $C = H$  and  $|\nu\rangle = |+\rangle := \frac{|0\rangle+|1\rangle}{\sqrt{2}}$ .) For example, Theorem 1.5 implies that a depth-2 QAC circuit constructing an approximate  $n$ -nekomata must have at least  $\Omega(n)$  multi-qubit gates acting on the targets of that nekomata. This  $\Omega(n)$  lower bound is tight, because Theorem 1.1 says that depth-2 QAC circuits can construct approximate  $n$ -nekomata, and a depth- $d$  QAC circuit can have at most  $nd$  multi-qubit gates acting on any given set of  $n$  qubits. Similarly, Corollary 1.6 implies that depth-7 QAC circuits approximating  $n$ -qubit parity, fanout, or restricted fanout require at least  $\Omega(n)$  multi-qubit gates acting on the  $n$  “input” qubits, and this  $\Omega(n)$  lower bound is tight as well by Corollary 1.2.

Theorem 1.5 also implies that the *total* number of multi-qubit gates, a.k.a. the size, of a depth- $d$  QAC circuit constructing an approximate  $n$ -nekomata must be at least  $\Omega(n/(d+1))$ . When  $d$  is  $o(\log n)$ , this lower bound is disappointingly far from the upper bounds of Theorem 1.1 and Corollary 1.2. However, Green et al. [8] observed that for some  $d = \Theta(\log n)$ , a depth- $d$  QAC circuit of size  $O(n)$  can construct an  $n$ -nekomata (specifically, the  $n$ -qubit cat state), so for this value of  $d$  our  $\Omega(n/d)$  size lower bound is tight to within a logarithmic factor. Similarly, for some  $d = \Theta(\log n)$ , the minimum size of a depth- $d$  QAC circuit that approximates  $n$ -qubit parity, fanout, or restricted fanout is between  $\Omega(n/\log n)$  and  $O(n)$ , by Corollary 1.6 and upper bounds of Green et al.

If a QAC circuit has size  $s \leq o(\sqrt{n})$  then its depth  $d$  satisfies  $d \leq s \leq o(\sqrt{n})$ , so  $s \leq o(\sqrt{n}) \leq o(n/(d+1))$ . It follows from Theorem 1.5 and Corollary 1.6 that QAC circuits of *arbitrary* depth require size at least  $\Omega(\sqrt{n})$  to construct approximate  $n$ -nekomata, or to approximately compute  $n$ -qubit parity, fanout, or restricted fanout.<sup>2</sup>

Finally, we remark that Theorem 1.5 is actually a special case of a more general result, Theorem 5.2, about states  $|\psi\rangle$  such that for some orthogonal projections<sup>3</sup>  $Q_1, \dots, Q_n$  on arbitrary numbers of qubits,  $\langle\psi|(\bigotimes_{j=1}^n Q_j \otimes I)|\psi\rangle = \langle\psi|(\bigotimes_{j=1}^n (I - Q_j) \otimes I)|\psi\rangle = 1/2$ . (For example,  $n$ -nekomata satisfy this criterion with  $Q_j = |0\rangle\langle 0|$  for all  $j$ .) We will comment on this generalization of Theorem 1.5 again in Section 1.2.7.

## 1.2.6 A Normal Form for Quantum Circuits

Integral to our proof of Theorem 1.5 is a certain normal form for QAC circuits, which may be of independent interest since the standard quantum circuit model is that of QAC circuits whose gates have maximum arity 2. Here we give the underlying intuition, by way of analogy with well-known facts from classical circuit complexity. If we define AC circuits as consisting only of AND and NOT gates, then it cannot in general be assumed that the NOT gates are

<sup>2</sup> In the full paper we generalize this argument to hold for the number of multi-qubit gates acting on the target/input qubits.

<sup>3</sup> I.e.  $Q_j = Q_j^2 = Q_j^\dagger$  for all  $j$ .

all adjacent to the inputs. However, by DeMorgan's laws we may equivalently allow OR gates in AC circuits as well, and then it *can* be assumed that the NOT gates are all adjacent to the inputs.<sup>4</sup> Similarly, we introduce a certain further generalization of generalized Toffoli gates which allows us to assume that the one-qubit gates in a QAC circuit are all adjacent to the input.

### 1.2.7 Depth-2 Lower Bounds

► **Theorem 1.7.** *Let  $C$  be a depth-2 QAC circuit of arbitrary size, acting on any number of qubits. Then for all states  $|\psi\rangle$ ,*

- (i) *for  $|\phi_\oplus\rangle = |0, +^{n-1}\rangle$ , the fidelity of  $C|\phi_\oplus, 0 \dots 0\rangle$  and  $U_\oplus|\phi_\oplus\rangle \otimes |\psi\rangle$  is at most  $1/2 + \exp(-\Omega(n))$ ;*
- (ii) *for  $|\phi_F\rangle = |+, 0^{n-1}\rangle$ , the fidelity of  $C|\phi_F, 0 \dots 0\rangle$  and  $U_F|\phi_F\rangle \otimes |\psi\rangle$  is at most  $1/2 + \exp(-\Omega(n))$ ;*
- (iii) *the fidelity of  $C|0 \dots 0\rangle$  and  $|\boxtimes_n, \psi\rangle$  is at most  $1/2 + \exp(-\Omega(n))$ .*

Our proof of Theorem 1.7 gives a multiplicative constant of roughly  $1/10^{60000}$  implicit in the  $\Omega(\cdot)$  notation in the above inequalities, which makes them trivial for small values of  $n$ . If  $n$  is sufficiently large however, then Theorem 1.7 implies that depth-2 QAC circuits cannot approximate  $n$ -qubit parity, fanout, or restricted fanout, or approximately construct the  $n$ -qubit cat state, even if these approximations are not required to be clean. Still taking  $n$  to be sufficiently large, this improves on the previously mentioned result of Padé et al. [13] that depth-2 QAC circuits cannot cleanly compute parity exactly on four or more qubits.

Theorem 1.7 and Corollary 1.2 imply that for all sufficiently large  $n$ , the minimum depth of a QAC circuit approximating  $n$ -qubit parity is between 3 and 7 inclusive, and likewise for fanout, restricted fanout, and constructing the cat state. By Theorem 1.1 there *is* a depth-2 QAC circuit that constructs an approximate  $n$ -nekomata for all  $n$ , so any proof of Theorem 1.7 must use some property of  $|\boxtimes_n, \psi\rangle$  that does not hold for an arbitrary  $n$ -nekomata. Ours uses a property similar to the fact that if we measure some of the qubits in the “ $B$ ” register of  $|\boxtimes_n\rangle_A \otimes |\psi\rangle_B$  in an arbitrary basis, then the resulting state in registers  $A$  and  $B$  is still an  $n$ -nekomata.

Our proof of Theorem 1.7 mostly uses different techniques than those of Padé et al. An exception is the observation, of which we use a generalization, that if we define a “generalized  $Z$  gate” on any number of qubits by  $Z = I - 2|1 \dots 1\rangle\langle 1 \dots 1|$  then  $Z|0, \phi\rangle = |0, \phi\rangle$  and  $Z|1, \phi\rangle = |1\rangle \otimes Z|\phi\rangle$  for all states  $|\phi\rangle$ . We also incorporate a variant of the proof given by Bene Watts, Kothari, Schaeffer and Tal [2, Theorem 16] that there is no QNC circuit (QAC circuit whose gates have maximum arity 2) of depth  $o(\log n)$  that maps  $|0 \dots 0\rangle$  to  $|\boxtimes_n, 0 \dots 0\rangle$ : Using a “light cone” argument they prove that out of any  $n$  output qubits, there are at least two whose standard-basis measurements would be independent, but the standard-basis measurements of any two qubits in  $|\boxtimes_n\rangle$  are dependent.

Our proof of Theorem 1.7 goes roughly as follows. If there are only  $o(n)$  multi-qubit gates acting on the  $n$  targets of  $|\boxtimes_n, \psi\rangle$  then the result follows from Theorem 1.5. Otherwise, out of the multi-qubit gates acting on the targets, the average gate acts on  $O(1)$  targets, as would be the case in a QNC circuit. Using a variant of a light cone argument, we choose  $\Theta(n)$  pairwise disjoint sets of qubits on which to define orthogonal projections, and apply the generalization of Theorem 1.5 that was mentioned at the end of Section 1.2.5.

<sup>4</sup> Invoking this assumption results in a constant-factor blowup in size and no blowup in depth, where (as is customary) we do not count NOT gates toward the size or depth of AC circuits.

### 1.3 Organization

In Section 1.4 we introduce some miscellaneous notation and definitions. In Section 2 we give multiple equivalent characterizations of QAC circuits, including the previously mentioned normal form, and introduce some related definitions which we will use in more general contexts as well. In Section 3 we give reductions between parity, fanout, restricted fanout, and constructing nekomata; we also use these reductions to prove that the  $d \geq 11$  case of Corollary 1.2 follows from Theorem 1.1 (the  $d < 11$  case is proved in the full paper), that Corollary 1.6 follows from Theorem 1.5, and that Theorems 1.7(i) and 1.7(ii) follow from Theorem 1.7(iii). In Section 4 we prove our upper and lower bounds for constructing approximate nekomata in mostly classical circuits, Theorems 1.1 and 1.4. In Section 5 we prove our other main results, Theorem 1.5 and Theorem 1.7(iii). Sections 3 to 5 may be read in any order.

### 1.4 Preliminaries

We write  $\log$  and  $\ln$  to denote the logarithms base 2 and  $e$  respectively, and  $(x_j)_j$  to denote the tuple of all  $x_j$  for  $j$  in some implicit index set. Also let  $[n] = \{1, \dots, n\}$  and  $\|\psi\| = \sqrt{\psi^* \psi}$ , i.e.  $\|\cdot\|$  denotes the 2-norm. Anything written as  $\langle \cdot |$  or  $|\cdot\rangle$  is implicitly unit-length. “Proof sketch” environments are replaced by complete proofs in the full paper.

*Orthogonal projections* are linear transformations  $Q$  such that  $Q = Q^2 = Q^\dagger$ . For an orthogonal projection  $Q$  and a state  $|\varphi\rangle$ , we call  $\langle \varphi | Q | \varphi \rangle$  “the probability that  $|\varphi\rangle$  measures to  $Q$ ”. If  $Q = |\psi\rangle\langle\psi|$  then we also call this “the probability that  $|\varphi\rangle$  measures to  $|\psi\rangle$ ”, and it equals  $|\langle \psi | \varphi \rangle|^2$ , a.k.a. the *fidelity* of  $|\varphi\rangle$  and  $|\psi\rangle$ . More generally, if  $Q$  is an orthogonal projection on some Hilbert space  $\mathcal{H}$  then we call  $\langle \varphi | (Q \otimes I) | \varphi \rangle$  “the probability that the  $\mathcal{H}$  qubits of  $|\varphi\rangle$  measure to  $Q$ ”.

We use standard notation for the Hadamard basis states  $|+\rangle = \frac{|0\rangle + |1\rangle}{\sqrt{2}}$ ,  $|-\rangle = \frac{|0\rangle - |1\rangle}{\sqrt{2}}$ , Hadamard gate  $H = |+\rangle\langle 0| + |-\rangle\langle 1|$ , and NOT gate  $X = |0\rangle\langle 1| + |1\rangle\langle 0|$ . We write  $I$  to denote the identity transformation,  $I_{\mathcal{H}}$  for the identity on the Hilbert space  $\mathcal{H}$ , and  $I_n$  for the identity on some  $n$ -qubit Hilbert space.

To be thorough, we remind the reader that an  $n$ -*nekomata* is a state with  $n$  qubits (called *targets*) that measure to  $0^n$  and to  $1^n$  each with probability  $1/2$ , or equivalently a state of the form  $\frac{1}{\sqrt{2}} \sum_{b=0}^1 |b^n, \psi_b\rangle$  for some states  $|\psi_0\rangle, |\psi_1\rangle$  on any number of qubits. For example, the  $n$ -qubit *cat state* is the state  $|\mathbb{E}_n\rangle = (|0^n\rangle + |1^n\rangle)/\sqrt{2}$ .

## 2 QAC Circuits

Consider a quantum circuit  $C$ , written as  $C = L_d M_d \cdots L_1 M_1 L_0$  such that each  $L_k$  consists only of one-qubit gates and each  $M_k$  is a layer (tensor product) of multi-qubit gates. We may assume that each  $L_k$  is a single layer as well, because the product of one-qubit gates is also a one-qubit gate. Define the *size* of  $C$  to be the number of multi-qubit gates in  $C$ , the *depth* of  $C$  to be the number of layers of multi-qubit gates in  $C$  (in this case,  $d$ ), and the *topology* of  $C$  to be the set of pairs  $(S, k)$  such that  $S$  equals the support of some gate in  $M_k$ , where the *support* of a gate is the set of qubits acted on by that gate. Note that the topology of  $C$  encodes its depth, size, and more generally the number of multi-qubit gates acting on any given set of qubits.

Recall that QAC circuits are quantum circuits with arbitrary one-qubit gates and generalized Toffoli gates of arbitrary arity, where  $(n+1)$ -ary generalized Toffoli gates are defined by  $|x, b\rangle \mapsto |x, b \oplus \bigwedge_{j=1}^n x_j\rangle$  for  $x = (x_1, \dots, x_n) \in \{0, 1\}^n$ ,  $b \in \{0, 1\}$ . Define an  $(n+1)$ -ary OR

■ **Figure 1** The multi-qubit gates on the left and right are OR and generalized Toffoli gates respectively, whose target qubits are on the bottom wire.

gate by  $|x, b\rangle \mapsto |x, b \oplus \bigvee_j x_j\rangle$  for  $x \in \{0, 1\}^n, b \in \{0, 1\}$ , and call the qubit corresponding to  $b$  in these definitions the *target* qubit of the gate. By the construction of an OR gate from a generalized Toffoli gate and NOT gates in Figure 1, we may add OR gates to the set of allowed gates when defining QAC circuits, without changing the set of topologies of QAC circuits computing any given unitary transformation.

For a state  $|\theta\rangle$  let  $R_{|\theta\rangle} = R_\theta = I - 2|\theta\rangle\langle\theta|$  (the R stands for “reflection”). Let a *mono-product state* be a tensor product of any number of one-qubit states. When  $|\theta\rangle$  is a mono-product state we call  $R_\theta$  an  $R_\otimes$  gate. For example, an  $(n+1)$ -qubit generalized Toffoli gate equals  $R_{|1^n, -\rangle}$ , because it acts on the basis  $\{|0\rangle, |1\rangle\}^{\otimes n} \otimes \{|+\rangle, |-\rangle\}$  by multiplying  $|1^n, -\rangle$  by -1 and leaving all other states in this basis unchanged.

Consider an  $(n+1)$ -qubit mono-product state  $|\theta\rangle$ , and let  $L$  be a layer of one-qubit gates such that  $|\theta\rangle = L|1^n, -\rangle$ . Then,

$$R_\theta = I - 2|\theta\rangle\langle\theta| = I - 2L|1^n, -\rangle\langle 1^n, -|L^\dagger = L(I - 2|1^n, -\rangle\langle 1^n, -|)L^\dagger = LR_{|1^n, -\rangle}L^\dagger, \quad (1)$$

i.e.  $R_\theta$  equals the conjugation of a generalized Toffoli gate by a layer of one-qubit gates. (Fang et al. [5] observed Equation (1) in the case where  $|\theta\rangle = |1^{n+1}\rangle$  and  $L = I_n \otimes H$ .) Therefore, similarly to the above, we may add arbitrary  $R_\otimes$  gates to the set of allowed gates when defining QAC circuits.

In fact, a stronger statement holds. Let a QAC circuit be in  $R_\otimes$  normal form if it can be written as  $CL$  such that  $C$  consists only of multi-qubit  $R_\otimes$  gates and  $L$  is a layer of single-qubit gates. We will use the following in Section 5:

► **Proposition 2.1.** *Every QAC circuit computes the same unitary transformation as a circuit in  $R_\otimes$  normal form with the same topology.*

**Proof sketch.** The proof is by induction on the depth of the circuit. Let  $C = LMD$  be the circuit, where  $L$  (resp.  $M$ ) is the top layer of one-qubit (resp. multi-qubit) gates in  $C$ . Then write  $C = (LML^\dagger)(LD)$ , and apply Equation (1) and the inductive hypothesis. ◀

### 3 Reductions to and from Constructing Nekomata

In Section 3.1 we define the problems mentioned in the following theorem, and in Sections 3.1 and 3.2 we prove the second and first paragraphs of this theorem respectively:

► **Theorem 3.1.** *For all  $\varepsilon \geq 0$ , if there is a QAC circuit of size  $s$ , depth  $d$ , and number of qubits acted on  $a$  that solves the  $(1 - \varepsilon)$ -approximate  $n$ -nekomata problem, then there is a QAC circuit of size  $O(s + n)$ , depth  $4d + 3$ , and number of ancillae  $a$  that solves the  $(1 - O(\varepsilon))$ -approximate  $(n+1)$ -qubit clean parity problem.*

■ **Figure 2** A visualization of Theorem 3.1; see the theorem statement for the meaning of the arrows.

For all  $0 \leq p \leq 1$  and every non-red<sup>5</sup> arrow from a problem  $P$  to a problem  $Q$  in Figure 2, if a QAC circuit  $C$  solves  $p$ -approximate,  $n$ -qubit  $P$  then there is a QAC circuit with the same topology as  $C$  that solves  $p$ -approximate,  $n$ -qubit  $Q$ . (If  $Q$  is the nekomata problem then substitute “ $n$ -nekomata” for “ $n$ -qubit nekomata” here.) Furthermore, if this arrow is dashed then  $C$  itself solves  $p$ -approximate,  $n$ -qubit  $Q$ .

Then, using Theorem 3.1, in Section 3.3 we prove that the  $d \geq 11$  case of Corollary 1.2 follows from Theorem 1.1. It is easy to prove Corollary 1.6 assuming Theorem 1.5, and to prove Theorems 1.7(i) and 1.7(ii) assuming Theorem 1.7(iii), using reasoning similar to that in the proof of Theorem 3.1.

### 3.1 Problem Definitions and Most Reductions

We omit certain elementary parts of the proof, which may be found in the full paper. Recall that we define the *phase-dependent fidelity* of states  $|\varphi\rangle$  and  $|\psi\rangle$  to be  $1 - \|\varphi - \psi\|^2$ . This quantity is at most the fidelity of  $|\varphi\rangle$  and  $|\psi\rangle$ , because

$$|\langle\psi|\varphi\rangle|^2 \geq \left( \frac{\langle\psi|\varphi\rangle + \langle\varphi|\psi\rangle}{2} \right)^2 = \left( 1 - \frac{\|\varphi - \psi\|^2}{2} \right)^2 \geq 1 - \|\varphi - \psi\|^2. \quad (2)$$

► **Remark.** If  $\langle\varphi|\psi\rangle$  is a real number close to 1, say  $\langle\varphi|\psi\rangle = 1 - \varepsilon$ , then  $|\varphi\rangle$  and  $|\psi\rangle$  have fidelity  $1 - 2\varepsilon + \varepsilon^2$  and a nearly identical phase-dependent fidelity of  $1 - 2\varepsilon$ . On the other hand, if the phases of  $|\varphi\rangle$  and  $|\psi\rangle$  differ, then these states may have low phase-dependent fidelity even if their fidelity is close to 1.

The following two definitions are with respect to an arbitrary unitary transformation  $U$  on  $n$  qubits:

► **Problem 3.2** ( $p$ -approximate Clean  $U$ ). Construct a circuit  $C$  on at least  $n$  qubits such that for all  $n$ -qubit states  $|\phi\rangle$ , the phase-dependent fidelity of  $C|\phi, 0 \dots 0\rangle$  and  $U|\phi\rangle \otimes |0 \dots 0\rangle$  is at least  $p$ .

<sup>5</sup> Only the arrow from “nekomata” to “clean parity” is red.

► **Problem 3.3** (*p*-approximate Dirty  $U$ ). Construct a circuit  $C$  on at least  $n$  qubits such that for all  $n$ -qubit states  $|\phi\rangle$ , the first  $n$  qubits of  $C|\phi, 0 \dots 0\rangle$  measure to  $U|\phi\rangle$  with probability at least  $p$ .

Given  $n$ , recall that the unitary transformations for  $n$ -qubit parity and fanout are defined respectively by  $U_{\oplus}|b, x\rangle = |b \oplus \bigoplus_{j=1}^{n-1} x_j, x\rangle$  and  $U_F|b, x\rangle = |b, x_1 \oplus b, \dots, x_{n-1} \oplus b\rangle$  for  $b \in \{0, 1\}$ ,  $x = (x_1, \dots, x_{n-1}) \in \{0, 1\}^{n-1}$ . Define the clean and dirty versions of approximating  $n$ -qubit parity and fanout as instances of Problems 3.2 and 3.3 with respect to  $U_{\oplus}$  and  $U_F$ .

Green et al. [8] proved that  $H^{\otimes n} U_{\oplus} H^{\otimes n} = U_F$ . In the full paper we prove that if a circuit  $C$  computes  $p$ -approximate,  $n$ -qubit clean (resp. dirty) parity, then the circuit  $(H^{\otimes n} \otimes I)C(H^{\otimes n} \otimes I)$  computes  $p$ -approximate,  $n$ -qubit clean (resp. dirty) fanout.

► **Problem 3.4** (*p*-approximate Clean Restricted Fanout). Construct a circuit  $C$  on at least  $n$  qubits such that for all one-qubit states  $|\phi\rangle$ , the phase-dependent fidelity of  $C|\phi, 0^{n-1}, 0 \dots 0\rangle$  and  $U_F|\phi, 0^{n-1}\rangle \otimes |0 \dots 0\rangle$  is at least  $p$ .

► **Problem 3.5** (*p*-approximate Dirty Restricted Fanout). Construct a circuit  $C$  on at least  $n$  qubits such that for all one-qubit states  $|\phi\rangle$ , the first  $n$  qubits of  $C|\phi, 0^{n-1}, 0 \dots 0\rangle$  measure to  $U_F|\phi, 0^{n-1}\rangle$  with probability at least  $p$ .

► **Problem 3.6** (*p*-approximate Clean  $|\mathbb{B}_n\rangle$ ). Construct a circuit  $C$  on at least  $n$  qubits such that the phase-dependent fidelity of  $C|0 \dots 0\rangle$  and  $|\mathbb{B}_n, 0 \dots 0\rangle$  is at least  $p$ .

► **Problem 3.7** (*p*-approximate Dirty  $|\mathbb{B}_n\rangle$ ). Construct a circuit  $C$  on at least  $n$  qubits such that the first  $n$  qubits of  $C|0 \dots 0\rangle$  measure to  $|\mathbb{B}_n\rangle$  with probability at least  $p$ .

► **Problem 3.8** (*p*-approximate  $n$ -nekomata). Construct a circuit  $C$  such that for some  $n$ -nekomata  $|\nu\rangle$ , the fidelity of  $C|0 \dots 0\rangle$  and  $|\nu\rangle$  is at least  $p$ .

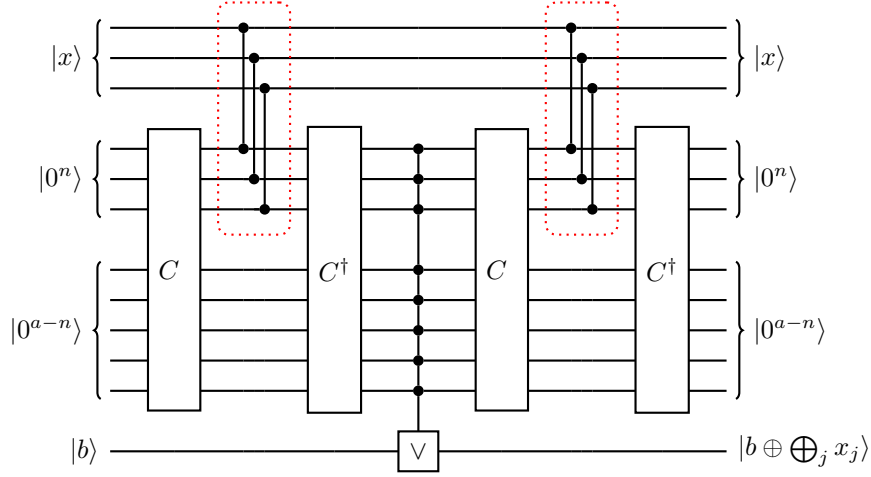

## 3.2 Reducing Clean Parity to Constructing Nekomata

Let  $C$  be a circuit on  $a$  qubits such that  $|\nu\rangle := C|0^a\rangle$  approximates an  $n$ -nekomata. A circuit for approximate  $(n+1)$ -qubit clean parity is shown in Figure 3, where the top  $n$  wires acted on by each of the  $C$  and  $C^\dagger$  subcircuits correspond to the targets of  $|\nu\rangle$ . Within each dotted rectangle is a layer of  $n$  copies of  $R_{|11\rangle}$ , the  $i$ 'th of which acts on the wires corresponding to the  $i$ 'th input qubit and the  $i$ 'th target of  $|\nu\rangle$  for  $i \in [n]$ . The gate  $R_{|11\rangle}$  is better known as a controlled  $Z$  gate, and acts as  $|xy\rangle \mapsto (-1)^{xy}|xy\rangle$  for  $x, y \in \{0, 1\}$ . In the middle of the circuit is an OR gate (recall Figure 1). The correctness of this circuit is proved in the full paper.

## 3.3 Proof of Corollary 1.2 ( $d \geq 11$ ) Assuming Theorem 1.1

► **Lemma 3.9** (essentially Green et al. [8]). *For all  $m \geq 2$  there is a quantum circuit of depth  $\lceil \log_m n \rceil$  and size at most  $n - 1$ , consisting only of restricted fanout gates of arity at most  $m$ , that computes  $n$ -qubit restricted fanout exactly using no ancillae.*

**Proof.** By linearity it suffices to consider input states of the form  $|b, 0^{n-1}\rangle$  for  $b \in \{0, 1\}$ . The proof is by induction on  $d = \lceil \log_m n \rceil$ , for a fixed value of  $m$ . Note that  $d - 1 < \log_m n \leq d$ , so  $m^{d-1} < n \leq m^d$ . If  $d = 0$  then  $n = 1$  and the identity circuit suffices. If  $d > 0$  then by induction we can map  $|b, 0^{n-1}\rangle$  to  $|b^{m^{d-1}}, 0^{n-m^{d-1}}\rangle$  in depth  $d - 1$  and size at most  $m^{d-1} - 1$ . Let  $n_1, \dots, n_{m^{d-1}} \in [m]$  be such that  $\sum_i n_i = n$ , and compute  $\bigotimes_i U_F|b, 0^{n_i-1}\rangle = |b^n\rangle$ . Since  $\bigotimes_i U_F$  has size at most  $n - m^{d-1}$  (omitting one-qubit gates), the total size of the circuit is at most  $(n - m^{d-1}) + (m^{d-1} - 1) = n - 1$ . ◀

■ **Figure 3** A circuit for parity, assuming  $C$  constructs an  $n$ -nekomata. See the surrounding text for further explanation.

Given Theorems 1.1 and 3.1 and Lemma 3.9, the proof of the  $d \geq 11$  case of Corollary 1.2 is elementary (if slightly tedious) and may be found in the full paper.

#### 4 Tight Bounds for Constructing Approximate Nekomata in “Mostly Classical” Circuits

Call a QAC circuit *purely classical* if it consists only of generalized Toffoli gates (including NOT gates, which are generalized Toffoli gates on one qubit). Call a QAC circuit *mostly classical* if it can be written as  $CL$  such that  $C$  is purely classical and  $L$  is a layer of  $R_\otimes$  gates; by Equation (1) this is equivalent to the definition from Section 1.2.4. Call a mostly classical QAC circuit *nice* if it can be written as  $CL$  in this way such that every multi-qubit gate  $R_\theta$  in  $L$  satisfies  $|\langle 0 \dots 0 | \theta \rangle|^2 \leq 1/4$ . (The niceness condition will allow us to express certain quantities as convex combinations in a convenient way, by ensuring that the coefficients in these convex combinations are between 0 and 1.) We prove the following generalizations of Theorems 1.1 and 1.4 respectively:

► **Theorem 4.1.** *For all  $2 \leq d \leq \log n$  and  $\varepsilon > 0$  there exists a nice, mostly classical, depth- $d$  QAC circuit  $C$  of size and number of qubits acted on  $\exp(O(n2^{-d} \log(n2^{-d}/\varepsilon))) + O(n)$  such that  $C|0 \dots 0\rangle$  has fidelity at least  $1 - \varepsilon$  with some  $n$ -nekomata.*

► **Theorem 4.2.** *Let  $C$  be a mostly classical circuit of size  $s$  and depth  $d$ .*

(i) *The fidelity of  $C|0 \dots 0\rangle$  and any  $n$ -nekomata is at most*

$$\frac{1}{2} + \exp\left(-\Omega\left(\frac{n/(4^d \log n)}{\max(\log s, \sqrt{n/(4^d \log n)})}\right)\right).$$

(ii) *If  $C$  is nice, then the fidelity of  $C|0 \dots 0\rangle$  and any  $n$ -nekomata is at most*

$$\frac{1}{2} + \exp\left(-\Omega\left(\frac{n/2^d}{\max(\log s, \sqrt{n/2^d})}\right)\right).$$

Theorems 4.1 and 4.2(ii) imply that for  $d \geq 2$ , the minimum size of a nice, mostly classical, depth- $d$  QAC circuit that “constructs an approximate  $n$ -nekomata” (i.e. maps  $|0 \dots 0\rangle$  to a state that has fidelity at least  $3/4$  with some  $n$ -nekomata) is between  $\exp(\Omega(n/2^d))$  and  $\exp(\tilde{O}(n/2^d)) + O(n)$ . We prove the  $d > 2$  case of Theorem 4.1 solely for the sake of comparison with Theorem 4.2(ii), as Theorem 4.1 gives a weaker upper bound than Corollary 1.2 when  $\omega(1) \leq d \leq o(\log n)$ . Theorem 4.2 makes a stronger statement about nice circuits than about non-nice circuits, since  $a/\max(\log s, \sqrt{a}) = \min(a/\log s, \sqrt{a})$  for all  $a > 0$ .

In Section 4.1 we make some general observations about mostly classical circuits and “approximate nekomata”, including observations common to the proofs of Theorems 4.1 and 4.2. In Section 4.2 we prove Theorem 4.1, and in Section 4.3 we prove Theorem 4.2(ii). We prove Theorem 4.2(i) in the full paper; its proof has a similar high-level idea to that of Theorem 4.2(ii), and is much more complicated.

## 4.1 Reduction to a Classical Sampling Problem

Collectively, the following observations reduce proving Theorems 4.1 and 4.2 to proving upper and lower bounds respectively for a certain type of sampling problem. This sampling problem can be succinctly characterized in purely classical and probabilistic terms, with only a transient reference to quantum circuits. Claims made in this subsection are proved in the full paper.

Recall that nekomata can be defined as states for which a standard-basis measurement of the targets is distributed in a certain way. The following two lemmas make similar statements about “approximate nekomata”, and are used to prove Theorems 4.1 and 4.2 respectively:

► **Lemma 4.3.** *Let  $|\varphi\rangle$  be a state with  $n$  “target” qubits that measure to all-zeros with probability exactly  $1/2$  and all-ones with probability at least  $1/2 - (2/3)\varepsilon$ . Then there exists an  $n$ -nekomata  $|\nu\rangle$  such that  $|\langle\nu|\varphi\rangle|^2 \geq 1 - \varepsilon$ .*

► **Lemma 4.4.** *Let  $|\varphi\rangle$  be a state with  $n$  “target” qubits that measure to all-zeros with probability  $p$  and all-ones with probability  $q$ . Then  $|\langle\nu|\varphi\rangle|^2 \leq 1/2 + \sqrt{\min(p, q)}$  for all  $n$ -nekomata  $|\nu\rangle$  with the same targets as  $|\varphi\rangle$ .*

Consider a mostly classical circuit, written as  $CL$  such that  $C$  is purely classical and  $L$  is a layer of  $R_{\otimes}$  gates. A standard-basis measurement of designated “target” qubits of  $CL|0 \dots 0\rangle$  is distributed identically to an appropriate marginal distribution of a standard-basis measurement of *all* qubits of  $CL|0 \dots 0\rangle$ . It is easy to see that standard-basis measurements commute with generalized Toffoli gates, so we may first measure  $L|0 \dots 0\rangle$  in the standard basis and then apply  $C$  to the result.

Finally, the following is straightforward to verify:

► **Lemma 4.5.** *Let  $(|\theta_j\rangle)_j$  be one-qubit states, and let  $p_j = |\langle 1|\theta_j\rangle|^2$  for all  $j$ . A standard-basis measurement of  $R_{\otimes_j |\theta_j\rangle}|0 \dots 0\rangle$  outputs all-zeros with probability  $\left(1 - 2\prod_j (1 - p_j)\right)^2$ , and any other boolean string  $(y_j)_j$  with probability  $4\prod_j (1 - p_j)P(\text{Bernoulli}(p_j) = y_j)$ .*

For mostly classical circuits that are nice, the following is a more convenient characterization of this distribution:

► **Corollary 4.6.** *If  $\prod_j (1 - p_j) \leq 1/4$  then the distribution from Lemma 4.5 is a convex combination of all-zeros with probability  $1 - 4\prod_j (1 - p_j)$  and  $(\text{Bernoulli}(p_j))_j$  with probability  $4\prod_j (1 - p_j)$ , where the  $\text{Bernoulli}(p_j)$  random variables are all independent.*

## 4.2 Proof of Theorem 4.1

Here we prove the depth-2 case of Theorem 4.1 (which is sufficient for all of our applications of Theorem 4.1); the generalization to depths greater than 2 is handled in the full paper.

► **Reminder** (depth-2 case of Theorem 4.1). *For all  $\varepsilon > 0$  there exists a nice, mostly classical, depth-2 QAC circuit  $C$  of size and number of qubits acted on  $\exp(O(n \log(n/\varepsilon)))$  such that  $C|0 \dots 0\rangle$  has fidelity at least  $1 - \varepsilon$  with some  $n$ -nekomata.*

**Proof.** Let  $M \in \mathbb{N}$  and  $\delta \in (0, 1)$  be parameters to be chosen later.<sup>6</sup> The circuit acts on  $n(M + 1)$  qubits, all initialized to  $|0\rangle$ , and arranged in a grid of dimensions  $n \times (M + 1)$  (Figure 4). Designate one column as the “target” column, and call the qubits in the  $M$  other columns “ancillae”. First, to each ancilla column, apply  $R_{(\sqrt{\delta}|0\rangle + \sqrt{1-\delta}|1\rangle)^{\otimes n}}$ . Second, to each row, apply an  $(M + 1)$ -qubit OR gate whose target qubit is in the target column. (A layer of OR gates is a depth-1 purely classical circuit, by the construction in Figure 1.)

All measurements described below are with respect to the state on the ancillae between the first and second layers of the above circuit. By Lemma 4.3 it suffices to choose  $M$  and  $\delta$  such that if we measure the ancillae in the standard basis, then with probability exactly  $1/2$  all of the ancillae measure to 0, and with probability at least  $1/2 - (2/3)\varepsilon$  at least one ancilla in each row measures to 1. We now choose  $\delta$  in terms of  $M$  such that the ancillae measure to all-zeros with probability  $1/2$ . By Lemma 4.5 and the independence of measurements of different columns, it suffices to ensure that  $(1 - 2\delta^n)^{2M} = 1/2$ . Choose  $\delta \in (0, (1/2)^{1/n})$  that satisfies this equation.

Let  $\varepsilon' = (2/3)\varepsilon$ . Below we will choose  $M$  such that the probability that there exists an ancilla column measuring to neither all-zeros nor all-ones is at most  $\varepsilon'$ . Equivalently, with probability at least  $1 - \varepsilon'$ , every ancilla column measures to either all-zeros or all-ones. Since the ancillae measure to all-zeros with probability  $1/2$ , it follows that with probability at least  $1/2 - \varepsilon'$ , every ancilla column measures to all-zeros or all-ones *and* at least one ancilla column measures to all-ones. Therefore the probability is at least  $1/2 - \varepsilon'$  that at least one ancilla in every row measures to 1, as desired.

By Lemma 4.5 and a union bound, the probability that there exists an ancilla column measuring to neither all-zeros nor all-ones is at most

$$M(1 - (1 - 2\delta^n)^2 - 4\delta^n(1 - \delta)^n) = 4M\delta^n(1 - \delta^n - (1 - \delta)^n) \leq 4Mn\delta^{n+1}.$$

Since  $1/2 = (1 - 2\delta^n)^{2M} \leq \exp(-4\delta^n M)$ , it follows that  $\delta^n \leq \ln(2)/4M$ , so

$$4Mn\delta^{n+1} \leq 4Mn(\ln(2)/4M)^{1+1/n} = \ln(2)n(\ln(2)/4M)^{1/n}.$$

To make this bound at most  $\varepsilon'$ , let  $M = \lceil (\ln(2)/4) \cdot (\ln(2)n/\varepsilon')^n \rceil \leq \exp(O(n \log(n/\varepsilon)))$ . Finally, the circuit is nice because  $\delta^n \leq \ln(2)/4M \leq \ln(2)/4 < 1/4$ . ◀

<sup>6</sup> Ultimately we will let  $M = \exp(\Theta(n \log(n/\varepsilon)))$  and  $\delta = \Theta(\varepsilon/n)$ .

■ **Figure 4** The layout of the circuit.

### 4.3 Proof of Theorem 4.2(ii)

We use the following concentration inequality of Gavinsky, Lovett, Saks and Srinivasan [6]:

► **Definition 4.7** ([6]). *Call a random string  $(Y_1, \dots, Y_n) \in \{0, 1\}^n$  a read- $r$  family if there exist  $m \in \mathbb{N}$ , independent random variables  $X_1, \dots, X_m$ , sets  $S_1, \dots, S_n \subseteq [m]$  such that  $|\{j \mid i \in S_j\}| \leq r$  for all  $i \in [m]$ , and functions  $f_1, \dots, f_n$  such that  $Y_j = f_j((X_i)_{i \in S_j})$  for all  $j \in [n]$ .*

► **Theorem 4.8** ([6]). *Let  $(Y_1, \dots, Y_n)$  be a read- $r$  family, and let  $\mu = \mathbb{E}\left[\sum_{j=1}^n Y_j\right]$ . Then for all  $\varepsilon \geq 0$ ,*

$$\begin{aligned} P(Y_1 + \dots + Y_n \geq \mu + \varepsilon n) &\leq \exp(-2\varepsilon^2 n/r), \\ P(Y_1 + \dots + Y_n \leq \mu - \varepsilon n) &\leq \exp(-2\varepsilon^2 n/r). \end{aligned}$$

► **Remark.** For example, if  $r = 1$  then  $Y_1, \dots, Y_n$  are all independent and so Theorem 4.8 recovers a well-known Chernoff bound for sums of independent Bernoulli random variables. Theorem 4.8 also recovers this Chernoff bound when  $n = rm$  and  $Y_j = X_{\lceil j/r \rceil}$  for all  $j$  [6].

Consider a string  $x$  of independent Bernoulli random variables. If  $G$  is a generalized Toffoli gate then  $G|x\rangle$  is a read-2 family, because for all  $i$  the  $i$ 'th bit of  $x$  can only influence the  $i$ 'th and target bits of  $G|x\rangle$ . More generally, if  $G$  is a generalized Toffoli gate and  $L_1, L_2$  are layers of NOT gates acting on subsets of the support of  $G$ , then  $L_1 G L_2 |x\rangle$  is a read-2 family. Even more generally, it follows by induction that if  $C$  is a depth- $d$  purely classical circuit then  $C|x\rangle$  is a read- $2^d$  family.

Before proving Theorem 4.2(ii), as a warmup we briefly prove the following:

► **Proposition 4.9.** *If  $C$  is a depth- $d$  purely classical circuit and  $|\phi\rangle$  is a mono-product state, then  $|\langle \nu | C | \phi \rangle|^2 \leq 1/2 + \exp(-\Omega(n/2^d))$  for all  $n$ -nekomata  $|\nu\rangle$ .*

**Proof.** Since standard-basis measurements of qubits in a mono-product state are independent, it follows from the above discussion that a standard-basis measurement of any  $n$  designated target qubits of  $C|\phi\rangle$  is a read- $2^d$  family. If the expected Hamming weight of a standard-basis measurement of the targets of  $C|\phi\rangle$  is less (resp. greater) than or equal to  $n/2$ , then Theorem 4.8 implies that the targets of  $C|\phi\rangle$  measure to all-ones (resp. all-zeros) with probability at most  $\exp(-\Omega(n/2^d))$ , and the result follows from Lemma 4.4. ◀

► **Reminder** (Theorem 4.2(ii)). *If  $C$  is a nice, mostly classical circuit of size  $s$  and depth  $d$ , then the fidelity of  $C|0 \dots 0\rangle$  and any  $n$ -nekomata is at most*

$$\frac{1}{2} + \exp\left(-\Omega\left(\frac{n/2^d}{\max(\log s, \sqrt{n/2^d})}\right)\right).$$

**Abridged proof.** Designate  $n$  qubits of  $C|0 \dots 0\rangle$  as targets, and assume without loss of generality that  $s \geq \exp(\sqrt{n/2^d})$ . We will prove that for some  $a \in \{0, 1\}$ , the targets of  $C|0 \dots 0\rangle$  measure to  $a^n$  with probability at most  $\exp(-\Omega(n2^{-d}/\log s))$ . The result then follows from Lemma 4.4.

Write  $C = D(L \otimes_{G \in \mathcal{G}} G)$  such that  $D$  is purely classical,  $L$  is a layer of single-qubit gates, and  $\mathcal{G}$  is a set of multi-qubit  $R_\otimes$  gates that each satisfy the precondition of Corollary 4.6. For all  $G \in \mathcal{G}$ , a standard-basis measurement of  $G|0 \dots 0\rangle$  is distributed identically to  $(b_G \wedge x_{G,i})_i$  for some independent Bernoulli random variables  $b_G, (x_{G,i})_i$ , where  $\mathbb{E}[b_G] = 4 \prod_i (1 - \mathbb{E}[x_{G,i}])$ . Let  $\mu_G = \sum_i \mathbb{E}[x_{G,i}]$ ; then  $\mathbb{E}[b_G] \leq 4 \exp(-\mu_G)$ .

By a union bound, the probability that there exists  $G \in \mathcal{G}$  such that  $\mu_G > 2 \ln s$  and  $b_G = 1$  is at most

$$\sum_{G: \mu_G > 2 \ln s} 4 \exp(-\mu_G) < 4s \exp(-2 \ln s) = \exp(-\Omega(\log s)) \leq \exp(-\Omega(n2^{-d}/\log s)).$$

Therefore it suffices to prove that for some  $a \in \{0, 1\}$ , the targets of  $|\varphi\rangle := D(L \otimes \bigotimes_{G: \mu_G \leq 2 \ln s} G \otimes I)|0 \dots 0\rangle$  measure to  $a^n$  with probability at most  $\exp(-\Omega(n2^{-d}/\log s))$ . Henceforth we will never refer to any gate  $G$  for which  $\mu_G > 2 \ln s$ ; phrases such as “for all  $G$ ” and “ $(\cdot)_G$ ” will implicitly quantify over only those gates  $G$  for which  $\mu_G \leq 2 \ln s$ .

Let  $b = (b_G)_G$  and  $x = (x_{G,i})_{G,i}$ . Call  $x$  “good” if  $\sum_i x_{G,i} \leq c \ln s$  for all  $G$ , where  $c > 2$  is a universal constant large enough so that  $e(2e/c)^c < 1$ . A well-known Chernoff bound states that if  $S$  is a sum of independent Bernoulli random variables, and  $\mu = \mathbb{E}[S]$ , then  $P(S > t) < (e\mu/t)^t e^{-\mu}$  for all  $t > \mu$ . Therefore, by a union bound and the fact that  $\max_G \mu_G \leq 2 \ln s$ , the probability that  $x$  fails to be good is at most

$$\sum_G (e\mu_G/c \ln s)^{c \ln s} \leq s(2e/c)^{c \ln s} = (e(2e/c)^c)^{\ln s} = e^{-\Omega(\log s)} \leq \exp(-\Omega(n2^{-d}/\log s)).$$

Let  $y$  be a string of independent Bernoulli random variables distributed identically to a standard-basis measurement of  $L|0 \dots 0\rangle$ . Call the targets of  $D|y, (b_G \wedge x_{G,i})_{G,i}, 0 \dots 0\rangle$  the “output bits”, and note that they are distributed identically to a standard-basis measurement of the targets of  $|\varphi\rangle$ . If  $b$  is fixed then the output bits are a read- $2^d$  family (as functions of the independent Bernoulli random variables in  $x$  and  $y$ ). Alternatively, if  $x$  and  $y$  are fixed and  $x$  is good then the output bits are a read- $O(2^d \log s)$  family (as functions of the independent Bernoulli random variables in  $b$ ).

The rest of the proof is given in the full paper, and involves the triangle inequality. ◀

## 5 Lower Bounds for General QAC Circuits

In Section 5.1 we prove a generalization of Theorem 1.5. The proof uses the following claim, which is proved in Section 5.2 (and is obtained as a corollary of a stronger result):

► **Corollary 5.1.** *For all  $d \geq 1$ , orthogonal projections  $Q_1, \dots, Q_d$ , and states  $|\phi\rangle$ ,*

$$\|Q_d \cdots Q_1 |\phi\rangle\| \leq \exp\left(-\frac{\langle \phi | (I - Q_d) | \phi \rangle}{2d}\right).$$

Then, using this generalization of Theorem 1.5, in Sections 5.3 and 5.4 we prove Theorem 1.7(iii).

### 5.1 Proof of Theorem 1.5

Theorem 1.5 is the case of the following in which  $\mathcal{H}_1, \dots, \mathcal{H}_n$  are single-qubit Hilbert spaces,  $|\phi\rangle$  is the all-zeros state,  $Q_j = |0\rangle\langle 0|$  for all  $j$ , and  $|\psi\rangle$  is an  $n$ -nekomata.

► **Theorem 5.2.** *There is a universal constant  $c > 0$  such that the following holds. Let  $\mathcal{H}_1, \dots, \mathcal{H}_n$  be Hilbert spaces, let  $\mathcal{H}_T = \bigotimes_{j=1}^n \mathcal{H}_j$  (for “targets”), and let  $\mathcal{H}_A$  be a Hilbert space (for “ancillae”). Let  $|\phi\rangle = |\phi_1, \dots, \phi_n, \phi_A\rangle$  for some states  $|\phi_j\rangle \in \mathcal{H}_j, j \in [n] \cup \{A\}$ . Let  $Q_j$  be an orthogonal projection on  $\mathcal{H}_j$  for  $j \in [n]$ , and let  $|\psi\rangle$  be a state in  $\mathcal{H}_T \otimes \mathcal{H}_A$  that measures to  $\bigotimes_{j=1}^n Q_j \otimes I_{\mathcal{H}_A}$  and to  $\bigotimes_{j=1}^n (I - Q_j) \otimes I_{\mathcal{H}_A}$  each with probability  $1/2$ . Let  $C$  be a depth- $d$  QAC circuit on  $\mathcal{H}_T \otimes \mathcal{H}_A$  with at most  $cn/(d+1)$  multi-qubit gates acting on  $\mathcal{H}_T$ . Then,  $|\langle \psi | C | \phi \rangle|^2 \leq 1/2 + \exp(-\Omega(n/(d+1)))$ .*

**Abridged proof.** By Proposition 2.1 we may write  $C = DL$  for some layer of single-qubit gates  $L$  and QAC circuit  $D$ , where  $D$  has the same topology as  $C$  and consists only of multi-qubit  $R_\otimes$  gates. Since  $L|\phi\rangle$  factors as a product state in the same way that  $|\phi\rangle$  does, we may assume without loss of generality that  $C$  consists only of multi-qubit  $R_\otimes$  gates, by replacing  $C$  and  $|\phi\rangle$  with  $D$  and  $L|\phi\rangle$  respectively.

We now generalize Lemma 4.4 from nekomata to states such as  $|\psi\rangle$ . Let  $Q = \bigotimes_{j=1}^n Q_j \otimes I_{\mathcal{H}_A}$  and  $Q' = \bigotimes_{j=1}^n (I - Q_j) \otimes I_{\mathcal{H}_A}$ , and let  $|\varphi\rangle = C|\phi\rangle$ . Since  $|\psi\rangle$  measures to  $Q + Q'$  with probability 1, it follows from the triangle inequality and Cauchy-Schwarz that

$$\begin{aligned} |\langle\psi|\varphi\rangle|^2 &= |\langle\psi|(Q + Q')|\varphi\rangle|^2 \leq (|\langle\psi|Q|\varphi\rangle| + |\langle\psi|Q'|\varphi\rangle|)^2 \\ &\leq (\|Q|\varphi\rangle\| \cdot \|Q|\psi\rangle\| + \|Q'|\varphi\rangle\| \cdot \|Q'|\psi\rangle\|)^2 = (\|Q|\varphi\rangle\|/\sqrt{2} + \|Q'|\varphi\rangle\|/\sqrt{2})^2 \\ &= \langle\varphi|(Q + Q')|\varphi\rangle/2 + \|Q|\varphi\rangle\| \cdot \|Q'|\varphi\rangle\| \leq 1/2 + \min(\|Q|\varphi\rangle\|, \|Q'|\varphi\rangle\|), \end{aligned}$$

so it suffices to prove that  $\min(\|Q|\varphi\rangle\|, \|Q'|\varphi\rangle\|) \leq \exp(-\Omega(n/(d+1)))$ .

Since  $\sum_{j=1}^n \langle\phi_j|Q_j|\phi_j\rangle + \sum_{j=1}^n \langle\phi_j|(I - Q_j)|\phi_j\rangle = n$ , either  $\sum_{j=1}^n \langle\phi_j|Q_j|\phi_j\rangle \geq n/2$  or  $\sum_{j=1}^n \langle\phi_j|(I - Q_j)|\phi_j\rangle \geq n/2$ . Assume without loss of generality that  $\sum_{j=1}^n \langle\phi_j|(I - Q_j)|\phi_j\rangle \geq n/2$ . We will prove that  $\|Q|\varphi\rangle\| \leq \exp(-\Omega(n/(d+1)))$ .

Let  $\mathcal{G}$  be the set of gates in  $C$ , ordered such that  $C = \prod_{G \in \mathcal{G}} G$  (where each gate  $G$  is implicitly tensored with the identity). Also let  $\mathcal{G}_T \subseteq \mathcal{G}$  be the set of gates in  $C$  that act on  $\mathcal{H}_T$ . For  $G \in \mathcal{G}_T$  let  $|\theta_G\rangle$  be the mono-product state, specified up to a phase factor, such that  $G = R_{\theta_G} = I - 2|\theta_G\rangle\langle\theta_G|$ . Let  $F$  be the set of functions with domain  $\mathcal{G}$  that map each gate  $G$  in  $\mathcal{G}_T$  to either  $I$  or  $|\theta_G\rangle\langle\theta_G|$ , and map each gate  $G$  in  $\mathcal{G} \setminus \mathcal{G}_T$  to  $G$  itself. Then  $C = \sum_{f \in F} (-2)^{|\{G: f(G)=|\theta_G\rangle\langle\theta_G|\}|} \prod_{G \in \mathcal{G}} f(G)$ , so by the triangle inequality,

$$\|Q|\varphi\rangle\| = \|QC|\phi\rangle\| \leq \sum_{f \in F} 2^{|\{G: f(G)=|\theta_G\rangle\langle\theta_G|\}|} \cdot \max_{f \in F} \left\| Q \prod_{G \in \mathcal{G}} f(G) \cdot |\phi\rangle \right\|.$$

By assumption,  $|\mathcal{G}_T| \leq cn/(d+1)$  (for a constant  $c$  to be specified later), so

$$\sum_{f \in F} 2^{|\{G: f(G)=|\theta_G\rangle\langle\theta_G|\}|} = \sum_{S \subseteq \mathcal{G}_T} 2^{|S|} = \prod_{G \in \mathcal{G}_T} (2^0 + 2^1) = 3^{|\mathcal{G}_T|} \leq 3^{cn/(d+1)}.$$

Consider an arbitrary function  $f \in F$ . In the full paper we write  $\|Q \prod_{G \in \mathcal{G}} f(G) \cdot |\phi\rangle\|$  as a product of  $n+1$  terms, one of which we bound by 1, and the other  $n$  of which we bound individually using Corollary 5.1. The result is that

$$\left\| Q \prod_{G \in \mathcal{G}} f(G) \cdot |\phi\rangle \right\| \leq \prod_{j=1}^n \exp\left(-\frac{\langle\phi_j|(I - Q_j)|\phi_j\rangle}{2(d+1)}\right) \leq \exp\left(-\frac{n/2}{2(d+1)}\right).$$

Altogether this implies that  $\|Q|\varphi\rangle\| \leq \exp((c \ln 3 - 1/4) \cdot n/(d+1))$ , and the result follows by taking  $c < 1/(4 \ln 3)$ .  $\blacktriangleleft$

## 5.2 Proof of Corollary 5.1

Let  $\Delta(|\alpha\rangle, |\beta\rangle) = \arccos |\langle\alpha|\beta\rangle|$ ; we will abbreviate this as  $\Delta(\alpha, \beta)$ . In the full paper we prove the following:

► **Lemma 5.3.** *The function  $\Delta$  satisfies the triangle inequality, i.e.  $\Delta(\alpha, \gamma) \leq \Delta(\alpha, \beta) + \Delta(\beta, \gamma)$  for all states  $|\alpha\rangle, |\beta\rangle, |\gamma\rangle$ .*

► **Remark.** For intuition as to why Lemma 5.3 is true, consider the similarly defined function  $\Delta'(u, v) = \arccos\langle u, v \rangle$  for unit vectors  $u, v \in \mathbb{R}^3$ , where  $\langle \cdot, \cdot \rangle$  denotes the usual inner product on  $\mathbb{R}^3$ . It is well known that  $\Delta'(u, v)$  equals the angle between  $u$  and  $v$ , which equals the length of the arc (Figure 5) formed by traversing a great circle on the unit sphere from  $u$  to  $v$  in the shorter of the two directions. This arc is known to be the shortest path on the unit sphere between  $u$  and  $v$ , so  $\Delta'$  represents distance on the unit sphere. See the full paper for more related discussion.

► **Proposition 5.4.** For all  $d \geq 1$ , nonzero orthogonal projections  $Q_d$ , and states  $|\phi\rangle$ ,

$$\max_{Q_1, \dots, Q_{d-1}} \|Q_d Q_{d-1} \cdots Q_1 |\phi\rangle\| = \cos\left(\frac{\arccos \|Q_d |\phi\rangle\|}{d}\right)^d,$$

where the maximum is taken over all orthogonal projections  $Q_1, \dots, Q_{d-1}$ .

**Abridged proof.** We first prove an analogous statement about rank-1 orthogonal projections, specifically that for all states  $|\theta_0\rangle$  and  $|\theta_d\rangle$ ,

$$\max_{|\theta_1\rangle, \dots, |\theta_{d-1}\rangle} \left| \prod_{j=1}^d \langle \theta_{j-1} | \theta_j \rangle \right| = \cos\left(\frac{\arccos |\langle \theta_0 | \theta_d \rangle|}{d}\right)^d. \quad (3)$$

Then, in the full paper, we prove that the original proposition follows from this rank-1 analogue.

On the image of  $\Delta$ , i.e. on the interval  $[0, \pi/2]$ , the cosine function is decreasing and concave. Therefore for all states  $|\theta_1\rangle, \dots, |\theta_{d-1}\rangle$ , by the AM-GM inequality, Jensen's inequality, and Lemma 5.3,

$$\begin{aligned} \left| \prod_{j=1}^d \langle \theta_{j-1} | \theta_j \rangle \right|^{1/d} &\leq \frac{1}{d} \sum_{j=1}^d |\langle \theta_{j-1} | \theta_j \rangle| = \frac{1}{d} \sum_{j=1}^d \cos \Delta(\theta_{j-1}, \theta_j) \leq \cos\left(\frac{1}{d} \sum_{j=1}^d \Delta(\theta_{j-1}, \theta_j)\right) \\ &\leq \cos\left(\frac{\Delta(\theta_0, \theta_d)}{d}\right) = \cos\left(\frac{\arccos |\langle \theta_0 | \theta_d \rangle|}{d}\right). \end{aligned}$$

In the full paper we give an example (Figure 6) which shows that this bound is tight. ◀

► **Reminder (Corollary 5.1).** For all  $d \geq 1$ , orthogonal projections  $Q_1, \dots, Q_d$ , and states  $|\phi\rangle$ ,

$$\|Q_d \cdots Q_1 |\phi\rangle\| \leq \exp\left(-\frac{\langle \phi | (I - Q_d) | \phi \rangle}{2d}\right).$$

**Proof sketch.** The case  $Q_d = 0$  is trivial. The case  $Q_d \neq 0$  is handled using Proposition 5.4 and the Lagrange remainder theorem. ◀

■ **Figure 5** A geodesic on the sphere.

■ **Figure 6** An optimal choice of  $|\theta_1\rangle, \dots, |\theta_{d-1}\rangle$  in the  $d = 4$  case of Equation (3).

### 5.3 Simplifying Depth-2 QAC Circuits by Measuring Ancillae

For a one-qubit state  $|\psi\rangle$ , let the  $|\psi\rangle$  basis be an orthonormal basis of  $\mathbb{C}^2$  that includes  $|\psi\rangle$ . (We refer to “the”  $|\psi\rangle$  basis because, up to a phase factor, there is a unique state orthogonal to  $|\psi\rangle$ .)

► **Lemma 5.5.** *Let  $\mathcal{H}_1$  be a one-qubit Hilbert space, and let  $\mathcal{H}_2$  and  $\mathcal{H}_3$  be Hilbert spaces on arbitrary numbers of qubits. Then for all  $|\psi\rangle \in \mathcal{H}_1$ ,  $|\theta\rangle \in \mathcal{H}_2$ ,  $|\phi\rangle \in \mathcal{H}_1 \otimes \mathcal{H}_2 \otimes \mathcal{H}_3$ , the following two procedures generate identically distributed random states in  $\mathcal{H}_1 \otimes \mathcal{H}_2 \otimes \mathcal{H}_3$ :*

- *measure the  $\mathcal{H}_1$  qubit of  $(R_{|\psi,\theta\rangle} \otimes I_{\mathcal{H}_3})|\phi\rangle$  in the  $|\psi\rangle$  basis;*
- *measure the  $\mathcal{H}_1$  qubit of  $|\phi\rangle$  in the  $|\psi\rangle$  basis, and then, conditioned on the outcome being  $|\psi\rangle$ , apply  $R_\theta$  on  $\mathcal{H}_2$ .*

**Proof.** This follows easily from the fact that  $R_{|\psi,\theta\rangle} = (I - |\psi\rangle\langle\psi|) \otimes I + |\psi\rangle\langle\psi| \otimes R_\theta$ . ◀

Theorem 1.7(iii) is clearly equivalent to the statement that if  $C$  is a depth-2 QAC circuit, then any  $n$  designated “target” qubits of  $C|0 \dots 0\rangle$  measure to  $|\otimes_n\rangle$  with probability at most  $1/2 + \exp(-\Omega(n))$ . The following is the starting point for our proof:

► **Proposition 5.6.** *Let  $p$  and  $|\psi\rangle$  be such that for some depth-2 QAC circuit  $C$ , designated “target” qubits of  $C|0 \dots 0\rangle$  measure to  $|\psi\rangle$  with probability  $p$ . Then there exist layers of  $R_\otimes$  gates  $L_2, L_1$  and a mono-product state  $|\phi\rangle$  such that for some partition of the qubits of  $L_2 L_1 |\phi\rangle$  into “targets” and “ancillae”,*

- (i) *the targets of  $L_2 L_1 |\phi\rangle$  measure to  $|\psi\rangle$  with probability at least  $p$ ;*
- (ii) *for all  $k \in \{1, 2\}$ , every ancilla is acted on by a gate in  $L_k$ , and every gate in  $L_k$  acts on at least one target.*

► **Remark.** Although not necessary for our purposes, using Proposition 2.1 it is easy to generalize the following argument to show that the gates in  $L_2$  and  $L_1$  may be assumed to be multi-qubit gates.

**Proof sketch.** By Proposition 2.1 there exist  $L_2, L_1, |\phi\rangle$  satisfying (i) but not necessarily (ii). We measure selected ancillae in an appropriate product basis; doing so simplifies the circuit due to Lemma 5.5, and in expectation does not change the probability that the targets measure to  $|\psi\rangle$ . ◀

### 5.4 Proof of Theorem 1.7(iii)

The  $\delta = 1$  case of the following is Markov’s inequality:

► **Lemma 5.7.** *Let  $0 < \delta \leq 1$ , let  $a > 0$ , and let  $X$  be a nonnegative random variable. Then there exists  $t \in [a, ae^{\delta^{-1}-1}]$  such that  $P(X \geq t) \leq \delta \mathbb{E}[X]/t$ .*

► **Remark.** The intuition behind our use of Lemma 5.7 is as follows. Theorem 5.2 implies that depth-2 QAC circuits require size at least  $\Omega(n)$  to approximately construct  $|\otimes_n, \psi\rangle$ , and Proposition 5.6 implies that depth-2 QAC circuits that approximately construct  $|\otimes_n, \psi\rangle$  have size at most  $2n$  without loss of generality, so these bounds are “just a constant factor” away from implying that depth-2 QAC circuits of arbitrary size cannot approximately construct  $|\otimes_n, \psi\rangle$ . This is analogous to how Markov’s inequality is “just a factor of  $\delta$ ” away from the conclusion of Lemma 5.7.

**Proof sketch.** Assume the contrary, write  $\mathbb{E}[X] = \int_0^\infty P(X \geq t) dt$ , and obtain the contradiction  $\mathbb{E}[X] > \mathbb{E}[X]$  using the assumed lower bound on  $P(X \geq t)$ . ◀

► **Theorem 5.8** (Turán’s theorem<sup>7</sup>). *Let  $\mathcal{G}$  be a simple undirected graph on  $n$  vertices, and let  $d$  be the average degree of the vertices in  $\mathcal{G}$ . Then  $\mathcal{G}$  contains an independent set of size at least  $n/(d+1)$ .*

In the full paper, we repeat the proof of Theorem 5.8 exposited by Alon and Spencer [1].

► **Remark.** For the intuition behind our use of Theorem 5.8, recall the discussion of disjoint light cones from Section 1.2.7.

Recall that  $|\phi\rangle, C, |\psi\rangle, (Q_j)_j$  are variables from the statement of Theorem 5.2. In upcoming applications of Theorem 5.2 we will refer to  $|\phi\rangle$  as the “input state”,  $C$  as the “circuit”,  $|\psi\rangle$  as the “desired output state”, and  $(Q_j)_j$  as “projections”.

► **Remark.** We will not actually use the full strength of Theorem 5.2, in the sense that we will always upper-bound the number of multi-qubit gates acting on the targets by upper-bounding the *total* number of gates. One could instead use the full strength of Theorem 5.2 in this regard, and forgo the use of Proposition 5.6 entirely by measuring selected ancillae all at once later in the proof, but we consider the current presentation to be simpler.

► **Reminder** (Theorem 1.7(iii), paraphrased). *If  $C$  is a depth-2 QAC circuit, then any  $n$  designated “target” qubits of  $C|0\dots 0\rangle$  measure to  $|\boxtimes_n\rangle$  with probability at most  $1/2 + \exp(-\Omega(n))$ .*

**Abridged proof.** Let  $L_2, L_1$  be layers of  $R_\otimes$  gates and let  $|\phi\rangle$  be a mono-product state, with  $n$  qubits designated as targets and all other qubits designated as ancillae. Assume that for all  $k \in \{1, 2\}$ , every ancilla is acted on by a gate in  $L_k$ , and every gate in  $L_k$  acts on at least one target. By Proposition 5.6 it suffices to prove that the targets of  $L_2 L_1 |\phi\rangle$  measure to  $|\boxtimes_n\rangle$  with probability at most  $1/2 + \exp(-\Omega(n))$ .

Let  $c$  be the constant from Theorem 5.2, and let  $\gamma = (c/2)(c/3)/(1+c/2)$  and  $\delta = (c/2)\gamma^2$ . Since Theorem 5.2 remains true if  $c$  is replaced by any constant between 0 and  $c$ , we may take  $c$  to be small enough so that  $\gamma, \delta \leq 1$ .

For a circuit  $C$  let  $|C|$  denote the number of gates in  $C$ , and write “ $G \in C$ ” to denote that  $G$  is a gate in  $C$ . First consider the case where  $|L_2| \leq \gamma n$ . It suffices to prove that  $L_2 L_1 |\phi\rangle$  and  $|\boxtimes_n, \psi\rangle$  have fidelity at most  $1/2 + \exp(-\Omega(n))$  for all states  $|\psi\rangle$ . If  $|L_1| \leq n(c/3)/(1+c/2)$  then  $|L_1| + |L_2| \leq (c/3)n$ , and the result follows from applying Theorem 5.2 with input state  $|\phi\rangle$ , circuit  $L_2 L_1$ , desired output state  $|\boxtimes_n, \psi\rangle$ , and  $n$  one-qubit projections  $|0\rangle\langle 0|$  acting on the targets. Alternatively, if  $|L_1| \geq n(c/3)/(1+c/2)$  then  $|L_2| \leq (c/2)|L_1|$ , and the result follows from applying Theorem 5.2 with input state  $L_1 |\phi\rangle$ , circuit  $L_2$ , desired output state  $|\boxtimes_n, \psi\rangle$ , and for every gate  $G \in L_1$  the projection  $|0\rangle\langle 0| \otimes I$  on the support of  $G$ , where  $|0\rangle\langle 0|$  acts on one of the targets acted on by  $G$ . (Here we used the fact that  $1/2 + \exp(-\Omega(|L_1|)) \leq 1/2 + \exp(-\Omega(n))$  by our assumption about  $|L_1|$ .)

The rest of the proof, i.e. the analysis of the case where  $|L_2| \geq \gamma n$ , is given in the full paper, and is a (relatively complicated) application of previously discussed ideas. ◀

<sup>7</sup> Usually Turán’s theorem is phrased as saying that dense graphs have large cliques, whereas Theorem 5.8 says that sparse graphs have large independent sets. These statements are equivalent, because taking the complement of a graph turns cliques into independent sets and vice versa.

## Abstract

A binary code  $\text{Enc} : \{0, 1\}^k \rightarrow \{0, 1\}^n$  is  $(\frac{1}{2} - \epsilon, L)$ -list decodable if for every  $w \in \{0, 1\}^n$ , there exists a set  $\text{List}(w)$  of size at most  $L$ , containing all messages  $m \in \{0, 1\}^k$  such that the relative Hamming distance between  $\text{Enc}(m)$  and  $w$  is at most  $\frac{1}{2} - \epsilon$ . A  $q$ -query local list-decoder for  $\text{Enc}$  is a randomized procedure  $\text{Dec}$  that when given oracle access to a string  $w$ , makes at most  $q$  oracle calls, and for every message  $m \in \text{List}(w)$ , with high probability, there exists  $j \in [L]$  such that for every  $i \in [k]$ , with high probability,  $\text{Dec}^w(i, j) = m_i$ .

We prove lower bounds on  $q$ , that apply even if  $L$  is huge (say  $L = 2^{k^{0.9}}$ ) and the rate of  $\text{Enc}$  is small (meaning that  $n \geq 2^k$ ):

- For  $\epsilon = 1/k^\nu$  for some constant  $0 < \nu < 1$ , we prove a lower bound of  $q = \Omega(\frac{\log(1/\delta)}{\epsilon^2})$ , where  $\delta$  is the error probability of the local list-decoder. This bound is tight as there is a matching upper bound by Goldreich and Levin (STOC 1989) of  $q = O(\frac{\log(1/\delta)}{\epsilon^2})$  for the Hadamard code (which has  $n = 2^k$ ). This bound extends an earlier work of Grinberg, Shaltiel and Viola (FOCS 2018) which only works if  $n \leq 2^{k^\nu}$  and the number of coins tossed by  $\text{Dec}$  is small (and therefore does not apply to the Hadamard code, or other codes with low rate).
- For smaller  $\epsilon$ , we prove a lower bound of roughly  $q = \Omega(\frac{1}{\sqrt{\epsilon}})$ . To the best of our knowledge, this is the first lower bound on the number of queries of local list-decoders that gives  $q \geq k$  for small  $\epsilon$ .

Local list-decoders with small  $\epsilon$  form the key component in the celebrated theorem of Goldreich and Levin that extracts a *hard-core predicate* from a one-way function. We show that black-box proofs *cannot* improve the Goldreich-Levin theorem and produce a hard-core predicate that is hard to predict with probability  $\frac{1}{2} + \frac{1}{\ell^{\omega(1)}}$  when provided with a one-way function  $f : \{0, 1\}^\ell \rightarrow \{0, 1\}^\ell$ , where  $f$  is such that circuits of size  $\text{poly}(\ell)$  cannot invert  $f$  with probability  $\rho = 1/2^{\sqrt{\ell}}$  (or even  $\rho = 1/2^{\Omega(\ell)}$ ). This limitation applies to any proof by black-box reduction (even if the reduction is allowed to use nonuniformity and has oracle access to  $f$ ).

## 1 Introduction

We prove limitations on local list-decoding algorithms and on reductions establishing hard-core predicates.

### 1.1 Locally list-decodable codes

List-decodable codes are a natural extension of (uniquely decodable) error-correcting codes, as it allows (list) decoding for error regimes where unique decoding is impossible. This is an extensively studied area; see [8] for a survey. In this paper, we will be interested in list-decoding of binary codes.

► **Definition 1** (List-decodable code). *For a function  $\text{Enc} : \{0, 1\}^k \rightarrow \{0, 1\}^n$ , and  $w \in \{0, 1\}^n$ , we define*

$$\text{List}_\alpha^{\text{Enc}}(w) = \{m \in \{0, 1\}^k : \text{dist}(\text{Enc}(m), w) \leq \alpha\}.$$
<sup>1</sup>

*We say that  $\text{Enc}$  is  $(\alpha, L)$ -list-decodable if for every  $w \in \{0, 1\}^n$ ,  $|\text{List}_\alpha^{\text{Enc}}(w)| \leq L$ .*

The task of *algorithmic* list-decoding is to produce the list  $\text{List}_\alpha^{\text{Enc}}(w)$  on input  $w \in \{0, 1\}^n$ .

*Local* unique decoding algorithms are algorithms that given an index  $i \in [k]$ , make few oracle queries to  $w$ , and reproduce the bit  $m_i$  (with high probability over the choice of their random coins), where  $m$  denotes the unique codeword close to  $w$ . This notion of *local decoding* has many connections and applications in computer science and mathematics [18].

We will be interested in *local* list-decoding algorithms that receive oracle access to a received word  $w \in \{0, 1\}^n$ , as well as inputs  $i \in [k]$  and  $j \in [L]$ . We will require that for every  $m \in \text{List}_\alpha^{\text{Enc}}(w)$ , with high probability, there exists a  $j \in [L]$  such that for every  $i \in [k]$ , when Dec receives oracle access to  $w$  and inputs  $i, j$ , it produces  $m_i$  with high probability over its choice of random coins. This motivates the next definition.

► **Definition 2** (Randomized local computation). *We say that a procedure  $P(i, r)$  locally computes a string  $m \in \{0, 1\}^k$  with error  $\delta$ , if for every  $i \in [k]$ ,  $\Pr[P(i, R) = m_i] \geq 1 - \delta$  (where the probability is over a uniform choice of the “string of random coins”  $R$ ).*

The definition of local list-decoders considers an algorithmic scenario that works in two steps:

- At the first step (which can be thought of as a preprocessing step) the local list-decoder Dec is given oracle access to  $w$  and an index  $j \in [L]$ . It tosses random coins (which we denote by  $r^{\text{shared}}$ ).
- At the second step, the decoder receives the additional index  $i \in [k]$ , and tosses additional coins  $r$ .

<sup>1</sup> For two strings  $x, y \in \{0, 1\}^n$  we use  $\text{dist}(x, y)$  to denote the relative Hamming distance between  $x$  and  $y$ , namely,  $\text{dist}(x, y) = |\{i \in [n] : x_i \neq y_i\}|/n$ .

- It is required that for every  $w \in \{0, 1\}^n$  and  $m \in \text{List}_\alpha^{\text{Enc}}(w)$ , with probability  $2/3$  over the choice of the shared coins  $r^{\text{shared}}$ , there exists  $j \in [L]$  such that when the local list-decoder receives  $j$ , it locally computes  $m$  (using its “non-shared” coins  $r$ ). The definition uses two types of random coins because the coins  $r^{\text{shared}}$  are “shared” between different choices of  $i \in [k]$  and allow different  $i$ ’s to “coordinate”. The coins  $r$ , are chosen independently for different choices of  $i \in [k]$ .

This is formally stated in the next definition.

► **Definition 3** (Local list-decoder). *Let  $\text{Enc} : \{0, 1\}^k \rightarrow \{0, 1\}^n$  be a function. An  $(\alpha, L, q, \delta)$ -local list-decoder (LLD) for  $\text{Enc}$  is an oracle procedure  $\text{Dec}^{(\cdot)}$  that receives oracle access to a word  $w \in \{0, 1\}^n$ , and makes at most  $q$  calls to the oracle. The procedure  $\text{Dec}$  also receives inputs:*

- $i \in [k]$  : The index of the symbol that it needs to decode.
- $j \in [L]$  : An index to the list.
- Two strings  $r^{\text{shared}}, r$  that are used as random coins.

*It is required that for every  $w \in \{0, 1\}^n$ , and for every  $m \in \text{List}_\alpha^{\text{Enc}}(w)$ , with probability at least  $2/3$  over choosing a uniform string  $r^{\text{shared}}$ , there exists  $j \in [L]$  such that the procedure*

$$P_{w,j,r^{\text{shared}}}(i, r) = \text{Dec}^w(i, j, r^{\text{shared}}, r)$$

*locally computes  $m$  with error  $\delta$ . If we omit  $\delta$ , then we mean  $\delta = 1/3$ .*

► **Remark 4** (On the generality of Definition 3). The goal of this paper is to prove lower bounds on local list-decoders, and so, making local list-decoders as general as possible, makes our results stronger. We now comment on the generality of Definition 3.

- In Definition 3 we do not require that  $L = |\text{List}_\alpha^{\text{Enc}}(w)|$ , and allow the local list-decoder to use a larger  $L$ . This means that on a given  $w$ , there may be many choices of  $j \in [L]$  such that the procedure  $P_{w,j,r^{\text{shared}}}(i, r) = \text{Dec}^w(i, j, r^{\text{shared}}, r)$  locally computes messages  $m \notin \text{List}_\alpha^{\text{Enc}}(w)$ .
- In Definition 3 we do not place any restriction on the number of random coins used by the local list-decoder, making the task of local list-decoding easier.
- We allow  $\text{Dec}$  to make *adaptive* queries to its oracle.
- We are only interested in the total number of queries made by the combination of the two steps. It should be noted that w.l.o.g., a local list-decoder can defer all its queries to the second step (namely, after it receives the input  $i$ ), and so, this definition captures local list-decoding algorithms which make queries to the oracle at both steps.
- To the best of our knowledge, all known local list-decoders in the literature are of the form presented in Definition 3.

### 1.1.1 Lower bounds on the query complexity of local list-decoders

In this paper we prove lower bounds on the number of queries  $q$  of  $(\frac{1}{2} - \epsilon, L, q, \delta)$ -local list-decoders. Our goal is to show that the number of queries  $q$  has to be large, when  $\epsilon$  is *small*. Our lower bounds apply even if the size of the list  $L$  is huge and approaches  $2^k$  (note that a local list-decoder can trivially achieve  $L = 2^k$  with a list of all messages). Our lower bounds also apply even if the rate of the code is very small, and  $n \geq 2^k$ .

We remark that this parameter regime is very different than the one studied in lower bounds on the number of queries of local decoders for *uniquely* decodable codes (that is, for  $L = 1$ ). By the Plotkin bound, uniquely decodable codes cannot have  $\epsilon < \frac{1}{4}$ , and so, the main focus in uniquely decodable codes is to show that local decoders for codes with “good rate” and “large”  $\epsilon = \Omega(1)$ , must make many queries. In contrast, we are interested in the case where  $\epsilon$  is small, and want to prove lower bounds that apply to huge lists and small rate.

### Lower bounds for large $\epsilon$

Our first result is a tight lower bound of  $q = \Omega(\frac{\log(1/\delta)}{\epsilon^2})$  on the number of queries, assuming  $\epsilon$  is sufficiently large, namely  $\epsilon \geq \frac{1}{k^\nu}$  for some constant  $0 < \nu \leq 1$ .

► **Theorem 5** (Tight lower bounds for large  $\epsilon$ ). *There exists a universal constant  $\nu > 0$  such that for any  $L \leq 2^{k^{0.9}}$ ,  $\epsilon \in (k^{-\nu}, \frac{1}{4})$ , and  $\delta \in (k^{-\nu}, \frac{1}{3})$ , we have that every  $(\frac{1}{2} - \epsilon, L, q, \delta)$ -local list-decoder for  $\text{Enc} : \{0, 1\}^k \rightarrow \{0, 1\}^n$  must have  $q = \Omega(\frac{\log(1/\delta)}{\epsilon^2})$ .*

Theorem 5 is tight in the sense that the Hadamard code (which has length  $n = 2^k$ ) has  $(\frac{1}{2} - \epsilon, L = O(1/\epsilon^2), q = O(\frac{\log(1/\delta)}{\epsilon^2}), \delta)$  local list-decoders [6]. In fact, the Hadamard code was the motivation for this research, and is a running example in this paper.

Our results show that even if we allow list sizes  $L$  which approach  $2^k$ , it is impossible to reduce the number of queries for the Hadamard code. Our results also show that even if we are willing to allow very small rate  $n \geq 2^k$ , and huge list sizes, it is impossible to have codes whose local list-decoders make fewer queries than the local list-decoders for the Hadamard code.

### Comparison to previous work

Theorem 5 improves and extends an earlier work by Grinberg, Shaltiel and Viola [7] that gave the same bound of  $q = \Omega(\frac{\log(1/\delta)}{\epsilon^2})$  for a more limited parameter regime: Specifically, in [7], for the lower bound to hold, it is also required that  $n \leq 2^{k^\nu}$ , for some constant  $\nu > 0$ , and that the total number of coins tossed by the local list-decoder is less than  $k^\nu - \log L$ .<sup>2</sup> We stress that because of these two limitations, the lower bounds of [7] do not apply to the Hadamard code and other low rate codes.

### Extensions to large alphabet and erasures

The scenario that we consider in Theorem 5 has *binary* alphabet, and decoding from *errors*. We remark that in the case of large alphabets, or decoding from erasures, there are local list-decoders which achieve  $q = O(\frac{\log(1/\delta)}{\epsilon})$  (which is smaller than what is possible for binary alphabet and decoding from errors), as was shown for the case of Hadamard codes in [11]. Our results extend to give a matching lower bound of  $q = \Omega(\frac{\log(1/\delta)}{\epsilon})$  for decoding from erasures (for any alphabet size), and also the same lower bound on decoding from errors for any alphabet size. The exact details are deferred to the final version.

### Lower bounds for small $\epsilon$

The best bound on  $q$  that Theorem 5 (as well as the aforementioned lower bounds of [7]) can give is  $q \geq k^{\Omega(1)}$ . The next theorem shows that even for small  $\epsilon < 1/k$ , we can obtain a lower bound on  $q$  which is polynomial in  $1/\epsilon$ .

► **Theorem 6** (Lower bounds for small  $\epsilon$ ). *There exist universal constants  $\beta, c_1, c_2 > 0$  such that for every  $L \leq \beta \cdot 2^k$ ,  $\delta < \frac{1}{3}$  and  $\epsilon \geq \frac{\beta}{\sqrt{n}}$  we have that every  $(\frac{1}{2} - \epsilon, L, q, \delta)$ -local list-decoder for  $\text{Enc} : \{0, 1\}^k \rightarrow \{0, 1\}^n$  must have  $q \geq \frac{1}{c_1 \log(k) \cdot \sqrt{\epsilon}} - c_2 \log L$ .*

<sup>2</sup> The work of [7] is concerned with proving lower bounds on the number of queries of “nonuniform reductions for hardness amplification” [17, 15, 3, 7]. As explained in [17, 15, 3, 7] such lower bounds translate into lower bounds on local list-decoders, by “trading” the random coins of a local list-decoder for “nonuniform advice” for the reduction, and proving a lower bound on the number of queries made by the reduction.

Note that for sufficiently small  $\epsilon = 1/(\log k)^{\omega(1)}$ , we get  $q = \Omega(\frac{1}{\epsilon^{1/2-o(1)}})$ . It follows that together, Theorems 5 and Theorem 6 give a lower bound of  $q = \Omega(\frac{1}{\epsilon^{1/2-o(1)}})$  that applies to every choice of  $\epsilon \geq \Omega(\frac{1}{\sqrt{n}})$ . To the best of our knowledge, Theorem 6 is the first lower bound on local list-decoders that is able to prove a lower bound of  $q \geq k$  (and note that this is what we should expect when  $\epsilon < \frac{1}{k}$ ). We also remark that the requirement that  $\epsilon$  is not too small compared to  $n$  (as is made in Theorem 6) is required (as we cannot prove lower bounds on the number of queries in case  $\epsilon < \frac{1}{n}$ ).

Goldreich and Levin [6] showed that locally list-decodable codes with small  $\epsilon < 1/k$  can be used to give constructions of hard-core predicates. We explain this connection in the next section.

## 1.2 Hard-core predicates

The celebrated Goldreich-Levin theorem [6] considers the following scenario: There is a computational task where the required output is *non-Boolean* and is hard to compute on average. We would like to obtain a *hard-core predicate*, which is a *Boolean* value that is hard to compute on average.

The Goldreich-Levin theorem gives a solution to this problem, and in retrospect, the theorem can also be viewed as a  $(\frac{1}{2} - \epsilon, L^{\text{Had}} = O(\frac{1}{\epsilon^2}), q^{\text{Had}} = O(\frac{k}{\epsilon^2}), \delta = \frac{1}{2k})$ -local list-decoder for the Hadamard code, defined by:  $\text{Enc}^{\text{Had}} : \{0, 1\}^k \rightarrow \{0, 1\}^{n=2^k}$ , where for every  $r \in \{0, 1\}^k$ ,

$$\text{Enc}^{\text{Had}}(x)_r = \left( \sum_{i \in [k]} x_i \cdot r_i \right) \bmod 2.$$

In retrospect, the Goldreich-Levin theorem can also be seen as showing that *any* locally list-decodable code with suitable parameters can be used to produce hard-core predicates.

We consider two scenarios for the Goldreich-Levin theorem depending on whether we want to extract a hard-core bit from a function  $g : \{0, 1\}^\ell \rightarrow \{0, 1\}^\ell$  that is *hard to compute* on a random input, or to extract a hard-core bit from a one-way function  $f : \{0, 1\}^\ell \rightarrow \{0, 1\}^\ell$  that is *hard to invert* on a random output.

### 1.2.1 Functions that are hard to compute

Here the goal is to transform a *non-Boolean function*  $g$  that is hard to compute on a random input, into a *predicate*  $g^{\text{pred}}$  that is hard to compute on a random input. More precisely:

- *Assumption:* There is a non-Boolean function that is hard to compute with probability  $\rho$ . Namely, a function  $g : \{0, 1\}^\ell \rightarrow \{0, 1\}^\ell$  such that for every circuit  $C$  of size  $s$ ,

$$\Pr_{x \leftarrow U_\ell} [C(x) = g(x)] \leq \rho.^3$$

- *Conclusion:* There is a predicate  $g^{\text{pred}} : \{0, 1\}^{\ell'} \rightarrow \{0, 1\}$  that is hard to compute with probability  $\frac{1}{2} + \epsilon$ .

Namely, for every circuit  $C'$  of size  $s'$ ,

$$\Pr_{x \leftarrow U_{\ell'}} [C'(x) = g^{\text{pred}}(x)] \leq \frac{1}{2} + \epsilon.$$

<sup>3</sup> We use  $U_\ell$  to denote the uniform distribution on  $\ell$  bits.

- *Requirements:* The goal is to show that for every  $g$ , there exists a function  $g^{\text{pred}}$  with as small an  $\epsilon$  as possible, without significant losses in the other parameters (meaning that  $s'$  is not much smaller than  $s$ , and  $\ell'$  is not much larger than  $\ell$ ).

The Goldreich-Levin theorem for this setting can be expressed as follows.

► **Theorem 7** (Goldreich-Levin for functions that are hard to compute [6]). *For every function  $g : \{0, 1\}^\ell \rightarrow \{0, 1\}^\ell$ , define  $g^{\text{pred}} : \{0, 1\}^{\ell'=2\ell} \rightarrow \{0, 1\}$  by  $g^{\text{pred}}(x, r) = \text{Enc}^{\text{Had}}(g(x))_r$ , and  $\rho = \frac{\epsilon}{2 \cdot L^{\text{Had}}} = \text{poly}(\epsilon)$ . If for every circuit  $C$  of size  $s$ ,*

$$\Pr_{x \leftarrow U_\ell} [C(x) = g(x)] \leq \rho,$$

*then for every circuit  $C'$  of size  $s' = \frac{s}{q^{\text{Had}} \cdot \text{poly}(\ell)} = s \cdot \text{poly}(\frac{\epsilon}{\ell})$ ,*

$$\Pr_{x \leftarrow U_{2\ell}} [C'(x) = g^{\text{pred}}(x)] \leq \frac{1}{2} + \epsilon.$$

The Hadamard code can be replaced by any locally list-decodable code with list size  $L$  for decoding from radius  $\frac{1}{2} - \epsilon$ , with  $q$  queries for  $\delta = 1/(2k)$ . For such a code (assuming also that the local list-decoder can be computed efficiently) one gets the same behavior. Specifically, if the initial function is sufficiently hard and  $\rho = \frac{\epsilon}{2L}$ , then the Boolean target function is hard to compute, up to  $\frac{1}{2} + \epsilon$  for circuits of size roughly  $s' = s/q$ .

#### Is it possible to improve the Goldreich-Levin theorem for $\rho \ll 1/s$ ?

Suppose that we are given a function  $g : \{0, 1\}^\ell \rightarrow \{0, 1\}^\ell$  that is hard to compute for circuits of size  $s = \text{poly}(\ell)$ , with success say  $\rho = 1/2^{\sqrt{\ell}}$ . When applying Theorem 7, we gain nothing compared to the case that  $\rho = 1/\text{poly}(\ell)$ . In both cases, we can obtain  $\epsilon = 1/\text{poly}(\ell)$ , but not smaller! (Since otherwise  $s' = s \cdot \text{poly}(\epsilon/\ell)$  is smaller than 1 and the result is meaningless).

This is disappointing, as we may have expected to obtain  $\epsilon \approx \rho = 1/2^{\sqrt{\ell}}$ , or at least, to gain over the much weaker assumption that  $\rho = 1/\text{poly}(\ell)$ . This leads to the following open problem:

► **Open problem 8** (Improve Goldreich-Levin for functions that are hard to compute). *Suppose we are given a function  $g : \{0, 1\}^\ell \rightarrow \{0, 1\}^\ell$  such that circuits  $C$  of size  $s = \text{poly}(\ell)$  cannot compute  $g$  with success  $\rho = 1/2^{\sqrt{\ell}}$ . Is it possible to convert  $g$  into a predicate with hardness  $\frac{1}{2} + \epsilon$  for  $\epsilon = 1/\ell^{\omega(1)}$ ?*

This is not possible to achieve using the Hadamard code, because the number of queries is  $q \geq 1/\epsilon$ , and Theorem 7 requires  $s \geq s' \cdot q \geq q \geq 1/\epsilon$ , which dictates that  $\epsilon \geq 1/s$ .

Note that when  $\rho$  is small, we can afford list-decodable codes with huge list sizes of  $L \approx 1/\rho$ . Motivated by this observation, we can ask the following question:

Is it possible to solve this open problem by substituting the Hadamard code with a better code? Specifically, is it possible for local list-decoders to have  $q = \frac{1}{\epsilon^{o(1)}}$  if allowed to use *huge* lists of size say  $2^{\sqrt{k}}$ , approaching the trivial bound  $2^k$ ? (Note that in the Hadamard code, the list size used is  $\text{poly}(1/\epsilon) = \text{poly}(k)$  which is exponentially smaller).

We show, in Theorem 6, that it is impossible to solve the open problem by replacing the Hadamard code with a different locally list-decodable code.

The natural next question is whether we can use other techniques (not necessarily local list-decoding) to achieve the goal stated above. In this paper, we show that this cannot be done by *black-box techniques*:

► **Informal Theorem 9** (Black-box impossibility result for functions that are hard to compute). *If  $\rho \geq \frac{1}{2^{\ell/3}}$ ,  $s = 2^{o(\ell)}$  is larger than some fixed polynomial in  $\ell$ , and  $\epsilon = \frac{1}{s^{\omega(1)}}$ , then there does not exist a map that converts a function  $g$  into a function  $g^{\text{pred}}$  together with a black-box reduction showing that  $g^{\text{pred}}$  is a hard-core predicate for  $g$ .*

The parameters achieved in Theorem 9 rule out black-box proofs in which  $\epsilon = \frac{1}{s^{\omega(1)}}$ , not only for  $s = \text{poly}(\ell)$  and  $\rho = 2^{-\sqrt{\ell}}$  (as in Open problem 8) but also for  $\rho = 2^{-\Omega(\ell)}$ , and allowing much larger  $s$  as long as  $s = 2^{o(\ell)}$ .

The precise statement of Theorem 9 is stated in Theorem 19, and the precise model is explained in Section 3.1.

To the best of our knowledge, this is the first result of this kind, that shows black-box impossibility results for Open problem 8. Moreover, we believe that the model that we introduce in Section 3.1 is very general and captures all known black-box techniques. In particular, our model (which we view as a conceptual contribution) allows the reduction to introduce nonuniformity when converting an adversary  $C'$  that breaks  $g^{\text{pred}}$  into an adversary  $C$  that breaks  $g$ . See discussion in Remark 14.

### 1.2.2 Functions that are hard to invert

Here the goal is to transform a one-way function  $f$  into a new one-way function  $f^{\text{newOWF}}$  and a predicate  $f^{\text{pred}}$  such that it is hard to compute  $f^{\text{pred}}(x)$  given  $f^{\text{newOWF}}(x)$ . More precisely:

- *Assumption:* There is a one-way function that is hard to invert with probability  $\rho$ .

Namely, a function  $f : \{0, 1\}^\ell \rightarrow \{0, 1\}^\ell$  such that for every circuit  $C$  of size  $s$ ,

$$\Pr_{x \leftarrow U_\ell} [C(f(x)) \in f^{-1}(f(x))] \leq \rho.$$

- *Conclusion:* There is a one-way function  $f^{\text{newOWF}} : \{0, 1\}^{\ell'} \rightarrow \{0, 1\}^{\ell'}$ , and a predicate  $f^{\text{pred}} : \{0, 1\}^{\ell'} \rightarrow \{0, 1\}$ , such that it is hard to predict  $f^{\text{pred}}(x)$  with advantage  $\frac{1}{2} + \epsilon$ , when given access to  $f^{\text{newOWF}}(x)$ .

Namely, for every circuit  $C'$  of size  $s'$ ,

$$\Pr_{x \leftarrow U_{\ell'}} [C'(f^{\text{newOWF}}(x)) = f^{\text{pred}}(x)] \leq \frac{1}{2} + \epsilon.$$

- The goal is to show that for every  $f$ , there exist functions  $f^{\text{newOWF}}, f^{\text{pred}}$  with as small  $\epsilon$  as possible, without significant losses in the other parameters (meaning that:  $s'$  is not much smaller than  $s$ , and  $\ell'$  is not much larger than  $\ell$ ).

The Goldreich-Levin theorem for this setting can be expressed as follows.

► **Theorem 10** (Goldreich-Levin for functions that are hard to invert). *For a function  $f : \{0, 1\}^\ell \rightarrow \{0, 1\}^\ell$ , define  $f^{\text{newOWF}} : \{0, 1\}^{2\ell} \rightarrow \{0, 1\}^{2\ell}$  by  $f^{\text{newOWF}}(x, r) = (f(x), r)$ ,  $f^{\text{pred}} : \{0, 1\}^{2\ell} \rightarrow \{0, 1\}$  by  $f^{\text{pred}}(x, r) = \text{Enc}^{\text{Had}}(x)_r$ , and  $\rho = \frac{\epsilon}{2 \cdot L^{\text{Had}}} = \text{poly}(\epsilon)$ . If for every circuit  $C$  of size  $s$ ,*

$$\Pr_{x \leftarrow U_\ell} [C(f(x)) \in f^{-1}(f(x))] \leq \rho,$$

*then for every circuit  $C'$  of size  $s' = \frac{s}{q^{\text{Had}} \cdot \text{poly}(\ell)} = s \cdot \text{poly}(\frac{\epsilon}{\ell})$ ,*

$$\Pr_{x \leftarrow U_{2\ell}} [C'((f^{\text{newOWF}}(x))) = f^{\text{pred}}(x)] \leq \frac{1}{2} + \epsilon.$$

► **Remark 11.** The problem of obtaining a hard-core predicate for one-way functions, is interesting only if an unbounded adversary  $\phi : \{0, 1\}^{\ell'} \rightarrow \{0, 1\}$  can predict  $f^{\text{pred}}(x)$  when given  $f^{\text{newOWF}}(x)$  as input. If this is not required, then one can take  $\ell' = \ell + 1$ ,  $f^{\text{pred}}(x) = x_1$ , and  $f^{\text{newOWF}}(x_1, \dots, x_{n+1}) = f(x_2, \dots, x_{n+1})$ . However, this is trivial, and is not useful in applications. Therefore, when considering this problem, we will assume that there exists such a  $\phi : \{0, 1\}^{\ell'} \rightarrow \{0, 1\}$ .

A natural example is the case where the original one-way function  $f$  and the constructed function  $f^{\text{newOWF}}$  are one-way permutations. In fact, in the case that  $f, f^{\text{newOWF}}(x)$  are permutations, the setup of “functions that are hard to invert” can be seen as a special case of the setup of functions that are “hard to compute” by taking  $g = f^{-1}$ , and  $g^{\text{pred}}(y) = f^{\text{pred}}((f^{\text{newOWF}})^{-1}(y))$ .

We point out that, in this setting, the circuit  $C'$  that is trying to invert  $f$  (that is, to compute  $g$ ) has an advantage over its counterpart in the setup of “functions that are hard to compute”: It can use the efficient algorithm that computes the “forward direction” of  $f$ , when trying to invert  $f$ . In terms of  $g$ , this means that the circuit  $C'$  can compute  $g^{-1}$  for free.

### Is it possible to improve the Goldreich-Levin theorem for $\rho \ll 1/s$ ?

The same problem that we saw with functions that are hard to compute, also shows up in the setup of functions that are hard to invert. Suppose that we are given a function  $f : \{0, 1\}^{\ell} \rightarrow \{0, 1\}^{\ell}$  that is hard to invert for circuits of size  $s = \text{poly}(\ell)$  with success, say,  $\rho = 1/2^{\sqrt{\ell}}$ . When applying Theorem 10, we gain nothing compared to the case that  $\rho = 1/\text{poly}(\ell)$ . In both cases, we can obtain  $\epsilon = 1/\text{poly}(\ell)$ , but not smaller! This is expressed in the next open problem:

► **Open problem 12** (Improve Goldreich-Levin for functions that are hard to invert). *If we are given a one-way function  $f : \{0, 1\}^{\ell} \rightarrow \{0, 1\}^{\ell}$  such that circuits  $C$  of size  $s = \text{poly}(\ell)$  cannot invert  $f$  with success  $\rho = 1/2^{\sqrt{\ell}}$ . Is it possible to obtain a hard-core predicate  $f^{\text{pred}}$  with hardness  $\frac{1}{2} + \epsilon$  for  $\epsilon = 1/\ell^{\omega(1)}$  for some choice of one-way function  $f^{\text{newOWF}}$ ?*

In this paper, we show that this cannot be done by *black-box techniques*. The formulation of Theorem 13 below, is very similar to that of Theorem 9 with some small modification in the parameters.

► **Informal Theorem 13** (Black-box impossibility result for functions that are hard to invert). *If  $\rho \geq 2^{-\ell/5}$ ,  $s = 2^{o(\ell)}$  is larger than some fixed polynomial in  $\ell$ , and  $\epsilon = \frac{1}{s^{\omega(1)}}$  then there does not exist a map that converts a function  $f$  into functions  $f^{\text{newOWF}}, f^{\text{pred}}$  together with a black-box reduction showing that  $f^{\text{pred}}$  is a hard-core predicate for  $f^{\text{newOWF}}$ .*

To the best of our knowledge, this is the first result of this kind, that shows black-box impossibility results for open problem 12. Moreover, we believe that the model that we introduce is very general, and captures all known black-box techniques. In particular, our model (which we view as a conceptual contribution) allows the reduction to compute the easy direction of the function  $f$ , and to introduce nonuniformity when converting an adversary  $C'$  that breaks  $f^{\text{pred}}$  into an adversary  $C$  that breaks  $f$ .

► **Remark 14** (The model we use for black-box proofs). Many different models of “black-box techniques” for cryptographic primitives were studied in the literature and the reader is referred to [12] for a discussion and a taxonomy. The model for “black-box technique” that we use is described in detail in Section 3. The notion that we use is incomparable to the ones discussed in [12], specifically:

- We require that there is a “transformation map” which given any function  $f$  produces functions  $f^{\text{newOWF}}$  and  $f^{\text{pred}}$ , however, unlike [12], we do not make the requirement that this transformation map can be efficiently computed.
- We require that there is a reduction  $\text{Red}$  such that for any  $f$ , and for every adversary  $C'$  (not necessarily efficient) breaking the security of  $f^{\text{pred}}$ ,  $\text{Red}^{f,C'}$  can be used to invert  $f$ .
- However, we give reductions more power: We also allow  $\text{Red}$  to introduce nonuniformity (that could depend on  $C'$  and  $f$ ). Formally, for every adversary  $C'$  that breaks the security of  $f^{\text{pred}}$ , we require that there exists a short nonuniform advice string  $\alpha$  such that  $\text{Red}^{C',f}(\cdot, \alpha)$  inverts  $f$ .

### 1.3 More related work

#### Lower bounds on the number of queries of local decoders for *uniquely* decodable codes

In this paper, we prove lower bounds on the number of queries of local list-decoders. There is a long line of work that is concerned with proving lower bounds on the number of queries of uniquely decodable codes. As we have explained in Section 1.1.1, the parameter regime considered in the setting of uniquely decodable codes is very different than the parameter regime we consider here [18].

#### Lower bounds on nonuniform black-box reductions for hardness amplification

A problem that is closely related to proving lower bounds on the number of queries of local list-decoders is the problem of proving lower bounds on the number of queries of nonuniform black-box reductions for hardness amplification. We have already discussed this line of work [17, 15, 3, 7, 14] in Section 1.1.1.

Lower bounds on such reductions can be translated to lower bounds on local list-decoders (as long as the number of coins tossed by the local list-decoders is small). We remark that for the purpose of hardness amplification, it does not make sense to take codes with small rate (namely, codes with  $n = 2^{k^{\Omega(1)}}$ ). The focus of Theorem 5 is to handle such codes.

Additionally, when using codes for hardness amplification, it does not make sense to take  $\epsilon < 1/k$  (or even  $\epsilon < 1/\sqrt{k}$ ). In contrast, the parameter regime considered in Theorem 6 focuses on small  $\epsilon$ .

Motivated by hardness amplification, there is also a related line of work studying limitations on the complexity of local list decoders (and specifically, whether these decoders need to compute the majority function) [17, 15, 9, 3, 7, 14].

Another approach to prove limitations on hardness amplification is to show that assuming certain cryptographic assumptions, hardness amplification that is significantly better than what is currently known is impossible, see e.g., [5] for a discussion.

#### Other improvements of the Goldreich-Levin theorem

In this paper, we are interested in whether the Goldreich-Levin theorem can be improved. Specifically, we are interested in improvements where, when the original function has hardness  $\rho = 2^{-\Omega(\ell)}$  for polynomial size circuits, then the hard-core predicate has hardness  $\frac{1}{2} + \epsilon$  for  $\epsilon = \ell^{-\omega(1)}$ . We remark that there are other aspects of the Goldreich-Levin theorem that one may want to improve.

- When given an initial non-Boolean function on  $\ell$  bits, the Goldreich-Levin theorem produces a hard-core predicate on  $\ell' = 2\ell$  bits. It is possible to make  $\ell'$  smaller (specifically,  $\ell' = \ell + O(\log(1/\epsilon))$ ) by using other locally list-decodable codes instead of Hadamard. Our limitations apply to *any* construction (even one that is not based on codes) and in particular also for such improvements.
- It is sometimes desirable to produce many hard-core bits (instead of the single hard-core bit) that is obtained by a hard-core predicate. This can be achieved by using “extractor codes” with a suitable local list-decoding algorithm. The reader is referred to [16] for more details. Once again, our limitations obviously apply also for the case of producing many hard-core bits.

## Organization of the paper

We give a high level overview of our technique in Section 2. Some of our results on hard-core predicates appear in Section 3 (which includes a precise description of the model and formal restatements of Theorem 9). We refer the interested reader to the full version [13] for a precise description of the model and formal restatement of Theorem 13. Section 4 contains some concluding remarks and open problems. All proofs can be found in the full version.

## 2 Technique

In this section we give a high level overview of our technique. Our approach builds on earlier work for proving lower bounds on the number of queries or reductions for hardness amplification [17, 15, 7]. In this section, we give a high level overview of the arguments used to prove our main theorems.

### 2.1 Local list-decoders on random noisy codewords

Following [17, 15, 7], we will consider a scenario which we refer to as “random noisy codewords” in which a uniformly chosen message  $m$  is encoded, and the encoding is corrupted by a binary symmetric channel.

► **Definition 15** (Binary symmetric channels). *Let  $\text{BSC}_p^n$  be the experiment in which a string  $Z \in \{0, 1\}^n$  is sampled, where  $Z = Z_1, \dots, Z_n$  is composed of i.i.d. bits, such that for every  $i \in [n]$ ,  $\Pr[Z_i = 1] = p$ .*

► **Definition 16** (Random noisy codewords). *Given a function  $\text{Enc} : \{0, 1\}^k \rightarrow \{0, 1\}^n$  and  $p > 0$  we consider the following experiment (which we denote by  $\text{RNSY}_p^{\text{Enc}}$ ):*

- *A message  $m \leftarrow \{0, 1\}^k$  is chosen uniformly.*
- *A noise string  $z \leftarrow \text{BSC}_p^n$  is chosen from a binary symmetric channel.*
- *We define  $w = \text{Enc}(m) \oplus z$ .*

*We use  $(m, z, w) \leftarrow \text{RNSY}_p^{\text{Enc}}$  to denote  $m, z, w$  which are sampled by this experiment. We omit  $\text{Enc}$  if it is clear from the context.*

Our goal is to prove lower bounds on the number of queries  $q$  of a  $(\frac{1}{2} - \epsilon, L, q, \delta)$ -local list-decoder  $\text{Dec}$  for a code  $\text{Enc} : \{0, 1\}^k \rightarrow \{0, 1\}^n$ . For this purpose, we will consider the experiment  $\text{RNSY}_p$  for the values  $p = \frac{1}{2} - 2\epsilon$  and  $p = \frac{1}{2}$ .

For  $p = \frac{1}{2} - 2\epsilon$ , and  $(m, z, w) \leftarrow \text{RNSY}_{\frac{1}{2}-\epsilon}$ , by a Chernoff bound, the Hamming weight of  $z$  is, with very high probability, less than  $\frac{1}{2} - \epsilon$ . This implies that  $\text{dist}(w, \text{Enc}(m)) \leq \frac{1}{2} - \epsilon$ , meaning that  $m \in \text{List}_{\frac{1}{2}-\epsilon}^{\text{Enc}}(w)$ . It follows that there must exist  $j \in [L]$  such that when given input  $j$ , and oracle access to  $w$ , the decoder  $\text{Dec}$  recovers the message  $m$ .

For  $p = \frac{1}{2}$ , and  $(m, z, w) \leftarrow \text{RNSY}_{\frac{1}{2}}$ , the string  $z$  is uniformly distributed and independent of  $m$ . This means that  $w = \text{Enc}(m) \oplus z$  is uniformly distributed and independent of  $m$ . Consequently, when Dec is given oracle access to  $w$ , there is no information in  $w$  about the message  $m$ , and so, for every  $j \in [L]$ , the probability that Dec recovers  $m$  when given input  $j$  and oracle access to  $w$  is exponentially small.

Loosely speaking, this means that Dec can be used to distinguish  $\text{BSC}_{\frac{1}{2}-2\epsilon}^n$  from  $\text{BSC}_{\frac{1}{2}}^n$ . It is known that distinguishing these two distributions requires many queries. We state this informally below.

► **Informal Theorem 17.** *Any function  $T : \{0, 1\}^q \rightarrow \{0, 1\}$  that distinguishes  $\text{BSC}_{\frac{1}{2}-2\epsilon}^q$  from  $\text{BSC}_{\frac{1}{2}}^q$  with advantage  $\delta$ , must have  $q = \Omega(\frac{\log(1/\delta)}{\epsilon^2})$ .*

Thus, in order to prove a tight lower bound of  $q = \Omega(\frac{\log(1/\delta)}{\epsilon^2})$ , it is sufficient to show how to convert a  $(\frac{1}{2} - \epsilon, L, q, \delta)$ -local list-decoder Dec, into a function  $T$  that distinguishes  $\text{BSC}_{\frac{1}{2}-2\epsilon}^q$  from  $\text{BSC}_{\frac{1}{2}}^q$  with advantage  $\delta$ . Note that we can allow  $T$  to be a “randomized procedure” that tosses coins, as by an averaging argument, such a randomized procedure can be turned into a deterministic procedure.

## 2.2 Warmup: the case of unique decoding

Let us consider the case that  $L = 1$  (that is unique decoding). We stress that this case is uninteresting, as by the Plotkin bound, it is impossible for nontrivial codes to be uniquely decodable for  $\epsilon < \frac{1}{4}$ , and so, there are no local decoders for  $L = 1$  and  $\epsilon < \frac{1}{4}$ , regardless of the number of queries. Nevertheless, this case will serve as a warmup for the approach we use later.

Our goal is to convert Dec into a randomized procedure  $T : \{0, 1\}^q \rightarrow \{0, 1\}$  that distinguishes  $\text{BSC}_{\frac{1}{2}-2\epsilon}^q$  from  $\text{BSC}_{\frac{1}{2}}^q$ . The procedure  $T$  will work as follows: On input  $x \leftarrow \{0, 1\}^q$ , we choose  $m \leftarrow \{0, 1\}^k$ , and  $i \leftarrow [k]$ . We then run Dec on input  $i$ , and when Dec makes its  $t$ 'th query  $\ell_t \in [n]$  to the oracle, we answer it by  $\text{Enc}(m)_{\ell_t} \oplus x_t$ . That is, we answer as if Dec is run with input  $i$  and oracle access to  $w = \text{Enc}(m) \oplus z$ , for  $z$  chosen from a binary symmetric channel. The final output of  $T$  is whether Dec reproduced  $m_i$ . This procedure  $T$  simulates  $\text{Dec}^w(i)$ , and therefore distinguishes  $\text{BSC}_{\frac{1}{2}-2\epsilon}^q$  from  $\text{BSC}_{\frac{1}{2}}^q$ , implying the desired lower bound.

Both Theorem 5 and Theorem 6 will follow by modifying the basic approach to handle  $L > 1$ . In the remainder of this section, we give a high level overview of the methods that we use. The formal section of this paper does not build on this high level overview, and readers can skip this high level overview and go directly to the formal section if they wish.

## 2.3 Reducing to the coin problem for $\text{AC}^0$

We start with explaining the approach of proving Theorem 6. Consider a randomized procedure  $C$  that on input  $z \in \{0, 1\}^n$ , chooses  $m \leftarrow \{0, 1\}^k$  and prepares  $w = \text{Enc}(m) \oplus z$ . The procedure then computes  $\text{Dec}^w(i, j)$  for all choices of  $i \in [k]$  and  $j \in [L]$  and accepts if there exists a  $j \in [L]$  such that  $\text{Dec}^w(\cdot, j)$  recovers  $m$ . By the same rationale as in Section 2.2,  $C$  distinguishes  $\text{BSC}_{\frac{1}{2}-2\epsilon}^n$  from  $\text{BSC}_{\frac{1}{2}}^n$ . This does not seem helpful, because  $C$  receives  $n$  input bits, and we cannot use Theorem 17 to get a lower bound on  $q$ .

Inspired by a lower bound on the size of nondeterministic reductions for hardness amplification due to Applebaum et al. [2], we make the following observation: The procedure  $C$  can be seen as  $k \cdot L$  computations (one for each choice of  $i \in [k]$  and  $j \in [L]$ ) such that:

- These  $k \cdot L$  computations can be run *in parallel*.
- Once these computations are made, the final answer  $C(z)$  is computed by a constant-depth circuit.
- Each of the  $k \cdot L$  computations makes  $q$  queries into  $z$ , and therefore can be simulated by a size  $O(q \cdot 2^q)$  circuit of depth 2.

Overall, this means that we can implement  $C$  by a circuit of size  $s = \text{poly}(k, L, 2^q)$  and constant depth. (In fact, a careful implementation gives depth 3).

This is useful because there are lower bounds showing that small constant-depth circuits cannot solve the “coin problem”. Specifically, by the results of Cohen, Ganor and Raz [4] circuits of size  $s$  and depth  $d$  cannot distinguish  $\text{BSC}_{\frac{1}{2}-2\epsilon}^n$  from  $\text{BSC}_{\frac{1}{2}}^n$  with constant advantage, unless  $s \geq \exp(\Omega(\frac{1}{\epsilon^{d-1}}))$ .<sup>4</sup> This gives the bound stated in Theorem 6.

We find it surprising that an *information theoretic* lower bound on the number of queries of local list-decoders is proven by considering concepts like constant-depth circuits from *circuit complexity*.

### Extending the argument to lower bounds on hard-core predicates

It turns out that this argument is quite versatile, and this is the approach that we use to prove Theorems 9 and 13. Loosely speaking, in these theorems, we want to prove a lower bound on the number of queries made by a reduction that, when receiving oracle access to an adversary that breaks the hard-core predicate, is able to compute (or invert) the original function too well. Such lower bounds imply that such reductions do not produce small circuits when used in black-box proofs for hard-core predicates.

We will prove such lower bounds by showing that a reduction that makes  $q$  queries can be used to construct a circuit of size  $s \approx 2^q$  and constant depth that solves the coin problem. Interestingly, this argument crucially relies on the fact that constant-depth circuits *can* distinguish  $\text{BSC}_{\epsilon}^n$  from  $\text{BSC}_{2\epsilon}^n$  with size  $\text{poly}(n/\epsilon)$  which follows from the classical results of Ajtai on constant depth circuits for approximate majority [1].<sup>5</sup>

## 2.4 Conditioning on a good $j$

A disadvantage of the approach based on the coin problem is that at best, it can give lower bounds of  $q = \Omega(1/\sqrt{\epsilon})$ , and cannot give tight lower bounds of the form  $q = \Omega(\frac{\log(1/\delta)}{\epsilon^2})$ . In order to achieve such a bound (as is the case in Theorem 5) we will try to reduce to Theorem 17 which *does* give a tight bound in case  $\epsilon$  is not too small.

Our approach builds on the earlier work of Grinberg, Shaltiel and Viola [7] that we surveyed in Section 1.1.1. When given a  $(\frac{1}{2} - \epsilon, L, q, \delta)$ -local list-decoder  $\text{Dec}$ , we say that an index  $j \in [L]$  is *decoding*, if in the experiment  $(m, z, w) \in \text{RNSY}_{\frac{1}{2}-2\epsilon}$ , when  $\text{Dec}$  is given oracle access to  $w$  and input  $j$ , then with probability  $1 - 10\delta$  over  $i \in [k]$ , we have that  $\text{Dec}^w(i, j)$  recovers  $m_i$ .

<sup>4</sup> These results of [4] improve upon earlier work of Shaltiel and Viola [15] that gave slightly worse bound. These results are tight as shown by Limaye et al. [10] (that also extended the lower bound to hold for circuits that are also allowed to use parity gates).

<sup>5</sup> The proof of Theorem 13 uses an additional versatility of the argument (which we express in the terminology of codes): The argument works even if the individual procedures that are run in parallel are allowed to have some limited access to the message  $m$ , as long as this does not enable them to recover  $m$ . This property is used to handle reductions in a cryptographic setup, where reductions have access to the easy direction of a one-way function.

We use a careful averaging argument to show that there exists an index  $j' \in [L]$ , and a fixed choice of the random coins of Dec, such that  $j'$  is decoding with probability at least  $\Omega(1/L)$ . We then consider the experiment  $\text{RNSY}'_{\frac{1}{2}-2\epsilon}$  in which we choose  $(m, z, w) \leftarrow \text{RNSY}'_{\frac{1}{2}-2\epsilon}$  *conditioned* on the event  $\{j' \text{ is decoding}\}$ .

We have made progress, because in the experiment  $\text{RNSY}'_{\frac{1}{2}-2\epsilon}$  there exists a unique  $j'$  that is decoding, and so, when we implement the strategy explained in Section 2.2 we only need to consider this *single*  $j'$ , which intuitively means that our scenario is similar to the warmup scenario of unique decoding described in Section 2.2.

The catch is that when choosing  $(m, z, w) \leftarrow \text{RNSY}'_{\frac{1}{2}-2\epsilon}$ , we no longer have that  $z$  is distributed like  $\text{BSC}_{\frac{1}{2}-2\epsilon}^n$  (as the distribution of  $z$  may be skewed by conditioning on the event that  $j'$  is decoding).

Shaltiel and Viola [15] (and later work [7, 14]) developed tools to handle this scenario. Loosely speaking, using these tools, it is possible to show that a large number of messages  $m$  are “useful” in the sense that there exists an event  $A_m$  such that if we consider  $(m, z, w)$  that are chosen from  $\text{RNSY}'_{\frac{1}{2}-2\epsilon}$  *conditioned* on  $A_m$ , then there exists a subset  $B(m) \subseteq [n]$  of small size  $b$ , such that  $z_{B(m)}$  is fixed, and  $z_{[n] \setminus B(m)}$  is distributed like  $\text{BSC}_{\frac{1}{2}-2\epsilon}^{n-b}$ .

If the number of possible choices for sets  $B(m)$  is small, then by the pigeon-hole principle, there exists a fixed choice  $B$  that is good for a large number of useful messages  $m$ . This can be used to imitate the argument we used in the warmup, and prove a lower bound.<sup>6</sup>

### Extending the argument to the case of small rate

A difficulty, that prevented [7] from allowing length as large as  $n = 2^k$ , is that  $B(m)$  is a subset of  $[n]$ , and so, even if  $b = |B| = 1$ , the number of possible choices for such sets is at least  $n$ . For the pigeon-hole principle argument above, we need that the number of messages (that is  $2^k$ ) is much larger than the number of possible choices for  $B(m)$  (which is at least  $n$ ). This means that one can only handle  $n$  which is sufficiently smaller than  $2^k$ , and this approach cannot apply to codes with small rate (such as the Hadamard code).

We show how to solve this problem, and prove lower bounds for small rate codes. From a high level, our approach can be explained as follows: We consider the distribution of  $B(m) = \{Y_1(m) < \dots < Y_b(m)\}$  for a uniformly chosen useful  $m$ . We first show that if all the  $Y_j$ 's have large min-entropy, then it is possible to prove a lower bound on  $q$  by reducing to Theorem 17 (the details of this are explained in the actual proof).

If on the other hand, one of the  $Y_j$ 's has low min-entropy, then we will restrict our attention to a subset of useful messages on which  $Y_j$  is fixed. Loosely speaking, this reduces  $b$  by one, while not reducing the number of useful messages by too much (because the low min-entropy condition says that the amount of information that  $Y_j$  carries on  $m$  is small). In this trench warfare, in every iteration, we lose a fraction of useful messages, for the sake of decreasing  $b$  by one. Thus, eventually, we either reach the situation that all the  $Y_j$ 's have large min-entropy, in which case we are done, or we reach the situation where  $B$  is fixed for all messages which we can also handle by the above.

We can withstand the losses and eventually win if  $\epsilon$  is sufficiently larger than  $1/\sqrt{k}$ .

<sup>6</sup> Loosely speaking, this is because for good messages, in the conditioned experiment,  $z$  is distributed like  $\text{BSC}_{\frac{1}{2}-2\epsilon}^n$  (except that some bits of  $z$  are fixed as a function of  $m$ ). Furthermore, as there are many good messages, the local list-decoder does not have enough information to correctly recover the message when given oracle access to  $\text{Enc}(m) \oplus \text{BSC}_{\frac{1}{2}}^n = \text{BSC}_{\frac{1}{2}}^n$ .

### 3 Limitations on black-box proofs for hard-core predicates

In this section, we present some of our results regarding the limitations on black-box proofs for hard-core predicate theorems. Specifically, we state our results for functions that are hard to compute, give a formal restatement of Theorem 9. Due to space limitation, the formal model and precise statement of results for the case of functions that are hard to invert appear in the full version [13].

#### 3.1 The case of functions that are hard to compute

##### 3.1.1 The model for black-box proofs

In this section, we state and explain our model for black-box proofs for hard core predicates, in the setting of functions that are hard to compute. The formal definition is given in Definition 18. Below, we provide a detailed explanation for the considerations made while coming up with the formal definition. The reader can skip directly to the formal definition if he wishes.

##### Explanation of the model

Recall that (as explained in Section 1.2.1) the Goldreich-Levin theorem (stated precisely in Theorem 7) has the following form:

- We are given an arbitrary hard function  $g : \{0, 1\}^\ell \rightarrow \{0, 1\}^\ell$ . (Intuitively, it is assumed that it is hard to compute  $g$  with success probability  $\rho$ ).
- There is a specified construction that transforms  $g$  into a predicate  $g^{\text{pred}} : \{0, 1\}^{\ell'} \rightarrow \{0, 1\}$  for some  $\ell'$  related to  $\ell$ . (Intuitively, we will want to argue that  $g^{\text{pred}}$  is a hard-core predicate that is hard to compute with success  $\frac{1}{2} + \epsilon$ ).

We will model this construction as a map  $\text{Con}$ , which, given  $g$  produces  $g^{\text{pred}}$ . We place *no limitations* on the map  $\text{Con}$  (and, in particular, do not require that  $g^{\text{pred}}$  can be efficiently computed if  $g$  is). This only makes our results stronger.

In the case of Theorem 7, we have that:  $\text{Con}(g) = g^{\text{pred}}$  where  $\ell' = 2\ell$  and we think of the  $\ell'$ -bit long input of  $g^{\text{pred}}$  as two strings  $x, r \in \{0, 1\}^\ell$ , setting:

$$g^{\text{pred}}(x, r) = \text{Enc}^{\text{Had}}(g(x))_r = \left( \sum_{i \in [\ell]} g(x)_i \cdot r_i \right) \bmod 2.$$

- We model the proof showing that  $g^{\text{pred}}$  is a hard-core predicate in the following way: The proof is a pair  $(\text{Con}, \text{Red})$  where  $\text{Red}^{(\cdot)}$  is an oracle procedure, such that when  $\text{Red}^{(\cdot)}$  receives oracle access to an “adversary”  $h : \{0, 1\}^{\ell'} \rightarrow \{0, 1\}$  that breaks the security of  $g^{\text{pred}}$ , we have that  $\text{Red}^h$  breaks the security of  $g$ . More precisely, we require that: for every  $g : \{0, 1\}^\ell \rightarrow \{0, 1\}^\ell$  and for every  $h : \{0, 1\}^{\ell'} \rightarrow \{0, 1\}$  such that:

$$\Pr_{x \leftarrow U_{\ell'}} [h(x) = g^{\text{pred}}(x)] \geq \frac{1}{2} + \epsilon,$$

it holds that:

$$\Pr_{x \leftarrow U_\ell} [\text{Red}^h(x) = g(x)] \geq \rho.$$

- In the actual definition, we will allow the reduction to have more power (which only makes our results stronger). As we are aiming to prove a result on circuits (which are allowed to use nonuniform advice) we will allow the reduction to receive an advice

string  $\alpha$  of length  $t$ , where, this advice string can depend on  $g$  and  $h$ . This leads to the following strengthening of the requirement above. Namely, we will require that: for every  $g : \{0, 1\}^\ell \rightarrow \{0, 1\}^\ell$  and for every  $h : \{0, 1\}^{\ell'} \rightarrow \{0, 1\}$ , that:

$$\Pr_{x \leftarrow U_{\ell'}} [h(x) = g^{\text{pred}}(x)] \geq \frac{1}{2} + \epsilon,$$

there exists  $\alpha \in \{0, 1\}^t$  such that:

$$\Pr_{x \leftarrow U_\ell} [\text{Red}^h(x, \alpha) = g(x)] \geq \rho.$$

We remark that in many related settings (for example, “hardness amplification”; see [15, 7], for a discussion) known proofs by reduction *critically make use* of the ability to introduce nonuniformity, and so, we feel that when ruling out black-box proofs in scenarios involving circuits, it is necessary to consider nonuniform black-box reductions.

- We make no restrictions on the complexity of the procedure  $\text{Red}^{(\cdot)}$ , except for requiring that it makes at most  $q$  queries to its oracle (for some parameter  $q$ ). Our black-box impossibility results will follow from proving lower bounds on  $q$ .

### Formal definition

We now give a formal definition of our model for black-box proofs for hard-core predicates.

► **Definition 18** (Nonuniform black-box proofs for hard-core predicates for hard-to-compute functions). *A pair  $(\text{Con}, \text{Red})$  is a nonuniform black-box proof for hard-core predicates for hard-to-compute functions with parameters  $\ell, \ell', \rho, \epsilon$ , that uses  $q$  queries, and  $t$  bits of advice if:*

- *Con is a construction map which given a function  $g : \{0, 1\}^\ell \rightarrow \{0, 1\}^\ell$ , produces a function  $\text{Con}(g) = g^{\text{pred}}$ , where  $g^{\text{pred}} : \{0, 1\}^{\ell'} \rightarrow \{0, 1\}$ .*
- *$\text{Red}^{(\cdot)}$  is a reduction, that is an oracle procedure that, given oracle access to a function  $h : \{0, 1\}^{\ell'} \rightarrow \{0, 1\}$ , makes at most  $q$  queries to its oracle.*

*Furthermore, for every functions  $g : \{0, 1\}^\ell \rightarrow \{0, 1\}^\ell$  and  $h : \{0, 1\}^{\ell'} \rightarrow \{0, 1\}$  such that:*

$$\Pr_{x \leftarrow U_{\ell'}} [h(x) = g^{\text{pred}}(x)] \geq \frac{1}{2} + \epsilon,$$

*there exists  $\alpha \in \{0, 1\}^t$ , such that:*

$$\Pr_{x \leftarrow U_\ell} [\text{Red}^h(x, \alpha) = g(x)] \geq \rho.$$

### The role of the number of queries, and black-box impossibility results

We now explain the role of the parameter  $q$  (that measures the number of queries made by  $\text{Red}$ ) and why lower bounds on  $q$  translate into black-box impossibility results.

For this purpose, it is illustrative to examine the argument showing that nonuniform black-box proofs yield hard-core predicates: When given a pair  $(\text{Con}, \text{Red})$  that is a nonuniform black-box proof for hard-core predicates for hard-to-compute functions with parameters  $\ell, \ell', \rho, \epsilon$ , that uses  $q$  queries, and  $t$  bits of advice, we obtain that for any function  $g : \{0, 1\}^\ell \rightarrow \{0, 1\}^\ell$ , if there exists a circuit  $C' : \{0, 1\}^{\ell'} \rightarrow \{0, 1\}$  of size  $s'$  such that:

$$\Pr_{x \leftarrow U_{\ell'}} [C'(x) = g^{\text{pred}}(x)] \geq \frac{1}{2} + \epsilon,$$

then there exists  $\alpha \in \{0, 1\}^t$ , such that:

$$\Pr_{x \leftarrow U_\ell} [\text{Red}^{C'}(x, \alpha) = g(x)] \geq \rho.$$

Note that if the reduction  $\text{Red}$  can be implemented by a circuit of size  $r$ , then the circuit  $C(x) = \text{Red}^{C'}(x, \alpha)$  is a circuit of size:

$$s = r + t + q \cdot s'$$

that computes  $g$  with success probability  $\rho$ .

It follows that in a black-box proof, with  $q$  queries, and  $t$  bits of advice, we get a hard-core theorem that needs to assume that the original function  $g$  has hardness against circuits of size  $s$ , for:

$$s \geq q + t.$$

### 3.1.2 Precise statements of limitations

Our main result on black-box proofs for hard-core predicates in the setting of functions that are hard to compute is the following theorem.

► **Theorem 19.** *There exists a universal constant  $\beta > 0$  such that for every sufficiently large  $\ell$  and  $\ell'$  we have that if  $(\text{Con}, \text{Red})$  is a nonuniform black-box proof for hard-core predicates for hard-to-compute functions with parameters  $\ell, \ell', \rho, \epsilon$ , that uses  $q$  queries, and  $t$  bits of advice, and furthermore  $\epsilon \geq \frac{1}{2^{\ell'/3}}$ ,  $t \leq 2^{\ell/3}$  and  $\rho \geq \frac{1}{2^{\ell/3}}$ , then*

$$q \geq \Omega\left(\frac{1}{\epsilon^\beta}\right) - O(t + \ell).$$

We now explain why Theorem 19 implies the informal statement made in Theorem 9. Recall that in Section 3.1.1 we explained that when using a nonuniform black-box proof to obtain a hard-core predicate, we get a hard-core predicate theorem in which  $s \geq q + t$ .

Theorem 19 implies that for  $s > \ell^{2/\beta}$  it is impossible for such a proof to establish  $\epsilon = 1/s^{2/\beta}$  (even if  $\rho$  is very small). This follows as otherwise, using the fact that  $s \geq q + t \geq t$ , we get that:

$$q \geq \Omega\left(\frac{1}{\epsilon^\beta}\right) - O(t + \ell) \geq \Omega(s^2) - O(t) > s,$$

which is a contradiction to  $s \geq q + t \geq q$ . In particular, the parameter setting considered in Theorem 9, in which  $s = 2^{o(\ell)}$  and  $\epsilon = \frac{1}{s^{\omega(1)}}$ , is impossible to achieve.

## 4 Conclusion and open problems

Unlike Theorem 5 (that handles large  $\epsilon$ ), Theorem 6 (that handles small  $\epsilon$ ) does not achieve a bound of  $q = \Omega\left(\frac{\log(1/\delta)}{\epsilon^2}\right)$ , and only achieves a bound of  $\Omega\left(\frac{1}{\sqrt{\epsilon}}\right)$ . A natural open problem is to improve the bound on  $q$  for small  $\epsilon$  to match the bound for large  $\epsilon$ .

In the case of large  $\epsilon$ , Theorem 5 can be extended to handle local list-decoding from erasures, and gives a lower bound of  $q = \Omega\left(\frac{\log(1/\delta)}{\epsilon}\right)$  on the number of queries of local list-decoders that decode from a  $1 - \epsilon$  fraction of erasures. We do not see how to extend the proof of Theorem 6 to erasures.

The model of black-box proofs that we introduce in Section 3 is quite general, and to the best of our knowledge, covers all known proofs in the literature on hard-core predicates for general one-way functions. Is it possible to circumvent the black-box limitations and answer open problems 8 and 12 for *specific candidates* for one-way functions?

More generally, is it possible to come up with non-black-box techniques that circumvent the limitations?

# Is the Space Complexity of Planted Clique Recovery the Same as That of Detection?

Jay Mardia

Department of Electrical Engineering, Stanford University, CA, USA  
jmardia@stanford.edu

---

## Abstract

We study the planted clique problem in which a clique of size  $k$  is planted in an Erdős-Rényi graph  $G(n, \frac{1}{2})$ , and one is interested in either detecting or recovering this planted clique. This problem is interesting because it is widely believed to show a statistical-computational gap at clique size  $k = \Theta(\sqrt{n})$ , and has emerged as the prototypical problem with such a gap from which average-case hardness of other statistical problems can be deduced. It also displays a tight computational connection between the detection and recovery variants, unlike other problems of a similar nature. This wide investigation into the computational complexity of the planted clique problem has, however, mostly focused on its time complexity. To begin investigating the robustness of these statistical-computational phenomena to changes in our notion of computational efficiency, we ask-

*Do the statistical-computational phenomena that make the planted clique an interesting problem also hold when we use “space efficiency” as our notion of computational efficiency?*

It is relatively easy to show that a positive answer to this question depends on the existence of a  $O(\log n)$  space algorithm that can recover planted cliques of size  $k = \Omega(\sqrt{n})$ . Our main result comes very close to designing such an algorithm. We show that for  $k = \Omega(\sqrt{n})$ , the recovery problem can be solved in  $O\left(\left(\log^* n - \log^* \frac{k}{\sqrt{n}}\right) \cdot \log n\right)$  bits of space.

1. If  $k = \omega(\sqrt{n} \log^{(\ell)} n)$ <sup>1</sup> for any constant integer  $\ell > 0$ , the space usage is  $O(\log n)$  bits.
2. If  $k = \Theta(\sqrt{n})$ , the space usage is  $O(\log^* n \cdot \log n)$  bits.

Our result suggests that there does exist an  $O(\log n)$  space algorithm to recover cliques of size  $k = \Omega(\sqrt{n})$ , since we come very close to achieving such parameters. This provides evidence that the statistical-computational phenomena that (conjecturally) hold for planted clique time complexity also (conjecturally) hold for space complexity.

<sup>1</sup> Here  $\log^{(\ell)} n$  means we repeatedly take the logarithm of  $n$   $\ell$  times. For example,  $\log^{(3)} n = \log \log \log n$ .

## 1 Introduction

The planted clique problem is a well-studied task in average-case computational complexity, in which a clique of size  $k$  is planted in an Erdős-Rényi graph of size  $n$ ,  $G(n, \frac{1}{2})$ . The problem comes in two flavours, detection ( $\text{PC}_D(n, k)$ ) and recovery ( $\text{PC}_R(n, k)$ ). In the former, we are given either a  $G(n, \frac{1}{2})$  graph or a planted clique graph and must identify the graph we have been given. That is, we must detect whether or not the graph has a planted clique. In the latter, we are given a planted clique graph and must recover all the vertices in the clique.

The planted clique problem shows a variety of interesting phenomena in its time complexity. Not only does it exhibit a statistical-computational gap at clique size  $k = \Theta(\sqrt{n})$ , it has also emerged as the central problem whose average-case hardness implies average-case hardness for many other problems with statistical-computational gaps. See [13, 12] for some examples. Further, the detection and recovery problems have the same threshold at which a polynomial time statistical-computational gap shows up, even though a priori the latter could be a harder problem than the former. In fact, for several other problems such as community detection/recovery in the stochastic block model [1] or planted submatrix detection/recovery [25, 14], there does indeed appear to be a difference between the time complexity of detection and recovery. They become polynomial time feasible at different signal-to-noise ratios, and this makes the lack of a gap between detection and recovery in planted clique all the more noteworthy.

Algorithmic progress on planted cliques has shown that both the detection and recovery problems can be solved “computationally efficiently” (i.e. in polynomial time) for large cliques of size  $k = \Omega(\sqrt{n})$  and less efficiently in quasi-polynomial time  $n^{O(\log n)}$  for cliques larger than the information-theoretic threshold,  $k \geq (2 + \epsilon) \log n$ . The widely believed *Planted Clique Conjecture* even states that if the clique size is small  $k = O(n^{\frac{1}{2}-\delta})$  for any constant  $\delta > 0$ , no polynomial time algorithm can solve the planted clique detection (and hence also the recovery) problem. We survey the results providing evidence for this conjecture in Section 1.1.

However, we do not know how robust these statistical-computational phenomena are to changes in our notion of “computational efficiency”. To begin investigating this, we ask the following question:

*Do the statistical-computational phenomena that make the planted clique an interesting problem also hold when we use “space efficiency” as our notion of computational efficiency?*

To answer this question, we must first discuss what a “space efficient” algorithm is. One of the most well studied classes of space bounded computation is that of logarithmic space, and it is widely considered a benchmark of “space efficient” computation.

Let us further motivate this target space complexity. For deterministic algorithms, this is the class that runs using  $O(\log n)$  bits of space on inputs of size  $\text{poly}(n)$ . It is well known that any deterministic algorithm that uses at most  $s(n)$  bits of space must also run in time  $2^{O(s(n) + \log n)}$  [7, Theorem 4.3]<sup>2</sup>. This means that deterministic logspace algorithms are a

<sup>2</sup> Strictly speaking, the theorem we point to relating deterministic space complexity to time complexity [7, Theorem 4.3] is for Turing machines. While it is convenient to define computational complexity classes using Turing machines, it is extremely inconvenient to design algorithms using them. Instead, we work with a slightly stronger model of computation that allows random access to the input to make algorithm design reasonable. However, the idea behind [7, Theorem 4.3] also holds in any reasonable RAM model and so we ignore this distinction for the purposes of our discussion.

subset of polynomial time algorithms, lending support to the belief that they are a good proxy for “efficient” computation. For algorithms that can use randomness, defining an appropriate notion of space bounded computation involves restricting algorithms that use  $s(n)$  bits of space to at most  $2^{O(s(n)+\log n)}$  time<sup>3</sup>. So, randomized logspace computation corresponds to algorithms running in  $O(\log n)$  space and at most  $\text{poly}(n)$  time on inputs of size  $\text{poly}(n)$ .

This means that if the *Planted Clique Conjecture* is true, no logarithmic space (deterministic or randomized) algorithm can solve the planted clique detection (or recovery) problems for  $k = O(n^{1/2-\delta})$ . If we can show logarithmic space algorithms exist above the polynomial time threshold  $k = \Omega(\sqrt{n})$ , we will have shown that the statistical-computational gap holds even for space complexity.

**Detection.** For detection, essentially the same straightforward algorithms that have been designed for time efficiency can also be implemented space efficiently. For clique sizes above the information theoretic threshold  $k \geq (2 + \epsilon) \log n$ , the same “exhaustively search over sets of  $\Theta(\log n)$  vertices” idea that gives a quasi-polynomial  $n^{O(\log n)}$  time algorithm also gives a  $O(\log^2 n)$  space algorithm<sup>4</sup>. For large cliques above the polynomial time threshold  $k = \Omega(\sqrt{n})$ , the folklore “sum test” or “edge counting” algorithm (see for example Section 1.5 of [36]) can be implemented in  $O(\log n)$  bits of space. We elaborate more on these algorithms in Section 1.3, but for now it suffices to observe that this means a statistical-computational gap holds for planted clique detection at  $k = \Theta(\sqrt{n})$  in terms of space complexity if it holds for time complexity.

**Recovery.** But what about planted clique recovery? Before we go any further, we should clarify what we mean by a small space algorithm for planted clique recovery. The size of the output is  $k \log n$  bits, which could be much larger than the space we are allowing the algorithm. However, the space bound applies only to the working-space of the algorithm, and the output is written on a *write-only* area which does not count towards the space bound. This is standard in the space complexity literature, so we can write-to-output very large answers. See, for example, Section 14.1 of [48].

Just like for detection, simple pre-existing ideas can easily be used to obtain a  $O(\log^2 n)$  space algorithm for recovering planted cliques above the information theoretic threshold, thus matching the detection space complexity in this range of parameters. We provide more details in Section 1.3. Also like for detection, we do not expect a  $O(\log n)$  space algorithm in this regime because of the *Planted Clique Conjecture* and the relation between space and time complexity.

If we can design a  $O(\log n)$  space algorithm that recovers large planted cliques  $k = \Omega(\sqrt{n})$ , we will have shown two things:

- If the conjectured statistical-computational gap at  $k = \Theta(\sqrt{n})$  holds for the time complexity of the planted clique recovery problem, it also holds for space complexity.

<sup>3</sup> See, for example, the section on Randomized Space-Bounded Computation in [7] or the discussion about *BPHSPACE* in [45]. Note that all the algorithms we discuss in this work are deterministic, so we will not need to explicitly analyse or discuss their running time.

<sup>4</sup> Since the best known time complexity for this problem is  $n^{O(\log n)}$ , we do not expect to solve this problem in  $o(\log^2 n)$  bits of space

- Assuming the above statistical-computational gap holds, the coarse-grained<sup>5</sup> computational complexity of planted clique detection and recovery are indeed the same, no matter the notion of complexity we use – time or space.

1. Our first hope for such a logspace recovery algorithm is to see if any pre-existing algorithms are space efficient. However, none of the polynomial time algorithms designed for recovery above  $k = \Omega(\sqrt{n})$  run in small space. They all require at least  $\text{poly}(n)$  bits of space, and in Section 1.3 we discuss, for each of them, why it seems hard to implement them in  $O(\log n)$  bits of space.

Of course, the “degree-counting” polynomial time recovery algorithm for large cliques of size  $k = \Omega(\sqrt{n \log n})$  from [32] *can* easily be implemented in  $O(\log n)$  space. This matches the space complexity for detection in this parameter range. For such large cliques, a simple threshold separates the degrees of non-clique vertices and clique vertices, so membership can easily be decided from a vertex’s degree. A space efficient implementation exists because we can easily count the degree of a vertex (which takes  $O(\log n)$  bits to store) and iterate over all vertices in logarithmic space, re-using the counter used to store the degree across vertices. However, this idea does not work for  $\Omega(\sqrt{n}) = k = o(\sqrt{n \log n})$ , and it is this parameter range in which most algorithmic work for the planted clique problem has been done in the past two decades. If we want to show that the statistical-computational phenomena that hold for time complexity also hold for space complexity, we will need to focus on these parameters.

2. Our next hope is to recall that the lack of a detection-recovery gap in the time complexity of the planted clique problem is not merely an algorithmic coincidence. Section 4.3.3 of [4] shows a black box way to convert a planted clique detection algorithm into a recovery algorithm. The key idea is that if a vertex  $v$  is in the clique, the subgraph induced on the vertex set that *does not* contain  $v$  or its neighbours is distributed as an Erdős-Rényi graph. But, if  $v$  is not in the clique, this induced subgraph is distributed as a planted clique graph. Then we can simply run the detection algorithm to decide if  $v$  is in the planted clique or not<sup>6</sup>. If we could use the edge counting detection algorithm and implement this reduction between recovery and detection in small space, then it seems we would be done. What is more, such a reduction *can* be implemented in small space!<sup>7</sup>

However, there is a slight issue. The statistical success of the reduction in [4] requires the failure probability of the detection algorithm to be at most  $o(\frac{1}{n})$ . This is because we need to repeat the detection algorithm  $n$  times, once for each vertex in the original graph, and thus need to take a union bound. However, as we can see from Section 1.5 in [36], the failure probability of the edge counting test is  $\exp\left(-\Theta\left(\frac{k^4}{n^2}\right)\right)$ . This means the failure probability is  $o(\frac{1}{n})$  only for  $k = \omega(\sqrt{n \log^{\frac{1}{4}} n})$ , which is not a huge improvement over the degree counting algorithm.

<sup>5</sup> By coarse-grained time complexity we mean that we do not distinguish between different  $\text{poly}(n)$  running times. If we were looking at a more fine-grained picture, a gap does emerge between detection and recovery. [37] showed that for  $k = \omega(n^{2/3})$ , planted clique detection can be solved in  $o(n)$  time. However, by results of [41] we know that any recovery algorithm must require  $\Omega(n)$  time. For space complexity, “coarse-grained” means we do not distinguish between any two  $O(\log n)$  space algorithms. Observe that even if there is a  $O(\log n)$  space algorithm that recovers cliques of size  $k = \Omega(\sqrt{n})$ , the fine-grained space complexity of detection and recovery could, in principle, be different. This would be the case if there exists a  $o(\log n)$  space algorithm for detection but not for recovery.

<sup>6</sup> Of course, such a reduction has a built in  $O(n)$  factor time overhead for the recovery algorithm above the detection algorithm.

<sup>7</sup> To count the number of edges induced in such a manner by a vertex  $v$ , we can simply iterate over all pairs  $u, w$  of vertices in the original graph. We increment the counter only if the edge  $(u, w)$  exists *and* neither of the vertices  $u, w$  have an edge to  $v$ .

Due to the discussion above, we need some new ideas to get small space recovery algorithms for planted cliques of size  $k = \Omega(\sqrt{n})$ . Our main result, stated informally below, is one that falls just short of our aim of a  $O(\log n)$  space algorithm. For a formal statement, see Theorem 2.4 in Section 2.

For some large enough constant  $C > 0$ , for planted cliques of size  $k \geq C\sqrt{n}$ , the recovery problem  $\text{PC}_R(n, k)$  can be solved in  $O\left(\left(\log^* n - \log^* \frac{k}{\sqrt{n}}\right) \cdot \log n\right)$  bits of space.

1. If  $k = \omega(\sqrt{n} \log^{(\ell)} n)$  for any constant integer  $\ell > 0$ , the space usage is indeed  $O(\log n)$  bits, which was our target.
2. However, if  $k = C\sqrt{n}$ , the space usage is  $O(\log^* n \cdot \log n)$  bits, which is just shy of what we were aiming for.

Our result suggests that there does exist an  $O(\log n)$  space algorithm to recover cliques of size  $k = \Omega(\sqrt{n})$ , since we come very close to achieving such parameters. We fail to answer our titular question, but only just. We provide strong evidence that the answer is “yes”, and the statistical-computational phenomena that (conjecturally) hold for planted clique time complexity also (conjecturally) hold for space complexity. We have thus initiated the study of high dimensional statistical problems in terms of their space complexity.

As we see in Section 1.1, a long line of work on restricted models of computation has been used to show hardness of the planted clique problem. On the other hand, this work (like [37]) studies a restricted model of computation with the primary aim of making algorithmic progress and further pushing down the complexity of successful planted clique algorithms.

**Open Problem.** Is there a logspace algorithm that recovers planted cliques of size  $k = \Omega(\sqrt{n})$  reliably, or is there a (tiny) detection-recovery gap in the space complexity of the planted clique problem?

## 1.1 Related Work

**Planted Clique Hardness.** It is widely believed that polynomial time algorithms can only detect or recover the planted clique for clique sizes above  $k = \Omega(\sqrt{n})$ . One piece of evidence for this belief is the long line of algorithmic progress using a variety of techniques that has been unable to break this barrier [32, 5, 20, 22, 6, 16, 14, 17, 25, 37]. The other piece of evidence comes from studying restricted but powerful classes of algorithms. [30] showed that a natural Markov chain based technique requires more than polynomial time below this threshold. Similar hardness results (for the planted clique problem or its variants) have been shown for statistical query algorithms [23], circuit classes [43, 44], the Lovász–Schrijver hierarchy [21], and the sum-of-squares hierarchy [39, 18, 26, 9]. Further evidence comes from the low-degree-likelihood method [28, 27, 29, 33] and through concepts from statistical physics [24].

**Statistical-Computational Gaps.** Statistical-computational gaps are not unique to the planted clique problem, and are found in problems involving community detection / recovery [15, 38, 40, 2], sparse PCA [10, 34], tensor PCA [42, 27], random CSPs [3, 31], and robust sparse estimation [35, 8]. However, the planted clique problem is special in that its hardness (or that of its close variants) can be used to show hardness and statistical-computational gaps for a variety of other problems. Such reductions can be seen in [10, 4, 13, 12]. See [12] for a more comprehensive list of examples. To the best of our knowledge, most of these

reductions use randomness quite heavily, so it is unclear if such connections can also be made using only logarithmic space reductions. It would be interesting to do so since this would tie these problems together even more tightly, and would show that planted clique is a central problem in average-case complexity not just for time but also space.

**Detection-Recovery Gaps.** As we have mentioned, the statistical-computational gap in the planted clique problem appears at  $k = \Theta(\sqrt{n})$  for both the detection and recovery variants. This means there is no detection-recovery gap in time complexity, and our work is trying to show that no such gap exists for space complexity either. To understand that the non-existence of this gap is not a foregone conclusion, we note that for several other problems, detection-recovery gaps *do* exist. For example, for communities in the stochastic block model [1], or planted submatrix problems [25, 14]. Moreover, the (non-)existence of a detection-recovery gap is not an inconsequential detail. Since the planted clique problem does not display such a gap, it is not straightforward to use it as a starting point to show detection-recovery gaps for other problems. [12] overcomes this issue for semirandom community recovery by starting from a variant of the planted clique problem, and [46] develops a low-degree-likelihood ratio technique tailored to recovery tasks to get around this problem.

## 1.2 Notation and Problem Definition

**Notation.** We will use standard big  $O$  notation ( $O, \Theta, \Omega$ ). An edge between vertices  $u, v$  is denoted  $(u, v)$ . We let  $\text{Bin}(n, \frac{1}{2})$  denote a Binomial random variable with parameters  $(n, \frac{1}{2})$ . Similarly,  $\text{Bern}(p)$  denotes a Bernoulli random variable that is 1 with probability  $p$  and 0 otherwise. Unless stated otherwise, all logarithms are taken base 2. For a vertex  $v$  in graph  $G = ([n], E)$ , we will denote its degree by  $\deg(v)$ . Throughout this work we identify the vertex set of the graph with the set  $[n] := \{1, 2, \dots, n\}$ . We will also crucially utilise the natural ordering this confers on the names of the vertices.

We also define the so-called binary iterated logarithm  $\log^* n$ .

$$\log^* n = \begin{cases} 0 & \text{if } n \leq 1 \\ 1 + \log^*(\log n) & \text{if } n > 1 \end{cases}$$

Below are formal definitions of the graphs ensembles we use and the planted clique problem.

► **Definition 1.1** (Erdős-Rényi graph distribution:  $G(n, \frac{1}{2})$ ). *Let  $G = ([n], E)$  be a graph with vertex set of size  $n$ . The edge set  $E$  is created by including each possible edge independently with probability  $\frac{1}{2}$ . The distribution on graphs thus formed is denoted  $G(n, \frac{1}{2})$ .*

► **Definition 1.2** (Planted Clique graph distribution:  $G(n, \frac{1}{2}, k)$ ). *Let  $G = ([n], E)$  be a graph with vertex set of size  $n$ . Moreover, let  $K \subset [n]$  be a set of size  $k$  chosen uniformly at random from all  $\binom{n}{k}$  subsets of size  $k$ . For all distinct pairs of vertices  $u, v \in K$ , we add the edge  $(u, v)$  to  $E$ . For all remaining distinct pairs of vertices  $u, v$ , we add the edge  $(u, v)$  to  $E$  independently with probability  $\frac{1}{2}$ . The distribution on graphs thus formed is denoted  $G(n, \frac{1}{2}, k)$ .*

► **Definition 1.3** (Planted Clique Detection Problem:  $\text{PC}_D(n, k)$ ). *This is the following hypothesis testing problem.*

$$H_0 : G \sim G(n, \frac{1}{2}) \quad \text{and} \quad H_1 : G \sim G(n, \frac{1}{2}, k).$$

*Give an algorithm  $\mathcal{A}$  that takes as input the graph  $G$  and outputs either 0 or 1 so that*

$$\Pr(\mathcal{A}(G) = 0 | H_0) + \Pr(\mathcal{A}(G) = 1 | H_1) \geq 4/3.$$

► **Definition 1.4** (Planted Clique Recovery Problem:  $\text{PC}_R(n, k)$ ). *Given an instance of  $G \sim \mathcal{G}(n, \frac{1}{2}, k)$ , recover the planted clique  $K$  with probability at least  $2/3$ .*

### 1.3 Our Techniques

Our space efficient recovery algorithm will depend on the ability to take a small subset of the planted clique and expand it to recover the entire clique. We first discuss such a subroutine, and then talk about our main result, the  $O\left(\left(\log^* n - \log^* \frac{k}{\sqrt{n}}\right) \cdot \log n\right)$  space algorithm for planted clique recovery for large cliques of size  $k = \Omega(\sqrt{n})$ . We do this by first studying polynomial time algorithms that work in this regime, discussing why they take polynomial amounts of space to implement, and then providing the high level ideas of our algorithm. After this, we end with some more details on the straightforward  $O(\log^2 n)$  space implementations of the known quasi-polynomial time algorithms for clique detection and recovery above the information theoretic threshold.

**Small space clique completion.** Several polynomial time recovery algorithms use clique completion / clean-up subroutines to find the entire planted clique after finding just a large enough (possibly noisy) subset of it [5, 22, 16, 17, 37]. However, none of these seem amenable to space efficient implementation, so we create a simple completion algorithm of our own.

We assume we have an algorithm that implicitly maps any planted clique graph to a specific large enough subset of the vertices of the planted clique, which we call  $S_C$ . If given any vertex as input, this algorithm can answer whether this vertex is in  $S_C$  or not using  $s(n)$  bits of space. This is what we mean by “having access to” a subset of the clique that we can now complete. Consider the set  $\tilde{V}$  of those vertices which are connected to every vertex in  $S_C$ . It is easy to show that this new set  $\tilde{V}$  contains the entire planted clique and very few non-clique vertices (see Lemma 3.2). As a result, the number of edges to  $\tilde{V}$  from a clique vertex is far larger than that of a non-clique vertex, and a simple logspace computable threshold can distinguish between the two cases. We show in Algorithm 1 (SMALL SPACE CLIQUE COMPLETION) and Lemma 2.1 that we can use this to decide if a given vertex is in the planted clique or not using  $O(\log n + s(n))$  bits of space. Then we simply loop over all vertices with a further  $O(\log n)$  bits of space and thus have a planted clique recovery algorithm.

**Recovery for  $k = \Omega(\sqrt{n})$ .** We first take a look at existing polynomial time algorithms for  $k = \Omega(\sqrt{n})$  to see why they all require  $\text{poly}(n)$  bits of space, and to see if they have good ideas that we can build on to get small space algorithms.

1. Optimization / SDP algorithms: Several optimization theoretic algorithms involving semidefinite programs have been designed that solve the planted clique recovery problem for  $k = \Omega(\sqrt{n})$  [20, 6, 14, 25]. However, we do not expect to have a general-purpose logarithmic space algorithm for semidefinite programs. The works [19, 47] show that even (approximately) solving linear programs, which are a special case of semidefinite programs, is logspace complete for P. This means that if we had a logspace algorithm for semidefinite programs, every problem with a polynomial time algorithm could also be solved in logarithmic space. Such a proposition is believed to be untrue [48, Conjecture 14.8].
2. (Nearly) Linear time algorithms:
  - a. The algorithm of [22] maintains a subset of “plausible clique vertices” and reduces the size of this subset by 1 in every round. As a result, it needs to maintain a polynomially large subset for most of the time it runs. There also does not seem to be a clever way to compress this set, since it depends crucially on the edge structure of the graph.

- b. The message passing algorithm of [17] is iterative and produces a new dense  $n \times n$  matrix at every iteration, which can not be done in logarithmic space. It is plausible that a more space efficient recursive algorithm that recomputes messages as needed exists. But, since the algorithm requires  $\Theta(\log n)$  sequential iterations / recursive calls, and we will need  $\Omega(\log n)$  bits of space for each level of recursion, we do not expect this space usage to be  $o(\log^2 n)$  bits. Since this does not improve the space usage over the simple algorithm that works above the information theoretic threshold, we do not pursue this idea further.
- c. The algorithm of [16], like [22], maintains a sequence of shrinking subsets of vertices where the ratio between the number of clique and non-clique vertices improves in every round. Further, these subsets are polynomial sized *and* random. Since the pruning of the set depends on randomness from the algorithm, any clever space efficient implementation that re-uses space would need to store the random coins it tosses, defeating the purpose of a space efficient implementation. However, the key idea behind this algorithm *can* be de-randomized, and this is the first observation that forms the basis of our  $O\left(\left(\log^* n - \log^* \frac{k}{\sqrt{n}}\right) \cdot \log n\right)$  space algorithm.

We briefly explain the technique of [16] in more detail, but using the notation of this work rather than that of [16]. Their algorithm runs for  $T$  rounds and maintains a sequence of vertex subsets  $\{N_t, V_t\}_{1 \leq t \leq T}$ .  $N_1 = V_1$  is essentially the entire vertex set  $[n]$ , and then each vertex of  $V_{t-1}$  is included in  $N_t$  iid with some probability and each vertex of  $N_t$  is added to  $V_t$  by cleverly using information from the edge structure of the input graph. This results in the ratio of clique vertices to non-clique vertices in  $V_t$  increasing by a constant factor in every round.  $T$  is then chosen large enough so that  $V_T$  is entirely a subset of the planted clique. The entire clique is now output using a clique completion subroutine.

Since the subsets  $N_t$  described above depend so heavily on the randomness of the algorithm as well as the edge structure of the input graph, this algorithm can not be implemented in less than  $\text{poly}(n)$  space. On the other hand, we have already noted that creating a space efficient clique completion algorithm can be done, and we have done so in Lemma 2.1 with Algorithm 1. So we now focus on trying to modify the first part of the algorithm to something that can be implemented space efficiently. Our challenge is to concisely represent the sets  $N_t$  (and by extension,  $V_t$ ).

Our observation is that the clever filtering of [16] does not depend crucially on the set  $N_t$  being a subset of  $V_{t-1}$  (which is what makes it depend on the edge structure of the graph). Nor does it depend on the set being random. The only thing we really need is that the proportion of clique to non-clique vertices in  $N_t$  is not too small, and that we can easily iterate over all the vertices in any set  $N_t$ . This gives us the freedom we require to design the sets  $N_t$  to be concisely representable, and we use our computer's representation of the vertex set to our advantage. For our computer, the names of the  $n$  vertices of the graph are  $\log n$  bit integers, and we can use the fact that integers have a natural ordering as well as the fact that simple arithmetic can easily be done in  $O(\log n)$  bits of space.

We first set up some notation. The quantities we define will be functions of  $n, k$ , and the graph  $G \sim G(n, \frac{1}{2}, k)$  although our notation will not explicitly denote this. The value of  $n, k$  and the graph will always be clear from context. Recall that  $[n]$  is the vertex set of a graph  $G \sim G(n, \frac{1}{2}, k)$  with  $n$  vertices and a planted clique called  $K$  of size  $k$  and a set of edges called  $E$ .

- Define  $n_0$  as the smallest integer that is a power of 2 and is at least  $n/2$ . This means  $n/2 \leq n_0 < n$ . Define  $k_0 := k \frac{n_0}{n}$
- For any integer  $0 < t < \log n_0$ , let  $n_t := \frac{n_0}{2^t}$ ,  $k_t := \frac{k_0}{2^t}$ . Note that  $n_t$  is always an integer.

■ **Figure 1** An example of our sets  $N_t$  for  $n = 17$ .

- We can now define the subsets  $N_t$  of the vertex set  $[n]$  that will be of particular interest in our filtering algorithm. Let  $N_t := [n_{t-1}] \setminus [n_t]$ , and note that the  $N_t$ 's are all disjoint sets. Clearly,  $|N_t| = n_t$ . See Figure 1 for an example.

It is easy to observe that given  $n, t$  we can iterate over the vertex set  $N_t$  in  $O(\log n)$  space, which is exactly what we wanted. In the analysis of Lemma 2.2, we will also show that the ratio of clique vertices to non-clique vertices in any  $N_t$  is roughly the same as in the whole graph, which is not too small. Now we must implement the rest of the ideas in [16], the ones that actually use the input graph to find the clique.

After setting  $V_1 = N_1$ , the filtering step of [16] fixes a threshold and adds a vertex in  $N_t$  to the set  $V_t$  if and only if that vertex has more edges to  $V_{t-1}$ <sup>8</sup> than the set threshold. Since clique vertices in  $N_t$  are likely to have a higher number of edges to  $V_{t-1}$  than non-clique vertices, the former are more likely to appear in  $V_t$  and the latter are more likely to be filtered out. This is how the ratio of clique to non-clique vertices in  $V_t$  gradually increases with  $t$ . If we had an algorithm to check membership in  $V_{t-1}$  that uses  $s_{t-1}(n)$  bits of space, we could design an algorithm to check for membership in  $V_t$  that uses  $O(\log n) + s_{t-1}(n)$  bits of space. To see this, suppose we have a vertex  $v \in N_t$  and we want to decide if it is in  $V_t$ . We can simply iterate over the set  $N_{t-1}$ , and for each vertex  $u \in N_{t-1}$ , check if it is also in  $V_{t-1}$  using our assumed algorithm. We can also maintain a  $O(\log n)$  bit counter to count the number of edges from  $v$  to all  $u$  that are in  $V_{t-1}$ . Since we can re-use the  $s_{t-1}(n)$  bits of space to check membership in  $V_{t-1}$  across different  $u$ , the whole thing can be done in  $O(\log n) + s_{t-1}(n)$  bits of space. By induction, this means we can check for membership in  $V_T$  using  $O(T \cdot \log n)$  bits of space. We provide a formal algorithm and proof of such a claim in Lemma 2.3 using Algorithm 2.

Overall, this promises to give a  $O(T \cdot \log n)$  space algorithm. What can we set  $T$  to be? Unfortunately, the algorithm of [16] uses  $T = \Theta(\log n)$  rounds, since it only gets a constant factor improvement in the ratio of clique to non-clique vertices in going from  $V_{t-1}$  to  $V_t$ . This gives a  $O(\log^2 n)$  space algorithm, which is not an improvement over the simple algorithm that works above the information theoretic threshold.

Our key idea, inspired by [37], is to implement a better filtering step that gets more than a constant factor of improvement in each round. The filtering / thresholding of [16] does not utilise the size of the planted clique  $k$  at all, other than the fact that it is  $\Omega(\sqrt{n})$ . On the other hand, [37] uses knowledge of  $k$  to design a single round filtering algorithm that recovers the planted clique for clique sizes  $\omega(\sqrt{n} \log \log n) = k = o(\sqrt{n} \log n)$  in sublinear time. By appropriately implementing this idea in our context for multiple rounds, we can utilize knowledge of the number of clique vertices in  $V_{t-1}$ ,  $|V_{t-1} \cap K|$ , to make sure that in going from  $V_{t-1}$  to  $V_t$  the following happens. The number of clique vertices decreases by at most a constant factor, while the number of non-clique vertices decreases by at least a factor of  $\exp\left(\Theta\left(\frac{|V_{t-1} \cap K|^2}{|V_{t-1}|}\right)\right)$ , which is  $\exp\left(\Theta\left(\frac{k^2}{n}\right)\right)$  for  $t = 2$ . For  $k = \Theta(\sqrt{n})$ , this is still a constant factor, but for larger  $k$ , this is much better than a constant factor improvement.

<sup>8</sup> Technically, [16] counts the number of edges to  $V_{t-1} \setminus N_t$ , but in our construction we will have  $V_{t-1} \setminus N_t = V_{t-1}$ .

## 34:10 Is the Space Complexity of Planted Clique Recovery the Same as That of Detection?

To use this idea, our algorithm needs to know  $|V_{t-1} \cap K|$ , which it does not. However, we do have high probability lower bounds on the size  $|V_{t-1} \cap K|$ . We design our thresholds using these estimates, and our analysis in Lemma 2.2 shows that this suffices to get the benefits of this better filter. Let us now define the sets  $V_t$  for our algorithm, thus specifying the filtering threshold. We proceed inductively.

- $V_1 := N_1$
- For any integer  $t > 1$ ,  $V_t$  is a subset of  $N_t$  of vertices which have “large”  $V_{t-1}$ -degree. Quantitatively,  $V_t := \{v \in N_t \mid \sum_{u \in V_{t-1}} \mathbb{1}_{(u,v) \in E} \geq \frac{|V_{t-1}|}{2} + k_{t+2} - 2\sqrt{|V_{t-1}|}\}$ .

It is this carefully chosen threshold sequence which, unlike in [16], varies with  $t$  and uses the value of  $k$  that allows us to improve on the  $O(\log^2 n)$  space bound. In Lemma 2.2 we will show that  $V_T$ , as defined above, is with high probability a subset of the planted clique if  $T$  is large enough. We can implement an algorithm to check membership in  $V_T$  in  $O(T \cdot \log n)$  bits of space as discussed above (and formalized in Lemma 2.3). Moreover, we get the benefits of a very quickly accelerating improvement in the ratio of clique to non-clique vertices from  $V_{t-1}$  to  $V_t$ . From [37] we know that one round of such a filter improves the ratio by a factor of  $\exp\left(\Theta\left(\frac{k^2}{n}\right)\right)$ , and the analysis of our filtering in Lemma 2.2 shows that after  $t$  rounds of such filtering, the ratio improves by what is essentially a tower of exponentials of height  $\frac{t}{2}$ , i.e.  $\exp\left(\exp\left(\dots \exp\left(\Theta\left(\frac{k}{\sqrt{n}}\right)\right)\right)\right)$ . This is why we are able to take  $T = O\left(\log^* n - \log^* \frac{k}{\sqrt{n}}\right)$  (Lemma 2.2). This gives us our main result, an algorithm that can recover planted cliques of size  $k \geq C\sqrt{n}$  in  $O\left(\left(\log^* n - \log^* \frac{k}{\sqrt{n}}\right) \cdot \log n\right)$  bits of space. The formal statement and proof can be found in Theorem 2.4.

### Detection.

1. It is well known (see [11] or Lemma 3.4) that for any positive constant  $\epsilon > 0$ , the probability that an Erdős-Rényi  $G(n, \frac{1}{2})$  graph has a clique of size at least  $(2 + \epsilon) \log n$  goes to 0. Meanwhile, if  $k \geq (2 + \epsilon) \log n$ , then by definition a planted clique graph  $G(n, \frac{1}{2}, k)$  has a clique of size  $(2 + \epsilon) \log n$ . The existence of a clique of this size is a well-known and simple detection test for  $\text{PC}_D(n, k)$  (see, for example, Proposition 1.3 [36]). Moreover, such a test only needs to iterate over all vertex subsets of size  $(2 + \epsilon) \log n$ , which can be done by maintaining a  $\log n$  bit name/number for each of the  $(2 + \epsilon) \log n$  vertices and looping over all possibilities. For a given possible clique, the algorithm needs to check if all  $\binom{(2+\epsilon)\log n}{2}$  edges exist. This can be done by looping over all these edges with 2 more  $O(\log \log n)$  bit counters. Overall, this implementation requires  $O(\log^2 n)$  bits of space.
2. The simple “sum test” or “edge counting” algorithm that is well-known to work for large planted clique  $k = \Omega(\sqrt{n})$  detection (see for example Section 1.5 of [36]) can easily be implemented in  $O(\log n)$  space. The planted graph has significantly more edges than the graph without a clique, so simply counting the number of edges in the input graph and using a threshold test gives a successful detection algorithm. The algorithm only needs to maintain the edge count, which is a number between 1 and  $n^2$  (which can be done with  $O(\log n)$  bits), and it can also easily iterate over all distinct vertex pairs in  $O(\log n)$  bits of space. Lastly, the algorithm also needs to compute the threshold (from [36], we can use the threshold  $\frac{\binom{n}{2}}{2} + \frac{\binom{k}{2}}{4}$ ), which can easily be computed from the input (which contains  $n, k$ ) in logarithmic space. This means that for planted clique detection, assuming we have a time complexity based statistical-computational gap, we also have a space complexity based statistical-computational gap.

**Recovery above the information theoretic threshold.** For cliques of size  $(2 + \epsilon) \log n \leq k = O(\log n)$ , with high probability the planted clique is the unique largest clique in  $\mathcal{G}(n, \frac{1}{2}, k)$  [36, Theorem 1.7]. This means that an algorithm that loops over all possible vertex subsets of size  $k$  can find and output the entire planted clique. To do this it only need to maintain  $k$  names of vertices (which takes  $O(k \log n)$  bits of space) and 2 counters of  $O(\log k)$  bits of space to check if a given set of  $k$  vertices form a clique. Overall, this implementation needs  $O(\log^2 n)$  bits of space.

A simple application of the reduction between detection and recovery from [4] combined with the  $O(\log^2 n)$  space detection algorithm for clique sizes above the information theoretic threshold  $k \geq (2 + \epsilon) \log n$  also gives a  $O(\log^2 n)$  space recovery algorithm for  $k = \omega(\log n)$ . We provide a formal statement and proof in Lemma 3.5.

## 2 Algorithms

We now prove our main results after formalizing our model of computation in Section 2.1. In Section 2.2 we give a space efficient algorithm for clique completion. In Section 2.3 we prove our  $O\left(\left(\log^* n - \log^* \frac{k}{\sqrt{n}}\right) \cdot \log n\right)$  space recovery algorithm for clique sizes above the polynomial time threshold  $k = \Omega(\sqrt{n})$ .

### 2.1 Model of Computation

We use a standard notion of deterministic space bounded computation. See, for example, [48, Section 14.1]. For a  $s(n)$ -space algorithm, the input is a read-only version of the  $n \times n$  adjacency matrix of the graph as well as the clique size  $k$ . Every entry in the matrix as well as the value of  $k$  is stored in its own register. The algorithm has access to  $s(n)$  bits of working space, and the output is write-only (and possibly much larger than  $s(n)$ ). The last fact allows us to solve problems whose outputs may be much larger than  $s(n)$ , a property we will use to solve  $\text{PC}_R(n, k)$ .

To make our model convenient for algorithm design, we also allow random access to the input registers. In our model, we assume basic arithmetic (addition, multiplication, subtraction, division) on  $O(\log n)$  bit numbers can be done in  $O(\log n)$  bits of space. We also assume that the algorithm can compute or knows  $n$  by accessing the adjacency matrix using  $O(\log n)$  bits of space.

### 2.2 Space bounded clique completion

The main idea behind this algorithm is discussed in Section 1.3. If we have access to a large enough subset of the clique, very few vertices that are adjacent to the entire subset (i.e “common neighbours”) are not in the planted clique. Counting the edges from a vertex  $v$  to this set of “common neighbours” of the known clique subset allows us to decide whether or not  $v$  is in the planted clique.

► **Lemma 2.1** (Deterministic + small space clique completion). *Let  $k = \omega(\log n)$ , and  $G \sim \mathcal{G}(n, \frac{1}{2}, k) = ([n], E)$ . Let  $O_{S_C}$  be a deterministic algorithm that uses  $s(n)$  bits of space and, except with probability at most  $p(n) \leq \frac{1}{2}$  (over the randomness in  $G$ ), has the following properties.*

1. *When given as input the graph  $G$  and clique size  $k$ , it implicitly defines a subset of the planted clique vertices  $S_C$  such that  $S_C \subset K$  and  $|S_C| \geq 2 \log n$ .*
2. *It does this by returning, for  $v \in [n]$ ,  $O_{S_C}(v) = 1$  if and only if  $v \in S_C$ , and 0 otherwise.*

---

**Algorithm 1** SMALL SPACE CLIQUE COMPLETION (SSCC).

---

**Input:** Graph  $G = ([n], E) \sim \mathcal{G}(n, \frac{1}{2}, k)$ , clique size  $k$ , oracle  $O_{S_C}$  with access to a clique set  $S_C \subset K : O_{S_C}(v) = 1$  if  $v \in S_C$ ,  $O_{S_C}(v) = 0$  if  $v \notin S_C$

**Output:** Clique  $K$

```

for  $v \in [n]$  do
  Initialize  $\widetilde{\deg}(v) = 0$ 
  for  $u \in [n]$  do
    Initialize  $\text{in}\widetilde{V}(u) = \text{TRUE}$ 
    for  $w \in [n]$  do
      if  $O_{S_C}(w) = 1$  and  $(w, u) \notin E$  then
        Set  $\text{in}\widetilde{V}(u) = \text{FALSE}$ 
      end
    end
    if  $\text{in}\widetilde{V}(u) = \text{TRUE}$  and  $(u, v) \in E$  then
       $\widetilde{\deg}(v) = \widetilde{\deg}(v) + 1$ 
    end
  end
  if  $\widetilde{\deg}(v) \geq \frac{2k}{3} + 3 \log k$  then
    write-to-output  $v$ 
  end

```

} Check if  $u$  is a common neighbour  
 } Use “common neighbour”-degree of  $v$

**end**

---

Then for large enough  $n$ , SMALL SPACE CLIQUE COMPLETION (Algorithm 1), when run on  $G$  with access to the algorithm  $O_{S_C}$ , runs deterministically in space  $O(s(n) + \log n)$  and writes to output the correct planted clique  $K$  except with probability at most  $p(n) + \left(\frac{1}{n}\right)^{\log k} + n \exp\left(-\frac{k}{54}\right)$  (which is over the randomness in  $G$ ).

**Proof.** The proof can be found in the arXiv version at <https://arxiv.org/abs/2008.12825>. ◀

### 2.3 Finding a clique subset in small space

We recall some notation defined in Section 1.3.

- Define  $n_0$  as the smallest integer that is a power of 2 and is at least  $n/2$ . This means  $n/2 \leq n_0 < n$ . Define  $k_0 := k \frac{n_0}{n}$
- For any integer  $0 < t < \log n_0$ , let  $n_t := \frac{n_0}{2^t}$ ,  $k_t := \frac{k_0}{2^t}$ . Note that  $n_t$  is always an integer.
- We also define some subsets of the vertex set  $[n]$  that will be of particular interest in our filtering algorithm. Let  $N_t := [n_{t-1}] \setminus [n_t]$ , and note that the  $N_t$ 's are all disjoint sets. Clearly,  $|N_t| = n_t$ .

So far, we have defined vertex subsets that do not depend at all on the edge structure of the graph. Now we define some subsets that do incorporate information about such edge structure (and hence will be useful in finding the planted clique). We proceed inductively.

- $V_1 := N_1$
- For any integer  $t > 1$ ,  $V_t$  is a subset of  $N_t$ <sup>9</sup> of vertices which have “large”  $V_{t-1}$ -degree<sup>10</sup>.

---

<sup>9</sup> Hence the  $V_t$ 's are all disjoint for different values of  $t$ .

<sup>10</sup> Defined as the number of edges from a vertex  $v \in V_t$  to  $V_{t-1}$ .

Quantitatively,  $V_t := \{v \in N_t \mid \sum_{u \in V_{t-1}} \mathbb{1}_{(u,v) \in E} \geq \frac{|V_{t-1}|}{2} + k_{t+2} - 2\sqrt{|V_{t-1}|}\}$ .

Our main structural lemma shows that for large enough  $T$ ,  $V_T$  is a large enough subset of the planted clique.

► **Lemma 2.2** (Filtering lemma). *Let  $C > 0$  be some large enough constant. Let  $G \sim \mathcal{G}(n, \frac{1}{2}, k)$ , with  $C\sqrt{n} \leq k$  and  $T$  be an integer such that  $2(\log^* n - \log^*(k/\sqrt{n})) + 3 \leq T = O(\log^* n)$ . Then for large enough  $n$ , except with probability at most  $O(\exp(-n^{0.48}))$ ,  $V_T \subset K$  and  $\omega(\log n) = \frac{k}{2^{T+3}} \leq |V_T|$ .*

**Proof.** The proof can be found in the arXiv version at <https://arxiv.org/abs/2008.12825>. ◀

■ **Algorithm 2**  $V_t$ -MEMBERSHIP ( $t \geq 2$ ).

---

**Input:** Graph  $G = ([n], E) \sim \mathcal{G}(n, \frac{1}{2}, k)$ , clique size  $k$ ,  $t$ , vertex  $v \in N_t$ , access to  $V_{t-1}$ -MEMBERSHIP

**Output:** Membership in  $V_t : \mathbb{1}_{v \in V_t}$

Initialize  $\text{size}V_{t-1} = 0, \deg V_{t-1} = 0$

**for**  $u \in N_{t-1}$  **do**

<p><b>if</b> <math>V_{t-1}</math>-MEMBERSHIP(<math>G, k, t-1, u</math>) = 1 <b>then</b></p> <p style="margin-left: 20px;"><math>\text{size}V_{t-1} = \text{size}V_{t-1} + 1</math></p> <p style="margin-left: 20px;"><math>\deg V_{t-1} = \deg V_{t-1} + \mathbb{1}_{(u,v) \in E}</math></p> <p><b>end</b></p>	}	Count $ V_{t-1} $ , “ $V_{t-1}$ ”-degree of $v$
--	---	---

**end**

**output**  $\mathbb{1}_{\{\deg V_{t-1} \geq \frac{\text{size}V_{t-1}}{2} + k_{t+2} - 2\sqrt{\text{size}V_{t-1}}\}}$

---

The  $V_t$ -MEMBERSHIP algorithm simply computes the number of edges from a vertex  $v$  to the set  $V_{t-1}$  and uses this to determine whether or not  $v$  is in  $V_t$ .

► **Lemma 2.3** (Small space filter implementation). *Let  $G = ([n], E) \sim \mathcal{G}(n, \frac{1}{2}, k)$  with a clique size  $k$ . Let  $V_1$ -MEMBERSHIP be an algorithm that returns 1 for every vertex in  $N_1$ , and let  $V_t$ -MEMBERSHIP be defined as in Algorithm 2 for  $t \geq 2$ . Given a vertex  $v \in N_t$ ,  $V_t$ -MEMBERSHIP( $G, k, t, v$ ) returns 1 if and only if  $v \in V_t$ . Otherwise it returns 0. Moreover, it runs in space  $O(t \cdot \log n)$ .*

**Proof.** The proof can be found in the arXiv version at <https://arxiv.org/abs/2008.12825>. ◀

► **Theorem 2.4.** *Let  $G = ([n], E) \sim \mathcal{G}(n, \frac{1}{2}, k)$  with a planted clique of size  $k \geq C\sqrt{n}$  with the constant  $C > 0$  chosen as in Lemma 2.2. Suppose  $T := 2(\log^* n - \log^*(k/\sqrt{n})) + 3$ . Then for large enough  $n$ , there exists a deterministic algorithm that takes as input the adjacency matrix of the graph and the size of the planted clique, exactly outputs the clique  $K$  with probability at least  $1 - O\left(\left(\frac{1}{n}\right)^{\log k}\right)$  over the randomness in the graph  $G$ , and runs using  $O(T \cdot \log n)$  bits of space.*

1. If  $k = C\sqrt{n}$ , the space usage is  $O(\log^* n \cdot \log n)$  bits.
2. If  $k = \omega(\sqrt{n} \log^{(\ell)} n)$  for some constant integer  $\ell > 0$ , the space usage is  $O(\log n)$  bits.

**Proof.** The proof can be found in the arXiv version at <https://arxiv.org/abs/2008.12825>. ◀

### 3 Auxiliary Lemmas

We state the Chernoff bound we use here, for the convenience of the reader.

► **Lemma 3.1.** *Let  $X = \sum_{i=1}^n X_i$  where  $X_i$  are independent  $\text{Bern}(p_i)$  random variables. Let  $\mu = \sum_{i=1}^n p_i$ , and  $0 < \delta$ . Then*

$$\mathbb{P}(X \geq (1 + \delta)\mu) \leq \exp\left(\frac{-\mu\delta^2}{2 + \delta}\right)^{11}$$

$$\mathbb{P}(X \leq (1 - \delta)\mu) \leq \exp\left(\frac{-\mu\delta^2}{3}\right).$$

We state some structural lemmas about the planted clique graph that follow from simple probabilistic arguments.

First we show that with high probability, *any* clique subset of size greater than  $2 \log n$  has at most  $3 \log k$  non-clique vertices connected to every vertex of the subset. The ideas of such an analysis are contained in the proof of [16, Lemma 2.9].

► **Lemma 3.2.** *Let  $G \sim \mathcal{G}(n, \frac{1}{2}, k)$  for  $k \geq 2 \log n$  and  $S$  be any arbitrary subset of the planted clique  $K$  with  $|S| \geq 2 \log n$ . Let  $T$  be the set of all non-clique vertices that are connected to every vertex in  $S$ . Then, except with probability at most  $(\frac{1}{n})^{\log k}$ ,  $|T| \leq 3 \log k$ .*

**Proof.** The proof can be found in the arXiv version at <https://arxiv.org/abs/2008.12825>. ◀

We also control the number of clique vertices any non-clique vertex is connected to.

► **Lemma 3.3.** *Let  $G \sim \mathcal{G}(n, \frac{1}{2}, k)$ , and let  $d$  be the maximum number of clique vertices connected to a non-clique vertex. Then  $\mathbb{P}(d \geq \frac{2k}{3}) \leq n \exp(-\frac{k}{54})$ .*

**Proof.** The proof can be found in the arXiv version at <https://arxiv.org/abs/2008.12825>. ◀

We state the following well known fact that Erdős-Rényi graphs do not have large cliques. See, for example, [11].

► **Lemma 3.4.** *Let  $G \sim \mathcal{G}(n, \frac{1}{2})$  and  $\epsilon > 0$  be a positive constant. Except with probability at most  $O(2^{-\epsilon \log^2 n})$ ,  $G$  contains no cliques of size  $(2 + \epsilon) \log n$  or larger.*

**Proof.** The proof can be found in the arXiv version at <https://arxiv.org/abs/2008.12825>. ◀

We show the existence of a  $O(\log^2 n)$  space recovery algorithm above the information theoretic threshold.

► **Lemma 3.5** ([4] reduction +  $O(\log^2 n)$  space detection). *Let  $\omega(\log n) = k = o(n)$  and  $G \sim \mathcal{G}(n, \frac{1}{2}, k) = ([n], E)$ . Then there is a deterministic  $O(\log^2 n)$  space algorithm that outputs the planted clique except with probability at most  $O(n \exp(-k/54) + n2^{-\Theta(\log^2 n)})$ .*

**Proof.** The proof can be found in the arXiv version at <https://arxiv.org/abs/2008.12825>. ◀

## Abstract

Traditional orthogonal range problems allow queries over a static set of points, each with some value. Dynamic variants allow points to be added or removed, one at a time. To support more powerful updates, we introduce the GRID RANGE class of data structure problems over arbitrarily large integer arrays in one or more dimensions. These problems allow range updates (such as filling all points in a range with a constant) and queries (such as finding the sum or maximum of values in a range). In this work, we consider these operations along with updates that replace each point in a range with the minimum, maximum, or sum of its existing value, and a constant. In one dimension, it is known that segment trees can be leveraged to facilitate any  $n$  of these operations in  $\tilde{O}(n)$  time overall. Other than a few specific cases, until now, higher dimensional variants have been largely unexplored.

Despite their tightly-knit complexity in one dimension, we show that variants induced by *subsets* of these operations exhibit polynomial separation in two dimensions. In particular, no truly subquadratic time algorithm can support certain pairs of these updates simultaneously without falsifying several popular conjectures. On the positive side, we show that truly subquadratic algorithms can be obtained for variants induced by other subsets.

We provide two general approaches to designing such algorithms that can be generalised to online and higher dimensional settings. First, we give almost-tight  $\tilde{O}(n^{3/2})$  time algorithms for single-update variants where the update and query operations meet a set of natural conditions. Second, for other variants, we provide a general framework for reducing to instances with a special geometry. Using this, we show that  $O(m^{3/2-\epsilon})$  time algorithms for counting paths and walks of length 2 and 3 between vertex pairs in sparse graphs imply truly subquadratic data structures for certain variants; to this end, we give an  $\tilde{O}(m^{(4\omega-1)/(2\omega+1)}) = O(m^{1.478})$  time algorithm for counting simple 3-paths between vertex pairs.

**2012 ACM Subject Classification** Theory of computation → Data structures design and analysis; Mathematics of computing → Graph algorithms

**Keywords and phrases** Orthogonal range, Range updates, Online and Dynamic Data Structures, Fine-grained complexity, Cycle counting

## 1 Introduction

Orthogonal range query problems are ubiquitous across various fields of Computer Science. In the simplest of these problems, a data set is modelled as a set of points in  $\mathbb{Z}^d$ , and the task is to design a data structure that can efficiently answer queries which ask: how many points lie within the (axis-aligned) orthogonal range  $[l_1, r_1] \times \dots \times [l_d, r_d]$ ? One can extend this

definition by assigning a value to each point in the input, and having queries ask instead for some aggregate (e.g. the maximum value) of the values of the points within the query range. This has been studied extensively [7, 4, 11, 22] (more in full version), along with models which ask to report all points in the range [2, 3]. *Dynamic* models, where a single point may be inserted or removed in a single operation, have also been studied [13, 12], corresponding to the addition or deletion of a single record. Queries may then be interspersed between these update operations, providing insight into the data set as it changes over time. Modelling data sets in this way has proven useful for Online Analytical Processing (OLAP) [15, 24] of databases.

In practice, however, one may wish to employ more powerful updates. In this work, we examine data structures which support updating the values of all points that fall within a range in addition to range queries. This models updates to the records in a database table whose numerical field values fall within designated ranges. For instance, this could be giving all employees who have been employed between 5 to 10 years, and have KPIs between 80 and 90 an “A” rating. We formalise this as follows.

► **Definition 1.1.** Let  $d$  be a positive integer constant,  $(\mathbb{Z}, q)$  be a commutative semigroup<sup>1</sup> and  $U = \{u_j\}$  be a set of integer functions. The (dD) RANGE  $(q, U)$  problem gives as input a set  $P = \{x_1, \dots, x_p\}$  of  $p$  points in  $\mathbb{Z}^d$ . A corresponding integer value  $v_i$  is also given for each point  $x_i$ , each initially 0. It requests a series of operations, each taking one of the following forms:

- $\text{update}_j((l_1, r_1), \dots, (l_d, r_d))$ : for each  $x_i \in [l_1, r_1] \times \dots \times [l_d, r_d]$ , set  $v_i := u_j(v_i)$
- $\text{query}((l_1, r_1), \dots, (l_d, r_d))$ : compute and return  $q(P')$ , where  $P'$  is the multiset  $\{v_i : x_i \in [l_1, r_1] \times \dots \times [l_d, r_d]\}$ .

Importantly, the operations may include updates of different types, and operations may occur in any order. All operations are given **online** and no information is known about them before the preceding operations are performed. There are  $n = n_u + n_q$  operations in all, with  $n_u$  and  $n_q$  of the first and second forms, respectively.

We are most interested in the case where update functions take the form  $*_c(x) = x * c$ , where  $*$  is a binary operation over the integers, and  $c$  is an operation-specific constant. Through a slight abuse of notation, we also use  $*$  to denote the set of all functions of the form  $*_c$ . We write  $*$  as a member of  $U$  as shorthand for  $*_c$  being a member of  $U$ , for all  $c$ . For example, RANGE  $(+, \{+, \max\})$  allows updates of the form  $+_c$  (increasing values by  $c$ ),  $\max_c$  (replacing values less than  $c$  with  $c$ ), and queries which ask for the sum of values in a range. For a single update function or binary operation  $u$ , we write RANGE  $(q, u)$  for short.

The GRID RANGE variants are those whose point set is  $P = [s]^d$ ;  $P$  is not given explicitly, but rather, is described in the input by the positive integer  $s$ . Hence, the size of input (and thus the running time) can be measured as a function of the number  $n$  of operations which occur, rather than the size of  $P$ . GRID RANGE problems will form our primary focus, but we first describe the context surrounding RANGE problems as a whole.

## 1.1 Motivation

In one dimension, RANGE problems can be viewed as operating over an array. In this case, balanced binary trees (such as binary search trees or *segment trees* [8]) over the array have been effective tools in solving RANGE problems. Such trees allow any range of the array to be canonically expressed as the disjoint union of  $O(\log p)$  subtrees of the tree.

<sup>1</sup> A *semigroup*  $(S, +)$  is a set  $S$  equipped with an associative binary operator  $+: S \times S \rightarrow S$ . A semigroup is *commutative* if  $x + y = y + x$  for all  $x, y \in S$ .

When the functions in  $U$  are closed under composition and each distributes<sup>2</sup> over  $q$ , the folklore technique of *lazy propagation* over a binary tree solves 1D RANGE ( $q, U$ ) in  $O(\log p)$  time in the worst case, per operation. Lazy propagation can be extended to support several types of updates: it can be applied to solve 1D RANGE ( $\max, \{+, \min, \text{set}, \max\}$ ) in worst-case  $O(\log p)$  time per operation, where *set* is the binary operation that returns its second operand. These techniques are described in more detail in Section 2. Ji [18] considered the 1D RANGE ( $+, \max$ ) problem, where the update operation does not distribute over the query operation, by introducing a technique known as a Ji-Driver Tree (informally “segment tree beats”), generalising lazy propagation. Using this technique, he showed that 1D RANGE ( $+, \{+, \min, \text{set}, \max\}$ ) can be solved in amortised  $O(\log^2 p)$  time per operation.

Let  $\mathfrak{B}$  be the set of RANGE ( $q, U$ ) problems with  $q \in \{+, \max\}$  and  $U \subseteq \{+, \min, \text{set}, \max\}$ . Motivated by the one dimensional results for problems in  $\mathfrak{B}$ , we seek general techniques addressing RANGE problems in two or more dimensions. This has been asked as an open question in the competitive programming community [19].

The RANGE problem on a  $p$  element array can be generalised to multiple dimensions in two natural ways: either a set of  $p$  points in  $\mathbb{Z}^d$  is provided explicitly, or the point set is considered to be  $[s]^d$ . In the former case, one dimensional techniques can be generalised to higher dimensions with the aid of an orthogonal space partition tree (hereafter simply *partition tree*), such as a *kd-tree* [7].

► **Lemma 1.2.** *If 1D RANGE ( $q, U$ ) on  $p$  points can be solved in time  $T(p)$  per operation and  $q$  is computable in  $O(1)$  time, then  $d$ D RANGE ( $q, U$ ) can be solved in time  $O(p^{1-1/d}T(p))$  per operation.*

We prove this result and provide almost-tight  $\Omega(p^{1/2-o(1)})$  time per-operation lower bounds conditioned on the Online-Matrix Vector (OMv) Conjecture of Henzinger et al. [16], for all RANGE problems in  $\mathfrak{B}$  when  $d = 2$ , in Section 7.

The latter case corresponds to the GRID RANGE class of problems, which is the subject of the remainder of this work. The same technique does not apply in these cases, as the number of points is  $p = s^d$ .

## 1.2 Prior work

Prior work on GRID RANGE problems has been limited to a few specific cases.

Since balanced binary trees have been rather effective in solving problems in one dimension, it is natural to ask whether they can be easily generalised to higher dimensions. Lueker [21] and Chazelle [13] generalised binary search trees and segment trees to higher dimensions to answer various  $d$ -dimensional range query problems (without updates) on sets of  $n$  points in  $O(\log^d n)$  time per query. This technique can be used to solve GRID RANGE problems in the special cases where all update ranges affect a single point, or when all query ranges contain a single point and the update functions are commutative. The latter can be seen as a generalisation of RECTANGLE STABBING [12] (which accepts a series of  $d$ -dimensional boxes and supports queries for the number of boxes covering a given point), a dual of traditional range queries. The same structure was used with scaling by Ibtehaz et al. [17] to solve GRID RANGE ( $+, +$ ) in worst-case  $O(\log^d s)$  time per operation; without scaling, a straightforward solution for GRID RANGE ( $\max, \max$ ) can be obtained in the same time. These upper bounds contrast with the abovementioned  $\Omega(p^{1/2-o(1)})$  time conditional lower bounds for

<sup>2</sup> An integer function  $u$  distributes over  $q$  if  $u(q(a, b)) = q(u(a), u(b))$

the corresponding 2D RANGE problems. For other problems in  $\mathfrak{B}$ , the lazy propagation technique used in one dimension cannot be directly applied over this structure, as it requires a partition tree of the coordinate space.

In the KLEE'S MEASURE problem,  $n$  rectangles are given in  $d$  dimensions, and one is asked to find the volume of their union. In WEIGHTED DEPTH, the rectangles each have a weight, and one is asked to find the maximum sum of weights of rectangles that cover a single point. In DYNAMIC versions of these problems, a single rectangle can be added or removed in a single operation, and the new answer must be returned after each one. These can be seen as special cases of GRID RANGE problems.

When only additions are supported, DYNAMIC KLEE'S MEASURE is a special case of GRID RANGE (+, set) or GRID RANGE (+, max). Overmars and Yap [23] gave a  $O(n^{(d+1)/2} \log n)$  time solution over  $n$  updates when *the rectangles' coordinates are known during preprocessing*. Chan [9] gave a sublogarithmic time improvement over this method and showed that this is nearly tight in two dimensions, giving an  $\Omega(\sqrt{n})$  time per update worst-case lower bound by reducing from DYNAMIC MATRIX-VECTOR MULTIPLICATION.

DYNAMIC WEIGHTED DEPTH is the special case of GRID RANGE (max, +), where the maximum value in the entire grid is queried after each update. It is closely related to DYNAMIC KLEE'S MEASURE, in that every known algorithm for one has been adaptable to the other, with running times differing by a sublogarithmic factor. Hence, with a slight modification of the result of Overmars and Yap [23], an  $\tilde{O}(n^{(d+1)/2})$  time algorithm for GRID RANGE (max, +) can be obtained. Chan [9] showed that DYNAMIC WEIGHTED DEPTH is solvable in time  $O(n^{(d+1)/2} \log^{d/2} \log n)$ , with sublogarithmic improvements specific to entire-grid queries.

When there are no updates, KLEE'S MEASURE and WEIGHTED DEPTH can be reduced to  $O(n)$  updates on a  $d - 1$  dimensional DYNAMIC instance with a sweepline, however Chan [10] gave faster  $O(n^{d/2-o(1)})$  time algorithms for these. Reductions by Chan [9] and Backurs et al. [6] showed that solving static variants of KLEE'S MEASURE or WEIGHTED DEPTH in time  $o(n^{d\omega/6})$  or  $O(n^{d/2-\epsilon})$  for some  $\epsilon > 0$ , respectively, would improve longstanding upper bounds for CLIQUE or MAX CLIQUE, respectively. It follows that these problems are W[1]-complete for parameter  $d$ . The same reductions can be appropriated for  $d = 3$  to show that an  $O(n^{3/2-\epsilon})$  time algorithm for 3D WEIGHTED DEPTH implies an  $O(n^{3-2\epsilon})$  time algorithm for NEGATIVE TRIANGLE. A truly subcubic algorithm for NEGATIVE TRIANGLE exists if and only if one exists for APSP [26], so an  $O(n^{3/2-\epsilon})$  time algorithm for 2D GRID RANGE (max, +) for some  $\epsilon > 0$  would falsify the APSP Conjecture.

### 1.3 Our contribution

Our main contributions are conditional lower bounds, which serve to elucidate and categorise the expressiveness of these data structures, and upper bounds in the form of general algorithms and frameworks for solving GRID RANGE problems (such as those in  $\mathfrak{B}$ ) in two or more dimensions. We do so on a Word RAM with  $\Omega(\log n)$ -bit words. In the sequel, we use  $\mathfrak{B}'$  to denote  $\mathfrak{B}$  without the problems GRID RANGE (+, +) and GRID RANGE (max, max), for which per-operation polylogarithmic time upper bounds are already known.

**Lower bounds.** First, we consider algorithms whose per-operation time complexity is a function of  $s$ , the side length of the grid. In two dimensions, we show that there is no algorithm running in time  $O(s^{1-\epsilon})$  per-operation for any  $\epsilon > 0$ , for any problem in  $\mathfrak{B}'$ , unless the OMv Conjecture is false. Further, for GRID RANGE (+, {+, max}) we obtain identical lower bounds, conditioned on the “extremely popular conjecture” of Abboud et al. [1] that at

■ **Table 1** Lower and upper bounds for GRID RANGE problems in  $\mathfrak{B}$ , exhibiting polynomial separation. All results are in two dimensions where  $d$  is unspecified, and in  $d$  dimensions otherwise, where  $d$  is a constant. All lower bounds hold offline, except those for OMv, and all upper bounds hold in fully online settings.

$q$	$U$	Lower bounds	Upper bound
max	max		$O(n \log^d s)$ (extension of segment trees)
+	+		$O(n \log^d s)$ [17]
max	+	$\Omega(n^{3/2-o(1)})$ APSP [6] or OMv $\Omega(n^{(d+1)/2-o(1)})$ MAXCLIQUE [6]	$\tilde{O}(n^{3/2})$ and $O(n \log^2 n)$ space $\tilde{O}(n^{(d+1)/2})$ [9, 10]
max	min	$\Omega(n^{3/2-o(1)})$ OMv	$\tilde{O}(n^{(d+1)/2})$
max	set		$\tilde{O}(n^{(d^2+2d-1)/2d})$
max	{min, set, max}		$\tilde{O}(n^{5/4+\omega/(\omega+1)}) = O(n^{1.954})$
+	set		$\tilde{O}(n^{5/4+(4\omega-1)/(4\omega+2)}) = O(n^{1.989})$
+	{+, set}		
max	{+, min}	$\Omega(n^{d-o(1)})$ $d$ -OV	$\tilde{O}(n^d)$
max	{+, min, set, max}		
+	{+, max}	$\Omega(n^{2-o(1)})$ 3SUM $\Omega(n^{d-o(1)})$ $d$ -OV	
+	{+, min, set, max}		

least one of the APSP, 3SUM and 2-OV (Orthogonal Vectors) Conjectures are true (the latter of which is implied by the Strong Exponential Time Hypothesis [27]). Hence, we cannot solve this variant in two dimensions in  $O(s^{1-\epsilon})$  time per operation for any  $\epsilon > 0$  without making a powerful breakthrough across several fields of Theoretical Computer Science. For GRID RANGE (max, {+, min}) and GRID RANGE (+, {+, max}), we generalise our results to  $d$  dimensions under the  $d$ -OV Conjecture to obtain an  $\Omega(s^{(d-1)-o(1)})$  time per-operation lower bound. All these lower bounds are almost-tight, as  $\tilde{O}(s^{d-1})$  time per-operation upper bounds can be obtained by maintaining  $s^{d-1}$  one dimensional instances.

These results, however, do not preclude the existence of efficient and practical algorithms for GRID RANGE problems whose overall complexity is a function of the number of operations,  $n$  – the true size of the input – rather than  $s$ . Our aforementioned lower bounds under the OMv and APSP Conjectures translate to conditional  $\Omega(n^{3/2-o(1)})$  lower bounds for all problems in  $\mathfrak{B}'$ , but our lower bound under the 3SUM Conjecture translates to conditional lower bounds of  $\Omega(n^{2-o(1)})$  for 2D GRID RANGE (+, {+, max}). In  $d$  dimensions, our lower bounds under the  $d$ -OV Conjecture translate to  $\Omega(n^{d-o(1)})$  time conditional lower bounds for GRID RANGE (max, {+, min}) and GRID RANGE (+, {+, max}). Our lower bounds are summarised in Table 1 and proven in Section 3.

**Upper bounds.** By reducing to algorithms in one dimension,  $\tilde{O}(n^d)$  time algorithms can be found for all these problems. Hence, we aim to determine which problems in  $\mathfrak{B}'$  can be solved more efficiently, by seeking truly subquadratic time algorithms in two dimensions. To this end, we provide two general frameworks for developing such algorithms, both based on the approach of Overmars and Yap [23] for DYNAMIC KLEE’S MEASURE. Their algorithm constructs a partition tree of the grid such that the rectangles intersecting each leaf region form a “trellis” pattern. This requires the coordinates of all rectangles to be known during precomputation.

First, we provide a fully-online generalisation of this approach, that does not require coordinates to be known ahead of time.

► **Theorem 1.3.** *Suppose  $q$  and  $u$  are associative, commutative binary operations, computable in  $O(1)$  time, such that  $u$  distributes over  $q$ , and  $0$  is an identity of  $u$ . Then GRID RANGE  $(q, u)$  can be solved in  $\tilde{O}(n^{(d+1)/2})$  time.*

This algorithm does not apply to problems such as the RANGE  $(+, \text{set})$  problem described in the abstract, as set does not distribute over  $+$ . Motivated by this, in Section 5 we show that in two dimensions, efficient solutions to static GRID RANGE  $(q, U)$  instances where the update ranges form the same “trellis” pattern can be used to give fully-online, truly subquadratic time solutions to many GRID RANGE  $(q, U)$  problems. We also extend these results to multiple dimensions, giving a detailed proof in the full version.

As an application, we use this approach to give a truly subquadratic time algorithm for 2D GRID RANGE  $(\max, \{\min, \text{set}, \max\})$ . We do the same for 2D GRID RANGE  $(+, \text{set})$  and 2D GRID RANGE  $(+, \{+, \text{set}\})$  in Section 6, by drawing an equivalence and a reduction between the respective “STATIC TRELLISED” instances and counting the number of 2- and 3-edge paths between vertex pairs, respectively. To this end, we prove the following result.

► **Theorem 1.4.** *Let  $G$  be a graph with  $m$  edges and  $O(m)$  vertices. The number of 3-edge walks between each of  $q$  vertex pairs in  $G$  can be found in  $O(m^{2\omega/(2\omega+1)}(m+q)^{(2\omega-1)/(2\omega+1)})$  time.*

In this way, queries on static graphs yield efficient, fully-online dynamic GRID RANGE data structures. We find it somewhat surprising that, though all of the problems in  $\mathfrak{B}$  can be solved in  $\tilde{O}(n)$  time in one dimension, our upper and lower bounds imply likely polynomial separation in two or more dimensions (see Table 1).

Lastly, we provide a fully-online algorithm for 2D GRID RANGE  $(\max, +)$  that uses  $O(n \log^2 n)$  space, and runs in a time comparable to that of existing algorithms.

► **Theorem 1.5.** *2D GRID RANGE  $(\max, +)$  can be solved in  $\tilde{O}(n^{3/2})$  time, and  $O(n \log^2 n)$  space.*

The proof of this result is omitted for space, and proven in the full version.

While our complexity is slower than existing results by Chan [9] by a polylogarithmic factor, those require  $O(n^{3/2+o(1)})$  space and are not fully-online. Overmars and Yap [23] also gave an  $O(n)$  space algorithm for static KLEE’S MEASURE in  $d$  dimensions using a sweepline, but this does not apply in the dynamic case.

In the remaining sections, due to space constraints, we omit some proofs and sketch others. We refer the reader to the full version for full details and proofs.

## 2 Preliminaries

**Model of computation.** All results are described are for a Word RAM over  $l$ -bit words, with  $l = \Omega(\log n)$ . We further assume that any coordinates or values given in the inputs can be represented in a constant number of words, and that basic arithmetic and the (binary) operations used in range problems can be performed on a constant number of words in constant time. In particular,  $s = O(n^c)$ , for some constant  $c$ .

**Notation.** We use the notation  $\tilde{O}(f(n)) = O(f(n)\text{poly log } n)$  to hide polylogarithmic factors. Note that  $\log^c s = \log^c n$  for any constant  $c$ . Where our algorithms and proofs use positive or negative  $\infty$  as a value, this can be replaced with a suitably large value, for a given input instance.

Where  $x \leq y$  are real numbers, we denote by  $[x, y]$  the set of all *integers* between  $x$  and  $y$ , inclusive. When  $y \geq 1$ , we write  $[y]$  as shorthand for  $[1, y]$ .

The binary operation *set* is the operation whose value is its second operand. That is,  $\text{set}(a, b) = b$ .

$\omega < 2.37286$  [5] is the exponent of multiplying two  $n \times n$  integer matrices. We also write  $\omega(a, b, c)$  for the time taken to multiply an  $a \times b$  matrix by a  $b \times c$  matrix.

**Ancillary problems and variants.** In RANGE problems, we say that the  $i$ th operation (update or query) occurs at *time*  $i$ . In OFFLINE variants, all operations are provided together with the initial input, and in STATIC variants, it is guaranteed that all updates precede all queries.

We formalise and appropriate the “trellis” pattern observed by Overmars and Yap [23] for our use, as follows. Call a GRID RANGE instance TRELLISED if for each update, there is a dimension  $d^*$  such that  $[l_{d'}, r_{d'}] = (-\infty, \infty)$  for all  $d' \in [d] \setminus \{d^*\}$ . When  $d = 2$ , updates must either cover all points in a range of rows, or all points in a range of columns, which we call *row updates* and *column updates*, respectively.

**Segment trees and lazy propagation.** Let  $s$  be a power of two. A *segment tree* over an array  $A$  containing  $s$  elements is a complete rooted binary tree of ranges over  $[s]$ . The root is  $[1, s]$ , and each node  $[a, b]$  has two children:  $[a, h]$ ,  $[h + 1, b]$ , where  $h = (a + b - 1)/2$ . Hence, there are  $O(s)$  nodes in the tree, with a depth of  $\log s$ . Given an interval  $I \subseteq [s]$ , we can write  $I$  as a canonical disjoint union of a set  $\text{base}(I)$  of  $O(\log s)$  nodes. These are defined as the nodes closest to the root that are fully contained in  $I$ , and can be found recursively.

Segment trees can be used to prove the following folklore proposition.

► **Proposition 2.1** (Lazy propagation). *Suppose  $U$  is a set of update functions, and  $q$  is a query function, computable in  $O(1)$  time. If there is a set  $\bar{U}$  such that:*

1.  $U \subseteq \bar{U}$  are sets of functions that can be represented and composed in  $\tilde{O}(1)$  space and time, such that the composition of any series of at most  $n$  (possibly non-distinct) functions of  $U$  results in a function in  $\bar{U}$ ; and
  2. For each  $u \in \bar{U}$ ,  $u$  distributes over  $q$
- then 1D GRID RANGE  $(q, U)$  is solvable in  $\tilde{O}(n)$  time.

**Hardness conjectures.** We base hardness on the following popular conjectures. The first is a conjecture of Henzinger et al. [16].

► **Conjecture 2.2** (OMv Conjecture). *No (randomized) algorithm can process a given  $m \times m$  boolean matrix  $M$ , and then in an online way compute the  $(\vee, \wedge)$ -product  $Mv_i$  for any  $m$  boolean vectors  $v_1, \dots, v_m$  in total time  $O(m^{3-\epsilon})$ , for any  $\epsilon > 0$ .*

In the OuMv problem, the same matrix  $M$  is given during preprocessing, and  $m$  pairs of boolean query vectors  $(u_1, v_1), \dots, (u_m, v_m)$  are given online. For each, the value of the product  $u_i^T Mv_i$  is requested. Note that the answer to each of these queries is a single bit. Henzinger et al. showed that if OuMv can be solved in  $O(m^{3-\epsilon})$  time, then OMv can be solved in  $O(m^{3-\epsilon/2})$  time, so these problems are subcubic equivalent.

We refer the reader to the survey by Vassilevska Williams [28] for more details on the remaining conjectures.

► **Conjecture 2.3** (APSP Conjecture). *No (randomized) algorithm can solve ALL-PAIRS SHORTEST PATHS (APSP) in  $O(v^{3-\epsilon})$  time for  $\epsilon > 0$ , on  $v$  vertex graphs with edge weights in  $\{-v^c, \dots, v^c\}$  and no negative cycles, for large enough  $c$ .*

► **Definition 2.4** ( $k$ -OV problem). *Let  $k \geq 2$  be a constant, and  $z = \omega(\log n)$ . Given  $k$  sets  $A_1, \dots, A_k \subseteq \{0, 1\}^z$  with each  $|A_i| = m$ , determine if there exist  $a_1 \in A_1, \dots, a_k \in A_k$  such that  $a_1 \cdot \dots \cdot a_k = 0$ , where  $a_1 \cdot \dots \cdot a_k := \sum_{i=1}^z \prod_{j=1}^k a_{ji}$ .*

► **Conjecture 2.5** ( $k$ -OV Conjecture). *No (randomized) algorithm can solve  $k$ -OV in  $m^{k-\epsilon} \text{poly}(z)$  time, for any  $\epsilon > 0$ .*

► **Conjecture 2.6** (3SUM Conjecture). *Any algorithm requires  $m^{2-o(1)}$  time in expectation to determine whether a set  $S \subset \{-m^3, \dots, m^3\}$  of  $m$  integers contains three distinct elements  $a, b, c \in S$  with  $a + b = c$ .*

### 3 Conditional lower bounds

In this section, we establish conditional hardness for problems in  $\mathfrak{B}'$  under popular conjectures. We do so by considering per-operation time complexity in terms of  $s$  (the side length of the grid), and overall complexity in terms of  $n$  (the number of operations).

Backurs et al. [6] gave a reduction from MAX  $k$ -CLIQUE to  $k$ D WEIGHTED DEPTH. When  $k = 3$ , MAX  $k$ -CLIQUE is equivalent to NEGATIVE TRIANGLE, which is subcubic equivalent to APSP [26]. Adapting this reduction with a sweepline implies conditional lower bounds for 2D GRID RANGE (max, +).

► **Proposition 3.1** (Modified from [6]). *If OFFLINE 2D GRID RANGE (max, +) can be solved in amortised  $O(s^{1-\epsilon})$  time per update and  $O(s^{2-\epsilon})$  time per query, or in  $O(n^{3/2-\epsilon})$  time overall, for any  $\epsilon > 0$ , then the APSP Conjecture is false.*

We now establish more general linear per-operation lower bounds for 2D GRID RANGE problems in terms of  $s$ , based on the OMv Conjecture.

► **Lemma 3.2.** *Suppose  $(\mathbb{Z}, +, 0)$  is a monoid<sup>3</sup> (resp. group<sup>4</sup>),  $(\mathbb{Z}, \cdot)$  is a commutative semigroup such that  $0r = r0 = 0$  for all  $r \in \mathbb{Z}$  and that there exists  $x \in \mathbb{Z}$  such that  $0 \in \{xz, (x+x)z, (x+x+x)z\}$  if and only if  $z = 0$ . Then, 2D GRID RANGE  $(\cdot, +)$  cannot be solved in worst-case (resp. amortised)  $O(s^{1-\epsilon})$  time per update and  $O(s^{2-\epsilon})$  time per query, for any  $\epsilon > 0$ , unless the OMv Conjecture is false. If  $(\mathbb{Z}, +, 0)$  is a group, 2D GRID RANGE  $(\cdot, +)$  also cannot be solved in  $O(n^{3/2-\epsilon})$  time overall, for any  $\epsilon > 0$ , unless the OMv Conjecture is false.*

**Proof.** We reduce OMv to an instance of 2D GRID RANGE  $(\cdot, +)$  with  $s = m$ . Let  $A_{(i,j)}$  denote the value of the point  $(i, j)$ . Initially, each  $A_{(i,j)} = 0$ . In preprocessing, for each  $M_{ij} = 0$ , add  $x$  to  $A_{(i,j)}$ . We now say the data structure is in its *ready state*.

Let  $(u, v)$  denote a pair of input vectors. For each  $u_i = 0$ , add  $x$  to the value of all points in row  $i$ , and for each  $v_j = 0$ , add  $x$  to the value of all points in column  $j$ . Every point now has a value in  $\{0, x, x+x, x+x+x\}$ . Now some point has value 0 if and only if the answer

<sup>3</sup>  $(\mathbb{Z}, +, 0)$  is a *monoid* if  $(\mathbb{Z}, +)$  is a semigroup, and the identity of  $+$  is 0.

<sup>4</sup>  $(\mathbb{Z}, +, 0)$  is a *group* if it is a monoid and  $+$  is invertible.

to the OuMv query is 1, so we establish this with a single range query. We then restore the data structure to its ready state, either by keeping a journal of updates (semigroup) or by updating with additive inverses (group). The reduction uses  $O(m^2)$  updates and  $O(m)$  queries, implying the stated conditional lower bounds.  $\blacktriangleleft$

This gives a  $\Omega(n^{3/2-o(1)})$  time conditional lower bound on 2D GRID RANGE (max, +), matching that of Proposition 3.1. Through different reductions, we are able to obtain matching lower bounds for the other problems in  $\mathfrak{B}'$ , under the same conjecture.

► **Lemma 3.3.** *If 2D GRID RANGE (+, max), 2D GRID RANGE (+, min) or 2D GRID RANGE (max, min) can be solved in  $O(n^{3/2-\epsilon})$  time overall, for some  $\epsilon > 0$ , then the OMv Conjecture is false.*

The proof is similar to Lemma 3.2, with a different ready state, and is in the full version.

► **Lemma 3.4.** *If 2D GRID RANGE (+, set) or 2D GRID RANGE (max, set) can be solved in  $O(n^{3/2-\epsilon})$  time overall, for some  $\epsilon > 0$ , then the OMv Conjecture is false.*

**Proof sketch.** We reduce from OuMv. In our data structure, we have  $s = m^2$  and utilise an  $m \times m^2$  area of this grid, with updates and queries restricted to this area. In preprocessing, we perform updates so that all points in the  $j$ -th column have a value of  $(j - 1 \bmod m) + 1$ . Each  $M_{ij}$  is represented in  $A$  by a  $1 \times m$  section of points with values  $[1, 2, 3, \dots, m]$ . For each  $M_{ij} = 0$ , we perform an additional update to set its section of points to 0.

For the  $k$ -th query, we only consider columns that were assigned a value of  $m - k + 1$  during preprocessing. Among these, we set to 0 columns  $j$  where  $v_j = 0$ , and query rows  $i$  where  $u_i = 1$  to check for the presence of  $m - k + 1$ .  $\blacktriangleleft$

Together, these give us conditional lower bounds for each of the single-update variants in  $\mathfrak{B}'$ .

► **Corollary 3.5.** *If  $q \in \{+, \max\}$  and  $u \in \{+, \text{set}, \min, \max\}$  and  $q \neq u$ , then 2D GRID RANGE ( $q, u$ ) cannot be solved in worst-case  $O(s^{1-\epsilon})$  time per update and  $O(s^{2-\epsilon})$  time per query, or in  $O(n^{3/2-\epsilon})$  time overall, for some  $\epsilon > 0$ , unless the OMv Conjecture is false. If  $u = +$ , then the lower bounds are amortised rather than worst-case, as addition is invertible.*

When measuring complexity in terms of  $s$ , it appears difficult to improve upon the naive solution which maintains a 1D instance for each column of the grid, for these problems. However, when we measure complexity in terms of  $n$ , there is a polynomial gap between the  $\Omega(n^{3/2-o(1)})$  time lower bound, and the  $\tilde{O}(n^2)$  time naive algorithm. Indeed, Chan [9] gave a  $\tilde{O}(n^{3/2})$  time solution for GRID RANGE (max, +). This might lead one to ask if there exists a general mechanism to adapt  $\tilde{O}(n)$  time algorithms in one dimension to  $\tilde{O}(n^{3/2})$  time algorithms in two dimensions, as there is for RANGE problems on a set of  $n$  explicitly provided points. Alas, when we consider variants with two simultaneous types of updates, we can obtain stronger reductions from the  $d$ -OV and 3SUM Conjectures, suggesting that it is unlikely that such a mechanism exists.

► **Lemma 3.6.** *Let  $d \geq 1$  be a constant. If OFFLINE STATIC TRELLISED  $d$ D GRID RANGE (+, {+, max}) or OFFLINE STATIC TRELLISED  $d$ D GRID RANGE (max, {+, min}) can be solved in amortised  $O(s^{(d-1)-\epsilon})$  time per update and amortised  $O(s^{d-\epsilon})$  time per query, or in  $O(n^{d-\epsilon})$  time overall, for any  $\epsilon > 0$ , then the  $d$ -OV Conjecture is false.*

**Proof sketch.** We reduce from  $d$ -OV with  $z = \log^2 n$  to an instance of  $d$ D GRID RANGE (+, {+, max}) or  $d$ D GRID RANGE (max, {+, min}) with  $s = m$  and  $n = \tilde{O}(m)$ , over the points  $[m]^d$ . Consider the first entry in each vector. Let  $v_{ji}$  be the  $i$ th vector in  $A_j$ . For each  $j \in [d]$

and each vector  $v_{ji} \in A_j$ , using the data structure, add  $(v_{ji})_1$  to all points with  $x_j = i$ . Now a point  $x = (x_1, \dots, x_d) \in [m]^d$  has value  $d$  if and only if  $(v_{jx_j})_1 = 1$  for every  $j \in [d]$ . We then undo these updates by repeating the operations with the negations of the added values, to restore every point to 0. We repeat this procedure for each of the  $z$  entries in the vectors.

Now observe that  $v_{1x_1} \cdot \dots \cdot v_{dx_d} = 0$  if and only if  $C_x$  never attained a value of  $d$  throughout this process. We check if such an  $x$  exists, by adapting a trick of Ji [18] to our data structure. This trick utilises max or min updates, in addition to the  $+$  updates described above.

We note that this reduction can be done offline, uses  $O(mdz) = \tilde{O}(m)$  updates (each of the form  $x_j = i$ ) and a single query spanning the whole grid, giving the required lower bounds.  $\blacktriangleleft$

► **Lemma 3.7.** *If OFFLINE TRELLISED 2D GRID RANGE  $(+, \{+, \max\})$  can be solved with amortised  $O(s^{1-\epsilon})$  time per update and query, or in  $O(n^{2-\epsilon})$  time overall, and any  $\epsilon > 0$ , then the 3SUM Conjecture is false.*

The proof of this result is omitted for space, and proven in the full version.

A modification of Proposition 3.1, together with the results above imply strong conditional hardness for OFFLINE 2D GRID RANGE  $(+, \{+, \max\})$ , when complexity is measured per-operation.

► **Corollary 3.8.** *If OFFLINE 2D GRID RANGE  $(+, \{+, \max\})$  can be solved in amortised  $O(s^{1-\epsilon})$  time per update and query, or in  $O(n^{3/2-\epsilon})$  overall, for any  $\epsilon > 0$ , then the APSP, 2-OV and 3SUM Conjectures are all false.*

Our lower bounds show that a general approach adapting almost-linear one dimensional algorithms for GRID RANGE problems to truly subquadratic solutions for two dimensional instances is unlikely to exist. However, these results do not preclude the existence of efficient and practical algorithms for specific problems, so we would like to classify which 2D GRID RANGE problems can (and can't) be solved in truly subquadratic time. To this end, we now describe truly subquadratic algorithms to some of the as-of-yet unclassified problems in  $\mathfrak{B}'$ , and generalise these to specific subclasses of 2D GRID RANGE problems.

## 4 Solving GRID RANGE problems with a Dynamic Partition

In the full version of the paper, we describe an extension of the partition of Overmars and Yap [23]. Notably, our data structure is fully-online in that it does not require the coordinates in the input to be known during preprocessing. We give a brief overview of the construction and provide some applications, leaving further details to the full version.

### 4.1 Dynamic Structure

First, we introduce some terminology to reason about orthogonal objects in  $d$  dimensions.

A *box* is a  $d$ -dimensional (orthogonal) range. For two boxes  $R_1 = \prod_{i=1}^d [l_i^1, r_i^1]$  and  $R_2 = \prod_{i=1}^d [l_i^2, r_i^2]$ , we say that  $R_1$  is an  *$i$ -pile* with respect to  $R_2$  if  $[l_j^2, r_j^2] \subseteq [l_j^1, r_j^1]$  for all dimensions  $j \in [d] \setminus \{i\}$ . Separately, we say that  $R_1$  *partially covers*  $R_2$  if  $\emptyset \subsetneq R_1 \cap R_2 \subsetneq R_2$ . Similarly,  $R_1$  *completely covers*  $R_2$  if  $R_2 \subseteq R_1$ .

An  *$i$ -slab* ( $i \in [d]$ ) is a box of the form  $[l_1, r_1] \times \dots \times [l_i, r_i] \times \mathbb{Z}^{d-i}$ . We define  $\mathbb{Z}^d$  to be a 0-slab. A *partition tree* is a rooted tree where

1. All nodes are orthogonal ranges of  $\mathbb{Z}^d$
2. The root is  $\mathbb{Z}^d$
3. Every non-leaf node is the disjoint union of its immediate children.

A partition tree is a *level partition tree* if it has depth  $d$ , and the nodes at depth  $i$  ( $i \in [0, d]$ ) are  $i$ -slabs. Hence, a node at depth  $i$  in a level partition tree is *cut* at a series of coordinates in dimension  $i + 1$  to form its children.

► **Theorem 4.1.** *There is a data structure that maintains a set  $V$  of boxes, and supports  $n$  fully-online box insertions to  $V$ . Throughout, it can maintain a level partition tree of  $\mathbb{Z}^d$  whose leaves partition  $\mathbb{Z}^d$  into a set of  $O(n^{d/2})$  axis-aligned regions (colloquially “ $t$ -regions”, short for “trellised-regions”) such that:*

1. *Every box in  $V$  does not intersect, completely covers or is a pile with respect to each  $t$ -region;*
2. *Each box partially covers  $O(n^{(d-1)/2})$   $t$ -regions;*
3. *Each  $t$ -region is partially covered by at most  $O(\sqrt{n})$  boxes;*
4. *Any line parallel to a coordinate axis intersects at most  $O(n^{(d-1)/2})$   $t$ -regions; and*
5. *A list of the boxes that partially cover each  $t$ -region is maintained.*

*This all can be done in amortised  $\tilde{O}(n^{(d-1)/2})$  time per insertion.*

**Proof sketch.** Overmars and Yap [23] construct such a partition tree during precomputation from the boxes’ coordinates, however this is not possible in a fully-online setting. Instead, we maintain the required properties as boxes are added by periodically rebuilding subtrees which exceed a certain size and strategically inserting additional boxes to preserve balance. The cost of rebuilding amortises over the  $n$  operations, giving the stated time complexities. ◀

Using this structure, we can reduce GRID RANGE problems to TRELLISED GRID RANGE problems when the update operation distributes over the query operation.

► **Theorem 4.2.** *Suppose  $q$  and  $u$  are associative operations, both computable in  $O(1)$  time, such that  $q$  is commutative,  $u$  distributes over  $q$ , and  $0$  is an identity of  $u$ . If TRELLISED  $d$ D GRID RANGE  $(q, u)$  can be solved in  $\tilde{O}(n)$  time, then GRID RANGE  $(q, u)$  can be solved in  $\tilde{O}(n^{(d+1)/2})$  time.*

**Proof sketch.** We use the structure given by a dynamic level partition tree  $J$  from Theorem 4.1. Recall that there are  $O(n^{(d-1)/2})$   $(d - 1)$ -slabs in  $J$ , and each is a parent of  $O(\sqrt{n})$   $t$ -regions, which are leaves of  $J$ . For each  $(d - 1)$ -slab, we maintain a data structure supporting range updates and queries within the slab. Conceptually, we maintain a 1D array over its children, in order of their  $d$ -coordinate, with each array entry containing a TRELLISED instance for the corresponding  $t$ -region. We support operations whose ranges completely cover multiple children by using a modified version of the 1D GRID RANGE  $(q, u)$  structure (see Proposition 2.1). Operations affecting only part of a child are handled by the corresponding TRELLISED instance.

Operations are then performed by iterating over all  $(d - 1)$ -slabs, and updating and querying the respective data structures, as necessary. Our data structure is maintained in such a way that over its lifetime, there will be  $O(n^{d/2})$  TRELLISED instances, each facilitating  $O(\sqrt{n})$  operations, giving the required time complexity. ◀

## 4.2 Applications

We apply Theorem 4.2 to give  $\tilde{O}(n^{(d+1)/2})$  time algorithms for particular problems.

First, we show that TRELLISED variants can be solved as separate one dimensional instances, when the conditions of Theorem 4.2 are met and  $u$  is also *commutative*.

► **Lemma 4.3.** *Suppose  $q$  and  $u$  are associative, commutative binary operations, computable in  $O(1)$  time, such that  $u$  distributes over  $q$ , and  $0$  is an identity of  $u$ . Then TRELLISED GRID RANGE  $(q, u)$  is solvable in  $\tilde{O}(n)$  time.*

**Proof.** For notational convenience we provide a proof for the case where  $q$  is  $\max$  and  $u$  is  $+$ ; other operations are proven identically. By the definition of TRELLISED, we can associate every update with a dimension  $i$  such that the update range is an  $i$ -pile with respect to  $\mathbb{Z}^d$ ; we call this an  $i$ -update for short. At any given point in time, let  $U_i(x)$  be the sum (with respect to  $u$ ) of all  $i$ -updates with coordinate  $x$  in dimension  $i$ .

Now consider a query over the range  $R = [l_1, r_1] \times \dots \times [l_d, r_d]$ . The answer to the query can be written as

$$\max_{(x_1, \dots, x_d) \in R} \sum_{i \in [d]} U_i(x_i) = \sum_{i \in [d]} \max_{(x_1, \dots, x_d) \in R} U_i(x_i) = \sum_{i \in [d]} \max_{x_i \in [l_i, r_i]} U_i(x_i)$$

by distributivity. Hence, we can reduce to  $d$  instances of 1D RANGE  $(q, u)$ , which each can be solved in  $\tilde{O}(n)$  time, by Proposition 2.1. ◀

This proves Theorem 1.3, giving efficient fully-online algorithms in these cases.

► **Corollary 4.4.** *GRID RANGE  $(\max, +)$  and GRID RANGE  $(\max, \min)$  can be solved in  $\tilde{O}(n^{(d+1)/2})$  time.*

There also exists some instances where  $u$  is not commutative for which an  $\tilde{O}(n)$  solution to TRELLISED GRID RANGE  $(q, u)$  exists, giving us algorithms with the same time complexity.

► **Lemma 4.5.** *TRELLISED GRID RANGE  $(\max, \text{set})$  can be solved in  $\tilde{O}(n)$  in  $d$  dimensions. Hence, GRID RANGE  $(\max, \text{set})$  can be solved in  $\tilde{O}(n^{(d+1)/2})$ .*

## 5 Reducing to STATIC TRELLISED instances

The technique from the previous section does not work on all variants. For instance, consider the 2D GRID RANGE  $(\max, \{\min, \max\})$  problem. While the update operations ( $\min$  and  $\max$ ) are individually associative, commutative and distribute over the query operation ( $\max$ ), they do not commute with each other. Given that the order of operations matters greatly, it is difficult to decompose this into separate one dimensional problems.

In this section, we describe a general framework for reducing multidimensional range problems to STATIC TRELLISED instances, using 2D GRID RANGE  $(\max, \{\min, \max\})$  as an example. For simplicity, we first give a reduction for OFFLINE instances. We describe how to generalise this approach to online settings, leaving the proof to the full version.

**General approach.** Our algorithm operates by partitioning operations into chronologically contiguous batches of at most  $k$  operations, for some function  $k$  of  $n$ . Each batch may contain both updates and queries. Let  $B$  be a particular batch, and let  $G_B$  be the state of the grid at the start of  $B$ . We will show how to answer the queries within  $B$ .

The  $\bar{k} = O(k)$  coordinates of  $B$ 's operations partition the grid into a  $\bar{k} \times \bar{k}$  *overlay grid* of *overlay regions*. Any update or query will concern all points that fall within a 2D range of whole overlay regions. Since the update operations  $\min_c$  and  $\max_c$  are monotonically increasing functions for any constant  $c$ , it suffices to know the maximum value within each overlay region according to  $G_B$ , to answer the queries of  $B$ . We use these maximums as initial values for a 2D GRID RANGE  $(\max, \{\min, \max\})$  instance over the overlay grid, which we solve by keeping  $\bar{k}$  1D RANGE instances, one for each column, and facilitating operations in  $\tilde{O}(k)$  time, by iterating over each one.

It remains to find the maximum value within each overlay region, according to  $G_B$ . To do so, consider an alternate partition of the grid into t-regions according to Theorem 4.1. In each t-region  $Y$ , we will form an instance of STATIC TRELLISED 2D GRID RANGE ( $\max, \{\min, \max\}$ ) with  $O(\sqrt{n})$  updates; we describe how to do so below. Then, to find the maximum value within an overlay region  $O$ , we issue queries to the instances corresponding to the t-regions intersecting  $O$ .

**Forming STATIC TRELLISED instances.** By construction, each t-region  $Y$  is affected by up to  $n$  whole updates which completely cover  $Y$ , and up to  $\sqrt{n}$  partial updates which cover all points in a range of rows or range of columns of  $Y$ . We can afford to include each partial update in our instance, but need to find a succinct way to represent whole updates.  $Y$  has at most  $\sqrt{n} + 1$  ranges of time between each of its partial updates, and with the aid of a lazy propagation structure over the t-region tree, we can compress the whole updates occurring during each of these ranges into a single update. Hence, we can form an instance of STATIC TRELLISED 2D GRID RANGE ( $\max, \{\min, \max\}$ ) with  $O(\sqrt{n})$  updates, as required.

We now analyse the time complexity of our approach.

► **Lemma 5.1.** *If there an algorithm for STATIC TRELLISED 2D GRID RANGE ( $\max, \{\min, \max\}$ ) running in  $\tilde{O}(n_u^{c-\gamma}(n_u + n_q)^\gamma)$  time for some  $c \geq 1$  and  $\gamma \in [0, 1]$ , then 2D GRID RANGE ( $\max, \{\min, \max\}$ ) can be solved in  $\tilde{O}(n^{5/4+c/2})$  time.*

**Proof.** We process each of the batches separately, and consider the time taken to answer the queries within a particular batch  $B$ .

Using the methods above, in  $\tilde{O}(n^{3/2})$  time we form an instance of STATIC TRELLISED 2D GRID RANGE ( $\max, \{\min, \max\}$ ) with  $n_u = O(\sqrt{n})$  updates in each of  $O(n)$  t-regions. Next, we bound the number of queries made to such instances within  $B$ . Consider the partition  $\mathcal{P}$  of the grid produced by refining each t-region by the overlay grid. A query to a STATIC TRELLISED instance is made for each region in  $\mathcal{P}$ , and the number of these regions and thus, queries, is  $O((k + \sqrt{n})^2) = O(k^2 + n)$ : this is the number of intersections found when the overlay grid is laid atop the t-regions.

For a given t-region  $Y$ , let the number of queries made to the instance in  $Y$  be  $n_{q_Y}$ . First, consider the regions  $y$  where  $n_{q_y} < \sqrt{n}$ . There are  $O(n)$  regions in total, so we spend  $\tilde{O}(n^{1+c/2})$  time answering queries for these regions.

Now consider the regions  $Y$  where  $n_{q_Y} \geq \sqrt{n}$ . Since  $n_{q_Y} = \Omega(n_u)$ , the running time of  $Y$ 's TRELLISED instance is subadditive with respect to  $n_{q_Y}$ . Thus, the total running time for these regions is maximised when the queries are distributed evenly among as many regions as possible. Subject to the constraint on these regions, this maximum is achieved, within a constant multiplicative factor, when there are at most  $O((k^2 + n)/\sqrt{n})$  regions, each with  $\sqrt{n}$  queries. Hence, in this case, the total running time is bounded by  $\tilde{O}((k^2 + n)n^{(c-1)/2})$ . We thus spend time  $\tilde{O}(n^{3/2} + n^{1+c/2} + k^2 n^{(c-1)/2})$  for each of  $n/k$  batches. For balance, we choose  $k = n^{3/4}$ , giving a running time of  $\tilde{O}(n^{5/4+c/2})$  overall. ◀

It remains to show that we can solve STATIC TRELLISED GRID RANGE ( $\max, \{\min, \max\}$ ) efficiently; we do so in the full version. By observing that  $\text{set}_z = \min_z \circ \max_z$ , we obtain the following result.

► **Corollary 5.2.** *2D GRID RANGE ( $\max, \{\min, \text{set}, \max\}$ ) can be solved in  $\tilde{O}(n^{7/4})$  time.*

Most of the steps in our approach are not specific to the update and query operations in our example. To generalise this approach to fully-online and multidimensional settings, we introduce the following “partial information” variant of 1D RANGE.

► **Definition 5.3** (1D PARTITIONED RANGE  $(q, U)$ ). Let  $A_0$  be an integer array of length  $s$  and let  $0 = a_0 < \dots < a_\rho = s$  be a sequence of indices. Let  $Q$  be a corresponding sequence of  $\rho$  integers, denoting the values  $q(A_0[a_0 + 1, a_1]), \dots, q(A_0[a_{\rho-1} + 1, a_\rho])$ . Initially,  $\rho = 1$ .

Let  $J$  be a list of range updates applicable to  $A_0$  in chronological order, initially empty. We write  $A_J$  for the result of applying the updates of  $J$  to  $A_0$ , in order.

Given an integer  $s$ , and the value of  $q(A_0[1, s])$ , support the following operations:

- *split* $(i, a, q_l, q_r)$ : given  $i \in [0, \rho - 1]$  and  $a_i < a < a_{i+1}$ , add  $a$  to the sequence of indices, and update  $Q$  with the knowledge that  $q(A_0[a_i + 1, a]) = q_l$  and  $q(A_0[a + 1, a_{i+1}]) = q_r$
- *update<sub>j</sub>* $(a_l, a_r)$ : append to  $J$ , the update: “for each  $i \in [a_l + 1, a_r]$ , set  $A[i] := u_j(A[i])$ ”
- *query* $(a_l, a_r)$ : return  $q(A_J[a_l + 1, a_r])$

It is guaranteed that every  $a_l$  or  $a_r$  provided as input will already be in the sequence.

Note that this problem is not solvable for all choices of  $q$  and  $U$ : one may need to know the individual values of  $A_0$ , and not just the result of  $q$  over some ranges, to facilitate queries after certain types of updates.

We use this to obtain the following general result, which we prove in the full version.

► **Theorem 5.4.** Suppose  $U$  is a set of update functions, and  $q$  is a query function, computable in  $O(1)$  time. If there is a set  $\bar{U}$  such that:

1.  $U \subseteq \bar{U}$  are sets of functions that can be represented and composed in  $\tilde{O}(1)$  space and time, such that the composition of any series of at most  $n$  (possibly non-distinct) functions of  $U$  results in a function in  $\bar{U}$ ;
2. There is an algorithm for 1D PARTITIONED RANGE  $(q, U)$  that performs both updates and queries in  $\tilde{O}(1)$  time;
3. There is an algorithm for STATIC TRELLISED  $d$ D GRID RANGE  $(q, \bar{U})$  that runs in  $\tilde{O}(n_u^{c-\gamma}(n_u + n_q)^\gamma)$  time for some  $\gamma \in [0, 1]$

then GRID RANGE  $(q, U)$  can be solved in  $\tilde{O}(n^{\frac{c+d+1}{2} - \frac{1}{2d}})$  time. When  $d = 2$ , this is  $\tilde{O}(n^{5/4+c/2})$  time.

This gives a  $\tilde{O}(n^{(d^2+2d-1)/2d})$  time algorithm for GRID RANGE  $(\max, \{\min, \text{set}, \max\})$ .

In the next section, we give two additional applications of this theorem.

## 6 Truly subquadratic set updates and + queries by counting paths

In this section, we apply Theorem 5.4 to give truly subquadratic algorithms for 2D GRID RANGE  $(+, \text{set})$  and 2D GRID RANGE  $(+, \{+, \text{set}\})$ .

### 6.1 2D GRID RANGE $(+, \text{set})$ by counting inversions

The first condition of Theorem 5.4 is met for  $U = \bar{U} = \{\text{set}\}$ , since  $\text{set}_a \circ \text{set}_b = \text{set}_a$  for any  $a$  and  $b$ . The second condition can be met with a data structure for 1D GRID RANGE  $(+, \text{set})$ , maintaining the invariant that a sum query over a range  $R$  in this structure yields the same result as a sum query over  $R$  in the PARTITIONED RANGE structure. Operations each occur in  $O(\log n) = \tilde{O}(1)$  time.

Finally, we address the third condition by drawing an equivalence between STATIC TRELLISED 2D GRID RANGE  $(+, \text{set})$  and a class of range query problems over arrays. The RANGE EQPAIRS QUERY accepts an array of size  $n$  as input, and asks for the number of pairs of equal elements within each of  $q$  given ranges. Duraj et al. [14] defined this weighted analogue for counting inversions between pairs of ranges.

► **Definition 6.1** (WEIGHTED 2RANGEINVERSIONSQUERY). *Given an integer array  $A$ , an integer array of weights  $W$ , both of length  $n$ , and a sequence of  $q$  pairs of non-overlapping ranges  $([l'_1, r'_1], [l''_1, r''_1]), \dots, ([l'_q, r'_q], [l''_q, r''_q])$ , with  $r'_i < l''_i$ , compute for each pair  $([l', r'], [l'', r''])$  the quantity*

$$\sum_{i \in [l', r']} \sum_{j \in [l'', r'']} 1_{A[i] > A[j]} \cdot W[i] \cdot W[j].$$

2RANGEINVERSIONSQUERY is the problem with the added restriction that every weight is 1.

They showed that RANGEQPAIRSQUERY is equivalent, up to polylogarithmic factors, to 2RANGEINVERSIONSQUERY, even when the time complexity is expressed as a function of both  $n$  and  $q$ . We extend this equivalence to STATIC TRELLISED 2D GRID RANGE (+, set).

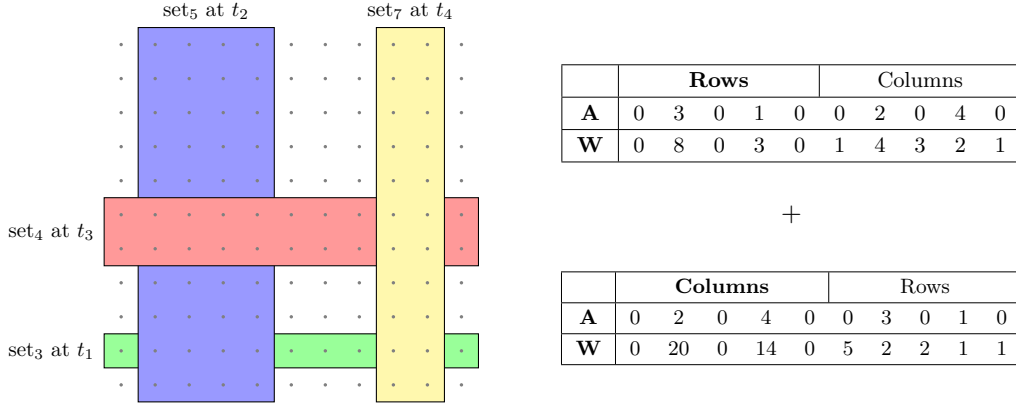

► **Lemma 6.2.** STATIC TRELLISED 2D GRID RANGE (+, set), WEIGHTED 2RANGEINVERSIONSQUERY and 2RANGEINVERSIONSQUERY all have the same complexity, up to polylogarithmic factors. This holds even when the queries are presented online, and with the complexity measured as a function of two variables,  $n$  and  $q$ .

**Proof.** (STATIC TRELLISED 2D GRID RANGE (+, set)  $\rightarrow$  WEIGHTED 2RANGEINVERSIONSQUERY). By adding a dummy update with value 0 covering the whole grid at time  $-1$ , we may assume – without loss of generality – that every row (column) is covered by at least one row (column) update. Now the value of a given point (after all updates) is equal to the value of the later of the latest row update and the latest column update affecting this point's row and column, respectively. Thus, for each row (column), it suffices to keep the latest row (column) update covering it. With a sort and sweep, we can process the row updates into  $O(n)$  disjoint row updates which preserve this property. Hence, without loss of generality, we may assume that the row updates are pairwise disjoint, as are the column updates. This preprocessing takes  $O(n \log n)$  time.

Consider a query over the points  $[l_1, r_1] \times [l_2, r_2]$ . We will show how to compute the contribution (sum of values) of those points whose value is determined by a row update: we can treat the contribution from column updates identically, and the sum of these contributions is the answer to the query. To form our instance of WEIGHTED 2RANGEINVERSIONSQUERY, create an array  $A$ , whose values are equal to the update time of each row update in order, from top to bottom, concatenated with the update time of each column update in order, from left to right. For the weights of our instance, let the weight corresponding to the row update with value  $v$  over rows  $[l_1, r_1]$  be  $v \times (r_1 - l_1 + 1)$ , and the weight corresponding to a column update over columns  $[l_2, r_2]$  be  $(r_2 - l_2 + 1)$ , irrespective of its value. This describes our instance (see Figure 1): we will now describe the queries made to this instance.

Since row (column) updates are disjoint, there is a contiguous range of row (column) updates in this array which lie entirely inside  $[l_1, r_1]$  ( $[l_2, r_2]$ ), whose indices can be found with binary search. The contribution of row updates to the points from these ranges is the result of a query on our instance over the corresponding ranges.  $O(1)$  parts of the query range may fall within part of a row or column update: the contribution from these can be found by scaling the result of a similarly constructed query.

For (WEIGHTED 2RANGEINVERSIONSQUERY  $\rightarrow$  2RANGEINVERSIONSQUERY) and (2RANGEINVERSIONSQUERY  $\rightarrow$  STATIC TRELLISED 2D GRID RANGE (+, set)) reductions, refer to full version. ◀

■ **Figure 1** Reducing STATIC TRELLISED 2D GRID RANGE (+, set) to WEIGHTED 2RANGEIN-VERSIONSQUERY. Updates occur at times  $t_1$  through  $t_4$ . Separate instances for row and column contributions.

Duraj et al. [14] gave an  $\tilde{O}(n^{(2\omega-2)/(\omega+1)}(n+q)^{2/(\omega+1)})$  time<sup>5</sup> algorithm for RANGEQPAIRSQUERY, so we obtain the following truly subquadratic time algorithm for 2D GRID RANGE (+, set).

► **Theorem 6.3.** 2D GRID RANGE (+, set) can be solved in  $\tilde{O}(n^{5/4+\omega/(\omega+1)}) = \tilde{O}(n^{1.954})$  time.

## 6.2 2D GRID RANGE (+, {+, set}) by counting 3-paths

We will once again employ Theorem 5.4 to give a truly subquadratic time algorithm for 2D GRID RANGE (+, {+, set}). The first two conditions are met with slight modifications to that in the previous section; fulfilling the third condition is the subject of the remainder of this section. We begin by defining the following graph problems.

► **Definition 6.4.** The  $k$ -WALKQUERY (resp. SIMPLE $k$ -PATHQUERY) problem gives, as input, a simple graph with  $m$  edges and  $O(m)$  vertices, and poses  $q$  online queries, each asking for the number of  $k$ -edge walks (resp. simple  $k$ -edge paths) between a given pair of vertices.

Duraj et al. [14] proved an equivalence between RANGEQPAIRSQUERY when  $n = q$ , and counting the number of triangles each edge is contained in, in a  $n$ -edge,  $O(n)$ -vertex graph. When the restriction  $n = q$  is relaxed, an equivalence can be drawn with 2WALKQUERY instead. In the same vein, we reduce STATIC TRELLISED 2D GRID RANGE (+, {+, set}) to 3WALKQUERY via a generalisation of RANGEQPAIRSQUERY.

► **Lemma 6.5.** If 3WALKQUERY can be solved in  $T(m, q)$  time then STATIC TRELLISED 2D GRID RANGE (+, {+, set}) can be solved in  $\tilde{O}(T(n_u, n_q))$  time.

To solve 3WALKQUERY, we generalise the 4-cycle detection and counting algorithms of Yuster and Zwick [29] and Vassilevska Williams et al. [25] to solve 3WALKQUERY. Specifically, we partition vertices into three groups based on their degree, and consider each

<sup>5</sup> The multivariate running time given in [14] is slightly better than this when  $q \leq n$ , but this simplified form suffices our purposes.

of the possible configurations of vertices in the 3-Walk with respect to these groups. For each configuration, we use a combination of rectangular matrix multiplication and enumerating edges, both during precomputation and on-the-fly for each query. Finally, we perform a multivariate analysis of the running time, obtaining the following result.

► **Theorem 6.6.** *3WALKQUERY is equivalent to SIMPLE3PATHQUERY, and both can be solved in  $O(m^{2\omega/(2\omega+1)}(m+q)^{(2\omega-1)/(2\omega+1)})$  time.*

Hence, this yields the following algorithm, by Theorem 5.4.

► **Theorem 6.7.** *2D GRID RANGE  $(+, \{+, \text{set}\})$  can be solved in time  $\tilde{O}(n^{5/4+(4\omega-1)/(4\omega+2)}) = O(n^{1.989})$ .*

## 7 RANGE problems over an explicit point set

► **Lemma 1.2.** *If 1D RANGE  $(q, U)$  on  $p$  points can be solved in time  $T(p)$  per operation and  $q$  is computable in  $O(1)$  time, then  $d$ D RANGE  $(q, U)$  can be solved in time  $O(p^{1-1/d}T(p))$  per operation.*

**Proof.** We construct a  $kd$ -tree [7]  $T$  over the points in  $P$ . There is a single point of  $P$  in each of the leaves of  $T$ : we assign these labels from 1 to  $p$ , according to the order of their appearance in a preorder traversal of  $T$ .

We can represent the points in any orthogonal range as those in the disjoint union of  $O(p^{1-1/d})$  subtrees of  $T$  [20]. The labels of points within these subtrees correspond to disjoint ranges of  $[p]$ . Hence, we can keep an instance of 1D RANGE  $(q, U)$ , and perform updates and queries on the corresponding ranges of labels using this data structure. ◀

► **Theorem 7.1.** *If either 2D RANGE  $(+, +)$  or 2D RANGE  $(\max, \max)$  can be solved in amortised  $O(p^{1/2-\epsilon})$  time per update or query, for any  $\epsilon > 0$ , then the OMv Conjecture is false.*

**Proof sketch.** We use a slight modification of Lemma 3.2, with a point in  $P$  for each  $M_{ij} = 1$ . For each pair of query vectors  $(u, v)$ , we use the update operation to mark row  $i$  for each  $u_i = 1$ . For each  $v_j = 1$ , we perform a query over column  $j$  to check if any points in that column were marked. A trick for 2D RANGE  $(\max, \max)$  allows us to reuse the same instance for all query vector pairs. ◀

► **Theorem 7.2.** *If any of 2D RANGE  $(+, \text{set})$ , 2D RANGE  $(\max, \text{set})$ , 2D RANGE  $(\max, +)$ , 2D RANGE  $(+, \max)$  or 2D RANGE  $(\max, \min)$  can be solved in amortised  $O(p^{1/2-\epsilon})$  time per update and amortised  $O(p^{1-\epsilon})$  time per query, for any  $\epsilon > 0$ , then the OMv Conjecture is false.*

The proof is similar to that of Lemma 3.2, and is omitted.

## 8 Open Problems

We have shown that 2D GRID RANGE  $(\max, \{\min, \text{set}, \max\})$  and 2D GRID RANGE  $(\max, +)$  can both be solved in truly subquadratic time, and found  $\Omega(n^{2-o(1)})$  time conditional lower bounds for 2D GRID RANGE  $(\max, \{+, \min\})$ . We also observe that 2D GRID RANGE  $(\max, \{+, \text{set}\})$  reduces to 2D GRID RANGE  $(\max, \{+, \max\})$ , since  $\text{set}_c = \max_c \circ +_{-\infty}$ . Hence, the remaining maximum query variants in  $\mathfrak{B}$  are each at least as hard as 2D GRID RANGE  $(\max, \{+, \text{set}\})$ .

► **Open Problem 8.1.** *Can (OFFLINE) 2D GRID RANGE (max, {+, set}) be solved in truly subquadratic time?*

Among variants supporting sum queries, we gave  $\Omega(n^{2-o(1)})$  time conditional lower bounds for 2D GRID RANGE (+, {+, max}). Using the identity  $\text{set}_c = \text{max}_c \circ +_{-\infty}$  once again, one can see that this is at least as hard as 2D GRID RANGE (+, {+, set}), which we solved in  $O(n^{1.989})$  time, using Theorem 5.4. Another problem easier than 2D GRID RANGE (+, {+, max}) is simply 2D GRID RANGE (+, max), which does not support + updates. This is also the easiest among the remaining sum query variants in  $\mathfrak{B}$ .

We make several comments regarding the hardness of 2D GRID RANGE (+, max). First, we observe that it is also at least as hard as its set “counterpart”, since any instance of GRID RANGE (+, set) can be simulated with two instances of GRID RANGE (+, max).

► **Lemma 8.2.** *GRID RANGE (+, set) can be solved in the same time as GRID RANGE (+, max).*

We solved 2D GRID RANGE (+, set) in  $O(n^{1.954})$  time using Theorem 5.4. However, it is easy to see that there is no solution to 1D PARTITIONED RANGE (+, max), which is required as a precondition of Theorem 5.4: it is simply not enough to know the sum of a range of points. One might instead determine for each overlay region  $O$ , query range  $R$  and  $\text{max}_c$  update: the number of points in  $O \cap R$  with value at most  $c$  and the sum of points in  $O \cap R$  with value greater than  $c$ . This requires  $O(k^3)$  values returned per batch, limiting precomputation to  $O(n^{3/2-\epsilon})$  time, for some  $\epsilon > 0$ , if a truly subquadratic time algorithm overall is desired. This cannot be achieved with a direct application of Theorem 5.4, since there are  $O(n^{3/2})$  updates across the t-regions.

► **Open Problem 8.3.** *Can (OFFLINE) 2D GRID RANGE (+, max) be solved in truly subquadratic time?*

Finally, our  $\Omega(n^{3/2-o(1)})$  conditional lower bounds do not match the upper bounds we gave for 2D GRID RANGE (+, {set, +}), 2D GRID RANGE (+, set) and 2D GRID RANGE (max, {min, set, max}). We ask if the gap can be closed for these problems to see if there exists an in-between complexity class of 2D GRID RANGE problems. In particular, this would be resolved in the affirmative if Theorem 5.4 is a tight reduction for any of these problems.

► **Open Problem 8.4.** *Are there any 2D GRID RANGE problems solvable in  $O(n^{2-\epsilon})$  time, for some  $\epsilon > 0$ , but require  $\Omega(n^{3/2-o(1)})$  time?*

We have studied just a small subset of RANGE and GRID RANGE problems in this work. Additional update or query operations, such as addition modulo a prime, can also be considered. Many existing variants of range searching (see [4]) can also be adapted to these problem classes. In particular, we have not investigated problems which deal with data points that have a “colour” or “category”, and ask for the number of distinct colours in a range. These may be of particular interest, as set updates could be used to facilitate changing the colour of several data points at the same time.

---

## Abstract

Despite the interest in the complexity class MA, the randomized analog of NP, there are just a few known natural (promise-)MA-complete problems. The first such problem was found by Bravyi and Terhal (SIAM Journal of Computing 2009); this result was then followed by Crosson, Bacon and Brown (PRE 2010) and then by Bravyi (Quantum Information and Computation 2015). Surprisingly, each of these problems is either from or inspired by quantum computation. This fact makes it hard for *classical* complexity theorists to study these problems, and prevents potential progress, e.g., on the important question of derandomizing MA.

In this note we define two new natural combinatorial problems and we prove their MA-completeness. The first problem, that we call approximately-clean approximate-connected-component (ACAC), gets as input a succinctly described graph, some of whose vertices are marked. The problem is to decide whether there is a connected component whose vertices are *all unmarked*, or the graph is *far* from having this property. The second problem, called **SetCSP**, generalizes in a novel way the standard constraint satisfaction problem (CSP) into constraints involving *sets* of strings.

Technically, our proof that **SetCSP** is MA-complete is a fleshing out of an observation made in (Aharonov and Grilo, FOCS 2019), where it was noted that a restricted case of Bravyi and Terhal's MA complete problem (namely, the *uniform* case) is already MA complete; and, moreover, that this restricted case can be stated using classical, combinatorial language. The fact that the first, arguably more natural, problem of ACAC is MA-hard follows quite naturally from this proof as well; while containment of ACAC in MA is simple, based on the theory of random walks.

We notice that this work, along with a translation of the main result of Aharonov and Grilo to the **SetCSP** problem, implies that finding a gap-amplification procedure for **SetCSP** (in the spirit of the gap-amplification procedure introduced in Dinur's PCP proof) would imply  $MA=NP$ . In fact, the problem of finding gap-amplification for **SetCSP** is *equivalent* to the  $MA=NP$  problem. This provides an alternative new path towards the major problem of derandomizing MA. Deriving a similar statement regarding gap amplification of a natural restriction of ACAC remains an open question.

## 1 Introduction

The complexity class MA is a natural extension of NP proof systems to the probabilistic setting [4]. There is a lot of evidence towards the fact that these two complexity classes are equal [14, 12, 13, 5, 18, 15, 20, 16], however the proof remains elusive. It is even open to show that every problem in MA can be solved in non-deterministic *sub-exponential* time.

Surprisingly, the very first *natural* MA-complete<sup>1</sup> problem, found by Bravyi and Terhal [8] only close to 25 years after the definition of the class (!) is defined using *quantum* terminology. But why would randomized NP have anything to do with quantum? Bravyi and Terhal show that deciding if a given stoquastic  $k$ -Local Hamiltonian<sup>2</sup> is frustration-free or at least inverse polynomially frustrated, is promise-MA-complete. Bravyi [6] also proved MA-completeness of yet another quantum Hamiltonian problem. A third MA-complete problem was proposed by Crosson, Bacon and Brown [9], inspired by quantum adiabatic computation.<sup>3</sup>

This leaves us in a strange situation in which the known MA complete problems are not stated using natural or standard complexity theory terminology. This makes us wonder if there is a fundamental reason why we cannot find classical MA-complete problems, or it is just an “accident” that the first MA-complete problems come from quantum computing. Moreover, we think that new natural (classically defined) complete problems for the class MA might enable access to the major open problem of derandomization of MA, and possibly to other related problems such as PCP for MA [1]<sup>4</sup>. In particular, though the problems proposed in [8, 6] are very natural within quantum complexity theory, the fact that they are defined within the area of quantum computation seems to pose a language and conceptual barrier that might delay progress on them, and make it hard for *classical* complexity theorists to study them.

The goal of this work is to provide classically, combinatorially-defined complete problems for MA. We hope that these definitions lead to further understanding of the class MA and the MA vs. NP question.

One of these problems, **SetCSP**, is morally based on the MA complete problem of [8], while the other problem, **ACAC**, seems to be a rather natural problem on graphs.

The definition of **SetCSP** as well as the proof of its MA-completeness rely on a simple but crucial insight: we can translate “testing history states”, a notion familiar in quantum complexity theory, into constraints on *sets* of strings. This idea is used here throughout, but in fact can be used to translate also other quantum results related to stoquastic Hamiltonians, to the classical combinatorial language of constraints on *sets of strings* (see Section 4.4.1 as

<sup>1</sup> For PromiseMA, it is folklore that one can define complete problems by extending NP-complete problems (see, e.g. [19]): we define an exponential family of 3SAT formulas (given as input succinctly) and we have to decide if there is an assignment that satisfies all of the formulas, or for every assignment, a random formula in the family will not be satisfied with good probability.

<sup>2</sup> Stoquastic Hamiltonians sit between classical Hamiltonians (CSPs) and general quantum Hamiltonians.

<sup>3</sup> Crosson et. al.’s problem asks about the properties of the Gibbs distribution corresponding to the temperature  $T$  of a specific family of *classical*, rather than quantum, physical systems, defined using local classical Hamiltonians. Though inspired by adiabatic quantum computation, this problem is in fact defined using *classical* terminology, since the classical Hamiltonians can be viewed as constraint satisfaction systems. Yet, we note that its definition uses a layer of physical notation, involving Gibbs distribution and temperature. Moreover, when stated using classical terminology, the input to this problem is restricted, in a fairly contrived way, to sets of classical constraints which can be associated with a (noisy) deterministic circuit. Both of these aspects seem to make handling this problem using standard combinatorial tools difficult or at least not very natural.

<sup>4</sup> We notice that Drucker [11] proves a PCP theorem for AM; in the definition he uses for AM, the coins are public and the prover sees them (See Section 2.3 in [11]); but his result does not hold when the coins are private, namely for MA.

well as Figure 1 for more intuition). However though this translation idea can be viewed as standing at the heart of many of the definitions and results presented here, it is in fact *not* necessary to understand the proofs.

Based on this idea, as well as a simple observation made in [1] which says that the problem of [8] remains promise-MA complete even when restricted to what is referred to in [1] as *uniform* stoquastic Hamiltonians, we can prove the MA-hardness proof of the SetCSP problem as a translation of the MA-hardness proof given in [8] into a classical language. We notice that the proof of [8] on its own heavily relies on the Quantum Cook-Levin proof of Kitaev [17].

It turns out that there is an easy reduction from the problem SetCSP to that of ACAC, and therefore the proof that ACAC is MA-hard follows immediately.

Interestingly, the proof of containment in MA is rather simple for ACAC (it is an easy application of a known result from random walk theory.) Finally, using the same reduction, we arrive at a proof that the SetCSP problem is also in MA<sup>5</sup>.

We stress that we present all proofs here avoiding any quantum notation or quantum jargon whatsoever. The main contribution of this work is in the definitions themselves, initiated by the small but important conceptual idea of the translation mentioned above; this translation thus provides two new, combinatorial, and natural MA-complete problems, which we believe are amenable to research in a language familiar to (classical) computer scientists.

We now describe the problems. In the ACAC problem, we consider an exponentially large graph, accompanied with a function on the vertices that marks some of them. Both graph and the function on the vertices are given implicitly (and succinctly) by a polynomial size circuit. We then ask if there exists a connected component of the graph that is “clean” (meaning that all of its vertices are *unmarked*) or if the graph is  $\varepsilon$ -far from having this property. The notion of “far” is defined as follows: every set of vertices which is close to being a connected component (i.e. its expansion is smaller than  $\varepsilon$ ) must have at least an  $\varepsilon$ -fraction of its vertices marked. In other words, either a set is  $\varepsilon$ -far from a connected component (i.e. has large expansion) or at least  $\varepsilon$  fraction of its vertices are marked. We call this problem *approximately-clean approximate-connected-component* (ACAC $_{\varepsilon}$ ).

Our second MA-complete problem, called the *Set-Constraint Satisfaction Problem*, or SetCSP, is a somewhat unexpected generalization of the standard Constraint Satisfaction Problem (CSP). While a constraint in CSP acts on a single string (deciding if it is valid or not), the generalized constraints act on *sets* of strings. We call the generalized constraints *set-constraints* (see Section 4 for the exact definition of a set-constraint.). The input to the SetCSP problem is a collection of such set-constraints, and the output is whether there is a set of strings  $S$  that satisfies *all* set-constraints in this collection, or any set of strings  $S$  is  $\varepsilon$ -far from satisfying this set-constraint collection (see Definitions 10 and 16 for formal definitions of “satisfying a set-constraint” and “far”). We denote this problem by SetCSP $_{\varepsilon}$ .

Following the ideas of [8, 17], we show the following three claims: *i*) for every inverse polynomial  $\varepsilon$ , we have that ACAC $_{\varepsilon}$  is in MA (Corollary 8); *ii*) there exists an inverse polynomial function  $\varepsilon = \varepsilon(n)$  such that SetCSP $_{\varepsilon}$  is MA-hard (Lemma 17); and *iii*) for all functions  $\varepsilon = \varepsilon(n) > 0$ , there is a polynomial-time reduction from SetCSP $_{\varepsilon}$  to ACAC $_{\varepsilon/2}$ . Together, these facts imply the following results (which are proven in Section 5).

<sup>5</sup> This in fact gives a significantly simpler version than [7] of the proof of containment in MA, in the restricted case of uniform stoquastic Hamiltonians.

► **Theorem 1.** *There exists some inverse polynomial  $p(x) = \Theta(1/x^3)$  such that for every inverse polynomial  $p' < p$ , the problems  $\text{SetCSP}_{p'(m)}$  and  $\text{ACAC}_{p'(m)}$  are MA-complete, where  $m$  is the size of the  $\text{SetCSP}$  or  $\text{ACAC}$  instance.*

We stress that the definitions of both these problems and the proofs presented in this paper only use standard combinatorial concepts from set- and graph-theory.

## 1.1 Conclusions, future work and open questions

In a similar way to what is done in this note, we claim that it is possible to translate several other results from the stoquastic local Hamiltonian language to the  $\text{SetCSP}$  language, bringing us to very interesting conclusions.

First, one could strengthen the MA-hardness of  $\text{SetCSP}$  (Lemma 17), whose proof is a translation of the proof of the quantum Cook-Levin theorem [17], to the restricted case in which the constraints are set on a 2D lattice. To do this, one could consider the result of [3] where they prove the QMA-hardness of local Hamiltonians on a 2D lattice (considering only the restricted family of stoquastic Hamiltonians), and translate it to the  $\text{SetCSP}$  language. In this way, it can be proven that  $\text{SetCSP}_\varepsilon$  with inverse polynomial  $\varepsilon$ , and with set-constraints arranged on a 2D-lattice with constant size alphabet is still MA-hard.<sup>6</sup> We omit here the details of the proof, since it is a straight forward translation of [3], similarly to what's done in Lemma 17. This leads to the following statement.

► **Lemma 2.** *There exists some inverse polynomial  $p$  such that for every inverse polynomial  $p' < p$ ,  $\text{SetCSP}_{p'}$  is MA-hard even when each bit participates in  $O(1)$  set-constraints, and each set-constraint acts on  $O(1)$  bits.*

We also claim that the main result of [1], which states that some problem called stoquastic local Hamiltonian with constant gap is in NP, can be translated to  $\text{SetCSP}$  language, using again the same translation. This means that the *gapped* version of the  $\text{SetCSP}$  problem is in NP. By the gapped version of the problem, we mean  $\text{SetCSP}_\varepsilon$  when  $\varepsilon$  is a constant; and where we also require that the locality  $k$  (number of bits in a set-constraint) and degree  $d$  (number of set-constraints each bit participates in) are bounded from above by a constant. More concretely, we have the following.

► **Lemma 3.** *For any constant  $\varepsilon$  and constants  $k$  and  $d$ ,  $\text{SetCSP}_\varepsilon$  is in NP if each bit participates in  $d$  set-constraints, and each set-constraint acts on  $k$  bits.*

Together these two results lead to a very important and surprising equivalence<sup>7</sup>:

**Proposition.** MA=NP iff there is a gap amplification reduction<sup>8</sup> for  $\text{SetCSP}$ . The existence of a gap amplification reduction means that there exists a constant  $\varepsilon > 0$ , such that for every inverse polynomial  $p$ , there is a polynomial time reduction from  $\text{SetCSP}_{p(n)}$  to  $\text{SetCSP}_\varepsilon$ .

We note that it is easy to see that MA=NP implies such gap-amplification for  $\text{SetCSP}$ : if MA = NP, then we can reduce  $\text{SetCSP}_{1/poly}$ , which is in MA-complete by Theorem 1, to  $\text{CSP}_{O(1)}$ , which is NP-complete by the PCP theorem [10]; then, since every CSP instance

<sup>6</sup> We conjecture that this hardness result works even with binary alphabet and we leave such a statement for future work.

<sup>7</sup> This equivalence was highlighted in [1] in a quantum language of stoquastic Hamiltonians

<sup>8</sup> In the same sense as Dinur's gap amplification reduction for CSP[10]

is also a **SetCSP** instance with the same parameters, we have the gap-amplification. It is the other direction of deriving  $\text{MA}=\text{NP}$  from gap-amplification for **SetCSP**, that is the new contribution. This implication suggests a new path to the long standing open problem of derandomizing  $\text{MA}$ .

Finally, we leave as an open problem deriving such a natural statement regarding gap amplification for the **ACAC** problem. Though the two problems are technically very related, defining a natural restricted version of the gapped **ACAC** problem, so that the [1] result would apply to show containment in  $\text{NP}$  (similarly to **SetCSP** with constant  $\varepsilon$ , locality  $k$  and degree  $d$ ) remains open. The problem is that the locality notions don't have a very natural analogues in the graph language of **ACAC**.

**Organization.** We provide notation and a few basic notions in Section 2. In Section 3, we define the approximately-clean approximate-connected-component problem and prove its containment in  $\text{MA}$ . The definition of **SetCSP** and the proof of its  $\text{MA}$ -hardness are in Section 4. The reduction from **SetCSP** to **ACAC** appear in Section 5.

## 2 Preliminaries

For  $n \in \mathbb{N}^+$ , we denote  $[n] = \{0, \dots, n-1\}$ . For any  $n$ -bit string, we index its bits from 0 to  $n-1$ . For  $x \in \{0,1\}^n$  and  $J \subseteq [n]$ , we denote  $x|_J$  as the substring of  $x$  on the positions contained in  $J$ . For  $x \in \{0,1\}^{|J|}$ ,  $y = \{0,1\}^{n-|J|}$  and  $J \subseteq [n]$ , we define  $x^J y^{\bar{J}}$  to be the unique  $n$ -bit string  $w$  such that  $w|_J = x$  and  $w|_{\bar{J}} = y$ , where  $\bar{J} = [n] \setminus J$ . For two strings,  $x$  and  $y$ , we denote by  $x || y$  their concatenation, and  $|x|$  denotes the number of bits in  $x$ .

### 2.1 Complexity classes

A (promise) problem  $A = (A_{\text{yes}}, A_{\text{no}})$  consists of two non-intersecting sets  $A_{\text{yes}}, A_{\text{no}} \subseteq \{0,1\}^*$ .

For the definitions of the two main complexity classes that are considered in this work,  $\text{NP}$  and  $\text{MA}$ , we refer to the full version of this paper [2].

The standard definition of  $\text{MA}$  [4] requires yes-instances to be accepted with probability at least  $\frac{2}{3}$ , but it has been shown that there is no change in the computational power if we require the verification algorithm to always accept yes-instances [21, 12].

### 2.2 Reversible circuits

It is folklore that the verification algorithms for  $\text{NP}$  and  $\text{MA}$  can be converted into a uniform family of polynomial-size Boolean circuits, made of reversible gates,  $\{\text{NOT}, \text{CNOT}, \text{CCNOT}\}$  by making use of additional auxiliary bits initialized to 0, with only linear overhead. For randomized circuits, we can also assume the circuit uses only reversible gates, by assuming that the random bits are part of input. See the full version of this paper [2] for more details.

Let  $G \in \{\text{NOT}, \text{CNOT}, \text{CCNOT}\}$  be a gate to be applied on the set of bits  $J$  out of some  $n$ -bit input  $x$ . We slightly abuse notation (but make it much shorter!) and denote  $G(x) \stackrel{\text{def}}{=} x|_{\bar{J}} G(z|_J)^J$ . Namely, we understand the action of the  $k$ -bit gate  $G$  on an  $n > k$  bit string  $x$  by applying  $G$  only on the relevant bits, and leaving all other bits intact.

### 3 Approximately-clean approximate-connected-component problem

In this section, our goal is to present the approximately-clean approximate-connected-component problem and prove its containment in MA. But before that, we explain the *exact* version of this problem.

For a fixed parameter  $n$ , we consider a graph  $G$  of  $2^n$  nodes, which is described by a classical circuit  $C_G$  of size (number of gates)  $\text{poly}(n)$ , as follows. For simplicity, we represent each vertex of  $G$  as an  $n$ -bit string, and  $C_G$ , on input  $x \in \{0,1\}^n$ , outputs the (polynomially-many) neighbors of  $x$  in  $G$ .<sup>9</sup> We are also given a circuit  $C_M$ , which when given input  $x \in \{0,1\}^n$ , outputs a bit indicating whether the vertex  $x$  is marked or not.

We define the clean connected component problem (CCC) which, on input  $(C_G, C_M)$ , asks if  $G$  has a connected component where *all vertices are unmarked* or if all connected components have at least one marked element. We give now the formal definition of this problem.

► **Definition 4** (Clean connected component(CCC)). *Fix some parameter  $n$ . An instance of the clean connected component problem consists of two classical  $\text{poly}(n)$ -size circuits  $C_G$  and  $C_M$ .  $C_G$  consists of a circuit succinctly representing a graph with  $G = (V, E)$  where  $V = \{0,1\}^n$  and each vertex has degree at most  $\text{poly}(n)$ . On input  $x \in \{0,1\}^n$ ,  $C_G$  outputs all of the neighbors of  $x$ .  $C_M$  is a circuit that on input  $x \in \{0,1\}^n$ , outputs a bit. The problem then consists of distinguishing the two following cases:*

**Yes.** *There exists one non empty connected component of  $G$  such that  $C_M$  outputs 0 on all of its vertices.*

**No.** *In every connected component of  $G$ , there is at least one vertex for which  $C_M$  outputs 1.*

We show in the full version of this paper [2] that this problem is PSPACE-complete. Our focus here is to study the *approximate* version of CCC, where we ask whether  $G$  has a clean connected component or it is “far” from having this property, meaning that for every set of vertices  $S$ , the boundary<sup>10</sup> of  $S$  is at least  $\varepsilon|S|$  (and therefore  $S$  is far from being a connected component), or, if the boundary is small (i.e.  $S$  is close to a connected component) it contains at least  $\varepsilon|S|$  marked elements. Here is the definition of the problem.

► **Definition 5** (Approximately-clean approximate-connected-component(ACAC $_\varepsilon$ )). *Same as Definition 4 with the following difference for no-instances:*

**No.** *For all non empty  $S \subseteq V$ , we have that either*

$$|\partial_G(S)| \geq \varepsilon|S| \quad \text{or} \quad |\{x \in S : C_M(x) = 1\}| \geq \varepsilon|S|.$$

In the remainder of this section, we show that ACAC $_\varepsilon$  is in MA for every inverse polynomial  $\varepsilon$ .

#### 3.1 Inclusion in MA

The idea of the proof is as follows. The prover sends a vertex that belongs to the (supposed) clean connected component and then the verifier performs a random-walk on  $G$  for sufficiently (but still polynomially-many) steps and rejects if the random walk encounters a marked element.

<sup>9</sup> We notice that usually we succinctly describe graphs by considering a circuit that, on input  $(x, y)$ , outputs 1 iff  $x$  is connected to  $y$ . In our result it is crucial that given  $x$ , we are able to efficiently compute *all* of its neighbors.

<sup>10</sup> The boundary of a set of vertices  $S \subseteq V$  is defined as  $\partial_G(S) = \{\{u, v\} \in E : u \in S, v \notin S\}$ .

In order to prove that this verification algorithm is correct, we first prove a technical lemma regarding the random-walk on no-instances.

► **Lemma 6** (In NO-instances the random walk reaches marked nodes quickly). *Let  $\varepsilon$  be an inverse polynomial function of  $n$ . If  $(C_G, C_M)$  is a no-instance of  $\text{ACAC}_\varepsilon$ , then there exist polynomials  $q_1$  and  $q_2$  such that for every  $x \in \{0, 1\}^n$ , a  $q_1(n)$ -step lazy random walk<sup>11</sup> starting at  $x$  reaches a marked vertex with probability at least  $\frac{1}{q_2(n)}$ .*

**Proof.** Let  $x$  be some initial (unmarked) vertex (notice that we can assume that  $x$  is unmarked since otherwise the lazy random walk reaches a marked vertex with probability 1). Let  $G_x$  be the connected component of  $x$  in  $G$  and  $V_x$  be the set of vertices in the connected component of  $x$ . We partition  $V_x$  into  $A$ , the unmarked vertices in  $V_x$  and  $B = V_x \setminus A$ , the marked vertices in  $V_x$ .

We want to upper bound the size of the edge boundary of any set  $S \subseteq A$  which contains only unmarked strings. We claim that by the conditions of the lemma, it must be that for any  $S \subseteq A$ , we have the following bound:

$$|\partial_G(S)| \geq \varepsilon|S|, \quad (1)$$

otherwise  $S$  would contradict the fact that  $(C_G, C_M)$  is a no-instance, since it only contains unmarked vertices.

We can now ask how fast does a lazy random walk starting from  $x$ , reach an element in  $B$ . This is a well known question from random walk theory, and it can be stated as follows.

► **Lemma 7** (Escaping time of high conductance subset). *Let  $G = (V = A \cup B, E)$  be a simple (no multiple edges) undirected connected graph, such that for every  $v \in A$   $d_G(v) \leq d$ , and such that for some  $\delta < \frac{1}{2}$ , for all  $A' \subseteq A$ , we have that  $|\partial_G(A')| \geq \delta|A'|$ . Then a  $\left(\frac{16d^2}{\delta^2} \ln \frac{2d|V|}{\delta}\right)$ -step lazy random walk starting in any  $v \in A$  reaches some vertex  $u \in B$  with probability at least  $\frac{\delta}{4d}$ .*

We defer the proof of this lemma to the full version of this paper [2] and we apply it using  $G = G_x$ ,  $A$ ,  $B$ ,  $d$  is the (poly( $n$ )-large) maximum degree of  $G$ , and  $\delta \geq \varepsilon$ . It follows that a  $\left(\frac{16d^2}{\varepsilon^2} (n + \ln(2d/\varepsilon))\right)$ -step lazy random walk starting on any  $x \in G_x$  reaches a marked vertex with probability at least  $\frac{\varepsilon}{4d}$ . ◀

From the previous lemma, we can easily achieve the following.

► **Corollary 8.** *For any inverse polynomial  $\varepsilon$ ,  $\text{ACAC}_\varepsilon$  is in MA.*

**Proof.** The witness for the  $\text{ACAC}$  instance consists of some string  $x$ , which is supposed to be in a clean connected component of  $G$ . Define  $q_1$  and  $q_2$  as the same polynomials of Lemma 6, namely, let  $q_1 = \left(\frac{16d^2}{\varepsilon^2} (n + \ln(2d/\varepsilon))\right)$  and  $q_2 = \frac{4d}{\varepsilon}$ . The MA-verification algorithm consists of repeating  $nq_2(n)$  times the following process: start from  $x$ , perform a  $q_1(n)$ -step lazy random walk in  $G$ , reject if any of these walks encounters a marked vertex, otherwise accept.

If  $(C_G, C_M)$  is a yes-instance, then the prover can provide a vertex  $x$  which belongs to the clean connected component. Any walk starting from  $x$  remains in its connected component and thus it will never encounter a marked vertex and the verifier accepts with probability 1.

<sup>11</sup>In a lazy random walk, at every step we stay in the current vertex with probability  $\frac{1}{2}$ , and with probability  $\frac{1}{2}$  we choose a random neighbor of the current vertex uniformly at random and move to it.

If  $(C_G, C_M)$  is a no-instance, from Lemma 6, each one of the random walks finds a marked vertex with probability at least  $\frac{1}{q_2(n)}$ . Thus, if we perform  $nq_2(n)$  lazy random walks, the probability that at least one of them finds a marked vertex is exponentially close to 1. ◀

#### 4 Set-Constraint Satisfaction Problem

In this section we present the Set Constraint Satisfaction Problem (SetCSP), and then prove its MA-hardness.

##### 4.1 Definition of the SetCSP problem

We start by recalling the standard Constraint Satisfaction Problem (CSP). We choose to present CSP in a way which is more adapted to our generalization (but still equivalent to the standard definition). An instance of  $k$ -CSP is a sequence of constraints  $C_1, \dots, C_m$ . In this paper, we see each constraint  $C_i$  as a tuple  $(J(C_i), Y(C_i))$ , where  $J(C_i) \subseteq [n]$  is a subset of at most  $k$  distinct elements of  $[n]$  (these are referred to as “the bits on which the constraint acts”) and  $Y(C_i)$  is a subset of  $k$ -bit strings, namely  $Y(C_i) \subseteq \{0, 1\}^{|J(C_i)|}$  (these are called the “allowed strings”). We say that a string  $x \in \{0, 1\}^n$  satisfies  $C_i$  if  $x|_{J(C_i)} \in Y(C_i)$ . The familiar problem of  $k$ -CSP, in this notation, is to decide whether there exists an  $n$ -bit string  $x$  which satisfies  $C_i$ , for all  $1 \leq i \leq m$ .

In  $k$ -SetCSP, our generalization of  $k$ -CSP, the constraints  $C_i$  are replaced by what we call “set-constraints” which are satisfied by (or alternatively, that *allow*), *sets* of strings  $S \subseteq \{0, 1\}^n$ .

► **Definition 9** (Set constraint). *A  $k$ -local set-constraint  $C$  consists of a) a tuple of  $k$  distinct elements of  $[n]$ , denoted  $J(C)$  (we have  $|J(C)| = k$ , and we refer to  $J(C)$  as the bits which the set-constraint  $C$  acts on), and b) a collection of sets of strings,  $Y(C) = \{Y_1, \dots, Y_\ell\}$ , where  $Y_i \subseteq \{0, 1\}^k$  is a set of  $k$ -bit strings and  $Y_i \cap Y_j = \emptyset$  for all distinct  $1 \leq i, j \leq \ell$ .*

► **Definition 10** (A set of strings satisfying a constraint). *We say that a set of strings  $S \subseteq \{0, 1\}^n$  satisfies the  $k$ -local set-constraint  $C$  if first, the  $k$ -bit restriction of any string in  $S$  to  $J(C)$  is contained in one of the sets in  $Y(C)$ , i.e., for all  $x \in S$ ,  $x|_{J(C)} \in \bigcup_j Y_j$ . Secondly we require that if  $x \in S$  and  $x|_{J(C)} \in Y_j$ , then for every  $y$  such that  $y|_{J(C)} \in Y_j$  and  $y|_{\overline{J(C)}} = x|_{\overline{J(C)}}$ , then  $y \in S$ . In other words, for any string  $s \in S$ , one can replace its  $k$ -bit restriction to the bits  $J(C)$ , which is a string in some  $Y_j \in Y(C)$ , with a different  $k$ -bit string in  $Y_j$ , and the resulting string  $s'$  must also be in  $S$ .*

An instance of  $k$ -SetCSP consists of  $m$  such  $k$ -local set-constraints, and we ask if there is some non-empty  $S \subseteq \{0, 1\}^n$  that satisfies each of the set constraints, or if any set  $S$  of  $n$ -bit strings is *far* from satisfying the collection of set-constraints. How to define *far*? We quantify the distance from satisfaction using a generalization of the familiar notation of *unsat* from PCP theory [10]; we denote the generalized notion by  $\text{set-unsat}(\mathcal{C}, S)$ . Intuitively, this quantity captures how much we need to modify  $S$  in order to satisfy the collection of set-constraints. Making this definition more precise will require some work; However we believe it already makes some sense intuitively, so we present the definition of the SetCSP problem now, and then provide the exact definition of  $\text{set-unsat}(\mathcal{C}, S)$  in Section 4.2.

► **Definition 11** ( $k$ -local Set Constraint Satisfaction problem ( $k$ -SetCSP $_\epsilon$ )). *Fix the two constants  $d, k \in \mathbb{N}^+$ , as well as a monotone function  $\epsilon : \mathbb{N}^+ \rightarrow (0, 1)$  to be some parameters of the problem. An instance to the  $k$ -local Set Constraint Satisfaction problem is a sequence*

of  $m(n)$   $k$ -local set-constraints  $\mathcal{C} = (C_1, \dots, C_m)$  on  $\{0, 1\}^n$ , where  $m$  is some polynomial in  $n$ . Under the promise that one of the following two holds, decide whether:

**Yes.** There exists a non-empty  $S \subseteq \{0, 1\}^n$  that satisfies all set constraints in  $\mathcal{C}$ , i.e.,  $\text{set-unsat}(\mathcal{C}, S) = 0$

**No.** For all  $S \subseteq \{0, 1\}^n$ ,  $\text{set-unsat}(\mathcal{C}, S) \geq \varepsilon(n)$ .

## 4.2 Satisfiability, frustration and the definition of $\text{set-unsat}(\mathcal{C}, S)$

We present some concepts required for the formal definition of  $\text{set-unsat}(\mathcal{C}, S)$ .

► **Definition 12** (*C*-Neighboring strings). Let  $C$  be some set-constraint. Two distinct strings  $x$  and  $y$  are said to be *C*-neighbors if  $x|_{\overline{J(C)}} = y|_{\overline{J(C)}}$  and  $x|_{J(C)}, y|_{J(C)} \in Y_i$ , for some  $Y_i \in Y(C)$ . We call a string  $x$  a *C*-neighbor of  $S$  if there exists a string  $y \in S$  such that  $x$  is a *C*-neighbor of  $y$ .

We also define the *C*-longing strings in a set of strings  $S$ : these are the strings that are in  $S$  but are *C*-neighbors of some string that is not in  $S$ .

► **Definition 13** (*C*-Longing strings). Given some set  $S \subseteq \{0, 1\}^n$  and a set-constraint  $C$ ,  $x \in S$  is a *C*-longing<sup>12</sup> string with respect to  $S$  if  $x$  is a *C*-neighbor of some  $y \notin S$ .

A useful definition is that of *bad* strings for some set-constraint  $C$ , which in short are the strings that do not appear in any subset of  $Y(C)$ .

► **Definition 14** (*C*-Bad string). Given a set-constraint  $C$ , with  $Y(C) = \{Y_1, \dots, Y_\ell\}$ , a string  $x \in \{0, 1\}^n$  is *C*-bad if  $x|_{J(C)} \notin \bigcup_i Y_i$ . We abuse the notation and whenever  $x$  is *C*-bad, we say  $x \notin Y(C)$ .

The following complementary definition will be useful:

► **Definition 15** (Good string). We say that a string is *C*-good if it is not *C*-bad. We say that it is a “good string for the set-constraint collection  $\mathcal{C}$ ” if it is *C*-good for all set-constraints  $C \in \mathcal{C}$ . When the collection  $\mathcal{C}$  is clear from context (as it is throughout this note), we omit mentioning of the set-constraints collection  $\mathcal{C}$  and just say that the string is “good”.

Given Definitions 13 and 14 above, it is easy to see that a set of strings  $S \subseteq \{0, 1\}^n$  satisfies a set-constraint  $C$  (by Definition 10) iff  $S$  contains no *C*-bad strings and no *C*-longing strings.

We now provide a way to quantify how far  $S$  is from satisfying  $C$ .

► **Definition 16** (Satisfiability of set-constraints). Let  $S \subseteq \{0, 1\}^n$  and  $C$  be a  $k$ -local set-constraint. Let  $B_C$  be the set of *C*-bad strings in  $S$  and  $L_C$  be the set of *C*-longing strings in  $S$ . Note that  $L_C \cap B_C = \emptyset$ . The  $\text{set-unsat}$  value (which we sometimes refer to as the *frustration*) of a set-constraint  $C$  with respect to  $S$ , is defined by

$$\text{set-unsat}(C, S) = \frac{|B_C|}{|S|} + \frac{|L_C|}{|S|} \quad (2)$$

<sup>12</sup> The term “*C*-longing” reflects the sentiment that the string  $x$  “wants” to be together with  $y$  in  $S$ ; the set constraint makes sure that there is an energy penalty if this is not the case.

Given a collection of  $m$   $k$ -local set-constraints  $\mathcal{C} = (C_1, \dots, C_m)$ , its **set-unsat** value (or frustration) with respect to  $S$  is defined as average frustration of the different set-constraints:

$$\text{set-unsat}(\mathcal{C}, S) = \frac{1}{m} \sum_{i=1}^m \text{set-unsat}(C_i, S). \quad (3)$$

We also define the frustration of the set collection  $\mathcal{C}$ :

$$\text{set-unsat}(\mathcal{C}) = \min_{\substack{S \subseteq \{0,1\}^n \\ S \neq \emptyset}} \{\text{set-unsat}(\mathcal{C}, S)\}. \quad (4)$$

We say that  $\mathcal{C}$  is satisfiable if  $\text{set-unsat}(\mathcal{C}) = 0$  and for  $\varepsilon > 0$ , we say that  $\mathcal{C}$  is  $\varepsilon$ -frustrated if  $\text{set-unsat}(\mathcal{C}) \geq \varepsilon$ .

Notice that the normalization factors in Equation (2) guarantees that the **set-unsat** value lies between 0 and 1.<sup>13</sup>

### 4.3 Intuition and standard CSP as special case

We can present a standard  $k$ -CSP instance consisting of constraints  $C_1, C_2, \dots, C_m$  as an instance of  $k$ -SetCSP in the following way: For each constraint  $C_\ell, \ell \in \{1, \dots, m\}$  out of the  $m$  constraints in the  $k$ -CSP instance, we consider the following set-constraint  $C'_\ell$ : for every  $k$ -bit string  $s$  that satisfies  $C_\ell$ , add the subset  $Y_s = \{s\}$  to  $C'_\ell$ . We arrive at a collection  $\mathcal{C}$  of  $m$  set-constraints, where each set-constraint  $C'_\ell$  in  $\mathcal{C}$  consists of single-string sets  $Y_i$  corresponding to all strings which satisfy  $C_\ell$ .

We claim that the resulting SetCSP instance has  $\text{set-unsat}(\mathcal{C}) = 0$  if and only if the original CSP instance was satisfiable. First, if the original CSP instance is satisfiable, we claim that for any satisfying string  $s$  we can define the set  $S = \{s\}$  consisting of that single string, and  $S$  indeed satisfies the collection of set-constraints defined above. To see this, note that in our case, there is no notion of  $C$ -neighbors (See Definition 12), since all  $Y_i$ 's contain only a single string. Hence, there are no longing strings; By the definition of **set-unsat** (Equation (2)) in this case  $\text{set-unsat}(\mathcal{C}, S) = 0$  if all strings in  $S$  are good for all set-constraints  $C'$ , namely each of them satisfies all constraints  $C$  in the original  $k$ -CSP instance, which is indeed the case if we pick a satisfying assignment. For the other direction, assume  $\text{set-unsat}(\mathcal{C}, S) = 0$  for some set  $S$ . This in particular means that all strings in  $S$  are  $C$ -good for all set-constraints in  $\mathcal{C}$ . By definition of our  $\mathcal{C}$ , this means any string  $s \in S$  is a satisfying assignment.

We give now some intuition about the **set-unsat** quantity (Equation (2)). We first note that it generalizes the by-now-standard notion of (un)satisfiability in CSP, which for a given string, counts the number of unsatisfied constraints, divided by  $m$ . We note that in Equation (2), if  $S = \{s\}$ , then  $|B_C|$  is either 0 or 1, depending on whether  $s$  satisfies the constraint or not. As previously remarked, in CSP the notion of neighboring and longing strings does not exist, and so  $L_C$  will always be empty. Thus, in the case where  $S = \{s\}$  and all set-constraints containing single strings, Equation (3) is indeed the number of violated constraints by the string, divided by  $m$  – which is exactly the standard CSP **unsat** used in PCP contexts [10]. (In the case of  $S$  containing more than one string, but all  $Y_i$ s are still single-strings, Equation (3) will just be the (non-interesting) average of the **unsat** of all strings in  $S$ ).

<sup>13</sup>The lower bound is trivial since the value cannot be negative. For the upper-bound, notice that  $B_C, L_C \subseteq S$  and  $B_C \cap L_C = \emptyset$ . This is because bad strings have no neighbors whereas longing strings do. Hence  $\frac{|B_C|}{|S|} + \frac{|L_C|}{|S|} \leq \frac{|S|}{|S|} = 1$ .

The interesting case is the general **SetCSP** case, when the  $Y_i$ 's contain more than a single string, i.e., when the notions of neighbors and longing strings become meaningful. In this case, the left term in the RHS of Equation (2) quantifies how far the set  $S$  is from the situation in which it contains only “good” (not “bad”) strings (this can be viewed as the standard requirement) but it adds to it the right term, which quantifies how far  $S$  is from being closed to the action of adding neighbors with respect to the set-constraints<sup>14</sup>. Loosely put, the generalization from constraints to set-constraints imposes strong “dependencies” between different strings, and the number of longing strings,  $L_C$ , counts to what extent these dependencies are violated.

#### 4.4 MA-hardness of **SetCSP**<sub>1/poly( $n$ )</sub>

In this subsection, we show the MA-hardness of **SetCSP**<sub>1/poly</sub>.

► **Lemma 17.** *There exists some inverse polynomial  $p(x) = \Theta(1/x^3)$  such that for every inverse polynomial  $p' < p$ , the problem **SetCSP** <sub>$p'(m)$</sub>  is MA-hard.*

To prove this lemma, we show how to reduce any language  $L \in \text{MA}$  to a 6-**SetCSP** instance. Our approach here is to “mimic” the Quantum Cook-Levin theorem due to Kitaev [17], but given that we only need to deal with set of strings and not arbitrary quantum states, our proof can in fact be stated in set-constraints language.

##### 4.4.1 Intuition for how set-constraints can check histories

In the celebrated proof of the (classical) Cook-Levin theorem, an instance of an NP-language is mapped to an instance for 3-SAT problem. More precisely, the verifier  $V$  of the NP-problem, which runs on an  $n$ -bit input string  $x$  and a  $\text{poly}(n)$  bit witness  $y$ , is mapped to a 3-SAT formula. To do this, a different variable is assigned to the value of each location of the tape of the Turing machine of  $V$  at any time step; these variables are used to keep track of the state of the computation of  $V$  (namely what is written on the tape) at the different time steps (see Figure 1 for an example). The formula acts on strings of bits, which can be viewed as assignments to *all* these variables; such an assignment encodes the *entire history* of a single possible computation. The clauses of the Boolean formula check if the history given by the assignment, indeed corresponds to a correct propagation of an *accepted* computation. More precisely, the constraints check that *a*) the assignment to the  $n$  Boolean variables at the first time step, associated with the input to the NP-problem, is indeed correct (namely equal to the true input  $x$ ); *b*) the assignment of the variables corresponding to any two subsequent time steps is consistent with a correct evolution of the appropriate gate in the computation; and *c*) the output bit, namely the value of the output variable in the *last* time step, is indeed *accept*. There exists a valid history which ends with accept (i.e.,  $x$  is in the language accepted by the verifier), iff the resulting  $k$ -CSP is satisfiable; in which case a satisfying assignment encodes a *history* of a correct computation of the verifier.

Now, suppose we want to apply a similar construction for some MA verification. The random bits are also given to the verification circuit as an input, and one could hope that the reduction of the Cook-Levin theorem would still work. However, the problem is that there could be *some* choice of random coins that makes the verification algorithm accept

<sup>14</sup>Notice that we could have chosen to define “far” here, by counting the number of strings *outside* of  $S$  that are neighbors of  $S$ . But since the degree of each string in the graph is bounded, the exact choice of the definition does not really matter; we chose the one presented here since it seems most natural.

even for no-instances, because the soundness parameter is not 0. Hence, the CSP would be satisfiable in this case, even though the input is a NO instance. It is thus not sufficient to verify the existence of a *single* valid history. In order to distinguish between YES and NO instances of the problem, we have to check in the YES case that *all* (or at least many of the) initializations of the random bits lead to accept. The key difficulty is how to check that not only a single string satisfies the constraints, but many.

This is exactly the reason for introducing the *set-constraints*. These set-constraints are able to verify that the random bits are indeed *uniformly random*; then the standard Cook-Levin approach described above can verify that (given the right witness) most of them leads to acceptance.

In order to implement such an approach, we first explain how to modify the original Cook-Levin proof, of the NP completeness of satisfiability, so that the strings that we check are not entire histories of a verification process of some NP problem; rather, the strings represent *snapshots* of the tape (or evaluations of all bits involved in the circuit at a certain time) for *different time-steps* of the computation. A satisfying assignment is no longer a single string but a whole collection of strings, denoted  $S$ , which would be the *collection of all snapshots of a single valid computation, at different times*.<sup>15</sup>

In this case (note that we have still not included random bits in the discussion) we need to show how to create *set-constraints* that verify that the set  $S$  really does contain *all* snapshots, and it also needs to verify that  $S$  contains nothing else. More precisely, we need to verify that *a)* the strings in  $S$  are consistent with being snapshots of a valid evolution of the computation *b)* the input is correct in the string corresponding to the first snapshot, and the output is accept in the string corresponding to the last snapshot, and *c)* the set  $S$  indeed contains the whole *history* of the computation, i.e. all the snapshots in a correct evolution, and without any missing step.

It turns out that this can be done using set-constraints; We depict the differences between the “original” Cook-Levin proof and the “set-constraints” one in Figure 1.

In reality, we need to do this not just for a single evolution but for the evolution over all possible assignments to the random strings. Moreover, we need to enforce that the random bits are indeed random; this requires further set-constraints (technically, this is done below in Equation (5)).

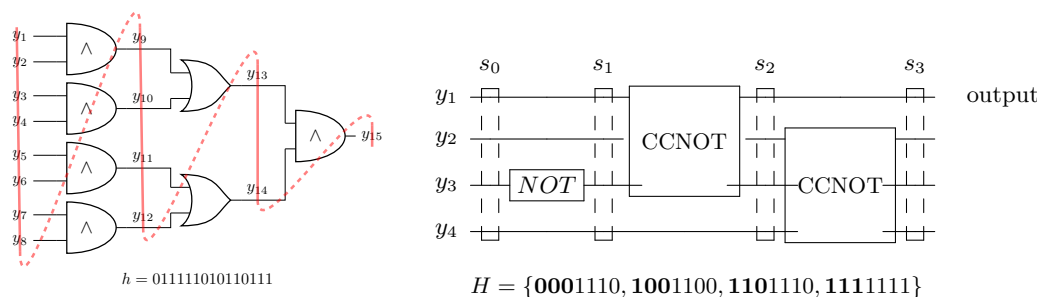

We note that the essence of the translation idea mentioned in the introduction appears already when there are no random bits involved at all; the reader is recommended to pretend that no random bits are used, at her first reading.

We next explain the reduction from MA-verification algorithms to 6-SetCSP in Section 4.4.2, and then prove its correctness in Section 4.4.3.

#### 4.4.2 The reduction

We assume, without loss of generality, that the MA verification algorithm is reversible, as described in Section 2.2: Given an input  $x \in \{0, 1\}^n$ , we assume a verification circuit  $C_x$  whose input is  $y \parallel 0^{a(n)} \parallel r$ , where  $y \in \{0, 1\}^{p(n)}$  is the polynomial-size MA witness, the middle register consists of the circuit auxiliary bits (needed for reversibility) and  $r \in \{0, 1\}^{q(n)}$  are the polynomially many random bits used during the MA verification. The circuit  $C_x$

<sup>15</sup> For quantum readers, we note that this reflects the main step in Kitaev’s modification of the Cook-Levin theorem, which enabled him to test that entangled quantum states evolved correctly.

■ **Figure 1** Comparison between the evolution of a circuit in the Cook-Levin proof and in our work.

consists of  $T$  gates  $G_1, \dots, G_T$ , where  $G_i \in \{\text{NOT}, \text{CNOT}, \text{CCNOT}\}$ .<sup>16</sup> At the end of the circuit, we assume WLOG that the first bit is the output bit. We describe now the reduction from the MA problem into a **SetCSP** instance  $\mathcal{C}$ . We will show in the next section that if there is an MA witness that makes the verification algorithm accept with probability 1, then  $\mathcal{C}$  is satisfiable, whereas if every witness makes the verifier reject with probability at least  $\frac{1}{2}$ , then  $\mathcal{C}$  is at least inverse polynomially frustrated.

We start with an MA verification circuit  $C_x$  (assumed to be reversible, as described in Section 2.2) acting on an input consisting of  $a(n)$  0-bits, witness  $y$  of  $p(n)$  bits and  $q(n)$  random bits. Thus, the number of bits which the reversible verification circuit acts on is  $w(n) = a(n) + p(n) + q(n)$ . The number of gates is  $T(n)$ ; denote these gates by  $G_1, \dots, G_T$ . Our set-constraint instance  $\mathcal{C}$  will act on strings of  $s(n) = T(n) + w(n)$  many bits. We omit  $n$  from such functions from now on, since it will be clear from the context.

We call the  $T$  first bits of such strings the *clock* register and the last  $w$  bits the *work* register. The work register comprises of three sub-registers: the witness register (first  $p(n)$  bits), the auxiliary register (middle  $a(n)$  bits) and the randomness register (last  $q(n)$  bits). We want to create set-constraints which force all the strings to be of the form  $z \in \{0, 1\}^s$  such that  $z_{[T]} = \text{unary}(t)$  for some  $t \in [T + 1]$  (where  $\text{unary}(t)$  denotes the integer  $t$  written in unary representation), and  $z_{[s] \setminus [T]}$  represents the *snapshot* of the computation at time  $t$  (as explained in Section 4.4.1 above) for the initial string  $y \parallel 0^{a(n)} \parallel r$ , for some witness  $y$  and some choice of random bits  $r$ .

<sup>16</sup> Recall that the gate CNOT on input  $a, b$  outputs  $a, b \oplus a$ , and the gate CCNOT on input bits  $a, b, c$ , outputs  $a, b, c \oplus ab$ .

### 36:14 Two Combinatorial MA-Complete Problems

We will construct  $\mathcal{C}$  in such a way that  $S \subseteq \{0, 1\}^s$  satisfies  $\mathcal{C}$  if and only if *i)* it contains *all* snapshots of the computation for some witness  $y$  and for *all* bit strings  $r$  input to the randomness register; and *ii)* the computations whose snapshots are contained in  $S$  are not only correct (meaning also that the auxiliary bits are all initialized to 0) but that they are *accepted* computations (meaning that the output is 1).

We do this by providing set-constraints of four types, as follows.

**Clock consistency.** We first impose that if  $z \in S$ , then  $z|_{[T]} = \text{unary}(t)$ , for some  $t \in [T + 1]$ .

Notice that a string is a valid unary encoding iff it does not contain 01 as a substring. To guarantee that the clock bits are consistent with some unary representation of an allowed  $t$ , we add for every  $t \in [T]$  the set-constraint  $C_t^{\text{clock}}$  defined by:

$$Y(C_t^{\text{clock}}) = (\{\{00\}, \{10\}, \{11\}\}) \text{ and } J(C_t^{\text{clock}}) = (t, t + 1).$$

Example: The string  $010^{T-2} || z$  is a bad string for  $C_1^{\text{clock}}$  since  $w|_{J(C_1^{\text{clock}})} = 01 \notin Y(C_1^{\text{clock}})$ .

**Initialization of Input bits and Random bits.** Here, we want to check that  $0^T || y || z || r$  is not in  $S$  whenever  $z \neq 0^a$ , which enforces the ancillary bits to be initialized to 0. In addition, we want to check that for any witness  $y$ , if one string of the form  $0^T || y || 0^a || r$  for some  $r$  is in  $S$ , then for all  $r' \in \{0, 1\}^q$ , we have  $0^T || y || 0^a || r'$  in  $S$ . In conclusion, we need to check two things: that all auxiliary bits are initialized to 0 and that all possible initializations of the random bits are present.

For each *auxiliary bit*  $j \in [a]$  we add a set-constraint  $C_j^{\text{aux}}$  and for every random bit  $j \in [q]$  we add the set constraint  $C_j^{\text{rand}}$  as follows.

We define

$$Y(C_j^{\text{aux}}) = (\{\{00\}, \{10\}, \{11\}\}) \text{ and } J(C_j^{\text{aux}}) = (0, T + p + j),$$

which forces that for  $t = 0$  (notice that the unique value of  $t$  for which  $\text{unary}(t)$  has the first bit 0 is  $t = 0$ ), the  $j$ -th auxiliary bit must be 0, because the string (01) is forbidden. For  $t \neq 0$  this is not enforced by allowing any value of the  $j$ -th auxiliary bit when the first clock bit is 1 (and therefore  $t \neq 0$ ).

Example: The string  $0^T || y || 10^{a-1} || r \in S$  is bad for  $C_0^{\text{aux}}$ .

For the *random bits*, we want to make sure that the  $j$ -th random bit has both values 0 and 1, over all the random bits. Therefore we define the constraints  $C_j^{\text{rand}}$  by

$$Y(C_j^{\text{rand}}) = (\{\{00, 01\}, \{10\}, \{11\}\}) \text{ and } J(C_j^{\text{rand}}) = (0, T + p + a + j). \quad (5)$$

These constraints will be useful in the following way. First, the propagation set-constraints that we will define soon, constrain  $S$  to make sure that there *exists* a string  $0^T || y || 0^a || r$  representing a snapshot at time 0 with some value of the random bits,  $r$ , which is indeed in  $S$ . The  $C_j^{\text{rand}}$  constraints enforce that given the existence of such a string in  $S$ , then for any other assignment to the random bits,  $r'$ , the string  $0^T || y || 0^a || r' \in S$ . Then, if many of these other strings are not in  $S$ , the frustration will be high.

Example: If  $s_1 = 0^T || y || 0^a || 0^r \in S$  but  $s_2 = 0^T || y || 0^a || 10^{r-1} \notin S$ , then  $s_1$  is a  $C_1^{\text{rand}}$ -longing string in  $S$  since  $s_1$  and  $s_2$  are  $C_1^{\text{rand}}$ -neighbors.

**Propagation.** Here we want to check that if  $\text{unary}(t-1) \parallel z \in S$  for some  $0 < t < T$ , then  $\text{unary}(t) \parallel G_t(z) \in S$ .

Let us consider the propagation constraint associated with the  $t$ -th timestamp (the one corresponding to the application of the  $t$ th gate,  $G_t$ ), for  $1 < t < T$ . Let us assume that the  $t$ -th gate acts on bits  $b_{t,1}, \dots, b_{t,k}$ . For this we add the set-constraint  $C_t^{\text{prop}}$  defined as follows:

$$Y(C_t^{\text{prop}}) = \bigcup_{z \in \{0,1\}^k} \{\{100 \parallel z, 110 \parallel G_t(z)\}\} \text{ and } J(C_t^{\text{prop}}) = (t-1, t, t+1, b_{t,1}, b_{t,2}, \dots, b_{t,k}).$$

For  $t = 1$  we simply erase the left clock bit from the above specification:

$$Y(C_1^{\text{prop}}) = \bigcup_{z \in \{0,1\}^k} \{\{00 \parallel z, 10 \parallel G_1(z)\}\} \text{ and } J(C_1^{\text{prop}}) = (1, 2, b_{1,1}, b_{1,2}, \dots, b_{1,k}).$$

Likewise if  $t = T$  erase the right most clock bit from the above.

Example: If  $s_1 = \text{unary}(t) \parallel z \in S$  but  $s_2 = \text{unary}(t+1) \parallel G_{t+1}(z) \notin S$ ,  $s_1$  is a  $C_{t+1}^{\text{prop}}$ -longing string in  $S$ , since the two strings are  $C_{t+1}^{\text{prop}}$ -neighbors.

**Output.** Finally, we need to check that for all strings of the form  $1^T \parallel z$ , the first bit of  $z$  is 1, namely, the last snapshot corresponds to accept. We define  $C^{\text{out}}$  such that

$$Y(C^{\text{out}}) = \{\{00\}, \{01\}, \{11\}\} \text{ and } J(C^{\text{out}}) = (T, T+1).$$

Here we use the fact that the  $T$ -th bit of  $\text{unary}(t)$  is 1 iff  $t = T$ . In this case, if this value is 1, we require that the output bit is 1, otherwise it could have any value.

Example: The string  $1^T \parallel 0 \parallel z$  is bad for  $C^{\text{out}}$ .

► **Remark 18.** We notice that for every set-constraint  $C$  that we constructed above, we have that  $Y(C)$  only contains sets of size 1 or 2. This property adds a bit more structure to SetCSP instances that are MA-hard, which could be useful in future work.

#### 4.4.3 Correctness

Given some MA-verification circuit  $C_x$ , we consider the following 6-SetCSP instance

$$\mathcal{C}_x = (C_1^{\text{clock}}, \dots, C_T^{\text{clock}}, C_1^{\text{aux}}, \dots, C_a^{\text{aux}}, C_1^{\text{rand}}, \dots, C_q^{\text{rand}}, C_1^{\text{prop}}, \dots, C_T^{\text{prop}}, C^{\text{out}}).$$

Let  $m$  be the number of terms in  $\mathcal{C}_x$  and when it is more convenient to us, we will refer to the set-constraints in  $\mathcal{C}_x$  as  $C_i$  for  $i \in [m]$ , where the terms have an arbitrary order. We show now that  $\mathcal{C}_x$  is satisfiable if  $x$  is a positive instance, and if  $x$  is a negative instance, then  $\mathcal{C}$  is at least  $\frac{1}{10(T+1)qm}$ -frustrated (where we remember that  $q$  is the number of random coins used by  $C_x$ ). Notice that  $m$ , the number of constraints in  $\mathcal{C}_x$ , is polynomial in  $T$ , which is also polynomial in  $|x|$ .

We start by proving completeness.

► **Lemma 19** (Yes-instances lead to satisfiable SetCSP instances). *If  $x \in \mathbf{L}$ , then  $\mathcal{C}_x$  is satisfiable.*

**Proof.** Let  $y$  be the witness that makes  $C_x$  accept with probability 1, and let

$$S = \{\text{unary}(t) \parallel G_t \dots G_1(y, 0^a, r) : r \in \{0,1\}^q, t \in [T+1]\}.$$

By construction, the initialization, clock and propagation constraints are satisfied by  $S$ . By the assumption that the MA verification circuit accepts with probability 1, the output constraints are also satisfied by  $S$ . ◀

Next we prove soundness.

► **Lemma 20** (NO-instances lead to frustrated SetCSP instances). *If  $x \notin L$ , then  $\text{set-unsat}(\mathcal{C}_x, S) \geq \frac{1}{10(T+1)qm}$  for every non-empty  $S \subseteq \{0, 1\}^n$ .*

**Proof.** Let  $S \subseteq \{0, 1\}^n$  be a non-empty set,  $B$  the set of bad strings in  $S$  (namely a string in  $S$  which is  $C$ -bad for at least one set-constraint  $C$ ) and  $L$  the set of longing strings in  $S$  (namely the strings in  $S$  which are  $C$ -longing for at least one set-constraint  $C$ ). Our goal here is to consider a partition  $\{K_i\}$  of  $S$ , such that for every  $K_i$ ,  $|K_i \cap (B \cup L)| \geq \frac{|K_i|}{10(T+1)q}$ , and from this we will show that  $\text{set-unsat}(\mathcal{C}_x, S) \geq \frac{1}{10(T+1)qm}$ .

Let us start by defining  $S_{ic} \subseteq S$  to be the subset of  $S$  with invalid clock register. Notice that every  $x \in S_{ic}$  is bad for at least one clock constraint and therefore  $|S_{ic} \cap B| = |S_{ic}|$ .

Now we notice that all other strings correspond to some valid clock register whose value (when read as a unary representation of some integer) is in  $[T + 1]$ . Let us partition the strings in  $S \setminus S_{ic}$  into disjoint sets  $H_1, \dots, H_\ell$  (which indicate different history-sets to which the strings belong) as follows. We define the *initial configuration* of some string in  $S \setminus S_{ic}$  like this. The string must be of the form  $\text{unary}(t) \parallel z$  for some  $t$  and  $z$ . Then  $\text{initial}(\text{unary}(t) \parallel z) = \text{unary}(0) \parallel G_1^{-1} \dots G_t^{-1}(z)$ , which is the assignment of the initial bits that leads to the configuration  $z$  at the  $t$ 'th step. We say then that two strings  $s_1, s_2 \in H_i$  iff  $\text{initial}(s_1) = \text{initial}(s_2)$  and we abuse the notation and call  $\text{initial}(H_i) = \text{initial}(s_1)$ . Notice that for  $i \neq j$ ,  $H_i$  and  $H_j$  are disjoint because the computation is reversible; thus the  $H_i$ 's constitute a partition of  $S \setminus S_{ic}$ . Notice also that each  $H_i$  contains at most  $T + 1$  strings, and the different strings in each  $H_i$  have different values of the clock register. We call these  $H_i$  *history-sets* for the reason that they correspond to a correct propagation of the computation of the circuit  $C_x$  for some initialization of all its bits.<sup>17</sup>

Let us first consider the history-sets whose initial configuration is not valid, i.e., it contains invalid (or non-zero) auxiliary bits:  $\mathbf{H}^{ia} = \{H_i : \text{initial}(H_i) = 0^T \parallel y \parallel z \parallel r \text{ for some } z \neq 0^a\}$ . We note that for any  $H_i \in \mathbf{H}^{ia}$ ,  $\text{initial}(H_i)$  is a  $C_j^{aux}$ -bad string in  $H_i$  for some  $j$ . If this string is in  $H_i$ , then we indeed have  $|H_i \cap (B \cup L)| \geq |H_i \cap B| \geq 1 \geq \frac{|H_i|}{T+1}$ . However, if  $H_i$  does not contain its initial string, then consider the minimal  $t$  such that  $\text{unary}(t) \parallel z \in H_i$  for some  $z$ , and by assumption we have  $t > 0$ . This means that the string  $\text{unary}(t) \parallel z$  is a  $C_t^{prop}$ -longing string, because it is a neighbor of  $\text{unary}(t-1) \parallel G_t^{-1}(z) \notin S$ . Hence, for such  $H_i$  we have  $|H_i \cap (B \cup L)| \geq |H_i \cap L| \geq 1 \geq \frac{|H_i|}{T+1}$ . This completes handling all the strings in  $S$  within a history set  $H_i$  with invalid auxiliary bits in  $\text{initial}(H_i)$ .

We now need to consider history sets in  $\{H_i\} \setminus \mathbf{H}^{ia}$ , namely, the history sets whose initial string is of the form  $0^T \parallel y \parallel 0^a \parallel r$  for some value of  $y$  and  $r$ . Let us group these history sets according to  $y$ , the value of the witness register. In other words, let us consider the sets of history sets:  $\mathbf{H}_y = \{H_i : H_i\text{'s initial string is of the form } 0^T \parallel y \parallel 0^a \parallel r\}$ . We fix now some  $y$  and the following arguments hold for each  $y$  separately. Notice that each  $H_i \in \mathbf{H}_y$  corresponds to a computation corresponding to a different initial random string for the witness  $y$ . Let us denote the union of strings in all sets in  $\mathbf{H}_y$  by  $\mathbf{S}_y = \bigcup_{H_i \in \mathbf{H}_y} \{s \mid s \in H_i\}$ . To finish handling all strings, we need to provide a bound on  $|\mathbf{S}_y \cap (L \cup B)|$  for all witnesses  $y$ .

To proceed, we need some additional notation. We note that  $\mathbf{H}_y$  can be written as the union of the history sets which contain their initial string, denoted  $\mathbf{H}_y^{\text{start}}$ , and the rest, denoted  $\mathbf{H}_y^{\text{nostart}}$ . We proceed by considering two cases separately:

<sup>17</sup> More precisely,  $H_i$  is a subset of the correct propagation because it involves only the snapshots in  $S$ .

1. Let us first consider the simpler case in which  $|\mathbf{H}_y^{nostart}| > \frac{|\mathbf{H}_y|}{10}$ . As above, we have that each  $H_i \in \mathbf{H}_y^{nostart}$  has a long string, and therefore we have that  $|\mathbf{S}_y \cap (L \cup B)| \geq |\mathbf{S}_y \cap L| \geq |\mathbf{H}_y^{nostart}| > \frac{|\mathbf{H}_y|}{10} \geq \frac{|\mathbf{S}_y|}{10(T+1)}$ . The last inequality is due to the fact that each  $H_i \in \mathbf{H}_y$  contains at most  $T+1$  strings. This finishes the treatment of all strings in  $\mathbf{S}$ , in the case  $|\mathbf{H}_y^{nostart}| > \frac{|\mathbf{H}_y|}{10}$ .
2. In the second case  $|\mathbf{H}_y^{start}| \geq \frac{9|\mathbf{H}_y|}{10}$ . We further denote  $\mathbf{S}_y^{init} = \{s | s = \text{initial}(H_i), H_i \in \mathbf{H}_y^{start}\}$  as the set of the initial strings of each  $H_i \in \mathbf{H}_y^{start}$ . Again (and for the last time) there are two cases.

- a. First, let us consider the case when  $|\mathbf{S}_y^{init}| \geq 2^{q-1}$ . This means that for this fixed  $y$ , for most values  $r$  of the random bits, the initial string  $0^T || y || 0^a || r$  of the history set corresponding to this  $y$  and  $r$  is present in  $\mathbf{S}_y$ . We use the facts that  $x \notin \mathbf{L}$ , and that at least  $2/3$  of the history sets must lead to rejection. From these observations, we will conclude that there will be either many bad strings due to the final accept constraint  $C^{out}$ , or many long strings.

Let  $\mathbf{Acc}_y = \{H_i \in \mathbf{H}_y : 1^T || z \in H_i \text{ and } z = 1 || z'\}$  be the set of history sets in  $\mathbf{H}_y$  that accept in the last step. We have that  $|\mathbf{Acc}_y|$  is at most the number of  $r \in \{0, 1\}^q$  which leads the circuit  $C_x$  to accept the witness  $y$ ; since  $x \notin \mathbf{L}$ , we have that the probability to accept for any  $y$  is most  $1/3$ . Hence  $|\mathbf{Acc}_y| \leq \frac{2^q}{3} \leq 2 \frac{|\mathbf{H}_y|}{3} \leq \frac{20|\mathbf{H}_y^{start}|}{27}$ , where we used the fact that  $2^{q-1} \leq |\mathbf{S}_y^{init}| = |\mathbf{H}_y^{start}| \leq |\mathbf{H}_y|$ , and in the last inequality, the fact that we are in the case  $|\mathbf{H}_y^{start}| \geq 9|\mathbf{H}_y|/10$ . Hence, there are at least  $\frac{2^q}{10}$  history sets in  $\mathbf{H}_y^{start}$  which do not end in accept. Such  $H_i$  either contains the string  $1^T || 0 || z$  (which is bad for  $C^{out}$ ), or does not contain a final state at all, namely does not contain a state of the form  $1^T || z$  for some  $z$ , resulting in a long string. Thus, there are at least  $\frac{2^q}{10}$  strings in  $|\mathbf{S}_y \cap (B \cup L)|$ ; and since  $|\mathbf{S}_y| \leq (T+1)|\mathbf{H}_y|$  and  $|\mathbf{H}_y| \leq 2^q$ , resulting in  $|\mathbf{S}_y| \leq 2^q(T+1)$ , we have that  $|\mathbf{S}_y \cap (B \cup L)| \geq \frac{2^q}{10} \geq \frac{|\mathbf{S}_y|}{10(T+1)}$ .

- b. Finally, let us consider the case where  $|\mathbf{S}_y^{init}| \leq 2^{q-1}$ . This is where we will need to apply conductance arguments. Let  $G_y^0$  be the subgraph of  $G_C^{18}$  induced by the vertices  $R_y = \{0^T || y || 0^a || r : r \in \{0, 1\}^q\}$ . Notice that  $G_y^0$  is isomorphic to the  $q$ -dimensional hypercube. This is true because the only remaining edges on  $G_y^0$  come from the set-constraints  $C_j^{rand}$ . Notice also that  $\mathbf{S}_y^{init}$  is a subset of the vertices of  $G_y^0$ . We now use the fact that the conductance of the  $q$ -dimensional hypercube is  $\frac{1}{q}$ . Applying this lemma to the graph  $G_y^0$  and the subset of its vertices,  $\mathbf{S}_y^{init}$  we conclude that  $\frac{|\partial_{G_y^0}(\mathbf{S}_y^{init})|}{q|\mathbf{S}_y^{init}|} \geq \frac{1}{q}$ , where we have used the fact that all vertices in  $G_y^0$  have the same degree,  $q$ , and the fact that we are now considering the case  $|\mathbf{S}_y^{init}| \leq 2^{q-1}$ . We can conclude then that there exists at least  $|\mathbf{S}_y^{init}|$  edges in the cut  $(\mathbf{S}_y^{init}, R_y \setminus \mathbf{S}_y^{init})$ . Since each vertex in  $G_y^0$  (in particular, each vertex in  $\mathbf{S}_y^{init}$ ) has  $q$  neighbors, it means that there exists at least  $\frac{|\mathbf{S}_y^{init}|}{q}$  long strings in  $\mathbf{S}_y^{init}$ . We conclude this case by noticing that

$$|\mathbf{S}_y \cap (L \cup B)| \geq |\mathbf{S}_y \cap L| \geq \frac{|\mathbf{S}_y^{init}|}{q} = \frac{|\mathbf{H}_y^{start}|}{q} \geq \frac{9|\mathbf{H}_y|}{10q} \geq \frac{9|\mathbf{S}_y|}{10q(T+1)},$$

where in the second inequality we use the fact that  $\mathbf{S}_y^{init} \subseteq \mathbf{S}_y$  and there are at least  $\frac{|\mathbf{S}_y^{init}|}{q}$  long strings in  $\mathbf{S}_y^{init}$ , the equality follows since  $|\mathbf{H}_y^{start}| = |\mathbf{S}_y^{init}|$ , the third inequality follows from our assumption that  $|\mathbf{H}_y^{start}| \geq \frac{9|\mathbf{H}_y|}{10}$  and finally we have that  $|H_i| \leq T+1$  (and therefore  $|\mathbf{H}_y| \geq \frac{|\mathbf{S}_y|}{T+1}$ ).

<sup>18</sup> Here, we use the same notation as Section 3.1.

## 36:18 Two Combinatorial MA-Complete Problems

To finish the proof, notice that  $S = S_{ic} \cup \bigcup_{H \in \mathbf{H}^{ia}} H \cup \bigcup_y \mathbf{S}_y$ . Since each of these subsets has at least a  $\frac{1}{10(T+1)q}$ -fraction of bad strings or longing strings, we have that  $|B \cup L| \geq \frac{|S|}{10(T+1)q}$ . It follows that

$$\text{set-unsat}(\mathcal{C}_x, S) = \frac{1}{m} \sum_i \left( \frac{|B_{C_i}|}{|S|} + \frac{|L_{C_i}|}{|S|} \right) \geq \frac{|B|}{m|S|} + \frac{|L|}{m|S|} \geq \frac{|B \cup L|}{m|S|} \geq \frac{1}{10(T+1)qm},$$

finishing the proof.  $\blacktriangleleft$

From the two previous lemmas, we have the following.

► **Lemma 17 (restated).** *There exists some inverse polynomial  $p(x) = \Theta(1/x^3)$  such that for every inverse polynomial  $p' < p$ , the problem  $\text{SetCSP}_{p'(m)}$  is MA-hard.*

**Proof.** It follows directly from Lemma 19, together with the fact that, regarding the parameters in Lemma 20, we have that  $T, q \leq m$ .  $\blacktriangleleft$

### 5 Reduction from SetCSP to ACAC

In this section we reduce the SetCSP problem to the ACAC, showing the containment of SetCSP in MA and the MA-hardness of ACAC.

Before showing the reduction, we prove a technical lemma that shows how, for a fixed  $S$ , the value of  $\text{set-unsat}(\mathcal{C}, S)$  and the number of bad and longing strings for  $\mathcal{C}$  are related.

► **Lemma 21.** *For some fixed non-empty  $S \subset \{0, 1\}^n$ , let  $B_{\mathcal{C}} = \bigcup_i B_{C_i}$  and  $L_{\mathcal{C}} = \bigcup_i L_{C_i}$ , the union of bad and longing strings for all set-constraints in  $\mathcal{C}$ , respectively. We have that  $\text{set-unsat}(\mathcal{C}, S) \leq \frac{1}{|S|}(|B_{\mathcal{C}}| + |L_{\mathcal{C}}|)$ .*

**Proof.** By definition of  $\text{set-unsat}(\mathcal{C}, S)$  and  $\text{set-unsat}(C_i, S)$ , we have that

$$\begin{aligned} \text{set-unsat}(\mathcal{C}, S) &= \frac{1}{m} \sum_{i=1}^m \text{set-unsat}(C_i, S) = \frac{1}{m|S|} \sum_{i=1}^m |B_{C_i}| + |L_{C_i}| \leq \frac{1}{m|S|} \sum_{i=1}^m |B_{\mathcal{C}}| + |L_{\mathcal{C}}| \\ &= \frac{1}{|S|}(|B_{\mathcal{C}}| + |L_{\mathcal{C}}|), \end{aligned}$$

where in the inequality we use the fact that  $B_{C_i} \subseteq B_{\mathcal{C}}$  and  $L_{C_i} \subseteq L_{\mathcal{C}}$ .  $\blacktriangleleft$

For some inverse polynomial  $\varepsilon$ , we consider an instance  $\mathcal{C}$  of  $k\text{-SetCSP}_{\varepsilon}$ . From  $\mathcal{C}$ , we construct the graph  $G_{\mathcal{C}} = (\{0, 1\}^n, E)$ , where  $(x, y) \in E$  if there exists a set-constraint  $C \in \mathcal{C}$  such that  $x$  and  $y$  are  $C$ -neighbors. We can define  $C_{G_{\mathcal{C}}}$  that on input  $x \in \{0, 1\}^n$ , outputs all neighbors of  $x$  by inspecting all set-constraints of  $\mathcal{C}$ . Finally, we define  $C_M$  as the circuit that on input  $x \in \{0, 1\}^n$ , outputs if  $x$  is a bad string for  $\mathcal{C}$ , again by inspecting all of its set-constraints.

► **Lemma 22 (Reduction from SetCSP to ACAC).** *For every  $\varepsilon$  we have that:*

- *If  $\mathcal{C} = (C_1, \dots, C_m)$  is a yes-instance of  $k\text{-SetCSP}_{\varepsilon}$ , then  $(C_{G_{\mathcal{C}}}, C_M)$  is a yes-instance of  $\text{ACAC}_{\varepsilon/2}$ .*
- *If  $\mathcal{C} = (C_1, \dots, C_m)$  is a no-instance of  $k\text{-SetCSP}_{\varepsilon}$ , then  $(C_{G_{\mathcal{C}}}, C_M)$  is a no-instance of  $\text{ACAC}_{\varepsilon/2}$ .*

**Proof.** To prove the first part of our statement, we show that a non-empty  $S \subseteq \{0, 1\}^n$  such that  $\text{set-unsat}(S, \mathcal{C}) = 0$  implies that the connected component of any string  $x \in S$  in  $G_{\mathcal{C}}$  contains only good strings. To show this, we notice that  $S$  is a union of connected components of  $G_{\mathcal{C}}$ . In this case, any of these connected components imply that  $(C_{G_{\mathcal{C}}}, C_M)$  is a yes-instance of ACAC.

Suppose towards contradiction that there exists a string  $x$  in  $S$  which is connected to a string  $y$  outside of  $S$  via an edge in  $G_C$ ; that means that  $x$  and  $y$  are  $C$ -neighbors for some set-constraint  $C$ . But this means that  $x$  is a  $C$ -longing string for  $S$ , and this contradicts  $\text{set-unsat}(S, C) = 0$ . We finish this part of the proof by stressing that, by assumption, no elements in  $S$  are marked, otherwise there would be a bad string in it.

For the second part, we show that if there is a set of vertices  $S$  such that  $\partial(S, \bar{S}) < \varepsilon|S|/2$  on  $G_C$  and the number of marked elements in  $S$  is strictly less than  $\varepsilon|S|/2$ , then  $\text{set-unsat}(S, C) < \varepsilon$ . In this case, if  $C$  is a no-instance of  $k\text{-SetCSP}_\varepsilon$ , then  $(C_{G_C}, C_M)$  must be a no-instance of  $\text{ACAC}_{\varepsilon/2}$ .

Notice that if there are at most  $\varepsilon|S|/2$  edges between  $S$  and  $\bar{S}$ , then there are at most  $\varepsilon|S|/2$  vertices in  $S$  that are connected to  $\bar{S}$  and, by definition of the edges in  $G_C$ , we have that  $S$  has at most  $\varepsilon|S|/2$   $C$ -longing strings. We also have that the number of bad strings in  $S$  is, by definition, the number of marked elements which is also strictly less than  $\varepsilon|S|/2$ . Therefore, by Lemma 21, we have that  $\text{set-unsat}(C, S) < \varepsilon$ . ◀

We can now finally prove Theorem 1:

▶ **Theorem 1 (restated).** *There exists some inverse polynomial  $p(x) = \Theta(1/x^3)$  such that for every inverse polynomial  $p' < p$ , the problems  $\text{SetCSP}_{p'(m)}$  and  $\text{ACAC}_{p'(m)}$  are MA-complete, where  $m$  is the size of the  $\text{SetCSP}$  or  $\text{ACAC}$  instance.*

**Proof.** From Lemma 17 we have that for some  $\tilde{p} = \Theta(1/x^3)$ ,  $\text{SetCSP}_{\tilde{p}}$  is MA-hard<sup>19</sup> and from Corollary 8 we have that  $\text{ACAC}_{\tilde{p}/2}$  is in MA.

In Lemma 22, we show a reduction  $\text{SetCSP}_{\tilde{p}}$  to  $\text{ACAC}_{\tilde{p}/2}$ , which implies, together with the aforementioned results, that  $\text{SetCSP}_{\tilde{p}}$  is in MA and that  $\text{ACAC}_{\tilde{p}/2}$  is MA-hard. Therefore, we can pick  $p(x) = \tilde{p}(x)/2$  and our statement holds. ◀

## Abstract

Delegation covers a broad class of problems in which a principal doesn't have the resources or expertise necessary to complete a task by themselves, so they delegate the task to an agent whose interests may not be aligned with their own. Stochastic probing describes problems in which we are tasked with maximizing expected utility by "probing" known distributions for acceptable solutions subject to certain constraints. In this work, we combine the concepts of delegation and stochastic probing into a single mechanism design framework which we term delegated stochastic probing. We study how much a principal loses by delegating a stochastic probing problem, compared to their utility in the non-delegated solution. Our model and results are heavily inspired by the work of Kleinberg and Kleinberg in "Delegated Search Approximates Efficient Search." Building on their work, we show that there exists a connection between delegated stochastic probing and generalized prophet inequalities, which provides us with constant-factor deterministic mechanisms for a large class of delegated stochastic probing problems. We also explore randomized mechanisms in a simple delegated probing setting, and show that they outperform deterministic mechanisms in some instances but not in the worst case.

## 1 Introduction

The division of labor and responsibility, based on expertise, is a defining characteristic of efficient organizations and productive economies. In the context of economic decision-making, such division often manifests through *delegation* scenarios of the following form: A decision maker (the *principal*), facing a multivariate decision beset by constraints and uncertainties, tasks an expert (the *agent*) with collecting data, exploring the space of feasible decisions, and proposing a solution.

As a running example, consider the leadership of a firm delegating some or all of its hiring decisions to an outside recruitment agency. When the principal and the agent have misaligned utilities – such as when the agency must balance the firm's preferences with its own preferences over, or obligations towards, potential hires – the principal faces a mechanism design problem termed *optimal delegation* (see e.g. [14, 3]). When the underlying optimization problem involves multiple inter-dependent decisions, such as when hiring a team which must collectively cover a particular set of skills, and when data collection is constrained by logistical or budget considerations, the problem being delegated fits in the framework of *stochastic probing*, broadly construed (see e.g. [26]).

The present paper is concerned with the above-described marriage of optimal delegation and stochastic probing. We restrict attention to protocols without payments, drawing our inspiration from the recent work of Kleinberg and Kleinberg [16]. The underlying (non-delegated) problem faced by the principal in their “distributional model” is the following: facing  $n$  i.i.d rewards, select the ex-post best draw. As for their “binary model”, there are  $n$  random rewards with binary support, and a cost associated with sampling each; the goal is to adaptively sample the rewards and select one, with the goal of maximizing the ex-post selected reward less sampling costs. For both models, they show that delegating the problem results in a loss of at most half the principal’s utility. Their analysis in both cases is through a reduction to the (classical) single-choice *prophet inequality* problem, and in particular to the threshold stopping rule of Samuel-Cahn [25].

Both the distributional and binary models of [16] can be viewed as stochastic probing problems, the former being trivial in the absence of delegation, and the latter corresponding to a special case of the well-studied box problem of Weitzman [27]. A number of stochastic probing problems have been known to reduce to *contention resolution schemes* (e.g. [10, 11, 7, 1, 9]), which in turn reduce to generalizations of the prophet inequality [21]. This suggests that the results of [16] might apply more broadly.

It is this suggestive thread which we pull on in this paper, unraveling what is indeed a broader phenomenon. We study optimal delegation for a fairly general class of stochastic probing problems with combinatorial constraints, and obtain delegation mechanisms which approximate, up to a constant, the principal’s non-delegated utility. Building on recent progress in the literature on stochastic optimization, our results reduce delegated stochastic probing to *generalized prophet inequalities* of a particular “greedy” form, as well as to the notion of *adaptivity gap* (e.g. [4, 5]).

## 1.1 Our Model

Our model features a collection of *elements*, each of which is associated with a (random) *utility* for each of the principal and the agent. We assume that different elements are independently distributed, though the principal’s and the agent’s utilities for the same element may be correlated. We allow constraining both the sampled and the selected set of elements via *outer* and *inner* constraints, respectively. Each constraint is a downwards-closed set system on the ground set of elements. A *probing algorithm* for an instance of our model adaptively *probes* some set of elements subject to the outer constraint, learning their associated utilities in the process. The algorithm then selects as its *solution* a subset of the probed elements satisfying the inner constraint. We assume that, for both the principal and the agent, utility for a solution is the sum of its per-element utilities.

To situate the non-game-theoretic component of our model within the literature on stochastic probing problems, note that we allow an arbitrary utility distribution for each element, rather than a binary-support distribution characterizing “feasibility”. Moreover, unlike “probe and commit” models, we also allow our algorithm to select its solution after all probes are complete. In both these respects, our model is akin to the stochastic multi-value probing model of [5]. As for our game-theoretic modeling, we assume that the utility distributions, as well as the inner and outer constraints, are common knowledge. The realized utilities, however, are only observed by the agent upon probing.

In the traditional (non-delegation) setting, the principal implements the probing algorithm optimizing her own utility, in expectation. In the delegation setting, the principal and agent engage in the following Stackelberg game. The principal moves first by *committing* to a *policy*, or *mechanism*. Such a policy is a (possibly randomized) map from a set of *signals*

to solutions satisfying the inner constraint, with each element in the solution labeled with its (presumptive) utility for both the principal and the agent. Moving second, the agent probes some set of elements subject to the outer constraint, and maps the observed utilities to a signal. The outcome of the game is then the solution which results from applying the principal's policy to the agent's signal. We assume that the principal and agent utilities are additive across elements in the solution, so long as it is labeled with the true per-element utilities. Otherwise, we assume that the principal can detect this discrepancy and effectively “quit” the game, imposing a utility of zero for both parties. We adopt the perspective of the principal, who seeks a policy maximizing her expected utility. The agent, naturally, responds with a strategy maximizing his own expected utility given the policy.

By an argument analogous to that in [16], which we prove in our general setting for completeness' sake, we can restrict attention to *single-proposal mechanisms*. In a deterministic single-proposal mechanism, the set of signals is a “menu” of *acceptable* (labeled) solutions satisfying the inner constraint, as well as a “null” signal which in our setting we can take to be the empty set. The agent, facing such a mechanism, without loss simply implements a probing algorithm to compute a “proposed” solution, tagging each element in the solution with its observed utilities, and ensuring that the solution is acceptable to the principal. We also consider randomized single-proposal mechanisms, where the menu consists of acceptable *lotteries* (i.e., distributions) over (labeled) solutions, and an agent's probing algorithm proposes a lottery on the menu.

## 1.2 Our Results

We study delegation mechanisms which approximate the principal's non-delegated utility. We refer to the best multiplicative approximation factor as the *delegation gap* of the associated instance.

Our main set of results concern the design of deterministic single-proposal mechanisms which prove constant delegation gaps for natural classes of inner and outer constraints. Our approach is modular, and reduces a (constructive)  $\alpha\beta$  bound on the delegation gap to a (constructive)  $\alpha$  generalized prophet inequality of a particular form on the inner constraint, and a (constructive) bound of  $\beta$  on the adaptivity gap associated with the outer constraint and the rank function of the inner constraint. Drawing on recent work in [9], which derives prophet inequalities of our required form, and in [4, 5], which bounds the adaptivity gap, we obtain constant bounds on the delegation gap for instances of our model with a variety of inner and outer constraints such as matroids and their intersections, among others.

We also begin an exploration of randomized single-proposal mechanisms, where the principal's menu consists of acceptable lotteries over solutions. We show that, even in the simple setting of no outer constraint and a 1-uniform inner constraint, there are instances for which randomized mechanisms significantly outperform optimal deterministic ones. Nevertheless, there exist worst-case instances where both deterministic and randomized mechanisms suffer a  $1/2$  delegation gap. We leave open whether randomized mechanisms can lead to better bounds on the worst-case delegation gap for more intricate classes of inner and outer constraints.

## 1.3 Additional Discussion of Related Work

Since the economic literature on delegation is extensive, we only describe a select sample here. The groundwork for the formal study of optimal delegation in economics was initially laid by Holstrom [14, 13]. Subsequent work in economics has considered a variety of optimization

problems as the task being delegated (e.g. [2, 23, 3]). We mention the work of Kovac and Mylovanov [18] as being related to our results in Section 5: To our knowledge, they were the first to examine the power of randomized mechanisms for delegation.

Most relevant to the present paper is the aforementioned work of Kleinberg and Kleinberg [16], who examine approximations for optimal delegation. Their distributional model is closely related to the model of Armstrong and Vickers [3], and the optimization problem being delegated in their binary model is a special case of Weitzman’s box problem [27]. Both optimization problems fit nicely in the general literature on stochastic probing (see e.g. [26]), motivating our examination of delegated stochastic probing more broadly.

Also related is the recent work of Khodabakhsh et al [15], who consider a very general model of delegation with discrete actions and states of the world, and an agent who fully observes the state (no outer constraints or sampling costs). They show optimal delegation to be NP-hard and examine limited “bias” assumptions under which simple threshold mechanisms are approximately optimal. Notably, they don’t impose sampling constraints on the agent and their approximations are with respect to the optimal delegation policy rather than the optimal non-delegated policy. For these reasons, our results are not directly comparable.

The optimization problems being delegated in our model fit in the broad class of *stochastic probing* problems. We do not attempt a thorough accounting of this literature, and instead refer the reader to related work discussions in [26, 5]. To our knowledge, the term “stochastic probing” was originally coined by Gupta and Nagarajan [10], though their binary probe-and-commit model is quite different from ours. More closely related to us are the models of [5, 4], which capture stochastic probing problems with multi-valued reward distributions, no commitment, and combinatorial inner and outer constraints.

As previously mentioned, our work draws on the literature on prophet inequalities. The foundational result in this setting is the (single-choice) prophet inequality of Krengel, Sucheston, and Garling [19, 20]. *Generalized prophet inequalities*, with respect to various combinatorial constraints, adversaries, and arrival models, have received much attention in the last decade (e.g. [12, 17, 8, 9]); the associated body of work is large, and we recommend the survey by [22]. Closely related to generalized prophet inequalities are *contention resolution schemes* (see e.g. [6, 9, 1]), with reductions going in both directions [21]. Key to our results are the “greedy” generalized prophet inequalities, derived through “greedy” contention resolution, by Feldman et al [9].

Finally, we briefly elaborate on the relationship between our model and the two models of Kleinberg and Kleinberg [16]. The natural variant of their binary model which replaces sampling costs with combinatorial constraints on the set of samples (outer constraints, in our nomenclature) fits squarely in our model. Their distributional model, which allows  $n$  i.i.d. samples from a distribution over utility pairs, initially appears to be a special case of ours. However, our principal is afforded additional power through their ability to distinguish elements by name alone. Nevertheless, we recover their main result as a special case of ours by observing that our mechanism treats elements symmetrically.

## 2 Preliminaries

Sections 2.1, 2.2, and 2.3 include brief introductions to some of the key ideas and notations used in this paper. Notably, Section 2.2 defines the key notion of “greedy” prophet inequalities.

## 2.1 Set Systems

A *set system* is a pair  $(E, \mathcal{I})$  where  $E$  is a finite set of *elements* and  $\mathcal{I} \subseteq 2^E$  is a family of *feasible* sets. We focus on *downwards-closed* set systems, satisfying the following two conditions: (1)  $\emptyset \in \mathcal{I}$ , i.e. the empty set is feasible, and (2) if  $T \in \mathcal{I}$  then  $S \in \mathcal{I}$  for all  $S \subseteq T$ , i.e. any subset of a feasible set is feasible. Matroids, matching constraints, and knapsack constraints are all examples of downwards-closed set systems.

For a set system  $\mathcal{M} = (E, \mathcal{I})$  and  $F \subseteq E$ , we use  $\mathcal{M}|F = (F, \mathcal{I} \cap 2^F)$  to denote the *restriction* of  $\mathcal{M}$  to  $F$ .

## 2.2 Prophet Inequalities

A *generalized prophet inequality problem* is given by a set system  $\mathcal{M} = (E, \mathcal{I})$ , and for each element  $e \in E$  an independent random variable  $X_e$  supported on the nonnegative real numbers. Here we adopt the perspective of a *gambler*, who is given  $\mathcal{M}$  and the distributions of the random variables  $\{X_e\}_{e \in E}$  in advance, then encounters the elements  $E$  in an order chosen by an *adversary*. On encountering  $e$ , the gambler observes the realization  $x_e$  of the random variable  $X_e$ , and must immediately decide whether to *accept*  $e$ , subject to the accepted set  $S$  of elements remaining feasible in  $\mathcal{M}$ . The gambler seeks to maximize his utility  $x(S) = \sum_{e \in S} x_e$ , and in particular to compete with a *prophet* who knows the realization of all random variables in advance. If the gambler can guarantee an  $\alpha$  fraction of the prophet's utility in expectation, we say that we obtain a generalized prophet inequality with a factor of  $\alpha$ .

For each possible realization  $x_e$  of  $X_e$ , we refer to the pair  $(e, x_e) \in E \times \mathbb{R}_+$  as an *outcome*. When the gambler accepts  $e \in E$  given a realization  $x_e$  of  $X_e$ , we also say the gambler accepts the outcome  $(e, x_e)$ .

Although it is most common to consider an adversary who fixes an order of the elements upfront, some recent work has investigated much more powerful adversaries [17, 9]. In this paper, we are interested in the *almighty adversary*, who knows in advance the realizations of all random variables as well as any random coin flips used by the gambler's strategy. The almighty adversary can perfectly predict the future and choose a truly worst-case ordering.

Key to our results is the notion of a “greedy” strategy for the gambler. We take inspiration from [9], who defined greedy online contention resolution schemes, and extend their definition to prophet inequality problems.

► **Definition 2.1.** Fix any instance of a generalized prophet inequality problem. A greedy strategy for the gambler is described by a downwards-closed family  $\mathcal{A} \subseteq 2^{E \times \mathbb{R}_+}$  of sets of outcomes. A gambler following greedy strategy  $\mathcal{A}$  accepts an outcome  $(e, x_e)$  if and only if the set of all accepted outcomes remains in  $\mathcal{A}$ .

We note that Samuel-Cahn's [25] threshold rule for the single-choice prophet inequality is greedy, and its competitive factor of  $\frac{1}{2}$  holds for the almighty adversary [24]. More generally, Feldman et al. [9] show that there exist constant-factor greedy prophet inequalities against the almighty adversary for many classes of constraints.

## 2.3 Adaptivity Gap

Another key notion we will use is the adaptivity gap for stochastic set function optimization problems. For a detailed introduction, see [4].

We consider maximizing a stochastic set function  $f : 2^E \rightarrow \mathbb{R}_+$  constrained by a downwards-closed set system  $\mathcal{M} = (E, \mathcal{I})$ . We assume  $f$  is determined by a collection  $\{X_e\}_{e \in E}$  of independent random variables, with the stipulation that  $f(S)$  does not depend

on any random variables  $X_e$  for which  $e \notin S$ .<sup>1</sup> We are tasked with “probing” some  $S \subseteq E$ , feasible for  $\mathcal{M}$ , with the goal of maximizing  $f(S)$ . An *adaptive* algorithm for this problem probes elements one at a time, where probing  $e$  results in learning the realization of  $X_e$ . Such an algorithm can use the realizations of probed variables to decide on a next element to probe. A *non-adaptive* algorithm chooses the set  $S$  all at once, independently of the random variables  $\{X_e\}_{e \in E}$ . The *adaptivity gap* is the minimum (worst-case) ratio of the expected value of the optimal non-adaptive algorithm versus the expected value of the optimal adaptive algorithm.

In [4], Asadpour and Nazerzadeh showed that the adaptivity gap for instances with monotone submodular functions and matroid constraints is  $1 - \frac{1}{e}$ . Furthermore, they provided an efficient non-adaptive algorithm that achieves this bound. Finally, in [5], Bradac et al. showed that the adaptivity gap is constant for instances with “prefix-closed” constraints (which include all downward-closed constraints) and functions that are the weighted rank function of the intersection of a constant number of matroids.

### 3 Model

#### 3.1 Formal Definition

► **Definition 3.1.** An instance  $I$  of the delegated stochastic probing problem consists of: two players, which we will call the principal and the agent; a ground set of elements  $E$ ; mutually independent distributions  $\mu_e$  with support in  $\mathbb{R}_+ \times \mathbb{R}_+$  for each element  $e \in E$ ; an outer constraint  $\mathcal{M}_{out} = (E, \mathcal{I}_{out})$  with feasible sets  $\mathcal{I}_{out}$ ; and an inner constraint  $\mathcal{M}_{in} = (E, \mathcal{I}_{in})$  with feasible sets  $\mathcal{I}_{in}$ .

Given such an instance, we will additionally define:  $(X_e, Y_e) \sim \mu_e$  as random variables denoting the utilities for the principal and agent of element  $e$ ;  $\Omega$  as the set of *outcomes*  $(e, x, y)$  for all  $e \in E$  and all  $(x, y) \in \text{supp}(\mu_e)$ ; and  $\Omega_{in} \subseteq 2^\Omega$  as the family of all sets of outcomes whose elements are distinct and feasible in the inner constraint. For convenience, we will also overload notation by considering  $x$  and  $y$  to be utility functions for the principal and agent. Given any subset of outcomes  $T \subseteq \Omega$ , let  $x(T) = \sum_{(e,x,y) \in T} x$  and  $y(T) = \sum_{(e,x,y) \in T} y$  be the total utility of outcomes in  $T$ . Similarly for any subset of elements  $F \subseteq E$ , let  $x(F) = \sum_{e \in F} X_e$  and  $y(F) = \sum_{e \in F} Y_e$  be random variables representing the randomized total utility of elements in  $F$ .

A natural mechanism that the principal might choose to implement is called a single-proposal mechanism. Here, the principal describes the space of solutions she is willing to accept, and then the agent uses this information to search the solution space and propose a single feasible solution.

In the deterministic single-proposal setting, the principal first commits to a family of sets of outcomes  $\mathcal{R} \subseteq \Omega_{in}$  and announces  $\mathcal{R}$  to the agent. The sets in  $\mathcal{R}$  are called *acceptable*, and the principal’s choice of  $\mathcal{R}$  is called their *policy* (or *mechanism*). After learning  $\mathcal{R}$ , the agent will select elements to probe, so long as each element is probed at most once and the set of probed elements is feasible in  $\mathcal{M}_{out}$ . We allow the agent to probe adaptively, deciding what to do next based on previously probed elements. Let’s say that they probe elements  $F \subseteq E$  and obtain outcomes  $S \subseteq \Omega$ . The agent will then choose some set of outcomes  $T \subseteq \Omega$  and *propose* it to the principal. If  $T$  is acceptable and also a subset of  $S$  then the principal and agent receive  $x(T)$  and  $y(T)$  utility, respectively. Otherwise, they both receive 0 utility.

<sup>1</sup> In other words, one can evaluate  $f(S)$  given access to the realizations of the random variables  $\{X_e\}_{e \in S}$ .

In the above-described mechanism design setting, we assume that both the principal and agent act to maximize their expected utility. We also assume that all parameters of the problem, except for the realizations of the random variables, are common knowledge.

We note that, similar to the setup in [16], our model assumes that our agent cannot benefit from lying, say by labeling an element  $e$  with utilities other than  $X_e$  and  $Y_e$ , or by proposing an element he has not probed. We argue that this is a natural assumption to make: In many applications we foresee (e.g., a firm hiring an employee, or exploring some mergers), a proposal will be accompanied by an easy to verify proof of the claimed utilities (e.g., in the form of a CV for the applicant, or a detailed analysis of the merger).

As in [16], we compare delegation mechanisms against the optimal *non-delegated* strategy. By non-delegated strategy, we mean the strategy of the principal when they act as both the principal and agent (i.e. they have power to probe and propose as well as accept outcomes).

Given any  $F \subseteq E$ , let  $u(F)$  be the optimal utility of the non-delegating principal when they probe elements in  $F$  and accept their own favorite set of outcomes, and let  $v_{\mathcal{R}}(F)$  be the utility of the delegating principal with policy  $\mathcal{R}$  when the agent probes elements in  $F$  and proposes their favorite acceptable set of outcomes. We can write  $u$  and  $v_{\mathcal{R}}$  as

$$u(F) = \max_{G \subseteq F, G \in \mathcal{I}_{\text{in}}} x(G)$$

$$v_{\mathcal{R}}(F) = x \left( \operatorname{argmax}_{G \subseteq F, \Omega_G \in \mathcal{R}} y(G) \right),$$

where  $\Omega_G \subseteq \Omega$  is the set of outcomes from the probed set of elements  $G$ . In the case of ties in the definition of  $v_{\mathcal{R}}$ , our results hold for arbitrary (even adversarial) tie-breaking.

► **Definition 3.2.** Fix any instance of delegated stochastic probing. Let  $F^*$  be a random variable containing the elements probed by an optimal adaptive non-delegating principal, and let  $F_{\mathcal{R}}^*$  be a random variable containing the elements probed by an optimal adaptive agent under policy  $\mathcal{R}$ . Then for any policy  $\mathcal{R}$  and  $\alpha \in [0, 1]$ , we say that  $\mathcal{R}$  is an  $\alpha$ -policy for this instance if

$$\mathbb{E} v_{\mathcal{R}}(F_{\mathcal{R}}^*) \geq \alpha \mathbb{E} u(F^*).$$

► **Definition 3.3.** The delegation gap of a family of instances of delegated stochastic probing is the minimum, over all instances in the family, of the maximum  $\alpha$  such that there exists an  $\alpha$ -policy for that instance. This gap measures the fraction of the principal's non-delegated utility they can achieve when delegating.

## 3.2 Signaling Mechanisms

Having formally defined the model, we will now describe a broad generalization of single-proposal mechanisms, called *signaling mechanisms*, and show that these mechanisms don't provide the principal with any additional power. Note that this discussion is inspired by Section 2.2 from [16], and we simply extend their work to our model.

A signaling mechanism allows the principal to ask the agent for more (or different) information than just a proposed solution. The principal will then take this information and transform it into a solution, which they will accept. One might suspect that expanding the space of mechanisms in this way would give the principal more power. However, as we will show, this isn't the case even for a broad class of delegation models, which we will now define formally.

► **Definition 3.4.** *An instance of the generalized delegation problem consists of two players called the principal and the agent, a state space  $S$ , a solution space  $\Psi$ , a set  $\mathcal{P}$  of probing strategies for the agent, a signaling function  $\sigma$  which maps  $\mathcal{P} \times S$  to strings, a utility function  $x : S \times \mathcal{P} \times \Psi \rightarrow \mathbb{R}_+$  for the principal, and a utility function  $y : S \times \mathcal{P} \times \Psi \rightarrow \mathbb{R}_+$  for the agent. We require that there is a null solution  $\perp \in \Psi$  such that  $x_{s,p}(\perp) = y_{s,p}(\perp) = 0$  for all  $s \in S$  and  $p \in \mathcal{P}$ .*

We assume the state of the world is some  $s \in S$  a-priori unknown to the principal and the agent, though they may have prior information. The agent obtains information about  $s$  by applying a probing strategy  $p \in \mathcal{P}$  to obtain a signal  $\sigma_p(s)$ . For a state  $s \in S$ , a probing strategy  $p \in \mathcal{P}$  chosen by the agent, and a solution  $\psi \in \Psi$ , we associate a utility of  $x_{s,p}(\psi)$  and  $y_{s,p}(\psi)$  for the principal and the agent, respectively.

We note that the above definition generalizes the delegation problems of Definition 3.1. In particular: the state space  $S$  represents all possible realizations of per-element utilities of the principal and the agent; the solution space  $\Psi$  is the family of feasible subsets of outcomes  $\Omega_{\text{in}}$ , where  $\perp$  is the empty set of outcomes;  $\mathcal{P}$  corresponds to probing algorithms which respect the outer constraint;  $\sigma_p(s)$  is the set of outcomes obtained by invoking algorithm  $p$  in state  $s$ ; both utility functions depend on the state  $s \in S$  and the probing algorithm  $p \in \mathcal{P}$ , evaluating to 0 for solutions  $\psi$  that are inconsistent with the state  $s$ , or if the probing algorithm  $p$  applied to  $s$  does not probe the elements in  $\psi$ .

Given a generalized delegation problem, we define signaling mechanisms as follows.

► **Definition 3.5.** *Fix some instance of the generalized delegation problem. A signaling mechanism proceeds in the following manner. The principal starts by choosing some signal space  $\Sigma$  of strings and a solution function  $\psi : \Sigma \rightarrow \Psi$ , and the agent responds by choosing a probing strategy  $p \in \mathcal{P}$  and a reporting function  $\tau$  from strings to  $\Sigma$ . Once these choices have been made, the agent will probe the underlying state  $s$  to obtain a signal  $\sigma = \sigma_p(s)$ , then transform this into a new signal  $\tau = \tau(\sigma)$  which he reports to the principal. The principal maps the reported signal to a solution  $\psi(\tau)$ , which they will accept.*

Notice that this model can be made to capture the design of randomized delegation mechanisms by extending  $\Psi$  to the space  $\Delta(\Psi)$  of distributions (henceforth *lotteries*) over solutions, and extending both utility functions to lotteries by taking expectations.

We contrast this broad definition of signaling mechanisms with the comparatively simple single-proposal mechanisms.

► **Definition 3.6.** *Fix an instance of the generalized delegation problem. A single-proposal mechanism is a special case of signaling mechanism in which the principal chooses some set  $\mathcal{R} \subseteq \Psi$  of acceptable outcomes, then sets  $\Sigma = \Psi$  and  $\psi(R) = R$  if  $R \in \mathcal{R}$  and  $\psi(R) = \perp$  otherwise.*

Intuitively, in a single proposal mechanism the principal declares a menu of acceptable solutions. The agent then proposes a solution, which is accepted if it is on the menu, and replaced with the null solution otherwise. Now we will show that single-proposal mechanisms are just as powerful as signaling mechanisms. In particular, for every signaling mechanism there is a single-proposal mechanism which selects the same solution and the same probing strategy for each state of nature, at equilibrium. This lemma is a simple extension of [16, Lemma 1] to the our generalized delegation model.

► **Lemma 3.7.** *Fix an instance of the generalized delegation problem, as well as the agent's prior distribution  $\mu$  on states  $S$ . For any signaling mechanism  $M = (\Sigma, \psi)$  and a corresponding best response strategy  $(p, \tau)$  for the agent, there exists a single-proposal mechanism  $M' = (\Sigma', \psi')$  and a corresponding best response  $(p, \tau')$  such that  $(\psi \circ \tau \circ \sigma_p)(s) = (\psi' \circ \tau' \circ \sigma_p)(s)$  for all states  $s \in S$ .*

**Proof.** Take any signaling mechanism  $M = (\Sigma, \psi)$  with best response  $(p, \tau)$  by the agent. Let  $\mathcal{R} = \psi(\Sigma)$  be the set of all possible outputs from this mechanism and let  $M' = (\Sigma', \psi')$  be the single-proposal mechanism defined by  $\mathcal{R}$ , i.e.  $\Sigma' = \Psi$  and  $\psi'$  is such that  $\psi'(R) = R$  if  $R \in \mathcal{R}$  and  $\psi'(R) = \perp$  otherwise. Finally, let  $\tau' = \psi \circ \tau$ .

Notice that the range of  $\tau'$  is contained in  $\psi(\Sigma) = \mathcal{R}$ , so by definition of  $\psi'$  and  $\tau'$  it follows that  $\psi \circ \tau = \psi' \circ \tau'$ . Therefore, it is also the case that  $(\psi \circ \tau \circ \sigma_p)(s) = (\psi' \circ \tau' \circ \sigma_p)(s)$  for all  $s \in S$ . Now we must show that  $(p, \tau')$  is a best-response strategy to mechanism  $M'$ . Consider any valid alternative strategy  $(p^*, \tau^*)$ . We aim to show that

$$\mathbb{E}_s y_{s,p^*}(\psi' \circ \tau^* \circ \sigma_{p^*})(s) \leq \mathbb{E}_s y_{s,p}(\psi' \circ \tau' \circ \sigma_p)(s). \quad (1)$$

First, we can assume without loss of generality that  $\tau^*$  always outputs a solution in  $\mathcal{R}$  because  $\psi'$  produces  $\perp$  (and a utility of 0) for all proposals in  $\Psi \setminus \mathcal{R}$ . Then  $\psi' \circ \tau^* = \tau^*$  and, by definition of  $\mathcal{R}$ , we can write  $\tau^* = \psi \circ \hat{\tau}$  for some function  $\hat{\tau}$  from strings to  $\Sigma$ . Then the left hand side of (1) becomes the expected utility of response  $(p^*, \hat{\tau})$  against mechanism  $M = (\Sigma, \psi)$ :

$$\mathbb{E}_s y_{s,p^*}(\psi' \circ \tau^* \circ \sigma_{p^*})(s) = \mathbb{E}_s y_{s,p^*}(\psi \circ \hat{\tau} \circ \sigma_{p^*})(s)$$

whereas the right hand side of (1) is the expected utility of response  $(p, \tau)$  against  $M$ :

$$\mathbb{E}_s y_{s,p}(\psi' \circ \tau' \circ \sigma_p)(s) = \mathbb{E}_s y_{s,p}(\psi \circ \tau \circ \sigma_p)(s).$$

Since  $(p, \tau)$  is a best response for this mechanism, the desired inequality (1) follows.  $\blacktriangleleft$

## 4 Deterministic Mechanisms

In this section, we will consider deterministic single-proposal mechanisms for delegated stochastic probing problems, as defined in Section 3.1. This is in contrast to randomized mechanisms which we will define later in Section 5. We will show that large classes of these problems have constant-factor policies, and therefore constant-factor delegation gaps.

The focus of this section is on Theorem 4.1 and Theorem 4.5, which together give us a general method of constructing competitive delegation policies from certain prophet inequalities and adaptivity gaps. In particular, Corollary 4.4 gives us constant-factor policies for delegated stochastic probing with no outer constraint and an inner constraint which is the intersection of a constant number of matroid, knapsack, and matching constraints. Similarly, Corollary 4.8 gives us constant-factor policies for delegated stochastic probing with any downwards-closed outer constraint and an inner constraint which is the intersection of a constant number of matroids.

### 4.1 Inner Constraint Delegation

We will now consider instances of delegated stochastic probing for which there is no outer constraint. We will then combine the results from this section with Theorem 4.5 to get solutions to delegation problems with both inner and outer constraints.

To simulate the lack of an outer constraint, we will consider instances of delegation for which the outer constraint is the trivial set system in which all subsets of the elements are feasible. For any ground set  $E$  of elements, we will write this trivial set system as  $\mathcal{M}_E^*$ , omitting the subscript when the set of elements  $E$  is clear from context.

► **Theorem 4.1.** *Given an instance  $I = (E, \mathcal{M}^*, \mathcal{M}_{in})$  of delegated stochastic probing without outer constraints, let  $J$  be an instance of the prophet inequality problem with random variables  $X_e$  for all  $e \in E$  and constraint  $\mathcal{M}_{in}$ . If there exists an  $\alpha$ -factor greedy strategy for  $J$  against the almighty adversary, then there exists a deterministic  $\alpha$ -policy for  $I$ . Furthermore, the proof is constructive when given the strategy for  $J$ .*

**Proof.** First, we have by our choice of  $J$  that the expected utility of the prophet in  $J$  is equal to the expected utility of the non-delegating principal in  $I$ . Notice that the principal has no outer constraint, so we can assume without loss of generality that they probe all elements. Then the prophet and non-delegating principal both get exactly

$$\mathbb{E} \max_{T \in \mathcal{M}_{in}} x(T).$$

Now consider the gambler's  $\alpha$ -factor greedy strategy, which consists of some collection  $\mathcal{A} \subseteq 2^{E \times \mathbb{R}_+}$  of “acceptable” sets of outcomes. We will define the delegating principal's policy as follows

$$\mathcal{R} = \{ \{(e, x, y) : (e, x) \in A, y \in \mathbb{R}_+\} : A \in \mathcal{A} \}.$$

Notice that policy  $\mathcal{R}$  is exactly the same as strategy  $\mathcal{A}$ , just translated into the language of delegation.

Now we will show that the utility of the delegating principal with policy  $\mathcal{R}$  is at least the utility of the gambler with greedy strategy  $\mathcal{A}$ . In the prophet inequality, the almighty adversary can order the random variables such that the gambler always gets their least favorite among all maximal acceptable sets (the set is always maximal because the gambler's strategy is greedy). Compare this with delegation, where the agent knows the result of all probed elements as well as the principal's acceptable sets  $\mathcal{R}$ . Since the agent has non-negative utility for all outcomes, we can assume without loss of generality that they will always propose a maximal acceptable set. For every corresponding set of realizations in each problem, the gambler will receive the maximal set in  $\mathcal{A}$  of minimum value and the principal will receive some maximal set in  $\mathcal{R}$ . Since we defined  $\mathcal{R}$  to correspond directly with  $\mathcal{A}$ , the principal's value must be at least as large as the gambler's. This is true of all possible realizations, so  $\mathcal{R}$  must be an  $\alpha$ -policy for  $I$ . ◀

We note that by construction of the principal's policy  $\mathcal{R}$ , this theorem holds even when the principal is unaware of the agent's utility values  $y$ . This is comparable to the reduction in [16] which similarly worked regardless of the principal's knowledge of the agent's utilities.

Unfortunately, applications of this theorem rely on the existence of competitive strategies against the almighty adversary, which is a very strong condition. It is natural to ask whether it's really necessary in the reduction for the adversary to be almighty. We provide some evidence that this is indeed necessary by considering the special case of a 1-uniform inner matroid. In this case, it's easy to construct instances for which the utility of the principal and agent sum to a constant value for all outcomes, i.e.  $X_e + Y_e = c$  for all  $e$  and some constant  $c$ . In such an instance, the agent's goals are directly opposed to the principal's, so the agent will always propose the principal's least favorite acceptable outcome. In the corresponding instance of the prophet inequality, the almighty adversary can guarantee that the gambler chooses their least favorite acceptable outcome, while weaker adversaries (that don't know the realizations of variables) cannot enforce the same guarantee.

Using some known greedy prophet inequalities against the almighty adversary, we get the following corollaries.

► **Corollary 4.2.** *There exist deterministic  $\frac{1}{2}$ -policies for delegated stochastic probing problems with no outer constraint and a 1-uniform inner constraint.*

**Proof.** This follows from the existence of  $\frac{1}{2}$  threshold rules (such as Samuel-Cahn’s median rule [25]) for the 1-uniform prophet inequality against the almighty adversary. ◀

► **Corollary 4.3.** *There exist constant-factor deterministic policies for delegated stochastic probing problems with no outer constraint and three classes of inner constraints. These factors are:  $\frac{1}{4}$  for matroid constraints,  $\frac{1}{2e} \approx 0.1839$  for matching constraints, and  $\frac{3}{2} - \sqrt{2} \approx 0.0857$  for knapsack constraints.*

**Proof.** This corollary is largely based on results from [9]. By combining [9, Theorem 1.8] with [9, Observation 1.6] and optimizing the parameters, we get randomized greedy online contention resolution schemes (OCRS) for three aforementioned constraint systems with the same factors listed above. Then, applying [9, Theorem 1.12], each randomized greedy OCRS corresponds to a randomized greedy prophet inequality against the almighty adversary with the same approximation factor. Since the adversary is almighty, they can predict any randomness in our strategy. Therefore, the randomized strategy is no better than the best deterministic strategy, and there must exist some deterministic strategy achieving the same factor. Finally, we apply our Theorem 4.1 to turn the prophet inequality strategy into a delegation policy with the same factor. ◀

► **Corollary 4.4.** *There exist constant-factor deterministic policies for delegated stochastic probing problems with no outer constraint and an inner constraint that is the intersection of a constant number of matroid, knapsack, and matching constraints.*

**Proof.** We use [9, Corollary 1.13] along with the same reasoning as Corollary 4.3. ◀

We note that it is open whether there exists a  $\frac{1}{2}$ -OCRS for matroids against the almighty adversary [21]. The existence of such an OCRS, if greedy, would imply the existence of  $\frac{1}{2}$ -policy for delegated stochastic probing with a matroid inner constraint and no outer constraint.

Although Corollary 4.2 applies to a model very similar to the distributional delegation model from [16], our principal has the additional power of being able to distinguish between otherwise identical elements by their name alone. However, by observing that Theorem 4.1 turns greedy prophet inequalities that don’t distinguish between identical elements into delegation policies that also don’t distinguish between identical elements, we can derive delegation policies that recover the  $\frac{1}{2}$ -factor guarantee from [16] for their distributional model. We leave the details for Section A.1.

## 4.2 Outer Constraint Delegation

Using the adaptivity gap from Section 2.3, we will now show that there are large classes of delegated stochastic probing problems with nontrivial outer constraints for which the principal can achieve, in expectation, a constant-factor of their non-delegated optimal utility.

► **Theorem 4.5.** *Let  $I = (E, \mathcal{M}_{out}, \mathcal{M}_{in})$  be an instance of delegated stochastic probing. Suppose that, for all  $F \in \mathcal{I}_{out}$ , there exists a deterministic  $\alpha$ -policy for the restriction  $I_F = (F, \mathcal{M}_F^*, \mathcal{M}_{in}|_F)$  of instance  $I$  to  $F$ . Suppose also that the adaptivity gap for weighted rank functions of  $\mathcal{M}_{in}$  on set system  $\mathcal{M}_{out}$  is at least  $\beta$ . Then there exists a deterministic  $\alpha\beta$ -policy for instance  $I$ .*

### 37:12 Delegated Stochastic Probing

**Proof.** Given any set of elements  $F \subseteq E$ , we can write the utility of the non-delegating principal who probes  $F$  as

$$u(F) = \max_{G \subseteq F, G \in \mathcal{I}_{\text{in}}} x(G)$$

and the utility of the delegating principal with policy  $\mathcal{R}$  who probes  $F$  as

$$v_{\mathcal{R}}(F) = x \left( \operatorname{argmax}_{G \subseteq F, \Omega_G \in \mathcal{R}} y(G) \right),$$

where  $\Omega_G \subseteq \Omega$  is the set of outcomes from the probed elements  $G$ .

Notice that for any fixed set of realizations from all random variables,  $u$  is just the weighted rank function of set system  $\mathcal{M}_{\text{in}}$ . Therefore, by the adaptivity gap for such a function over set system  $\mathcal{M}_{\text{out}}$ , there exists a fixed set  $F \in \mathcal{I}_{\text{out}}$  such that

$$\mathbb{E} u(F) \geq \beta \mathbb{E} u(E^*), \quad (2)$$

where  $E^* \in \mathcal{I}_{\text{out}}$  is a random variable representing the optimal set of elements selected by an adaptive non-delegating principal. Notice that expectation is also over the randomness of  $E^*$ .

Now we will consider the same delegation instance with access to only the elements in  $F$ , i.e. instance  $(F, \mathcal{M}_{\text{out}}|F, \mathcal{M}_{\text{in}}|F)$ . Since  $F \in \mathcal{I}_{\text{out}}$ , the outer matroid doesn't restrict probing at all and this instance is equivalent to  $I_F = (F, \mathcal{M}_F^*, \mathcal{M}_{\text{in}}|F)$ . By our assumption, this problem has some  $\alpha$ -approximate delegation policy. Let  $\mathcal{R}$  be one such policy. Then we have

$$\mathbb{E} v_{\mathcal{R}}(F) \geq \alpha \mathbb{E} u(F). \quad (3)$$

Since  $\mathcal{R}$  contains outcomes only from elements in  $F$ , an agent restricted to  $\mathcal{R}$  in the original instance  $I$  has no incentive to probe elements outside of  $F$ . Because  $F \in \mathcal{I}_{\text{out}}$ , the agent can probe all of  $F$ . Therefore, we can assume without loss of generality that an optimal adaptive strategy will choose to probe exactly the elements in  $F$ . Then

$$\mathbb{E} v_{\mathcal{R}}(E_{\mathcal{R}}^*) = \mathbb{E} v_{\mathcal{R}}(F), \quad (4)$$

where  $E_{\mathcal{R}}^* \subseteq E$  is a random variable containing exactly the elements probed by an optimal adaptive agent when restricted to acceptable set  $\mathcal{R}$  in the original instance  $I$ .

Combining (2), (3), and (4), we get the desired inequality:

$$\begin{aligned} \mathbb{E} v_{\mathcal{R}}(E_{\mathcal{R}}^*) &= \mathbb{E} v_{\mathcal{R}}(F) \\ &\geq \alpha \mathbb{E} u(F) \\ &\geq \alpha \beta \mathbb{E} u(E^*). \end{aligned} \quad \blacktriangleleft$$

► **Corollary 4.6.** *There exist deterministic  $\frac{1}{2} \left(1 - \frac{1}{e}\right) \approx 0.3160$ -policies for delegated stochastic probing problems with matroid outer constraints and a 1-uniform inner constraint.*

**Proof.** By Corollary 4.2, there is a  $\frac{1}{2}$ -policy for any instance of delegated stochastic probing with a 1-uniform inner constraint and no outer constraint. Every restriction of our present instance  $I$  to some independent set  $F$  of the outer matroid is of this form.

From [4], we have a  $1 - \frac{1}{e}$  adaptivity gap for stochastic submodular on matroid constraints. Since the weighted rank function of any matroid is submodular, the adaptivity gap of weighted rank functions of the inner 1-uniform matroid constraint on the outer matroid constraint is also  $1 - \frac{1}{e}$ .

Therefore, the conditions of Theorem 4.5 hold with  $\alpha = \frac{1}{2}$  and  $\beta = 1 - \frac{1}{e}$ , and we get the desired factor. ◀

► **Corollary 4.7.** *There exist deterministic  $\frac{1}{4}(1 - \frac{1}{e}) \approx 0.1580$ -policies for delegated stochastic probing problems with matroid outer and inner constraints.*

**Proof.** Similar to Corollary 4.6, we use the  $1 - \frac{1}{e}$  adaptivity gap for submodular functions over matroid constraints along with Corollary 4.3. ◀

► **Corollary 4.8.** *There exist constant-factor deterministic policies for delegated stochastic probing with any downward-closed outer constraint and an inner constraint which is the intersection of a constant number of matroids.*

**Proof.** By [5, Theorem 1.2], we have constant-factor adaptivity gaps for weighted rank functions of the intersection of a constant number of matroids over “prefix-closed” constraints, which include all downward-closed constraints. By Corollary 4.4, we have constant-factor policies for delegated stochastic probing with no outer constraint and an inner constraint which is the intersection of a constant number of matroids. Combining these results with Theorem 4.5, we get the desired constant factors. ◀

## 5 Lottery Mechanisms

One natural generalization of the delegated stochastic probing model defined in section 3.1 is to allow the principal to use randomized mechanisms. For example, one may consider the generalization of single-proposal mechanisms which attaches a probability  $p_R$  to each set of outcomes  $R \subseteq \Omega_{\text{in}}$ , and accepts a proposed set  $R$  with precisely that probability (and accepts the empty set otherwise). More general lotteries (i.e. with non-binary support) are also possible. It’s then natural to ask whether there exist instances for which some randomized policy does better than all deterministic ones. Even further, we can ask whether there exists a randomized policy that strictly outperforms deterministic ones in the worst case. In other words, can randomization give us a strictly better delegation gap?

In this section, we will broadly discuss randomized mechanisms and then consider the special case of delegation with 1-uniform inner constraints and no outer constraints. In this special case, there exist instances for which randomization significantly helps the principal, and there are worst-case instances in which the delegation gap of  $\frac{1}{2}$  is tight for randomized mechanisms as well as deterministic ones. Before getting to these results, we will discuss methods of randomization and then formalize what we mean by a randomized mechanism.

There are two obvious ways that the single-proposal mechanism can be randomized. The first is for the principal to sample a deterministic policy  $\mathcal{R}$  from some distribution and then run the single proposal mechanism defined by  $\mathcal{R}$ . However, noticing that our model of delegation is a Stackelberg game, we can conclude that there always exists a pure optimal strategy for the principal, so this type of randomization doesn’t give the principal any more power.

The second type of randomness is for the policy itself to be a set of acceptable distributions over sets of outcomes (i.e. a menu of lotteries), from which the agent may propose one. The principal then samples a set of outcomes from the proposed lottery. This expands the space of mechanisms, conceivably affording the principal more power in influencing the agent’s behavior. We will focus on these randomized mechanisms for the rest of this section.

► **Definition 5.1.** *A lottery mechanism is a randomized mechanism for delegated stochastic probing consisting of a set  $\mathcal{R}$  of distributions, or lotteries, each with support in  $\Omega_{\text{in}}$ . After the set of acceptable lotteries  $\mathcal{R}$  is selected and announced to the agent, the delegated stochastic probing mechanism proceeds largely the same. The agent probes outcomes  $S$  and proposes*

one of the lotteries  $L \in \mathcal{R}$ . The principal then samples a set of outcomes  $T \sim L$  from that lottery. If  $T \subseteq S$ , then the principal and agent receive  $x(T)$  and  $y(T)$  utility, respectively. Otherwise, they both receive 0 utility.

We note that this sort of mechanism is a generalized single-proposal mechanism in the sense of Section 3.2: Each lottery represents a solution and an agent's expected utility for a lottery represents their utility for that solution. Therefore, Lemma 3.7 applies to lottery mechanisms as well.

## 5.1 Power of Lotteries

The increased power of lottery mechanisms means that for some instances of delegated stochastic probing there exist lottery policies that provide the principal with a better expected utility than the best deterministic policies. In fact, we will show that there are instances for which some lottery policies nearly achieve the principal's non-delegated expected utility, while the best deterministic policies achieve only about half of this value.

First, we will make the observation that it never benefits the principal to declare two lotteries in  $\mathcal{R}$  with identical support but different distributions. This is because the principal knows the utility function of the agent and can predict which lottery the agent will prefer. Therefore, we can assume that for any given support, the principal will declare at most one lottery.

► **Proposition 5.2.** *For all  $0 < \epsilon < 1$ , there exists an instance of delegated stochastic probing for which the best lottery mechanisms achieve  $\frac{2-3\epsilon+2\epsilon^2}{2-\epsilon}$  of the principal's non-delegated expected utility, while the best deterministic mechanisms achieve  $\frac{1}{2-\epsilon}$  of the principal's non-delegated expected utility. As  $\epsilon$  approaches 0, the former approaches 1 while the latter approaches  $\frac{1}{2}$ .*

**Proof.** Consider an instance with elements  $E = \{1, 2\}$ , a 1-uniform matroid inner constraint, no outer constraint, and distributions for elements 1 and 2 as detailed in Table 1.

■ **Table 1** Each row represents a single outcome and contains its name, element  $e$ , utilities  $x$  and  $y$ , and the probability that it is probed from element  $e$ .

Outcome	Element $e$	Utility $x$	Utility $y$	Probability $\mathbb{P}_e[(x, y)]$
$\omega_0$	1	0	0	$1 - \epsilon$
$\omega_1$	1	$1/\epsilon$	$1 - \epsilon$	$\epsilon$
$\omega_2$	2	1	1	1

Since there are no outer constraints we assume that both elements are probed. The non-delegating principal can accept  $\omega_1$  when it appears and accept  $\omega_2$  otherwise. This gives them an expected utility of  $\epsilon/\epsilon + 1 - \epsilon = 2 - \epsilon$ . By enumerating all deterministic policies, we can confirm that the best such policy gives the delegating principal an expected utility of 1. Therefore, the best deterministic policy achieves  $\frac{1}{2-\epsilon}$  of the principal's non-delegated utility.

Now consider a lottery policy with lotteries  $A$  and  $B$  such that  $\mathbb{P}_A[\omega_1] = 1$ ,  $\mathbb{P}_B[\omega_2] = 1 - 2\epsilon$ , and  $\mathbb{P}_B[\omega_0] = 2\epsilon$ . We can quickly verify that this gives the delegating principal an expected utility of  $2 - 3\epsilon + 2\epsilon^2$ . Therefore, at least one lottery policy achieves  $\frac{2-3\epsilon+2\epsilon^2}{2-\epsilon}$  of the principal's non-delegated utility. ◀

Unfortunately, there is good reason not to be too optimistic about the increased power of lottery mechanisms. As we will now show, there also exist instances for which the best lottery policies and the best deterministic policies all achieve approximately half of the principal's

non-delegated expected utility. Since Corollary 4.2 gives us a deterministic  $\frac{1}{2}$ -policy, this tells us that, in the worst case, the factor  $\frac{1}{2}$  is tight even for lottery policies in the special case of no outer constraint and a 1-uniform inner constraint.

► **Proposition 5.3.** *For all  $0 < \epsilon < 1$ , there exists an instance of delegated stochastic probing with a 1-uniform inner constraint and no outer constraint for which the best lottery policies and the best deterministic policies all achieve  $\frac{1}{2-\epsilon}$  of the principal's non-delegated expected utility. As  $\epsilon$  approaches 0, this approaches  $\frac{1}{2}$ .*

**Proof.** Consider an instance with elements  $E = \{1, 2\}$ , a 1-uniform matroid inner constraint, no outer constraint, and distributions for elements 1 and 2 as detailed in Table 2.

■ **Table 2** Each row represents a single outcome and contains its name, element  $e$ , utilities  $x$  and  $y$ , and the probability that it is probed from element  $e$ . Notice that this instance is identical to the one from Table 1 except for the agent's utility for outcome  $\omega_1$ .

Outcome	Element $e$	Utility $x$	Utility $y$	Probability $\mathbb{P}_e[(x, y)]$
$\omega_0$	1	0	0	$1 - \epsilon$
$\omega_1$	1	$1/\epsilon$	0	$\epsilon$
$\omega_2$	2	1	1	1

In the case of ties, we assume that the agent prefers to break ties first in the principal's favor and then arbitrarily among any remaining ties. This assumption serves only to simplify the proof, and can be avoided with careful modifications to the utility table.

The non-delegating principal can accept  $\omega_1 = (1, 1/\epsilon, 0)$  when it appears and accept  $\omega_2 = (2, 1, 1)$  otherwise. This gives them an expected utility of  $\epsilon/\epsilon + 1 - \epsilon = 2 - \epsilon$ . By enumerating all deterministic policies, we can confirm that the best such policy gives the delegating principal an expected utility of 1. Therefore, the best deterministic policy achieves  $\frac{1}{2-\epsilon}$  of the principal's non-delegated utility.

Finding the best menu of lotteries takes slightly more work. Since the inner constraint is 1-uniform, each lottery is supported on singletons as well as the empty set. Recall also that we can restrict attention to menus where no two lotteries have the same support. We claim that we can further restrict attention to menus with exactly two lotteries  $A$  and  $B$ , with  $A$  supported on  $\{\omega_0, \omega_2\}$  and  $B$  supported on  $\{\omega_1, \omega_2\}$ . To see this, observe that:

1. Shifting all probability mass from the empty set to  $\omega_0$  or  $\omega_1$  in any lottery does not affect the agent's utility and can only increase the principal's utility. In the case of tie-breaking, the principal's favorite remaining lottery is no worse than before.
2. If there is a lottery with both  $\omega_0$  and  $\omega_1$  in its support, shifting all probability mass from one of these outcomes to the other does not affect the agent's utility, and in at least one direction this shift of probability mass will make the policy no worse for the principal. Again, in the case of tie-breaking, the principal's favorite remaining lottery is no worse than before.
3. A menu without lottery  $A$  is no better than the same menu with lottery  $A$  for which all probability mass of  $A$  is assigned to  $\omega_0$ . Similarly, a menu without lottery  $B$  is no better than the same menu with lottery  $B$  for which all probability mass of  $B$  is assigned to  $\omega_1$ .

Parametrizing the probability of each outcome, we get:  $\mathbb{P}_A[\omega_2] = a$ ,  $\mathbb{P}_A[\omega_0] = 1 - a$ ,  $\mathbb{P}_B[\omega_2] = b$ , and  $\mathbb{P}_B[\omega_1] = 1 - b$  for some  $a, b \in [0, 1]$ . No matter what the agent probes ( $\{\omega_0, \omega_2\}$  or  $\{\omega_1, \omega_2\}$ ), their favorite lottery is  $B$  if  $b \geq a$  and  $A$  otherwise. If we choose  $b \geq a$ , the delegating principal gets expected utility  $\epsilon(b + (1 - b)/\epsilon) + (1 - \epsilon) \cdot b = 1$ . Otherwise, the principal gets  $\epsilon \cdot a + (1 - \epsilon) \cdot a = a$ , which can be made as large as 1 for  $a = 1$ . Therefore, the best lottery policy achieves  $\frac{1}{2-\epsilon}$  of the principal's non-delegated utility. ◀

## 6 Open Questions

Due to this novel combination of delegation with stochastic probing, we believe that this paper ultimately opens up many more questions than it answers. In this section, we will make some of these questions explicit.

- While we focused on the existence of constant-factor delegation policies regardless of their computational complexity, applying these solutions to practical problems requires some guarantee that they can be easily computed and represented. Are there delegated stochastic probing problems for which constant-factor policies are NP-hard to compute in general? Are there special cases for which constant-factor policies can always be computed in polynomial time?
- In Section 5, we showed that the constant given in Corollary 4.2 is tight. Are the other factors given in Section 4.1 tight? We note that this is related to an open question by [21] about  $\frac{1}{2}$  prophet inequalities on matroids against the almighty adversary.
- Are the constant factors given in Section 4.2 tight? Due to the broad applicability of adaptivity gaps, our method is unlikely to take advantage of special structure that may be present in delegated stochastic probing problems. Therefore, it seems probable that better constants exist, but we make no claim to a conjecture.
- Our model assumes that probing is always zero-cost, so it doesn't generalize the binary model from [16] or the box problem of [27]. It's natural to ask whether we can get constant-factor delegation gaps with probing costs in addition to (or as a replacement for) outer constraints.
- Our model doesn't allow the principal to incentivize the agent with transfers (such as payments), so it's natural to ask how such an extension to the model could improve the principal's worst-case guarantees.
- If the principal is delegating to multiple agents simultaneously, can they get better worst-case guarantees than delegating to a single agent? We note that there are many ways to define this formally. For example, a stronger principal may be able to define different acceptable sets for each agent whereas a weaker principal may be forced to declare one acceptable set for all agents.
- It's not hard to imagine practical applications of stochastic probing for which elements are not independently distributed. Can we get competitive guarantees even in the absence of the independence assumption?

## A

 Appendix

### A.1 Symmetric Delegation Policies

While our model is not a direct generalization of the distributional model used by Kleinberg and Kleinberg, we can obtain a generalization by considering delegated stochastic probing with a restricted class of policies, which we call symmetric policies. Given this variant, we can recover the  $\frac{1}{2}$  factor that they obtained. First, we need to define some notation and terminology.

Given any object  $X$  (such as a set, tuple, or recursive combination of the two) containing atomic elements  $E$ , we can consider the operation of taking two elements  $e_1, e_2 \in E$  and swapping all instances of  $e_1$  and  $e_2$  in  $X$ . More generally, for any permutation  $\pi$  of elements in  $E$ , we can consider rewriting all elements  $e$  to  $\pi(e)$  simultaneously. We will denote the object obtained from this operation as  $X[E \rightarrow \pi(E)]$ .

► **Definition A.1.** Fix an instance of delegated stochastic probing with elements  $E$ , outer constraint  $\mathcal{M}_{out}$ , and inner constraint  $\mathcal{M}_{in}$ . We say that a subset of elements  $F \subseteq E$  are symmetric if  $\mu_e = \mu_f$  for all  $e, f \in F$  and for all permutations  $\pi$  on  $F$  we have that  $\mathcal{M}_{in}[F \rightarrow \pi(F)] = \mathcal{M}_{in}$  and  $\mathcal{M}_{out}[F \rightarrow \pi(F)] = \mathcal{M}_{out}$ .

► **Definition A.2.** Fix an instance of delegated stochastic probing with elements  $E$ , outer constraint  $\mathcal{M}_{out}$ , and inner constraint  $\mathcal{M}_{in}$ . We say that a policy  $\mathcal{R}$  is symmetric if  $\mathcal{R}[F \rightarrow \pi(F)] = \mathcal{R}$  for all symmetric sets of elements  $F \subseteq E$  and all permutations  $\pi$  on  $F$ .

Intuitively, symmetric elements are ones which are identical in everything except name. Then symmetric policies are ones that don't distinguish between symmetric elements. Using this intuition, we will now consider the problem of delegated stochastic probing with  $k$  identically distributed elements  $E$ , a 1-uniform inner constraint, and no outer constraint. Given any such instance, it's easy to see that all elements  $E$  are symmetric. Notice the similarity between such an instance and the distributional model. The only difference is that our principal has the power to distinguish between outcomes sampled from different elements. However, if the principal is restricted to symmetric policies, then their policy cannot distinguish between different elements, so it must characterize acceptable outcomes based only on their  $(x, y)$  utility. This is equivalent to the distributional model.

There are also natural definitions of symmetric elements and strategies in the prophet inequality problem.

► **Definition A.3.** Fix an instance of the prophet inequality problem with elements  $E$  and feasibility constraint  $\mathcal{M}$ . We say that a subset of elements  $F \subseteq E$  are symmetric if  $X_e$  and  $X_f$  are identically distributed for all  $e, f \in F$  and for all permutations  $\pi$  on  $F$  we have that  $\mathcal{M}[F \rightarrow \pi(F)] = \mathcal{M}$ .

► **Definition A.4.** Fix an instance of the prophet inequality problem with elements  $E$  and feasibility constraint  $\mathcal{M}$ . We say that a strategy  $\mathcal{A}$  is symmetric if  $\mathcal{A}[F \rightarrow \pi(F)] = \mathcal{A}$  for all symmetric sets of elements  $F \subseteq E$  and all permutations  $\pi$  on  $F$ .

Given these definitions, we will show that Theorem 4.1 actually transforms symmetric greedy prophet inequalities against the almighty adversary into symmetric delegation policies. This is stated formally in Proposition A.5.

► **Proposition A.5.** *Given an instance  $I = (E, \mathcal{M}^*, \mathcal{M}_{in})$  of delegated stochastic probing without outer constraints, let  $J$  be an instance of the prophet inequality problem with random variables  $X_e$  for all  $e \in E$  and constraint  $\mathcal{M}_{in}$ . If there exists a symmetric  $\alpha$ -factor greedy strategy for  $J$  against the almighty adversary, then there exists a symmetric deterministic  $\alpha$ -policy for  $I$ . Furthermore, the proof is constructive when given the strategy for  $J$ .*

**Proof.** The proof is identical to the proof of Theorem 4.1, but we observe that the greedy strategy  $\mathcal{A}$  for prophet inequality problem  $J$  is symmetric, so the policy  $\mathcal{R}$  derived from  $\mathcal{A}$  must also be symmetric by construction. ◀

Since the  $\frac{1}{2}$  prophet inequality used in Corollary 4.2 is a threshold policy, it must be symmetric. Therefore, we have a symmetric  $\frac{1}{2}$ -policy for delegated stochastic probing problems with no outer constraint and a 1-uniform inner constraint. This recovers a  $\frac{1}{2}$ -factor for the distributional model of [16], as well as for the slight generalization of this model with multiple distributions and a separate cardinality constraint for each one.

## Abstract

We construct an explicit and structured family of 3XOR instances which is hard for  $O(\sqrt{\log n})$  levels of the Sum-of-Squares hierarchy. In contrast to earlier constructions, which involve a random component, our systems are highly structured and can be constructed explicitly in deterministic polynomial time.

Our construction is based on the high-dimensional expanders devised by Lubotzky, Samuels and Vishne, known as LSV complexes or Ramanujan complexes, and our analysis is based on two notions of expansion for these complexes: cosystolic expansion, and a local isoperimetric inequality due to Gromov.

Our construction offers an interesting contrast to the recent work of Alev, Jeronimo and the last author (FOCS 2019). They showed that 3XOR instances in which the variables correspond to vertices in a high-dimensional expander are easy to solve. In contrast, in our instances the variables correspond to the edges of the complex.

## 1 Introduction

We describe a new family of instances of 3XOR, based on high-dimensional expanders, that are hard for the Sum-of-Squares (SoS) hierarchy of semidefinite programming relaxations, which is the most powerful algorithmic framework known for optimizing over constraint satisfaction problems. Unlike previous constructions of 3XOR hard instances for SoS, our construction is explicit, as it is based on the explicit construction of high-dimensional expanders due to Lubotzky, Samuels and Vishne [34, 35], which we refer to henceforth as LSV complexes.

► **Theorem 1.1.** *There exists a constant  $\mu \in (0, 1)$  and an infinite family of 3XOR instances on  $n$  variables, constructible in deterministic polynomial time, satisfying the following:*

- *No assignment satisfies more than  $1 - \mu$  fraction of the constraints.*
- *Relaxations obtained by  $O(\sqrt{\log n})$  levels of the SoS hierarchy fail to refute the instances.*

We remark that the result in the above theorem differs from the previous results for random instances of 3XOR, proved by Grigoriev [20] and Schoenebeck [36], in two ways.

- While random instances are known to be hard for  $\Omega(n)$  levels of the SoS hierarchy, the above theorem only gives a gap for  $\Omega(\sqrt{\log n})$  levels.
- Our instances on the LSV complexes exhibit an integrality gap of  $1 - \mu$  vs. 1, while random instances exhibit a gap of  $1/2 + \varepsilon$  vs. 1. However, our construction can also be combined with reductions in the SoS hierarchy [37] hierarchy, reductions can be used to obtain explicit 3XOR instances with a gap of  $1/2 + \varepsilon$  vs.  $1 - \varepsilon$  for any  $\varepsilon > 0$ . Indeed, this yields explicit hard instances with optimal gaps for all approximation resistant predicates based on pairwise independent subgroups [10].

### Structured instances from high-dimensional expanders

High-dimensional expanders (HDXs) are a high-dimensional analog of expander graphs. In recent years they have found a variety of applications in theoretical computer science, such as efficient CSP optimization [3], improved sampling algorithms [6, 4, 5, 11], quantum LDPC codes [17, 30], novel lattice constructions [29], direct sum testing [19], and others. Explicit constructions of HDXs have also led to improved list-decoding algorithms [13, 2] and to sparser agreement tests [14, 12]. In this work, we show how these explicit constructions can be used to construct explicit hard instances for SoS.

High-dimensional expanders are bounded-degree (hyper)graphs (or rather, simplicial complexes) with certain expansion properties. A simplicial complex is a non-empty collection of down-closed sets. Given a simplicial complex  $X$ , we will refer by  $X(i)$  the family of all  $i$ -dimensional sets in  $X$  (i.e., sets of size  $i + 1$ ). The dimension of the simplicial complex  $X$  is the maximal dimension of any set in it. It will be convenient to refer to the sets of dimension 0, 1, 2, 3 as vertices, edges, triangles, tetrahedra, respectively. Thus, a graph  $G = (V, E)$  is a 1-dimensional complex, while in this work we will be using complexes of dimension at least 2. Given a 2-dimensional complex  $X = (X(0), X(1), X(2))$ , there are two natural ways to construct a 3XOR instance based on  $X$  – a vertex-variable construction and an edge-variable construction. Let  $\beta: X(2) \rightarrow \mathbb{F}_2$  be any  $\mathbb{F}_2$ -valued function on the set  $X(2)$  of triangles.

**Vertex-variable construction:** The 3XOR instance corresponding to  $(X, \beta)$  consists of the following constraints:  $x_u + x_v + x_w = \beta_{\{u,v,w\}}$  for each  $\{u, v, w\} \in X(2)$ .

**Edge-variable construction:** The 3XOR instance corresponding to  $(X, \beta)$  consists of the following constraints:  $x_{\{u,v\}} + x_{\{v,w\}} + x_{\{w,u\}} = \beta_{\{u,v,w\}}$  for each  $\{u, v, w\} \in X(2)$ .

The vertex-variable construction whose underlying structure is a high-dimensional expander has been studied by Alev, Jeronimo and the last author [3]. They gave an efficient algorithm for approximating vertex-variable constraint satisfaction problems (not necessarily 3XOR) on an underlying high-dimensional expander. Their result is a generalization to higher dimensions of the corresponding result for graphs that “CSPs are easy on expanders” [7, 24]. They prove this by showing that certain types of random walks on vertices converge very fast on high-dimensional expanders. However, the same analysis fails to show a similar result for the edge-variable construction, as the corresponding random walk on edges of a high-dimensional expander does not mix. Our work shows that this difference isn’t just a technical limitation of their analysis; it is inherent. The edge-variable variant is truly hard, at least for SoS. This demonstrates an interesting subtlety in the structure of high-dimensional expanders, and how it relates to optimization.

To understand our edge-variable construction better, it will be convenient to set up some notation. Let  $C^i$  denote the set of all  $\mathbb{F}_2$ -valued functions on  $X(i)$ . For each  $0 \leq i < d$ , consider the operator  $\delta_i: C^i \rightarrow C^{i+1}$  defined as follows:

$$\delta_i f(s) := \sum_{u \in s} f(s - \{u\}).$$

This is usually referred to as the coboundary operator. Let  $B^i$  be the image of  $\delta_{i-1}$ , and let  $Z^i$  be the kernel of  $\delta_i$ . Clearly,  $B^i, Z^i \subseteq C^i$ . Furthermore, it is not hard to see that  $B^i \subseteq Z^i$ . It easily follows from the definitions that the edge-variable construction corresponding to  $(X, \beta)$  is a satisfiable instance iff  $\beta \in B^2$ .

Typically, soundness of SoS-hard instances is proved by choosing  $\beta$  at random from  $C^2$ . In contrast, we construct our explicit instances by choosing the function  $\beta$  more carefully, and relying on a certain type of expansion property of the complex. Recall that  $B^2 \subset Z^2$ , and the instance is satisfiable iff  $\beta \in B^2$ . Complexes for which  $B^2 = Z^2$  are said to have trivial second cohomology. We will be working with complexes with non-trivial second cohomology, i.e.,  $B^2 \neq Z^2$ . This lets us choose a  $\beta \in Z^2 \setminus B^2$  to prove soundness. It is known that the explicit constructions of HDXs due to Lubotzky, Samuels and Vishne [34, 35] have non-trivial second cohomology.<sup>1</sup> In fact, these complexes have the stronger property (due to a theorem of Evra and Kaufman [16]) that all  $\beta \in Z^2 \setminus B^2$  are not only not in  $B^2$ , but in fact far from any function in  $B^2$ . This latter property follows from the cosystolic expansion of the complex, and forms the basis for the soundness of our instances.

How do we prove the completeness of our instance, namely, that SoS fails to detect that it is a negative instance? The LSV construction is a quotient of the so-called affine building which is, from a topological point of view, a simple “Euclidean-like” object with trivial cohomologies. The hardness of our instance comes from the inherent difference between the LSV complex and the building, which cannot be seen through local balls whose radius is at most the injectivity radius of the complex, in our case  $\Theta(\log n)$ . Locally, the LSV quotient is isomorphic to the building. However, unlike the building, the LSV complex is a quotient with non-trivial cohomologies. The hardness comes from the fact that local views cannot capture the cohomology, which is a global property. Given this observation, the proof of completeness can be carried out following the argument of Ben-Sasson and Wigderson [8] that any short resolution proof is narrow, and Grigoriev [20] and Schoenebeck [36]’s transformation from resolution lower bounds to SoS lower bounds.

<sup>1</sup> More accurately, their construction depends on the group defining the quotient. They show that a certain choice of groups yields non-trivial second cohomology.

Technically, we rely on two very different types of expansion or isoperimetry. In our proof of completeness, we rely on an isoperimetric inequality called Gromov’s filling inequality, that says that balls are essentially the objects with smallest boundary in any CAT(0) space (a class of spaces that includes both Euclidean spaces and the affine building). In our proof of soundness, we rely on the cosystolic expansion of the LSV complex, as proven by Evra and Kaufman [16], which implies that any non-trivial element in the cohomology has constant weight. Both of these statements are related to expansion, yet they are distinct from other notions of expansion used in previous SoS lower bounds. Interestingly, both notions are natural generalizations of edge-expansion to higher dimensions. Isoperimetric expansion is a classical notion asking for the smallest possible boundary of a body with certain volume. In graphs, it is common to interpret this notion as the edge-expansion, bounding the smallest possible number of edges leaving a set, relative to its size. Moving to higher dimensions, there are several nonequivalent [23] ways to generalize edge-expansion, most notably a spectral variant and a topological variant. The topological variant is the one we require for our soundness analysis. This type of expansion is an extension of the notion of coboundary expansion first defined by Linial-Meshulam [32] and then independently by Gromov [22]. This is a subtle notion that is related to the local-testability of the cocycle space, see [28].

### Relation to previous SoS gap constructions

All previous constructions of hard instances for SoS can be viewed in the vertex/edge-variable framework (typically vertex-variable). To the best of our knowledge, all known hard instances, proving inapproximability in the SoS hierarchy, are *random* instances; either both the complex  $X$  and the function  $\beta$  are random, or just the function  $\beta$  is random. The proof of SoS hardness of these random instances relies on very strong expansion of the underlying complex [36] or on certain pseudorandom properties [31], both of which are not yet known to be explicitly constructible. Moreover, the randomness in the choice of the  $\beta$  specifying the right-hand sides of the equations in these constructions, is used for a union bound over all (exponentially many) assignments to the variables, and such arguments are often difficult to derandomize.

On the other hand, explicit hard instances for SoS are known in proof complexity (e.g., Tseitin tautologies on expanders). However, these instances are only minimally unsatisfiable, and transforming them to an integrality gap instance requires a highly *non-local* reduction (such as the PCP theorem). While SoS gap instances can easily be combined with local reductions, this is not true for non-local ones.

In contrast to the above, our integrality gap instances are “anti-random”. They are very structured and easily distinguishable from random instances. For example, all balls around a vertex up to some radius are identical and have very specific structure. Naturally, the typical analysis that works for random instances cannot work here. For example, soundness for random instances is based on choosing a random  $\beta$  and using a union-bound argument to show that with high probability, every solution violates nearly half of the constraints. In contrast, for us, a random  $\beta$  is not a good choice because the local structure will quickly detect local contradictions, ruining the completeness altogether.

### Open directions

Our construction of explicit hard SoS instances based on HDXs begs several questions, some of which we discuss below.

**Improved soundness** Our construction yields 3XOR hard instances which are at most  $(1 - \mu)$ -satisfiable, owing to the cosystolic expansion of the underlying HDX (more precisely,  $\text{CoSys}^2(X) \geq \mu$ , see Section 2.2 for the definition of  $\text{CoSys}^2$ ). Coupled with reductions

in the SoS hierarchy [37], this yields 3XOR hard instances which are at most  $(1/2 + \varepsilon)$ -satisfiable for every  $\varepsilon \in (0, 1)$ . Can we obtain such a result directly from the HDX construction (bypassing reductions), say by constructing HDXs which satisfy  $\text{CoSys}^2(X) \geq 1/2 - \varepsilon$ ? In addition to maintaining the HDX structure, bypassing reductions would also allow for perfect completeness, which is lost while using NP-hardness reductions.

**Fooling more levels of the SoS hierarchy** Our hard instances fool only  $O(\sqrt{\log n})$  levels of the SoS hierarchy, as our argument is based on the injectivity radius of the complexes, which is  $O(\log n)$ , and we suffer a further square-root loss due to the use of Gromov's isoperimetry inequality. It is possible that a much stronger lower bound holds for these instances. Can one construct explicit hard instances that fool linearly many levels of the SoS hierarchy?

**HDX dimension and CSP definition** We find the contrast between the vertex-variable and edge-variable constructions baffling: while the vertex-variable construction is easy, our result demonstrates the hardness of the edge-variable construction. As we go to higher dimensions of HDX, there are more ways to define CSPs. Which of these are easy and which are hard?

## 2 Preliminaries

### 2.1 The Sum-of-Squares Hierarchy

The sum-of-squares hierarchy<sup>2</sup> provides a hierarchy of semidefinite programming (SDP) relaxations, for various combinatorial optimization problems. Figure 1 describes the relaxation given by  $t$  levels of the hierarchy for an instance  $\mathcal{I}$  of 3XOR in  $n$  variables, with  $m$  constraints of the form  $x_{i_1} + x_{i_2} + x_{i_3} = \beta_{i_1 i_2 i_3}$  over  $\mathbb{F}_2$ . We also use  $\mathcal{I}$  to denote the set of all tuples  $\{i_1, i_2, i_3\}$  present as constraints. A solution to the relaxation is specified by a collection of unit vectors  $\{\mathbf{u}_S\}_{S \subseteq [n], |S| \leq t}$ , satisfying the constraints in the program. The objective equals the fraction of constraints “satisfied” by the SDP solution. To prove a lower bound on the

$$\begin{array}{ll} \text{maximize} & \frac{1}{2} + \frac{1}{2m} \cdot \sum_{\{i_1, i_2, i_3\} \in \mathcal{I}} (-1)^{\beta_{i_1 i_2 i_3}} \cdot \langle \mathbf{u}_{\{i_1, i_2, i_3\}}, \mathbf{u}_\emptyset \rangle \\ \text{subject to} & \langle \mathbf{u}_{S_1}, \mathbf{u}_{S_2} \rangle = \langle \mathbf{u}_{S_3}, \mathbf{u}_{S_4} \rangle \quad \forall S_1 \Delta S_2 = S_3 \Delta S_4, |S_1|, \dots, |S_4| \leq t \\ & \|\mathbf{u}_S\| = 1 \quad \forall S, |S| \leq t \end{array}$$

■ **Figure 1** Relaxation for 3XOR given by  $t$  levels of the SoS hierarchy.

value of the SDP relaxation, we will use the following result, which shows the existence of vectors  $\mathbf{u}_S$  yielding an objective value of 1, when the given system of XOR constraints does not have any “low-width” refutations. Formally, we consider a system called XOR-resolution, where the only rule allows us to combine two equations  $\ell_1 = b_1$  and  $\ell_2 = b_2$  to derive the equation  $\ell_1 + \ell_2 = b_1 + b_2$ . A refutation is a derivation of  $0 = 1$ . The width of a refutation is the maximum number of variables in any equation used in the refutation. We include a proof of the following lemma in Appendix A.

<sup>2</sup> For more on Sum-of-Squares, see the recent monograph by Fleming, Kothari and Pitassi [18].

► **Lemma 2.1** ([36, Lemma 13], [37, Theorem 4.2]). *Let  $\Lambda$  be a system of equations in  $n$  variables over  $\mathbb{F}_2$ , which does not admit any refutations of width at most  $2t$ . Then there exist vectors  $\{\mathbf{u}_S\}_{S \subseteq [n], |S| \leq t}$  satisfying the constraints in Figure 1, such that for all equations  $\sum_{i \in T} x_i = b_T$  in  $\Lambda$  with  $|T| \leq t$ , we have  $\langle \mathbf{u}_T, \mathbf{u}_\emptyset \rangle = (-1)^{b_T}$ .*

## 2.2 Simplicial Complexes

A simplicial complex  $X$  is a non-empty collection of sets (known as faces) which is closed downwards. The  $i$ -dimensional faces  $X(i)$  are all sets of size  $i + 1$ . The dimension of the complex is the maximal dimension of a face. Faces of that dimension are known as facets. Faces of dimensions 0, 1, 2, 3 are called vertices, edges, triangles, and tetrahedra, respectively.

Graphs are 1-dimensional simplicial complexes. The skeleton of a simplicial complex is the graph obtained by retaining only faces of dimension at most 1.

**Links.** Let  $X$  be a  $d$ -dimensional simplicial complex. The link  $X_s$  of a face  $s \in X(i)$  is a simplicial complex of dimension  $d - (i + 1)$  given by  $X_s(j) := \{t : s \cup t \in X(j + i + 1)\}$ . In other words,  $X_s$  contains all faces in  $X$  which contain  $s$ , with  $s$  itself removed.

**Balls.** Let  $X$  be a simplicial complex. A ball of radius  $r$  around a vertex  $v$  is the subcomplex induced by all vertices at distance at most  $r$  from  $v$ , as measured on the skeleton of  $X$ . That is, the subcomplex contains a face of  $X$  if it contains all the vertices of the face.

**Covering map.** A *covering map* from a simplicial complex  $Y$  to a simplicial complex  $X$  is a *surjective* map  $\psi : Y(0) \rightarrow X(0)$  from the vertices of  $Y$  to  $X$  such that for every  $k \leq \dim Y$  the image of every  $k$ -face  $\{v_0, \dots, v_k\} \in Y(k)$  is a  $k$ -face  $\{\psi(v_0), \dots, \psi(v_k)\} \in X(k)$ . We then say that  $X$  is *covered* by  $Y$ .

**Chains.** Fix a  $d$ -dimensional simplicial complex  $X$ . Let  $C^i := C^i(X, \mathbb{F}_2)$  be the set of all functions from  $X(i)$  to  $\mathbb{F}_2$ . Elements of  $C^i$  are also known as  $i$ -chains.

For an  $i$ -chain  $f$ , we define  $|f|$  to be the number of non-zero elements in  $f$ . For two  $i$ -chains  $f$  and  $g$ , we define the distance between  $f$  and  $g$  to be  $\text{dist}(f, g) := |f + g|$ .

**Inner product.** For  $f, f' \in C^i$ , let us denote by  $\langle f, f' \rangle_i$  the following sum modulo 2:

$$\langle f, f' \rangle_i := \sum_{s \in X(i)} f(s) f'(s).$$

This is not an inner product in the usual sense as we are working over a field of non-zero characteristic, but it is convenient notation. We will usually drop the subscript  $i$ .

**Dual space.** Given any subspace  $V \subset C^i$ , the dual of  $V$  (under  $\langle \cdot, \cdot \rangle_i$ ) is defined as:

$$V^\perp := \{f \in C^i \mid \text{for all } g \in V, \langle f, g \rangle_i = 0\}.$$

**Boundaries, Cycles, Homology.** The boundary operator  $\partial_i : C^i \rightarrow C^{i-1}$  is given by

$$\partial_i f(s) := \sum_{t \in X(i) : t \supset s} f(t).$$

It gives rise to boundaries  $B_i$  and cycles  $Z_i$ :

$$B_i := \text{im } \partial_{i+1}, \quad Z_i := \ker \partial_i.$$

In the case of graphs,  $Z_1$  consists of all sums of cycles (in the usual sense).

The coboundary operator  $\delta_i: C^i \rightarrow C^{i+1}$ , which is the adjoint of the boundary operator, is given by

$$\delta_i f(t) := \sum_{s \in X(i): s \subset t} f(s) = \sum_{u \in t} f(t - \{u\}).$$

It gives rise to coboundaries and cocycles:

$$B^i := \text{im } \delta_{i-1}, \quad Z^i := \ker \delta_i.$$

We will usually drop the subscript  $i$  when invoking  $\partial, \delta$ .

It is easy to see that  $B_i \subset Z_i$  (every boundary is a cycle) and  $B^i \subset Z^i$  (every coboundary is a cocycle). For example, in a 2-dimensional complex, the boundary of every triangle is a cycle. We call such cycles *trivial cycles*. Modding out by trivial cycles and cocycles, we obtain the homology and cohomology spaces

$$H_i := Z_i / B_i, \quad H^i := Z^i / B^i.$$

The dimensions of these spaces (which are identical) measure the number of “holes” in a particular dimension. Nice complexes (such as the buildings considered below) have no holes.

The following claim shows that the coboundary operator is the adjoint of the boundary operator.

▷ **Claim 2.2.** Let  $f \in C^i, g \in C^{i-1}$ . Then  $\langle f, \delta g \rangle_i = \langle \partial f, g \rangle_{i-1}$ .

Proof.

$$\begin{aligned} \langle f, \delta_{i-1} g \rangle_i &= \sum_{t \in X(i)} f(t) \cdot \delta_{i-1} g(t) = \sum_{t \in X(i)} f(t) \cdot \left( \sum_{s \in X(i-1): s \subset t} g(s) \right) \\ &= \sum_{s \in X(i-1)} \left( \sum_{t \in X(i): t \supset s} f(t) \right) \cdot g(s) = \langle \partial_i f, g \rangle_{i-1}. \end{aligned} \quad \triangleleft$$

The following two claims show that the dimensions of homology and cohomology spaces are identical.

▷ **Claim 2.3.**  $Z_i = (B^i)^\perp, \quad Z^i = (B_i)^\perp$ .

Proof.  $Z_i = \ker \partial_i = \ker \delta_{i-1}^* = (\text{im } \delta_{i-1})^\perp = (B^i)^\perp$ . ◁

▷ **Claim 2.4.**  $\dim H_i = \dim H^i$

Proof.

$$\begin{aligned} \dim H_i &= \dim Z_i - \dim B_i \\ &= \dim C^i - \dim B^i - \dim B_i && \text{[By Claim 2.3]} \\ &= \dim Z^i - \dim B^i && \text{[By Claim 2.3]} \\ &= \dim H^i. \end{aligned} \quad \triangleleft$$

**Cosystoles.** We define, following Evra and Kaufman [16, Definition 2.14], the  $i$ -cosystole of a complex  $X$  to be the minimal (fractional) size of  $f \in Z^i \setminus B^i$ ,

$$\text{CoSys}^i(X) := \min_{f \in Z^i \setminus B^i} |f|/|X(i)|.$$

## 2.3 The Building $\mathcal{B}^{(d+1)}$

The infinite  $k$ -regular tree is the unique connected  $k$ -regular graph without cycles. Affine buildings are higher-dimensional analogs of the infinite  $k$ -regular tree. For  $d = 1$ , the one-dimensional affine building  $\mathcal{B}^{(1)}$  is the  $k$ -regular tree. For higher dimensions they are *regular* in the sense that all vertex links are bounded and identical in structure, they are connected and contractible,<sup>3</sup> and so have vanishing cohomologies, that is, the cohomology spaces  $H^1, \dots, H^{d-1}$  are trivial, where  $d$  is the dimension.

We won't describe  $\mathcal{B}^{(d+1)}$  any further; the interested reader can check [26, 1]. A crucial property of  $\mathcal{B}^{(d+1)}$  which we will need in the sequel is its being a CAT(0) space,<sup>4</sup> which is a geometric definition capturing non-positive curvature; see [9] for more information. The property of being CAT(0) has the following implication, due to Gromov [21, 25, 38]:

► **Theorem 2.5** (Gromov's filling inequality for CAT(0) spaces). *For every cycle  $f \in Z_1$  there is a filling  $g \in C_2$  such that  $f = \partial g$  and  $|g| = O(|f|^2)$ .*

Gromov's filling inequality is an isoperimetric inequality. It generalizes the classic isoperimetric inequality in the plane, which states that any simple closed curve of length  $L$  encloses a region whose area is at most  $L^2/4\pi$ .

The isoperimetric inequality in the plane can be stated in an equivalent way: the boundary of any *bounded* region of area  $A$  is a curve whose length is at least  $\sqrt{4\pi A}$ . This inequality fails for unbounded regions, which could have infinite area but finite boundary (for example, consider the complement of a circle). In the same way, Gromov's inequality doesn't imply that each  $g \in C_2$  satisfies  $|\partial g| = \Omega(\sqrt{|g|})$ . Rather, we have to replace  $|g|$  with  $\min_{h \in Z_2} |g + h|$ .

Gromov's filling inequality also applies to  $i$ -chains, with an exponent of  $i + 1$ , but we will only need the case  $i = 1$ .

In the sequel, we will apply Gromov's filling inequality not to the building itself, but rather to balls in the building. The CAT(0) property almost immediately implies that a ball in a CAT(0) space is itself CAT(0) [9, Exercise II.1.6]. Furthermore, it is well-known that CAT(0) spaces are contractible, and so have vanishing homologies.

► **Lemma 2.6.** *Balls in  $\mathcal{B}^{(d+1)}$  have vanishing homologies and satisfy Gromov's filling inequality.*

## 2.4 The LSV quotient

Whereas the affine building is an infinite simplicial complex, Lubotzky, Samuels and Vishne constructed a growing family of finite complexes that are obtained from quotients of the affine building. These quotients have a growing number of vertices, and locally, in a ball

<sup>3</sup> A complex is contractible, roughly speaking, if it can be continuously deformed to a point (technically, it is homotopy-equivalent to a point). Since (co)homologies are preserved by such deformations, all (co)homologies of a contractible complex vanish.

<sup>4</sup> A space is CAT(0) if for every triangle  $x, y, z$ , the distance between  $x$  and the midpoint of  $y, z$  is at most the corresponding distance in a congruent triangle in Euclidean space.

around each vertex, the complex is isomorphic to the affine building. Moreover, they gave a very explicit algorithm for constructing these complexes by first constructing a Cayley graph with an explicit set of generators, and then the higher dimensional faces are simply the cliques in the Cayley graph.

► **Theorem 2.7** (Lubotzky, Samuels, Vishne [34, Theorem 1.1]). *Let  $q$  be a prime power,  $d \geq 2$ . For every  $\epsilon > 1$  the group  $G = PGL_d(\mathbb{F}_{p^\epsilon})$  has an (explicit) set of  $\binom{d}{1}_q + \binom{d}{2}_q + \dots + \binom{d}{d-1}_q$  generators, such that the Cayley complex of  $G$  with respect to these generators is a Ramanujan complex  $X$  covered by  $\mathcal{B}^{(d)}(F)$  for  $F = \mathbb{F}_q((y))$ .*

The precise definition of “Ramanujan complex” is not important for this context. For us, there are three important aspects of this theorem: efficient construction, local structure, and global structure.

**Efficient construction** Firstly, the fact that the complex is constructible in polynomial time.

**Local structure** Next, we highlight the fact that locally the complex looks like the building.

The fact that  $X$  is covered by  $\mathcal{B}^{(d)}$  means that the neighborhood of a vertex in  $X$  and in  $\mathcal{B}^{(d)}$  look exactly the same. It turns out that for the LSV complexes this continues to be true also for balls of larger radius around any vertex. This is a higher-dimensional analog of the graph property of containing no short cycles (locally looking like a tree). Define the injectivity radius of  $X$  to be the largest  $r$  such that the covering map  $\mathcal{B}^{(d)} \xrightarrow{\psi} X$  is injective from balls of radius  $\leq r$  in  $\mathcal{B}^{(d)}$  and the ball of radius  $\leq r$  in  $X$ . We do not mention the centers of the balls as they are all isomorphic.

► **Theorem 2.8** (Lubotzky and Meshulam [33], see also [15, Corollary 5.2]). *Let  $X$  be the LSV complex above. Then the injectivity radius <sup>5</sup>  $r(X)$  of  $X$  satisfies*

$$r(X) \geq \frac{\log_q |X|}{2(d-1)(d^2-1)} - \frac{1}{2}$$

where  $|X|$  is the number of vertices in  $X$ .

**Global structure** Finally, we look at the second cohomology group of the LSV complexes.

Kaufman, Kazhdan and Lubotzky [27] showed that the groups defining the LSV quotient complexes can be chosen so that the second homology is non-empty.

► **Proposition 2.9** (Kaufman, Kazhdan, Lubotzky [27, Proposition 3.6]). *There is an infinite and explicit sequence of LSV complexes with a non-vanishing second cohomology.*

We remark that Kaufman, Kazhdan and Lubotzky [27] proved that these complexes exist. To show that they are also efficiently constructible, we look into their proof to recall the construction: start with any LSV complex  $X$  viewed as a Cayley graph of a group  $G$ . Find some element of order 2 in  $G$  (such an element always exists), and then quotient  $X$  by this element, thus obtaining a complex  $Y$  that is itself is a Ramanujan complex because it is a quotient of one.  $Y$  is clearly efficiently constructible from  $X$ , and has half as many vertices. This construction shows (see [27, Proposition 3.5]) that  $H^1(Y) \neq 0$ . Furthermore, the proof of [27, Proposition 3.6] shows that because  $G$  has “property  $T$ ” one can deduce also that  $H^2(Y) \neq 0$ .

<sup>5</sup> This theorem was proven by Lubotzky and Meshulam [33]. They stated their theorem using a slightly different definition for injectivity radius but one can prove that the two definitions coincide in this case. This was reproven by Evra, Golubev and Lubotzky [15] who use the definition of injectivity radius that is convenient for us.

Evra and Kaufman proved [16, Theorem 1] that quotients of  $\mathcal{B}^{(d)}$  (and even a more general class of complexes) are so-called “cosystolic expanders” which in particular implies the following.

► **Theorem 2.10** (Evra and Kaufman [16, Part of Theorem 1]). *Let  $\{X_n\}$  be a family of LSV complexes. There exists some constant  $\mu > 0$  that depends only on  $q$  and  $d$  but not on the size  $n$  of the complex, such that every  $f \in Z^2(X) \setminus B^2(X)$  must have weight at least  $\mu \cdot |X(2)|$ .*

### 3 Main Result

#### 3.1 Local Geometry of LSV Complexes

The infinite sequence of complexes we will be working with are the LSV complexes described in Section 2.4 above. The properties we care about are (1) that they are efficiently constructible, (2) that small balls in these complexes are isomorphic to the affine building, which satisfies certain isoperimetric inequalities because it is a CAT(0) space, and (3) that each complex has a two-dimensional cocycle with linear distance from the set of coboundaries. The second and third properties provide the tension between the local and the global structure of these complexes that we now harness for our hardness.

To construct an SDP solution, we will need to show that our instance based on the LSV complex “locally looks satisfiable”. To this end, we will first develop some local properties of the LSV complex.

Note that each  $h \in C^2$  corresponds to a set of triangles. For the following statements, we consider two triangles to be connected if they share an edge. This can be used to define connected components. Note that if  $h$  can be split into connected components  $h_1, \dots, h_s$ , then the components correspond to *disjoint* sets of triangles. Moreover, no triangle in  $h_i$  shares an edge with a triangle in  $h_j$  when  $i \neq j$ , which also implies that the boundaries  $\partial h_i$  and  $\partial h_j$  correspond to disjoint sets of edges.

We prove the following claims by mapping small connected sets in  $X(2)$  to corresponding sets in the infinite building  $\mathcal{B}$ . The first proposition shows that there can be no small non-trivial cancellations (i.e., not coming from tetrahedra).

► **Proposition 3.1.** *Let  $h_0 \in C^2$  be a connected set of triangles such that  $|h_0| < r$  and  $\partial h_0 = 0$ . Then  $h_0 \in B_2$ .*

**Proof.** Since  $|h_0| < r$ , there is a ball  $N$  of radius  $r$  that contains the support of  $h_0$ . By assumption, the covering map  $\psi: \mathcal{B} \rightarrow X$  has injectivity radius of at least  $r$ . This means that there is a radius- $r$  ball  $\hat{N} = \psi^{-1}(N)$  in  $\mathcal{B}$  that is isomorphically mapped by  $\psi$  to  $N$ . Look at  $\hat{h}_0 = \psi^{-1}(h_0) \in C^2(\hat{N})$ , the chain isomorphic to  $h_0$  in the building. Clearly  $\partial \hat{h}_0 = \psi^{-1}(\partial h_0) = 0$ , and since balls in the building have zero homologies by Lemma 2.6, we deduce that  $\hat{h}_0$  itself must be a boundary, i.e. there must be some  $\hat{g}_0 \in C^3(\hat{N})$  such that  $\partial \hat{g}_0 = \hat{h}_0$ . Moving back to  $X$ , we see that  $g_0 := \psi(\hat{g}_0) \in C^3(X)$  necessarily satisfies  $\partial g_0 = h_0$ , and so  $h_0 \in B_2$ . ◀

This proposition states that locally (i.e., within the injective radius  $r$ ),  $Z_2$  looks like  $B_2$ . We thus have a complex whose cohomology group is non-trivial, yet locally, the *homology* group “looks” trivial. Note that this is a twist on what we had claimed in the introduction, a complex whose cohomology group is non-trivial, yet locally, the *cohomology* group “looks” trivial. However, these are identical statements owing to Claim 2.4.

The next proposition shows that Gromov’s filling inequality in the infinite building  $\mathcal{B}$  can be used to yield a similar consequence for small sets in the finite complex  $X$ .

► **Proposition 3.2.** *Let  $h_0 \in C_2$  be a connected set of triangles such that  $|h_0| < r$  and  $|h_0| \leq |h_0 + h|$  for all  $h \in B_2$ . Then,  $|\partial h_0| \geq c \cdot |h_0|^{1/2}$ , where  $c > 0$  is an absolute constant.*

**Proof.** As before, the support of  $h_0$  is contained in a ball  $\mathbf{N}$  of  $X$  which is isomorphic under  $\psi$  to a ball  $\hat{\mathbf{N}}$  in  $\mathcal{B}$ . Let  $\hat{h}_0 = \psi^{-1}(h_0) \in C^2(\mathcal{B})$ , and let  $\hat{f}_0 = \partial \hat{h}_0$ . We now apply the filling theorem of Gromov, which holds in  $\hat{\mathbf{N}}$  due to Lemma 2.6, to deduce that there is some  $\hat{h}_1$  that fills  $\hat{f}_0$ , namely  $\partial \hat{h}_1 = \hat{f}_0$ , and whose size is at most  $|\hat{h}_1| = O(|\hat{f}_0|^2)$ .

Now  $\partial(\hat{h}_0 - \hat{h}_1) = \hat{f}_0 - \hat{f}_0 = 0$ . Since the ball  $\hat{\mathbf{N}}$  has zero homologies by Lemma 2.6,  $\hat{h}_0 - \hat{h}_1$  itself must be a boundary: there must be some  $\hat{g} \in C^3(\hat{\mathbf{N}})$  such that  $\partial \hat{g} = \hat{h}_0 - \hat{h}_1$ . Pushing  $\hat{g}$  and  $\hat{h}_1$  back to  $X$ , we get  $g = \psi(\hat{g})$  and  $h_1 = \psi(\hat{h}_1)$ , which satisfy  $\partial g = h_0 - h_1$ . At this point we have a *small*  $h_1$  that is close via a boundary to  $h_0$ . Finally, observe that  $f_0 = \partial h_0$  satisfies  $f_0 = \psi^{-1}(\hat{f}_0)$ . So

$$|f_0| = |\hat{f}_0| \geq c \cdot |\hat{h}_1|^{1/2} = c \cdot |h_1|^{1/2} \geq c \cdot |h_0|^{1/2},$$

where the last inequality used that  $|h_0| \leq |h_0 + (h_1 - h_0)|$ , since  $h_1 - h_0 = \partial g \in B_2$ . ◀

### 3.2 Fooling $\Omega(\sqrt{\log n})$ levels of SoS Hierarchy

Let  $X$  be a  $d$ -dimensional LSV complex, with  $|X(1)| = n$  and non-trivial second cohomology group, as per Proposition 2.9. Below, we construct an instance of 3XOR in  $n$  variables using this complex, and prove a lower bound on the integrality gap of the relaxation obtained by  $\Omega(\sqrt{\log n})$  levels of the SoS hierarchy.

#### Construction

We construct a system of equations on  $X$  by putting a variable  $x_{\{a,b\}}$  for each edge  $\{a,b\} \in X(1)$  of the complex, and an equation

$$x_{\{a,b\}} + x_{\{b,c\}} + x_{\{c,a\}} = \beta_{\{a,b,c\}}$$

for each triangle  $\{a,b,c\} \in X(2)$ , where  $\beta$  is an arbitrary element of  $Z^2 \setminus B^2$ .

Recall that  $X$  can be constructed efficiently. Given  $X$ , we can find a vector  $\beta \in Z^2 \setminus B^2$  using elementary linear algebra. Therefore the entire system can be constructed efficiently.

#### Soundness

Soundness of this system follows easily from the fact that the cosystole is large.

▷ **Claim 3.3 (Soundness).** Every assignment to the system defined above falsifies at least  $\mu$  fraction of the equations.

**Proof.** An assignment to the variables is equivalent to an  $f \in C^1$ . Every equation satisfied by  $f$  is a triangle in which  $\delta f(\{a,b,c\}) = \beta_{\{a,b,c\}}$ , and so the number of unsatisfied equations is  $\text{dist}(\delta f, \beta) = |\delta f + \beta|$ . Since  $\delta f \in B^2$  and  $\beta \in Z^2 \setminus B^2$ , also  $\delta f + \beta \in Z^2 \setminus B^2$ , and so  $|\delta f + \beta|/|X(2)| \geq \text{CoSys}^2(X) \geq \mu$ . In other words, the assignment falsifies at least a  $\mu$  fraction of the equations. ◀

The main work is to prove completeness, namely to show that the system looks locally satisfiable.

### Completeness

Our main result is that this system appears satisfiable to the Sum-of-Squares hierarchy with  $O(\sqrt{\log n})$  levels. Grigoriev [20] and Schoenebeck [36] showed that to prove such a statement it suffices to analyze the *refutation width* of the system of equations (see Lemma 2.1). If the refutation width is at least  $w$ , then  $w/2$  levels of the Sum-of-Squares hierarchy cannot refute the system.

A system of linear equations over  $\mathbb{F}_2$  can be *refuted* using a proof system known as *XOR-resolution*, in which the only inference rule is: given  $\ell_1 = b_1$  and  $\ell_2 = b_2$ , deduce  $\ell_1 + \ell_2 = b_1 + b_2 \pmod{2}$ ; here  $\ell_1, \ell_2$  are XORs of variables, and  $b_1, b_2$  are constants. A refutation has the structure of a directed acyclic graph (DAG) where each non-leaf node has two incoming edges. A *refutation* is a derivation which starts with the given linear equations, placed at the leaves of a DAG, and reaches the equation  $0 = 1$  at the root of the DAG. The *width* of a linear equation  $\ell = b$  is the number of variables appearing in  $\ell$ . The width of a refutation is the maximum width of an equation in any of the nodes of the DAG.

In the remainder of this section, we prove the following theorem, which together with Lemma 2.1 implies Theorem 1.1.

► **Theorem 3.4.** *The construction above requires width at least  $\Omega(\sqrt{r})$  to refute in XOR-resolution, where  $r = \Theta(\log n)$  is the injectivity radius of the complex.*

The proof follows classical arguments of Ben-Sasson and Wigderson [8] regarding lower bounds on resolution width, which were also used in the proof of Schoenebeck [36]. Whereas Ben-Sasson and Wigderson relied on boundary expansion, we rely on Gromov’s filling inequality (and so lose a square root).

Suppose we are given a refutation for this system, and consider the corresponding DAG. Each leaf  $\nu$  in the DAG is labeled by a triangle  $T_\nu \in X(2)$ . Define

$$h_\nu := \mathbf{1}_{T_\nu} \in C^2, \quad b_\nu := \beta_{T_\nu} \in \mathbb{F}_2.$$

For each inner node  $\nu$  in the DAG, let  $\nu_1, \nu_2$  be its two incoming nodes. Define inductively,

$$h_\nu := h_{\nu_1} + h_{\nu_2} \in C^2, \quad b_\nu := b_{\nu_1} + b_{\nu_2} \in \mathbb{F}_2.$$

► **Proposition 3.5.** *For every node  $\nu$ ,  $b_\nu = \langle \beta, h_\nu \rangle$ .*

**Proof.** This is immediate by following inductively the structure of the DAG. ◀

As in [8], we next define a complexity measure for each node of the DAG. While in [8] the complexity measure is based on the number of “leaf equations” used to derive the one at a given node, we will need to discount sets of triangles corresponding to tetrahedra, as these cannot lead to contradictions. Recall that  $B_2 = \text{im } \partial_3$  is the set of triangle chains that “come from” tetrahedra chains, which we consider as the “trivial” cycles. We define a complexity measure at each node,

$$\kappa(\nu) := \text{dist}(h_\nu, B_2) = \min_{h \in B_2} |h_\nu + h|$$

that measures the distance of  $h_\nu$  from these trivial cycles. The complexity measure  $\kappa$  satisfies the following sub-additivity property.

► **Proposition 3.6.** *If  $\nu$  is an inner node in the DAG with  $\nu_1, \nu_2$  its two incoming nodes, then*

$$\kappa(\nu) \leq \kappa(\nu_1) + \kappa(\nu_2).$$

**Proof.** Let  $h_1, h_2 \in B_2$  be such that  $\kappa(\nu_1) = |h_{\nu_1} + h_1|$  and  $\kappa(\nu_2) = |h_{\nu_2} + h_2|$ . Recall that  $h_\nu = h_{\nu_1} + h_{\nu_2}$ . Then, we have

$$\begin{aligned} \kappa(\nu_1) + \kappa(\nu_2) &= |h_{\nu_1} + h_1| + |h_{\nu_2} + h_2| \geq |h_{\nu_1} + h_{\nu_2} + h_1 + h_2| \\ &= |h_\nu + h_1 + h_2| \geq \kappa(\nu). \end{aligned} \quad \blacktriangleleft$$

We also need the fact that the complexity of a node with a contradiction must be non-zero.

► **Proposition 3.7.** *If  $\kappa(\nu) = 0$  then  $b_\nu = 0$ .*

**Proof.** If  $\kappa(\nu) = 0$  then  $h_\nu \in B_2$ . Hence  $b_\nu = \langle \beta, h_\nu \rangle = 0$  since  $\beta \in Z^2 = (B_2)^\perp$  (Claim 2.3).  $\blacktriangleleft$

Next, we consider the width of each node in the DAG. For a node  $\nu$ , let

$$f_\nu := \partial h_\nu \in C^1.$$

Thus  $f_\nu$  indicates the set of variables appearing in the left-hand side of the equation on node  $\nu$ . So the width of the system is the maximum, over all nodes  $\nu$  in the DAG, of  $|f_\nu|$ .

We can now prove Theorem 3.4 using the above complexity measure, and results from Section 3.1.

**Proof of Theorem 3.4.** Let  $\nu^*$  denote the root of the DAG. By virtue of being a refutation,  $b_{\nu^*} = 1$  while  $f_{\nu^*} = 0$ . In other words,  $\partial h_{\nu^*} = f_{\nu^*} = 0$ , which means that  $h_{\nu^*} \in Z_2$ . Since  $b_{\nu^*} = 1$ , we also have by Proposition 3.7 that  $\kappa(\nu^*) > 0$ .

Let  $h \in B_2$  be such that  $\kappa(\nu^*) = |h_{\nu^*} + h|$ , and let  $h_1, \dots, h_s$  be the disjoint connected components of  $h_{\nu^*} + h$ . We will first show that  $\kappa(\nu^*) = |h_{\nu^*} + h| \geq r$ . Assuming  $\kappa(\nu^*) < r$ , we have that

$$|h_1| + \dots + |h_s| = |h_{\nu^*} + h| < r.$$

Also, since

$$\partial h_1 + \dots + \partial h_s = \partial(h_{\nu^*} + h) = \partial h_{\nu^*} = 0,$$

we must have that  $\partial h_i = 0$  for each  $i \in [s]$ , since connected components have disjoint boundaries. Applying Proposition 3.1 to each  $h_i$ , we get that  $h_i \in B_2$  for each  $i \in [s]$ . However, this implies  $h_{\nu^*} + h \in B_2$  and hence  $\kappa(\nu^*) = 0$ , which is a contradiction.

Using sub-additivity (Proposition 3.6),  $\kappa(\nu^*) \geq r$ , and the fact that the leaves of the DAG satisfy  $\kappa(\nu) = 1$ , we get that there must be some internal node  $\nu$  for which  $r/2 \leq \kappa(\nu) < r$ . We can find such a node by starting at the root and always going to the child with higher complexity, until reaching a node  $\nu$  such that  $\kappa(\nu) < r$ . We will prove that for such a node, we must have  $|f_\nu| = \Omega(\sqrt{r})$ .

As before, let  $h \in B_2$  now be such that  $\kappa(\nu) = |h_\nu + h|$ , and let  $h_1, \dots, h_s$  be the disjoint connected components of  $h_\nu + h$ . We have that  $|h_i| \leq |h_\nu + h| < r$  for each  $i \in [s]$ . By the minimality of  $|h_\nu + h|$ , we also have that for any  $h' \in B_2$  and any  $i \in [s]$ ,

$$|h_i| + |h_\nu + h - h_i| = |h_\nu + h| \leq |h_\nu + h + h'| \leq |h_i + h'| + |h_\nu + h - h_i|.$$

Thus,  $|h_i|$  is also minimal for each  $i$ , and we can apply Proposition 3.2 to each connected component  $h_i$ , to obtain

$$\begin{aligned} |f_\nu| &= |\partial(h_\nu + h)| = |\partial h_1| + \cdots + |\partial h_s| \geq c \cdot |h_1|^{1/2} + \cdots + c \cdot |h_s|^{1/2} \\ &\geq c \cdot (|h_1| + \cdots + |h_s|)^{1/2} \\ &= c \cdot |h_\nu + h|^{1/2} \geq (c/\sqrt{2}) \cdot \sqrt{r}. \quad \blacktriangleleft \end{aligned}$$

## A Proof of Lemma 2.1

► **Lemma 2.1** ([36, Lemma 13], [37, Theorem 4.2]). *Let  $\Lambda$  be a system of equations in  $n$  variables over  $\mathbb{F}_2$ , which does not admit any refutations of width at most  $2t$ . Then there exist vectors  $\{\mathbf{u}_S\}_{S \subseteq [n], |S| \leq t}$  satisfying the constraints in Figure 1, such that for all equations  $\sum_{i \in T} x_i = b_T$  in  $\Lambda$  with  $|T| \leq t$ , we have  $\langle \mathbf{u}_T, \mathbf{u}_\emptyset \rangle = (-1)^{b_T}$ .*

**Proof.** We assume that  $\Lambda$  is closed under width- $2t$  XOR-resolution, replacing  $\Lambda$  by its closure if necessary, and also that it contains the trivial equation  $0 = 0$ . We will now construct the unit vectors  $\mathbf{u}_S$ .

Define a relation  $\sim$  on subsets of  $[n]$  of size at most  $t$  as follows:  $S \sim T$  iff there exists an equation  $\sum_{i \in S \Delta T} x_i = b$  in  $\Lambda$  for some  $b \in \mathbb{F}_2$ . It is easy to check that the relation is reflexive and symmetric. It is also transitive since for  $S_1 \sim S_2$ ,  $S_2 \sim S_3$ , we can add the corresponding equations to obtain one of the form  $\sum_{i \in S_1 \Delta S_3} x_i = b$  for some  $b \in \mathbb{F}_2$ . Since  $|S_1|, |S_3| \leq t$ , this equation has at most  $2t$  variables and must be in  $\Lambda$  by the closure property. Thus, we have an equivalence relation which partitions all sets of size at most  $t$  into equivalence classes, say  $\mathcal{C}_1, \dots, \mathcal{C}_s$ . Choose an arbitrary representative  $R_i$  for each class  $\mathcal{C}_i$ , and let  $R(S)$  denote the representative for the class containing  $S$ . For convenience, we choose  $R(\emptyset) = \emptyset$ .

We now construct the SDP vectors. Let  $e_1, \dots, e_s$  be an arbitrary orthonormal set of vectors, and assign  $\mathbf{u}_{R_i} = e_i$  for all  $i \in [s]$ . Note that for any  $S$  with  $|S| \leq t$ , there must be a *unique* equation of the form  $\sum_{i \in S \Delta R(S)} x_i = b_S$  in  $\Lambda$ , since two different equations can be used to obtain a width- $2t$  refutation. We assign the vector for  $S$  as

$$\mathbf{u}_S := (-1)^{b_S} \cdot \mathbf{u}_{R(S)}.$$

The vectors are unit-length by construction. Note that if  $S_1 \Delta S_2 = S_3 \Delta S_4$ , we must have  $S_1 \sim S_2 \Leftrightarrow S_3 \sim S_4$ . If  $S_1 \not\sim S_2$ , then we have that  $\langle \mathbf{u}_{S_1}, \mathbf{u}_{S_2} \rangle = \langle \mathbf{u}_{S_3}, \mathbf{u}_{S_4} \rangle = 0$ . Otherwise, we have  $R(S_1) = R(S_2)$ ,  $R(S_3) = R(S_4)$ , and equations of the form

$$\sum_{i \in S_j \Delta R(S_j)} x_i = b_{S_j}, \quad j \in \{1, 2, 3, 4\}.$$

We must also have  $b_{S_1} + b_{S_2} = b_{S_3} + b_{S_4}$ , since otherwise we obtain two different equations with variables in  $S_1 \Delta S_2 = S_3 \Delta S_4$ , yielding a refutation. This suffices to satisfy the SDP constraints, since

$$\langle \mathbf{u}_{S_1}, \mathbf{u}_{S_2} \rangle = (-1)^{b_{S_1} + b_{S_2}} \cdot \langle \mathbf{u}_{R(S_1)}, \mathbf{u}_{R(S_2)} \rangle = (-1)^{b_{S_1} + b_{S_2}} = (-1)^{b_{S_3} + b_{S_4}} = \langle \mathbf{u}_{S_3}, \mathbf{u}_{S_4} \rangle.$$

Finally, for any equation  $\sum_{i \in T} x_i = b_T$  in  $\Lambda$  with  $|T| \leq t$ , we get  $\langle \mathbf{u}_T, \mathbf{u}_\emptyset \rangle = (-1)^{b_T}$ , since we must have  $T \sim \emptyset$  and  $R(T) = \emptyset$ . ◀

# Lower Bounds on the Running Time of Two-Way Quantum Finite Automata and Sublogarithmic-Space Quantum Turing Machines

Zachary Remscrim

Department of Computer Science, The University of Chicago, IL, USA  
remscrim@uchicago.edu

---

## Abstract

The two-way finite automaton with quantum and classical states (2QCFA), defined by Ambainis and Watrous, is a model of quantum computation whose quantum part is extremely limited; however, as they showed, 2QCFA are surprisingly powerful: a 2QCFA with only a single-qubit can recognize the language  $L_{pal} = \{w \in \{a, b\}^* : w \text{ is a palindrome}\}$  with bounded error in expected time  $2^{O(n)}$ .

We prove that their result cannot be improved upon: a 2QCFA (of any size) cannot recognize  $L_{pal}$  with bounded error in expected time  $2^{o(n)}$ . This is the first example of a language that can be recognized with bounded error by a 2QCFA in exponential time but not in subexponential time. Moreover, we prove that a quantum Turing machine (QTM) running in space  $o(\log n)$  and expected time  $2^{n^{1-\Omega(1)}}$  cannot recognize  $L_{pal}$  with bounded error; again, this is the first lower bound of its kind. Far more generally, we establish a lower bound on the running time of any 2QCFA or  $o(\log n)$ -space QTM that recognizes any language  $L$  in terms of a natural “hardness measure” of  $L$ . This allows us to exhibit a large family of languages for which we have asymptotically matching lower and upper bounds on the running time of any such 2QCFA or QTM recognizer.

## 1 Introduction

Quantum algorithms, such as Shor’s quantum polynomial time integer factorization algorithm [31], Grover’s algorithm for unstructured search [16], and the linear system solver of Harrow, Hassidim, and Lloyd [17], provide examples of natural problems on which quantum computers seem to have an advantage over their classical counterparts. However, these algorithms are designed to be run on a quantum computer that has the full power of a quantum Turing machine, whereas current experimental quantum computers only possess a rather limited quantum part. In particular, current state-of-the-art quantum computers have a very small amount of quantum memory. For example, Google’s “Sycamore” quantum computer, used in their famous recent quantum supremacy experiment [5], operates on only 53 qubits.

In this paper, we study the power quantum computers that have only a small amount of memory. We begin by considering two-way finite automata with quantum and classical states (2QCFA), originally defined by Ambainis and Watrous [2]. Informally, a 2QCFA is a two-way deterministic finite automaton (2DFA) that has been augmented by a quantum register of

constant size. 2QCFA are surprisingly powerful, as originally demonstrated by Ambainis and Watrous, who showed that a 2QCFA, with only a single-qubit quantum register, can recognize, with bounded error, the language  $L_{eq} = \{a^m b^m : m \in \mathbb{N}\}$  in expected time  $O(n^4)$  and the language  $L_{pal} = \{w \in \{a, b\}^* : w \text{ is a palindrome}\}$  in expected time  $2^{O(n)}$ . In a recent paper [27], we presented further evidence of the power of few qubits by showing that 2QCFA are capable of recognizing many group word problems with bounded error.

It is known that 2QCFA are more powerful than 2DFA and two-way probabilistic finite automata (2PFA). A 2DFA can only recognize regular languages [25]. A 2PFA can recognize some nonregular languages with bounded error, given sufficient running time: in particular, a 2PFA can recognize  $L_{eq}$  with bounded error in expected time  $2^{O(n)}$  [13]. However, a 2PFA cannot recognize  $L_{eq}$  with bounded error in expected time  $2^{o(n)}$ , by a result of Greenberg and Weiss [14]; moreover, a 2PFA cannot recognize  $L_{pal}$  with bounded error in any time bound [11]. More generally, the landmark result of Dwork and Stockmeyer [10] showed that a 2PFA cannot recognize any nonregular language in expected time  $2^{n^{o(1)}}$ . In order to prove this statement, they defined a particular “hardness measure”  $D_L : \mathbb{N} \rightarrow \mathbb{N}$  of a language  $L$ . They showed that, if a 2PFA recognizes some language  $L$  with bounded error in expected time at most  $T(n)$  on all inputs of length at most  $n$ , then there is a positive real number  $a$  (that depends only on the number of states of the 2PFA), such that  $T(n) = \Omega(2^{D_L(n)^a})$  [10, Lemma 4.3]; we will refer to this statement as the “Dwork-Stockmeyer lemma.”

Very little was known about the limitations of 2QCFA. Are there any languages that a single-qubit 2QCFA can recognize with bounded error in expected exponential time but not in expected subexponential time? In particular, is it possible for a single-qubit 2QCFA to recognize  $L_{pal}$  in subexponential time, or perhaps even in polynomial time? More generally, are there any languages that a 2QCFA (that is allowed to have a quantum register of any constant size) can recognize with bounded error in exponential time but not in subexponential time? These natural questions, to our knowledge, were all open (see, for instance, [2, 3, 39] for previous discussions of these questions).

In this paper, we answer these and other related questions. We first prove an analogue of the Dwork-Stockmeyer lemma for 2QCFA.

► **Theorem 1.** *If a 2QCFA recognizes some language  $L$  with bounded error in expected time at most  $T(n)$  on all inputs of length at most  $n$ , then there a positive real number  $a$  (that depends only on the number of states of the 2QCFA), such that  $T(n) = \Omega(D_L(n)^a)$ .*

This immediately implies that the result of Ambainis and Watrous [2] cannot be improved.

► **Corollary 2.** *2QCFA (of any size) cannot recognize  $L_{pal}$  with bounded error in time  $2^{o(n)}$ .*

One of the key tools used in our proof is a quantum version of Hennie’s [18] notion of a crossing sequence, which may be of independent interest. Crossing sequences played an important role in the aforementioned 2PFA results of Dwork and Stockmeyer [10] and of Greenberg and Weiss [14]. We note that, while our lower bound on the running time of a 2QCFA is exponentially weaker than the lower bound on the running time of a 2PFA provided by the Dwork-Stockmeyer lemma, both lower bounds are in fact (asymptotically) tight; the exponential difference provides yet another example of a situation in which quantum computers have an exponential advantage over their classical counterparts. We also establish a lower bound on the expected running time of a 2QCFA recognizer of  $L$  in terms of the one-way deterministic communication complexity of testing membership in  $L$ .

We then generalize our results to prove a lower bound on the expected running time  $T(n)$  of a quantum Turing machine (QTM) that uses sublogarithmic space (i.e.,  $o(\log n)$  space) and recognizes a language  $L$  with bounded error, where this lower bound is also in terms

of  $D_L(n)$ . In particular, we show that  $L_{pal}$  cannot be recognized with bounded error by a QTM that uses sublogarithmic space and runs in expected time  $2^{n^{1-\Omega(1)}}$ . This result is particularly intriguing, as  $L_{pal}$  can be recognized by a *deterministic* TM in  $O(\log n)$  space (and, trivially, polynomial time); therefore,  $L_{pal}$  provides an example of a natural problem for which polynomial time *quantum* TMs have no (asymptotic) advantage over polynomial time *deterministic* TMs in terms of the needed amount of space.

Furthermore, we show that the class of languages recognizable with bounded error by a 2QCFA in expected polynomial time is contained in  $L/poly$ . This result, which shows that the class of languages recognizable by a particular quantum model is contained in the class of languages recognizable by a particular classical model, is a type of *dequantization* result. It is (qualitatively) similar to the Adleman-type [1] *derandomization* result  $BPL \subseteq L/poly$ , where  $BPL$  denotes the class of languages recognizable with bounded error by a probabilistic Turing machine (PTM) that uses  $O(\log n)$  space and runs in expected polynomial time. The only previous dequantization result was of a very different type: the class of languages recognizable by a 2QCFA, or more generally a QTM that uses  $O(\log n)$  space, with algebraic number transition amplitudes (even with unbounded error and with no time bound), is contained in  $DSPACE(O(\log^2 n))$  [35]. This dequantization result is analogous to the derandomization result: the class of languages recognizable by a PTM that uses  $O(\log n)$  space (even with unbounded error and with no time bound), is contained in  $DSPACE(O(\log^2 n))$  [7].

We also investigate which group word problems can be recognized by 2QCFA or QTMs with particular resource bounds. Informally, the word problem of a finitely generated group is the problem of determining if the product of a sequence of elements of that group is equal to the identity element. There is a deep connection between the algebraic properties of a finitely generated group  $G$  and the complexity of its word problem  $W_G$ , as has been demonstrated by many famous results; for example,  $W_G \in REG \Leftrightarrow G$  is finite [4],  $W_G \in CFL \Leftrightarrow G$  is virtually free [23, 9],  $W_G \in NP \Leftrightarrow G$  is a subgroup of a finitely presented group with polynomial Dehn function [6]. We have recently shown that if  $G$  is virtually abelian, then  $W_G$  may be recognized with bounded error by a single-qubit 2QCFA in polynomial time, and that, for any group  $G$  in a certain broad class of groups of exponential growth,  $W_G$  may be recognized with bounded error by a 2QCFA in time  $2^{O(n)}$  [27].

We now show that, if  $G$  has exponential growth, then  $W_G$  cannot be recognized by a 2QCFA with bounded error in time  $2^{o(n)}$ , thereby providing a broad and natural class of languages that may be recognized by a 2QCFA in time  $2^{O(n)}$  but not  $2^{o(n)}$ . We also show that, if  $W_G$  is recognizable by a 2QCFA with bounded error in expected polynomial time, then  $G$  must be virtually nilpotent (i.e.,  $G$  must have polynomial growth), thereby obtaining progress towards an exact classification of those word problems recognizable by a 2QCFA in polynomial time. Furthermore, we show analogous results for sublogarithmic-space QTMs.

## 2 Preliminaries

### 2.1 Quantum Computation

In this section, we briefly recall the fundamentals of quantum computation needed in this paper (see, for instance, [37, 24] for a more detailed presentation of the material in this section). We begin by establishing some notation. Let  $V$  denote a finite-dimensional complex Hilbert space with inner product  $\langle \cdot, \cdot \rangle : V \times V \rightarrow \mathbb{C}$ . We use the standard Dirac bra-ket notation throughout this paper. We denote elements of  $V$  by *kets*:  $|\psi\rangle, |\varphi\rangle, |q\rangle$ , etc. For the *ket*  $|\psi\rangle \in V$ , we define the corresponding *bra*  $\langle\psi| \in V^*$  to be the linear functional on  $V$  given by  $\langle\psi| \cdot \rangle : V \rightarrow \mathbb{C}$ . We write  $\langle\psi|\varphi\rangle$  to denote  $\langle\psi| \cdot \rangle(|\varphi\rangle)$ . Let  $L(V)$  denote the  $\mathbb{C}$ -vector

space consisting of all  $\mathbb{C}$ -linear maps of the form  $A : V \rightarrow V$ . For  $|\psi\rangle, |\varphi\rangle \in V$ , we define  $|\psi\rangle\langle\varphi| \in L(V)$  in the natural way: for  $|\rho\rangle \in V$ ,  $|\psi\rangle\langle\varphi|(|\rho\rangle) = |\psi\rangle\langle\varphi|\rho\rangle = \langle\varphi|\rho\rangle|\psi\rangle$ . Let  $\mathbb{1}_V \in L(V)$  denote the identity operator on  $V$  and let  $0_V \in L(V)$  denote the zero operator on  $V$ . For  $A \in L(V)$ , we define  $A^\dagger \in L(V)$ , the *Hermitian transpose* of  $A$ , to be the unique element of  $L(V)$  such that  $\langle A|\psi_1\rangle, |\psi_2\rangle\rangle = \langle|\psi_1\rangle, A^\dagger|\psi_2\rangle\rangle$ ,  $\forall |\psi_1\rangle, |\psi_2\rangle \in V$ . Let  $\text{Herm}(V) = \{A \in L(V) : A = A^\dagger\}$ ,  $\text{Pos}(V) = \{A^\dagger A : A \in L(V)\}$ ,  $\text{Proj}(V) = \{A \in \text{Pos}(V) : A^2 = A\}$ ,  $\text{U}(V) = \{A \in L(V) : AA^\dagger = \mathbb{1}_V\}$ , and  $\text{Den}(V) = \{A \in \text{Pos}(V) : \text{Tr}(A) = 1\}$  denote, respectively, the set of Hermitian, positive semi-definite, projection, unitary, and density operators on  $V$ .

A *quantum register* is specified by a finite set of *quantum basis states*  $Q = \{q_0, \dots, q_{k-1}\}$ . Corresponding to these  $k$  quantum basis states is an orthonormal basis  $\{|q_0\rangle, \dots, |q_{k-1}\rangle\}$  of the finite-dimensional complex Hilbert space  $\mathbb{C}^Q \cong \mathbb{C}^k$ . The quantum register stores a *superposition*  $|\psi\rangle = \sum_q \alpha_q |q\rangle \in \mathbb{C}^Q$ , where each  $\alpha_q \in \mathbb{C}$  and  $\sum_q |\alpha_q|^2 = 1$ ; in other words, a superposition  $|\psi\rangle$  is simply an element of  $\mathbb{C}^Q$  of norm 1.

Following the original definition of Ambainis and Watrous [2], a 2QCFA may only interact with its quantum register in two ways: by applying a *unitary transformation* or performing a *quantum measurement*. If the quantum register is currently in the superposition  $|\psi\rangle \in \mathbb{C}^Q$ , then after applying the unitary transformation  $T \in \text{U}(\mathbb{C}^Q)$ , the quantum register will be in the superposition  $T|\psi\rangle$ . A *von Neumann measurement* is specified by some  $P_1, \dots, P_l \in \text{Proj}(\mathbb{C}^Q)$ , such that  $P_i P_j = 0_{\mathbb{C}^Q}$ ,  $\forall i, j$  with  $i \neq j$ , and  $\sum_j P_j = \mathbb{1}_{\mathbb{C}^Q}$ . Quantum measurement is a probabilistic process where, if the quantum register is in the superposition  $|\psi\rangle$ , then the *result* of the measurement has the value  $r \in \{1, \dots, l\}$  with probability  $\|P_r |\psi\rangle\|^2$ ; if the result is  $r$ , then the quantum register collapses to the superposition  $\frac{1}{\|P_r |\psi\rangle\|} P_r |\psi\rangle$ . We emphasize that quantum measurement changes the state of the quantum register.

An *ensemble of pure states* of the quantum register is a set  $\{(p_i, |\psi_i\rangle) : i \in I\}$ , for some index set  $I$ , where  $p_i \in [0, 1]$  denotes the probability of the quantum register being in the superposition  $|\psi_i\rangle$ , and  $\sum_i p_i = 1$ . This ensemble corresponds to the density operator  $A = \sum_i p_i |\psi_i\rangle\langle\psi_i| \in \text{Den}(\mathbb{C}^Q)$ . Of course, many distinct ensembles correspond to the density operator  $A$ ; however, all ensembles that correspond to a particular density operator will behave the same, for our purposes (see, for instance, [24, Section 2.4] for a detailed discussion of this phenomenon, and of the following claims). That is to say, for any ensemble described by a density operator  $A \in \text{Den}(\mathbb{C}^Q)$ , applying the transformation  $T \in \text{U}(\mathbb{C}^Q)$  produces an ensemble described by the density operator  $TAT^\dagger$ . Similarly, when performing the von Neumann measurement specified by some  $P_1, \dots, P_l \in \text{Proj}(\mathbb{C}^Q)$ , the probability that the result of this measurement is  $r$  is given by  $\text{Tr}(P_r A P_r^\dagger)$ , and if the result is  $r$  then the ensemble collapses to an ensemble described by the density operator  $\frac{1}{\text{Tr}(P_r A P_r^\dagger)} P_r A P_r^\dagger$ .

Let  $V$  and  $V'$  denote a pair of finite-dimensional complex Hilbert spaces. Let  $\text{T}(V, V')$  denote the  $\mathbb{C}$ -vector space consisting of all  $\mathbb{C}$ -linear maps of the form  $\Phi : L(V) \rightarrow L(V')$ . Define  $\text{T}(V) = \text{T}(V, V)$  and let  $\mathbb{1}_{L(V)} \in \text{T}(V)$  denote the identity operator. Consider some  $\Phi \in \text{T}(V, V')$ . We say that  $\Phi$  is *positive* if,  $\forall A \in \text{Pos}(V)$ , we have  $\Phi(A) \in \text{Pos}(V')$ . We say that  $\Phi$  is *completely-positive* if, for every finite-dimensional complex Hilbert space  $W$ ,  $\Phi \otimes \mathbb{1}_{L(W)}$  is positive, where  $\otimes$  denotes the tensor product. We say that  $\Phi$  is *trace-preserving* if,  $\forall A \in L(V)$ , we have  $\text{Tr}(\Phi(A)) = \text{Tr}(A)$ . If  $\Phi$  is both completely-positive and trace-preserving, then we say  $\Phi$  is a *quantum channel*. Let  $\text{Chan}(V, V') = \{\Phi \in \text{T}(V, V') : \Phi \text{ is a quantum channel}\}$  denote the set of all such channels, and define  $\text{Chan}(V) = \text{Chan}(V, V)$ .

As we wish for our lower bound to be as strong as possible, we wish to consider a variant of the 2QCFA model that is as strong as possible; in particular, we will allow a 2QCFA to perform any physically realizable quantum operation on its quantum register.

Following Watrous [35], a *selective quantum operation*  $\mathcal{E}$  is specified by a set of operators  $\{E_{r,j} : r \in R, j \in \{1, \dots, l\}\} \subseteq L(\mathbb{C}^Q)$ , where  $R$  is a finite set and  $l \in \mathbb{N}_{\geq 1}$  (throughout the paper, we write  $\mathbb{N}_{\geq 1}$  to denote the positive natural numbers,  $\mathbb{R}_{\geq 0}$  to denote the nonnegative real numbers, etc.), such that  $\sum_{r,j} E_{r,j}^\dagger E_{r,j} = \mathbb{1}_{\mathbb{C}^Q}$ . For  $r \in R$ , we define  $\Phi_r \in T(\mathbb{C}^Q)$  such that,  $\Phi_r(A) = \sum_j E_{r,j} A E_{r,j}^\dagger, \forall A \in L(V)$ . Then, if the quantum register is described by some density operator  $A \in \text{Den}(\mathbb{C}^Q)$ , applying  $\mathcal{E}$  will have result  $r \in R$  with probability  $\text{Tr}(\Phi_r(A))$ ; if the result is  $r$ , then the quantum register is described by density operator  $\frac{1}{\text{Tr}(\Phi_r(A))} \Phi_r(A)$ . Both unitary transformations and von Neumann measurements are special cases of selective quantum operations. For any  $\mathcal{E}$ , one may always obtain a family of operators that represent  $\mathcal{E}$  with  $l \leq |Q|^2$  [37, Theorem 2.22], and therefore with  $l = |Q|^2$  (by defining any extraneous operators to be  $\mathbb{0}_{\mathbb{C}^Q}$ ). Let  $\text{QuantOp}(\mathbb{C}^Q, R)$  denote the set of all selective quantum operations specified by some  $\{E_{r,j} : r \in R, j \in \{1, \dots, |Q|^2\}\} \subseteq L(\mathbb{C}^Q)$ .

## 2.2 Definition of the 2QCFA Model

Next, we define two-way finite automata with quantum and classical states (2QCFA), essentially following the original definition of Ambainis and Watrous [2], with a few alterations that (potentially) make the model stronger. We wish to define the 2QCFA model to be as strong as possible so that our lower bounds against this model are as general as possible.

Informally, a 2QCFA is a two-way DFA that has been augmented with a quantum register of constant size; the machine may apply unitary transformations to the quantum register and perform (perhaps many) measurements of its quantum register during its computation. Formally, a 2QCFA is a 10-tuple,  $N = (Q, C, \Sigma, R, \theta, \delta, q_{\text{start}}, c_{\text{start}}, c_{\text{acc}}, c_{\text{rej}})$ , where  $Q$  is a finite set of quantum basis states,  $C$  is a finite set of classical states,  $\Sigma$  is a finite input alphabet,  $R$  is a finite set that specifies the possible results of selective quantum operations,  $\theta$  and  $\delta$  are the quantum and classical parts of the transition function,  $q_{\text{start}} \in Q$  is the quantum start state,  $c_{\text{start}} \in C$  is the classical start state, and  $c_{\text{acc}}, c_{\text{rej}} \in C$ , with  $c_{\text{acc}} \neq c_{\text{rej}}$ , specify the classical accept and reject states, respectively. We define  $\#_L, \#_R \notin \Sigma$ , with  $\#_L \neq \#_R$ , to be special symbols that serve as a left and right end-marker, respectively; we then define the tape alphabet  $\Sigma_+ = \Sigma \cup \{\#_L, \#_R\}$ . Let  $\hat{C} = C \setminus \{c_{\text{acc}}, c_{\text{rej}}\}$  denote the non-halting classical states. The components of the transition function are as follows:  $\theta : \hat{C} \times \Sigma_+ \rightarrow \text{QuantOp}(\mathbb{C}^Q, R)$  specifies the selective quantum operation that is to be performed on the quantum register and  $\delta : \hat{C} \times \Sigma_+ \times R \rightarrow C \times \{-1, 0, 1\}$  specifies how the classical state and (classical) head position evolve.

On an input  $w = w_1 \dots w_n \in \Sigma^*$ , with each  $w_i \in \Sigma$ , the 2QCFA  $N$  operates as follows. The machine has a read-only tape that contains the string  $\#_L w_1 \dots w_n \#_R$ . Initially, the classic state of  $N$  is  $c_{\text{start}}$ , the quantum register is in the superposition  $|q_{\text{start}}\rangle$ , and the head is at the left end of the tape, over the left end-marker  $\#_L$ . On each step of the computation, if the classic state is currently  $c \in \hat{C}$  and the head is over the symbol  $\sigma \in \Sigma_+$ ,  $N$  behaves as follows. First, the selective quantum operation  $\theta(c, \sigma)$  is performed on the quantum register producing some result  $r \in R$ . If the result was  $r$ , and  $\delta(c, \sigma, r) = (c', d)$ , where  $c' \in C$  and  $d \in \{-1, 0, 1\}$ , then the classical state becomes  $c'$  and the head moves left (resp. stays put, moves right) if  $d = -1$  (resp.  $d = 0, d = 1$ ).

Due to the fact that applying a selective quantum operation is a probabilistic process, the computation of  $N$  on an input  $w$  is probabilistic. We say that a 2QCFA  $N$  recognizes a language  $L$  with *two-sided bounded error*  $\epsilon$  if,  $\forall w \in L, \Pr[N \text{ accepts } w] \geq 1 - \epsilon$ , and,  $\forall w \notin L, \Pr[N \text{ accepts } w] \leq \epsilon$ . We then define  $\text{B2QCFA}(k, d, T(n), \epsilon)$  as the class of languages  $L$  for which there is a 2QCFA, with at most  $k$  quantum basis states and at most  $d$  classical states, that recognizes  $L$  with two-sided bounded error  $\epsilon$ , and has expected running time at most

$T(n)$  on all inputs of length at most  $n$ . In order to make our lower bound as strong as possible, we do *not* require  $N$  to halt with probability 1 on all  $w \in \Sigma^*$  (i.e., we permit  $N$  to reject an input by looping).

### 3 2QCFA Crossing Sequences

In this section, we develop a generalization of Hennie’s [18] notion of crossing sequences to 2QCFA, in which we make use of several ideas from the 2PFA results of Dwork and Stockmeyer [10] and Greenberg and Weiss [14]. This notion will play a key role in our proof of a lower bound on the expected running time of a 2QCFA.

When a 2QCFA  $N = (Q, C, \Sigma, R, \theta, \delta, q_{\text{start}}, c_{\text{start}}, c_{\text{acc}}, c_{\text{rej}})$  is run on an input  $w = w_1 \cdots w_n \in \Sigma^*$ , where each  $w_i \in \Sigma$ , the tape consists of  $\#_L w_1 \cdots w_n \#_R$ . One may describe the configuration of a *single probabilistic branch* of  $N$  at any particular point in time by a triple  $(A, c, h)$ , where  $A \in \text{Den}(\mathbb{C}^Q)$  describes the current state of the quantum register,  $c \in C$  is the current classical state, and  $h \in \{0, \dots, n+1\}$  is the current head position. To clarify, each step of the computation of  $N$  involves applying a selective quantum operation, which is a probabilistic process that produces a particular result  $r \in R$  with a certain probability (depending on the operation that is performed and the state of the quantum register); that is to say, the 2QCFA probabilistically branches, with a child for each  $r \in R$ .

We partition the input as  $w = xy$ , in some manner to be specified later. We then imagine running  $N$  beginning in the configuration  $(A, c, |x|)$ , where  $|x|$  denotes the length of the string  $x$  (i.e., the head is initially over the rightmost symbol of  $\#_L x$ ). We wish to describe the configuration (or, more accurately, ensemble of configurations) that  $N$  will be in when it “finishes computing” on the prefix  $\#_L x$ , either by “leaving” the string  $\#_L x$  (by moving its head right when over the rightmost symbol of  $\#_L x$ ), or by accepting or rejecting its input. Of course,  $N$  may leave  $\#_L x$ , then later reenter  $\#_L x$ , then later leave  $\#_L x$  again, and so on, which will naturally lead to our notion of a crossing sequence. Note that the string  $y$  does not affect this subcomputation as it occurs entirely within the prefix  $\#_L x$ .

More generally, we consider the case in which  $N$  is run on the prefix  $\#_L x$ , where  $N$  starts in some ensemble of configurations  $\{(p_i, (A_i, c_i, |x|)) : i \in I\}$ , where the probability of being in configuration  $(A_i, c_i, |x|)$  is given by  $p_i$  (note that the head position in each configuration is over the rightmost symbol of  $\#_L x$ ); we call this ensemble a *starting ensemble*. We then wish to describe the ensemble of configurations that  $N$  will be in when it “finishes computing” on the prefix  $\#_L x$ , (essentially) as defined above; we call this ensemble a *stopping ensemble*<sup>1</sup>. Much as it was the case that an ensemble of pure states of a quantum register can be described by a density operator, we may also describe an ensemble of configurations of a 2QCFA using density operators. This will greatly simplify our definition and analysis of the crossing sequence of a 2QCFA.

#### 3.1 Describing Ensembles of Configurations of 2QCFA

The 2QCFA  $N$  possesses both a constant-sized *quantum register*, that is described by some density operator at any particular point in time, and a constant-sized *classical register*, that stores a classical state  $c \in C$ . We can naturally interpret each  $c \in C$  as an element  $|c\rangle \in \mathbb{C}^C$ , of a special type; that is to say, each classical state  $c$  corresponds to some element  $|c\rangle$  in the

<sup>1</sup> We use the terms “starting ensemble” and “stopping ensemble” to make clear the similarity to the notion of a “starting condition” and of a “stopping condition” used by Dwork and Stockmeyer [10] in their 2PFA result.

natural orthonormal basis of  $\mathbb{C}^C$  (whereas each superposition  $|\psi\rangle$  of the quantum register corresponds to an element of  $\mathbb{C}^Q$  of norm 1). One may also view  $N$  as possessing a *head register* that stores a (classical) head position  $h \in H_x = \{0, \dots, |x| + 1\}$  (when computing on the prefix  $\#_L x$ ); of course, the size of this pseudo-register grows with the input prefix  $x$ . We analogously interpret a head position  $h \in H_x$  as being the “classical” element  $|h\rangle \in \mathbb{C}^{H_x}$ . A configuration  $(A, c, h) \in \text{Den}(\mathbb{C}^Q) \times C \times H_x$  is then simply a state of the *combined register*, which consists of the quantum, classical, and head registers.

We then consider an *ensemble of configurations*  $\{(p_i, (A_i, c_i, h_i)) : i \in I\}$ , where  $p_i$  denotes the probability of being in configuration  $(A_i, c_i, h_i)$ . We represent this ensemble (non-uniquely) by the density operator  $Z = \sum_i (p_i A_i \otimes |c_i\rangle\langle c_i| \otimes |h_i\rangle\langle h_i|) \in \text{Den}(\mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^{H_x})$ . Let  $\hat{i}(c, h) = \{i \in I : (c_i, h_i) = (c, h)\}$  denote the indices of those configurations in classical state  $c$  and with head position  $h$ . We then define  $p : C \times H_x \rightarrow [0, 1]$  such that  $p(c, h) = \sum_{i \in \hat{i}(c, h)} p_i$  is the total probability of being in classical state  $c$  and having head position  $h$ . We define  $A : C \times H_x \rightarrow \text{Den}(\mathbb{C}^Q)$  such that, if  $p(c, h) \neq 0$ , then  $A(c, h) = \sum_{i \in \hat{i}(c, h)} \frac{p_i}{p(c, h)} A_i$  is the density operator obtained by “merging” all density operators  $A_i$  that come from configurations  $(A_i, c_i, h_i)$  with classical state  $c_i = c$  and head position  $h_i = h$ ; if  $p(c, h) = 0$ , then we define  $A(c, h)$  arbitrarily. Then  $Z = \sum_{c, h} (p(c, h) A(c, h) \otimes |c\rangle\langle c| \otimes |h\rangle\langle h|)$ . Let  $\widehat{\text{Den}}(\mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^{H_x})$  denote the set of all density operators given by some  $Z$  of the above form (i.e., those density operators that respect the fact that both the classical state and head position are classical).

We also consider the case in which we are only interested in the states of the quantum and classical registers, but not the head position. We then analogously describe an ensemble  $\{(p_i, (A_i, c_i)) : i \in I\}$  by  $Z = \sum_i (p_i A_i \otimes |c_i\rangle\langle c_i|) \in \text{Den}(\mathbb{C}^Q \otimes \mathbb{C}^C)$ , and we define  $\widehat{\text{Den}}(\mathbb{C}^Q \otimes \mathbb{C}^C)$  to be the set of all such density operators. In a starting ensemble, all configurations have the same head position:  $|x|$ . We define  $I_x \in \text{T}(\mathbb{C}^Q \otimes \mathbb{C}^C, \mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^{H_x})$  such that  $I_x(Z) = Z \otimes |x\rangle\langle x|$ . Similarly, in a stopping ensemble, all configurations either have head position  $|x| + 1$  or are accepting or rejecting configurations (in which the head position is irrelevant). Let  $\text{Tr}_{\mathbb{C}^{H_x}} = \mathbb{1}_{\mathbb{C}^Q \otimes \mathbb{C}^C} \otimes \text{Tr} \in \text{T}(\mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^{H_x}, \mathbb{C}^Q \otimes \mathbb{C}^C)$  denote the *partial trace with respect to  $\mathbb{C}^{H_x}$* .

### 3.2 Definition and Properties of 2QCFA Crossing Sequences

We now formally define the notion of a crossing sequence of a 2QCFA and prove certain needed properties. We begin by establishing some notation.

► **Definition 3.** Consider a 2QCFA  $N = (Q, C, \Sigma, R, \theta, \delta, q_{\text{start}}, c_{\text{start}}, c_{\text{acc}}, c_{\text{rej}})$ . For  $c \in \widehat{C} = C \setminus \{c_{\text{acc}}, c_{\text{rej}}\}$ ,  $\sigma \in \Sigma_+ = \Sigma \sqcup \{\#_L, \#_R\}$ ,  $r \in R$ , and  $j \in J = \{1, \dots, |Q|^2\}$ , we make the following definitions.

- (i) Define  $E_{c, \sigma, r, j} \in \text{L}(\mathbb{C}^Q)$  such that  $\theta(c, \sigma) \in \text{QuantOp}(\mathbb{C}^Q, R)$  is described by  $\{E_{c, \sigma, r, j} : r \in R, j \in J\}$ .
- (ii) Define  $\Phi_{c, \sigma, r} \in \text{T}(\mathbb{C}^Q)$  such that  $\Phi_{c, \sigma, r}(A) = \sum_j E_{c, \sigma, r, j} A E_{c, \sigma, r, j}^\dagger$ ,  $\forall A \in \text{L}(\mathbb{C}^Q)$ .
- (iii) Let  $\gamma_{c, \sigma, r} \in C$  and  $d_{c, \sigma, r} \in \{-1, 0, 1\}$  denote, respectively, the new classical state and the motion of the head, if the result of applying  $\theta(c, \sigma)$  is  $r$ ; i.e.,  $\delta(c, \sigma, r) = (\gamma_{c, \sigma, r}, d_{c, \sigma, r})$ .

Consider some  $x \in \Sigma^*$ . Let  $\widehat{H}_x = \{0, \dots, |x|\}$  denote the head positions corresponding to the prefix  $\#_L x$ , and let  $H_x = \{0, \dots, |x| + 1\}$  denote the set of possible positions the head of  $N$  may be in until it “finishes computing” on the prefix  $\#_L x$ . We define an operator  $S_x \in \text{T}(\mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^{H_x})$  that describes a single step of the computation of  $N$  on  $\#_L x$ , as follows. If  $(c, h) \in \widehat{C} \times \widehat{H}_x$ , then  $S_x(A \otimes |c\rangle\langle c| \otimes |h\rangle\langle h|)$  describes the ensemble of configurations of  $N$  after running  $N$  for a single step beginning in the configuration  $(A, c, h)$ ;

otherwise (i.e., if  $c \in \{c_{\text{acc}}, c_{\text{rej}}\}$  or  $h = |x| + 1$ , which means  $N$  has “finished computing” on  $\#_L x$ )  $S_x$  leaves the configuration unchanged. We will observe that  $S_x$  correctly describes the behavior of  $N$  on an ensemble of configurations, and that  $S_x$  is a quantum channel.

► **Definition 4.** Using the notation of Definition 3, consider a 2QCFA  $N$  and a string  $x \in \Sigma^*$ . Let  $x_h \in \Sigma$  denote the symbol of  $x$  at position  $h$ , and let  $x_0 = \#_L$  denote the left end-marker.

(i) For  $(c, h, r, j) \in C \times H_x \times R \times J$ , define  $\tilde{E}_{x,c,h,r,j} \in L(\mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^{H_x})$  as follows.

$$\tilde{E}_{x,c,h,r,j} = \begin{cases} E_{c,x_h,r,j} \otimes |\gamma_{c,x_h,r}\rangle \langle c| \otimes |h + d_{c,x_h,r}\rangle \langle h|, & \text{if } (c, h) \in \hat{C} \times \hat{H} \\ \frac{1}{\sqrt{|R||J|}} \mathbb{1}_{\mathbb{C}^Q} \otimes |c\rangle \langle c| \otimes |h\rangle \langle h|, & \text{otherwise.} \end{cases}$$

(ii) Define  $S_x \in T(\mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^{H_x})$  such that

$$S_x(Z) = \sum_{(c,h,r,j) \in C \times H_x \times R \times J} \tilde{E}_{x,c,h,r,j} Z \tilde{E}_{x,c,h,r,j}^\dagger, \quad \forall Z \in L(\mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^{H_x}).$$

► **Lemma 5.** Using the above notation, consider some  $x \in \Sigma^*$  and  $(A, \hat{c}, \hat{h}) \in \text{Den}(\mathbb{C}^Q) \times \hat{C} \times \hat{H}_x$ . Let  $\hat{Z} = A \otimes |\hat{c}\rangle \langle \hat{c}| \otimes |\hat{h}\rangle \langle \hat{h}|$ .  $S_x(\hat{Z})$  describes the ensemble of configurations obtained after running  $N$  for one step, beginning in the configuration  $(A, \hat{c}, \hat{h})$ , on input prefix  $\#_L x$ .

**Proof.** Let  $\tilde{R}_{x,c,\hat{h},A} = \{r \in R : \text{Tr}(\Phi_{c,x_{\hat{h}},r}(A)) \neq 0\}$ . Note that  $A \in \text{Den}(\mathbb{C}^Q) \subseteq \text{Pos}(\mathbb{C}^Q)$ , which implies  $\Phi_{c,x_{\hat{h}},r}(A) \in \text{Pos}(\mathbb{C}^Q)$ ; therefore, we have  $\text{Tr}(\Phi_{c,x_{\hat{h}},r}(A)) = 0$  precisely when  $\Phi_{c,x_{\hat{h}},r}(A) = 0_{\mathbb{C}^Q}$ . After running  $N$  as described, it is in an ensemble of configurations

$$\left\{ \left( \text{Tr}(\Phi_{c,x_{\hat{h}},r}(A)), \left( \frac{1}{\text{Tr}(\Phi_{c,x_{\hat{h}},r}(A))} \Phi_{c,x_{\hat{h}},r}(A), \gamma_{c,x_{\hat{h}},r}, \hat{h} + d_{c,x_{\hat{h}},r} \right) \right) : r \in \tilde{R}_{x,c,\hat{h},A} \right\}.$$

This ensemble of configurations is described by the density operator  $\hat{Z}'$  given by

$$\begin{aligned} \hat{Z}' &= \sum_{r \in \tilde{R}_{x,c,\hat{h},A}} \left( \frac{\text{Tr}(\Phi_{c,x_{\hat{h}},r}(A))}{\text{Tr}(\Phi_{c,x_{\hat{h}},r}(A))} \Phi_{c,x_{\hat{h}},r}(A) \otimes |\gamma_{c,x_{\hat{h}},r}\rangle \langle \gamma_{c,x_{\hat{h}},r}| \otimes |\hat{h} + d_{c,x_{\hat{h}},r}\rangle \langle \hat{h} + d_{c,x_{\hat{h}},r}| \right) \\ &= \sum_{r \in R} \left( \Phi_{c,x_{\hat{h}},r}(A) \otimes |\gamma_{c,x_{\hat{h}},r}\rangle \langle \gamma_{c,x_{\hat{h}},r}| \otimes |\hat{h} + d_{c,x_{\hat{h}},r}\rangle \langle \hat{h} + d_{c,x_{\hat{h}},r}| \right). \end{aligned}$$

Let  $B_{x,c,\hat{h},r} = |\gamma_{c,x_{\hat{h}},r}\rangle \langle \gamma_{c,x_{\hat{h}},r}| \otimes |\hat{h} + d_{c,x_{\hat{h}},r}\rangle \langle \hat{h} + d_{c,x_{\hat{h}},r}|$ . If  $(c, h) \in \hat{C} \times \hat{H}_x$ , then

$$\begin{aligned} \tilde{E}_{x,c,h,r,j} \hat{Z} \tilde{E}_{x,c,h,r,j}^\dagger &= \tilde{E}_{x,c,h,r,j} (A \otimes |\hat{c}\rangle \langle \hat{c}| \otimes |\hat{h}\rangle \langle \hat{h}|) \tilde{E}_{x,c,h,r,j}^\dagger \\ &= E_{c,x_h,r,j} A E_{c,x_h,r,j}^\dagger \otimes |\gamma_{c,x_h,r}\rangle \langle c| \langle \hat{c}| \langle \gamma_{c,x_h,r}| \otimes |h + d_{c,x_h,r}\rangle \langle \hat{h}| \langle \hat{h}| \langle h + d_{c,x_h,r}| \\ &= \begin{cases} E_{c,x_{\hat{h}},r,j} A E_{c,x_{\hat{h}},r,j}^\dagger \otimes B_{x,c,\hat{h},r}, & \text{if } (c, h) = (\hat{c}, \hat{h}) \\ 0_{\mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^{H_x}}, & \text{otherwise.} \end{cases} \end{aligned}$$

If, instead,  $(c, h) \notin \hat{C} \times \hat{H}_x$ , then  $\tilde{E}_{x,c,h,r,j} \hat{Z} \tilde{E}_{x,c,h,r,j}^\dagger = 0_{\mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^{H_x}}$ . Therefore

$$\begin{aligned} S_x(\hat{Z}) &= \sum_{(r,j) \in R \times J} \sum_{(c,h) \in C \times H_x} \tilde{E}_{x,c,h,r,j} \hat{Z} \tilde{E}_{x,c,h,r,j}^\dagger = \sum_{(r,j) \in R \times J} \left( E_{c,x_{\hat{h}},r,j} A E_{c,x_{\hat{h}},r,j}^\dagger \otimes B_{x,c,\hat{h},r} \right) \\ &= \sum_{r \in R} \left( \left( \sum_{j \in J} E_{c,x_{\hat{h}},r,j} A E_{c,x_{\hat{h}},r,j}^\dagger \right) \otimes B_{x,c,\hat{h},r} \right) = \sum_{r \in R} \left( \Phi_{c,x_{\hat{h}},r}(A) \otimes B_{x,c,\hat{h},r} \right) = \hat{Z}'. \quad \blacktriangleleft \end{aligned}$$

► **Lemma 6.** Consider some  $x \in \Sigma^*$  and  $Z \in \widehat{\text{Den}}(\mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^{H_x})$ . If  $\{(p_i, (A_i, c_i, h_i)) : i \in I\}$  is some ensemble of configurations described by  $Z$ , then  $S_x(Z)$  describes the ensemble of configurations obtained by replacing each configuration with  $(c_i, h_i) \in (\widehat{C} \times \widehat{H}_x)$  by the ensemble (scaled by  $p_i$ ) of configurations obtained by running  $N$  for one step beginning in the configuration  $(A_i, c_i, h_i)$ , and leaving each configuration with  $(c_i, h_i) \notin (\widehat{C} \times \widehat{H}_x)$  unchanged.

**Proof.** This follows immediately from Lemma 5 and linearity. ◀

► **Lemma 7.**  $S_x \in \text{Chan}(\mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^{H_x})$ ,  $\forall x \in \Sigma^*$ .

**Proof.**  $\{\tilde{E}_{x,c,h,r,j} : (c, h, r, j) \in C \times H_x \times R \times J\}$  is a Kraus representation of  $S_x$ ; therefore,  $S_x \in \text{Chan}(\mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^{H_x}) \Leftrightarrow \sum_{c,h,r,j} \tilde{E}_{x,c,h,r,j}^\dagger \tilde{E}_{x,c,h,r,j} = \mathbb{1}$  [37, Corollary 2.27]. This latter statement follows from a straightforward calculation; see the full paper [26] for a proof. ◀

For  $m \in \mathbb{N}$ , we define the  $m$ -truncated stopping ensemble as the ensemble of configurations that  $N$  will be in when it “finishes computing” on  $\#_L x$ , as defined earlier, with the modification that if any particular branch of  $N$  runs for more than  $m$  steps, the computation of that branch will be “interrupted” immediately before it attempts to perform the  $m+1^{\text{st}}$  step and instead immediately reject. To be clear, this truncation occurs only in the *analysis* of  $N$ ; we do not modify the 2QCFA. The following truncation operator  $T_x$ , which terminates all branches on which  $N$  has not yet “finished computing,” will help us do this.

► **Definition 8.** For  $(c, h) \in (C, H_x)$ , let  $\hat{E}_{x,c,h} = \mathbb{1}_{\mathbb{C}^Q} \otimes |c'\rangle\langle c'| \otimes |h\rangle\langle h|$ , where  $c' = c_{\text{rej}}$  if  $(c, h) \in \widehat{C} \times \widehat{H}_x$ , and  $c' = c$  otherwise. We then define  $T_x \in \text{T}(\mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^{H_x})$  such that  $T_x(Z) = \sum_{(c,h) \in C \times H_x} \hat{E}_{x,c,h} Z \hat{E}_{x,c,h}^\dagger$ .

► **Lemma 9.** Using the above notation, the following statements hold.

- (i) For any  $Z \in \widehat{\text{Den}}(\mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^{H_x})$ , if  $\{(p_i, (A_i, c_i, h_i)) : i \in I\}$  is any ensemble of configurations described by  $Z$ , then  $T_x(Z)$  describes the ensemble of configurations in which each configuration with  $(c_i, h_i) \in \widehat{C} \times \widehat{H}_x$  is replaced by the configuration  $(A_i, c_{\text{rej}}, h_i)$  (i.e., all configurations in which  $N$  has not yet “finished computing” on  $\#_L x$  become rejecting configurations) and all other configurations are left unchanged.
- (ii)  $T_x \in \text{Chan}(\mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^{H_x})$ .

**Proof.**

- (i) Immediate from definitions.
- (ii) As in the proof of Lemma 7, we may straightforwardly show  $\sum_{c,h} \hat{E}_{x,c,h}^\dagger \hat{E}_{x,c,h} = \mathbb{1}_{\mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^{H_x}}$ , which implies  $T_x \in \text{Chan}(\mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^{H_x})$  [37, Corollary 2.27]. ◀

The following operator converts starting ensembles to  $m$ -truncated stopping ensembles.

► **Definition 10.** For  $x \in \Sigma^*$  and  $m \in \mathbb{N}$ , we define the  $m$ -truncated transfer operator  $N_{x,m}^\Leftarrow = \text{Tr}_{\mathbb{C}^{H_x}} \circ T_x \circ S_x^m \circ I_x \in \text{T}(\mathbb{C}^Q \otimes \mathbb{C}^C)$ . For  $y \in \Sigma^*$ , we next consider the “dual case” of running  $N$  on the suffix  $y\#_R$  beginning in some ensemble of configurations  $\{(p_i, (A_i, c_i, |x|+1)) : i \in I\}$  (i.e., the head position of every configuration is over the leftmost symbol of  $y\#_R$ ). We define the notion of an  $m$ -truncated stopping ensemble, and all other notions, symmetrically. That is to say, a branch of  $N$  “finishes computing” on  $y\#_R$  when it either “leaves”  $y\#_R$  (by moving its head left from the leftmost symbol of  $y\#_R$ ), or accepts or rejects the input, or runs for more than  $m$  steps. We then define  $N_{y,m}^\Leftarrow \in \text{T}(\mathbb{C}^Q \otimes \mathbb{C}^C)$  as the corresponding “dual”  $m$ -truncated transfer operator for  $y$ .

► **Lemma 11.** *Using the notation of Definition 10, the following statements hold.*

- (i) *For  $Z \in \widehat{\text{Den}}(\mathbb{C}^Q \otimes \mathbb{C}^C)$ , if  $N$  is run on  $\#_L x$  beginning in any ensemble of configurations described by  $I_x(Z)$  (i.e., the head position of every configuration is over the rightmost symbol of  $\#_L x$ ), then the  $m$ -truncated stopping ensemble is described by  $N_{x,m}^{\leftarrow}(Z)$ .*
- (ii) *For  $Z \in \widehat{\text{Den}}(\mathbb{C}^Q \otimes \mathbb{C}^C)$ , if  $N$  is run on  $y\#_R$  beginning in any ensemble of configurations described by  $I_{x+1}(Z)$ , then the  $m$ -truncated stopping ensemble is described by  $N_{y,m}^{\rightarrow}(Z)$ .*
- (iii) *We have  $N_{x,m}^{\leftarrow}, N_{y,m}^{\rightarrow} \in \text{Chan}(\mathbb{C}^Q \otimes \mathbb{C}^C)$ ,  $\forall x, y \in \Sigma^*, \forall m \in \mathbb{N}$ .*

**Proof.**

- (i) Immediate by Definition 10, Lemma 6, and Lemma 9(i).
- (ii) Immediate by Definition 10, and analogous versions of Lemma 6, and Lemma 9(i).
- (iii) By definition,  $N_{x,m}^{\leftarrow} = \text{Tr}_{\mathbb{C}^{H_x}} \circ T_x \circ S_x^m \circ I_x$ . By Lemma 7 and Lemma 9(ii), we have  $S_x, T_x \in \text{Chan}(\mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^{H_x})$ . It is straightforward to see that  $I_x \in \text{Chan}(\mathbb{C}^Q \otimes \mathbb{C}^C, \mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^{H_x})$  and  $\text{Tr}_{\mathbb{C}^{H_x}} \in \text{Chan}(\mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^{H_x}, \mathbb{C}^Q \otimes \mathbb{C}^C)$  and that the composition of quantum channels is a quantum channel (see, for instance, [37, Section 2.2]). The claim for  $N_{y,m}^{\rightarrow}$  follows by an analogous argument. ◀

Given a 2QCFA  $N$ , we produce an equivalent  $N'$  of a certain convenient form, in much the same way that Dwork and Stockmeyer [10] converted a 2PFA to a convenient form. The 2QCFA  $N'$  is identical to  $N$ , except for the addition of two new classical states,  $c'_{\text{start}}$  and  $c'$ , where  $c'_{\text{start}}$  will be the start state of  $N'$ . On any input,  $N'$  will move its head to the right until it reaches  $\#_R$ , performing the trivial transformation to its quantum register along the way. When it reaches  $\#_R$ ,  $N'$  will enter  $c'$ ; then,  $N'$  will move its head to the left until it reaches  $\#_L$ , again performing the trivial transformation to its quantum register. When it reaches  $\#_L$ ,  $N'$  will enter the original start state  $c_{\text{start}}$  and behave identically to  $N$  from this point. For the remainder of the paper, we assume all 2QCFA have this form.

Finally, we define the  $m$ -truncated crossing sequence.

► **Definition 12.** For  $x, y \in \Sigma^*$  and  $m \in \mathbb{N}$ , the  $m$ -truncated crossing sequence of  $N$  with respect to the (partitioned) input  $xy$  is the sequence  $Z_1, Z_2, \dots \in \widehat{\text{Den}}(\mathbb{C}^Q \otimes \mathbb{C}^C)$ , defined as follows. The density operator  $Z_1$  describes the ensemble consisting of the single configuration (of the quantum register and classical register)  $(|q_{\text{start}}\rangle, c_{\text{start}})$  that  $N$  is in when it first crosses from  $\#_L x$  into  $y\#_R$ , which is of this simple form due to the assumed form of  $N$ . The sequence  $Z_1, Z_2, \dots$  is then obtained by starting with  $Z_1$  and alternately applying  $N_{y,m}^{\rightarrow}$  and  $N_{x,m}^{\leftarrow}$ . To be precise,

$$Z_i = \begin{cases} |q_{\text{start}}\rangle \langle q_{\text{start}}| \otimes |c_{\text{start}}\rangle \langle c_{\text{start}}|, & i = 1 \\ N_{y,m}^{\rightarrow}(Z_{i-1}), & i > 1, i \text{ is even} \\ N_{x,m}^{\leftarrow}(Z_{i-1}), & i > 1, i \text{ is odd.} \end{cases}$$

► **Remark.** Note that the  $\{Z_i\}$  that comprise a crossing sequence do *not* describe the ensemble of configurations of  $N$  at particular points in time during its computation on the input  $xy$ ; instead,  $Z_i$  describes the ensemble of configurations of the set of all the probabilistic branches of  $N$  at the  $i^{\text{th}}$  time each branch crosses between  $\#_L x$  and  $y\#_R$ .

## 4 Lower Bounds on the Running Time of 2QCFA

Dwork and Stockmeyer proved a lower bound [10, Lemma 4.3] on the expected running time  $T(n)$  of any 2PFA that recognizes any language  $L$  with bounded error, in terms of their hardness measure  $D_L(n)$ . We prove that an analogous claim holds for any 2QCFA.

The preceding quantum generalization of a crossing sequence plays a key role in the proof, essentially taking the place of the Markov chains used both in the aforementioned result of Dwork and Stockmeyer and in the earlier result of Greenberg and Weiss [14], which showed that 2PFA cannot recognize  $L_{eq}$  in subexponential time.

## 4.1 Nonregularity

For a language  $L$ , Dwork and Stockmeyer [10] defined a particular “hardness measure”  $D_L : \mathbb{N} \rightarrow \mathbb{N}$ , which they called the *nonregularity* of  $L$ , as follows. Let  $\Sigma$  be a finite alphabet,  $L \subseteq \Sigma^*$  a language, and  $n \in \mathbb{N}$ . Let  $\Sigma^{\leq n} = \{w \in \Sigma^* : |w| \leq n\}$  denote the set of all strings over  $\Sigma$  of length at most  $n$  and consider some  $x, x' \in \Sigma^{\leq n}$ . We say that  $x$  and  $x'$  are  $(L, n)$ -dissimilar, which we denote by writing  $x \not\sim_{L,n} x'$ , if  $\exists y \in \Sigma^{\leq n - \max(|x|, |x'|)}$ , such that  $xy \in L \Leftrightarrow x'y \notin L$ . Recall the classic Myhill-Nerode inequivalence relation, in which  $x, x' \in \Sigma^*$  are  $L$ -dissimilar if  $\exists y \in \Sigma^*$ , such that  $xy \in L \Leftrightarrow x'y \notin L$ . Then  $x, x' \in \Sigma^{\leq n}$  are  $(L, n)$ -dissimilar precisely when they are  $L$ -dissimilar, and the dissimilarity is witnessed by a “short” string  $y$ . We then define  $D_L(n)$  to be the largest  $h \in \mathbb{N}$  such that  $\exists x_1, \dots, x_h \in \Sigma^{\leq n}$  that are pairwise  $(L, n)$ -dissimilar (i.e.,  $x_i \not\sim_{L,n} x_j$ ,  $\forall i, j$  with  $i \neq j$ ).

In fact,  $D_L$  has been defined by many authors, both before and after Dwork and Stockmeyer, who gave many different names to this quantity and who (repeatedly) rediscovered certain basic facts about it; we refer the reader to the excellent paper of Shallit and Breitbart [30] for a detailed history of the study of  $D_L$  and related hardness measures.

## 4.2 A 2QCFA Analogue of the Dwork-Stockmeyer Lemma

We now prove that an analogue of the Dwork-Stockmeyer lemma holds for 2QCFA. The main idea is as follows. Suppose the 2QCFA  $N$  recognizes  $L \subseteq \Sigma^*$ , with two-sided bounded error  $\epsilon$ , in expected time at most  $T(n)$ . We show that, if  $D_L(n)$  is “large,” then, for any  $m \in \mathbb{N}$ , we can find  $x, x' \in \Sigma^{\leq n}$  such that  $x \not\sim_{L,n} x'$  and the distance between the corresponding  $m$ -truncated transfer operators  $N_{x,m}^{\leftarrow}$  and  $N_{x',m}^{\leftarrow}$  is “small.” By definition,  $\exists y \in \Sigma^{\leq n - \max(|x|, |x'|)}$ , such that  $xy \in L \Leftrightarrow x'y \notin L$ ; note that  $xy, x'y \in \Sigma^{\leq n}$ . Without loss of generality, we assume  $xy \in L$ , and hence  $x'y \notin L$ . We also show that, for  $m$  sufficiently large, if the distance between  $N_{x,m}^{\leftarrow}$  and  $N_{x',m}^{\leftarrow}$  is “small,” then the behavior of  $N$  on the partitioned inputs  $xy$  and  $x'y$  will be similar; in particular, if  $T(n)$  is “small,” then  $\Pr[N \text{ accepts } xy] \approx \Pr[N \text{ accepts } x'y]$ . However, as  $xy \in L$ , we must have  $\Pr[N \text{ accepts } xy] \geq 1 - \epsilon$ , and as  $x'y \notin L$ , we must have  $\Pr[N \text{ accepts } x'y] \leq \epsilon$ , which is impossible. This contradiction allows us to establish a lower bound on  $T(n)$  in terms of  $D_L(n)$ . In this section, we formalize this idea.

Recall that the *trace norm*  $\|\cdot\|_1 : L(V) \rightarrow \mathbb{R}_{\geq 0}$  is given by  $\|Z\|_1 = \text{Tr}(\sqrt{Z^\dagger Z})$ ,  $\forall Z \in L(V)$ , and the *induced trace norm*  $\|\cdot\|_1 : T(V, V') \rightarrow \mathbb{R}_{\geq 0}$ , is given  $\|\Phi\|_1 = \sup\{\|\Phi(Z)\|_1 : Z \in L(V), \|Z\|_1 \leq 1\}$ ,  $\forall \Phi \in T(V, V')$ . Suppose  $N$  is run on two distinct partitioned inputs  $xy$  and  $x'y$ , producing two distinct  $m$ -truncated crossing sequences, following Definition 12. We first show that if  $\|N_{x,m}^{\leftarrow} - N_{x',m}^{\leftarrow}\|_1$  is “small,” then these crossing sequences are similar.

► **Lemma 13.** *Consider a 2QCFA  $N$  with quantum basis states  $Q$ , classical states  $C$ , and input alphabet  $\Sigma$ . For  $x, x', y \in \Sigma^*$  and  $m \in \mathbb{N}$ , let  $Z_1, Z_2, \dots \in \widehat{\text{Den}}(\mathbb{C}^Q \otimes \mathbb{C}^C)$  (resp.  $Z'_1, Z'_2, \dots \in \widehat{\text{Den}}(\mathbb{C}^Q \otimes \mathbb{C}^C)$ ) denote the  $m$ -truncated crossing sequence obtained when  $N$  is run on  $xy$  (resp.  $x'y$ ). Then  $\|Z_i - Z'_i\|_1 \leq \lfloor \frac{i-1}{2} \rfloor \|N_{x,m}^{\leftarrow} - N_{x',m}^{\leftarrow}\|_1$ ,  $\forall i \in \mathbb{N}_{\geq 1}$ .*

**Proof.** By definition,  $Z_1 = |q_{\text{start}}\rangle \langle q_{\text{start}}| \otimes |c_{\text{start}}\rangle \langle c_{\text{start}}| = Z'_1$ , and so  $\|Z_1 - Z'_1\|_1 = 0$ . Note that  $\|\Phi(Z)\|_1 \leq \|Z\|_1$ ,  $\forall Z \in L(\mathbb{C}^Q \otimes \mathbb{C}^C)$ ,  $\forall \Phi \in \text{Chan}(\mathbb{C}^Q \otimes \mathbb{C}^C)$  [37, Corollary 3.40]. Therefore, for any  $\Phi \in \text{Chan}(\mathbb{C}^Q \otimes \mathbb{C}^C)$  and any  $Z, Z' \in L(\mathbb{C}^Q \otimes \mathbb{C}^C)$ , we have

$\|\Phi(Z) - \Phi(Z')\|_1 = \|\Phi(Z - Z')\|_1 \leq \|Z - Z'\|_1$ . By Lemma 11(iii),  $N_{x,m}^{\leftarrow}, N_{x',m}^{\leftarrow}, N_{y,m}^{\rightarrow} \in \text{Chan}(\mathbb{C}^Q \otimes \mathbb{C}^C)$ . For  $i$  even,  $Z_i = N_{y,m}^{\rightarrow}(Z_{i-1})$  and  $Z'_i = N_{y,m}^{\rightarrow}(Z'_{i-1})$ . We then have

$$\|Z_i - Z'_i\|_1 = \|N_{y,m}^{\rightarrow}(Z_{i-1}) - N_{y,m}^{\rightarrow}(Z'_{i-1})\|_1 \leq \|Z_{i-1} - Z'_{i-1}\|_1.$$

For odd  $i > 1$ ,  $Z_i = N_{x,m}^{\leftarrow}(Z_{i-1})$  and  $Z'_i = N_{x',m}^{\leftarrow}(Z'_{i-1})$ . We have  $\|Z\|_1 = 1$ ,  $\forall Z \in \text{Den}(\mathbb{C}^Q \otimes \mathbb{C}^C)$ , which implies  $\|\Phi(Z)\|_1 \leq \|\Phi\|_1$ ,  $\forall \Phi \in \text{T}(\mathbb{C}^Q \otimes \mathbb{C}^C)$ . Therefore,

$$\begin{aligned} \|Z_i - Z'_i\|_1 &= \|N_{x,m}^{\leftarrow}(Z_{i-1}) - N_{x',m}^{\leftarrow}(Z'_{i-1})\|_1 \\ &\leq \|N_{x,m}^{\leftarrow}(Z_{i-1}) - N_{x,m}^{\leftarrow}(Z'_{i-1})\|_1 + \|N_{x,m}^{\leftarrow}(Z'_{i-1}) - N_{x',m}^{\leftarrow}(Z'_{i-1})\|_1 \\ &= \|N_{x,m}^{\leftarrow}(Z_{i-1} - Z'_{i-1})\|_1 + \|(N_{x,m}^{\leftarrow} - N_{x',m}^{\leftarrow})(Z'_{i-1})\|_1 \leq \|Z_{i-1} - Z'_{i-1}\|_1 + \|N_{x,m}^{\leftarrow} - N_{x',m}^{\leftarrow}\|_1 \end{aligned}$$

The claim then follows by induction on  $i \in \mathbb{N}_{\geq 1}$ .  $\blacktriangleleft$

► **Lemma 14.** *Consider a language  $L \subseteq \Sigma^*$ . Suppose  $L \in \text{B2QCFA}(k, d, T(n), \epsilon)$ , for some  $k, d \in \mathbb{N}_{\geq 2}$ ,  $T : \mathbb{N} \rightarrow \mathbb{N}$ , and  $\epsilon \in [0, \frac{1}{2}]$ . If, for some  $n \in \mathbb{N}$ ,  $\exists x, x' \in \Sigma^{\leq n}$  such that  $x \not\sim_{L,n} x'$ , then  $T(n) \geq \frac{(1-2\epsilon)^2}{2} \|N_{x,m}^{\leftarrow} - N_{x',m}^{\leftarrow}\|_1^{-1}$ ,  $\forall m \geq \lceil \frac{2}{1-2\epsilon} T(n) \rceil$ .*

**Proof.** By definition,  $x \not\sim_{L,n} x'$  precisely when  $\exists y \in \Sigma^*$  such that  $xy, x'y \in \Sigma^{\leq n}$ , and  $xy \in L \Leftrightarrow x'y \notin L$ . Fix such a  $y$ , and assume, without loss of generality, that  $xy \in L$  (and hence  $x'y \notin L$ ). For  $m \in \mathbb{N}$ , suppose that, when  $N$  is run on the partitioned input  $xy$  (resp.  $x'y$ ), we obtain the  $m$ -truncated crossing sequence  $Z_{m,1}, Z_{m,2}, \dots \in \widehat{\text{Den}}(\mathbb{C}^Q \otimes \mathbb{C}^C)$  (resp.  $Z'_{m,1}, Z'_{m,2}, \dots \in \widehat{\text{Den}}(\mathbb{C}^Q \otimes \mathbb{C}^C)$ ). For  $c \in C$ , let  $E_c = \mathbb{1}_{\mathbb{C}^Q} \otimes |c\rangle\langle c| \in \text{L}(\mathbb{C}^Q \otimes \mathbb{C}^C)$ . For  $s \in \mathbb{N}_{\geq 1}$ , define  $p_{m,s}, p'_{m,s} : C \rightarrow [0, 1]$  such that  $p_{m,s}(c) = \text{Tr}(E_c Z_{m,s} E_c^\dagger)$  and  $p'_{m,s}(c) = \text{Tr}(E_c Z'_{m,s} E_c^\dagger)$ . Then, for any  $c \in C$ , Lemma 13 implies

$$\begin{aligned} |p_{m,s}(c) - p'_{m,s}(c)| &= |\text{Tr}(E_c Z_{m,s} E_c^\dagger) - \text{Tr}(E_c Z'_{m,s} E_c^\dagger)| = |\text{Tr}(E_c (Z_{m,s} - Z'_{m,s}) E_c^\dagger)| \\ &\leq \|Z_{m,s} - Z'_{m,s}\|_1 \leq \frac{s-1}{2} \|N_{x,m}^{\leftarrow} - N_{x',m}^{\leftarrow}\|_1. \end{aligned}$$

Notice that  $p_{m,s}(c_{\text{acc}})$  (resp.  $p'_{m,s}(c_{\text{acc}})$ ) is the probability that  $N$  accepts  $xy$  (resp.  $x'y$ ) within the first  $s$  times (on a given branch of the computation) the head of  $N$  crosses the boundary between  $x$  (resp.  $x'$ ) and  $y$ , where any branch that runs for more than  $m$  steps between consecutive boundary crossings is forced to halt and reject immediately before attempting to perform the  $m+1^{\text{st}}$  such step. Let  $p_N(w)$  denote the probability that  $N$  accepts an input  $w \in \Sigma^*$ , let  $p_N(w, s)$  denote the probability that  $N$  accepts  $w$  within  $s$  steps, and let  $h_N(w, s)$  denote the probability that  $N$  halts on input  $w$  within  $s$  steps.

Note that  $x'y \notin L$  implies  $p_N(x'y) \leq \epsilon$ . Clearly,  $p'_{m,s}(c_{\text{acc}}) \leq p_N(x'y)$ , for any  $m$  and  $s$ , as all branches that attempt to perform more than  $m$  steps (between consecutive crossings) are considered to reject the input in the  $m$ -truncated crossing sequence. Suppose  $s \leq m$ . Any branch that runs for a total of at most  $s$  steps before halting is unaffected by  $m$ -truncation. Moreover, if a branch accepts within  $s$  steps, it will certainly accept within  $s$  crossings between  $\#_L x$  and  $y \#_R$ . This implies  $p_N(xy, s) \leq p_{m,s}(c_{\text{acc}})$ . Therefore, if  $s \leq m$ ,

$$p_N(xy, s) \leq p_{m,s}(c_{\text{acc}}) \leq p'_{m,s}(c_{\text{acc}}) + |p_{m,s}(c_{\text{acc}}) - p'_{m,s}(c_{\text{acc}})| \leq \epsilon + \frac{s-1}{2} \|N_{x,m}^{\leftarrow} - N_{x',m}^{\leftarrow}\|_1.$$

The expected running time of  $N$  on input  $xy$  is at most  $T(|xy|)$ . By Markov's inequality,  $1 - h_N(xy, s) \leq \frac{T(|xy|)}{s}$ . Note that  $xy \in L$  implies  $p_N(xy) \geq 1 - \epsilon$ . Thus, for any  $m \geq s \geq 1$ ,

$$1 - \epsilon \leq p_N(xy) \leq p_N(xy, s) + (1 - h_N(xy, s)) \leq \epsilon + \frac{s-1}{2} \|N_{x,m}^{\leftarrow} - N_{x',m}^{\leftarrow}\|_1 + \frac{T(|xy|)}{s}.$$

Set  $s = \lceil \frac{2}{1-2\epsilon} T(n) \rceil$ , and notice that  $|xy| \leq n$  implies  $T(|xy|) \leq T(n)$ . For any  $m \geq s$ ,

$$1-2\epsilon \leq \frac{\lceil \frac{2}{1-2\epsilon} T(n) \rceil - 1}{2} \|N_{x,m}^{\leftarrow} - N_{x',m}^{\leftarrow}\|_1 + \frac{T(|xy|)}{\lceil \frac{2}{1-2\epsilon} T(n) \rceil} \leq \frac{T(n)}{1-2\epsilon} \|N_{x,m}^{\leftarrow} - N_{x',m}^{\leftarrow}\|_1 + \frac{1-2\epsilon}{2}.$$

Therefore,  $T(n) \geq \frac{(1-2\epsilon)^2}{2} \|N_{x,m}^{\leftarrow} - N_{x',m}^{\leftarrow}\|_1^{-1}$ ,  $\forall m \geq \left\lceil \frac{2}{1-2\epsilon} T(n) \right\rceil$ .  $\blacktriangleleft$

**► Lemma 15.** *Consider a 2QCF A  $N = (Q, C, \Sigma, R, \theta, \delta, q_{start}, c_{start}, c_{acc}, c_{rej})$ . Let  $k = |Q|$  and  $d = |C|$ . Consider any finite  $X \subseteq \Sigma^*$  such that  $|X| \geq 2$ . Then  $\forall m \in \mathbb{N}$ ,  $\exists x, x' \in X$  such that  $x \neq x'$  and  $\|N_{x,m}^{\leftarrow} - N_{x',m}^{\leftarrow}\|_1 \leq 4\sqrt{2}k^4d^2 \left(|X|^{\frac{1}{k^4d^2}} - 1\right)^{-1}$ .*

**Proof.** For  $q, q' \in Q$  and  $c, c' \in C$ , let  $F_{q,q',c,c'} = |q\rangle\langle q'| \otimes |c\rangle\langle c'| \in L(\mathbb{C}^Q \otimes \mathbb{C}^C)$ . Let  $J : T(\mathbb{C}^Q \otimes \mathbb{C}^C) \rightarrow L(\mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^Q \otimes \mathbb{C}^C)$  denote the *Choi isomorphism*, which is given by  $J(\Phi) = \sum_{(q,q',c,c') \in Q^2 \times C^2} F_{q,q',c,c'} \otimes \Phi(F_{q,q',c,c'})$ ,  $\forall \Phi \in T(\mathbb{C}^Q \otimes \mathbb{C}^C)$ . Consider any  $x \in \Sigma^*$  and  $m \in \mathbb{N}$ . We first show that, if  $(c_1, c_2) \neq (c'_1, c'_2)$ , then  $\langle q_2 c_2 | N_{x,m}^{\leftarrow}(F_{q_1, q'_1, c_1, c'_1}) | q'_2 c'_2 \rangle = 0$ . To see this, recall that, by Definition 10,  $N_{x,m}^{\leftarrow} = \text{Tr}_{\mathbb{C}^{H_x}} \circ T_x \circ S_x^m \circ I_x$ . If  $c_1 \neq c'_1$ , then  $N_{x,m}^{\leftarrow}(F_{q_1, q'_1, c_1, c'_1}) = 0_{\mathbb{C}^Q \otimes \mathbb{C}^C}$ , which implies  $\langle q_2 c_2 | N_{x,m}^{\leftarrow}(F_{q_1, q'_1, c_1, c'_1}) | q'_2 c'_2 \rangle = 0$ . If  $c_2 \neq c'_2$ , then  $\forall Z \in L(\mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^{H_x})$ ,  $\langle q_2 c_2 | \text{Tr}_{\mathbb{C}^{H_x}}(T_x(Z)) | q'_2 c'_2 \rangle = 0$ , which implies  $\langle q_2 c_2 | N_{x,m}^{\leftarrow}(F_{q_1, q'_1, c_1, c'_1}) | q'_2 c'_2 \rangle = 0$ .

Therefore,  $\langle q_2 c_2 | N_{x,m}^{\leftarrow}(F_{q_1, q'_1, c_1, c'_1}) | q'_2 c'_2 \rangle$  is only potentially non-zero at the  $k^4d^2$  elements where  $(c_1, c_2) = (c'_1, c'_2)$ . By Lemma 11(iii),  $N_{x,m}^{\leftarrow} \in \text{Chan}(\mathbb{C}^Q \otimes \mathbb{C}^C)$ , which implies  $J(N_{x,m}^{\leftarrow}) \in \text{Pos}(\mathbb{C}^Q \otimes \mathbb{C}^C \otimes \mathbb{C}^Q \otimes \mathbb{C}^C)$  [37, Corollary 2.27]. Therefore, the elements where  $(q_1, q_2) \neq (q'_1, q'_2)$  come in conjugate pairs, and the elements with  $(q_1, q_2) = (q'_1, q'_2)$  are real. We define the function  $g_{N,m} : \Sigma^* \rightarrow \mathbb{R}^{k^4d^2}$  such that  $g_{N,m}(x)$  encodes all the potentially non-zero  $\langle q_2 c_2 | N_{x,m}^{\leftarrow}(F_{q_1, q'_1, c_1, c'_1}) | q'_2 c'_2 \rangle$ , without redundancy (only encoding one element of a conjugate pair). To be precise, the first  $k^2d^2$  entries of  $g_{N,m}(x)$  are given by  $\{\langle q_2 c_2 | N_{x,m}^{\leftarrow}(F_{q_1, q_1, c_1, c_1}) | q_2 c_2 \rangle : q_1, q_2 \in Q, c_1, c_2 \in C\} \subseteq \mathbb{R}$ . Establish some total order  $\geq$  on  $Q$ , and let  $\widehat{Q}^4 = \{(q_1, q'_1, q_2, q'_2) \in Q^4 : q'_1 > q_1 \text{ or } (q'_1 = q_1 \text{ and } q'_2 > q_2)\}$ . The remaining  $k^4d^2 - k^2d^2$  entries are given by encoding each of the  $\frac{1}{2}(k^4d^2 - k^2d^2)$  potentially non-zero entries  $\{\langle q_2 c_2 | N_{x,m}^{\leftarrow}(F_{q_1, q'_1, c_1, c_1}) | q'_2 c_2 \rangle : (q_1, q'_1, q_2, q'_2) \in \widehat{Q}^4, c_1, c_2 \in C\} \subseteq \mathbb{C}$  as the pair of real numbers that comprise their real and imaginary parts.

Let  $h = k^4d^2$ . Let  $\|\cdot\| : \mathbb{R}^h \rightarrow \mathbb{R}_{\geq 0}$  denote the Euclidean 2-norm and  $\|\cdot\|_2 : L(V) \rightarrow \mathbb{R}_{\geq 0}$  denote the Schatten 2-norm. Note that  $\|\Phi\|_1 \leq \|J(\Phi)\|_1$ ,  $\forall \Phi$  [37, Section 3.4]. We have,

$$\begin{aligned} \|N_{x,m}^{\leftarrow} - N_{x',m}^{\leftarrow}\|_1 &\leq \|J(N_{x,m}^{\leftarrow} - N_{x',m}^{\leftarrow})\|_1 \leq \sqrt{\text{rank}(J(N_{x,m}^{\leftarrow} - N_{x',m}^{\leftarrow}))} \|J(N_{x,m}^{\leftarrow} - N_{x',m}^{\leftarrow})\|_2 \\ &\leq \sqrt{h} \|J(N_{x,m}^{\leftarrow}) - J(N_{x',m}^{\leftarrow})\|_2 \leq \sqrt{2h} \|g_{N,m}(x) - g_{N,m}(x')\|. \end{aligned}$$

Note that  $N_{x,m}^{\leftarrow} \in \text{Chan}(\mathbb{C}^Q \otimes \mathbb{C}^C)$ , which implies  $\|N_{x,m}^{\leftarrow}\|_1 = 1$  [37, Corollary 3.40]. Then,  $\forall q, q' \in Q, \forall c \in C$ , we have  $\|F_{q,q',c,c}\|_1 = 1$ , which implies  $\|N_{x,m}^{\leftarrow}(F_{q,q',c,c})\|_1 \leq 1$ . Therefore,

$$\|g_{N,m}(x)\| \leq \|J(N_{x,m}^{\leftarrow})\|_2 \leq \|J(N_{x,m}^{\leftarrow})\|_1 \leq \sum_{q,q' \in Q, c \in C} \|N_{x,m}^{\leftarrow}(F_{q,q',c,c})\|_1 \leq k^2d = \sqrt{h}.$$

For  $v_0 \in \mathbb{R}^h$  and  $r \in \mathbb{R}_{>0}$ , let  $B(v_0, r) = \{v \in \mathbb{R}^h : \|v_0 - v\| \leq r\}$  denote the closed ball centered at  $v_0$  of radius  $r$  in  $\mathbb{R}^h$ , which has volume  $\text{vol}(B(v_0, r)) = c_h r^h$ , for some constant  $c_h \in \mathbb{R}_{>0}$ . By the above,  $\|g_{N,m}(x)\| \leq \sqrt{h}$ , which implies that  $B(g_{N,m}(x), \delta) \subseteq B(0, \sqrt{h} + \delta)$ ,  $\forall \delta \in \mathbb{R}_{>0}$ . Suppose  $\forall x, x' \in X$  with  $x \neq x'$ , we have  $B(g_{N,m}(x), \delta) \cap B(g_{N,m}(x'), \delta) = \emptyset$ .

Then  $\sqcup_{x \in X} B(g_{N,m}(x), \delta) \subseteq B(0, \sqrt{h} + \delta)$ , which implies  $|X|c_h\delta^h \leq c_h(\sqrt{h} + \delta)^h$ . Set  $\delta = \frac{2\sqrt{h}}{|X|^{1/h} - 1}$ . Then  $\exists x, x' \in X$ , with  $x \neq x'$ , such that  $B(g_{N,m}(x), \delta) \cap B(g_{N,m}(x'), \delta) \neq \emptyset$ , which implies  $\|g_{N,m}(x) - g_{N,m}(x')\| \leq 2\delta$ . Therefore,

$$\|N_{x,m}^{\leftarrow} - N_{x',m}^{\leftarrow}\|_1 \leq \sqrt{2h}\|g_{N,m}(x) - g_{N,m}(x')\| \leq \sqrt{2h}2\delta \leq 4\sqrt{2}k^4d^2 \left(|X|^{\frac{1}{k^4d^2}} - 1\right)^{-1}. \blacktriangleleft$$

We now prove a 2QCFA analogue of the Dwork-Stockmeyer lemma.

► **Theorem 16.** *If  $L \in \text{B2QCFA}(k, d, T(n), \epsilon)$ , for some  $k, d \in \mathbb{N}_{\geq 2}$ ,  $T : \mathbb{N} \rightarrow \mathbb{N}$ , and  $\epsilon \in [0, \frac{1}{2})$ , then  $\exists N_0 \in \mathbb{N}$  such that  $T(n) \geq \frac{(1-2\epsilon)^2}{16\sqrt{2}k^4d^2} D_L(n)^{\frac{1}{k^4d^2}}$ ,  $\forall n \geq N_0$ .*

**Proof.** Consider some  $L \subseteq \Sigma^*$ . By [10, Lemma 3.1],  $L \in \text{REG} \Leftrightarrow \exists b \in \mathbb{N}_{\geq 1}$  such that  $D_L(n) \leq b$ ,  $\forall n \in \mathbb{N}$ . Thus, if  $L \in \text{REG}$ , the claim is immediate (recall that  $T(n) \geq n$ ). Next, suppose  $L \notin \text{REG}$ . For  $n \in \mathbb{N}$ , define  $X_n = \{x_1, \dots, x_{D_L(n)}\} \subseteq \Sigma^{\leq n}$  such that the  $x_i$  are pairwise  $(L, n)$ -dissimilar. As  $D_L(n)$  is not bounded above by any constant,  $\exists N_0 \in \mathbb{N}$  such that  $D_L(N_0) \geq 2^{k^4d^2}$ . Then,  $\forall n \geq N_0$ , we have  $|X_n| = D_L(n) \geq D_L(N_0) \geq 2^{k^4d^2}$ . Fix  $n \geq N_0$  and set  $m = \lceil \frac{1-2\epsilon}{2} T(n) \rceil$ . By Lemma 15,  $\exists x, x' \in X_n$  such that  $x \neq x'$  and

$$\|N_{x,m}^{\leftarrow} - N_{x',m}^{\leftarrow}\|_1 \leq 4\sqrt{2}k^4d^2 \left(|X_n|^{\frac{1}{k^4d^2}} - 1\right)^{-1} \leq 8\sqrt{2}k^4d^2 |X_n|^{-\frac{1}{k^4d^2}} = 8\sqrt{2}k^4d^2 D_L(n)^{-\frac{1}{k^4d^2}}.$$

Fix such a pair  $x, x'$ , and note that  $x \not\sim_{L,n} x'$ , by construction. By Lemma 14,

$$T(n) \geq \frac{(1-2\epsilon)^2}{2} \|N_{x,m}^{\leftarrow} - N_{x',m}^{\leftarrow}\|_1^{-1} \geq \frac{(1-2\epsilon)^2}{16\sqrt{2}k^4d^2} D_L(n)^{\frac{1}{k^4d^2}}. \blacktriangleleft$$

### 4.3 2QCFA Running Time Lower Bounds and Complexity Class Separations

Let  $\text{B2QCFA}(T(n)) = \cup_{k,d \in \mathbb{N}_{\geq 2}, \epsilon \in [0, \frac{1}{2})} \text{B2QCFA}(k, d, T(n), \epsilon)$  denote the class of languages recognizable with two-sided bounded error by a 2QCFA with any constant number of quantum and classical states, in expected time at most  $T(n)$ . For a family  $\mathcal{T}$  of functions of the form  $T : \mathbb{N} \rightarrow \mathbb{N}$ , let  $\text{B2QCFA}(\mathcal{T}) = \cup_{T \in \mathcal{T}} \text{B2QCFA}(T(n))$ . We then write, for example,  $\text{B2QCFA}(2^{o(n)})$  to denote the union, taken over every function  $T : \mathbb{N} \rightarrow \mathbb{N}$  such that  $T(n) = 2^{o(n)}$ , of  $\text{B2QCFA}(T(n))$ . Let  $C_L : \mathbb{N} \rightarrow \mathbb{N}$  denote the *one-way deterministic communication complexity* of testing membership in  $L$ ; note that  $C_L(n) = \log D_L(n)$ ,  $\forall n$  [8]. We immediately obtain the following corollaries of Theorem 16.

► **Corollary 17.** *If  $L \in \text{B2QCFA}(T(n))$ , then  $D_L(n) = T(n)^{O(1)}$  and  $C_L(n) = O(\log T(n))$ .*

► **Corollary 18.** *If a language  $L$  satisfies  $D_L(n) = 2^{\Omega(n)}$ , then  $L \notin \text{B2QCFA}(2^{o(n)})$ .*

Notice that  $D_L(n) = 2^{O(n)}$ , for any  $L$ . We next exhibit a language for which  $D_L(n) = 2^{\Omega(n)}$ , thereby yielding a strong lower bound on the running time of any 2QCFA that recognizes  $L$ . For  $w = w_1 \dots w_n \in \Sigma^*$ , let  $w^{\text{rev}} = w_n \dots w_1$  denote the reversal of the string  $w$ . Let  $L_{\text{pal}} = \{w \in \{a, b\}^* : w = w^{\text{rev}}\}$  consist of all palindromes over the alphabet  $\{a, b\}$ .

► **Corollary 19.**  $L_{\text{pal}} \notin \text{B2QCFA}(2^{o(n)})$ .

**Proof.** For  $n \in \mathbb{N}$ , let  $W_n = \{w \in \{a, b\}^* : |w| = n\}$  denote all words over the alphabet  $\{a, b\}$  of length  $n$ . For any  $w, w' \in W_n$ , with  $w \neq w'$ , we have  $|ww^{\text{rev}}| = 2n = |w'w^{\text{rev}}|$ ,  $ww^{\text{rev}} \in L_{\text{pal}}$ , and  $w'w^{\text{rev}} \notin L_{\text{pal}}$ ; therefore,  $w \not\sim_{L_{\text{pal}}, 2n} w'$ ,  $\forall w, w' \in W_n$  such that  $w \neq w'$ . This implies that  $D_{L_{\text{pal}}}(2n) \geq |W_n| = 2^n$ . Corollary 18 then implies  $L_{\text{pal}} \notin \text{B2QCFA}(T(n))$ . ◀

We define  $\text{BQE2QCFA} = \text{B2QCFA}(2^{O(n)})$  to be the class of languages recognizable with two-sided bounded error in expected exponential time (with linear exponent) by a 2QCFA. Next, we say that a 2QCFA  $N$  recognizes a language  $L$  with *negative one-sided bounded error*  $\epsilon \in \mathbb{R}_{>0}$  if,  $\forall w \in L$ ,  $\Pr[N \text{ accepts } w] = 1$ , and,  $\forall w \notin L$ ,  $\Pr[N \text{ accepts } w] \leq \epsilon$ . We define  $\text{coR2QCFA}(k, d, T(n), \epsilon)$  as the class of languages recognizable with negative one-sided bounded error  $\epsilon$  by a 2QCFA, with at most  $k$  quantum basis states and at most  $d$  classical states, that has expected running time at most  $T(n)$  on all inputs of length at most  $n$ . We define  $\text{coR2QCFA}(T(n))$  and  $\text{coRQE2QCFA}$  analogously to the two-sided bounded error case.

Ambainis and Watrous [2] showed that  $L_{\text{pal}} \in \text{coRQE2QCFA}$ ; in fact, their 2QCFA recognizer for  $L_{\text{pal}}$  has only a single-qubit. Clearly,  $\text{coR2QCFA}(T(n)) \subseteq \text{B2QCFA}(T(n))$ , for any  $T$ , and  $\text{coRQE2QCFA} \subseteq \text{BQE2QCFA}$ . Therefore, the class of languages recognizable by a 2QCFA with bounded error in *subexponential* time is properly contained in the class of languages recognizable by a 2QCFA in *exponential* time.

► **Corollary 20.**  $\text{B2QCFA}(2^{o(n)}) \subsetneq \text{BQE2QCFA}$  and  $\text{coR2QCFA}(2^{o(n)}) \subsetneq \text{coRQE2QCFA}$ .

We next define  $\text{BQP2QCFA} = \text{B2QCFA}(n^{O(1)})$  to be the class of languages recognizable with two-sided bounded error in expected polynomial time by a 2QCFA. See the full version [26] for a proof of the following corollary.

► **Corollary 21.** If  $L \in \text{BQP2QCFA}$ , then  $D_L(n) = n^{O(1)}$ . Therefore,  $\text{BQP2QCFA} \subseteq L/\text{poly}$ .

Of course, there are many languages  $L$  for which one can establish a strong lower bound on  $D_L(n)$ , and thereby establish a strong lower bound on the expected running time  $T(n)$  of any 2QCFA that recognizes  $L$ . In Section 6, we consider the case in which  $L$  is the word problem of a group, and we show that very strong lower bounds can be established on  $D_L(n)$ . In the current section, we consider two especially interesting languages; the relevance of these languages was brought to our attention by Richard Lipton (personal communication). For  $p \in \mathbb{N}$ , let  $\langle p \rangle_2 \in \{0, 1\}^*$  denote its binary representation; let  $L_{\text{primes}} = \{\langle p \rangle_2 : p \text{ is prime}\}$ . Note that  $D_{L_{\text{primes}}}(n) = 2^{\Omega(n)}$  [29], which immediately implies the following.

► **Corollary 22.**  $L_{\text{primes}} \notin \text{B2QCFA}(2^{o(n)})$ .

Say a string  $w = w_1 \cdots w_n \in \{0, 1\}^n$  has a length-3 arithmetic progression (3AP) if  $\exists i, j, k \in \mathbb{N}$  such that  $1 \leq i < j < k \leq n$ ,  $j - i = k - j$ , and  $w_i = w_j = w_k = 1$ ; let  $L_{3\text{ap}} = \{w \in \{0, 1\}^* : w \text{ has a 3AP}\}$ . It is straightforward to show the lower bound  $D_{L_{3\text{ap}}}(n) = 2^{n^{1-o(1)}}$ , as well as the upper bound  $D_{L_{3\text{ap}}}(n) = 2^{n^{o(n)}}$ . Therefore, one obtains the following lower bound on the running time of a 2QCFA that recognizes  $L_{3\text{ap}}$ , which, while still quite strong, is not as strong as that of  $L_{\text{pal}}$  or  $L_{\text{primes}}$ .

► **Corollary 23.**  $L_{3\text{ap}} \notin \text{B2QCFA}(2^{n^{1-\Omega(1)}})$ .

► **Remark.** While  $L_{\text{primes}}$  and  $L_{3\text{ap}}$  provide two more examples of natural languages for which our method yields strong lower bound on the running time of any 2QCFA recognizer, they also suggest the potential of proving a stronger lower bound for certain languages. That is to say, for  $L_{\text{pal}}$ , one has (essentially) matching lower and upper bounds on the running time of any 2QCFA recognizer; this is certainly not the case for  $L_{\text{primes}}$  and  $L_{3\text{ap}}$ . In fact, we currently do not know if either  $L_{\text{primes}}$  or  $L_{3\text{ap}}$  can be recognized by a 2QCFA with bounded error *at all* (i.e., regardless of time bound).

#### 4.4 Transition Amplitudes of 2QCFA

As in Definition 3, for some 2QCFA  $N = (Q, C, \Sigma, R, \theta, \delta, q_{\text{start}}, c_{\text{start}}, c_{\text{acc}}, c_{\text{rej}})$ , let  $\{E_{c,\sigma,r,j} : r \in R, j \in J\} \subseteq L(\mathbb{C}^Q)$  denote the set of operators that describe the selective quantum operation  $\theta(c, \sigma) \in \text{QuantOp}(\mathbb{C}^Q, R)$  that is applied to the quantum register when the classical state of  $N$  is  $c \in \hat{C}$  and the head of  $N$  is over the symbol  $\sigma \in \Sigma_+$ . The *transition amplitudes* of  $N$  are the set of numbers  $\{\langle q | E_{c,\sigma,r,j} | q' \rangle : c \in \hat{C}, \sigma \in \Sigma_+, r \in R, j \in J, q, q' \in Q\} \subseteq \mathbb{C}$ .

While other types of finite automata are often defined without any restriction on their transition amplitudes, for 2QCFA, and other types of QFA, the allowed class of transition amplitudes strongly affects the power of the model. For example, using non-computable transition amplitudes, a 2QCFA can recognize certain undecidable languages with bounded error in expected polynomial time [28]. Our lower bound holds even in this setting of unrestricted transition amplitudes. For  $\mathbb{F} \subseteq \mathbb{C}$ , we define complexity classes  $\text{coR2QCFA}_{\mathbb{F}}(k, d, T(n), \epsilon)$ ,  $\text{coRQE2QCFA}_{\mathbb{F}}$ , etc., that are variants of the corresponding complexity class in which the 2QCFA are restricted to have transition amplitudes in  $\mathbb{F}$ . Using our terminology, Ambainis and Watrous [2] showed that  $L_{\text{pal}} \in \text{coRQE2QCFA}_{\overline{\mathbb{Q}}}$ , where  $\overline{\mathbb{Q}}$  denotes the algebraic numbers, which are, arguably, the natural choice for the permitted class of transition amplitudes of a quantum model of computation. Therefore,  $L_{\text{pal}}$  can be recognized with negative one-sided bounded error by a single-qubit 2QCFA with transition amplitudes that are all algebraic numbers in expected exponential time; however,  $L_{\text{pal}}$  cannot be recognized with two-sided bounded error (and, therefore, not with one-sided bounded error) by a 2QCFA (of any constant size) in subexponential time, regardless of the permitted transition amplitudes.

### 5 Lower Bounds on the Running Time of Small-Space QTM

We next show that our technique also yields a lower bound on the expected running time of a quantum Turing machine (QTM) that uses sublogarithmic space (i.e.,  $o(\log n)$  space). The key idea is that a QTM  $M$  that uses  $S(n)$  space can be viewed as a sequence  $(M_n)_{n \in \mathbb{N}}$  of 2QCFA, where  $M_n$  has  $2^{O(S(n))}$  (classical and quantum) states and  $M_n$  simulates  $M$  on all inputs of length at most  $n$  (therefore,  $M_n$  and  $M$  have the same probability of acceptance and the same expected running time on any such input). The techniques of the previous section apply to 2QCFA with a sufficiently slowly growing number of states.

We consider the *classically controlled* space-bounded QTM model that allows *intermediate measurements*, following the definition of Watrous [35]. While several such QTM models have been defined, we focus on this model as we wish to prove our lower bound in the greatest generality possible. We note that the definitions of such QTM models by, for instance, Ta-Shma [32], Watrous [36, Section VII.2], and (essentially, without the use of random access) van Melkebeek and Watson [22] are special cases of the QTM model that we consider. In the case of time-bounded quantum computation, it is well-known that allowing a QTM to perform intermediate measurements provably does not increase the power of the model; very recently, this fact has also been shown to hold in the simultaneously time-bounded and space-bounded setting [12]. Let  $\text{BQTISP}(T(n), S(n))$  denote the class of languages recognizable with bounded error by a QTM in time  $T(n)$  and space  $S(n)$ . See the full version [26] for a complete definition of the QTM model and a proof of the following theorem.

► **Theorem 24.** *Suppose  $L \in \text{BQTISP}(T(n), S(n))$ , and suppose further that  $S(n) = o(\log \log D_L(n))$ . Then  $\exists b_0 \in \mathbb{R}_{>0}$  such that,  $T(n) = \Omega(2^{-b_0 S(n)} D_L(n)^{2^{-b_0 S(n)}})$ .*

► **Corollary 25.** *If  $D_L(n) = 2^{\Omega(n)}$ , then  $L \notin \text{BQTISP}(2^{n^{1-\Omega(1)}}, o(\log n))$ . In particular,  $L_{\text{pal}} \notin \text{BQTISP}(2^{n^{1-\Omega(1)}}, o(\log n))$ .*

► **Remark.** Of course,  $L_{pal}$  can be recognized by a *deterministic* TM in  $O(\log n)$  space (and, trivially, polynomial time). Therefore, the previous corollary exhibits a natural problem for which polynomial time *quantum* TM cannot outperform polynomial time *deterministic* TM in terms of the amount of space used.

## 6 The Word Problem of a Group

We begin by formally defining the word problem of a group; for further background, see, for instance [21]. For a set  $S$ , let  $F(S)$  denote the free group on  $S$ . For sets  $S, R$  such that  $R \subseteq F(S)$ , let  $N$  denote the normal closure of  $R$  in  $F(S)$ ; for a group  $G$ , if  $G \cong F(S)/N$ , then we say that  $G$  has *presentation*  $\langle S|R \rangle$ , which we denote by writing  $G = \langle S|R \rangle$ . Suppose  $G = \langle S|R \rangle$ , with  $S$  finite; we now define  $W_{G=\langle S|R \rangle}$ , the *word problem of  $G$  with respect to the presentation  $\langle S|R \rangle$* . We define the set of formal inverses  $S^{-1}$ , such that, for each  $s \in S$ , there is a unique corresponding  $s^{-1} \in S^{-1}$ , and  $S \cap S^{-1} = \emptyset$ . Let  $\Sigma = S \sqcup S^{-1}$ , let  $\Sigma^*$  denote the free monoid over  $\Sigma$ , and let  $\phi : \Sigma^* \rightarrow G$  be the natural (monoid) homomorphism that takes each string in  $\Sigma^*$  to the element of  $G$  that it represents. We use  $1_G$  to denote the identity element of  $G$ . Then  $W_{G=\langle S|R \rangle} = \phi^{-1}(1_G)$ . Note that the definition of the word problem does depend on the choice presentation. However, if  $\mathcal{L}$  is any complexity class that is closed under inverse homomorphism, then if  $\langle S|R \rangle$  and  $\langle S'|R' \rangle$  are both presentations of some group  $G$ , and  $S$  and  $S'$  are both finite, then  $W_{G=\langle S|R \rangle} \in \mathcal{L} \Leftrightarrow W_{G=\langle S'|R' \rangle} \in \mathcal{L}$  [19]. As all complexity classes considered in this paper are easily seen to be closed under inverse homomorphism, we will simply write  $W_G \in \mathcal{L}$  to mean that  $W_{G=\langle S|R \rangle} \in \mathcal{L}$ , for every presentation  $G = \langle S|R \rangle$ , with  $S$  finite. We note that the languages  $L_{pal}$  and  $L_{eq}$ , which Ambainis and Watrous [2] showed satisfy  $L_{pal} \in \text{coRQE2QCFA}_{\mathbb{Q}}$  and  $L_{eq} \in \text{BQP2QCFA}$ , are closely related to the word problems of the groups  $F_2$  and  $\mathbb{Z}$ , respectively.

### 6.1 The Growth Rate of a Group and Nonregularity

Consider a group  $G = \langle S|R \rangle$ , with  $S$  finite. Define  $\Sigma$  and  $\phi$  as in the previous section. For  $g \in G$ , let  $l_S(g)$  denote the smallest  $m \in \mathbb{N}$  such that  $\exists \sigma_1, \dots, \sigma_m \in \Sigma$  such that  $g = \phi(\sigma_1 \cdots \sigma_m)$ . For  $n \in \mathbb{N}$ , we define  $B_{G,S}(n) = \{g \in G : l_S(g) \leq n\}$  and we further define  $\beta_{G,S}(n) = |B_{G,S}(n)|$ , which we call the *growth rate of  $G$  with respect to  $S$* . The following straightforward lemma demonstrates an important relationship between  $\beta_{G,S}$  and  $D_{W_{G=\langle S|R \rangle}}$ .

► **Lemma 26.** *Suppose  $G = \langle S|R \rangle$  with  $S$  finite. Using the notation established above, let  $W_G := W_{G=\langle S|R \rangle} = \phi^{-1}(1_G)$  denote the word problem of  $G$  with respect to this presentation. Then,  $\forall n \in \mathbb{N}$ ,  $D_{W_G}(2n) \geq \beta_{G,S}(n)$ .*

**Proof.** Fix  $n \in \mathbb{N}$ , let  $k = \beta_{G,S}(n)$ , and let  $B_{G,S}(n) = \{g_1, \dots, g_k\}$ . For a string  $x = x_1 \cdots x_m \in \Sigma^*$ , where each  $x_j \in \Sigma$ , let  $|x| = m$  denote the (string) length of  $x$  and define  $x^{-1} = x_m^{-1} \cdots x_1^{-1}$ . Note that,  $\forall g \in G$ ,  $l_S(g) = \min_{w \in \phi^{-1}(g)} |w|$ . Therefore, for each  $i \in \{1, \dots, k\}$  we may define  $w_i \in \phi^{-1}(g_i)$  such that  $|w_i| = l_S(g_i)$ . Observe that  $w_i w_i^{-1} \in W_G$  and  $|w_i w_i^{-1}| = 2|w_i| = 2l_S(g_i) \leq 2n$ ; moreover, for each  $j \neq i$ , we have  $w_j w_i^{-1} \notin W_G$  and  $|w_j w_i^{-1}| = |w_j| + |w_i| = l_S(g_j) + l_S(g_i) \leq 2n$ . Therefore,  $w_1, \dots, w_k$  are pairwise  $(W_G, 2n)$ -dissimilar, which implies  $D_{W_G}(2n) \geq k = \beta_{G,S}(n)$ . ◀

For a pair of non-decreasing functions  $f_1, f_2 : \mathbb{R}_{\geq 0} \rightarrow \mathbb{R}_{\geq 0}$ , we write  $f_1 \prec f_2$  if  $\exists C_1, C_2 \in \mathbb{R}_{>0}$  such that  $\forall r \in \mathbb{R}_{\geq 0}$ ,  $f_1(r) \leq C_1 f_2(C_1 r + C_2) + C_2$ ; we write  $f_1 \sim f_2$  if both  $f_1 \prec f_2$  and  $f_2 \prec f_1$ . Suppose  $\langle S|R \rangle$  and  $\langle S'|R' \rangle$  are both presentations of  $G$ , with  $S$  and  $S'$  finite. It is straightforward to show that  $\beta_{G,S}$  and  $\beta_{G,S'}$  are non-decreasing, and that  $\beta_{G,S} \sim \beta_{G,S'}$  [21, Proposition 6.2.4]. For this reason, we will simply write  $\beta_G$  to denote the growth rate of  $G$ .

► **Definition 27.** Suppose  $G$  is a finitely generated group. If  $\beta_G \sim (n \mapsto e^n)$ , we say  $G$  has *exponential growth*. If  $\exists c \in \mathbb{R}_{\geq 0}$  such that  $\beta_G \prec (n \mapsto n^c)$ , we say  $G$  has *polynomial growth*. Otherwise, we say  $G$  has *intermediate growth*. Note that, for any finitely generated group  $G$ , we have  $\beta_G \prec (n \mapsto e^n)$ , and so the term “intermediate growth” is justified.

## 6.2 Word Problems Recognizable by 2QCFA and Small-Space QTM

By making use of two very powerful results in group theory, the Tits’ Alternative [34] and Gromov’s theorem on groups of polynomial growth [15], we exhibit useful lower bounds on  $D_{W_G}$ , which in turn allows us to show a strong lower bound on the expected running time of a 2QCFA that recognizes  $W_G$ . We obtain an analogous result for sublogarithmic-space QTM; see the full paper [26] for details.

► **Theorem 28.** *For any finitely generated group  $G$ , the following statements hold.*

- (i) *If  $W_G \in \text{B2QCFA}(k, d, T(n), \epsilon)$ , then  $\beta_G \prec (n \mapsto T(n)^{k^4 d^2})$ .*
- (ii) *If  $G$  has exponential growth, then  $W_G \notin \text{B2QCFA}(2^{o(n)})$ .*
- (iii) *If  $G$  is a linear group over a field of characteristic 0, and  $G$  is not virtually nilpotent, then  $W_G \notin \text{B2QCFA}(2^{o(n)})$ .*
- (iv) *If  $W_G \in \text{BQP2QCFA}$ , then  $G$  is virtually nilpotent.*

**Proof.**

- (i) Follows immediately from Lemma 26 and Corollary 17.
- (ii) Follows immediately from Definition 27 and part (i) of this theorem.
- (iii) As a consequence of the famous Tits’ Alternative [34], every finitely generated linear group over a field of characteristic 0 either has polynomial growth or exponential growth, and has polynomial growth precisely when it is virtually nilpotent ([34, Corollary 1], [38]). The claim then follows by part (ii) of this theorem.
- (iv) If  $W_G \in \text{BQP2QCFA}$ , then  $W_G \in \text{B2QCFA}(k, d, n^c, \epsilon)$  for some  $k, d, c \in \mathbb{N}_{\geq 1}, \epsilon \in [0, \frac{1}{2})$ . By part (i) of this theorem,  $\beta_G \prec (n \mapsto n^{ck^4 d^2})$ , which implies  $G$  has polynomial growth. By Gromov’s theorem on groups of polynomial growth [15], a finitely generated group has polynomial growth precisely when it is virtually nilpotent. ◀

► **Remark.** All *known*  $G$  of intermediate growth have  $\beta_G \sim (n \mapsto e^{n^c})$ , for some  $c \in (1/2, 1)$ . Therefore, a strong lower bound may be established on the running time of any 2QCFA that recognizes  $W_G$ , for any known group of intermediate growth.

Let  $\mathcal{G}_{\mathbf{vAb}}$  (resp.  $\mathcal{G}_{\mathbf{vNilp}}$ ) denote the collection of all finitely generated virtually abelian (resp. nilpotent) groups. Let  $U(k, \overline{\mathbb{Q}})$  denote the group of  $k \times k$  unitary matrices with algebraic number entries, and let  $\mathcal{U}$  consist of all finitely generated subgroups of any  $U(k, \overline{\mathbb{Q}})$ . We have recently shown that if  $G \in \mathcal{U}$ , then  $W_G \in \text{coRQE2QCFA}_{\overline{\mathbb{Q}}}$  [27, Corollary 1.4.1]. Observe that  $\mathcal{G}_{\mathbf{vAb}} \subseteq \mathcal{U}$  and that all groups in  $\mathcal{U}$  are finitely generated linear groups over a field of characteristic zero. Moreover,  $\mathcal{U} \cap \mathcal{G}_{\mathbf{vNilp}} = \mathcal{G}_{\mathbf{vAb}}$  [33, Proposition 2.2]. We, therefore, obtain the following corollary of Theorem 28, which exhibits a broad and natural class of languages that a 2QCFA can recognize in exponential time, but not in subexponential time.

► **Corollary 29.**  $\forall G \in \mathcal{U} \setminus \mathcal{G}_{\mathbf{vAb}}$ , we have  $W_G \in \text{coRQE2QCFA}_{\overline{\mathbb{Q}}}$  but  $W_G \notin \text{B2QCFA}(2^{o(n)})$ .

We have also recently shown that  $W_G \in \text{coRQP2QCFA}_{\overline{\mathbb{Q}}}(2) \subseteq \text{BQP2QCFA}$ ,  $\forall G \in \mathcal{G}_{\mathbf{vAb}}$  [27, Theorem 1.2]. By Theorem 28, if  $W_G \in \text{BQP2QCFA}$ , then  $G \in \mathcal{G}_{\mathbf{vNilp}}$ . This naturally raises the question of whether or not there is some  $G \in \mathcal{G}_{\mathbf{vNilp}} \setminus \mathcal{G}_{\mathbf{vAb}}$  such that  $W_G \in \text{BQP2QCFA}$ . Consider the (three-dimensional discrete) Heisenberg group  $H = \langle x, y, z \mid z = [x, y], [x, z] = [y, z] = 1 \rangle$ .  $W_H$  is a natural choice for a potential “hard” word problem for 2QCFA, due

to the lack of faithful finite-dimensional unitary representations of  $H$  (see [27] for further discussion). We next show that if  $W_H \notin \text{BQP2QCFA}$ , then we have a complete classification of those word problems recognizable by 2QCFA in polynomial time.

► **Proposition 30.** *If  $W_H \notin \text{BQP2QCFA}$ , then  $W_G \in \text{BQP2QCFA} \Leftrightarrow G \in \mathcal{G}_{vAb}$ .*

**Proof.** By the above discussion, it suffices to show the following claim: if  $W_G \in \text{BQP2QCFA}$ , for some  $G \in \mathcal{G}_{vNilp} \setminus \mathcal{G}_{vAb}$ , then  $W_H \in \text{BQP2QCFA}$ . Begin by noting that  $\forall G \in \mathcal{G}_{vNilp} \setminus \mathcal{G}_{vAb}$ ,  $G$  has a subgroup isomorphic to  $H$  [20, Theorem 12]. It is straightforward to see that BQP2QCFA is closed under inverse homomorphism and intersection with regular languages. Therefore, if  $W_G \in \text{BQP2QCFA}$ , then  $W_H \in \text{BQP2QCFA}$  [20, Lemma 2]. ◀

# On the Complexity of $\#CSP^d$

Jiabao Lin

Shanghai University of Finance and Economics, China

jiabaolincs@gmail.com

---

## Abstract

Counting  $CSP^d$  is the counting constraint satisfaction problem ( $\#CSP$  in short) restricted to the instances where every variable occurs a multiple of  $d$  times. This paper revisits tractable structures in  $\#CSP$  and gives a complexity classification theorem for  $\#CSP^d$  with algebraic complex weights. The result unifies affine functions (stabilizer states in quantum information theory) and related variants such as the local affine functions, the discovery of which leads to all the recent progress on the complexity of Holant problems.

The Holant is a framework that generalizes counting CSP. In the literature on Holant problems, weighted constraints are often expressed as tensors (vectors) such that projections and linear transformations help analyze the structure. This paper gives an example showing that different classes of tensors distinguished by these algebraic operations may share the same closure property under tensor product and contraction.

## 1 Introduction

In the constraint satisfaction problem (CSP), constraints are specified by relations on a finite domain  $D = \{0, 1, \dots, q-1\}$  with  $q \geq 2$ . A relation  $R \subseteq D^n$  can be seen as a function  $f_R : D^n \rightarrow \{0, 1\}$  where  $f_R(\mathbf{x}) = 1$  if and only if  $\mathbf{x} \in R$ . To express weighted constraints, we replace relations with complex-valued functions. Let  $\mathbb{C}$  denote the set of algebraic complex numbers. Throughout this paper, we refer to them simply as complex numbers. Let  $\mathcal{F} = \{f_1, \dots, f_l\}$  be a finite function set where  $f_i : D^{n_i} \rightarrow \mathbb{C}$  with arity  $n_i > 0$ . Then the weighted counting CSP specified by the set  $\mathcal{F}$ , denoted by  $\#CSP(\mathcal{F})$ , is defined as follows. An input instance  $I$  of the problem consists of

- A finite set of variables  $V = \{x_1, \dots, x_n\}$ ;
- A finite set of constraints  $\{(F_1, \mathbf{x}_1), \dots, (F_m, \mathbf{x}_m)\}$  where  $F_i \in \mathcal{F}$  and  $\mathbf{x}_i \in V^{\text{arity}(F_i)}$  is a tuple of (not necessarily distinct) variables.

Following [4], we say that the instance  $I$  defines a function of arity  $n$ :

$$F_I(x_1, \dots, x_n) = \prod_{i=1}^m F_i(\mathbf{x}_i).$$

## 40:2 On the Complexity of $\#\text{CSP}^d$

The output of the problem  $\#\text{CSP}(\mathcal{F})$  is the following sum (also called the *partition function*):

$$Z(I) = \sum_{\mathbf{x} \in D^n} F_I(\mathbf{x}).$$

The problem is the counting version of a classical CSP, if we restrict  $\mathcal{F}$  to functions with range  $\{0, 1\}$ . Weighted constraints make the  $\#\text{CSP}$  framework more expressive. For a binary function  $f : D^2 \rightarrow \mathbb{C}$ ,  $\#\text{CSP}(f)$  is the problem of counting graph homomorphisms into the graph on  $D$  with edge weights  $f(i, j)$ . A wide range of graph parameters can be encoded by graph homomorphisms (see, e.g. [22]), which also play an important role in statistical physics.

The complexity of counting CSP has been intensively studied over the last two decades. Bulatov [3] first gave a complexity dichotomy theorem for unweighted  $\#\text{CSP}$ s: Each problem is either solvable in polynomial time or proved to be  $\#\text{P}$ -hard. Understanding the proof requires knowledge of universal algebra. Later, Dyer and Richerby [18] found a new tractability criterion and their proof is elementary. Based on the techniques developed for unweighted  $\#\text{CSP}$ , the dichotomy was generalized to cover nonnegative [6] and complex weights [4]. Given a function  $F : D^n \rightarrow \mathbb{C}$ , we use  $F^{[t]}$ , for each  $t \in [n] = \{1, \dots, n\}$ , to denote the following function of arity  $t$ :

$$F^{[t]}(x_1, \dots, x_t) = \sum_{x_{t+1}, \dots, x_n} F(x_1, \dots, x_t, x_{t+1}, \dots, x_n).$$

And for a function set  $\mathcal{F}$ , we define the set

$$\mathcal{W}_{\mathcal{F}} = \{F^{[t]} \mid F \text{ is a function defined by an instance of } \#\text{CSP}(\mathcal{F}) \text{ and } 1 \leq t \leq \text{arity of } F\}.$$

The dichotomy theorem for complex-weighted  $\#\text{CSP}$  is stated as follows.

► **Theorem 1** ([4]). *Let  $\mathcal{F}$  be a finite set of complex-valued functions. The problem  $\#\text{CSP}(\mathcal{F})$  is solvable in polynomial time if the set  $\mathcal{W}_{\mathcal{F}}$  satisfies three conditions: the Block Orthogonality condition, the Type Partition condition, and the Mal'tsev condition. Otherwise  $\#\text{CSP}(\mathcal{F})$  is  $\#\text{P}$ -hard.*

Roughly speaking, the three conditions require the function defined by any instance to be well-structured, such that the sum of function values can be computed by an efficient algorithm instead of brute-force enumeration. Actually, even if a problem  $\#\text{CSP}(\mathcal{F})$  is  $\#\text{P}$ -hard, it is still possible that the algorithm succeeds on a nontrivial subset of instances. In this paper, we consider a special case denoted by  $\#\text{CSP}^d$ , which was first studied by Huang and Lu [20].

► **Definition 2.** *Let  $d \geq 1$  be an integer and let  $\mathcal{F}$  be a set of complex-valued functions. The problem  $\#\text{CSP}^d(\mathcal{F})$  is the restriction of  $\#\text{CSP}(\mathcal{F})$  to the instances where every variable occurs a multiple of  $d$  times.*

By definition, if  $d = 1$ , then the problem  $\#\text{CSP}^d(\mathcal{F})$  is exactly  $\#\text{CSP}(\mathcal{F})$ . For a function set  $\mathcal{F}$ ,  $\#\text{CSP}^d(\mathcal{F})$  is a subproblem of  $\#\text{CSP}(\mathcal{F})$ . We consider a subset of  $\mathcal{W}_{\mathcal{F}}$ :

$$\mathcal{W}_{\mathcal{F}}^d = \{F^{[t]} \mid F \text{ is a function defined by an instance of } \#\text{CSP}^d(\mathcal{F}) \text{ and } 1 \leq t \leq \text{arity of } F\}.$$

A slight modification of the proof of Theorem 1 yields a unified dichotomy theorem for the  $\#\text{CSP}^d$  family.

► **Theorem 3.** *Let  $d \geq 1$  be an integer and let  $\mathcal{F}$  be a finite set of complex-valued functions. The problem  $\#\text{CSP}^d(\mathcal{F})$  is solvable in polynomial time if the set  $\mathcal{W}_{\mathcal{F}}^d$  satisfies three conditions: the Block Orthogonality condition, the Type Partition condition, and the Mal'tsev condition. Otherwise  $\#\text{CSP}^d(\mathcal{F})$  is  $\#\text{P}$ -hard.*

The tractability criteria survive because, as mentioned before, they are imposed on definable functions and hence not sensitive to how many times a variable appears in an instance. Unfortunately, none of the three conditions is known to be decidable. It is desirable to derive more explicit criteria for constraint functions instead of the functions “generated” by them. However, closed-form formulas or a succinct description of the function values might not exist for arbitrary domains. In graph homomorphisms with real or complex weights [19, 5], the classification of binary functions is explicit but very complicated.

By the definition of  $\#\text{CSP}$ , a variable can occur arbitrarily many times in an instance. However, in many graph satisfaction problems like matchings, vertices are viewed as constraints and edges as variables. That is, each variable appears exactly twice. Inspired by holographic algorithms [24], Cai, Lu, and Xia [13] proposed the Holant framework.

► **Definition 4.** *The problem  $\text{Holant}(\mathcal{F})$  is the restriction of  $\#\text{CSP}(\mathcal{F})$  to the instances where every variable occurs exactly twice.*

On the one hand, the Holant is more expressive than  $\#\text{CSP}$  because any  $\#\text{CSP}(\mathcal{F})$  is polynomial-time equivalent to the problem  $\text{Holant}(\mathcal{F} \cup \{\text{EQ}\})$  where  $\text{EQ}(x_1, x_2, x_3) = 1$  if  $x_1 = x_2 = x_3$  and otherwise  $\text{EQ}(x_1, x_2, x_3) = 0$ . On the other hand, by definition,  $\text{Holant}(\mathcal{F})$  is a subproblem of  $\#\text{CSP}(\mathcal{F})$ . The partition function of a bipartite Holant instance is invariant under the operations of the linear group  $GL_q(\mathbb{C})$  on constraint functions. These operations are also called *holographic transformations* [24, 13], which turn out to be one of the new sources of tractability [10, 21, 2, 23].

Early study of Holant problems has a similar flavor to that of  $\#\text{CSP}$  (see, e.g. [17, 13, 12]). Based on the dichotomy for a special family of Holant problems, Cai, Lu, and Xia [15] gave an explicit criterion for complex-weighted  $\#\text{CSP}$  on the Boolean domain  $\{0, 1\}$  (Boolean  $\#\text{CSP}$  in short).

► **Theorem 5** ([15]). *Let  $\mathcal{F}$  be a set of complex-valued functions on the Boolean domain. Then the problem  $\#\text{CSP}(\mathcal{F})$  is solvable in polynomial time if  $\mathcal{F} \subseteq \mathcal{P}$  or  $\mathcal{F} \subseteq \mathcal{A}$ . Otherwise  $\#\text{CSP}(\mathcal{F})$  is  $\#\text{P}$ -hard.*

The definitions of product-type functions  $\mathcal{P}$  and affine functions  $\mathcal{A}$  are given in Section 3. Affine functions are discovered in the first paper on Holant problems [13], and recently these functions are shown to be equivalent to Clifford gates and stabilizer circuits in quantum computing [11, 1].

Significant progress has been made towards a complexity dichotomy for complex-weighted Holant [7, 21, 2, 23, 14, 9]. However, it remains open even on the Boolean domain. Since it was first proposed, the  $\#\text{CSP}^d$  family becomes increasingly important in understanding the relationship between Holant and  $\#\text{CSP}$ . Cai, Lu, and Xia [16] proved a dichotomy theorem for Boolean  $\#\text{CSP}^2$  and discovered a new tractable class called *local affine* functions (see Definition 15). This result laid the foundation for all the recent progress on real or complex Holant [2, 8, 23]. In fact, several major Holant dichotomies inevitably go through the  $\#\text{CSP}^d$  family whose complexity, before Theorem 3, is known only for some special cases [20, 16, 8]. Moreover, the proofs of these results on  $\#\text{CSP}^d$  are complicated, partially because explicit criteria are expected as in Theorem 5.

Although Theorem 3 shows a complexity dichotomy, it is too general to say much about the Boolean domain. Of course we can check the three conditions and derive a simplified version, but there is a direct generalization of Theorem 5. Both product-type and affine functions have a nice closure property:  $\mathcal{W}_{\mathcal{P}} \subseteq \mathcal{P}$  and  $\mathcal{W}_{\mathcal{A}} \subseteq \mathcal{A}$ . This fact and inspiration from Theorem 3 lead to the following theorem.

► **Theorem 6.** *Let  $d \geq 1$  be an integer and let  $\mathcal{F}$  be a set of complex-valued functions on the Boolean domain. Then the problem  $\#CSP^d(\mathcal{F})$  is solvable in polynomial time if  $\mathcal{W}_{\mathcal{F}}^d \subseteq \mathcal{P}$  or  $\mathcal{W}_{\mathcal{F}}^d \subseteq \mathcal{A}$ . Otherwise  $\#CSP^d(\mathcal{F})$  is  $\#P$ -hard.*

The remainder of this paper is organized as follows. In Section 2, we give a proof of Theorem 3. In Section 3, a simple proof of Theorem 6 is presented. This theorem looks very different from the previous results. For example, holographic transformations seem necessary for the definition of the local affine functions and the algorithm that efficiently solves the problem they define. It will be clear why these transformations disappear in Theorem 6. Some concluding remarks appear in Section 4.

## 2 On General Finite Domains

This section is devoted to the proof Theorem 3. Most of the work was done in [4] and we only show necessary modifications.

Throughout this section, we assume that functions and relations are defined on a fixed finite domain  $D = \{0, 1, \dots, q-1\}$ . And we use  $\mathcal{F}$  to denote a finite set of functions on  $D$ . Let  $\leq_T$  denote the polynomial-time Turing reductions.

► **Lemma 7.** *For any finite set  $\mathcal{G} \subset \mathcal{W}_{\mathcal{F}}^d$ ,  $\#CSP(\mathcal{G}) \leq_T \#CSP^d(\mathcal{F})$ .*

**Proof.** For any function  $f \in \mathcal{G} \subset \mathcal{W}_{\mathcal{F}}^d$ , there exists some instance  $I_f$  of the problem  $\#CSP^d(\mathcal{F})$  such that  $f$  is exactly the function defined by  $I_f$ . Note that  $I_f$  is of constant size, since  $\mathcal{G}$  is a finite set.

Let  $I_1$  be an instance of the problem  $\#CSP(\mathcal{G})$ . We replace each constraint  $(f, \mathbf{x}) \in I_1$  with the instance  $I_f$  (in variables  $\mathbf{x}$ ). Then we get a new instance  $I_2$  of the problem  $\#CSP^d(\mathcal{F})$  because the sum of multiples of an integer  $d$  is still a multiple of  $d$ . It is easy to verify that  $Z(I_1) = Z(I_2)$ . The size of  $I_2$  is polynomial in that of  $I_1$ . ◀

The readers can find the statements of the conditions of Theorem 1 in [4, Subsection 3.1]. We say that the function set  $\mathcal{W}_{\mathcal{F}}^d$  violates any of the three conditions, if there exists a finite set  $\mathcal{G} \subset \mathcal{W}_{\mathcal{F}}^d$  violates any of the three. The hardness part of Theorem 1 can be summarized as follows.

► **Lemma 8** (Lemmas 3.2, 3.4, 3.5 in [4]). *If a finite function set  $\mathcal{G}$  violates one of the three conditions in Theorem 1, then the problem  $\#CSP(\mathcal{G})$  is  $\#P$ -hard.*

**Hardness Part of Theorem 3.** Suppose that a finite set  $\mathcal{G} \subset \mathcal{W}_{\mathcal{F}}^d$  violates any of the three conditions. Then the problem  $\#CSP(\mathcal{G})$  is  $\#P$ -hard by Lemma 8. Moreover,  $\#CSP^d(\mathcal{F})$  is  $\#P$ -hard because  $\#CSP(\mathcal{G}) \leq_T \#CSP^d(\mathcal{F})$ . ◀

Now we consider the algorithmic part.

Consider a relation  $R \subseteq D^n$  and a map  $\varphi : D^3 \rightarrow D$ . We say the relation  $R$  is *closed* under the map  $\varphi$ , if for any three tuples  $\mathbf{u} = (u_i), \mathbf{v} = (v_i), \mathbf{w} = (w_i) \in R$ , it holds that

$$(\varphi(u_1, v_1, w_1), \varphi(u_2, v_2, w_2), \dots, \varphi(u_n, v_n, w_n)) \in R.$$

In this case, we also say  $\varphi$  is a *polymorphism* of the relation  $R$ .

► **Definition 9** (Mal'tsev Polymorphism). *Suppose that a relation  $R \subseteq D^n$  is closed under a map  $\varphi : D^3 \rightarrow D$ . We say that  $\varphi$  is a Mal'tsev polymorphism of  $R$ , if*

$$\varphi(a, b, b) = \varphi(b, b, a) = a$$

for all  $a, b \in D$ .

Given a function  $f$ , we use  $R_f$  denote the relation  $\{\mathbf{x} \in D^n \mid f(\mathbf{x}) \neq 0\}$  (called the *support* of  $f$ ). And for every function  $f \in \mathcal{W}_{\mathcal{F}}^d$  of arity  $n \geq 2$ , a relation  $\Omega_f \subseteq D^{2n-2}$  is defined as:

$$(\mathbf{x}, \mathbf{y}) \in \Omega_f \iff f(\mathbf{x}, *) \text{ and } f(\mathbf{y}, *) \text{ are both nonzero and linearly dependent,}$$

where  $f(\mathbf{x}, *)$  denotes the  $q$ -dimensional vector  $(f(\mathbf{x}, 0), f(\mathbf{x}, 1), \dots, f(\mathbf{x}, q-1))$ . Now we define the set

$$\Lambda_{\mathcal{F}}^d = \{R_f \mid f \in \mathcal{W}_{\mathcal{F}}^d\} \cup \{\Omega_f \mid f \in \mathcal{W}_{\mathcal{F}}^d \text{ of arity } \geq 2\}.$$

► **Definition 10** (The Mal'tsev Condition). *All the relations in  $\Lambda_{\mathcal{F}}^d$  have a common Mal'tsev polymorphism.*

We have the following lemma after checking the algorithm (say, denoted by  $\mathcal{A}$ ) for Theorem 1.

► **Lemma 11.** *Suppose that the set  $\mathcal{W}_{\mathcal{F}}^d$  satisfies the three conditions. Then the algorithm  $\mathcal{A}$  can solve the problem  $\#\text{CSP}^d(\mathcal{F})$  in polynomial time if all the relations in  $\Lambda_{\mathcal{F}}^d \cup \{R_f \mid f \in \mathcal{F}\}$  have a common Mal'tsev polymorphism.*

In fact, the Mal'tsev condition already implies the condition in Lemma 11. This completes the algorithmic part of Theorem 3.

► **Lemma 12.** *Suppose that the Mal'tsev condition holds. Then all the relations in  $\Lambda_{\mathcal{F}}^d \cup \{R_f \mid f \in \mathcal{F}\}$  have a common Mal'tsev polymorphism.*

**Proof.** The conclusion is trivial if  $d = 1$ , since  $\mathcal{F} \subset \mathcal{W}_{\mathcal{F}}$ .

For any function  $f : D^n \rightarrow \mathbb{C}$ , we consider the function  $f^d(\mathbf{x}) = (f(\mathbf{x}))^d$  for all  $\mathbf{x} \in D^n$ . The two functions  $f$  and  $f^d$  have the same support:  $R_f = R_{f^d}$ . Then the conclusion follows because  $f^d \in \mathcal{W}_{\mathcal{F}}^d$  for every function  $f \in \mathcal{F}$ . ◀

Some remarks that may help the readers. A relation  $R \subseteq D^n$  with a Mal'tsev polymorphism can be of exponential size in  $n$ . However, Dyer and Richerby [18] showed that, there is a succinct representation of  $R$  determined by the Mal'tsev polymorphism, called the *witness function*, which has linear size in  $n$ . Here we do not introduce the definition of the witness function. Given an instance  $I$ , the algorithm  $\mathcal{A}$  starts with a witness function of the support  $R_{F_I}$ . The algorithm for constructing witness functions, by Dyer and Richerby, works no matter how many times a variable occurs but only requires a Mal'tsev polymorphism shared by all the relations  $R_f$  for  $f \in \mathcal{F}$ . Lemma 11 covers the requirement, which is satisfied trivially when  $d = 1$  since  $\{R_f \mid f \in \mathcal{F}\} \subset \Lambda_{\mathcal{F}}^1$ . Later, the instance  $I$  is only used for evaluating the function  $F_I$  at some points in  $D^n$ . To compute the sum  $Z(I) = \sum_{\mathbf{x} \in D^n} F_I(\mathbf{x})$ , the algorithm  $\mathcal{A}$  produces a data structure, called the *row representation*, for each  $F_I^{[t]}$  ( $t \in [n]$ ). Now suppose that  $I$  is a  $\#\text{CSP}^d$  instance. By definition,  $F_I^{[t]} \in \mathcal{W}_{\mathcal{F}}^d$  for all  $t \in [n]$ . To obtain the row representations, it is sufficient to impose the three conditions on  $\mathcal{W}_{\mathcal{F}}^d$  under which all the functions and relations involved in the computation are well-structured.

### 3 On the Boolean Domain

In this section, all the functions and relations are defined on the Boolean domain  $D = \{0, 1\}$ .

We start with the definition of product-type functions and affine functions. Let  $EQ(x, y)$  denote the equality function:  $EQ(x, y) = 1$  if  $x = y$ , otherwise  $EQ(x, y) = 0$ . And let  $NE(x, y)$  denote the disequality function:  $NE(x, y) = 1 - EQ(x, y)$ .

► **Definition 13** (Product-Type Functions). *A function is of product type if it is defined by a  $\#CSP$  instance where every constraint function is a unary function or the binary function  $EQ$  or  $NE$ . Let  $\mathcal{P}$  denote the set of all product-type functions.*

A Boolean relation is *affine* if it is the set of solutions to a system of linear equations over the field  $\mathbb{Z}_2$ . We say that  $f$  has affine support if its support is affine. Recall that the support of  $f$  is the relation  $R_f = \{\mathbf{x} \in \{0, 1\}^n \mid f(\mathbf{x}) \neq 0\}$ .

► **Definition 14** (Affine Functions). *A function  $f$  of arity  $n$  is affine if its support is affine and there is a constant  $\lambda \in \mathbb{C}$  such that for all  $\mathbf{x} \in R_f$ ,*

$$f(\mathbf{x}) = \lambda \cdot i^{Q(\mathbf{x})},$$

where  $i = \sqrt{-1}$  and  $Q$  is a homogeneous quadratic polynomial

$$Q(x_1, \dots, x_n) = \sum_{i=1}^n a_i x_i^2 + 2 \sum_{1 \leq i < j \leq n} b_{ij} x_i x_j$$

with  $a_i \in \mathbb{Z}_4$  and  $b_{ij} \in \{0, 1\}$ . We use  $\mathcal{A}$  to denote the set of all affine functions.

**Proof of Theorem 6.** Suppose that there are two functions  $f, g \in \mathcal{W}_{\mathcal{F}}^d$  (they can be the same) such that  $f \notin \mathcal{P}$  and  $g \notin \mathcal{A}$ . By Theorem 5, the problem  $\#CSP(\{f, g\})$  is  $\#P$ -hard. Then  $\#CSP^d(\mathcal{F})$  is also  $\#P$ -hard since  $\#CSP(\{f, g\}) \leq_{\tau} \#CSP^d(\mathcal{F})$  by Lemma 7.

Now we assume that  $\mathcal{W}_{\mathcal{F}}^d \subseteq \mathcal{P}$  or  $\mathcal{W}_{\mathcal{F}}^d \subseteq \mathcal{A}$ . In both cases, for any instance  $I$ , the function  $F_I$  (say, of arity  $n$ ) has affine support and the linear system for the support can be constructed efficiently from that of the constraint functions. There are two cases:

- $F_I \in \mathcal{P}$ . We can determine the variable dependence on the support:  $x_i = x_j$  or  $x_i \neq x_j$  or they are independent. Then the evaluation of the partition function  $Z(I)$  reduces to a trivial case where every constraint is unary.
- $F_I \in \mathcal{A}$ . We can obtain the explicit formula (in Definition 14) for the function  $F_I$ , by evaluating it at  $O(n^2)$  many points, using the instance  $I$ . Then the algorithm for Theorem 5 is able to compute  $Z(I)$ . See [15] for more details.

Therefore, the partition function is computable in polynomial time. ◀

The remainder of this section is devoted to the connection between Theorem 6 and the dichotomy for Boolean  $\#CSP^2$  in [16]. Before this, we need to introduce some notations and definitions.

A function of arity  $n \geq 2$  can be expressed as a  $2^{n-r} \times 2^r$  matrix ( $0 \leq r \leq n$ ), denoted by  $M_r(f)$ . The rows and columns are indexed by  $\mathbf{x} \in \{0, 1\}^{n-r}$  and  $\mathbf{y} \in \{0, 1\}^r$ , respectively, and  $f(\mathbf{x}, \mathbf{y})$  is the  $(\mathbf{x}, \mathbf{y})^{\text{th}}$  entry of the matrix  $M_r(f)$ . In particular, when  $r = 0$ ,  $M_r(f)$  is a column vector of dimension  $2^n$ . In the following, we do not distinguish a function from its matrix representations. The integer  $r$  will be clear in matrix multiplication.

Given two matrices  $A$  and  $B$ , we use  $A \otimes B$  to denote their tensor product.

Let  $\alpha = \frac{1+i}{\sqrt{2}}$  where  $i = \sqrt{-1}$ . Then  $\alpha^2 = i$ . And let  $M_x = \begin{bmatrix} 1 & 0 \\ 0 & x \end{bmatrix}$  for  $x \in \mathbb{C}$ . We define the following set of functions:

$$\mathcal{A}^\alpha = \{M_\alpha^{\otimes n} g \mid g \in \mathcal{A} \text{ and } n \text{ is the arity of } g\},$$

which is a tractable class for  $\#\text{CSP}^2$ .

Recall that  $R_f = \{\mathbf{x} \in \{0, 1\}^n \mid f(\mathbf{x}) \neq 0\}$  for a function  $f$  of arity  $n$ .

► **Definition 15** (Local Affine Functions). *A function  $f$  (of arity  $n$ ) is called local affine, if for every element  $(s_1, s_2, \dots, s_n) \in R_f$ ,*

$$(M_{\alpha^{s_1}} \otimes M_{\alpha^{s_2}} \otimes \dots \otimes M_{\alpha^{s_n}})f \in \mathcal{A},$$

where  $\alpha^s = 1$  if  $s = 0$ ,  $\alpha^s = \alpha$  if  $s = 1$ . The set of all local affine functions is denoted by  $\mathcal{L}$ .

► **Theorem 16** ([16]). *Let  $\mathcal{F}$  be a set of functions on the Boolean domain. If  $\mathcal{F} \subseteq \mathcal{C}$  for  $\mathcal{C} \in \{\mathcal{P}, \mathcal{A}, \mathcal{A}^\alpha, \mathcal{L}\}$ , then the problem  $\#\text{CSP}^2(\mathcal{F})$  is solvable in polynomial time. Otherwise  $\#\text{CSP}^2(\mathcal{F})$  is  $\#\text{P}$ -hard.*

Since the theorem above is a special case of Theorem 6, the two tractability criteria should be compatible. In fact, we have the following observation.

► **Lemma 17.** *If  $\mathcal{F} \subseteq \mathcal{C}$  for  $\mathcal{C} \in \{\mathcal{P}, \mathcal{A}, \mathcal{A}^\alpha, \mathcal{L}\}$ , then  $\mathcal{W}_{\mathcal{F}}^2 \subseteq \mathcal{P}$  or  $\mathcal{W}_{\mathcal{F}}^2 \subseteq \mathcal{A}$ .*

The algorithms in [16] for the two classes  $\mathcal{A}^\alpha$  and  $\mathcal{L}$  start with local transformations induced by the matrix  $M_\alpha$ , such that every constraint function of an instance  $I$  becomes affine and hence the function  $F_I$  is also affine. However, as stated in Lemma 17,  $F_I$  is already affine. Before proving the lemma, we need some preparations.

► **Lemma 18** (Closure Property). *Let  $\mathcal{C} = \mathcal{P}$  or  $\mathcal{C} = \mathcal{A}$ , then  $\mathcal{W}_{\mathcal{F}} \subseteq \mathcal{C}$  for any set  $\mathcal{F} \subseteq \mathcal{C}$ . In particular, for any  $n$ -ary function  $f \in \mathcal{C}$ :*

- $f^{[t]} \in \mathcal{C}$  for all  $t \in [n]$ ;
- $f_\pi \in \mathcal{C}$  for any permutation  $\pi$  on  $[n]$ , where  $f_\pi(x_1, x_2, \dots, x_n) = f(x_{\pi(1)}, x_{\pi(2)}, \dots, x_{\pi(n)})$ .

**Proof.** We only show that  $g(x_1, \dots, x_{n-1}) = \sum_{x_n \in \{0,1\}} f(x_1, \dots, x_{n-1}, x_n) \in \mathcal{C}$  for any  $n$ -ary function  $f \in \mathcal{C}$ . The case  $\mathcal{C} = \mathcal{A}$  was proved in [11, Lemma 3.1]. Now suppose that  $f \in \mathcal{P}$ . By the definition of product-type functions, it is sufficient to consider the case where  $f$  has support

$$R_f \subseteq \{(u_1, \dots, u_n), (1 - u_1, \dots, 1 - u_n)\} \text{ for some } u_i \in \{0, 1\}.$$

It then follows that  $R_g \subseteq \{(u_1, \dots, u_{n-1}), (1 - u_1, \dots, 1 - u_{n-1})\}$ . Thus  $g \in \mathcal{P}$ . ◀

► **Lemma 19** (Closure under Matrix Multiplication). *Let  $f \in \mathcal{A}$  be a function of arity  $n$ . And let  $g \in \mathcal{A}$  be a function of arity  $m$ . Then it holds that*

$$M_r(f)M_{m-r}(g) \in \mathcal{A},$$

for all  $0 \leq r \leq \min\{n, m\}$ .

**Proof.** For any  $0 \leq r \leq \min\{n, m\}$ , we consider the function of arity  $n + m - 2r$ :

$$\begin{aligned} & h(x_1, \dots, x_{n-r}, y_1, \dots, y_{m-r}) \\ &= \sum_{z_1, \dots, z_r \in \{0,1\}} f(x_1, \dots, x_{n-r}, z_1, \dots, z_r) g(z_1, \dots, z_r, y_1, \dots, y_{m-r}). \end{aligned}$$

Then it follows that  $M_{m-r}(h) = M_r(f)M_{m-r}(g)$ . By Lemma 18, we have  $h \in \mathcal{A}$ . ◀

► **Lemma 20** (Closure under Tensor Product). *Let  $A, B \in \mathcal{A}$  be two matrices. Then  $A \otimes B \in \mathcal{A}$ .*

**Proof.** Let  $f, g \in \mathcal{A}$  be two functions such that  $A = M_r(f)$  and  $B = M_t(g)$  for some integers  $r, t \geq 0$ . Consider the function

$$h(\mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{w}) = f(\mathbf{x}, \mathbf{z})g(\mathbf{y}, \mathbf{w})$$

where  $\mathbf{z} \in \{0, 1\}^r$  and  $\mathbf{w} \in \{0, 1\}^t$ . Then  $A \otimes B = M_{r+t}(h)$ . ◀

► **Lemma 21.** *Let  $f$  be a function of arity  $n$ . Suppose that there exist matrices  $A_1, A_2, \dots, A_n \in \left\{ \begin{bmatrix} 1 & 0 \\ 0 & i^r \end{bmatrix} \mid r = 0, 1, 2, 3 \right\}$  where  $i = \sqrt{-1}$ , such that  $(A_1 \otimes A_2 \otimes \dots \otimes A_n)f \in \mathcal{A}$ . Then  $f \in \mathcal{A}$ .*

**Proof.** Set  $A = A_1 \otimes A_2 \otimes \dots \otimes A_n$ . The matrix  $A$  is invertible and  $A^{-1} = A_1^{-1} \otimes A_2^{-1} \otimes \dots \otimes A_n^{-1} \in \mathcal{A}$  by Lemma 20. Then it follows that  $f = (A^{-1}A)f = A^{-1}(Af) \in \mathcal{A}$ , according to Lemma 19. ◀

Now we are ready to prove Lemma 17.

**Proof of Lemma 17.** Due to the closure property of product-type and affine functions (Lemma 18), the two cases  $\mathcal{F} \subseteq \mathcal{A}^\alpha$  and  $\mathcal{F} \subseteq \mathcal{L}$  remain to be verified. Furthermore, by Lemma 18, we only need to check the definable functions.

Let  $I$  be an instance of  $\#CSP^2(\mathcal{F})$ . Suppose that the instance  $I$  has  $n$  variables  $\{x_1, x_2, \dots, x_n\}$  and  $m$  constraints  $\{(f_1, \mathbf{x}_1), (f_2, \mathbf{x}_2), \dots, (f_m, \mathbf{x}_m)\}$ . Then the function defined by  $I$  is

$$F_I(x_1, \dots, x_n) = f_1(\mathbf{x}_1)f_2(\mathbf{x}_2) \cdots f_m(\mathbf{x}_m).$$

Suppose that each variable  $x_j$  occurs  $k_j$  times in the instance  $I$ . By definition,  $k_j$  is even for each  $j \in [n]$  and we set  $k = k_1 + k_2 + \dots + k_n$ .

Consider the function of arity  $k$ :  $g = f_1 \otimes f_2 \otimes \dots \otimes f_m$ . There is a permutation  $\pi$  on  $[k]$  such that

$$F_I(x_1, \dots, x_n) = g_\pi(\underbrace{x_1, \dots, x_1}_{k_1 \text{ times}}, \underbrace{x_2, \dots, x_2}_{k_2 \text{ times}}, \dots, \underbrace{x_n, \dots, x_n}_{k_n \text{ times}}).$$

Suppose that  $\mathcal{F} \subseteq \mathcal{L}$ . We show that  $F_I \in \mathcal{A}$ . If the function  $F_I$  is identically zero, then we are done. Suppose not. Then there exist  $s_1, s_2, \dots, s_n \in \{0, 1\}$  such that

$$F_I(s_1, s_2, \dots, s_n) = g_\pi(\underbrace{s_1, \dots, s_1}_{k_1 \text{ times}}, \underbrace{s_2, \dots, s_2}_{k_2 \text{ times}}, \dots, \underbrace{s_n, \dots, s_n}_{k_n \text{ times}}) \neq 0.$$

By the definition of local affine functions, we have

$$(M_{\alpha^{s_1}}^{\otimes k_1} \otimes M_{\alpha^{s_2}}^{\otimes k_2} \otimes \dots \otimes M_{\alpha^{s_n}}^{\otimes k_n})g_\pi \in \mathcal{A}. \quad (*)$$

The relation between the two functions  $F_I$  and  $g_\pi$  shows that

$$(M_{\alpha^{s_1}}^{k_1} \otimes M_{\alpha^{s_2}}^{k_2} \otimes \dots \otimes M_{\alpha^{s_n}}^{k_n})F_I \in \mathcal{A}.$$

For each  $j \in [n]$ ,  $M_{\alpha^{s_j}}^{k_j} \in \left\{ \begin{bmatrix} 1 & 0 \\ 0 & i^r \end{bmatrix} \mid r = 0, 1, 2, 3 \right\}$ , since  $k_j$  is even. By Lemma 21, we have  $F_I \in \mathcal{A}$ .

Now suppose that  $\mathcal{F} \subseteq \mathcal{A}^\alpha$ . However, this case has been considered, because the relation  $(*)$  holds by setting  $s_1 = s_2 = \dots = s_n = 1$ . This completes the proof. ◀

## 4 Conclusion

Local affine functions partially reflect the difficulty in proving a Holant dichotomy: Nice structures hide in strange supports and we lack powerful tools.

Theorem 3 and Theorem 6 give a unified complexity dichotomy for the whole  $\#\text{CSP}^d$  family. Being abstract enough, they reveal that essentially there is no new tractable structure for  $d > 1$ . This fact is obtained by considering barriers to efficient evaluations of the partition functions, but not simply the set of constraint functions which defines the problem though. Moreover, the proof of Theorem 6 is much simpler than those of the partial results on  $\#\text{CSP}^d$ .

It is not clear whether or not the dichotomies in this paper can help the study of Holant problems at large. They are much more conceptual than existing dichotomies and techniques for the Holant.

## Abstract

We consider the following question: using a source of labeled data and interaction with an untrusted prover, what is the complexity of verifying that a given hypothesis is “approximately correct”? We study interactive proof systems for *PAC verification*, where a verifier that interacts with a prover is required to accept good hypotheses, and reject bad hypotheses. Both the verifier and the prover are efficient and have access to labeled data samples from an unknown distribution. We are interested in cases where the verifier can use significantly less data than is required for (agnostic) PAC learning, or use a substantially cheaper data source (e.g., using only random samples for verification, even though learning requires membership queries). We believe that today, when data and data-driven algorithms are quickly gaining prominence, the question of verifying purported outcomes of data analyses is very well-motivated.

We show three main results. First, we prove that for a specific hypothesis class, verification is significantly cheaper than learning in terms of sample complexity, even if the verifier engages with the prover only in a single-round (NP-like) protocol. Moreover, for this class we prove that single-round verification is also significantly cheaper than testing closeness to the class. Second, for the broad class of Fourier-sparse boolean functions, we show a multi-round (IP-like) verification protocol, where the prover uses membership queries, and the verifier is able to assess the result while only using random samples. Third, we show that verification is not always more efficient. Namely, we show a class of functions where verification requires as many samples as learning does, up to a logarithmic factor.

*A simple idea underpins science: “trust, but verify”. Results should always be subject to challenge from experiment. That simple but powerful idea has generated a vast body of knowledge. Since its birth in the 17th century, modern science has changed the world beyond recognition, and overwhelmingly for the better. But success can breed complacency. Modern scientists are doing too much trusting and not enough verifying – to the detriment of the whole of science, and of humanity.*

The Economist, “How Science Goes Wrong” (2013)

## 1 Introduction

Data and data-driven algorithms are transforming science and society. State-of-the-art machine learning and statistical analysis algorithms use access to data at scales and granularities that would have been unimaginable even a few years ago. From medical records and genomic information to financial transactions and transportation networks, this revolution spans scientific studies, commercial applications and the operation of governments. It holds transformational promise, but also raises new concerns. If data analysis requires huge amounts of data and computational power, how can one verify the correctness and accuracy of the results? Might there be asymmetric cases, where performing the analysis is expensive, but verification is cheap?

There are many types of statistical analyses, and many ways to formalize the notion of verifying the outcome. In this work we focus on interactive proof systems [12] for verifying supervised learning, as defined by the PAC model of learning [22]. Our emphasis throughout is on access to the underlying data distribution as the critical resource: both quantitatively (how many samples are used for learning versus for verification), and qualitatively (what types of samples are used). We embark on tackling a series of new questions:

Suppose a learner (which we also call *prover*) claims to have arrived at a good hypothesis with regard to an unknown data distribution by analyzing random samples from the distribution. Can one verify the quality of the hypothesis with respect to the unknown distribution by using significantly fewer samples than the number needed to independently repeat the analysis? The crucial difference between this question and questions that appear in the property testing and distribution testing literature is that we allow the prover and verifier to engage in an *interactive* communication protocol (see Section 1.1.1 for a comparison). We are interested in the case where both the verifier and an honest prover are efficient (i.e., use polynomial runtime and sample complexity), and furthermore, a dishonest prover with unbounded computational resources cannot fool the verifier:

► **Question 1 (Runtime and sample complexity of learning vs. verifying).** *Are there machine learning tasks for which the runtime and sample complexity of learning a good hypothesis is significantly larger than the complexity of verifying a hypothesis provided by someone else?*

In the learning theory literature, various types of access to training data have been considered, such as random samples, membership queries, and statistical queries. In the real world, some types of access are more costly than others. Therefore, it is interesting to consider whether it is possible to verify a hypothesis using a cheaper type of access than is necessary for learning:

► **Question 2 (Sample type of learning vs. verifying).** *Are there machine learning problems where membership queries are necessary for finding a good hypothesis, but verification is possible using random samples alone?*

The answers to these fundamental questions are motivated by real-world applications. If data analysis requires huge amounts of data and computational resources while verification is a simpler task, then a natural approach for individuals and weaker entities would be to delegate the data collection and analysis to more powerful entities. Going beyond machine learning, this applies also to verifying the results of scientific studies without replicating the entire experiment. We elaborate on these motivating applications in Section 1.2 below.

## 1.1 PAC Verification: A Proposed Model

Our primary focus in this work is verifying the results of agnostic supervised machine learning algorithms that receive a labeled dataset, and aim to learn a classifier that predicts the labels of unseen examples. We introduce a notion of interactive proof systems for verification of PAC learning, which we call *PAC Verification* (see Definition 4). Here, the entity running the learning algorithms (which we refer to as the *prover* or the *learner*) proves the correctness of the results by engaging in an interactive communication protocol with a verifier. One special case is where the prover only sends a single message constituting an (NP-like) certificate of correctness. The honest prover should be able to convince the verifier to accept its proposed hypothesis with high probability. A dishonest prover (even an unbounded one) should not be able to convince the verifier to accept a hypothesis that is not sufficiently good (as defined below), except with small probability over the verifier's random coins and samples. The proof system is interesting if the amount of resources used for verification is significantly smaller than what is needed for performing the learning task. We are especially interested in *doubly-efficient* proof systems [11], where the honest prover also runs in polynomial time.

More formally, let  $\mathcal{X}$  be a set, and consider a distribution  $\mathcal{D}$  over samples of the form  $(x, y)$  where  $x \in \mathcal{X}$  and  $y \in \{0, 1\}$ . Assume there is some *hypothesis class*  $\mathcal{H}$ , which is a set of functions  $\mathcal{X} \rightarrow \{0, 1\}$ , and we are interested in finding a function  $h \in \mathcal{H}$  that predicts the label  $y$  given a previously unseen  $x$  with high accuracy with respect to  $\mathcal{D}$ . To capture this we use the *loss function*  $L_{\mathcal{D}}(h) = \mathbb{P}_{(x,y) \in \mathcal{D}} [h(x) \neq y]$ . Our goal is to design protocols consisting of a prover and verifier that satisfy: (i) When the verifier interacts with an honest prover, with high probability the verifier outputs a hypothesis  $h$  that is  $\varepsilon$ -good, meaning that

$$L_{\mathcal{D}}(h) \leq L_{\mathcal{D}}(\mathcal{H}) + \varepsilon, \tag{1}$$

where  $L_{\mathcal{D}}(\mathcal{H}) = \inf_{f \in \mathcal{H}} L_{\mathcal{D}}(f)$ ; (ii) For any (possibly dishonest and unbounded) prover, the verifier can choose to reject the interaction, and with high probability the verifier will not output a hypothesis that is not  $\varepsilon$ -good.

Observe that in the *realizable case* (or *promise case*), where we assume that  $L_{\mathcal{D}}(\mathcal{H}) = 0$ , one immediately obtains a strong result: given a hypothesis  $\tilde{h}$  proposed by the prover, a natural strategy for the verifier is to take a few samples from  $\mathcal{D}$ , and accept if and only if  $\tilde{h}$  classifies at most, say, an  $\frac{9}{10}\varepsilon$ -fraction of them incorrectly. From Hoeffding's inequality,

taking  $O(\frac{1}{\varepsilon^2})$  samples is sufficient to ensure that with probability at least  $\frac{9}{10}$  the *empirical loss*<sup>1</sup> of  $\tilde{h}$  is  $\frac{\varepsilon}{10}$ -close to the true loss. Therefore, if  $L_{\mathcal{D}}(\tilde{h}) \leq \frac{8}{10}\varepsilon$  then  $\tilde{h}$  is accepted with probability at least  $\frac{9}{10}$ , and if  $L_{\mathcal{D}}(\tilde{h}) > \varepsilon$  then  $\tilde{h}$  is rejected with probability at least  $\frac{9}{10}$ . In contrast, PAC learning a hypothesis that with probability at least  $\frac{9}{10}$  has loss at most  $\varepsilon$  requires  $\Omega(\frac{d}{\varepsilon})$  samples, where the parameter  $d$ , which is the VC dimension of the class, can be arbitrarily large.<sup>2</sup> That is, in the realizable case there is a sample complexity and time complexity separation of unbounded magnitude between learning and verifying. Furthermore, this result holds also under the weaker assumption that  $L_{\mathcal{D}}(\mathcal{H}) \leq \frac{\varepsilon}{2}$ .

Encouraged by this strong result, the present paper focuses on the *agnostic case*, where no assumptions are made regarding  $L_{\mathcal{D}}(\mathcal{H})$ . Here, things become more interesting, and deciding whether a proposed hypothesis  $\tilde{h}$  is  $\varepsilon$ -good is non-trivial. Indeed, the verifier can efficiently estimate  $L_{\mathcal{D}}(\tilde{h})$  using Hoeffding's inequality as before, but estimating the term  $L_{\mathcal{D}}(\mathcal{H})$  on the right hand side of (1) is considerably more challenging. If  $\tilde{h}$  has a loss of say 15%, it could be an amazingly-good hypothesis compared to the other members of  $\mathcal{H}$ , or it could be very poor. Distinguishing between these two cases may be difficult when  $\mathcal{H}$  is a large and complicated class.

### 1.1.1 Related Models

We discuss two related models studied in prior work, and their relationship to the PAC verification model proposed in this work.

**Property Testing.** Goldreich, Goldwasser and Ron [9] initiated the study of a property testing problem that naturally accompanies proper PAC learning: Given access to samples from an unknown distribution  $\mathcal{D}$ , decide whether  $L_{\mathcal{D}}(\mathcal{H}) = 0$  or  $L_{\mathcal{D}}(\mathcal{H}) \geq \varepsilon$  for some fixed hypothesis class  $\mathcal{H}$ . Further developments and variations appeared in Kearns and Ron [15] and Balcan et. al [2]. Blum and Hu [4] consider *tolerant* closeness testing and a related task of distance approximation (see [19]), where the algorithm is required to approximate  $L_{\mathcal{D}}(\mathcal{H})$  up to a small additive error. As discussed above, the main challenge faced by the verifier in PAC verification is approximating  $L_{\mathcal{D}}(\mathcal{H})$ . However, there is a crucial difference between testing and PAC verification: In addition to taking samples from  $\mathcal{D}$ , the verifier in PAC verification can also interact with a prover, and thus PAC verification can (potentially) be easier than testing. Indeed, this difference is exemplified by the *proper* testing question, where we only need to distinguish the zero-loss case from large loss. As discussed above, proper PAC verification is trivial. Proper testing, on the other hand, can be a challenging goal (and, indeed, has been the focus of a rich body of work). For the *tolerant* setting, we prove a separation between testing and PAC verification: we show a hypothesis class for which the help of the prover allows the verifier to save a (roughly) quadratic factor over the number of samples that are required for closeness testing or distance approximation. See Section 3 for further details.

**Proofs of Proximity for Distributions.** Chiesa and Gur [6] study interactive proof systems for distribution testing. For some fixed property  $\Pi$ , the verifier receives samples from an unknown distribution  $\mathcal{D}$ , and interacts with a prover to decide whether  $\mathcal{D} \in \Pi$  or whether  $\mathcal{D}$  is  $\varepsilon$ -far in total variation distance from any distribution in  $\Pi$ . While that work does not consider

<sup>1</sup> I.e., the fraction of the samples that is misclassified.

<sup>2</sup> See preliminaries in [13, Section 1.6.2] for more about VC dimension.

machine learning, the question of verifying a lower bound  $\ell$  on the loss of a hypothesis class can be viewed as a special case of distribution testing, where  $\Pi = \{\mathcal{D} : L_{\mathcal{D}}(\mathcal{H}) \geq \ell\}$ . Beyond our focus on PAC verification, an important distinction between the works is that in Chiesa and Gur’s model and results, the honest prover’s access to the distribution is unlimited – the honest prover can have complete information about the distribution. In this paper, we focus on doubly-efficient proofs, where the verifier and the honest prover must both be efficient in the number of data samples they require. With real-world applications in mind, this focus seems quite natural.<sup>3</sup>

We survey further related works in Section 1.5 in the full version of the paper [13].

## 1.2 Applications

The P vs. NP problem asks whether finding a solution ourselves is harder than verifying a solution supplied by someone else. It is natural to ask a similar question in learning theory: Are there machine learning problems for which learning a good hypothesis is harder than verifying one proposed by someone else? We find this theoretical motivation compelling in and of itself. Nevertheless, we now proceed to elaborate on a few more practical aspects of this question.

### 1.2.1 Delegation of Learning

In a commercial context, consider a scenario in which a client is interested in developing a machine learning (ML) model, and decides to outsource that task to a company  $P$  that provides ML services. For example,  $P$  promises to train a deep neural net using a big server farm. Furthermore,  $P$  claims to possess a large amount of high quality data that is not available to the client, and promises to use that data for training.

How could the client ascertain that a model provided by  $P$  is actually a good model? The client could use a general-purpose cryptographic delegation-of-computation protocol, but that would be insufficient. Indeed, a general-purpose delegation protocol can only ensure that  $P$  executed the computation as promised, but it cannot provide any guarantees about the quality of the outcome, and in particular cannot ensure that the outcome is  $\varepsilon$ -good: If  $P$  used skewed or otherwise low-quality training data (whether maliciously or inadvertently), a general-purpose delegation protocol has no way of detecting that. Moreover, even if the the data and the execution of the computation were both flawless, this still provides no guarantees on the quality of the output, because an ML model might have poor performance despite being trained as prescribed.<sup>4,5</sup>

A different solution could be to have  $P$  provide a proof to establish that its output is indeed  $\varepsilon$ -good. In cases where the resource gap between learning and verifying is significant enough, the client could cost-effectively verify the proof, obtaining sound guarantees on the quality of the ML model it is purchasing from  $P$ .

<sup>3</sup> In Chiesa and Gur’s setting, it would also be sufficient for the prover to only know the distribution up to  $O(\varepsilon)$  total variation distance, and this can be achieved using random samples from the distribution. However, the number of samples necessary for the prover would be linear in the domain size, which is typically exponential, and so this approach would not work for constructing doubly-efficient PAC verification protocols.

<sup>4</sup> E.g., a neural network might get stuck at a local minimum.

<sup>5</sup> Additionally, note that state-of-the-art delegation protocols are not efficient enough at present to make it practicable to delegate intensive ML computations. See the survey by Walfish and Blumberg [23] for progress and challenges in developing such systems.

### 1.2.2 Verification of Scientific Studies

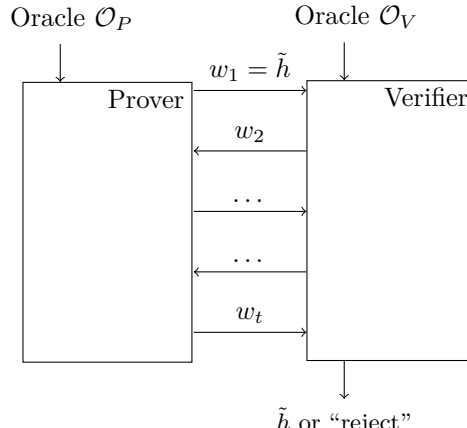

It has been claimed that many or most published research findings are false [14]. Others refer to an ongoing *replication crisis* [20, 7], where many scientific studies are hard or impossible to replicate or reproduce [21, 3]. Addressing these issues is a scientific and societal priority.

There are many factors contributing to this problem, including: structural incentives faced by researchers, scientific journals, referees, and funding bodies; the level of statistical expertise among researchers and referees; differences in the sources of data used for studies and their replication attempts; choice of standards of statistical significance; and norms pertaining to the publication of detailed replicable experimental procedures and complete datasets of experimental results.

We stress that the current paper does not touch on the majority of these issues, and our discussion of the replication crisis (as well as our choice of quotation at the beginning of the paper) does *not* by any means suggest that adoption of PAC verification protocols will single-handedly solve all issues pertaining to replication. Rather, the contribution of the current paper with respect to scientific replication is very specific: we suggest that for some specific types of experiments, PAC verification can be used to design protocols that allow to verify the results of an experiment in a manner that uses a quantitatively smaller (or otherwise cheaper) set of independent experimental data than would be necessary for a traditional replication that fully repeats the original experiment. In [13, Appendix A] we list four such types of experiments. We argue that devising PAC verification protocols that make scientific replication procedures even modestly cheaper for specific types of experiments is a worthwhile endeavor that could help increase the amount of scientific replication or verification that occurs, and decrease the prevalence of errors that remain undiscovered in the scientific literature.

### 1.3 Our Setting

In this paper we consider the following form of interaction between a verifier and a prover.

■ **Figure 1** The verifier and prover each have access to an oracle, and they exchange messages with each other. Eventually, the verifier outputs a hypothesis, or rejects the interaction. One natural case is where the prover suggests a hypothesis  $\tilde{h}$ , and the verifier either accepts or rejects this suggestion.

Let  $\mathcal{H} \subseteq \{0, 1\}^{\mathcal{X}}$  be a class of hypotheses, and let  $\mathcal{D}$  be a distribution over  $\mathcal{X} \times \{0, 1\}$ . The verifier and the prover each have access to an oracle, denoted  $\mathcal{O}_V$  and  $\mathcal{O}_P$  respectively. In the simplest case, both oracles provide i.i.d. samples from  $\mathcal{D}$ . That is, each time an oracle is accessed, it returns a sample from  $\mathcal{D}$  taken independently of all previous samples and

events. In addition, the verifier and prover each have access to a (private) random coin value, denoted  $\rho_V$  and  $\rho_P$  respectively, which are sampled from some known distributions over  $\{0, 1\}^*$  independently of each other and of all other events. During the interaction, the prover and verifier take turns sending each other messages  $w_1, w_2, \dots$ , where  $w_i \in \{0, 1\}^*$  for all  $i$ . Finally, at some point during the exchange of messages,  $V$  halts and outputs either “reject” or a hypothesis  $h : \mathcal{X} \rightarrow \{0, 1\}$ . The goal of the verifier is to output an  $\varepsilon$ -good hypothesis, meaning that

$$L_{\mathcal{D}}(h) \leq L_{\mathcal{D}}(\mathcal{H}) + \varepsilon.$$

A natural special case of interest is when the prover’s and verifier’s oracles provide sample access to  $\mathcal{D}$ . The prover can learn a “good” hypothesis  $\tilde{h} : \mathcal{X} \rightarrow \{0, 1\}$  and send it to the verifier as its first message, as in Figure 1 above. The prover and verifier then exchange further messages, wherein the prover tries to convince the verifier that  $\tilde{h}$  is  $\varepsilon$ -good, and the verifier tries to assess the veracity of that claim. If the verifier is convinced, it outputs  $\tilde{h}$ , otherwise it rejects.

We proceed with an informal definition of PAC verification (see full definitions in Section 1.5). Before doing so, we first recall a relaxed variant of PAC learning, called *semi-agnostic* PAC learning, where we allow a multiplicative slack of  $\alpha \geq 1$  in the error guarantee.

► **Definition** ( $\alpha$ -PAC Learnability – informal version of [13, Definition 1.22]). *A class of hypothesis  $\mathcal{H}$  is  $\alpha$ -PAC learnable (or semi-agnostic PAC learnable with parameter  $\alpha$ ) if there exists an algorithm  $A$  such that for every distribution  $\mathcal{D}$  and every  $\varepsilon, \delta > 0$ , with probability at least  $1 - \delta$ ,  $A$  outputs  $h$  that satisfies*

$$L_{\mathcal{D}}(h) \leq \alpha \cdot L_{\mathcal{D}}(\mathcal{H}) + \varepsilon. \quad (2)$$

PAC verification is the corresponding notion for interactive proof systems:

► **Definition** ( $\alpha$ -PAC Verifiability – informal version of Definition 4). *A class of hypothesis  $\mathcal{H}$  is  $\alpha$ -PAC verifiable if there exists a pair of algorithms  $(P, V)$  that satisfy the following conditions for every distribution  $\mathcal{D}$  and every  $\varepsilon, \delta > 0$ :*

- **Completeness.** *After interacting with  $P$ ,  $V$  outputs  $h$  such that with probability at least  $1 - \delta$ ,  $h \neq \text{reject}$  and  $h$  satisfies (2).*
- **Soundness.** *After interacting with any (possibly unbounded) prover  $P'$ ,  $V$  outputs  $h$  such that with probability at least  $1 - \delta$ , either  $h = \text{reject}$  or  $h$  satisfies (2).*

► **Remark 1.** We insist on double efficiency; that is, that the sample complexity and running times of both  $V$  and  $P$  must be polynomial in  $\frac{1}{\varepsilon}$ ,  $\log(\frac{1}{\delta})$ , and perhaps also in some parameters that depend on  $\mathcal{H}$ , such as the VC dimension or Fourier sparsity of  $\mathcal{H}$ . ┐

## 1.4 Overview of Results

In this paper, we start charting the landscape of machine learning problems with respect to Questions 1 and 2 mentioned above. First, in Section 2 we provide evidence for an affirmative answer to Questions 2. We show an interactive proof system that efficiently verifies the class of Fourier-sparse boolean functions, where the prover uses an oracle that provides query access, and the verifier uses an oracle that only provides random samples. In this proof system, both the verifier and prover send and receive messages.

The class of Fourier-sparse functions is very broad, and includes decision trees, bounded-depth boolean circuits and many other important classes of functions. Moreover, the result is interesting because it supplements the widely-held learning parity with noise (LPN) assumption, which entails that PAC learning this class from random samples alone without the help of a prover is hard [5, 24].

► **Lemma** (Informal version of Lemma 14). *Let  $\mathcal{H}$  be the class of boolean functions  $\{0, 1\}^n \rightarrow \mathbb{R}$  that are  $t$ -sparse.<sup>6</sup> Then  $\mathcal{H}$  is 1-PAC verifiable with respect to the uniform distribution using a verifier that has access only to random samples of the form  $(x, f(x))$ , and a prover that has query access to  $f$ . The verifier in this protocol is not proper; the output is not necessarily  $t$ -sparse, but it is  $\text{poly}(n, t)$ -sparse. The number of samples used by the verifier, the number of queries made by the prover, and their running times are all bounded by  $\text{poly}(n, t, \log(\frac{1}{\delta}), \frac{1}{\epsilon})$ .*

**Proof Idea.** The proof uses two standard tools, albeit in a less-standard way. The first standard tool is the Kushilevitz-Mansour algorithm [16], which can PAC learn any  $t$ -sparse function using random samples, but only if the set of non-zero Fourier coefficients is *known*. The second standard tool is the Goldreich-Levin algorithm [10] and [8, Section 2.5.2.3], which can identify the set of non-zero Fourier coefficients, but requires *query access* in order to do so. The protocol combines the two tools in a manner that overcomes the limitations of each of them. First, the verifier executes the Goldreich-Levin algorithm, but whenever it needs to query the target function, it requests that the prover perform the query and send back the result. However, the verifier cannot trust the prover, and so the verifier engineers the queries in such a way that the answers to a certain random subset of the queries are known to the verifier based on its random sample access. This allows the verifier to detect dishonest provers. When the Goldreich-Levin algorithm terminates and outputs the set of non-zero coefficients, the verifier then feeds them as input to the Kushilevitz-Mansour algorithm to find an  $\epsilon$ -good hypothesis using its random sample access. ◀

In [13, Section 3] we formally answer Question 1 affirmatively by showing that a certain simple class of functions (generalized thresholds) exhibits a quadratic gap in sample complexity between learning and verifying:

► **Lemma** (Informal version of Lemma 15). *There exists a sequence of classes of functions  $\mathcal{T}_1, \mathcal{T}_2, \mathcal{T}_3, \dots \subseteq \{0, 1\}^{\mathbb{R}}$  such that for any fixed  $\epsilon, \delta \in (0, \frac{1}{2})$ :*

- (i) *The class  $\mathcal{T}_d$  is proper 2-PAC verifiable, where both the verifier and prover have access to random samples, and the verifier requires only  $\tilde{O}(\sqrt{d})$  samples. Moreover, both the prover and verifier are efficient.*
- (ii) *PAC learning the class  $\mathcal{T}_d$  requires  $\Omega(d)$  samples.*

At this point, a perceptive reader would be justified in raising the following challenges. Perhaps 2-PAC verification requires less samples than 1-PAC learning simply because of the multiplicative slack factor of 2? Alternatively, perhaps the separation follows trivially from property testing results: maybe it is possible to achieve 2-PAC verification simply by having the verifier perform closeness testing using random samples, without needing the help of the prover except for finding the candidate hypothesis? The second part of the lemma dismisses both of these concerns.

---

<sup>6</sup> A function  $f : \{0, 1\}^n \rightarrow \mathbb{R}$  is  $t$ -sparse if it has at most  $t$  non-zero Fourier coefficients, namely  $|\{S \subseteq [n] : \hat{f}(S) \neq 0\}| \leq t$ . See preliminaries in [13, Section 1.6.3] for further details.

- **Lemma** (Informal version of Lemma 15 – Continued). *Furthermore, for any fixed  $\varepsilon, \delta \in (0, \frac{1}{2})$ :*
- (iii) *2-PAC learning the class  $\mathcal{T}_d$  requires  $\tilde{\Omega}(d)$  samples. This is true even if we assume that  $L_{\mathcal{D}}(\mathcal{T}_d) > 0$ , where  $\mathcal{D}$  is the underlying distribution.<sup>7</sup>*
  - (iv) *Testing whether  $L_{\mathcal{D}}(\mathcal{T}_d) \leq \alpha$  or  $L_{\mathcal{D}}(\mathcal{T}_d) \geq \beta$  for any  $0 < \alpha < \beta < \frac{1}{2}$  with success probability at least  $1 - \delta$  when  $\mathcal{D}$  is an unknown distribution (without the help of a prover) requires  $\tilde{\Omega}(d)$  random samples from  $\mathcal{D}$ .*

**Proof Idea.** (ii) follows from a standard application of [13, Theorem 1.13], because  $\text{VC}(\mathcal{T}_d) = d$ . (iii) follows by a reduction from (iv). We prove (iv) by showing a further reduction from the problem of approximating the support size of a distribution, and applying a lower bound for that problem (see [13, Theorem 3.20]).

For (i), recall from the introduction that the difficulty in designing a PAC verification proof system revolves around convincing the verifier that the term  $L_{\mathcal{D}}(\mathcal{H})$  in Equation (1) is large. Therefore, we design our class  $\mathcal{T}_d$  such that it admits a simple *certificate of loss*, which is a string that helps the verifier ascertain that  $L_{\mathcal{D}}(\mathcal{H}) \geq \ell$  for some value  $\ell$ .

To see how that works, first consider the simple class  $\mathcal{T}_1$  of monotone increasing threshold functions  $\mathbb{R} \rightarrow \{0, 1\}$ , as in Figure 5a on page 17 below. Observe that if there are two events  $A = [0, a) \times \{1\}$  and  $B = [b, 1] \times \{0\}$  such that  $a \leq b$  and  $\mathcal{D}(A) = \mathcal{D}(B) = \ell$ , then it must be the case that  $L_{\mathcal{D}}(\mathcal{T}_1) \geq \ell$ . This is true because  $a \leq b$ , and so if a monotone increasing threshold classifies any point in  $A$  correctly it must classify all point in  $B$  incorrectly. Furthermore, if the prover sends a description of  $A$  and  $B$  to the verifier, then the verifier can check, using a constant number of samples, that each of these events has weight approximately  $\ell$  with high probability.

This type of certificate of loss can be generalized to the class  $\mathcal{T}_d$ , in which each function is a concatenation of  $d$  monotone increasing thresholds. A certificate of loss for  $\mathcal{T}_d$  is simply a set of  $d$  certificates of loss  $\{A_i, B_i\}_{i=1}^d$ , one for each of the  $d$  thresholds. The question that arises at this point is how can the verifier verify  $d$  separate certificates while using only  $\tilde{O}(\sqrt{d})$  samples. This is performed using tools from distribution testing: the verifier checks whether the distribution of “errors” in the sets specified by the certificates is close to the prover’s claims. I.e., whether the “weight” of 1-labels in each  $A_i$  and 0-labels in each  $B_i$  in the actual distribution, are close to the weights claimed by the prover. Using an identity tester for distributions this can be done using  $O(\sqrt{d})$  samples (note that the identity tester need not be tolerant!). See [13, Theorem E.1] for further details. ◀

In contrast, in [13, Section 4] we show that verification is not always easier than learning:

► **Lemma** (Informal version of [13, Lemma 4.1]). *There exists a sequence of classes  $\mathcal{H}_1, \mathcal{H}_2, \dots$  such that:*

- *It is possible to PAC learn the class  $\mathcal{H}_d$  using  $\tilde{O}(d)$  samples.*
- *For any interactive proof system that properly 1-PAC verifies  $\mathcal{H}_d$ , in which the verifier uses an oracle providing random samples, the verifier must use at least  $\Omega(d)$  samples.*

► **Remark 2.** The lower bound on the sample complexity of the verifier holds regardless of what oracle is used by the prover. ┘

**Proof Idea.** We specify a set  $\mathcal{X}$  of cardinality  $\Omega(d^2)$ , and take  $\mathcal{H}_d$  to be a randomly-chosen subset of all the balanced functions  $\mathcal{X} \rightarrow \{0, 1\}$  (i.e., functions  $f$  such that  $|f^{-1}(0)| = |f^{-1}(1)|$ ). The sample complexity of PAC learning  $\mathcal{H}_d$  follows from its VC dimension being

<sup>7</sup> In the case where  $L_{\mathcal{D}}(\mathcal{T}_d) = 0$ , 2-PAC learning is the same as PAC learning, so the stronger lower bound in (ii) applies.

$\tilde{O}(d)$ . For the lower bound, consider proper PAC verifying  $\mathcal{H}_d$  in the special case where the distribution  $\mathcal{D}$  satisfies  $\mathbb{P}_{(x,y) \in \mathcal{D}}[y = 1] = 1$ , but the marginal of  $\mathcal{D}$  on  $\mathcal{X}$  is unknown to the verifier. Because every hypothesis in the class assigns the incorrect label 0 to precisely half of the domain, a hypothesis achieves minimal loss if it assigns the 0 labels to a subset of size  $\frac{|\mathcal{X}|}{2}$  that has minimal weight. Hence, the verifier must learn enough about the distribution to identify a specific subset of size  $\frac{|\mathcal{X}|}{2}$  with weight close to minimal. We show that doing so requires  $\Omega\left(\sqrt{|\mathcal{X}|}\right) = \Omega(d)$  samples.  $\blacktriangleleft$

Finally, in [13, Section 5] we show that in the setting of semi-supervised learning, where unlabeled samples are cheap, it is possible to perform PAC verification such that the verifier requires significantly less labeled samples than are required for learning. This verification uses a technique we call *query delegation*, and is efficient in terms of time complexity whenever there exists an efficient ERM algorithm that PAC learns the class using random samples.

## 1.5 Definition of PAC Verification

In Section 1.3 we informally described the setting of this paper. Here, we complete that discussion by providing a formal definition of PAC verification, which is the main object of study in this paper.

► **Notation 3.** We write  $[V^{\mathcal{O}_V}(x_V), P^{\mathcal{O}_P}(x_P)]$  for the random variable denoting the output of the verifier  $V$  after interacting with a prover  $P$ , when  $V$  and  $P$  receive inputs  $x_V$  and  $x_P$  respectively, and have access to oracles  $\mathcal{O}_V$  and  $\mathcal{O}_P$  respectively. The inputs  $x_V$  and  $x_P$  can specify parameters of the interaction, such as the accuracy and confidence parameters  $\varepsilon$  and  $\delta$ . This random variable takes values in  $\{0, 1\}^{\mathcal{X}} \cup \{\text{reject}\}$ , namely, it is either a function  $\mathcal{X} \rightarrow \{0, 1\}$  or it is the value “reject”. The random variable depends on the (possibly randomized) responses of the oracles, and on the random coins of  $V$  and  $P$ .

For a distribution  $\mathcal{D}$ , we write  $V^{\mathcal{D}}$  (or  $P^{\mathcal{D}}$ ) to denote use of an oracle that provides i.i.d. samples from the distributions  $\mathcal{D}$ . Likewise, for a function  $f$ , we write  $V^f$  (or  $P^f$ ) to denote use of an oracle that provides query access to  $f$ . That is, in each access to the oracle,  $V$  (or  $P$ ) sends some  $x \in \mathcal{X}$  to the oracle, and receives the answer  $f(x)$ .

We also write  $[V(S_V, \rho_V), P(S_P, \rho_P)] \in \{0, 1\}^{\mathcal{X}} \cup \{\text{reject}\}$  to denote the deterministic output of the verifier  $V$  after interacting with  $P$  in the case where  $V$  and  $P$  receive fixed random coin values  $\rho_V$  and  $\rho_P$  respectively, and receive fixed samples  $S_V$  and  $S_P$  from their oracles  $\mathcal{O}_V$  and  $\mathcal{O}_P$  respectively.

We are interested in classes  $\mathcal{H}$  for which an  $\varepsilon$ -good hypothesis can always be verified with high probability via this form of interaction between an efficient prover and verifier, as formalized in the following definition. Note that the following definitions include an additional multiplicative slack parameter  $\alpha \geq 1$  in the error guarantee. This parameter does not exist in the standard definition of PAC learning; the standard definition corresponds to the case  $\alpha = 1$ .

► **Definition 4 ( $\alpha$ -PAC Verifiability).** Let  $\mathcal{H} \subseteq \{0, 1\}^{\mathcal{X}}$  be a class of hypotheses, let  $\mathfrak{D} \subseteq \Delta(\mathcal{X} \times \{0, 1\})$  be some family of distributions, and let  $\alpha \geq 1$ . We say that  $\mathcal{H}$  is  $\alpha$ -PAC verifiable with respect to  $\mathfrak{D}$  using oracles  $\mathcal{O}_V$  and  $\mathcal{O}_P$  if there exists a pair of algorithms  $(V, P)$  that satisfy the following conditions for every input  $\varepsilon, \delta > 0$ :

■ **Completeness.** For any distribution  $\mathcal{D} \in \mathfrak{D}$ , the random variable  $h := [V^{\mathcal{O}_V}(\varepsilon, \delta), P^{\mathcal{O}_P}(\varepsilon, \delta)]$  satisfies

$$\mathbb{P}\left[h \neq \text{reject} \wedge \left(L_{\mathcal{D}}(h) \leq \alpha \cdot L_{\mathcal{D}}(\mathcal{H}) + \varepsilon\right)\right] \geq 1 - \delta.$$

- **Soundness.** For any distribution  $\mathcal{D} \in \mathfrak{D}$  and any (possibly unbounded) prover  $P'$ , the random variable  $h := [V^{\mathcal{O}_V}(\varepsilon, \delta), P'^{\mathcal{O}_P}(\varepsilon, \delta)]$  satisfies

$$\mathbb{P} \left[ h \neq \text{reject} \wedge \left( L_{\mathcal{D}}(h) > \alpha \cdot L_{\mathcal{D}}(\mathcal{H}) + \varepsilon \right) \right] \leq \delta.$$

► **Remark 5.** Some comments about this definition:

- The behavior of the oracles  $\mathcal{O}_V$  and  $\mathcal{O}_P$  may depend on the specific underlying distribution  $\mathcal{D} \in \mathfrak{D}$ , which is unknown to the prover and verifier. For example, they may provide samples from  $\mathcal{D}$ .
- We insist on double efficiency; that is, that the sample complexity and running times of both  $V$  and  $P$  must be polynomial in  $\frac{1}{\varepsilon}$ ,  $\log(\frac{1}{\delta})$ , and perhaps also in some parameters that depend on  $\mathcal{H}$ , such as the VC dimension or Fourier sparsity of  $\mathcal{H}$ .
- If for every  $\varepsilon, \delta > 0$ , and for any (possibly unbounded) prover  $P'$ , the value  $h := [V^{\mathcal{O}_V}(\varepsilon, \delta), P'^{\mathcal{O}_P}(\varepsilon, \delta)]$  satisfies  $h \in \mathcal{H} \cup \{\text{reject}\}$  with probability 1 (i.e.,  $V$  never outputs a function that is not in  $\mathcal{H}$ ), then we say that  $\mathcal{H}$  is proper  $\alpha$ -PAC verifiable, and that the proof system proper  $\alpha$ -PAC verifies  $\mathcal{H}$ . ─

► **Remark 6.** An important type of learning (studied e.g. by Angluin [1] and Kushilevitz and Mansour [16]) is *learning with membership queries with respect to the uniform distribution*. In this setting, the family  $\mathfrak{D}$  consists of distributions  $\mathcal{D}$  such that: (1) the marginal distribution of  $\mathcal{D}$  over  $\mathcal{X}$  is uniform; (2)  $\mathcal{D}$  has a target function  $f : \mathcal{X} \rightarrow \{1, -1\}$  satisfying  $\mathbb{P}_{(x,y) \sim \mathcal{D}}[y = f(x)] = 1$ .<sup>8</sup> In Section 2, we will consider protocols for this type of learning that have the form  $[V^{\mathcal{D}}, P^f]$ , such that the verifier has access to an oracle providing random samples from a distribution  $\mathcal{D} \in \mathfrak{D}$ , and the prover has access to an oracle providing query access to  $f$ , the target function of  $\mathcal{D}$ . This type of protocol models a real-world scenario where  $P$  has qualitatively more powerful access to training data than  $V$ . ─

## 2 Efficient Verification for the Class of Fourier-Sparse Functions

In Section 3 below we show that in some cases verification is strictly easier than learning and closeness testing. The verification protocol presented there has a single round, where the prover simply sends a hypothesis and a proof that it is (approximately) optimal. In this section, we describe a multi-round protocol that demonstrates that interaction is helpful for verification.

The interactive protocol we present PAC verifies the class of *Fourier-sparse functions*. This is a broad class of functions, which includes decision trees, DNF formulas with small clauses, and  $\text{AC}^0$  circuits.<sup>9</sup> Every function  $f : \{0, 1\}^n \rightarrow \mathbb{R}$  can be written as a linear combination  $f = \sum_{T \subseteq [n]} \hat{f}(T) \chi_T$ .<sup>10</sup> In Fourier-sparse functions, only a small number of coefficients are non-zero. Note that according to the learning parity with noise (LPN) assumption [5, 24] it is not possible to learn the Fourier-sparse functions efficiently using random samples only.

An important technicality is that throughout this section we focus solely on PAC verification with respect to families of distributions that have a uniform marginal over  $\{0, 1\}^n$ , and have a target function  $f : \{0, 1\}^n \rightarrow \{1, -1\}$  such that  $\mathbb{P}_{(x,y) \sim \mathcal{D}}[y = f(x)] = 1$ . See further discussion in Remark 6 on page 11. In this setting, in order to learn  $f$  it is sufficient to approximate its heavy Fourier coefficients.

<sup>8</sup> Note that  $f$  is not necessarily a member of  $\mathcal{H}$ , so this is still an *agnostic* (rather than *realizable*) case.

<sup>9</sup> See Mansour [18, Section 5.2.2, Theorems 5.15 and 5.16]. ( $\text{AC}^0$  is the set of functions computable by constant-depth boolean circuits with a polynomial number of AND, OR and NOT gates.)

<sup>10</sup> The real numbers  $\hat{f}(T)$  are called *Fourier coefficients*, and the functions  $\chi_T$  are called *characters*.

► **Notation 7.** Let  $f : \{0, 1\}^n \rightarrow \mathbb{R}$ , and let  $\tau \geq 0$ . The set of  $\tau$ -heavy coefficients of  $f$  is  $\hat{f}^{\geq \tau} = \{T \subseteq [n] : |\hat{f}(T)| \geq \tau\}$ .

Furthermore, approximating a single coefficient is easy given random samples from the uniform distribution [13, Claim 2.11]. There are, however, an exponential number of coefficients, so approximating all of them is not feasible. This is where verification comes in. If the set of heavy coefficients is known, and if the function is Fourier-sparse, then one can efficiently learn the function by approximating that particular set of coefficients. The prover can provide the list of heavy coefficients, and then the verifier can learn the function by approximating these coefficients.

The challenge that remains in designing such a verification protocol is to verify that the provided list of heavy coefficients is correct. If the list contains some characters that are not actually heavy, no harm is done.<sup>11</sup> However, if a dishonest prover omits some of the heavy coefficients from the list, how can the verifier detect this omission? The following result provides an answer to this question.

► **Lemma 8 (Interactive Goldreich-Levin).** *There exists an interactive proof system  $(V, P^*)$  as follows. For every  $n \in \mathbb{N}$ ,  $\delta > 0$ , every  $\tau \geq 2^{-\frac{n}{10}}$ , every function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ , and every prover  $P$ , let*

$$L_P = [V(S, n, \tau, \delta, \rho_V), P^f(n, \tau, \delta, \rho_P)]$$

be a random variable denoting the output of  $V$  after interacting with the prover  $P$ , which has query access to  $f$ , where  $S = ((x_1, f(x_1)), \dots, (x_m, f(x_m)))$  is a random sample with  $x_1, \dots, x_m$  taken independently and uniformly from  $\{0, 1\}^n$ , and  $\rho_V, \rho_P$  are strings of private random coins.  $L_P$  takes values that are either a collection of subsets of  $[n]$ , or “reject”.

The following properties hold:

- **Completeness.**  $\mathbb{P} \left[ L_{P^*} \neq \text{reject} \wedge \hat{f}^{\geq \tau} \subseteq L_{P^*} \right] \geq 1 - \delta$ .
- **Soundness.** For any (possibly unbounded) prover  $P$ ,

$$\mathbb{P} \left[ L_P \neq \text{reject} \wedge \hat{f}^{\geq \tau} \not\subseteq L_P \right] \leq \delta.$$

- **Double efficiency.** The verifier  $V$  uses at most  $O\left(\frac{n}{\tau} \log\left(\frac{n}{\tau}\right) \log\left(\frac{1}{\delta}\right)\right)$  random samples from  $f$  and runs in time  $\text{poly}\left(n, \frac{1}{\tau}, \log\left(\frac{1}{\delta}\right)\right)$ . The runtime of the prover  $P^*$ , and the number of queries it makes to  $f$ , are at most  $O\left(\frac{n^3}{\tau^5} \log\left(\frac{1}{\delta}\right)\right)$ . Whenever  $L_P \neq \text{reject}$ , the cardinality of  $L_P$  is at most  $O\left(\frac{n^2}{\tau^5} \log\left(\frac{1}{\delta}\right)\right)$ .

All proofs for this section appear in Section 2 in the full version of the paper [13].

► **Remark 9.** In Section 1.5 we defined interactive proof systems specifically for PAC verification. The proof system in Lemma 8 is technically different. The verifier outputs a collection of sets instead of a function, and it satisfies different completeness and soundness conditions. ┘

The verifier  $V$  operates by simulating the Goldreich-Levin (GL) algorithm for finding  $\hat{f}^{\geq \tau}$ . However, the GL algorithm requires query access to  $f$ , while  $V$  has access only to random samples. To overcome this limitation,  $V$  delegates the task of querying  $f$  to the

---

<sup>11</sup> The verifier can approximate each coefficient in the list and discard of those that are not heavy. Alternatively, the verifier can include the additional coefficients in its approximation of the target function, because the approximation improves as the number of estimated coefficients grows (so long as the list is polynomial in  $n$ ).

prover  $P$ , who does have the necessary query access. Because  $P$  is not trusted,  $V$  engineers the set of queries it delegates to  $P$  in such a way that some random subset of them already appear in the sample  $S$  which  $V$  has received as input. This allows  $V$  to independently verify a random subset of the results sent by  $P$ , ensuring that a sufficiently dishonest prover is discovered with high probability.

**The Interactive Goldreich-Levin Protocol.** The verifier for Lemma 8 uses Protocol 2 (IGL), which repeatedly applies Protocol 3 (IGL-ITERATION).

■ **Protocol 2** Interactive Goldreich-Levin:  $\text{IGL}(n, \tau, \delta)$ .

```

V performs the following:
   $r \leftarrow \lceil (\frac{4n}{\tau} + 1) \log(\frac{1}{\delta}) \rceil$ 
  for  $i \in [r]$  do
     $L_i \leftarrow \text{IGL-ITERATION}(n, \tau)$ 
    if  $L_i = \text{reject}$  then
      output reject
   $L \leftarrow \bigcup_{i \in [r]} L_i$ 
  output  $L$ 

```

Lemma 8 follows from two claims: Claim 10 says that if the prover is mostly honest, then the output is correct. Claim 11 says that if the prover is too dishonest, it will be rejected.

▷ **Claim 10 (Completeness of IGL).** Consider an execution of  $\text{IGL-ITERATION}(n, \tau)$  for  $\tau \geq 2^{-\frac{n}{10}}$ . For any prover  $P$  and any randomness  $\rho_P$ , if  $V$  did not reject, and the evaluations provided by  $P$  were mostly honest, in the sense that  $\forall i \in [n] : \mathbb{P}_{x \in H} [\tilde{f}(x \oplus e_i) \neq f(x \oplus e_i)] \leq \frac{\tau}{4}$ , then  $\mathbb{P}[\hat{f}^{\geq \tau} \subseteq L] \geq \frac{1}{2}$ , where the probability is over the sample  $S$  and the randomness  $\rho_V$ . ◀

**Proof Idea.** We show that for every heavy coefficient  $T \in \hat{f}^{\geq \tau}$ ,  $\mathbb{P}[T \notin L] \leq \frac{\tau^2}{4}$ . From a union bound, this is sufficient to prove the claim, because Parseval's identity implies that  $|\hat{f}^{\geq \tau}| \leq \frac{1}{\tau^2}$ . The main observation is that the Goldreich-Levin algorithm is resilient to some *adversarial* noise. To see this, note that if  $T \in \hat{f}^{\geq \tau}$ , then  $\mathbb{P}_{x \in \{0,1\}^n} [f(x) = \ell(x)] \geq \frac{1}{2} + \frac{\tau}{2}$  for the linear function  $\ell(x) = \oplus_{i \in T} x_i$  (or its negation  $\neg \ell$ ). Therefore,  $f$  agrees with  $\ell$  with probability at least  $\frac{1}{2} + \frac{\tau}{4}$ , even if a  $\frac{\tau}{4}$ -fraction of  $f$ 's values are adversarially corrupted. Hence, in the iteration of the outer loop in Step 4 in which  $y_j = \ell(b_j)$  for all  $j \in [k]$ , the majority function will output the correct value of  $f(x^K \oplus e_i) \oplus y^K = \ell(x^K \oplus e_i) \oplus \ell(x^K) = \ell(e_i)$ , and this results in  $T$  being added to the output set  $L$ . Some finer details are discussed in the full version of the paper. ◀

▷ **Claim 11 (Soundness of IGL).** Consider an execution of  $\text{IGL-ITERATION}(n, \tau)$ . For any prover  $P$  and any randomness value  $\rho_P$ , if there exists  $i \in [n]$  for which  $P$  was too dishonest in the sense that  $\mathbb{P}_{x \in H} [\tilde{f}(x \oplus e_i) \neq f(x \oplus e_i)] > \frac{\tau}{4}$ , then  $\mathbb{P}[L = \text{reject}] \geq \frac{\tau}{4n}$ , where the probability is over the sample  $S$  and the randomness  $\rho_V$ . ◀

<sup>12</sup> For any  $j$ ,  $e_j$  is a vector in which the  $j$ -th entry is 1 and all other entries are 0.

■ **Protocol 3** Interactive Goldreich-Levin Iteration: IGL-ITERATION( $n, \tau$ ).

**Assumption:**  $V$  receives a sample  $S = ((x_1, f(x_1)), \dots, (x_m, f(x_m)))$  such that  $m = \lceil \log(\frac{40n}{\tau^4} + 1) \rceil$ , for all  $i \in [m]$ ,  $x_i \in \{0, 1\}^n$  is chosen independently and uniformly, and  $f(x_i) \in \{0, 1\}$ .

1.  $V$  selects  $i^* \in [n]$  uniformly at random, and then sends  $B$  to  $P$ , where  $B = \{b_1, \dots, b_k\} \subseteq \{0, 1\}^n$  is a basis chosen uniformly at random from the set of bases of the subspace  $H = \text{span}(\{x_1 \oplus e_{i^*}, \dots, x_m \oplus e_{i^*}\})$ .<sup>12</sup>
2.  $P$  sends  $V$  the set  $\{(x \oplus e_i, \tilde{f}(x \oplus e_i)) : i \in [n] \wedge x \in H\}$ , where for any  $z$ ,  $\tilde{f}(z)$  is purportedly the value of  $f(z)$  obtained using  $P$ 's query access to  $f$ .
3.  $V$  checks that for all  $i \in [m]$ , the evaluation  $f(x_i)$  provided by  $P$  equals that which appeared in the sample  $S$ . If there are any discrepancies,  $V$  rejects the interaction and terminates. Otherwise:
4. Let  $\mathcal{K} = \{K : \emptyset \subsetneq K \subseteq [k]\}$ .  $V$  Performs the following computation and outputs  $L$ :

```

 $L \leftarrow \emptyset$ 
for  $(y_1, \dots, y_k) \in \{0, 1\}^k$  do
  for  $K \in \mathcal{K}$  do
     $x^K \leftarrow \bigoplus_{i \in K} b_i$ 
     $y^K \leftarrow \bigoplus_{i \in K} y_i$ 
  for  $i \in [n]$  do
     $a_i \leftarrow \text{majority}_{K \in \mathcal{K}} (\tilde{f}(x^K \oplus e_i) \oplus y^K)$ 
  add  $\{i : a_i = 1\}$  and  $\{i : a_i = 0\}$  to  $L$ 
output  $L$ 

```

**Proof Idea.** In Protocol 3, the verifier “hides” the sample it knows in the random subspace  $H \oplus e_{i^*}$  for an index  $i^* \in [n]$  chosen uniformly at random. With probability at least  $\frac{1}{n}$ ,  $i^*$  is an index for which the prover was too dishonest. If that is the case, then in expectation a  $\frac{\tau}{4}$ -fraction of the prover’s answers on the known sample were dishonest, because the known sample is a random subset of  $H \oplus e_{i^*}$ . The claim now follows from Markov’s inequality. ◀

► **Remark 12.** It is possible to run all repetitions of the IGL protocol in parallel such that only 2 messages are exchanged. ┘

**Efficient Verification of Fourier-Sparse Functions.** As a corollary of Lemma 8, we obtain the following lemma, which is an interactive version of the Kushilevitz-Mansour algorithm [16, 17, 18]. It says that the class of  $t$ -sparse boolean functions is efficiently PAC verifiable with respect to the uniform distribution using an interactive proof system (Protocol 4) of the form  $[V^{\mathcal{D}}, P^f]$ , where the prover has query access and the verifier has random samples.

Protocol 4 uses a procedure ESTIMATECOEFFICIENT [13, Algorithm 4] that estimates a single fourier coefficient  $\hat{f}(T)$  up to precision  $\lambda$  with confidence  $\delta$  using  $\left\lceil \frac{2 \ln(2/\delta)}{\lambda^2} \right\rceil$  random samples. Note that the output of Protocol 4 is a function  $h : \{0, 1\}^n \rightarrow \mathbb{R}$ , not necessarily a boolean function.

► **Notation 13.** Let  $\mathcal{X}$  be a finite set. We write  $\mathfrak{D}_{\mathcal{U}}^{\text{func}}(\mathcal{X})$  to denote the set of all distributions  $\mathcal{D}$  over  $\mathcal{X} \times \{1, -1\}$  that have the following two properties:

- The marginal distribution of  $\mathcal{D}$  over  $\mathcal{X}$  is uniform. Namely,  $\sum_{y \in \{1, -1\}} \mathcal{D}((x, y)) = \frac{1}{|\mathcal{X}|}$  for all  $x \in \mathcal{X}$ .
- $\mathcal{D}$  has a target function  $f: \mathcal{X} \rightarrow \{1, -1\}$  satisfying  $\mathbb{P}_{(x, y) \sim \mathcal{D}}[y = f(x)] = 1$ .

► **Lemma 14.** Let  $\mathcal{X} = \{0, 1\}^n$ , and let  $\mathcal{H}$  be the class of functions  $\mathcal{X} \rightarrow \mathbb{R}$  that are  $t$ -sparse.<sup>6</sup> The class  $\mathcal{H}$  is 1-PAC verifiable for any  $\varepsilon \geq 4t \cdot 2^{-\frac{n}{10}}$  with respect to  $\mathfrak{D}_{\mathcal{U}}^{\text{func}}(\mathcal{X})$  by a proof system in which the verifier has access to random samples from a distribution  $\mathcal{D} \in \mathfrak{D}_{\mathcal{U}}^{\text{func}}(\mathcal{X})$ , and the honest prover has oracle access to the target function  $f: \mathcal{X} \rightarrow \{1, -1\}$  of  $\mathcal{D}$ . The running time of both parties is at most poly  $(n, t, \frac{1}{\varepsilon}, \log(\frac{1}{\delta}))$ . The verifier in this protocol is not proper; the output is not necessarily  $t$ -sparse, but it is poly  $(n, t, \frac{1}{\varepsilon}, \log(\frac{1}{\delta}))$ -sparse.

■ **Protocol 4** PAC Verification of  $t$ -Sparse Functions:  $\text{VERIFYFOURIERSPARSE}(n, t, \varepsilon, \delta)$ .

$V$  performs the following:

```

 $\tau \leftarrow \frac{\varepsilon}{4t}$ 
 $L \leftarrow \text{IGL}(n, \tau, \frac{\delta}{2})$ 
if  $L = \text{reject}$  then
  output reject
else
   $\lambda \leftarrow \sqrt{\frac{\varepsilon}{8|L|}}$ 
  for  $T \in L$  do
     $\alpha_T \leftarrow \text{ESTIMATECOEFFICIENT}(T, \lambda, \frac{\delta}{2|L|})$ 
   $h \leftarrow \sum_{T \in L} \alpha_T \chi_T$ 
  output  $h$ 

```

Complete proofs appear in Section 2 in the full version of the paper [13].

### 3 Separation Between Learning, Testing, and PAC Verification

In this section we present the following gap in sample complexity between *learning* and *verification*. Conceptually, the result tells us that at least in some scenarios, delegating a learning task to an untrusted party is worthwhile, because verifying that their final result is correct is significantly cheaper than finding that result ourselves.

► **Lemma 15** (Separation Between Learning, Testing, and Verification). *There exists a sequence of classes of functions  $\mathcal{T}_1, \mathcal{T}_2, \mathcal{T}_3, \dots \subseteq \{0, 1\}^{\mathbb{R}}$  such that for any fixed  $\varepsilon, \delta \in (0, \frac{1}{2})$  all of the following hold:*

- (i)  $\mathcal{T}_d$  is proper 2-PAC verifiable, where the verifier uses<sup>13</sup>

$$m_V = O\left(\frac{\sqrt{d} \log(d) \log(\frac{1}{\delta})}{\varepsilon^6}\right)$$

random samples, the honest prover uses

<sup>13</sup>We believe that the dependence of  $m_V$  on  $\varepsilon$  can be improved, see [13, Remark 3.15].

$$m_P = O\left(\frac{d^3 \log^2(d)}{\varepsilon^4} \log\left(\frac{d}{\varepsilon}\right) + \frac{d\sqrt{d} \log(d)}{\varepsilon^2} \log\left(\frac{1}{\delta}\right)\right)$$

random samples, and each of them runs in time polynomial in its number of samples.<sup>14</sup>

- (ii) Agnostic PAC learning  $\mathcal{T}_d$  requires  $\Omega\left(\frac{d+\log(\frac{1}{\delta})}{\varepsilon^2}\right)$  samples.
- (iii) If  $\varepsilon \leq \frac{1}{32}$  then 2-PAC learning the class  $\mathcal{T}_d$  requires  $\Omega\left(\frac{d}{\log(d)}\right)$  samples. This is true even if we assume that  $L_{\mathcal{D}}(\mathcal{T}_d) > 0$ , where  $\mathcal{D}$  is the underlying distribution.
- (iv) Testing whether  $L_{\mathcal{D}}(\mathcal{T}_d) \leq \alpha$  or  $L_{\mathcal{D}}(\mathcal{T}_d) \geq \beta$  for any  $0 < \alpha < \beta < \frac{1}{2}$  with success probability at least  $1 - \delta$  when  $\mathcal{D}$  is an unknown distribution (without the help of a prover) requires  $\Omega\left(\frac{d}{\log(d)}\right)$  random samples from  $\mathcal{D}$ .

Our exposition in this section is partial, and aims only to convey the main ideas of part (i). Complete formal proofs appear in [13, Section 3]. We show an MA-like proof system wherein the prover sends a single message  $(\tilde{h}, \tilde{C}, \tilde{\ell})$  such that allegedly  $\tilde{h}$  is an  $\varepsilon$ -good hypothesis with loss at most  $\tilde{\ell} > 0$ .  $\tilde{C} \in \{0, 1\}^*$  is a string called a *certificate of loss*, which helps the verifier ascertain that  $\mathcal{H}$  has a large loss with respect to the unknown distribution  $\mathcal{D}$ . The verifier operates as follows:<sup>15</sup>

- Verifies that  $L_{\mathcal{D}}(\tilde{h}) \leq \tilde{\ell}$  with high probability. That is, it estimates the loss of  $\tilde{h}$  with respect to  $\mathcal{D}$ , and checks that with high probability it is at most  $\tilde{\ell}$ .
- Uses the certificate of loss  $\tilde{C}$  to verify that with high probability,  $L_{\mathcal{D}}(\mathcal{H}) \geq \tilde{\ell} - \varepsilon$ . This step is called *verifying the certificate*.

The class  $\mathcal{T}_d$  of *multi-thresholds* that satisfies Lemma 15 is illustrated in Figure 5, and is defined as follows.

► **Definition 16.** For any  $d \in \mathbb{N}$ , denote by  $\mathcal{T}_d$  the class of functions  $\mathcal{T}_d = \{f_{t_1, \dots, t_d} : t_1, \dots, t_d \in \mathbb{R}\}$  where for all  $t_1, \dots, t_d \in \mathbb{R}$  and  $x \in [0, d]$ , the function  $f_{t_1, \dots, t_d} : \mathbb{R} \rightarrow \{0, 1\}$  is given by

$$f_{t_1, \dots, t_d}(x) = \begin{cases} 0 & x < t_{\lceil x \rceil} \\ 1 & x \geq t_{\lceil x \rceil}, \end{cases}$$

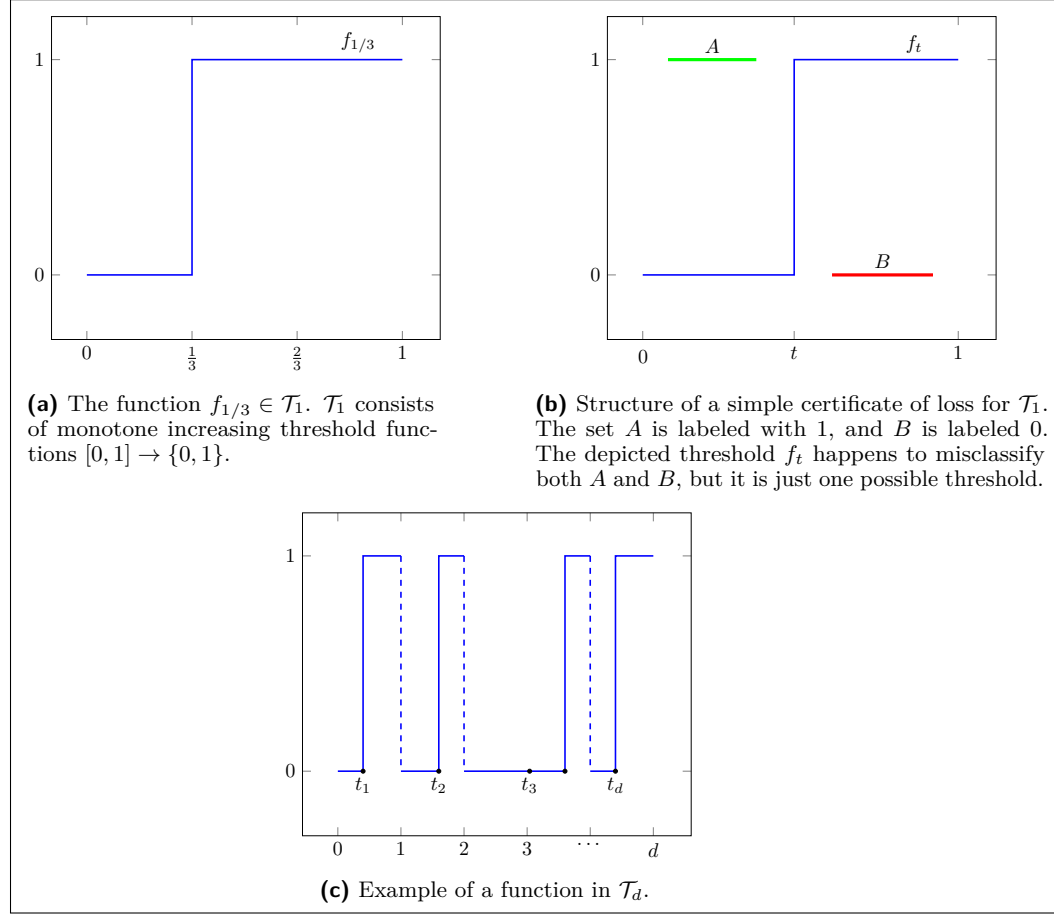

and  $f_{t_1, \dots, t_d}$  vanishes on the complement of  $[0, d]$ .

► **Remark 17.** For convenience, we present the separation result with respect to functions defined over  $\mathbb{R}$ , we assume that the marginal distribution of the samples on  $\mathbb{R}$  is absolutely continuous with respect to the Lebesgue measure, and we ignore issues relating to the representation of real numbers in computations and protocol messages. This provides for a smoother exposition of the ideas. In [13, Appendix C], we show how the results can be discretized. ┘

We first present the certificate structure for the class of threshold functions, namely  $\mathcal{T}_d$  with  $d = 1$ . Certificates of loss for  $\mathcal{T}_1$  are easy to visualize, and they induce a proof system for PAC verifying  $\mathcal{T}_1$  that is complete, sounds, and doubly efficient. However, verifying certificates for  $\mathcal{T}_1$  requires as much resources as PAC learning  $\mathcal{T}_1$  without the help of a prover. The next step is to show that these certificates generalize to the class  $\mathcal{T}_d$  of multi-thresholds, and that for  $\mathcal{T}_d$  there indeed is a gap in sample complexity between verifying and learning.

<sup>14</sup> Subsequent unpublished work by JS and Saachi Mutreja suggests that it is possible to strengthen this to obtain 1-PAC verification with better sample complexity bounds.

<sup>15</sup> We provide a more detailed description of the verification procedure below, and in [13, Claim 3.14].

■ **Figure 5** The class  $\mathcal{T}_d$  of multi-thresholds, with the special case  $\mathcal{T}_1$  and its certificate structure.

**Certificates of loss for  $\mathcal{T}_1$ .** Consider two sets  $A \subseteq [0, 1] \times \{1\}$  and  $B \subseteq [0, 1] \times \{0\}$ , such that all the points in  $A$  are located to the left of all the points in  $B$ , as in Figure 5b. Because we only allow thresholds that are monotone increasing, a threshold that labels any point in  $A$  correctly must label all points of  $B$  incorrectly, and vice versa. Hence, any threshold must have loss at least  $\min\{\mathcal{D}(A), \mathcal{D}(B)\}$ . Estimating  $\mathcal{D}(A)$  and  $\mathcal{D}(B)$  is easy (by Hoeffding's inequality). Formally:

► **Definition 18.** Let  $\mathcal{D} \in \Delta([0, 1] \times \{0, 1\})$  be a distribution and  $\ell, \eta \geq 0$ . A certificate of loss at least  $\ell$  for class  $\mathcal{T}_1$  is a pair  $(a, b)$  where  $0 < a \leq b < 1$ .

We say that the certificate is  $\eta$ -valid with respect to distribution  $\mathcal{D}$  if the events  $A = [0, a] \times \{1\}$  and  $B = [b, 1] \times \{0\}$  satisfy  $|\mathcal{D}(A) - \ell| + |\mathcal{D}(B) - \ell| \leq \eta$ .

▷ **Claim 19** ([13, Claims 3.5 and 3.4]). Let  $\mathcal{D} \in \Delta([0, 1] \times \{0, 1\})$  be a distribution and  $\ell, \eta \geq 0$ .

- Soundness. If  $\mathcal{D}$  has a certificate of loss at least  $\ell$  which is  $\eta$ -valid with respect to  $\mathcal{D}$ , then  $L_{\mathcal{D}}(\mathcal{T}_1) \geq \ell - \eta$ .
- Completeness. If  $L_{\mathcal{D}}(\mathcal{T}_1) = \ell$  then there exists a 0-valid certificate of loss at least  $\frac{\ell}{2}$  with respect to  $\mathcal{D}$ . ┘

**Certificates of loss for  $\mathcal{T}_d$  with  $d > 1$ .** A certificate of loss is simply a collection of  $d$  certificates of loss for  $\mathcal{T}_1$ , one for each unit interval in  $[0, d]$ . Standard techniques from VC theory show that it is possible to efficiently generate certificates for  $\mathcal{T}_d$  for a particular distribution using  $\tilde{O}(d^2)$  samples [13, Claim 3.13]. This is more expensive than learning the class  $\mathcal{T}_d$ , but it may be worthwhile seeing as the verifier can apply techniques from distribution testing to verify purported certificates using only  $\tilde{O}(\sqrt{d})$  samples – which is cheaper than learning [13, Claim 3.14].

Further discussion and complete proofs of Lemma 15(ii)-(iv), including the lower bound for closeness testing, appear in the full version of the paper [13].

## 4 Directions for Future Work

This work initializes the study of verification in the context of machine learning. We have seen separations between the sample complexity of verification versus learning and testing, a protocol that uses interaction to efficiently learn sparse boolean functions, and have seen that in some cases the sample complexities of verification and learning are the same.

Building a theory that can help guide verification procedures is a main objective for future research. A specific approach is to identify dimension-like quantities that describe the sample complexity of verification, similarly to role VC dimension plays in characterizing learnability. A different approach is to understand the trade-offs between the various resources in the system – the amount of time, space and samples used by the prover and the verifier, as well as the amount of interaction between the parties.

From a practical perspective, we described potential applications for delegation of machine learning, and for verification of experimental data. It seems beneficial to build efficient verification protocols for machine learning problems that are commonly used in practice, and for the types of scientific experiments mentioned in [13, Appendix A]. This would have commercial and scientific applications.

There are also some technical improvements that we find interesting. For example, is there a simple way to improve the MA-like protocol for the multi-thresholds class  $\mathcal{T}_d$  to achieve 1-PAC verification (instead of 2-PAC verification)?

Finally, seeing as learning verification is still a new concept, it would be good to consider alternative formal definitions, investigate how robust our definition is, and discuss what the “right” definition should be.

Additional directions are discussed in Section 6 in the full version of the paper [13]. ◀

## Abstract

The emerging theory of graph limits exhibits an analytic perspective on graphs, showing that many important concepts and tools in graph theory and its applications can be described more naturally (and sometimes proved more easily) in analytic language. We extend the theory of graph limits to the ordered setting, presenting a limit object for dense vertex-ordered graphs, which we call an *orderon*. As a special case, this yields limit objects for matrices whose rows and columns are ordered, and for dynamic graphs that expand (via vertex insertions) over time. Along the way, we devise an ordered locality-preserving variant of the cut distance between ordered graphs, showing that two graphs are close with respect to this distance if and only if they are similar in terms of their ordered subgraph frequencies. We show that the space of orderons is compact with respect to this distance notion, which is key to a successful analysis of combinatorial objects through their limits. For the proof we combine techniques used in the unordered setting with several new techniques specifically designed to overcome the challenges arising in the ordered setting.

We derive several applications of the ordered limit theory in extremal combinatorics, sampling, and property testing in ordered graphs. In particular, we prove a new ordered analogue of the well-known result by Alon and Stav [RS&A'08] on the furthest graph from a hereditary property; this is the first known result of this type in the ordered setting. Unlike the unordered regime, here the Erdős-Rényi random graph  $G(n, p)$  with an ordering over the vertices is *not* always asymptotically the furthest from the property for some  $p$ . However, using our ordered limit theory, we show that random graphs generated by a stochastic block model, where the blocks are consecutive in the vertex ordering, are (approximately) the furthest. Additionally, we describe an alternative analytic proof of the ordered graph removal lemma [Alon et al., FOCS'17].

## 1 Introduction

Large graphs appear in many applications across all scientific areas. Naturally, it is interesting to try to understand their structure and behavior: When can we say that two graphs are similar (even if they do not have the same size)? How can the convergence of graph sequences be defined? What properties of a large graph can we capture by taking a small sample from it?

The theory of graph limits addresses such questions from an analytic point of view. The investigation of convergent sequences of dense graphs was started to address three seemingly unrelated questions asked in different fields: statistical physics, theory of networks and the Internet, and quasi-randomness. A comprehensive series of papers [12, 13, 28, 21, 29, 14, 11, 30, 15] laid the infrastructure for a rigorous study of the theory of dense graph limits, demonstrating various applications in many areas of mathematics and computer science. The book of Lovász on graph limits [27] presents these results in a unified form.

A sequence  $\{G_n\}_{n=1}^\infty$  of finite graphs, whose number of vertices tends to infinity as  $n \rightarrow \infty$ , is considered *convergent*<sup>1</sup> if the frequency<sup>2</sup> of any fixed graph  $F$  as a subgraph in  $G_n$  converges as  $n \rightarrow \infty$ . The limit object of a convergent sequence of (unordered) graphs in the dense setting, called a *graphon*, is a measurable symmetric function  $W: [0, 1]^2 \rightarrow [0, 1]$ , and it was proved in [28] that, indeed, for any convergent sequence  $\{G_n\}$  of graphs there exists a graphon serving as the limit of  $G_n$  in terms of subgraph frequencies. Apart from their role in the theory of graph limits, graphons are useful in probability theory, as they give rise to exchangeable random graph models; see e.g. [17, 33]. An analytic theory of convergence has been established for many other types of discrete structures. These include sparse graphs, for which many different (and sometimes incomparable) notions of limits exist – see e.g. [16, 10] for two recent papers citing and discussing many of the works in this field; permutations, first developed in [25] and further investigated in several other works; partial orders [26]; and high dimensional functions over finite fields [35]. The limit theory of dense graphs has also been extended to hypergraphs, see [36, 18] and the references within.

In this work we extend the theory of dense graph limits to the ordered setting, establishing a limit theory for vertex-ordered graphs in the dense setting, and presenting several applications of this theory. An *ordered graph* is a symmetric function  $G: [n]^2 \rightarrow \{0, 1\}$ .  $G$  is *simple* if  $G(x, x) = 0$  for any  $x$ . A *weighted ordered graph* is a symmetric function  $F: [n]^2 \rightarrow [0, 1]$ . Unlike the unordered setting, where  $G, G': [n]^2 \rightarrow \Sigma$  are considered isomorphic if there is a permutation  $\pi$  over  $[n]$  so that  $G(x, y) = G'(\pi(x), \pi(y))$  for any  $x \neq y \in [n]$ , in the ordered setting, the automorphism group of a graph  $G$  is trivial:  $G$  is only isomorphic to itself through the identity function.

For simplicity, we consider in the following only graphs (without edge colors). All results here can be generalized in a relatively straightforward manner to edge-colored graph-like ordered structures, where pairs of vertices may have one of  $r \geq 2$  colors (the definition above corresponds to the case  $r = 2$ ). This is done by replacing the range  $[0, 1]$  with the  $(r - 1)$ -dimensional simplex (corresponding to the set of all possible distributions over  $[r]$ ).

Two interesting special cases of two-dimensional ordered structures for which our results naturally yield a limit object are *images*, i.e., ordered matrices, and *dynamic graphs* with vertex insertions. Specifically, (binary)  $m \times n$  images can be viewed as ordered bipartite

<sup>1</sup> In unordered graphs, this is also called *convergence from the left*; see the discussion on [14].

<sup>2</sup> The frequency of  $F$  in  $G$  is roughly defined as the ratio of induced subgraphs of  $G$  isomorphic to  $F$  among all induced subgraphs of  $G$  on  $|F|$  vertices.

graphs  $I: [m] \times [n] \rightarrow \{0, 1\}$ , and our results can be adapted to get a bipartite ordered limit object for them as long as  $m = \Theta(n)$ . Meanwhile, a dynamic graph with vertex insertions can be viewed as a sequence  $\{G_i\}_{i=1}^\infty$  of ordered graphs, where  $G_{i+1}$  is the result of adding a vertex to  $G_i$  and connecting it to the previous vertices according to some prescribed rule. It is natural to view such dynamic graphs that evolve with time as ordered ones, as the time parameter induces a natural ordering. Thus, our work gives, for example, a limit object for time-series where there are pairwise relations between events occurring at different times.

As we shall see in Subsection 1.2, the main results proved in this paper are, in a sense, natural extensions of results in the unordered setting. However, proving them requires machinery that is heavier than that used in the unordered setting: the tools used in the unordered setting are not rich enough to overcome the subtleties materializing in the ordered setting. In particular, the limit object we use in the ordered setting – which we call an *orderon* – has a 4-dimensional structure that is more complicated than the analogous 2-dimensional structure of the graphon, the limit object for the unordered setting. The tools required to establish the ordered theory are described next.

## 1.1 Main ingredients

Let us start by considering a simple yet elusive sequence of ordered graphs, which has the makings of convergence. The *odd-clique* ordered graph  $H_n$  on  $2n$  vertices is defined by setting  $H_n(i, j) = 1$ , i.e., having an edge between vertices  $i$  and  $j$ , if and only if  $i \neq j$  and  $i, j$  are both odd, and otherwise setting  $H_n(i, j) = 0$ . In this subsection we closely inspect this sequence to demonstrate the challenges arising while trying to establish a theory for ordered graphs, and the solutions we propose for them. First, let us define the notions of subgraph frequency and convergence.

The (induced) frequency  $t(F, G)$  of a simple ordered graph  $F$  on  $k$  vertices in an ordered graph  $G$  with  $n$  vertices is the probability that, if one picks  $k$  vertices of  $G$  uniformly and independently (repetitions are allowed) and reorders them as  $x_1 \leq \dots \leq x_k$ ,  $F$  is isomorphic to the induced ordered subgraph of  $G$  over  $x_1, \dots, x_k$ . (The latter is defined as the ordered graph  $H$  on  $k$  vertices satisfying  $H(i, j) = G(x_i, x_j)$  for any  $i, j \in [k]$ .) A sequence  $\{G_n\}_{n=1}^\infty$  of ordered graphs is *convergent* if  $|V(G_n)| \rightarrow \infty$  as  $n \rightarrow \infty$ , and the frequency  $t(F, G_n)$  of any simple ordered graph  $F$  converges as  $n \rightarrow \infty$ . Observe that the odd-clique sequence  $\{H_n\}$  is indeed convergent: The frequency of the empty  $k$ -vertex graph in  $H_n$  tends to  $(k+1)2^{-k}$  as  $n \rightarrow \infty$ , the frequency of any non-empty  $k$ -vertex ordered graph containing only a clique and a (possibly empty) set of isolated vertices tends to  $2^{-k}$ , and the frequency of any other graph in  $H_n$  is 0.<sup>3</sup>

In light of previous works on the unordered theory of convergence, we look for a limit object for ordered graphs that has the following features.

**Representation of finite ordered graphs.** The limit object should have a natural and consistent representation for finite ordered graphs. As in graphons, we allow graphs  $G$  and  $H$  to have the same representation when one is a blowup<sup>4</sup> of the other.

**Usable distance notion.** Working directly with the definition of convergence in terms of subgraph frequencies is difficult. The limit object we seek should be endowed with a metric, like the cut distance for unordered graphs (see discussion below), that should be easier to work with and must have the following property: A sequence of ordered graph is convergent (in terms of frequencies) if and only if it is Cauchy in the metric.

<sup>3</sup> To see why the sum of frequencies is 1, note that for  $k \geq \ell \geq 2$ , the number of  $k$ -vertex ordered graphs consisting of an  $\ell$ -vertex clique and  $k - \ell$  isolated vertices is  $\binom{k}{\ell}$ .

<sup>4</sup> A graph  $G$  on  $nt$  vertices is an ordered  $t$ -blowup of  $H$  on  $n$  vertices if  $G(x, y) = H(\lceil x/t \rceil, \lceil y/t \rceil)$  for any  $x$  and  $y$ .

**Completeness and compactness.** The space of limit objects must be complete with respect to the metric: Cauchy sequences should converge in this metric space. Combined with the previous requirements, this will ensure that any convergent sequence of ordered graphs has a limit (in terms of ordered frequencies), as desired. It is even better if the space is compact, as compactness is essentially an “ultimately strong” version of Szemerédi’s regularity lemma [34], and will help to develop applications of the theory in other areas.

Additionally, we would like the limit object to be as simple as possible, without unnecessary over-representation. In the unordered setting, the metric used is the *cut distance*, introduced by Frieze and Kannan [22, 23] and defined as follows. First, we define the *cut norm*  $\|W\|_{\square}$  of a function  $W: [0, 1]^2 \rightarrow \mathbb{R}$  as the supremum of  $|\int_{S \times T} W(x, y) dx dy|$  over all measurable subsets  $S, T \subseteq [0, 1]$ . The *cut distance* between graphons  $W$  and  $W'$  is the infimum of  $\|W^{\phi} - W'\|_{\square}$  over all measure-preserving bijections  $\phi: [0, 1] \rightarrow [0, 1]$ , where  $W^{\phi}(x, y) \stackrel{\text{def}}{=} W(\phi(x), \phi(y))$ .

For the ordered setting, we look for a similar metric; the cut distance itself does not suit us, as measure-preserving bijections do not preserve ordered subgraph frequencies in general. A first intuition is then to try graphons as the limit object, endowed with the metric  $d_{\square}(W, W') \stackrel{\text{def}}{=} \|W - W'\|_{\square}$ . However, this metric does not satisfy the second requirement: the odd-clique sequence is convergent, yet it is not Cauchy in  $d_{\square}$ , since  $d_{\square}(H_n, H_{2n}) = 1/2$  for any  $n$ . Seeing that  $d_{\square}$  seems “too strict” as a metric and does not capture the similarities between large odd-clique graphs well, it might make sense to use a slightly more “flexible” metric, which allows for measure-preserving bijections, as long as they do not move any of the points too far from its original location. In view of this, we define the *cut-shift distance* between two graphons  $W, W'$  as

$$d_{\triangle}(W, W') \stackrel{\text{def}}{=} \inf_f (\text{Shift}(f) + \|W^f - W'\|_{\square}), \quad (1)$$

where  $f: [0, 1] \rightarrow [0, 1]$  is a measure-preserving bijection,  $\text{Shift}(f) = \sup_{x \in [0, 1]} |f(x) - x|$ , and  $W^f(x, y) = W(f(x), f(y))$  for any  $x, y \in [0, 1]$ . As we show in this paper (Theorem 2 below), the cut-shift distance settles the second requirement: a sequence of ordered graphs is convergent *if and only if* it is Cauchy in the cut-shift distance.

Consider now graphons as a limit object, coupled with the cut-shift distance as a metric. Do graphons satisfy the third requirement? In particular, does there exist a graphon whose ordered subgraph frequencies are equal to the limit frequencies for the odd-clique sequence? The answers to both of these questions are negative: it can be shown that such a graphon cannot exist in view of Lebesgue’s density theorem, which states that there is no measurable subset of  $[0, 1]$  whose density in every interval  $(a, b)$  is  $(b - a)/2$  (see e.g. Theorem 2.5.1 in the book of Franks on Lebesgue measure [20]). Thus, we need a somewhat richer ordered limit object that will allow us to “bypass” the consequences of Lebesgue’s density theorem. Consider for a moment the graphon representations of the odd clique graphs. In these graphons, the domain  $[0, 1]$  can be partitioned into increasingly narrow intervals that alternately represent odd and even vertices. Intuitively, it seems that our limit object needs to be able to contain infinitesimal odd and even intervals at any given location, leading us to the following limit object candidate, which we call an *orderon*.

An orderon is a symmetric measurable function  $W: ([0, 1]^2)^2 \rightarrow [0, 1]$  viewed, intuitively and loosely speaking, as follows. In each point  $(x, a) \in [0, 1]^2$ , corresponding to an infinitesimal “vertex” of the orderon, the first coordinate,  $x$ , represents a location in the linear order of  $[0, 1]$ . Each set  $\{x\} \times [0, 1]$  can thus be viewed as an infinitesimal probability space of vertices that have the same location in the linear order. The role of the second coordinate is to allow “variability” (in terms of probability) of the infinitesimal “vertex” occupying this point in

the order. The definition of the frequency  $t(F, W)$  of a simple ordered graph  $F = ([k], E)$  in an orderon  $W$  is a natural extension of frequency in graphons. First, define the random variable  $\mathbf{G}(k, W)$  as follows: Pick  $k$  points in  $[0, 1]^2$  uniformly and independently, order them according to the first coordinate as  $(x_1, a_1), \dots, (x_k, a_k)$  with  $x_1 \leq \dots \leq x_k$ , and then return a  $k$ -vertex graph  $G$ , in which the edge between each pair of vertices  $i$  and  $j$  exists with probability  $W((x_i, a_i), (x_j, a_j))$ , independently of other edges. The frequency  $t(F, W)$  is defined as the probability that the graph generated according to  $\mathbf{G}(k, W)$  is isomorphic to  $F$ .

Consider the orderon  $W$  satisfying  $W((x, a), (y, b)) = 1$  if and only if  $a, b \leq 1/2$ , and otherwise  $W((x, a), (y, b)) = 0$ .  $W$  now emerges as a natural limit object for the odd-clique sequence: one can verify that the subgraph frequencies in it are as desired.

The cut-shift distance for orderons is defined similarly to (1), except that  $f$  is now a measure-preserving bijection from  $[0, 1]^2$  to  $[0, 1]^2$  and  $\text{Shift}(f) = \sup_{(x,a) \in [0,1]^2} |\pi_1(f(x, a)) - x|$ , where  $\pi_1(y, b) \stackrel{\text{def}}{=} y$  is the projection to the first coordinate.

## 1.2 Main results

Let  $\mathcal{W}$  denote the space of orderons endowed with the cut-shift distance. In view of Lemma 19 below,  $d_\Delta$  is a pseudo-metric for  $\mathcal{W}$ . By identifying  $W, U \in \mathcal{W}$  whenever  $d_\Delta(W, U) = 0$ , we get a metric space  $\widetilde{\mathcal{W}}$ . The following result is the main component for the viability of our limit object, settling the third requirement above.

► **Theorem 1.** *The space  $\widetilde{\mathcal{W}}$  is compact with respect to  $d_\Delta$ .*

The proof of Theorem 1 is significantly more involved than the proof of its unordered analogue. While at a very high level, the roadmap of the proof is similar to that of the unordered one, our setting induces several new challenges, and to handle them we develop new *shape approximation* techniques. These are presented along the proof of the theorem in Section 4.

The next result shows that convergence in terms of frequencies is equivalent to being Cauchy in  $d_\Delta$ . This settles the second requirement.

► **Theorem 2.** *Let  $\{W_n\}_{n=1}^\infty$  be a sequence of orderons. Then  $\{W_n\}$  is Cauchy in  $d_\Delta$  if and only if  $t(F, W_n)$  converges for any fixed simple ordered graph  $F$ .*

As a corollary of the last two results, we get the following.

► **Corollary 3.** *For every convergent sequence of ordered graphs  $\{G_n\}_{n \in \mathbb{N}}$ , there exists an orderon  $W \in \mathcal{W}$  such that  $t(F, G_n) \rightarrow t(F, W)$  for every ordered graph  $F$ .*

The next main result is a sampling theorem, stating that a large enough sample from an orderon is almost always close to it in cut-shift distance. For this, we define the orderon representation  $W_G$  of an  $n$ -vertex ordered graph  $G$  by setting  $W_G((x, a), (y, b)) = G(Q_n(x), Q_n(y))$  for any  $x, a, y, b$ , where we define  $Q_n(x) = \lceil nx \rceil$  for  $x > 0$  and  $Q_n(0) = 1$ . This addresses the first requirement.

► **Theorem 4.** *Let  $k$  be a positive integer and let  $W \in \mathcal{W}$  be an orderon. Let  $G \sim \mathbf{G}(k, W)$ . Then,*

$$d_\Delta(W, W_G) \leq C \left( \frac{\log \log k}{\log k} \right)^{1/3}$$

*holds with probability at least  $1 - C \exp(-\sqrt{k}/C)$  for some constant  $C > 0$ .*

Theorem 4 implies, in particular, that ordered graphs are a dense subset in  $\mathcal{W}$ .

► **Corollary 5.** *For every orderon  $W$  and every  $\varepsilon > 0$ , there exists a simple ordered graph  $G$  on at most  $2^{\varepsilon^{-3+o(1)}}$  vertices such that  $d_\Delta(W, W_G) \leq \varepsilon$ .*

Our next result asserts that any orderon  $W \in \mathcal{W}$  can be approximated in  $L_1$ -distance by an orderon  $U$  with a finite block structure, with the added property that any ordered finite structure that appears with positive density in  $U$  also has positive density in  $W$ .<sup>5</sup> The orderon  $U$  is described as follows. The point set  $[0, 1]^2$  is divided into  $b$  “blocks”, which are subsets of the form  $[(i-1)/b, i/b] \times [0, 1]$  for some  $i \in [b]$ . Each block is decomposed into  $l$  “layers”, of the form  $[(i-1)/b, i/b] \times [(j-1)/l, j/l]$  where  $j \in [l]$ . The value of  $U((x, a), (y, b))$  is now only dependent on which blocks  $x, y$  belong to, which layers  $a, b$  belong to, and possibly whether  $x < y$ . For example, the orderon  $U$  representing the limit of the odd-clique sequence (defined by  $U((x, a), (y, b)) = 1$  if  $a, b \leq 1/2$ , and  $U((x, a), (y, b)) = 0$  elsewhere) has one block and two layers in it. Roughly speaking, one can think of such  $U$  as the orderon representation of a “pixelized” ordered graph, where each vertex (block) consists of multiple “pixels” (here a pixel corresponds to a block-layer pair), and there is a weighted edge<sup>6</sup> between each pair of pixels. Therefore we call an orderon  $U$  with such structure a *pixelized* orderon and term our result the *pixelization lemma*.

► **Theorem 6** (Pixelization lemma; informal). *For any orderon  $W$  and  $\varepsilon > 0$ , there exists a pixelized orderon  $U$  so that  $d_1(U, W) \leq \varepsilon$ , satisfying the following: for all ordered graphs  $F$  with  $t(F, U) > 0$ , we have  $t(F, W) > 0$ .*

We note that the pixelized structure of  $U$  is necessary for this statement to be correct; it is no longer correct in general if we insist that  $U$  must be the orderon representation of a standard edge-weighted ordered graph.

The pixelization lemma is especially useful for applications where the  $L_1$ -distance comes into play. Two such applications, reproving the ordered graph removal lemma [2] and proving a new result in extremal combinatorics, are described next.

### 1.3 The furthest ordered graph from a hereditary property

Here and in the next subsection we describe three applications of our ordered limit theory. We start with an extensive discussion on the first application: A new result on the maximum edit<sup>7</sup> distance  $d_1(G, \mathcal{H})$  of an ordered graph  $G$  from a hereditary<sup>8</sup> property  $\mathcal{H}$ .

For a hereditary property  $\mathcal{H}$  of simple ordered graphs, define  $\overline{d_{\mathcal{H}}} = \sup_G d_1(G, \mathcal{H})$  where  $G$  ranges over all simple graphs (of any size). The parameter  $d_{\mathcal{H}}$  has been widely investigated for unordered graphs. A well-known surprising result of Alon and Stav [6] states, roughly speaking, that  $d_{\mathcal{H}}$  is always “achieved” by the Erdős-Rényi random graph  $\mathbf{G}(n, p)$  for an appropriate choice of  $p$  and large enough  $n$ .

<sup>5</sup> A weaker result, in which the  $L_1$ -distance is replaced by the cut-shift distance, is not hard to prove using our previous main results; we note that it is indeed strictly weaker since the  $L_1$ -distance between any two orderons  $U$  and  $W$  is always at least as large as (and sometimes much larger than)  $d_\Delta(U, W)$ .

<sup>6</sup> In fact, a weighted bi-directed edge, with possibly different weights in the two different directions.

<sup>7</sup> For our purposes, define the edit (or Hamming) distance between two ordered graphs  $G$  and  $G'$  on  $n$  vertices as the smallest number of entries that one needs to change in the adjacency matrix  $A_G$  of  $G$  to make it equal to  $A_{G'}$ , divided by  $n^2$ . For this matter, the adjacency matrix  $A_G$  of a graph  $G$  over vertices  $v_1 < \dots < v_n$  is a binary  $n \times n$  matrix where  $A_G(i, j) = 1$  if and only if there is an edge between  $v_i$  and  $v_j$  in  $G$ . The distance between  $G$  and a property  $\mathcal{P}$  of ordered graphs is  $\min_{G'} d_1(G, G')$  where  $G'$  ranges over all graphs  $G'$  of the same size as  $G$ . The definition for unordered graphs is similar; the only difference is in the notion of isomorphism.

<sup>8</sup> A property of (ordered or unordered) graphs is *hereditary* if it is closed under taking induced subgraphs.

► **Theorem 7** ([6]). *For any hereditary property  $\mathcal{H}$  of unordered graphs there exists  $p_{\mathcal{H}} \in [0, 1]$  satisfying the following. A graph  $G \sim \mathbf{G}(n, p_{\mathcal{H}})$  satisfies  $d_1(G, \mathcal{H}) \geq \overline{d_{\mathcal{H}}} - o(1)$  with high probability.*

In other words, a random graph  $\mathbf{G}(n, p_{\mathcal{H}})$  is with high probability asymptotically (that is, up to relative edit distance of  $o(1)$ ) the furthest from the property  $\mathcal{H}$ . From the analytic perspective, Lovász and Szegedy [30] were able to reprove (and extend) this result using graph limits.

The surprising result of Alon and Stav has led naturally to a very interesting and highly non-trivial question, now known as the (extremal) *graph edit distance problem* [31], which asks the following: Given a hereditary property of interest  $\mathcal{H}$ , what is the value (or values)  $p_{\mathcal{H}}$  that maximizes the distance of  $\mathbf{G}(n, p)$  from  $\mathcal{H}$ ? The general question of determining  $p_{\mathcal{H}}$  given any  $\mathcal{H}$  is currently wide open, although there have been many interesting developments for various classes of hereditary properties; see [31] for an extensive survey of previous works and useful techniques.

While the situation in unordered graphs, and even in (unordered) directed graphs [7] and matrices [32] has been thoroughly investigated, for ordered graphs no result in the spirit of Theorem 7 is known. The first question that comes to mind is whether the behavior in the ordered setting is similar to that in the unordered case: Is it true that for any hereditary property  $\mathcal{H}$  of *ordered* graphs there exists  $p = p_{\mathcal{H}}$  for which  $G \sim \mathbf{G}(n, p)$  satisfies  $d_1(G, \mathcal{H}) \geq \overline{d_{\mathcal{H}}} - o(1)$  with high probability?

As we show, the answer is in fact *negative*. Consider the ordered graph property  $\mathcal{H}$  defined as follows:  $G \in \mathcal{H}$  if and only if there do not exist vertices  $u_1 < u_2 \leq u_3 < u_4$  in  $G$  where  $u_1 u_2$  is a non-edge and  $u_3 u_4$  is an edge.  $\mathcal{H}$  is clearly a hereditary property, defined by a finite family of forbidden ordered subgraphs. In the full version [9], we prove that the typical distance of  $G \sim \mathbf{G}(n, p)$  from  $\mathcal{H}$  is no more than  $1/4 + o(1)$  (the maximum is asymptotically attained for  $p = 1/2$ ). In contrast, we show there exists a graph  $G$  satisfying  $d_1(G, \mathcal{H}) = 1/2 - o(1)$ , which is clearly the furthest possible up to the  $o(1)$  term (every graph  $G$  is  $1/2$ -close to either the complete or the empty graph, which are in  $\mathcal{H}$ ), and is substantially further than the typical distance of  $\mathbf{G}(n, p)$  for any choice of  $p$ . This shows that Theorem 7 *cannot be true* for the ordered setting.

However, the news are not all negative: We present a positive result in the ordered setting, which generalizes the unordered statement in some sense, and whose proof makes use of our ordered limit theory. While it is no longer true that  $\mathbf{G}(n, p)$  generates graphs that are asymptotically the furthest from  $\mathcal{H}$ , we show that a random graph generated according to a *consecutive stochastic block model* is approximately the furthest. A *stochastic block model* [1] with  $M$  blocks is a well-studied generalization of  $\mathbf{G}(n, p)$ , widely used in the study of community detection, clustering, and various other problems in mathematics and computer science. A stochastic block model is defined according to the following three parameters:  $n$ , the total number of vertices;  $(q_1, \dots, q_M)$ , a vector of probabilities that sum up to one; and a symmetric  $M \times M$  matrix of probabilities  $p_{ij}$ . A graph on  $n$  vertices is generated according to this model as follows. First, we assign each of the vertices independently<sup>9</sup> to one of  $M$  parts  $A_1, \dots, A_M$ , where the probability of any given vertex to fall in  $A_i$  is  $q_i$ . Then, for any  $(i, j) \in [M]^2$ , and any pair of disjoint vertices  $u \in A_i$  and  $v \in A_j$ , we add an edge between  $u$  and  $v$  with probability  $p_{ij}$ . By *consecutive*, we mean that all vertices assigned to  $A_i$  precede (in the vertex ordering) all vertices assigned to  $A_{i+1}$ , for any  $i \in [M - 1]$ . Our main result now is as follows.

<sup>9</sup> In some contexts, the stochastic block model is defined by determining the *exact* number of vertices in each  $A_i$  in advance, rather than assigning the vertices independently; all results here are also true for this alternative definition.

► **Theorem 8.** *Let  $\mathcal{H}$  be a hereditary property of simple ordered graphs and let  $\varepsilon > 0$ . There exists a consecutive stochastic block model with at most  $M = M_{\mathcal{H}}(\varepsilon)$  blocks with equal containment probabilities (i.e.,  $q_i = 1/M$  for any  $i \in [M]$ ), satisfying the following. A graph  $G$  on  $n$  vertices generated by this model satisfies  $d_1(G, \mathcal{H}) \geq \overline{d_{\mathcal{H}}} - \varepsilon$  with probability that tends to one as  $n \rightarrow \infty$ .*

The proof, given in the full version of this paper [9], is a good example of the power of the analytic perspective, combining our ordered limit theory with standard measure-theoretic tools and a few simple lemmas proved in [30].

## 1.4 Sampling and property testing

We finish by showing two additional applications of the ordered limit theory. These applications are somewhat more algorithmically oriented – concerning sampling and property testing – and illustrate the use of our theory for algorithmic purposes. The first of them is concerned with naturally estimable ordered graph parameters, defined as follows.

► **Definition 9** (naturally estimable parameter). *An ordered graph parameter  $f$  is naturally estimable if for every  $\varepsilon > 0$  and  $\delta > 0$  there is a positive integer  $k = k(\varepsilon, \delta) > 0$  satisfying the following. If  $G$  is an ordered graph with at least  $k$  nodes and  $G|_{\mathbf{k}}$  is the subgraph induced by a uniformly random ordered set of exactly  $k$  nodes of  $G$ , then*

$$\Pr_{G|_{\mathbf{k}}} [|f(G) - f(G|_{\mathbf{k}})| > \varepsilon] < \delta.$$

The following result provides an analytic characterization of ordered natural estimability, providing a method to study estimation problems on ordered graphs from the analytic perspective.

► **Theorem 10.** *Let  $f$  be a bounded simple ordered graph parameter. Then, the following are equivalent:*

1.  *$f$  is naturally estimable.*
2. *For every convergent sequence  $\{G_n\}_{n \in \mathbb{N}}$  of ordered simple graphs with  $|V(G_n)| \rightarrow \infty$ , the sequence of numbers  $\{f(G_n)\}_{n \in \mathbb{N}}$  is convergent.*
3. *There exists a functional  $\hat{f}(W)$  over  $\mathcal{W}$  that satisfies the following:*
  - a.  *$\hat{f}(W)$  is continuous with respect to  $d_{\Delta}$ .*
  - b. *For every  $\varepsilon > 0$ , there is  $k = k(\varepsilon)$  such that for every ordered graph  $G$  with  $|V(G)| \geq k$ , it holds that  $|\hat{f}(W_G) - f(G)| \leq \varepsilon$ .*

Our third application is a new analytic proof of the ordered graph removal lemma of [2], implying that every hereditary property of ordered graphs (and images over a fixed alphabet) is testable, with one-sided error, using a constant number of queries. (For the relevant definitions, see [2] and Definition 9 here.)

► **Theorem 11** ([2]). *Let  $\mathcal{H}$  be a hereditary property of simple ordered graphs, and fix  $\varepsilon, c > 0$ . Then there exists  $k = k(\mathcal{H}, \varepsilon, c)$  satisfying the following: For every ordered graph  $G$  on  $n \geq k$  vertices that is  $\varepsilon$ -far from  $\mathcal{H}$ , the probability that  $G|_{\mathbf{k}}$  does not satisfy  $\mathcal{H}$  is at least  $1 - c$ .*

Our proof of Theorem 11 utilizes the analytic tools developed in this work, and bypasses the need for many of the sophisticated combinatorial techniques from [2], resulting in an arguably cleaner proof.

## 1.5 Related work

The theory of graph limits has strong ties to the area of property testing, especially in the dense setting. Regularity lemmas for graphs, starting with the well-known regularity lemma of Szemerédi [34], later to be joined by the weaker (but more efficient) versions of Frieze and Kannan [22, 23] and the stronger variants of Alon et al. [3], among others, have been very influential in the development of property testing. For example, regularity was used to establish the testability of all hereditary properties in graphs [5], the relationship between the testability and estimability of graph parameters [19], and combinatorial characterizations of testability [4].

The analytic theory of convergence, built using the cut distance and its relation to the weak regularity lemma, has proved to be an interesting alternative perspective on these results. Indeed, the aforementioned results have equivalent analytic formulations, in which both the statement and the proof seem cleaner and more natural. A recent line of work has shown that many of the classical results in property testing of dense graphs can be extended to dense ordered graph-like structures, including vertex-ordered graphs and images. In [2], it was shown that the testability of hereditary properties extends to the ordered setting (see Theorem 11 above). Shortly after, in [8] it was proved that characterizations of testability in unordered graphs can be partially extended to similar characterizations in ordered graph-like structures, provided that the property at stake is sufficiently “well-behaved” in terms of order.

Graphons and their sparse analogues have various applications in different areas of mathematics, computer science, and even social sciences. The connections between graph limits and real-world large networks have been very actively investigated; see the survey of Borgs and Chayes [16]. Graph limits have applications in probability and data analysis [33]. Graphons were used to provide new analytic proofs of results in extremal graph theory; see Chapter 16 in [27]. Through the notion of free energy, graphons were also shown to be closely connected to the field of statistical physics [15]. We refer the reader to [27] for more details.

We remark that an independent work, by Frederik Garbe, Robert Hancock, Jan Hladky, and Maryam Sharifzadeh, investigates an alternative limit object for the ordered setting in the context of latin squares. See [24] for their findings, as well as connections between orderons and their limit object, called a latinon.

## 1.6 Organization

Due to space limitations, much of the technical content is missing from this version of the paper. Specifically, we only include here the following components. In Section 2, we present basic definitions for our ordered limit theory. Section 3 contains the main ingredients for the the proof that ordered graphs are dense in the space of orderons (some technical details are relegated to the full version). Section 4 presents the proof that the space of orderons is compact (Theorem 1). The reader is referred to [9] for a full version of this paper, including proofs of all results stated in this manuscript.

## 2 Preliminaries

In this section we formally describe some of the basic ingredients of our theory, including the limit object – the *orderon*, and several distance notions including the cut-norm for orderons (both unordered and ordered variants are presented), and the cut-shift distance. We then

show that the latter is a pseudo-metric for the space of orderons. This will later allow us to view the space of orderons as a metric space, by identifying orderons of cut-shift distance 0.

The measure used here is the Lebesgue measure, denoted by  $\lambda$ . We start with the formal definition of an orderon.

► **Definition 12 (orderon).** *An orderon is a measurable function  $W : ([0, 1]^2)^2 \rightarrow [0, 1]$  that is symmetric in the sense that  $W((x, a), (y, b)) = W((y, b), (x, a))$  for all  $(x, a), (y, b) \in [0, 1]^2$ . For the sake of brevity, we also denote  $W((x, a), (y, b))$  by  $W(v_1, v_2)$  for  $v_1, v_2 \in [0, 1]^2$ .*

We denote the set of all orderons by  $\mathcal{W}$ .

► **Definition 13 (measure-preserving bijection).** *A map  $g : [0, 1]^2 \rightarrow [0, 1]^2$  is measure preserving if the pre-image  $g^{-1}(X)$  is measurable for every measurable set  $X$  and  $\lambda(g^{-1}(X)) = \lambda(X)$ . A measure preserving bijection is a measure preserving map whose inverse map exists (and is also measure preserving).*

Let  $\mathcal{F}$  denote the collection of all measure preserving bijections from  $[0, 1]^2$  to itself. Given an orderon  $W \in \mathcal{W}$  and  $f \in \mathcal{F}$ , we define  $W^f$  as the unique orderon satisfying  $W^f((x, a), (y, b)) = W(f(x, a), f(y, b))$  for any  $x, a, y, b \in [0, 1]$ . Additionally, denote by  $\pi_1 : [0, 1]^2 \rightarrow [0, 1]$  the projection to the first coordinate, that is,  $\pi_1(x, a) = x$  for any  $(x, a) \in [0, 1]^2$ .

## 2.1 Cut-norm and ordered cut-norm

The definition of the (unordered) cut-norm for orderons is analogous to the corresponding definition for graphons.

► **Definition 14 (cut-norm).** *Given a symmetric measurable function  $W : ([0, 1]^2)^2 \rightarrow \mathbb{R}$ , we define the cut-norm of  $W$  as*

$$\|W\|_{\square} \stackrel{\text{def}}{=} \sup_{S, T \subseteq [0, 1]^2} \left| \int_{(x, a) \in S} \int_{(y, b) \in T} W((x, a), (y, b)) dx da dy db \right|.$$

As we are working with ordered objects, the following definition of *ordered cut-norm* will sometimes be of use (see the full version [9] for more details). Given  $v_1, v_2 \in [0, 1]^2$ , we write  $v_1 \leq v_2$  to denote that  $\pi_1(v_1) \leq \pi_1(v_2)$ . Let  $\mathbf{1}_E$  be the indicator function for the event  $E$ .

► **Definition 15 (ordered cut-norm).** *Let  $W : ([0, 1]^2)^2 \rightarrow \mathbb{R}$  be a symmetric measurable function. The ordered cut norm of  $W$  is defined as*

$$\|W\|_{\square'} = \sup_{S, T \subseteq [0, 1]^2} \left| \int_{(v_1, v_2) \in S \times T} W(v_1, v_2) \mathbf{1}_{v_1 \leq v_2} dv_1 dv_2 \right|.$$

We mention two important properties of the ordered-cut norm. The first is a standard smoothing lemma, and the second is a relation between the ordered cut-norm and the unordered cut-norm. The proof of both lemmas can be found in the full version [9].

► **Lemma 16.** *Let  $W \in \mathcal{W}$  and  $\mu, \nu : [0, 1]^2 \rightarrow [0, 1]$ . Then,*

$$\left| \int_{v_1, v_2} \mu(v_1) \nu(v_2) W(v_1, v_2) \mathbf{1}_{v_1 \leq v_2} dv_1 dv_2 \right| \leq \|W\|_{\square'}.$$

► **Lemma 17.** *Let  $W : ([0, 1]^2)^2 \rightarrow [-1, 1]$  be a symmetric measurable function. Then,*

$$\frac{\|W\|_{\square'}^2}{4} \leq \|W\|_{\square} \leq 2\|W\|_{\square'}.$$

## 2.2 The cut and shift distance

The next notion of distance is a central building block in this work. It can be viewed as a locality preserving variant of the unordered cut distance, which accounts for order changes resulting from applying a measure preserving function.

► **Definition 18.** *Given two orderons  $W, U \in \mathcal{W}$  we define the CS-distance (cut-norm+shift distance) as:*

$$d_{\Delta}(W, U) \stackrel{\text{def}}{=} \inf_{f \in \mathcal{F}} (\text{Shift}(f) + \|W - U^f\|_{\square}),$$

where  $\text{Shift}(f) \stackrel{\text{def}}{=} \sup_{x, a \in [0, 1]} |x - \pi_1(f(x, a))|$ .

► **Lemma 19.**  $d_{\Delta}$  is a pseudo-metric on the space of orderons.

For the proof, see the full version [9].

## 3 Block orderons and their density in $\mathcal{W}$

Here we show that weighted ordered graphs are dense in the space of orderons coupled with the cut-shift distance. To start, we have to define the orderon representation of a weighted ordered graph, called a *naive block orderon*. A naive  $n$ -block orderon is defined as follows.

► **Definition 20 (naive block orderon).** *Let  $m \in \mathbb{N}$ . For  $z \in (0, 1]$ , we denote  $Q_n(z) = \lceil nz \rceil$ ; we also set  $Q_n(0) = 1$ . An  $m$ -block naive orderon is a function  $W: ([0, 1]^2)^2 \rightarrow [0, 1]$  that can be written, for some weighted ordered graph  $G$  on  $n$  vertices, as*

$$W((x, a), (y, b)) = G(Q_n(x), Q_n(y)), \quad \forall x, a, y, b \in [0, 1].$$

Following the above definition, we denote by  $W_G$  the naive block orderon defined using  $G$ , and view  $W_G$  as the orderon “representing”  $G$  in  $\mathcal{W}$ . Similarly to the unordered setting, this representation is slightly ambiguous (but this will not affect us). Indeed, it is not hard to verify that two weighted ordered graphs  $F$  and  $G$  satisfy  $W_F = W_G$  if and only if both  $F$  and  $G$  are blowups of some weighted ordered graph  $H$ . Here, a weighted ordered graph  $G$  on  $nt$  vertices is a  $t$ -blowup of a weighted ordered graph  $H$  on  $n$  vertices if  $G(x, y) = H(\lceil x/t \rceil, \lceil y/t \rceil)$  for any  $x, y \in [nt]$ .

We call an orderon  $U \in \mathcal{W}$  a *step function with at most  $k$  steps* if there is a partition  $\mathcal{R} = \{S_1, \dots, S_k\}$  of  $[0, 1]^2$  such that  $U$  is constant on every  $S_i \times S_j$ .

► **Remark 21 (The name choices).** The definition of a step function in the space of orderons is the natural extension of a step function in graphons. Note that a naive block orderon is a special case of a step function, where the steps  $S_i$  are rectangular (this is why we call these “block orderons”). The “naive” prefix refers to the fact that we do not make use of the second coordinate in the partition.

For every  $W \in \mathcal{W}$  and every partition  $\mathcal{P} = \{S_1, \dots, S_k\}$  of  $[0, 1]^2$  into measurable sets, let  $W_{\mathcal{P}}: ([0, 1]^2)^2 \rightarrow [0, 1]$  denote the step function obtained from  $W$  by replacing its value at  $((x, a), (y, b)) \in S_i \times S_j$  by the average of  $W$  on  $S_i \times S_j$ . That is,

$$W_{\mathcal{P}}((x, a), (y, b)) = \frac{1}{\lambda(S_i)\lambda(S_j)} \int_{S_i \times S_j} W((x', a'), (y', b')) dx' da' dy' db',$$

Where  $i$  and  $j$  are the unique indices such that  $(x, a) \in S_i$  and  $(y, b) \in S_j$ , respectively.

The next lemma is an extension of the regularity lemma to the setting of Hilbert spaces.

## 42:12 Ordered Graph Limits and Their Applications

► **Lemma 22** ([29], Lemma 4.1). *Let  $\{\mathcal{K}_i\}_i$  be arbitrary non-empty subsets of a Hilbert space  $\mathcal{H}$ . Then, for every  $\varepsilon > 0$  and  $f \in \mathcal{H}$  there is an  $m \leq \lceil 1/\varepsilon^2 \rceil$  and there are  $f_i \in \mathcal{K}_i$  ( $1 \leq i \leq k$ ) and  $\gamma_1, \dots, \gamma_k \in \mathbb{R}$  such that for every  $g \in \mathcal{K}_{k+1}$*

$$|\langle g, f - (\gamma_1 f_1 + \dots + \gamma_k f_k) \rangle| \leq \varepsilon \|f\| \|g\|$$

The following is a direct consequence of Lemma 22.

► **Lemma 23.** *For every  $W \in \mathcal{W}$  and  $\varepsilon > 0$  there is a step function  $U \in \mathcal{W}$  with at most  $\lceil 2^{8/\varepsilon^2} \rceil$  steps such that*

$$\|W - U\|_{\square} \leq \varepsilon.$$

Similarly to the graphon case, the step function  $U$  might not be a stepping of  $W$ . However, it can be shown that these steppings are almost optimal.

► **Claim 24.** Let  $W \in \mathcal{W}$ , let  $U$  be a step function, and let  $\mathcal{P}$  denote the partition of  $[0, 1]^2$  into the steps of  $U$ . Then  $\|W - W_{\mathcal{P}}\|_{\square} \leq 2\|W - U\|_{\square}$ .

Using Lemma 23 and Claim 24 we can obtain the following lemma.

► **Lemma 25.** *For every function  $W \in \mathcal{W}$  and every  $\varepsilon > 0$ , there is a partition  $\mathcal{P}$  of  $[0, 1]^2$  into at most  $2^{\lceil 32/\varepsilon^2 \rceil}$  sets with positive measure such that  $\|W - W_{\mathcal{P}}\|_{\square} \leq \varepsilon$ .*

Using the above lemma, we can impose stronger requirements on our partition. In particular, we can show that there exists a partition of  $[0, 1]^2$  to sets of the same measure. Such a partition is referred to as an *equipartition*. Also, we say that a partition  $\mathcal{P}$  *refines*  $\mathcal{P}'$ , if  $\mathcal{P}$  can be obtained from  $\mathcal{P}'$  by splitting each  $P_j \in \mathcal{P}'$  into a finite number of sets (up to sets of measure 0).

► **Lemma 26.** *Fix some  $\varepsilon > 0$ . Let  $\mathcal{P}$  be an equipartition of  $[0, 1]^2$  into  $k$  sets, and fix  $q \geq 2k^2 \cdot 2^{162/\varepsilon^2}$  such that  $k$  divides  $q$ . Then, for any  $W \in \mathcal{W}$ , there exists an equipartition  $\mathcal{Q}$  that refines  $\mathcal{P}$  with  $q$  sets, such that  $\|W - W_{\mathcal{Q}}\|_{\square} \leq \frac{8\varepsilon}{9} + \frac{2}{k}$ .*

The next lemma is an (easier) variant of Lemma 26, in the sense that we refine two given partitions. However, the resulting partition will not be an equipartition.

► **Lemma 27.** *Fix some  $\varepsilon > 0$  and  $d \in \mathbb{N}$ . Let  $\mathcal{I}_d$  be an equipartition of  $[0, 1]^2$  into  $2^d$  sets,  $\mathcal{P}$  be a partition of  $[0, 1]^2$  into  $k$  sets, and fix  $q \geq 2(k \cdot 2^d)^2 \cdot 2^{162/\varepsilon^2}$  such that both  $k$  and  $2^d$  divide  $q$ . Then, for any  $W \in \mathcal{W}$ , there exists a partition  $\mathcal{Q}$  that refines both  $\mathcal{P}$  and  $\mathcal{I}_d$  with  $q$  sets, such that  $\|W - W_{\mathcal{Q}}\|_{\square} \leq \frac{8\varepsilon}{9} + \frac{2}{k \cdot 2^d}$ .*

**Proof.** Let  $\mathcal{P}' = \{P'_1, \dots, P'_{p'}\}$  be a partition of  $[0, 1]^2$  into  $p' \leq 2^{162/\varepsilon^2}$  sets such that  $\|W - W_{\mathcal{P}'}\|_{\square} \leq \frac{4\varepsilon}{9}$ , and let  $\mathcal{Q} = \{Q_1, \dots, Q_q\}$  be a common refinement of the three partitions  $\mathcal{P}$ ,  $\mathcal{P}'$  and  $\mathcal{I}_d$ . Note that we do not repartition further to get an equipartition. The rest of the proof is similar to the proof of Lemma 26. ◀

The following theorem shows that naive block orderons are a dense subset in  $\mathcal{W}$ .

► **Theorem 28.** *For every orderon  $W \in \mathcal{W}$  and every  $\varepsilon > 0$ , there exist a naive  $\frac{c}{\varepsilon^4} 2^{162/\varepsilon^2}$ -block orderon  $W'$  (for some constant  $c > 0$ ) such that*

$$d_{\Delta}(W, W') \leq \varepsilon.$$

**Proof.** Fix  $\varepsilon > 0$  and  $\gamma = \gamma(\varepsilon) > 0$ . We consider an interval equipartition  $J = \{J_1, \dots, J_{1/\gamma}\}$  of  $[0, 1]$  (namely, for each  $j \in [\frac{1}{\gamma} - 1]$ ,  $J_j = [(j-1) \cdot \gamma, j \cdot \gamma)$ , and for  $j = 1/\gamma$ ,  $J_j = [(j-1) \cdot \gamma, j \cdot \gamma]$ ). In addition, let  $\mathcal{P} = (J_i \times J_j \mid i, j \in [1/\gamma])$  be an equipartition of  $[0, 1]^2$ . By Lemma 26, there exists an equipartition  $\mathcal{Q}$  of  $[0, 1]^2$  of size  $q = \frac{2}{\gamma^4} 2^{162/\varepsilon^2}$  that refines  $\mathcal{P}$ , such that

$$\|W - W_{\mathcal{Q}}\|_{\square} \leq \frac{8\varepsilon}{9} + 2\gamma^2.$$

Next we construct a small shift measure preserving function  $f$  as follows. For every  $i \in [1/\gamma]$ , consider the collection of sets  $\{Q_k^i \mid k \in [\gamma q]\}$  in  $\mathcal{Q}$  such that

$$(J_i \times [0, 1]) \cap \mathcal{Q} = \{Q_k^i \mid k \in [\gamma q]\}.$$

For each  $k \in [\gamma q]$ , the function  $f$  maps  $Q_k^i$  to a rectangular set

$$\left[ (i-1)\gamma + \frac{(k-1)}{q}, (i-1)\gamma + \frac{k}{q} \right) \times [0, 1].$$

Finally, for every  $i, j \in [q]$  and every  $(x, a), (y, b) \in Q_i \times Q_j$ , we define

$$W'(f(x, a), f(y, b)) = W_{\mathcal{Q}}((x, a), (y, b))$$

Note that the resulting function  $W'$  obeys the definition of a naive  $q$ -block orderon and  $\text{Shift}(f) \leq \gamma$ . Therefore, setting  $\gamma = \varepsilon/100$ , we get that

$$d_{\Delta}(W, W') \leq \gamma + \frac{8\varepsilon}{9} + 2\gamma^2 \leq \varepsilon/100 + 8\varepsilon/9 + 2\varepsilon^2/100^2 \leq \varepsilon,$$

as desired. ◀

## 4 Compactness of the space of orderons

In this section we prove Theorem 1. We construct a metric space  $\widetilde{\mathcal{W}}$  from  $\mathcal{W}$  with respect to  $d_{\Delta}$ , by identifying  $W, U \in \mathcal{W}$  with  $d_{\Delta}(W, U) = 0$ . Let  $\widetilde{\mathcal{W}}$  be the image of  $\mathcal{W}$  under this identification. On  $\mathcal{W}$  the function  $d_{\Delta}$  is a distance function.

We start with some definitions and notations. Let  $(\Omega, \mathcal{M}, \lambda)$  be some probability space,  $\mathcal{P}_{\ell} = \{P_i^{(\ell)}\}_i$  a partition of  $\Omega$ , and let  $\beta(\mathcal{P}_{\ell} : \cdot) : \mathcal{P}_{\ell} \rightarrow [0, 1]$  be a function. For  $v \in \Omega$ , we slightly abuse notation and write  $\beta(\mathcal{P}_{\ell} : v)$  to denote  $\beta(\mathcal{P}_{\ell} : i)$  for  $v \in P_i^{(\ell)}$ . With this notation, observe that for every  $\ell$

$$\int_{v \in \Omega} \beta(\mathcal{P}_{\ell} : v) dv = \sum_{i \in [|\mathcal{P}_{\ell}|]} \lambda(P_i^{(\ell)}) \beta(\mathcal{P}_{\ell} : i). \quad (2)$$

The following two results serve as useful tools to prove convergence. The first result is known as the *martingale convergence theorem*, see e.g. Theorem A.12 in [27]. The second result is an application of the martingale convergence theorem, useful for our purposes.

► **Theorem 29** (see [27], Theorem A.12). *Let  $\{\mathbf{X}_i\}_{i \in \mathbb{N}}$  be a martingale satisfying  $\sup_n \mathbf{E}[|\mathbf{X}_n|] < \infty$ . Then  $\{\mathbf{X}_i\}_{i \in \mathbb{N}}$  is convergent with probability 1.*

► **Lemma 30.** *Let  $\{\mathcal{P}_{\ell}\}_{\ell}$  be a sequence of partitions of  $\Omega$  such that for every  $\ell$ ,  $\mathcal{P}_{\ell+1}$  refines  $\mathcal{P}_{\ell}$ . Assume that for every  $\ell$  and  $j \in [|\mathcal{P}_{\ell}|]$ , the functions  $\beta(\mathcal{P}_{\ell} : \cdot)$  satisfy*

$$\lambda(P_j^{(\ell)}) \beta(\mathcal{P}_{\ell} : j) = \sum_{i \in [|\mathcal{P}_{\ell+1}|]} \lambda(P_j^{(\ell)} \cap P_i^{(\ell+1)}) \beta(\mathcal{P}_{\ell+1} : i). \quad (3)$$

*Then, there is a measurable function  $\beta : \Omega \rightarrow [0, 1]$  such that  $\beta(v) = \lim_{\ell \rightarrow \infty} \beta(\mathcal{P}_{\ell} : v)$  for almost all  $v \in \Omega$ .*

**Proof.** Fix some  $\ell \in \mathbb{N}$ . Let  $\mathbf{X}$  be a uniformly distributed random variable in  $\Omega$ . Let  $\psi_\ell: \Omega \rightarrow [|\mathcal{P}_\ell|]$  be the function mapping each  $v \in \Omega$  to its corresponding part in  $\mathcal{P}_\ell$  and let  $\mathbf{Z}_\ell = \beta(\mathcal{P}_\ell: \mathbf{X})$ . We now show that the sequence  $(\mathbf{Z}_1, \mathbf{Z}_2, \dots)$  is a martingale. That is,  $\mathbf{E}_{\mathbf{X} \sim \Omega} [\mathbf{Z}_{\ell+1} \mid \mathbf{Z}_1, \dots, \mathbf{Z}_\ell] = \mathbf{Z}_\ell$ , for every  $\ell \in \mathbb{N}$ . Note that by the fact that  $\mathcal{P}_{\ell+1}$  refines  $\mathcal{P}_\ell$ ,  $\psi_\ell(\mathbf{X})$  determines  $\psi_i(\mathbf{X})$  for every  $i < \ell$ . By definition, the value  $\beta(\mathcal{P}_\ell: \mathbf{X})$  is completely determined by  $\psi_\ell(\mathbf{X})$ , and so it suffices to prove that  $\mathbf{Z}_\ell = \mathbf{E}_{\mathbf{X} \sim \Omega} [\mathbf{Z}_{\ell+1} \mid \psi_\ell(\mathbf{X})]$ . By the fact that for every  $j \in [|\mathcal{P}_\ell|]$  Equation (3) holds (and in particular holds for  $\psi_\ell(\mathbf{X})$ ), we can conclude that the sequence  $(\mathbf{Z}_1, \mathbf{Z}_2, \dots)$  is a martingale.

Since  $\mathbf{Z}_\ell$  is bounded, we can invoke the martingale convergence theorem (Theorem 29) and conclude that  $\lim_{\ell \rightarrow \infty} \mathbf{Z}_\ell$  exists with probability 1. That is,  $\beta(v) = \lim_{\ell \rightarrow \infty} \beta(\mathcal{P}_\ell: v)$  exists for almost all  $v \in \Omega$ .  $\blacktriangleleft$

► **Definition 31.** Fix some  $d \in \mathbb{N}$  and define  $\mathcal{I}_d = \{I_1^{(d)}, \dots, I_{2^d}^{(d)}\}$  so that for every  $t \in [2^d]$ ,  $I_t^{(d)} = \left[\frac{t-1}{2^d}, \frac{t}{2^d}\right) \times [0, 1]$ . We refer to this partition as the strip partition of order  $d$ .

The next lemma states that for any orderon  $W$  we can get a sequence of partitions  $\{\mathcal{P}_\ell\}_\ell$ , with several properties that will be useful later on.

► **Lemma 32.** For any orderon  $W \in \mathcal{W}$  and  $\ell \in \mathbb{N}$ , there is a sequence of partitions  $\{\mathcal{P}_\ell\}_\ell$  of  $[0, 1]^2$  with the following properties.

1.  $\mathcal{P}_\ell$  has  $g(\ell)$  many sets (for some monotone increasing  $g: \mathbb{N} \rightarrow \mathbb{N}$ ).
2. For every  $\ell$ ,  $\Gamma_\ell \stackrel{\text{def}}{=} \frac{g(\ell)}{g(\ell-1)} \in \mathbb{N}$ .
3. For every  $\ell' \geq \ell$ , the partition  $\mathcal{P}_{\ell'}$  refines both  $\mathcal{P}_\ell$  and the strip partition  $\mathcal{I}_{\ell'}$ . In particular, for every  $j \in [g(\ell-1)]$ ,

$$P_j^{(\ell-1)} = \bigcup_{j'=(j-1) \cdot \Gamma_\ell + 1}^{j \cdot \Gamma_\ell} P_{j'}^{(\ell)}.$$

4.  $W_\ell = (W)_{\mathcal{P}_\ell}$  satisfies  $\|W - W_\ell\|_\square \leq \frac{4}{g(\ell-1)2^\ell}$ .

**Proof.** We invoke Lemma 27 with the trivial partition  $\{[0, 1]^2\}$  and the strip partition  $\mathcal{I}_1$ , to get a partition  $\mathcal{P}_{n,1}$  with  $g(1)$  many sets such that  $\mathcal{P}_{n,1}$  refines  $\mathcal{I}_1$  and  $\|W_n - W_{n,1}\|_\square \leq 1$ . For  $\ell > 1$ , we invoke Lemma 27 with  $\mathcal{I}_\ell$  and  $\mathcal{P}_{n,\ell-1}$  to get a partition  $\mathcal{P}_{n,\ell}$  of size  $g(\ell) = (g(\ell-1) \cdot 2^\ell)^2 \cdot 2^{O(g(\ell-1)^2)}$  which refines both  $\mathcal{I}_\ell$  and  $\mathcal{P}_{n,\ell-1}$  such that  $\|W_n - W_{n,\ell}\|_\square \leq \frac{4}{g(\ell-1)2^\ell}$ . In order to take care of divisibility, we add empty (zero measure) sets in order to satisfy items (2) and (3).  $\blacktriangleleft$

Consider a sequence of orderons  $\{W_n\}_{n \in \mathbb{N}}$ . For every  $n \in \mathbb{N}$ , we use Lemma 32 to construct a sequence of functions  $\{W_{n,\ell}\}_\ell$  such that  $\|W_n - W_{n,\ell}\|_\square$  is small. For each  $\ell$ , we would like to approximate the shape of the limit partition resulting from taking  $n \rightarrow \infty$ . Inside each strip  $I_t^{(\ell)}$ , we consider the relative measure of the intersection of each set contained in  $I_t^{(\ell)}$ , with a finer strip partition  $\mathcal{I}_{\ell'}$ .

► **Definition 33 (shape function).** For fixed  $n \in \mathbb{N}$ , let  $\{\mathcal{P}_{n,\ell}\}_\ell$  be partitions of  $[0, 1]^2$  with the properties listed in Lemma 32. For every  $\ell' > \ell$  and  $I_{t'}^{(\ell')} \in \mathcal{I}_{\ell'}$ , we define  $\alpha_j^{(n,\ell)}(\mathcal{I}_{\ell'}: t') \stackrel{\text{def}}{=} 2^{\ell'} \cdot \lambda\left(P_j^{(n,\ell)} \cap I_{t'}^{(\ell')}\right)$  to be the relative volume of the set  $P_j^{(n,\ell)}$  in  $I_{t'}^{(\ell')}$ .

For any  $\ell' \geq \ell$  and  $I_{t'}^{(\ell')} \in \mathcal{I}_{\ell'}$ , by the compactness of  $[0, 1]$ , we can select a subsequence of  $\{W_n\}_{n \in \mathbb{N}}$  such that  $\alpha_j^{(n,\ell)}(\mathcal{I}_{\ell'}: t')$  converges for all  $j \in [g(\ell)]$  as  $n \rightarrow \infty$ . Let

$$\alpha_j^{(\ell)}(\mathcal{I}_{\ell'}: t') \stackrel{\text{def}}{=} \lim_{n \rightarrow \infty} \alpha_j^{(n,\ell)}(\mathcal{I}_{\ell'}: t').$$

Next we define the limit density function.

► **Definition 34** (density function). *For fixed  $n \in \mathbb{N}$ , let  $\{\mathcal{P}_{n,\ell}\}_\ell$  be partitions of  $[0, 1]^2$  with the properties listed in Lemma 32. We let  $\delta^{(n,\ell)}(\mathcal{P}_{n,\ell} \times \mathcal{P}_{n,\ell} : i, j) \stackrel{\text{def}}{=} W_{n,\ell}((x, a), (y, b))$  for  $(x, a) \in P_i^{(n,\ell)}$  and  $(y, b) \in P_j^{(n,\ell)}$ .*

*By the compactness of  $[0, 1]$ , we can select a subsequence of  $\{W_n\}_{n \in \mathbb{N}}$  such that  $\delta^{(n,\ell)}(\mathcal{P}_{n,\ell} \times \mathcal{P}_{n,\ell} : i, j)$  converge for all  $i, j \in [g(\ell)]$  as  $n \rightarrow \infty$ . Let*

$$\delta^{(\ell)}(i, j) \stackrel{\text{def}}{=} \lim_{n \rightarrow \infty} \delta^{(n,\ell)}(\mathcal{P}_{n,\ell} \times \mathcal{P}_{n,\ell} : i, j) .$$

The following lemma states that by taking increasingly refined strip partitions  $\mathcal{I}_{\ell'}$ , we obtain a limit shape function for each set contained in any strip of  $\mathcal{I}_\ell$ .

► **Lemma 35.** *For fixed  $\ell$  and  $j \in [g(\ell)]$ , there is a measurable function  $\alpha_j^{(\ell)} : [0, 1] \rightarrow [0, 1]$  such that  $\alpha_j^{(\ell)}(x) = \lim_{\ell' \rightarrow \infty} \alpha_j^{(\ell)}(\mathcal{I}_{\ell'} : x)$  for almost all  $x \in [0, 1]$ .*

**Proof.** Fix  $n, \ell$  and  $\ell' > \ell$ . For every  $j \in [g(\ell)]$ , by the definition of  $\alpha_j^{(n,\ell)}(\mathcal{I}_{\ell'} : t')$  and the strip partition  $\mathcal{I}_{\ell'}$

$$\lambda \left( I_{t'}^{(\ell')} \right) \cdot \alpha_j^{(n,\ell)}(\mathcal{I}_{\ell'} : t') = \lambda \left( P_j^{(n,\ell)} \cap I_{t'}^{(\ell')} \right) \quad \forall t' \in [2^\ell] .$$

On the other hand, since  $\mathcal{I}_{\ell'+1}$  refines  $\mathcal{I}_{\ell'}$ ,

$$\begin{aligned} \lambda \left( P_j^{(n,\ell)} \cap I_{t'}^{(\ell')} \right) &= \lambda \left( P_j^{(n,\ell)} \cap I_{2t'-1}^{(\ell'+1)} \right) + \lambda \left( P_j^{(n,\ell)} \cap I_{2t'}^{(\ell'+1)} \right) \\ &= \lambda \left( I_{2t'-1}^{(\ell'+1)} \right) \cdot \alpha_j^{(n,\ell)}(\mathcal{I}_{\ell'+1} : 2t' - 1) + \lambda \left( I_{2t'}^{(\ell'+1)} \right) \cdot \alpha_j^{(n,\ell)}(\mathcal{I}_{\ell'+1} : 2t') . \end{aligned}$$

Therefore, when  $n \rightarrow \infty$  we get that,

$$\lambda \left( I_{t'}^{(\ell')} \right) \cdot \alpha_j^{(\ell)}(\mathcal{I}_{\ell'} : t') = \lambda \left( I_{2t'-1}^{(\ell'+1)} \right) \cdot \alpha_j^{(\ell)}(\mathcal{I}_{\ell'+1} : 2t' - 1) + \lambda \left( I_{2t'}^{(\ell'+1)} \right) \cdot \alpha_j^{(\ell)}(\mathcal{I}_{\ell'+1} : 2t') ,$$

which is exactly the condition in Equation (3). By applying Lemma 30 with the sequence of strip partitions  $\{\mathcal{I}_{\ell'}\}_{\ell'}$  on  $\alpha_j^{(\ell)}$  the lemma follows. ◀

The next lemma asserts that the limit shape functions behave consistently.

► **Lemma 36.** *For every  $\ell$  and  $j \in [g(\ell - 1)]$ ,*

$$\alpha_j^{(\ell-1)}(x) = \sum_{j'=(j-1) \cdot \Gamma_\ell + 1}^{j \cdot \Gamma_\ell} \alpha_{j'}^{(\ell)}(x) ,$$

*for almost all  $x \in [0, 1]$ .*

**Proof.** Fix some  $n, \ell$  and  $\ell' > \ell$ . By the additivity of the Lebesgue measure,

$$\alpha_j^{(n,\ell-1)}(\mathcal{I}_{\ell'} : x) = \sum_{j'=(j-1) \cdot \Gamma_\ell + 1}^{j \cdot \Gamma_\ell} \alpha_{j'}^{(n,\ell)}(\mathcal{I}_{\ell'} : x) \quad \forall x \in [0, 1] .$$

By the fact that for every  $j \in [g(\ell - 1)]$  and  $x \in [0, 1]$  the sequence  $\left\{ \alpha_j^{(n,\ell-1)}(\mathcal{I}_{\ell'} : x) \right\}_n$  converges to  $\alpha_j^{(\ell-1)}(\mathcal{I}_{\ell'} : x)$  as  $n \rightarrow \infty$ , we get that

$$\alpha_j^{(\ell-1)}(\mathcal{I}_{\ell'} : x) = \sum_{j'=(j-1) \cdot \Gamma_\ell + 1}^{j \cdot \Gamma_\ell} \alpha_{j'}^{(\ell)}(\mathcal{I}_{\ell'} : x) \quad \forall x \in [0, 1] .$$

## 42:16 Ordered Graph Limits and Their Applications

By applying Lemma 35 on each  $j' \in [g(\ell)]$ , where  $\ell' \rightarrow \infty$ , we get that

$$\alpha_j^{(\ell-1)}(x) = \sum_{j'=(j-1) \cdot \Gamma_\ell + 1}^{j \cdot \Gamma_\ell} \alpha_{j'}^{(\ell)}(x),$$

for almost all  $x \in [0, 1]$ . ◀

Using the sequence of  $\{\alpha_j^{(\ell)}\}_j$  we define a limit partition  $\mathcal{A}_\ell = \{A_1^{(\ell)}, \dots, A_{g(\ell)}^{(\ell)}\}$  of  $[0, 1]^2$  as follows.

► **Definition 37** (limit partition). *For every  $\ell \in \mathbb{N}$ , let  $\mathcal{A}_\ell = \{A_1^{(\ell)}, \dots, A_{g(\ell)}^{(\ell)}\}$  be a partition of  $[0, 1]^2$  such that,*

$$A_j^{(\ell)} = \left\{ (x, a) : \sum_{i < j} \alpha_i^{(\ell)}(x) \leq a < \sum_{i \leq j} \alpha_i^{(\ell)}(x) \right\} \quad \forall j \in [g(\ell)].$$

► **Lemma 38.** *For any  $\ell$ , the partition  $\mathcal{A}_\ell$  has the following properties*

1.  $\mathcal{A}_\ell$  refines the strip partition  $\mathcal{I}_\ell$ .
2. The partition  $\mathcal{A}_\ell$  refines  $\mathcal{A}_{\ell-1}$ .
3. For every  $j \in [g(\ell)]$ ,  $\lambda(A_j^{(\ell)}) = \lim_{n \rightarrow \infty} \lambda(P_j^{(n, \ell)})$ .

**Proof.** The first item follows by the fact that each  $\alpha_j^{(\ell)}$  is non-zero inside only one strip.

By the definition of the sets  $A_j^{(\ell)}$  and Lemma 36 it follows that for each  $j \in [g(\ell-1)]$ ,

$$A_{j'}^{(\ell)} \subset A_j^{(\ell-1)} \quad \text{for all} \quad (j-1) \cdot \Gamma_\ell + 1 \leq j' \leq j \cdot \Gamma_\ell,$$

and therefore,

$$A_j^{(\ell-1)} = \bigcup_{j'=(j-1) \cdot \Gamma_\ell + 1}^{j \cdot \Gamma_\ell} A_{j'}^{(\ell)},$$

which shows the second item. To prove the third item of the lemma, note that for every  $n, \ell$  and  $\ell' > \ell$ ,

$$\begin{aligned} \lim_{n \rightarrow \infty} \lambda(P_j^{(n, \ell)}) &= \lim_{n \rightarrow \infty} \sum_{t' \in [2^{\ell'}]} 2^{-\ell'} \cdot \alpha_j^{(n, \ell)}(\mathcal{I}_{\ell'} : t') \\ &= \sum_{t' \in [2^{\ell'}]} 2^{-\ell'} \cdot \alpha_j^{(\ell)}(\mathcal{I}_{\ell'} : t') = \int_x \alpha_j^{(\ell)}(\mathcal{I}_{\ell'} : x) dx, \end{aligned}$$

where the last equality follows from Equation (2). Finally, by taking  $\ell' \rightarrow \infty$  and using Lemma 35, we get

$$\lim_{n \rightarrow \infty} \lambda(P_j^{(n, \ell)}) = \int_x \alpha_j^{(\ell)}(x) dx = \lambda(A_j^{(\ell)})$$

as desired. ◀

Using the definition of  $\delta^{(\ell)}$  and  $\mathcal{A}_\ell$ , we define a density function on the limit partition. For  $(x, a) \in A_i^{(\ell)}$  and  $(y, b) \in A_j^{(\ell)}$ , let

$$\delta(\mathcal{A}_\ell \times \mathcal{A}_\ell : (x, a), (y, b)) \stackrel{\text{def}}{=} \delta^{(\ell)}(i, j).$$

► **Lemma 39.** *For each  $\ell \in \mathbb{N}$  and  $i, j \in [g(\ell - 1)]$ ,*

$$\begin{aligned} \sum_{i'=(i-1) \cdot \Gamma_\ell + 1}^{i \cdot \Gamma_\ell} \sum_{j'=(j-1) \cdot \Gamma_\ell + 1}^{j \cdot \Gamma_\ell} \lambda(A_{i'}^{(\ell)}) \cdot \lambda(A_{j'}^{(\ell)}) \delta(\mathcal{A}_\ell \times \mathcal{A}_\ell : i', j') \\ = \lambda(A_i^{(\ell-1)}) \cdot \lambda(A_j^{(\ell-1)}) \delta(\mathcal{A}_{\ell-1} \times \mathcal{A}_{\ell-1} : i, j) . \end{aligned}$$

**Proof.** Fix  $n, \ell$  and  $i, j \in [g(\ell - 1)]$ . By the definition of the partitions  $\mathcal{P}_{n,\ell}$ ,  $\mathcal{P}_{n,\ell-1}$  and the density functions  $\delta^{(n,\ell)}$ ,  $\delta^{(n,\ell-1)}$

$$\begin{aligned} \sum_{i'=(i-1) \cdot \Gamma_\ell + 1}^{i \cdot \Gamma_\ell} \sum_{j'=(j-1) \cdot \Gamma_\ell + 1}^{j \cdot \Gamma_\ell} \lambda(P_{i'}^{(n,\ell)}) \cdot \lambda(P_{j'}^{(n,\ell)}) \delta^{(n,\ell)}(\mathcal{P}_{n,\ell} \times \mathcal{P}_{n,\ell} : i', j') \\ = \lambda(P_i^{(n,\ell-1)}) \cdot \lambda(P_j^{(n,\ell-1)}) \delta(\mathcal{P}_{n,\ell-1} \times \mathcal{P}_{n,\ell-1} : i, j) . \end{aligned}$$

By taking the limit as  $n \rightarrow \infty$  and using the third item of Lemma 38,

$$\begin{aligned} \sum_{i'=(i-1) \cdot \Gamma_\ell + 1}^{i \cdot \Gamma_\ell} \sum_{j'=(j-1) \cdot \Gamma_\ell + 1}^{j \cdot \Gamma_\ell} \lambda(A_{i'}^{(\ell)}) \cdot \lambda(A_{j'}^{(\ell)}) \delta(\mathcal{A}_\ell \times \mathcal{A}_\ell : i', j') \\ = \lambda(A_i^{(\ell-1)}) \cdot \lambda(A_j^{(\ell-1)}) \delta(\mathcal{A}_{\ell-1} \times \mathcal{A}_{\ell-1} : i, j) , \end{aligned}$$

which completes the proof. ◀

The next Lemma asserts that the natural density function of the limit partition is measurable. It follows directly from the combination of Lemma 30 and Lemma 39.

► **Lemma 40.** *There exists a measurable function  $\delta : ([0, 1]^2)^2 \rightarrow [0, 1]$  such that  $\delta((x, a), (y, a)) = \lim_{\ell \rightarrow \infty} \delta(\mathcal{A}_\ell \times \mathcal{A}_\ell : (x, a), (y, b))$  for almost all  $(x, a), (y, b) \in ([0, 1]^2)^2$ .*

Finally, we are ready to prove Theorem 1.

**Proof of Theorem 1.** We start by giving a high-level overview of the proof. Let  $\{W_n\}_{n \in \mathbb{N}}$  be a sequence of functions in  $\mathcal{W}$ . We show that there exists a subsequence that has a limit in  $\widetilde{\mathcal{W}}$ .

For every  $n \in \mathbb{N}$ , we use Lemma 32 to construct a sequence of functions  $\{W_{n,\ell}\}_\ell$  such that  $\|W_n - W_{n,\ell}\|_\square \leq \frac{4}{g(\ell-1)2^\ell}$ . Then, for every fixed  $\ell \in \mathbb{N}$ , we find a subsequence of  $\{W_{n,\ell}\}$  such that their corresponding  $\alpha_j^{(n,\ell)}$  and  $\delta^{(n,\ell)}(i, j)$  converge for all  $i, j \in [g(\ell)]$  (as  $n \rightarrow \infty$ ). For every  $\ell$ , we consider the partition  $\mathcal{A}_\ell$  (which by Definition 37, is determined by  $\{\alpha_j^{(\ell)}\}_j$ ) and  $\delta^{(\ell)}$ . Using  $\mathcal{A}_\ell$  and  $\delta^{(\ell)}$ , we can define the function  $U_\ell$ , such that  $W_{n,\ell} \rightarrow U_\ell$  almost everywhere as  $n \rightarrow \infty$ .

Given the sequence of functions  $\{U_\ell\}_\ell$ , we use Lemma 40 to show that  $\{U_\ell\}_\ell$  converges to some  $U$  almost everywhere as  $\ell \rightarrow \infty$  (where  $U$  is defined according the limit density function  $\delta$ ). Finally we show that for any fixed  $\varepsilon > 0$ , there is  $n_0(\varepsilon)$  such that for any  $n > n_0(\varepsilon)$ ,  $d_\Delta(W_n, U) \leq \varepsilon$ .

Fix some  $\varepsilon > 0$  and  $\xi(\varepsilon) > 0$  which will be determined later. Consider the sequence  $\{U_\ell\}_\ell$  which is defined by the partition  $\mathcal{A}_\ell$  and the density function  $\delta^{(\ell)}$ . By Lemma 40, the sequence  $\{U_\ell\}_\ell$  converges (as  $\ell \rightarrow \infty$ ) almost everywhere to  $U$ , which is defined by the limit density function  $\delta$ . Therefore, we can find some  $\ell > 1/\xi$  such that  $\|U_\ell - U\|_1 \leq \xi$ .

Fixing this  $\ell$ , we show that there is  $n_0$  such that  $d_\Delta(W_{n,\ell}, U_\ell) \leq 2^{-\ell} + 3\xi$  for all  $n > n_0$ . We shall do it in two steps by defining an interim function  $W'_{n,\ell}$  and using the triangle inequality.

## 42:18 Ordered Graph Limits and Their Applications

Recall that the function  $W_{n,\ell}$  is defined according to the partition  $\mathcal{P}_{n,\ell}$  and the density function  $\delta^{(n,\ell)}$ . Let  $W'_{n,\ell}$  be the function defined according to the partition  $\mathcal{A}_\ell$  and the density function  $\delta^{(n,\ell)}$ . That is, for every  $(x, a) \in A_i^{(\ell)}$  and  $(y, b) \in A_j^{(\ell)}$ ,  $W'_{n,\ell}((x, a), (y, b)) \stackrel{\text{def}}{=} \delta^{(n,\ell)}(\mathcal{P}_{n,\ell} \times \mathcal{P}_{n,\ell} : i, j)$ . By the third item of Lemma 38, for every  $j \in [g(\ell)]$ ,  $\lambda(A_j^{(\ell)}) = \lim_{n \rightarrow \infty} \lambda(P_j^{(n,\ell)})$ . Then, we can find  $n'_0(\ell)$  such that for all  $n > n'_0$ ,

$$\max\left(\lambda(A_j^{(\ell)}), \lambda(P_j^{(n,\ell)})\right) - \min\left(\lambda(A_j^{(\ell)}), \lambda(P_j^{(n,\ell)})\right) \leq \frac{\xi}{g(\ell)} \quad \forall j \in [g(\ell)]. \quad (4)$$

We define a measure preserving map  $f$  from  $W_{n,\ell}$  to  $W'_{n,\ell}$  as follows. For every strip  $I_t^{(\ell)} \in \mathcal{I}_\ell$ , we consider all the sets  $\{P_{j_1}^{(n,\ell)}, \dots, P_{j_t}^{(n,\ell)}\}$  in  $\mathcal{P}_{n,\ell}$  such that  $\bigcup_{j'=j_1}^{j_t} P_{j'}^{(n,\ell)} = I_t^{(\ell)}$ . Similarly, consider all the sets  $\{A_{j_1}^{(\ell)}, \dots, A_{j_t}^{(\ell)}\}$  in  $\mathcal{A}_\ell$  such that  $\bigcup_{j'=j_1}^{j_t} A_{j'}^{(\ell)} = I_t^{(\ell)}$ . For every  $j' \in \{j_1, \dots, j_t\}$ , we map an arbitrary subset  $S_{j'}^{(n,\ell)} \subseteq P_{j'}^{(n,\ell)}$  of measure  $\min\left(\lambda(A_{j'}^{(\ell)}), \lambda(P_{j'}^{(n,\ell)})\right)$  to an arbitrary subset (with the same measure) of  $A_{j'}^{(\ell)}$ . Next, we map  $I_t^{(\ell)} \setminus \bigcup_{j'=j_1}^{j_t} S_{j'}^{(n,\ell)}$  to  $I_t^{(\ell)} \setminus \bigcup_{j'=j_1}^{j_t} f(S_{j'}^{(n,\ell)})$ . Note that by (4) and the fact that  $W_{n,\ell}$  and  $W'_{n,\ell}$  have the same density function  $\delta^{(n,\ell)}$ , the functions  $W_{n,\ell}$  and  $W'_{n,\ell}$  disagree on a set of measure at most  $2\xi$ . Note that for every  $I_t^{(\ell)} \in \mathcal{I}_\ell$ , the function  $f$  maps sets from  $\mathcal{P}_{n,\ell}$  that are contained in  $I_t^{(\ell)}$  to sets in  $\mathcal{A}_\ell$  that are contained in  $I_t^{(\ell)}$ , and thus,  $\text{Shift}(f) \leq 2^{-\ell}$ . Therefore, for  $n > n'_0$ , we get that  $d_\Delta(W_{n,\ell}, W'_{n,\ell}) \leq 2^{-\ell} + 2\xi$ , and the first step is complete.

In the second step we bound  $d_\Delta(W'_{n,\ell}, U_\ell)$ . The two functions  $W'_{n,\ell}$  and  $U_\ell$  are defined on the same partition  $\mathcal{A}_\ell$ , however, their values are determined by the density functions  $\delta^{(n,\ell)}$  and  $\delta^{(\ell)}$  respectively. By the fact that  $\delta^{(n,\ell)}$  converges to  $\delta^{(\ell)}$  (as  $n \rightarrow \infty$ ), we can find  $n''_0(\ell)$  such that for all  $n > n''_0$ ,

$$\left|\delta^{(n,\ell)}(i, j) - \delta^{(\ell)}(i, j)\right| \leq \frac{\xi}{g(\ell)^2} \quad \forall i, j \in [g(\ell)].$$

Thus, for every  $n > n''_0$ , it holds that  $d_\Delta(W'_{n,\ell}, U_\ell) \leq \|W'_{n,\ell} - U_\ell\|_1 \leq \xi$ . By choosing  $n_0 = \max(n'_0, n''_0)$  we get that

$$d_\Delta(W_{n,\ell}, U_\ell) \leq d_\Delta(W_{n,\ell}, W'_{n,\ell}) + d_\Delta(W'_{n,\ell}, U_\ell) \leq 2^{-\ell} + 3\xi.$$

By putting everything together we get that for every  $n > n_0$

$$\begin{aligned} d_\Delta(W_n, U) &\leq d_\Delta(W_n, W_{n,\ell}) + d_\Delta(W_{n,\ell}, U_\ell) + d_\Delta(U_\ell, U) \\ &\leq \|W_n - W_{n,\ell}\|_\square + d_\Delta(W_{n,\ell}, U_\ell) + \|U_\ell - U\|_1 \\ &\leq O\left(\frac{1}{g(\ell-1)2^\ell}\right) + 2^{-\ell} + 3\xi + \xi. \end{aligned}$$

By our choice of  $\ell > 1/\xi$  we get that

$$d_\Delta(W_n, U) \leq 6\xi.$$

By choosing  $\xi = \varepsilon/6$  the theorem follows. ◀

## Abstract

Most types of messages we transmit (e.g., video, audio, images, text) are not fully compressed, since they do not have known efficient and information theoretically optimal compression algorithms. When transmitting such messages, standard error correcting codes fail to take advantage of the fact that messages are not fully compressed.

We show that in this setting, it is sub-optimal to use standard error correction. We consider a model where there is a set of “valid messages” which the sender may send that may not be efficiently compressible, but where it is possible for the receiver to recognize valid messages. In this model, we construct a (probabilistic) encoding procedure that achieves better tradeoffs between data rates and error-resilience (compared to just applying a standard error correcting code).

Additionally, our techniques yield improved efficiently decodable (probabilistic) codes for fully compressed messages (the standard setting where the set of valid messages is all binary strings) in the high-rate regime.

We also thank anonymous reviewers for many useful comments on earlier versions of this work.

## 1 Introduction

If Alice wishes to send a message  $m$  to Bob, she might first compress it as well as she can. In this work, we focus on *lossless* compression, meaning that Bob must recover  $m$  *exactly*. There are many types of data (e.g. images, audio, video, text) that we do not know how

to compress and decompress efficiently and information-theoretically optimally. For such messages, this compression step will result in a longer-than-optimal message. For example, the best efficient compression scheme may result in a  $b$ -bit long compressed message, whereas an information theoretically optimal compression scheme might be able to obtain  $0.5b$  bits.

After compressing, Alice can apply an error correcting code to the compressed message, ensuring that Bob can recover the message in the presence of corruptions. Suppose Alice wishes to have her message be resilient against up to 5% worst-case errors. Then, the best known construction of a code with efficient unique decoding and public randomness will result in a total of approximately  $3.64b$  bits sent to Bob (using bounds implicit in [22, 17]).

We show that in this setting it is sub-optimal to treat compression and error correction as two orthogonal concerns. We instead address both compression and error correction simultaneously, constructing an error correcting code that exploits the fact that messages are not fully compressed. This allows Alice to send only fewer bits to Bob with the same error resilience. For example, with the above parameters Alice can send  $2.24b$  bits.

## 1.1 Contextually Unique Decoding

We define a new notion, *contextually unique decoding*, that formalizes the idea of encoding a message that is not fully compressed. Roughly speaking, we let  $S \subseteq \{0, 1\}^k$  denote a set of “valid messages” that Alice may send. Suppose, for example, that Alice is sending English text of a certain size to Bob. Then we think of  $S$  as the set of all “reasonable” texts Alice can send. For example, “meet me at 5pm” (when translated to binary) is in  $S$ . However, “wef ojip447oll” is not in  $S$ . We assume that Bob has oracle access to  $S$  – he has the power to determine whether a message is reasonable or not. Because most strings do not look like reasonable texts, we see that  $S$  is pretty small<sup>1</sup>. We now wish to say that whenever Alice encodes an element  $m$  of  $S$ , Bob will be able to recover  $m$ .

Motivated by this, we say that a family of codes  $\{C_i : \{0, 1\}^k \rightarrow \{0, 1\}^n\}$  is *contextually uniquely decodable* if there is a decoding algorithm  $D$  such that for any sufficiently small set of messages  $S \subseteq \{0, 1\}^k$ , it holds w.h.p. for a random  $i$  that for all  $m \in S$ , the algorithm  $D$  (with oracle access to  $S$ ) can recover  $m$  given  $i$  and an adversarially corrupted  $C_i(m)$  (where the adversary may depend on  $i$ ).

Alice may have partially compressed the text she wishes to send (we assume she cannot fully compress it, since we don’t know any efficient practical information theoretically optimal compression schemes for text). In this case, a message is in  $S$  if it looks like reasonable text once it is decompressed.

A code with contextually unique decoding would (assuming public randomness) allow Alice to send a message to Bob, so that he can recover Alice’s message even in the presence of corruptions.

Formally, we define:

► **Definition 1** ( $\delta$ -Hamming Adversary). *A  $\delta$ -Hamming adversary is a function  $\mathcal{A} : \{0, 1\}^n \rightarrow \{0, 1\}^n$  such that for all  $c \in \{0, 1\}^n$ , the Hamming distance between  $c$  and  $\mathcal{A}(c)$  is at most  $\delta n$ .*

<sup>1</sup> Notice that if  $S$  is of size  $2^{k'}$ , then information theoretically it would be possible for Alice to compress the message to  $k'$  bits, and then apply an error correcting code.

► **Definition 2** (Contextually Unique Decoder). *An oracle algorithm  $D$  is an  $(r, \delta, \epsilon, \tau)$ -contextually unique decoder for a family of probabilistic codes  $\{C_i : \{0, 1\}^k \xrightarrow{\$} \{0, 1\}^n\}_{i \in \mathcal{I}}$  if for all sets  $S \subseteq \{0, 1\}^k$  with  $|S| \leq 2^{rn}$ , it holds with probability at least  $1 - \epsilon$  over the choice of  $i \leftarrow \mathcal{I}$  that for all messages  $m \in S$  and all  $\delta$ -Hamming adversaries  $\mathcal{A}$  (that may depend on  $i$ ),*

$$\Pr_{c \leftarrow C_i(m)} [D^S(i, \mathcal{A}(c)) \neq m] \leq \tau.$$

We emphasize the order of quantifiers in the definition. We use randomness in two different ways. First, randomness is used to pick a code from the family  $\{C_i\}$ . This choice of randomness is agreed upon by all parties ahead of time and is publicly known (to the sender, receiver, and the adversary), and must work for all messages. Randomness is then also used by the sender (Alice) when encoding. That is, even after fixing the message  $m$  and the choice of  $C_i$ , the encoding of a message  $m$  using  $C_i$  depends on the encoder's randomness (we use the notation  $C_i : \{0, 1\}^k \xrightarrow{\$} \{0, 1\}^n$  to denote that  $C_i$  is a function taking an input from  $\{0, 1\}^k$ , along with some randomness, and outputs an element of  $\{0, 1\}^n$ , which may depend on the randomness). The decoder only needs to know the randomness used in picking  $C_i$ , and not the randomness used by the encoder in *evaluating*  $C_i$ .

## 1.2 Main Result and Construction Overview

We first overview our construction of contextually unique decodable codes, and then we formally describe our main result (Theorem 3).

### 1.2.1 Construction Overview

#### The Main Idea

In the standard model of error correcting codes, we have a code  $C$ , which we use to encode a message  $m$  as  $C(m)$ . Then, even when an adversary may corrupt a bounded number of entries of  $C(m)$ , it is still possible to recover  $m$ . This is called unique decoding. List decoding [6, 28] is a generalization of unique decoding where instead of recovering  $m$ , the decoding algorithm outputs a short (polynomial sized) list  $m_1, m_2, \dots, m_\ell$  such that the real message  $m$  is in the list. This relaxation makes it possible to handle more errors.

The key in our construction is to have Alice send a coded version of the message  $m$  with good list decoding properties. Then, the goal will be that when Bob list-decodes Alice's message, only one of the elements in Bob's list will be a "valid message" (that is, only one element of the list will be in  $S$ ). Then, the hope is that Bob can correct errors up to the list decoding radius, instead of the unique decoding radius.

So for example, Alice might encode the message "call me at 4pm", and after an adversary adds some errors, and Bob decodes, he will have a list of messages. Ideally, the list will look something like "kwjlewf 6oahzm", "aowi2ifmlpzo", "wef ojip447oll", "call me at 4pm", and "5ncbzmap89pqq". From this list, it will be easy for Bob to infer that the message Alice sent was "call me at 4pm" (formally, he will use his oracle access to  $S$  to check which of the strings are in  $S$ , and we hope that only one will be in the set  $S$  of valid messages). Note, however, that if Bob's list contains more than one valid message – for example, if the list of messages is "call me at 7pm", "my phone broke", "call me at 4pm", and "come to my office" – then it will not be possible for Bob to determine which was the intended message (formally, this situation corresponds to Bob's list containing more than one element in  $S$ ).

The technical focus of our constructions is ensuring that within the set of candidate messages provided by a list-decoding algorithm, with high probability only one message will be valid. Our main theorem (Theorem 3) can indeed be viewed as a transformation from a list-decodable code to a contextually-uniquely decodable code.

### Randomizing the message space

Let  $S$  be the set of valid messages. To ensure that only one elements of Bob's list is in  $S$ , the idea is to randomize the message space. If the messages in Bob's list are more or less random (other than Alice's intended message), it is unlikely that more than one of the messages will be in  $S$  (we assume that  $|S|$  is small relative to the entire message space  $\{0, 1\}^k$ ). So ideally, what we would want to do is pick a random permutation  $\pi$  of  $\{0, 1\}^k$  (which is the set of all possible messages, including those not in  $S$ ) using public randomness, and then use an error correcting code  $C$  with good list decoding parameters on  $\pi(m)$ . Then, the set of messages that the adversary can cause to be in Bob's list will be a random small subset of  $\{0, 1\}^k$ , which, because  $S$  is small, will likely not intersect  $S$ .

There are some issues with the approach described above. One issue is that picking a random permutation of  $\{0, 1\}^k$  requires a number of bits exponential in  $k$ , but we want Alice and Bob to be efficient. This issue can be solved by using pairwise independence. Roughly speaking, one can see why pairwise independence is enough as follows. The choice of  $\pi$  is bad if there are two messages  $m_1$  and  $m_2$  in  $S$  such that  $C(\pi(m_1))$  is close to  $C(\pi(m_2))$ . This causes the adversary to be able to corrupt few entries of an encoding of  $m_1$  and cause it to be close to an encoding of  $m_2$ . One can see that the probability  $C(\pi(m_1))$  is close to  $C(\pi(m_2))$  is the same for a random  $\pi$  and a  $\pi$  chosen from a pairwise independent family, since it depends on only two evaluations of  $\pi$ .

Another issue with the construction as described above is that the probability that there exist  $m_1, m_2 \in S$  with  $C(\pi(m_1))$  close to  $C(\pi(m_2))$  is not that low (it is  $2^{-cn}$ , for some  $c$ . Ideally, we would like it to be  $2^{-\omega(n)}$ , so we can apply a union bound over all of  $S$  and not worry about the value of  $c$ ). We alter the construction by instead of picking a single  $\pi$ , picking a collection  $\pi_1, \pi_2, \dots, \pi_N$  which will be agreed on using public randomness. Then, the encoder (Alice) will pick a random  $j \in [N]$ , and use  $C(\pi_j(m))$  as the message sent to Bob. To decode, Bob will decode  $C$  to get a list  $L$ , and then for each  $j \in [N]$  and for each  $x \in L$  he will check if  $\pi_j^{-1}(x) \in S$ , and with high probability only one such pair  $(x, j)$  will satisfy  $\pi_j^{-1}(x) \in S$ . Then Bob will know that the message  $m$  that Alice sent is  $\pi_j^{-1}(x)$ .

We now outline how we show that Bob's list with high probability indeed contains only one element in  $S$ . Consider the probability that for a certain  $m$  in  $S$ , we have  $C(\pi(m))$  close to some  $C(\pi(m'))$ . Call this probability  $p$ . Then, the probability that for most  $j$ , we have  $C(\pi_j(m))$  close to some  $C(\pi_j(m'))$  will be approximately  $p^{\Omega(N)}$  (by a Chernoff bound), which is much smaller than  $p$ . This allows us to apply a union bound over all messages in  $S$  without losing anything significant.

### Amplifying the success probability (Section 4)

The construction described above works, but it has a downside that there is inverse polynomial probability of error. That is, with probability inversely polynomial in the message lengths, Bob may be unable to recover the message Alice sent, since with probability approximately  $\frac{1}{N}$  Alice may pick a bad choice of  $i$ .

Ideally, we would want to succeed with all but negligible probability. One approach is to set  $N$  to be superpolynomial. The problem with this is that now Bob will not be able to efficiently decode, since his decoding algorithm requires trying every one of the  $N$

permutations. To fix this, instead of Alice sending Bob  $C(\pi_i(m))$ , she will send him  $C(\pi_i(m), i)$  (we apply  $C$  to the string which is the concatenation of  $\pi_i(m)$  and  $i$ ). Now, when Bob list decodes  $C$ , he will get a list of the form  $(x_1, i_1), (x_2, i_2), \dots, (x_\ell, i_\ell)$ . Now, he can check if  $\pi_{i_1}^{-1}(x_1) \in S$ , or if  $\pi_{i_2}^{-1}(x_2) \in S$ , and so on. Crucially, we see that for each element  $(x_j, i_j)$  in the list, Bob needs to try only a single permutation (namely  $i_j$ ), instead of all permutations. This allows Bob to remain efficient even when there are superpolynomially many permutations for Alice to pick from.

This leads to a new issue, since one needs to agree on a superpolynomially sized family of permutations sampled from a family of pairwise independent permutations. Also, we want this family to be efficiently sampleable, and for each element to have a succinct description. It turns out that this can be solved using  $k$ -wise independence (and  $k$ -wise  $\epsilon$ -dependence). This part is more technical, and we refer the reader to the body of the paper for details.

### 1.2.2 The main theorem

Here we formally describe the main theorem. We say that an  $n$ -bit code is **combinatorially**  $(\rho, \lambda)$ -list decodable if for any  $y \in \{0, 1\}^n$ , there are at most  $\approx 2^{\lambda n}$  codewords within relative Hamming distance  $\rho$  of  $y$ . We are also interested in the asymptotic computational efficiency of encoding and decoding procedures, so we consider ensembles of codes  $\{C_n : \{0, 1\}^{k_n} \rightarrow \{0, 1\}^n\}_{n \in \mathbb{Z}^+}$ . We will restrict our attention to ensembles where  $r = \lim_{n \rightarrow \infty} \frac{k_n}{n}$  exists, and we call  $r$  the **rate** of the ensemble. We say that  $\{C_n\}$  is **efficiently**  $\rho$ -list-decodable if there is a polynomial-time algorithm that on input  $y \in \{0, 1\}^n$ , outputs all codewords of  $C_n$  that are within relative Hamming distance  $\rho$  of  $y$ .

► **Theorem 3** (Simplified Main Theorem). *Suppose that  $\{C'_n : \{0, 1\}^{k'_n} \rightarrow \{0, 1\}^n\}_{n \in \mathbb{Z}^+}$  is a rate- $r'$  ensemble of (deterministic) codes that is efficiently  $\rho$ -list-decodable. Suppose also that  $\{C'_n\}$  is combinatorially  $(2\rho, \lambda)$ -list decodable.*

*Then for some negligible function  $\epsilon(n)$ , there is a rate- $r'$  ensemble of probabilistic codes  $\{C_n\}$  such that  $C_n$  has a polynomial-time  $(r' - \lambda - o(1), \rho, \epsilon, \epsilon)$ -contextually unique decoder.*

So, suppose we wish to construct contextually unique codes where the message can be recovered when there are up to 0.1 fraction of corruptions. So we have  $\rho = 0.1$ . We now wish to find an  $r'$  and  $\lambda$  which maximize  $r' - \lambda$  such that there are deterministic codes which are of rate  $r'$ , and are combinatorially  $(2\rho, \lambda)$ -list decodable (we also have make sure the codes are *efficiently*  $\rho$ -list decodable).

Once fixing  $\rho$ , the tradeoff here is between  $r'$  and  $\lambda$ . The best contextually unique codes will have high rates  $r' - \lambda - o(1)$ , so we want  $\lambda$  to be small, and  $r'$  to be large. However, the codes  $\{C'_n\}$  must be combinatorially  $(2\rho, \lambda)$ -list decodable. So, as we increase  $r'$ , the lowest possible value of  $\lambda$  decreases.

We give some examples of parameter settings to Theorem 3 in Table 1.

### 1.3 Improvements for standard randomized setting

An important special case of contextually unique decoding is obtained by fixing  $S = \{0, 1\}^{k_n}$ , viewed as a subset of  $\{0, 1\}^{k'_n}$  for  $k'_n > k_n$  by zero-padding. In this case, a contextually uniquely decodable code is quite similar to a standard error-correcting code – the main difference is in the use of randomness both in generating the code and encoding messages. Perhaps surprisingly, we obtain better parameters in the high-rate regime than any other known efficiently decodable code (including probabilistic constructions with public randomness).

■ **Table 1** This table shows some example values of what rates can be achieved with our main theorem (Theorem 3) together with the best of the Blokh-Zyablov (Fact 6) and Thommesen-Rudra bounds. If  $|S| = 2^{s \cdot k}$ , and  $S \subseteq \{0, 1\}^k$ , we say that the *sparsity* of  $S$  is  $s$ . So, for example, if  $S$  is of size  $2^{.5k}$ , and there are 3% fraction of errors, we see that we can achieve rate .574 (and so Alice’s message size would be  $k/.574$ , or approximately  $1.74k$ ). The best Alice would be able to do without contextually unique decoding would be rate .396, which corresponds to over  $2.52k$  bits sent (this can be seen by looking at the sparsity 1 row, which corresponds to using standard unique decoding, since in this case  $S$  is the whole message space  $\{0, 1\}^k$ ).

Errors \ Sparsity	0.01	0.02	0.03	0.05	0.1	0.2

## Discussion

If there is a (deterministic) code that can be *efficiently* list decoded up to  $\rho$  errors, and *combinatorially* uniquely decoded up to  $\rho'$  errors, then it is possible to efficiently uniquely decode up to  $\min(\rho, \rho')$  errors. This can be done by simply list decoding, and then going over every element in the list to determine which of the elements, when encoded, is closest to the received message. So, in short, it is not hard to see that good efficient list decoding and good combinatorial unique decoding implies good efficient unique decoding (this idea is, roughly speaking, what gives the green line (TR bound) in Figure 1).

Our corollary can be viewed as a strengthening of this result. We show that rather than requiring good efficient list decoding and good combinatorial unique decoding, we can use codes with good efficient list decoding and good combinatorial *list* decoding. The idea, roughly speaking, is to use our efficient list decoding algorithm to obtain a list of candidate messages, and we use our main theorem on contextually unique decoding to ensure that only one of these messages will be a “valid” message. Then, we can go through each candidate in the list, and pick the one which is a valid message.

► **Corollary 4** (Simplified Main Corollary). *Suppose that  $\{\tilde{C}^{(n)} : \{0, 1\}^{k'_n} \rightarrow \{0, 1\}^n\}_{n \in \mathbb{Z}^+}$  is a rate- $r'$  ensemble of (deterministic) codes that is efficiently  $\rho$ -list-decodable. Suppose also that  $\{\tilde{C}^{(n)}\}$  is combinatorially  $(2\rho, \lambda)$ -list decodable.*

*Then there exists an ensemble  $\{C^{(n)}\}_{n \in \mathbb{Z}^+}$ , where  $C^{(n)} = \{C_i : \{0, 1\}^{k_n} \xrightarrow{\$} \{0, 1\}^n\}_{i \in \mathcal{I}^{(n)}}$  is a family of probabilistic codes, such that:*

1.  $\lim_{n \rightarrow \infty} \frac{k_n}{n} = r' - \lambda$ , and
2. *There are poly( $n$ )-time algorithms to:*
  - *Sample from  $\mathcal{I}^{(n)}$  given  $1^n$ .*
  - *Probabilistically encode  $C_i(m)$  given  $i$  and  $m$ ,*
  - *Decode  $\rho$ -corrupted codewords of  $C_i$ . That is, there is a deterministic poly( $n$ )-time algorithm  $D$  and a negligible function  $\epsilon(n)$  such that with probability at least  $1 - \epsilon(n)$  over the choice of  $i \leftarrow \mathcal{I}^{(n)}$ , it holds for all messages  $m \in \{0, 1\}^{k_n}$  and all  $\rho$ -Hamming adversaries  $\mathcal{A}$ , that*

$$\Pr_{c \leftarrow C_i(m)} [D(i, \mathcal{A}(c)) \neq m] \leq \epsilon(n).$$

► **Remark 5.** An interesting weakening of the conclusion of Corollary 4 is that for sufficiently large  $n$ , there exists  $i \in \mathcal{I}^{(n)}$  such that for all messages  $m \in \{0, 1\}^{k_n}$ , there exists randomness  $s$  such that for all  $c' \approx_\delta C_i(m; s)$ , it holds that  $D(i, c') = m$ . In other words,  $D(i, \cdot)$  is a polynomial-size error-correcting circuit for an (inefficiently computable and non-explicit) *deterministic* code.

We compare the conclusion of Corollary 4 to what is known for standard (deterministic) binary codes.

To our knowledge, the best known rate vs. error tolerance tradeoff for efficiently decodable and deterministic binary codes is given by the Blokh-Zyablov (BZ) bound [2], and is attained by multi-level concatenated codes (see Fact 6). With probabilistically constructed codes, it is possible to do better for sufficiently low rates. It is known that for rates below about 0.02, the concatenation of a folded Reed-Solomon code with random linear codes simultaneously achieves high distance (matching the GV bound) [26] and efficient list-decodability for a larger number of errors [22]. This implies an efficient unique decoding procedure (by list decoding and then taking the candidate that is closest to the received word). While not made explicit in previous work, the same ideas achieve performance that is intermediate between the BZ and GV bounds for rates up to about 0.3. We will refer to the resulting rate-distance tradeoff as the Thommesen-Rudra (TR) bound. In [17], the authors implicitly show that that one can achieve *near linear* time decoders up to the TR bound.

In the high rate regime there were no codes, even probabilistic constructions, that were efficiently decodable beyond the BZ bound.

► **Fact 6** (Blokh-Zyablov bound [2, 14]). *For any  $\rho \in (0, \frac{1}{2})$  and any*

$$0 < R < R_{\text{BZ}}(\rho) \stackrel{\text{def}}{=} 1 - H(\rho) - \rho \cdot \int_0^{1-H(\rho)} \frac{dx}{H^{-1}(1-x)},$$

*there exists a rate- $R$  ensemble of codes  $\{C_n\}_{n \in \mathbb{Z}^+}$  that is efficiently  $\rho$ -list decodable and efficiently uniquely-decodable against up to a  $\frac{\rho}{2}$  fraction of errors.*

Note that efficient  $\rho$ -list decodability generically implies combinatorial  $(\rho', H(\rho') - H(\rho) + o(1))$ -list decodability for any  $\frac{1}{2} \geq \rho' \geq \rho$ . By combining this with Corollary 4, we obtain bounds that improve over the BZ (and TR) bound for rates above roughly 0.3. This is illustrated in Figure 1.

## 1.4 Related Work

Our work is an application of list decoding, a notion that was introduced by Elias in the 50's [6]. The notion was then (implicitly) revisited with a focus on algorithmic efficiency by Goldreich and Levin [10], who showed how to efficiently list-decode the Hadamard code, and later by Sudan [24], who showed the same for Reed-Solomon codes. List decoding has proven to be a useful notion in computational complexity theory, and has recently been the focus of extensive research (see e.g. the surveys of Sudan [25] and Guruswami [13]).

Several works have studied variants of the error correction problem in which it is possible to obtain improved results on worst-case unique decoding. Guruswami [12] considered a model in which a sender is able send a small amount of information over a noise-free channel, and showed that this enables unique decoding up to the list-decoding radius. Langberg [20] considered the different notion of “private codes”, in which the sender and receiver share some secret randomness, and showed that it is possible to achieve better parameters in this model. Our constructions in contrast use only public randomness, and does not require any noise-free channel.

■ **Figure 1** We improve over previous efficiently decodable binary codes (even probabilistic constructions) [2, 22] for rates above about 0.3. Although it appears in this plot as if the TR bound slightly beats the GV bound for very low rates, this is an artifact of our plotting software that disappears upon zooming in.

Perhaps a more relevant line of work to us is one that studies, loosely speaking, whether imperfectly shared context can improve the efficiency of interactive protocols. This question has been articulated and studied in the settings of interactive communication complexity [3, 7, 8], simultaneous message passing [1], and message compression [18, 16], and in the general setting of “goal-oriented communication” [9].

Our work can be viewed through a similar lens. We seek to improve the efficiency of communication, leveraging context (which implies that only a small number of messages “make sense”). Like in prior works, the context is not fully known to both parties. In fact, we go further: the sender may know *nothing* about the context, other than that the message he is sending makes sense. At the same time, the receiver may know very little about the context – only enough to answer a polynomial number of questions on whether a given message makes sense. Moreover, in contrast to prior works, we do not assume error-free communication channels, and we emphasize the importance of efficient algorithms, while prior works have focused primarily on minimizing communication.

A main idea in this paper is to use list decodable codes, and to permute the message space in such a way as to achieve unique decoding instead of just list decoding. Similar ideas have been used for example in [15] and [4]. However, in those works the adversary is not fully general like in this work, but is restricted (either computationally, or by having to corrupt the codeword in an online fashion).

## 2 Preliminaries

### 2.1 Codes

A deterministic code of dimension  $k$  and block length  $n$  over an alphabet  $\Sigma$  is a (multi-)subset  $\mathcal{C} \subseteq \Sigma^n$  of size  $|\Sigma|^k$ , whose elements are called codewords. The rate of such a code is the quantity  $\frac{k}{n}$ . Throughout this paper, we focus on the case when  $\Sigma$  is a finite field  $\mathbb{F}_q$  and when the dimension  $k$  is integral. In such cases, we associate the codewords of  $\mathcal{C}$  with  $\Sigma^k$ , and we abuse notation by writing  $\mathcal{C}$  to refer both to the multiset of codewords and the corresponding mapping from  $\Sigma^k$  to  $\Sigma^n$ . A code  $\mathcal{C}$  as above is said to be linear if it is a subspace of  $\Sigma^n$ , and in this case the associated mapping can be taken to be a linear function.

For any alphabet  $\Sigma$ , any  $n$ , and any  $u, v \in \Sigma^n$ , the Hamming distance between  $u$  and  $v$ , denoted  $\Delta(u, v)$ , is

$$\Delta(u, v) \stackrel{\text{def}}{=} \left| \{i \in [n] : u_i \neq v_i\} \right|.$$

When  $\Delta(u, v) \leq \delta n$ , we write  $u \approx_\delta v$ . If  $S$  is a set, we write  $\Delta(u, S)$  to denote  $\min_{v \in S} \Delta(u, v)$ . The distance of a code  $\mathcal{C}$  is  $\min_{c \neq c' \in \mathcal{C}} \Delta(c, c')$ .

We also consider probabilistic codes, focusing on codes over binary alphabets.

► **Definition 7.** A probabilistic binary code of block length  $n$  and dimension  $k$  is a randomized function  $\mathcal{C} : \{0, 1\}^k \xrightarrow{\$} \{0, 1\}^n$ .

When discussing the asymptotic performance of (deterministic or probabilistic) codes, it makes sense to consider ensembles of codes  $\{\mathcal{C}_n : \{0, 1\}^{k_n} \rightarrow \{0, 1\}^{\ell_n}\}$  with varying message lengths and block lengths. We will always assume several restrictions on  $k_n$  and  $\ell_n$  to rule out pathological examples. Specifically, we will assume that:

- The limit  $r = \lim_{n \rightarrow \infty} \frac{k_n}{\ell_n}$  exists with  $r \in (0, 1)$ . We call  $r$  the rate of the ensemble.
- $\lim_{n \rightarrow \infty} \frac{\ell_n}{n} = 1$ . This is important so that for a large message of length  $k$ , the cost of padding to length  $k_n$  is not too large.

Given these two assumptions, it is possible without loss of generality to assume  $\ell_n = n$  (we can always take a code from the ensemble with larger  $\ell_n$ , and truncate it; asymptotically, this affects neither its rate nor its error tolerance).

► **Definition 8.** We say that an ensemble of codes  $\{C_n : \{0, 1\}^{k_n} \rightarrow \{0, 1\}^n\}_{n \in \mathbb{Z}^+}$  is combinatorially  $(\rho, \lambda)$ -list decodable if there is some  $L(n) \leq 2^{(\lambda + o(1)) \cdot n}$  and  $\rho'(n) \geq \rho - o(1)$  such that for any  $y \in \{0, 1\}^n$ , there are at most  $L(n)$  values of  $m \in \{0, 1\}^{k_n}$  for which  $C_n(m) \approx_{\rho'(n)} y$ . If there is a polynomial-time algorithm that outputs all such  $m$  (in which case we can assume  $\lambda = 0$ ), then we say that  $\{C_n\}$  is efficiently  $\rho$ -list decodable.

We will also say that  $\{C_n\}$  is combinatorially  $\rho$ -list decodable if it is combinatorially  $(\rho, 0)$ -list decodable.

### 2.2 Binomial Coefficients

We will use the following approximations of binomial coefficients.

► **Fact 9.** For any  $n, k \in \mathbb{Z}^{\geq 0}$ , it holds that

$$\left(\frac{n}{k}\right)^k \leq \binom{n}{k} \leq \left(\frac{en}{k}\right)^k.$$

## 43:10 Error Correcting Codes for Uncompressed Messages

For all constant  $0 \leq \delta \leq 1$ , as  $n$  goes to infinity

$$\binom{n}{\delta n} = \tilde{\Theta}(2^{H(\delta)n}),$$

where  $H(p) = -p \log_2 p - (1-p) \log_2 (1-p)$  is the binary entropy function.

We will also use the standard notion of  $q$ -ary entropy.

► **Definition 10.** The  $q$ -ary entropy function is

$$H_q(x) = x \log_q(q-1) - x \log_q x - (1-x) \log_q(1-x).$$

We define the inverse function  $H_q^{-1}$  to map any  $y \in [0, 1]$  to the unique value  $x \in [0, 1 - 1/q]$  for which  $H_q(x) = y$ .

### 2.3 Covering Numbers for Hamming Balls

For  $x \in \{0, 1\}^n$ , we will denote by  $B_r(x)$  the Hamming ball of radius  $r$  centered at  $x$ , i.e. the set  $\{x' \in \{0, 1\}^n : \Delta(x, x') \leq r\}$ .

► **Definition 11.** Let  $S$  be a subset of  $\{0, 1\}^n$ , and let  $r$  be a positive real number. An  $r$ -covering of  $S$  is a subset  $C$  of  $\{0, 1\}^n$  such that  $S \subseteq \cup_{x \in C} B_r(x)$ . The  $r$ -covering number of  $S$ , denoted  $N_r(S)$ , is the minimum cardinality of any  $r$ -covering of  $S$ .

A volume argument with Fact 9 shows, for any  $0 < \delta_0 < \delta_1 \leq \frac{1}{2}$ , that  $N_{\delta_0 n}(B_{\delta_1 n}) \geq \tilde{\Omega}(2^{(H(\delta_1) - H(\delta_0)) \cdot n})$ . In fact, a simple application of the probabilistic method (due to Dumer et al.) also shows that  $N_{\delta_0 n}(B_{\delta_1 n}) \leq \tilde{O}(2^{(H(\delta_1) - H(\delta_0)) \cdot n})$ . These two statements are combined in the following fact.

► **Fact 12** ([5, Eq. 2.4]). For any  $0 \leq \delta_0 < \delta_1 \leq \frac{1}{2}$  and any  $x \in \{0, 1\}^n$ , it holds that

$$N_{\delta_0 n}(B_{\delta_1 n}(x)) = \tilde{\Theta}(2^{(H(\delta_1) - H(\delta_0)) \cdot n}).$$

### 2.4 $t$ -wise Independence

► **Definition 13.** A family of hash functions  $\{h_i : X \rightarrow Y\}_{i \in \mathcal{I}}$  is said to be  $t$ -wise independent if for all distinct  $x_1, \dots, x_t \in X$ , the distribution of  $(h_i(x_1), \dots, h_i(x_t))$  for a uniformly random  $i \in \mathcal{I}$  is uniformly random over  $Y^t$ .

► **Imported Theorem 14** ([27]). For any  $n, m, t \in \mathbb{Z}^+$ , there exists a  $t$ -wise independent family of hash functions mapping  $\{0, 1\}^n$  to  $\{0, 1\}^m$  such that it takes  $\text{poly}(n, m, t)$  time to sample or evaluate a hash function.

► **Definition 15.** A family of permutations  $\{\pi_i : X \rightarrow X\}_{i \in \mathcal{I}}$  is said to be  $t$ -wise  $\epsilon$ -dependent if for all distinct  $x_1, \dots, x_t \in X$  it holds for uniformly random  $i \in \mathcal{I}$  that the distribution of  $(\pi_i(x_1), \dots, \pi_i(x_t))$  is  $\epsilon$ -close in statistical distance to uniformly random over tuples of distinct  $y_1, \dots, y_t \in X$ .

► **Imported Theorem 16** ([19, Theorem 5.9]). For any  $\epsilon > 0$  and any  $t \in \mathbb{Z}^+$ , there exists a  $t$ -wise  $\epsilon$ -dependent family of permutations on  $\{0, 1\}^n$  with description length  $O(nt + \log(\frac{1}{\epsilon}))$  such that it takes time  $\text{poly}(n, t, \log(\frac{1}{\epsilon}))$  to sample, evaluate, or invert a permutation.

### 3 Contextually Unique Decoding

In this section we present the notion of contextually-unique decoding, and we give some simple constructions of contextually-unique decoders with qualitatively worse parameters than our main result.

► **Definition 17.** An oracle algorithm  $D$  is an  $(r, \delta, \epsilon, \tau)$ -contextually unique decoder for a family of probabilistic codes  $\{C_i : \{0, 1\}^k \xrightarrow{\$} \{0, 1\}^n\}_{i \in \mathcal{I}}$  if for all sets  $S \subseteq \{0, 1\}^k$  with  $|S| \leq 2^{rn}$ , it holds with probability at least  $1 - \epsilon$  over the choice of  $i \leftarrow \mathcal{I}$  that for all messages  $m \in S$  and all  $\delta$ -Hamming adversaries  $\mathcal{A}$ ,

$$\Pr_{c \leftarrow C_i(m)} [D^S(i, \mathcal{A}(c)) \neq m] \leq \tau.$$

#### On the order of quantifiers

In the definitions above, we fix a family of codes, then say that for all small enough  $S$ , a random code from the family is good for  $S$ . In particular, we do not allow an adversary to choose  $S$  after the code is sampled. This may be problematic in some cases, but Definition 17 suffices in the common case of languages that are already established (but not perfectly compressible). This includes languages like “English sentences” or “images of dogs”. In this case, since the set  $S$  is already in principle determined (albeit not fully understood), it suffices to pick and agree upon a random code from the family ahead of time, and always use that code in the future.

#### 3.1 Inefficient Decoding

It is possible to show that for fixed deterministic codes, contextually unique decoding is no easier than unique decoding for the entire ambient message space. In Theorems 18 and 20, we show that randomly sampled codes can do better (albeit with an inefficient decoder).

A family of codes  $\{C_i : \{0, 1\}^k \rightarrow \{0, 1\}^n\}_i$  is said to be **pairwise independent** if for all distinct  $x, x' \in \{0, 1\}^k$ , the distribution of  $(C_i(x), C_i(x'))$  for random  $i$  is uniform over  $\{0, 1\}^n \times \{0, 1\}^n$ . For instance, a random linear code is pairwise independent.

► **Theorem 18.** Let  $\{\mathcal{C}_n\}_{n \in \mathbb{Z}^+}$  be an ensemble of pairwise independent code families<sup>2</sup>, where each code in the family  $\mathcal{C}_n$  has  $n$ -bit codewords. Then for all  $r, \delta \in (0, 1)$  with  $H(2\delta) + 2r < 1$ , there is a  $(r, \delta, \exp(-\Omega(n)), 0)$ -contextually unique decoder for  $\mathcal{C}_n$ .

**Proof.** Let  $S$  be a message space with  $|S| \leq 2^{rn}$ . We will show that with all but  $\exp(-\Omega(n))$  probability over the choice of code  $C \leftarrow \mathcal{C}_n$ , the restriction  $C|_S$  of  $C$  to  $S$  has relative distance  $2\delta$ .

For any distinct  $m, m' \in S$ , it follows from pairwise independence and Fact 9 that

$$\Pr_C[C(m) \approx_{2\delta} C(m')] \leq \frac{\tilde{O}(2^{H(2\delta)n})}{2^n} \leq \frac{1}{\tilde{\Omega}(2^{(1-H(2\delta)) \cdot n})}.$$

Union bounding over all pairs of  $m, m'$ ,

$$\Pr_C[\exists m, m' \in S \text{ s.t. } m \neq m' \text{ and } C(m) \approx_{2\delta} C(m')] \leq \frac{1}{\tilde{\Omega}(2^{(1-2r-H(2\delta)) \cdot n})} \leq \exp(-\Omega(n)). \blacktriangleleft$$

<sup>2</sup> Note that we do not explicitly make any assumption on the rate vs. distance tradeoff of  $\mathcal{C}_n$ ; instead, we implicitly use the fact that any code drawn from a pairwise independent family has relatively good distance with high probability.

### Discussion

One interesting aspect of Theorem 18 is that it demonstrates a family of codes with an “apparent rate” that is independent of the number of tolerable errors, as long as the “true” message space is sufficiently sparse. For example, each  $C_n$  might map  $\{0, 1\}^{2n} \rightarrow \{0, 1\}^n$ , yet as long as the  $2n$ -bit messages have some structure that is known to the receiver (not necessarily to the sender!), it can be guaranteed that the receiver will reconstruct the sender’s message.

However, the parameters achieved by Theorem 18 are not optimal. In particular, its error-tolerance is not competitive with the alternative approach of first compressing messages in  $S$  into  $rn$ -bit representations, and then applying a good error-correcting code to this representation. The GV bound for binary codes states that there exist codes with rate  $r$  and relative distance  $2\delta$  whenever  $H(2\delta) + r < 1$ . It is consistent with current knowledge that this bound is tight.

Our next result closes this gap by sampling a probabilistic code rather than a deterministic code.

► **Construction 19.** Let  $C_1, \dots, C_N : \{0, 1\}^k \rightarrow \{0, 1\}^n$  be deterministic binary codes. We define the probabilistic code  $C_{\text{mix}}[C_1, \dots, C_N] : \{0, 1\}^k \xrightarrow{\$} \{0, 1\}^n$  so that  $C_{\text{mix}}[C_1, \dots, C_N](m)$  is  $C_i(m)$  for a uniformly random  $i \leftarrow [N]$ .

► **Theorem 20.** Let  $\{C_n\}_{n \in \mathbb{Z}^+}$  be an ensemble, where  $C_n$  is a pairwise independent family of codes with  $n$ -bit codewords.

For all  $r, \delta \in (0, 1)$  with  $H(2\delta) + r < 1$  and any  $\tau \geq n^{-O(1)}$ , there exists  $N \leq n^{O(1)}$  such that there is an (inefficient)  $(r, \delta, \exp(-\Omega(n)), \tau)$ -contextually unique decoder for  $\{C_{\text{mix}}[C_1, \dots, C_N]\}_{C_i \in C_n}$ .

In other words,  $C_n$  pairwise independent family of codes with  $n$ -bit codewords, and the code we use is  $\{C_{\text{mix}}[C_1, \dots, C_N]\}_{C_i \in C_n}$ , where the  $C_1, \dots, C_N$  are randomly chosen elements of  $C_n$ .

**Proof Overview.** Suppose that a sender encodes a message  $m$ , and the receiver gets an adversarially perturbed codeword  $c'$ . We define the (inefficient) decoder so that it finds all  $i'$  and all  $m' \in S$  for which  $C_{i'}(m')$  is within distance  $\delta n$  of  $c'$ . We claim that with high probability, the only such  $(i', m')$  is in fact  $(i, m)$ .

To see this, we first fix  $m$ , and consider two different ways in which an encoding of  $m$  can be confused for an encoding of a different message. Using Fact 9 one can show that, for each  $i$ :

1. The probability over the choice of  $C_i$  that there exists  $m' \in S \setminus \{m\}$  such that  $C_i(m')$  and  $C_i(m)$  are within Hamming distance  $2\delta n$  is at most  $2^{(r+H(2\delta)-1)n}$ .
  2. The probability over  $C_1, \dots, C_{i-1}, C_{i+1}, \dots, C_N$  that there exists  $m' \in S \setminus \{m\}$  and  $i' \neq i$  such that  $C_{i'}(m')$  and  $C_i(m)$  are within Hamming distance  $\delta n$  is at most  $N \cdot 2^{(r+H(2\delta)-1)n}$ .
- At this point, unless  $H(2\delta) + 2r < 1$ , we cannot simply apply a union bound to argue that with high probability  $C_i(m)$  and  $C_{i'}(m')$  are  $2\delta n$ -far for all  $m \neq m'$ .

To rely only on the weaker condition that  $H(2\delta) + r < 1$ , the key insight is that for any fixed  $m$ , “most” (all but a  $\tau$  fraction) of  $C_i$ ’s will be good in the above sense with all but  $2^{-(r+\Omega(1)) \cdot n}$  probability. To show this, we must set  $N$  to be a sufficiently large polynomial and use Azuma’s inequality (rather than Chernoff) because the events  $\{(2) \text{ holds for } i\}_i$  are not mutually independent. After this, the probability  $2^{-(r+\Omega(1)) \cdot n}$  is sufficiently small that we can union bound over all  $2^{rn}$  choices of  $m$ . ◀

Rather than elaborating on the details here, we instead defer to our full proof of Theorem 21, which uses the same approach.

## Discussion

Unlike Theorem 18, Theorem 20 matches (other than the arbitrarily small inverse polynomial probability of decoding error) the rate vs. error tolerance tradeoff that is known to be achievable with inefficient decoding for *known, efficiently compressible* sets  $S$  (the GV bound).

## 3.2 Efficient Decoding with Noticeable Error

To obtain an efficient contextually-unique decoder, we adapt the ideas of Theorem 20. Instead of using a pairwise independent family of codes (which is not efficiently decodable), we use a “random” efficiently list-decodable code. Specifically, we use a fixed efficiently list-decodable deterministic code, composed with a random (efficiently evaluable and invertible) permutation  $\pi$ .

Recall the definition of  $C_{\text{mix}}$  from Construction 19.

► **Theorem 21.** *Let  $\{C'_n : \{0,1\}^{k_n} \rightarrow \{0,1\}^n\}_{n \in \mathbb{Z}^+}$  be a rate- $r'$  ensemble of (deterministic) binary codes that is efficiently  $\rho$ -list decodable and combinatorially  $(2\delta, \lambda)$ -list decodable.*

*Then, for any  $r < r' - \lambda$  and any  $\tau(n) \geq n^{-O(1)}$ , there exists  $N(n) \leq n^{O(1)}$  such that for any pairwise independent family  $\Pi_n$  of permutations of  $\{0,1\}^{k_n}$ , the family of codes  $\{C_{\text{mix}}[C'_n \circ \pi_1, \dots, C'_n \circ \pi_N]\}_{\pi_1, \dots, \pi_N \in \Pi_n}$  has a  $(r, \delta, \exp(-\Omega(n)), \tau)$ -contextually unique decoder.*

## Discussion

The main advantage of Theorem 21 over Theorem 20 is that the decoder can run in  $\text{poly}(n)$  time. The main disadvantage compared to Theorem 18 is that the probability of incorrectly decoding is relatively high; in particular, the length of the description of a code (and therefore also the encoder’s and decoder’s running times) are inversely proportional to the error probability.

Our proof of Theorem 21 relies on the following version of the Azuma-Hoeffding inequality, which can be found as Equation (3) in [23]:

► **Imported Theorem 22** (Azuma-Hoeffding). *Let  $\{X_k\}_{k=0}^\infty$  be a real-valued martingale with  $a_k \leq X_k - X_{k-1} \leq b_k$ . Then for every  $r \geq 0$ ,*

$$\Pr[|X_n - X_0| \geq t] \leq 2 \cdot \exp\left(-\frac{2t^2}{\sum_{k=1}^n (b_k - a_k)^2}\right).$$

We now commence the proof of Theorem 21.

**Proof.** We first describe the decoding algorithm. We are given as input a corrupted codeword  $y \in \{0,1\}^n$ , and given oracle access to a set  $S$  of “valid messages”. We run the list-decoding algorithm for  $C'_n$  on  $y$  to obtain a list of codewords  $c_i = C'_n(m_i)$  for  $i = 1, \dots, L$ . We find  $i \in [L], j \in [N]$  that  $\pi_j^{-1}(m_i)$  is in  $S$ . If no such  $(i, j)$  exists, or if multiple such  $(i, j)$  exists, we reject (output  $\perp$ ). Otherwise, we output  $\pi_j^{-1}(m_i)$ .

Let  $p_0$  denote the quantity  $2^{r_n} \cdot \max_{c \in \{0,1\}^n} \Pr_{m \leftarrow \{0,1\}^{r'_n}}[\Delta(C_n(m), c) \leq 2\delta n]$ . Using a union bound, we can see that  $p_0$  bounds the probability, for any fixed  $c$ , that  $C'_n(y)$  is  $2\delta n$ -close to  $c$  for any of  $2^{r_n}$  different uniformly random  $y$ . The combinatorial list-decodability

## 43:14 Error Correcting Codes for Uncompressed Messages

of  $\{C'_n\}$  implies that  $p_0 \leq 1/\tilde{\Omega}(2^{(r'-r-\lambda) \cdot n})$ . By assumption on  $r$ , this decreases exponentially with  $n$ , and in particular for any  $N \leq n^{O(1)}$ , it holds that

$$\tau \geq \omega(p_0 \cdot N^2). \quad (1)$$

Let  $N(n)$  be a sufficiently large polynomial such that  $2\tau^2 N - \ln(2) \cdot rn \geq \Omega(n)$ .

▷ **Claim 23.** For any permutations  $\pi_1, \dots, \pi_N$ , let  $C_{\pi_1, \pi_2, \dots, \pi_N}$  denote  $C_{\text{mix}}[C'_n \circ \pi_1, \dots, C'_n \circ \pi_N]$ . For every  $m \in S$ , it holds that

$$\begin{aligned} \Pr_{\substack{\pi_1, \dots, \pi_N \\ C := C_{\pi_1, \pi_2, \dots, \pi_N}}} \left[ \begin{array}{l} \exists \delta\text{-Hamming adversary } \mathcal{A} \text{ s.t.} \\ \Pr_{c \leftarrow C(m)}[D^S(\mathcal{A}(c)) \neq m] \geq 3\tau \end{array} \right] &\leq e^{-(2-o(1))\tau^2 N} \\ &\leq 2^{-(r+\Omega(1))n}. \end{aligned}$$

**Proof.** Consider the probability space defined by sampling  $\pi_1, \dots, \pi_N \leftarrow \Pi$ . For each  $i \in [N]$ , define random variables

$$X_i^{(<)} = \begin{cases} 1 & \text{if } \exists j < i \text{ and } \exists m' \in S \text{ s.t. } C_n(\pi_j(m')) \approx_{2\delta} C_n(\pi_i(m)) \\ 0 & \text{otherwise.} \end{cases}$$

Define random variables  $\{X_i^{(=)}\}_{i \in [N]}$  and  $\{X_i^{(>)}\}_{i \in [N]}$  analogously – that is, replace the condition “ $j < i$ ” by “ $j = i$ ” or “ $j > i$ ” respectively.

Note that  $X_1^{(=)}, \dots, X_N^{(=)}$  are mutually independent because  $X_i^{(=)}$  depends only on  $\pi_i$ . The pairwise independence of  $\Pi$  and a union bound over all  $m'$  implies that for each  $i$ ,  $\Pr[X_i^{(=)} = 1] \leq p_0 \leq N \cdot p_0$ .

The random variables  $X_1^{(<)}, \dots, X_N^{(<)}$  are not independent. However, conditioned on  $X_1^{(<)}, \dots, X_{i-1}^{(<)}$  (indeed on any value of  $\pi_1, \dots, \pi_{i-1}$ ) the pairwise independence of  $\pi_i$  and a union bound over  $j < i$  and over  $m'$  implies that

$$\Pr[X_i^{(<)} = 1 | X_1^{(<)}, \dots, X_{i-1}^{(<)}] \leq i \cdot p_0 \leq N \cdot p_0.$$

Similarly,

$$\Pr[X_i^{(>)} = 1 | X_{i+1}^{(>)}, \dots, X_N^{(>)}] \leq (N - i) \cdot p_0 \leq N \cdot p_0.$$

Azuma's inequality (Imported Theorem 22) implies that

$$\begin{aligned} \Pr\left[\sum_i X_i^{(<)} \geq \tau N\right] &\leq 2e^{-2(\tau - p_0 N^2)^2 N} \\ &\leq e^{-(2-o(1))\tau^2 N} \quad \text{by (1),} \end{aligned}$$

and we obtain the same bound on  $\Pr[\sum_i X_i^{(>)} \geq \tau N]$  and  $\Pr[\sum_i X_i^{(=)} \geq \tau N]$ . So

$$\Pr\left[\sum_i (X_i^{(<)} + X_i^{(=)} + X_i^{(>)}) \geq 3\tau N\right] \leq 3 \cdot e^{-(2-o(1))\tau^2 N} \leq e^{-(2-o(1))\tau^2 N},$$

which is equivalent to the statement of the claim. ◁

Theorem 21 follows from union bounding over all  $2^{rn}$  values of  $m \in S$ . ◀

#### 4 Main Theorem: Efficient Decoding with Negligible Error

In our previous constructions, we always had some inverse polynomial probability (over the choice of encoding randomness) of incorrectly decoding. We now show how to reduce this error probability to negligible by using a super-polynomial number of permutations, but preserving the polynomial-time efficiency of encoding and decoding. This is Theorem 25 below, from which Theorem 3 follows immediately (after using Theorem 14 and Theorem 16).

► **Construction 24.** Let  $C' : \{0, 1\}^{r'n} \rightarrow \{0, 1\}^n$  be a deterministic code, let  $\Pi = \{\pi_k : \{0, 1\}^{r'n-s} \rightarrow \{0, 1\}^{r'n-s}\}_{k \in \mathcal{K}}$  be a family of efficiently evaluable and invertible permutations, and let  $h : \{0, 1\}^s \rightarrow \mathcal{K}$  be a hash function.

We define a probabilistic code  $C_{C', \Pi, h} : \{0, 1\}^{r'n-s} \xrightarrow{\$} \{0, 1\}^n$  that encodes a message  $m \in \{0, 1\}^{r'n-s}$  by picking  $x \leftarrow \{0, 1\}^s$  at random, and outputting  $C'(\pi_{h(x)}(m), x)$ .

► **Theorem 25.** Suppose that:

- $C' : \{0, 1\}^{r'n} \rightarrow \{0, 1\}^n$  is a (deterministic) binary code that is efficiently  $\rho_e$ -list-decodable
- $\delta \leq \rho_e$  and  $\lambda$  are such that  $C'$  is combinatorially  $(2\delta, \lambda)$ -list decodable.
- For some  $t = t(n)$  and  $s = s(n)$  satisfying  $\Omega(n) \leq t(n) \leq n^{O(1)}$  and  $\omega(\log n) \leq s(n) \leq o(n)$ :
  - $\Pi = \{\pi_k : \{0, 1\}^{r'n-s} \rightarrow \{0, 1\}^{r'n-s}\}_{k \in \mathcal{K}}$  is a  $(t+1)$ -wise  $\epsilon$ -dependent family of permutations with  $\epsilon \leq 2^{-n}$ , and
  - $\mathcal{H} = \{h_i : \{0, 1\}^s \rightarrow \mathcal{K}\}_{i \in \mathcal{I}}$  is a  $2t$ -wise independent hash family.

Then the family  $\{C_{C', \Pi, h}\}_{h \in \mathcal{H}}$  has an  $(r, \delta, \exp(-\omega(n)), \frac{t}{2^s})$ -contextually unique decoder for any  $r < r' - \lambda$ .

**Proof.** Let  $S \subseteq \{0, 1\}^{r'n-s}$  be any set of messages with  $|S| \leq 2^{rn}$ . We describe the contextually unique decoding algorithm on input  $y \in \{0, 1\}^n$ . First, the algorithm applies the efficient list-decoding algorithm to obtain all codewords  $y'_1, \dots, y'_L$  of  $C'$  that are within relative Hamming distance  $\rho_e$  of  $y$ . Then each  $y'_i$  is parsed as  $(\pi_{h(x)}(m_i), x)$ . The decoding algorithm outputs any  $m_i$  that is in  $S$ . It is immediate from efficient list-decodability that there is at least one such  $m_i$ . We need to show that with high probability there is at most one such  $m_i$ .

We will rely on the following variant of the Chernoff bound for binary random variables, which does not require the random variables to be fully independent. Instead, it only requires bounding the probability that relatively small subsets of variables are simultaneously 1.

► **Imported Theorem 26** ([21]). Let  $X_1, \dots, X_N$  be  $\{0, 1\}$ -valued random variables, let  $0 < \beta < 1$ , and let  $0 < t < \beta N$ . Then

$$\Pr \left[ \sum_{i=1}^N X_i \geq \beta N \right] \leq \frac{1}{\binom{\beta N}{t}} \cdot \sum_{A \in \binom{[N]}{t}} \mathbb{E} \left[ \prod_{i \in A} X_i \right].$$

We will write  $N$  to denote  $2^s$ , and for brevity of notation we will view any hash function  $h \in \mathcal{H}$  directly as the corresponding tuple of permutations  $(\pi_{k_0}, \dots, \pi_{k_{N-1}})$ , where  $k_i = h(i)$ .

It is sufficient to show that for  $\tau(n) = \frac{t}{N}$ , it holds for every  $m \in S$  that

$$\Pr_{(\pi_1, \dots, \pi_N) \leftarrow \mathcal{H}} \left[ \left| \{i : \exists j \in [N], m' \in S \setminus \{m\} \text{ s.t. } C'(\pi_i(m), i) \approx_{2\delta} C'(\pi_j(m'), j)\} \right| \geq \tau \cdot N \right]$$

is at most  $2^{-rn} \cdot \exp(-\omega(n))$ .

## 43:16 Error Correcting Codes for Uncompressed Messages

We will use the Chernoff variant to prove the above inequality. Let  $X_i$  denote the indicator random variable for the event

$$\exists j \in [N], m' \in S \setminus \{m\} \text{ s.t. } C'(\pi_i(m), i) \approx_{2\delta} C'(\pi_j(m'), j),$$

so what we want to bound is  $\Pr \left[ \sum_{i=1}^N X_i \geq \tau \cdot N \right]$ .

For  $i, j \in [N]$  and  $m' \in S \setminus \{m\}$ , let  $Y_{i,j,m'}$  denote the indicator random variable for the event

$$C'(\pi_i(m), i) \approx_{2\delta} C'(\pi_j(m'), j).$$

Let  $A \subseteq [N]$  be a subset of size  $|A| = t$ . Say  $A = \{a_1, \dots, a_t\}$ . We have

$$\begin{aligned} \mathbb{E} \left[ \prod_{a \in A} X_a \right] &\leq \mathbb{E} \left[ \prod_{a \in A} \sum_{\substack{j \in [N] \\ m' \in S \setminus \{m\}}} Y_{a,j,m'} \right] \\ &= \sum_{\substack{j_1, \dots, j_t \in [N] \\ m'_1, \dots, m'_t \in S \setminus \{m\}}} \mathbb{E} \left[ \prod_{i=1}^t Y_{a_i, j_i, m'_i} \right]. \end{aligned} \quad (2)$$

We now would like to use the independence of  $\mathcal{H}$  and of  $\Pi$  to equate  $\mathbb{E} \left[ \prod_i Y_{a_i, j_i, m'_i} \right]$  with  $\prod_i \mathbb{E}[Y_{a_i, j_i, m'_i}]$ . However this is not quite true, for two reasons. First,  $\Pi$  is only *approximately*  $(t+1)$ -wise independent. Second,  $\Pi$  is a family of  $(t+1)$ -wise (almost) independent *permutations*, rather than unstructured functions.

Still, an only slightly worse bound holds for  $\mathbb{E} \left[ \prod_{i=1}^t Y_{a_i, j_i, m'_i} \right]$ . Conditioned on  $\pi_{j_1}(m'_1), \dots, \pi_{j_t}(m'_t)$  and  $\pi_{a_1}(m), \dots, \pi_{a_{t-1}}(m)$ , the  $2t$ -wise independence of  $\mathcal{H}$  and the  $(t+1)$ -wise  $\epsilon$ -dependence of  $\Pi$  imply that the distribution of  $\pi_{a_t}(m)$  is  $(\epsilon + \frac{t}{2^{r'n-s}})$ -close to uniform over  $\{0, 1\}^{r'n-s}$ . The combinatorial list-decodability of  $C'$  asserts that the number of  $y$  for which  $C'(y) \approx_{2\delta} C'(\pi_{j_i}(m'), j_i)$  is at most  $2^{\lambda \cdot n}$ .

We can therefore continue bounding (2) as follows:

$$\begin{aligned} &\leq \sum_{\substack{j_1, \dots, j_t \in [N] \\ m'_1, \dots, m'_t \in S \setminus \{m\}}} \prod_{i=1}^t \left( \frac{2^{\lambda \cdot n}}{2^{r'n-s}} + \epsilon + \frac{t}{2^{r'n-s}} \right) \\ &\leq (N \cdot 2^{rn})^t \cdot 2^{(\lambda - r' + o(1)) \cdot nt} \\ &\leq \alpha(n)^t, \end{aligned}$$

where we define  $\alpha(n) = N(n) \cdot \tilde{O}(2^{(\lambda + r - r' + o(1)) \cdot n})$ , which is  $\exp(-\Omega(n))$  by assumption on  $\delta$  and  $r$  and because  $N \leq 2^{o(n)}$ . Thus for  $\tau(n) = \frac{t}{N} \geq \omega(\alpha(n))$ , it holds by Imported Theorem 26 that

$$\begin{aligned} \Pr \left[ \sum_{i=1}^N X_i \geq \tau \cdot N \right] &\leq \frac{\binom{N}{t}}{\binom{\tau \cdot N}{t}} \cdot \alpha(n)^t \\ &\leq \left( \frac{e\alpha}{\tau} \right)^t \\ &\leq \exp(-\omega(t)) \\ &\leq \exp(-\omega(n)) \\ &\leq 2^{rn} \cdot \exp(-\omega(n)). \end{aligned}$$

Theorem 25 follows by union bounding over all  $2^{rn}$  choices of  $m \in S$ . ◀

## 5 Future Directions

There are several interesting directions that we have not yet explored. We highlight a few below:

- How well is it possible to perform contextually unique decoding in different error models? For example, one might consider adversarial erasures, insertions, deletions, random errors, and so on.
- What are the optimal achievable parameters for contextually unique decoding?
- Is it possible to have a single probabilistic code that simultaneously works well for all message sets  $S$  of bounded size? If so, with what parameters?
- When  $S = \{0, 1\}^k$  padded with zeroes, can our construction be made explicit?

## Abstract

We identify several genres of search problems beyond **NP** for which existence of solutions is guaranteed. One class that seems especially rich in such problems is **PEPP** (for “polynomial empty pigeonhole principle”), which includes problems related to existence theorems proved through the union bound, such as finding a bit string that is far from all codewords, finding an explicit rigid matrix, as well as a problem we call **COMPLEXITY**, capturing Complexity Theory’s quest. When the union bound is generous, in that solutions constitute at least a polynomial fraction of the domain, we have a family of seemingly weaker classes  $\alpha$ -**PEPP**, which are inside  $\mathbf{FP}^{\mathbf{NP}}|_{\text{poly}}$ . Higher in the hierarchy, we identify the constructive version of the Sauer-Shelah lemma and the appropriate generalization of **PPP** that contains it, as well as the problem of finding a king in a tournament (a vertex  $k$  such that all other vertices are defeated by  $k$ , or by somebody  $k$  defeated).

## 1 Introduction

The complexity of total functions has emerged over the past three decades as an intriguing and productive branch of Complexity Theory. Subclasses of **TFNP**, the set of all total functions in **FNP**, have been defined and studied: **PLS**, **PPP**, **PPA**, **PPAD**, **PPADS**, and **CLS**. These classes are replete with natural problems, several of which turned out to be complete for the corresponding class, see e.g. [9, 10].

Each of these classes corresponds naturally to a very simple existential argument. For example, **PLS** is the class of all total functions whose proof of totality relies on the fact that *every finite dag must have a sink*, while **PPAD** captures this true existential statement: “*If a finite directed graph has an unbalanced node (i.e., a node whose in-degree differs from its out-degree), then it must have another unbalanced node.*” The class of total functions **PPP** (for “polynomial pigeonhole principle”) captures the well known fact that “*if there are more*

*pigeons than pigeonholes, there must be a pigeonhole with two or more pigeons.*” This latter complexity class has attracted much attention due to its close connections to cryptography, and there has been recent progress towards natural complete problems [5, 22, 14].

More recently a logic-inspired class **PTFNP** (for “provable **TFNP**”) was identified containing all of the above classes [11], its definition motivated by the existential proof point of view described above. It was also pointed out in [11] that finitariness is necessary for the definition of a meaningful class of total functions, in that any non-finitary existence theorem – that is, one that also holds for infinite structures – results in a computational problem that is provably easy. Also recently, an intriguing link between the possibility of **TFNP**-hardness and average-case hardness was discovered [12].

The simple statement on which **PPP** is based has a very natural “dual” variant, call it the *empty pigeonhole principle*, namely: “*if there are more pigeonholes than pigeons, then there must be an empty pigeonhole.*” Concretely, given a circuit  $C$  mapping  $[2^n - 1]$  to  $[2^n]^1$ , find a bit string of length  $n$  that is not in  $C$ ’s range. Call this problem **EMPTY**. One could even define a class based on the empty pigeonhole principle, call it **PEPP** (for “polynomial empty pigeonhole principle,” the set of all total function problems polynomial-time reducible to **EMPTY**). At first sight, **PEPP** may seem very close to **PPP** – identical, perhaps? – *until one notices that **PEPP** is not obviously in NP!* For **PPP**, one can guess and check the offending pigeonhole *and* the two pigeons in it – but for **PEPP**? Once the empty pigeonhole has been guessed, proving it is empty requires one to look at all pigeons. An alternation of quantifiers appears to be at work!

*In this paper we introduce a hierarchy of total search problems analogous to the polynomial hierarchy of decision problems.* **TFNP** is the first level of the hierarchy, and the class **PEPP** just defined is at the second level of this hierarchy, denoted **TFΣ<sub>2</sub>**. Actually, we shall soon see that there are natural and interesting search problems occupying the third level of the hierarchy. (For the formal definition of **TFΣ<sub>i</sub>** and some basic facts about this hierarchy, see the Appendix.)

The first result we prove in this direction is that, despite the apparent similarity and “symmetry” outlined above, **PEPP** contains **PPP** – *and in fact, all of FNP* (Theorem 1; the proof is easy).

**EMPTY** and **PEPP** are closely associated with the familiar probabilistic argument known as *the union bound*. There is a formal way to see this: Consider a generic instance of **EMPTY**, that is, a circuit  $C$  mapping  $[2^n - 1]$  to  $[2^n]$ ; the task is to find a possible output in  $[2^n]$  not in the circuit’s range. Interpret now an input  $x$  as  $x = yz$ , where  $|z| = n - m$  and  $|y| = m$ , and where  $y$  encodes a “bad event” – in the sense of the union bound – with probability  $2^{-m}$  ( $2^{-m} - 2^{-n}$  for one of the events), while  $z$  indexes the  $2^{n-m}$  (respectively,  $2^{n-m} - 1$ ) elements of the whole probability space of size  $2^n$  that constitute the bad event. Hence, the empty pigeonhole principle can be interpreted as the union bound. Many of the important natural problems in **PEPP** correspond to existential proofs through the union bound, or more generally through counting.

One of these problems is **REMOTE POINT**: Given a code – generically, a circuit mapping  $[2^k]$  to  $[2^n]$  where  $k < n$  and the codewords are the range of the circuit – find an  $n$ -bit string that is far from all codewords (as far in Hamming distance, that is, as is guaranteed by the union bound). It is not hard to see that **REMOTE POINT** is **PPEP**-complete. The important open problem here is the complexity of the special case of **REMOTE POINT** in which the circuit is a linear function in **GF<sub>2</sub>**; this is a much studied problem [2].

---

<sup>1</sup> We denote the set  $\{0, 1, \dots, M - 1\}$  by  $[M]$ . We shall see that it is easy to construct circuits with arbitrary integer domains and ranges.

Other natural problems in **PEPP** capture interesting aspects of *complexity*. To start with the more indirect one, RIGID MATRIX COMPLETION is the following problem: find a rigid matrix in  $\mathbf{GF}_2^{n \times n}$  (that is, an  $n \times n$  matrix whose rank cannot collapse to something tiny by manipulating very few entries, details supplied later) given several of its entries. Rigid matrices have been shown [24] to be abundant, and to capture logarithmic-depth circuit complexity, while their explicit construction has remained an important open problem since Valiant's paper. We define the relevant problem as a *completion* variant of the explicit construction problem – that is, part of the matrix is specified – to overcome a familiar impediment: without a binary input of some substantial length, one is dealing with a *sparse* problem, and current techniques seem unable to fathom the complexity of such problems (see the related work subsection for a further discussion of this). A second problem in the same vein, RAMSEY-ERDŐS COMPLETION, embodies Erdős's famous 1959 proof that the  $n$ -th Ramsey number is at least  $2^{\frac{n}{2}}$ .

COMPLEXITY is a problem asking, given a bit string of length  $n$ , to find an explicit Boolean function with  $\log n$  inputs which requires  $\Omega(\frac{n}{\log^2 n})$  gates – that is, an explicit exponential lower bound. The problem is, again, defined through a circuit. The circuit interprets its input gates as the representation of a circuit with  $\log n$  inputs and  $O(\frac{n}{\log^2 n})$  gates, where besides the usual Boolean gates we also allow *oracle gates* with fan-in  $\log n$ . The output of the circuit is the Boolean function computed by this circuit, encoded as a bit string of length  $2^{\log n} = n$ . The input to the problem (on the basis of which the circuit is constructed and the computation of the circuit is carried out) is also interpreted as an *oracle*, encoding in its  $n$  bits the answers to all possible oracle inputs. The task is to discover an  $n$ -bit string that is not in the range of this circuit under this oracle – that is to say, a Boolean function with  $\log n$  variables which therefore requires  $\Omega(\frac{n}{\log^2 n})$  gates to be computed with the given oracle. The oracle here is needed, again, to render a sparse function exponentially dense.

Is this problem **PEPP**-complete, or otherwise hard in a demonstrable sense? This is an important problem left open in this paper. We are aware of one immediate obstacle: it turns out that many of the problems we discussed above, COMPLEXITY among them, belong in a significantly weakened subclass of **PEPP**. Let  $\alpha$  be a positive quantity, possibly a function of  $n$ , and define the class  $\alpha$ -**PEPP** (pronounced *abundant PEPP*) to be the variant in which the given circuit does not map  $[2^n]$  to  $[2^n + 1]$ , but instead  $[2^n]$  to  $[(1 + \alpha) \cdot 2^n + 1]$ ; evidently, **PEPP** = 0-**PEPP**, while many of the problems in **PEPP** discussed are known to belong to  $\alpha$ -**PEPP** for some constant  $\alpha$ . In particular, we denote 1-**PEPP** by **APEPP**, circuits with twice as many outputs than inputs.

We prove two theorems on  $\alpha$ -**PEPP**. First, we establish that the precise value of  $\alpha$  is in some sense irrelevant, in that any class  $\alpha$ -**PEPP** with  $\alpha$  between  $\frac{1}{\text{poly}}$  and  $\text{poly}$  can be reduced to any other such class *through* **FP<sup>NP</sup>** reductions (Theorem 7; it is not known whether polynomial time reductions are possible here). Second, it turns out that for  $\alpha \geq \frac{1}{\text{poly}}$ , for any problem in  $\alpha$ -**PEPP** with  $n$  input gates there is a small set of outputs (strings of length  $\lceil n \log(1 + \alpha) \rceil$ ) such that, for any input, one of them is an empty pigeonhole. (The proof is by – what else? – the union bound.) It follows that  $\alpha$ -**PEPP** is contained in **FZPP<sup>NP</sup>** – *functional ZPP* (Monte Carlo algorithms) with a satisfiability oracle – and, analogously to Adleman's theorem [1], that  $\alpha$ -**PEPP** is contained in **FP<sup>NP</sup>**|poly, **FP<sup>NP</sup>** with polynomial advice; we see no reason why **PEPP** = 0-**PEPP** should be so confined.

So far we have been discussing problems and classes in **TFΣ<sub>2</sub>**, the next level after **TFNP** of what can be called the polynomial total function hierarchy. It turns out that there are also interesting problems further up. SHATTERING is the following problem: we are given a circuit  $C$  with  $k$  input gates and  $n$  output gates, which is supposed to represent a family of

$2^k$  subsets of  $[n]$ . We must return either a collision in this circuit, establishing that the family has fewer than  $2^k$  distinct sets; or otherwise a  $d$ -subset of  $[n]$ , call it  $D$ , which is *shattered* by the family – that is, every subset of  $D$  can be written as  $D \cap C(x)$  for some set  $C(x)$  in the family; such a set is guaranteed to exist by the Sauer-Shelah lemma [19, 21, 25], as long as  $C$  has no collisions and  $k$  is large enough as a function of  $n$  and  $d$ . Notice immediately that there are two alternations of quantifiers in this existential result: *there is* a set  $D$  such that *for every* subset  $G$  of  $D$  *there is* an output  $C(x)$  of  $C$  such that  $G = D \cap C(x)$ : we are in the class  $\mathbf{TF}\Sigma_3$ ! In fact, we show that SHATTERING belongs to a very natural subclass of  $\mathbf{TF}\Sigma_3$ : it belongs to  $\mathbf{PPP}^{\Sigma_2}$ , the pigeonhole principle class when the function mapping pigeons to pigeonholes can use a  $\Sigma_2$  oracle in its computations.

We present another  $\mathbf{TF}\Sigma_3$  problem, which we denote as KING: given a tournament (succinctly described by a circuit), find a vertex  $v$  such that every other vertex is reachable from  $v$  by a directed path of length one or two. The proof that such a vertex must exist is a local-search argument dating back to the 1950's [15], but the potential function used in the proof is  $\#\mathbf{P}$ -hard to compute, hence the KING problem does not evidently belong to any natural subclass of  $\mathbf{TF}\Sigma_3$  such as  $\mathbf{PLS}^{\Sigma_2}$ .

## Related Work

The difficulty of making existential arguments based on the union bound *constructive* has in fact been a fundamental problem in Complexity Theory and combinatorics for over seven decades. Already in 1947, after Erdős published his paper proving Ramsey lower bounds via the probabilistic method, he recognized the difficulty of matching this with a constructive proof, and offered a \$100 prize to anyone who could do so [8]. Two years after that, Shannon used the union bound to give a nonconstructive proof that some functions require exponential size circuits, and also noted the difficulty in finding constructive proofs of size lower bounds for explicit functions, comparing it to the difficulty of proving that particular numbers are transcendental [20]. At this time, “constructive” was a rather informal concept, but a few decades later Complexity Theory offered us a plausible definition: a constructive proof is an algorithm that constructs an object with the desired properties from scratch, in time polynomial in the size of the object. Over time, an important research tradition in Complexity Theory has developed around such explicit construction problems, pertaining mostly to the construction of computational devices (pseudorandom generators, randomness extractors, exponentially hard Boolean functions in the worst or average case, etc.) whose existence is guaranteed by the union bound. Many celebrated results in this domain compare the difficulty of such explicit construction problems through, essentially, reductions [24, 17, 13, 6, 23]. In particular, already in 1977 Les Valiant [24] showed that an explicit construction of a rigid matrix would imply an explicit Boolean function requiring shallow circuits of superlinear size – a reduction between two explicit construction problems whose corresponding existence proofs rely on the union bound. Next, Nisan and Wigderson established in 1995 that an explicit pseudorandom generator can be constructed in polynomial time, given an explicit construction of a truth table which is hard to approximate for exponentially large circuits, and Impagliazzo and Wigderson [13] showed a decade later that such hard-to-approximate truth tables can in fact be constructed in polynomial time from truth tables which are very hard to compute in the worst case. More recently, an equivalence has been shown between the explicit construction of randomness dispersers and the construction of Ramsey graphs, and a significant body of work has been devoted to deriving more efficient constructions of such objects [8, 6].

Many results in this realm can be reformulated as reductions between total function problems in a particular subclass of **APEPP**, which could be called **SAPEPP** (for “sparse **APEPP**”). Every problem in **SAPEPP** is defined by a polynomial-time Turing machine-computable function  $M : \{0, 1\}^* \mapsto \{0, 1\}^*$  such that for all  $x \in \{0, 1\}^*$ ,  $|M(x)| = f(|x|)$ , where  $f(n) > n$ . The total search problem associated with  $M$  asks: given  $n$  in unary, find a bit string  $y$  of length  $f(n)$  such that for all  $x$  with  $|x| = n$ ,  $M(x) \neq y$ . That **SAPEPP** is a subset of **APEPP** follows easily from the basic fact that any fixed polynomial-time Turing machine with a given input length can be rendered as a Boolean circuit in time polynomial in the input length. For a concrete example, for the problem of explicitly constructing a truth table for a function  $[N] \rightarrow \{0, 1\}$  which requires circuits of size greater than  $\frac{N}{3 \log N}$ ,  $M$  is a machine which transforms concisely encoded circuits of size  $\frac{N}{3 \log N}$  into truth tables, and  $f(n) = n + 1$ . The associated function problem in **SAPEPP**, which could be called **SPARSE COMPLEXITY**, seeks the explicit construction of a hard Boolean function; a polynomial-time solution for this problem would imply, among other tectonic consequences, that  $\mathbf{P} = \mathbf{BPP}$  [13].

## 2 The Problems in PEPP

**EMPTY** is the following search problem: Given a circuit  $C$  with Boolean gates mapping  $[2^n - 1]$  to  $[2^n]$ , find a  $y \in [2^n]$  such that  $y \neq C(x)$  for all  $x \in [2^n - 1]$ .

► **Remark.** In this paper, we shall blur the distinction between bitstrings and binary integers. Our Boolean circuits have a domain and range whose cardinality is not necessarily a power of two, which may seem peculiar. In this paper we shall consider Boolean circuits mapping  $[M]$  to  $[N]$ , where  $M, N$  are arbitrary integers greater than one. Such a circuit  $C$  has  $\lceil \log M \rceil$  inputs and  $\lceil \log N \rceil$  outputs, and for all  $x$   $C(x)$  is defined to be  $C(M - 1)$  if  $x \geq M$ , and also for all  $x$   $C(x) = N - 1$  whenever the value computed by  $C$  on input  $x$  (or on input  $M - 1$  if  $x \geq M$ ) is at least  $N$ . Hence, **EMPTY** can be defined in terms of any circuit  $C : [M] \mapsto [M + 1]$  – or even  $C : [M] \mapsto [N]$  as long as  $M < N$ . For larger  $N$  the problem may be easier, but it is reducible to **EMPTY** (as long as  $\log N \leq \text{poly log } M$ ).

Coming back to **EMPTY**, we can now define a class of total functions **PEPP** as all total functions that are polynomial-time reducible to **EMPTY**. One rather immediate – and yet a little surprising – fact to observe about **PEPP** is the following:

► **Theorem 1.**  $\mathbf{FNP} \subseteq \mathbf{PEPP}$ .

**Proof.** We prove that **SAT** can be reduced to **EMPTY**. Let  $\phi$  be a CNF formula with  $n$  variables, without loss of generality not satisfied by the all-true truth assignment. Consider now the following polynomially computable function  $C$  from  $[2^n - 1]$  to  $[2^n]$ : For every truth assignment  $t$  different from the all-true one  $1^n$ ,  $C$  tests whether  $t$  satisfies  $\phi$ . If it does, then  $C(t) = 1^n$ , and if it does not then  $C(t) = t$ . Now, if we could solve **EMPTY**, that is, if we could find a solution  $s \in [2^n]$  not in the range of  $C$ , then we would have solved the **SAT** problem for  $\phi$ : If  $s \neq 1^n$  then  $\phi$  is satisfiable and  $s$  satisfies it; otherwise,  $\phi$  is unsatisfiable. ◀

This result suggests that **PEPP** is genuinely a subclass of  $\mathbf{TF}\Sigma_2$ , the generalization of **TFNP** to the first level of the polynomial hierarchy. Once we are dealing with  $\mathbf{TF}\Sigma_2$ , it is tempting to define classes such as **PEPP** as the set of all problems that can be reduced through  $\mathbf{FP}^{\mathbf{NP}}$  reductions – not just polynomial-time reductions – to a specific problem, such as **EMPTY** in the case of **PEPP**. This option becomes relevant when dealing with  $\alpha$ -**PEPP** in the next subsection.

As we sketched in the introduction, **EMPTY** and **PEPP** can be alternatively thought as a computationally constructive form of the union bound. A most prominent and early use of the union bound is in Shannon’s work on codes. The following problem motivated by Shannon’s construction has been recently identified: Given a code, which generically means a circuit  $C$  mapping  $[M]$  to  $[N]$  with  $N > M$ , find a bitstring  $x \in [N]$  whose Hamming distance from any codeword  $y$ , that is, any  $y$  such that  $y = C(z)$  for some  $z \in [M]$  is at least  $d$ , where  $d$  is the largest integer such that the Hamming ball of radius  $d - 1$  has fewer than  $N/M$  elements. This is known as the **REMOTE POINT** problem, studied extensively in Complexity and Cryptography [2, 3, 4].

► **Proposition 2.** **REMOTE POINT** is in **PEPP**.

**Proof.** Its proof of totality is an application of the union bound. ◀

In fact, **REMOTE POINT** is strictly speaking **PEPP**-complete, because any instance of **EMPTY** is also an instance of **REMOTE POINT** with  $d = 1$ .

Another natural problem lying in **PEPP** comes from the fact that graphs of bounded degree have logarithmic diameter. One way to capture this is through the problem **REMOTE VERTEX**: given a directed graph on  $[N]$  with vertices of outdegree at most 2, specified by circuits  $C_L, C_R : [N] \rightarrow [N]$  which output the “left” and “right” successors of a given node respectively, find a vertex whose distance from the all-zero vertex is at least  $\log N$ .

► **Proposition 3.** **REMOTE VERTEX** is in **PEPP**.

**Proof.** Consider the circuit that takes as input a string  $s \in \{L, R\}^*$  of length  $0 \leq |s| \leq \log N - 1$ , and outputs the vertex we arrive at by starting with the all-zero vertex and repeatedly applying  $C_L$  or  $C_R$  to the current input based on the next character in  $s$ . This circuit maps each path of length at most  $\log N - 1$  starting at the all-zero vertex to its endpoint, a vertex in  $[N]$ . As there are at most  $N - 1$  such paths, this is a valid instance of **EMPTY**, whose solution is indeed a remote vertex. ◀

One can define several variants of **REMOTE VERTEX** using other implicit representations of graphs, for example the representations for undirected and directed graphs used to define the canonical problems of bounded degree for **PPA** and **PPAD** [18]. Both of these variants reduce to the version of **REMOTE VERTEX** defined above.

Next we introduce two problems in **PEPP** capturing two other classical applications of the union bound. In  $\delta$ -**RIGID MATRIX COMPLETION**, where  $0 < \delta < \frac{1}{3}$ , we are given the first  $\lceil \log n \rceil$  rows of an  $n \times n$  matrix with elements in  $\mathbf{GF}_2$ . We seek to complete this to a full matrix in  $\mathbf{GF}_2^{n \times n}$  that is  $\delta$ -rigid: it cannot be turned into a matrix of rank  $\leq \delta n$  by changing  $n^\delta$  or fewer entries in each row.

Why do we have to phrase the quest for the rigid matrix as a completion problem? The reason is that the alternative (“Given  $n$ , find an  $n \times n$  rigid matrix”) is a *sparse* problem, that is, it has a polynomially (in  $n$ ) many instances of length  $\leq n$ , which places it in complexity limbo, see e.g. [16]; alternatively, if  $n$  is given in binary, then the problem is even more ill-posed since an exponentially long output is required<sup>2</sup>.

To see that  $\delta$ -**RIGID MATRIX COMPLETION** reduces to **EMPTY**, let  $N = 2^{n^2 - n \log n}$  denote the total number of possible completions of the matrix, and let  $M$  denote the number of pairs  $(L, S)$  where  $L$  is a  $n \times n$  matrix of rank at most  $\delta n$  and  $S$  is a matrix that has at

<sup>2</sup> A related question is, how large should be the given part of the matrix in order to avoid sparsity? Giving the first row is not enough, since there are, up to isomorphism,  $n + 1$  such rows, and a similar argument precludes finitely many rows. With  $\log n$  rows in the input, the problem is arguably no longer sparse.

most  $n^\delta$  ones per row. There are at most  $2^{2\delta n^2}$  choices for  $L$  and at most  $\binom{n}{n^\delta}^n < 2^{n^{1+\delta} \log n}$  choices for  $S$ , hence  $M < 2^{2\delta n^2 + n^{1+\delta} \log n}$ . Now consider the circuit  $C : [M] \mapsto [N]$  that takes an input in  $[M]$ , interprets it as the encoding of a pair  $(L, S)$ , computes the sum  $L + S$ , and outputs the element of  $[N]$  encoding this sum if it is a completion of the given matrix, or else it outputs an arbitrary element of  $[N]$ , for example the element representing the trivial matrix completion that sets all remaining entries of the given matrix to zero. Note that  $M < N$  as long as  $n$  is large enough that  $(1 - 2\delta)n^2 > (n^{1+\delta} + n) \log n$ . Any element of  $[N]$  not in the range of  $C$  must be the encoding of a matrix completion that cannot be expressed in the form  $L + S$ , hence is rigid.

RAMSEY-ERDŐS COMPLETION is the problem of finding an  $n$ -node graph with no independent set of size  $k = 4\lceil \log n \rceil$  and no clique of this size, given the connectivity of  $\ell = \lceil \log n \rceil$  nodes in the graph.

There are  $N = 2^{\binom{n-\ell}{2}}$  completions of the given graph. The completions containing a clique or independent set of size  $k$  are parameterized by tuples  $(A, b, x)$  where  $A$  is a vertex set of size  $k$ ,  $b$  is a bit indicating whether  $A$  forms a clique or independent set, and  $x$  is a bitstring indicating which edges belong to the completion, excluding those having both endpoints in  $A$  and those having one endpoint among the  $\ell$  vertices whose connectivity is given in the problem input. There are  $\binom{n}{k}$  possible values for  $A$ , 2 possible values for  $b$ , and at most  $2^{\binom{n-\ell}{2} - \binom{k-\ell}{2}}$  possible values for  $x$ , hence at most  $M = \binom{n}{k} 2^{1 + \binom{n-\ell}{2} - \binom{k-\ell}{2}}$  possible values for the triple  $(A, b, x)$ . When  $k = 4\ell$  and  $\ell = \lceil \log n \rceil$ , it follows from a standard calculation that  $M < N$ .

We have established this result:

► **Proposition 4.**  $\delta$ -RIGID MATRIX COMPLETION and RAMSEY-ERDŐS COMPLETION are in PEPP.

Of these problems RAMSEY-ERDŐS COMPLETION seems the easiest computationally, as it belongs in a variant of **BPP** in which  $n^{O(\log n)}$  computations are allowed.

## 2.1 The Problem COMPLEXITY

The field of Circuit Complexity is about identifying a Boolean function with  $v$  variables requiring a number of gates that grows faster than polynomially in  $v$ . It is well known since Shannon's union bound proof [20] that almost all Boolean functions with  $v$  variables have complexity at least  $2^{\frac{cv}{\log v}}$  for some  $c > 0$ ; however, no explicit function of complexity that is not  $O(v)$  is known.

We can now define COMPLEXITY: given a bitstring  $x$  of length  $n$ , find a Boolean function with  $v = \lceil \log n \rceil + 1$  inputs which cannot be computed by an  $x$ -oracle circuit with  $c \cdot \frac{n}{\log^2 n}$  gates, where  $c > 0$  is a fixed constant. Here, by " $x$ -oracle circuit" we mean a Boolean circuit which, besides the traditional AND, OR, NOT gates also has an ORACLE gate, with fan-in  $\lceil \log n \rceil$ , which when its inputs are the bits  $b_1, \dots, b_{\lceil \log n \rceil}$ , the value of the gate is the  $b+1$ -th bit of  $x$ , where  $b < n$  is the integer spelled by the bits.

We shall assume that, for each  $k, \ell > 0$ , we have a standard representation  $R^{k, \ell}$  of such oracle circuits, where  $k$  is the number of inputs to the circuit and  $\ell$  is the fan-in of the oracle gates.  $R^{k, \ell}$  is a partial function (that is, possibly undefined) from bitstrings to circuits, such that:

- Every  $x$ -oracle circuit  $K$  has at least one bitstring  $z$  such that  $R^{k, \ell}(z) = K$ .
- Given  $z$ ,  $K = R^{k, \ell}(z)$  can be decoded in polynomial time.
- If  $K$  has  $g$  gates, the length of all  $z$ 's such that  $R^{k, \ell}(z) = K$  is at most  $c \cdot g \log^2 g$ , where  $c$  is a constant.

It is easy to see that these desiderata are satisfied by several standard and natural representations (for example, encoding every bit by two bits to create delimiters, encoding gate names by binary integers  $\leq g$  and similarly with gate types, and finally encoding the adjacency lists of the circuit graph). The extra  $\log g$  in the last item is due to the oracle gate, whose adjacency list requires  $\log^2 g$  bits.

Coming back to **COMPLEXITY**, it is, evidently, a computational problem that captures certain aspects of Complexity Theory. We shall show that it is a total problem, and in fact one in the class **PEPP**.

The argument is essentially Shannon's: given input  $x$  of length  $n$ , we construct a circuit  $C_x$  implementing the following polynomial-time (in  $n$ ) algorithm: on any input  $y$  also of length  $n$ ,  $C_x$  interprets  $y$  as a binary representation of an  $x$ -oracle circuit  $K_y = R^{k,\ell}(y)$  with  $k = \lfloor \log n \rfloor + 1$  input gates and fan-in  $\ell = \lfloor \log n \rfloor$ , and goes on to construct it (if  $R^{k,\ell}(y)$  is undefined,  $C_x$  outputs a default string). Next,  $C_x$  simulates  $K_y$  consecutively on each possible input in  $[2^{\lfloor \log n \rfloor + 1}]$ . The output of  $C_x$  is then the concatenation of these  $2^{\lfloor \log n \rfloor + 1}$  bits output by the circuit  $K_y$ , in the order in which they were produced.

In other words, the circuit  $C_x$  maps  $M = [2^n]$  (all inputs  $y$  of length  $n$ ) to  $N = 2^{2^{\lfloor \log n \rfloor + 1}}$  possible outputs, and it is clear that  $N > M$ . Therefore, if we were able to solve **EMPTY** and obtain a possible output not realized by any possible input, we would be able to find the table of a Boolean function with  $\lfloor \log n \rfloor + 1$  inputs which cannot be represented by  $n$  bits, and therefore requires  $\Omega(\frac{n}{\log^2 n})$  gates. This completes the proof of the following result:

► **Proposition 5.** *COMPLEXITY is in PEPP.*

## 2.2 Wasteful counting and $\alpha$ -PEPP

When the union bound is used to prove the existence of objects with a certain property by showing that a random object satisfies the property with positive probability, this success probability is typically not exponentially small. The reason is that this genre of existence proof seems inherently wasteful: the union bound adds probabilities of events that typically overlap, while counting objects such as non-rigid matrices and circuits typically counts the same object many times (for example, all permutations of gate names), and there seems to be no way to be accurate enough. To capture the complexity of the search problems implied by union bound arguments with a significant “margin of error”, we define a family of complexity classes  $\alpha$ -**PEPP**, parameterized by a function  $\alpha : \mathbb{N} \rightarrow \mathbb{R}_+$ .

The complexity class  $\alpha$ -**PEPP** is defined to consist of all total functions that are polynomial-time reducible to the following  $\alpha$ -**EMPTY** problem. An instance of  $\alpha$ -**EMPTY** is given by a bitstring of length  $n$  interpreted as a description of a circuit  $C$  mapping  $[M]$  to  $[N]$ , where  $N/M > 1 + \alpha$ . The search problem is to find  $y \in [N]$  such that  $y \neq C(x)$  for all  $x \in [M]$ .

Note that **0-PEPP** = **PEPP**. The complexity class **1-PEPP**, which we will denote by **APEPP** in the sequel, contains most of the search problems introduced earlier in this section.

► **Proposition 6.** *The problems  $\delta$ -RIGID MATRIX COMPLETION, RAMSEY-ERDŐS COMPLETION, and COMPLEXITY all belong to APEPP.*

**Proof.** Above, we presented reductions from  $\delta$ -RIGID MATRIX COMPLETION, RAMSEY-ERDŐS COMPLETION, and COMPLEXITY to **EMPTY** with the following parameters.

- For a  $\delta$ -RIGID MATRIX COMPLETION instance of size  $n \times n$ , the reduction yields a circuit of size  $\text{poly}(n)$  mapping  $[M]$  to  $[N]$ , where  $M = 2^{2\delta n^2 + n^{1+\delta} \log n}$  and  $N = 2^{n^2 - n \log n}$ ,

$$N/M = 2^{(1-2\delta)n^2 - (n^{1+\delta} + n) \log n}.$$

The ratio  $N/M$  exceeds 2 when  $\delta < \frac{1}{3}$ ,  $n > 125$ .

- For a RAMSEY-ERDŐS COMPLETION instance with  $n$  vertices, the reduction yields a circuit of size  $\text{poly}(n)$  mapping  $[M]$  to  $[N]$ , where  $M = \binom{n}{4^{\lceil \log n \rceil}} 2^{1 + \binom{n - \lceil \log n \rceil}{2} - \binom{3^{\lceil \log n \rceil}}{2}}$ ,  $N = 2^{\binom{n - \lceil \log n \rceil}{2}}$ ,

$$\frac{N}{M} = \frac{2^{\binom{3^{\lceil \log n \rceil}}{2} - 1}}{\binom{n}{4^{\lceil \log n \rceil}}}.$$

The ratio  $N/M$  exceeds 2 when  $n > 8$ .

- For a COMPLEXITY instance of length  $n$ , the reduction yields a circuit of size  $\text{poly}(n)$  mapping  $[M]$  to  $[N]$ , where  $M = 2^n$ ,  $N = 2^{2^{\lceil \log n \rceil + 1}}$ ,

$$N/M = 2^{2^{\lceil \log n \rceil + 1} - n}.$$

The ratio  $N/M$  is greater than 2 for all  $n \in \mathbb{N}$ .<sup>3</sup>

Thus, the reductions presented earlier verify that all three problems belong to **APEPP**. ◀

It seems unlikely that **APEPP** contains a **PEPP**-complete problem, due to the following upper bound on the complexity of **APEPP**.

► **Theorem 7.** *For any function  $\alpha(n) > \frac{1}{\text{poly}(n)}$ , we have  $\alpha\text{-PEPP} \subseteq \mathbf{FZPP}^{\mathbf{NP}} \subseteq \mathbf{FP}^{\mathbf{NP}}|_{\text{poly}}$  where **FZPP** denotes functional **ZPP**.*

**Proof.** First we show  $\alpha\text{-EMPTY} \in \mathbf{FZPP}^{\mathbf{NP}}$ . Consider a circuit  $C$  mapping  $[M]$  to  $[N]$ , where  $N/M > 1 + \alpha$ . Let  $R(C)$  denote the range of  $C$ , i.e. the set of all  $y \in [N]$  such that there exists  $x \in [M]$  with  $C(x) = y$ . The probability that a random  $y \in [N]$  belongs to  $R(C)$  is at most  $M/N < 1/(1 + \alpha)$ . Hence, if  $k = \lceil n/\alpha \rceil$  and  $y_1, y_2, \dots, y_k$  are independent random elements of  $[N]$ , the probability that  $\{y_1, \dots, y_k\} \subseteq R(C)$  is less than  $(1 + \alpha)^{-k} < e^{-n}$ . Consider an algorithm that randomly samples the  $y_i$ , and queries an **NP** oracle whether there exists  $x \in [M]$  such that  $C(x) = y_i$ , and outputs the first  $y_i$  for which the oracle confirms no such  $x$  exists: this shows  $\alpha\text{-EMPTY} \in \mathbf{FZPP}^{\mathbf{NP}}$ .

To see the second inclusion of the theorem, suppose an algorithm that uses randomness  $r$ ,  $|r| \leq \text{poly}(n)$  fails with probability  $< e^{-n}$  for any length  $n$  input. By the union bound, a random sample of  $r$  has positive probability of containing a valid solution to *every* length- $n$  input instance. In fact, this probability is greater than  $1 - 2^n \cdot e^{-n}$ . Hence, there exists an advice string such that for every length- $n$  instance, the algorithm finds a correct output. ◀

We conclude this section by showing a collapse of the complexity classes  $\alpha\text{-PEPP}$  for  $\frac{1}{\text{poly}(n)} \leq \alpha(n) \leq 2^{\text{poly}(n)}$  under  $\mathbf{FP}^{\mathbf{NP}}$  reductions.

<sup>3</sup> Actually, the ratio is greater than or equal to 2 for all  $n$ , but it is equals 2 when  $n + 1$  is a power of 2. Since the definition of  $\alpha\text{-EMPTY}$  requires the strict inequality  $N/M > 1 + \alpha$ , we need to correct for this technicality with a small modification in the definition of COMPLEXITY, tweaking the problem definition to use a slightly smaller constant  $c$  so that all circuits of the appropriate size or less can be encoded in  $n - 1$  bits, instead of  $n$ .

## 44:10 Total Functions in the Polynomial Hierarchy

► **Theorem 8.** *If  $\frac{1}{\text{poly}(n)} \leq \alpha(n) \leq 2^{\text{poly}(n)}$ , then  $\alpha$ -PEPP and APEPP are equivalent under  $\mathbf{FP}^{\mathbf{NP}}$  reductions.*

**Proof.** For any positive integers  $N, k$ , let  $T : [N^k] \rightarrow [N]^k$  denote the function that takes the binary representation of a number  $x \in [N^k]$ , writes  $x$  in base  $N$  as a sequence of  $k$  digits (each an element of  $[N]$ ), and outputs the binary string obtained by concatenating the binary representations of each of these  $k$  base- $N$  digits.

Suppose  $\beta(n), \gamma(n) : \mathbb{N} \rightarrow \mathbb{R}_+$  are any two functions such that

$$k(n) \triangleq \lceil \log_{1+\beta(n)}(1 + \gamma(n)) \rceil \leq \text{poly}(n).$$

We can reduce  $\beta$ -EMPTY to  $\gamma$ -EMPTY as follows. Given a length- $n$  bitstring describing a circuit that computes a function  $C : [M] \rightarrow [N]$ , let  $k = k(n)$  and construct the description of a circuit that computes the function  $C' : [M^k] \rightarrow [N^k]$  defined via the following composition:

$$[M^k] \xrightarrow{T} [M]^k \xrightarrow{C^k} [N]^k \xrightarrow{T^{-1}} [N^k].$$

Here  $C^k$  denotes the function that applies  $C$  to each element of a  $k$ -tuple.

Assuming  $N/M > 1 + \beta(n)$ , we have  $N^k/M^k > (1 + \beta(n))^k \geq 1 + \gamma(n)$ , by the definition of  $k$ . Hence, by solving an instance of  $\gamma$ -EMPTY and applying the function  $T$ , we obtain a  $k$ -tuple  $(y_1, \dots, y_k)$  that is not in the range of the function  $C^k : [M]^k \rightarrow [N]^k$ . Now, given an  $\mathbf{NP}$  oracle, we can proceed as in the proof of Theorem 7 to find  $y \in [N]$  such that for all  $x \in [M]$ ,  $y \neq C(x)$ . Namely, for  $1 \leq i \leq k$  one queries the  $\mathbf{NP}$  oracle to find out if there exists some  $x_i \in [M]$  such that  $C(x_i) = y_i$ . If such an  $x_i$  existed for each  $i$ , then  $C^k(x_1, \dots, x_k)$  would equal  $(y_1, \dots, y_k)$  contradicting our assumption that  $(y_1, \dots, y_k)$  is not in the range of  $C^k$ . Therefore, for at least one value of  $i$  the oracle will answer that no  $x_i \in [M]$  satisfies  $C(x_i) = y_i$ , and we can output this  $y_i$  as a solution of the given  $\beta$ -EMPTY instance.

We have shown a  $\mathbf{FP}^{\mathbf{NP}}$  reduction from  $\beta$ -PEPP to  $\gamma$ -PEPP whenever  $\log_{1+\beta(n)}(1 + \gamma(n)) = \text{poly}(n)$ . If  $\frac{1}{\text{poly}(n)} \leq \alpha(n) \leq 2^{\text{poly}(n)}$ , then a reduction from  $\alpha$ -PEPP to APEPP is obtained by taking  $\beta = \alpha$  and  $\gamma \equiv 1$ , and a reduction from APEPP to  $\alpha$ -PEPP is obtained by taking  $\beta \equiv 1$  and  $\gamma = \alpha$ . ◀

### 3 The SHATTERING Problem

We recall the definition of *shattering*, an important notion in finite set theory and classical learning theory:

► **Definition 9.** *A family of sets over some finite universe,  $F = \{s_1, s_2, \dots\}$ , shatters a set  $s$  if for every subset  $t \subseteq s$ , there exists  $s_i \in F$  such that  $t = s \cap s_i$ .*

The famous Sauer-Shelah lemma guarantees shattering properties if the family is large enough. Here it is stated in its “strong” form:

► **Theorem 10** (Sauer-Shelah Lemma, Strong). *A family  $F$  of finite sets shatters at least  $|F|$  sets.*

The more well-known statement of the Sauer-Shelah lemma is the weak form, which follows from the above:

► **Corollary 11** (Sauer-Shelah Lemma, Weak). *If a family of sets  $F$  over a universe of  $n$  elements satisfies  $|F| > \sum_{i=0}^{d-1} \binom{n}{i}$ , then  $F$  must shatter a set of cardinality at least  $d$ .*

**Proof.** (Of the weak form from the strong form:) There are at most  $\sum_{i=0}^{d-1} \binom{n}{i}$  sets in an  $n$ -element universe that have size less than  $d$ . ◀

It is natural to consider the search problem resulting from this lemma: given a family of sets over  $n$  elements, which can be represented as  $n$  bit strings, find a large shattered set. This search problem is interesting for two reasons: first, its standard proof uses a counting argument that is, in essence, non-constructive, and second, it involves multiple alternations: given a family find the set (*exists*) such that *for all* subsets there *exists* a corresponding set in the family. In fact, this has one more alternation than all the problems we have considered previously, which belong in  $\mathbf{TF}\Sigma_2$ . Instead, this belongs in  $\mathbf{TF}\Sigma_3$ .

► **Definition 12.** Let  $\text{BinomSum}(n, d)$  denote  $\sum_{i=0}^{d-1} \binom{n}{i}$ .

► **Definition 13.** In the SHATTERING problem, we are given as inputs parameters  $n$ ,  $d$ , and  $k > \log(\text{BinomSum}(n, d))$ , and a circuit computing a function  $C : \{0, 1\}^k \rightarrow \{0, 1\}^n$ , representing  $2^k$  indexed sets the collection of which we will denote  $F$ . The search problem is to output either a pair of indices  $x_1 \neq x_2$  such that  $C(x_1) = C(x_2)$  (a collision, in which case the premise of the Sauer-Shelah lemma is not satisfied), or a subset  $Y \subseteq [n]$  of size  $|Y| = d$  that is shattered by the  $F$ , the range of  $C$ .

The following is now clear:

► **Proposition 14.** SHATTERING is in  $\mathbf{TF}\Sigma_3$ .

**Proof.** Consider the Turing Machine  $M((n, d, k, C), s, (u, i))$ , which:

1. checks that  $k > \log(\text{BinomSum}(n, d))$ ;
2. checks whether  $s$  is a string representing a tuple  $x_1, x_2$  of  $k$ -bit strings, in which case it accepts if  $C(x_1) = C(x_2)$  and rejects otherwise;
3. checks whether  $s$  is an  $n$ -bit string, in which case it accepts if  $s \cap u = s \cap C(i)$  and rejects otherwise.

Clearly,  $s$  solves SHATTERING on the input  $(n, d, k, C)$  when the conditions of the Sauer-Shelah lemma are not satisfied, or, if  $\forall u \exists i$  s.t.  $M((n, d, k, C), s, (u, i)) = 1$ . That SHATTERING is total is a consequence of the Sauer-Shelah lemma. ◀

More interestingly, we can place SHATTERING in a generalization of  $\mathbf{PPP}$  that lies within  $\mathbf{TF}\Sigma_3$ :

► **Theorem 15.** SHATTERING is in  $\mathbf{PPP}^{\Sigma_2}$

The main technical result is the following lemma, from which the theorem follows naturally.

► **Lemma 16.** Using a  $\Sigma_2$  oracle, one can compute a polynomial time function  $M$  mapping distinct sets in  $F$  to distinct sets shattered by  $F$ .

**Proof (Lemma 16, informal).**  $M$  is defined recursively on the size of  $F$ . For collections of size  $|F| = 1$ , the single element of  $F$  is mapped to the empty set which is certainly shattered by  $F$ .

Assume now that  $M(F')$  is defined for all collections  $F'$  of size  $|F'| < |F|$  (i.e.  $M$  defined for collection of size  $1, \dots, |F| - 1$ ). We show how to define  $M$  on  $F$ , first with an informal argument.

Suppose we have identified an element  $x$  that is in *at least one but not all* sets of  $F$ . Then we can write  $F = F_0 \cup F_1$ , dividing  $F$  into collections  $F_0$  of sets containing  $x$ , and  $F_1$  of sets that do not contain  $x$ .

Since  $|F_0|, |F_1| < |F|$ , by induction there exists  $M_0 : F_0 \rightarrow \{0, 1\}^n$  and  $M_1 : F_1 \rightarrow \{0, 1\}^n$  mapping each subcollection to sets shattered by that subcollection. Define  $M : F \rightarrow \{0, 1\}^n$  as follows:

## 44:12 Total Functions in the Polynomial Hierarchy

1. For  $s \in F_1$ , reuse the shattered set, i.e. let  $F(s) = F_1(s)$ .
2. For  $s \in F_0$ , if  $\forall s' \in F_1, M_1(s') \neq M_0(s)$ , we reuse the label for  $s$ , i.e.  $M(s) = M_0(s)$ . If  $\exists s' \in F_1$  such that  $M_1(s') = M_0(s)$ , then it must be that  $F$  shatters both  $M_0(s)$  and  $M_0(s) \cup x$ . Hence we can assign  $M(s) = M_0(s) \cup x$ .

In the informal construction above, we assumed that  $x$  is in some but not all sets of  $F$ . To define  $M$  consistently, we go through all elements in the universe  $\{0, 1, \dots, n-1\}$  in order, and we divide  $F$  into those sets that contain the element and those that don't – since these sets are  $n$ -bit strings, we divide them into those strings with 1 in the first coordinate, and those with 0 in first coordinate). It is possible that one side is empty and the other is all of  $F$ ; in this case, we continue splitting by containment of subsequent elements. When one side is empty, then all labels assigned to sets in the non-empty side are reused. This gives a way to build a complete binary tree of subfamilies starting with  $F$  at level 0, and where the  $i+1$ -st level comes from splitting the previous level by containment of element  $i$ .  $M$  then is built recursively from the leaves up. ◀

**Proof (Lemma 16).** We describe how to compute  $M(s)$  for a given  $s \in F$ . Define  $T_n$  to be the labeled binary tree with  $2^n$  leaves representing  $n$ -bit strings; level  $i$  contains nodes labelled by the  $2^i$  binary strings of length  $i$ , and the children of a node labelled with  $s \in \{0, 1\}^i$  is  $s \cdot 0$  and  $s \cdot 1$ .

The idea is to go up  $T_n$ , beginning from the leaf representing set  $s$ , computing  $y^{(n)}, y^{(n-1)}, \dots, y^1$ . This path is unique and has length  $n$ ; denote this path with  $P$ , and its nodes as  $P(n), \dots, P(0)$ , from leaf to root (we will interchangeably use  $P(i)$  to refer to both a node in  $T_n$ , and its associated label, a string of length  $i$ ).

1. When we begin at node  $P(n)$  we initialize  $y$  with the empty set label  $y^n = 0^n$ .
2. Assume we have traversed  $T_n$  up to level  $i$ , i.e.  $P(i)$ .
3. If the node  $P(i)$  is the right child of  $P(i-1)$ , move up to  $P(i-1)$  with  $y^{(i-1)} := y^i$ .
4. For  $P(i)$  that is the left child of  $P(i-1)$ , denote the right child of  $P(i-1)$  (sibling of  $P(i)$ ) and its label as  $P'(i)$ , and denote by  $F_{P'(i)}$  the subcollection of sets in  $F$  that have the label  $P'(i)$  as its prefix (i.e., those sets that agree on the inclusion/exclusion decisions of the first  $i$  elements represented by node  $P'(i)$ ). We check whether  $F_{P'(i)}$  also shatters  $y^i$ , in which case we reuse  $y^i$  but flipping bit  $i$  to 1, i.e.  $y^{(i-1)} := y^i; y_i^{(i-1)} := 1$ . Whether  $F_{P'(i)}$  (or any particular subfamily corresponding to a node in  $T_n$ ) shatters  $y$  can be established in  $O(i)$  time: the algorithm checks whether  $\forall z \in \{0, 1\}^n \exists w \in \{0, 1\}^k (C(w) \in F_{P'(i)}) \wedge (z \cap y = C(w) \cap y)$ . This can be determined with one call to the  $\Sigma_2$  oracle. Note that  $C(w) \in F_{P'(i)}$  can be represented as an  $\wedge$  of  $i$  equalities.

The following invariant is maintained throughout the algorithm: after completing level  $i$ ,  $F_{P(i)}$  shatters  $y^i$ . This is clearly true at level  $n$ . With level  $i$  completed, if the algorithm assigns  $y^{i-1} = y^i$ , the invariant is maintained as  $y$  does not change. The only way  $y^{i-1}$  changes is if  $y_1^{i-1} = 1$ ; this implies both  $F_{P(i)}$  and  $F_{P'(i)}$  shattered  $y^i$ .

If  $|F| = 1$  (the range of  $C$  is one set), assigning the empty set to the lone element is correct. For  $s \neq s'$  in the range of  $C$ , let  $P(i)$  be their lowest common ancestor in level  $i < n$ . Denote its children as  $P(i+1)$  and  $P'(i+1)$ ; without loss of generality,  $P(i)$  is on the path for  $s$  and  $P'(i)$  is on the path for  $s'$ . Consider the algorithm at level  $i+1$  when run on both inputs to compute the shattered sets  $y$  and  $y'$ : if  $y^{(i+1)} \neq y'^{(i+1)}$ , they will remain different for the remainder of the algorithm since at level  $j$  we can only change the  $j$ -th bit. If  $y^{(i+1)} = y'^{(i+1)}$ , then both  $P(i+1)$  and  $P'(i+1)$  shatter  $y^{(i+1)}$  so the algorithm will set  $y^i \neq y'^i$ . ◀

**Proof (Lemma 16  $\implies$  Theorem).** Given an instance  $C$  of SHATTERING, we shall describe an instance  $H$  of PIGEONHOLE $^{\Sigma_2}$  – that is, a hashing circuit with  $k$  input gates and  $2^k - 1$  possible outputs, whose computation makes calls to a  $\Sigma_2$  oracle – which solves this instance. First, the circuit  $H$  determines through an oracle call if  $C$  has a collision, and, if it does – two strings  $x, y \in [2^k]$  such that  $x > y$  and  $C(x) = C(y)$  – it computes a perturbation of the identity permutation on  $[2^k]$  which exposes the collision:  $H$  maps  $x$  to  $y$ , if  $x \neq 2^k - 1$  it maps  $2^k - 1$  to  $x$ , and  $H$  is the identity on all other strings.

If  $C$  has no collision, then on input  $x \in [2^k]$   $H$  first computes the distinct set  $C(x)$  and then implements the lemma to compute the corresponding set  $M(C(x))$  shattered by the  $C$  family of sets. If the set  $M(C(x))$  is smaller than  $d$ , the computation ends here and the set is output, in a representation which encodes subsets of  $[n]$  in order of increasing size; since by assumption  $2^k - 1 \geq \text{BinomSum}(n, d)$ , any set smaller than  $d$  can be represented. If the set is of size  $d$  or larger, then the first  $d - 1$  elements of the set are output. This completes the reduction.  $\blacktriangleleft$

It turns out that  $\text{TF}\Sigma_3$  contains another natural problem aside from SHATTERING, based on a simple fact in graph theory dating back to the 1950's [15].

► **Definition 17.** A vertex  $v$  in a digraph  $G$  is called a king if every vertex can be reached from  $v$  by a path of length at most 2.

► **Definition 18.** A digraph  $G$  is called a tournament if for every pair of distinct vertices  $u, v \in G$ , exactly one of the directed edges  $(u, v)$  or  $(v, u)$  is present in  $G$ .

► **Lemma 19.** Every tournament has a king [15].

**Proof.** Given a vertex  $v$ , will say that the *court* of  $v$  is the set of vertices reachable from  $v$  in exactly one step, and the *domain* of  $v$  is the set of vertices reachable from  $v$  in exactly 1 or 2 steps. By definition, a king is a vertex whose domain contains all other vertices. Starting with an arbitrary vertex  $v$ , we can now locate a king as follows: if the domain of  $v$  contains all other vertices then  $v$  is a king and we are done. Otherwise there exists a  $u \neq v$  outside the domain of  $v$ , and we continue our search from  $u$ . To see that this iterative process terminates, note that at each step the size of the court of our current vertex strictly increases: if  $u$  is outside the domain of  $v$ ,  $u$ 's court must contain at least every element of  $v$ 's court, and must also contain  $v$ .  $\blacktriangleleft$

This gives rise to the following total search problem KING: given a tournament, represented as a circuit  $C : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  determining if the directed edge  $(u, v)$  is present, find either a king or a pair of inputs  $x \neq y$  such that  $C(x, y) = C(y, x)$  (proving that  $C$  does not define a tournament). Since KING seeks a vertex  $k$  such that for all other vertices  $v$  there is an intermediate vertex  $i$  which is reachable from  $k$  in one or zero steps, and such that  $(i, v)$  is an edge, this alternation of quantifiers implies the following:

► **Proposition 20.** KING is in  $\text{TF}\Sigma_3$ .

The proof of Lemma 19 showing the totality of KING is eerily reminiscent of familiar totality arguments for the class PLS. In PLS, the input is an implicitly defined directed graph, along with a polynomial time “potential function” mapping vertices to natural numbers, such that the potential is strictly increasing along edges. The goal is to find a vertex with no outgoing edges, and the potential function gives us a syntactic guarantee that the underlying graph is acyclic and therefore that such a vertex must exist. In the case of KING, we have a similar situation. Given a circuit defining a tournament, we can generate another implicitly

defined graph which has a directed edge  $(v, u)$  if and only if  $u$  is outside the domain of  $v$ , and a potential function which assigns each vertex a potential equal to the size of its court. A vertex with no outgoing edges in this graph will be a king, and since the potential increases along edges, such a vertex must exist. If both the “edge function” (the function finding an outgoing edge of a vertex or telling us that none exists) and the potential function were computable in  $\Sigma_2$ , this would place KING in  $\mathbf{PLS}^{\Sigma_2}$ . However, it seems that only the edge function has this property: computing the potential requires solving a rather generic counting problem. This leaves us in a curious situation, where the proof that a solution exists uses an implicit potential function, but directly computing the potential is seemingly harder than finding a solution. We do not know of another natural total function with this property.

## 4 Discussion and Open Problems

We have introduced a polynomial hierarchy of total functions, whose first couple of levels are populated with interesting computational problems and complexity subclasses with intriguing structural properties. Naturally, a host of questions remain:

- Does the total function hierarchy behave in similar ways as the polynomial hierarchy – for example, does it collapse upwards? As we have mentioned, the answer to this question is already known, modulo relativization, and it is negative: there are oracles with respect to which  $\mathbf{TFNP} = \mathbf{FP}$  and yet  $\mathbf{TF}\Sigma_2 \neq \mathbf{FP}^{\mathbf{NP}}$  [7]. We have not explored how this result extends to higher levels. After a preprint of this article was posted online, Ofer Grossman showed us a sketch of an argument that, if  $\mathbf{TFNP} = \mathbf{TF}\Sigma_2$ , then the decisional polynomial hierarchy does collapse (Ofer Grossman, personal communication). This can be shown to imply that the total function hierarchy collapses.
- A very striking apparent difference between  $\mathbf{TFNP}$  and  $\mathbf{TF}\Sigma_2$  is the dearth of diversity in the latter. There are half a dozen apparently distinct complexity subclasses of  $\mathbf{TFNP}$ , corresponding to natural genres of existence proofs. In contrast, in  $\mathbf{TF}\Sigma_2$  we have identified  $\mathbf{PPEP}$ , but – despite some intense daydreaming – no other credible class. For example, recall that  $\mathbf{PLS}$  is the class of all problems in  $\mathbf{TFNP}$  reducible to SINK: “Given the circuit representation of a DAG, find a sink” (details of the representation omitted). It is natural to ask – and we did: “How about the problem SOURCE? It is in  $\mathbf{TF}\Sigma_2$ , of course, but does it define its own class?” It turns out that SOURCE is in  $\mathbf{PEPP}$ ...  
For  $\mathbf{TFNP}$ , the invention of new natural subclasses is impeded by the result in [11], establishing, through Herbrand’s Theorem, that any such subclass capturing a style of existence proofs in first-order logic must correspond to a *finitary* property of first-order structures: one that is false for infinite structures. How about the logic formulae corresponding to  $\mathbf{TF}\Sigma_2$ ? These would be the so-called Schönfinkel-Bernays formulae (first-order formulae preceded by a sequence of quantifiers of the form  $\forall^*\exists^*$ ), a much studied class in Logic but also in Complexity (it had been known since the 1930s that this is a decidable class). Is there a result restricting the usefulness of such formulae in characterizing total search problems, analogous to – but perhaps stricter than – Herbrand’s theorem for existentially quantified (Herbrand) formulas?
- Is COMPLEXITY complete for  $\mathbf{APEPP}$  under  $\mathbf{P}^{\mathbf{NP}}$  reductions? This would be a tremendously interesting result. Naturally, any finer completeness result for COMPLEXITY would be even more exciting.
- Is REMOTE POINT with large  $d$  complete for  $\mathbf{APEPP}$  under  $\mathbf{P}^{\mathbf{NP}}$  reductions? That would be very interesting as well – especially if it holds true even in the special case in which the code is *linear*.

- The **SAPEPP** class, as defined in the related work subsection, encompasses some of the most important problems in Complexity Theory. Sparsity complicates proving these problems intractable, and yet we know already some fascinating reductions between them. Does **SAPEPP** have natural complete problems? Is **SPARSE COMPLEXITY** complete for it?
- The problem **KING** encompasses a novel aspect of total functions related to local optimality. Problems in the class **PLS** are presented in terms of an implicit DAG defined in terms of an edge function and a potential function. Higher in the hierarchy, **KING** is defined only in terms of an edge function, while the DAG property is established through an *extraneous proof*, that is, a proof not encoded in the instance's description in terms of an explicit potential function. Unless  $\#P$  is in the polynomial hierarchy, **KING** does not appear to belong in  $\mathbf{PLS}^{\Sigma_2}$ : it is a problem in  $\mathbf{TF}\Sigma_3$  whose totality follows from a local optimality argument, and yet one that is *sui generis*, in a class in and by itself. Are there such problems in **TFNP**?

---

## A

 Total Function Polynomial Hierarchy

► **Definition 21 (TFNP).** A relation  $R(x, y)$  is in **TFNP** if it is polynomial and **total** (for every  $x$  there exists  $y$  such that  $(x, y)$  is in the relation) and there exists a polynomial time Turing machine  $M$  such that  $M(x, y)$  accepts iff  $R(x, y)$  holds.

► **Definition 22 (TFΣ<sub>2</sub>).** A relation  $R(x, y)$  is in **TFΣ<sub>2</sub>** if it is polynomial, total, and there exists a polynomial time Turing machine  $M$  and polynomial  $p(n)$  such that  $R(x, y) \iff \forall z \in \{0, 1\}^{p(|x|)} M(x, y, z)$  accepts.

► **Definition 23 (TFΣ<sub>i</sub>).** A relation  $R(x, y)$  is in **TFΣ<sub>i</sub>** if it is polynomial, total, and there exists a polynomial time Turing machine  $M$  and polynomials  $p(n)_1, \dots, p(n)_{i-1}$  such that  $R(x, y) \iff \forall z_1 \in \{0, 1\}^{p(|x|)_1} \exists z_2 \in \{0, 1\}^{p(|x|)_2} \forall z_3 \in \{0, 1\}^{p(|x|)_3} \dots M(x, y, z_1, z_2, z_3, \dots, z_{i-1})$  accepts.

At this point one may ask, what about a **TFΠ<sub>i</sub>**? Could we define total function complexity classes where the first quantifier is an *exists*? It turns out that such a definition results in a complexity class that is polynomial-time reducible to **TFΣ<sub>i-1</sub>** and vice versa, and hence, does not capture anything new. In this way, the total function hierarchy is different from its decision-problem analogue, where, by the way of oracles,  $\Sigma_{i-1} \neq \Pi_i \neq \Sigma_i$ .

► **Proposition 24.** Let  $R(x, y)$  be a polynomial, total relation such that there exists a polynomial time Turing machine  $M$  and polynomials  $p_1(n), \dots, p_{i-1}(n)$  such that  $R(x, y) \iff \exists z_1 \in \{0, 1\}^{p_1(|x|)} \forall z_2 \in \{0, 1\}^{p_2(|x|)} \exists z_3 \in \{0, 1\}^{p_3(|x|)} \dots M(x, y, z_1, z_2, z_3, \dots, z_{i-1})$  accepts. Every search problem in **TFΣ<sub>i-1</sub>** can be expressed with such a relation, and the search problem for any such relation is polynomial-time reducible to **TFΣ<sub>i-1</sub>**.

**Proof.** The fact that any search problem in **TFΣ<sub>i-1</sub>** can be expressed with such a relation (one that starts with  $\exists$ ) is trivial: the relation is the same, and one can reuse the **TFΣ<sub>i-1</sub>** Turing Machine  $M$ , simply by ignoring  $z_1$ . On the other hand, given a  $R(x, y)$  as above, by totality for every  $x$  there is a  $y$  such that there exists  $z$  satisfying the rest of the condition; hence, the relation  $R(x, (y, z))$  defined by  $R(x, (y, z)) \iff \forall z_2 \in \{0, 1\}^{p(|x|)_2} \exists z_3 \in \{0, 1\}^{p(|x|)_3} \dots M(x, y, z_1, z_2, z_3, \dots)$  is total, and is clearly in **TFΣ<sub>i-1</sub>**. Hence one can solve  $R(x, y)$  with one call to a **TFΣ<sub>i-1</sub>** oracle, obtaining a pair  $(y, z)$  and discarding  $z$ . ◀

In other words, the total function polynomial hierarchy does not have “two symmetric sides” like the classical one, but is a single tower of classes.

Finally, analogously to the decision problem polynomial hierarchy, the total function polynomial hierarchy can be understood through oracles; **TFΣ<sub>i</sub>**  $\subseteq$  **TFNP<sup>Σ<sub>i-1</sub></sup>**, and **TFNP<sup>Σ<sub>i-1</sub></sup>** is polynomial time reducible to **TFΣ<sub>i</sub>**.

► **Theorem 25.** **TFΣ<sub>i</sub>**  $\subseteq$  **TFNP<sup>Σ<sub>i-1</sub></sup>**  $\leq_T^P$  **TFΣ<sub>i</sub>**, where the latter class indicates **TFNP<sup>Σ<sub>i-1</sub></sup>** problems where the verifying Turing Machine has access to a **Σ<sub>i-1</sub>** oracle.

**Proof.** We present the proof for **TFΣ<sub>2</sub>**; the proof for other levels is analogous. The trivial direction is that **TFΣ<sub>2</sub>**  $\subseteq$  **TFNP<sup>Σ<sub>1</sub></sup>**. For a relation  $R(x, y)$  with verifying machine  $M(x, y, z)$  we define a **TFNP<sup>Σ<sub>1</sub></sup>** machine  $M'(x, y)$  which issues a single **Σ<sub>1</sub>** query for whether  $\forall z M(x, y, z)$  accepts, and outputs the answer. For the other direction, let  $R(x, y)$  be a **TFNP<sup>Σ<sub>1</sub></sup>** relation with verifying Turing Machine  $M^{\Sigma_1}(x, y)$  which makes at most  $p(|x|)$  oracle queries in its computation, each of length at most  $p(|x|)$ . Define  $R'(x, (y, \mathbf{a}, \mathbf{z}))$  where  $\mathbf{a} \in \{0, 1\}^{p(|x|)}$ ,  $\mathbf{z} \in \{0, 1\}^{2p(|x|)}$  by whether  $\mathbf{w} \in \{0, 1\}^{2p(|x|)} M'(x, (y, \mathbf{a}, \mathbf{z}, \mathbf{w}))$  accepts, where  $M'$  only accepts if:

#### 44:18 Total Functions in the Polynomial Hierarchy

1.  $M(x, y)$  is an accepting computation given oracle answers  $\mathbf{a}$ ;
2. if the  $i$ -th oracle answer in  $\mathbf{a}$  is a *yes* answer, then the  $i$ -th string in  $\mathbf{z}$  is a satisfying assignment to the  $i$ -th query in the computation  $M(x, y)$  (possibly using only a prefix of  $\mathbf{z}$ );
3. if the  $i$ -th oracle answer in  $\mathbf{a}$  is a *no* answer, then the  $i$ -th string in  $\mathbf{w}$  does not satisfy the  $i$ -th query in the computation  $M(x, y)$ .

Indeed,  $R(x, y) \iff \exists \mathbf{a}, \mathbf{z} R'(x, (y, \mathbf{a}, \mathbf{z}))$ , and the latter is a  $\mathbf{TF}\Sigma_2$  relation; to reduce  $R$  to  $R'$ , compute  $R'$  and discard  $\mathbf{a}, \mathbf{z}$ . ◀

# Relaxing Common Belief for Social Networks

## Abstract

We propose a relaxation of common belief called *factional belief* that is suitable for the analysis of strategic coordination on social networks. We show how this definition can be used to analyze revolt games on general graphs, including by giving an efficient algorithm that characterizes a structural result about the possible equilibria of such games.

This extends prior work on common knowledge and common belief, which has been too restrictive for use in understanding strategic coordination and cooperation in social network settings.

**2012 ACM Subject Classification** Theory of computation → Social networks; Theory of computation → Network games; Theory of computation → Algorithmic game theory

**Keywords and phrases** Social networks, network revolt games, common belief

## 1 Introduction

Common knowledge and its analogues (e.g. common belief) are fundamental in the analysis of coordination and cooperation in strategic settings. Informally, common knowledge is the phenomenon that, within a population, everyone knows that a proposition is true, everyone knows that everyone knows that it is true, everyone knows that everyone knows that everyone knows that it is true, and so on, ad infinitum. The existence of common knowledge often shows up as an assumption that underlies some kind of strategic coordination. For example, in the standard game theoretic setting, it is typically assumed that the agents playing a game have common knowledge both of the payoffs of the game and of the rationality of each agent. This assumption undergirds the agents' ability to coordinate on equilibria.

A rigorous investigation into the consequences of this type of assumption can be traced back to Robert Aumann [1], who showed that if two rational agents have the same prior, and their posteriors for an event are common knowledge, then their posteriors must be equal (i.e. it is impossible for such agents to “agree to disagree”). Later work considered whether assumptions about common knowledge, and the mathematical consequences of those assumptions, were realistic for trying to explain economic phenomena. In particular, it seemed unrealistic to expect agents to reason about infinite hierarchies of knowledge. Initial attempts to address this critique involved truncating the infinite hierarchy that is required in our informal definition of common knowledge after some large, but finite, number of levels. However, this line of inquiry resulted in the discovery of “common knowledge paradoxes” that arose from examples like Ariel Rubinstein’s Electronic Mail Game [15]. Such examples demonstrated that in situations where common knowledge was required for coordination, if the infinite hierarchy were truncated to be any finite hierarchy, strategic

agents behaved unexpectedly and unrealistically. That is, they behaved very differently when a proposition was close to common knowledge, in the sense that many – but only finitely many – hierarchies of knowledge were satisfied, then they did when the proposition was actually common knowledge (and therefore infinitely many hierarchies of knowledge were satisfied).

An important breakthrough came from Dov Monderer and Dov Samet in 1989 [8]. Inspired by an earlier version of Rubinstein’s work [15] and the work of Aumann [1], Monderer and Samet proposed an alternative to truncating the infinite hierarchy of knowledge: relaxing the requirement of “knowledge” at each level in the hierarchy. They introduced the notion of *common belief* – an analogous concept to common knowledge that is defined by replacing “everyone knows” with “everyone believes with probability (at least)  $p$ ” at each place where it occurs in our informal definition of common knowledge. Under this definition, they showed that common belief approximates common knowledge in precisely the way that truncating the infinite hierarchy did not: When common knowledge of some proposition is relaxed to common belief, agents behave in approximately the same way they did when they had common knowledge of the proposition. For example, common belief can be applied to generalize Aumann’s result that was mentioned above: when rational agents have the same prior and their posteriors about an event are commonly believed, these posteriors must be approximately equal.

In the same paper, they also detailed a key insight that allowed them to address the critique that common knowledge might be too unrealistic to have explanatory power in Economics. They showed that common knowledge has an alternative definition (used implicitly in [1]), that is formally equivalent to the more natural definition, but simpler to reason about. This alternative – inspired by the example of public announcements – defines common knowledge in terms of events that are *evident knowledge*: events for which their occurrence implies knowledge of their occurrence within the entire population. Common belief has a similar formally equivalent, alternative definition in terms of events that are *evident belief*: events for which their occurrence implies belief with probability at least  $p$  of their occurrence within the entire population.

Here, it is worth noting that our work most heavily borrows from that of Monderer and Samet and, as such, their paper [8] is highly recommended both as a primer for what follows here and as an introduction to common knowledge and common belief in general.

In a somewhat orthogonal line of research, Michael Suk-Young Chwe studied common knowledge (not common belief) on networks in the context of a revolt game [3, 4]. In his setting, each agent has a threshold that represents the size of the revolt in which she would agree to participate. For example, an agent with a threshold of 3 would need to know that at least 2 other agents would participate in order to herself agree to participate in the revolt. To decide whether this threshold is met, agents learn the thresholds of their neighbors. They use this information (and knowledge of their 2-hop neighborhood in the graph) to reason about which agents have their thresholds satisfied and consequently whether their own threshold is satisfied. Because agents require absolute certainty in this setting, they only consider their neighbors when conducting this reasoning.

The strict requirement that absolute certainty is necessary for an agent to revolt implies that for a group of agents to revolt, it must be common knowledge among them that all of their thresholds are satisfied. Consequently, the problem of finding groups of revolting agents reduces to the problem of finding cliques of a certain size in the network. However, an important innovation of Chwe’s work, in contrast to the settings described above, is that common knowledge in his setting is a local phenomenon occurring within those cliques, not a global phenomenon occurring within the entire population.

Both approaches – that of Monderer and Samet and that of Chwe – are limited in their usefulness in social network settings, because their respective notions are unlikely to apply in many natural graphs that are used to model social networks. For example, an Erdős-Rényi random graph of  $n$  vertices with  $p = \frac{10}{n}$  will almost certainly be sparse, so population-level phenomenon like common belief will not arise. On the other hand, an Erdős-Rényi random graph of  $n$  vertices with  $p = \frac{1}{2}$  would be unlikely to contain large cliques, so the phenomenon of local common knowledge would be severely limited despite the fact that each agent, in seeing about half the graph, should have a lot of information about the entire population and might be expected to be able to coordinate with some large fraction of it.

We propose that Monderer’s and Samet’s concept of common belief – itself a relaxation of common knowledge – can be further relaxed to a notion of common belief among a faction (i.e. a minimal-size subset) of the population, while retaining both its mathematical simplicity (in being defined in terms of events that are evident belief) and its economic explanatory power. We refer to this notion as *factional belief*.

Factional belief is a natural application of the ideas of Monderer and Samet to network settings similar to those of Chwe. It retains from Chwe the idea that common knowledge/belief can occur in only a subset of the population and still motivate their behavior. However, it is not prohibitively strict, such that it would be unlikely to occur endogenously in many natural graphs. Factional belief is not necessarily local – agents can and may need to reason about agents outside of their neighborhood. As such, it does not require cliques.

## 1.1 Our Contributions

- We formally define a notion of factional belief (Section 2), which can be used to analyze revolt games on general graphs (Section 3). Prior notions of common knowledge and common belief were insufficient for this type of analysis.
- We provide an algorithm that characterizes a structural result about the types of equilibria that are possible in instances of the network revolt games described in Section 3 (Section 4) and a natural extension of those games (Section 5).
- We show that, surprisingly, it is sufficient for our algorithm to only have access to the degree sequence of the network; additional details of the network beyond the degree sequence are not relevant.
- In the full version of the paper, we describe algorithms for additional natural extensions of the network revolt game model. Further, we demonstrate the practical utility of our algorithms by applying them to simulated network data to explore how various parameters of networks and of the model relate to the size of revolts that are supported in equilibria of the network revolt game.

## 1.2 Additional Related Work

The work of Stephen Morris is particularly notable when surveying the literature related to common knowledge and common belief. Morris, often following the work of Monderer and Samet, has done much theoretical work relating to common knowledge and common belief [9, 11, 12, 13]. More recently, he has also collaborated with Benjamin Golub to study higher-order reasoning, reminiscent of the infinite hierarchy of reasoning in the initial definitions of common knowledge and common belief, in network settings [6, 7].

Underlying Morris’ work, above, and our work is our assertion that common knowledge, common belief, and factional belief are useful, not just as mathematical concepts, but for understanding real social and economic phenomena. Here, we briefly outline some relevant

work in applying common knowledge and common belief to explaining such phenomena. One clear direction for future research is to try to similarly apply factional belief as an explanatory tool in these and other settings.

Morris has applied common knowledge/belief to settings such as contagion [10] and global games [14].

Chwe, in 2013, revisited his earlier work and expanded his purview to consider how common knowledge is generated in society [5]. He proposed that the importance of rituals in society can be understood from the perspective that rituals create conditions under which common knowledge can be generated. This theory fits nicely with understanding common knowledge through the lens of evident knowledge events. Another potential direction for future research would be to try to mathematically model this ritualistic generation of common knowledge.

Finally, common knowledge, common belief, and factional belief can be used as tools to help understand the formation and transformation of social norms. In particular, Cristina Bicchieri proposed and meticulously advocated for a definition of social norms of which our definition of factional belief is very reminiscent [2].

## 2 Defining Factional Belief

For the following definitions, let  $(\Omega, \Sigma, \text{Pr})$  be a probability space, where  $\Omega$  denotes a set of states,  $\Sigma$  denotes a  $\sigma$ -algebra of events, and  $\text{Pr}$  denotes a probability measure on  $\Sigma$ . Let  $I$  denote a set of agents.

For each  $i \in I$ ,  $\Pi_i$  is a partition of  $\Omega$  into measurable sets with positive probability. It is, therefore, a countable partition. For  $\omega \in \Omega$ , the element of  $\Pi_i$  that contains  $\omega$  is written as  $\Pi_i(\omega)$ .  $\Pi_i$  can be interpreted as the information available to agent  $i$ . That is,  $\Pi_i(\omega)$  is the set of states that are indistinguishable to  $i$  when  $i$  observes  $\omega$ . Let  $B_i^p(E)$  denote the event that agent  $i$  believes in event  $E$  with probability at least  $p$ . Formally, we write  $B_i^p(E) = \{\omega : \text{Pr}[E|\Pi_i(\omega)] \geq p\}$ . Lastly, for events  $E$  and  $F$ , we use the notation  $E \subseteq F$  to denote that, whenever  $E$  occurs,  $F$  occurs.<sup>1</sup>

The following examples are helpful to illustrate this notation. When rolling a fair die, with equally probable outcomes in the set  $\{1, 2, 3, 4, 5, 6\}$  we have  $\{2, 4\} \subseteq \{\text{Outcome is even}\}$ . Similarly, when the die has been tossed, but the outcome has not been revealed, we have the event  $B_i^{\frac{1}{2}}(\{\text{Outcome is even}\})$  for any agent  $i$ .

This notation is borrowed from Monderer and Samet [8], and the rest of the terms and claims in this section are defined and stated, respectively, to be analogous to those from their paper.

► **Definition 1** (Evident  $(p, \mu)$ -belief). *An event  $E$  is an evident  $(p, \mu)$ -belief if there exists (at least) a  $\mu$  fraction of agents such that whenever  $E$  occurs, those agents assign a probability of at least  $p$  to its occurrence. That is:*

$$\exists J \subseteq I \text{ with } |J| \geq \mu|I| \text{ such that for each } j \in J, E \subseteq B_j^p(E).$$

Following, Monderer and Samet, we first define our notion of factional belief in terms of events that are evident  $(p, \mu)$ -belief. To maintain consistency with their work, we refer to this notion of factional belief as common  $(p, \mu)$ -belief.

<sup>1</sup> Note that, unlike with knowing, it is possible for an agent to believe something that is not true. In particular,  $B_i^p(E)$  need not be a subset of  $E$ .

► **Definition 2** (Common  $(p, \mu)$ -belief). *An event  $F$  is common  $(p, \mu)$ -belief at  $\omega \in \Omega$  if there exists an evident  $(p, \mu)$ -belief event  $E$  such that  $\omega \in E$  and*

$$\exists J \subseteq I \text{ with } |J| \geq \mu|I| \text{ such that for each } j \in J, E \subseteq B_j^p(F).$$

That is,  $F$  is common  $(p, \mu)$ -belief whenever there is an event ( $E$ ) that is an evident  $(p, \mu)$ -belief whose occurrence implies the existence of (at least) a  $\mu$  fraction of agents that believe with probability at least  $p$  in  $F$ . Note that any event  $E$  that is an evident  $(p, \mu)$ -belief is trivially also common  $(p, \mu)$ -belief (with  $F = E$ ).

Now, an important property shared by common knowledge and common belief is the formal equivalence of their definitions in terms of evident events and their intuitive definitions as infinite hierarchies. Common  $(p, \mu)$ -belief retains this property. In order to state this result formally in Proposition 4, we need to formally define the infinite hierarchy, which is done below in Definition 3.

Informally, each level ( $n \geq 1$ ) in this hierarchy, refers to the event that there exists (at least) a  $\mu$  fraction of agents who believe with probability (at least)  $p$  in the previous level of the hierarchy. The initial level ( $n = 0$ ) is simply the relevant event  $F$ . So, written out entirely, the full informal definition would be that an event  $F$  is common  $(p, \mu)$ -belief if there exists a  $\mu$  fraction of agents who believe  $F$  with probability  $p$ , there exists a  $\mu$  fraction of agents who believe with probability  $p$  that there exists a  $\mu$  fraction of agents who believe  $F$  with probability  $p$ , and so on, ad infinitum.

► **Definition 3.** *For every event  $F$  and every  $0 \leq p \leq 1$  let*

$$E^{p,\mu}(F) = \bigcap_{n \geq 1} F_\mu^n,$$

where  $F_\mu^0 = F$  and  $F_\mu^n$  is the event “ $\exists J \subseteq I$  with  $|J| \geq \mu|I|$  such that  $\forall j \in J, B_j^p(F_\mu^{n-1})$ ”.

► **Proposition 4.** *For every event  $F$ , every  $0 \leq p \leq 1$ , and every  $0 \leq \mu \leq 1$ :*

1.  $E^{p,\mu}(F)$  is an evident  $(p, \mu)$ -belief and  $\exists J \subseteq I$  with  $|J| \geq \mu|I|$  such that  $\forall j \in J, E^{p,\mu}(F) \subseteq B_j^p(F)$ .
2.  $F$  is common  $(p, \mu)$ -belief at  $\omega$  if and only if  $\omega \in E^{p,\mu}(F)$ .

The proof of this proposition is essentially the same as the proof of the analogous proposition (Proposition 2) in Monderer’s and Samet’s paper [8]. However, the details of the proof are not particularly relevant or instructive with regard to our contributions in this work, so we omit them here and consign them to an appendix of the full version of the paper. The important takeaway from this proposition, is, as noted above, the formal equivalence between the definition of common  $(p, \mu)$ -belief in terms of evident  $(p, \mu)$ -belief (Definition 2) and the hierarchical definition (Definition 3). As with the analogous definitions for common knowledge and common belief, the latter definition is more intuitive and perhaps more natural, but the former definition is more mathematically convenient and is what we will reference in what follows. The former definition is also a notion that better corresponds to how agents might be expected to reason about this type of belief in reality, since it is unrealistic to suppose that they consider infinite hierarchies of beliefs.

### 3 Model

Let  $G = (V, E)$  be a graph and  $I$  be a set of  $n$  agents, such that each vertex  $v_i \in V$  corresponds to an agent  $i \in I$ . We will think of  $G$  as representing a social network of strategic agents who are participating in a revolt game. The graph  $G$  is common knowledge among the agents.

Nature draws the state of the world  $s \in S$  according to a distribution  $D_S$  and selects a type  $t_i \in T = \{\alpha, \nu\} \cup X$  for each agent  $i$ , where  $X = \cup_j \{\chi_j\}$  is non-empty (and finite). The types are selected independently at random according to a distribution  $D_T^s$  associated with state  $s$ .  $D_S$  and  $D_T^s$  for each  $s \in S$  are common knowledge among the agents.

Each agent  $i$  will observe the type of each agent  $k \in I$  such that  $(v_i, v_k) \in E$  (this set of agents constitutes the set of *neighbors* of  $i$ ). The information resulting from this observation – an agent’s type and the types of all of her neighbors – defines that agent’s *context*. When agent  $i$  has the context  $c$ , we write it as  $c(i) = c$ . We use  $C$  to denote the set of all contexts that are possible in  $G$ .

*Ex ante*, or, before selection of the state, the assignment of types, and the observation of contexts, agents choose a pure *strategy*  $\sigma : C \rightarrow \{R, Y\}$ , where  $\{R, Y\}$  is the set of *actions*.<sup>2</sup> A *strategy profile*  $(\sigma_1, \sigma_2, \dots, \sigma_n)$  is collection of strategies for each agent. Let  $\sigma_{-i} = (\sigma_1, \sigma_2, \dots, \sigma_{i-1}, \sigma_{i+1}, \dots, \sigma_n)$  denote the strategies of all the agents except for  $i$ . Similarly, *ex post*, or, after the selection of types and observation of contexts, an *action profile*  $(a_1, a_2, \dots, a_n)$  where  $a_i = \sigma_i(c(i))$  is a collection of actions for each agent.

Let  $\mathcal{R}(a_1, a_2, \dots, a_n) = \{i \in [n] : a_i = R\}$  denote the set of agents who play the action  $R$  (revolt) given their context and strategy. Agent  $i$  with type  $t_i = t$  receives a payoff according to the function  $f_i^t : \{R, Y\}^n \rightarrow [0, 1]$ :

$$f_i^\alpha(a_1, a_2, \dots, a_n) = \begin{cases} 1, & \text{if } a_i = R, \\ 0, & \text{otherwise,} \end{cases}$$

$$f_i^\nu(a_1, a_2, \dots, a_n) = \begin{cases} 1, & \text{if } a_i = Y, \\ 0, & \text{otherwise,} \end{cases}$$

and

$$f_i^{\chi_j}(a_1, a_2, \dots, a_n) = \begin{cases} 1 - p_j, & \text{if } |\mathcal{R}(a_1, a_2, \dots, a_n)| \geq \mu_j \cdot n \text{ and } a_i = R, \\ p_j, & \text{if } |\mathcal{R}(a_1, a_2, \dots, a_n)| < \mu_j \cdot n \text{ and } a_i = Y, \\ 0, & \text{otherwise.} \end{cases}$$

where  $p_j, \mu_j \in [0, 1]$  for each  $j$  and are common knowledge among the agents.

We call  $\sigma_i$  a *best-response* to  $\sigma_{-i}$  when  $\sigma_i$  maximizes agent  $i$ ’s *ex ante* expected payoff given  $\sigma_{-i}$ , which, by linearity of expectation, is equivalent to maximizing her expected payoff for each  $c \in C$  (using the beliefs she would have about the contexts of the other agents after observing  $c$ ).

We say that a strategy profile  $(\sigma_1, \sigma_2, \dots, \sigma_n)$  is an *equilibrium* when each strategy  $\sigma_i$  is a best-response to  $\sigma_{-i}$ .

Intuitively, the game is defined so that there is a natural strategy for each agent based on type:

- Agents of type  $\alpha$  should always revolt.
- Agents of type  $\nu$  should never revolt.
- Agents of type  $\chi_j$  should conditionally revolt:
  - Each type  $\chi_j$  is characterized by a pair of thresholds  $(p_j, \mu_j)$  that indicate an agent of type  $\chi_j$  should revolt when she believes that  $\Pr[|\mathcal{R}(a_1, a_2, \dots, a_n)| \geq \mu_j] \geq p_j$ .

An important thing to note about this game is that when there are agents of type  $\nu$ , there is not an equilibrium where each agent revolts regardless of her beliefs. Similarly, when there are agents of type  $\alpha$ , there is not an equilibrium where each agent chooses not to revolt regardless of her beliefs.

<sup>2</sup> “Revolt” and “Yield,” respectively.

Even without these, though, there are still potentially multiple equilibria corresponding to revolts of different sizes, and our work does not address equilibrium selection. Consequently, in what follows, we will write that a revolt (of a particular size) is *supported* in equilibrium instead of writing that a revolt will occur. Similarly, we write that agents are *secure enough to revolt* when they sufficiently believe their thresholds are met instead of writing that agents will revolt.

Lastly, in this work we primarily consider the *largest* revolts that are supported in some equilibrium. Such revolts are supported by *symmetric* equilibria, in which each agent adopts the same strategy – namely, the strategy detailed in the bullet points above.

### 3.1 Motivating Example

To see this model in practice and get a feeling for how agents need to reason about the concepts that we have introduced, we will work through a modest example.

Suppose that  $G$  is a grid of  $n$  vertices embedded on a torus, so that each the vertex associated with each agent is adjacent to the vertices representing exactly four other agents (and there is no boundary). Thus, a context in this graph consists of the central agent and her type plus the types of each of her neighbors in  $G$ . In this example, we will have two types of agents: (1) Agents of type  $\chi$ , who want to revolt conditionally; they feel secure enough to revolt when the threshold pair  $(p = \frac{2}{5}, \mu = \frac{1}{2})$  is satisfied. (2) Agents of type  $\nu$ , who never want to revolt. We will also have two equally-likely states: an anti-government state  $A$ , where agents are of type  $\chi$  with probability  $\frac{4}{5}$  and a pro-government state  $B$  where agents are of type  $\nu$  with probability  $\frac{4}{5}$ .

We also define the notion of a *candidate agent*. In this setting, for reasons that will become clear in the proof of the following proposition, we refer to agents of type  $\chi$  with two or more neighbors of type  $\chi$  as *candidate agents*.

► **Proposition 5.** *In this model, when  $G$  is sufficiently large, the event that at least  $\frac{1}{2}$  of the agents are candidate agents is an evident  $(\frac{2}{5}, \frac{1}{2})$ -belief. When it occurs, it is common  $(\frac{2}{5}, \frac{1}{2})$ -belief that supports a revolt of size  $\frac{1}{2}$ .*

**Proof.** First, we will compute  $\Pr[\text{State} = A|c]$  for each context  $c$  and use the computed values to demonstrate that our definition of candidate agents is the correct one for this setting; candidates are likely to feel secure enough to revolt, based on their  $p$ -thresholds.

Each agent has 5 independent samples from the probability distribution defined by the state, with which to calculate the probability of each state, given her information. The first step in this is to compute the likelihood of her context given the state, which can be calculated by evaluating the probability mass function of a binomial distribution with the appropriate parameters. Then, the probability for each state given a certain neighborhood can be calculated using Bayes' rule. The results of these calculations are shown in Table 1.

Now, agents of type  $\chi$  that only have at most one other neighbor of type  $\chi$ , believe that the state is  $A$  with probability at most  $\frac{1}{5}$ , so they will not feel secure enough to revolt; a revolt of size  $\mu = \frac{1}{2}$  is very unlikely to be supported when the state is  $B$ , and they do not sufficiently believe that the state is  $A$ .

As a result, it is exactly agents of type  $\chi$  with contexts such that they have two or more neighbors of type  $\chi$ , which we defined earlier as candidate agents, in which we are interested (cases with  $k \geq 3$  in Table 1b). In particular, we are interested in the probability that a majority of agents are candidates.

▷ **Claim.** The probability that at least half the agents are candidates, given that the state is  $A$  is at least  $\frac{1739}{3125}$ .

Proof of Claim. For this, we can try to count all the non-candidate agents and see how likely they are to outnumber the candidates.

Let  $X$  count the number of non-candidate agents. Specifically, let  $X = \sum_{i \in [n]} X_i$ , where  $X_i$  is an indicator variable that is 1 if and only if agent  $i$  is not a candidate. For each  $X_i$ , therefore, the expectation of  $X_i$  is equal to the probability that  $i$  is not a candidate, which can happen in three ways: (1)  $i$  is of type  $\nu$ , (2)  $i$  is of type  $\chi$  and has no neighbors of type  $\chi$ , or (3)  $i$  is of type  $\chi$  and has one neighbor of type  $\chi$ . The probability of (1) is trivially  $\frac{1}{5}$ . Conditioned on  $i$  being of type  $\chi$ , the respective probabilities of the remaining possibilities are (2)  $\frac{1}{625}$  and (3)  $\frac{16}{625}$ . To obtain unconditional probabilities for (2) and (3), we multiply each conditional probability by  $\frac{4}{5}$ . Consequently, since the events (1), (2), and (3) are disjoint, we have the following:

$$\mathbb{E}[X_i] = \frac{1}{5} + \frac{4}{5} \left( \frac{1}{625} \right) + \frac{4}{5} \left( \frac{16}{625} \right) = \frac{693}{3125}.$$

Therefore, by linearity of expectation,  $\mathbb{E}[X] = \frac{693n}{3125}$ .

Now, we need to upper bound the probability that the number of non-candidate agents is the majority. Ideally for this, we would like to use something tight, like a typical Chernoff-Hoeffding bound. Unfortunately, here, the  $X_i$ 's are not independent; the contexts of agents that share neighbors are correlated, which complicates the calculation.

For our more rigorous analysis later, we will insist on tighter probability bounds. But for the sake of simplicity, in this example, Markov's inequality is sufficient:

$$\Pr \left[ X \geq \frac{n}{2} \right] \leq \frac{\frac{693n}{3125}}{\frac{n}{2}} = \frac{1386}{3125} \approx 0.44.$$

Consequently, the probability that at least half the agents are candidates, given that the state is  $A$ , is at least  $(1 - \frac{1386}{3125}) = \frac{1739}{3125}$ .  $\triangleleft$

Candidate agents can perform this exact same calculation and, further, they believe that the state is  $A$  with probability at least  $\frac{4}{5}$ . Thus, when the graph is large enough that the context of any individual agent is inconsequential in their reasoning about the total fraction of candidate agents, the probability that they assign to at least half of the agents being candidate agents is at least  $\frac{4}{5} \cdot (\frac{1739}{3125}) \geq \frac{2}{5}$ .

That is, in sufficiently large graphs, candidate agents believe with probability at least  $\frac{2}{5}$  that at least  $\frac{1}{2}$  of the agents are candidate agents. As a result, the event that at least  $\frac{1}{2}$  of the agents are candidate agents is an evident  $(\frac{2}{5}, \frac{1}{2})$ -belief. Consequently, when it occurs, by definition, it is common  $(\frac{2}{5}, \frac{1}{2})$ -belief. In this event, a revolt of size  $\frac{1}{2}$  is supported, since at least half of the agents have their thresholds satisfied, and consequently feel secure enough to revolt.  $\blacktriangleleft$

## 4 Applying Factional Belief: A Computational Perspective

The network revolt game model described in Section 3 gives us a useful setting in which to apply our definitions from Section 2 and demonstrate how they can provide insight into strategic coordination. In this section, we explore the interaction between factional belief and strategic coordination from a computational perspective, by trying to answer an elementary question: When can we efficiently determine if strategic coordination (i.e. in our model, a revolt) is supported under given conditions?

■ **Table 1** Results of the probabilistic calculations for the motivating example.

(a) The likelihood, in each state, of having a context with  $k$  agents of type  $\chi$ .      (b) The likelihood of state  $A$ , given a context with  $x$  agents of type  $\chi$ .

	$\Pr[c \text{State} = A]$	$\Pr[c \text{State} = B]$
$k = 0$	$\frac{1}{3125}$	$\frac{1024}{3125}$
$k = 1$	$\frac{4}{625}$	$\frac{256}{625}$
$k = 2$	$\frac{32}{625}$	$\frac{128}{625}$
$k = 3$	$\frac{128}{625}$	$\frac{32}{625}$
$k = 4$	$\frac{256}{625}$	$\frac{4}{625}$
$k = 5$	$\frac{1024}{3125}$	$\frac{1}{3125}$

	$\Pr[\text{State} = A k = x]$
$x = 0$	$\frac{1}{1025}$
$x = 1$	$\frac{1}{65}$
$x = 2$	$\frac{1}{5}$
$x = 3$	$\frac{4}{5}$
$x = 4$	$\frac{64}{65}$
$x = 5$	$\frac{1024}{1025}$

In pursuing an answer to this question, we seek to apply the intuition that we have constructed in our motivating example to a more general setting. Toward that end, a relatively modest generalization of the model used in the example – our Fundamental Case, below – is rich enough to provide an interesting, non-trivial answer to our question and to provide robust intuition that guides us through the various extensions of the model that we discuss in Section 5.

#### 4.1 Fundamental Case: Low-Degree Graphs, Two States, and Three Types

Recall that our model requires a description of possible agent types and possible states (which specify probability distributions over those types). For our initial case, there are three agent types and two possible states.

Our focus will be on agents who want to revolt conditionally – agents of type  $\chi$  – who have the threshold pair  $(p, \mu)$  for an arbitrary  $0 \leq p \leq 1$  and  $0 \leq \mu \leq 1$ . In some sense, these are the truly “strategic” agents; they need to coordinate with other agents in order to feel secure enough to revolt. There are also agents who always behave in a prescribed manner, regardless of their contexts or the state: pro-government agents of type  $\nu$ , who will never revolt, and anti-government agents of type  $\alpha$ , who will always revolt.

The possible states are  $A$ , an anti-government state, and  $B$ , a pro-government state.  $D_S$ , the distribution over the states,  $D_T^A$  and  $D_T^B$ , the distributions over the types in each state, and  $p$  and  $\mu$ , the threshold values for agents of type  $\chi$ , are commonly known to the agents under the prior  $P$ . Intuitively, the labels assigned to the states as being anti- and pro-government correspond to an implication that as the number of agents grows, the size of the largest revolt supported in state  $A$  should be larger than in state  $B$ . In what follows, we assume that the given labels are assigned correctly, but in practice the correct labels can be determined by running an algorithm that we present later with each possible labeling and comparing the results: When the states are correctly labeled, Algorithm 1 will return  $X_A$  and  $X_B$  such that  $X_A \geq X_B$ .

In this more concrete setting, we are able to pose a straightforward question: Given values  $\mu^*$  and  $q^*$ , is a revolt of size (at least)  $\mu^*$  supported with probability at least  $q^*$ ? We refer to this problem as REVOLT.

► **Definition 6 (REVOLT).**

**Given:**  $(G, P, \mu^*, q^*)$ , where  $G$  is a graph with  $n$  vertices and  $P = (p, \mu, D_T^A, D_T^B, D_S)$  is the common prior.

**Question:** Is a revolt of size at least  $\mu^*$  supported with probability at least  $q^*$ ?

Note that there is a nuance regarding the timing of the network revolt game model described in Section 3. REVOLT considers the likelihood of revolt of a certain size being supported in a given network *ex ante* – i.e. before the selection of the state and the assignment of types to agents.

Although the question posed by REVOLT is straightforward to state, it is not straightforward to solve efficiently. In fact, we have the following hardness result, which we prove in an appendix of the full version of the paper:

► **Proposition 7.** *REVOLT is NP-hard.*

Consequently, we will instead consider a relaxed version of the problem that we will be able to solve efficiently. In order to define this new problem, we first require  $p$  and  $\mu$  to be strictly between 0 and 1. We will also need two error terms, which will be constants given as input:  $\epsilon, \delta > 0$ . Lastly, we introduce two additional priors, as follows (recall  $P = (p, \mu, D_T^A, D_T^B, D_S)$  is the common prior given as input to both problems):

$$P^- = (p - \delta, \mu - \epsilon, D_T^A, D_T^B, D_S), \quad P^+ = (p + \delta, \mu + \epsilon, D_T^A, D_T^B, D_S).$$

Now, we are ready to define our new problem, PROMISE REVOLT.

► **Definition 8** (PROMISE REVOLT).

**Given:**  $(G, P, \mu^*, \epsilon, \delta)$ , where  $G$  is a graph with  $n$  vertices,  $P = (p, \mu, D_T^A, D_T^B, D_S)$  is the common prior, and  $\epsilon, \delta > 0$  are constants.

**Output:** When exactly one of the following cases is true, output the corresponding symbol:  
 $\Omega$ : A revolt of size  $\mu^* - \epsilon$  is supported with probability  $q^* \geq 1 - \delta$  under the prior  $P^-$ .

$A$ : A revolt of size  $\mu^*$  is supported with probability  $q^* \in [\Pr[\text{State} = A] - \delta, \Pr[\text{State} = A] + \delta]$  under the prior  $P$ .

$\emptyset$ : A revolt of size  $\mu^* + \epsilon$  is supported with probability  $q^* \leq \delta$  under the prior  $P^+$ .

PROMISE REVOLT is named so as to emphasize that this it is a promise problem, in the typical sense. The “promise” is that the given instance is such that exactly one of the cases from the definition of the problem is true. Given that promise, the three cases are mutually exclusive and any solution is required to always output the correct answer. It is exactly this promise to exclude difficult inputs that makes PROMISE REVOLT easier to solve than REVOLT.

Still, in providing an algorithm to solve PROMISE REVOLT, we will see that the problem has a structure that allows us to closely approximate REVOLT by solving PROMISE REVOLT (for large graphs). This structure is discussed in more detail at the end of this subsection (4.1), particularly with respect to Figure 1, which helps to illustrate this intuition.

Lastly, note that we assume all inputs to REVOLT and PROMISE REVOLT are given as rational numbers. This leads us to state our first theorem:

► **Theorem 9.** *Given  $\epsilon > 0$ , the prior  $P$ , and  $\mu^* \in [0, 1]$ , there exists  $\delta(n) \in \frac{1}{\exp(\Omega_{\epsilon, P}(\sqrt[3]{n}))}$  such that for any graph  $G$  with  $n$  vertices where the largest degree of any vertex is  $O_{\epsilon, P}(\sqrt[3]{n})$ , Algorithm 3 can be used to solve PROMISE REVOLT( $G, P, \mu^*, \epsilon, \delta = \delta(n)$ ) in polynomial time.*

Before we get to the proof of Theorem 9, we briefly discuss our assumption that each agent has a degree that is  $O(\sqrt[3]{n})$ . Primarily, this assumption serves to simplify our analysis. For simplicity, it is convenient to make some distinction between “low-degree” agents and “high-degree” agents to highlight the fact that a prototypical high-degree agent would have a lot more information about the state than a prototypical low-degree agent. However, any

■ **Algorithm 1** Finding the expected size of largest revolt supported in each state.

---

**Input:** A graph  $G = (V, E)$  of  $n$  vertices, the prior  $P = (p, \mu, D_T^A, D_T^B, D_S)$ .  
**Output:**  $X_A$  and  $X_B$ , the expected size of the largest revolt supported in states  $A$  and  $B$ , respectively.

Let  $e_s(\tau)$  denote the expected fraction of type  $\tau$  agents in state  $s$ .  
Define the set of candidate states  $S_C = \{s \in \{A, B\} : e_s(\chi \cup \alpha) \geq \mu\}$ .

**Algorithm 3** Solving PROMISE REVOLT.

---

**Input:**  $(G, P, \mu^*, \epsilon, \delta)$ , where  $G$  is a graph of  $n$  vertices,  $P = (p, \mu, D_T^A, D_T^B, D_S)$  is the common prior, and  $\epsilon, \delta > 0$  are constants

**Output:**  $\Omega$ ,  $\mathbf{A}$ ,  $\emptyset$ , or **Null**.

$X_{A_1}, X_{B_1} \leftarrow \text{Algorithm 1}(G, P = (p', \mu', D_T^A, D_T^B, D_S))$ , where  $p' = p + \frac{\delta}{3}$ ,  
 $\mu' = \mu + \frac{\epsilon}{3}$ .

$S_1 \leftarrow \text{Algorithm 2}(X_{A_1}, X_{B_1}, \mu^*)$ .

$X_{A_2}, X_{B_2} \leftarrow \text{Algorithm 1}(G, P = (p', \mu', D_T^A, D_T^B, D_S))$ , where  $p' = p - \frac{\delta}{3}$ ,  
 $\mu' = \mu - \frac{\epsilon}{3}$ .

$S_2 \leftarrow \text{Algorithm 2}(X_{A_2}, X_{B_2}, \mu^*)$ .

**if**  $S_1 = S_2$  **then**  
     **return**  $S_1$

**end**

**else**

**return** **Null**

**end**

---

particular choice of cutoff to separate high- and low-degree agents is somewhat arbitrary. Here, we choose  $O(\sqrt[3]{n})$ , which is mathematically convenient for defining an upper bound on our error function  $\delta(n)$  in Theorem 9.

Given this cutoff, we focus first on the case where there are only low-degree agents, which is sufficient to provide the guiding intuition that we will follow in the next section, when we discuss broadening the setting in various ways. One such extension will involve allowing vertices of arbitrary degree.

We now proceed by making several arguments which form the building blocks of the proof of Theorem 9 that follows.

► **Lemma 10.** *Algorithms 1 and 2 terminate in polynomial time with respect to the number of agents.*

**Proof.** The key for this property of Algorithm 1 is that contexts are identity-agnostic, so the number of contexts is polynomial in  $n$  when the number of types is a constant. Therefore, we are able to enumerate all of the possible contexts in polynomial time. For each of these contexts  $c$ , we can compute the relevant probabilities –  $\Pr[\text{State} = s|c]$  and  $\Pr[c|\text{State} = s]$  for both states  $s$  – using Bayes’ rule. The rest of the steps in the algorithm are linear in the number of contexts, and therefore also computable in polynomial time. Algorithm 2 is trivially computable in constant-time. ◀

Having shown that they are polynomial-time computable, we now demonstrate the correctness of Algorithms 1 and 2 under idealized conditions.

▷ **Claim.** When agents believe with probability 1 that the actual size of the largest supported revolt in each state will exactly equal its expected size, then Algorithm 1 correctly computes the expected size of the largest revolt in each state. When, further, it is true that the actual size of the largest supported revolt in each state will exactly equal its expected size, then Algorithm 2 identifies the set of states in which revolt of size  $\mu^*$  is supported with no error.

**Proof of Claim.** Algorithm 1 first defines the set of candidate states – these are the states in which it is possible, but not necessarily the case, that type- $\chi$  agents will feel secure enough to revolt, because there are at least  $\mu$   $\alpha$ - and  $\chi$ -type agents. If there are no such states, then

only agents of type  $\alpha$  will revolt. If both states are candidates, then all  $\alpha$ - and  $\chi$ -type agents will feel secure enough to revolt: Agents of type  $\alpha$  always revolt and agents of type- $\chi$  have their  $\mu$  threshold met in both states, by the definition of a candidate state. As a result, their  $p$  threshold is also necessarily met, because the probability of the state being either  $A$  or  $B$  is  $1 \geq p$ . The most interesting case is when only  $A$  is a candidate state. In this case, only type  $\chi$  agents who  $p$ -believe that the state is  $A$  will have their  $p$ -threshold met. So, similarly to our example from Section 3.1, we call those agents candidate agents (and refer to their contexts as candidate contexts.) If the number of candidate agents and  $\alpha$ -type agents, given that the state is  $A$ , is at least  $\mu$ , then all of those agents feel secure enough to revolt. This is true in any state, because even when the state is  $B$ , candidate agents, by definition,  $p$ -believe that the state is  $A$ .

Algorithm 2 simply compares the size of the expected revolt in each state to  $\mu^*$  to decide in which states, if any, a revolt of expected size at least  $\mu^*$  is supported. If the actual size of the revolt in any state is exactly equal to its expectation, as we assume, then Algorithm 2 introduces no error.  $\triangleleft$

Now, the assumption that the actual supported revolt exactly equals the expected size of the supported revolt is, of course, too strict. However, we will be able to show that the actual size of the supported revolt concentrates around its expectation, and consequently, the errors in our algorithms decrease quickly as  $n$  grows.

Recall that computing the expected size of a supported revolt involves counting the number of some subset of three kinds of agents:  $\alpha$ -type agents,  $\chi$ -type agents, and candidate agents. For  $\alpha$ -type and  $\chi$ -type agents, it is simple to show that the number of such agents concentrates around its expectation because agent types are assigned independently at random.

► **Lemma 11.** *Given  $\epsilon > 0$ , the probability that, in a given state, the number of agents of type  $\chi$  and of type  $\alpha$  differ from the expected number of agents of type  $\chi$  and of type  $\alpha$  by a multiplicative factor of  $\epsilon$  is at most  $\delta = \delta(n)$  for some  $\delta(n) \in \frac{1}{\exp(\Omega_{\epsilon,P}(\sqrt[3]{n}))}$ .*

**Proof.** Because the agent types are drawn independently at random, we can use a standard Chernoff-Hoeffding bound on the expected number of each type of agents. Consequently, the difference between the actual and expected number of each type of agent decays exponentially with  $n$ , and therefore we can choose  $\delta(n) \in \frac{1}{\exp(\Omega_{\epsilon,P}(\sqrt[3]{n}))}$  so that the difference is trivially smaller.  $\blacktriangleleft$

Counting the number of candidate agents, as foreshadowed in the Motivating Example of Section 3.1, is somewhat more complicated. Here, we need to consider the contexts of agents – not just their type – and agents' contexts are correlated with the contexts of their neighbors and their neighbors' neighbors in  $G$ . We will show, though, that as the graph grows, the effect of this correlation is small. In fact, we will still be able to prove an exponentially-decreasing bound on the difference between the actual and expected number of candidate agents.

► **Lemma 12.** *Given  $\epsilon > 0$ , the probability that, in a given state, the number of candidate agents is less than the expected number of candidate agents by a multiplicative factor of  $\epsilon$  is at most  $\delta = \delta(n)$  for some  $\delta(n) \in \frac{1}{\exp(\Omega_{\epsilon,P}(\sqrt[3]{n}))}$ .*

**Proof.** Let  $X_C$  be a random variable that denotes the number of candidate agents. We can write  $X_C = \sum_{i=1}^n X_{i,C}$  where  $X_{i,C}$  is an indicator variable that indicates whether or not agent  $i$  is a candidate.

As we have noted above, an agent's status as a candidate is dependent on her context, and as a result, the variables  $X_{i,C}$  are not independent. However – given our assumption that the maximum degree of any vertex in  $G$  is  $O(\sqrt[3]{n})$  – their dependence is constrained enough that we are able to apply a useful exponential bound involving the *fractional chromatic number*  $\chi^*(\Gamma)$  of the constraint graph  $\Gamma$  of the random variables  $X_{i,C}$ .

(See the appendix section of the full version of the paper for additional details).

For our purposes, it is sufficient to use a trivial bound on the fractional chromatic number of any graph. The fractional chromatic number of a graph is at most the *chromatic number* of the graph, which is at most the maximum degree of any vertex plus one. So in  $\Gamma$ , where edges correspond to dependencies between pairs of random variables  $(X_{i,C}, X_{j,C})$ , the maximum degree of any vertex – and therefore the fractional chromatic number  $\chi^*(\Gamma)$  – is  $O_{\epsilon,P}(n^{\frac{2}{3}})$ . Applying the bound, then, gives

$$\Pr[|X_C - \mathbb{E}[X_C]| \geq \epsilon n] \leq 2 \exp\left(\frac{-2\epsilon^2 n}{\chi^*(\Gamma)}\right) \in \frac{1}{\exp(\Omega_{\epsilon,P}(\sqrt[3]{n}))}. \quad \blacktriangleleft$$

► **Lemma 13.**

1. Suppose Algorithm 1 is run with the given inputs, but with modified  $\mu' = \mu + \frac{\epsilon}{3}$  and  $p' = p + \frac{\delta}{3}$ , and Algorithm 2 is run with the resulting  $X_A$  and  $X_B$  and the given  $\mu^*$ . If the result is  $\Omega$ , then a revolt of size  $\mu^* - \epsilon$  is supported with probability at least  $1 - \delta$  under the prior  $P$ . If the result is  $\mathbf{A}$ , then a revolt of size  $\mu^* - \epsilon$  is supported with probability at least  $\Pr[\text{State} = A] - \delta$  under the prior  $P$ .
2. On the other hand, suppose Algorithm 1 is run with the given inputs, with modified  $\mu' = \mu - \frac{\epsilon}{3}$  and  $p' = p - \frac{\delta}{3}$ , and Algorithm 2 is run with the resulting  $X_A$  and  $X_B$  and the given  $\mu^*$ . If the result is  $\emptyset$ , then a revolt of size  $\mu^* + \epsilon$  is supported with probability at most  $\delta$  under the prior  $P$ . If the result is  $\mathbf{A}$ , then a revolt of size  $\mu^* + \epsilon$  is supported with probability at most  $\Pr[\text{State} = A] + \delta$  under the prior  $P$ .

**Proof.** This proof decomposes into two analogous arguments about (1) and (2), which themselves each contain two analogous arguments. We include only the first one in detail here, below, and claim the rest via analogy.

▷ **Claim.** Suppose that, in instance (1), the result is  $\Omega$ . Then, the probability that a revolt of size  $\mu^* - \epsilon$  is supported in both states is at least  $1 - \frac{1}{\exp(\Omega(\sqrt[3]{n}))}$ .

Proof of Claim. There are three cases for the nature of this revolt.

- (I) The revolt consists of all  $\alpha$ -type agents.

By Lemma 11, we know that, in either state, the probability that the expected number of  $\alpha$ -type agents differs from the expected number of  $\alpha$ -type agents by a multiplicative factor of  $\epsilon$  is  $\frac{1}{\exp(\Omega(\sqrt[3]{n}))}$ . Therefore, the probability that a revolt of size  $\mu^* - \epsilon$  is supported in both states is at least  $1 - \frac{1}{\exp(\Omega(\sqrt[3]{n}))}$ .

- (II) The revolt consists of all  $\alpha$ - and all  $\chi$ -type agents.

In this case, the presence of  $\chi$ -type agents slightly complicates the analysis. Actual  $\chi$ -type agents have slightly easier thresholds to satisfy ( $p$  and  $\mu$ ) than the  $\chi$ -type agents considered by the algorithms ( $p'$  and  $\mu'$ ). Our algorithms determined that, in expectation, agents with  $p'$  and  $\mu'$  thresholds would feel secure enough to revolt. Each actual  $\chi$ -type agent, then, must also feel secure enough to revolt, not just in expectation: By Lemma 11, the probability that the actual number each of  $\alpha$ -type and  $\chi$ -type agents differs from its respective expectation by a multiplicative factor of  $\frac{\epsilon}{6}$  is  $\frac{1}{\exp(\Omega(\sqrt[3]{n}))}$ . Combining these,

then,  $\chi$ -type agents believe with probability  $1 - \frac{1}{\exp(\Omega(\sqrt[3]{n}))} \geq p$  that at least  $\mu' - \frac{\epsilon}{3} = \mu$  agents feel secure enough to revolt, and are thus themselves secure enough to revolt. Applying Lemma 11 (from the perspective of Algorithm 2 this time, not the perspective of  $\chi$ -type agents) we again incur two error terms of  $\frac{\epsilon}{6}$  (one each for the  $\chi$ - and  $\alpha$ -type agents). Thus, we can conclude the probability that a revolt of size  $\mu^* - \epsilon$  is supported in both states is at least  $1 - \frac{1}{\exp(\Omega(\sqrt[3]{n}))}$ .

(III) The revolt consists of all  $\alpha$ -type agents and all candidate agents.

In the final case, we consider candidate agents instead of all agents of type  $\chi$ , and proceed exactly as we did in the second case, using Lemma 11 to conclude that the number of  $\alpha$ -type agents concentrate and Lemma 12 to conclude that the number of candidate agents concentrates. Once again, the result is that the probability that a revolt of size  $\mu^* - \epsilon$  is supported in both states is at least  $1 - \frac{1}{\exp(\Omega(\sqrt[3]{n}))}$ .  $\triangleleft$

$\triangleright$  **Claim.** Suppose that, in instance (1), the result is **A**. Then, the probability that a revolt of size  $\mu^* - \epsilon$  is supported in both states is at least  $\Pr[\text{State} = A] - \frac{1}{\exp(\Omega(\sqrt[3]{n}))}$ .

**Proof of Claim.** The proof of this claim is analogous to the previous proof, where events that are assigned probability at least  $1 - \frac{1}{\exp(\Omega(\sqrt[3]{n}))}$  are instead assigned probability at least  $\Pr[\text{State} = A] - \frac{1}{\exp(\Omega(\sqrt[3]{n}))}$ .  $\triangleleft$

The proof of the analogous claims for (2) are themselves analogous to the above cases for (1).

Finally, we note here that when  $\chi$ -type agents decide whether or not their thresholds are satisfied, they are not solely relying on their estimates of the fractions of different kinds of agents, as we describe above. They have additional knowledge, since they see the realized types of the agents in their context. However, for small graphs,  $\delta(n)$  can be chosen to account for this. As the graph grows, since each agent has at most  $O(\sqrt[3]{n})$  neighbors, the consequences of observing the types of a few adjacent agents is negligible after conditioning on the state. As a result, for large enough  $n$ , after the agent reasons about the state, the probabilistic effect of the agent viewing the types in her context is subsumed by the  $\epsilon$  error term. Furthermore, the appropriate choice of  $\delta(n)$  also accounts for the  $\frac{1}{\exp(\Omega(\sqrt[3]{n}))}$  terms present in each of the claims stated above, for each  $n$ .  $\blacktriangleleft$

**Proof of Theorem 9.** It follows from Lemma 10 that Algorithm 3 terminates in polynomial time with respect to the inputs  $G$  and  $P$ . We also note that Algorithm 3 terminates in polynomial time with respect to  $\frac{1}{\epsilon}$  and  $\frac{1}{\delta}$ .

Further, it follows from Lemma 13 that when Algorithm 3 outputs a case, that case is always true. It only remains to show that when exactly one case in the statement of PROMISE REVOLT is true, then Algorithm 3 necessarily outputs that case:

Here, the key is our use of three different potential revolt sizes ( $\mu^* - \epsilon$ ,  $\mu^*$ , and  $\mu^* + \epsilon$ ) and 3 different priors ( $P^-$ ,  $P$ , and  $P^+$ ) in defining the three cases of PROMISE REVOLT. By promising that exactly one of those three cases is true, we guarantee that the values of  $\mu$  and  $p$  are sufficiently far – distance at least  $\epsilon$  for  $\mu$  and distance at least  $\delta$  for  $p$  – from the crucial decision thresholds in Algorithm 1 (e.g. the value  $e_B(\chi \cup \alpha)$ , which is used to determine whether or not  $B$  is a candidate state)<sup>3</sup>. This ensures that both calls to Algorithm 1 will return the same values.

<sup>3</sup> Whether or not a decision threshold is in the set of *crucial* decision thresholds – the thresholds from which our promise guarantees  $p$  and  $\mu$  are sufficiently far – depends on  $\mu^*$ . In addition to  $e_B(\chi \cup \alpha)$ ,

We can illustrate this counterfactually:

Let  $\mu = e_B(\chi \cup \alpha) + \frac{\epsilon}{2}$  with  $e_B(\chi \cup \alpha) > \mu^* > e_B(C_C \cup \alpha)$  and let  $e_A(C_C \cup \alpha) > \mu + \frac{\epsilon}{2}$ .

Then,  $A$  and  $B$  would both be candidate states under the prior  $P^-$ . As a result, Algorithm 1 (run with prior  $P^-$ ) would return  $X_A = e_A(\chi \cup \alpha)$  and  $X_B = e_B(\chi \cup \alpha)$ . Note that  $X_A > X_B > \mu^*$ , so Algorithm 2 would return  $\Omega$  when run with inputs  $X_A$ ,  $X_B$ , and  $\mu^*$ . The same analysis holds for  $P^-$  with  $\mu$  and  $p$  incremented by  $\frac{\epsilon}{3}$  and  $\frac{\delta}{3}$ , respectively, so applying Lemma 13 implies that the case  $\Omega$  is true.

On the other hand, only  $A$  would be a candidate state under the prior  $P$ . Algorithm 1 run with the prior  $P$  would return  $X_A = e_A(C_C \cup \alpha)$  and  $X_B = e_B(C_C \cup \alpha)$ . Run with these inputs (and  $\mu^*$ ), Algorithm 2 would return  $\mathbf{A}$ . The same analysis holds for  $P$  with  $\mu$  and  $p$  incremented *and* decremented by  $\frac{\epsilon}{3}$  and  $\frac{\delta}{3}$ , which by Lemma 13 implies that the case  $\mathbf{A}$  is true. We can conclude that these values of  $\mu$  and  $\mu^*$  must be excluded by our promise for any input to PROMISE REVOLT for which our assumed constraints hold.

An argument similar to this counterfactual argument suffices to exclude any value of  $p$  or  $\mu$  that is insufficiently far from a crucial decision threshold in Algorithm 1 (along with associated constraints on  $\mu^*$ ) present in an instance of PROMISE REVOLT. ◀

Now we can discuss the information that we gain from solving PROMISE REVOLT. In doing so, it is useful to refer to Figure 1, which contains the following illustration: Given  $\mu^*$ , we identify all values of  $q$  for which a revolt of size  $\mu^*$  is supported with probability at least  $q$  (dark blue and yellow regions), all values of  $q$  for which revolt of size  $\mu^*$  may be supported with probability  $q$  (light blue, yellow, and grey regions), and all values of  $q$  for which a revolt of size  $\mu^*$  is supported with probability strictly less than  $q$  (white regions). The blurry regions between distinct colors represent the inputs to PROMISE REVOLT for which two of the cases would overlap (and are therefore excluded from the set of inputs by the “promise”).

If we could perfectly solve REVOLT, then we would be able to perfectly define the boundaries – there would be no blurry regions between distinct colors, as in Figure 1. The shape of the resulting figure would characterize the equilibria of the network revolt game in the following sense: The blue column (corresponding to values of  $\mu^*$  for which only case  $\Omega$  of PROMISE REVOLT is true) would show the sizes of revolts that are supported in equilibrium with high probability regardless of the state, the next yellow and white column (corresponding to values of  $\mu^*$  for which only case  $\mathbf{A}$  is true) would show the sizes of revolts that are supported in equilibrium with high probability given that the state is  $A$ , and the last grey and white column (corresponding to values of  $\mu^*$  for which case  $\emptyset$  is true) would show the sizes of revolts that, with high probability, are not supported in equilibrium (or, equivalently, the sizes of revolts that are supported in equilibrium with low probability).

Although we cannot perfectly solve REVOLT, as shown in Figure 1, solving PROMISE REVOLT with Algorithm 3 allows us to approximate this shape. By choosing  $\epsilon$  to be very small, we can make the boundary cases only relevant for very small subsets of possible values of  $\mu^*$  and values of  $\mu$  in the prior  $P$ . And, as we have shown via the proof of Theorem 9, as  $n$  grows,  $\delta(n)$  quickly becomes very small. Consequently, the range of possibly forbidden values of  $p$  in the prior  $P$  also quickly becomes small and the probabilities for each class of distinct equilibria described above (when they exist), converge to 1,  $\Pr[\text{State} = A]$ , and 0, respectively.

---

it can also include  $e_A(C_C \cup \alpha)$  and the value of  $p$  below which  $e_A(C_C \cup \alpha) \geq \mu$  holds for candidate contexts and above which  $e_A(C_C \cup \alpha) < \mu$ .

■ **Figure 1** Illustrating what we learn from solving PROMISE REVOLT in an archetypal case. Here,  $e_B$  and  $e_A$  denote the expected size of the revolt supported in states  $B$  and  $A$ , respectively.

Lastly, we note that an interesting and surprising corollary to our analysis above is that Algorithms 1, 2, and 3 never use any information about the graph beyond the *degree sequence* of  $G$  – an anonymous list that records the degree of each vertex in the graph. That is, our algorithms require a list of the degrees of the agents, but do not require that any degree value be labelled with the identity of any agent, nor do they require any further information about the set of edges in the graph. Rather, the results of the algorithms are valid for any graph that is consistent with the provided degree sequence, because the concentration of the fraction of candidate agents and agents of each type supersedes the additional structure imposed by any concrete edge set consistent with the degree sequence.

We record this fact with the following proposition:

► **Proposition 14.** *To compute PROMISE REVOLT in polynomial time, we only require the degree sequence of the graph  $G$ ; the graph itself is not required.*

## 5 Broadening the Setting

The core intuition from our analysis above actually applies more generally than just to the setting of Section 4.1. In the full version of the paper, we explore settings where the value of interest is the size of the smallest supported revolt in each state (as opposed to the largest) and where there is an arbitrary number of states.

Here, we only discuss the most fundamental of the more general settings – extending our result to general graphs. In doing so, we focus on changes to Algorithm 1; the subsequent changes required to adapt Algorithms 2 and 3 are straightforward.

### 5.1 General Graphs

Suppose that we impose no restriction on the degree of the vertices in  $G$  in the statement of Theorem 9. It turns out that our results still hold. The existence of high-degree  $\chi$ -type vertices (i.e. those that would not exist when we assume an  $O(\sqrt[3]{n})$  bound on the maximum degree of any vertex), complicates the analysis, but only in the case where  $A$  is the only

candidate state. When  $A$  and  $B$  are both candidate states, we only need to calculate the expected number of all  $\chi$ -type agents, regardless of their degree. When there are no candidate states,  $\chi$ -type vertices are irrelevant.

When  $A$  is the only candidate state, however, there is a key difference: The presence of high-degree agent contexts in the set of candidate contexts would affect our earlier analysis using the concentration bound for the sum of random variables with limited dependence based on the fractional chromatic number of the constraint graph of the random variables (in the proof of Lemma 12), because the contexts of high-degree agents are correlated with many other agents' contexts.

Because of this, though, high-degree agents (with degree at least  $c \cdot \sqrt[3]{n}$  for sufficiently large  $c$ ) have a unique perspective on the graph; their contexts contain a significant amount of information that they can use in determining the state. More concretely, suppose that agent  $i$  is a high-degree agent and let  $N(i)$  be the set of neighbors of  $i$  in  $G$ .

Let  $X = \sum_{j \in N(i)} X_j$ , where  $X_j$  is an indicator random variable that is 1 when agent  $j$  is of type  $\alpha$  or type  $\chi$  and 0 otherwise.

Now, for any  $\epsilon_0 > 0$ , applying a standard Chernoff-Hoeffding bound, we have:

$$\Pr [|X - \mathbb{E}[X]| \geq \epsilon_0 (c \cdot \sqrt[3]{n})] \leq 2 \exp \left( \frac{-2(\epsilon_0 c)^2 n^{\frac{2}{3}}}{n^{\frac{1}{3}}} \right) \in \frac{1}{\exp(\Omega_{\epsilon, P}(\sqrt[3]{n}))}. \quad (1)$$

In particular, if we choose  $\epsilon_0$  such that  $|\mathbb{E}[X|\text{State} = A] - \mathbb{E}[X|\text{State} = B]| > 2\epsilon_0 (c \cdot \sqrt[3]{n})$ , then agent  $i$  (and by the same argument, any high-degree agent) can correctly determine the state with enough accuracy that their error can be absorbed into the  $\delta$  error term with an appropriate choice of  $\delta(n)$ . As a result, when the state is  $A$ , all high-degree  $\chi$ -type agents will behave like candidate agents (recall that  $A$  is a candidate state).

However, for computational purposes, we will not lump them in with the low-degree candidate agents, because Lemma 12 can only apply to low-degree candidates. Instead, in the first **if** statement after the condition that  $A$  is the only candidate state (the line in Algorithm 1 that reads “**if**  $e_A(C_C \cup \alpha) \geq \mu$  **then**”), we calculate  $e_A(C_C \cup \alpha \cup H_\chi)$  instead of just  $e_A(C_C \cup \alpha)$ , where  $H_\chi$  refers to the set of high-degree  $\chi$ -type vertices. If this is at least  $\mu$ , then when we calculate  $X_A$ , we include  $H_\chi$ . However, when we calculate  $X_B$ , we only include  $H_\chi$  if  $e_B(C_C \cup \alpha \cup H_\chi) \geq \mu$ , since those high-degree agents will not  $p$ -believe that the state is  $A$  regardless of the state the way that (low-degree) candidate agents will. If  $e_B(C_C \cup \alpha \cup H_\chi) < \mu$ , we calculate  $X_B = e_B(C_C \cup \alpha)$ , as described in Algorithm 1.

Next, we must show it is possible for the agents (and the algorithm) to accurately calculate the expected number of high-degree agents of type  $\chi$  and know that the actual number of such agents sufficiently concentrates around that expected number. Here, we can rely on the fact that the agents and the algorithm know the degree sequence of the graph. There is some subtlety involved: If the number of high-degree agents is small – less than  $\epsilon n$  – then we cannot provide a very useful concentration bound for the number of high-degree agents of type  $\chi$ . However, we can essentially ignore the high-degree agents in this case and absorb the error we incur by ignoring them into our choice of  $\delta(n)$ .

On the other hand, if there are at least  $\epsilon n$  high-degree agents, we can again use a standard Chernoff-Hoeffding bound to conclude that the actual number of high-degree  $\chi$ -type agents will, with high probability, be close to the expected number of such agents. The error here will be smaller than the error from Lemma 12 and so can be absorbed there.

Finally, there is one additional subtlety we must address for high-degree agents. While it is true that, as previously mentioned, their contexts contain a significant amount of information that they can use in determining the state, their contexts actually contain more than just

information about the state – they contain information about the actual realization of types for a significant number of agents. This point is the primary conceptual reason to make the distinction between high-degree and low-degree agents in the first place. Consequently, we need to show that high-degree agents tend to behave as if they only knew the state, when in fact it is possible that the number of agents of a certain type in their context differs greatly from its expectation and as a result they have additional information to use beyond the state of the world. For this, we again appeal to our previous argument that resulted in the bound expressed by the inequality (1), above.

That argument demonstrates that it is highly improbable for the information in a high-degree agent’s context to contradict what their belief would be solely given knowledge of the state. For example, if a high-degree agent uses her context to determine that the state is  $A$ , with high probability it will not also be the case that the context that she uses to make that determination has (far) fewer agents of any type than would be expected given that the state is  $A$ . Consequently, a high-degree agent will tend to act as if she is just calculating expectations and acting off of them (like a low-degree agent would), even though in actuality she has quite a bit of additional information.

## 6 Discussion

We proposed that the notion of common belief could be relaxed to a notion of factional belief in order to be more suited to social network settings and gave a natural definition of factional belief, drawing heavily from previous work on common belief. We then applied this definition theoretically and experimentally in a setting inspired by prior work about common knowledge and revolt games on networks to show how this definition moves beyond the limitations of previous work by being applicable in general graphs.

### 6.1 Open Questions and Future Work

The most clear direction for future work is to continue to apply factional belief in new settings and use it as a tool to understand strategic coordination and cooperation on networks. In particular, as mentioned in the introduction, the work of Stephen Morris provides many examples of applying common belief as a tool for gaining insight into a diverse range of settings. We believe that applying factional belief can yield similar results in social network settings, and that this paper represents an initial step in that process.

Additionally, though, there are some more subtle technical open questions regarding our definition of factional belief that are also worth exploring in future work:

1. Considering our definition of factional belief from the perspective of an infinite hierarchy of reasoning, akin to the initial definition for common knowledge that we provided (3), with regard to the  $\mu$  fraction of agents at each step in the hierarchy, it is not required by our definition that this be the same  $\mu$  fraction of agents at each step in the hierarchy. However, it is not clear whether or not this should always be the case. Is it possible to describe an event that is common  $(p, \mu)$ -belief, but for which the infinite hierarchy refers to a different  $\mu$  fraction of agents at some step? If so, what are the consequences of this for strategic coordination and cooperation?
2. It is not too difficult to modify the setting described in Section 4 to create a model where the underlying event that supports revolt does not necessarily neatly reduce to a single event that is common  $(p, \mu)$ -belief. For example, if there are multiple types of conditionally-revolting agents with different  $p$  and  $\mu$  thresholds, the event supporting revolt is more like a  $\mu$  fraction of agents believe with sufficient probability that their

thresholds are satisfied. This event encompasses common  $p$ -beliefs among certain agents of the same type regarding their  $\mu$  thresholds, but not precisely common  $(p, \mu)$ -beliefs. Is there a more general definition of factional belief that allows for the existence of different thresholds for different types of agents to still be encompassed in a single event that is a factional belief among all of the agents who feel satisfied enough to revolt?

We believe that answering these questions could yield further insight into factional belief that could inform its application in other settings.

## Abstract

We study the stable marriage problem in two-sided markets with randomly generated preferences. Agents on each side of the market are divided into a constant number of “soft” tiers, which capture agents’ qualities. Specifically, every agent within a tier has the same public score, and agents on each side have preferences independently generated proportionally to the public scores of the other side.

We compute the expected average rank which agents in each tier have for their partners in the man-optimal stable matching, and prove concentration results for the average rank in asymptotically large markets. Furthermore, despite having a significant effect on ranks, public scores do not strongly influence the probability of an agent matching to a given tier of the other side. This generalizes the results by Pittel [20], which analyzed markets with uniform preferences. The results quantitatively demonstrate the effect of competition due to the heterogeneous attractiveness of agents in the market.

## 1 Introduction

The theory of stable matching, initiated by Gale and Shapley [9], has led to a deep understanding of two-sided matching markets and inspired successful real-world market designs. Examples of such markets include marriage markets, online dating, assigning students to

schools, labor markets, and college admissions. In a market matching “men” to “women” (a commonly used analogy), a matching is stable if no man-woman pair prefer each other over their assigned partners.

A fundamental issue is characterizing stable outcomes of matching markets, i.e. the outcome agents should *expect* based on market characteristics. Such characterizations are not only useful for describing outcomes but also likely to be fruitful in market designs. Numerous papers so far have studied stable matchings in random markets, in which agents’ preferences are generated uniformly at random [20, 16, 3, 22]. This paper contributes to the literature by expanding these results to a situation where preferences are drawn according to different tiers of “public scores”, generalizing the uniform case. We ask how public scores, which correspond to the attractiveness of agents, impact the outcome in the market.

Formally, we study the following class of *tiered random markets*. There are  $n$  men and  $n$  women. Each side of the market is divided into a constant number of “soft tiers”. There is a fraction of  $\epsilon_i$  women in tier  $i$ , each of which has a public score  $\alpha_i$ . And there is a fraction of  $\delta_j$  men in tier  $j$ , each of which has a public score  $\beta_j$ . For each agent we draw a complete preference list by sampling without replacement proportionally to the public scores of agents on the other side of the market.<sup>1</sup> So a man’s preference list is generated by sampling women one at a time without replacement according to a distribution that is proportional to their public scores. Using  $\alpha, \epsilon$  to denote the vector of scores and proportions of tiers on the women’s side, we see that the marginal probability of drawing a woman in tier  $i$  is  $\alpha_i / (n\epsilon \cdot \alpha)$ . An analogous statement holds for the tier configuration  $\beta, \delta$  of the men. These preferences are a natural next-step beyond the uniform distribution over preference lists, and provide a priori heterogeneous quality of agents while still being tractable to theoretical analysis.

Our primary goal is to study the *average rank* of agents in each tier under the man-optimal stable matching, with a focus on the asymptotic behavior in large markets. The rank of an agent is defined to be the index of their partner on their full preference list, where lower is better. Additionally, we prove results on the *match type distribution*, i.e. the fraction of tier  $i$  women matched to tier  $j$  men (for each  $i, j$ ).

We show that, for large enough markets, the following hold to within an arbitrarily small approximation factor:

- (i) (Theorem 4.8.) With high probability, the average rank of men in tier  $j$  is

$$\frac{\epsilon \cdot \alpha}{\alpha_{\min}} \cdot \frac{1}{\delta \cdot \beta^{-1}} \cdot \frac{\ln n}{\beta_j}.$$

- (ii) (Theorem 5.1.) With high probability, the average rank of women in tier  $i$  is

$$(\delta \cdot \beta)(\delta \cdot \beta^{-1}) \frac{\alpha_{\min}}{\alpha_i} \frac{n}{\ln n}.$$

- (iii) (Theorem 5.2.) The probability that a woman in tier  $i$  matches to a man in tier  $j$  is  $\delta_j$ .

In the above,  $\beta^{-1} = \{1/\beta_j\}$  denotes the vector of the reciprocals of men’s public scores,  $\alpha_{\min}$  denotes the smallest public score on the women’s side, and  $\mathbf{x} \cdot \mathbf{y}$  denotes the dot product of the vectors  $\mathbf{x}$  and  $\mathbf{y}$ .

<sup>1</sup> These are also termed popularity-based preferences [10, 13] and also equivalent to generating preferences according to a Multinomial-Logit (MNL) induced by the public scores.

**Intuition and Observations.** As in the case of uniform preferences [20], in the man-optimal stable outcome, men get a much lower rank than women. Indeed, both men and women get the same order of rank as in the uniform case ( $\ln n$  and  $n/\ln n$ , respectively). This in itself is an interesting consequence of this work – a constant tier structure affects the market only up to constants. This fact also highlights that determining these constants is an interesting area for investigation, as the constants capture how the outcome of the market changes with respect to the public scores. The first observation we make is that agents on each side get a rank inversely proportional to their public score.

Perhaps more interesting is the following observation: The rank of both sides depends on the tier structure of the other side, but *each tier is affected the same amount* by the tier parameters of the other side. This is closely related to the fact that the probability of a woman matching to a man in tier  $j$  is proportional to only the number of men in tier  $j$  (regardless of the tier the woman lies in). Moreover, both  $\epsilon \cdot \alpha / \alpha_{\min}$  and  $(\delta \cdot \beta)(\delta \cdot \beta^{-1})$  are always greater than or equal to one<sup>2</sup>. Thus, in these markets, any heterogeneity in the public scores of one side harms the average ranks of the other side (but does not significantly affect the likelihood that an agent matches to a certain tier on the other side).

Another interesting feature is the following: While the average ranks for men's tiers depend on public score distributions on both sides of the market, the average rank of women in tier  $i$  depends only on the ratio between  $\alpha_i$  and the public score  $\alpha_{\min}$  of the bottom tier of women (and the distribution of public scores on the men's side). Intuitively, the rank of the men depends on the distribution of scores of the women because *men are competing to avoid being matched to the lowest tier of women*.

To elaborate on that last point, let us first consider the total number of proposals made during the man-proposing deferred acceptance process (DA). The algorithm will terminate when the last woman receives a proposal. Naturally one would expect that this woman will belong to the bottom tier. Therefore, using standard coupon collector arguments, the total number of proposals made to women *in the bottom tier* until they all receive a proposal is expected to be  $(\epsilon_{\min} n) \ln(\epsilon_{\min} n)$ , where  $\epsilon_{\min}$  is the fraction of women in the bottom tier. These proposals are a  $\epsilon_{\min} \alpha_{\min} / \epsilon \cdot \alpha$  fraction of the total proposals, so one expects the number of total proposals to be

$$\frac{(\epsilon_{\min} n) \ln(\epsilon_{\min} n)}{\epsilon_{\min} \alpha_{\min} / \epsilon \cdot \alpha} = \frac{\epsilon \cdot \alpha}{\alpha_{\min}} \cdot n \ln n - O(n).$$

This introduces the factor of  $\epsilon \cdot \alpha / \alpha_{\min}$  in result (i) on the men's ranks (i.e. the number of proposals per man).

On the other hand, the probability that one of these proposals goes to a woman in tier  $i$  is  $\alpha_i / (n \epsilon \cdot \alpha)$ , implying that such a woman should receive roughly  $(\alpha_i / \alpha_{\min}) \ln n$  proposals. Thus, for a given woman, the increase in the total number of proposals caused by the tier proportions  $\epsilon$  is exactly canceled out by the likelihood that a proposal goes to that woman, and the only thing that matters is the woman's score (relative to the bottom tier). If men are uniform, women should then expect rank roughly  $(\alpha_{\min} / \alpha_i)(n / \ln n)$ , which helps explain the corresponding factors in result (ii).

Consider now the public scores of the men, and for simplicity assume that the bottom tier of men has score 1. Suppose for the sake of demonstration that every time a man with public score  $\beta_j$  proposes to a woman who is already matched, this man is  $\beta_j$  times more likely to

<sup>2</sup> To prove  $(\delta \cdot \beta)(\delta \cdot \beta^{-1}) \geq 1$ , use Jensen's inequality to conclude that  $\sum_j \delta_j \beta_j \geq (\sum_j \delta_j \beta_j^{-1})^{-1}$ .

be accepted than a man with public score 1.<sup>3</sup> We would expect that such a man makes a  $1/\beta_j$  fraction fewer proposals before his next acceptance, and indeed  $1/\beta_j$  fewer proposals overall. Let  $S$  be the total number of proposals, let  $r_j$  denote the rank of a man in tier  $j$ , and  $r_{\min}$  the rank of the bottom tier of men. If every tier of size  $\delta_j n$  each accounts for a share of proposals proportional to  $1/\beta_j$ , then we should have

$$S = \sum_j (n\delta_j)\beta_j^{-1}r_{\min} \implies r_{\min} = \frac{S}{n\delta \cdot \beta^{-1}}, \quad r_j = \frac{S}{(n\delta \cdot \beta^{-1})\beta_j},$$

which introduces the factor of  $1/((\delta \cdot \beta^{-1})\beta_j)$  in result (i) on the men's rank.

The final remaining factor in our results is  $(\delta \cdot \beta)(\delta \cdot \beta^{-1})$  in result (ii). Deriving this term requires reasoning about the number of proposals from each tier of men received by a fixed woman  $w$ . Building from the previous paragraph, we reason that each of the  $\delta_j n$  men in tier  $j$  makes a number of proposals proportional to  $1/\beta_j$ . Each such proposal has the same probability of going to  $w$ , regardless of the tier  $j$ . So the number of proposals  $w$  receives from tier  $j$  men is proportional to  $\delta_j/\beta_j$ . The factor  $(\delta \cdot \beta)(\delta \cdot \beta^{-1})$  then arises for somewhat technical reasons (described in Section 5) which have to do with the way women generate their preference lists.

We now describe how result (iii), which may seem somewhat more mysterious than the other results, emerges as a corollary of computing the ranks women receive. We argued above that a woman  $w$  in tier  $i$  receives approximately  $(\delta_j/\beta_j)U_i$  proposals from men in tier  $j$ , for some value of  $U_i$  independent of  $j$ . Recall that  $w$  applies weight  $\beta_j$  to each proposal she sees from a man in tier  $j$ . Moreover, the identity of  $w$ 's favorite proposal is independent of the order in which  $w$  saw proposals. Thus, the probability that  $w$ 's favorite proposal (i.e. the proposal of the man she matches to) came from tier  $j$  is approximately  $(\delta_j U_i)/U_i = \delta_j$ , which is *independent of*  $\beta_j$ , as well as independent of the tier  $w$  is in. Thus, up to lower order terms, the distribution of match types is the same as it would be in a uniformly random matching market, and the match is not assortative.

Intuitively, result (iii) arises when men make enough proposals to offset any disadvantage (in the type of their match) they have due to public score. Due to the highly connected and relatively competitive nature of our markets, men in the lowest tier make more proposals, but they are not more likely to end up matched with lower tier agents. Put another way, men in lower tiers are less likely to attain matches they idiosyncratically like, but often settle for a high-quality agent which is low on their personal preference list. This indicates that public scores that differ by constant weight do not provide any significant a priori predictive power over the matches agents receive. In particular, agents with lower public scores can still hope to achieve high-tier matches if they consider enough options.

**Techniques.** Our proofs require developing some technical tools that may be of independent interest, especially when we reason about the ranks achieved by the men. We build on the analysis of DA from [23, 20, 13, 3] to handle public scores rather than just uniform random preferences. As in these previous works, a key step in our proof is letting all men but one (call him  $m$ ) first propose and match through DA, and then tracking the proposals of  $m$  (this works because DA is independent of the order of proposals). For demonstration purposes,

<sup>3</sup> As we discuss below, this approximation is only valid if the woman is already matched with a man she ranks highly. A major technical step in our proof is showing that, in certain situations, "enough" women are "matched well enough" for this approximation to be used.

let's call the proposals before man  $m$  the “setup”. A key fact in previous works is that the distribution of proposals made by  $m$  is identical for every man, and moreover that the distribution of setups is identical as well. This fails to hold in tiered random markets, and thus we must develop new techniques.

We prove that, for “most” setups, the rank a man can achieve is approximately given by a certain geometric distribution, whose parameter  $p$  is essentially the probability that a proposal by that man will be accepted. We then prove that, up to lower order terms, this success parameter scales up with the public score of the men. This gives the fact that the rank of men is inversely proportional to public score.

Characterizing the setups where our proof goes through requires a technical analysis, and we term the setups which work “smooth matching states”. The most crucial thing we need for these setups is that *many women are matched to partners they rank highly*, which helps us prove that 1) men are likely to remain matched to their first acceptance (so our approximation with a geometric distribution is valid), and 2) a man with fitness  $\beta$  is approximately  $\beta$  times more likely to be accepted every time. For details, see Section 4.

Finally, to prove that the average rank of men within a tier *concentrates*, we need to show the correlation between the ranks of different men is not too large. Thus, we track the proposals of the last *two* men to propose, and find that the joint distribution of the ranks of these men can be approximated by a pair of independent geometric distributions. Intuitively, this is because men do not propose to very many women overall, and thus the last two men are unlikely to interfere with each other as they make proposals.

The crucial aspects of our model are that preferences of each agent are independent and identically distributed, that preference weights are constant, and that the market is roughly in balance. While our techniques are useful to reason about markets which do not have these properties, the results are not nearly as clean; indeed the tier structure simplifies our analysis, but most of it goes through if each agent has an individual, constant, bounded public score.

## 1.1 Related literature

Several papers have studied matching markets with complete preference lists that are generated uniformly at random. Coupon collector techniques are used in [23] to upper bound the men's average rank by  $\ln n$ . The papers [20, 16, 21] analyze further balanced markets with  $n$  men and  $n$  women. They find that in the man-optimal stable matching in balanced markets, men and women match on average to their  $\ln n$  and  $\frac{n}{\ln n}$  ranks, respectively. Our results generalize these findings to markets with preferences induced by public scores, thus incorporating much more heterogeneity in the market.

Several papers study markets with uniformly drawn preferences and an imbalance between men and women ([3, 22, 6]). These papers find that in any stable matching the average ranks of men and women are similar to the average ranks under the short-side-proposing DA. Additionally, [14] investigates the relation between the imbalance and the length of preference lists (though the model is still uniform for each agent). This paper does not consider imbalanced markets but we believe that similar techniques to those we develop will be useful to reason about unbalanced tiered random markets.

Several papers look at random matching markets in which preferences are generated based on public scores [13, 17, 1]. These papers restrict attention to the size of the core (a measure of the difference between the man-optimal and woman-optimal outcome) and strategic manipulation of agents under a stable matching mechanism. Key assumptions in

these papers generate outcomes which leave many agents unmatched. In particular, their models either assume that preference lists of men are of constant length, or, alternatively, one side has many more agents than the other.<sup>4</sup>

Closely related to this paper is [10], which primarily studies a special case of highly correlated popularity preferences which is termed “geometric preferences”. While our work focuses on the rank agents achieve in the man-optimal outcome (a canonical stable matching), [10] focuses on the size of the core (more specifically, they study the number of stable partners that agents have in typical stable matchings) using techniques specialized to geometric preferences.

Other papers have addressed tiered matching markets, especially in market design settings. However, these papers mostly study “hard tiers”, i.e. such that agents in higher tiers are deterministically ranked above lower tiers by every agent on the other side. Examples include [4, 2]. [18] also considers a certain restricted tiered model of cardinal utilities (which is incomparable with our model), focusing on which tier of agents match to which tier.

Our contribution to the literature is a detailed study of “soft tiers”, a natural special case of the popularity preferences of [13, 17, 10]. In cases where each agent’s utility for each match on the other side is independent and identically distributed, popularity preferences are the natural next step beyond uniform markets, as they model situations where agents on each side have significant but non-definitive variation in a priori quality. Our techniques build on the large body of work analyzing the “proposal dynamics” of deferred acceptance for random preferences, such as [23, 13, 3, 10]. Our results give insight into how constant-factor preference biases affect stable matching markets, including the first explicit calculations of expected rank beyond uniform markets.

The rest of the paper is organized as follows: Section 2 offers basic definitions and preliminaries for our discussion. Section 3 studies the tiered coupon collector process, which serves as an important coupling process for the deferred acceptance algorithm. Section 4 and 5 present the core results of this paper, namely the average rank among tiers of men and women. For missing proofs, see the full version of this paper.

## 2 Definitions and Preliminaries

A matching market consists of a finite set of men  $M$  and a finite set of women  $W$ . Each man (woman) has a complete and strict preference list over women (men). A matching is a mapping  $\mu : M \cup W \rightarrow M \cup W$  such that: for every  $m \in M$ ,  $\mu(m) \in W$  (or  $\mu(m)$  is undefined), for every woman  $w \in W$ ,  $\mu(w) \in M$  (or  $\mu(w)$  is undefined), and for every  $m \in M$  and  $w \in W$ ,  $\mu(m) = w$  if and only if  $\mu(w) = m$ . A matching  $\mu$  is *stable* if no man-woman pair who are not matched in  $\mu$  prefer each other to their matched partners.

It is well-known that there is a unique man-optimal stable matching, which can be found using the man-proposing deferred acceptance algorithm (DA). While this algorithm does not fully specify an execution order, it is a classically known result that the order does not affect the final outcome.

► **Lemma 2.1** ([9, 19]). *The same proposals are made in every run of DA, regardless of which man is chosen to propose at each step.*

---

<sup>4</sup> Some papers additionally consider manipulations in more restricted randomized settings [7] or in deterministic (worst case) settings [11].

---

**Algorithm 1** (Man-Proposing) Deferred Acceptance Algorithm (DA).

---

```

1 Initialize matching  $\mu$  to be empty (i.e. every agent's partner is undefined);
2 Initialize  $\mathcal{U} = M$  to be the set of all unmatched men;
3 while  $|\mathcal{U}| > 0$  do
4   Choose any  $m \in \mathcal{U}$ ;
5   Let  $m$  propose to his most preferred woman  $w$  to whom he has not made a
   proposal yet;
6   if  $w$  prefers  $m$  to  $\mu(w)$  (or if  $\mu(w)$  is undefined) then
7     if  $\mu(w)$  is defined then Add  $\mu(w)$  to  $\mathcal{U}$ ;
8     Remove  $m$  from  $\mathcal{U}$ ;
9     Assign  $\mu(w) = m$ ;
10  end
11 end

```

---

We study the man-optimal stable matching in a class of tiered random markets, which will be defined below. We will assume that  $|M| = |W|$  and that no agent finds any other agent on the other side unacceptable. We will also assume that each side draws their preferences from an identical and independent underlying distribution, and moreover these preferences are generated by repeatedly sampling without replacement from a fixed distribution on the *agents* of each side. In [13, 10], this assumption is termed “popularity-based preferences”, with the weight of an agent in the distribution intuitively indicating their popularity for agents on the other side.

Our main goal is to study randomized matching markets with a *constant number of constant weight tiers* of agents on each side. For this entire paper, we consider the tier structure to be defined by fixed proportions  $\epsilon, \delta$  of agents in each tier and constant weights  $\alpha, \beta$  for each tier, and we investigate the outcome of the man-proposing DA as  $n \rightarrow \infty$ .

► **Definition 2.2.** Consider constant vectors  $\alpha, \epsilon \in \mathbb{R}_{>0}^{k_1}$  and  $\beta, \delta \in \mathbb{R}_{>0}^{k_2}$ , where  $\|\epsilon\|_1, \|\delta\|_1 = 1$ . A tiered matching market of size  $n$  with respect to  $\alpha, \epsilon, \beta, \delta$  is defined by generating agents’ preference lists as follows:

- The set of  $n$  women  $W$  is divided into tiers  $T_1, \dots, T_{k_1}$ , of size  $|T_i| = \epsilon_i n$  each<sup>5</sup>. Define a distribution  $\mathcal{W}$  on women such that a woman in tier  $i$  is selected with probability proportional to  $\alpha_i$ . That is, the weight of  $w \in T_i$  in  $W$  is  $\alpha_i / (n\epsilon \cdot \alpha)$  (which we often denote by  $\pi_i$ ).
- The set of  $n$  men  $M$  is divided into tiers  $T_1, \dots, T_{k_2}$ , of size  $|T_j| = \delta_j n$  each. Define a distribution  $\mathcal{M}$  on men such that a man in tier  $j$  is selected with probability proportional to  $\beta_j$ . That is, the weight of  $m \in T_j$  in  $M$  is  $\beta_j / (n\delta \cdot \beta)$ .

For each man  $m$  independently, women are repeatedly sampled from  $\mathcal{W}$  without replacement, and the order in which women are selected is  $m$ ’s preference list. Preferences for the women are analogously drawn over the distribution  $\mathcal{M}$ . The rank that a man has for a woman  $w$  is the index of  $w$  on his preference list (where lower is better).

---

<sup>5</sup> Note that, for most vectors  $\epsilon, \delta$ , many values of  $n$  will produce tier sizes which are not integers. However, as all our results are *continuous* in  $\epsilon, \delta$  this is not a problem – for any particular fixed  $n$ , each tier size can be rounded in a way that effectively just changes  $\epsilon, \delta$  by a tiny amount, and our results will still hold as written as  $n \rightarrow \infty$ .

We refer to each  $\alpha_i$  as the *weight* or *public score* of the women in tier  $i$ , and similarly for the men. For simplicity of certain arguments, we assume that each  $\alpha_i \geq 1$  and each  $\beta_j \geq 1$  (although for clarity of our results, we do not assume that the smallest weight is exactly 1). We write  $\alpha_{\min}$  for the weight of the bottom tier of women, and  $\epsilon_{\min}$  for the corresponding tier proportion.

Using a simple generalization of the “principle of deferred decisions” used in [15], we can arrive at a characterization of the random process of running DA with a tiered matching market.

► **Lemma 2.3.** *The distribution of runs of DA for a tiered matching market can be generated as follows: For the men, every time a man is chosen to propose, he samples a woman at random from  $\mathcal{W}$ , and repeats this until he samples a woman who he has not yet proposed to.*

*For the women, suppose  $w$  has seen proposals from a set of men  $p(w)$ , and let  $\Gamma_w = \sum_{m \in p(w)} \beta(m)$ , where  $\beta(m)$  denotes the public score of a man  $m \in p(w)$ . Then if a proposal from a man  $m_*$  with public score  $\beta_*$  arrives,  $w$  accepts the proposal from  $m_*$  with probability*

$$\frac{\beta_*}{\beta_* + \Gamma_w}.$$

**Proof.** The above formula gives the probability that  $m_*$  is chosen as  $w$ ’s favorite out of the set of men  $p(w) \cup \{m_*\}$ . The only additional observation we need to make is that the probability that  $m_*$  is the new favorite is independent of the identity of the old favorite. ◀

We often call  $\Gamma_w$  the total “weight of proposals” woman  $w$  has seen at some point during DA.

## 2.1 Deferred acceptance with re-proposals

With respect to any popularity-based model of preferences, we can define a procedure analogous to DA. In our case, we will show that the difference between DA and this procedure is indeed small.

► **Definition 2.4.** *Consider any random matching market with men’s preferences determined by sampling from a distribution  $\mathcal{W}$  over women. The deferred acceptance with re-proposals algorithm is defined as being identical to Algorithm 1, except*

- *Every time a man is chosen to propose to a woman, he draws a woman from  $\mathcal{W}$  with replacement, and may propose more than once to a single woman.*
- *Women’s preferences are consistent throughout proposals from the same man (so if a woman rejected a man before, she will reject him again).*

Since re-proposals are ignored, this process will always yield the same outcome as algorithm 1.

**Notation.** We write  $x = (1 \pm \epsilon)y$  to mean  $(1 - \epsilon)y \leq x \leq (1 + \epsilon)y$ . We let  $\epsilon$  denote an arbitrarily small constant greater than 0, while  $\epsilon$  and  $\epsilon_i$  denote the tier parameters of the women. We let  $\alpha_{\min}$  denote the smallest public score for the women’s side, and  $\epsilon_{\min}$  denotes the corresponding tier proportion. We let  $\mathbf{v} \cdot \mathbf{w}$  denote the inner product of vectors  $\mathbf{v}, \mathbf{w}$ . We denote the exponential and geometric distributions by  $\text{Exp}(\lambda)$  and  $\text{Geo}(p)$ , respectively. We denote the fact that a random variable  $X$  is a draw from a distribution  $D$  by  $X \sim D$ . We use  $X \preceq Y$  to denote the fact that  $X$  is statistically dominated by  $Y$  (i.e. for all  $t \in \mathbb{R}$ , we have  $\mathbb{P}[X \geq t] \leq \mathbb{P}[Y \geq t]$ ). We let  $\text{Cov}(X, Y)$  denote the covariance of  $X$  and  $Y$ . We write  $f(n) = \tilde{O}(g(n))$  if there exists a constant  $k$  such that  $f(n) = O(g(n) \log^k(g(n)))$ .

### 3 The Coupon Collector and the Total Number of Proposals

Fix a tier structure  $\alpha, \epsilon$  corresponding to men's preferences over the women. Consider running deferred acceptance with re-proposals. Recall that each man samples a woman in tier  $i$  with probability  $\pi_i = \alpha_i / (n\epsilon \cdot \alpha)$  each draw. Define  $\pi_{\min} = \alpha_{\min} / (n\epsilon \cdot \alpha)$  as the probability of drawing a woman in the lowest tier (and keep in mind that  $\pi_{\min}$  scales like  $O(1/n)$ ).

The core tool we use to reason about the total number of proposals in DA is the classically studied coupon collector process. In particular, we study this process when coupons from different tiers are drawn with a constant-factor difference in probability.

► **Definition 3.1.** *Given a probability distribution  $(p_i)_{i \in [n]}$ , we define the coupon collector with unequal probabilities as follows: once every time step, an integer from  $[n]$  is drawn independently and with replacement according to distribution  $(p_i)_{i \in [n]}$ . The coupon collector random variable with respect to  $(p_i)_{i \in [n]}$  is defined as the number of total draws required before every integer in  $[n]$  has appeared at least once.*

*The coupon collector  $T$  which we are interested in is defined by taking the distribution  $\mathcal{W}$  of men's preferences.*

We will show in Section 3.1 that, in our case, this random process is also very close to that of DA (without re-proposals). For now, we simply bound the expectation of the coupon collector (with the proof deferred to the full version). Note that similar probabilistic problems have been considered before (see e.g. [5, 8]) but we include our own full proofs in the full version for completeness.

► **Theorem 3.2.** *Let  $T$  denote the number of draws in a coupon collector process with weights proportional to  $\mathcal{W}$ . We have*

$$\mathbb{E}[T] = (1 \pm O(1/\ln n)) \frac{\epsilon \cdot \alpha}{\alpha_{\min}} n \ln n.$$

► **Remark 3.3.** While we are mostly interested in the asymptotic performance of these matching markets, we make one comment here that the above big- $O$  notation hides a constant factor of order  $\ln(1/\epsilon_{\min})$ . For small values of  $\epsilon_{\min}$ , this can be much larger than  $\ln n$  for most realistic market sizes. Note that this error term already showed up in the intuition given in Section 1, where our estimate for the total number of proposals had an additive term of  $O(\ln(\epsilon_{\min})n)$ . For more information, see the discussion of coupon collector lower bound in the full version of this paper.

#### 3.1 The Total Number of Proposals in Deferred Acceptance

Let  $S = S_n$  denote the total number of proposals made a run of DA with random preferences given by our tiered market. As before, let  $T = T_n$  denote the distribution of a coupon collector with distribution  $\mathcal{W}$ . As in many prior studies of randomized deferred acceptance, our starting point is the fact that  $S$  is statistically dominated by  $T$ :

The connection to stable matchings is the following very simple observation, which has been used in many previous works [16, 20]:

► **Proposition 3.4.** *The coupon collector random variable  $T$  is distributed identically to the total number of proposals made in deferred acceptance with re-proposals (regardless of the preferences that women have for men).*

*Moreover, if  $S$  is the number of proposals in DA, then  $S \preceq T$  (i.e.  $S$  is statistically dominated by  $T$ ).*

**Proof.** First, recall that DA terminates as soon as every man is matched. Observe that women never return to being unmatched once they receive a single proposal. Because the market is balanced (i.e.  $|W| = |M|$ ), this means DA will terminate as soon as every woman has been proposed to. Moreover, because re-proposals are allowed, every proposal is distributed exactly according to  $\mathcal{W}$ . Thus, ignoring the identity of the man doing the proposing,  $T$  is distributed exactly according to the coupon collector random process.

Furthermore, we can recover the exact distribution  $S$  of proposal in DA simply by ignoring each repeated proposal in  $T$ . Thus,  $S \leq T$  for each run of deferred acceptance with re-proposals, so  $S \preceq T$ .  $\blacktriangleleft$

We proceed to show that the upper bound provided by  $T$  is essentially tight, i.e. there is not a big difference between  $T$  and  $S$ . The key step will be to upper bound maximum number of distinct women any man proposes to in  $S$ , and thus upper bound the probability that any proposal in  $T$  is a repeat for the man making the proposal. Crucially, this lemma will have to account for the preferences of the women (which up until this point have been ignored, but which play a significant role in the distribution of proposals in DA). Recall that we denote the sizes of the tiers of the men by the vector  $\delta$ , and the public scores of the men in each tier by  $\beta$ .

► **Lemma 3.5.** *Consider running DA with all men except  $m_*$ , and suppose that at most  $O(n \ln n)$  proposals are made during this process. Afterwards, consider  $m_*$  joining and run DA until the end. Then for any  $C \geq 0$ , with probability  $1 - 1/n^C$ , the number of proposals made by  $m_*$  is at most  $O(C \ln^2 n)$ .*

**Proof.** This proof follows a similar logic as the proof of Lemma B.4 (ii) in [3]. Suppose  $m_*$  has public score  $\beta_*$ , and that he proposes at the end (and  $O(n \ln n)$  prior proposals have been made). We proceed as follows:

1. When  $m_*$  makes a proposal, he will choose a woman who he has not yet proposed to. For some fixed proposal index  $i$  of  $m_*$ , let's denote the set of all women  $m_*$  has not proposed to by  $W_*$ , and denote by  $\mathcal{W}_*$  the distribution of  $m_*$ 's next proposal, i.e. a sample over  $W_*$  weighted by the public scores  $\alpha_i$ . For a women  $w$  denote her sample weight by  $\alpha(w)$  and the set of proposals she has received by  $p(w)$ . Further denote by  $\Gamma_w = \sum_{m \in p(w)} \beta(m)$  the sum of the public scores of men who have proposed to  $w$ . Suppose that  $|W_*| \geq n/2$ , i.e. that  $m_*$  has not yet proposed to over half the women. Using the assumption that the total number of proposals made is at most  $O(n \ln n)$ , we can bound the expected total weight of proposals women have seen by

$$\mathbb{E}_{w \sim \mathcal{W}_*} [\Gamma_w] = \frac{\sum_{w \in W_*} \alpha(w) \Gamma_w}{\sum_{w \in W_*} \alpha(w)} \leq \frac{\alpha_{\max} \sum_{w \in W} \Gamma_w}{|W_*| \alpha_{\min}} \leq \frac{\alpha_{\max} \beta_{\max} \cdot O(n \ln n)}{|W_*| \alpha_{\min}} \leq O(\ln n).$$

Thus, by lemma 2.3, the probability that the proposal by  $m_*$  will be accepted is

$$p_1 := \mathbb{E}_{w \sim \mathcal{W}_*} \left[ \frac{\beta_*}{\beta_* + \Gamma_w} \right] \geq \frac{\beta_*}{\beta_* + \mathbb{E}_{w \sim \mathcal{W}_*} [\Gamma_w]} \geq \Omega(1/\ln n).$$

where the first inequality is due to Jensen's inequality.

2. If  $m_*$  proposes to  $w$  and is accepted, then the subsequent rejection chain can either end at the last woman without proposals,  $w_{\text{last}}$ , or cycles back to  $w$  who this time rejects  $m_*$ . Notice that for each subsequent proposal, the ratio between the probability that it goes to  $w_{\text{last}}$  (in which case the process will be terminated) and the probability that it returns to  $w$  is at most  $\alpha_{\max} : \alpha_{\min}$  (and possibly less if the proposing man has already proposed to  $w$ ). Hence, the probability that the chain ends at the last women  $w_{\text{last}}$  is bounded below by

$$p_2 := \frac{\alpha_{\min}}{\alpha_{\max} + \alpha_{\min}} \geq \Omega(1).$$

Note that this is ignoring the chance that a new proposal by  $w$  is rejected, but it still suffices for a lower bound.

3. The probability that  $m_*$  makes more than  $K \ln^2 n$  proposals is thus bounded above by

$$(1 - p_1 p_2)^{K \ln^2 n} \leq \exp(-p_1 p_2 K \ln^2 n) = \exp(-\Omega(K \ln n)) \leq n^{-C}$$

as long as we choose  $K = \Omega(C)$  large enough.  $\blacktriangleleft$

► **Corollary 3.6.** *For any constant  $C \geq 1$ , with probability  $1 - 1/n^C$ , the maximum number of proposals made by any man in DA is  $O(C \ln^2 n)$ .*

**Proof.** By 3.4 and the upper bound for coupon collector (see the full version of this paper), the total number of proposals made in DA is  $O(Cn \ln n)$  with probability  $1 - 1/n^C$ . In particular, if we consider any  $m_*$  and let all other agents propose, this will be true. Recall that by lemma 2.1, DA is independent of the order in which men are chosen to propose. Thus, for each man  $m_*$  we can apply lemma 3.5 to get that, with probability  $1 - 1/n^{C+1}$ ,  $m_*$  makes fewer than  $O((C+1) \ln^2 n) = O(C \ln^2 n)$  proposals. Taking a union bound over the  $n$  men gets the desired result.  $\blacktriangleleft$

► **Remark 3.7.** Both of the above results hold for deferred acceptance with re-proposals as well as deferred acceptance. Indeed, even with re-proposals, deferred acceptance will be independent of the order of proposals (as re-proposals are ignored by the women). Moreover, the logic required to prove points 1. and 2. of the proof of lemma 3.5 is only easier to prove when men sample over all of  $W$  as opposed to just the set  $W_*$ .

The above result is enough to show that proposition 3.2 holds for DA as well for the coupon collector, because repeated proposals are at most a  $O(\ln^2 n/n) = o(1)$  fraction of total proposals in deferred acceptance with re-proposals. We defer the proof to the full version.

► **Theorem 3.8.** *Let  $S$  be the total number of proposals made in DA with tiers of women  $\epsilon, \alpha$ , and arbitrary constant tiers on the men. We have*

$$\mathbb{E}[S] = (1 - O(\ln^2 n/n)) \mathbb{E}[T] = (1 \pm O(1/\ln n)) \frac{\epsilon \cdot \alpha}{\alpha_{\min}} n \ln n.$$

## 4 Rank Achieved by the Men

Up until this point, our arguments have only crudely considered the preferences women have for men. Due to the asymmetry across the different tiers, this means we cannot yet calculate the expected rank men get.

Consider a man  $m$  in tier  $j$ . Our main goal is to prove that the rank of  $m$  is inversely proportional to  $\beta_j$ . As in 3.5, the core tool of our proof will be the fact that deferred acceptance is independent of execution order (by 2.1), and thus we can wait until all other men have finished proposing and found a match before letting  $m$  propose. Once this is done, the major ideas are

1. Suppose  $m$  has public score 1, and define

$$p = \mathbb{E}_{w \sim \mathcal{W}} [\mathbb{P}[w \text{ accepts a proposal from } m]].$$

Note that, if  $m$  were able to propose to a woman independently multiple times, the number of proposals until  $m$  gets his first acceptance would be distributed exactly according to  $\text{Geo}(p)$ , and the expected value would be  $1/p$ . We show that (because men make much less than  $n$  proposals) the difference due to re-proposals is not large.

2. Because  $m$  is the last man to propose, most women have already seen many proposals and arrived at a decent match. When  $m$  gets his first acceptance, he should thus be likely to stay where he is. We show that, while the probability of  $m$  proposing to more women is non-negligible, it still contributes only  $O(1)$  in expectation. So  $m$ 's expected rank is  $1/p$  up to lower-order terms.
3. Another consequence of a woman  $w$  receiving a large number of proposals is the following:

$$\begin{aligned} & \mathbb{P}[w \text{ accepts a proposal from } m' \text{ with weight } \beta] \\ & \approx \beta \cdot \mathbb{P}[w \text{ accepts a proposal from } m \text{ with weight } 1]. \end{aligned}$$

simply by 2.3 and the fact that  $\beta/(\beta + \Gamma_w) \approx \beta \cdot 1/(1 + \Gamma_w)$  for  $\Gamma_w$  (the sum of public scores of men who proposed to  $w$ ) large. Thus, if  $m$  had public score  $\beta$ , the effective value of  $p$  would be approximately  $\beta p$ , and the expected rank of  $m$  would become approximately  $1/(\beta p)$ . In other words, while we are not able to calculate  $p$  directly, we show that  $p$  scales properly with  $m$ 's score.

4. Finally, we prove that the above holds for most sequences of proposals of men before  $m$ , and thus holds in expectation over the entire execution of DA. Note that the distribution of proposals before  $m$  changes slightly depending on which tier  $m$  is chosen from, but in a large market, we do not expect this to make a big difference.

The biggest difference between the above proof sketch and its implementation is that we focus on *two* men proposing at the end of DA. This serves to address point 4 above – we are able to show that, for the vast majority of sequences of proposals before the last two men, their expected ranks are proportional to the ratio of their scores. Thus, this ratio holds in expectation over all of DA. Focusing on two men also allows us to bound the *correlation* between the two men's ranks, which is crucial for our concentration results.

In our proof, we also formalize what it means for all men other than two to propose, with the notion of a “partial matching state”. Moreover, we give the term *smooth* to those states in which the proof sketch above goes through. Most crucially, in smooth matching states, “most women have received a lot of proposals”, so that the reasoning in points 2 and 3 are valid. Additionally, to address certain technicalities (such as being able to bound the magnitude of the expected number of proposals) we define smooth matching states to not have too many proposals in total.

#### 4.1 Smooth matching states

► **Definition 4.1.** *Given a set of men  $L$ , we define the partial matching state excluding  $L$ , denoted  $\mu_{-L}$ , as follows: Run DA with men in  $M \setminus L$  proposing to  $W$ , and keep track of which proposals were made. More specifically, if  $\mu$  is the (partial) matching resulting from running DA with a set of men  $M \setminus L$  and set of women  $W$ , and  $P = \{(m_{i_\ell}, w_{j_\ell})\}_\ell$  is the set of all tuples  $(m_i, w_j)$  where  $m_i$  proposed to  $w_j$  during this process, then  $\mu_{-L} = (\mu, P)$ .*

In a random matching market, we consider this state as a random variable. In a tiered random matching market, to specify this random variable, it suffices to give a multiset of tiers which the men in  $L$  belong to. For a fixed  $\mu_{-L}$ , denote by  $\Gamma_w$  the total sum of weights which woman  $w$  received in  $P$ .

Note that the state  $\mu_{-L}$  keeps track of which proposals have been made (in addition to which current matches are formed) before the men in  $L$  propose.

► **Definition 4.2.** We call a partial matching state  $\mu_{-L}$  smooth if the following hold for some constants  $C_1, C_2, C_3 > 0$ :

1. At most  $C_1 n \ln n$  proposals were made to women overall.
2. At most  $n^{1-C_2}$  women have received fewer than  $C_3 \ln n$  proposals.

The constants  $C_1, C_2, C_3$  in the above depend on the tier structure, and can simply be chosen such that the following proposition holds. Our arguments will go through if smoothness holds with respect to any  $C_1, C_2, C_3$  which are held constant as  $n \rightarrow \infty$ .

► **Proposition 4.3.** Let  $L = \{m_1, m_2\}$  be any pair of men. After running deferred acceptance,  $\mu_{-L}$  is smooth with probability  $1 - n^{-\Omega(1)}$ .

Once we know that  $\mu_{-L}$  is smooth, our two main tasks are to show that men's ranks scale inverse-proportionally to their score, and that the ranks of different men do not correlate too highly. These are the main technical novelties of the paper. The exact details are given in the full version.

► **Proposition 4.4.** Suppose  $\mu_{-L}$  is smooth, and let  $r_1$  and  $r_2$  be the ranks of  $m_1$  and  $m_2$  after running DA with  $m_1$  and  $m_2$  starting from  $\mu_{-L}$ . We have

$$\mathbb{E}_L[r_1] = (1 \pm O(1/\ln n)) \frac{\beta_2}{\beta_1} \mathbb{E}_L[r_2].$$

where we use  $\mathbb{E}_L[\cdot]$  to denote taking an expectation over the random process of  $m_1, m_2$  proposing in DA after starting from state  $\mu_{-L}$ .

► **Proposition 4.5.** Suppose  $\mu_{-L}$  is smooth, and let  $r_1$  and  $r_2$  be the ranks of  $m_1$  and  $m_2$  after running DA with  $m_1$  and  $m_2$  starting from  $\mu_{-L}$ . Then we have  $\text{Cov}(r_i, r_j) = O(\ln^{3/2} n)$ .

## 4.2 Expected rank of the men

In this subsection, we show that overall, expected rank scales proportionally to fitness (in addition to under smooth matching states). This allows us to compute the expected rank of the men. The proofs (deferred to the full version) follow by carefully keeping track of the (limited) effect of non-smooth matching states on the expectation.

► **Proposition 4.6.** Let  $r_i$  and  $r_j$  denote the rank of a man in tiers  $i$  and  $j$ . Then we have

$$\mathbb{E}[r_i] = (1 \pm O(1/\ln n)) \frac{\beta_j}{\beta_i} \mathbb{E}[r_j].$$

► **Theorem 4.7.** Let  $\beta^{-1}$  denote the vector  $(1/\beta_i)_i$ . For each tier  $j$ , the rank  $r_j$  of men in tier  $j$  has expectation

$$\mathbb{E}[r_j] = (1 \pm O(1/\ln n)) \frac{\mathbb{E}[S]}{(n\delta \cdot \beta)\beta_j} = (1 \pm O(1/\ln n)) \frac{\epsilon \cdot \alpha}{\alpha_{\min}} \cdot \frac{1}{(\delta \cdot \beta^{-1})} \cdot \frac{\ln n}{\beta_j}.$$

Finally, we also use our results on the covariance of men's ranks to prove concentration. We defer the proof to the full version. At a high level, the proof follows simply because the weak correlation implied by 4.5 means that the variance of the average of the ranks is lower-order (compared to its expectation), so Chebyshev's inequality can be used.

► **Theorem 4.8.** *For any tier  $j$ , let  $\bar{R}_j^M = (\delta_j n)^{-1} \sum_m r_m$  denote the average rank of men in tier  $j$ . Then, for any  $\epsilon > 0$ ,*

$$\bar{R}_j^M = (1 \pm \epsilon) \frac{\epsilon \cdot \alpha}{\alpha_{\min}} \cdot \frac{1}{(\delta \cdot \beta^{-1})} \cdot \frac{\ln n}{\beta_j}$$

*with probability approaching 1 as  $n \rightarrow \infty$ .*

## 5 Expected rank of the women and the distribution of match types

### 5.1 Expected rank of women

We saw in Section 4.2 that men achieve ranks proportional to the inverse of their public scores. In this section, we turn to the women.

To study the rank the women achieve, we need to reason about the number of proposals women receive on average. By theorem 4.8, we expect that for each tier  $j$  of men, the  $\delta_j n$  men make a total number of proposals approximately

$$\frac{\delta_j \beta_j^{-1}}{\delta \cdot \beta^{-1}} \cdot \frac{\alpha \cdot \epsilon}{\alpha_{\min}} n \ln n.$$

Each of these proposals goes to a woman in tier  $i$  with probability  $\pi_i = \alpha_i / (n \epsilon \cdot \alpha)$ , so we expect such a woman to receive approximately  $(\delta_j \beta_j^{-1}) / (\delta \cdot \beta^{-1}) \cdot (\alpha_i / \alpha_{\min}) \ln n$  proposals from men in tier  $j$ . Each of these men has public score  $\beta_j$ , so we expect  $\Gamma_w$ , the total sum of public scores of men proposing to  $w$ , to be roughly

$$\Gamma_w \approx \sum_j \beta_j \frac{\delta_j \beta_j^{-1}}{\delta \cdot \beta^{-1}} \cdot \frac{\alpha_i}{\alpha_{\min}} \ln n = \frac{\alpha_i \ln n}{\alpha_{\min} (\delta \cdot \beta^{-1})}.$$

It is not immediately clear how the above value of  $\Gamma_w$  should translate to the *rank* that  $w$  gets. Unlike in the case where men are uniform, we cannot simply divide  $n$  by the number of proposals which  $w$  receives.

Indeed, suppose a woman  $w$  receives exactly the total sum of weight  $\Gamma_w$  predicted above. What should her rank be? This is essentially the following: across all tiers of  $\delta_j n$  men each, how many do we expect to beat her best proposal so far? The probability that  $w$  ranks a man  $m$  higher than her match, when viewed according to 2.3, is a function only of the weight  $\beta(m)$  of  $m$  and the weight of proposals  $\Gamma_w$  which  $w$  received. Specifically, this probability is  $\beta(m) / (\beta(m) + \Gamma_w) \approx \beta_j / \Gamma_w$ . Summing this across all the men, we get

$$\mathbb{E}[r_w] \approx \sum_m \frac{\beta(m)}{\beta(m) + \Gamma_w} \approx \frac{n \delta \cdot \beta}{\Gamma_w} \approx (\delta \cdot \beta) (\delta \cdot \beta^{-1}) \frac{\alpha_{\min}}{\alpha_i} \cdot \frac{n}{\ln n}.$$

Note that this ignores the fact that a woman will never rank  $m$  higher than her match if that  $m$  already proposed to her during DA. But since  $w$  only likely receives  $\ln n \ll n / \ln n$  proposals, the difference is not noticeable.

It turns out that, with a detailed probabilistic analysis, the above proof sketch goes through. The details are given in the full version of this paper online.

► **Theorem 5.1.** Let  $\bar{R}_i^W = (\epsilon_i n)^{-1} \sum_{w \in T_i} r_w$  denote the average rank of women in tier  $i$ . For all  $\epsilon > 0$ , we have

$$\bar{R}_i^W = (1 \pm \epsilon)(\delta \cdot \beta)(\delta \cdot \beta^{-1}) \frac{\alpha_{\min}}{\alpha_i} \frac{n}{\ln n}$$

with probability approaching 1 as  $n \rightarrow \infty$ .

## 5.2 The distribution of match types

Fix a woman  $w$  in tier  $i$ . We now study the probability that  $w$  is matched to a man from some tier  $j$ . In the previous section, we argued that with high probability  $w$  receives approximately a total of

$$\frac{\delta_j \beta_j^{-1}}{\delta \cdot \beta^{-1}} \cdot \frac{\alpha \cdot \epsilon}{\alpha_{\min}} n \ln n$$

proposals from men in tier  $j$ . Thus, the contribution to  $\Gamma_w$  (the total weight of proposals  $w$  received) from men in tier  $j$  is

$$\Gamma_{j \rightarrow w} \approx \frac{\delta_j}{\delta \cdot \beta^{-1}} \cdot \frac{\alpha \cdot \epsilon}{\alpha_{\min}} n \ln n \approx \delta_j \Gamma_w.$$

Moreover, it turns out that, with high probability, the above holds up to  $(1 \pm \epsilon)$  for all tiers  $j$  simultaneously. Regardless of the order in which  $w$  saw proposals, the probability that  $w$ 's favorite proposal came from a man in tier  $j$  is  $\Gamma_{j \rightarrow w} / \Gamma_w$ . Thus, this probability is approximately  $\delta_j$ . See the full version for a formal implement of the proof.

► **Theorem 5.2.** Consider an arbitrary tier  $i$  of women and  $j$  of men. For all  $\epsilon > 0$ , there is an  $n$  large enough such that the probability that a woman in tier  $i$  matches to a man in tier  $j$  is  $(1 \pm \epsilon)\delta_j$ .

## 6 Summary

The model and findings in this paper contribute to the understanding of random stable matching markets. Indeed, the results quantify the effect of competition that arises from heterogeneous quality in agents, specifically, when the agents fall into different constant-factor tiers of quality. Novel technical tools are developed in order to reason about the proposal dynamics of deferred acceptance.

Relaxing some of the modeling assumptions raises interesting questions that cannot be trivially answered. This includes having non-constant (size, or public score) tiers, personalized private scores which give agents different distributions of preferences, and imbalance in the number of agents on each side of the market. Moreover, it is natural to ask when one should expect the matching to be sorted, i.e., higher tiers will be more likely to match with higher tiers (e.g., [12] demonstrates the presence of sorting in dating markets).

## Abstract

Black-box separations have been successfully used to identify the limits of a powerful set of tools in cryptography, namely those of black-box reductions. They allow proving that a large set of techniques are not capable of basing one primitive  $\mathcal{P}$  on another  $\mathcal{Q}$ . Such separations, however, do not say anything about the power of the *combination* of primitives  $\mathcal{Q}_1, \mathcal{Q}_2$  for constructing  $\mathcal{P}$ , even if  $\mathcal{P}$  cannot be based on  $\mathcal{Q}_1$  or  $\mathcal{Q}_2$  alone.

By introducing and formalizing the notion of *black-box uselessness*, we develop a framework that allows us to make such conclusions. At an informal level, we call primitive  $\mathcal{Q}$  black-box useless (BBU) for  $\mathcal{P}$  if  $\mathcal{Q}$  cannot help constructing  $\mathcal{P}$  in a black-box way, even in the presence of another primitive  $\mathcal{Z}$ . This is formalized by saying that  $\mathcal{Q}$  is BBU for  $\mathcal{P}$  if for *any* auxiliary primitive  $\mathcal{Z}$ , whenever there exists a black-box construction of  $\mathcal{P}$  from  $(\mathcal{Q}, \mathcal{Z})$ , then there must already also exist a black-box construction of  $\mathcal{P}$  from  $\mathcal{Z}$  alone. We also formalize various other notions of black-box uselessness, and consider in particular the setting of *efficient* black-box constructions when the number of queries to  $\mathcal{Q}$  is below a threshold.

Impagliazzo and Rudich (STOC'89) initiated the study of black-box separations by separating key agreement from one-way functions. We prove a number of initial results in this direction, which indicate that one-way functions are perhaps also *black-box useless* for key agreement. In particular, we show that OWFs are black-box useless in any construction of key agreement in either of the following settings: (1) the key agreement has perfect correctness and one of the parties calls the OWF a constant number of times; (2) the key agreement consists of a single round of interaction (as in Merkle-type protocols). We conjecture that OWFs are indeed black-box useless for general key agreement.

We also show that certain techniques for proving black-box separations can be lifted to the uselessness regime. In particular, we show that the lower bounds of Canetti, Kalai, and Paneth (TCC'15) as well as Garg, Mahmoody, and Mohammed (Crypto'17 & TCC'17) for assumptions behind indistinguishability obfuscation (IO) can be extended to derive black-box uselessness of a variety of primitives for obtaining (approximately correct) IO. These results follow the so-called “compiling out” technique, which we prove to imply black-box uselessness.

Eventually, we study the complementary landscape of black-box uselessness, namely black-box *helpfulness*. We put forth the conjecture that one-way functions are black-box *helpful* for building collision-resistant hash functions. We define two natural relaxations of this conjecture, and prove that both of these conjectures are implied by a natural conjecture regarding random permutations equipped with a collision finder oracle, as defined by Simon (Eurocrypt'98). This conjecture may also be of interest in other contexts, such as amplification of hardness.

## 1 Introduction

### 1.1 Background

Black-box reductions are a central tool in Cryptography. They have helped shape a rich landscape of relations between different cryptographic notions, allowing us to develop a better understanding of their powers and limitations.

Roughly speaking, in a (fully) black-box reduction both the design and analysis of a protocol treat the underlying primitives and adversaries in a black-box way, obviously of their internals. More precisely, we say there is a fully black-box construction of a primitive  $\mathcal{P}$  from a primitive  $\mathcal{Q}$  if there is an efficient construction  $\mathcal{P}^{\mathcal{Q}}$  that for every implementation  $\mathcal{Q}$  of primitive  $\mathcal{Q}$  implements primitive  $\mathcal{P}$ , and further, there is an efficient security reduction  $\mathcal{S}^{\mathcal{Q},A}$  which for every adversary  $A^{\mathcal{P}}$  that breaks  $\mathcal{P}$ , breaks  $\mathcal{Q}$ . This notion originates in the seminal work of Impagliazzo and Rudich [20], and it was later refined by Reingold, Trevisan, and Vadhan [26] as well as Baecher, Brzuska, and Fischlin [3] who proposed a taxonomy of notions of reducibility between cryptographic primitives.

Impagliazzo and Rudich showed how to attack any key-agreement (KA) protocol in the random-oracle (RO) model with only a polynomial number queries to the random oracle.<sup>1</sup> This result is sufficient to rule out fully black-box reductions, since, roughly speaking, the construction is assumed to work for any OWF oracle  $f$ , and in particular for a RO and moreover, the security reduction works for any adversary  $A$ , and in particular for those that do not necessarily run in polynomial time but makes a polynomial number of queries to  $f$ .

Following this work, a successful and long line of research studying separations between different cryptographic primitives followed (e.g., see [2, 4, 9, 13, 16, 17, 28] and references therein). In this work we will revisit these works and ask if and to what extent their results hold in the presence of other primitives.

### 1.2 Black-Box Uselessness

Cryptographic constructions typically rely on multiple, incomparable building blocks. This raises the question if, and to what extent, a black-box separation result proves that some primitive is *useless* for building another even with other primitives. Take, for example, the case of key-agreement (KA) and one-way functions (OWFs). Although OWFs on their own are insufficient to build KA, this leaves the possibility that together with some other primitive  $\mathcal{Z}$  they do imply KA in a black-box way, even if  $\mathcal{Z}$  also does not black-box imply KA.<sup>2</sup> More generally, suppose we have separated primitive  $\mathcal{P}$  from primitives  $\mathcal{Q}_1$  and  $\mathcal{Q}_2$  with respect to black-box reductions. That is, neither  $\mathcal{Q}_1$  nor  $\mathcal{Q}_2$  can be used to build  $\mathcal{P}$ . Does it then necessarily follow that  $\mathcal{P}$  is also black-box separated from  $\mathcal{Q}_1$  and  $\mathcal{Q}_2$  put together? More generally, one may ask:

*Which black-box impossibility results compose?*

<sup>1</sup> More precisely, their attack made  $\mathcal{O}((qm)^3)$  RO queries, where  $q$  is the number of queries of the protocol to the RO and  $m$  is the number of messages exchanged.

<sup>2</sup> Note that constructions of PKE from OWFs plus indistinguishability obfuscation are *non-black-box* [27].

In general, not all black-box impossibility results compose. Indeed, consider a primitive  $\mathcal{P}$  that is set to be the “union” of primitives  $\mathcal{Q}_1$  and  $\mathcal{Q}_2$ , where  $\mathcal{Q}_1$  and  $\mathcal{Q}_2$  are mutually separated (i.e., neither can be based on the other). Then although  $\mathcal{P}$  cannot be based on  $\mathcal{Q}_1$  or  $\mathcal{Q}_2$ , it can be trivially based on their union.<sup>3</sup> This situation is somewhat unsatisfying: due to a joint effort of the cryptographic community in the past three decades, we have at our disposal a large number of black-box separations between pairs of primitives, yet we know essentially nothing about whether this situation changes if we are willing to use several primitives in a black-box construction – and of course, black-box separating subsets of primitives from a target primitive would be tedious. This leaves out the possibility that such separations could be obtained more systematically.

In this work, we seek to devise a more efficient strategy, by identifying conditions under which a primitive  $\mathcal{P}$  is black-box separated from primitive  $\mathcal{Q}$  in a *composable way*. That is, primitive  $\mathcal{Q}$  in conjunction with *any* other primitive  $\mathcal{Z}$  cannot be used to build  $\mathcal{P}$ , unless of course  $\mathcal{P}$  can be built using  $\mathcal{Z}$  alone. Our starting point is the following notion of *black-box uselessness*:<sup>4</sup>

► **Definition 1** (Black-box uselessness, informal). *A primitive  $\mathcal{Q}$  is black-box useless (BBU) for primitive  $\mathcal{P}$  if for any auxiliary primitive  $\mathcal{Z}$ , whenever there is a black-box construction of  $\mathcal{P}$  from  $(\mathcal{Q}, \mathcal{Z})$  there also exist a black-box construction of  $\mathcal{P}$  from the auxiliary primitive  $\mathcal{Z}$  alone.*

A *composition theorem* for black-box uselessness immediately follows: if  $\mathcal{Q}_1$  is BBU for  $\mathcal{P}$  and  $\mathcal{Q}_2$  is BBU for  $\mathcal{P}$  then  $\mathcal{Q}_1$  and  $\mathcal{Q}_2$  put together are BBU for  $\mathcal{P}$ . Indeed, for any  $\mathcal{Z}$ , if  $(\mathcal{Q}_1, \mathcal{Q}_2, \mathcal{Z}) = (\mathcal{Q}_1, (\mathcal{Q}_2, \mathcal{Z}))$  black-box implies  $\mathcal{P}$ , then  $(\mathcal{Q}_2, \mathcal{Z})$  must black-box imply  $\mathcal{P}$  (by the black-box uselessness of  $\mathcal{Q}_1$ ). This in turn implies, by the black-box uselessness of  $\mathcal{Q}_2$ , that  $\mathcal{Z}$  alone black-box imply  $\mathcal{P}$ .

► **Remark 2.** A black-box uselessness result of  $\mathcal{Q}$  for  $\mathcal{P}$  implies in particular that  $\mathcal{Q}$  does not black-box imply  $\mathcal{P}$ , as long as  $\mathcal{P}$  is not a (trivial) primitive that exists unconditionally. Indeed, by the black-box uselessness of  $\mathcal{Q}$ , if  $\mathcal{Q}$  black-box implies  $\mathcal{P}$ , then taking  $\mathcal{Z}$  as the “empty primitive” we get that  $\mathcal{P}$  exists unconditionally in the plain model. For instance, although one-way functions are black-box useless for the one-time pad (since the latter exists unconditionally in the presence of any auxiliary oracle), one-way functions black-box imply the one-time pad (for essentially the same reason).

### 1.3 One-Way Functions and Key Agreement

Perhaps one of the most fundamental questions regarding black-box uselessness is to understand whether or not one-way functions are black-box useless for key agreement. We start with an observation on a natural approach for building key-agreement from one-way functions together with other primitives.

<sup>3</sup> This formal counterexample can be converted into more “natural” ones. Take identity-based encryption (IBE) with *compact* user keys, whose lengths are independent of the length of user identities. One can use a standard IBE and a collision-resistance hash function (CRHF) to build a compact IBE (by simply hashing the identities). Yet, compact IBE cannot be based on CRHFs in a black-box way (since PKE cannot be based on ROs). Furthermore, compact IBE cannot be based on standard IBE, since compact IBE implies CRHF (the keys must be collision-free for otherwise the compact IBE can be broken by finding a collision among keys) and standard IBE does not imply CRHFs [21].

<sup>4</sup> The terminology “a primitive  $X$  is useless for black-box constructions of a primitive  $Y$ ” has been used sometimes in the literature, e.g. in [25], to mean that  $Y$  does not black-box reduce to  $X$ . Our notion of black-box uselessness should not be confused with this terminology, which only refers to conventional black-box separations.

► **Remark 3.** When looking for candidate primitives that, combined with one-way functions, imply key-agreement, the notion of indistinguishability obfuscation (iO, [27]) might be the first that comes to mind to a reader familiar with the literature on cryptography. As we mentioned, however, the construction of PKE from iO+OWFs in [27] is not black-box. Furthermore, one can observe that this is actually unavoidable: the seminal work of Impagliazzo and Rudich [20], which showed that there is no black-box construction of key agreement from one-way function, actually already shows that there is no black-box construction of key agreement from one-way functions *together with iO*. This is because the result of [20] shows that, relative to a random oracle *and a PSPACE oracle*, there is no key-agreement, yet there are one-way functions. However, relative to these oracles, there is also a perfectly-seure deterministic iO scheme: on input a circuit of a given size, the obfuscation scheme uses the PSPACE oracle to efficiently compute the lexicographically-first functionally equivalent circuit of the same size. This simple observation implies in particular that there is no black-box construction of key-agreement from iO and OWFs.

In this work, we provide a partial answer to the question of whether or not one-way functions are black-box useless for key agreement, by showing that one-way functions are black-box useless in any construction of key agreement satisfying certain restrictions. To describe our result, it is instructive to start with the separation of perfectly correct KA from OWFs by Brakerski, Katz, Segev, and Yerukhimovich [9].

### BKSY11 in a nutshell

Given a perfectly correct, two-party KA protocol in the RO model, where Alice and Bob place at most  $q$  queries to the RO, consider an attacker Eve that proceeds as follows. Given a transcript  $T$  of the protocol, Eve samples coins  $r'_A$  and a random oracle  $RO'$  for Alice that are consistent with  $T$ . Eve then runs Alice on  $r'_A$  and  $RO'$  and records all oracle queries and the resulting key. It then places all these queries to the real RO to obtain an assignment (a list of query-answer pairs)  $L$ . Eve repeats this process, appending to  $L$  and storing keys, while ensuring that the sampling of  $RO'$  is consistent with  $L$  computed so far. Now, if in a sampled run of Alice, there are no queries of Alice in common with those of Bob outside  $L$ , by perfect correctness, the correct key will be computed. Otherwise, a query of Bob will be discovered. Since Bob has at most  $q$  queries, if Eve executes this procedure  $2q + 1$  times, in at least  $q$  of the runs no intersection queries will be discovered, and in these runs the correct key will be computed. Thus taking a majority over the set of keys computed, Eve obtains the key with probability one.

### Upgrading to BBU

In order to convert this proof into a black-box uselessness result, we make a case distinction based on whether or not one can “lift” the sampling procedure to a  $Z$ -relativized world for any oracle  $Z$ . Given a construction  $KA^{F,Z}$  of KA from a OWF  $F$  and  $Z$ , if the sampling procedure can be successfully carried out in the presence of  $Z$ , then we could efficiently break any perfectly correct KA protocol in the presence of  $Z$  only (since the attacker computes the correct key with probability one).

Now suppose at some iteration Eve is no longer able to find coins and a random oracle consistent with the transcript while making polynomially many queries to  $Z$ . We claim that in this case we can construct a *weak* one-way function. Indeed, consider the function that runs the above attack procedure up to but excluding the stage where Eve fails. Thus, this function starts by running the protocol, then uses the sampler for the first iteration (if

sampling was not already impossible at this stage) to obtain an assignment, and continues with another round of sampling, until it arrives at the stage where sampling is no longer possible. The transcript of the protocol at this stage together with the list of assignments so far constitutes the challenge for which there is no inverter. From a weak one-way function, a full-fledged one-way function follows by the result of [29], as this construction is black-box and hence relativizes with respect to  $Z$ .

We may now use the one-way function obtained from  $Z$  in place of the original one-way function  $F$  to remove reliance on the  $F$  all together. Thus, we obtain a KA protocol which relies only on  $Z$ , as required. We emphasize that this proof only shows the uselessness of OWFs for (perfect) KA and not that of random oracles, since we only obtain a one-way function using  $Z$ .

Note that since we recursively rely on the existence of an inverter, the query complexity (to  $Z$ ) of the samplers can potentially blow up. Indeed, suppose for some  $Z$ , any sampler needs to place  $\mathcal{O}(n^2)$  queries to  $Z$  to invert a function that places  $n$  queries to  $Z$ . After the first iteration, we arrive at the construction of a function that places  $n + \mathcal{O}(n^2) = \mathcal{O}(n^2)$  queries to  $Z$ . Thus, it may well be that a successful inverter at this step needs to place  $\mathcal{O}(n^4)$  queries to  $Z$ . This in particular implies that the recursive argument above can be applied for only a *constant* number of steps. Since we only need to apply the recursive sampling for *either* Alice *or* Bob, we obtain a BBU result as long as either Alice or Bob makes a constant number of queries to the RO (but polynomially many calls to  $Z$ ). We formalize this proof in Section 4, where we point out the other subtleties that arise.

Currently, we are not able to extend the proof to arbitrary protocols where both Alice and Bob make a polynomial number of RO queries. Despite this, we can show that OWFs are black-box useless for building *constant-round*, *imperfect* key agreements when both parties make a constant number of queries to the OWF (and an arbitrary number of queries to the auxiliary oracle), and that OWFs are black-box useless for *one-round* key agreement (without restriction on the queries made by the parties). We defer the details to Section 4.2.

## 1.4 The Compilation Technique

A number of black-box separation results rely on what we here refer to as the *efficient compiling-out* (or simply compilation) paradigm [1, 7, 10, 12, 13, 15, 16]. At a high-level, here given a construction  $G_1^P$  one compiles out the primitive  $P$  via an (oracle-free) simulator  $\text{Sim}$  which simulates  $P$  for the construction in a consistent way and without affecting security. The result is a new construction  $G_2$  that no longer uses  $P$ . This proof technique is closely related to black-box uselessness, and as we will see can often be turned into a black-box uselessness result with minor modifications. This in turn highlights the advantage of separation results that are achieved using this technique.

In order to show how this can be done, we briefly discuss this in the context of the work of Canetti, Kalai, Paneth [10], who showed that obfuscation cannot be based on random oracles.<sup>5</sup>

<sup>5</sup> The work of [10] dealt with *virtual-black-box* obfuscation, but as it turned out [8, 22, 23], their proof could also be applied to the case of indistinguishability obfuscation.

**CKP and black-box uselessness of random oracles for indistinguishability obfuscation**

Consider an obfuscator  $\text{Obf}^{\text{RO}}$  that makes use of a random oracle RO. On input a circuit without random oracle gates<sup>6</sup> the obfuscation algorithm outputs a circuit  $C^{\text{RO}}$ , which may also call the random oracle RO. CKP compile out the random oracle RO from any such construction as follows. First they convert  $\text{Obf}^{\text{RO}}$  to an obfuscator in the plain model by simulating the RO for the obfuscator via lazy sampling. Next to ensure that the oracle expected by an obfuscated circuit  $C^{\text{RO}}$  is consistent with the oracle simulated for obfuscation, CKP execute  $C$  on multiple randomly chosen inputs at obfuscation phase while simulating the random oracle consistently, record all query made and answers simulated, and return them together with the obfuscated oracle circuit. Leaking this list cannot hurt security as an adversary in the RO model can also compute such a list given an obfuscated circuit. On the other hand, having this list allows the evaluation of  $C^{\text{RO}}$  to be consistent with the obfuscation phase with high probability on a *random* input. (This is why the obtained primitive is only an *approximate-correct* IO.)

As can be seen, this proof Z-relativizes in the sense that the simulation of the random oracle RO and the execution of the obfuscated circuit can be both done in the presence of any other oracle Z. By compiling out the random oracle RO in the presence of Z, we obtain a construction that relies on Z. That is, we obtain that random oracles are black-box uselessness for obfuscation.

A number of other impossibility results follow the compilation paradigm and here we observe that they can be lifted to the black-box uselessness regime. In particular, we go over such observations about results from [10, 13, 15, 16] and show how they can be lifted to black-box uselessness. Indeed, as long as compilation is performed for a constant “number of rounds” and each step can be done efficiently we obtain black-box uselessness.<sup>7</sup> As a result we get that approximate IO cannot be obtained from a black-box *combination* of random oracles, predicate encryption, fully homomorphic encryption and witness encryption.<sup>8</sup>

► **Remark 4.** We note that some previous works (e.g., [10]) have described the result of Impagliazzo and Rudich as “compiling out” the random oracle from any key-agreement protocol. This process, however, differs from the compiling-out technique that we study in this paper in two aspects. First, compilation is inefficient and uses the sampling algorithm. Second, the process is carried out adaptively for multiple rounds. The inefficiency of the sampler translates to obtaining BBU for one-way functions only; adaptivity restricts our final result to protocols where one party makes at most a constant number of RO queries. On a similar note, the recent work of Maji and Wang [25] uses the term “black-box useless” as an alternative to proving (traditional) black-box separations. So, despite similarity in the terms, our notion of uselessness is quite different.

**1.5 The Case of Collision Resistance**

A classic result of Simon [28] separates collision-resistance hash functions (CRHFs) from one-way functions (and indeed one-way permutations). This is done by giving a pair of oracles  $(\pi, \text{Coll}^\pi)$  relative to which one-way permutations (and hence one-way functions) exist,

<sup>6</sup> This restriction only makes the results of CKP stronger.

<sup>7</sup> Lemma 3.25 in [14] shows a similar phenomenon in a context where we completely compile out a sequence of idealized oracles. Here we deal with a setting that an auxiliary oracle remains at the end.

<sup>8</sup> We note that this does not apply in the so-called monolithic model.

but CRHFs don't. Here  $\pi$  implements a random permutation, and  $\text{Coll}^\pi$  is an oracle that takes as input a circuit with  $\pi$ -gates and returns a random collision for it (by first computing the circuit on a random point and then picking a random preimage).

Are one-way functions/permutations also black-box useless for collision resistance? One way to answer this question affirmatively would be to extend Simon's result along the lines of what was done for the separation results above. However, in this case we have an oracle separation result, and it is not clear how to "relativize" the proof. Indeed, we conjecture the opposite: OWFs are black-box *helpful* for building CRHFs. To this end, we would need to show that for *any* one-way function  $F$  there is a primitive  $Z$ , which although on its own is insufficient for building CRHFs, together with  $F$  can be used to build CRHFs. We present two possible approaches for proving this conjecture.

One approach follows the recent result of Holmgren and Lombardi [18], who showed how to obtain CRHFs from exponentially secure *one-way product functions* (OWPFs) in a black-box way. Roughly speaking, a OWP is a tuple of one-way functions  $(F_1, \dots, F_k)$  where any polynomial-time adversary can invert  $(F_1(x_1), \dots, F_k(x_k))$  for random  $x_i$  with probability at most  $\text{negl}(n)/2^n$  (where  $n$  is the security parameter). A good candidate for primitive  $Z$  is thus a random permutation  $\pi$  together with Simon's oracle  $\text{Coll}^\pi$  for it. To get a positive helpfulness result we need to show that for any one-way function  $F$  the pair of functions  $(F, (\pi, \text{Coll}^\pi))$  is product one-way. We intuitively expect this result to hold since  $\pi$  is fully independent of  $F$  and essentially all an adversary can do is to invert the  $F$  and  $(\pi, \text{Coll}^\pi)$  independently. Formalizing this observation requires handling additional technicalities; we refer the reader to the full version for details. We did not manage to prove this conjecture, and leave it as an interesting open problem which might be of independent interest.<sup>9</sup>

A second approach follows the work of Bauer, Farshim, Mazaheri [5], who defined a new idealized model of computation, known as the backdoored random oracle (BRO) model, whereby an adversary can obtain arbitrary leakage of the function table of the RO. Under a communication complexity conjecture related to the set-intersection problem, BFM show that two independent BROs can be used to build a CRHF by simply xoring their outputs. The leakage oracle defined by BFM is sufficiently powerful to allow implementing Simon's collision-finding oracle. As a result, although a single BRO as an idealized primitive is black-box separated from CRHFs, conjecturally it is not black-box useless for building CRHFs.

## Open problems

The central open problem left by our work is that of black-box uselessness of OWFs for arbitrary key agreement protocols. Given our BBU results for special classes of KA protocols, this conjecture may well be within reach. On the other hand, a straightforward generalization seems to require a refined sampler technique with low *adaptivity*. At the moment, however, it seems challenging to reduce the adaptivities of known samplers [4, 9, 20, 24]. Besides OWFs, whether or not CRHFs, or for that matter random oracles, are black-box useless for key agreement remains open. More generally, black-box separation results can be revisited from the point of view of uselessness. In particular, it would be interesting to consider extensions of the recent *monolithic* models to the BBU setting, as these capture certain well-known non-black-box techniques in cryptography.

<sup>9</sup> It might be helpful to consider weaker versions of this problem. For example, given an  $\varepsilon$ -secure one-way permutation and a random oracle, can an attacker invert both simultaneously with probability better than  $\text{negl}(n)/2^n$ ?

## 2 Preliminaries

### Notation

PPT stands for probabilistic polynomial time. An oracle-aided PPT machine/circuit  $A^O$  is a PPT machine/circuit with oracle access/gates, such that for any oracle  $O$  machine/circuit  $A^O$  runs in probabilistic polynomial time, where we count each call to the oracle as one step. For any  $n \in \mathbb{N}$ , we let  $[n]$  denote the set  $\{1, \dots, n\}$ . Given an interactive protocol between two parties Alice and Bob with access to an oracle  $O$ , we let  $\langle \text{Alice}^O, \text{Bob}^O \rangle$  denote the distribution of triples  $(T, y_A, y_B)$  over the randomness of the parties and the oracle, where  $T$  denotes the transcript of the protocol, and  $y_A$  (resp.,  $y_B$ ) denotes the output of Alice (resp., Bob). We also use the same notation when  $O$  comes from a *distribution* over the oracles, in which case the probability distribution of the outputs are also over the randomness of the oracle.

### 2.1 Black-Box Reductions

The definitions and notions in this section mostly follow those in [26]. Throughout, we use calligraphic letters such as  $\mathcal{P}$  or  $\mathcal{KA}$  for a cryptographic primitive, sans-serif letters (for example  $P$  or  $KA$ ) for specific implementations,  $S$  for the security reduction/proof and  $P$  for a “generic” implementation. We denote an auxiliary oracle by  $Z$  and an adversary by  $A$ .

► **Definition 5** (Cryptographic primitive). *A cryptographic primitive  $\mathcal{P}$  is a pair  $(F_{\mathcal{P}}, R_{\mathcal{P}})$ , where  $F_{\mathcal{P}}$  is the set of functions implementing  $\mathcal{P}$ , and  $R_{\mathcal{P}}$  is a relation. For each  $P \in F_{\mathcal{P}}$ , the relation  $(P, A) \in R_{\mathcal{P}}$  means that the adversary  $A$  breaks the implementation  $P$  (according to  $\mathcal{P}$ ). It is required that at least one function  $P \in \mathcal{P}$  is computable by a PPT algorithm.*

► **Definition 6** (Fully black-box reduction). *A fully black-box reduction of a primitive  $\mathcal{P}$  to another primitive  $\mathcal{Q}$  is a pair  $(P, S)$  of oracle-aided PPT machine such that for any implementation  $Q \in \mathcal{Q}$  the following two conditions hold.*

- **Implementation reduction:**  $P^Q$  implements  $\mathcal{P}$ , that is,  $P^Q \in F_{\mathcal{P}}$ .
- **Security reduction:** For any function (adversary)  $A$  that  $\mathcal{P}$ -breaks  $P^Q \in F_{\mathcal{P}}$ , i.e.,  $(P^Q, A) \in R_{\mathcal{P}}$ , it holds that  $S^{Q,A}$   $\mathcal{Q}$ -breaks  $Q$ , i.e.,  $(Q, S^{Q,A}) \in R_{\mathcal{Q}}$ .

When clear from context, we will refer to fully black-box reductions simply as black-box reductions, to the implementation reduction as the *construction*, and to the security reduction as the *security proof*.

► **Definition 7** (Semi and weakly black-box reductions). *We say there is a semi-black-box reduction of a primitive  $\mathcal{P}$  to primitive  $\mathcal{Q}$  if there is an oracle-aided PPT  $P$  such that for any implementation  $Q \in \mathcal{Q}$ ,*

- **Implementation reduction:**  $P^Q \in F_{\mathcal{P}}$ .
- **Security reduction:** If there exists an oracle-aided PPT  $A$  such that  $A^Q$   $\mathcal{P}$ -breaks  $P^Q$ , then there exists an oracle-aided PPT  $S$  such that  $S^Q$   $\mathcal{Q}$ -breaks  $Q$ .

*If the order of the quantifiers for the implementation reduction is switched in the sense that for any implementation  $Q \in \mathcal{Q}$  there is an oracle-aided PPT  $P$  such that the above two conditions hold, then we say there is a  $\forall\exists$ -semi-black-box reduction of  $\mathcal{P}$  to  $\mathcal{Q}$ .*

*Weakly black-box reductions and a  $\forall\exists$  variant thereof are defined analogously with the difference that the security reduction  $S$  is a PPT (instead of an oracle-aided PPT) machine and can no longer call  $Q$ .*

► **Definition 8** (Existence relative to an oracle). *A primitive  $\mathcal{P}$  is said to exist relative to an oracle  $O$  whenever (1) there is an oracle-aided PPT  $P$  such that  $P^O \in F_{\mathcal{P}}$ ; and (2) no oracle-aided PPT machine  $A^O$  can  $\mathcal{P}$ -break  $P^O$ .*

*Non-uniform* variants of security reductions were formalized in [11]. The following definition extends this to non-uniform implementation reductions.

► **Definition 9.** A fully black-box reduction  $(P, S)$  of a primitive  $\mathcal{P}$  from primitive  $\mathcal{Q}$  is said to have a non-uniform implementation if  $P$  additionally takes as input a polynomial-sized non-uniform advice that can also depend on its oracle  $\mathcal{Q}$ . The reduction is said to have a non-uniform security reduction if  $S$  additionally takes as input a polynomial-sized non-uniform advice that can also depend on its oracles  $\mathcal{Q}$  and  $A$ .

## 2.2 Specific Cryptographic Primitives

► **Definition 10** (One-way functions). A one-way function  $F$  relative to an oracle  $\mathcal{O}$  is an oracle-aided PPT machine such that for any PPT adversary  $A$  (modeled as an oracle-aided PPT machine) and any sufficiently large values of the security parameter  $\lambda$ , it holds that

$$\Pr_{x \xleftarrow{\$} \{0,1\}^n} [F^{\mathcal{O}}(A^{\mathcal{O}}(1^\lambda, F^{\mathcal{O}}(x))) = F^{\mathcal{O}}(x)] = \text{negl}(\lambda) .$$

If the above is only required to hold for infinitely many values of  $\lambda \in \mathbb{N}$ , then  $F$  is an infinitely-often one-way function (*io-F*).

► **Definition 11** (Key agreement). An oracle-aided  $\varepsilon$ -key agreement with respect to an oracle  $\mathcal{O}$  is an interactive protocol between two oracle-aided PPT machines Alice and Bob that satisfies the following  $\varepsilon$ -correctness and security properties.

■ ( $\varepsilon$ -correctness) For any  $\lambda \in \mathbb{N}$ ,

$$\Pr[(T, K_A, K_B) \xleftarrow{\$} \langle \text{Alice}^{\mathcal{O}}(1^\lambda), \text{Bob}^{\mathcal{O}}(1^\lambda) \rangle : K_A = K_B] \geq \varepsilon(\lambda) .$$

■ (Security) For any PPT adversary Eve, any polynomial  $p$ , and any sufficiently large  $\lambda$ ,

$$\Pr[(T, K_A, K_B) \xleftarrow{\$} \langle \text{Alice}^{\mathcal{O}}(1^\lambda), \text{Bob}^{\mathcal{O}}(1^\lambda) \rangle, K_E \xleftarrow{\$} \text{Eve}^{\mathcal{O}}(1^\lambda, T) : K_E = K_B] \leq \frac{\varepsilon(\lambda)}{p(\lambda)} .$$

If security is only required to hold for infinitely many values of  $\lambda \in \mathbb{N}$  in the sense that for every polynomial  $p$  and all adversaries, there exists an infinite set of  $\lambda$  for which the adversary's winning probability is below  $\varepsilon(\lambda)/p(\lambda)$ , then the construction is called an infinitely-often key agreement. If the number of queries to  $\mathcal{O}$  is bounded by a constant for either Alice or Bob, then we say that the key agreement is unbalanced with respect to  $\mathcal{O}$ . We say that the key agreement is a perfectly correct when  $\varepsilon(\lambda) \equiv 1$ .

## 3 Defining Black-Box Uselessness

To formally define black-box uselessness, we first formalize joint primitives, to simplify statements about black-box constructions from several primitives:

► **Definition 12** (Joint primitive). Given two primitives  $\mathcal{P} = (F_{\mathcal{P}}, R_{\mathcal{P}})$  and  $\mathcal{Q} = (F_{\mathcal{Q}}, R_{\mathcal{Q}})$  the joint primitive  $(\mathcal{P}, \mathcal{Q}) = (F_{(\mathcal{P}, \mathcal{Q})}, R_{(\mathcal{P}, \mathcal{Q})})$  is defined by  $F_{(\mathcal{P}, \mathcal{Q})} := F_{\mathcal{P}} \times F_{\mathcal{Q}}$  and for each  $G = (P, Q) \in F_{(\mathcal{P}, \mathcal{Q})}$  and any  $A = (A_{\mathcal{P}}, A_{\mathcal{Q}})$ , we define  $(G, A) \in R_{(\mathcal{P}, \mathcal{Q})}$  iff  $(P, A_{\mathcal{P}}) \in R_{\mathcal{P}}$  or  $(Q, A_{\mathcal{Q}}) \in R_{\mathcal{Q}}$ .

We are now ready to formally define what it means for a cryptographic primitive  $\mathcal{Q}$  to be black-box useless for a primitive  $\mathcal{P}$ .

### 3.1 Definition

The following definition is more general than complete black-box uselessness of a primitive  $\mathcal{P}$  for obtaining another primitive  $\mathcal{Q}$ . In particular, the definition states a *set* of primitives  $\mathbb{Z}$  such that  $\mathcal{P}$  is useless for obtaining  $\mathcal{Q}$  in the presence of *any* of the primitives  $\mathcal{R} \in \mathbb{Z}$ .

► **Definition 13** (Black-box uselessness). *Suppose  $\mathbb{Z}$  is a set of primitives. A cryptographic primitive  $\mathcal{Q}$  is resp., fully, semi,  $\forall\exists$ -semi black-box useless for constructing a primitive  $\mathcal{P}$  in the presence of auxiliary primitives  $\mathbb{Z}$ , if the following holds: For every auxiliary primitive  $\mathcal{Z} \in \mathbb{Z}$  whenever there exists a resp., fully, semi,  $\forall\exists$ -semi black-box reduction of  $\mathcal{P}$  to the joint primitive  $(\mathcal{Q}, \mathcal{Z})$  there also exists a resp., fully, semi,  $\forall\exists$ -semi black-box reduction of  $\mathcal{P}$  to  $\mathcal{Z}$  alone. In the special case where  $\mathbb{Z}$  contains all primitives, then we simply say that  $\mathcal{Q}$  is resp., fully, semi,  $\forall\exists$ -semi black-box useless for constructing a primitive  $\mathcal{P}$ .*

► **Remark 14** (Other special cases of Definition 13). Here we point out to two other important special cases of Definition 13 that could be obtained  $\mathbb{Z}$  differently. If  $\mathbb{Z} = \emptyset$ , then black-box uselessness is the same as a traditional black-box separation showing that  $\mathcal{Q}$  cannot be black-box reduced to  $\mathcal{P}$ . In addition, when  $\mathbb{Z}$  contains a specific primitive  $\mathcal{Z}$ , then Definition 13 captures the notion that  $\mathcal{P}$  is useless for building  $\mathcal{Q}$  when we already assume the existence of  $\mathcal{Z}$  as a black-box.

► **Remark 15** (Other variants of Definition 13). By default we consider the three main cases where the source construction and the target construction in Definition 13 both use the same flavor of black-box reduction, and accordingly use the terms fully, semi, or  $\forall\exists$ -semi to describe the corresponding notion of black-box uselessness. However, we can (and will) also consider more general notions of black-box uselessness whereby the source construction and the target construction use different notions of black-box reduction. For example, we will write that  $\mathcal{Q}$  is [semi  $\rightarrow$   $\forall\exists$ -semi] black-box useless for  $\mathcal{P}$  if for every auxiliary primitive  $\mathcal{Z}$ , whenever there exists a semi-black-box reduction of  $\mathcal{P}$  to the joint primitive  $(\mathcal{Q}, \mathcal{Z})$  there is a  $\forall\exists$ -semi-black-box reduction of  $\mathcal{P}$  to  $\mathcal{Z}$  alone.

### 3.2 Composition

Given the definition of black-box uselessness, the following composition theorem follows easily. Here, we use the term black-box uselessness to refer to any fixed flavor of black-box uselessness.

► **Theorem 16.** *Let  $\mathcal{P}$ ,  $\mathcal{Q}$  and  $\mathcal{R}$  be three cryptographic primitives. If  $\mathcal{Q}$  is black-box useless for  $\mathcal{P}$  and  $\mathcal{R}$  is black-box useless for  $\mathcal{P}$  (for the same flavor), then the joint primitive  $(\mathcal{Q}, \mathcal{R})$  is black-box useless for  $\mathcal{P}$  (for the same flavor).*

**Proof.** Let  $\mathcal{Z}$  be an arbitrary auxiliary primitive. If there is a black-box reduction of  $\mathcal{P}$  to the joint primitive  $(\mathcal{Z}, (\mathcal{Q}, \mathcal{R})) = ((\mathcal{Z}, \mathcal{Q}), \mathcal{R})$ , then by the black-box uselessness of  $\mathcal{R}$  for  $\mathcal{P}$ , there is a black-box reduction of  $\mathcal{P}$  to  $(\mathcal{Z}, \mathcal{Q})$  (viewing  $(\mathcal{Z}, \mathcal{Q})$  as an auxiliary primitive). In turn, using the black-box uselessness of  $\mathcal{Q}$  for  $\mathcal{P}$ , we obtain a black-box construction of  $\mathcal{P}$  from  $\mathcal{Z}$  alone. Hence,  $(\mathcal{Q}, \mathcal{R})$  is black-box useless for  $\mathcal{P}$ . ◀

We note that a similar composition theorem can be easily established even when  $\mathcal{Q}$  and  $\mathcal{R}$  do not satisfy the same flavor of black-box uselessness for  $\mathcal{P}$ , in the following sense: if a primitive  $\mathcal{Q}$  is  $[X \rightarrow Y]$  BBU for  $\mathcal{P}$  and a primitive  $\mathcal{R}$  is  $[X' \rightarrow Y']$  BBU for  $\mathcal{P}$ , where  $X, Y, X', Y'$  are flavors of black-box reduction, then  $(\mathcal{Q}, \mathcal{R})$  is  $[X' \rightarrow Y]$  BBU for  $\mathcal{P}$  as long as  $X$  is a stronger flavor than  $Y'$  (e.g.,  $X$  is “fully” and  $Y'$  is “semi”).

### 3.3 Restricted Black-Box Uselessness

In many settings, it can be useful to consider a more general notion of black-box uselessness, which restricts the type of primitive (e.g., only infinitely-often variants) or the type of construction for which black-box uselessness is shown to hold. For readability, we will not define cumbersome formal notations for such variants, but instead will simply state the restriction explicitly when needed.

This generalization is especially useful to study the *efficiency* of black-box reductions. Indeed, black-box separations in cryptography are not limited to only showing their nonexistence. A more concrete treatment would make statements of the form “in any black-box construction of  $\mathcal{P}$  from  $\mathcal{Q}$ , any implementation of  $\mathcal{P}$  must call an implementation of  $\mathcal{Q}$  at least  $q$  times,” or for interactive primitives states that “any black-box construction of  $\mathcal{P}$  from  $\mathcal{Q}$  must have at least  $r$  rounds”. This approach to bounding the efficiency of generic cryptographic construction was initiated in the seminal work of Gennaro, Gertner, Katz, and Trevisan [16] and has subsequently proven very fruitful.

## 4 On the Black-Box Uselessness of OWFs for Key Agreement

In this section, we prove black-box uselessness of OWFs for key agreement for several natural special forms of key agreement protocols. We leave the proof of black-box uselessness of OWFs for general key agreement protocols as an intriguing open question.

### 4.1 Theorem Statement for Perfectly Correct Key Agreement

In this section, we prove the following:

► **Theorem 17** (Black-box uselessness of OWFs for perfect unbalanced KA). *Infinitely-often one-way functions are [semi  $\rightarrow$   $\forall\exists$ -semi] black-box useless for infinitely-often perfect key agreement in any construction which is unbalanced with respect to the io-OWF.*

Before proving Theorem 17, let us breakdown its content. The “dream result” here would be to show that one-way functions are black-box useless for any key agreement. Unfortunately, we do not know how to prove this result. Theorem 17 provides a meaningful step in this direction, but it suffers from three limitations:

1. It only applies to *infinitely-often* one-way functions (though it is incomparable in that it shows black-box uselessness for infinitely-often key agreement, which is a weaker primitive).
2. It only applies to constructions where one of the parties makes a *constant* number of queries to the io-OWF oracle, which we call unbalanced key agreement. Note that the key agreement can still make an arbitrary number of queries to the auxiliary primitive.
3. It only applies to *perfectly correct* key agreement.

The first limitation stems from the fact that our proof of Theorem 17 relies on a case distinction based on the existence of one-way functions: if they exist, we get a construction of key agreement, else we get an attack on the candidate construction. However, this attack requires applying a one-way function inverter to several functions at once. But since a one-way function inverter is only guaranteed to succeed on *infinitely many* security parameters, which need not be equal across the different functions that we need to invert (and in fact could be exponentially far apart), this approach fails. To get around this, we rely on an inverter for an infinitely-often OWF, which gives an inverter which is guaranteed to work for *all* sufficiently large security parameters and we can use to simultaneously invert several functions. This,

however, comes at the cost of getting instead a black-box uselessness result for infinitely-often OWFs (for infinitely-often key agreements). Such technicalities are relatively common in cryptography and stem from the asymptotic nature of primitives.

► **Remark 18.** In general, statements of the form “ $\mathcal{A}$  and  $\mathcal{B}$  black-box imply  $\mathcal{C}$ ” and statements of the form “io- $\mathcal{A}$  and io- $\mathcal{B}$  black-box imply io- $\mathcal{C}$ ”, where io- $\mathcal{X}$  denotes an infinitely-often flavor of a primitive  $\mathcal{X}$ , can be incomparable for the trivial reason that io- $\mathcal{A}$  and io- $\mathcal{B}$  can never be simultaneously secure on the same security parameters. However, this situation does not arise in the setting of black-box uselessness, since the statement “io- $\mathcal{A}$  is BBU for io- $\mathcal{C}$ ” refers to the inexistence of black-box construction of io- $\mathcal{C}$  from io- $\mathcal{A}$  together with any other primitive  $\mathcal{Z}$  – and not only “infinitely-often” types of primitives. In general, it is easy to show that the statement “ $\mathcal{A}$  is BBU for  $\mathcal{C}$ ” is stronger than (i.e., implies) the statement “io- $\mathcal{A}$  is BBU for io- $\mathcal{C}$ ” for all notions of black-box uselessness.

The second limitation stems from the fact that the proof requires to iteratively define efficient functions  $F_i$ , where each  $F_i$  builds upon an (efficient) OWF inverter applied to  $F_{i-1}$ . The total number of functions can be picked to be the minimum of the number of queries to the OWF made by either of the two parties. However, this argument crucially relies on the fact that the number of functions  $F_i$  is a constant; to see this, imagine that we have at our disposal a OWF inverter that would always makes a number of queries quadratic in the number of queries made by the function in the forward direction. Such an inverter would be efficient (i.e., it inverses any poly time function in poly time), yet one cannot obtain a poly time function by iteratively defining a function  $F_i$  which invokes  $\text{Inv}_{F_{i-1}}$  unless  $i$  is constant, since the complexity of  $F_i$  grows as  $\text{runtime}(F_1)^{2^i}$ .

Eventually, our result in this section focuses on perfectly correct key agreement. We discuss the case of imperfect key agreement in Section 4.2.

#### 4.1.1 A Helpful Logical Lemma

Below, we state a simple lemma which allows for more direct proofs of [semi  $\rightarrow$   $\forall\exists$ -semi] black-box uselessness.

► **Lemma 19.** *Let  $\mathcal{P}$  and  $\mathcal{Q}$  be two primitives. Then whenever the following statement is established, it implies in particular that  $\mathcal{Q}$  is [semi  $\rightarrow$   $\forall\exists$ -semi] black-box useless for  $\mathcal{P}$ :*

*“Fix any primitive  $\mathcal{Z}$  and any  $Z \in F_Z$ . Assume that there exists an oracle-aided PPT  $P_1$  such that for any  $Q \in F_Q$ ,  $P_1^{Q,Z} \in F_P$ . Further assume that whenever  $(Q, Z)$  is a secure implementation of  $(\mathcal{Q}, \mathcal{Z})$ , then  $P_1^{Q,Z}$  is a secure implementation of  $\mathcal{P}$ . Then there exists an efficient implementation  $P_2^Z$  of  $\mathcal{P}$  relative to  $Z$ , and furthermore, whenever  $Z$  is a secure implementation of  $\mathcal{Z}$ ,  $P_2^Z$  is a secure implementation of  $\mathcal{P}$ .”*

We prove this lemma in the full version of the paper.

#### 4.1.2 Proof of Theorem 17

Let io- $\mathcal{F}$  be the io-OWF primitive. To prove of Theorem 17, we will prove the following:

► **Lemma 20.** *Fix any primitive  $\mathcal{Z}$  and any  $Z \in F_Z$ . Assume that there exists an oracle-aided PPT  $KA_1$  such that for any implementation ioF of an infinitely-often one-way function,  $KA_1^{\text{ioF}, Z}$  implements an infinitely-often perfect key agreement unbalanced with respect to ioF, relative to  $(\text{ioF}, Z)$ . Assume furthermore that if  $(\text{ioF}, Z)$  is a secure implementation of  $(\text{io-}\mathcal{F}, \mathcal{Z})$ , then  $KA_1^{\text{ioF}, Z}$  is a secure implementation of infinitely-often key agreement, unbalanced with respect to ioF. Then there exists an efficient implementation  $KA_2$  of (infinitely-often) key agreement relative to  $Z$ , and furthermore, if  $Z$  is a secure implementation of  $\mathcal{Z}$ , then  $KA_2^Z$  is a secure implementation of infinitely-often key agreement.*

The proof of Theorem 17 follows directly from the above lemma by applying Lemma 19. To prove Lemma 20, we rely on the following lemma.

► **Lemma 21.** *Let  $\text{RO}$  be a random oracle. For any auxiliary oracle  $\mathcal{Z}$ , if there exists no infinitely-often one-way function relative to  $\mathcal{Z}$ , then there exists no construction  $\text{KA}^{\text{RO}, \mathcal{Z}}$  of a perfect infinitely-often key agreement which is unbalanced with respect to  $\text{RO}$ .*

Given Lemma 21, the proof of Lemma 20 follows from a disjunction argument: fix any auxiliary primitive  $\mathcal{Z}$  and any  $Z \in F_{\mathcal{Z}}$ . Two complementary cases can occur:

- Either there exists an efficient implementation of an infinitely-often one-way function  $\text{ioF}^Z$  relative to  $\mathcal{Z}$ . By the assumption of Lemma 20, there exists an efficient implementation  $\text{KA}_1$  of key agreement relative to  $(\text{ioF}', \mathcal{Z})$  for any  $\text{ioF}' \in F_{\text{io-}\mathcal{F}}$ . Define the following efficient construction  $\text{KA}_2^Z$ :  $\text{KA}_2^Z := \text{KA}_1^{\text{ioF}^Z, \mathcal{Z}}$ . By our assumption, this is therefore an efficient implementation of key agreement relative to  $\mathcal{Z}$ , which is also secure if  $(\text{ioF}, \mathcal{Z})$  is secure.
- Or there exists no efficient implementation of an infinitely-often one-way function  $\text{ioF}^Z$  relative to  $\mathcal{Z}$ . By Lemma 21, for a random oracle  $\text{RO}$ , there must therefore exist an efficient attack on  $\text{KA}_1^{\text{RO}, \mathcal{Z}}$ . By Theorem 5.2 of [20], with measure 1 over the choice of the random oracle  $\text{RO}$ ,  $\text{RO}$  is a one-way function (and therefore in particular an  $\text{io-OWF}$ ; note that this theorem holds also in the presence of an arbitrary other oracle). Therefore,  $\text{KA}_1$  is not a secure implementation of key agreement with respect to any  $(\text{ioF}', \mathcal{Z})$  with  $\text{ioF}' \in F_{\text{io-}\mathcal{F}}$ , and by the assumptions of Lemma 21,  $(\text{RO}, \mathcal{Z})$  is not a secure implementation of  $(\text{io-}\mathcal{F}, \mathcal{Z})$ . Since  $\text{RO}$  is a secure implementation of  $\text{io-OWF}$ , this implies that  $\mathcal{Z}$  is not a secure implementation of  $\mathcal{Z}$ . Therefore, we can define  $\text{KA}_2$  to be the trivial protocol in which Alice samples the output key and sends it to Bob. This is an efficient implementation of key agreement (it need not be secure since  $\mathcal{Z}$  is not a secure implementation of  $\mathcal{Z}$ ).

### 4.1.3 Proof of Lemma 21

It remains to prove Lemma 21. Consider a candidate construction  $\text{KA}^{\text{RO}, \mathcal{Z}}$  of key agreement such that one of Alice and Bob makes a constant number of queries to  $\text{RO}$ . Let  $\lambda \in \mathbb{N}$  be the security parameter, and consider a run  $(T, K_A, K_B) \xleftarrow{\$} \langle \text{Alice}^{\text{RO}, \mathcal{Z}}(1^\lambda), \text{Bob}^{\text{RO}, \mathcal{Z}}(1^\lambda) \rangle$  of the construction  $\text{KA}^{\text{RO}, \mathcal{Z}}$ . We will describe an efficient attacker  $\text{Eve}^{\text{RO}, \mathcal{Z}}$  that breaks  $\text{KA}^{\text{RO}, \mathcal{Z}}$  for infinitely many  $\lambda$ . The attack closely follows the (inefficient) strategy of [9], but relies on  $\text{Inv}^Z$  to make the attack efficient. Without loss of generality, assume that Bob makes a constant number of queries; let  $q_B$  be a constant bound on the number of queries made by Bob in any execution of the protocol. Furthermore, let  $r_A(\lambda)$  and  $r_B(\lambda)$  be (polynomial) bounds on the length of the random tape of Alice and Bob respectively, and let  $q(\lambda) = q_A(\lambda) + q_B$  be a (polynomial) bound on the total number of queries to  $\text{RO}$  made by both parties in any execution.

#### 4.1.3.1 Lazy oracle sampling

Let  $q \in \mathbb{N}$ . For any string  $r$  of length  $q$ , and any list  $L$  of (query, answer) pairs, we let  $\text{SimRO}[L]_q(\cdot; r)$  be a stateful *lazy sampler* for a random oracle consistent with  $L$ . Namely,  $\text{SimRO}[L]_q(\cdot; r)$  works as follows: it maintains a counter  $i$  (initialized to 1) and a list  $L'$  of pairs (query, answer), which is initially empty. Each time it receives an input  $x$ ,  $\text{SimRO}[L]_q(x; r)$  first checks whether or not the query belongs to  $L \cup L'$ , and outputs the corresponding answers if this holds. If the query does not belong to  $L$  or  $L'$ , algorithm  $\text{SimRO}[L]_q(x; r)$  defines  $q_i$  to be the answer to the query, adds (query,  $q_i$ ) to  $L'$ , and sets  $i \leftarrow i + 1$ . Note that for any interactive protocol  $\Pi^{\text{RO}}$  where the parties make less than  $q$  queries in total,

and any list  $L$  of (query, answer) pairs consistent with  $\text{RO}$ , the distribution of the views of all parties obtained by sampling a random oracle  $\text{RO}$  and running  $\Pi^{\text{RO}}$  is identical to the distribution of the views of all parties obtained by sampling a  $q$ -bit string  $r$  and running  $\Pi$  while emulating  $\text{RO}$  using  $\text{SimRO}[L]_q(\cdot; r)$ .

#### 4.1.3.2 An inefficient attack

We first describe an inefficient attack on the candidate construction  $\text{KA}^{\text{RO}, \text{Z}}$ , taken almost verbatim from [9]. The attacker  $\text{Eve}^{\text{RO}, \text{Z}}$ , given a transcript  $T$  of an execution of  $\text{KA}^{\text{RO}, \text{Z}}$ , maintains a set  $Q_E$  of query/answer pairs for  $\text{Z}$ , and a multi-set of candidate keys  $\mathcal{K}$ , both initialized to  $\emptyset$ . Eve runs  $2q_B(\lambda) + 1$  iterations of the following procedure.

- *Simulation phase:* Eve finds a view of  $\text{Alice}^{\text{RO}', \text{Z}}$  with respect to some (possibly different) oracle  $\text{RO}'$ , consistent with the transcript  $T$  and all pairs query/answer in  $Q_E$ . This view contains a random tape  $r_A$ , the set of queries  $Q_A$  made by  $\text{Alice}^{\text{RO}', \text{Z}}$  (which is consistent with  $Q_{\text{Eve}}$ , but not necessarily with  $\text{RO}$ ), and the key  $K_A$  computed by Alice. Eve adds  $K_A$  to  $\mathcal{K}$ .
- *Update phase:*  $\text{Eve}^{\text{RO}, \text{Z}}$  makes all queries in  $Q_A$  to the true random oracle  $\text{RO}$ , and adds the results to  $Q_E$ .

After running  $2q_B(\lambda) + 1$  iterations of the above attack, Eve has a multi-set  $\mathcal{K}$  of  $2q_B + 1$  possible keys; Eve outputs the majority value in  $\mathcal{K}$ . Observe that during each round of the attack, two events can happen:

1. Either one of the new queries (not already contained in  $Q_E$ ) made by Alice in the simulated run was made by Bob in the real execution of the protocol. In this case, Eve discovers (and adds to  $Q_E$ ) a new query of Bob.
2. Or none of the new queries of Alice was made by Bob in the real protocol, in which case there exists an oracle  $\text{RO}'$  which is consistent with the view of Bob in the real protocol, and the view of Alice in the simulated run. By perfect correctness, this means that the key  $K_A$  computed by Alice in this run is necessarily the correct key.

Now, since Bob makes at most  $q_B$  distinct queries, the first of the two events can happen at most  $q_B$  times, hence the second event necessarily happens at least  $q_B + 1$  times, which guarantees that the majority value in the multi-set  $\mathcal{K}$  is indeed the correct key with probability 1.

The above attack requires  $\mathcal{O}(q_A q_B)$  queries to  $\text{RO}$ . However, it requires to find a view for  $\text{Alice}^{\text{RO}', \text{Z}}$  consistent with a given transcript, where  $\text{RO}'$  is a simulated random oracle, but  $\text{Z}$  is a “true” auxiliary oracle. In general, this might require exponentially many queries to  $\text{Z}$ , hence  $\text{Eve}^{\text{RO}, \text{Z}}$  is not an efficient oracle-aided algorithm. In the following, we show how to make the attack efficient given an inverter for io-OWFs.

#### 4.1.3.3 Lazy protocol emulation

Let  $L$  be a list of (query, answer) pairs to  $\text{RO}$ . Given the construction  $\text{KA}^{\text{RO}, \text{Z}}$ , let  $\text{SimC}_L^{\text{Z}}$  be an oracle-aided PPT algorithm that emulates a run of Alice and Bob in  $\text{KA}^{\text{RO}, \text{Z}}$  that is consistent with  $L$  (but not necessarily with the rest of  $\text{RO}$ ). That is, given a random string  $r_A || r_B || q$  of length  $r_A(\lambda) + r_B(\lambda) + q(\lambda)$ ,  $\text{SimC}_L^{\text{Z}}(1^\lambda; r_A || r_B || q)$  does the following: it runs Alice and Bob with input  $1^\lambda$  and respective random tapes  $r_A$  and  $r_B$ , while using  $\text{SimRO}[L]_q(\cdot; q)$  to lazily emulate the random oracle  $\text{RO}$ . After completion of the protocol,  $\text{SimC}$  outputs the transcript  $T$  of the interaction, the lists  $(Q_A, Q_B)$  of all queries to  $\text{RO}$  made by Alice and Bob during the emulation of the protocol (together with their answers), and the outputs  $(K_A, K_B)$  of both parties. Observe that  $\text{SimC}$  corresponds to a valid interaction between  $\text{Alice}^{\text{RO}'}(1^\lambda; r_A)$  and  $\text{Bob}^{\text{RO}'}(1^\lambda; r_B)$  with respect to a random oracle  $\text{RO}'$  sampled uniformly at random, conditioned on being consistent with  $L$ .

#### 4.1.3.4 The inverter

Since there is no infinitely-often OWF relative to  $Z$ , there exists an efficient inverter for any efficient oracle-aided function:

► **Lemma 22.** *For any oracle-aided PPT function  $F^Z$  and any polynomial  $p$ , there exists an oracle-aided PPT inverter  $\text{Inv}_{F,p}^Z$  such that for all large enough  $n \in \mathbb{N}$ , it holds that*

$$\Pr_{x \leftarrow \{0,1\}^n} [\text{Inv}_{F,p}^Z(F^Z(x), 1^n) \in (F^{-1})^Z(F^Z(x))] \geq 1 - \frac{1}{p(n)}.$$

**Proof.** This follows directly from the fact that the inexistence of io-OWFs relative to  $Z$  implies the inexistence of *weak* io-OWFs relative to  $Z$  (a weak OWF is a OWF where security is relaxed by saying that there exists a polynomial  $p$  such that no efficient adversary can invert with probability better than  $1 - 1/p(n)$ ). The latter follows from standard hardness amplification methods as was initially proven by Yao [29]. ◀

#### 4.1.3.5 The sequence of functions

Let  $p : \lambda \rightarrow 1/(6q_B + 3)$  be a constant polynomial. We iteratively define a sequence of  $2(q_B + 1)$  oracle functions  $(F_0^Z, G_0^Z), \dots, (F_{q_B}^Z, G_{q_B}^Z)$  as follows.

- $F_0^Z$  gets as input a string  $(r_A || r_B || q_0)$  of length  $r_A(\lambda) + r_B(\lambda) + q(\lambda)$ , computes
 
$$(T, Q_A, Q_B, K_A, K_B) \leftarrow \text{SimC}_\emptyset^Z(1^\lambda; r_A || r_B || q),$$
 and outputs  $T$ . The function  $G_0^Z$  is defined similarly, but outputs  $(T, Q_A, Q_B, K_A)$ .
- $F_1^Z$  gets as input a string  $(r_A || r_B || q_0 || q_1)$  of length  $r_A(\lambda) + r_B(\lambda) + 2q(\lambda)$ . First, it computes  $(T, Q_A, Q_B, K_A) \leftarrow G_0^Z(r_A || r_B || q_0)$ . Second, it sets  $n \leftarrow r_A(\lambda) + r_B(\lambda) + q(\lambda)$  and runs  $(r'_A || r'_B || q'_0) \leftarrow \text{Inv}_{F_0,p}^Z(T, 1^n)$ . Third, it computes  $(T', Q'_A, Q'_B, K'_A) \leftarrow G_0^Z(1^\lambda; r'_A || r'_B || q'_0)$ . Eventually, it uses  $\text{SimRO}[Q_A \cup Q_B](\cdot; q_1)$  to lazily sample the answers to all queries contained in  $Q'_A$ , and stores the results in a set  $Q_E$  of pairs query/answer.  $F_1^Z$  outputs  $(T, Q_E)$ . We also define  $G_1^Z$  to be the function defined as  $F_1^Z$  except that it additionally outputs  $(Q_A, Q_B, K'_A)$ .
- $F_i^Z$  gets as input a string  $(r_A || r_B || q_0 || \dots || q_i)$  of length  $r_A(\lambda) + r_B(\lambda) + (i + 1) \cdot q(\lambda)$ . First, it computes  $(T, Q_E, Q_A, Q_B) \leftarrow G_{i-1}^Z(r_A || r_B || q_0 || \dots || q_{i-1})$ . Second, it sets  $n \leftarrow r_A(\lambda) + r_B(\lambda) + i \cdot q(\lambda)$  and runs  $(r'_A || r'_B || q'_0 || \dots || q'_{i-1}) \leftarrow \text{Inv}_{F_{i-1},p}^Z((T, L_{i-1}), 1^n)$ . Third, it computes  $(T', Q'_A, Q'_B) \leftarrow G_0^Z(1^\lambda; r'_A || r'_B || q'_0)$ . Eventually, it uses  $\text{SimRO}[Q_A \cup Q_B](\cdot; q_i)$  to lazily sample the answers to all queries contained in  $Q'_A$ , and add the results to  $Q_E$ .  $F_i^Z$  outputs  $(T, Q_E)$ . We also define  $G_i^Z$  to be the function defined as  $F_i^Z$  except that it additionally outputs  $(Q_A, Q_B, K'_A)$ .

For readability, we also provide a pseudocode for the function  $F_i^Z$  below:

```

function  $F_i^Z(r_A || r_B || q_0 || \dots || q_i)$   $\triangleright (r_A || r_B || q_1 || \dots || q_i)$  is of length
 $r_A(\lambda) + r_B(\lambda) + (i + 1) \cdot q(\lambda)$ 
   $(T, Q_E, Q_A, Q_B, K_A) \leftarrow G_{i-1}^Z(r_A || r_B || q_1 || \dots || q_{i-1})$ 
   $n \leftarrow r_A(\lambda) + r_B(\lambda) + i \cdot q(\lambda)$ 
   $(r'_A || r'_B || q'_0 || \dots || q'_{i-1}) \leftarrow \text{Inv}_{F_{i-1},p}^Z((T, Q_E), 1^n)$   $\triangleright p : \lambda \rightarrow 1/(6q_B + 3)$ 
   $(T', Q'_A, Q'_B, K'_A) \leftarrow G_0^Z(1^\lambda; r'_A || r'_B || q'_0)$ 
  for  $(x, y) \in Q'_A$  do
     $Q_E \leftarrow Q_E \cup (x, \text{SimRO}[Q_A \cup Q_B](x; q_i))$ 
  end for
  return  $(T, Q_E)$   $\triangleright G_i^Z$  is similar but additionally outputs  $(Q_A, Q_B, K'_A)$ 
end function

```

#### 4.1.3.6 Making the [9] attack efficient with Inv

To overcome the inefficiency of the attack of [9], we leverage the fact that, by assumption, there exists no infinitely-often one-way function relative to  $Z$ . As before, the attacker  $\text{newEve}^{\text{RO}, Z}$ , given a transcript  $T$  of an execution of  $\text{KA}^{\text{RO}, Z}$ , maintains a set  $Q_E$  of query/answer pairs for  $Z$ , and a multi-set of candidate keys  $\mathcal{K}$ , both initialized to  $\emptyset$ . Let  $p : \lambda \rightarrow 1/(6q_B + 3)$  be a constant polynomial.  $\text{newEve}$  runs  $2q_B + 1$  iterations of the following attack.

- *Simulation phase:* During the  $i$ -th round of attack,  $\text{newEve}$  does the following:
  1. *Finding a view of Alice consistent with  $T$  and  $Q_E$ :*  $\text{newEve}$  sets  $n \leftarrow r_A(\lambda) + r_B(\lambda) + i \cdot q(\lambda)$  and computes  $(r'_A || r'_B || q'_0 || \dots || q'_{i-1}) \leftarrow \text{Inv}_{F_{i-1}, p}^Z((T, Q_E); 1^n)$ .
  2. *Simulating the run of Alice with the view above:*  $\text{newEve}$  computes  $(T', Q'_A, Q'_B, K'_A) \leftarrow G_1^Z(1^\lambda; r'_A || r'_B || q'_0)$ .
  3. *Storing the key:*  $\text{newEve}$  adds  $K'_A$  to  $\mathcal{K}$ .
- *Update phase:*  $\text{Eve}^{\text{RO}, Z}$  makes all queries in  $Q'_A$  to the true random oracle  $\text{RO}$ , and adds the results to  $Q_E$ .

After running  $2q_B + 1$  iterations of the above attack,  $\text{Eve}$  has a multi-set  $\mathcal{K}$  of  $2q_B + 1$  possible keys;  $\text{Eve}$  outputs the majority value in  $\mathcal{K}$ . We now analyze the success probability of the attack.

▷ **Claim 23.**  $\text{newEve}$  outputs the correct key with probability at least  $2/3$ .

First, observe that by definition of  $F_0^Z$ , the distribution of transcripts  $T$  of the real execution of the protocol (which  $\text{newEve}$  gets as input) is distributed exactly as  $F_0^Z(r_A || r_B || q_0)$  for uniformly random  $(r_A, r_B, q_0)$ , where  $r_A$  (resp.,  $r_B$ ) is the real random tape of  $\text{Alice}^{\text{RO}, Z}$  (resp.,  $\text{Bob}^{\text{RO}, Z}$ ) and  $q_0$  is the ordered string of all answers of  $\text{RO}$  to distinct queries from Alice and Bob. Therefore, by definition of  $\text{Inv}_{F_0, p}^Z$ , the tuple  $(r'_A || r'_B || q'_0)$  computed in the first iteration of the attack is consistent with the real transcript  $T$  with probability at least  $p = 1/(6q_B + 3)$ .

Consider now the set  $Q_E$  of queries obtained by  $\text{newEve}$  after the update phase of the first iteration.  $(T, Q_E)$  is distributed exactly as  $F_1^Z(r_A || r_B || q_0 || q_1)$  for uniformly random  $(r_A, r_B, q_0, q_1)$ . This is because  $Q_E$  in  $F_1^Z$  is computed by lazily sampling the answers of a random oracle, conditioned on being consistent with all queries made by Alice and Bob in the execution of  $F_0^Z(r_A || r_B || q_0)$ . Since the real run of the protocol corresponds to an execution of  $F_0^Z$  on a random input  $(r_A || r_B || q_0)$ , and making the queries in  $Q'_A$  to  $\text{RO}$  is identical to lazily sampling  $\text{RO}$  while being consistent with  $q_0$  (i.e., the query/answer pairs obtained by Alice and Bob in the real execution). Therefore, the tuple  $(r'_A || r'_B || q'_0 || q'_1)$  which  $\text{newEve}$  computes in the second iteration of the attack is consistent with the real transcript  $T$  with probability at least  $p = 1/(6q_B + 3)$ .

More generally, the distribution of  $(T, Q_E)$  obtained by  $\text{newEve}$  during the  $i$ -th iteration of the attack after receiving the transcript  $T$  of a real execution of the protocol is distributed exactly as  $F_i^Z(r_A || r_B || q_0 || \dots || q_i)$  for uniformly random  $(r_A, r_B, q_0, \dots, q_i)$ , hence the tuple  $(r'_A || r'_B || q'_0 || \dots || q'_i)$  which  $\text{newEve}$  computes in the  $(i+1)$ -th iteration of the attack is consistent with the real transcript  $T$  with probability at least  $p = 1/(6q_B + 3)$ .

Putting everything together, after finishing the attack, by a straightforward union bound, all simulated views computed by  $\text{newEve}$  during the attack are consistent with  $T$  with probability at least  $1 - (2q_B + 1) \cdot 1/(6q_B + 3) = 2/3$ . When this happens, by the same argument as for the inefficient attack, the majority key in  $\mathcal{K}$  is necessarily the correct key, and the claim follows.

▷ **Claim 24.** The number of queries made by  $\text{newEve}$  to  $\text{RO}$  and  $Z$  is bounded by a polynomial.

As in the inefficient attack, `newEve` makes at most  $\mathcal{O}(q_A q_B) = \mathcal{O}(q_A)$  queries to RO. The polynomial bound on the number of queries to  $Z$  follows from the efficiency of  $\text{Inv}$ :  $\text{Inv}_{F_0,p}^Z$  is efficient by definition, hence  $F_1^Z$  (which invokes  $\text{Inv}_{F_0,p}^Z$  internally) is an efficient function, from which we get that  $\text{Inv}_{F_1,p}^Z$  is also efficient, and so on, and the claim follows.

## 4.2 Black-Box Uselessness of OWFs for Imperfect KA

In this section, we discuss how our result of the previous section can be extended to the case of imperfect key agreement. More precisely, we provide a sketch of how to modify our previous proof to show the following:

- **Theorem 25.** *Infinitely-often one-way functions are [semi  $\rightarrow \forall\exists$ -semi] black-box useless for infinitely-often perfect key agreement in any construction where:*
- *Both parties make a constant number of queries to the io-OWF (but any polynomial number of queries to the auxiliary oracle)*
  - *The key agreement protocol has a constant number of rounds.*

**Proof Sketch.** The natural approach to extend our result is to replace the attack of [9] by an attack that applies to any imperfect key agreement protocol in the random-oracle model, such as those of Impagliazzo and Rudich [20] or Barak and Mahmoody [4], making the same case distinction based on the existence of io-OWFs to make the attack efficient. The structure of these attacks are very similar, though more involved than the attack of [9]: they proceed in a sequence of steps, where each step has a simulation phase, in which the attacker samples views consistent with (a portion of) the transcript and a set of queries, and an update phase, where the attacker makes some queries based on the simulated run.

Two important technicalities arise when modifying our previous proof with the attacks of [4, 20]:

First, in the simpler attack of [9], the perfect correctness guarantees that finding *any* consistent view is sufficient; in the attacks of [4, 20], however, the attacker is required to *sample* views from a distribution close to the uniform distribution over views conditioned on a transcript and a set of queries. This can still be achieved assuming only the inexistence of io-OWFs: the inexistence of io-OWFs further entails the inexistence of *distributional* io-OWFs [19]. Namely, we must rely on the following lemma, a proof of which can be found in [6].

- **Lemma 26.** *Assume that there exists no infinitely-often one-way function relative to  $Z$ . Then for any efficient oracle-aided function  $F^Z$  and any polynomial  $p$ , there exists an inverter  $\text{Inv}_F^Z$  such that for all large enough  $n \in \mathbb{N}$ ,*

$$\Pr_{x \xleftarrow{\$} \{0,1\}^n, y \leftarrow F^Z(x)} \left[ \text{SD} \left( (F^{-1})^Z(y), \text{Inv}_F^Z(y, 1^n) \right) > \frac{1}{p(n)} \right] \leq \frac{1}{p(n)},$$

where  $\text{SD}$  denotes the statistical distance between the two distributions.

Second, the attacks of [4, 20] proceed in a number of steps that grows with the number of queries of *both* parties (to the random oracle) *and* the round complexity of the protocol. More precisely, the attack requires executing several simulation and updates phases (of the order of  $\tilde{\mathcal{O}}(q_A q_B)$ , where  $q_A, q_B$  bound the respective number of queries of Alice and Bob to the random oracle) for each round of the protocol, where the simulation phase for the round  $i$  inverse samples views consistent with the set of queries made by the attacker so far and the transcript of the protocol *up to round  $i$* . This means that to be carried efficiently, the key agreement must be constant round, and both parties must make a constant number of queries to the random oracle.

From here, a proof of Theorem 25 follows by fixing a (constant) bound  $B$  on the total number of steps of the (inefficient) attacker, and using the inverse sampler guaranteed by Lemma 26 for statistical distance  $1/(10B)$  to make it efficient, similarly as in our previous proof. By a union bound over all steps, the  $B$  steps of the inverse sampling will simultaneously guarantee that, with probability at least  $1/10$ , at any round  $i$ , no intersection query between Alice and Bob made prior to round  $i$  has been missed by the attacker. This allows us to conclude that the overall success probability of the efficient attacker (which uses the inverse sampler) is at most a tenth of the success probability of the inefficient attacker described in [4, 20].

With these technicalities in mind, this proof shows that io-OWFs are  $[\text{semi} \rightarrow \forall\exists\text{-semi}]$  black-box useless for constant-query constant-round constructions of imperfect key agreement. ◀

## Abstract

Random walks on expanders are a central and versatile tool in pseudorandomness. If an arbitrary half of the vertices of an expander graph are marked, known Chernoff bounds for expander walks imply that the number  $M$  of marked vertices visited in a long  $n$ -step random walk strongly concentrates around the expected  $n/2$  value. Surprisingly, it was recently shown that the parity of  $M$  also has exponentially small bias.

Is there a common unification of these results? What other statistics about  $M$  resemble the binomial distribution (the Hamming weight of a random  $n$ -bit string)? To gain insight into such questions, we analyze a simpler model called the *sticky random walk*. This model is a natural stepping stone towards understanding expander random walks, and we also show that it is a necessary step. The sticky random walk starts with a random bit and then each subsequent bit independently equals the previous bit with probability  $(1 + \lambda)/2$ . Here  $\lambda$  is the proxy for the expander's (second largest) eigenvalue.

Using Krawtchouk expansion of functions, we derive several probabilistic results about the sticky random walk. We show an asymptotically tight  $\Theta(\lambda)$  bound on the total variation distance between the (Hamming weight of the) sticky walk and the binomial distribution. We prove that the correlation between the majority and parity bit of the sticky walk is bounded by  $O(n^{-1/4})$ . This lends hope to unifying Chernoff bounds and parity concentration, as well as establishing other interesting statistical properties, of expander random walks.

## 1 Introduction

Expander graphs and random walks on their vertices are an essential and widely employed tool in pseudorandomness, and related areas like coding theory. In this paper, we are interested in a particular simple random walk model where we mark half of the vertices of an

expander graph, and look at how many marked vertices an  $n$ -step random walk visits. This model has already been explored in many influential works. In particular, expander Chernoff bounds show that the number of marked vertices visited is concentrated around  $n/2$  with exponential tails [4, 7]. In his recent breakthrough construction of  $\varepsilon$ -balanced codes, Ta-Shma [12] proved that the parity of the number of visited marked nodes has exponentially small bias. This fact is quite striking since there are distributions on  $n$  bits that are  $(n-1)$ -wise independent yet have fixed parity, so one might not expect a sensitive function like parity to exhibit such strong concentration for expander random walks in general.

Let  $\mathbf{w}$  denote the bit string indicating which steps visit a marked node in an  $n$ -step expander random walk starting at a random node. The above two results show nontrivial properties that  $\mathbf{w}$  shares with a purely random bit string. This naturally raises questions about what other statistical similarities might hold between  $\mathbf{w}$  and purely random strings. For instance, are the parity bit and majority bit of  $\mathbf{w}$  (almost) uncorrelated? This can be viewed as a unification of the above-mentioned concentration results for the high order bit and low order bit of the Hamming weight of  $\mathbf{w}$ . More generally, given some arbitrary symmetric property of  $\mathbf{w}$  (i.e., one that only depends on its Hamming weight), how does its probability deviate in an expander random walk compared to a purely random string? What is the total variation distance (TVD) between the Hamming weight distribution of  $\mathbf{w}$  and the binomial distribution? Surprisingly, to the best of our knowledge, these and many other similar questions relating to the “pseudobinomiality” properties of the weight of the sequence  $\mathbf{w}$ , seem unexplored.

Towards gaining insight into and making progress on such questions, we analyze a simpler distribution over the  $n$ -bit strings called the *sticky random walk* as a necessary stepping stone towards understanding the general expander walk. The sticky random walk  $S(n, \lambda)$  is an  $n$ -step walk on a Markov chain with two states 0, 1. The start state is chosen uniformly at random, and at each subsequent step, we stick to the same state with probability  $\frac{1+\lambda}{2}$ , and change states with probability  $\frac{1-\lambda}{2}$ . Let  $\mathbf{s}$  be the  $n$ -bit string listing the states visited by  $S(n, \lambda)$ . The sticky random walk has served as a useful proxy for analyzing the actual expander random walk. Chernoff bounds for a slight variant of the sticky random walk imply similar bounds on the expander random walk, as explicitly pointed out by Kahale [7] and also revisited in the recent work by Rao and Regev [10] who obtained tighter bounds. Such a translation, however, only works for estimating the probability of monotone events. For non-monotone functions like parity, it is not known if one can deduce bounds for the expander random walk from their counterparts for the sticky random walk.

Nevertheless, understanding the simpler sticky random walk model is a meaningful first step towards understanding the general expander walk model. In fact, it is a *necessary* step, as there are expanders where the behavior of the random walk coincides with the sticky walk (i.e., the sequences  $\mathbf{w}$  and  $\mathbf{s}$  above are identically distributed). We make this (probably folklore) relationship between these two models explicit in Section 7 (see Theorem 4 below).

## 1.1 Our Results

We answer some of the questions proposed above in the case of the sticky random walk. Our main technique is to represent (a function related to) the probability density function of the Hamming weight of the sticky random walk in the basis of Krawtchouk functions. The Krawtchouk basis is a handy choice to compare this distribution with the binomial distribution. We show the following result on the TVD between these distributions in Section 4. In all our results we think of  $\lambda$  as being fixed and the length of the walk  $n$  to be growing.

► **Theorem 1.** *The total variation distance between the weight distribution of the sticky random walk and the binomial distribution is  $\Theta(\lambda)$ .*

Note that the above shows both an upper and lower bound. For the upper bound, we show a stronger claim that an appropriately weighted  $\ell_2$  distance between the two distributions is bounded from above by  $O(\lambda^2)$  for  $\lambda$  small enough (the above then follows by Cauchy-Schwarz). However, as  $\lambda \rightarrow 1$ , the  $\ell_2$  version of the bound fails to hold, and in fact we prove that this distance grows exponentially in  $n$  for  $\lambda > 0.95$  (Section 4.2). For the lower bound, the event of the Hamming weight being in the range  $n/2 \pm \sqrt{n}$  exhibits a  $\Omega(\lambda)$  deviation in probability between these two distributions.

Our next result (in Section 5) shows that the parity and majority bits of the sticky random walk are uncorrelated (up to lower order terms).

► **Theorem 2.** *The probability that the Hamming weight of an  $n$ -step sticky random walk is even and larger than  $n/2$  is  $\frac{1}{4} + o(1)$ . The same result holds for the other three symmetric cases.*

The analysis hinges on an upper estimate for the probability that the sticky random walk has weight exactly  $\lfloor n/2 \rfloor$ , which is again obtained via the Krawtchouk expansion. We note that the arguments for the parity bias from [12] and the Chernoff bound from [4] are quite different. The above theorem hints that Krawtchouk functions might offer a more general tool that can unify these two arguments.

Next, we verify that the residues of the Hamming weight of the sticky walk with respect to any fixed modulus  $m$  are almost equidistributed (Section 6). This in particular shows that for any fixed  $\ell$  the  $\ell$  least significant bits of the (binary representation of the) Hamming weight of the sticky random walk are nearly uniformly distributed.

► **Theorem 3.** *For any fixed  $m \geq 2$ , the total variation distance between the residues modulo  $m$  of the binomial random variable and the Hamming weight of the  $n$ -step sticky walk is at most  $\exp(-\Omega_m(n))$ .*

Recall that Ta-Shma established such a result for the  $m = 2$  case even for the expander random walk [12]. We execute a similar analysis, albeit only for the sticky walk, using  $m$ 'th roots of unity (in the place  $\pm 1$ ) to track the bias. We suspect extending this analysis to adjacency matrices of expanders (instead of the  $2 \times 2$  sticky walk transition matrix) can establish this equidistribution result for general expander walks, though we have not verified this.

Finally, the following confirms that analyzing sticky random walks is necessary in order to establish the corresponding claim for expander random walks. We should note that the graph family constructed does not fit the standard definition of an expander family, as degree-boundedness of the graph is not enforced. This is not a significant issue as the analysis of random walks on graphs always proceed by abstracting only the spectral properties of the graph. Further, we believe sampling a sparse regular subgraph with a similar structure should yield a similar claim for a bounded-degree expander family.

► **Theorem 4.** *There is a family of regular graphs whose nontrivial eigenvalues are bounded in magnitude by  $\lambda$ , half of whose vertices are marked, such that the bit string indicating which steps of a random walk visits a marked vertex has the same distribution as the sticky random walk.*

We conclude the introduction by mentioning a very interesting work of Bazzi on pseudobinominality [1]. This work establishes an upper bound on the total variation distance between the binomial distribution and the weight distribution of a  $\delta$ -biased random sequence, based

on the entropy of the latter distribution. One can show that the sticky random walk sequence  $\mathbf{s}$  is  $\lambda$ -biased (see Lemma 11). The bound on TVD in [1] is at best  $O(\sqrt{\delta n})$  and is only meaningful when the bias is tiny, which isn't the case for the sticky random walk. Also, calculating the entropy of the weight distribution of  $\mathbf{s}$  seems as hard, if not harder, than the Krawtchouk based calculations we use to directly bound the total variation distance in Section 4. In fact, it could be the case that the best approach to estimate the entropy of the weight distribution of the sticky random walk is via the entropy-difference bound [3] together with our bound on total variation distance.

## 1.2 Open Problems

Our results give rise to some immediate follow-up questions. Can the weighted  $\ell_2$  bound between the sticky and binomial distribution established in Lemma 13 be extended to give a non-trivial bound (that is bounded away from 1) for any fixed  $\lambda < 1$ ? Theorem 3 showed that any fixed number of least significant bits of (the Hamming weight of) the sticky walk are near uniform, but can this result be extended to other bits, for example the middle bit? Are there other symmetric properties of the sticky walk that resemble purely random strings?

A more important family of questions relate to extending our results from the sticky walk to the general expander walk model. Can the  $O(\lambda)$  TVD bound between the sticky and binomial distribution established in Theorem 1 be lifted to the general expander walk setting? Also, can the method of Krawtchouk functions used in Theorem 2 give insight towards unifying the Chernoff and parity bias results for expander random walks? In general, can we show distributions of various symmetric functions on expander walks are statistically close to the corresponding distributions on random strings? Moment generating function results from [7, 10] allow bounds on monotone symmetric functions to be lifted from the sticky walk to the expander walk, but no relationships are known for non-monotone functions like parity.

Recently, a TVD bound of  $O(\lambda \log^{3/2}(1/\lambda))$  between the Hamming weight of the general expander walk variant and the binomial distribution was proven using similar Fourier analytic techniques [2]. Removing this lower order polylogarithmic factor of  $\log^{3/2}(1/\lambda)$  remains an open problem. Theorem 4.8 in [2] also improved on Theorem 19 in this paper to an  $O(n^{-1/2})$  bound for the general expander walk, which consequently implies a tighter  $O(n^{-1/2})$  bound in the error term in Theorem 2. However, due to the lack of bit-flipping symmetry in the general expander walk, the extension of Theorem 2 to the expander walk remains open.

## 2 Preliminaries

### 2.1 Conventions and Notation

**Asymptotics.** In our asymptotic analysis, we will take  $\lambda$  to be constant and observe asymptotics as  $n \rightarrow \infty$ . Take  $o, O, \omega, \Omega$  to be the standard definitions. We will say  $f \lesssim g$  to mean  $f \leq Cg$  for some absolute constant  $C$  independent of  $n$  and  $\lambda$ . We also say  $f = g + O(h)$  when we mean  $|f - g| \leq O(h)$ , and analogously for  $o, \Omega$ , and  $\omega$ . We also denote  $\sim$  to be shorthand for  $= (1 + o(1))$ .

**Miscellaneous.** For a bit string  $s$ , we will denote  $|s|$  to be the Hamming weight of  $s$ .  $\mathcal{N}(\mu, \sigma^2)$  is the Gaussian distribution with mean  $\mu$  and variance  $\sigma^2$ . We write  $\text{Ber}(p)$  to be the Bernoulli distribution on  $\{0, 1\}$  where 1 has probability  $p$  and 0 has probability  $1 - p$ , and write  $\text{Bin}(n, 1/2)$  to be the binomial distribution of  $\sum_{i=1}^n b_i$  with independent choices of

$b_i \sim \text{Ber}(1/2)$ . Let  $\mathbf{1}_E$  represents the indicator variable of the event  $E$ . When written as a function,  $\mathbf{1}_S(i)$  is 1 if  $i \in S$ , and is 0 otherwise.  $[n] = \{1, 2, \dots, n\}$  denotes the set of the first  $n$  positive integers, and  $[n]_0 = \{0\} \cup [n]$ .  $\binom{[n]}{k}$  denotes the set of all size  $k$  subsets of  $[n]$ .

## 2.2 Definitions

In this paper, we will work with distributions on  $[n]_0$  and see how close they are to one another. For this reason, we state the standard definitions of the  $\ell_p$  distance between distributions

► **Definition 5** ( $\ell_p$  Distance/TVD). *Let  $Y$  and  $Z$  be distributions on  $[n]_0$ . For  $p \geq 1$ , we define the  $\ell_p$  distance between  $Y$  and  $Z$  to be*

$$\|Y - Z\|_p = \left( \sum_{i=0}^n |Y(i) - Z(i)|^p \right)^{1/p}.$$

The total variation distance (TVD) between  $Y$  and  $Z$  is simply  $\frac{1}{2}\|Y - Z\|_1$ .

Of course the first type of distribution we should formally define is the sticky random walk itself.

► **Definition 6** (Sticky Random Walk). *The sticky random walk  $S(n, \lambda)$  is a distribution on  $n$ -bit strings  $s$ , where  $s_1 \sim \text{Ber}(1/2)$ , and for  $2 \leq i \leq n$  and  $b \in \{0, 1\}$ , we have  $\Pr[s_i = b | s_{i-1} = b] = \frac{1+\lambda}{2}$ . In cases where  $n$  and  $\lambda$  are evident, only  $S$  may be used to denote the distribution.*

Define a bit string to be *homogeneous* if it only consists of 1's or of 0's. Given a bit string, we define a *run* to be a homogeneous substring that isn't a proper substring of another homogeneous substring. Intuitively, the sticky walk can be seen as a Markov chain on two states, where you stick to the same state with probability  $\frac{1+\lambda}{2}$  and transition to the other with probability  $\frac{1-\lambda}{2}$ . Thus the probability of a string is really only dependent on how many consecutive pair of bits are equal (equivalently the number of runs), rather than the precise value of the bits. Another thing to note is that  $\lambda$  can be seen as a parameter measuring the stickiness of a bit to its preceding one. Notice when  $\lambda = 0$  there is no stickiness present, and the sticky walk is just  $n$  independent coin flips.

## 2.3 Krawtchouk Functions

To analyze this sticky random walk, we heavily rely on the basis of Krawtchouk functions. Hence we define these functions here and state some standard identities of these functions without proof.

► **Definition 7** (Krawtchouk Functions). *The Krawtchouk function  $K_k : [n]_0 \rightarrow \mathbb{R}$  is defined to be*

$$K_k(\ell) = \sum_{\substack{y \in \{0,1\}^n \\ |y| = k}} (-1)^{\alpha \cdot y}$$

for each integer  $0 \leq \ell \leq n$  and an arbitrary  $n$ -bit string  $\alpha$  of Hamming weight  $\ell$  (the specific choice of  $\alpha$  does not matter due to symmetry).

## 48:6 Pseudobinomiality of the Sticky Random Walk

It can be shown that these functions form an orthogonal basis of the functions mapping  $[n]_0 \rightarrow \mathbb{R}$  with respect to the inner product

$$\langle f, g \rangle = \mathbb{E}_{\mathbf{b} \sim \text{Bin}(n, 1/2)} [f(\mathbf{b})g(\mathbf{b})]. \quad (1)$$

From the definition it is not hard to show that (e.g. Section 2.2 of [11]).

$$\mathbb{E}_{\mathbf{b} \sim \text{Bin}(n, 1/2)} [K_r(\mathbf{b})K_s(\mathbf{b})] = 0, \quad (2)$$

which shows that the Krawtchouk functions indeed form an orthogonal basis with respect to the inner product in (1). Furthermore, one can verify the following identities hold (see [11]).

$$\mathbb{E}_{\mathbf{b} \sim \text{Bin}(n, 1/2)} [K_k(\mathbf{b})^2] = \binom{n}{k} \quad (3)$$

$$\binom{n}{\ell} K_k(\ell) = \binom{n}{k} K_\ell(k). \quad (4)$$

Identities (2) and (3) allow us to explicitly expand any function uniquely as a sum of Krawtchouk functions.

► **Proposition 8.** *For function  $f : [n]_0 \rightarrow \mathbb{R}$ , there exists a unique expansion  $f(\ell) = \sum_{k=0}^n \hat{f}(k) K_k(\ell)$  where*

$$\hat{f}(k) = \frac{1}{\binom{n}{k}} \mathbb{E}_{\mathbf{b} \sim \text{Bin}(n, 1/2)} [f(\mathbf{b}) K_k(\mathbf{b})]$$

for each integer  $0 \leq k \leq n$ .

### 3 Using Krawtchouk Functions to Analyze the Sticky Walk

To help us analyze the sticky walk, we define the function  $p : [n]_0 \rightarrow \mathbb{R}$  to be  $p(\ell) = \frac{\Pr_{\mathbf{s} \sim S}[|\mathbf{s}|=\ell]}{\binom{n}{\ell} 2^{-n}}$ , and look at the Krawtchouk expansion. Doing so results in the following lemma.

► **Lemma 9.** *We have*

$$\hat{p}(k) = \frac{1}{\binom{n}{k}} \mathbb{E}_{\mathbf{s} \sim S} [K_k(|\mathbf{s}|)].$$

**Proof.** We just apply Proposition 8 to get that

$$\begin{aligned} \hat{p}(k) &= \frac{1}{\binom{n}{k}} \mathbb{E}_{\mathbf{b} \sim \text{Bin}(n, 1/2)} [p(\mathbf{b}) K_k(\mathbf{b})] \\ &= \frac{1}{\binom{n}{k}} \sum_{b=0}^n \binom{n}{b} 2^{-n} p(b) K_k(b) \\ &= \frac{1}{\binom{n}{k}} \sum_{b=0}^n \Pr_{\mathbf{s} \sim S} [|\mathbf{s}| = b] K_k(b) \\ &= \frac{1}{\binom{n}{k}} \mathbb{E}_{\mathbf{s} \sim S} [K_k(|\mathbf{s}|)]. \end{aligned} \quad \blacktriangleleft$$

What follows is a useful lemma that displays how Krawtchouk expanding  $p(\ell)$  can help analyze probabilities of the sticky distribution.

► **Lemma 10.** For  $\mathbf{s} \sim S(n, \lambda)$ , we can evaluate

$$\Pr[|\mathbf{s}| = \ell] = \frac{1}{2^n} \sum_{k=0}^n K_\ell(k) \mathbb{E}[K_k(|\mathbf{s}|)]$$

**Proof.** To estimate this probability, we can use Lemma 9 to find

$$\begin{aligned} \Pr[|\mathbf{s}| = \ell] &= \binom{n}{\ell} 2^{-n} p(\ell) \\ &= \frac{\binom{n}{\ell}}{2^n} \sum_{k=0}^n \hat{p}(k) K_k(\ell) \\ &= \frac{1}{2^n} \sum_{k=0}^n \frac{\binom{n}{\ell} K_k(\ell) \mathbb{E}[K_k(|\mathbf{s}|)]}{\binom{n}{k}} \\ &= \frac{1}{2^n} \sum_{k=0}^n K_\ell(k) \mathbb{E}[K_k(|\mathbf{s}|)] \end{aligned}$$

where we used the reciprocity relation (4) at the end. ◀

Notice that these lemmas didn't depend on the specific distribution  $S(n, \lambda)$ , and so these lemmas are applicable for arbitrary distributions on  $[n]_0$ . For our purposes, the sticky walk versions will be used for our analysis done in the next sections.

## 4 Total Variation Distance Bounds

### 4.1 Upper Bounding the TVD Between the Sticky and Binomial Distribution

Upper bounding the TVD requires calculating the expectation of various sums and products of sticky walk random variables. We will abstract out these calculations in the following lemmas. Analogous expressions for the general expander walk model were also analyzed in Lemmas 3.3 and 4.2 in Rao and Regev [10]. In particular, [10] gives upper bounds on these quantities in the general expander walk, while we give exact values for the simpler sticky walk.

► **Lemma 11.** Let  $\mathbf{s} \sim S(n, \lambda)$ . For even-sized subsets  $A \subset [n]$  where  $a_1 < \dots < a_m$  are the elements of  $A$  in increasing order, define  $\text{shift}(A) = \sum_{i=1}^{|A|/2} (a_{2i} - a_{2i-1})$ . For any  $A \subset [n]$ , we have

$$\mathbb{E} \left[ \prod_{i \in A} (-1)^{\mathbf{s}_i} \right] = \begin{cases} 0 & |A| \text{ odd} \\ \lambda^{\text{shift}(A)} & |A| \text{ even} \end{cases}.$$

**Proof.** Since the sticky walk is a Markov chain where  $(-1)^{\mathbf{s}_i}$  has the same sign as  $(-1)^{\mathbf{s}_{i-1}}$  with probability  $\frac{1+\lambda}{2}$ , we can rewrite these random variables in terms of a product of independent random variables representing the transitions of the chain. In particular, we define a new random variable  $\mathbf{u} \in \{0, 1\}^n$ , where  $\mathbf{u}_1 \sim \text{Ber}(1/2)$  and  $\mathbf{u}_i \sim \text{Ber}(\frac{1-\lambda}{2})$  for  $2 \leq i \leq n$ . One can easily check that  $(-1)^{\mathbf{s}_i}$  is the same random variable as  $\prod_{j=1}^i (-1)^{\mathbf{u}_j} = (-1)^{\sum_{j=1}^i \mathbf{u}_j}$ . Hence we have

$$\mathbb{E} \left[ \prod_{i \in A} (-1)^{\mathbf{s}_i} \right] = \mathbb{E} [ (-1)^{\sum_{i \in A} \sum_{j=1}^i \mathbf{u}_j} ] = \prod_{j=1}^{a_m} \mathbb{E} [ (-1)^{\sum_{i \in A; i \geq j} \mathbf{u}_j} ]$$

Note when  $|A|$  is odd, the factor when  $j = 1$  is 0 since  $\mathbb{E}[(-1)^{\sum_{i \in A} u_i}] = \mathbb{E}[(-1)^{u_1}] = 0$ . Hence the total expectation is 0. Otherwise, when  $|A|$  is even, the  $j = 1$  term is just  $\mathbb{E}[(-1)^{|A|u_1}] = 1$ . For  $j \geq 2$ , one sees that if  $A_j = \{i \in A : i \geq j\}$  is of odd cardinality, then  $\mathbb{E}[(-1)^{\sum_{i \in A; i \geq j} u_i}] = \mathbb{E}[(-1)^{u_j}] = \lambda$ , and is 1 otherwise. The set of  $j$  such that  $|A_j|$  is odd is simply the integers in  $(a_1, a_2] \cup (a_3, a_4] \cup \dots \cup (a_{m-1}, a_m]$ , of which there are  $\text{shift}(A)$ . Consequently, upon multiplying all the  $j$  factors, we derive that the expectation is  $\lambda^{\text{shift}(A)}$  for  $|A|$  even.  $\blacktriangleleft$

► **Lemma 12.** For all nonnegative integers  $k$  and  $s \sim S(n, \lambda)$ ,

- $\mathbb{E}[K_{2k}(|s|)] = \sum_{m=k}^{n-k} \binom{m-1}{k-1} \binom{n-m}{k} \lambda^m$ , and
- $\mathbb{E}[K_{2k+1}(|s|)] = 0$

with the convention that  $\binom{-1}{-1} = 1$  and  $\binom{j}{-1} = 0$  for  $j \geq 0$ .

**Proof.** Using the definition, we rewrite

$$K_k(|s|) = \sum_{\substack{\alpha \in \{0,1\}^n \\ |\alpha| = k}} (-1)^{\sum_{i=1}^n \alpha_i s_i} = \sum_{T \in \binom{[n]}{k}} (-1)^{\sum_{i \in T} s_i} = \sum_{T \in \binom{[n]}{k}} \prod_{i \in T} (-1)^{s_i}. \quad (5)$$

Then from Lemma 11, we have

$$\mathbb{E}[K_k(|s|)] = \sum_{T \in \binom{[n]}{k}} \mathbb{E} \left[ \prod_{i \in T} (-1)^{s_i} \right] = \begin{cases} 0 & k \text{ odd} \\ \sum_{T \in \binom{[n]}{k}} \lambda^{\text{shift}(T)} & k \text{ even} \end{cases}.$$

We now evaluate

$$\mathbb{E}[K_{2k}(|s|)] = \sum_{T \in \binom{[n]}{2k}} \lambda^{\text{shift}(T)} = \sum_{m=k}^{n-k} \left( \sum_{\substack{T \in \binom{[n]}{2k} \\ \text{shift}(T) = m}} 1 \right) \lambda^m$$

Hence to prove the lemma, it suffices to show the number of subsets  $T \in \binom{[n]}{2k}$  with  $\text{shift}(T) = m$  is  $\binom{m-1}{k-1} \binom{n-m}{k}$ . Let  $t_1 < t_2 < \dots < t_{2k}$  be the elements of  $T$ . We claim the desired subsets  $T$  are in bijection with a  $k$ -tuple  $(d_1, \dots, d_k)$  of positive integers summing to  $m$ , paired with an  $n - m$  letter word consisting of  $n - m - k$   $A$ 's and  $k$   $B$ 's. To construct the pair from a subset  $T$ , we can set  $d_i = t_{2i} - t_{2i-1}$  and the  $n - m$  letter word to be  $A^{t_1-1} C B A^{n-t_{2k}}$  where  $C = \bigcirc_{i=1}^{k-1} (B A^{t_{2i+1}-t_{2i}-1})$  ( $\bigcirc$  is concatenation). Since  $\text{shift}(T) = m$ , the  $d_i$  are positive integers summing to  $m$ , and the word can easily be verified to have  $n - m - k$   $A$ 's and  $k$   $B$ 's.

Now given a  $(d_1, \dots, d_k)$  and a word, we can construct a  $T$  with  $\text{shift}(T) = m$  as follows. The word will be of the form  $A^{a_1} B A^{a_2} B \dots A^{a_k} B A^{a_{k+1}}$  where each  $a_i \geq 0$ . We then set  $t_1 = a_1 + 1$ , and assign  $t_2, \dots, t_{2k}$  inductively as follows.

$$t_{2i} = t_{2i-1} + d_i$$

$$t_{2i+1} = t_{2i} + a_{i+1} + 1$$

Finally we set  $T = \{t_i\}_{i=1}^{2k}$ . It can then be verified all  $t_i \in [n]$  and  $\text{shift}(T) = m$ . In fact, one can check the two constructed maps are inverses of each other. Hence we have established the bijection and counting the number of such  $T$  is simply counting the number of  $k$ -tuples and word pairs, which by standard counting methods is  $\binom{m-1}{k-1} \binom{n-m}{k}$ . The desired result follows.  $\blacktriangleleft$

We are now ready to establish some upper bounds using the lemmas above. We first upper bound the weighted  $\ell_2$  distance between the sticky walk and binomial distribution by defining a suitable function and taking the Krawtchouk expansion.

► **Lemma 13.** *Let  $\mathbf{s} \sim S(n, \lambda)$  for  $\lambda < .16$  and define  $p(\ell) := \frac{\Pr_{\mathbf{s} \sim S}(|\mathbf{s}| = \ell)}{\binom{n}{\ell} 2^{-n}}$ . Then we have*

$$\mathbb{E}_{\mathbf{b} \sim \text{Bin}(n, 1/2)} [(p(\mathbf{b}) - 1)^2] \leq O(\lambda^2).$$

**Proof.** Let us write  $p(\ell) = \sum_{k=0}^n \hat{p}(k) K_k(\ell)$  where

$$\hat{p}(k) = \frac{1}{\binom{n}{k}} \mathbb{E}_{\mathbf{b} \sim \text{Bin}(n, 1/2)} [p(\mathbf{b}) K_k(\mathbf{b})] \quad (6)$$

from Proposition 8. From the definition, we can verify  $K_0(\ell) = 1$  for all  $\ell$ . Combining this fact with (6) implies that  $\hat{p}(0) = 1$  too. Hence,

$$\begin{aligned} \mathbb{E}_{\mathbf{b} \sim \text{Bin}(n, 1/2)} [(p(\mathbf{b}) - 1)^2] &= \mathbb{E}_{\mathbf{b} \sim \text{Bin}(n, 1/2)} \left[ \left( \sum_{k=1}^n \hat{p}(k) K_k(\mathbf{b}) \right)^2 \right] \\ &= \sum_{k=1}^n \hat{p}(k)^2 \binom{n}{k} \\ &= \sum_{k=1}^n \frac{1}{\binom{n}{k}} \mathbb{E}[K_k(|\mathbf{s}|)]^2 \end{aligned} \quad (7)$$

where only the diagonal terms of the square survive due to the orthogonality relations (2) and (3). Adding the  $k = 0$  term back in (7) will simply give the expression for  $\mathbb{E}[p(\mathbf{b})^2]$  (and will be stated as a subsequent corollary).

From Lemma 12 and the generating function relation  $(\frac{x}{1-x})^k = \sum_{m \geq k} \binom{m-1}{k-1} x^m$ ,

$$\mathbb{E}_{\mathbf{b} \sim \text{Bin}(n, 1/2)} [(p(\mathbf{b}) - 1)^2] = \sum_{1 \leq k \leq n/2} \frac{1}{\binom{n}{2k}} \left( \sum_{m=k}^{n-k} \binom{m-1}{k-1} \binom{n-m}{k} \lambda^m \right)^2 \quad (8)$$

$$\begin{aligned} &\leq \sum_{1 \leq k \leq n/2} \frac{\binom{n}{k}^2}{\binom{n}{2k}} \left( \sum_{m=k}^{n-k} \binom{m-1}{k-1} \lambda^m \right)^2 \\ &\leq \sum_{1 \leq k \leq n/2} \frac{\binom{n}{k}^2}{\binom{n}{2k}} \left( \frac{\lambda}{1-\lambda} \right)^{2k} \end{aligned} \quad (9)$$

With the following claim (whose proof will be deferred to the appendix) we can deduce a lower bound.

► **Claim 14.** For  $1 \leq k \leq n/2$ , we can bound  $\frac{\binom{n}{k}^2}{\binom{n}{2k}} \leq \frac{e^3 \sqrt{2}}{4\pi^2} \cdot 4^{2k}$ .

Hence by combining (9) and Claim 14, we conclude

$$\begin{aligned} \mathbb{E}_{\mathbf{b} \sim \text{Bin}(n, 1/2)} [(p(\mathbf{b}) - 1)^2] &\leq \frac{e^3 \sqrt{2}}{4\pi^2} \sum_{1 \leq k \leq n/2} \left( \frac{4\lambda}{1-\lambda} \right)^{2k} \\ &\leq \frac{4e^3 \sqrt{2}}{\pi^2} \frac{\lambda^2}{(1-5\lambda)(1+3\lambda)} \\ &< \left( \frac{\lambda}{0.16} \right)^2, \end{aligned}$$

which is a nontrivial  $O(\lambda^2)$  bound that is strictly less than 1. ◀

## 48:10 Pseudobinomiality of the Sticky Random Walk

Remembering our prior observation that the sum in Equation (7) is 1 less than  $\mathbb{E}[p(\mathbf{b})^2]$ , we immediately get the following corollary.

► **Corollary 15.** *Let  $\mathbf{s}, p$  be defined as in Lemma 13. We can then bound*

$$\mathbb{E}_{\mathbf{b} \sim \text{Bin}(n, 1/2)}[p(\mathbf{b})^2] = \sum_{k=0}^n \frac{1}{\binom{n}{k}} \mathbb{E}[K_k(|\mathbf{s}|)]^2 \leq 1 + O(\lambda^2).$$

Going back to proving the main result of the section, the brunt of the work was actually done in Lemma 13. We can now simply apply convexity to establish the desired TVD upper bound between the sticky and binomial distribution.

► **Theorem 16.** *Let  $\mathbf{s} \sim S(n, \lambda)$ . We can then bound the TVD between  $S(n, \lambda)$  and  $\text{Bin}(n, 1/2)$ ,*

$$\frac{1}{2} \sum_{\ell=0}^n \left| \Pr[|\mathbf{s}| = \ell] - \binom{n}{\ell} 2^{-n} \right| \leq O(\lambda).$$

**Proof.** By convexity, and then Lemma 13, we get

$$\sum_{\ell=0}^n \left| \Pr[|\mathbf{s}| = \ell] - \binom{n}{\ell} 2^{-n} \right| = \mathbb{E}_{\mathbf{b} \sim \text{Bin}(n, 1/2)}[|p(\mathbf{b}) - 1|] \leq \sqrt{\mathbb{E}_{\mathbf{b} \sim \text{Bin}(n, 1/2)}[(p(\mathbf{b}) - 1)^2]} \leq O(\lambda)$$

for  $\lambda < 0.16$ , and clearly the TVD is bounded by 1 for  $\lambda$  greater. ◀

### 4.2 Limitations to the Upper Bound Approach

Unfortunately, the weighted  $\ell_2$  distance studied in Lemma 13 blows up as  $\lambda$  approaches 1. Looking at the term in the sum of Equation (8) when  $k = m = (1/2 - \varepsilon)n$  for some  $\varepsilon > 0$  (will be specified later), and applying the bounds  $\left(\frac{n}{k}\right)^k \leq \binom{n}{k} \leq \left(\frac{n\varepsilon}{k}\right)^k$  yields

$$\begin{aligned} \sum_{1 \leq k \leq n/2} \frac{1}{\binom{n}{2k}} \left( \sum_{m=k}^{n-k} \binom{m-1}{k-1} \binom{n-m}{k} \lambda^m \right)^2 &\geq \frac{1}{\binom{n}{(1-2\varepsilon)n}} \left( \frac{(1/2 + \varepsilon)n}{(1/2 - \varepsilon)n} \right)^2 \lambda^{(1/2 - \varepsilon)n} \\ &\geq \left( \frac{n}{2\varepsilon n} \right)^{-1} \left( \frac{(1/2 + \varepsilon)n}{2\varepsilon n} \right)^2 \lambda^{n/2} \\ &\geq \left( \frac{\lambda^{1/2}}{(8\varepsilon)^{2\varepsilon}} \right)^n \end{aligned}$$

For  $\lambda \geq .94$  and  $\varepsilon = .017$ , we have  $\lambda^{1/2} > .969$  and  $(8\varepsilon)^{2\varepsilon} < .967$ . Thus

$$\mathbb{E}_{\mathbf{b} \sim \text{Bin}(n, 1/2)}[(p(\mathbf{b}) - 1)^2] > \left( \frac{.969}{.967} \right)^n$$

which grows exponentially in  $n$ . Consequently, in order to show an  $O(\lambda)$  bound for all  $\lambda < 1$ , an approach different from using the weighted  $\ell_2$  distance is required.

### 4.3 Showing the TVD Bound is Tight

Consider  $\mathbf{s} \sim S(n, \lambda)$  and  $\mathbf{N} \sim \mathcal{N}(0, 1)$ . Set  $\mathbf{Y}_i = (-1)^{\mathbf{s}_i}$  and let  $\mathbf{Y} = \sum_{i=1}^n (-1)^{\mathbf{s}_i}$  be the  $\pm 1$  variant of the sticky distribution. Similarly, let  $b_i \sim \text{Ber}(1/2)$  for  $1 \leq i \leq n$ . Set  $\mathbf{Z}_i = (-1)^{b_i}$  and let  $\mathbf{Z} = \sum_{i=1}^n \mathbf{Z}_i$  be the usual  $\pm 1$  unbiased random walk. By the central limit theorem, we already know  $\frac{\mathbf{Z}}{\sqrt{n}} \rightarrow \mathbf{N}$  in distribution as  $n \rightarrow \infty$ . We now state a similar result for  $\mathbf{Y}$ , and defer the proof to the appendix, as it requires lengthy calculation of the moments.

► **Lemma 17.** *As  $n \rightarrow \infty$ ,  $\mathbf{Y} \sqrt{\frac{1-\lambda}{(1+\lambda)n}} \rightarrow \mathcal{N}$  in distribution.*

With this lemma, we have a good understanding of  $\mathbf{Y}$ , and can show the tightness of the TVD bound. The suggestion to consider an event like  $|\mathbf{Y}| \leq O(\sqrt{n})$  was made by Salil Vadhan [13].

► **Theorem 18.** *For  $\mathbf{Y}$  and  $\mathbf{Z}$  defined above as the  $\pm 1$  version of the  $S(n, \lambda)$  walk and the  $n$ -step unbiased walk, respectively, we have*

$$|\Pr[|\mathbf{Z}| \leq \sqrt{n}] - \Pr[|\mathbf{Y}| \leq \sqrt{n}]| \geq \Omega(\lambda)$$

for  $\lambda < 1$ .

**Proof.** By Lemma 17, for  $\varepsilon < \int_{\sqrt{\frac{1-\lambda}{1+\lambda}}}^1 e^{-x^2} dx$ , there exists a constant  $N(\varepsilon)$  such that for  $n > N(\varepsilon)$ ,

$$\begin{aligned} |\Pr[|\mathbf{Z}| \leq \sqrt{n}] - \Pr[|\mathbf{Y}| \leq \sqrt{n}]| &= \left| \Pr\left[\frac{|\mathbf{Z}|}{\sqrt{n}} \leq 1\right] - \Pr\left[|\mathbf{Y}| \sqrt{\frac{1-\lambda}{(1+\lambda)n}} \leq \sqrt{\frac{1-\lambda}{1+\lambda}}\right] \right| \\ &\geq 2 \int_{\sqrt{\frac{1-\lambda}{1+\lambda}}}^1 e^{-x^2} dx - \varepsilon \\ &\geq \int_{\sqrt{\frac{1-\lambda}{1+\lambda}}}^1 e^{-x^2} dx \geq e^{-1} \left(1 - \sqrt{\frac{1-\lambda}{1+\lambda}}\right) \geq \frac{\lambda}{2e} \end{aligned}$$

where the last step follows from the easily verifiable inequality  $1 - \sqrt{\frac{1-x}{1+x}} \geq \frac{x}{2}$  for  $0 \leq x \leq 1$ . Hence we have demonstrated an event that gives an  $\Omega(\lambda)$  gap between the distributions of  $\mathbf{Y}$  and  $\mathbf{Z}$  for  $\lambda < 1$ . Since  $\mathbf{Y}$  and  $\mathbf{Z}$  are just shifted and dilated versions of the Hamming weight of  $S(n, \lambda)$  and  $\text{Bin}(n, 1/2)$ , respectively, we can deduce the TVD is  $\Theta(\lambda)$  due to Theorem 16. ◀

## 5 Parity and Majority of the Sticky Walk are Almost Uncorrelated

Following the spirit of how Ta-Shma [12] showed the bias of the parity of an expander walk sampler is exponentially small, we show some parity events of the sticky random walk are very close in probability to the corresponding probability under the binomial distribution. An interesting question to consider is whether more refined events, such as whether the output is even and above expectation is close to  $\frac{1}{4}$ . We show such results for the sticky distribution. Note that from Theorem 16 we know the event probability in the sticky distribution will be within  $O(\lambda)$  of  $\frac{1}{4}$ , but in this section, we derive an  $o(1)$  error bound.

Let  $\mathbf{s} \sim S(n, \lambda)$ . We first demonstrate that similar to the binomial distribution,  $\Pr[|\mathbf{s}| \text{ even}]$  and  $\Pr[|\mathbf{s}| \geq n/2]$  are close to  $1/2$ . For the parity, we straightforwardly calculate

$$\Pr[|\mathbf{s}| \text{ even}] - \Pr[|\mathbf{s}| \text{ odd}] = \sum_{t=0}^n (-1)^t \Pr[|\mathbf{s}| = t] = \mathbb{E}[(-1)^{|\mathbf{s}|}] = \lambda^{n/2} \cdot \mathbf{1}_{n \text{ even}} \quad (10)$$

using Lemma 11. Hence  $|\Pr[|\mathbf{s}| \text{ even}] - \frac{1}{2}| \leq \frac{\lambda^{n/2}}{2}$ . Interestingly enough, this  $\lambda^{n/2}$  bias is also present in the parity bias calculation done by Ta-Shma for the expander walk in [12] (Section 3.2). Furthermore, this calculation (combined with our work in Section 7) shows that this error term cannot be improved to something smaller like  $\lambda^n$ .

## 48:12 Pseudobinomiality of the Sticky Random Walk

Let  $a$  be a string and let  $\bar{a}$  be the string formed by toggling every bit of  $a$ . Notice that  $\Pr[\mathbf{s} = a] = \Pr[\mathbf{s} = \bar{a}]$  since the number of runs are the same in both strings. Summing over all strings of Hamming weight  $t$ , we get the symmetric relation  $\Pr[|\mathbf{s}| = t] = \Pr[|\mathbf{s}| = n - t]$ , which directly implies  $\Pr[|\mathbf{s}| > n/2] = \Pr[|\mathbf{s}| < n/2]$ . In the case  $n$  is odd, we immediately have  $\Pr[|\mathbf{s}| > n/2] = 1/2$ . When  $n$  is even, we have

$$\Pr[|\mathbf{s}| > n/2] = \frac{1}{2} - \frac{\Pr[|\mathbf{s}| = n/2]}{2}. \quad (11)$$

We now prove a lemma that will help us bound  $\Pr[|\mathbf{s}| = n/2]$  in the sticky distribution.

► **Theorem 19.** *For  $\mathbf{s} \sim S(n, \lambda)$ ,  $\lambda < 1/5$ , and  $\mathbf{b} \sim \text{Bin}(n, 1/2)$ , we can bound*

$$\Pr[|\mathbf{s}| = \ell] \lesssim \sqrt{(1 + O(\lambda^2)) \Pr[\mathbf{b} = \ell]}.$$

**Proof.** To estimate this probability, we can use Lemma 10 to find

$$\Pr[|\mathbf{s}| = \ell] = \frac{1}{2^n} \sum_{k=0}^n K_\ell(k) \mathbb{E}[K_k(|\mathbf{s}|)] \leq \frac{1}{2^n} \sqrt{\sum_{k=0}^n \binom{n}{k} K_\ell(k)^2} \sqrt{\sum_{k=0}^n \frac{\mathbb{E}[K_k(|\mathbf{s}|)]^2}{\binom{n}{k}}} \quad (12)$$

by Cauchy-Schwarz. Notice by Corollary 15,

$$\sqrt{\sum_{k=0}^n \frac{\mathbb{E}[K_k(|\mathbf{s}|)]^2}{\binom{n}{k}}} \lesssim \sqrt{1 + O(\lambda^2)}. \quad (13)$$

Finally, by using Equation (3) we get

$$\sqrt{\sum_{k=0}^n \binom{n}{k} K_\ell(k)^2} = \sqrt{\binom{n}{\ell} 2^n} \quad (14)$$

Combining (12), (13), and (14) yields

$$\Pr[|\mathbf{s}| = \ell] \lesssim \frac{1}{2^n} \sqrt{\binom{n}{\ell} 2^n (1 + O(\lambda^2))} = \sqrt{(1 + O(\lambda^2)) \Pr[\mathbf{b} = \ell]}$$

as desired. ◀

Going back to (11), Theorem 19 with  $\ell = n/2$  now allows us to deduce

$$\Pr[|\mathbf{s}| > n/2] = \frac{1}{2} + O(n^{-1/4} \sqrt{1 + \lambda^2}).$$

Thus, we have shown that  $\Pr[|\mathbf{s}| \text{ even}]$  and  $\Pr[|\mathbf{s}| > n/2]$  are near  $1/2$ , which are properties shared by purely random strings. However, we can go further and show a more refined equidistribution result. One can calculate for  $\mathbf{b} \sim \text{Bin}(n, 1/2)$  that  $\Pr[(|\mathbf{b}| \text{ odd}) \wedge (|\mathbf{b}| > n/2)] = \frac{1}{4} + O(n^{-1/2})$ . We show an analogous result for the sticky walk, albeit with a worse  $o(1)$  error term.

► **Theorem 20.** *Let  $\mathbf{s} \sim S(n, \lambda)$ . For  $a, b \in \{0, 1\}$ , denote the event*

$$E_{ab} = (|\mathbf{s}| \equiv a \pmod{2}) \wedge ((-1)^b |\mathbf{s}| > (-1)^b n/2)$$

and  $p_{ab} = \Pr[E_{ab}]$ . Then  $p_{ab} = \frac{1}{4} + O(n^{-1/4} \sqrt{1 + \lambda^2})$  for all  $a, b$ .

**Proof.** We show the result for  $p_{00}$  (symmetric arguments work for any  $p_{ab}$ ). We split into cases when  $n$  is even and odd. When  $n$  is even, notice that due to the symmetry  $\Pr[|s| = t] = \Pr[|s| = n - t]$ ,  $p_{00} = p_{01}$  and  $p_{10} = p_{11}$ . Hence from (10) we have  $\lambda^{n/2} \geq |p_{10} + p_{11} - p_{01} - p_{00}| = 2|p_{10} - p_{00}|$ . From (11) and Theorem 19, we have  $p_{10} + p_{00} = \frac{1}{2} + O(n^{-1/4}\sqrt{1+\lambda^2})$ , and so we can conclude  $p_{00} = \frac{1}{4} + O(n^{-1/4}\sqrt{1+\lambda^2})$  as desired.

When  $n$  is odd, a little more effort is required to exploit symmetry. Let  $S$  be the set of  $n$ -bit strings having a run of size  $\geq 2$  which doesn't contain the  $n$ th bit, and let  $T$  be the set of  $n$ -bit strings having a run of size  $\geq 2$  which doesn't contain the 1st bit. Consider the map  $g : S \rightarrow T$  defined by toggling the last bit of the first run of size  $\geq 2$ . It can be easily seen that  $g$  is a bijection. Note that for any  $s \in S$ ,  $s$  and  $g(s)$  have the same probability under the sticky walk distribution (the map preserves the number of runs in the string). Furthermore,  $g$  changes the parity of the input string. The image of all strings in  $S$  with even parity and Hamming weight  $> n/2$  under  $g$  will be all strings in  $T$  with odd parity and Hamming weight  $> n/2$ , along with some rogue strings in  $T$  with Hamming weight  $(n-1)/2$ . If we isolate these rogue cases, we can deduce, due to the fact  $g$  preserves probability, that

$$\begin{aligned} \Pr[(s \in S) \wedge E_{00}] &= \Pr[(s \in T) \wedge E_{10}] + \Pr\left[(s \in S) \wedge \left(|g(s)| = \frac{n-1}{2}\right) \wedge E_{00}\right] \\ &\leq \Pr[(s \in T) \wedge E_{10}] + O(n^{-1/4}\sqrt{1+\lambda^2}) \end{aligned} \quad (15)$$

by Theorem 19 with  $\ell = \frac{n-1}{2}$ . Notice any  $n$ -bit string has probability measure at most  $\frac{1}{2} \left(\frac{1+\lambda}{2}\right)^{n-1}$  in the sticky distribution. Furthermore, there are only  $O(n)$  strings not contained in  $S$  (such strings must be of form  $0^k A$  or  $1^k A$  where  $A$  is a binary string that alternates 0s and 1s). Therefore we can bound

$$|\Pr[(s \in S) \wedge E_{00}] - \Pr[E_{00}]| \leq \Pr[s \notin S] \lesssim n \left(\frac{1+\lambda}{2}\right)^n. \quad (16)$$

An analogous argument with set  $T$  gives

$$|\Pr[(s \in T) \wedge E_{01}] - \Pr[E_{01}]| \lesssim n \left(\frac{1+\lambda}{2}\right)^n. \quad (17)$$

Combining (15), (16), and (17) using an application of the triangle inequality allows us to bound

$$\begin{aligned} |p_{00} - p_{01}| &\leq |\Pr[E_{00}] - \Pr[(s \in S) \wedge E_{00}]| + |\Pr[(s \in S) \wedge E_{00}] - \Pr[(s \in T) \wedge E_{01}]| \\ &\quad + |\Pr[(s \in T) \wedge E_{01}] - \Pr[E_{01}]| \\ &\lesssim n^{-1/4}\sqrt{1+\lambda^2}. \end{aligned}$$

Since  $p_{00} + p_{01} = 1/2$  for  $n$  odd, we can deduce  $p_{00} = \frac{1}{4} + O(n^{-1/4}\sqrt{1+\lambda^2})$ . ◀

## 6 Sticky Walk Modulo $m$ is Close to Uniform

In [12], Ta-Shma provides an argument on how the parity of the expander walk is unbiased. In this section we use his method to show the sticky distribution modulo  $m$  is approximately uniform for any fixed  $m$  and large  $n$ .

► **Lemma 21.** *Fix  $\lambda < 1$  and  $m \geq 2$ . For any nontrivial  $m$ 'th root of unity  $\zeta \neq 1$  and  $s \sim S(n, \lambda)$ , we have  $|\mathbb{E}[\zeta^{|s|}]| \leq \exp(-\Omega(n))$ .*

## 48:14 Pseudobinomiality of the Sticky Random Walk

**Proof.** One can verify  $E[\zeta^{|s|}] = \mathbf{1}^\top M^n \mathbf{1}$  where  $\mathbf{1}$  is the unit vector with all coordinates equal and

$$M = \begin{pmatrix} \frac{1+\lambda}{2} & \frac{1-\lambda}{2} \\ \frac{1-\lambda}{2} & \frac{1+\lambda}{2} \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & \zeta \end{pmatrix} = \begin{pmatrix} \frac{1+\lambda}{2} & \frac{1-\lambda}{2}\zeta \\ \frac{1-\lambda}{2} & \frac{1+\lambda}{2}\zeta \end{pmatrix}.$$

Let  $\lambda_1, \lambda_2$  be the eigenvalues of  $M$ . If  $M$  is diagonalizable, we know  $\mathbf{1}^\top M^n \mathbf{1} = c_1 \lambda_1^n + c_2 \lambda_2^n$ , and if  $M$  is not diagonalizable we can write  $\mathbf{1}^\top M^n \mathbf{1} = (c_1 + nc_2) \lambda_1^n$  for constants  $c_1$  and  $c_2$  (this can be seen by writing  $M$  in Jordan normal form). Thus in either case, it suffices to show the norm of both eigenvalues are strictly less than 1 to prove the lemma. From Gershgorin's circle theorem, we know the norms of the eigenvalues are at most  $\frac{1+\lambda}{2} + \frac{1-\lambda}{2} = 1$ .

Assume one eigenvalue has norm 1. Since the product of the eigenvalues is  $\det(M) = \lambda\zeta$ , we deduce the eigenvalues are  $\lambda z, \zeta/z$  for some  $|z| = 1$ . Since  $\lambda z + \zeta/z = \text{Tr}(M) = \frac{1+\lambda}{2}(1+\zeta)$ , we particularly know  $\lambda z + \zeta/z$  and  $1 + \zeta$  have the same argument angle.

If  $\zeta \neq -1$ , we must have the quotient of these two complex numbers be real. Consequently

$$0 = \frac{\lambda z + \zeta/z}{1 + \zeta} - \overline{\left( \frac{\lambda z + \zeta/z}{1 + \zeta} \right)} = \frac{\lambda z + \zeta/z}{1 + \zeta} - \frac{\lambda/z + z/\zeta}{1 + 1/\zeta} = \frac{(\lambda - 1)(z - \zeta/z)}{1 + \zeta}.$$

Since  $\lambda \neq 1$ , we have  $z = \zeta/z$  and so the eigenvalues are  $\lambda z, z$ . The trace is  $\frac{1}{2}(1 + \lambda)(1 + \zeta) = \frac{1}{2}(1 + \lambda)(1 + z^2)$ , so

$$\lambda z + z = \frac{1}{2}(1 + \lambda)(1 + z^2) \iff z = \frac{1 + z^2}{2} \iff z = 1.$$

However  $\zeta = z^2 = 1$ , a contradiction.

If  $\zeta = -1$ , then  $\lambda z, -1/z$  are the eigenvalues. The trace is now zero, so  $\lambda z = 1/z$ . Since  $\lambda$  is a nonnegative real, taking norms of both sides implies  $\lambda = 1$ , a contradiction. Hence the eigenvalues are indeed less than 1.  $\blacktriangleleft$

Lemma 21 allows us to employ Lemma 4.2 in [9] (since all characters of  $\mathbb{Z}/m\mathbb{Z}$  are  $\chi(n) = \zeta^n$  for some  $m$ 'th root of unity  $\zeta$ ) to deduce the following.

► **Theorem 22.** *Let  $U_m$  be the uniform distribution over  $[m]$ , and let  $S_m(n, \lambda)$  be the distribution of  $|s| \pmod{m}$  over  $[m]$ , where  $s \sim S(n, \lambda)$ . The  $\ell_1$  distance between these two distributions can then be bounded by*

$$\|U_m - S_m(n, \lambda)\|_1 \leq \exp(-\Omega(n))$$

where the implied constants only depend on  $m$ .

## 7 Relationship Between the Sticky Walk and Expander Walk

Define a  $\lambda$ -expander<sup>1</sup> to be a regular graph  $G$  such that all eigenvalues  $\lambda_1 \leq \dots \leq \lambda_m$  of the normalized adjacency matrix satisfy  $|\lambda_i| \leq \lambda$  for  $1 \leq i \leq m - 1$ . One of the main motivations to study the sticky random walk is because of its perceived close relationship with the distributions generated by expander walks. In particular, if  $(v_1, \dots, v_n)$  is a  $n$ -step

<sup>1</sup> Unlike standard definitions, we do not restrict the degree of each vertex to be constant. The purpose of this section is to show any analysis of expander walks cannot give better bounds than the sticky walk. Since analyses on expander walks are based off of the spectral properties of the graph rather than its degree, restriction of the degrees are unnecessary for our purposes.

expander walk on a  $\lambda$ -expander  $G = (V, E)$ , and  $W \subset V$  with  $|W| = |V|/2$ , we believe the distribution  $(\mathbf{1}_{v_1 \in W}, \dots, \mathbf{1}_{v_n \in W})$  is linked to the sticky walk  $S(n, \lambda)$ . In this section, we demonstrate one direction of this relationship by explicitly constructing a  $\lambda$ -expander and vertex subset  $W$  of half the size such that the distribution of  $(\mathbf{1}_{v_1 \in W}, \dots, \mathbf{1}_{v_n \in W})$  is precisely  $S(n, \lambda)$ .

► **Theorem 23.** *There exists  $\lambda$ -expander  $G = (V, E)$  and vertex set  $W \subset V$  with  $|W| = |V|/2$  such that if  $(v_1, \dots, v_n)$  is a random walk on  $G$ , the random  $n$ -bit string  $(\mathbf{1}_{v_1 \in W}, \dots, \mathbf{1}_{v_n \in W}) \sim S(n, \lambda)$ .*

**Proof.** For simplicity, assume  $\lambda$  is rational, and take integer  $m$  such that  $(\frac{1-\lambda}{1+\lambda})m$  is an integer. Let  $C_0$  and  $C_1$  be two  $m$ -cliques with an added self-loop at each vertex. Construct the graph  $G$  by taking each vertex in  $C_0$  and connect it to  $(\frac{1-\lambda}{1+\lambda})m$  vertices in  $C_1$  in a cyclic uniform manner to make this graph  $\frac{2m}{1+\lambda}$ -regular (i.e. if we arbitrarily number the vertices in  $C_0$  and  $C_1$  from 1 to  $m$ , just connect vertex  $i$  in  $C_0$  with the  $C_1$  vertices  $i, i+1, \dots, i + (\frac{1-\lambda}{1+\lambda})m - 1 \pmod{m}$ ). Note upon setting  $W = C_1$ , a random walk on this expander resembles the sticky random walk, because at each step,  $m$  edges will keep us in the same clique, and  $(\frac{1-\lambda}{1+\lambda})m$  will move us to the other, which gives us a  $\frac{1+\lambda}{2}$  chance of staying in the same clique and  $\frac{1-\lambda}{2}$  chance of moving to the other. Our aim is to now show the eigenvalues of the normalized Laplacian,  $\bar{L}$ , are within  $\lambda$  of 1.

To do so, we will first show all eigenvalues of  $\bar{L}$  are  $\leq 1 + \lambda$ , and then demonstrate  $\bar{L}$  has second smallest eigenvalue  $1 - \lambda$ . Note that the second smallest eigenvalue is  $\min_{v \perp \mathbf{1}, \|v\|_2=1} v^\top \bar{L} v$ , and the largest eigenvalue is  $w^\top \bar{L} w$ , where  $w$  is the corresponding normalized eigenvector of this largest eigenvalue. Since  $\mathbf{1} \perp w$ , it suffices to show that for  $v \in \mathbb{R}^{2m}$  with  $\|v\|_2 = 1$  and  $v \perp \mathbf{1}$ , we have  $1 - \lambda \leq v^\top \bar{L} v \leq 1 + \lambda$ . WLOG assume the first  $m$  rows/columns are the vertices in  $C_0$  and the latter  $m$  are the vertices in  $C_1$ . Let  $t = \frac{1-\lambda}{1+\lambda}m$  and let  $v = (a_1, \dots, a_m, b_1, \dots, b_m)$ . Recall from the quadratic form version of the Laplacian and by construction of  $G$  that

$$(m+t)v^\top \bar{L} v = \sum_{1 \leq i < j \leq m} (a_i - a_j)^2 + \sum_{1 \leq i < j \leq m} (b_i - b_j)^2 + \sum_{\substack{1 \leq i \leq m \\ 0 \leq j < t}} (a_i - b_{i+j})^2$$

where indices are taken modulo  $m$ . Since  $v \perp \mathbf{1}$ , we have

$$\begin{aligned} 0 &= \left( \sum_{i=1}^m a_i + \sum_{i=1}^m b_i \right)^2 \\ &= 2m \left( \sum_{i=1}^m a_i^2 + \sum_{i=1}^m b_i^2 \right) - \sum_{1 \leq i < j \leq m} (a_i - a_j)^2 \\ &\quad - \sum_{1 \leq i < j \leq m} (b_i - b_j)^2 - \sum_{\substack{1 \leq i \leq m \\ 0 \leq j < m}} (a_i - b_{i+j})^2 \\ &= 2m\|v\|_2^2 - (m+t)v^\top \bar{L} v - \sum_{\substack{1 \leq i \leq m \\ t \leq j < m}} (a_i - b_{i+j})^2 \\ v^\top \bar{L} v &= \frac{2m}{m+t} - \frac{1}{m+t} \sum_{\substack{1 \leq i \leq m \\ t \leq j < m}} (a_i - b_{i+j})^2 \end{aligned} \tag{18}$$

For one side, we can trivially upper bound (18)

$$v^\top \bar{L} v \leq \frac{2m}{m+t} = 1 + \lambda.$$

For the lower bound of (18), we can use Cauchy-Schwarz to get

$$\begin{aligned} v^\top \bar{L} v &\geq \frac{2m}{m+t} - \frac{2}{m+t} \sum_{\substack{1 \leq i \leq m \\ t \leq j < m}} (a_i^2 + b_{i+j}^2) \\ &= \frac{2m}{m+t} - \frac{2m-2t}{m+t} \|v\|_2^2 \\ &= \frac{2m}{m+t} \\ &= 1 - \lambda. \end{aligned}$$

Hence we can conclude the nonzero eigenvalues of  $\bar{L}$  are within  $\lambda$  of 1. Thus,  $G$  is indeed a  $\lambda$ -expander that models a  $S(n, \lambda)$  sticky walk.  $\blacktriangleleft$

Note that this construction gives a family of  $\lambda$ -expanders: one for each  $m$  where  $\left(\frac{1-\lambda}{1+\lambda}\right)m$  is an integer. In order to extend the above theorem to degree-bounded expanders, we believe replacing the cliques  $C_0$  and  $C_1$  with degree  $d$  expanders, and adding a random bi-regular bipartite graph with degree  $\left(\frac{1-\lambda}{1+\lambda}\right)d$  between them will suffice, but we have not verified this.

---

## A

 Deferred Proofs

▷ **Claim 14.** For  $1 \leq k \leq n/2$ , we can bound  $\frac{\binom{n}{k}^2}{\binom{n}{2k}} \leq \frac{e^3 \sqrt{2}}{4\pi^2} \cdot 4^{2k}$ .

**Proof.** We can use Stirling's approximation  $\sqrt{2\pi} \left(\frac{n}{e}\right)^n \sqrt{n} \leq n! \leq e \left(\frac{n}{e}\right)^n \sqrt{n}$  to bound

$$\begin{aligned}
 \frac{\binom{n}{k}^2}{\binom{n}{2k}} &= \frac{n!(2k)!(n-2k)!}{k!^2(n-k)!^2} \\
 &\leq \frac{e^3}{4\pi^2} \cdot \frac{n^n (2k)^{2k} (n-2k)^{n-2k}}{k^{2k} (n-k)^{2n-2k}} \sqrt{\frac{2n(n-2k)}{k(n-k)^2}} \\
 &\leq \frac{e^3}{4\pi^2} \cdot 2^{2k} \left(\frac{n}{n-k}\right)^n \left(\frac{n-2k}{n-k}\right)^{n-2k} \sqrt{\frac{2}{k}} \\
 &\leq \frac{e^3 \sqrt{2}}{4\pi^2} \left(\frac{2n}{n-k}\right)^{2k} \\
 &\leq \frac{e^3 \sqrt{2}}{4\pi^2} \cdot 4^{2k}
 \end{aligned}
 \quad \triangleleft$$

► **Lemma 17.** As  $n \rightarrow \infty$ ,  $\mathbf{Y} \sqrt{\frac{1-\lambda}{(1+\lambda)n}} \rightarrow \mathbf{N}$  in distribution.

**Proof.** The idea is to use the method of moments (see Theorem 8.6 of [6]), which states the lemma can be deduced if all moments of  $\mathbf{Y}$  approach the moments of  $\mathbf{N}$  as  $n \rightarrow \infty$ . The odd moments of the Gaussian distribution is zero, and the  $2k$ 'th moment is  $(2k-1)!! := \frac{(2k)!}{2^k k!}$  for all  $k \geq 1$  (see [8]). Clearly  $\mathbb{E} \left[ \left( \mathbf{Y} \sqrt{\frac{1-\lambda}{(1+\lambda)n}} \right)^{2k+1} \right] = 0$  by the symmetry of  $\mathbf{Y}$ .

It now remains to show that  $\mathbb{E} \left[ \left( \mathbf{Y} \sqrt{\frac{1-\lambda}{(1+\lambda)n}} \right)^{2k} \right] \rightarrow (2k-1)!!$  as  $n \rightarrow \infty$ . Let  $P_k$  denote the set of unordered partitions of  $k$  into positive parts, where we express each partition as a multiset of positive integers  $A = [a_1, \dots, a_m]$  where  $\sum_{i=1}^m a_i = k$ . We define  $g([a_1, \dots, a_m]) = \frac{(\sum_{i=1}^m a_i)!}{\prod_{i=1}^m a_i!}$ . By expanding  $(\sum_{i=1}^n \mathbf{Y}_i)^{2k}$ , collecting terms with the same multiset of degrees, and taking exponents modulo 2,

$$\begin{aligned}
 \mathbb{E}[\mathbf{Y}^{2k}] &= \mathbb{E} \left[ \left( \sum_{i=1}^n \mathbf{Y}_i \right)^{2k} \right] = \sum_{P \in P_{2k}} g(P) \mathbb{E} \left[ \sum_{T \in \binom{[n]}{P}} \prod_{i=1}^{|P|} \mathbf{Y}_{t_i}^{p_i} \right] \\
 &= \sum_{P \in P_{2k}} g(P) \mathbb{E} \left[ \sum_{T \in \binom{[n]}{P}} \prod_{i: 2 \nmid p_i} \mathbf{Y}_{t_i} \right]
 \end{aligned}
 \quad (19)$$

where  $P = [p_1, \dots, p_{|P|}]$  and  $T = \{t_1, \dots, t_{|P|}\}$ . Now let  $P_o$  and  $P_e$  be the multiset containing all odd and even elements of  $P$  (with multiplicity), respectively. Define  $h([a_1, \dots, a_m])$  to

## 48:18 Pseudobinomiality of the Sticky Random Walk

be the number of ways to permute  $(a_1, \dots, a_n)$  (e.g.  $g([1, 2, 2, 6]) = 12$  since there are 12 ways of permuting  $(1, 2, 2, 6)$ ,  $g([2, 2, 2]) = 1$ , and  $g([1, 4, 5, 6]) = 24$ ). By Equation 5 and Lemma 12, we have

$$\mathbb{E} \left[ \sum_{T \in \binom{[n]}{|P_o|}} \prod_{i \in T} \mathbf{Y}_i \right] = \mathbb{E}[K_{|P_o|}(|\mathbf{s}|)] = \sum_{m=|P_o|/2}^{n-|P_o|/2} \binom{m-1}{|P_o|/2-1} \binom{n-m}{|P_o|/2} \lambda^m.$$

With this, we can rewrite

$$\begin{aligned} \mathbb{E} \left[ \sum_{T \in \binom{[n]}{|P|}} \prod_{i \in T} \mathbf{Y}_{t_i} \right] &= h(P_e) \binom{n-|P_o|}{|P_e|} \mathbb{E} \left[ \sum_{T \in \binom{[n]}{|P_o|}} \prod_{i \in T} \mathbf{Y}_i \right] \\ &= h(P_e) \binom{n-|P_o|}{|P_e|} \sum_{m=|P_o|/2}^{n-|P_o|/2} \binom{m-1}{|P_o|/2-1} \binom{n-m}{|P_o|/2} \lambda^m \\ &\sim h(P_e) \frac{n^{|P_e|}}{(|P_e|)!} \sum_{m=|P_o|/2}^{n-|P_o|/2} \binom{m-1}{|P_o|/2-1} \frac{n^{|P_o|/2}}{(|P_o|/2)!} \lambda^m \\ &= n^{|P|-|P_o|/2} \cdot \frac{h(P_e)}{(|P_o|/2)! (|P_e|)!} \sum_{m=|P_o|/2}^{n-|P_o|/2} \binom{m-1}{|P_o|/2-1} \lambda^m \end{aligned} \quad (20)$$

and so by combining (19) and (20), we have

$$\mathbb{E}[Y^{2k}] \sim \sum_{P \in P_{2k}} n^{|P|-|P_o|/2} \cdot \frac{g(P)h(P_e)}{(|P_o|/2)! (|P_e|)!} \sum_{m=|P_o|/2}^{n-|P_o|/2} \binom{m-1}{|P_o|/2-1} \lambda^m. \quad (21)$$

We just have to look at the leading term of this sum, which is when  $|P| - |P_o|/2$  is maximized (since  $|P_{2k}|$ ,  $g(P)$ , and  $h(P_e)$  don't depend on  $n$ ). Note

$$|P| - \frac{|P_o|}{2} = (|P_o| + |P_e|) - \frac{|P_o|}{2} = \frac{|P_o| + 2|P_e|}{2} \leq \frac{\sum_{p \in P_o} p + \sum_{p \in P_e} p}{2} = k.$$

Hence the leading terms are when  $|P| - |P_o|/2 = k$ , and these terms correspond to when all elements of  $P$  are 1 or 2. In particular, the leading terms correspond to the multisets  $P$  with  $2r$  1's and  $k-r$  2's for  $0 \leq r \leq k$ . In these cases, we can calculate  $|P| = k+r$ ,  $|P_o| = 2r$ ,  $h(P_e) = 1$  and  $g(P) = \frac{(2k)!}{2^{k-r}}$ . Hence from (21) we get

$$\begin{aligned} \mathbb{E}[Y^{2k}] &\sim \sum_{r=0}^k \frac{(2k)!}{2^{k-r} r! (k-r)!} \left( \sum_{m=r}^{n-r} \binom{m-1}{r-1} \lambda^m \right) n^k \\ &= (2k-1)!! \sum_{r=0}^k \binom{k}{r} 2^r \left( \sum_{m=r}^{n-r} \binom{m-1}{r-1} \lambda^m \right) n^k. \end{aligned}$$

Consequently, we have the  $2k$ 'th moment of  $\mathbf{Y} \sqrt{\frac{1-\lambda}{(1+\lambda)n}}$  is

$$\sim (2k-1)!! \left( \frac{1-\lambda}{1+\lambda} \right)^k \sum_{r=0}^k \binom{k}{r} 2^r \left( \sum_{m=r}^{n-r} \binom{m-1}{r-1} \lambda^m \right)$$

Taking  $n \rightarrow \infty$  and evaluating the series with the well-known generating function identity  $(\frac{x}{1-x})^r = \sum_{m \geq r} \binom{m-1}{r-1} x^m$ , we get that the  $2k$ 'th moment approaches

$$\begin{aligned}
 (2k-1)!! \left( \frac{1-\lambda}{1+\lambda} \right)^k \sum_{r=0}^k \binom{k}{r} 2^r \left( \sum_{m=r}^{\infty} \binom{m-1}{r-1} \lambda^m \right) \\
 &= (2k-1)!! \left( \frac{1-\lambda}{1+\lambda} \right)^k \sum_{r=0}^k \binom{k}{r} \left( \frac{2\lambda}{1-\lambda} \right)^r \\
 &= (2k-1)!! \left( \frac{1-\lambda}{1+\lambda} \right)^k \left( 1 + \frac{2\lambda}{1-\lambda} \right)^k \\
 &= (2k-1)!! .
 \end{aligned}$$

Hence by the method of moments  $\mathbf{Y}_{\sqrt{\frac{1-\lambda}{(1+\lambda)n}}} \rightarrow \mathbf{N}$  in distribution as  $n \rightarrow \infty$ . ◀

# Robust Quantum Entanglement at (Nearly) Room Temperature

## Abstract

We formulate an average-case analog of the NLTS conjecture of Freedman and Hastings (QIC 2014) by asking whether there exist topologically ordered systems with corresponding local Hamiltonians for which the thermal Gibbs state for constant temperature cannot even be approximated by shallow quantum circuits. We then prove this conjecture for nearly optimal parameters: we construct a quantum error correcting code whose corresponding (log) local Hamiltonian has the following property: for nearly constant temperature (temperature decays as  $1/\log^2 \log(n)$ ) the thermal Gibbs state of that Hamiltonian cannot be approximated by any circuit of depth less than  $\log(n)$ , and it is highly entangled in a well-defined way. This implies that appropriately chosen local Hamiltonians can give rise to ground-state long-range entanglement which can survive without active error correction at temperatures which are nearly independent of the system size: thereby improving exponentially upon previously known bounds.

## 1 General

In order to perform universal quantum computation, one should at the very least be able to store quantum states for long periods of time. While the Fault Tolerance theorem [1] makes this possible using active error correction, in parallel, and in part due to the limitations of the FT theorem (see e.g. [4]) a huge research effort was devoted to finding quantum systems that can retain quantum information passively - namely a self-correcting quantum memory.

Self-correcting quantum memories are often referred to as topologically-ordered systems (or TQO) which is a phase of matter that exhibits long-range entanglement at 0 temperature. Since 0 temperature states are essentially theoretical objects that one does not expect to encounter in the lab, the race was on to find TQO systems whose long-range entanglement can survive at very high temperatures - ideally at a constant temperature  $T > 0$  that is independent of the system size.

In recent years there has been progress in ruling out such robustness for low-dimensional systems like the 2-D and 3-D Toric Code, but there has been an indication that perhaps in 4 dimensions and above, robustness is more likely (see Section 2.1.2 for a summary of these results). Intriguingly, it seems that quantum mechanics does not fundamentally limit the ability to store quantum states for long times, at least for high-dimensional systems. Despite

Leibniz International Proceedings in Informatics

LIPICs Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

that there remains today a large gap between our physical intuition and our ability to provide formal proofs on the existence of robust systems. Hence the problem of establishing the existence of robust TQO systems, even for high dimensions is wide open.

## 2 Topological Quantum Order (TQO)

TQO is a phase of matter (i.e. in addition to the traditional gas, liquid, and solid states) defined as the zero eigenspace of a local Hamiltonian which is “robust” in the sense that there can be no transition between orthogonal zero eigenstate without a phase transition (See survey of TQO in [19]). Formally one says that a system is  $\varepsilon$ -TQO if any sufficiently local observable  $O$  is unable to discern orthogonal states of the groundspace - i.e. there exists some  $z \neq 0$  such that

$$\|POP - zP\| \leq \varepsilon$$

where  $P$  is the projection onto the groundspace.

In the language of quantum computing, TQO is mostly synonymous with quantum error correcting codes, and specifically topological quantum codes - these are  $\varepsilon$ -TQO systems with  $\varepsilon = 0$ . Under error-correction terminology the TQO property of robustness of ground-state degeneracy is the quantum error-correcting minimal distance: i.e. the system can retain its logical encoded state in the presence of sufficiently small errors.

Thus, TQO systems have the promise that at zero temperature, their entanglement can passively sustain itself (i.e. without active error-correction) as a form of self-correcting quantum memory. It is this stability that brought forth the immensely influential paradigm of the topological quantum computer by Kitaev [14, 8], and even initiated large-scale engineering efforts in trying to build such a set-up [9].

However, since a physicist attempting to prepare a TQO state in a lab can only expect to encounter a Gibbs state (i.e. a thermal state) of the Hamiltonian governing the TQO for some low temperature, then for TQO to serve as a self-correcting quantum memory a necessary property for such a system is that it retains its long-range entanglement at some non-zero temperature  $T > 0$  that is independent of the size of the system.

A natural treatment of robustness of TQO systems can be made using quantum circuit lower bounds, a form of analysis initially considered in [11]. Under TQO terminology, topologically ordered states *cannot* be generated from a tensor product state using a shallow circuit, whereas a state is said to be “trivial” if it *can* be generated from product states by shallow circuits - namely it is nearly equivalent to a product state in its lack of quantum entanglement. With this terminology in mind we consider the following conjecture:

► **Conjecture 1** (Robust Circuit Depth for Topologically Ordered Systems). *There exists a number  $\beta > 0$  and a family of topologically-ordered systems (local Hamiltonians)  $\{H_n\}_n$  on  $n$  qubits such that for all  $\gamma \geq \beta$  we have: Any quantum circuit  $U$  that approximates the thermal Gibbs state  $e^{-\gamma H}$  to vanishing trace distance has depth  $\Omega(\log(n))$ .*

In words: the conjecture posits the existence of a TQO system (say, a quantum error-correcting code) for which one can show a circuit lower bound for the thermal state for all  $T$  from 0 (i.e. the ground-state) up to some constant temperature. Such a system exhibits “robustness” in the sense that the circuit lower bound for approximating its Gibbs state does not collapse when temperature is increased, with the logarithmic bound potentially allowing the coupling of *every* pair of qubits in the system, using a locally-defined quantum circuit.

Similar variants of this conjecture have been studied in physics literature: for example, in [20] Yoshida provides a negative solution to a similar conjecture for codes embeddable in 2 or 3 dimensional lattices. On the other hand, in [11, 13] the authors provided an indication to the affirmative of this conjecture by considering the 4-dimensional Toric Code: for example, Hastings [11] assumes the existence of certain error operators from which he derived a related property. In [3] the authors use an approximation of thermal systems called the weak Markovian limit, and conclude that certain topological measurements are preserved at constant temperatures for exponentially long time in the system size (exponential coherence times). However, to the best of our knowledge there is no formal proof of conjecture 1.

Here, we make progress towards affirming this conjecture formally by proving conjecture 1 for nearly-optimal parameters:

► **Theorem (sketch).** (Robust TQO at nearly Room Temperature). *There exists a log-local family of quantum error-correcting codes  $\{\mathcal{C}_n\}_n$  with polynomial minimal distance  $n^{\Omega(1)}$  (in particular, a topologically-ordered system) and a corresponding family of commuting local Hamiltonians  $\{H_n\}_n$  such that for any  $\beta_n = O(\log^2 \log(n))$  the following holds: any quantum circuit  $V$  that acts on a  $\geq n$  qubits and approximates the thermal state at temperature at most  $T_n = 1/(\kappa\beta_n)$  on a set of qubits  $S$ ,  $|S| = n$ :*

$$\left\| \frac{1}{Z} e^{-\beta_n H_n} - \text{tr}_{-S}(V|0^{\otimes a}\rangle\langle 0^{\otimes a}|V^\dagger) \right\|_1 = o(1), \quad Z = \text{tr}(e^{-\beta_n H_n})$$

satisfies a circuit lower bound:

$$d(V) = \Omega(\ln(n)).$$

Our proof will actually show a stronger statement: namely that the thermal Gibbs state of these codes, for sufficiently low, yet nearly constant temperature, can be decoded using a shallow circuit to a bona-fide quantum code state. This implies that the Gibbs state retains topological order (up to a shallow decoder) at very high temperatures: if we initialize our system in some ground-state of the TQO, and allow it to thermalize, we can later recover that code-state with little extra cost (see Section 2.1.7 discussing the possible implementation error of such a set-up). In particular, it implies that appropriately chosen local Hamiltonians can give rise to ground-state multi-partite entanglement which can survive without active error correction at nearly-constant temperatures.

## 2.1 Some Perspective

### 2.1.1 The Thermal Gibbs State

This study explores quantum circuit lower bounds on arguably the most natural of physical states - namely the thermal Gibbs state  $e^{-\beta H}$  - which can be formed by coupling a ground-state of a physical system  $H$  to a “heat bath” at temperature  $1/\beta$  - meaning it is allowed to interact indefinitely with an environment to which we have no access to. (see definition 3)

### 2.1.2 The Regimes of “Inverse-Temperature” $\beta$

We consider here a summary of prior art: the temperature at which one can establish an  $\Omega(\log(n))$  (i.e. “global”) circuit lower bound for the Gibbs state of a Hamiltonian:

Hamiltonian	Temperature	Result	Comments
QECC with large distance	0	Folklore	
2 or 3-D systems	$O(1/\text{poly}(n))$ <sup>1</sup>	[20]	No-go theorem
Projective Code	$\Omega(1/\text{polylog}(n))$	This work	By definition, Without amplification
Amplified Projective Code	$\Omega(1/\text{polyloglog}(n))$	This work	With amplification
4-D Toric Code	$\Omega(1)$	[11]	Heuristic argument.

Our main theorem establishes the existence of log-local Hamiltonians for which the thermal state  $e^{-\beta H}$  for  $\beta = (\log\log(n))^2$  requires a logarithmic circuit depth. Therefore it improves exponentially on previous work in terms of the provable highest temperature as a function of system size  $n$  at which circuit lower bounds can be maintained.

Notably, observe that the rate of errors experienced by quantum states from this ensemble scales like  $n/\text{polylog}(n)$  - i.e. a nearly linear fraction. Such error rates result in error patterns whose weight is much larger than the minimal error-correcting distance of the quantum code, and hence it is not immediately clear, at least from an information-theoretic perspective, whether these states - that formally cannot protect quantum information - can be assigned circuit lower bounds.

### 2.1.3 Is it Entangled?

Any quantum system satisfying Conjecture 1 has a highly entangled ground-space, because for  $T = 0$  a Gibbs state can be any (possibly pure) ground-state of a topologically ordered system. That said, for  $T > 0$  the circuit lower bound is applied to mixed states: assigning a quantum circuit lower bound for the task of approximating a quantum mixed state (as opposed to a pure state) does not necessarily indicate the existence of quantum correlations but rather the presence of long-range correlations, which may or may not be quantum. In fact, by using the argument of Lovett and Viola [17] one can show a  $\Omega(\log(n))$  circuit lower bound for the Gibbs state at constant temperature  $T = \Omega(1)$  of any good classical locally testable code, though, this bound breaks for  $T = 0$  since any classical string codeword, which is unentangled, is a valid Gibbs state.

However, as noted above even this somewhat weaker notion of a quantum system with a highly-entangled ground-space that retains a quantum circuit lower bound at very high temperature isn't known to exist (at least formally), and is related to major open questions in quantum complexity theory. See in this context the NLTS conjecture discussed in the section 2.1.6.

### 2.1.4 Quantum Circuit Lower Bounds

This work adds to the set of available tools for showing quantum circuit lower bounds - by combining quantum locally-testable codes, an analysis of the thermal state as a truncated Markov chain, and a local decoder that relies on these two properties to decode a thermal state to a bona-fide quantum code-state which can be assigned a circuit lower bound by information-theoretic arguments. Previous works have either used quantum locally testable codes [5] to argue direct circuit lower bounds, or local decoders [11, 16] but as far as we know these strategies were never used in conjunction. We outline our strategy in more detail in Section 2.3

### 2.1.5 Energy versus error

An important distinction that one needs to make early on is that having a quantum state with low-energy *does not* necessarily imply it is generated by applying few errors to a ground-state. This is only true if the Hamiltonian governing the quantum state is a so-called qLTC [2]. qLTC's are quantum analogs of locally-testable codes (and see Definition 7).

Like their classical counterparts qLTC's are (local) Hamiltonians for which large errors necessarily result in a large number of violations from a set of local check terms. To give an example - consider Kitaev's 2-dimensional Toric Code [14] at very low-temperature, say  $T = O(1/\sqrt{n})$ . At that temperature the probability of an error of weight  $\sqrt{n}$ , at least one which is composed of strings of weight  $\sqrt{n}$  is proportional to the probability of observing an error of constant energy, i.e.:  $e^{-\beta O(1)}$  i.e. comparable to the probability of a single error. So, unless additional structure of the problem is used, for all we know the number of errors could be  $\Omega(n)$ . The reason for the above is that the Toric Code is known to have very poor soundness as a locally testable code: in fact one can have an error of size  $\sqrt{n}$  with only two violations.

### 2.1.6 The relation to NLTS

Conjecture 1 above is a mixed-state analog (albeit with a slightly more stringent requirement on the circuit depth) of the NLTS conjecture due to Freedman and Hastings [7] - which posits the existence of local Hamiltonians for which *any* low-energy state can only be generated by circuits of diverging depth. As far as we know neither conjecture is stronger than the other.

Arguably, the only known strategy to establishing the NLTS conjecture, outlined in [5], is to show a construction of quantum locally-testable codes (qLTC's) with constant soundness and linear minimal quantum error correcting distance. However, such a statement by itself requires the construction of quantum LDPC codes with distance growing linearly in the number of qubits - a conjecture now open for nearly 30 years. Thus our inability to make progress on qLDPC is a significant barrier to any progress on the NLTS conjecture.

In this work, we show that by considering a mixed-state (or average-case) analog of NLTS (while still placing a more stringent requirement on the circuit depth) one can break away from this strategy using the tools we already have today - namely qLTC's with  $1/\text{polylog}$  soundness and code distance which is sub-linear in  $n$ , in this case  $\sqrt{n}$ , and achieve a construction with nearly optimal parameters. Nevertheless, it could be the case that the construction provided here is in fact NLTS - meaning there are no trivial states of the code Hamiltonian for sufficiently small constant temperature.

### 2.1.7 Implementation Error

Above, we mentioned the ability of the proposed system to allow thermalization of an initialized state, and still be able to recover that state using a local decoder. Arguably, one can argue against such a statement that one also needs to account for the implementation error of the Hamiltonian governing the TQO state, as well as the decoding Hamiltonian. There exist analogous claims against active fault-tolerance in the form of implementation error of the error-correcting unitary circuits.

However, we conjecture that the system we construct, insofar as the check terms of the Hamiltonians are concerned  $\{C_i\}$ , is in fact robust against implementation error by virtue of local testability. Recall that a locally testable code (see Definition 7) satisfies the following operator inequality:  $\frac{1}{m} \sum_{i=1}^m C_i \succeq \frac{s}{n} D_C$ . where  $D_C$  is an operator that relates a state to its distance from the code-space.

One can check that if the LHS above suffers from an additive error quantified by a Hermitian error operator  $\mathcal{E}$ ,  $\frac{1}{m} \sum_{i=1}^m C_i + \mathcal{E}$  then using standard results about stability of Hermitian operators under Hermitian perturbation, the resulting code will still be, for sufficiently weak error  $\mathcal{E}$ , a locally testable code albeit with slightly worse parameters, and for a smaller range of distances from the codespace: it will not be able to faithfully test very small errors, but only large errors.

Still, this code will possess the key property that we use here to argue the main theorem: that for sufficiently low temperature (depending on the strength of the implementation error  $\|\mathcal{E}\|$ ) - the code reins in the error weight to small weights, and these errors are far apart to allow for local error correction. Notably, the actual shallow decoder used in the argument will also suffer from implementation noise, undoubtedly, but as a theoretic argument about entanglement, it is only important to account for implementation error of the Hamiltonian, and not the decoding circuit.

Hence the system proposed has apparently two advantages: not only it is able to sustain long-range entanglement for high temperatures as established in Theorem 31, one doesn't even need to implement it precisely to gain the first advantage. We leave for future research to quantify precisely the degree to which this system is robust against implementation error.

## 2.2 Some Open Questions

We end this section with several questions for further research. First, it is desirable to improve (reduce) the value of  $\beta$  and improve (reduce) the locality of checks (currently they are log-local). We note that a limiting factor to decreasing  $\beta$  is the maximal size set for which one can show near-optimal expansion, for qLTC's.

An interesting extension of this work is to extend it to actual quantum information - namely show the system can store an arbitrary quantum state for long periods of time: notably here we have only showed that one can recover the uniform distribution on code-states, but it is not immediately clear that it can preserve a single arbitrarily encoded code-state. In addition, it would be insightful to understand the actual coherence time of such a system as a self-correcting quantum memory - we conjecture that it is polynomial in  $n$ .

Finally, one could explore the possibility that the constructed code in fact satisfies the NLTS condition: namely that any low-energy state is highly entangled.

## 2.3 Overall Strategy

In figure 1 we outline the main steps of our argument. To recall, the main goal of this study is to demonstrate that the thermal state  $e^{-\beta H}/Z$  is hard to produce for sufficiently small  $\beta$ , and show the same for any ground-state of  $H$  - mixed or pure.

Our overall strategy is to demonstrate a *shallow* quantum circuit that allows to correct this thermal state to some code-state of a quantum code with large minimal distance. For a quantum code with large minimal error-correcting distance it is a folklore fact (made formal here) that any quantum state in that codespace is hard to approximate (the gray-shaded box in Figure 1), thereby satisfying the hardness-of-approximation requirement for groundstates. Furthermore, together with the existence of a shallow decoder, it implies a lower-bound on the circuit depth for  $e^{-\beta H}$  as the lower-bound on a circuit generating a quantum code-state, minus the depth of the decoder. Thus, working in the diagram of Figure 1 backwards we translate our overall theorem to demonstrating a shallow error-correcting circuit from a thermal state to a code-state with polynomial distance.

### 2.3.1 Translating Energy to Error

The strategy outlined above requires us to demonstrate a shallow decoder for thermal states of sufficiently low temperatures. Here we are faced with a severe obstacle: a thermal Gibbs state is defined in terms of energy, whereas the natural language for decoders is the language of “errors” (whether they are average-case or worst-case). Hence we need a scheme to argue about the error distribution of the Gibbs state.

To our aid come quantum locally testable codes (qLTCs) [2] (and see Definition 7). The main use of locally testable codes is to rein in the error weight of low-energy states. We use this property in conjunction with the well-known Metropolis-Hastings algorithm (or MH) on Hamiltonians corresponding to the check terms of qLTC’s. The MH algorithm is a standard tool in physics to simulate the thermal Gibbs state by a random walk where transition probabilities between quantum states are dictated by their relative energies (see Section 7).

Applying this tool to local Hamiltonians corresponding to qLTCs we show that the thermal Gibbs state  $e^{-\beta H}$ , for  $H$  corresponding to a qLTC, can in fact be approximated by a so-called “truncated” MH process. These arguments correspond to the top Vanilla-colored boxes in the diagram.

As a general note, as far as we know, no previous work using qLTC’s made such a translation from energy to error weight: in [5] the authors show that qLTC’s with linear distance are NLTS, but since such codes are not known to exist, they end up proving a somewhat weaker version called NLETS thus bypassing the energy-to-error translation. On the other hand, such a translation is probably the most natural way to proceed w.r.t. quantum codes: we do not know how to treat “energies” on quantum states, but if we can model the errors they experience we can leverage our vast knowledge of quantum *error-correction* to handle them. Hence, we believe that the use of the MH random process is of conceptual importance and will be useful elsewhere, since it allows for the first time, to bring the analysis from a point we want to argue about (“energies”) to a point where we have powerful analysis tools (“errors”).

### 2.3.2 Shallow Decoding from Local Expansion

To recap the flow of arguments: the arguments about the MH random process (Vanilla-colored boxes in Figure 1) allow us to argue that the thermal Gibbs state  $e^{-\beta H}$ , for a qLTC Hamiltonian  $H$ , can be simulated by sampling an error according to an MH random walk that is controlled by the inverse temperature  $\beta$  and the soundness of the qLTC. We would now like to leverage that property to demonstrate a shallow decoder for this state.

A key observation towards that end (corresponding to the bottom Vanilla-colored box) is that while the MH random process is not an i.i.d. process, it does in fact conform to a somewhat weaker characterization called “locally-stochastic” (or “locally-decaying”) [15, 6, 10], which are a main source of inspiration of this work. A noise is locally-stochastic if the probability of a large cluster of errors decays exponentially in its size (see Definition 23).

Concretely, using the truncated MH random process we conclude (orange box) that for sufficiently large  $\beta$  (low temperature) the errors experienced by the Gibbs state are locally-stochastic, and hence typically form only small clusters whose size is, say, at most  $\log(n)$ .

In effect, a stronger notion is true: we show that local-stochasticity of these random errors means that their clusters are also far away from each other - in the sense that even if we “blow up” each cluster by a factor of  $1/\alpha$  (for small  $\alpha > 0$ ) they are still at most the size above. This definition is called  $\alpha$ -subset and it too, is due to [15, 6].

In these works, error patterns that are locally-stochastic were shown to be amenable to correction by a local decoder, since intuitively, these errors can be “divided-and-conquered” locally. In this context, the notion of  $\alpha$ -subsets was used to handle the possibility that the decoder can introduce errors to qubits which weren’t initially erred, by arguing that even if such an event occurs it will not cause the initial clusters to aggregate together to form large, undecodable clusters.

Our choice for a shallow “local-decoder” is to use a straightforward quantum generalization of the Sipser-Spielman decoder (notably, a variant of this decoder was used in [15]). This decoder is desirable since it is able, under certain conditions to decode an error of weight  $w$  in time  $\log(w)$ , and do so locally. That would imply that for error patches of logarithmic size, the decoder would run in depth  $O(\log\log(n))$  - i.e. a very shallow decoder.

However, such a decoder comes attached with a very stringent condition: it requires the Tanner graph of the code to be a very strong bi-partite expander. That condition is too stringent for our purposes, since we also need the quantum code to be locally-testable, and it is not known how to make even classical local-testability co-exist with the code’s Tanner graph being a bi-partite expander.

In our study, we relax the stringent expansion condition, and require that only very small errors, i.e. those of logarithmic size which we’ve shown to be the typical error size for the Gibbs state - those errors are required to expand well (“small-set expansion”), while requiring nothing for linear-weight errors, which is the regime of interest of the standard Sipser-Spielman decoder. Hence, we are able to use a code whose Tanner graph is not a true expander. This while still being able to use the Sipser-Spielman approach to a fast parallel decoder by considering only small sets. These arguments are outlined in the pink-shaded boxes in the middle of the diagram.

## 2.4 The construction

To recap again, starting from the previous section, our goal is to find quantum a code, whose thermal state can be corrected quickly and in parallel. We’ve shown that if a code is qLTC then the Gibbs state can be essentially modeled as an error process that is locally-stochastic. Locally-stochastic errors can be decoded quickly, if the underlying topology is a good expander - at least for the typical error size. Hence, our interim goal is to find a quantum code  $\mathcal{C}$  that satisfies simultaneously three requirements:

1. It has a minimal quantum error-correcting distance that is some polynomial in the number of qubits  $n$ , say  $\sqrt{n}$  - to allow a circuit lower bound for proper code-states.
2. It is *locally-testable* - to allow translation from energies to errors in the truncated-MH modeling of the Gibbs state.
3. Expansion of the bi-partite Tanner graph corresponding to the checks of the code, for errors of small weight (or “small-set expansion”) - to allow for shallow decoding using the Sipser-Spielman algorithm.

### 2.4.1 The Choice of Quantum Code

In [12] Hastings found a way to make progress on the qLTC conjecture [2] by considering high-dimensional manifolds: he showed that by tessellating a high-dimensional sphere using a regular grid (or some other topology for improved rate) the resulting quantum code on  $n$  qubits has soundness  $1/\text{polylog}(n)$ . We make a crucial use of his approach here.

Recently, Leverrier et al. [16] have proposed the projective code, which is an arguably simpler variant of this high-dimensional construction whereby a length-3 complex chain of  $p$ -faces of the binary  $N$ -cube (modulo the all-ones vector), for  $p = \Omega(N)$  is used to derive

a quantum code on  $n$  qubits with distance scaling like  $n^c$ , for some constant  $c > 0$ . This code has improved soundness compared to the one in [12]. Our construction is based on the projective code on  $n$  qubits, using  $p$ -faces of the  $N$ -dimensional cube for  $p = N/2$ , where  $N = \Theta(\log(n))$ .

On one hand, by the minimal distance of the projective code one immediately gains a circuit lower bound of  $\Omega(\log(n))$  on the minimal depth circuit generating its ground-state (corresponding to the gray-shaded block in Figure 1. This satisfies the first requirement above. It is also a qLTC with reasonable  $(1/\log^2(n))$  soundness, (see navy-shaded block in Figure 1) thus satisfying the second requirement.

However, the last critical advantage that we gain by using this code, as opposed to say the original high-dimensional manifold of Hastings, is not its improved soundness parameter but rather the underlying structure of the high-dimensional cube: namely its property of small-set expansion that exists in addition to its non-negligible soundness. This property of small set expansion is the turnkey for allowing the application of a shallow decoder to combat the typical errors of a thermal state with large  $\beta$  parameter.

More specifically, we make crucial use of the structure of the  $N$ -cube to establish the third requirement - namely, show that small error sets expand significantly - i.e. have many unique incident constraints. This emanates from the fact that small subsets of  $p$ -faces of the  $n$ -cube for  $p = n/2$  have many adjacent  $p + 1$ -faces and many adjacent  $p - 1$ -faces.

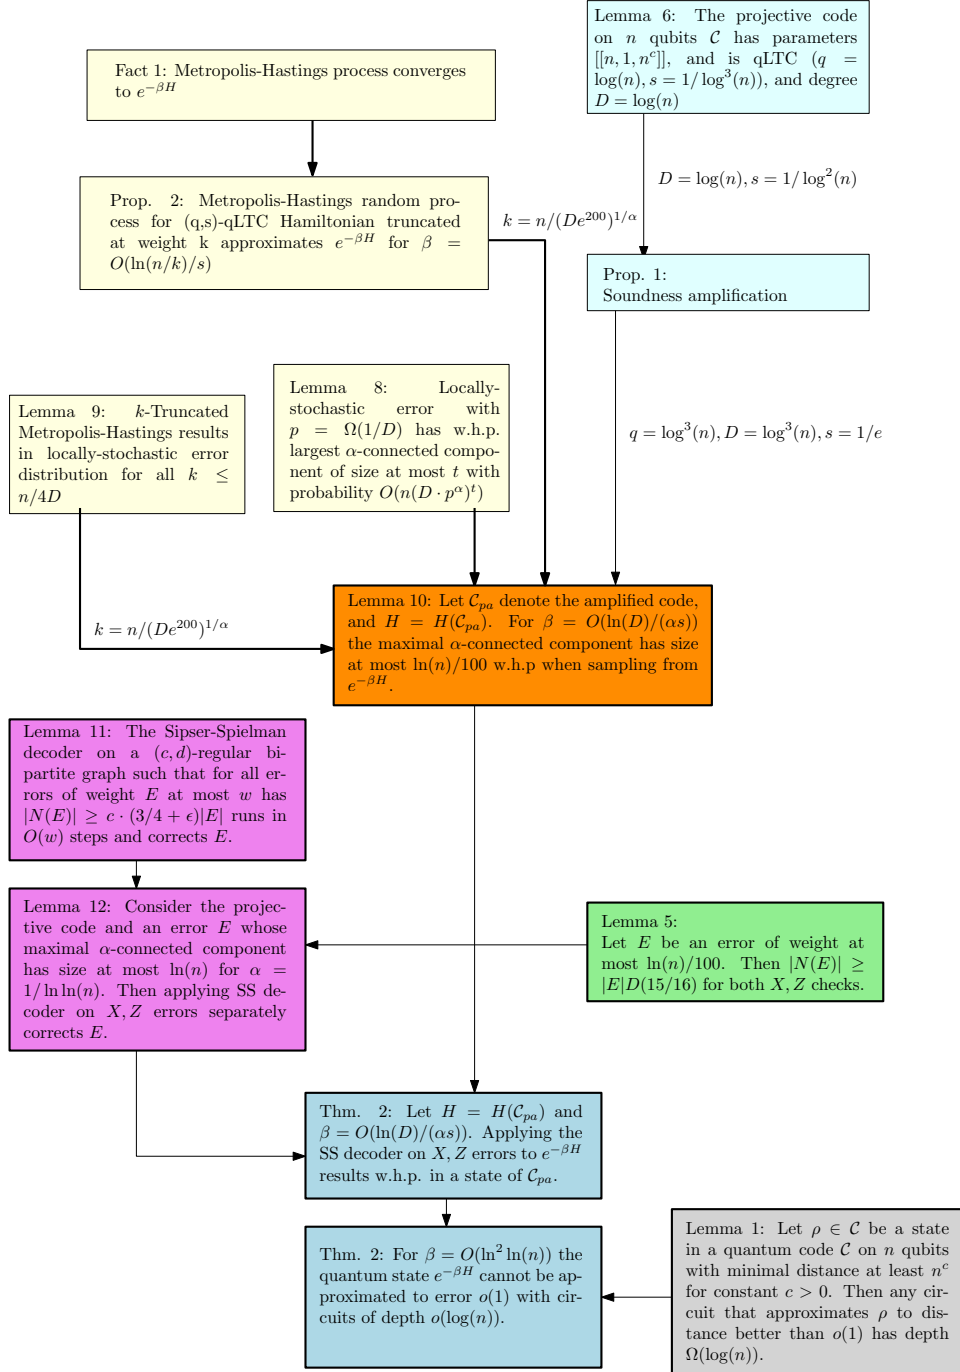

## 2.4.2 Efficient Soundness Amplification

The flow of arguments until this point results in lemma 27 which roughly states that a qLTC with soundness  $s$  and qubit degree  $D$  has the property that its thermal state for sufficiently large inverse temperature:  $\beta \geq \log(D)/s$ . has error patterns that form clusters of only logarithmic size. Such errors admit a shallow-depth parallel decoding scheme resulting in a circuit lower bound for approximating this thermal state.

Consider, for example the projective code of [16]. We have  $D = \log(n)$ ,  $s = 1/\log^2(n)$ . Using these parameters one would only be able to establish a circuit lower bound for  $\beta = \text{polylog}(n)$ . Hence, by the behavior of  $\beta$  as a function of  $D$  and  $s$  one sees it is desirable to trade-off increased degree for improved soundness so long as these two quantities are increased/decreased in a commensurate manner.

Using standard probabilistic analysis we show that it is sufficient to choose a random family of  $\Omega(n\log^2(n))$  subsets - each set comprised of  $1/s$  checks in order to achieve a qLTC with constant soundness and query size  $q/s$ . This corresponds to the second navy-shaded box in Figure 1.

This amplification procedure results in a somewhat peculiar situation that we'd like to point out: the thermal Gibbs state  $e^{-\beta H}$  is defined w.r.t. the Hamiltonian  $H = H(\mathcal{C}_{pa})$  where  $\mathcal{C}_{pa}$  is the result of the amplification of the projective code formed by choosing a sufficiently large random family of subsets of check terms of size  $1/s$  each. However, the decoding procedure, using the Sipser-Spielman algorithm uses the original checks of  $\mathcal{C}$  to locate and correct errors, and not the amplified ones: this is because we do not establish local expansion for the amplified checks, only for the original checks. Still, both sets of checks share the same code-space - namely the original projective code  $\mathcal{C}$ . Hence, the set of checks used for *testing* are not the same as the ones used for *correcting errors*.

■ **Figure 1** Flow of the main arguments.

### 3 Notation

A quantum CSS code on  $n$  qubits is a pair of codes  $\mathcal{C} = (\mathcal{C}_x, \mathcal{C}_z)$ , where  $\mathcal{C}_x, \mathcal{C}_z$  are subspaces of  $\mathbb{F}_2^n$ . For a thermal state  $\rho = (1/Z)e^{-\beta H}$ ,  $\beta$  signifies the “inverse temperature”  $\beta = 1/(\kappa T)$  where  $\kappa$  is the Boltzmann constant, and  $Z = \text{tr}(e^{-\beta H})$  is the partition function of this state. For a finite discrete set  $S$ ,  $|S|$  denotes the cardinality of the set. For  $\mathcal{E} \in \{0, 1\}^n$  the support of  $\mathcal{E}$ ,  $\text{supp}(\mathcal{E})$  is the set of non-zero positions of  $\mathcal{E}$ .  $|\mathcal{E}|$  is the Hamming weight of  $\mathcal{E}$ . For quantum density matrices  $A, B$ , the trace distance between  $A, B$  is denoted by  $\|A - B\|_1$ , and the quantum fidelity between these states is denoted by  $\mathcal{F}(A, B)$ . A density matrix  $\rho$  of rank  $r$  is said to be a *uniform mixture* if it can be written as  $\rho = \frac{1}{r} \sum_{i=1}^r |u_i\rangle\langle u_i|$  where  $\{|u_i\rangle\}$  are an orthonormal set of vectors.

We say that a quantum circuit  $U$  on a set  $T$  of  $N$  qubits approximates a quantum state  $\rho$  on a set  $S \subseteq T$  of  $n \leq N$  qubits, to error  $\delta$  if  $\|\text{tr}_{T-S}(U|0^{\otimes n}\rangle\langle 0^{\otimes n}|U^\dagger) - \rho\|_1 \leq \delta$

In this work, we will consider random error models  $\mathcal{E}$  supported on the  $n$ -th fold tensor product Pauli group  $\mathcal{P}^n$ , where  $\mathcal{P} = \{X, Z, Y, I\}$ . For an error  $\mathcal{E} = \mathcal{E}_1 \otimes \dots \otimes \mathcal{E}_n$ ,  $\mathcal{E}_i \in \mathcal{P}$  we denote by  $|\mathcal{E}|$  the Hamming weight of  $\mathcal{E}$  - namely the number of terms  $\mathcal{E}_i$  that are not equal to  $I$ . Often we will use  $|\mathcal{E}|$  to denote the minimal weight of  $\mathcal{E}$  modulo a stabilizer subgroup of  $\mathcal{P}^n$ . For a stabilizer code  $\mathcal{C}$  with local check terms  $\{C_i\}_{i=1}^m$ ,  $C_i \in \mathcal{P}^n$ , the Hamiltonian  $H = H(\mathcal{C})$  is the local Hamiltonian  $\sum_{i=1}^m (I - C_i)/2$  - i.e. its ground-space is the intersection of the 1-eigenspaces of all check terms  $C_i$ .

The  $N$ -cube is the binary cube in  $N$  dimensions. We will use capital  $N$  to denote the dimension of the cube. The projective cube results in a code of  $n$  qubits. When considering  $n$  in the context of the projective cube we will use lower-case  $n$  to denote the number of qubits, i.e.  $n = 2^N$ .

The letter  $a$  will be used to denote an initial set of qubits  $a \geq n$  that also include any ancillary qubits used to generate the state of  $n$  qubits, i.e. to generate a mixed state on  $n$  qubits one applies a unitary transformation on the state  $|0^{\otimes a}\rangle\langle 0^{\otimes a}|$ , traces out  $a - n$  qubits.

Let  $G = (V, E)$  be a graph. For a set  $S \subseteq V$  the set  $\Gamma(S) \subseteq V$  is the set of all vertices that neighbor  $S$  in  $G$ . The degree of a vertex  $v \in V$  is the number of edges incident on that vertex. The degree  $D$  of a graph is the maximal degree of any vertex  $v \in V$ . A graph is  $D$ -regular if the degrees of all vertices are equal. We will use  $a \propto b$  to signify that  $a = c \cdot b$  for some  $c$  that does not depend on  $b$ . Throughout the paper we will use the binary logarithm  $\log(n)$  in the context of quantum circuit lower bounds, and the natural logarithm  $\ln(n)$  in the context of errors occurring on a thermal state  $e^{-\beta H}$ .

### 4 Preliminaries I: Thermal Gibbs State of a Local Hamiltonian

When considering the thermal Gibbs state for a local Hamiltonian  $H = \sum_i H_i$ ,  $\|H_i\| \leq 1$ , care needs to be taken as to how to scale the energy of the Hamiltonian. On one hand, we would like the Gibbs state of a Hamiltonian  $H$  to be invariant under scaling of  $H$ , or perhaps rewriting  $H$  as a sum of possibly lower-rank projections. On the other hand, we note that it is unreasonable to expect to have a family of local Hamiltonians  $\{H_n\}_n$  with entanglement at room temperature (i.e. constant  $\beta > 0$ ), if the norm of  $H_n$  doesn't grow with the number of qubits  $n$ . Hence, we introduce the definition of energy density - which captures the average “energy” invested into a qubit in the system:

► **Definition 2 (Energy density).** A local Hamiltonian on  $n$  qubits with  $m$  local terms  $H = \sum_{i=1}^m H_i$ ,  $\|H_i\| \leq 1$  is said to have energy density  $\lambda = m/n$ .

The thermal Gibbs state is defined for a local Hamiltonian as follows:

► **Definition 3** (Gibbs state of a local Hamiltonian). *Let  $H = \sum_{i \in [m]} H_i$ , be a local Hamiltonian on  $n$  qubits  $\mathcal{H} = \mathbb{C}^{\otimes n}$ ,  $m$  local terms, and energy density  $\lambda = m/n$ . The Gibbs state of  $H$  for finite  $\beta > 0$  is the following density matrix:  $\frac{1}{Z}e^{-\beta \tilde{H}}$  where  $Z = \text{tr}(e^{-\beta \tilde{H}})$  and  $\tilde{H} = H/\lambda$ . For  $\beta \rightarrow \infty$  the Gibbs state is any  $\rho \in \ker(H)$ .*

#### Remark about the definition

One could also define the Gibbs state more strictly for  $T = 0$  or  $\beta \rightarrow \infty$  as the uniform mixture over codestates. Such a definition would not change the “quantumness” of the conjecture 1 nor the proof: the conjecture requires that at 0 temperature the system be topologically-ordered, so it must be highly entangled. As to the proof - it shows a circuit lower bound for every mixed ground-state, and in particular the uniform mixture thereof. The more relaxed definition here for  $T = 0$  is designed to include every state which is a stationary distribution of the Metropolis-Hastings algorithm, and indeed any mixed/pure ground-state is such a stationary distribution.

## 5 Preliminaries II :Quantum Error-Correcting Codes

We require the basic definition of stabilizer codes and CSS codes

► **Definition 4** (Quantum Stabilizer Code and Quantum CSS Code). *A stabilizer group  $\mathcal{G} \subseteq \mathcal{P}^n$  is an Abelian subgroup of  $\mathcal{P}^n$ . The codespace  $\mathcal{C}$  is then defined as the centralizer of  $\mathcal{G}$ , denoted by  $C[\mathcal{G}]$ , or equivalently - the mutual 1-eigenspace of  $\mathcal{G}$ . A CSS code  $\mathcal{C} = (\mathcal{C}_x, \mathcal{C}_z)$  is a stabilizer code where the check terms (i.e. generators of the group) are tensor-products of either only Pauli  $X$  or only Pauli  $Z$ . In particular regarding  $\mathcal{C}_x, \mathcal{C}_z$  as  $\mathbb{F}_2$  subspaces of  $\mathbb{F}_2^n$  we have  $\mathcal{C}_x \subseteq \mathcal{C}_z^\perp$  and vice versa.*

In this work, we will require some bounds on the minimal depth of a quantum circuit to generate a quantum code state. We recall a slight rephrasing of Prop. 45 in [5] to mixed states: <sup>2</sup>

► **Lemma 5** (Robust circuit lower bound for CSS code-states, [5]). *Let  $\mathcal{C}$  be a quantum CSS code of non-zero number of logical qubits  $k > 1$  on  $n$  qubits with minimal distance  $n^\epsilon$  for some  $\epsilon > 0$ . Let  $\rho_{gs}$  be a mixture on a set of code-states of  $\mathcal{C}$  and let  $V$  be a unitary circuit on  $N \geq n, N = \text{poly}(n)$  qubits that approximates  $\rho_{gs}$ :  $\rho = \text{tr}_T(V|0^{\otimes N}\rangle\langle 0^{\otimes N}|V^\dagger)$   $\|\rho - \rho_{gs}\|_1 \leq n^{-2}$ ,  $\rho_{gs} \in \mathcal{C}$  Then the depth of  $V$  is  $\Omega(\log(n))$ .*

### 5.1 Quantum Locally Testable Codes

In [2] Aharonov and the author defined quantum locally testable codes (qLTC’s). We state here a version due to Eldar and Harrow [5]: a quantum locally testable code can be defined by the property that quantum states on  $n$  qubits at distance  $d$  to the codespace have energy  $\Omega(d/n)$ .

<sup>2</sup> The only change required to achieve a mixed-state version of Prop. 45 is to construct distant subsets  $C_0, C_1$  of  $\mathbb{F}_2^n$  that each has a non-negligible probability, when measuring the ground-state  $\rho$  in one of the  $X/Z$  bases. Such sets are readily available: consider some eigenbasis of the code: In at least one of the  $Z$  or  $X$  bases the state  $\rho$  has support at least  $1/2$  on basis vectors such that each of them is a “well-partitioned” pure-state. One then constructs the sets  $C_0, C_1$  by “cutting in half” each such well-partitioned eigenstate, sending each half to a different set. By the minimal distance of the code, the “half” of each eigenstate is far from any “half” of any other eigenstate.

► **Definition 6.** If  $V$  is a subspace of  $(\mathbb{C}^2)^{\otimes n}$  then define its  $t$ -fattening to be  $V_t := \text{Span}\{(A_1 \otimes \cdots \otimes A_n)|\psi\rangle : |\psi\rangle \in V, \#\{i : A_i \neq I\} \leq t\}$ . Let  $\Pi_{V_t}$  project onto  $V_t$ . Then define the distance operator  $D_V := \sum_{t \geq 1} t(\Pi_{V_t} - \Pi_{V_{t-1}})$ .

This reflects the fact that for quantum states, Hamming distance should be thought of as an observable, meaning a Hermitian operator where a given state can be a superposition of eigenstates.

► **Definition 7** (Quantum locally testable code). An  $(q, s)$ -quantum locally testable code  $\mathcal{C} \subseteq (\mathbb{C}^2)^{\otimes n}$ , is a quantum code with  $q$ -local projection  $C_1, \dots, C_m$  such that  $\frac{1}{m} \sum_{i=1}^m C_i \succeq \frac{s}{n} D_{\mathcal{C}}$ .  $s$  is called the soundness parameter of the code.

We note that the soundness parameter  $s$  in this definition generalizes the standard notion of soundness of a classical LTC as a special case, where all  $C_i$ 's are diagonal in the computational basis. In particular, if the quantum code is a stabilizer code, then the definition of quantum local testability can be further simplified to resemble classical local testability more closely:

► **Definition 8** (Stabilizer Locally-Testable Codes (sLTC)). An sLTC is a quantum stabilizer code that is qLTC. An equivalent group-theoretic of an sLTC is as follows:  $\mathcal{C}$  is a stabilizer code generated by stabilizer group  $\mathcal{G}$ . It is  $(q, s)$ -sLTC if there exists a set  $S$  of  $q$ -local words in the stabilizer group  $g_1, \dots, g_t \in \mathcal{G}$  such that for  $P \in \mathcal{P}^n$  we have  $\mathbb{P}_{g \sim U[S]}([g, P] \neq 0) \geq (|P|/n) \cdot s$  where  $|P|$  is the Hamming weight of  $P$  modulo the centralizer of  $\mathcal{G}$ ,  $C[\mathcal{G}]$ :  $|P| = \min_{z \in C[\mathcal{G}]} \text{wt}(P + z)$  where for  $x \in \mathcal{P}^n$   $\text{wt}(x)$  counts the number of non-identity entries in  $x$ .

See [5] and [2] for the derivation of this definition as a special case of Definition 7: the operator  $D_{\mathcal{C}}$  penalizes a quantum state according to the “weighted” distance of that state from the codespace, whereas in definition 8 the penalty is defined w.r.t. each Pauli error separately, and as a function of the standard Hamming weight of the error, modulo the code.

Given a  $(q, s)$ -sLTC one can generate a sLTC with parameters  $(\lceil q/s \rceil, 1/e)$  by amplification as follows:

► **Proposition 9** (Randomized Amplification). Given is a  $(q, s)$  sLTC on  $n$  qubits with  $\text{poly}(n)$  checks. There exists a qLTC  $\mathcal{C}_{\text{amp}}$  of  $\text{poly}(n)$  checks with parameters  $(\lceil q/s \rceil, 1/e)$  where each qubit is incident on at most  $D' = \lceil q \log^2(n)/s \rceil$  checks.

## 6 Preliminaries III: Expansion of Small Errors on the Projective Hypercube

The main observation of this section is that while the projective code is a qLTC with a mild soundness parameter  $1/\log^2(n)$ , the soundness parameter for *small* errors is much better, and in fact for very small errors, their boundary (i.e. the Hamming weight of their image) is very close to maximal. We begin with a couple of standard definitions:

► **Definition 10** (Shadow). Let  $[n]^r$  denote the set of all  $r$ -subsets of  $[n]$ , and let  $\mathcal{A} \subseteq [n]^r$ . The lower shadow of  $\mathcal{A}$  is the set of all  $r-1$  subsets which are contained in at least one element of  $\mathcal{A}$ :  $\partial^- \mathcal{A} = \{A - \{i\} : A \in \mathcal{A}, i \in A\}$  and the upper shadow of  $\mathcal{A}$  is the set of all  $r+1$  subsets that contain at least one element of  $\mathcal{A}$ :  $\partial^+ \mathcal{A} = \{A + \{i\} : A \in \mathcal{A}, i \notin A\}$

Recall our notation that  $n$  denotes the dimension of the cube, and  $N = 2^n$  signifies the number of qubits in the context of the quantum error correcting code generated by the projective code of dimension  $n$ . We define  $p$ -faces as follows:

► **Definition 11** (*p*-face, set of *p*-faces, subspaces of *p*-faces). For integer  $n \geq 1$  a *p*-face is a word in  $\{0, 1, *\}^n$  that contains exactly *p* positions with \*. We denote by  $\mathcal{K}_p^N$  as the set of *p*-faces of the *n*-th cube. Let  $C_p^N$  denote the space spanned by  $\mathcal{K}_p^N$  with coefficients from  $\mathbb{F}_2$ .

One can think about a *p*-face as a subset of  $\{0, 1\}^n$  of all points that are equal to the *p*-face in its non-\* positions. Under this notation one can naturally define upper and lower shadow of *p*-faces as follows:

► **Definition 12** (Shadow of *p*-faces of  $\mathcal{K}_p^N$ ). The lower-shadow  $\partial^-$  of a *p*-face *f* is the set of all  $p - 1$  faces derived by replacing any \* entry with either 0 or 1. The upper-shadow  $\partial^+$  of a *p*-face *f* is the set of all  $p + 1$  faces that can be derived by replacing any non-\* entry of *p* with \*.

To connect the definitions above, note that the  $\mathbb{F}_2$ -boundary operator  $\partial_{p+1}$  associated with the  $\mathbb{F}_2$ -complex chain  $\{C_p^n\}_p$  maps each  $p + 1$ -face *f* to a summation over the set of *p*-faces  $\partial^- f$  with coefficient 1 in  $\mathbb{F}_2$ , whereas the co-boundary map  $\partial_p^T$  sends each  $p - 1$  face *f* to a summation over the set of *p*-faces  $\partial^+ f$  with coefficient 1.

Importantly, in this work, we will focus on the *p*-faces of the projective cube as the combinatorial set  $\mathcal{K}_p^N$ , and not on the corresponding  $\mathbb{F}_2$ -space  $C_p^N$ . This is because we are interested in establishing a combinatorial expansion property of the boundary maps  $\partial^+, \partial^-$ , to be later used in conjunction with the Sipser-Spielman decoder.

However, we will use, in a black box fashion, the properties of these maps, as maps over an  $\mathbb{F}_2$  complex chain that appeared in [16]: these properties are namely the soundness and minimal distance of a quantum code derived by the pair  $(\partial^+, \partial^-)$ .

In this study, we consider *p*-faces of the *n*-hypercube. While this resembles the case of subsets of  $[n]^r$  there is a major difference - since now any \*-entry replaced, can assume a value either 0 or 1, and the isoperimetric inequality needs to account for this larger set. Bollobas and Radcliffe provide an isoperimetric inequality for the regular grid [Thm. 10, Bollobas and Radcliffe]. Their bounds are useful especially when the set of faces is exponentially large in the dimension of the embedding space. For our purposes though, we are interested in set of *p*-faces that are polynomial in that dimension so simpler bounds are available as follows:

► **Lemma 13.** Let  $\mathcal{A} \subseteq \mathcal{K}_{p-1}^n$  be a set of  $(p - 1)$ -faces for  $p = n/2$ ,  $|\mathcal{A}| \leq n/32$ . Then  $|\partial^+ \mathcal{A}| \geq |\mathcal{A}| \cdot (n/2 + 1) \cdot (15/16)$ . Let  $\mathcal{A} \subseteq \mathcal{K}_{p+1}^n$  be a set of  $p + 1$ -faces for  $p = n/2$ ,  $|\mathcal{A}| \leq n/8$ . Then  $|\partial^- \mathcal{A}| \geq 2 \cdot |\mathcal{A}| \cdot (n/2 + 1) \cdot (15/16)$

## 6.1 The Projective Code

► **Definition 14** (The Projective Cube). Let  $\mathcal{K}_p^N$  denote the set of *p*-faces of the *N*-th cube. The projective cube, denoted by  $\tilde{\mathcal{K}}_p^N$  is formed by identifying  $x \sim \bar{x}$  iff  $x = \bar{x} + \mathbf{1}$ . Let  $\tilde{C}_p^N$  denote the space spanned by  $\tilde{\mathcal{K}}_p^N$  with coefficients in  $\mathbb{F}_2$ .

In this study, we will use build upon the projective code defined by Leverrier et al. [16]:

► **Definition 15** (Projective code). Extend the operators  $\partial^+, \partial^-$  from  $\mathcal{K}_p^N$  to  $\tilde{\mathcal{K}}_p^N$  and consider the complex chain formed by the  $\mathbb{F}_2$  span of  $\tilde{\mathcal{K}}_p^N$ , namely the spaces  $\{\tilde{C}_p^N\}_p$ :  $\tilde{C}_{p+1}^N \xrightarrow{\partial_{p+1}} \tilde{C}_p^N \xrightarrow{\partial_p} \tilde{C}_{p-1}^N$  the quantum CSS code (see Definition 4) defined by  $\mathcal{C}_x = \ker(\partial_p), \mathcal{C}_z = (\text{Im} \partial_p)^\perp$  is called the  $(N, p)$ -projective code and denoted by  $\mathcal{C}_{N,p} = (\mathcal{C}_x, \mathcal{C}_z)$ .

► **Lemma 16** (Properties of the projective code, [16]). For every sufficiently large *N* there exists  $n = 2^{\Omega(N)}$  such that the  $(N, p)$ -projective code  $\mathcal{C}_{N,p}$  for  $p = N/2$  has parameters  $[[n, 1, n^c]]$ , for some constant  $c > 0$ . It has soundness  $1/\log^2(n)$  and each qubit is incident on at most  $D = 2\log(n)$  checks.

We conclude this section by reducing the isoperimetric inequality for the projective cube to the isoperimetric inequality for the  $N$ -cube.

► **Lemma 17** (Isoperimetric inequalities for the projective hypercube). *Let  $\mathcal{C} = (\mathcal{C}_x, \mathcal{C}_z)$  denote the  $(N, p)$ -projective code with  $p = N/2$ . Let  $\mathcal{E}$  be a subset of errors of weight at most  $N/64$ . Then the number of checks  $\mathcal{C}_x$  incident on  $\mathcal{E}$  is at least  $|\mathcal{E}| \cdot (N/2) \cdot (15/16)$  and the number of  $\mathcal{C}_z$  checks incident is at least  $|\mathcal{E}| \cdot (N) \cdot (15/16)$*

### Some context

To provide some context, we note that at first sight it is unclear why considering such small weight ( $N/64$ ) may provide a non-trivial result: after all, for the regime of temperatures we are considering the typical error has nearly linear weight - i.e.  $n/\text{polylog}(n)$ , and since  $n = 2^N$  the weight considered above is merely  $\text{polylog}(n)$ . The reason is that as we later show in the proof, the typical error of the Gibbs state is not arbitrary, but can be further characterized as being formed on very small clusters - clusters of logarithmic size (see Lemma 27). We would like the check terms of the  $p$ -th projective code  $\mathcal{C}_{N,p}$  to be such that *any* error of logarithmic size expands very well in the Tanner graph of the code. The isoperimetric inequality provided here on this very restricted error model will allow us to argue that we can use a Sipser-Sipelman type decoder to correct all errors of the thermal state with high probability.

## 7 Behavior of Errors in the Gibbs State of qLTCs

### 7.1 The Thermal Gibbs by the Metropolis-Hastings Algorithm

As mentioned in the introduction, a recurring barrier in the emergent field of robust quantum entanglement is to establish a connection between the energy of a state, w.r.t. some local Hamiltonian, and the “error” experienced by that state.

The main observation in this section is that specifically for qLTC’s the Gibbs state can be formulated as a random error process (and specifically, a discrete finite Markov process) where the errors occur independently at each step, with an error rate that is comparable to the energy parameter of the state. This will then allow us to conclude that for sufficiently small energy of the Gibbs state the resulting errors can only form very small clusters.

► **Definition 18** (The Metropolis-Hastings Random Process Stabilizer Hamiltonians). *Let  $\mathcal{G}$  be a stabilizer group with a corresponding Hamiltonian  $H = H(\mathcal{G})$  on  $n$  qubits  $H = \sum_{i=1}^m H_i$  with  $m$  local terms, and  $\lambda(H) = \lambda = m/n$ . Let  $\beta \geq 0$  be finite. Define a Markov random process  $\mathcal{M}$  on a finite graph  $G = (V, E)$  whose vertex set  $V$  is formed by considering the uniform mixture  $\tau_0$  on the set of zero-eigenstates of  $H$ , and an additional vertex for each unique state formed by applying a Pauli error applied to  $\tau_0$ :  $V := \{P \cdot \tau_0 \cdot P, \quad P \in \mathcal{P}^n\}$ . For any two vertices  $\tau_i, \tau_j$  such that  $\tau_j = P\tau_i P$  where  $P$  is a single qubit Pauli  $P \in \mathcal{P}$  we define the following transition probabilities:  $\forall i \neq j \quad \mathcal{M}_{i,j} = \frac{1}{4n} \min \{1, \exp \{ \beta(E_{\tau_i} - E_{\tau_j}) / \lambda \} \}$  and  $\mathcal{M}_{i,i} = 1 - \sum_{j \neq i} \mathcal{M}_{i,j}$  where  $E(\tau_i) = \text{tr}(\tau_i H)$*

We note that under the definition above, any two vertices connected by an element of the stabilizer group  $g \in \mathcal{G}$ , i.e.  $\tau_i = g\tau_j g^\dagger$  will correspond to the same vertex - since it preserves the uniform distribution on the codespace. In particular we have  $|V| = |\mathbb{F}_2^n / \mathcal{C}_x| = |\mathbb{F}_2^n / \mathcal{C}_z|$ . More generally for stabilizer codes, each vertex corresponds to a minimal weight error modulo the stabilizer group. Also note, that the transition probabilities  $\mathcal{M}_{i,j}$  correspond to a 2-step process, where at the first step one samples a uniformly random index  $k \in [n]$  and then

applies a uniformly random Pauli error  $\mathcal{E}$  on that index with probability corresponding to the exponent of energy differences. We also note that the normalization by factor of  $4n$  stems from the size of the single-qubit Pauli group  $|\mathcal{P}| = 4$ .

► **Fact 19.** *There exists a stationary distribution of  $\mathcal{M}$ , denoted by  $\rho_0$  and it satisfies:  $\rho_0 = \frac{1}{Z} e^{-\beta \tilde{H}}$  where  $\tilde{H} = H/\lambda$  and  $Z = \text{tr}(e^{-\beta \tilde{H}})$  is the partition function for value  $\beta$ .*

## 7.2 The Thermal Gibbs Markov Process for qLTC's

As a next step, we consider a *truncated* random process  $\mathcal{M}_k$  for integer  $k$  where one only considers errors up to some “typical” weight  $k$ , beyond which the measure of the stationary distribution of the original process  $\mathcal{M}$  is negligible.

► **Definition 20** (*k*-Truncated Markov chain). *Let  $\mathcal{C}$  be a quantum stabilizer code on  $n$  qubits with  $m$  checks, and let  $H = H(\mathcal{C})$ . Set  $\lambda(H) = \lambda = m/n$ . Let  $\beta \geq 0$  be finite. For any two vertices  $\tau_i, \tau_j$  such that  $\tau_j = P\tau_i P$  where  $P$  is a single qubit Pauli  $P \in \mathcal{P}$  we define the following transition probabilities:*

$$\forall i \neq j \quad \mathcal{M}_{i,j} = \begin{cases} 0 & \text{if } \Delta(\tau_j, \tau_0) > k/n \\ \frac{1}{4n} \min \{1, \exp \{ \beta(E_{\tau_i} - E_{\tau_j})/\lambda \} \} & \text{o/w} \end{cases}$$

where  $\Delta(\tau_i, \tau_j)$  is the minimal weight of a Pauli  $P$  such that  $P\tau_i P = \tau_j$ , and  $\mathcal{M}_{i,i} = 1 - \sum_{i \neq j} \mathcal{M}_{i,j}$

In general, given the energy parameter  $\beta > 0$  one cannot bound a so-called “typical” weight, for which the measure of errors above that weight are negligible in the thermal Gibbs state  $e^{-\beta H}$ . However, for the specific case of qLTC's such a bound is readily available, via the soundness parameter  $\varepsilon > 0$ .

► **Proposition 21** (Truncated Metropolis Hastings Approximates the Gibbs State of a qLTC). *Suppose in particular that  $H = H(\mathcal{C})$  where  $\mathcal{C}$  is a  $(q, s)$  sLTC, and set  $\lambda = \lambda(H)$ . Let  $0 < \delta < 1/2$  and denote  $k = n\delta$ . Let  $\rho_k$  denote a stationary distribution of the  $k$ -th truncated Markov chain  $\mathcal{M}_k$ . Then for  $\beta \geq 5 \ln(1/\delta)/s$  the  $k$ -th truncated Markov chain approximates the thermal Gibbs state of the scaled Hamiltonian  $\tilde{H} = H/\lambda$ :  $\left\| \rho_k - \frac{1}{Z} e^{-\beta \tilde{H}} \right\| \leq 2n \cdot e^{-2n \cdot \ln(1/\delta) \cdot \delta}$ ,  $Z = \text{tr}(e^{-\beta \tilde{H}})$*

## 7.3 Percolation Behavior of Random Errors in the Gibbs State of qLTC's

We now recall some of the definitions of Fawzi et al. [6]. The first one is that of an  $\alpha$ -subset which is a subset that has a large intersection with some fixed subset:

► **Definition 22** ( $\alpha$ -subset). *Let  $G = (V, E)$  be a graph,  $X \subseteq V$ , and  $\alpha \in [0, 1]$ . An  $\alpha$ -subset of  $X$  is a set  $S \subseteq V$  such that  $|S \cap X| \geq \alpha \cdot |S|$ . We denote by  $\text{maxconn}_\alpha(X)$  as the maximum size of an  $\alpha$  connected subset of  $X$ .*

The second definition is that of a locally-stochastic random error model, which generalizes an independent random error model in that the probability of a set decays exponentially in its size:

► **Definition 23** (Locally-stochastic). *Let  $V$  be a set of  $n$  elements. A random subset  $X \subseteq V$  is said to be locally-stochastic with parameter  $p \in [0, 1]$  if for every  $S \subseteq V$  we have  $P(X \supseteq S) \leq p^{|S|}$*

We now recall Theorem 17 of [6] on the percolation behavior of  $\alpha$ -subsets. It states, roughly, that the size of the maximal  $\alpha$ -connected component when choosing vertices at random with probability  $p$  drops exponentially in  $dp^\alpha$ . We rephrase the theorem as the following lemma:

► **Lemma 24** (Percolation behavior for locally-stochastic random errors). *Let  $G = (V, E)$  be a graph on  $n$  vertices, such that each vertex has at most  $D = D(n)$  neighboring edges. Let  $\alpha > 0$ . Let  $X \subseteq V$  be a random subset of  $V$  that is locally stochastic with parameter  $p$ . There exists a constant  $c$  such that if  $p < c/D$  we have  $\mathbb{P}(\text{maxconn}_\alpha(X) \geq t) \leq 2n \cdot (2Dep^\alpha)^t$*

Consider now a local Hamiltonian  $H$ , we define its interaction graph as follows:

► **Definition 25** (Interaction graph of a local Hamiltonian). *Let  $H = \sum_i H_i$  denote a local Hamiltonian on  $n$  qubits. The interaction graph of  $H$ ,  $G(H) = (V, E)$  is defined by  $V = [n]$  corresponding to the  $n$  qubits, and  $e = (i, j) \in E$  if qubits  $i$  and  $j$  share a local term  $H_e$  in  $H$ .*

We would like to show that the  $k$ -th truncated Metropolis-Hastings random process on  $H$  is locally-stochastic for sufficiently small  $k$ .

To see why this is a non-trivial statement, recall that the MH random process does not induce independent errors, since the probability of adding error to a given qubit depends on the additional energy cost induced by flipping that qubit, and that additional energy depends on the specific error configuration on its neighboring qubits.

In fact this random error model implies that errors are *more likely* to occur near previously sampled errors thus leading to a behavior that is completely opposite to local stochasticity. However, we show that if  $k$  is significantly less than  $n/D$  then this effect is negligible compared to the probability of sampling an error that is not connected to any other error, and hence approximately these errors are locally-stochastic.

► **Lemma 26** (The Thermal Gibbs State is Locally-Stochastic). *Let  $\mathcal{C}$  be a stabilizer code and let  $H = H(\mathcal{C})$  denote the corresponding local Hamiltonian. Suppose that the corresponding interaction graph  $G(H)$  has degree at most  $D$ . Let  $\alpha \in (0, 1]$ , and consider the  $k$ -th truncated Markov chain  $\mathcal{M}_k$  and its stationary distribution  $\rho_k$ , for  $k \leq \frac{n}{2e(De^{300})^{1/\alpha}}$ . If the energy density is sufficiently large compared to the inverse temperature:  $\lambda \geq \beta \ln(n)$  then  $\mathcal{E} \sim \rho_k$  is locally-stochastic with parameter at most  $p_0 \leq 2ke/n$  with probability at least  $1 - (k+1)n^{-4}$ .*

We conclude our central lemma of this section - which is that the thermal Gibbs state  $e^{-\beta H}$  where  $H$  is a Hamiltonian corresponding to a qLTC, and  $\beta$  is sufficiently large, satisfies a percolation property - namely that the maximal  $\alpha$ -connected component of a typical error  $\mathcal{E}$  is of logarithmic size:

► **Lemma 27** (Typical error components are small for the thermal state of qLTC's). *Let  $\mathcal{C}$  be a  $(q, s)$ -sLTC on  $n$  qubits and let  $H(\mathcal{C})$  be its corresponding Hamiltonian,  $\lambda(H) = \lambda$ . Suppose that the interaction graph of  $H$ ,  $G(H)$ , is of degree most  $D$ . Let  $\alpha > 0$ . Let  $\tau = \mathcal{E} \cdot \tau_0 \cdot \mathcal{E}$  be a random state (the uniform code mixed state conjugated by a random error  $\mathcal{E}$ ) sampled according to the distribution  $e^{-\beta H/\lambda}/Z$  for  $(10/\alpha) \cdot \ln(D)/s \leq \beta \leq \lambda/\ln(n)$ . Then  $\mathbb{P}(\text{maxconn}_\alpha \mathcal{E} > \ln(n)/100) \leq n^{-3}$*

### The range of values $\beta$

It is insightful at this point to consider the statement of the lemma w.r.t. the parameter  $\beta$ : the statement of the lemma requires that  $\beta$  is within some range - between  $\log\log(n)$  and  $\log(n)$ . This initially might seem strange as intuitively, increasing  $\beta$  can only improve the ability to correct errors since it corresponds to a regime of much fewer errors - e.g. lower temperature.

However in Lemma 26 it turns out that the analysis is more subtle: indeed we require  $\beta$  to be also sufficiently small so that the error model is locally stochastic: if  $\beta$  is too large (i.e. the temperature is very low) it turns out that a qubit that is hit by an error is much more likely to be hit by another error - this contrary to local stochasticity, whereas for higher temperatures this phenomenon is greatly alleviated.

Hence, the phenomenon of locally stochastic errors, that we exploit to demonstrate a shallow decoder is in fact relevant only for a median range of temperatures: for very low temperatures, the error is no longer locally stochastic, but in that range - the *absolute* number of errors is extremely small to allow worst-case error correction. For higher temperatures, the absolute number of errors is very large but conforms to the locally stochastic model which is treatable by a local decoder. This results in a “win-win” situation, which is handled case-by-case in the proof of the main theorem.

## 8 A Shallow Decoder for Low Error Rate

The last component of the proof is to demonstrate a shallow circuit that can correct the thermal state  $e^{-\beta H}$  to a code-state, for sufficiently large  $\beta > 0$  (finite or not). In the previous section we’ve seen that such a state can be modeled as a random error process with small rate. We would now like to leverage that understanding, together with the small-set expansion property of the  $n$ -projective cube to show that the quantum version of the Sipser Spielman decoder yields a shallow decoder.

Inspired by the decoding algorithm of Fawzi et al. [6] we propose an algorithm for decoding a random error  $\mathcal{E}$  in depth proportional to  $\log(\max\text{conn}_\alpha(\mathcal{E}))$ . It is based on a parallel version of the Sipser-Spielman decoder, which we state as follows:

► **Lemma 28** ([18], Theorem 11). (Parallel decoder for small-set expander graphs). *Let  $C$  be a code on  $n$  bits and let  $G$  denote the Tanner graph of  $C$ . Suppose  $G$  is a  $(c, d)$ -bi-regular graph on  $n$  vertices. The parallel decoder  $\mathcal{A}$  is an algorithm that given error  $\mathcal{E} = \mathcal{E}_1$  iteratively replaces it with errors  $\mathcal{E}_i$  for  $i \geq 1$ . At step  $i$  the algorithm may modify bits only in the support of  $\mathcal{E}_i \cup \Gamma(\mathcal{E}_i)$ , and in particular, examines for each bit  $k$  only  $\Gamma(k)$ . If, in addition, at the beginning of iteration  $i$  we have:  $|\Gamma(\mathcal{E}_i)| \geq |\mathcal{E}_i| \cdot c \cdot (3/4 + \varepsilon)$  for some constant  $\varepsilon > 0$ , then after step  $i$  the weight of the residual error  $\mathcal{E}_i$  decreases by a multiplicative factor:  $|\mathcal{E}_{i+1}| \leq |\mathcal{E}_i| \cdot (1 - 4\varepsilon)$*

Our quantum decoder is an application of the Sipser-Spielman decoder on the individual  $X, Z$  errors.

► **Algorithm 29** (Shallow Decoder  $\mathcal{B}$ ).

*Input: a quantum state  $\rho$  on  $n$  qubits, a set of  $X$  checks  $\mathcal{C}_x$  and a set of  $Z$  checks  $\mathcal{C}_z$ .*

1. *Run the decoder  $\mathcal{A}$  w.r.t.  $Z$  errors using  $\mathcal{C}_x$ .*
2. *Run the decoder  $\mathcal{A}$  w.r.t  $X$  errors using  $\mathcal{C}_z$ .*

► **Lemma 30.** *Consider the projective code  $\mathcal{C} = (\mathcal{C}_x, \mathcal{C}_z)$  on  $n$  qubits with  $p = n/2$ , and let  $\mathcal{E} \in \mathcal{P}^n$  denote an error with far-away and small connected components:  $\max\text{conn}_\alpha(\mathcal{E}) \leq \ln(n)/100$ ,  $\alpha = 1/(\gamma \log \log(n))$  where  $\gamma = \log(1 - 4 \cdot (3/16))$  is the constant implied by Lemma 28 for  $\varepsilon = 3/16$ . Then shallow decoder  $\mathcal{B}$  runs in depth at most  $2\gamma \log^2 \log(n)$  steps and satisfies:  $\mathcal{B} \circ \mathcal{E} \circ \rho = \rho \quad \forall \rho \in \mathcal{C}$*

We note here that the decoder  $\mathcal{B}$  requires extra ancillary bits for syndrome computation, hence the notation  $\mathcal{B} \circ \mathcal{E} \circ \rho$  signifies a quantum channel, where some of the qubits are discarded after computation.

## 9 Global Entanglement for Thermal States

### 9.1 The construction

#### 1. Step 1 – The projective code:

Fix  $n$  as the number of qubits in the code. As the basis for our construction we consider the  $(N, p)$  projective code  $\mathcal{C}$  for  $p = N/2$ . By Lemma 16 we can choose  $N = \Theta(\log(n))$  such that  $\mathcal{C}$  is a qLTC  $[[n, 1, n^c]]$  for some  $c > 0$  with qLTC parameters  $(q = \log(n), s = 1/\log^2(n))$ . By construction, the interaction graph of  $H(\mathcal{C})$ , i.e.  $G(H(\mathcal{C}))$  is  $D$ -regular with  $D = 2 \cdot \log(n)$  and the local Hamiltonian  $H$  has  $m = 2n \cdot \log(n)$  check terms.

#### 2. Step 2 – Amplification:

We apply Proposition 9 to conclude the existence of a qLTC, denoted by  $\mathcal{C}'$  with parameters  $(q' = \lceil \log^3(n) \rceil, s' = 1/e)$  and  $\lambda = \log^4(n)$ . The interaction graph of the Hamiltonian of  $\mathcal{C}'$ , i.e.  $G(H(\mathcal{C}'))$  has degree at most  $D' \leq \lceil \log^7(n) \rceil$ .

#### 3. Step 3 – Union:

Finally, we consider the union of the checks of  $\mathcal{C}$  and  $\mathcal{C}'$  and denote the union by  $\mathcal{C}_{pa}$  - this is our construction. We denote the number of checks by  $m_{pa}$ . We have that,  $\mathcal{C}_{pa}$  is  $[[n, 1, n^c]]$  quantum code, and is qLTC with parameters:  $(q_{pa} = \log^3(n), s_{pa} = 1/2e, D_{pa} \leq 2\log^7(n))$  and  $\lambda_{pa} \geq 2\log^4(n)$ .

We note that the amplified code  $\mathcal{C}'$  has constant soundness for all *non-zero* distances, but it is not clear a-priori why it should also satisfy  $\ker(\mathcal{C}) = \ker(\mathcal{C}')$ . Hence, the union of  $\mathcal{C}$  and  $\mathcal{C}'$  is taken in order to enforce the ground-state of the final code to equal that of  $\mathcal{C}_{pa}$ . This slightly reduces the soundness, and increases the degree of the interaction graph of the final code. Also note that the check terms of  $\mathcal{C}_{pa}$  commute in pairs.

### 9.2 Main Theorem

We now state formally our main theorem.

► **Theorem 31.** *Let  $\mathcal{C}_{pa}$  denote the code constructed above on  $n$  qubits, and let  $H = H(\mathcal{C}_{pa})$ ,  $\lambda = \lambda(H)$  and inverse temperature:  $\beta \geq 20e \cdot \log^2 \log(n)$ . Any quantum circuit  $U$  on  $a \geq n$  qubits that approximates the thermal state of  $\tilde{H} = H/\lambda$  on a set of qubits  $S$ ,  $|S| = n$ , at inverse temperature  $\beta$ ,  $\left\| \text{tr}_{-S}(U|0^{\otimes a}\rangle\langle 0^{\otimes a}|U^\dagger) - e^{-\beta \tilde{H}}/Z \right\|_1 \leq 0.1n^{-2}$  has depth at least  $d(U) = \Omega(\log(n))$*

---

## Abstract

A line of work initiated by Fortnow in 1997 has proven model-independent time-space lower bounds for the SAT problem and related problems within the polynomial-time hierarchy. For example, for the SAT problem, the state-of-the-art is that the problem cannot be solved by random-access machines in  $n^c$  time and  $n^{o(1)}$  space simultaneously for  $c < 2 \cos(\frac{\pi}{7}) \approx 1.801$ .

We extend this lower bound approach to the quantum and randomized domains. Combining Grover's algorithm with components from SAT time-space lower bounds, we show that there are problems verifiable in  $O(n)$  time with quantum Merlin-Arthur protocols that cannot be solved in  $n^c$  time and  $n^{o(1)}$  space simultaneously for  $c < \frac{3+\sqrt{3}}{2} \approx 2.366$ , a super-quadratic time lower bound. This result and the prior work on SAT can both be viewed as consequences of a more general formula for time lower bounds against small-space algorithms, whose asymptotics we study in full.

We also show lower bounds against randomized algorithms: there are problems verifiable in  $O(n)$  time with (classical) Merlin-Arthur protocols that cannot be solved in  $n^c$  randomized time and  $O(\log n)$  space simultaneously for  $c < 1.465$ , improving a result of Diehl. For quantum Merlin-Arthur protocols, the lower bound in this setting can be improved to  $c < 1.5$ .

## 1 Introduction

A flagship problem in computational complexity is to prove lower bounds for the SAT problem. While it is conjectured that no polynomial-time algorithms exist for SAT (in other words,  $P \neq NP$ ), not much progress has been made in that direction. Furthermore, several significant barriers towards such a separation are known [3, 22, 1]. Therefore, approaches have centered around proving weaker lower bounds on SAT first.

A natural preliminary step in showing that no polynomial-time algorithm can decide SAT is showing that no algorithms of logarithmic space can decide SAT, or in other words, showing that  $L \neq NP$ . Unlike the P vs. NP problem, the aforementioned complexity barriers (arguably) do not apply as readily to L vs. NP, and concrete progress has been made.<sup>1</sup>

Following a line of work [11], R. Williams [25] proved that SAT (equivalently<sup>2</sup> NTIME[ $n$ ], nondeterministic linear time) cannot be decided by algorithms (even with constant-time random access to their input and storage) using both  $n^{o(1)}$  space and  $n^c$  time, for  $c < 2 \cos(\frac{\pi}{7}) \approx 1.802$ . If one could show the same lower bound for arbitrarily large constant  $c$ , the separation  $L \neq NP$  would follow immediately. In the following we use  $TS[n^c]$  to denote the class of languages decidable by  $n^{o(1)}$ -space algorithms using  $n^c$  time.

All the aforementioned work builds on the *alternation-trading proofs* approach [27]. This approach combines two elements: a *speedup rule* that reduces the runtime of an algorithm by “adding a quantifier” ( $\exists$  or  $\forall$ ) to an alternating algorithm, and a *slowdown rule* that uses a complexity theoretic assumption (for example,  $SAT \in TS[n^c]$ ) to “remove a quantifier” and slightly increase the runtime of the resulting algorithm. Both rules yield inclusions of complexity classes. Our ultimate goal is to contradict a time hierarchy theorem (e.g., proving  $n^{100}$  time computations can be simulated in  $n^{99}$  time) by applying these rules in a nice order, and with appropriately chosen parameters.

One may hope that the constant  $c$  from [25] can be made arbitrarily large, and eventually show that  $L \neq NP$ . Unfortunately, in [7], R. Williams and S. Buss showed that no alternation-trading proof based purely on the speedup and slowdown rules from that line of work could improve on the exponent of [25].

Nevertheless, there is hope that alternation-trading proofs might yield stronger lower bounds for problems harder than SAT. For example, R. Williams [27] showed that the  $\Sigma_2P$ -complete problem  $\Sigma_2SAT$  is not in  $TS[n^c]$ , for  $c < 2.903$ . In this paper, we make further progress in this direction. In particular, we focus on the quantum and randomized analogues of NTIME[ $n$ ], QCMATIME[ $n$ ] and MATIME[ $n$ ], obtaining stronger lower bounds against both classes.<sup>3</sup> We believe our lower bound for QCMATIME[ $n$ ] (Main Theorem 2) to be particularly interesting because it yields a *nontrivial* separation between a quantum complexity class and a classical complexity class *without the need for oracles*.<sup>4</sup> While there are several results [6, 21, 24] demonstrating the power of quantum computation against very restricted low-depth classical circuit models ( $NC^0$ ,  $AC^0$ ,  $AC^0[2]$ ) which also imply strong oracle separation results, our result appears to be the first non-trivial lower bound for a quantum class against the much more general random-access machine model (with simultaneous time and space constraints).

## 1.1 Our Results

### 1.1.1 Generic slowdown rules and a lower bound for QCMATIME[ $n$ ]

For showing stronger lower bounds on QCMATIME[ $n$ ], our key observation is that the stronger assumption  $QCMATIME[n] \subseteq TS[n^c]$  (compared to  $NTIME[n] \subseteq TS[n^c]$ ) can be applied to construct a stronger conditional slowdown rule. Formally, we generalize the

<sup>1</sup> For example, there exist oracles relative to which the lower bounds in the following paragraph are false.

<sup>2</sup> At least, up to polylogarithmic factors.

<sup>3</sup> Recall that QCMA (quantum classical Merlin-Arthur) is essentially NP with a quantum verifier and MA (Merlin-Arthur) is essentially NP with a randomized verifier.

<sup>4</sup> By “nontrivial”, we mean a separation that does not immediately follow from known classical results. For example,  $QCMATIME[n] \not\subseteq TS[n^{1.8}]$  follows immediately from the classical lower bound  $NTIME[n] \not\subseteq TS[n^{1.8}]$ , but our result does not.

previous framework of alternation-trading proofs by introducing the notion of a *generic slowdown rule* (defined formally in Definition 11), which are slowdown rules parameterized by a constant  $\alpha \in (0, 1]$  controlling the runtime cost associated with removing a quantifier. Smaller values of  $\alpha$  correspond to stronger slowdown rules. We prove the following theorem showing how generic slowdown rules imply time-space lower bounds.

► **Main Theorem 1.** *Fix  $\alpha \in (0, 1]$  and let  $\mathcal{C}$  be a complexity class. Let  $r_1$  be the largest root of the polynomial  $P_\alpha(x) := \alpha^2 x^3 - \alpha x^2 - 2\alpha x + 1$ . If  $\mathcal{C} \subseteq \text{TS}[n^c]$  implies a generic slowdown rule with parameters  $\alpha$  and  $c$ , then  $\mathcal{C} \not\subseteq \text{TS}[n^c]$  for  $c < r_1$ .*

The assumption  $\text{NTIME}[n] \subseteq \text{TS}[n^c]$  implies a slowdown rule with  $\alpha = 1$ . The previous  $\text{NTIME}[n] \not\subseteq \text{TS}[n^c]$  for  $c < 2 \cos(\frac{\pi}{7})$  lower bound [25] becomes an immediate corollary of Main Theorem 1 if we take  $\mathcal{C} = \text{NTIME}[n]$ . The stronger slowdown rule that we obtain from the stronger assumption  $\text{QCMATIME}[n] \subseteq \text{TS}[n^c]$  has  $\alpha = \frac{2}{3}$ , which allows us to derive lower bounds for larger values of  $c$ . In particular, we obtain the following lower bound for Quantum (Classical) Merlin-Arthur linear time.

► **Main Theorem 2.**  $\text{QCMATIME}[n] \not\subseteq \text{TS}[n^c]$  for  $c < \frac{3+\sqrt{3}}{2} \approx 2.366$ .

The main advantage of the generic slowdown approach and Main Theorem 1 is that improvements in slowdown rules translate immediately into stronger bounds against TS. Figure 1 shows how the lower bound exponent we obtain changes as  $\alpha$  does. As expected, the lower bound exponent goes to infinity as  $\alpha$  approaches zero, but we see that even modest improvements in  $\alpha$  yield substantially stronger bounds. We discuss potential applications further in Section 1.3. In the full version of the paper, we show that this dependence between the generic slowdown parameter and lower bound exponent is “optimal” for the tools we use, extending the optimality theorem of Buss and Williams [7] to the general case while also providing a shorter proof of their optimality theorem.

■ **Figure 1** The lower bound exponent as a function of the generic slowdown parameter  $\alpha$ .

### 1.1.2 Lower bounds against randomized logspace

We also prove lower bounds against randomized logspace with two-sided error. While the techniques used in this setting are similar, the results do not follow from Main Theorem 1, so we state them separately. When discussing the randomized setting, we will slightly abuse

notation by referring to the class of languages decidable by a logspace machine in  $n^c$  time as  $\text{BPTS}[n^c]$ .<sup>5</sup> We prove lower bounds for both linear-time Merlin-Arthur protocols and linear-time Classical-Merlin Quantum-Arthur protocols.

► **Main Theorem 3.** *Let  $r_1 \approx 1.465$  be the largest root of the polynomial  $x^3 - x^2 - 1$ . Then,  $\text{MATIME}[n] \not\subseteq \text{BPTS}[n^c]$  for  $c < r_1$ . Furthermore,  $\text{QCMATIME}[n] \not\subseteq \text{BPTS}[n^c]$  for  $c < 1.5$ .*

Prior to this work, the state-of-the-art, due to [10, 8], was that  $\text{MATIME}[n] \not\subseteq \text{BPTS}[n^c]$  for  $c < \sqrt{2} \approx 1.414$ . Observe that  $\text{MATIME}[t] \subseteq \text{PPTIME}[t^2]$  because we can amplify Arthur’s completeness and soundness to  $(1 - 2^{-100t}, 2^{-100t})$  while increasing the runtime of the verifier by a factor of  $O(t)$ , and we can union bound over Merlin’s strings.<sup>6</sup> A similar argument, coupled with the quasilinear-time simulation of bounded-error quantum computation with unbounded-error random computation of [23], shows that  $\text{QCMATIME}[t] \subseteq \text{PPTIME}[t^2]$ . Therefore, pushing either of the lower bound exponents in Main Theorem 3 to beyond 2 would yield superlinear bounds for decision versions of counting-type problems (e.g. MAJ-SAT) against randomized logspace. (Note it is known that  $\#\text{SAT}$  requires  $\tilde{O}(n^2)$  time for randomized logspace [17].) While these results are admittedly incremental improvements, they use some different ideas compared to previous works, and may be amenable to further improvement (see Section 1.3 for more details).

The lower bounds of Main Theorem 2 and Main Theorem 3 actually hold for complexity classes that are presumably even “smaller” than  $\text{QCMATIME}[n]$  and  $\text{MATIME}[n]$ ; we describe these further in Section 2.

## 1.2 Techniques

### 1.2.1 Alternation-trading proofs

Many time-space lower bounds for SAT and related problems are proved via *alternation-trading proofs*, which give a chain of inclusions of complexity classes. We will formally define alternation-trading proofs in Section 2; for now, let us give a cursory explanation. An *alternation-trading proof* consists of a sequence of containments of *alternating complexity classes*. An alternating complexity class can be thought of as a “fine-grained” version of  $\Sigma_k\text{P}$  or  $\Pi_k\text{P}$ : it is a complexity class parameterized by  $(k + 1)$  positive constants bounding the length of the output of each quantifier and the verifier runtime. For example,

$$(\exists n^2)(\forall n^2)\text{TS}[n^5]$$

is an alternating complexity class. This notation refers to the class of languages decided by a  $\Sigma_2$  machine where, on inputs of length  $n$ , the two quantifiers each quantify over  $\tilde{O}(n^2)$  bit strings and the *verifier runtime* is  $\tilde{O}(n^5)$ .

In an alternation-trading proof, there are two main ways of passing from one alternating complexity class to the next. The first is a **speedup rule**, which adds a quantifier to the class, and decreases the verifier runtime. For example, a speedup rule might yield an inclusion of the form

$$\dots \text{TS}[n^d] \subseteq \dots (Qn^x)(\neg Qx \log n) \text{TS}[n^{d-x}] \quad (1)$$

<sup>5</sup> We call this a “slight abuse” because we defined  $\text{TS}$  to be a class of languages decided using  $n^{o(1)}$  space, whereas  $\text{BPTS}$  is defined with respect to  $O(\log n)$  space.

<sup>6</sup> By a union bound, there is a gap between the case where all  $2^t$  Merlin strings have a  $2^{-100t}$  chance of accepting, and the case where a single Merlin string accepts with probability at least  $1 - 2^{-100t}$ .

for some constant  $0 < x < d$  and quantifier  $Q \in \{\exists, \forall\}$ , where  $\neg Q$  denotes the opposite quantifier and the  $\dots$  refer to other quantifiers. Two important points to note are that (a) the speedup rule is generally an unconditionally true inclusion and (b) the second quantifier has only  $O(\log n)$  bits.

The second major component of alternation-trading proofs is a **slowdown rule**, which removes a quantifier and increases the verifier runtime. We will use slowdown rules that hold conditioned on complexity-theoretic assumptions (that we will later contradict). For example, the slowdown rule used to prove lower bounds on  $\text{NTIME}[n]$  can be informally stated as follows: assuming  $\text{NTIME}[n] \subseteq \text{TS}[n^c]$  for some  $c > 0$ ,

$$\dots(Qn^a)(\neg Qn^b)\text{TS}[n^d] \subseteq \dots(Qn^a)\text{TS}[n^{c \cdot \max(a,b,d)}]. \quad (2)$$

where again  $Q \in \{\exists, \forall\}$  and  $\neg Q$  denotes the opposite quantifier. This rule follows from an application of padding/translation.

While the speedup and slowdown rules are themselves simple, the existing lower bounds on  $\text{NTIME}[n]$  arise by applying these rules in a long intricate sequence, with appropriately chosen parameters for the speedup rule applications. Ultimately, we aim to use slowdown and speedup rules to exhibit a sequence of inclusions that shows (for example) that  $\text{NTIME}[n^d] \subseteq \text{NTIME}[n^{d'}]$  for  $d' < d$ , contradicting the nondeterministic time hierarchy theorem and demonstrating that our initial assumption must have been false.

All time-space lower bounds for SAT against random-access models of computation, including the state-of-the-art bound [25], use an alternation-trading proof. This particular proof will be a starting point for this work.

### 1.2.2 Generic slowdown rules

We start by introducing the notion of a generic slowdown rule. Generic slowdown rules are parameterized by a constant  $\alpha$  such that  $0 < \alpha \leq 1$ , along with a constant  $c \geq 1$  that generally comes with an assumption being made. Informally, generic slowdown rules allow us to – under an appropriate assumption – prove conditional inclusions of the form

$$\dots(Qn^a)(\neg Qn^b)\text{TS}[n^d] \subseteq \dots(Qn^a)\text{TS}[n^{\alpha c \cdot \max(a,b,d)}].$$

Observe that when  $\alpha = 1$  we recover (2), but when  $\alpha < 1$  we obtain stronger inclusions. In Main Theorem 1, we use generic slowdowns in the alternation-trading proof from [25] and characterize the lower bound we obtain as a function of the parameter  $\alpha$  in our generic slowdown rule. While the core idea of this proof is essentially the same as the presentation of the proof in [27] (and the result can be thought of as “putting  $\alpha$  everywhere”), our proof technique is somewhat different. In the full version of the paper, this different approach yields a shorter proof of optimality than the one presented by Buss and Williams [7].

### 1.2.3 A generic slowdown rule from Grover search

In order to apply Main Theorem 1 to  $\mathcal{C} = \text{QCMATIME}[n]$  and obtain a better lower bound for QCMA, we show that the assumption  $\text{QCMATIME}[n] \subseteq \text{TS}[n^c]$  implies a generic slowdown rule for  $\alpha = \frac{2}{3}$ . Recall that Grover’s algorithm lets us search a space of size  $N$  with only  $O(\sqrt{N})$  quantum queries. We obtain our stronger slowdown rule by showing that Grover’s algorithm can be used to more efficiently remove the  $(x \log n)$ -bit quantifiers that arise after applications of the speedup rule, such as (1). In the  $\text{NTIME}$  vs  $\text{TS}$  setting, there are two ways to remove an  $(x \log n)$ -bit quantifier. First, we could remove it with an  $O(n^x)$

multiplicative blowup, by having the verifier exhaustively search through all strings of length  $x \log n$ . However, naively running  $n^x$  trials of an  $n^{d-x}$  computation would take  $n^d$  time, and our simulation would end up no faster than it was initially. Second, we may try to use a slowdown rule as in (2), but this incurs a runtime cost that depends on  $c$ . This option becomes expensive as we try to increase  $c$  and prove stronger lower bounds. Our key insight is that if our verifier is allowed to be quantum, Grover’s algorithm can be applied to perform this quantifier elimination in only  $O(n^{x/2})$  extra time overhead, independent of  $c$ . Then, by applying the assumption  $\text{QCMATIME}[n] \subseteq \text{TS}[n^c]$ , we can remove this quantum verifier along with the quantifier  $(\exists n^x)$  and ultimately demonstrate the inclusions

$$\begin{aligned}
& \dots (Qn^a)(\neg Qn^b)\text{TS}[n^d] \\
& \subseteq \dots (Qn^a)(\neg Qn^b)(Qn^x)(\neg Qx \log n)\text{TS}[n^{d-x}] && \text{Speedup Rule} \\
& \subseteq \dots (Qn^a)(\neg Qn^b)(Qn^x)\text{BQTIME}[n^{d-\frac{x}{2}}] && \text{Grover's Algorithm} \\
& \subseteq \dots (Qn^a)(\neg Qn^b)\text{TS}[n^{c \cdot \max(b, x, d-\frac{x}{2})}]. && \text{Assumption on QCMATIME}[n]
\end{aligned}$$

Letting  $x := \frac{2d}{3}$ , we obtain a generic slowdown rule with  $\alpha = \frac{2}{3}$ .

### 1.2.4 Lower bounds against randomized logspace

Some obstacles arise when trying to prove Main Theorem 3, which shows lower bounds against BPTS. The main problem is that the usual speedup rules for deterministic computation do not tell us how to use quantifiers to speedup randomized small-space computations. Fortunately, this particular issue was resolved by Diehl and Van Melkebeek [10], who gave a speedup rule for small-space randomized machines by coupling Nisan’s space-bounded derandomization [20] with the Sipser-Gács-Lautemann theorem [16]. This speedup rule, while somewhat less efficient than the speedup rule for deterministic machines, is still enough to obtain interesting superlinear time lower bounds. Applying this speedup rule, similar arguments as used in Main Theorem 1 yield the desired lower bounds.

## 1.3 Future Work

As mentioned earlier, the main advantage of the generic slowdown framework and Main Theorem 1 is that improvements in slowdown rules translate immediately into stronger bounds against TS. To this end, we highlight two particularly interesting directions.

1. Is it possible to prove a “quantum speedup rule”, whereby the runtime of quantum computations could be reduced by adding quantifiers (possibly over quantum states)? Presently, we are forced to use a slowdown rule to remove a quantum verifier from an alternating complexity class as soon as it is added. Having a quantum speedup rule would enable us to work with the quantum verifier before removing it, drastically widening the scope for potential alternation-trading proofs. It’s not hard to show that even certain weak forms of a quantum speedup rule would improve the generic slowdown parameter  $\alpha$  we can obtain in the QCMA vs. TS setting. Speedup rules also have applications outside complexity theory. For example, versions of speedup rules for low-space computation appear in the construction of delegation schemes in cryptography [4, 13, 14], and quantum speedup rules could play a part in extending such work to the quantum domain.

2. Can we use the ideas of this paper to improve existing lower bounds on counting-type ( $\#P$  related) problems, such as  $\#SAT$  and  $MAJ-SAT$ ? For example, could our super-quadratic time lower bound for  $QCMATIME[n]$  be somehow applied to obtain super-quadratic lower bounds for  $\#SAT$  as well? Because

$$MATIME[t] \subseteq QCMATIME[t] \subseteq PPTIME[t^{2+o(1)}]$$

as discussed in Section 1.1.2, lower bounds on  $QCMATIME[n]$  and  $MATIME[n]$  do translate to some lower bounds for counting problems against small-space. However, the known reductions from classes like  $MA$  and  $QCMA$  to counting problems incur a quadratic blowup. Furthermore, there is evidence that a quadratic blowup is necessary for black-box techniques [8, 9]. As such, it appears we must either improve the lower bound exponent, or prove that we can bypass the quadratic blowup outside of black-box settings.

## 1.4 Organization

Section 2 covers relevant background, especially on alternation-trading proofs. In Section 3, we study alternation-trading proofs with generic slowdowns and prove Main Theorem 1. In Section 4, we use Grover's algorithm to prove Lemma 30, allowing us to obtain a generic slowdown with  $\alpha = \frac{2}{3}$  and prove Main Theorem 2. In Section 5, we prove Main Theorem 3.

## 2 Preliminaries

We assume familiarity with classical complexity and quantum computing on the levels of [2] and [19], respectively.

### 2.1 Alternation-Trading Proofs

We start by defining various time-space complexity classes particular to this work. For a simple example of an alternation-trading proof, see Section 2.1.1 of the full version.

► **Definition 1.**  $TS[t(n)]$  is the class of languages computable by a deterministic random-access machine using space  $n^{o(1)}$  and time  $\tilde{O}(t(n))$  on an  $n$ -bit input.  $BPTS[t(n)]$  is the class of languages computable by a two-sided error randomized random-access machine using space  $O(\log n)$  and time  $\tilde{O}(t(n))$  on an  $n$ -bit input.

Note that a *randomized* random-access machine with random access to its input has only read-once access to its randomness.

► **Definition 2.** For positive constants  $\{a_i\}_{i \geq 1}$  and  $\{b_i\}_{i \geq 1}$  and quantifiers  $Q_i \in \{\exists, \forall\}$ , the **alternating complexity class**  $(Q_1 n^{a_1})^{b_1} (Q_2 n^{a_2})^{b_2} \dots (Q_k n^{a_k})^{b_k} TS[n^d]$  is the set of languages decidable by a machine operating in the following fashion on an  $n$ -bit input. Computation occurs in  $k + 1$  stages. In the  $i^{th}$  stage, for  $1 \leq i \leq k$ , the machine obtains from  $Q_i$  a string of length  $\tilde{O}(n^{a_i})$ . It then uses an  $n^{o(1)}$ -space machine and  $\tilde{O}(n^{b_i})$  time to compute  $\tilde{O}(n^{b_i})$  bits that are passed on to the next stage, taking as input the  $\tilde{O}(n^{a_i})$  bit string from the quantifier and the  $\tilde{O}(n^{b_{i-1}})$ -bit input from the previous stage of computation. The input to the first stage ( $i = 1$ ) is the  $n$ -bit input string itself. The verifier at the end receives an  $\tilde{O}(n^{b_k})$ -bit input and uses a  $n^{o(1)}$ -space machine and  $\tilde{O}(n^d)$  time to compute the final answer. The criteria for acceptance and rejection are analogous to those for  $\Sigma_k P$  and  $\Pi_k P$ .

Note that our notation obscures  $n^{o(1)}$  factors everywhere, although we may occasionally write out small factors for clarity. We index our  $b_i$  differently from the notation of [27], as our  $b_i$  is their  $b_{i+1}$ . This difference will be immaterial.

► **Definition 3.** Given an alternating complexity class  $(Q_1 n^{a_1})^{b_1} \dots (Q_k n^{a_k})^{b_k} \text{TS}[n^d]$ , we will refer to  $n^d$  as the **verifier runtime**.

► **Lemma 4** (Speedup Lemma [18][15]). For every  $0 < x < d$ ,

$$\text{TS}[n^d] \subseteq (Q n^x)^{\max(x,1)} (\neg Q x \log n)^1 \text{TS}[n^{d-x}].$$

Because our notation obscures  $n^{o(1)}$  factors, we may write this as

$$\text{TS}[n^d] \subseteq (Q n^x)^{\max(x,1)} (\neg Q n^0)^1 \text{TS}[n^{d-x}]. \quad (3)$$

**Proof.** We will prove the lemma when  $Q = \exists$ ; the other case follows because  $\text{TS}[n^d]$  is closed under complementation. The idea is that we can break up the transcript of a deterministic computation of length  $n^d$  into  $n^x$  pieces each of length  $n^{d-x}$ . Let  $M$  be an  $n^d$  time machine using  $n^{o(1)}$  space. On an  $n$ -bit input, our  $\Sigma_2$  machine will:

1. **Existentially** guess  $n^x - 1$  intermediate machine configurations  $X_1, \dots, X_{n^x-1}$  of  $M$ , each of size  $n^{o(1)}$ . These are passed, along with the input, to the next stage. This corresponds to the  $(Q n^x)^{\max(x,1)}$  part of the class in (3).
2. **Universally** quantify over all intermediate configurations, picking one. There are  $n^x$  pieces so our quantifier only needs  $O(\log n^x) \leq \tilde{O}(n^0)$  bits. If the quantifier picks the  $i^{\text{th}}$  configuration, then we pass the state pair  $(X_{i-1}, X_i)$  (along with the input) on to the next stage. We take  $X_0$  to be the initial configuration of  $M$ , and  $X_n$  to be the (WLOG unique) accepting machine configuration. This corresponds to the  $(\neg Q n^0)^1$  part in (3).
3. Given input  $x$  and a pair of configurations  $(X, Y)$  of  $M$ , the verifier simulates  $M$  starting at  $X$  for  $n^{d-x}$  steps, accepting if the configuration at the end is  $Y$  and rejecting otherwise. This corresponds to the  $\text{TS}[n^{d-x}]$  part of (3).

This completes the proof. ◀

As an extension, we may derive the speedup rule that we will use throughout this paper.

► **Corollary 5** (“Usual” Speedup Rule, [27]). For every  $0 < x < d$ ,

$$\begin{aligned} & (Q_1 n^{a_1})^{b_1} \dots (Q_k n^{a_k})^{b_k} \text{TS}[n^d] \\ & \subseteq (Q_1 n^{a_1})^{b_1} \dots (Q_k n^{\max(a_k, x)})^{\max(b_k, x)} (Q_{k+1} x \log n)^{b_k} \text{TS}[n^{d-x}]. \end{aligned}$$

**Proof.** Observe that we may merge together two quantifiers of the same type. Thus, taking  $Q = Q_k$  in Lemma 4, we find that

$$\begin{aligned} & (Q_1 n^{a_1})^{b_1} \dots (Q_k n^{a_k})^{b_k} \text{TS}[n^d] \\ & \subseteq (Q_1 n^{a_1})^{b_1} \dots (Q_k n^{a_k})^{b_k} (Q_k n^x)^{\max(b_k, x)} (Q_{k+1} x \log n)^{b_k} \text{TS}[n^{d-x}] \\ & \subseteq (Q_1 n^{a_1})^{b_1} \dots (Q_k n^{\max(a_k, x)})^{\max(b_k, x)} (Q_{k+1} x \log n)^{b_k} \text{TS}[n^{d-x}] \end{aligned}$$

where the second containment follows from Lemma 4. ◀

One might wonder whether we can do any better by also considering the containment arising from taking  $Q = \neg Q_k$  in Lemma 4. It turns out that any alternation-trading proof using this latter rule can be obtained with Corollary 5, and therefore we may safely ignore this option. This is Lemma 3.2 of [27].

► **Definition 6.** We refer to the value  $x$  in an application of the speedup rule as the **speedup parameter** for that application.

In Section 5, we will work with alternating complexity classes with randomized space-bounded verifiers, rather than deterministic ones. We will use a speedup rule due to Diehl and van Melkebeek [10].

► **Theorem 7** ([10]).  $\text{BPTS}[n^d] \subseteq (\forall n^0)^1 (\exists n^x)^{\max(x,1)} (\forall x \log n) \text{TS}[n^{d-x}]$ .

A sketch of the proof is in the full version. Note again that our notation allows us to hide  $n^{o(1)}$  factors. We chose not to obscure the last  $x \log n$  bits, as they will be extremely relevant later when we use Grover’s algorithm to remove  $O(\log n)$ -bit quantifiers.

As before, we may express Theorem 7 as a rule that can be applied to alternating complexity classes.

► **Corollary 8** (The “Randomized” Speedup Rule). *For every  $0 < x < d$ ,*

$$\begin{aligned} & (Q_1 n^{a_1})^{b_1} \dots (Q_k n^{a_k})^{b_k} \text{BPTS}[n^d] \\ & \subseteq (Q_1 n^{a_1})^{b_1} \dots (Q_k n^{a_k})^{b_k} (Q_{k+1} n^x)^{\max(b_k, x)} (Q_{k+2} x \log n)^{b_k} \text{TS}[n^{d-x}]. \end{aligned}$$

Note that unlike Corollary 5, which adds two quantifiers to speed up a deterministic computation, Corollary 8 adds three<sup>7</sup>.

We’ve already introduced the usual slowdown lemma, which we restate for convenience.

► **Lemma 9** (Slowdown Lemma [11]). *Assume that  $\text{NTIME}[n] \subseteq \text{TS}[n^c]$  for some  $c > 1$ . Then for all  $d \geq 1$ ,  $\text{NTIME}[n^d] \cup \text{coNTIME}[n^d] \subseteq \text{TS}[n^{cd}]$ .*

The slowdown rule follows from a padding argument and the observation that  $\text{TS}[n^c]$  is closed under complementation.

► **Corollary 10** (“Usual” Slowdown Rule [27]). *Assuming  $\text{NTIME}[n] \subseteq \text{TS}[n^c]$ , we have*

$$\begin{aligned} & (Q_1 n^{a_1})^{b_1} \dots (Q_k n^{a_k})^{b_k} \text{TS}[n^d] \\ & \subseteq (Q_1 n^{a_1})^{b_1} \dots (Q_{k-1} n^{a_{k-1}})^{b_{k-1}} \text{TS}[n^{c \cdot \max(d, b_k, a_k, b_{k-1})}]. \end{aligned}$$

Note that the exponent  $b_{k-1}$  is present in the maximum, because our assumption is  $\text{NTIME}[n] \subseteq \text{TS}[n^c]$  rather than  $\text{NTIME}[n^\delta] \subseteq \text{TS}[n^{c\delta}]$  for all  $\delta > 0$ .

► **Definition 11.** *Let  $c, \alpha \in \mathbb{R}$  such that  $0 < \alpha \leq 1 < c$ . A **generic slowdown rule with parameters  $\alpha$  and  $c$**  shows that*

$$(Q_1 n^{a_1})^{b_1} \dots (Q_k n^{a_k})^{b_k} \text{TS}[n^d] \subseteq (Q_1 n^{a_1})^{b_1} \dots (Q_{k-1} n^{a_{k-1}})^{b_{k-1}} \text{TS}[n^{c \cdot \max(\alpha d, b_k, a_k, b_{k-1})}].$$

Intuitively, having a generic slowdown rule with parameters  $c$  and  $\alpha$  means that we can turn classes like

$$\exists \forall \dots \exists \forall \text{TIME}[n^d]$$

into

$$\exists \forall \dots \forall \text{TIME}[n^{\alpha c d}].$$

We are now ready to define alternation-trading proofs.

<sup>7</sup> In both cases, the first quantifier is absorbed into the previous quantifier if one exists, in which case the number of “new” quantifiers is one and two respectively.

► **Definition 12** ([27]). An **alternation-trading proof** is a list of alternating complexity classes, where each subsequent class on the list is contained in the previous class. Each class is derived from the previous by applying one of the following rules.

1. If the class is  $\text{TS}[n^d]$  (i.e., the verifier is deterministic and there are no quantifiers), we may apply Lemma 4:

$$\text{TS}[n^d] \subseteq (\exists n^x)^{\max(x,1)} (\forall x \log n)^1 \text{TS}[n^{d-x}]$$

for some  $x \in (0, d)$ .

2. If the class has at least one quantifier and the verifier is deterministic (i.e., the class ends with  $\text{TS}[n^d]$ ), we may apply Corollary 5:

$$\begin{aligned} & (Q_1 n^{a_1})^{b_1} \dots (Q_k n^{a_k})^{b_k} \text{TS}[n^d] \\ & \subseteq (Q_1 n^{a_1})^{b_1} \dots (Q_k n^{\max(a_k, x)})^{\max(b_k, x)} (Q_{k+1} x \log n)^{b_k} \text{TS}[n^{d-x}] \end{aligned}$$

for some  $x \in (0, d)$ .

3. If the class is  $\text{BPTS}[n^d]$  (i.e., the verifier is randomized and there are no quantifiers), we may apply Theorem 7:

$$\text{BPTS}[n^d] \subseteq (\exists n^0)^1 (\forall n^x)^{\max(x,1)} (\exists x \log n) \text{TS}[n^{d-x}]$$

for some  $x \in (0, d)$ .

4. If the class has at least one quantifier and the verifier is randomized (i.e., the class ends with  $\text{BPTS}[n^d]$ ), we may apply Corollary 8:

$$\begin{aligned} & (Q_1 n^{a_1})^{b_1} \dots (Q_k n^{a_k})^{b_k} \text{BPTS}[n^d] \\ & \subseteq (Q_1 n^{a_1})^{b_1} \dots (Q_k n^{a_k})^{b_k} (Q_{k+1} n^x)^{\max(b_k, x)} (Q_{k+2} x \log n)^{b_k} \text{TS}[n^{d-x}] \end{aligned}$$

for some  $x \in (0, d)$ .

5. If the class has at least one quantifier, and a generic slowdown rule with parameters  $\alpha$  and  $c$  hold for the class, we may apply it:

$$\dots (Q_k n^{a_k})^{b_k} (\text{BP}) \text{TS}[n^d] \subseteq \dots (Q_{k-1} n^{a_{k-1}})^{b_{k-1}} (\text{BP}) \text{TS}[n^{c \cdot \max(\alpha d, b_k, a_k, b_{k-1})}].$$

We say that an alternation-trading proof **shows a contradiction for  $c$**  if it contains an application of a speedup rule and the proof shows either  $\text{TS}[n^d] \subseteq \text{TS}[n^{d'}]$  for  $d' \leq d$  or  $\text{BPTS}[n^d] \subseteq \text{BPTS}[n^{d'}]$  for  $d' \leq d$ .

Note that rules 3 and 4 only apply when proving lower bounds against BPTS.

The containment  $\text{TS}[n^d] \subseteq \text{TS}[n^{d'}]$  for  $d \geq d'$  does not automatically yield a contradiction<sup>8</sup>. Fortunately however, we are still able to derive contradictions from this.

► **Theorem 13** (Lemma 3.1 of [27]). If, under the assumption  $\text{NTIME}[n] \subseteq \text{TS}[n^c]$ , there is an alternation-trading proof with at least two inclusions showing that  $\text{TS}[n^d] \subseteq \text{TS}[n^{d'}]$  for  $d' \leq d$ , then the assumption must have been false and  $\text{NTIME}[n] \not\subseteq \text{TS}[n^c]$

<sup>8</sup> To apply the naive approach, we need a single machine in  $\text{TS}[n^d]$  that can simulate everything in  $\text{TS}[n^{d'}]$ . However, any fixed machine in  $\text{TS}[n^d]$  cannot simulate things use more space than it does. If our simulating machine in  $\text{TS}[n^d]$  uses space  $f(n) = n^{o(1)}$  then there is always a machine in  $\text{TS}[n^{d'}]$  that uses more space while still being  $n^{o(1)}$  and our simulating machine cannot simulate this one.

In Section 5, we will show that similar statements hold for BPTS in the contexts in which we need them to hold, thus allowing us to derive contradictions from  $\text{BPTS}[n^d] \subseteq \text{BPTS}[n^{d'}]$  for  $d' \leq d$ .

► **Definition 14** ([27]). *An alternating complexity class  $(Q_1 n^{a_1})^{b_1} \dots (Q_k n^{a_k})^{b_k} (\text{BP})\text{TS}[n^d]$  is **orderly** if for all  $i \in [k]$ ,  $a_i \leq b_i$ .*

► **Lemma 15** ([27]). *Any alternation-trading proof using rules from Definition 12 is orderly.*

As noted by Buss and Williams [7], Lemma 15 implies that, when describing an alternation-trading proof consisting of speedups and slowdowns, it is sufficient to only specify the  $\{b_i\}$  and disregard the  $\{a_i\}$ . We will be somewhat more careful when we apply Grover’s algorithm in the quantum setting, but when we can we will simplify our notation by writing only a single exponent inside the parenthesis. Thus, we may abuse notation to write alternating complexity classes in the form  $(Q_1 n^{a_1}) \dots (Q_k n^{a_k}) (\text{BP})\text{TS}[n^d]$ , where the  $a_i$  are then understood to be the maxima of the corresponding pairs of exponents in the full notation.

► **Definition 16** ([27]). *A **proof annotation** is a way of specifying a sequence of applications of speedup and slowdown rules. We write **1** to denote a speedup rule and **0** to denote a (possibly generic) slowdown rule. When appropriate, we put a subscript under a **1** to denote the speedup parameter used for that speedup rule application.*

In this paper, we will work with alternation-trading proofs which apply only one slowdown rule (many times). For such proofs, the sequence of speedups and slowdowns fully determines whether the verifier is deterministic or randomized at a given line of the proof. This means that, when specifying a proof annotation, we do not need to specify which speedup rule we are applying between Corollary 5 and Corollary 8. When the verifier is randomized we must apply Corollary 8, and when the verifier is deterministic we should always apply Corollary 5 as it is strictly more efficient than Corollary 8.

## 2.2 Computational Model

All functions used to bound runtime or space are assumed to be constructible in the given resources. Our model for classical computation is the space-bounded random-access machine, unless specified otherwise. Our proofs are robust to all notions of random access we know.

Our model for quantum computation will be that of Van Melkebeek and Watson [23], but our results hold for any reasonable quantum model capable of *obliviously* applying unitaries from a fixed universal set and with quantum random-access to the input.<sup>9</sup> Recall that if  $x \in \{0, 1\}^n$  is an input, an algorithm is said to have quantum random-access to  $x$  if it can perform the transformation

$$\sum_{i \in [n]} \alpha_i |i\rangle |b\rangle \mapsto \sum_{i \in [n]} \alpha_i |i\rangle |b \oplus x_i\rangle,$$

where  $i$  is an index and  $x_i$  denotes the bit at the  $i^{\text{th}}$  position of  $x$ . The model of [23] is capable of simulating all the usual models of quantum computing, and deals carefully with issues like intermediate measurements and numerical precision.

<sup>9</sup> Here, “obliviously” means that the unitaries applied depend only on the length of the input.

### 2.3 Some Atypical Complexity Classes

We stated our lower bounds in Section 1 in terms of QCMA and MA. However, our results actually hold for slightly smaller classes, which we describe below.

► **Definition 17.** *The complexity class  $\exists \cdot \text{BQP}$  is the set of languages  $L$  for which there exists a BQP verifier  $\mathcal{A}$  such that*

- $x \in L \implies (\exists w) \Pr[\mathcal{A}(x, w) = 1] \geq \frac{2}{3}$
- $x \notin L \implies (\forall w) \Pr[\mathcal{A}(x, w) = 1] \leq \frac{1}{3}$ .

*We will write  $\exists \cdot \text{BQP}_{s,c}$  to denote  $\exists \cdot \text{BQP}$  where Arthur has completeness  $c$  and soundness  $s$ . We will write  $\exists \cdot \text{BQTIME}[t(n)]$  to denote  $\exists \cdot \text{BQP}$  where the length of Merlin's proof and the runtime of the verifier are both  $O(t(n))$ .*

We may define  $\exists \cdot \text{BPP}$  and  $\exists \cdot \text{BPTIME}$  analogously.

► **Remark 18.** Note that, while  $\exists \cdot \text{BQP} \subseteq \text{QCMA} \subseteq \text{QMA}$  (respectively,  $\exists \cdot \text{BPP} \subseteq \text{MA}$ ), it is not clear if  $\exists \cdot \text{BQP} = \text{QCMA}$  ( $\exists \cdot \text{BPP} = \text{MA}$ ) due to differences in the promise conditions. In  $\exists \cdot \text{BQP}$ , we require that the verifier  $\mathcal{A}(x, w)$  lie in BQP, meaning that it satisfies the promise on every input pair  $(x, w)$ . On the other hand, in the “yes” case of QCMA (when a string  $x$  is in the language), we require only that there exists a polynomial-sized witness  $y$  making the verifier  $\mathcal{A}(x, w)$  accept with probability exceeding  $\frac{2}{3}$ . This does not preclude the existence of a witness string  $w'$  such that  $\frac{1}{3} < \Pr[\mathcal{A}(x, w') = 1] < \frac{2}{3}$ .

## 3 Lower Bounds With Generic Slowdowns

We will start by introducing a method to reduce the verifier runtime of a class without increasing any of the quantifier exponents, assuming that the verifier runtime isn't too large. This was the main feature in the alternation-trading proofs of [26] that allowed improvement beyond the results of Lipton-Fortnow-Van Melkebeek-Viglas [11].

► **Lemma 19** (Generalizes [26]). *Let  $0 < \alpha \leq 1$  be a real number. Let  $c$  be a positive real such that  $c < \frac{1+\alpha}{\alpha}$ . Given any class*

$$\dots (Q_k n^{a_k}) \text{TS}[n^{a_{k+1}}]$$

*where  $ca_k \leq a_{k+1} < \frac{\alpha c}{\alpha c - 1} a_k$ , there is a nonnegative integer  $N := N(a_k)$  such that the annotation  $(10)^N \mathbf{0}$  with the appropriate speedup parameters proves that*

$$\dots (Q_k n^{a_k}) \text{TS}[n^{a_{k+1}}] \subseteq \dots (Q_k n^{a_k}) \text{TS}[n^{ca_k}] \subseteq \dots \text{TS}[n^{c^2 a_k}].$$

We prove this lemma in the full version. The use of  $a_k$  as the speedup parameter in Lemma 19 may seem arbitrary, but it will turn out that this is in fact the best speedup parameter in this setting. Based on this lemma, we can define a new rule that we may use in alternation-trading proofs.

► **Definition 20.** *Consider an alternating complexity class  $(Q_1 n^{a_1}) \dots (Q_k n^{a_k}) \text{TS}[n^d]$ . Given  $0 < \alpha \leq 1$  and  $c > 0$  satisfying  $c < \frac{1+\alpha}{\alpha}$ , we define the **wiggle rule** with parameters  $\alpha, c$  to be the following:*

- *If  $d < \frac{\alpha c}{\alpha c - 1} a_k$ , apply  $(1_{a_k} \mathbf{0})^t$  for  $t := \left\lceil \frac{a_{k+1}}{a_t} \right\rceil$ .*
- *Otherwise, do nothing.*

*We call an application of the wiggle rule **proper** if we are in the first case and **improper** otherwise. In a proof annotation, when  $\alpha$  and  $c$  are fixed, we will denote an application of the wiggle rule by 2.*

It is worth remembering the ratio

$$\frac{\alpha c}{\alpha c - 1}$$

as it will show up frequently in the remainder of this paper. Following the notation of Definition 20, if the value of  $d$  (the verifier runtime exponent) for an alternating complexity class is at most  $\frac{\alpha c}{\alpha c - 1}$  times  $a_k$  (the exponent in the final quantifier), we may reduce the verifier runtime to its smallest possible value  $ca_k$  with an application of Definition 20 and Lemma 19, as the following corollary shows.

► **Corollary 21** (Corollary of Lemma 19). *Consider a class*

$$(Q_1 n^{a_1}) \dots (Q_k n^{a_k}) \text{TS}[n^d].$$

*Given  $0 < \alpha \leq 1$  and  $c > 0$  satisfying  $c < \frac{1+\alpha}{\alpha}$ , applying the wiggle rule (Definition 20) yields the class:*

- $(Q_1 n^{a_1}) \dots (Q_k n^{a_k}) \text{TS}[n^{ca_k}]$ , if  $d < \frac{\alpha c}{\alpha c - 1} a_k$ .
- $(Q_1 n^{a_1}) \dots (Q_k n^{a_k}) \text{TS}[n^d]$  otherwise.

We are now in a position to prove Main Theorem 1, which we restate for convenience.

► **Main Theorem 1.** *Fix  $\alpha \in (0, 1]$  and let  $\mathcal{C}$  be a complexity class. Let  $r_1$  be the largest root of the polynomial  $P_\alpha(x) := \alpha^2 x^3 - \alpha x^2 - 2\alpha x + 1$ . If  $\mathcal{C} \subseteq \text{TS}[n^c]$  implies a generic slowdown rule with parameters  $\alpha$  and  $c$ , then  $\mathcal{C} \not\subseteq \text{TS}[n^c]$  for  $c < r_1$ .*

We will use the following lemma in the proof of Main Theorem 1; its proof can be found in the full version.

► **Lemma 22.** *If  $r_1$  and  $r_2$  are the two largest roots of  $P_\alpha(x) := \alpha^2 x^3 - \alpha x^2 - 2\alpha x + 1$  then*

$$r_2(\alpha) < \frac{1 + \sqrt{1 + 4\alpha}}{2\alpha} < r_1(\alpha) < \frac{1 + \alpha}{\alpha}$$

*for all  $\alpha > 0$ .*

**Proof of Main Theorem 1.** The lower bound will follow from applying the annotation  $1^k \mathbf{0}(20)^k$  as  $k \rightarrow \infty$ . (Recall that  $\mathbf{2}$  denotes an application of the wiggle rule of Definition 20.) We will choose speedup parameters  $\{x_i\}$  so that the following sequence of inclusions is valid and every application of the wiggle rule is proper.

$$\begin{aligned} \text{TS}[n^d] &\subseteq (\exists n^{x_1})(\forall n^{x_2}) \dots (Q_k n^{x_k})(Q_{k+1} n^{x_k}) \text{TS}[n^{(d-x_1-x_2-\dots-x_k)}] & 1^k \mathbf{0}(20)^k \\ &\subseteq (\exists n^{x_1})(\forall n^{x_2}) \dots (Q_k n^{x_k}) \text{TS}[n^{\alpha c(d-x_1-x_2-\dots-x_k)}] & 1^k \mathbf{0}(20)^k \\ &\subseteq (\exists n^{x_1})(\forall n^{x_2}) \dots (Q_k n^{x_k}) \text{TS}[n^{cx_k}] & 1^k \mathbf{0}20(20)^{k-1} \\ &\subseteq (\exists n^{x_1})(\forall n^{x_2}) \dots (Q_{k-1} n^{x_{k-1}}) \text{TS}[n^{\alpha c^2 x_k}] & 1^k \mathbf{0}20(20)^{k-1} \\ &\subseteq (\exists n^{x_1})(\forall n^{x_2}) \dots (Q_{k-1} n^{x_{k-1}}) \text{TS}[n^{cx_{k-1}}] & 1^k \mathbf{0}2020(20)^{k-2} \\ &\dots & 1^k \mathbf{0}2020(20)^{k-2} \\ &\subseteq \text{TS}[n^{\alpha c^2 x_1}]. \end{aligned}$$

In order to ensure a contradiction at the end, we will set  $x_1 := \frac{d}{\alpha c^2}$ . In order to ensure that the first application of the wiggle rule is proper, we require that the  $\{x_i\}$  satisfy

$$\alpha c(d - x_1 - \dots - x_k) < \frac{\alpha c}{\alpha c - 1} x_k \iff d - x_1 - x_2 - \dots - x_k < \frac{1}{\alpha c - 1} \cdot x_k. \quad (4)$$

In order to ensure that we can apply the wiggle rule properly in all other steps, we require that the  $\{x_i\}$  satisfy

$$\alpha c^2 x_i < \frac{\alpha c}{\alpha c - 1} \cdot x_{i-1} \quad (5)$$

for all  $2 \leq i \leq k$ .

The next claim lets us find valid speedup parameters  $\{x_i\}$  for certain values of  $c$  depending on the number of iterations  $k$  that we allow in our annotation. The expression will look somewhat hairy, but fortunately most of it will disappear in the limit as  $k$  becomes large.

▷ **Claim 23.** Pick  $\epsilon > 0$ , and let  $\tau := \frac{1-\epsilon}{c(\alpha c-1)}$ . There are choices of the speedup parameter  $x_i$  such that the annotation  $\mathbf{1}^k \mathbf{0}(\mathbf{20})^k$  implies a contradiction for all  $c$  satisfying

$$\alpha c^2 - \frac{\tau^k - 1}{\tau - 1} < \frac{\tau^k}{\alpha c - 1}. \quad (6)$$

Proof of Claim. Let  $x_i := \left(\frac{1-\epsilon}{c(\alpha c-1)}\right)^{i-1} x_1 = \left(\frac{1-\epsilon}{c(\alpha c-1)}\right)^{i-1} \frac{d}{c^2}$  for  $i \geq 2$ . Observe that all the  $x_i$  are positive and satisfy the constraints of (5) for all  $i$ . If we take  $d$  to be sufficiently large we can ensure that every exponent in the proof exceeds 1. Therefore, if we can show that our selection of  $\{x_i\}$  satisfies the first constraint, (4), we will have a valid sequence of rules and, by our choice of  $x_1$  above, have derived a contradiction.

Plugging our choice of  $\{x_i\}$  into (4) yields the constraint

$$d - \frac{d}{\alpha c^2} \left(1 + \frac{1-\epsilon}{c(\alpha c)} + \cdots + \left(\frac{1-\epsilon}{c(\alpha c-1)}\right)^{k-1}\right) < \frac{1-\epsilon}{\alpha c-1} \left(\left(\frac{1-\epsilon}{c(\alpha c-1)}\right)^{k-1} \frac{d}{\alpha c^2}\right). \quad (7)$$

This is equivalent to

$$\alpha c^2 - \frac{\tau^k - 1}{\tau - 1} < \frac{\tau^k}{\alpha c - 1}, \quad (8)$$

as desired. ◁

The lemma condition  $c > \frac{1+\sqrt{1+4\alpha}}{2\alpha}$  means that  $(c(\alpha c-1))^{-1} < 1$ . Now, let  $\epsilon := \frac{1}{k}$  and allow  $k \rightarrow \infty$  in (6). Since  $\tau \rightarrow (c(\alpha c-1))^{-1}$  as  $k \rightarrow \infty$ , we see that (6) becomes

$$\alpha c^2 - \frac{c(\alpha c-1)}{c(\alpha c-1)-1} < 0 \iff \alpha^2 c^3 - \alpha c^2 - 2\alpha c + 1 < 0$$

in the limit. More formally, we have shown that for every  $c$  satisfying this constraint, if we take  $k$  to be large enough, then our choice of  $\{x_i\}$  satisfies (4). The leading coefficient is positive so we satisfy all the constraints (i.e. the alternation-trading proof shows a contradiction) when  $c$  lies between the largest and second largest roots of this cubic. Implicitly, we require  $c < \frac{1+\alpha}{\alpha}$  so that we can apply Lemma 19 and  $c > \frac{1+\sqrt{1+4\alpha}}{2\alpha}$  so that the undesired terms in (6) vanish. By Lemma 22, these are satisfied when  $\frac{1+\sqrt{1+4\alpha}}{2\alpha} < c < r_1$ . Furthermore, if  $\mathcal{C} \not\subseteq \text{TS}[n^{c'}]$  for some  $c'$  then we automatically have  $\mathcal{C} \not\subseteq \text{TS}[n^c]$  for all  $c < c'$ . ◀

From Main Theorem 1, we immediately obtain the following corollary.

► **Corollary 24** ([25]). For  $c < 2 \cos(\frac{\pi}{7}) \approx 1.801$ ,  $\text{NTIME}[n] \not\subseteq \text{TS}[n^c]$ .

**Proof.** Taking  $\alpha = 1$  (as this is normal slowdown) yields  $c^3 - c^2 - 2c + 1 < 0$ . The largest root is  $2 \cos(\frac{\pi}{7})$ , so we have  $\text{NTIME}[n] \not\subseteq \text{TS}[n^{2 \cos(\frac{\pi}{7}) - o(1)}]$  ◀

## 4 A Generic Slowdown Rule From Grover's Algorithm

Now that we've proved the general case, we turn to an application. Observe that any application of a speedup rule with parameter  $x$  results in an alternating complexity class whose final quantifier is over  $x \log n$  bits, as this quantifier indexes over the  $n^x$  states that it receives from the penultimate quantifier. For example,

$$\text{TS}[n^d] \subseteq (\exists n^x)(\forall x \log n)^1 \text{TS}[n^{d-x}].$$

Normally, we could remove the last quantifier with a slowdown rule, yielding the inclusion

$$\text{TS}[n^d] \subseteq (\exists n^x) \text{TS}[n^{c \cdot \max(x, d-x, 1)}]. \quad (9)$$

We could also remove the quantifier by having the deterministic verifier try all  $n^x$  possible strings it could receive, but this yields the useless inclusion  $\text{TS}[n^d] \subseteq (\exists n^x) \text{TS}[n^d]$ . However, if we allow alternating complexity classes with quantum verifiers rather than deterministic verifiers, we can remove the last quantifier more efficiently. In particular, we can think of the last quantifier as a search problem over a space of size  $N := n^x$ . Classically, no blackbox algorithm can search over  $N$  items with fewer than  $N$  queries in the worst case, but in the quantum setting Grover's algorithm lets us do this in  $O(\sqrt{N})$  queries! This gives us, for some informal notion of quantum time,

$$\text{TS}[n^d] \subseteq (\exists n^x) \text{QTIME}[n^{d-\frac{x}{2}}]. \quad (10)$$

This method of quantifier removal allows us to remove quantifiers more efficiently than (9) when  $c$  is large at the cost of introducing a quantum verifier. However, the quantum verifier can be replaced with a deterministic verifier, under the assumption  $\text{QCMATIME}[n] \subseteq \text{TS}[n^c]$ ! Ultimately, we will find that combining a speedup (adding one quantifier), (10) (removing one quantifier), and the assumption (removing one quantifier) yields a generic slowdown rule with  $\alpha = \frac{2}{3}$ .

### 4.1 Review of Grover's Algorithm

Given (quantum) query access to a function  $f: [N] \rightarrow \{0, 1\}$ , Grover's algorithm tells us whether or not there exists an  $\alpha \in [N]$  such that  $f(\alpha) = 1$ . For a given  $f$ , let  $S := \{\alpha \in [N]: f(\alpha) = 1\}$ . It turns out, per [12], that the probability of success of Grover search after  $j$  iterations is  $\sin^2(2(j+1)\theta)$  where  $\theta = \sin^{-1} \sqrt{\frac{|S|}{N}}$ . Regardless of  $\frac{|S|}{N}$ , a sufficiently large random number of iterations should succeed with probability roughly  $\frac{1}{2}$ , which is the average value of  $\sin^2 x$ . The following lemma of [5] formalizes this.

► **Lemma 25** ([5]). *Let  $k$  be an arbitrary positive integer and let  $j$  be an integer chosen uniformly at random from  $[0, k-1]$ . If we observe the register after applying  $j$  Grover iterations starting from the uniform state, the probability of obtaining a solution is at least  $\frac{1}{4}$  when  $k \geq \frac{1}{\sin 2\theta}$ .*

► **Corollary 26.** *Let  $j$  be an integer chosen uniformly at random from  $[0, (\sin \frac{2}{\sqrt{N}})^{-1}]$ . If we observe the register after applying  $j$  Grover iterations starting from the uniform state, the probability of obtaining a solution is at least  $\frac{1}{4}$ .*

## 4.2 Using Grover's Algorithm to Invert RAMs

In order to apply Grover's algorithm to remove the quantifier in expressions like  $(\exists \log n) \text{TS}[n^d]$  – specifically, to perform Grover diffusion – we must be able to implement the relevant function  $f \in \text{TS}[n^d]$  in our quantum computational model. The following lemma converts the classical random-access machine of  $f$  to a “normal form” that is more amenable to implementation in a quantum computer. The workspace of  $A$  includes an input address register used to specify which bit of the input the machine wishes to read and an input query bit which stores the result of the most recent query of the input. Assume without loss of generality that the first  $\lceil \log n \rceil$  bits of the workspace hold the input address register, and bit  $\lceil \log n \rceil + 1$  holds the current bit of input being read.

► **Lemma 27** (Normal Form Circuit for Time-Space Bounded Computation). *Let  $f$  be a function computed by a random-access machine  $A$  in time  $t(n)$  and space  $s(n)$  on inputs of length  $n$ . Then, there exists a sequence of uniform Boolean circuits  $\mathcal{C}_1, \dots, \mathcal{C}_r$ , such that:*

1. *for all  $1 < i \leq r - 1$ ,  $\mathcal{C}_i$  has  $s$  inputs and  $s$  outputs,*
2.  *$\mathcal{C}_1$  has no inputs and  $s$  outputs,*
3.  *$\mathcal{C}_r$  has  $s$  inputs and 1 output,*
4.  *$\sum_{i=1}^r |\mathcal{C}_i| = O(ts^2)$  where  $|\mathcal{C}_i|$  denotes the size of  $\mathcal{C}_i$ , and furthermore*

$$f(y) = \mathcal{C}_r \circ R \circ \mathcal{C}_{r-1} \circ \dots \circ R \circ \mathcal{C}_1, \quad (11)$$

where  $R: \{0, 1\}^{s(n)} \rightarrow \{0, 1\}^{s(n)}$ , on input  $z \in \{0, 1\}^{s(n)}$ , sets  $z_{\lceil \log n \rceil + 1} = y_{z_1 z_2 \dots z_{\lceil \log n \rceil}}$  and leaves the remainder of  $z$  unchanged. Here, we write  $s_j$  to denote the  $j^{\text{th}}$  bit of a string  $s$ .

In Lemma 27, the circuits  $\mathcal{C}_i$  are used to simulate steps in the workspace of the machine, and the function  $R$  perform random accesses to the  $n$ -bit input  $y$ , by setting its  $(\lceil \log n \rceil + 1)^{\text{th}}$  output bit to the bit of  $y$  whose index is specified by the first  $\lceil \log n \rceil$  bits. Note that  $y$  is the original length- $n$  input to  $f$  and  $n$  may be much larger than  $s(n)$ . Lemma 27, along with Corollary 28 allow us to translate a RAM to a quantum circuit with  $s(n)$  wires and with intermittent QRAM calls: the Boolean circuits  $\{\mathcal{C}_i\}$  can be replaced with quantum circuits in the usual way and each  $R$  can be replaced by a QRAM call. Proofs of Lemma 27 and Corollary 28 can be found in the full version.

► **Corollary 28.** *Let  $f: \{0, 1\}^m \rightarrow \{0, 1\}$  be a function computable in classical time  $t$  and space  $s$  by a random-access machine. Then, the transformation  $|y\rangle |0\rangle \mapsto |y\rangle |f(y)\rangle$  can be implemented by a quantum computer with quantum random-access to its input in time  $O(ts^2)$ .*

We now state the main lemma of this subsection.

► **Lemma 29** (Grover's Algorithm for Time-Space Bounded Computation). *Given a function  $f: \{0, 1\}^m \rightarrow \{0, 1\}$  that can be computed in classical time  $t$  and space  $s$  by a random-access machine, there is a quantum algorithm taking time  $O(2^{\frac{m}{2}}(ts^2 + m))$  that finds a value  $\alpha \in \{0, 1\}^m$  such that  $f(\alpha) = 1$ , assuming one exists, with probability at least  $\frac{2}{3}$ . In particular, when  $m = x \log n$ ,  $t = n^d$ ,  $s = O(\log n)$ , we obtain a time bound of  $\tilde{O}(n^{d+\frac{x}{2}})$ .*

**Proof.** (Sketch) We run Grover's algorithm. Per Corollary 26, we need  $O(2^{\frac{m}{2}})$  Grover iterations. Grover diffusion is dominated by the cost of implementing the function itself, which by Corollary 28 is  $O(ts^2)$ . Inversion about the mean takes  $O(m)$  time. ◀

### 4.3 Proving Main Theorem 2

We are now in a position to apply Grover's algorithm to prove a generic slowdown rule.

► **Lemma 30.** *If  $\exists \cdot \text{BQTIME}_{\frac{1}{3},1}[n] \subseteq \text{TS}[n^c]$  then*

$$\dots (Q_{k-1}n^{a_{k-1}})^{b_{k-1}} (Q_k n^{a_k})^{b_k} \text{TS}[n^d] \subseteq \dots (Q_{k-1}n^{a_{k-1}})^{b_{k-1}} \text{TS}[n^{c \cdot \max(a_k, b_k, b_{k-1}, 1, \frac{2d}{3})}].$$

Therefore, under the assumption  $\exists \cdot \text{BQTIME}_{\frac{1}{3},1}[n] \subseteq \text{TS}[n^c]$  we may apply a generic slowdown rule with parameters  $\alpha = \frac{2}{3}$  and  $c$ . Lemma 30 corresponds to the following sequence of operations:

1. Classical Speedup (Corollary 5)
2. Grover's algorithm to invert a classical function with classical input (Lemma 29)
3. Direct application of  $\exists \cdot \text{BQTIME}[n] \subseteq \text{TS}[n^c]$

**Proof.** By classical speedup, we have

$$\dots (Q_k n^{a_k})^{b_k} \text{TS}[n^d] \subseteq \dots (Q_k n^{\max(a_k, x)})^{\max(b_k, x)} (Q_{k+1} x \log n)^{b_k} \text{TS}[n^{d-x}]. \quad (12)$$

Consider the function  $g: \{0, 1\}^{n^{\max(b_k, x)}} \times \{0, 1\}^{x \log n} \rightarrow \{0, 1\}$  which implements the  $\text{TS}[n^{d-x}]$  verifier from the right-hand-side of (12) given as inputs the  $n^{\max(b_k, x)}$  bits of output from the  $k^{\text{th}}$  stage/quantifier and the  $(x \log n)$ -bit string chosen by the  $(k+1)^{\text{th}}$  stage/quantifier. We will apply Lemma 29 to the function  $g_z := g(z, \cdot)$ , where  $z$  is the output from the  $k^{\text{th}}$  stage of the class (not the  $(k+1)^{\text{th}}$  stage!). In particular, we can use Grover's algorithm to search over the space of possible values of the last quantifier of  $(x \log n)$  bits. Thus, the inputs to  $g_z$  are strings of length  $m = x \log n$ . The runtime of  $g_z$  is  $O(ts^2)$  by Corollary 28, as  $g_z$  just needs to evaluate the verifier on  $z$  (the output of the  $k^{\text{th}}$  stage) and a length  $m$ -input. Therefore, applying Lemma 29,

$$\subseteq \dots (Q_{k-1}n^{a_{k-1}})^{b_{k-1}} (Q_k n^{\max(a_k, x)})^{\max(b_k, x)} \text{BQTIME}[n^{d-\frac{x}{2}}].$$

Without loss of generality, suppose that  $Q_k = \exists$ . Then, we can continue the sequence of inclusions as follows:

$$\begin{aligned} &\subseteq \dots (Q_{k-1}n^{a_{k-1}})^{b_{k-1}} \exists \cdot \text{BQTIME}[n^{\max(a_k, b_k, x, d-\frac{x}{2})}] \\ &\subseteq \dots (Q_{k-1}n^{a_{k-1}})^{b_{k-1}} \text{TS}[n^{c \cdot \max(b_{k-1}, a_k, b_k, x, d-\frac{x}{2}, 1)}]. \end{aligned}$$

(Note we need a 1 in the maximum in the last equation, because our assumption  $\exists \cdot \text{BQTIME}_{\frac{1}{3},1}[n] \subseteq \text{TS}[n^c]$  only implies  $\exists \cdot \text{BQTIME}[n^\delta] \subseteq \text{TS}[n^c]$  for  $\delta < 1$ .) To minimize the exponent, we take  $x = \frac{2a_0}{3}$ , yielding the exponent in the lemma statement. ◀

► **Remark 31.** Note that in the proof of Lemma 30 we do not need to account for the  $n^{b_k}$  exponent on the  $(k+1)^{\text{th}}$  stage/quantifier when computing the runtime of  $g_z$  when preparing to apply Lemma 29. This is because the quantifier  $(Q_{k+1} x \log n)^{b_k}$  on the right-hand-side of (12), which arises due to a speedup rule, has a  $b_k$  in the exponent only because it needs to copy and pass on the output of the  $k^{\text{th}}$  stage. This is normally necessary because the verifier on the right-hand-side of (12) needs to run from configuration to configuration on the original verifier's input and hence needs to be able to access the original input (i.e., the input to the verifier on the left-hand-side of the inclusion). However, by our definition of  $g_z$ , we don't need to worry about the cost of copying the output from the  $k^{\text{th}}$  stage  $z$  is itself the output of the  $k^{\text{th}}$  stage. We don't need to copy and pass on the original input because  $g_z$  already has it! Put differently, because we're collapsing two stages into one, we don't need to expend time on computation that's only used to pass input along.

Note that every possible proof involving slowdown and Grover's algorithm (Lemma 29) can be carried out using Lemma 30 as the only rule for removing quantifiers, as we can only apply Lemma 29 between a speedup and a slowdown. (More details on why are in the full version.) Plugging  $\alpha = \frac{2}{3}$  into Main Theorem 1, we obtain the following corollary.

► **Corollary 32.**  $\exists \cdot \text{BQTIME}_{\frac{1}{3},1}[n] \not\subseteq \text{TS}[n^c]$  for  $c < \frac{3+\sqrt{3}}{2} \approx 2.366$ .

Since  $\exists \cdot \text{BQTIME}[n] \subseteq \text{QCMATIME}[n]$ , this proves Main Theorem 2.

## 5 Lower Bounds Against BPTS

We turn to proving lower bounds against randomized algorithms. In this section, we will use both Corollary 5 and Corollary 8 as speedup rules. The randomized slowdown rule is straightforward.

► **Lemma 33** (“Randomized” Slowdown Rule). *Assuming  $\exists \cdot \text{BPTIME}[n] \subseteq \text{BPTS}[n^c]$ , we have*

$$(Q_1 n^{a_1})^{b_1} \dots (Q_k n^{a_k})^{b_k} \text{BPTS}[n^d] \subseteq (Q_1 n^{a_1})^{b_1} \dots (Q_{k-1} n^{a_{k-1}})^{b_{k-1}} \text{BPTS}[n^{c \cdot \max(d, b_k, a_k, b_{k-1})}].$$

► **Lemma 34.** *Suppose that, under the assumption  $\exists \cdot \text{BPTIME}[n] \subseteq \text{BPTS}[n^c]$  for some  $c$ , there is an alternation-trading proof with at least two inclusions proving that  $\text{BPTS}[n^d] \subseteq \text{BPTS}[n^{d'}]$  for  $d < d'$ . Then, the assumption is false.*

A proof of this lemma can be found in the full version. Recall that by Lemma 15, we may suppress some of the exponents when writing alternating complexity classes. We will do so throughout the remainder of this section.

Now that we have the preliminaries out of the way, let us prove some lower bounds. The first part of Main Theorem 3 is an immediate corollary of the following theorem.

► **Theorem 35.**  $\exists \cdot \text{BPTIME}[n] \not\subseteq \text{TS}[n^c]$  for  $c < r_1$ , where  $r_1 \approx 1.466$  is the largest root of the polynomial  $x^3 - x^2 - 1 = 0$ .

**Proof.** Our analysis is similar to the proof of Main Theorem 1. The bound will arise by applying the annotation  $\mathbf{1}^k \mathbf{0}^{k+2}$  with the appropriate speedup parameters as  $k \rightarrow \infty$ . We will choose parameters  $\{x_i\}$  so that the following sequence of inclusions is valid.

$$\begin{aligned} \text{BPTS}[n^d] &\subseteq (\exists n^1)(\forall n^{x_1})(\exists n^{x_2}) \dots (Q_k n^{x_k})(Q_{k+1} n^{x_k}) \text{TS}[n^{(d-x_1-x_2-\dots-x_k)}] && \mathbf{1}^k \mathbf{0}^{k+2} \\ &\subseteq (\exists n^1)(\forall n^{x_1})(\exists n^{x_2}) \dots (Q_k n^{x_k}) \text{BPTS}[n^{c(d-x_1-x_2-\dots-x_k)}] && \mathbf{1}^k \mathbf{0}^{k+1} \\ &\subseteq (\exists n^1)(\forall n^{x_1}) \dots (Q_k n^{x_k}) \text{BPTS}[n^{c x_k}] \\ &\subseteq (\exists n^1)(\forall n^{x_1}) \dots (Q_{k-1} n^{x_{k-1}}) \text{BPTS}[n^{c^2 x_k}] && \mathbf{1}^k \mathbf{0}^{k+1} \\ &\subseteq (\exists n^1)(\forall n^{x_1}) \dots (Q_{k-1} n^{x_{k-1}}) \text{BPTS}[n^{c^2 x_{k-1}}] \\ &\dots && \mathbf{1}^k \mathbf{0}^{k+1} \mathbf{0} \\ &\subseteq (\exists n^1) \text{BPTS}[n^{c^2 x_1}] \\ &\subseteq \text{BPTS}[n^{c^3 x_1}] && \mathbf{1}^k \mathbf{0}^{k+1} \mathbf{0} \\ &\subseteq \text{BPTS}[n^d] \end{aligned}$$

In order for all of the above inclusions to hold, we take

$$x_1 := \frac{d}{c^3}, \quad x_i := (c(1-\epsilon))^{1-i} \cdot x_1 = \frac{d(1-\epsilon)^{1-i}}{c^{i+2}}$$

for  $\epsilon := \frac{1}{k}$ . This automatically satisfies all the constraints except for the one corresponding to the third line, which requires

$$\begin{aligned}
& c(d - x_1 - x_2 - \cdots - x_k) \leq cx_k \\
& \iff 1 - \frac{1}{c^3} \left( \frac{1-\epsilon}{c} \right)^{k-1} - \frac{1}{c^3} \sum_{i=0}^{k-1} \left( \frac{1-\epsilon}{c} \right)^i < 0 \\
& \iff 1 - \frac{1}{c^3} \left( \frac{1-\epsilon}{c} \right)^{k-1} - \frac{1}{c^3} \frac{1 - \frac{1-\epsilon}{c^k}}{1 - \frac{1-\epsilon}{c}} < 0.
\end{aligned}$$

As  $k \rightarrow \infty$ , several terms vanish. We are left with

$$1 - \frac{1}{c^3(1 - \frac{1}{c})} < 0 \iff c^3 - c^2 - 1 < 0.$$

The largest root is at  $c \approx 1.466$ . ◀

When we are allowed to introduce quantum operations and use Lemma 30, we can do slightly better than this.

► **Theorem 36.**  $\exists \cdot \text{BQTIME}[n] \not\subseteq \text{TS}[n^c]$  for  $c < 1.5$ .

The second part of Main Theorem 3 is an immediate corollary of the previous theorem.

**Proof.** (Sketch) Let  $d > 1.5$ . We have the following sequence of containments:

$$\begin{aligned}
\text{BPTS}[n^d] & \subseteq (\exists n^1)(\forall n^{\frac{2d}{3}})(\exists \frac{2d}{3} \log n)^1 \text{TS}[n^{\frac{d}{3}}] \\
& \subseteq (\exists n^1)(\forall n^{\frac{2d}{3}}) \text{BQTIME}[n^{\frac{2d}{3}}] \\
& \subseteq (\exists n^1) \text{BPTS}[n^{\frac{2cd}{3}}],
\end{aligned}$$

where we've used Lemma 29 in the second inclusion. When  $c < 1.5$ , we have  $\frac{2c}{3} < 1$ . Thus, we can repeat this procedure until we derive the inclusion

$$\begin{aligned}
\text{BPTS}[n^d] & \subseteq (\exists n^1) \text{BPTS}[n^{\frac{d}{c}}] \\
& \subseteq \text{BPTS}[n^{d'}]
\end{aligned}$$

for  $d' < d$ . To get a contradiction, we can apply the ideas of Lemma 34 modulo some additional technical details that we relegate to the full version. ◀

## Abstract

The *linear search* problem, informally known as the *cow path* problem, is one of the fundamental problems in search theory. In this problem, an immobile target is hidden at some unknown position on an unbounded line, and a mobile searcher, initially positioned at some specific point of the line called the *root*, must traverse the line so as to locate the target. The objective is to minimize the worst-case ratio of the distance traversed by the searcher to the distance of the target from the root, which is known as the *competitive ratio* of the search.

In this work we study this problem in a setting in which the searcher has a *hint* concerning the target. We consider three settings in regards to the nature of the hint: i) the hint suggests the exact position of the target on the line; ii) the hint suggests the direction of the optimal search (i.e., to the left or the right of the root); and iii) the hint is a general  $k$ -bit string that encodes some information concerning the target. Our objective is to study the *Pareto*-efficiency of strategies in this model. Namely, we seek optimal, or near-optimal tradeoffs between the searcher's performance if the hint is correct (i.e., provided by a trusted source) and if the hint is incorrect (i.e., provided by an adversary).

## 1 Introduction

Searching for a target is a common task in everyday life, and an important computational problem with numerous applications. Problems involving search arise in such diverse areas as drilling for oil in multiple sites, the forest service looking for missing backpackers, search-and-rescue operations in the open seas, and navigating a robot between two points on a terrain. All these problems involve a mobile *searcher* which must locate an immobile *target*, often also called *hider*, that lies in some unknown point in the *search domain*, i.e., the environment in which the search takes place. The searcher starts from some initial placement within the domain, denoted by  $O$ , which we call the *root*. There is, also, some underlying concept of quality of search, in the sense that we wish, in informal terms, for the searcher to be able to locate the target as efficiently as possible.

One of the simplest, yet fundamental search problems is searching on an infinite line that is unbounded both to the left and to the right of the root. In this problem, which goes back to Bellman [17] and Beck and Newman [10], the objective is to find a search strategy that

minimizes the *competitive ratio* of search. More precisely, let  $S$  denote the *search strategy*, i.e., the sequence of moves that the searcher performs on the line. Given a target  $t$ , let  $d(S, t)$  denote the total distance that the searcher has traveled up to the time it locates the target, and  $d(t)$  the distance of  $t$  from  $O$ . We define the competitive ratio of  $S$  as

$$\text{cr}(S) = \sup_t \frac{d(S, t)}{d(t)}.$$

A strategy of minimum competitive ratio is called *optimal*. The problem of optimizing the competitive ratio of search on the line is known as the *linear search* problem (mostly within Mathematics and Operations Research), but is also known in Computer Science as the *cow path* problem.

It has long been known that the optimal (deterministic) competitive ratio of linear search is 9 [15], and is derived by a simple *doubling* strategy. Specifically, let the two semi-infinite branches of the line be labeled with 0, 1 respectively. Then in iteration  $i$ , with  $i \in \mathbb{N}$ , the searcher starts from  $O$ , traverses branch  $i \bmod 2$  to distance  $2^i$ , and returns to the root.

Linear search, and its generalization, the  $m$ -ray search problem, in which the search domain consists of  $m$  semi-infinite branches have been studied in several settings. Substantial work on linear search was done in the '70s and '80s predominantly by Beck and Beck, see e.g., [11, 16, 12, 13, 14]. Gal showed that a variant of the doubling strategy is optimal for  $m$ -ray search [25, 26]. These results were later rediscovered and extended in [9].

Other related work includes the study of randomization [41] and [30]; multi-searcher strategies [35]; searching with turn cost [23, 3]; the variant in which some probabilistic information on the target is known [27, 28]; the related problem of designing *hybrid algorithms* [29]; searching with an upper bound on the distance of the target from the root [34] and [20]; fault tolerant search [22, 33]; and performance measures beyond the competitive ratio [31, 38, 4]. Competitive analysis has been applied beyond the linear and star search, for example in searching within a graph [32, 24, 6].

## 1.1 Searching with a hint

Previous work on competitive analysis of deterministic search strategies has mostly assumed that the searcher has no information about the target, whose position is adversarial to the search. In practice, however, we expect that the searcher may indeed have some information concerning the target. For instance, in a search-and-rescue mission, there may be some information on the last sighting of the missing person, or the direction the person had taken when last seen. The question then is: how can the searcher leverage such information, and to what possible extent?

If the hint comes from a source that is trustworthy, that is, if the hint is guaranteed to be correct, then the performance of search can improve dramatically. For example, in our problem, if the hint is the branch on which the target lies, then the optimal search is to explore that branch until the target is found, and the competitive ratio is 1. There is, however, an obvious downside: if the hint is incorrect, the search may be woefully inefficient since the searcher will walk eternally on the wrong branch, and the competitive ratio in this case is unbounded.

We are thus interested in analyzing the efficiency of search strategies in a setting in which the hint may be compromised. To this end, we first need to define formally the concept of the hint, as well as an appropriate performance measure for the search strategy. In general, the hint  $h$  is a binary string of size  $k$ , where the  $i$ -th bit is a response to a *query*  $Q_i$ . For example, one can define a single query  $Q$  as “Is the target within distance at most 100 from

$O?$ ” and a one-bit hint, so that the hint answers a range query. For another example, if  $Q$  = “Is the target to the left or to the right of  $O$ ?”, then a 1-bit hint informs the searcher about the direction it should pursue. From the point of view of upper bounds (positive results), we are interested in settings in which the queries and the associated hints have some natural interpretation, such as the ones given above. From the point of view of lower bounds (impossibility results), we are interested on the limitations of general  $k$ -bit hint strings which may be associated with *any* query, as we will discuss in more detail later.

Concerning the second issue, namely evaluating the performance of a search strategy  $S$  with a hint  $h$ , note first that  $S$  is a function of  $h$ . We will analyze the competitiveness of  $S(h)$  in a model in which the competitive ratio is not defined by a single value, but rather by a pair  $(c_{S,h}, r_{S,h})$ . The value  $c_{S,h}$  describes the competitive ratio of  $S(h)$  assuming that  $h$  is *trusted*, and thus guaranteed to be correct. The value  $r_{S,h}$  describes the competitive ratio of  $S(h)$  when the hint is given by an *adversarial* source. More formally, we define

$$c_{S,h} = \sup_t \inf_h \frac{d(S(h), t, h)}{d(t)}, \quad \text{and} \quad r_{S,h} = \sup_t \sup_h \frac{d(S(h), t, h)}{d(t)}, \quad (1)$$

where  $d(S(h), t, h)$  denotes the distance traversed in  $S(h)$  for locating a target  $t$  with a hint  $h$ . We will call  $c_{S,h}$  the *consistency* of  $S(h)$ , and  $r_{S,h}$  the *robustness* of  $S(h)$ . To simplify notation, we will often write  $S$  instead of  $S(h)$  when it is clear from context that we refer to a strategy with a hint  $h$ .

For example, if the hint  $h$  is the branch on which the target lies, then the strategy that always trusts the hint is  $(1, \infty)$  competitive, whereas the strategy that ignores the hint entirely is  $(9, 9)$ -competitive. Our objective is then to find strategies that are provably *Pareto-optimal* or *Pareto-efficient* in this model, and thus identify the strategies with the best tradeoff between robustness and consistency.

Our model is an adaptation, to search problems, of the untrusted advice framework for online algorithms proposed by Angelopoulos *et al.* [5]. In their work, the online algorithm is given some additional information, or *advice* which may, or may not be correct. To the best of our knowledge, our setting is a first attempt to quantify, in an adversarial setting, the impact of general types of *predictions* in search games. It is also in line with recent advances on improving the performance of online algorithms using predictions, such as the work of Lykouris and Vassilvitskii [36], who introduced the concepts of consistency and robustness in the context of paging, and the work of Purohit *et al.* [39], who applied it to general online problems. Our framework for the  $k$ -bit hint is also related to other work in Machine Learning, such as clustering with  $k$  noisy queries, e.g., the work of Mazumdar and Saha [37].

It should be emphasized that there is previous work that has studied the impact of specific types of hints on the performance of search strategies, such as bounds on the maximum or the minimum distance of the target from the root, e.g., [34, 20, 27]. However, the hint in these works is always assumed to be trusted and correct.

## 1.2 Contribution

In this work we study the power of limitations of linear search with hints. Let  $r \geq 9$  be a parameter that in general will denote the robustness of a search strategy, and let  $b_r$  be defined as

$$b_r = \frac{\rho_r + \sqrt{\rho_r^2 - 4\rho_r}}{2}, \quad \text{where } \rho_r = (r - 1)/2.$$

We consider the following classes of hints:

- *The hint is the position of the target.* Here, the hint describes the exact location of the target on the line: its distance from  $O$ , along with the branch (0 or 1) on which it lies. We present a strategy that is  $(\frac{b_r-1}{b_r+1}, r)$ -competitive, and we prove it is Pareto-optimal.
- *The hint is the branch on which the target lies.* Here, the hint is information on whether the searcher is to the left or to the right of the root. We present a strategy that, given parameters  $b > 1$  and  $\delta \in (0, 1)$ , has consistency  $c = 1 + 2 \cdot (\frac{b^2}{b^2-1} + \delta \frac{b^3}{b^2-1})$ , and robustness  $r = 1 + 2 \cdot (\frac{b^2}{b^2-1} + \frac{1}{\delta} \frac{b^3}{b^2-1})$ . Again, we prove that this strategy is Pareto-optimal.
- *The hint is a general  $k$ -bit string.* In the previous settings, the hint is a single bit, which answers the corresponding query. Here we address the question: how powerful can be a single-bit hint, or more generally a  $k$ -bit hint? In other words, how powerful can  $k$  binary queries be for linear search? We give several upper and lower bounds on the competitiveness of strategies in this setting. First, we look at the case of a single-bit hint. Here, we give a 9-robust strategy that has consistency at most  $1 + 4\sqrt{2}$ , whereas we show that no 9-robust strategy can have consistency less than 5, for *any* associated query. For general robustness  $r$ , we give upper and lower bounds that apply to some specific, but broadly used class of strategies, including *geometric* strategies (see Section 2 for a definition and Theorem 10 for the statement of the result). For general  $k$ , and for a given  $r \geq 9$ , we give an  $r$ -robust strategy whose consistency decreases rapidly as function of  $k$  (Proposition 11).

In terms of techniques, for the first setting described above (in which the hint is the position of the target), the main idea is to analyze a geometric strategy with “large” base, namely  $b_r$ , for  $r \geq 9$ . The technical difficulty here is the lower bound; to this end, we prove a lemma that shows, intuitively, that for any  $r$ -robust strategy, the search length of the  $i$ -th iteration cannot be too big compared to the previous search lengths (Lemma 2). This technical result may be helpful in more broad settings (e.g., we also apply it in the setting in which the advice is a general  $k$ -bit string).

Concerning the second setting, in which the hint describes the branch, we rely on tools developed by Schuierer [40] for lower-bounding the performance of search strategies; more precisely on a theorem for lower-bounding the supremum of a sequence of functionals. But unlike [40], we use the theorem in a *parameterized* manner, that allows us to express the tradeoffs between the consistency and the robustness of a strategy, instead of their average.

Concerning the third, and most general setting, our upper bounds (i.e., the positive results) come from a strategy that has a natural interpretation: it determines a partition of the infinite line into  $2^k$  subsets, and the hint describes the partition in which the target lies. The lower bounds (negative results) come from information-theoretic arguments, as is typical in the field of *advice complexity* of online algorithms (see, e.g., the survey [21]).

The broader objective of this work is to initiate the study of search games with some limited, but potentially untrusted information concerning the target. As we will show, the problem becomes challenging even in a simple search domain such as the infinite line. The framework should be readily applicable to other search games, and the analysis need not be confined to the competitive ratio, or to worst-case analysis. For example, search games in bounded domains are often studied assuming a probability distribution on the target, with the objective to minimize the expected search time (for several such examples see the book [1]). However, very little work has addressed the setting in which the searcher may have access to hints, such as the *High-Low* search games described in Section 5.2 of [1], in which a searcher wants to locate a hider on the unit interval by a sequence of guesses. Again, our model is applicable, in that one would like to find the best tradeoff on the expected time to locate the target assuming a trusted or untrusted hint.

## 2 Preliminaries

In the context of searching on the line, a search strategy  $X$  can be defined as an infinite set of pairs  $(x_i, s_i)$ , with  $i \in \mathbb{N}$ ,  $x_i \in \mathbb{R}_{\geq 1}$  and  $s_i \in \{0, 1\}$ . We call  $i$  an *iteration* and  $x_i$  the *length* of the  $i$ -th search *segment*. More precisely, in the  $i$ -th iteration, the searcher starts from the root  $O$ , traverses branch  $s_i$  up to distance  $x_i$  from  $O$ , then returns to  $O$ . It suffices to focus on strategies for which  $x_{i+2} \geq x_i$ , i.e., in any iteration the searcher always searches a new part of the line. We will sometimes omit the  $s_i$ 's from the definition of the strategy, if the direction is not important, i.e., the searcher can start by moving either to the left or to the right of  $O$ . In this case, there is the implicit assumption that  $s_i$  and  $s_{i+1}$  have complementary parities, since any strategy that revisits the same branch in consecutive iterations can be transformed to another strategy that is no worse, and upholds the assumption. We make the standing assumption that the target lies within distance at least a fixed value, otherwise every strategy has unbounded competitive ratio. In particular, we will assume that  $t$  is such that  $d(t) \geq 1$ .

Given a strategy  $X = (x_0, x_1, \dots)$  (which we will denote by  $X = (x_i)$ , for brevity), its competitive ratio is given by the expression

$$\text{cr}(X) = 1 + 2 \sup_{i \geq 0} \frac{\sum_{j=1}^i x_j}{x_{i-1}}, \quad (2)$$

where  $x_{-1}$  is defined to be equal to 1. This expression is obtained by considering all the worst-case positions of the target, namely immediately after the turn point of the  $i$ -th segment (see e.g., [40]).

Geometric sequences are important in search problems, since they often lead to efficient, or optimal strategies (see, e.g., Chapters 7 and 9 in [1]). We call the search strategy  $G_b = (b^i)$  *geometric with base  $b$* . From (2), we obtain that

$$\text{cr}(G_b) = 1 + 2 \frac{b^2}{b-1}. \quad (3)$$

For example, for the standard doubling strategy in which  $x_i = 2^i$ , hence  $b = 2$ , the above expression implies a competitive ratio of 9.

For any  $r \geq 4$  define  $\rho_r$  to be such that  $r = 1 + 2\rho_r$ , thus  $\rho_r = (r-1)/2$ . Moreover, from (3) and the definition of  $b_r$ , we have that  $\text{cr}(G_{b_r}) = r$ .

In the context of searching with a hint, we will say that a strategy is  $(c, r)$ -competitive if it has consistency at most  $c$  and robustness at most  $r$ ; equivalently we say that the strategy is  $c$ -consistent and  $r$ -robust. Clearly, an  $r$ -robust strategy gives rise to a strategy with no hints, and with competitive ratio at most  $r$ .

We conclude with some definitions that will be useful in Section 4. Let  $X = (x_0, x_1, \dots)$  denote a sequence of positive numbers. We define  $\alpha_X$  as

$$\alpha_X = \overline{\lim}_{n \rightarrow \infty} x_n^{1/n}.$$

We also define as  $X^{+i}$  the subsequence of  $X$  starting at  $i$ , i.e.,  $X^{+i} = (x_i, x_{i+1}, \dots)$ . Last, we define the sequence  $G_b(\gamma_0, \dots, \gamma_{n-1})$  as

$$G_b(\gamma_0, \dots, \gamma_{n-1}) = (\gamma_0, \gamma_1 a, \gamma_2 a^2, \dots, \gamma_{n-1} a^{n-1}, \gamma_0 a^n, \gamma_1 a^{n+1}, \dots).$$

### 3 Hint is the position of the target

In this section we study the setting in which the hint is related to the exact position of the target. Namely, the hint  $h$  describes the distance  $d(t)$  of the target  $t$  from the root, as well as the branch on which it hides. For any  $r \geq 9$ , we will give a strategy that is  $(\frac{b_r+1}{b_r-1}, r)$ -competitive. Moreover, we will show that this is Pareto-optimal. We begin with the upper bound.

► **Theorem 1.** *For any  $r \geq 9$  there exists a  $(\frac{b_r+1}{b_r-1}, r)$ -competitive strategy for linear search in which the hint is the position of the target.*

**Proof.** From the hint  $h$ , we have as information the distance  $d(t)$  as well as the branch  $t$  on which the target  $t$  lies; without loss of generality, suppose that this branch is the branch 0. Recall that this information may or may not be correct, and the searcher is oblivious to this.

Consider the geometric strategy  $G_{b_r} = (b_r^i)$ , with  $i \in \mathbb{N}$ , and recall that  $G_{b_r}$  is  $r$ -robust (as discussed in Section 2). There must exist an index  $j_t$  such that  $b_r^{j_t-2} < d(t) \leq b_r^{j_t}$ . Define  $\lambda = b_r^{j_t}/d(t) \geq 1$ , and let  $G'$  denote the strategy  $G' = (\{\frac{1}{\lambda}b_r^i, s_i\})$ , where the  $s_i$ 's are defined such that that  $s_{i+1} \neq s_i$ , for all  $i$ , and  $s_{j_t} = 0$ .

In words,  $G'$  is obtained by “shrinking” the search lengths of  $G_{b_r}$  by a factor equal to  $\lambda$ , and by choosing the right parity of branch for starting the search, in a way that, if the hint is trusted, then in  $G'$  the searcher will locate the target right as it is about to turn back to  $O$  at the end of the  $j_t$ -th iteration.

Since  $G_{b_r}$  is  $r$ -robust, so is the scaled-down strategy  $G'$ ; this is because the worst-case competitive ratio is attained for targets hiding right after the turn points of the segments. It remains then to bound the consistency  $c_{G'}$  of  $G'$ . Suppose that the hint is trusted. We have that

$$d(G', t) = \frac{1}{\lambda} \left( 2 \sum_{i=0}^{j_t-1} b_r^i + b_r^{j_t} \right),$$

and since  $d(t) = b_r^{j_t}/\lambda$  we can bound  $c_{G'}$  from above by

$$\frac{d(G', t)}{d(t)} = 1 + 2 \frac{b_r^{j_t} - 1}{b_r^{j_t}(b_r - 1)} \leq 1 + \frac{2}{b_r - 1} = \frac{b_r + 1}{b_r - 1}.$$

We conclude that  $G'$  is  $(\frac{b_r+1}{b_r-1}, r)$ -competitive. ◀

Next, we will show that the strategy of Theorem 1 is Pareto-optimal. To this end, we will need a technical lemma concerning the segment lengths of any  $r$ -robust strategy.

► **Lemma 2.** *For any  $r$ -robust strategy  $X = (x_i)$ , it holds that*

$$x_i \leq \left( b_r + \frac{b_r}{i+1} \right) x_{i-1},$$

for all  $i \geq 1$ , where  $x_{-1}$  is defined to be equal to 1.

We obtain a useful corollary concerning the sum of the first  $i-1$  search lengths of an  $r$ -robust strategy.

► **Corollary 3.** *For any  $r$ -robust strategy  $X = (x_i)$ , it holds that*

$$\sum_{j=0}^{i-1} x_j \geq \frac{x_i}{1 + \frac{1}{i+1}} \left( \frac{b_r}{b_r - 1} - \frac{i+2}{i+1} \right),$$

and for every  $\epsilon \in (0, 1]$ , there exists  $i_0$  such that for all  $i > i_0$ ,  $\sum_{j=0}^{i-1} x_j \geq (\frac{1}{b_r-1} - \epsilon)x_i$ .

We can now show a lower bound on the competitiveness of every strategy that matches the upper bound of Theorem 1.

► **Theorem 4.** *For every  $(c, r)$ -competitive strategy for linear search in which the hint is the position of the target, it holds that  $c \geq \frac{b_r+1}{b_r-1} - \epsilon$ , for any  $\epsilon > 0$ .*

**Proof.** Let  $X = (x_i)$  denote an  $r$ -robust strategy, with a hint that specifies the position of a target  $t$ . Suppose that  $X$  locates the target at the  $j_t$ -th iteration. We have that

$$c = \frac{d(X, t)}{d(t)} = \frac{2 \sum_{i=0}^{j_t-1} x_i + d(t)}{d(t)} \geq \frac{2 \sum_{i=0}^{j_t-1} x_i + x_{j_t}}{x_{j_t}} = 1 + 2 \frac{\sum_{i=0}^{j_t-1} x_i}{x_{j_t}}.$$

Note that the target  $t$  can be chosen to be arbitrarily far from  $O$ , which means that  $j_t$  can be unbounded (otherwise the strategy would not have bounded robustness). From Corollary 3 this implies that  $\sum_{i=0}^{j_t-1} x_i$  can be arbitrarily close to  $x_{j_t} \frac{1}{b_r-1}$ , and therefore  $c$  is arbitrarily close to  $1 + 2 \frac{1}{b_r-1} = \frac{b_r+1}{b_r-1}$ , which concludes the proof. ◀

#### 4 Hint is the direction of search

In this section we study the setting in which the hint is related to the *direction* of the search. More precisely, the hint is a single bit that dictates whether the target is to the left or to the right of the root  $O$ . Again, we are interested in Pareto-optimal strategies with respect to competitiveness: namely, for any fixed  $r \geq 9$ , what is the smallest  $c$  such that there exist  $(c, r)$ -competitive strategies?

A related problem was studied by Schuierer [40], which is called *biased search*. One defines the *left* and *right* competitive ratios, as the competitive ratio of a search, assuming that the target hides to the left of the root, or to the right of the root, respectively. However, the searcher does not know the target's branch. Of course we know that the maximum of the left and the right competitive ratios is at least 9 (and for the doubling strategy, this is tight). [40] shows that for any search strategy on the line (not necessarily 9-robust), the *average* of the left and the right competitive ratios is at least 9. At first glance, one may think that this could be an unsurprising, and perhaps even trivial result; however this is not the case. The proof in [40] is not straightforward, and relies in a generalization of a theorem of [25] which lower bounds the supremum of a sequence of functionals by the supremum of much simpler, geometric functionals. We will discuss this theorem shortly.

The problem studied in [40] is related to our setting: the left and right competitive ratios correspond to the consistency  $c$  and the robustness  $r$  of the strategy. Hence from [40] we know that  $c + r \geq 18$ . However, there is a lot of room for improvement. In this section we will show a much stronger tradeoff between  $c$  and  $r$ , and we will further prove that it is tight. For example, we will show that for any  $(c, r)$ -competitive strategy, if  $c$  approaches 5 from above, then  $r$  approaches infinity (in contrast, in this case, the lower bound of [40] yields  $r \geq 13$ ). In fact, we will show that  $c + r$  is minimized when  $c = r = 9$ . To this end, we will apply a parameterized analysis based on Schuierer's approach. We begin with the upper bound, by analyzing a specific strategy.

► **Theorem 5.** *For every  $b \geq 1$ , and  $\delta \in (0, 1]$ , there is a  $(c, r)$ -competitive strategy for linear search with the hint being the direction of search, in which*

$$c = 1 + 2 \cdot \left( \frac{b^2}{b^2 - 1} + \delta \frac{b^3}{b^2 - 1} \right) \text{ and } r = 1 + 2 \cdot \left( \frac{b^2}{b^2 - 1} + \frac{1}{\delta} \frac{b^3}{b^2 - 1} \right).$$

**Proof.** Suppose, without loss of generality, that the hint points to branch 0. Consider a strategy  $X = (\{x_i, i \bmod 2\})$ , which starts with branch 0, and alternates between the two branches. This strategy has consistency and robustness given by the following expressions, as a consequence of (2):

$$c = 1 + 2 \cdot \sup_{k \geq 0} \left\{ \frac{\sum_{i=0}^{2k+1} x_i}{x_{2k}} \right\} \quad \text{and} \quad r = 1 + 2 \cdot \sup_{k \geq 0} \left\{ \frac{\sum_{i=0}^{2k} x_i}{x_{2k-1}} \right\}, \quad (4)$$

where  $x_{-1}$  is defined to be equal to 1.

In addition, the search lengths of  $X$  are defined by

$$x_i = b^i, \text{ if } i \text{ even and } x_i = \delta b^i, \text{ if } i \text{ is odd,}$$

where we require that  $b > 1$ , and  $\delta \in (0, 1]$ . Note that  $X$  is “biased” with respect to branch 0, which makes sense since the hint points to that branch.

Substituting these values into (4), we obtain that

$$\begin{aligned} c &= 1 + 2 \cdot \sup_{k \geq 0} \left\{ \frac{\sum_{i=0}^k b^{2i}}{b^{2k}} + \delta \frac{\sum_{i=0}^k b^{2i+1}}{b^{2k}} \right\} = 1 + 2 \cdot \sup_{k \geq 0} \left\{ \frac{b^{2(k+1)} - 1}{(b^2 - 1)b^{2k}} + \delta \frac{b^{2k+3} - 1}{(b^2 - 1)b^{2k}} \right\} \\ &\leq 1 + 2 \cdot \left( \frac{b^2}{b^2 - 1} + \delta \frac{b^3}{b^2 - 1} \right). \end{aligned}$$

Similarly, we have that

$$\begin{aligned} r &= 1 + 2 \cdot \sup_{k \geq 0} \left\{ \frac{1}{\delta} \frac{\sum_{i=0}^k b^{2i}}{b^{2k-1}} + \frac{\sum_{i=0}^{k-1} b^{2i+1}}{b^{2k-1}} \right\} = 1 + 2 \cdot \sup_{k \geq 0} \left\{ \frac{1}{\delta} \frac{b^{2(k+1)} - 1}{(b^2 - 1)b^{2k-1}} + \frac{b^{2k+1} - 1}{(b^2 - 1)b^{2k-1}} \right\} \\ &\leq 1 + 2 \cdot \left( \frac{1}{\delta} \frac{b^3}{b^2 - 1} + \frac{b^2}{b^2 - 1} \right). \end{aligned} \quad \blacktriangleleft$$

For example, if  $\delta = 1$ , and  $b = 2$ , then Theorem 5 shows that there exists a (9, 9)-competitive strategy. Interestingly, the theorem shows that as the consistency  $c$  approaches 5 from above, the robustness  $r$  of the strategy must approach infinity. This is because the function  $\frac{b^2}{b-1}$  is minimized for  $b = 2$ , and hence for  $c$  to approach 5 from above, it must be that  $b$  approaches 2, and  $\delta$  approaches 0. But then  $\frac{1}{\delta}$  must approach infinity, and so must  $r$ .

We will show that the strategy of Theorem 5 is Pareto-optimal. To this end, we will use the following theorem of [40]. Recall the definitions of  $\alpha_X$ ,  $X^{+i}$  and  $G_a(\gamma_0, \dots, \gamma_{n-1})$  given in Section 2.

► **Theorem 6** (Theorem 1 in [40]). *Let  $p, q$  be two positive integers, and  $X = (x_0, x_1, \dots)$  a sequence of positive numbers with  $\sup_{n \geq 0} x_{n+1}/x_n < \infty$  and  $\alpha_X > 0$ . Suppose that  $F_k$  is a sequence of functionals that satisfy the following properties:*

- (1)  $F_k(X)$  depends only on  $x_0, x_1, \dots, x_{pk+q}$ ,
- (2)  $F_k(X)$  is continuous in every variable, for all positive sequences  $X$ ,
- (3)  $F_k(aX) = F_k(X)$ , for all  $a > 0$ ,
- (4)  $F_k(X + Y) \leq \max(F_k(X), F_k(Y))$ , for all positive sequences  $X, Y$ , and
- (5)  $F_{k+i}(X) \geq F_k(X^{+ip})$ , for all  $i \geq 1$ .

*Then there exist  $p$  positive numbers  $\gamma_0, \gamma_1, \gamma_{p-1}$  such that*

$$\sup_{0 \leq k < \infty} F_k(X) \geq \sup_{0 \leq k < \infty} F_k(G_{\alpha_X}(\gamma_0, \dots, \gamma_{p-1})).$$

We will use Theorem 6 to prove a tight lower bound on the competitiveness of any strategy  $X$ .

► **Theorem 7.** *For every  $(c, r)$ -competitive strategy, there exists  $\alpha > 1$ , and  $\delta \in (0, 1]$  such that  $c \geq 1 + 2 \cdot (\frac{\alpha^2}{\alpha^2-1} + \delta \frac{\alpha^3}{\alpha^2-1})$ , and  $r \geq 1 + 2 \cdot (\frac{\alpha^2}{\alpha^2-1} + \frac{1}{\delta} \frac{\alpha^3}{\alpha^2-1})$ .*

**Proof.** Let  $X = (x_0, x_1, \dots)$  denote a  $(c, r)$ -competitive strategy, and suppose, without loss of generality, that the hint specifies that the target is in the branch labeled 0. There are two cases concerning  $X$ : either the first exploration is on the branch labeled 0, or on the branch labeled 1. Let us assume the first case; at the end, we will argue that the second case follows from a symmetrical argument. As we argued in the proof of Theorem 5, in this case the competitiveness of  $X$  is described by (4). Let us define the functionals

$$C_k = \frac{\sum_{i=0}^{2k+1} x_i}{x_{2k}} \quad \text{and} \quad R_k = \frac{\sum_{i=0}^{2k} x_i}{x_{2k-1}}.$$

Then we have that

$$c = 1 + 2 \cdot \sup_{k \geq 0} C_k \quad \text{and} \quad r = 1 + 2 \cdot \sup_{k \geq 0} R_k. \quad (5)$$

The functional  $C_k$  satisfies the conditions of Theorem 6 with  $p = 2$ , as shown in [40] therefore there exist  $\gamma_0, \gamma_1 > 0$  such that

$$\begin{aligned} \sup_{k \geq 0} C_k &\geq \sup_{k \geq 0} C_k(G_{\alpha_X}(\gamma_0, \gamma_1)) = \sup_{k \geq 0} \frac{\gamma_0 + \gamma_1 \alpha_X + \gamma_0 \alpha_X^2 + \dots + \gamma_0 \alpha_X^{2k} k + \gamma_1 \alpha_X^{2k+1}}{\gamma_0 \alpha_X^{2k}} \\ &= \sup_{k \geq 0} \left\{ \frac{\sum_{i=0}^k \alpha_X^{2i}}{\alpha_X^{2k}} + \frac{\gamma_1}{\gamma_0} \frac{\sum_{i=0}^k \alpha_X^{2i+1}}{\alpha_X^{2k}} \right\}. \end{aligned}$$

If  $\alpha_X \leq 1$ , then the above implies that  $\sup_{k \geq 0} C_k = \infty$  (another way of dismissing this case is that if  $\alpha_X \leq 1$ , then  $X$  is bounded and the two branches are not explored to infinity, as required by any strategy of bounded consistency). We can thus assume that  $\alpha_X > 1$ , and we obtain that

$$\sup_{k \geq 0} C_k \geq \sup_{k \geq 0} \left\{ \frac{\alpha_X^{2k+2} - 1}{(\alpha_X^2 - 1) \alpha_X^{2k}} + \frac{\gamma_1}{\gamma_0} \frac{\alpha_X^{2k+3} - 1}{(\alpha_X^2 - 1) \alpha_X^{2k}} \right\} = \frac{\alpha_X^2}{\alpha_X^2 - 1} + \frac{\gamma_1}{\gamma_0} \frac{\alpha_X^3}{\alpha_X^2 - 1}. \quad (6)$$

We can lower-bound  $r$  using a similar argument, and obtain

$$\sup_{k \geq 0} R_k \geq \sup_{k \geq 0} \left\{ \frac{\gamma_0}{\gamma_1} \frac{\alpha_X^{2k+2} - 1}{(\alpha_X^2 - 1) \alpha_X^{2k-1}} + \frac{\alpha_X^{2k+1} - 1}{(\alpha_X^2 - 1) \alpha_X^{2k-1}} \right\} = \frac{\gamma_0}{\gamma_1} \frac{\alpha_X^3}{\alpha_X^2 - 1} + \frac{\alpha_X^2}{\alpha_X^2 - 1}. \quad (7)$$

Let us define  $\delta = \frac{\gamma_1}{\gamma_0} > 0$ . The result follows then by combining (5), (6) and (7). Note that if we require that  $c \leq r$ , it must be that  $\delta \leq 1$ , since  $\alpha_X > 1$ .

It remains to consider the symmetric case, in which in  $X$ , the first explored branch is branch 1. In this case the analysis is essentially identical: in (5) we substitute  $C_k$  with  $R_k$  and vice versa, in the expressions of  $c$  and  $r$ , and in the resulting lower bounds we require that  $\delta > 1$ . ◀

It is important to note that in the proof of Theorem 7 we used the fact that the values  $\gamma_0$  and  $\gamma_1$  depend only on  $X$  and not on any functionals defined over  $X$ , as follows from the proof of Theorem 6 in [40].

Theorem 7 implies that any  $(c, r)$ -competitive strategy  $X$  is such that

$$c + r \geq 2 + 4 \frac{\alpha_X^2}{\alpha_X^2 - 1} + 2 \left( \delta + \frac{1}{\delta} \right) \frac{\alpha_X^3}{\alpha_X^2 - 1},$$

which is minimized at  $\delta = 1$ , hence  $c + r$  is minimized only if  $c = r = 1 + 2 \frac{\alpha_X^2}{\alpha_X^2 - 1} \geq 9$ . We conclude that the average of a strategy's consistency and robustness (or the average of the left and right competitive ratio, in the terminology of [40]) is minimized only by strategies that are 9-robust.

## 5 Hint is a $k$ -bit string

In this section we study the setting in which the searcher has access to a *hint string* of  $k$  bits. We first consider the case  $k = 1$ . In Section 5.1 we will study the more general case.

It should be clear that even a single-bit hint is quite powerful, and that the setting is non-trivial. For example, the bit can indicate the right direction for search, as discussed in Section 4, but it allows for other possibilities, such as whether the target is at distance at most  $D$  from the root, for some chosen  $D$ . The latter was studied in [27], assuming that the hint is correct. More generally, the hint can induce a partition of the infinite line into two subsets  $L_1$  and  $L_2$ , such that the hint dictates whether the target is hiding on  $L_1$  or  $L_2$ .

We begin with the upper bound, namely we describe a specific search strategy, and the corresponding hint bit (as well as the query which it responds). Consider two strategies of the form

$$X_1 = (b_r^i) \text{ and } X_2 = (b_r^{i+\frac{1}{2}}).$$

Note that both  $X_1$  and  $X_2$  are  $r$ -robust:  $X_1$  is geometric with base  $b_r$ , whereas  $X_2$  is obtained from  $X_1$  by scaling the search lengths by a factor equal to  $b_r^{1/2}$ . We also require that the two strategies start by searching the same branch, hence in every iteration, they likewise search the same branch.

We can now define a strategy  $Z$  with a single bit hint, which indicates whether the searcher should choose strategy  $X_1$  or strategy  $X_2$ . For any given target, one of the two strategies will outperform the other, assuming the hint is trusted. Thus, an equivalent interpretation of the hint is in the form of a partition of the infinite line into two sets  $L_1$  and  $L_2$ , such that if the target is in  $L_i$ , then  $X_i$  is the preferred strategy, with  $i \in [1, 2]$ . See Figure 1 for an illustration.

The following result bounds the performance of this strategy, and its proof will follow as a corollary of a more general theorem concerning  $k$ -bit strings that we show in Section 5.1 (Theorem 11).

► **Proposition 8.** *For given  $r \geq 9$ , the above-defined strategy  $Z$  is  $r$ -robust and has consistency at most  $1 + 2 \frac{a^{3/2}}{a-1}$ , where  $a = b_r$ , if  $r \leq 10$ , and  $a = 3$ , otherwise.*

Note that if  $r = 9$ , then  $Z$  has consistency  $1 + 4\sqrt{2} \approx 6.657$ . For  $r \in [9, 10]$ , the consistency of  $Z$  is decreasing in  $r$ , as one expects. For  $r \geq 10$ , the consistency is  $1 + 3\sqrt{3} \approx 6.196$ .

We now turn our attention to lower bounds. To this end, we observe that a single-bit hint  $h$  has only the power to differentiate between two *fixed* strategies, say  $X = (x_i)$ , and  $Y = (y_i)$ , i.e., two strategies that are not defined as functions of  $h$ . We say that  $Z$  is *determined* by strategies  $X$  and  $Y$ , and the bit  $h$ .

■ **Figure 1** Illustration of strategy  $Z$ , using the first four segments of strategies  $X_1$  and  $X_2$ . Blue (dark) and orange (faded) segments correspond to the search segments of strategies  $X_1$  and  $X_2$ , respectively. The parts of the line in blue (resp. orange) indicate the hiding intervals for the target such that  $X_1$  (resp.  $X_2$ ) is preferred, and thus chosen by the hint.

### Setting up the lower-bound proofs

We give some definitions and notation that will be used in the proofs of Theorems 9 and 10. Let  $Z$  be determined by strategies  $X$  and  $Y$ , and a single-bit hint  $h$ . Let  $C$  denote the lower bound on the consistency of  $Z$  that we wish to show. For given  $i$ , define  $T_X^i = 2 \sum_{j=0}^i x_j + x_{i-1}$ , and similarly for  $T_Y^i$ . Define also  $q = r/C$ .

Note that a searcher that follows strategy  $X$  will turn towards the root at iteration  $i - 1$ , after having explored some branch  $\beta_i \in \{0, 1\}$  up to distance  $x_{i-1}$ . Thus,  $X$  barely misses a target that may be hiding at branch  $\beta_i$ , and at distance  $x_{i-1} + \epsilon$  from  $O$ , with  $\epsilon > 0$  infinitesimally small, and thus requires time  $T_X^i$  to discover it. We will denote this hiding position of a potential target by  $P_i$ . If, on the other hand, the searcher follows  $Y$ , then it can locate a target at position  $P_i$  at a time that may be smaller than  $T_X^i$ ; let  $\tau_i$  denote this time. When strategy  $Y$  locates a target hiding at  $P_i$ , it does so by exploring branch  $\beta_i$  to a length greater than  $x_{i-1}$ . Let  $j_i$  be the iteration at which  $Y$  locates  $P_i$ , thus  $y_{j_i} \geq x_{i-1}$ . Last, let  $Q_i$  denote the position in branch  $\beta_i$  and at distance  $y_{j_i} + \epsilon$  from  $O$ . In words, if a target hides at  $Q_i$ , then strategy  $Y$  barely misses it when executing the search segment  $y_{j_i}$ .

We first show a lower bound on the consistency of 9-robust strategies. In the proof we will not replace all parameters with the corresponding values (e.g., we will sometimes use  $r$  to refer to robustness, instead of the value 9). We do so because the arguments in the proof can be applied to other settings, as will become clear in the proof of Theorem 10.

► **Theorem 9.** *For any  $(c, 9)$ -competitive strategy with single-bit hint, it holds that  $c \geq 5$ .*

**Proof.** We will prove the result by way of contradiction. Let  $C = 5$ , and suppose that there is a strategy  $Z$  of consistency strictly less than  $C$ . Let  $Z$  be determined by two fixed strategies  $X$  and  $Y$ . Both  $X$  and  $Y$  must be  $r$ -robust (i.e., 9-robust), otherwise  $Z$  cannot be  $r$ -robust.

Fix  $i_0 \in \mathbb{N}$ . Suppose first that  $i_0$  is such that for all  $i \geq i_0$ , we have  $\tau_i \geq \frac{1}{q} T_X^i$ . In this case, for a target at position  $P_i$ , defined earlier,  $X$  requires time  $T_X^i$  to locate it, whereas  $Y$  requires time at least  $\tau_i \geq \frac{1}{q} T_X^i$  to locate it, thus the minimum time  $X$  or  $Y$  can locate this target is  $\frac{1}{q} T_X^i$ . Therefore, the consistency of  $Z$  is at least

$$c \geq \sup_{i \geq i_0} \frac{T_X^i}{q \cdot x_{i-1}} = \frac{1}{q} \sup_{i \geq i_0} \frac{T_X^i}{x_{i-1}} \geq \frac{C}{r} \cdot r = C, \quad (8)$$

which is a contradiction. Here, we used crucially the fact that  $\sup_{i \geq i_0} \frac{T_X^i}{x_{i-1}} \geq 9$ , for any 9-robust strategy  $X$  and any  $i_0$ <sup>1</sup>. Specifically, there exists sufficiently large  $i$  such that  $T_X^i$  is arbitrarily close to  $9x_{i-1}$ .

It must then be that  $i_0$  does not obey the property described above, namely for some  $i \geq i_0$  we have that  $\tau_i \leq \frac{1}{q}T_X^i$ . Since  $X$  is  $r = 9$ -robust, it must also be that  $\frac{T_X^i}{x_{i-1}} \leq r$ , as can be seen if a target hides at  $P_i$ . We therefore obtain that

$$\tau_i \leq \frac{1}{q}T_X^i \leq \frac{1}{q} \cdot r \cdot x_{i-1} = Cx_{i-1}. \quad (9)$$

We can also give a lower bound on  $\tau_i$ , as follows. Recall that we denote by  $y_{j_i}$  the segment at which strategy  $Y$  locates a target at position  $P_i$ . For arbitrarily small  $\epsilon > 0$ , we can choose  $i_0$  sufficiently large, which also implies that  $j_i$  can also be sufficiently large (since otherwise  $Y$  would not have finite robustness), so that Corollary 3 applies. To simplify the arguments, in the remainder of the proof we will assume that the corollary applies with  $\epsilon = 0$ ; this has no effect on correctness, since we want to show a lower bound of the form  $C - \delta$  on the consistency, and  $\epsilon$  can be made as small as we want in comparison to  $\delta$ . More precisely, we obtain that

$$\tau_i = 2 \sum_{l=0}^{j_i} y_l + x_{i-1} \geq \frac{2}{b_r - 1} y_{j_i} + x_{i-1}. \quad (10)$$

Combining (9) and (10) we have

$$y_{j_i} \leq \frac{C-1}{2}(b_r - 1)x_{i-1}. \quad (11)$$

In particular, since  $r = 9$  and  $C = 5$ , we have that  $y_{j_i} \leq 2x_{i-1}$ .

Consider now a target at position  $Q_i$ , and recall that this position is at distance infinitesimally larger than  $y_{j_i}$ . We will show that in both  $X$  and  $Y$ , there exists an  $i \geq i_0$  such that the searcher walks distance at least  $C \cdot y_{j_i}$  before reaching this position, which implies that  $Z$  has consistency at least  $C$ , and which yields the contradiction.

Consider first strategy  $Y$ . In this case, the searcher walks distance at least  $T_Y^{j_i}$ , to reach  $Q_i$ , from the definition of  $T_Y$ . Since  $r = 9$ , we know that  $\sup_{i \geq i_0} \frac{T_Y^{j_i}}{y_{j_i}} \geq 9$ , for any  $i_0$ , hence there exists an  $i \geq i_0$  such that the distance walked by the searcher is at least  $r \cdot y_{j_i}$ , and hence at least  $C \cdot y_{j_i}$ .

Consider now strategy  $X$ . In this case, in order to arrive at position  $Q_i$ , the searcher needs to walk distance  $T_X^i$ , then at least an additional distance  $y_{j_i} - x_{i-1}$  to reach  $Q_i$ . Let us denote by  $D_X^i$  this distance. We have

$$\begin{aligned} D_X^i &= T_X^i + y_{j_i} - x_{i-1} \\ &\geq 9x_{i-1} + y_{j_i} - x_{i-1} \quad (\text{From Corollary 3 and since } T_X^i \text{ is arbitrarily close to } 9x_{i-1}) \\ &= 8x_{i-1} + y_{j_i}. \end{aligned} \quad (12)$$

We then bound the ratio  $D_X^i/y_{j_i}$  from below as follows.

$$\begin{aligned} \frac{D_X^i}{y_{j_i}} &\geq \frac{8x_{i-1} + y_{j_i}}{y_{j_i}} = 1 + 8 \frac{x_{i-1}}{y_{j_i}} \\ &\geq 1 + 8 \frac{x_{i-1}}{2 \cdot x_{i-1}} \quad (\text{From the fact that } y_{j_i} \leq 2 \cdot x_{i-1}) \\ &= 5. \end{aligned} \quad (13)$$

We thus conclude that  $C \geq 5$ , which yields the contradiction, and completes the proof. ◀

---

<sup>1</sup> In general, this statement is not immediately true for arbitrary  $r > 9$ .

Showing a lower bound on the consistency, as a function of general  $r > 9$  is quite hard, even for the case of a single-bit hint. The reason is that as  $r$  increases, so does the space of  $r$ -robust strategies. For example, any geometric strategy  $G_b$  has robustness  $r$ , as long as  $b \in [\frac{\rho_r - \sqrt{\rho_r^2 - 4\rho_r}}{2}, \frac{\rho_r + \sqrt{\rho_r^2 - 4\rho_r}}{2}]$ . In what follows we will show a lower bound for a class of strategies which we call *asymptotic*. More precisely, recall the definition of  $T_X^i$ . We call an  $r$ -robust strategy  $S$  *asymptotic* if  $\sup_{i \geq i_0} \frac{T_X^i}{x_{i-1}} = r$ , for all fixed  $i_0$ . In words, in an asymptotic strategy, the worst-case robustness (i.e., the worst case competitive ratio without any hint) can always be attained by targets placements sufficiently far from the root. All geometric strategies, including the doubling strategy, have this property, and this holds for many strategies that solve search problems on the line and the star, such as the ones described in the introduction. Note also that the strategies  $X_1$  and  $X_2$  that determine the strategy  $Z$  in the statement of Proposition 8 are asymptotic, since they are near-geometric. Thus, the lower bound we show in the next theorem implies that in order to substantially improve consistency, one may have to resort to much more complex, and most likely irregular strategies.

► **Theorem 10.** *Let  $Z$  denote a strategy with 1-bit hint which is determined by two  $r$ -robust, asymptotic strategies  $X$  and  $Y$ . Then  $Z$  is  $(c, r)$ -competitive, with  $c \geq 1 + \frac{2b_r}{b_r - 1}$ .*

### 5.1 $k$ -bit hints

Here we consider the general setting in which the hint is a  $k$ -bit string, for some fixed  $k$ . First, we give an upper bound that generalizes Proposition 8. We will adapt an algorithm proposed in [5] for the *online bidding* problem with untrusted advice. Consider  $2^k$  strategies  $X_0, \dots, X_{2^k-1}$ , where

$$X_j = (a^{i + \frac{j}{2^k}})_{i \geq 0},$$

for some  $a$  to be determined later, and where all the  $X_j$  have the same parity: they all search the same branch in their first iteration and, therefore in every iteration as well. Define a strategy  $Z$ , which is determined by  $X_0, \dots, X_{2^k-1}$ , and in which the  $k$ -bit hint  $h$  dictates the index  $j$  of the chosen strategy  $X_j$ . In other words,  $h$  answers the query  $Q_h$  = “which strategy among  $X_0, \dots, X_{2^k-1}$  should the searcher choose?”. An equivalent interpretation is that the statements of the  $X_j$ ’s induce a partition of the line, such that for every given target position, one of the  $X_j$ ’s is the preferred strategy. Thus every bit  $i$  of the hint can be thought, equivalently, as the answer to a partition query  $Q_i$  of the line, i.e., of the form “does the target belong in a subset  $L_i$  of the line or not?”.

► **Theorem 11.** *For every  $r \geq 9$ , the strategy  $Z$  defined above is  $(c, r)$ -competitive with  $c \leq 1 + 2^{\frac{1 + \frac{1}{2^k}}{a-1}}$ , where  $a = b_r$ , if  $\rho_r \leq \frac{(1+2^k)^2}{2^k}$ , and  $a = 1 + 2^k$ , otherwise.*

For example, for  $r = 9$ , we obtain a strategy that is  $(1 + 2^{2 + \frac{1}{2^k}}, 9)$ -competitive. Thus, the consistency decreases rapidly, as function of  $k$ , and approaches 5.

Last, it is easy to see that no 9-robust strategy with hint string of any size can have consistency better than 3. To see this, let  $X$  be any 9-robust strategy, and let  $i_t$  be the iteration in which it locates a target  $t$ . Since  $t$  can be arbitrarily far from  $O$ ,  $i_t$  is unbounded, and thus Corollary 3 applies. We thus have that

$$\frac{d(X, t)}{d(t)} = \frac{\sum_{j=0}^{i_t-1} x_j + d(t)}{d(t)} = 1 + 2 \frac{\sum_{j=0}^{i_t-1} x_j}{d(t)} \geq 1 + 2 \frac{\sum_{j=0}^{i_t-1} x_j}{x_{i_t}} \geq 1 + 2 \frac{(1 - \epsilon)x_{i_t}}{x_{i_t}},$$

thus the consistency of  $X$  cannot be smaller than  $3 - \epsilon$ , for any  $\epsilon$ . The same holds then for any strategy that is determined by any number of 9-robust strategies, and thus for any hint.

## 6 Conclusion

We introduced a model that allows us to analyze the performance of search strategies with some information on the target. As explained in the introduction, the eventual goal is to apply this model to many other search problems, within or beyond competitive analysis, and for deterministic or randomized strategies. A good starting point is the generalization of linear search, namely the  $m$ -ray star problem, which has a long history of research, and has a broad connection to resource allocation problems (see, e.g. [33, 8, 18]). In this context, there are  $m$  tasks and the goal is to allocate resources to each of them, without knowing ahead of time which task will be the crucial one. The hint can be interpreted as some information concerning the instance (e.g., the index of the crucial task, or the time we may have to allocate to each one of the tasks in order to guarantee some good solution).

Another direction is to consider the case in which the hint comes with some error  $\eta$ , as in recent works in Machine Learning [36, 39, 37]. The ultimate goal would be to describe Pareto-efficient solutions in which the competitive ratio of the search also degrades gently as  $\eta$  increases. This is a challenging task, since one will have to strike a balance between the robustness, the consistency, and the competitive ratio, both from the point of upper and lower bounds. But there is a major obstacle as far as linear search is concerned. That is, unlike other online problems, the competitive ratio of linear search is not necessarily an increasing function of the error  $\eta$ . For example, consider the case in which there is a prediction of the position of the target, and suppose that we have a “bad” search strategy, which does not perform well if the error is small (i.e., turns right before discovering the target). However, it is possible that with significant error, the target happens to be found just as the searcher is about to turn and return to  $O$ , in one of the iterations. In this case, the strategy is quite efficient. These are counterintuitive complications that need to be taken into consideration in terms of defining efficiency in this setting.

In very recent work [7], we addressed the above questions in the context of a related problem in AI, namely the problem of *contract scheduling* under the *acceleration ratio*. There are interesting connections between searching on the line and contract scheduling [19, 2], and the techniques we developed and the results we showed in [7] should be readily applicable in searching on the line with noisy predictions.

## Abstract

We consider financial networks, where banks are connected by contracts such as debts or credit default swaps. We study the clearing problem in these systems: we want to know which banks end up in a default, and what portion of their liabilities can these defaulting banks fulfill. We analyze these networks in a sequential model where banks announce their default one at a time, and the system evolves in a step-by-step manner.

We first consider the *reversible model* of these systems, where banks may return from a default. We show that the stabilization time in this model can heavily depend on the ordering of announcements. However, we also show that there are systems where for any choice of ordering, the process lasts for an exponential number of steps before an eventual stabilization. We also show that finding the ordering with the smallest (or largest) number of banks ending up in default is an NP-hard problem. Furthermore, we prove that defaulting early can be an advantageous strategy for banks in some cases, and in general, finding the best time for a default announcement is NP-hard. Finally, we discuss how changing some properties of this setting affects the stabilization time of the process, and then use these techniques to devise a *monotone model* of the systems, which ensures that every network stabilizes eventually.

## 1 Introduction

The world's financial system is a highly complex network where banks and other financial institutions are interconnected by various kinds of contracts. These connections create a strong interdependence between the banks: if one of them goes bankrupt, then this also affects others, causing a cascading effect through the network. Such ripple effects also had an important role in the financial crisis of 2008, and hence there is an increasing interest in the network-based properties of these systems.

One fundamental question in these networks is the so-called *clearing problem*: given a network of banks and contracts, we need to decide which of the banks can fulfill their payment obligations, and which of the banks cannot, and thus have to report a default. This question is of high interest both for financial authorities and for the banks involved.

With two simple kinds of contracts, one can already build a financial network model that captures a wide range of phenomena in real-life financial systems. Previous work has mostly focused on the equilibrium states in these models, i.e. the fixed final states where the recovery rates of banks are consistent with their current assets and liabilities. However, in practice, most events in a financial system happen gradually, one after another: a single

bank announces a default, which might prompt another bank to reevaluate its situation, and also need to call being in default. This sequential development is an inherent part of the way financial networks behave, and as such, it is crucial to understand.

In particular, there is a range of natural questions that only arise if we study how the system develops in a step-by-step fashion. Can we reach every equilibrium state in a sequential manner? How does the ordering of default announcements influence the final outcome? Is there an optimal strategy of timing the announcements, either from a financial authority's or a single bank's perspective? How long can the sequential process last, and in particular, is it guaranteed to always stabilize eventually?

In this paper we analyze the development of financial systems in a sequential model, where banks update their situation one after another. We first study the *reversible model*, which is a natural sequential setting in such networks. We analyze this model from three main perspectives:

- *Stabilization time*: We show that a system can easily keep running infinitely in this model. Moreover, the time of stabilization heavily depends on the ordering of default announcements. We also present a more complex system that does stabilize eventually, but only after exponentially many steps.
- *Globally best solution*: We show that finding the ordering which results in the smallest (or largest) number of defaulting banks in the final state is NP-hard.
- *Defaulting strategies*: We study the best defaulting strategy of a single bank, and show that surprisingly, a bank may achieve the best outcome by announcing its default as early as possible. We also prove that in general, finding the best time to report a default is NP-hard.

Moreover, since the possibly infinite runtime is the most unrealistic aspect of this model, we analyze the reasons behind this phenomenon, and we discuss how it can be avoided in our sequential model.

- *Monotone sequential model*: We show that with two minor changes to the setting (a more sophisticated update rule and a slightly different handling of defaulting banks), we can develop a monotone model variant where the recovery rate of banks can only decrease, and the system is always guaranteed to stabilize after quadratically many steps. We also compare this setting to the reversible model in terms of defaulting strategies.

## 2 Related Work

The network-based analysis of financial systems has been rapidly gaining attention in the last decade. Most studies are based on the early financial network model of Eisenberg and Noe [11], which only assumes simple debt contracts between the banks. The propagation of shocks has been analyzed in many variants of this base model over the last decade [9, 5, 4, 1, 13, 15]; in particular, the model has been extended by default costs [20], cross-ownership relations [24, 12] or game-theoretic aspects [6].

However, the common ground in these model variants is that they can only describe *long positions* between the banks: a better outcome for one bank always means a better (or the same) outcome for other banks. This already allows us to capture how the default of a single bank can cause a ripple effect in the system, but it also ensures that there is always an equilibrium which is simultaneously best for all banks [11, 20]. As such, long positions cannot represent e.g. the opposing interests of banks in real-world financial systems. In particular, banks in practice often have *short positions* on each other when a worse situation for one bank is more favorable to another bank, mostly due to various kinds of financial derivatives.

The recent work of Schuldenzucker et. al. [22] presents a more refined model where the network also contains credit default swaps (CDSs) besides regular debt contracts. CDSs are financial derivatives that essentially allow banks to bet on the default of another bank in the system; they have played a dominant role in the financial crisis of 2008 [14], and have been thoroughly studied in the financial literature [10, 16]. While CDSs are still a rather simple kind of derivative, they already allow us to model short positions in the network; as such, their introduction to the system leads to remarkably richer behavior. In our paper, we also assume these two kinds of contracts in the network.

The work of [22, 23] discusses various properties of this new model: they show that systems may have multiple solutions (equilibrium states) in this model, and finding a solution is PPAD-complete. They also show that with default costs, these systems might not have a solution at all, and deciding whether a solution exists becomes NP-hard. The work of [19] studies a range of objective functions for selecting the best solution in this model, showing that the best equilibrium is not efficiently approximable to a  $n^c$  factor for any  $c < \frac{1}{4}$ . The work of [18] analyzes the model from a game-theoretical perspective, discussing how the removal or modification of contracts can lead to more favorable equilibria for the acting banks, and showing that such operations can lead to game-theoretical dilemmas.

However, all these results only analyze the model in terms of equilibrium states. This is indeed important when the market is hit by a large shock, and a central authority has to analyze the whole system, identify its equilibria, and possibly select one of them to artificially implement. However, apart from these rare occasions, the network mostly evolves sequentially, with banks announcing defaults in a step-by-step manner. For an understanding of real-world networks, it is also essential to study this gradually developing behavior of the process besides the equilibrial outcomes.

Sequential models of financial networks have already been studied in several papers; however, most of them consider some variant of the debt-only model with long positions [7, 2]. The paper of [22] notes that sequential clearing in their model would be dependent on the order of defaults, but does not investigate this direction any further. At the other end of the scale, the work of [3] introduces a very general sequential model (where payment obligations can be a function of all banks and all previous time steps), with a specific focus on expressing concrete real-world examples in this setting. As such, to our knowledge, there is no survey that considers a simple network model with both long and short positions, and analyzes the step-by-step development of financial systems in this model.

Finally, we point out that the clearing problem indeed has a high relevance in practice, e.g. when financial authorities conduct stress tests to analyze the sensitivity of real-world networks. One concrete example for a study of this problem is the European Central Bank's stress test framework [8].

## 3 Model Definition

### 3.1 Banks and contracts

Our financial system model consists of a set of *banks* (or *nodes*)  $B$ . We denote individual banks by  $u, v$  or  $w$ , and the number of banks by  $n = |B|$ . Banks are connected by two kinds of contracts that both describe a specific payment obligation from a debtor bank  $u$  to a creditor bank  $v$ . The amount of payment obligation is called the *weight* of the contract.

The simpler kind of connection is a *simple debt* contract, which obliges the debtor  $u$  to pay a specific amount  $\delta$  to the creditor  $v$ . This liability is unconditional, i.e.  $u$  owes this amount to  $v$  in any case.

Besides debts, banks can also enter into *conditional debt contracts* where the payment obligation depends on some external event in the system. One of the most frequent forms of such a conditional debt is a credit default swap (*CDS*), which obliges  $u$  to pay a specific amount to  $v$  in case a specific third bank  $w$  (the *reference entity*) is in default. More specifically, if  $w$  can only fulfill a  $r_w$  portion of its payment obligations (known as the recovery rate of  $w$ ), then a CDS of weight  $\delta$  implies a payment obligation of  $\delta \cdot (1 - r_w)$  from  $u$  to  $v$ . For simplicity, we assume that all conditional debt contracts are CDSs.

In practice, CDS contracts can, for example, be used by a bank as an insurance policy against the default of its debtors. If  $v$  suspects that its debtor  $w$  might not be able to fulfill its payment obligation, then  $v$  can enter into a CDS contract (as creditor) in reference to  $w$ ; if  $w$  goes into default and is indeed unable to pay, then  $v$  receives some payment on this CDS instead. However, banks may also enter into CDSs for other reasons, e.g. speculative bets about future developments in the market. As a sanity assumption, we assume that no bank can enter into a contract with itself or in reference to itself.

Besides the contracts between banks, a financial system is described by the amount of funds (in financial terms: *external assets*) owned by each bank, denoted by  $e_v$  for a specific bank  $v$ . The external assets and the incoming payments describe the total amount of assets available to  $v$ , while the outgoing contracts describe the total amount of payment obligations of  $v$ . If  $v$  is not able to fulfill all these obligations from its assets, then we say that  $v$  is *in default*. If  $v$  is in default, then the fraction of liabilities that  $v$  is able to pay is the *recovery rate* of  $v$ , denoted by  $r_v$ . Note that  $r_v \in [0, 1]$ , and  $v$  is in default if  $r_v < 1$ . We represent the recovery rates of all banks in a recovery rate vector  $r \in [0, 1]^B$ .

For an example, consider the financial system in Figure 1a with 3 banks. The banks have external assets of  $e_u = 2$ ,  $e_v = 1$  and  $e_w = 0$ . Bank  $u$  has a debt of weight 2 towards both  $v$  and  $w$ , and there is a CDS of weight 2 from  $w$  to  $v$ , with  $u$  as the reference entity. In this network,  $u$  has a total payment obligation of 4, but only has assets of 2, so  $u$  is in default, with a recovery rate of  $r_u = \frac{2}{4} = \frac{1}{2}$ . Bank  $u$  must use its funds of 2 to pay 1 unit of money to both  $w$  and  $v$ , proportionally to its obligations. Since  $r_u = \frac{1}{2}$ , the CDS from  $w$  to  $v$  will induce a payment obligation of  $2 \cdot (1 - r_u) = 1$ . The payment of 1 coming from  $u$  allows  $w$  to fulfill this obligation to  $v$ , thus narrowly avoiding default (hence  $r_w = 1$ ). Finally,  $v$  receives 1 unit from both  $u$  and  $w$ , has funds of 1 itself, and no payment obligations, so it has a positive equity of 3, and  $r_v = 1$ .

For convenience, we will use a simplified version of this notation in our figures: we only show the weight  $\delta$  of a contract when  $\delta \neq 1$ , and we only show the external assets of  $v$  explicitly if  $e_v \neq 0$ . We also write  $e_v = \infty$  to conveniently indicate that  $v$  can pay its liabilities in any case.

We also note that many of our constructions in the paper contain banks that have the exact same amount of assets and liabilities, like  $w$  in this example. This is a somewhat artificial “edge case” that still ensures  $r_w = 1$ . However, this is only for the sake of simplicity; we could avoid these edge cases by providing more assets to the banks in question.

Finally, we point out that contracts in a real-world financial system are often results of an earlier transaction between the banks, i.e. the creditor  $v$  previously offering a loan to the debtor  $u$ . We assume that such earlier payments are implicitly represented in  $e_u$ , and as such, the external assets and the contracts are together sufficient to describe the current state of the system.

■ **Figure 1** Two example systems on 3 banks. External assets are shown in rectangles besides the banks. Simple debts are denoted by blue arrows from debtor to creditor, while CDSs are denoted by light brown arrows from debtor to creditor, with the payment obligation shown beside the arrow.

### 3.2 Assets, liabilities and equilibria

We now formally define the liabilities and assets of banks in our systems. Note that due to the conditional debts, the payment obligations in a network are always a function of the recovery rate vector  $r$ .

Assuming a specific vector  $r$ , the liability  $l_{u,v}$  of a bank  $u$  towards a bank  $v$  is defined as the sum of payment obligation from  $u$  to  $v$  on all contracts, i.e.

$$l_{u,v}(r) = \delta_{u,v} + \sum_{w \in V} \delta_{u,v}^w \cdot (1 - r_w),$$

where  $\delta_{u,v}$  is the weight of the simple debt contract from  $u$  to  $v$  (if this contract exists, and 0 otherwise), and  $\delta_{u,v}^w$  is the weight of the CDS from  $u$  to  $v$  in reference to  $w$  (if it exists, and 0 otherwise). The total *liability* of  $u$  is simply the sum of liabilities to all other banks:  $l_u(r) = \sum_{v \in V} l_{u,v}(r)$ .

However, the actual *payment*  $p_{u,v}$  from  $u$  to  $v$  can be less than  $l_{u,v}$  if  $u$  is in default. If  $u$  is in default, then it has to spend all of its assets to make payments to creditors. Most financial system models assume that in this case,  $u$  has to follow the *principle of proportionality*, i.e. it has to make payments proportionally to the corresponding liabilities. This means that if  $u$  can pay an  $r_u$  portion of its total liabilities, and it has a liability of  $l_{u,v}$  towards  $v$ , then the payment from  $u$  to  $v$  is  $p_{u,v}(r) = r_u \cdot l_{u,v}(r)$ .

On the other hand, we can define the *assets* of a bank  $v$  as the sum of  $v$ 's external assets and its incoming payments in the network; that is,

$$a_v(r) = e_v + \sum_{u \in V} p_{u,v}(r).$$

If  $v$  is in default, then all these assets are used for  $v$ 's payment obligations; otherwise,  $a_v - l_v$  of these assets remain at  $v$ . Note that while both  $a_v(r)$  and  $l_v(r)$  are formally a function of  $r$ , we often simplify this notation to  $a_v$  and  $l_v$  when the recovery rate is clear from the context.

Recall that the recovery rate of  $v$  indicates the portion of payment obligations that  $v$  is able to fulfill. As such, a valid choice of  $r_v$  requires  $r_v = 1$  if we have  $a_v \geq l_v$ , and  $r_v = \frac{a_v}{l_v}$  if  $a_v < l_v$ . For simplicity, let us introduce a separate function  $R$  to denote this dependence on  $a_v$  and  $l_v$ ; that is, we define the function  $R : [0, \infty) \times [0, \infty) \rightarrow [0, 1]$  as

$$R(a, l) = \begin{cases} 1, & \text{if } a \geq l \\ \frac{a}{l}, & \text{otherwise.} \end{cases}$$

We say that a vector  $r \in [0, 1]^B$  is an *equilibrium* (or a *clearing vector*) of the system if for each bank  $v \in B$ , we have  $r_v = R(a_v(r), l_v(r))$ ; that is, if the recovery rate vector is consistent with the assets and liabilities it generates in the network. Previous work has

mostly focused on the analysis of different equilibrium states. Recall that while it is mostly straightforward to find the equilibrium states in our example constructions, the problem is PPA-hard in general [23].

We have already seen a simple example equilibrium in Figure 1a; for another example that is slightly more challenging to compute, let us consider Figure 1b. Here bank  $u$  is again always able to pay its liabilities, so  $r_u = 1$  in any case. Furthermore, neither  $r_v = 1$  nor  $r_w = 1$  can provide an equilibrium in this network, so both  $v$  and  $w$  must be in default in any solution. Thus any equilibrium must have

$$r_v = \frac{a_v}{l_v} = \frac{1 + 1 - r_w}{3} \quad \text{and} \quad r_w = \frac{a_w}{l_w} = \frac{3 \cdot r_v}{2}.$$

This implies that the only equilibrium is  $r_v = \frac{4}{9}$ ,  $r_w = \frac{2}{3}$ .

### 3.3 Sequential models of defaulting

We have defined the equilibria of the system as the states  $r$  that would fulfill the payment criteria if every bank were to simultaneously update its recovery rate to  $r$ . However, in practice, the announcement of defaults usually happens in a sequential manner, due to different sources of delay in the system: even if it is clear from  $a_v$  and  $l_v$  that a bank  $v$  is only able to fulfill a specific  $r_v$  portion of its liabilities, this might not be immediately known to the creditors of  $v$  (due to incomplete information), or the legal framework may first allow  $v$  to try to obtain further funds before officially having to announce its default. As such, the officially announced recovery rate  $r_v$  might not always equal  $R(a_v, l_v)$ , and  $v$  has to explicitly announce the changes in  $r_v$  in order to make other banks aware of this situation.

Hence in our sequential model, each step of the process will consist of a single bank announcing an *update* to its recovery rate. That is, given the assets  $a_v$  and liabilities  $l_v$  currently available to  $v$ , if the official recovery rate  $r_v$  does not equal  $R(a_v, l_v)$ , then bank  $v$  can (and eventually has to) announce a new official recovery rate of  $r_v := R(a_v, l_v)$ . Since this affects both the payments received by the debtors of  $v$  and the payment obligations on CDSs in reference to  $v$ , it can have various effects on the system, providing new assets and liabilities to some banks; as a result, these banks may also end up with a higher or lower asset/liability balance than their currently announced recovery rate, and thus they will also have to execute a new update at some point.

More formally, we consider discrete time steps  $t = 0, 1, 2, \dots$ . Each step consists of a single bank  $v$  announcing an update to  $r_v$ . That is, if  $v$  has assets  $a_v^{(t-1)}$  and liabilities  $l_v^{(t-1)}$ , but a recovery rate of  $r_v^{(t-1)} \neq R(a_v^{(t-1)}, l_v^{(t-1)})$  at time  $t - 1$ , then we say that  $v$  is *updatable* at time  $t - 1$ . In each time step  $t$ , we select a bank  $v$  that is updatable at time  $t - 1$ , and define the state of the system at time  $t$  by (i) setting  $r_v^{(t)} = R(a_v^{(t-1)}, l_v^{(t-1)})$  for the bank  $v$  that executes the update, (ii) setting  $r_u^{(t)} = r_u^{(t-1)}$  for every other bank  $u \neq v$ , and (iii) calculating  $a_u^{(t)}$  and  $l_u^{(t)}$  for all  $u \in B$  based on this new vector  $r^{(t)}$ .

We assume that initially, each bank  $v$  has  $r_v^{(0)} = 1$ , and we compute  $a_v^{(0)}$  and  $l_v^{(0)}$  accordingly. We say that the sequential process *stabilizes* in round  $t$  if there is no updatable bank in round  $t$ .

## 4 Basic Properties

We begin by discussing some fundamental properties of this sequential setting.

### 4.1 Reversibility and infinite cycling

One important property of the sequential model is that even if a bank  $v$  goes into default, it can easily return from this default later. That is, future updates in the system might increase the payment obligation on an incoming CDS of  $v$ , thus increasing  $a_v$  and possibly raising  $\frac{a_v}{l_v}$  above 1 again. This is in line with real-world financial systems, where returning from a default is also often possible if a bank acquires new assets. Due to this property, we also refer to this setting as the *reversible model*.

Note that in practice, defaulting banks are often given a limited amount of time to obtain new assets and thus reverse a default; however, our sequential setting does not define an explicit timing of defaults (only their order), so such rules are not straightforward to include in our model. Nonetheless, we point out that many of our example constructions also work if we assume that defaults are only reversible for a specific (constant) number of rounds.

Another important property is that in a cyclic network topology, our model can easily result in an infinite loop of updates. Consider the example in Figure 2, where the default of  $v$  indirectly provides new assets to  $v$ . Since  $r_v = 1$  initially,  $u$  must first update to  $r_u = 0$ , and as a result,  $v$  must update to  $r_v = 0$ . However, this leads to new liabilities in the network, providing assets to both  $u$  and (indirectly) to  $v$ , so  $u$  (and then  $v$ ) must update its rate back to  $r_u = r_v = 1$ . This returns the system to its initial state, where  $u$  (and  $v$ ) will continue by updating their recovery rates to 0 again.

If we keep repeating these few steps, then  $u$  and  $v$  alternate between  $r_u = r_v = 0$  and  $r_u = r_v = 1$  endlessly. Note that the system does have an equilibrium in  $r_u = r_v = \frac{1}{2}$ ; however, instead of converging to this state, the banks keep on periodically repeating the same few steps. The possibility of such behavior in a sequential setting has already been noted in [22] or [3] before. While this looping behavior is certainly undesired, it follows straightforwardly from the reversibility of defaults and the existence of cycles in the network topology. As such, these situation could also occur in real-world systems, requiring a financial authority to intervene and set the system artificially to its equilibrium.

### 4.2 Dependence on the order of updates

Another key property of the sequential model is that the final outcome becomes dependent on the ordering of updates, i.e. whether some banks announce their default earlier or later.

We show a simple example of this dependence on the *branching gadget* of Figure 3, which has already been used as a building block in the works of [23] and [19]. In this system, neither of the two banks  $u$  and  $v$  have any assets initially, so they are unable to fulfill their obligations. However, if  $u$  is the first one to report default (updating to a new recovery rate of  $a_v^{(0)}/l_v^{(0)} = 0$ ), then this provides 1 unit of new assets to  $v$ , which means that  $v$  does not default anymore; the system stabilizes with  $r_u = 0$ ,  $r_v = 1$ . Similarly, if  $v$  is the first one to execute an update, then this provides new assets to  $u$ , and the system stabilizes with  $r_u = 1$ ,  $r_v = 0$ . Thus both banks are strongly motivated to delay their default announcement as long as possible, as this might allow them to avoid defaulting entirely.

We can also note that there are further equilibrium states where both  $u$  and  $v$  are in default, e.g. when  $r_u = \frac{1}{2}$  and  $r_v = \frac{1}{2}$ ; due to its symmetry, one might even argue that this is the “fair” equilibrium to implement. However, this equilibrium is not reachable in any way through sequential updates; the only possible endstates of the sequential model are  $(r_u, r_v) = (0, 1)$  and  $(r_u, r_v) = (1, 0)$  as described above.

■ **Figure 2** Example system for an infinite loop in the reversible model.

■ **Figure 3** Example system where the outcome depends on the order of announcements.

■ **Figure 4** Example of an equilibrium that is not reachable in the sequential model.

This shows that even in terms of the final outcome, the sequential model can significantly differ from the static analysis of the system. This is not due to the presence of fractional recovery rates: we can also easily have equilibria with integer (i.e., 0 or 1) recovery rates that is not reachable in a sequential setting. In Figure 4, bank  $u$  is the only node who can execute an update, which immediately leads to the unique final state  $r_u = 0$ ,  $r_v = r_w = 1$ . However,  $r_u = 1$  with  $r_v = r_w = 0$  also forms an equilibrium in this system, so this phenomenon is indeed a result of the sequential nature of our model.

## 5 Results

We now move on to a deeper analysis of the model. We mainly focus on the length and outcome of the sequential process, and how the ordering of updates affects these properties.

Since our proofs will require more complex constructions, we switch to a simpler notation in our figures: instead of directly showing the liability  $\delta \cdot (1 - r_w)$  on a CDS, we only label the CDS by the weight  $\delta$  and the reference entity  $w$ , or simply by  $w$  when  $\delta = 1$ . Nonetheless, recall that each such CDS still denotes a liability of  $\delta \cdot (1 - r_w)$ .

### 5.1 Stabilization time

One fundamental question is the number of rounds it takes until the sequential process stabilizes, i.e. until no node can execute an update anymore. We first analyze this aspect in detail.

We have already seen in Figure 2 that even in simple examples, it can easily happen that the system does not stabilize at all.

► **Corollary 1.** *There is a system which never stabilizes.*

Furthermore, with the appropriate ordering of default announcements, we can also obtain any finite value as a stabilization time.

► **Lemma 2.** *For any integer  $k$ , there exists a system and an ordering such that the system stabilizes after exactly  $k$  steps.*

**Proof.** Consider the system on Figure 5. Similarly to Figure 2, this system allows us to produce an arbitrarily long sequence by switching only  $u$  and  $v$  repeatedly. However, when  $w$  announces a default, then both  $u$  and  $v$  gain enough assets to fulfill their obligations, so the system stabilizes after at most 2 more updates.

This allows us reach any magnitude of stabilization time, apart from a constant offset. We can then simply add  $O(1)$  more independent defaulting nodes to reach the desired value  $k$ . ◀

This already shows that stabilization time can heavily depend on the order of updates. A more extreme case of this is when the choice of the first update already decides between two very different outcomes for the system.

► **Lemma 3.** *There is a system where depending on the first update, the system either stabilizes in 1 step, or does not ever stabilize.*

**Proof.** Figure 6 is obtained by combining the base ideas of Figures 2 and 3. In this network, either bank  $w_1$  or  $w_2$  must execute the first update.

If  $w_2$  is the first to announce  $r_{w_2} = 0$ , then  $w_1$  receives a payment of 1, and the system immediately stabilizes; no other bank will make an update.

However, if we update  $r_{w_1} = 0$  first, then  $w_2$  survives, but on the other hand,  $u$  receives no assets at all. In this case, nodes  $u$  and  $v$  are in the same situation as in Figure 2, and thus the upper part of the system will never stabilize. ◀

Finally, infinite loops are not the only examples of long stabilization: it is also possible that the system does stabilize eventually, but for any ordering of updates, this only happens after exponentially many steps.

► **Theorem 4.** *There is a system where for any possible ordering, the system eventually stabilizes, but only after  $2^{\Omega(n)}$  steps.*

**Proof sketch.** This proof requires a significantly more complex construction than our previous statements. We only outline the main idea of the construction here, and we discuss the details in the full version of the paper.

The first step of the proof is to build a *stable bit gadget*, which represents a mutable binary variable. The gadget offers a simple interface to set the bit to 0 or 1 through external conditions, and otherwise maintains its current value until the next such operation is executed.

Besides this, we create gadgets that describe logical states of an abstract process, similarly to a finite automaton. We also encode conditional transitions between these state gadgets, i.e. ensure that the system can only enter a given logical state if some banks currently have a specific recovery rate. This allows us to describe a logical process where the next state of the system is always determined by the current state and the current value of some stable bit gadgets.

Using these tools, we can essentially design a binary counter on  $k = \Omega(n)$  bits, with  $k$  stable bits representing the bits of the counter. This counter will proceed to count from 0 to  $2^k - 1$ , and only stabilize after the counting has finished, resulting in a sequence of at least  $2^k$  steps.

The most challenging task is to ensure that in every step of the process, there is only one possible update we can execute next: the appropriate next step of the counting procedure. To achieve this, we not only need to ensure that some banks become updatable at specific times, but we also have to force the banks to indeed execute these updates, by encoding them as requirements in the transition conditions of our logical states. This results in a heavily restricted construction where there is essentially only one valid ordering of updates: the one that corresponds to the step-by-step incrementation of the binary counter. ◀

Note that another possible approach for measuring the stabilization time of our systems is to consider the number of *defaulting steps*, i.e. to only count the steps when a bank  $v$  updates from  $r_v = 1$  to  $r_v < 1$ . One can check that our results on stabilization time also hold for this alternative metric.

■ **Figure 5** Example system for Lemma 2. Recall that a CDS labeled with  $v$  still describes a payment obligation of  $1 - r_v$ .

■ **Figure 6** Example system for Lemma 3, where stabilization time depends on the choice of the first update.

■ **Figure 7** Example system for Lemma 6, i.e. where the number of defaults depends on the choice of the first update.

Finally, as a theoretical curiosity, we point out that our binary variable and state machine gadgets in the proof of Theorem 4 demonstrate that we can essentially use financial networks as a model of computation. We discuss the expressive power of this model in the full version of the paper.

► **Theorem 5.** *We can use financial networks to simulate any Turing-machine with a finite tape.*

## 5.2 Outcome with the fewest defaults

In case of a larger shock, a financial authority could also be interested in the final state of the system, and in particular, the number of banks that end up in default. This can again heavily depend on the order of updates; in fact, even a single decision in the ordering can be critical from this perspective.

► **Lemma 6.** *Depending on the first update, the number of defaults can be either  $O(1)$  or  $n - O(1)$ .*

**Proof.** Consider the system on Figure 7. If  $u$  is the first to report a default with  $r_u = 0$ , then  $v$  receives 1 unit of payment, and thus no other node defaults. On the other hand, if  $v$  reports a default first, then  $u$  survives, but all the nodes in the lower chain have no incoming assets, and thus they all have to report a default eventually. So based on the first update, the number of defaults is either 1 or  $n - 3$ . ◀

Hence if the authority has some influence over the ordering of updates, e.g. by allowing more flexibility to some banks than to others, then it could dramatically reduce the number of banks that end up in default. Unfortunately, even if we have complete control over the ordering, it is still hard to find the best possible ordering (in terms of the number of defaults in the final outcome).

► **Theorem 7.** *It is NP-hard to find the number of defaulting nodes in the best possible ordering.*

**Proof.** We reduce the question to the MAXSAT problem: given a boolean formula in conjunctive normal form, the goal of MAXSAT is to find the assignment of variables that satisfies the highest possible number of clauses [17].

■ **Figure 8** Clause gadget for the MAXSAT reduction in Theorem 7.

■ **Figure 9** Clause gadget for the MAXSAT reduction in Theorem 8.

Assume we have a MAXSAT problem on  $k$  variables  $x_1, \dots, x_k$ , and  $m$  clauses. Note that in our financial systems, the branching gadget of Figure 3 is a natural candidate for representing a boolean variable, since in any sequence, exactly one of  $u$  and  $v$  will eventually default. We point out that this gadget has already been used for similar purposes before in [23] and [19].

Hence for each variable  $x_i$ , we create a separate branching gadget in our system, and consider node  $u$  to represent the literal  $x_i$ , and node  $v$  to represent the literal  $\neg x_i$ . That is, we will consider  $x_i = \text{TRUE}$  if  $u$  defaults, while we consider  $x_i = \text{FALSE}$  if  $v$  defaults.

Furthermore, for each clause of the input formula, we create the clause gadget shown in Figure 8, with the CDSs labeled by the banks representing the literals in the clause. For example, the gadget in the figure is obtained for the clause  $(x_1 \vee x_3 \vee \neg x_4)$ . If any of the banks  $x_1$ ,  $x_3$  or  $\neg x_4$  default, then  $v$  receives enough assets to pay its debt, whereas otherwise,  $v$  must eventually default.

If we aim to avoid as many defaults as possible, then the reasonable ordering strategy is to first evaluate all the variable gadgets, and the clause gadgets only afterwards. In this case, each bank  $v$  of a clause gadget survives if and only if there is a true literal in the corresponding clause. This way the number of defaulting nodes in the final state is always exactly  $k$  in the variable gadgets, and at most  $m - \text{OPT}$  in the clause gadgets, where  $\text{OPT}$  denotes the maximal number of satisfiable clauses in our MAXSAT problem. Thus the minimal number of defaulting nodes in the system is altogether  $k + m - \text{OPT}$ . Finding this value also allows us to determine  $\text{OPT}$ , which completes our reduction. ◀

To analyze the effects of a shock, one might also be interested in the worst possible ordering; a similar reduction shows that this is also hard to find.

► **Theorem 8.** *It is NP-hard to find the number of defaulting nodes in the worst possible ordering.*

**Proof.** We can apply the same reduction from MAXSAT as before; we only need to slightly change the clause gadgets. Consider the clause gadget of Figure 9 for the example clause  $(x_1 \vee x_3 \vee \neg x_4)$ . To maximize the number of defaulting banks in this system, we can first evaluate the variables gadgets, which then allows us to produce an extra default for each clause that has a true literal. Thus the maximum number of defaulting nodes is  $k + \text{OPT}$ , which completes our reduction. ◀

### 5.3 Individual defaulting strategies

It is also natural to consider the effect of the ordering from the perspective of a single bank  $v$ . More specifically, is  $v$  motivated to immediately report its own default? Can it achieve a better outcome for itself by carefully timing its updates?

Intuitively, one would expect that banks are motivated to report their default as late as possible, in hope of obtaining further assets in the meantime. This is indeed true in many cases. For example, in the branching gadget of Figure 3,  $u$  and  $v$  clearly have a short position

in each other, and if either of them can wait long enough such that the other bank reports a default first, then it obtains new assets from the incoming CDS and thus manages to avoid a default entirely.

However, due to the complex interconnections in a network, it is in fact also possible that  $v$  achieves a better outcome if it reports a default earlier; it is even possible that this is the only strategy which allows  $v$  to avoid a default in the endstate of the system. We consider this one of our most surprising results.

► **Theorem 9.** *There exists a system where a bank  $v_1$  can only avoid a default in the final state of the system if  $v_1$  is the first bank to report a default.*

**Proof.** Consider the system in Figure 10, where only  $v_1$  or  $v_2$  can report a default initially, since no other node has any liabilities.

Assume that  $v_1$  is the first to report a default, updating to  $r_{v_1} = 0$ . This influences the network in two ways:  $v_2$  obtains assets of 1, and  $u_2$  now has a new liability of 1 as a result.

Thus the next update can only be executed by  $u_2$ , resulting in  $r_{u_2} = 0$ . On the one hand, this provides assets to  $u_1$ ; on the other hand, it creates liabilities for  $w_2$ . As a result, the next update can only be executed by  $w_2$ .

When  $w_2$  announces  $r_{w_2} = 0$ , this results in more liabilities for the defaulting  $u_2$ , and more assets for  $v_1$ . These assets make  $v_1$  the only updatable next node, bringing  $v_1$  back from its default with  $r_{v_1} = 1$ .

When  $v_1$  announces  $r_{v_1} = 1$ , then  $u_2$  loses some of its liabilities, and  $v_2$  loses its assets. This does not affect  $u_2$ , which remains at  $r_{u_2} = 0$  due to the default of  $w_2$ ; however,  $v_2$  now also has to report a default. The system finally stabilizes after  $v_2$  updates to  $r_{v_2} = 0$ : the assets/liabilities of  $v_1$  and  $u_1$  are affected, but neither of them has to make an update. Thus the final solution has  $r_{v_1} = 1$  and  $r_{v_2} = 0$ .

On the other hand, if  $v_2$  is the first to report default, then due to the symmetry of the system, the final outcome will have  $r_{v_1} = 0$  and  $r_{v_2} = 1$ . Note that in both cases, after the first update is executed, the remaining steps are already determined, and no alternative ordering is possible. Hence the only way for  $v_1$  to avoid a default in the final outcome is to be the first one to report a default. ◀

We can also show that in general, it is NP-hard to find the best default-reporting strategy for a bank. This even holds if the behavior of the rest of the network is “predictable”, i.e. if there is essentially only one ordering that the system can follow. This implies that any interpretation of this problem, e.g. optimizing a bank’s best-case payoff or worst-case payoff, is also hard.

► **Theorem 10.** *It is NP-hard to find the time of defaulting that provides the highest payoff to a specific bank in the final outcome.*

**Proof sketch.** The main idea of the proof is to combine the binary counter construction of Theorem 4 with the MAXSAT reduction. That is, given a binary counter on  $k = \Theta(n)$  bits, we add a new node  $v$  to the system such that

- (a)  $v$  can choose to default anytime,
- (b) the default of  $v$  terminates the counting process, stabilizing the counter in its current state,
- (c)  $v$  then comes back from its default, and its assets in the final state are proportional to the amount of clauses satisfied in a SAT formula, where the value of the variables is derived from the finalized state of the bits in the counter.

■ **Figure 10** Example where early defaulting is the best strategy, with multiple source and sink nodes for a cleaner topology.

■ **Figure 11** Infinite convergence to an equilibrium state.

This means that the counter essentially enumerates all the possible value assignments of the variables, and the best defaulting strategy is obtained if counting is terminated at the assignment that satisfies the highest number of clauses. However, finding this assignment is NP-hard.

The details of the construction are discussed in the full version of the paper. ◀

## 6 Achieving Stabilization

While the reversible sequential model is realistic from many perspectives, the infinite looping property is clearly not reasonable in real-world systems. As such, it is natural to ask if there is a way to modify the model to avoid this situation, and instead ensure that every financial system stabilizes eventually.

In this section, we investigate the causes of this infinite behavior in the sequential model. We first show that we require more sophisticated update rules to avoid a specific kind of infinite behavior, namely when the system converges to an equilibrium. We then discuss liability freezing, a different (but in some sense also realistic) approach of handling defaulting banks in the network. Finally, we show that if we combine these two modifications, we can obtain a monotone sequential model where our systems always stabilize after polynomially many steps.

### 6.1 More sophisticated update rules

**Convergence to an equilibrium.** Since the addition of conditional debt contracts drastically increases the complexity of the model, it is a natural first assumption that such an infinite pattern can only arise if the system contains a CDS. However, this is not the case: we can also obtain a (slightly different kind of) infinite sequence in systems with only regular debts.

Consider the example system in Figure 11. Since bank  $u$  has  $l_u = 2$  and  $a_u = 1$  initially, it can begin by updating its recovery rate to  $r_u = \frac{1}{2}$ . As a result,  $v$  and  $w$  must also announce recovery rates of  $r_v = r_w = \frac{1}{2}$ . With  $a_u = \frac{1}{2}$ , bank  $u$  now has to update to  $r_u = \frac{1}{4}$ , which then gives  $r_v = r_w = \frac{1}{4}$ . Each such round prompts another round of updates, slowly converging to  $r_u = r_v = r_w = 0$ . While this is indeed the only equilibrium of the system, the process takes infinitely many steps to reach this state.

**Explicit computation of equilibria.** Such a convergence process can easily occur in any network with cycles; as real-world financial systems are also known to contain cycles [21], we can easily encounter such a situation in practice. In this case, it seems that a financial authority (or the banks involved) have no other option than to explicitly compute this equilibrium, and set their recovery rates to the appropriate values.

Fortunately, it is known that in case of fixed liabilities in the network (i.e. only simple debts), this is computationally feasible: there always exists a single maximal solution that is simultaneously best for all banks, and this solution can be found in polynomial time [20], essentially by repeatedly solving a system of linear equations. Thus an authority could indeed find this solution, and banks could directly update to these recovery rates in order to skip the convergence steps.

This allows us to introduce the notion of *smart updates*: after each updating step, we can consider the current liabilities in the network fixed, and we assume that the equilibrium of the system is computed under these liabilities (essentially reducing the convergence process to a single step). This equilibrium defines a *tentative recovery rate* for each bank  $v$ , denoted by  $\bar{r}_v$ . In smart updates, we assume that whenever  $v$  executes an update, it always updates to  $r_v := \bar{r}_v$ .

In the example of Figure 11, this means that the tentative recovery rates  $\bar{r}_u = \bar{r}_v = \bar{r}_w = 0$  are already computed initially, and thus any bank executing an update will immediately set its recovery rate to 0. This way the process already stabilizes after each bank has executed one update. In general, we achieve stabilization in this setting when  $r_v = \bar{r}_v$  for each bank  $v$  in the network.

While the explicit computation of equilibria may seem artificial, in practice, defaulting banks are often subject to more thorough supervision by the authorities. As such, it is not so unrealistic that the situation of a defaulting bank  $v$  is first analyzed by an authority, and this analysis determines the official recovery rate of  $v$ .

Also, recall that while equilibria are easy to find in debt-only networks, the introduction of CDSs changes this picture entirely. With CDSs, there can easily be multiple equilibria that are Pareto-optimal, and finding any of them is already a PPAD-hard problem [23]. Thus this explicit computation of  $\bar{r}_v$  is only possible for a single step of the process, when we consider the current payment obligation on each CDS fixed. As defaults rarely happen simultaneously in practice, it can indeed be realistic to assume that we can analyze the current (fixed) liabilities in the network after each new update.

Finally, note that smart updating is not yet enough to avoid an infinite convergence. In the system shown in Figure 12,  $v$  can initially fulfill its obligations, while  $u$  must update to  $r_u = \frac{1}{2}$ . This creates new liabilities of 2 for  $v$ , leading to the tentative recovery rates  $\bar{r}_v = \frac{2}{3}$  and thus  $\bar{r}_u = \frac{1}{3}$  after this first step. If  $u$  updates again (to  $r_u = \frac{1}{3}$ ), then the liability on the CDS again increases, and thus the next computed equilibrium has an even lower  $\bar{r}_u$ .

Each step of this process provides new tentative recovery rates, obtained as  $\bar{r}_v = \frac{2}{5-4 \cdot r_u}$  and  $\bar{r}_u = \frac{\bar{r}_v}{2} = \frac{1}{5-4 \cdot r_u}$ . This results in an infinite convergence to the equilibrium  $r_v = \frac{1}{2}$ ,  $r_u = \frac{1}{4}$ . Note that we can observe this behavior regardless of whether  $v$  ever updates its recovery rate to the new  $\bar{r}_v$  value; the assets of  $u$  are calculated independently of the recovery rate reported by  $v$ .

**Optimistic updates.** Another natural variant of smart updates is the *optimistic update* rule. To avoid the convergence phenomenon of Figure 11, this setting also assumes that the system is analyzed by an authority after each update. However, defaulting and non-defaulting nodes are now handled in a different manner in this analysis. More specifically, if a bank  $v$  is not

■ **Figure 12** Example of infinite convergence in a network, even in case of smart updates. Recall that the label  $4u$  on the CDS describes a payment obligation of  $4 \cdot (1 - r_u)$ .

in default (it has  $r_v = 1$  currently), then it is given the benefit of a doubt: we assume that it can fulfill its obligations, regardless of how many assets it currently has. On the other hand, banks in default are handled the same way as in case of smart updates.

This distinction can indeed be realistic: if  $v$  is non-defaulting, then  $a_v$  might not even be known to other banks, so the creditors of  $v$  have no better option than to assume that they will receive all payments from  $v$ . On the other hand, the assets of defaulting banks are under more thorough scrutiny in most legal frameworks.

Formally, optimistic update means that after each step of the process, we use a modified version of the liability network to compute the equilibrium. Whenever there is a contract of current weight  $\delta$  from  $u$  to  $v$  with  $r_u = 1$ , then we remove this contract from the network, and instead (i) we add a new debt of weight  $\delta$  from  $u$  to an artificial sink node  $s$ , ensuring that  $u$  still has this liability, and (ii) we increase the value of  $e_v$  by  $\delta$ , ensuring that  $v$  always has these assets. In contrast, if  $r_u < 1$ , we do not execute any changes on the outgoing contracts. This modified network ensures that until a bank reports a default, its lack of assets does not affect its creditors. We then use the same algorithm of [20] to find the equilibrium in this modified system, and set the next tentative recovery rates accordingly.

Revisiting the system in Figure 12, we see that bank  $u$  can again first update to  $r_u = \frac{1}{2}$ , which results in  $\bar{r}_v = \frac{2}{3}$ . However, with optimistic updates,  $u$  cannot make an update again: until  $v$  adjusts its recovery rate to this new value, the tentative recovery rate of  $u$  remains  $\frac{1}{2}$ , since we still expect to get the entire payment from the non-defaulting  $v$ . Note, however, that optimistic updating still does not prevent an infinite convergence in this system if, for example,  $u$  and  $v$  keep on updating alternately.

## 6.2 Liability freezing

We have seen that neither smart nor optimistic updating prevents an infinite sequential process in itself. For this, we also need to change another aspect of our model, namely how the contracts of  $v$  are handled once  $v$  goes into default.

Debts are rather simple from this perspective: they describe a previously established payment obligation in the network, so there is no incentive to change them if  $v$  defaults.

CDSs, however, pose a more complicated question, since they describe payment obligations that are dynamically changing. So far, we assumed that even after  $v$  defaults, the payment obligations on its CDSs keep changing as the reference entities are updated. Another possible approach is to assume *liability freezing*: whenever  $v$  goes into default, the liabilities on any incoming or outgoing CDS are fixed at the current value for the rest of the process. That is, a CDS with weight  $\delta$  and reference entity  $w$  at time  $t$  is essentially converted into a simple debt contract with weight  $\delta \cdot (1 - r_w^{(t)})$ , and this weight does not change in the future, even if  $r_w$  is updated.

This can be realistic when there is a larger time difference between subsequent defaults: by the time the next default happens, the previous bank has already completed the first phase of the insolvency process, and its incoming/outgoing payments have been established

and fixed. Indirectly, such a framework suggests that if  $v$  defaults, then it is expected to immediately “cash in” its incoming debts and fulfill its payment obligations, and not wait for a more favorable situation.

The main advantage of this approach is that if we combine liability freezing with optimistic updates, it provides a *monotone sequential model* where recovery rates can only decrease throughout the process. Intuitively, when a bank  $w$  makes an update, then CDSs in reference to  $w$  could only provide more assets to a bank  $v$  if we still have  $r_v = 1$ , as otherwise the liability on the CDS is already fixed. However, if  $r_v = 1$ , then the optimistic approach assumes anyway that  $v$  can pay its liabilities, and thus the update has no effect on other banks in the system.

This monotonic property ensures that any system stabilizes eventually in this model; on the other hand, it also means that once a bank  $v$  announces a default in this model, it has no possibility to reverse this default in the future, and its recovery rate can only get smaller with further updates.

By revisiting Figure 2, we can observe that both liability freezing and optimistic updates are crucial ingredients to achieve this monotonicity. Without liability freezing, the system loops infinitely if  $u$  and  $v$  make updates in an alternating fashion, both with smart and with optimistic updates. On the other hand, if we combine liability freezing with smart updates, then  $v$  can still alternate between  $r_v = 0$  and  $r_v = 1$  indefinitely; if  $u$  never makes an update, then the liability on the CDS will never be fixed at a specific value.

### 6.3 Stabilization in the monotone model

We now discuss the main properties of the monotone model. We first show that the model indeed ensures an eventual stabilization for any ordering. The key observation for this is that the recovery rate of banks can never increase in this model.

► **Theorem 11.** *The recovery rate of a bank can only decrease in the monotone model.*

**Proof.** The main idea is to show that for any bank  $v$ ,  $\bar{r}_v$  can only increase if we still have  $r_v = 1$  currently. This shows that we can never have  $\bar{r}_v > r_v$ , and thus no update can increase  $r_v$ .

Assume that node  $w$  updates  $r_w$  in a specific step, and assume for contradiction that this is the first step that increases  $\bar{r}_v$  for some bank  $v$  with  $r_v < 1$ . This means that the current update is still a decrease of  $r_w$ , since we must have  $\bar{r}_w < r_w$ . The update of  $r_w$  can have two kinds of effects on the system: it can change the liabilities on CDSs that are in reference to  $w$ , and it can result in a lower amount of assets for the creditors of  $w$ . We analyze these two effects separately.

Since the monotone model has liability freezing, the liability on a CDS from  $u$  to  $v$  (in reference to  $w$ ) can only change if we currently still have  $r_u = r_v = 1$ . Thus while this extra payment may increase  $\bar{r}_v$ , we will still have  $\bar{r}_v \leq r_v$  afterwards. Since the model uses optimistic updates and  $r_u = r_v = 1$ , both  $u$  and  $v$  only have debts towards the artificial sink  $s$  in the input graph of the equilibrium algorithm (which computes the tentative recovery rates), so the changes to  $\bar{r}_u$  and  $\bar{r}_v$  do not affect the tentative recovery rate of any other node.

As for the creditors of  $w$ , we consider two cases. If this is not a defaulting step (we already had  $r_w < 1$  before the update), then updating  $r_w$  does not change the liabilities in the input graph of the equilibrium algorithm (apart from the case of some non-defaulting nodes, as discussed above), so the tentative recovery rates will remain unchanged.

On the other hand, if this is a defaulting step, then the outgoing debts of  $w$  will now be redirected from  $s$  to the actual creditors of  $w$ . However, this operation can only result in less assets for a bank. More specifically, one can observe that any configuration of payments in this new graph is also a valid configuration of payments in the original graph before the redirection step. Hence if the  $\bar{r}_v$  value of any bank  $v$  increases with this step, then this contradicts the fact that the previous  $\bar{r}_v$  was obtained from a maximal equilibrium of the system. ◀

► **Theorem 12.** *The monotone model allows at most  $n$  defaulting and  $O(n^2)$  updating steps.*

**Proof.** Since recovery rates are always decreasing, every bank can default at most once, thus the number of defaulting steps is at most  $n$ .

For the  $O(n^2)$  upper bound, we show that there are at most  $n$  updating steps between any two consecutive defaulting steps. This is rather straightforward: recall from the proof of Theorem 11 that if bank  $w$  executes a non-defaulting update, then this can only change the value of  $\bar{r}_v$  for banks  $v$  that are not in default. Thus for any bank  $v$  in default,  $\bar{r}_v$  can not change between two defaulting steps of the process. This means that any bank can execute at most 1 updating step between two consecutive defaulting steps, limiting the number of steps in this period to  $n$ . ◀

We point out that this upper bound is asymptotically tight: we can easily construct a system and an ordering that indeed takes  $\Omega(n^2)$  steps in the monotone model. The construction does not even require CDSs in the network; it only contains simple debt contracts.

► **Lemma 13.** *There is a system with an ordering that lasts for  $\Omega(n)$  defaulting and  $\Omega(n^2)$  updating steps.*

**Proof.** Let  $m$  be a parameter with  $m = \Theta(n)$ , and consider Figure 13. All the banks  $w_1, \dots, w_m$  will eventually report a default in this system, so the number of defaulting steps is indeed  $m = \Omega(n)$ .

Let  $w_1, \dots, w_m$  report a default in this order throughout the process. After  $w_i$  has reported a default, bank  $v$  can always decrease its recovery rate to a new value of  $r_v = \frac{m-i}{m}$ . Finally, after each such update of  $v$ , assume that all the nodes  $u_1, \dots, u_m$  make an update step, also announcing a new recovery rate of  $\frac{m-i}{m}$ ; they can indeed all do this due to the update executed by  $v$ . This ordering has  $\Omega(m^2) = \Omega(n^2)$  updating steps altogether. ◀

## 6.4 Defaulting strategies

Finally, we discuss how the monotone model compares to the reversible model in terms of defaulting strategies.

When finding the globally best ordering, the two models turn out to be very similar. In fact, our proofs from Section 5.2 can also be carried over to the monotone model without any changes.

► **Corollary 14.** *Lemma 6 and Theorems 7 and 8 also hold in the monotone model.*

In terms of individual defaulting strategies, the branching gadget again provides a simple example where late defaulting is beneficial: by delaying their updates, banks  $u$  and  $v$  can again entirely avoid a default.

■ **Figure 13** Example system for  $\Theta(n^2)$  stabilization time in the monotone model.

■ **Figure 14** Example system where early defaulting is the best strategy in the monotone model.

However, early defaulting is a more difficult question in this setting. In particular, we cannot hope for a result that is analogous to Theorem 9, since once a bank reports a default, there is no way to reverse this in the future. Nonetheless, early defaulting can still be a beneficial strategy in the monotone model: there are cases when a bank cannot avoid an eventual default in any way, but early defaulting can still allow the bank to have a higher recovery rate in the final state.

► **Theorem 15.** *There exists a system where a bank  $v$  only obtains its highest possible recovery rate in the final state of the system if  $v$  is the first bank to report a default.*

**Proof.** Consider the system in Figure 14, where either  $v_1$  or  $v_2$  can execute the first update. We analyze the defaulting strategies of bank  $v_1$  in this system.

Assume that  $v_1$  is the first to execute a step, announcing  $r_{v_1} = \frac{3}{4}$ . This gives new assets to  $v_2$  (resulting in  $\bar{r}_{v_2} = 1$ ), and new liabilities to  $u_2$  (resulting in  $\bar{r}_{u_2} = 0$ ). The next update can only be executed by  $u_2$ , setting  $r_{u_2} = 0$ ; at this point, the system stabilizes.

On the other hand, assume that  $v_2$  first announces  $r_{v_2} = 0$ . This provides  $\bar{r}_{v_1} = 1$  and  $\bar{r}_{u_1} = 0$ , so as a next step,  $u_1$  will announce a default. However, this results in new liabilities for  $w$ , so as a next step,  $w$  has to update to  $r_w = \frac{1}{3}$ . With this,  $v_1$  only has 2 assets altogether, so  $v_1$  must announce  $r_{v_1} = \frac{1}{2}$ . Hence  $v_1$  achieves a lower recovery rate in the final state if it is not the first bank to announce a default.

Note that with some further modifications, we can also make the example symmetric to ensure that both  $v_1$  and  $v_2$  are motivated to be the first one to default. ◀

Finally, one might also wonder if the monotone model allows an analogous result to Theorem 10, i.e. a hardness result on finding the best defaulting strategy of a single bank. However, note that the simple formulation of Theorem 10 was possible due to the fact that the proof construction only allowed one possible ordering in the rest of the system.

If we were to introduce a similar setting in the monotone model, then the banks could always find the best outcome in polynomial time, since the sequence can only last for  $O(n^2)$  steps. As such, in the monotone model, we can only expect similar hardness results for more complex formulations of this problem, such as finding the best defaulting time with respect to, e.g., the best-case or worst-case ordering of the remaining banks in the system.

## Abstract

We study the first-order convex optimization problem, where we have black-box access to a (not necessarily smooth) function  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  and its (sub)gradient. Our goal is to find an  $\epsilon$ -approximate minimum of  $f$  starting from a point that is distance at most  $R$  from the true minimum. If  $f$  is  $G$ -Lipschitz, then the classic gradient descent algorithm solves this problem with  $O((GR/\epsilon)^2)$  queries. Importantly, the number of queries is independent of the dimension  $n$  and gradient descent is optimal in this regard: No deterministic or randomized algorithm can achieve better complexity that is still independent of the dimension  $n$ .

In this paper we reprove the randomized lower bound of  $\Omega((GR/\epsilon)^2)$  using a simpler argument than previous lower bounds. We then show that although the function family used in the lower bound is hard for randomized algorithms, it can be solved using  $O(GR/\epsilon)$  quantum queries. We then show an improved lower bound against quantum algorithms using a different set of instances and establish our main result that in general even quantum algorithms need  $\Omega((GR/\epsilon)^2)$  queries to solve the problem. Hence there is no quantum speedup over gradient descent for black-box first-order convex optimization without further assumptions on the function family.

## 1 Introduction

The classic gradient descent algorithm, first proposed by Cauchy in 1847, is a popular algorithm for minimizing functions in high-dimensional spaces. For some problems, such as the case of convex function minimization that we consider in this paper, gradient descent

provably converges to the function’s global minimum. For other problems, such as finding good parameters of a deep neural network, gradient descent does not necessarily converge to a global minimum, and yet it has remarkable performance in practice.

Given the algorithm’s popularity, it is interesting to ask if gradient descent can be sped up on a quantum computer. However, it’s not obvious how to formalize this question since it’s not clear what it means for a quantum algorithm to speed up a given classical algorithm. For example, the best known classical algorithm for integer factorization is the general number field sieve (GNFS). Does Shor’s quantum algorithm for integer factorization speed up GNFS, or is it simply a different algorithm that solves the same problem?

One way to formalize the question *Can quantum computers speed up gradient descent?* is to consider a computational problem that is provably solved by gradient descent, and for which gradient descent is optimal among all classical algorithms. We can then ask if quantum algorithms can solve this problem faster than gradient descent. The second condition, that gradient descent is optimal among classical algorithms, is required since otherwise quantum computers would trivially be able to outperform gradient descent by using the best classical algorithm.

Fortunately, there is a canonical optimization task that is solved optimally by gradient descent: convex optimization with black-box first-order oracles. A more thorough introduction to the theory of black-box convex optimization can be found in the textbooks by Nemirovsky and Yudin [22], Nesterov [23, 24], and the monograph by Bubeck [11].

## 1.1 First-order convex optimization

Let’s start with the unconstrained convex minimization problem for a convex function  $f : \mathbb{R}^n \rightarrow \mathbb{R}$ . Here we want to find an  $x \in \mathbb{R}^n$  that’s  $\epsilon$ -close to minimizing the function  $f$ . More precisely, if we let  $x^* := \operatorname{argmin}_{x \in \mathbb{R}^n} f(x)$ , then our goal is to find any  $x \in \mathbb{R}^n$  such that  $f(x) - f(x^*) \leq \epsilon$ .

To obtain algorithms that are very general, this problem is often studied in the setting of black-box optimization. Here we do not assume any particular structure of the function  $f$  (e.g., that  $f$  is a low-degree polynomial), and only assume that we have some efficient method of computing  $f$  by an algorithm or circuit. In other words, we view  $f$  as a black box.

If we only had access to a black-box computing  $f$ , this would be zeroth-order optimization. In first-order optimization, we additionally assume we can also compute the gradient of  $f$ , or more precisely, since the gradient may not exist, we assume we can compute some subgradient of  $f$  (defined in Section 2). We call this oracle the *first-order oracle* and denote it by  $\mathcal{FO}(f)$ . In this work we consider arbitrary convex functions that are not necessarily smooth,<sup>1</sup> and so we cannot assume that the gradient exists. Our goal is to solve the function minimization problem while minimizing the number of calls or queries to the black boxes for  $f$  and some subgradient of  $f$ .

One might wonder why we consider queries to  $f$  and the subgradient of  $f$  to cost the same. This assumption is justified in many practical situations because of the *cheap gradient principle* [16], which says that “the cost to evaluate the gradient  $\nabla f$  is bounded above by a small constant times the cost to evaluate the function itself.” This provably holds in many models of computation; E.g., for arithmetic circuits over  $+$  and  $\times$ , it can be proved that the complexity of computing the gradient is at most 5 times the complexity

---

<sup>1</sup> In the optimization literature, a *smooth function* is a function that is differentiable everywhere in its domain, so the gradient is well defined, and whose gradient has bounded Lipschitz constant.

of computing  $f$  [6]. The conversion of source code computing  $f$  to code computing  $\nabla f$  can often be done automatically in many programming languages, and such methods are called *automatic differentiation* or *algorithmic differentiation* [16]. These same principles essentially carry over to the computation of subgradients [18]. In the quantum setting, there is additional motivation to assume that a function and its gradient cost roughly the same since we can obtain the gradient (or a subgradient) of a function from a black-box computing the function, as shown in a sequence of papers that make increasingly weaker assumptions on the function oracle [17, 15, 13, 3].

Now that we have black-box access to  $f$  and  $\mathcal{FO}(f)$ , we also need a starting point  $x_0 \in \mathbb{R}^n$  to begin our search for a minimum. We require this to be an input, and the complexity will depend on how close this is to  $x^*$ , since otherwise the interesting portion of the function where the minimum is achieved might be hiding in some small corner of  $\mathbb{R}^n$  that we cannot efficiently locate with only black-box access. Since we can easily shift the function by a fixed vector, without loss of generality we assume  $x_0 = \vec{0}$  is the origin. Let the distance between  $x_0 = \vec{0}$  and  $x^*$  be  $R := \|x^*\|$ .<sup>3</sup> For convenience, we will assume that  $R$  is part of the input as well, although this can be relaxed by binary searching for the correct value of  $R$ .

Finally, it is also reasonable that the complexity of our algorithms depend on how quickly  $f$  can change, since the value of  $f$  at some point only constrains its values at nearby points if the function does not change too rapidly. Let  $G$  be an upper bound on the Lipschitz constant of  $f$  (defined in Section 2), and we assume this is part of the input as well.

We are now ready to formally define the first-order convex minimization problem in the black-box setting. We use  $B(x, R) := \{y : \|x - y\| \leq R\}$  to denote an  $\ell_2$ -ball of radius  $R$  around  $x$ .

► **Problem 1** (First-order convex minimization). *Let  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  have Lipschitz constant at most  $G$  on  $B(\vec{0}, R)$ , and let*

$$x^* := \operatorname{argmin}_{x \in B(\vec{0}, R)} f(x). \quad (1)$$

*Then given  $n$ ,  $G$ ,  $R$ , and  $\epsilon > 0$ , the goal is to output a solution  $x \in B(\vec{0}, R)$  such that  $f(x) - f(x^*) \leq \epsilon$  while minimizing the number of queries to  $f$  and  $\mathcal{FO}(f)$ .<sup>4</sup>*

Note that we allow algorithms to query the function and gradient oracles at any point in  $\mathbb{R}^n$  even though the domain we are minimizing over is  $B(\vec{0}, R)$ . This only makes our lower bounds stronger, and the algorithms discussed in this paper never query the oracles outside the domain.

As we discuss in Section 2, although the problem seems to involve 4 parameters, the parameters  $G$ ,  $R$ , and  $\epsilon$  are not independent since we can rescale the input and output spaces of  $f$  and assume  $G = 1$  and  $R = 1$  without loss of generality. Thus any upper or lower bound on the complexity of this problem will be a function of  $n$  and  $GR/\epsilon$ .

## 1.2 Classical algorithms for first-order convex minimization

Gradient descent, or in this case subgradient descent, is a simple algorithm that starts from a point  $x_0$  and takes a small step (governed by a step size  $\eta$ ) in the opposite direction of the subgradient returned at  $x_0$ . Intuitively this brings us closer to the minimum since we are stepping in the direction where  $f$  decreases the most.

<sup>2</sup> If  $x^*$  is not unique, we can let  $R$  be the distance between  $x_0$  and the closest  $x^*$  to it.

<sup>3</sup> Throughout this paper  $\|\cdot\|$  always denotes the standard  $\ell_2$  norm in  $\mathbb{R}^n$  defined as  $\|z\| := \sqrt{\sum_i z_i^2}$ .

<sup>4</sup> For simplicity, we assume that these oracles output real numbers to arbitrarily many bits of precision. Since the main results of this paper are lower bounds, this only makes our results stronger.

We can now describe the performance of subgradient descent for Problem 1. Since this is a constrained optimization problem, we use the projected subgradient descent algorithm, which is subgradient descent with the added step of projecting the current vector back onto the ball  $B(\vec{0}, R)$  after every step.

► **Theorem 2** (Complexity of projected subgradient descent). *The projected subgradient descent algorithm solves Problem 1 using  $(GR/\epsilon)^2$  queries to  $f$  and  $\mathcal{FO}(f)$ .*

A proof of this is included in the full version of this paper. Observe that the query complexity of this algorithm, the number of queries made by the algorithm, is independent of  $n$ .<sup>5</sup> This is quite surprising at first and partly explains why gradient descent and its variants are popular in high-dimensional applications. More generally, we call such algorithms *dimension-independent algorithms*.

There also exist dimension-dependent algorithms for Problem 1 that work well when  $n$  is small. For example, the center of gravity method [11] solves this problem with  $O(n \log(GR/\epsilon))$  queries, which is very reasonable when  $n$  is small (and the algorithm is very efficient in terms of  $\epsilon$ ). In this work we focus on dimension-independent algorithms and assume that  $n$  is polynomially larger than the other parameters in the problem.

When  $n$  is large, we cannot improve over projected subgradient descent (Theorem 2) using any deterministic or randomized algorithm. We reprove the (well known) optimality of this algorithm among deterministic and randomized algorithms. This result is presented in Section 3.

► **Theorem 3** (Randomized lower bound). *For any  $G$ ,  $R$ , and  $\epsilon$ , there exists a family of convex functions  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  with  $n = O((GR/\epsilon)^2)$ , with Lipschitz constant at most  $G$  on  $B(\vec{0}, R)$ , such that any classical (deterministic or bounded-error randomized) algorithm that solves Problem 1 on this function family must make  $\Omega((GR/\epsilon)^2)$  queries to  $f$  or  $\mathcal{FO}(f)$  in the worst case.*

This lower bound on query complexity has been shown in several prior works [22, 26, 12], but we believe our proof is simpler and the dimension  $n$  required in our proof seems to be smaller than that in prior works. Note that while several expositions of gradient descent prove the lower bound for deterministic algorithms, very few sources establish a lower bound against randomized algorithms.

Our lower bound uses the following hard family of functions: For any  $z \in \{-1, +1\}^n$ , let  $f_z(x_1, \dots, x_n) = \max_{i \in [n]} z_i x_i$ ,<sup>6</sup> where  $n = O(1/\epsilon^2)$ . These functions are convex with Lipschitz constant 1. We show that finding an  $\epsilon$ -approximate minimum within  $B(\vec{0}, 1)$  requires  $\Omega(n)$  queries to the oracles. We establish the lower bound by showing that with high probability, every query of a randomized algorithm only reveals  $O(1)$  bits of information about the string  $z$ , but an  $\epsilon$ -approximate solution to this problem allows us to reconstruct the string  $z$ , which has  $n$  bits of information.

### 1.3 Quantum algorithms for first-order convex minimization

We then turn to quantum algorithms for solving Problem 1. At first, it might seem that since gradient descent is a sequential, adaptive algorithm where each step depends on the previous one, there is little hope of quantum algorithms outperforming gradient descent.

<sup>5</sup> Of course, the time complexity of implementing this algorithm will be at least linear in  $n$  since each query to either oracle requires us to manipulate a vector of length  $n$ .

<sup>6</sup> We use  $[n]$  to denote the set of positive integers less than or equal to  $n$ , i.e.,  $[n] := \{1, \dots, n\}$ .

On the other hand, consider the hard family of functions described above that witnesses the classical randomized lower bound in Theorem 3. While this is hard for classical algorithms, we show in Section 3.1 that there is a quantum algorithm that solves the problem on this family obtaining a quadratic speedup over any classical algorithm (and in particular, over gradient descent).

► **Theorem 4** (Quantum algorithm for classically hard function family). *There is a quantum algorithm that solves Problem 1 on the class of functions that appear in the classical lower bound of Theorem 3 using  $O(GR/\epsilon)$  queries to the oracle for  $f$ .*

Notably, unlike most quadratic speedups in quantum computing, the source of this quadratic speedup is not Grover’s algorithm or amplitude amplification. Theorem 4 uses Belovs’ quantum algorithm for learning symmetric juntas, which is constructed by exhibiting a feasible solution to the dual semidefinite program of the negative-weights adversary bound [7].

Now that we have shown a quadratic quantum speedup on a family of instances known to be hard for classical algorithms, there is some hope that quantum algorithms may provide some speedup for the general first-order convex minimization problem. Alas, our next result (established in Section 4), which is our main result, shows that this is not the case, and quantum algorithms cannot in general yield a speedup over classical algorithms for first-order convex minimization.

► **Theorem 5** (Quantum lower bound). *For any  $G$ ,  $R$ , and  $\epsilon$ , there exists a family of convex functions  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  with  $n = \widetilde{O}((GR/\epsilon)^4)$ , with Lipschitz constant at most  $G$  on  $B(\vec{0}, R)$ , such that any quantum algorithm that solves Problem 1 with high probability on this function family must make  $\Omega((GR/\epsilon)^2)$  queries to  $f$  or  $\mathcal{FO}(f)$  in the worst case.*

Our lower bound uses ideas from the lower bound against parallel randomized algorithms recently established by Bubeck, Jiang, Lee, Li, and Sidford [12].

At a high level, the hard family of functions used in the randomized lower bound does not work for quantum algorithms because although classical algorithms can only learn  $O(1)$  bits of information per query, quantum algorithms can make queries in superposition and learn a little information about many bits simultaneously. We remedy this by choosing a new family of functions in which with high probability, no matter what query the quantum algorithm makes, the oracle’s response is essentially the same. This allows us to control what the quantum algorithm learns per query, but now the instance is more complicated and the quantum algorithm learns  $O(n)$  bits of information per query. Since the final output of the algorithm is a vector in  $\mathbb{R}^n$ , we cannot use the argument used before that simply compared the information learned per query to the total information that needs to be learned. Instead we use the venerable hybrid argument [8] to control what the quantum algorithm learns and show that it cannot find an  $\epsilon$ -approximate solution to the minimization problem.

## 1.4 Related work

Classically, there is a long history of the study of oracle complexity (also known as black-box complexity or query complexity) for deterministic and randomized algorithms for non-smooth and smooth convex optimization. The setting considered in this paper, first-order convex optimization, where the algorithm has query access to the function value and the gradient, is very well studied. This topic is too vast to survey here, but we refer the reader to [22, 23, 24, 11] for more information about upper and lower bounds that can be shown in this setting.

There also has been work in the classical parallel setting, where in each round the algorithm is allowed to query polynomially many points and the goal is to minimize the number of rounds [21, 4, 14, 12]. Our work is most closely related to this setting and borrows many ideas from these works. Although quantum algorithms and parallel classical algorithms are incomparable in power, the constructions used to thwart parallel classical algorithms in these papers also help with showing quantum lower bounds.

In the quantum setting, there has been some work on convex optimization in the oracle model. There is also work on quantum gradient descent not in the oracle model. For example, one situation studied is where the dimension  $n$  of the optimization space is very large and the vectors are encoded in quantum states of dimension  $\log n$ . See [25, 19] and the references therein for more information. Another setting is the work on semidefinite programming, an important special case of convex optimization, but these algorithms exploit the specific structure of semidefinite programs [10, 2, 9, 1] and are not directly related to our work.

While in the classical setting, in general, a function value oracle is weaker than a gradient oracle, this is not the case in the quantum setting. Given a function value oracle, one can get a gradient oracle quite efficiently (with an  $\tilde{O}(1)$  overhead) [17, 15, 3, 13]. A similar result also holds for simulating a separation oracle given a membership oracle for convex bodies [3, 13]. As discussed before, our focus in this paper is to see if quantum algorithms can outperform classical algorithms when given a function oracle and gradient oracle since in many relevant settings, gradient computation is cheap in the classical case as well.

The most related works are the papers by Chakrabarti, Childs, Li, and Wu [13] and van Apeldoorn, Gilyén, Gribling, and de Wolf [3]. These papers establish very similar results so we cover them together. These papers study the problem of black-box convex optimization, and their results are phrased in the slightly different language of membership and separation oracles, but this is not the main difference between their work and our work. Indeed, it is possible to recast our problem in their setting (see the discussion in the introduction in [3] for how to do this). The main difference is that their algorithms are dimension-dependent and have complexities that depend on  $n$ , whereas we're working in the parameter regime where  $n$  is large and so we seek algorithms that are independent of  $n$ .

Specifically, [13] and [3] consider the problem of minimizing a linear function over a convex body given via a membership or separation oracle. A membership oracle for a convex body tells us whether a given point  $x$  is in the convex body and a separation oracle in addition when  $x$  is not in the body outputs a hyperplane that separates  $x$  from the convex body. Classically, the problem of outputting an  $\epsilon$ -approximate solution can be solved with  $O(n^2 \text{polylog}(\cdot))$  queries to a membership oracle [20], where we are suppressing polylogarithmic dependence on several parameters (including  $\epsilon$ ). These two papers show a quantum algorithm that makes only  $O(n \text{polylog}(\cdot))$  membership queries. The key technical component of this is a construction of a separation oracle from a membership oracle with only polylogarithmic overhead. To do this, they first show how to obtain an approximate subgradient oracle from a function oracle with only polylogarithmic overhead.

There are also several lower bounds shown in these papers. In [3], the authors prove that quantum algorithms do not give any advantage over classical algorithms in the setting where we are not given a point inside the convex body to start with. This setting is not directly comparable to our setting, as far as we are aware. In the setting where we do know a point inside the convex body, which is very similar to our setting, [3, 13] prove a lower bound of  $\Omega(\sqrt{n})$ , which is quadratically worse than their algorithm. While, in general, their results are incomparable to our results, one specific comparison to our results is that [13, Theorem 3.3] essentially shows a  $\tilde{\Omega}(\min\{GR/\epsilon, \sqrt{n}\})$  lower bound on the number of oracle

calls to a function value oracle for the setting in Problem 1.<sup>7</sup> Note that this is quadratically worse than our tight lower bound (Theorem 5) in the dimension-independent setting (i.e., when the dimension  $n$  is large compared to  $GR/\epsilon$ ).

## 1.5 Paper organization and summary of contributions

We first present some preliminaries on convex optimization in Section 2. In Section 3 we reprove the lower bound for randomized algorithms (Theorem 3) using a simpler argument compared to prior works. In Section 3.1, we show that quantum algorithms can solve the hard instance from Theorem 3 faster than randomized algorithms, obtaining a quadratic speedup (Theorem 4). In Section 4, we present a different hard instance and show our main result that quantum algorithms cannot obtain any speedup over gradient descent for the first-order convex optimization problem (Theorem 5). We conclude with open problems in Section 5.

## 2 Convex optimization preliminaries

As described in the introduction, we are interested in approximately minimizing a convex function  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  on some closed convex set  $\mathcal{K} \subseteq \mathbb{R}^n$ . A function  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  is convex if for all  $x, y \in \mathbb{R}^n$  and  $t \in [0, 1]$ ,

$$tf(x) + (1-t)f(y) \geq f(tx + (1-t)y). \quad (2)$$

A set  $\mathcal{K} \subseteq \mathbb{R}^n$  is convex if the line segment joining two points in  $\mathcal{K}$  is also contained in  $\mathcal{K}$ . We will consider convex sets of bounded size, and specifically let  $2R$  be the diameter of  $\mathcal{K}$ , i.e.,

$$\max_{x, y \in \mathcal{K}} \|x - y\| \leq 2R, \quad (3)$$

where  $\|z\| := \sqrt{\sum_i z_i^2}$  is the Euclidean norm.

It turns out that the query complexity of first-order convex optimization depends only on  $R$  no matter how complicated the set  $\mathcal{K}$  happens to be. However, to obtain an algorithm with efficient time complexity we require that the set  $\mathcal{K}$  be simple enough that we can efficiently implement a projection operator for  $\mathcal{K}$ . This means given any  $y \in \mathbb{R}^n$ , we can efficiently compute  $\mathcal{P}_{\mathcal{K}}(y) \in \mathcal{K}$ , which satisfies  $\|\mathcal{P}_{\mathcal{K}}(y) - y\| = \min_{z \in \mathcal{K}} \|z - y\|$ . Since the main result of this paper is a lower bound, our lower bound is stronger if shown for a simple convex set  $\mathcal{K}$ . So throughout this paper we work with the set  $\mathcal{K} = B(\vec{0}, R)$ , the  $\ell_2$ -ball of radius  $R$  around the origin.

In the model of first-order black-box optimization, we have access to a black-box that computes the function  $f$  on any input  $x \in \mathbb{R}^n$ . In addition to this, we also have a *first-order oracle*,  $\mathcal{FO}(f)$ , which when queried at any point  $x \in \mathbb{R}^n$  returns some vector  $g_x \in \mathbb{R}^n$  that satisfies for all  $y \in \mathbb{R}^n$ ,

$$f(y) \geq f(x) + \langle g_x, y - x \rangle. \quad (4)$$

Since  $f$  is convex, it is known that such a vector  $g_x$  exists for all  $x \in \mathbb{R}^n$  [23]. Any vector  $g_x$  satisfying (4) is called a subgradient of  $f$  at  $x$ , and the set of all subgradients at  $x$  is called the subdifferential at  $x$  and denoted by  $\partial f(x)$ . If  $f$  is differentiable at  $x$  then  $g_x$  is unique and equal to  $\nabla f(x)$ , the gradient of  $f$  at  $x$ , defined as

<sup>7</sup> This is equivalent to our setting, where we have a function value and gradient oracle, due to their results.

$$\nabla f(x) := \left( \frac{\partial f(x)}{\partial x_1}, \dots, \frac{\partial f(x)}{\partial x_n} \right). \quad (5)$$

We will say that the function  $f$  has Lipschitz constant at most  $G$  in  $\mathcal{K}$  if  $\|g_x\| \leq G$  for every  $x \in \mathcal{K}$ .<sup>8</sup>

As described in Problem 1, we are interested in algorithms that take as inputs the parameters  $n$ ,  $G$ ,  $R$ , and  $\epsilon > 0$ , and have access to  $f$  and a first-order oracle  $\mathcal{FO}(f)$ , and output  $x \in B(\vec{0}, R)$  such that  $f(x) - f(x^*) \leq \epsilon$ , where  $x^* := \operatorname{argmin}_{x \in B(\vec{0}, R)} f(x)$ .

In the quantum setting, we have quantum analogues of these oracles. There is a straightforward generalization of any oracle to the quantum setting, which makes the classical oracle reversible and then allows queries in superposition to this oracle. This quantum generalization of the oracle is justified by the fact that if we had a classical circuit or algorithm computing a function  $f$ , then it is possible in a completely black-box manner to construct the quantum oracle corresponding to  $f$ , and this oracle would then support superposition queries. We discuss quantum oracles in more detail in Section 4, but for now it is sufficient to consider them as computing the same functions as the classical oracles, except that they can additionally be queried in superposition.

Note that it is sufficient to consider the special case of the problem where  $G = R = 1$ . While this seems like a special case, given an  $f$  and  $\mathcal{K}$  with Lipschitz constant  $G$ , radius  $R$ , and optimization accuracy  $\epsilon$ , we can instead minimize  $\hat{f}(x) := \frac{1}{GR} f(Rx)$  over  $\hat{\mathcal{K}} := \mathcal{K}/R$ , which have Lipschitz constant and radius 1 up to an accuracy of  $\frac{\epsilon}{GR}$ . So we consider  $G = R = 1$  without loss of generality, or for general  $G$  and  $R$ , the complexity must be a function of  $GR/\epsilon$ .

The query complexity of an algorithm that solves Problem 1 is the maximum number of oracle calls it makes for fixed values of  $n$ ,  $G$ ,  $R$ , and  $\epsilon$ , where the maximum is taken over all convex functions  $f$  with Lipschitz constant at most  $G$ , and all first order oracles  $\mathcal{FO}(f)$  for  $f$  (i.e., the algorithm must work for any choice of first-order oracle that correctly outputs some subgradient of  $f$  at  $x$ ). As discussed, the query complexity must be a function of  $n$  and  $GR/\epsilon$ . Furthermore, since we're interested in dimension-independent algorithms, we study algorithms that only depend on  $GR/\epsilon$  and not on  $n$ .

Given a class of algorithms, such as deterministic, randomized, or quantum algorithms, the query complexity of first-order Lipschitz convex optimization for that class of algorithms is the minimum query complexity of any algorithm in that class that solves Problem 1.

As we will see in the next section, the randomized query complexity of this problem (and hence the deterministic query complexity) is at least  $\Omega((GR/\epsilon)^2)$  in the dimension-independent setting.

### 3 Randomized Lower Bound

In this section, we prove a lower bound for randomized first-order methods for non-smooth convex optimization, restated here for convenience:

<sup>8</sup> This is slightly different from the usual definition of the Lipschitz constant where we would say  $f$  is  $G$ -Lipschitz in  $\mathcal{K}$  if for all  $x, y \in \mathcal{K}$ ,  $|f(x) - f(y)| \leq G\|x - y\|$ . Our definition is the same as requiring the function  $f$  to be  $G$ -Lipschitz according to this definition in an open set that contains  $\mathcal{K}$ .

► **Theorem 3** (Randomized lower bound). *For any  $G$ ,  $R$ , and  $\epsilon$ , there exists a family of convex functions  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  with  $n = O((GR/\epsilon)^2)$ , with Lipschitz constant at most  $G$  on  $B(\vec{0}, R)$ , such that any classical (deterministic or bounded-error randomized) algorithm that solves Problem 1 on this function family must make  $\Omega((GR/\epsilon)^2)$  queries to  $f$  or  $\mathcal{FO}(f)$  in the worst case.*

This randomized lower bound is known and multiple proofs can be found in the literature [22, 26]. Our proof is elementary and we did not find it written anywhere, although it is conceptually similar to the one in [22], and so we include it here for completeness. Our proof also has the dimension  $n = \Theta(1/\epsilon^2)$ , without any log factors, which is the best possible. As far as we are aware, the previous proofs (for randomized algorithms) required larger dimension than this.<sup>9</sup> As we will see later, the family of instances used is also interesting because we can get a quantum speedup for it, because of which we have to look at other instances to prove the quantum lower bound.

We can now define the family of convex functions used in the lower bound. For any  $\epsilon > 0$ , we set  $n = \lfloor .9/\epsilon^2 \rfloor$  and look at the following class of functions.

► **Definition 6.** *Let  $z \in \{-1, +1\}^n$ . Let  $f_z : \mathbb{R}^n \rightarrow \mathbb{R}$  be defined as*

$$f_z(x_1, \dots, x_n) = \max_{i \in [n]} z_i x_i. \quad (6)$$

Each such function is convex since it is a maximum of convex functions [23, Theorem 3.1.5]. Note that if  $f_z(x) = z_i x_i$  for some  $i \in [n]$ , then  $z_i e_i$  is a subgradient of  $f_z$  at  $x$  (since  $f_z(x) + \langle z_i e_i, y - x \rangle = z_i y_i \leq f_z(y)$ ). Hence the function is 1-Lipschitz. We can also see that within the unit ball the function is minimized at the point

$$x^* = \frac{-1}{\sqrt{n}} \sum_{i \in [n]} z_i e_i, \quad (7)$$

and  $f_z(x^*) = -1/\sqrt{n}$ . Clearly given  $x^*$  we can recover  $z$  from it. We now show  $z$  can even be recovered from an  $\epsilon$ -approximate minimum of  $f_z$ .

► **Lemma 7.** *Let  $x$  be such that  $f_z(x) - f_z(x^*) \leq \epsilon$ . Then we can recover  $z \in \{-1, +1\}^n$  from  $x \in \mathbb{R}^n$ .*

**Proof.** Let  $s_x \in \{-1, +1\}^n$  be the vector with  $(s_x)_i = \text{sign}(x_i)$ , where  $\text{sign}(a) = +1$  if  $a \geq 0$  and  $\text{sign}(a) = -1$  otherwise. We claim that  $z = -s_x$ . Toward a contradiction, if  $(s_x)_i \neq -z_i$  for some  $i$ , then  $(s_x)_i = z_i$ , since these only take values in  $\{-1, +1\}$ . In this case,  $x_i$  and  $z_i$  agree in sign, and hence  $f_z(x) \geq z_i x_i \geq 0$ . Since  $\epsilon < 1/\sqrt{n}$  (because of our choice of  $n$  above) the point  $x$  cannot satisfy  $f_z(x) - f_z(x^*) \leq \epsilon$ . ◀

Since this function is not differentiable everywhere, for our lower bound we need to specify the behavior of the subgradient oracle on all inputs. The function is not differentiable only at  $x \in \mathbb{R}^n$  where the maximum is achieved at multiple indices. In this case, the subgradient oracle responds as if the maximum was achieved on the smallest such index  $i$ , i.e., it responds with  $z_i e_i$ . Note that for this function, querying the subgradient oracle allows us to simulate a call to the function oracle as well, since the response is  $z_i e_i$  for the index  $i$  that achieves the maximum, so the function evaluates to  $z_i x_i$  at that point, which we can compute since we know  $x$ . So we can assume without loss of generality that an algorithm only queries the subgradient oracle.

<sup>9</sup> The result of [26] requires dimension roughly  $1/\epsilon^8$ . We also believe the result in [22] requires a larger dimension than our claim.

Now that the problem is fully specified, we will show that any randomized optimization algorithm using the function oracle and this subgradient oracle will require  $\Omega(n)$  queries in order to solve Problem 1 with a constant probability of success.

The following will be the crux of the lower bound. Let  $I \subseteq [n]$ . We say a distribution  $\mathcal{D}$  over  $\{-1, +1\}^n$  is  $I$ -fixed if for  $z \sim \mathcal{D}$  the random variable  $z_I$  is fixed and  $z_{\bar{I}}$  is uniform over  $\{-1, +1\}^{\bar{I}}$ .

► **Lemma 8.** *Let  $z$  be distributed according to an  $I$ -fixed distribution. Let  $x$  be an arbitrary query made to the  $f_z$  oracle. After one query to the subgradient oracles, the conditional distribution on  $z$  given the answer is  $I'$ -fixed with  $I \subseteq I'$  and  $\mathbb{E}[|I'|] \leq |I| + 2$ .*

**Proof.** Let  $x$  be the algorithm's query. The index  $i$  that achieves the maximum in the definition of  $f_z(x)$  can be computed as follows. Let  $i_1, \dots, i_n$  be the ordering of the indices 1 to  $n$  in decreasing order of  $|x_i|$ , with ties broken with the natural ordering on integers. The oracle outputs  $f_z(x) = z_{i_j} x_{i_j}$  and chooses the subgradient  $z_{i_j} e_{i_j}$  where  $j$  is the smallest index for which  $x_{i_j}$  agrees in sign with  $z_{i_j}$ , and if no such index exists, then  $j = n$ .

Since  $f_z(x)$  can be computed given the subgradient  $z_{i_j} e_{i_j}$ , the only information obtained from a query is the prefix  $\{z_{i_k}\}_{k \leq j}$ . In other words, if the subgradient oracle responds with  $z_{i_j} e_{i_j}$ , then we have learned that for all indices  $k \leq j$ , we must have  $\text{sign}(x_i) = -z_i$ , but we have not learned any more since the oracle's output does not depend on the bits of  $z$  with index  $i_k$  with  $k > j$ . After this query, we know the bits  $z_{i_k}$  with  $k \leq j$ , but conditioned on these, the distribution on the remaining bits of  $z$  continues to be uniform. This is an  $I'$ -fixed distribution with  $I' = I \cup \{i_k\}_{k \leq j}$ . Intuitively,  $I'$  cannot be much larger than  $I$  since an index  $i_k$  is part of this set only if the algorithm correctly guessed the sign of  $z_{i_k}$  for this index and all indices with a smaller value of  $k$ . Since the initial distribution  $z$  was uniformly at random outside of  $I$  and  $x$  is fixed, the probability of correctly guessing the first index (according to the  $i_j$  ordering) that was not fixed is  $1/2$ , the probability of guessing the first two is  $1/4$  and so on. Thus the expected number of new entries fixed by one query is  $\sum_{k=1}^{n \setminus |I|} k \cdot \frac{1}{2^k} \leq 2$ . ◀

We can use this to show establish the final claim.

► **Lemma 9.** *Let  $z$  be sampled uniformly at random from  $\{-1, +1\}^n$ . If a randomized algorithm  $\mathcal{A}$  outputs an  $x$  with  $f_z(x) - f_z(x^*) \leq \epsilon$  with probability at least  $2/3$ , then its query complexity is at least  $n/3 - 1$ .*

**Proof.** When  $\mathcal{A}$  outputs a point  $x$ , we will require it to also query the oracle at  $x$  to see if it is indeed  $\epsilon$ -optimal. This can increase its query complexity by at most one. Let the query complexity of this modified  $\mathcal{A}$  be  $t$ . Whenever  $\mathcal{A}$  does output an  $\epsilon$ -optimal point, Lemma 7 implies that the conditional distribution on  $z$  is  $[n]$ -fixed. For each  $i \in [0, \dots, t]$ , let  $I_i$  be the random variable such that the distribution on  $z$  after  $i$  queries of  $\mathcal{A}$  is  $I_i$ -fixed (Lemma 8 implies that after any sequence of queries it will be an  $I$ -fixed distribution for some  $I$ ). Since  $z$  is sampled uniformly at random from  $\{-1, +1\}^n$ ,  $I_0 = \emptyset$ . And since we want the algorithm to succeed with probability at least  $2/3$ ,  $\mathbb{E}[|I_t|] \geq 2n/3$ .

However,  $|I_t| = \sum_{i=1}^t |I_i| - |I_{i-1}|$ , and it is a simple consequence of Lemma 8 that  $\mathbb{E}[|I_i| - |I_{i-1}|] \leq 2$  for all  $i$ . So by the linearity of expectation,  $\mathbb{E}[|I_t|] \leq 2t$  and hence  $t \geq n/3$ . ◀

This proves a lower bound of  $\Omega(1/\epsilon^2)$  on the randomized query complexity of first-order convex minimization for a function with  $G = R = 1$ . As noted earlier, this is without loss of generality and implies the more general bound in Theorem 3.

### 3.1 Quantum speedup

In this section we discuss Theorem 4, restated for convenience:

► **Theorem 4** (Quantum algorithm for classically hard function family). *There is a quantum algorithm that solves Problem 1 on the class of functions that appear in the classical lower bound of Theorem 3 using  $O(GR/\epsilon)$  queries to the oracle for  $f$ .*

The quantum speedup for the above class of functions relies on Belovs' quantum algorithm for Combinatorial Group Testing [7]. Belovs showed that given access to an oracle making OR queries to an  $n$ -bit string, the  $n$ -bit string can be learned in  $O(\sqrt{n})$  quantum queries. The proof of Theorem 4 then follows by noting that for any  $S \subseteq [n]$ , one can find out if there is an  $i \in S$  such that  $z_i = 1$  by querying  $x = \frac{1}{\sqrt{n}} \sum_{i \in S} e_i$ . Hence within  $O(\sqrt{n})$  queries, the entire string  $z \in \{-1, +1\}^n$  can be learned. This proof is provided in more detail in the full version of the paper.

A similar problem is also studied in [13], which they solve using a quantum algorithm for the search with wildcards problem, which is a special case of the combinatorial group testing problem studied by Belovs.

Note that this quantum algorithm is also essentially optimal for this problem and it is not hard to show an  $\Omega(\sqrt{n}/\log n)$  lower bound for quantum algorithms. A similar lower bound is shown in [13, Theorem 3.3], and a simpler sketch of such a lower bound is also given in the full version.

## 4 Quantum lower bound

In this section, we show that for any  $\epsilon$ , there exists a 1-Lipschitz family of functions such that any quantum algorithm that solves Problem 1 on the unit ball must make  $\frac{1}{100\epsilon^2}$  queries. In other words, there is no quantum first-order convex optimization algorithm that always outperforms the classical gradient descent algorithm described in Theorem 2. The function we will use was introduced by Nemirovsky and Yudin [22]. To show the quantum lower bound, we adapt to the quantum setting the lower bound strategy of Bubeck et al. [12] in the model of parallel algorithms.

We restate the main result proved in this section for convenience:

► **Theorem 5** (Quantum lower bound). *For any  $G$ ,  $R$ , and  $\epsilon$ , there exists a family of convex functions  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  with  $n = \tilde{O}((GR/\epsilon)^4)$ , with Lipschitz constant at most  $G$  on  $B(\vec{0}, R)$ , such that any quantum algorithm that solves Problem 1 with high probability on this function family must make  $\Omega((GR/\epsilon)^2)$  queries to  $f$  or  $\mathcal{FO}(f)$  in the worst case.*

We start by first proving a qualitatively similar, but simpler result with a larger value of  $n = \tilde{O}((GR/\epsilon)^6)$  in Section 4.4. If we only care about the optimality of gradient descent in the dimension-independent setting, this lower bound is sufficient. But if we also want to understand the trade-off between dimension-independent and dimension-dependent algorithms, then we would like to show this lower bound with as small a value of  $n$  as we can. In the full version of the paper, we improve the lower bound to achieve the value of  $n$  stated in this theorem.

### 4.1 Function family and basic properties

We start by defining the family of functions  $\mathcal{F} = \{f : \mathbb{R}^n \rightarrow \mathbb{R}\}$  that we use. The function family  $\mathcal{F}$  depends on the dimension  $n$  and two other parameters  $k$  and  $\gamma$ . Since the function family we choose depends on  $\epsilon$ , the parameters  $n$ ,  $k$ , and  $\gamma$  will be functions of  $\epsilon$ . Our choice of  $n$ ,  $k$ , and  $\gamma$  will become clear later, but for now we simply choose them as follows. Let

$$k := \frac{1}{100\epsilon^2} \implies \epsilon = \frac{1}{10\sqrt{k}} \quad \text{and} \quad \gamma := \frac{1}{10k^{3/2}} = 100\epsilon^3. \quad (8)$$

We choose  $n$  such that it satisfies

$$\gamma \geq 8\sqrt{\frac{\log n}{n}} \implies n := O\left(\frac{\log(1/\epsilon)}{\epsilon^6}\right) = \tilde{O}\left(\frac{1}{\epsilon^6}\right). \quad (9)$$

The discussion before Lemma 11 explains the choice of  $k$  and the discussion after Lemma 12 explains the choice of  $\gamma$ . For the dimension  $n$ , see the discussion at the beginning of Section 4.2.

We now define the function family for these specific choices of  $n$ ,  $k$ , and  $\gamma$ .

► **Definition 10** (Hard function family). *Let  $\mathcal{V} = \{(v_1, \dots, v_k) \mid \forall i, j, \in [k], \langle v_i, v_j \rangle = \delta_{ij}\}$  be the set of all  $k$ -tuples of orthonormal vectors in  $\mathbb{R}^n$ . Let the family of functions  $\mathcal{F} = \{f_V\}_{V \in \mathcal{V}}$  be defined as*

$$f_{(v_1, v_2, \dots, v_k)}(x) := \max_{i \in [k]} \{g_V^{(i)}(x)\}, \quad \text{where } g_V^{(i)}(x) := \langle v_i, x \rangle + (k-i)\gamma\|x\|. \quad (10)$$

We will show that any quantum algorithm that solves Problem 1 on the functions in this family must make  $k$  queries. As we will prove, informally what happens is each query of the quantum algorithm to the gradient oracle only reveals a single direction  $v_i$  to the algorithm. In fact, with very high probability the vectors are revealed in order, so that the algorithm first learns  $v_1$ , then  $v_2$ , and so on. As we will show in Lemma 12, any  $\epsilon$ -optimal solution must overlap significantly with all  $v_i$ , and thus any quantum algorithm must make  $k$  queries. Since we want to show an  $\Omega(1/\epsilon^2)$  bound, we choose  $k$  to be a small multiple of  $1/\epsilon^2$ , which explains our choice for  $k$  in Equation (8).

We now establish some basic properties of these functions.

► **Lemma 11** (Properties of  $f_V$ ). *For any  $V \in \mathcal{V}$ , let  $f_V$  and  $g_V^{(i)}$  be as in Definition 10. Then  $f_V$  is convex with Lipschitz constant at most  $1 + k\gamma \leq 2$  on  $B(\vec{0}, 1)$ , and*

$$\text{for } x \neq \vec{0}, \quad \nabla g_V^{(i)}(x) = v_i + (k-i)\gamma x/\|x\|, \quad \text{and} \quad (11)$$

$$\text{for } x = \vec{0}, \quad \partial g_V^{(i)}(\vec{0}) = \{v_i + (k-i)\gamma u \mid u \in B(\vec{0}, 1)\}, \quad \text{and} \quad (12)$$

$$\text{for any } x, \quad \partial f_V(x) = \text{ConvexHull}(\{u \in \partial g_V^{(i)}(x) \mid g_V^{(i)}(x) = f_V(x)\}), \quad (13)$$

where the convex hull of a set of vectors is the set of all convex combinations of vectors in the set. Lastly, for any  $\alpha > 0$ ,  $f_V(\alpha x) = \alpha f_V(x)$  and  $\partial f_V(\alpha x) = \partial f_V(x)$ .

**Proof.** For all  $V \in \mathcal{V}$ ,  $f_V : \mathbb{R}^n \rightarrow \mathbb{R}$  is convex. This follows because linear functions and norms are convex functions [23, Example 3.1.1], and the sum or maximum of convex functions is convex [23, Theorem 3.1.5].

Let us now compute the subgradients of  $g_V^{(i)}(x) = \langle v_i, x \rangle + (k-i)\gamma\|x\|$ . The linear function  $\langle v_i, x \rangle$  is differentiable and its gradient is simply  $v_i$ . The Euclidian norm  $\|x\|$  is differentiable everywhere except at  $x = \vec{0}$ . At  $x \neq \vec{0}$ , the gradient of  $\|x\|$  is  $x/\|x\|$  and at  $x = 0$ , the set of subgradients is  $B(\vec{0}, 1)$  [23, Example 3.1.5]. We also know that  $\partial(\alpha_1 f_1(x) + \alpha_2 f_2(x)) = \alpha_1 \partial f_1(x) + \alpha_2 \partial f_2(x)$  [23, Lemma 3.1.9], which gives us the expressions for the subgradients of  $g_V^{(i)}$ .

For a function that is the maximum of functions  $g_V^{(i)}$ , we know that the set of subgradients is simply the convex hull of subgradients of those  $g_V^{(i)}$  which achieve the maximum at the given point  $x$  [23, Lemma 3.1.10].

The Lipschitz constant of a function is the maximum norm of any subgradient of the function. Since any vector in  $\partial g_V^{(i)}$  has norm  $1 + k\gamma$ , and any vector in  $\partial f_V$  is the convex combination of vectors with norm at most  $1 + k\gamma$ , the Lipschitz constant of  $f_V$  is at most  $1 + k\gamma \leq 2$ .

Finally, it is easy to see from the definition of  $f_V$  that for  $\alpha > 0$ ,  $f_V(\alpha x) = \alpha f(x)$  since each term in the max gets multiplied by  $\alpha$ . For  $\partial f_V(\alpha x)$ , note that this is a convex combination of  $\partial g_V^{(i)}(\alpha x)$ , and these do not depend on  $\alpha$ . ◀

For convenience we work with this family of functions with Lipschitz constant at most 2 instead of 1, which doesn't change the asymptotic bounds since we could just divide every function  $f_V$  by 2.

The last property essentially says that querying the function or its subgradient on a scalar multiple of a vector  $x$  gives us only as much information as querying it on  $x$ . Thus we can assume that an algorithm only queries the oracles within the unit ball without loss of generality.

Now let us discuss the vector  $x^* \in B(\vec{0}, 1)$  that minimizes  $f_V(x)$  and vectors that  $\epsilon$ -approximately solve the minimization problem. First note that if  $\gamma$  were equal to 0, then the function would simply be  $\max_{i \in [k]} \langle v_i, x \rangle$ , which requires us to minimize the component of  $x$  in  $k$  different directions subject to it being a unit vector. The solution to this is simply  $\frac{-1}{\sqrt{k}} \sum_i v_i$ . Now  $-1/\sqrt{k} = -10\epsilon$ , so the overlap of  $x$  with each direction  $v_i$  is a large multiple of  $\epsilon$ . So even an  $\epsilon$ -approximate solution must have reasonable overlap with each of the vectors  $v_i$ . Specifically, each overlap must be at least  $-9\epsilon$ . Now in our function  $f_V$  the term  $\gamma$  is not 0, but that term at most perturbs the function by  $k\gamma = \epsilon$ , which again is much smaller than  $10\epsilon$ , and thus even approximate solutions must have significant overlaps with all  $v_i$ . We formalize these properties below.

► **Lemma 12** (Properties of the minimum). *For any  $V \in \mathcal{V}$ , let  $f_V : \mathbb{R}^n \rightarrow \mathbb{R}$  be the function in Definition 10 and let  $x^* := \operatorname{argmin}_{x \in B(\vec{0}, 1)} f_V(x)$ . Then  $f_V(x^*) \leq -9\epsilon$ . Furthermore, any  $x \in \mathbb{R}^n$  that satisfies  $|f_V(x) - f_V(x^*)| \leq \epsilon$  must satisfy for all  $i \in [k]$ ,  $\langle v_i, x \rangle \leq -8\epsilon$ .*

**Proof.** Consider the vector  $y = \frac{-1}{\sqrt{k}} \sum_{i \in [k]} v_i$ . This is a vector in  $B(\vec{0}, 1)$ , satisfying  $f_V(y) \leq \frac{-1}{\sqrt{k}} + (k-1)\gamma \leq \frac{-1}{\sqrt{k}} + k\gamma = -10\epsilon + \epsilon = -9\epsilon$ , because we have  $10\epsilon = \frac{1}{\sqrt{k}}$  and  $k\gamma = \frac{1}{10\sqrt{k}} = \epsilon$ . Thus  $f_V(x^*) \leq f_V(y) \leq -9\epsilon$ .

Now consider any vector  $x$  with  $|f_V(x) - f_V(x^*)| \leq \epsilon$ , which implies  $f_V(x) \leq -8\epsilon$ . If  $\langle v_i, x \rangle > -8\epsilon$  for any  $i \in [k]$ , then  $f_V(x) \geq \langle v_i, x \rangle + (k-i)\gamma\|x\| > -8\epsilon$ , which is a contradiction. ◀

This result crucially uses the relation between  $\gamma$  and  $k$  and because we want  $k\gamma$  to be a constant factor (say 10) smaller than  $1/\sqrt{k}$ , this informs our choice of  $\gamma$  in Equation (8). Our choice of  $n$  in Equation (9) will be discussed in the next section.

## 4.2 Probabilistic facts about the function family

So far all the properties we have discussed of our function family hold for any  $V \in \mathcal{V}$ , but now we want to talk about a hard distribution over such functions. Specifically we want to talk about choosing a uniformly random (according to the Haar measure)  $V$  from the infinite set  $\mathcal{V}$ . It is easy to see how to sample a random  $V$  once we can sample unit vectors from a subspace. We start by choosing  $v_1$  to be a Haar random unit vector from  $\mathbb{R}^n$ , let  $v_2$  be a Haar random unit vector from  $\operatorname{span}(v_1)^\perp$ , and so on, until  $v_k$  is a Haar random unit vector in  $\operatorname{span}(v_1, v_2, \dots, v_{k-1})^\perp$ .

We can now discuss what determines our choice of  $n$ . By construction, the family of functions  $\mathcal{F}$  has the property that if the input vector  $x$  has equal inner product with all vectors  $v_i$ , then the maximum will be achieved uniquely on the first term  $i = 1$  because the additive term  $(k - i)\gamma\|x\|$  is largest for  $i = 1$ . Now what we want to ensure is that this property holds even when  $x$  does not have equal inner product with all  $v_i$ , but  $x$  is chosen uniformly at random from  $B(\vec{0}, 1)$ . Or equivalently, we want this property to hold when  $x$  is fixed, but the set  $V$  is chosen uniformly at random.

In either case, the inner product of  $x$  with a random unit vector  $v$  will be a random variable with mean 0 due to symmetry. But the expected value of  $|\langle v, x \rangle|^2$  for a random unit vector  $v$  is  $1/n$ , and in fact it will be tightly concentrated around  $1/n$ . The following proposition follows from [5, Lemma 2.2].

► **Proposition 13.** *Let  $x \in B(\vec{0}, 1)$ . Then for a random unit vector  $v$ , and all  $c > 0$ ,*

$$\Pr_v(|\langle x, v \rangle| \geq c) \leq 2e^{-nc^2/2}. \quad (14)$$

We choose  $\gamma$  so that it is very unlikely (polynomially small in  $n$ ) that the maximum is not achieved at  $i = 1$ . From Proposition 13, we see that the probability of any  $|\langle v_i, x \rangle|^2$  being larger than a constant multiple of  $\log n/n$  is inverse polynomially small. So it is sufficient to take  $\gamma^2$  to be a large constant multiple of  $\log n/n$  as in Equation (9).

In our lower bound we will need a slightly stronger result. We can show that if the vectors  $v_1, \dots, v_{t-1}$  are fixed (and hence known to the algorithm), and the remaining vectors  $v_t, \dots, v_k$  are chosen uniformly at random such that the set of vectors  $\{v_1, \dots, v_k\}$  is orthonormal, then the maximum will be achieved in the set  $[t]$  with high probability. This generalizes the previous claim, which is the case of  $t = 1$ , where none of the vectors were fixed.

► **Lemma 14 (Most probable argmax).** *Let  $1 \leq t \leq k$  be integers and  $\{v_1, \dots, v_{t-1}\}$  be a set of orthonormal vectors. Let  $\{v_t, \dots, v_k\}$  be chosen uniformly at random so that the set  $\{v_1, \dots, v_k\}$  is orthonormal. Then*

$$\forall x \in B(\vec{0}, 1) : \Pr_{v_t, \dots, v_k} \left( \max_{i \in [k]} \langle v_i, x \rangle + (k - i)\gamma\|x\| \neq \max_{i \in [t]} \langle v_i, x \rangle + (k - i)\gamma\|x\| \right) \leq \frac{1}{n^7}. \quad (15)$$

**Proof.** Let  $E_x$  denote the event whose probability we want to upper bound. Since  $E_x$  and  $E_{\alpha x}$ , for any  $\alpha \in [0, 1]$ , are the same event, we can assume without loss of generality that  $\|x\| = 1$ . If event  $E_x$  occurs, then it must hold that

$$\max_{i \in \{t+1, \dots, k\}} \langle v_i, x \rangle + (k - i)\gamma > \max_{i \in [t]} \langle v_i, x \rangle + (k - i)\gamma \geq \langle v_t, x \rangle + (k - t)\gamma. \quad (16)$$

We want to show that this event is very unlikely. To do so, let  $F_x$  be the event that for all  $i \in \{t, \dots, k\}$ ,  $\langle v_i, x \rangle \in [-\frac{\gamma}{2}, +\frac{\gamma}{2}]$ . Note that if  $F_x$  occurs, then the terms in the max are in decreasing order, and we have

$$\langle v_t, x \rangle + (k - t)\gamma \geq \langle v_{t+1}, x \rangle + (k - t - 1)\gamma \geq \dots \geq \langle v_{k-1}, x \rangle + \gamma \geq \langle v_k, x \rangle, \quad (17)$$

which contradicts Equation (16). Thus if  $E_x$  holds then the complement of  $F_x$ ,  $\bar{F}_x$  must hold, which means  $\Pr(E_x) \leq \Pr(\bar{F}_x)$ . So let us show that  $F_x$  is very likely.

The event  $\bar{F}_x$  holds only if there exists an  $i \in \{t, \dots, k\}$  such that  $\langle v_i, x \rangle \notin [-\frac{\gamma}{2}, +\frac{\gamma}{2}]$ . We can upper bound this probability for any particular  $i \in \{t, \dots, k\}$  using Proposition 13 and the fact that  $v_i$  is chosen uniformly at random from an  $n - t + 1$ -dimension ball. This probability is at most  $2e^{-(n-t+1)\gamma^2/8} = 2e^{-(n-t+1) \cdot 8 \frac{\log n}{n}} \leq 2 \cdot 2^{-8 \log n} = 2/n^8$ , with the inequality holding because  $n > 4t$ . The probability that this happens for any  $i$  is at most  $(k - t + 1) \leq k$  times this probability, by the union bound. Using the fact that  $2k < n$ , we get that  $\Pr(E_x) \leq \Pr(\bar{F}_x) < 1/n^7$ . ◀

Finally, we show that even if we knew the vectors  $v_1, \dots, v_{k-1}$ , we cannot guess a vector  $x$  that is an  $\epsilon$ -approximate solution to our problem, because it won't have enough overlap with  $v_k$ , which is unknown. In other words, for an algorithm to output an  $\epsilon$ -optimal solution, it essentially must know the entire set  $V$ .

► **Lemma 15** (Cannot guess  $x^*$ ). *Let  $k > 0$  be an integer and  $\{v_1, \dots, v_{k-1}\}$  be a set of orthonormal vectors. Let  $v_k$  be chosen uniformly at random from  $\text{span}(v_1, \dots, v_{k-1})^\perp$  and let  $V = (v_1, \dots, v_k)$ . Then*

$$\forall x \in B(\vec{0}, 1) : \Pr_{v_k}(f_V(x) - f_V(x^*) \leq \epsilon) \leq 2e^{-\Omega(k^2)}. \quad (18)$$

**Proof.** From Lemma 12, we know that an  $\epsilon$ -optimal solution  $x$  must satisfy  $\langle v_k, x \rangle \leq -8\epsilon$ . But  $v_k$  is chosen uniformly at random from the space  $\text{span}(v_1, \dots, v_{k-1})^\perp$  and any vector  $x \in B(\vec{0}, 1)$  projected to that space also has length at most 1. So from Proposition 13 we know that for any  $x \in B(\vec{0}, 1)$ ,

$$\Pr_{v_k}(\langle v_k, x \rangle \leq -8\epsilon) \leq \Pr_{v_k}(|\langle v_k, x \rangle| \geq 8\epsilon) \leq 2e^{-32(n-k+1)\epsilon^2} \leq 2e^{-\Omega(k^2)}. \quad (19)$$

### 4.3 Quantum query model

We now formally define the quantum query model in our setting. In the usual quantum query model the set of allowed queries is finite, whereas in our setting it is natural to allow the quantum algorithm to query the oracles at any point  $x \in \mathbb{R}^n$ . Due to Lemma 11, it is sufficient to allow the algorithm to query any  $x \in B(\vec{0}, 1)$ , but this is still a continuous space of queries, and hence a query vector could be a superposition over infinitely many states. Instead of formalizing this notion of quantum algorithms, we allow the algorithm to make discrete queries only, but to arbitrarily high precision. The reader is encouraged to not get bogged down by details and to think of the registers as storing the real values that they ideally should, but in the rest of this section we define these algorithms more carefully so that all the spaces involved are finite and well defined. This formalization is not specific to the quantum setting and is done classically as well if we do not want to manipulate real numbers as atomic objects.

All the real numbers that appear will be represented using some  $b$  bits of precision, where  $b$  can be chosen by the algorithm. The reader should imagine  $b$  being arbitrarily large, say exponentially larger than all the parameters involved in the problem, so that the inaccuracy involved by using this representation is negligible. Then the algorithm represents the input  $x \in B(\vec{0}, 1)$  using  $b$  bits of precision per coordinate. The oracle's response will also use  $b$  bits of precision per real number. For a given choice of  $b$ , the quantum algorithm will have some probability of success of solving the problem at hand. We then define the success probability of quantum algorithms that make  $q$  queries by taking a supremum over all  $b$  of  $q$ -query algorithms that solve the problem.

We can now define the oracles more precisely. Classically, the function oracle for a function  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  would simply implement the map  $x \mapsto f(x)$ , where we represent each entry of  $x$  and the output  $f(x)$  using  $b$  bits, so  $x \in \{0, 1\}^{bn}$  and  $f(x) \in \{0, 1\}^b$ . Let's say we have a classical circuit that implements this map using  $G$  gates, say over the gate set of AND, OR, and NOT gates. Then it is easy to construct, in a completely black-box way, a quantum circuit using  $O(G)$  gates (say over the gate set of Hadamard, CNOT, and T) that performs the unitary  $U|x\rangle|y\rangle = |x\rangle|y \oplus f(x)\rangle$ , for every  $x \in \{0, 1\}^{bn}$ , and  $y \in \{0, 1\}^b$ . This is why it is standard to assume that the quantum oracle corresponding to the classical map  $x \mapsto f(x)$  is a unitary that performs  $U|x\rangle|y\rangle = |x\rangle|y \oplus f(x)\rangle$ . We apply the same construction for

the  $\mathcal{FO}(f)$  oracle to get the quantum analogue of the classical map  $x \mapsto g_x$ , where  $g_x$  is some subgradient of  $f$  at  $x$ . Lastly, for convenience we will combine both the function and subgradient oracle into one oracle that when queried with  $x$  returns  $f(x)$  and a subgradient at  $x$ . Since our function family is parameterized by  $V \in \mathcal{V}$ , we call this oracle  $O_V$ .

Let  $\mathcal{A}$  be a quantum query algorithm that makes  $q$  queries.  $\mathcal{A}$  is described by a sequence of unitaries  $U_q O_V U_{q-1} O_V U_{q-2} O_V \cdots U_1 O_V U_0$  applied to an initial state, say  $|0\rangle$ . We assume that the output of  $\mathcal{A}$ , which is a vector  $x$ , is determined by measuring the first  $n$  registers storing real numbers using  $b$  bits.

#### 4.4 Lower bound

We can now prove the quantum lower bound. Let  $\mathcal{A}$  be a  $k-1$  query quantum algorithm that solves Problem 1 on all the functions  $f_V$  for  $V \in \mathcal{V}$ . Due to Lemma 11, we can assume that the algorithm only queries the oracles with vectors  $x \in B(\vec{0}, 1)$ . We also need to describe the behavior of the subgradient oracle on inputs where the subgradient is not unique. On such inputs  $x$ , the subgradient is not unique because several indices  $i \in [k]$  simultaneously achieve the maximum in  $f_V(x)$ . In this case, the subgradient will answer as if the smallest index  $i$  in this set achieved the maximum. Now let  $\mathcal{A}$  be described by the sequence of unitaries  $U_{k-1} O_V U_{k-2} O_V \cdots O_V U_1 O_V U_0$  acting on the starting state  $|0\rangle$ . Let this sequence of unitaries be called  $A$ . Then the final state of the algorithm is  $A|0\rangle$ .

Recall that we defined  $f_V(x) = \max_{i \in [k]} \{g_V^{(i)}(x)\}$ . Let us also define functions  $f_V^{(j)}$  where the maximization is only over the first  $j$  indices instead of all  $k$  indices. Specifically, let  $f_V^{(j)} := \max_{i \in [j]} \{g_V^{(i)}(x)\}$ . We previously defined the oracle  $O_V$  as corresponding to the function  $f_V$ . Let  $O_V^{(j)}$  be the oracle corresponding to the functions  $f_V^{(j)}$ .

Now we define a sequence of unitaries starting with  $A_0 = A$  as follows:

$$\begin{aligned} A_0 &:= U_{k-1} O_V U_{k-2} O_V \cdots O_V U_1 O_V U_0 \\ A_1 &:= U_{k-1} O_V U_{k-2} O_V \cdots O_V U_1 O_V^{(1)} U_0 \\ A_2 &:= U_{k-1} O_V U_{k-2} O_V \cdots O_V^{(2)} U_1 O_V^{(1)} U_0 \\ &\vdots \\ A_{k-1} &:= U_{k-1} O_V^{(k-1)} U_{k-2} O_V^{(k-2)} \cdots O_V^{(2)} U_1 O_V^{(1)} U_0 \end{aligned} \tag{20}$$

We want to show that the algorithm  $A_0$  does not solve our problem. To do so, we will employ the hybrid argument, in which we show that the output of the algorithm  $A_i$  and  $A_{i+1}$  is close, and thus the output of  $A_0$  and  $A_{k-1}$  is close. Finally, we argue that the algorithm  $A_{k-1}$  does not solve our problem because the oracles in the algorithm do not know  $v_k$ . Let us first establish these two claims.

► **Lemma 16** ( $A_{k-1}$  does not solve the problem). *Let  $\mathcal{A}$  be a  $k-1$  query algorithm and let  $A_{k-1}$  be defined as above. Let  $p_V$  be the probability distribution over  $x \in B(\vec{0}, 1)$  obtained by measuring the output state  $A_{k-1}|0\rangle$ . Then  $\Pr_{V, x \sim p_V} (f_V(x) - f_V(x^*) \leq \epsilon) \leq 2e^{-\Omega(k^2)}$ .*

**Proof.** We want to show that the probability (over the random choice of  $V$  and the internal randomness of the algorithm) that  $A_{k-1}$  outputs an  $x$  that satisfies  $f(x) - f(x^*) \leq \epsilon$  is very small.

Let us establish the claim for any fixed choice of  $v_1, \dots, v_{k-1}$ , since if the claim holds for any fixed choice of these vectors, then it also holds for any probability distribution over them. For a fixed choice of vectors, this claim is just  $\Pr_{v_k, x \sim p_V} (f_V(x) - f_V(x^*) \leq \epsilon) \leq 2e^{-\Omega(k^2)}$ .

Now since the algorithm  $A_{k-1}$  only has oracles  $O_V^{(i)}$  for  $i < k$ , the probability distribution  $p_V$  only depends on  $v_1, \dots, v_{k-1}$ . Since these are fixed, this is just a fixed distribution  $p$ . So we can instead establish our claim for all  $x \in B(\vec{0}, 1)$ , which will also establish it for any distribution.

So what we need to establish is that for any  $x \in B(\vec{0}, 1)$ ,  $\Pr_{v_k}(f_V(x) - f_V(x^*) \leq \epsilon) \leq 2e^{-\Omega(k^2)}$ , which is exactly what we showed in Lemma 15.  $\blacktriangleleft$

► **Lemma 17** ( $A_t$  and  $A_{t-1}$  have similar outputs). *Let  $\mathcal{A}$  be a  $k-1$  query algorithm and let  $A_t$  for  $t \in [k-1]$  be the unitaries defined in Equation (20). Then*

$$\mathbb{E}_V(\|A_t|0\rangle - A_{t-1}|0\rangle\|^2) \leq \frac{4}{n^7}. \quad (21)$$

**Proof.** From the definition of the unitaries in Equation (20) and the unitary invariance of the spectral norm, we see that  $\|A_t|0\rangle - A_{t-1}|0\rangle\| = \|(O_V^{(t)} - O_V)U_{t-1}O_V^{(t-1)} \dots O_V^{(1)}U_0|0\rangle\|$ . Let us again prove the claim for any fixed choice of vectors  $v_1, \dots, v_{t-1}$ , which will imply the claim for any distribution over those vectors. Once we have fixed these vectors, the state  $U_{t-1}O_V^{(t-1)} \dots O_V^{(1)}U_0|0\rangle$  is a fixed state, which we can call  $|\psi\rangle$ . Thus our problem reduces to showing for all quantum states  $|\psi\rangle$ ,

$$\mathbb{E}_{v_t, \dots, v_k}(\|(O_V^{(t)} - O_V)|\psi\rangle\|^2) \leq \frac{4}{n^7}. \quad (22)$$

Now we can write an arbitrary quantum state as  $|\psi\rangle = \sum_x \alpha_x |x\rangle |\phi_x\rangle$ , where  $x$  is the query made to the oracle, and  $\sum_x |\alpha_x|^2 = 1$ . Thus the LHS of Equation (22) is equal to

$$\mathbb{E}_{v_t, \dots, v_k} \left( \left\| \sum_x \alpha_x (O_V^{(t)} - O_V) |x\rangle |\phi_x\rangle \right\|^2 \right) \leq \sum_x |\alpha_x|^2 \mathbb{E}_{v_t, \dots, v_k} \left( \|(O_V^{(t)} - O_V)|x\rangle |\phi_x\rangle\|^2 \right). \quad (23)$$

Since  $|\alpha_x|^2$  defines a probability distribution over  $x$ , we can again upper bound the right hand side for any  $x$  instead. Since  $O_V^{(t)}$  and  $O_V$  behave identically for some inputs  $x$ , the only nonzero terms are those where the oracles respond differently, which can only happen if  $f_V^{(t)}(x) \neq f_V(x)$ . When the response is different, we can upper bound  $\|(O_V^{(t)} - O_V)|x\rangle |\phi_x\rangle\|^2$  by 4 using the triangle inequality. Thus for any  $x \in B(\vec{0}, 1)$ , we have

$$\mathbb{E}_{v_t, \dots, v_k} \left( \|(O_V^{(t)} - O_V)|x\rangle |\phi_x\rangle\|^2 \right) \leq 4 \Pr_{v_t, \dots, v_k} (f_V^{(t)}(x) \neq f_V(x)) \leq 4/n^7, \quad (24)$$

where the second inequality follows from Lemma 14. The first inequality requires more explanation. It is based on the claim that if  $f_V^{(t)}(x) = f_V(x)$  then on such inputs  $x$ , the oracles  $O_V^{(t)}$  and  $O_V$  must behave identically. In other words, for such an input  $x$ , for any  $|\phi_x\rangle$ , we have  $O_V^{(t)}|x\rangle |\phi_x\rangle = O_V|x\rangle |\phi_x\rangle$ . The oracle responds with the function value and the subgradient, and we have already assumed that the function values are equal, so we only need to show that if  $f_V^{(t)}(x) = f_V(x)$ , then the subgradient oracle's response is also identical for both functions. Since  $f_V^{(t)}(x) = f_V(x)$ , the maximum in the definition of  $f_V$  was achieved by some index in the first  $t$  indices (and possibly other indices as well). But our definition of the subgradient oracle says that if multiple indices achieve the maximum, the subgradient oracle will respond as if the smallest index achieved the maximum. Hence the response of the subgradient oracle for the two functions will also be identical.  $\blacktriangleleft$

Finally we can put these two lemmas together to prove our lower bound.

► **Lemma 18** ( $\mathcal{A}$  does not solve the problem). *Let  $\mathcal{A}$  be a  $k - 1$  query algorithm. Let  $p_V$  be the probability distribution over  $x \in B(\vec{0}, 1)$  obtained by measuring the output state  $A|0\rangle$ . Then  $\Pr_{V, x \sim p_V}(f_V(x) - f_V(x^*) \leq \epsilon) \leq \frac{1}{\text{poly}(n)}$ .*

**Proof.** Let  $P_V$  be the projection operator that projects a quantum state  $|\psi\rangle$  onto the space spanned by vectors  $|x\rangle$  for  $x$  such that  $f_V(x) - f_V(x^*) \leq \epsilon$ . Then  $\|P_V A|0\rangle\|^2 = \Pr_{x \sim p_V}(f_V(x) - f_V(x^*) \leq \epsilon)$ . We know from Lemma 16 that  $\mathbb{E}_V(\|P_V A_{k-1}|0\rangle\|^2) \leq 2e^{-\Omega(k^2)}$ . We prove our upper bound on the probability by showing that it is approximately the same as  $\mathbb{E}_V(\|P_V A_{k-1}|0\rangle\|^2)$ .

Lemma 17 states that for all  $1 \leq t < k$ ,  $\mathbb{E}_V(\|A_t|0\rangle - A_{t-1}|0\rangle\|^2) \leq \frac{4}{n^7}$ . Using telescoping sums and the Cauchy-Schwarz inequality, we see that

$$\mathbb{E}_V(\|A_{k-1}|0\rangle - A|0\rangle\|^2) \leq \mathbb{E}_V\left(\left(\sum_{t \in [k-1]} \|A_t|0\rangle - A_{t-1}|0\rangle\|\right)^2\right) \quad (25)$$

$$\leq \mathbb{E}_V\left(\sum_{t \in [k-1]} \|A_t|0\rangle - A_{t-1}|0\rangle\|^2\right) \left(\sum_{t \in [k-1]} 1^2\right) \leq \frac{4k}{n^7} \cdot k. \quad (26)$$

For all  $V$ ,

$$\| \|P_V A_{k-1}|0\rangle\| - \|P_V A|0\rangle\| \| \leq \|P_V A_{k-1}|0\rangle - P_V A|0\rangle\| \leq \|A_{k-1}|0\rangle - A|0\rangle\| \quad (27)$$

and so

$$\mathbb{E}_V(\left(\|P_V A_{k-1}|0\rangle\| - \|P_V A|0\rangle\|\right)^2) \leq \frac{4k^2}{n^7}. \quad (28)$$

We want an upper bound on  $\mathbb{E}_V(\|P_V A|0\rangle\|^2 - \|P_V A_{k-1}|0\rangle\|^2)$ , which is no larger than  $2\mathbb{E}_V(\|P_V A|0\rangle\| - \|P_V A_{k-1}|0\rangle\|)$  since  $\|P_V A|0\rangle\| + \|P_V A_{k-1}|0\rangle\| \leq 2$ . We get such a bound by applying Jensen's inequality to Equation (28):  $\mathbb{E}_V(\|P_V A|0\rangle\| - \|P_V A_{k-1}|0\rangle\|) \leq 2k/\sqrt{n^7}$ , and so  $\mathbb{E}_V(\|P_V A|0\rangle\|^2 - \|P_V A_{k-1}|0\rangle\|^2) \leq 4k/\sqrt{n^7}$ .

We can now use linearity of expectation and upper bound our required probability as

$$\Pr_{V, x \sim p_V}(f_V(x) - f_V(x^*) \leq \epsilon) = \mathbb{E}_V(\|P_V A|0\rangle\|^2) \leq 2e^{-\Omega(k^2)} + 4k/\sqrt{n^7} \leq \frac{1}{\text{poly}(n)}. \quad (29)$$

Note that this establishes a statement similar to Theorem 5, except with a polynomially larger value of  $n$ . This result is sufficient to establish the optimality of gradient descent in the dimension-independent setting. To reduce the value of  $n$ , we modify the function above using a *wall function* introduced by [12]. The details of this modification and the resulting quantitatively better lower bound can be found in the full version of the paper.

## 5 Open problems

We showed that in the black-box setting, no quantum algorithm can beat gradient descent in general, in the dimension-independent regime. Here are some interesting questions left open by our work:

1. We showed in Theorem 4 that the class of functions used in the randomized lower bound can be solved faster with quantum queries. Is there a more interesting class of functions on which we can achieve a quantum speedup?

2. Can the quantum lower bound in Section 4 be made to work using the simpler class of functions  $f_V(x) = \max_i \langle v_i, x \rangle$ , which is our function with  $\gamma = 0$ ? If so, this might also decrease the dimension  $n$  required.
3. Can we establish tight quantum lower bounds in the parameter regime where dimension-dependent algorithms outperform gradient descent? When  $1/\epsilon$  is a large polynomial in  $n$ , the complexity of gradient descent is also a large polynomial in  $n$ , but a dimension-dependent algorithm such as the center of gravity method [11] yields an  $O(n \log n)$  upper bound. Can we establish an  $\tilde{\Omega}(n)$  lower bound in this regime? The function used in the randomized lower bound in Section 3 yields an  $\tilde{\Omega}(\sqrt{n})$  lower bound and this is the best bound we are aware of. This is essentially the same as the problem left open by [13, 3], but phrased in the language of membership and separation oracles.
4. What can we say about other standard settings in convex optimization beyond first-order non-smooth convex optimization? Other natural settings include assuming the function is smooth, having the ability to query a prox oracle instead of a subgradient oracle, etc. Can quantum algorithms provide a speedup in the black-box model in these settings over the respective best classical algorithms in that setting?

## Abstract

We study a new type of separations between quantum and classical communication complexity, separations that are obtained using quantum protocols where all parties are **efficient**, in the sense that they can be implemented by small quantum circuits, with oracle access to their inputs. Our main result qualitatively matches the strongest known separation between quantum and classical communication complexity [8] and is obtained using a quantum protocol where all parties are efficient. More precisely, we give an explicit partial Boolean function  $f$  over inputs of length  $N$ , such that:

- (1)  $f$  can be computed by a simultaneous-message quantum protocol with communication complexity  $\text{polylog}(N)$  (where at the beginning of the protocol Alice and Bob also have  $\text{polylog}(N)$  entangled EPR pairs).
- (2) Any classical randomized protocol for  $f$ , with any number of rounds, has communication complexity at least  $\tilde{\Omega}(N^{1/4})$ .
- (3) All parties in the quantum protocol of Item (1) (Alice, Bob and the referee) can be implemented by quantum circuits of size  $\text{polylog}(N)$  (where Alice and Bob have oracle access to their inputs).

Items (1), (2) qualitatively match the strongest known separation between quantum and classical communication complexity, proved by Gavinsky [8]. Item (3) is new. (Our result is incomparable to the one of Gavinsky. While he obtained a quantitatively better lower bound of  $\Omega(N^{1/2})$  in the classical case, the referee in his quantum protocol is inefficient).

Exponential separations of quantum and classical communication complexity have been studied in numerous previous works, but to the best of our knowledge the efficiency of the parties in the quantum protocol has not been addressed, and in most previous separations the quantum parties seem to be inefficient. The only separations that we know of that have efficient quantum parties are the recent separations that are based on lifting [10, 5]. However, these separations seem to require quantum protocols with at least two rounds of communication, so they imply a separation of two-way quantum and classical communication complexity but they do not give the stronger separations of simultaneous-message quantum communication complexity vs. two-way classical communication complexity (or even one-way quantum communication complexity vs. two-way classical communication complexity).

Our proof technique is completely new, in the context of communication complexity, and is based on techniques from [15]. Our function  $f$  is based on a lift of the FORRELATION problem, using XOR as a gadget.

## 1 Introduction

Exponential separations between quantum and classical communication complexity have been established in various models and settings. These separations give explicit examples of partial functions that can be computed by quantum protocols with very small communication complexity, while any classical randomized protocol requires significantly higher communication complexity. However, to the best of our knowledge, in all these works the efficiency of the quantum players in the quantum protocol has not been addressed and in most of these separations, the quantum players are inefficient.

Communication complexity studies the amount of communication needed to perform computational tasks that depend on two (or more) inputs, each given to a different player. The efficiency of the players in a communication complexity protocol is usually not addressed. If the players need to read their entire inputs, their time complexity is at least the length of the inputs. However, the inputs may be represented compactly by a black box and (particularly in the quantum case) we can hope for players that can be implemented very efficiently by small (say, poly-logarithmic size) quantum circuits, with oracle access to their inputs.

Our main result qualitatively matches the strongest known separation between quantum and classical communication complexity [8] and is obtained using quantum protocols where all players are efficient. To prove our results we use a completely different set of techniques, based on techniques from the recent oracle separation of BQP and PH [15].

### 1.1 Previous Work

The relative power of quantum and classical communication complexity has been studied in numerous of works. While it is unknown whether quantum communication can offer exponential advantage over randomized communication for total functions, a series of works gave explicit examples of partial Boolean functions (promise problems) that have quantum protocols with very small communication complexity, while any classical protocol requires exponentially higher communication complexity. The history of exponential advantage of quantum communication, that is most relevant to our work, is briefly summarized below.

Buhrman, Cleve and Wigderson gave the first (exponential) separation between zero-error quantum communication complexity and classical deterministic communication complexity [4]. Raz gave the first exponential separation between two-way quantum communication complexity and two-way randomized communication complexity [14]. Bar-Yossef et al [3] (for search problems) and Gavinsky et al [9] (for promise problems) gave the first (exponential) separations between one-way quantum communication complexity and one-way randomized communication complexity. Klartag and Regev gave the first (exponential) separation between one-way quantum communication complexity and two-way random-

ized communication complexity [16]. Finally, Gavinsky gave an (exponential) separation between simultaneous-message quantum communication complexity and two-way randomized communication complexity [8].

We note that Gavinsky's work is the strongest separation known today and essentially subsumes the separations discussed above. More precisely, Gavinsky [8] gave an explicit partial Boolean function  $f$  over inputs of length  $N$ , such that:

1.  $f$  can be computed by a simultaneous-message quantum protocol with communication complexity  $\text{polylog}(N)$ : Alice and Bob simultaneously send quantum messages of length  $\text{polylog}(N)$  to a referee, who performs a quantum measurement on the messages and announces the answer. (At the beginning of the protocol Alice and Bob also have  $\text{polylog}(N)$  entangled EPR pairs).

We note that this also implies a one-way quantum protocol where Alice sends a message of length  $\text{polylog}(N)$  qubits to Bob, who performs a measurement and announces the answer (or vice versa).

2. Any classical randomized protocol for  $f$  has communication complexity at least  $\Omega(N^{1/2})$ .

A drawback of Gavinsky's separation, in the context of our work, is that the referee in his quantum protocol is inefficient as it is required to perform  $O(N)$  quantum operations (and this seems to be crucial in his lower bound proof).

As mentioned before, to the best of our knowledge, the efficiency of the quantum players has not been addressed in previous works on separations of quantum and classical communication complexity. The only separations that we know of that do have efficient quantum parties are the separations that follow from the recent randomized query-to-communication lifting theorems of [10, 5], applied to problems for which we know that quantum decision trees offer an exponential advantage over randomized ones, such as the FORRELATION problem of [1, 2]. However, lifting with the gadgets used in [10, 5] seems to require quantum protocols with two rounds of communication. Thus, these theorems only imply a separation of two-way quantum and classical communication complexity and do not give the stronger separations of simultaneous-message quantum communication complexity vs. two-way classical communication complexity (or even one-way quantum communication complexity vs. two-way classical communication complexity).

## 1.2 Our Result

We recover Gavinsky's state of the art separation, using entirely different techniques. While the parameters in our bounds are weaker, our quantum protocol is *efficient*, in the sense that it involves just  $\text{polylog}(N)$  amount of work by Alice, Bob and the referee, when the players have blackbox access to their inputs. In other words, the output of the entire simultaneous protocol can be described by a  $\text{polylog}(N)$  size quantum circuit, with oracle access to the inputs.

More precisely, our main result gives an explicit partial Boolean function  $f$  over inputs of length  $N$ , such that:

1. As in Gavinsky's work,  $f$  can be computed by a simultaneous-message quantum protocol with communication complexity  $\text{polylog}(N)$ : Alice and Bob simultaneously send quantum messages of length  $\text{polylog}(N)$  to a referee, who performs a quantum measurement on the messages and announces the answer. (At the beginning of the protocol Alice and Bob also have  $\text{polylog}(N)$  entangled EPR pairs).

As before, this also implies a one-way quantum protocol where Alice sends a message of length  $\text{polylog}(N)$  qubits to Bob, who performs a measurement and announces the answer (or vice versa).

2. Any classical randomized protocol for  $f$  has communication complexity at least  $\tilde{\Omega}(N^{1/4})$ .
3. All parties in the quantum protocol of Item (1) (Alice, Bob and the referee) can be implemented by quantum circuits of size  $\text{polylog}(N)$  (where Alice and Bob have oracle access to their input).

The problem that we define is a lift of the FORRELATION problem of [1, 2, 15] with XOR as the gadget. Our proof technique follows the Fourier-analysis framework of [15]. Our proof offers an entirely new and possibly simpler approach for communication complexity lower bounds. We believe this technique may be applicable in a broader setting. We note that lower bounds for lifting by XOR, using a Fourier-analysis approach, were previously studied in [13, 11].

### 1.3 Our Communication Complexity Problem

Let  $N = 2^n$  and  $H_N$  be the  $N \times N$  normalized Hadamard matrix. Let  $x = (x_1, x_2)$  be an input where  $x_1, x_2 \in \{-1, 1\}^N$ . We define the forrelation of  $x$  as the correlation between the second half  $x_2$  and the Hadamard transform of the first half  $x_1$ .

$$\text{forr}(x) := \left\langle \frac{1}{\sqrt{N}} H_N(x_1) \middle| \frac{1}{\sqrt{N}} x_2 \right\rangle$$

The communication problem for which our separation holds is a lift of the forrelation problem of [15], with XOR as the gadget. Let  $x, y \in \{-1, 1\}^{2N}$ . Alice gets  $x$  and Bob gets  $y$  and their goal is to compute the partial function  $F$  defined by

$$F(x, y) := \begin{cases} 1 & \text{if } \text{forr}(x \cdot y) \geq \frac{1}{200} \cdot \frac{1}{\ln N} \\ -1 & \text{if } \text{forr}(x \cdot y) \leq \frac{1}{400} \cdot \frac{1}{\ln N}. \end{cases}$$

Here  $x \cdot y$  refers to the coordinate-wise product of the vectors  $x, y$ . We refer to this problem as the forrelation problem.

► **Theorem 1.** *The forrelation problem can be solved in the quantum simultaneous with entanglement model with  $O(\log^3 N)$  bits of communication, when Alice and Bob are given access to  $O(\log^3 N)$  bits of shared entanglement. Moreover, the protocol is efficient, as it can be implemented by a  $O(\log^3 N)$  size quantum circuit with oracle access to inputs.*

The quantum upper bound on  $F$  follows from the fact that the XOR of the inputs can be computed by a simultaneous-message quantum protocol, when the players share entanglement, and the fact that  $\text{forr}(x)$  can be estimated by a small size quantum circuit [1, 2, 15].

► **Theorem 2.** *The randomized bounded-error interactive communication cost of the forrelation problem is  $\tilde{\Omega}(N^{\frac{1}{4}})$ .*

### 1.4 An Overview of the Lower Bound

In this section, we outline the proof of the lower bound. We use the forrelation distribution  $\mathcal{D}$  on  $\{-1, 1\}^{2N}$  as defined by [15]. We define a distribution  $\mathcal{V}$  on inputs to the communication problem, obtained by sampling  $z \sim \mathcal{D}$ , and  $x \in \{-1, 1\}^{2N}$  uniformly at random, and setting  $y := x \cdot z$ . Alice gets  $x$  and Bob gets  $y$ . It can be shown that the distribution  $\mathcal{V}$  has considerable support over the yes instances of  $F$ , while the uniform distribution  $\mathcal{U}$  on  $\{-1, 1\}^{4N}$  has large support over the no instances of  $F$ . This fact along with the following theorem implies a lower bound on the randomized communication cost of  $F$ .

► **Theorem 3.** *Consider the following distribution. A string  $z \in \{-1, 1\}^{2N}$  is drawn from the forrelation distribution,  $x \sim U_{2N}$  is drawn uniformly and  $y := x \cdot z$ . Alice gets  $x$  and Bob gets  $y$ . Given any deterministic communication protocol  $C : \{-1, 1\}^{2N} \times \{-1, 1\}^{2N} \rightarrow \{-1, 1\}$  of cost  $c \geq 1$ , its expectation when the inputs are drawn from this distribution is close to when the inputs are drawn from the uniform distribution. That is,*

$$\left| \mathbb{E}_{\substack{x \sim U_{2N} \\ z \sim \mathcal{D}}} [C(x, x \cdot z)] - \mathbb{E}_{x, y \sim U_{2N}} [C(x, y)] \right| \leq O\left(\frac{c^2}{N^{1/2}}\right).$$

*In other words, no deterministic protocol of cost  $o(N^{1/4})$  has considerable advantage in distinguishing the above distribution from the uniform distribution.*

We now outline the proof of this theorem. Any cost  $c$  protocol induces a partition of the input space into at most  $2^c$  rectangles. Let  $A \times B$  be any rectangle, and let  $\mathbb{1}_A, \mathbb{1}_B : \{-1, 1\}^{2N} \rightarrow \{0, 1\}$  be the indicator functions of  $A$  and  $B$  respectively. Note that for all distributions  $\mathcal{S}$  on  $\{-1, 1\}^{2N}$ , we have

$$\mathbb{E}_{z \sim \mathcal{S}} \mathbb{E}_{x \sim U_{2N}} [\mathbb{1}_A(x) \mathbb{1}_B(x \cdot z)] = \mathbb{E}_{z \sim \mathcal{S}} [(\mathbb{1}_A * \mathbb{1}_B)(z)].$$

Here, the notation  $f * g$  refers to the convolution of Boolean functions  $f$  and  $g$ . This identity implies that our goal is to show that the expectation of the function  $\sum_{A \times B} (\mathbb{1}_A * \mathbb{1}_B)(z)$  over a uniformly distributed  $z$  is close to the expectation over  $z \sim \mathcal{D}$ . An essential contribution of the works of [15] and [7] is the following result. For any family of functions  $\mathcal{F}$  that is closed under restrictions, to show that the family is fooled by the forrelation distribution, it suffices to bound the  $\ell_1$ -norm of the second level Fourier coefficients of the family. More precisely, the maximum advantage of a function  $f \in \mathcal{F}$  in distinguishing the uniform distribution and  $\mathcal{D}$ , is at most  $O\left(\frac{1}{\sqrt{N}}\right)$  times the maximum second level Fourier mass of a function  $f \in \mathcal{F}$ . Since small cost communication protocols form a family of functions closed under restrictions, the same reasoning applies here. In this paper however, we present a complete proof of this connection. We then provide the following bound on the second level Fourier mass corresponding to a small cost protocol.

▷ **Claim 1.** Let  $C(x, y) : \{-1, 1\}^{2N} \times \{-1, 1\}^{2N} \rightarrow \{-1, 1\}$  be any deterministic protocol of cost  $c \geq 1$ , let  $D(x, z) : \mathbb{R}^{2N} \times \mathbb{R}^{2N} \rightarrow \mathbb{R}$  refer to the unique multilinear extension of  $C(x, x \cdot z)$  and  $H : \mathbb{R}^{2N} \rightarrow \mathbb{R}$  be defined by  $H(z) = \mathbb{E}_{x \sim U_{2N}} D(x, z)$ . Then,

$$L_2(H) \triangleq \sum_{|S|=2} |\widehat{H}(S)| \leq 120c^2.$$

We now describe the proof of this claim. Let  $A \times B$  be a rectangle in the partition induced by the cost  $c$  protocol. An important property of the convolution of two functions  $f, g$  is that for all subsets  $S \subseteq [n]$ , we have  $\widehat{f * g}(S) = \widehat{f}(S) \widehat{g}(S)$ . This, along with Cauchy-Schwarz implies that

$$\sum_{|S|=2} |\widehat{\mathbb{1}_A * \mathbb{1}_B}(S)| = \sum_{|S|=2} |\widehat{\mathbb{1}_A}(S) \widehat{\mathbb{1}_B}(S)| \leq \left( \sum_{|S|=2} \widehat{\mathbb{1}_A}(S)^2 \right)^{1/2} \left( \sum_{|S|=2} \widehat{\mathbb{1}_B}(S)^2 \right)^{1/2}.$$

We then use a well known inequality on Fourier coefficients. It appears as “Level-k Inequalities” in Ryan Odonnell’s book [12, Chapter 9.5] and it states that for a function  $f : \{-1, 1\}^n \rightarrow \{0, 1\}$  with expectation  $\mathbb{E}[f] = \alpha$ , for any  $k \leq 2 \ln(1/\alpha)$ , we have  $\sum_{|S|=k} (\widehat{f}(S))^2 \leq$

$O(\alpha^2 \ln^k(1/\alpha))$ . For simplicity, assume that  $|A| = |B| = 2^{(n-c)/2}$ . The previous paragraphs and the assumption that  $\mathbb{E}[\mathbb{1}_A], \mathbb{E}[\mathbb{1}_B] = \frac{1}{2^{c/2}}$  imply that the advantage of a rectangle is at most  $O\left(\frac{1}{\sqrt{N}} \frac{1}{2^c} c^2\right)$ . Adding the contributions from all rectangles implies that the advantage of a cost  $c$  protocol is at most  $O\left(\frac{c^2}{\sqrt{N}}\right)$ . This implies that every protocol of cost  $o(N^{1/4})$  has advantage at most  $o(1)$  in distinguishing between  $\mathcal{U}$  and  $\mathcal{V}$ . The bound in the case of a general partition follows from a concavity argument. This completes the proof overview.

### Open Questions

We conjecture that the correct randomized communication complexity for this problem is  $\tilde{\Omega}(\sqrt{N})$  and that the above proof technique can be strengthened to show this. One way to do this would be to show a better bound on the Fourier coefficients of deterministic communication protocols. In particular, it would suffice to show a bound of  $O(c \cdot \text{poly} \log(N))$  on the second level Fourier mass of protocols with  $c$ -bits of communication.

## 2 Preliminaries

For  $n \in \mathbb{N}$ , let  $[n]$  denote the set  $\{1, 2, \dots, n\}$ . For a vector  $x \in \mathbb{R}^n$  and  $i \in [n]$ , we refer to the  $i$ -th coordinate of  $x$  by either  $x(i)$  or  $x_i$ . For a subset  $S \subset [n]$ , let  $x_S \in \mathbb{R}^{|S|}$  be the restriction of  $x$  to coordinates in  $S$ . For vectors  $x, y \in \mathbb{R}^n$ , let  $x \cdot y$  be their point-wise product, i.e., the vector whose  $i$ -th coordinate is  $x_i y_i$ . Let  $\langle x | y \rangle$  be the real inner product  $\sum_i x_i y_i$  between  $x$  and  $y$ . Let  $v^{-1}$  be the coordinate-wise inverse of a vector  $v \in (\mathbb{R} \setminus 0)^n$ .

### 2.1 Fourier Analysis on the Boolean Hypercube

The set  $\{-1, 1\}^n$  is referred to as the Boolean hypercube in  $n$  dimensions, or the  $n$ -dimensional hypercube. We sometimes refer to it by  $\{0, 1\}^n$ , using the bijection mapping  $(x_1, \dots, x_n) \in \{0, 1\}^n$  to  $((-1)^{x_1}, \dots, (-1)^{x_n}) \in \{-1, 1\}^n$ . We also represent elements of  $\{-1, 1\}^n$  by elements of  $[2^n]$ , using the bijection mapping  $((-1)^{x_1}, \dots, (-1)^{x_n}) \in \{-1, 1\}^n$  to  $1 + \sum_{i=1}^n 2^{i-1} x_i \in [2^n]$ . We typically use  $N$  to denote  $2^n$ . Let  $\mathbb{I}_n$  denote the  $n \times n$  identity matrix. Let  $U_n$  be the uniform distribution on  $\{-1, 1\}^n$ . Let  $\mathcal{F} := \{f : \{-1, 1\}^n \rightarrow \mathbb{R}\}$  be the set of all functions from the  $n$ -dimensional hypercube to the real numbers. This is a real vector space of dimension  $2^n$ . We define an inner product over this space. For every  $f, g \in \mathcal{F}$ , let

$$\langle f, g \rangle := \mathbb{E}_{x \sim U_n} [f(x)g(x)].$$

For any universe  $\mathcal{U}$  and a subset  $S \subseteq \mathcal{U}$ , we use  $\mathbb{1}_S : \mathcal{U} \rightarrow \{0, 1\}$  to refer to the indicator function of  $S$  defined by:

$$\mathbb{1}_S(x) := \begin{cases} 1 & \text{if } x \in S \\ 0 & \text{otherwise.} \end{cases}$$

The set of indicator functions of singleton sets  $\{\mathbb{1}_{\{a\}} : a \in \{-1, 1\}^n\}$  is the standard orthogonal basis for  $\mathcal{F}$ . The character functions form an orthonormal basis for  $\mathcal{F}$ . These are functions  $\chi_S : \{-1, 1\}^n \rightarrow \{-1, 1\}$  associated to every set  $S \subseteq [n]$  and are defined at every point  $x \in \{-1, 1\}^n$  by  $\chi_S(x) := \prod_{i \in S} x_i$ . For a function  $f \in \mathcal{F}$ , and  $S \subseteq [n]$ , we define its  $S$ -th Fourier coefficient to be  $\hat{f}(S) := \mathbb{E}_{x \sim U_n} [f(x) \chi_S(x)]$ . Every  $f \in \mathcal{F}$  can be expressed as  $f(x) = \sum_{S \subseteq [n]} \hat{f}(S) \chi_S(x)$ . For  $f : \{-1, 1\}^n \rightarrow \mathbb{R}$  and  $k \in \{0, \dots, n\}$ , let  $L_k(f) := \sum_{S \subseteq [n], |S|=k} |\hat{f}(S)|$  refer to the level  $k$  Fourier mass of  $f$ .

Given functions  $f, g : \{-1, 1\}^n \rightarrow \mathbb{R}$ , their convolution  $f * g : \{-1, 1\}^n \rightarrow \mathbb{R}$  is defined as  $f * g(x) := \mathbb{E}_{y \sim U_n} [f(y)g(y \cdot x)]$ . A standard fact about convolution of functions is that  $\widehat{f * g}(S) = \widehat{f}(S)\widehat{g}(S)$  for all  $S \subseteq [n]$ .

## 2.2 Quantum Computation

Let  $\mathcal{H}_m$  be the Hilbert space of dimension  $2^m$  defined by the complex span of the orthonormal basis  $\{|x\rangle : x \in \{-1, 1\}^m\}$ . We sometimes express these basis elements by integers  $\{|i\rangle : i \in [2^m]\}$  by the same correspondence as before.

Fix any universal set of gates for quantum computation. A quantum circuit  $Q : \{-1, 1\}^n \rightarrow \{-1, 1\}^m$  of space  $S$  consists of a set of  $S$  registers, the first  $n$  of which are initialized to  $|x\rangle$ , the input, while the rest are initialized to  $|1\rangle$ . It further consists of a sequence of operators chosen from the universal set of gates, along with a description of which register they act on. The size of a circuit is the number of operators. The output of a circuit is defined to be the contents of the first  $m$  registers. Since we want the output to be Boolean, we assume that the circuit measures these registers and returns the outcome. Thus, a quantum circuit is inherently probabilistic.

We now describe quantum circuits with *query or oracle* access. In this model, all registers are initialized to  $|1\rangle$  and the input  $x \in \{-1, 1\}^n$  is not written into the registers. Instead, it is compactly presented to the algorithm using a blackbox, a device which for every index  $i \in [n]$ , returns  $x(i)|i\rangle$  when it is given  $|i\rangle$  as input. More precisely, for every possible input  $x \in \{-1, 1\}^n$ , the oracle to  $x$  is the linear operator  $O_x : \mathcal{H}_{\lceil \log n \rceil} \rightarrow \mathcal{H}_{\lceil \log n \rceil}$  which maps the basis states  $|i\rangle$  to  $x_i|i\rangle$  whenever  $i \in [n]$  and otherwise leaves it fixed. This indeed restricts to a unitary operation on pure states, as its action on the basis states is described by a diagonal  $\{-1, 1\}$ -matrix. This serves as the quantum analogue of a classical oracle, which is a blackbox that returns  $x(i)$  on input  $i \in [n]$ . A *quantum circuit with oracle access to inputs* is a quantum circuit that is allowed to use the  $O_x$  operator in addition to the usual operators, where  $x$  is the input to the computation. The *size* of the circuit is the total number of gates used from the universal gate set plus the number of oracle queries used. We say that an algorithm is *efficient*, if it is described by a circuit of size at most  $\text{poly} \log n$  with oracle access to inputs. Note that it is possible to use the oracle  $O_x$  to explicitly write down the input  $x$  into  $n$  registers, however, this requires  $n$  oracle calls and  $n$  registers. It is often the case that this step is unnecessary.

## 2.3 Classical & Quantum Communication Complexity

Let  $f : \{-1, 1\}^n \times \{-1, 1\}^m \rightarrow \{-1, 1\}$  be a partial Boolean function. Alice (respectively Bob) receives a private input  $x \in \{-1, 1\}^n$  (respectively  $y \in \{-1, 1\}^m$ ) and the players' goal is to compute  $f(x, y)$  if  $(x, y)$  is in the support of  $f$ , while exchanging as few bits as possible. An input  $(x, y)$  is said to be a YES (respectively NO) instance if  $f(x, y) = -1$  (respectively if  $f(x, y) = 1$ ). We assume familiarity with *bounded-error randomized* and *quantum communication complexity*. In quantum communication with *entanglement*, Alice and Bob are given  $m$  independent copies of the Bell state for some  $m \in \mathbb{N}$ . In this case, we say that Alice and Bob share  $m$  bits of entanglement. In the *simultaneous* model of communication, Alice and Bob are not allowed to exchange messages with each other. Instead, they are allowed one round of communication with a referee Charlie, to whom they can only send qubits. The referee then performs some quantum operation on the qubits he receives and returns a bit as the output. As before, a bounded-error simultaneous protocol computes  $f$  if for all  $(x, y)$  in the support of  $f$ , with probability at least  $2/3$ , the referee's output agrees with  $f(x, y)$ . The cost is the total number of qubits that Alice and Bob send the referee.

Note that in each of the above models of communication, every function  $f : \{-1, 1\}^n \times \{-1, 1\}^m \rightarrow \{-1, 1\}$  has communication cost at most  $n + m$ , since the players may simply reveal their entire inputs. Hence, a small cost protocol is one in which the communication cost is at most  $\text{poly} \log(n + m)$ .

A communication protocol is said to be *efficient* if it can be implemented by a small size circuit with oracle access  $O_x, O_y$  to the inputs  $x, y$ . Protocols with small communication cost are not necessarily efficient, as they may require computationally intensive processing on the messages, or they may require the players to make several probes into their inputs.

## 2.4 The Forrelation Distribution $\mathcal{D}$

Let  $x \sim \mathcal{D}$  refer to a random variable  $x$  distributed according to the probability distribution  $\mathcal{D}$ . We use  $\mathbb{P}_{\mathcal{D}}$  to refer to the probability measure associated with  $\mathcal{D}$  and  $\mathbb{P}_{x \sim \mathcal{D}}(E(x))$  to refer to the probability of event  $E(x)$  when  $x \sim \mathcal{D}$ . For an event  $E(x)$ , we will denote by  $\mathcal{D}|E(x)$  (respectively  $\mathcal{D}|\neg E(x)$ ), the distribution  $\mathcal{D}$  conditioned on the event  $E(x)$  occurring (respectively, the event  $E(x)$  not occurring). Let  $\epsilon \geq 0$  be a parameter,  $f(x) : \mathbb{R}^n \rightarrow \mathbb{R}$  a function and  $\mathcal{D}$  a distribution on  $\mathbb{R}^n$ . We say that  $\mathcal{D}$  fools  $f$  with error  $\epsilon$  if  $\left| \mathbb{E}_{x \sim U_n}[f(x)] - \mathbb{E}_{x \sim \mathcal{D}}[f(x)] \right| \leq \epsilon$ .

Let  $\mathcal{N}(\mu, \sigma^2)$  denote a Gaussian distribution of mean  $\mu \in \mathbb{R}$  and variance  $\sigma^2 \in \mathbb{R}_{\geq 0}$ . We will repeatedly use the following standard facts about Gaussians.

- Gaussian Concentration inequality: For  $X \sim \mathcal{N}(\mu, \sigma^2)$ , we have  $\mathbb{P}[|X - \mu| \geq a] \leq e^{-\frac{a^2}{2\sigma^2}}$ .
- The sum  $\sum_i X_i$  of independent Gaussians  $X_i \sim \mathcal{N}(\mu_i, \sigma_i^2)$  is distributed according to  $\mathcal{N}(\sum_i \mu_i, \sum_i \sigma_i^2)$ .

Let  $N = 2^n$ . The Hadamard matrix  $H_N$  is an  $N \times N$  unitary matrix. We let  $x$  and  $y$  in  $\{0, 1\}^n$  index rows and columns of  $H_N$  respectively. The entries of  $H_N$  are as follows.

$$H_N(x, y) := \begin{cases} \frac{1}{\sqrt{N}} & \text{if } \sum_i x_i y_i \bmod 2 = 0 \\ \frac{-1}{\sqrt{N}} & \text{otherwise} \end{cases}$$

Let  $x = (x_1, x_2)$  for  $x_1, x_2 \in \{-1, 1\}^N$ . We define the forrelation of  $x$  as the correlation between the second half  $x_2$  and the Hadamard transform of the first half  $x_1$ .

$$\text{forr}(x) := \left\langle \frac{1}{\sqrt{N}} H_N(x_1) \middle| \frac{1}{\sqrt{N}} x_2 \right\rangle$$

We state the definition of the forrelation distribution, as defined in [15]. Fix a parameter  $\epsilon = \frac{1}{50 \ln N}$ . We first define an auxilliary Gaussian distribution  $\mathcal{G}$  generated by sampling the first half uniformly at random and letting the second half be the Hadamard transform of the first half. More precisely,

1. Sample  $x_1, \dots, x_N \sim \mathcal{N}(0, \epsilon)$ .
2. Let  $y = H_N x$ .
3. Output  $(x, y)$ .

This is a Gaussian random variable in  $2N$  dimensions of mean 0 and covariance matrix given by

$$\epsilon \begin{bmatrix} \mathbb{I}_N & H_N \\ H_N & \mathbb{I}_N \end{bmatrix}.$$

Let  $\text{trnc} : \mathbb{R} \rightarrow [-1, 1]$  be the truncation function which on input  $\alpha > 1$ , returns 1,  $\alpha < -1$  returns  $-1$  and otherwise returns  $\alpha$ . This naturally defines a function  $\text{trnc} : \mathbb{R}^{2N} \rightarrow [-1, 1]^{2N}$  obtained by truncating each coordinate. We now define a distribution  $\mathcal{D}$  over  $\{-1, 1\}^{2N}$  generated from  $\mathcal{G}$  by truncating the sample and then independently sampling each coordinate as follows.

1. Sample  $z \in \mathcal{G}$ .
2. For each coordinate  $i \in [2N]$  independently, let  $z'_i = 1$  with probability  $\frac{1+\text{trnc}(z_i)}{2}$  and  $-1$  with probability  $\frac{1-\text{trnc}(z_i)}{2}$ .
3. Output  $z'$ .

We refer to the distribution  $\mathcal{D}$  as the *forrelation* distribution. We state Claim 6.3 from [15] which implies that a vector drawn from this distribution has large forrelation on expectation. The proof is omitted.

► **Lemma 2.** *Let  $\mathcal{D}$  be the forrelation distribution as defined previously. Then,*

$$\mathbb{E}_{z \sim \mathcal{D}}[\text{forr}(z)] \geq \frac{\epsilon}{2}.$$

## 2.5 Multilinear Functions on $\mathcal{D}$

Given a function  $f : \{-1, 1\}^n \rightarrow \mathbb{R}$ , there is a unique multilinear polynomial  $\tilde{f} : \mathbb{R}^n \rightarrow \mathbb{R}$  which agrees with  $f$  on  $\{-1, 1\}^n$ . This polynomial is called the multilinear extension of  $f$ . The multilinear extension of any character function  $\chi_S(x)$  is precisely  $\prod_{i \in S} x_i$ . The multilinear extension  $\tilde{f}$  of  $f$  satisfies  $\tilde{f}(x) = \sum_{S \subseteq [n]} \hat{f}(S) \prod_{i \in S} x_i$  for all  $x \in \mathbb{R}^n$ . We sometimes identify  $f$  with its multilinear extension. The main content of this section is that bounded multilinear functions have similar expectations under  $\mathcal{G}$  and under  $\mathcal{D}$ .

▷ **Claim 3.** Let  $F : \mathbb{R}^{2N} \rightarrow \mathbb{R}$  be any multilinear function  $F = \sum_S \hat{F}(S) \chi_S$ . Then,

$$\mathbb{E}_{z' \sim \mathcal{D}}[F(z')] = \mathbb{E}_{z \sim \mathcal{G}}[F(\text{trnc}(z))].$$

The proof of this claim is identical to that of Equation (2) in [15]. The details can be found in the full version of this paper. The following claim states that  $\mathbb{E}_{z \sim \mathcal{G}}[F(\text{trnc}(z))]$  is pretty close to  $\mathbb{E}_{z \sim \mathcal{G}}[F(z)]$  for a bounded multilinear function  $F$ . Its proof is identical to that in [15], so we omit it. The underlying idea is that  $\epsilon$  is small, so the random variable  $z \sim \mathcal{G}$  has an exponentially decaying norm, furthermore, bounded multilinear functions  $F$  on  $\{-1, 1\}^{2N}$  cannot grow faster than exponentially in the norm of the argument.

▷ **Claim 4.** Let  $F(z)$  be any multilinear polynomial mapping  $\{-1, 1\}^{2N}$  to  $[-1, 1]$ . Let  $z_0 \in [-1/2, 1/2]^{2N}$ ,  $p \leq \frac{1}{2}$  and  $N > 1$ . Then,

$$\mathbb{E}_{z \sim \mathcal{G}}[|F(\text{trnc}(z_0 + pz)) - F(z_0 + pz)|] \leq \frac{8}{N^5}.$$

We remark that the bound in [15] is  $\frac{8}{N^2}$ . The improved bound of  $\frac{8}{N^5}$  in Claim 4 follows from our choice of  $\epsilon = \frac{1}{50 \ln N}$ , as opposed to  $\epsilon = \frac{1}{24 \ln N}$  as in [15].

## 2.6 Moments of $\mathcal{G}$

In this section we state some facts about the moments of the forrelation distribution that will be useful later. We use the following notation to refer to the moments of  $\mathcal{G}$ .

$$\hat{\mathcal{G}}(S, T) := \mathbb{E}_{(x, y) \sim \mathcal{G}} \left[ \prod_{i \in S} x_i \prod_{j \in T} y_j \right]$$

The following claim and its proof are analogous to Claim 4.1 in [15].

▷ **Claim 5.** Let  $S, T \subseteq [N]$  and  $i, j \in [N]$ . Let  $k_1 = |S|, k_2 = |T|$ . Then,

1.  $\widehat{\mathcal{G}}(\{i\}, \{j\}) = \epsilon N^{-1/2} (-1)^{\langle i, j \rangle}$ .
2.  $\widehat{\mathcal{G}}(S, T) = 0$  if  $k_1 \neq k_2$ .
3.  $|\widehat{\mathcal{G}}(S, T)| \leq \epsilon^k k! N^{-k/2}$  if  $k = k_1 = k_2$ .
4.  $|\widehat{\mathcal{G}}(S, T)| \leq \epsilon^{|S|}$  for all  $S, T$ .

### 3 The Forrelation Communication Problem

In this section we formally state the main theorems of this paper.

Let  $\epsilon = \frac{1}{50 \ln N}$  be the parameter as before, defining the forrelation distribution. We restate Theorem 3.

► **Theorem 3.** Consider the following distribution. A string  $z \in \{-1, 1\}^{2N}$  is drawn from the forrelation distribution,  $x \sim U_{2N}$  is drawn uniformly and  $y := x \cdot z$ . Alice gets  $x$  and Bob gets  $y$ . Given any deterministic communication protocol  $C : \{-1, 1\}^{2N} \times \{-1, 1\}^{2N} \rightarrow \{-1, 1\}$  of cost  $c \geq 1$ , its expectation when the inputs are drawn from this distribution is close to when the inputs are drawn from the uniform distribution. That is,

$$\left| \mathbb{E}_{\substack{x \sim U_{2N} \\ z \sim \mathcal{D}}} [C(x, x \cdot z)] - \mathbb{E}_{x, y \sim U_{2N}} [C(x, y)] \right| \leq O\left(\frac{c^2}{N^{1/2}}\right).$$

In other words, no deterministic protocol of cost  $o(N^{1/4})$  has considerable advantage in distinguishing the above distribution from the uniform distribution.

► **Definition 6 (The Forrelation Problem).** Alice is given  $x \in \{-1, 1\}^{2N}$  and Bob is given  $y \in \{-1, 1\}^{2N}$ . Their goal is to compute the partial boolean function  $F$  defined as follows.

$$F(x, y) = \begin{cases} -1 & \text{if } \text{forr}(x \cdot y) \geq \epsilon/4 \\ 1 & \text{if } \text{forr}(x \cdot y) \leq \epsilon/8. \end{cases}$$

We restate Theorem 1 and Theorem 2.

► **Theorem 1.** The forrelation problem can be solved in the quantum simultaneous with entanglement model with  $O(\log^3 N)$  bits of communication, when Alice and Bob are given access to  $O(\log^3 N)$  bits of shared entanglement. Moreover, the protocol is efficient, as it can be implemented by a  $O(\log^3 N)$  size quantum circuit with oracle access to inputs.

The upper bound on the quantum communication complexity of the forrelation problem follows from the fact that the XOR of the inputs can be computed by a simultaneous-message quantum protocol, when the players share entanglement, and the fact that  $\text{forr}(\circ)$  can be estimated by a small size quantum circuit [1, 2, 15]. The proof of Theorem 1 can be found in the full version of this paper.

► **Theorem 2.** The randomized bounded-error interactive communication cost of the forrelation problem is  $\Omega(N^{\frac{1}{4}})$ .

The lower bound on the randomized communication complexity of the forrelation problem follows from Theorem 3 and Lemma 2. The proof of Theorem 2 can be found in the full version of this paper. We now describe the proof of Theorem 3.

#### 4 Proof of Theorem 3 : Distributional Lower Bound

Let  $C : \{-1, 1\}^{2N} \times \{-1, 1\}^{2N} \rightarrow \{-1, 1\}$  be any deterministic protocol of cost at most  $c$ . Let  $D : \{-1, 1\}^{2N} \times \{-1, 1\}^{2N} \rightarrow \{-1, 1\}$  be defined as follows. For  $x, z \in \{-1, 1\}^{2N}$ ,

$$D(x, z) := C(x, x \cdot z).$$

We will also use  $D(x, z)$  to refer to its multilinear extension. Note that our goal is to show that the function  $\mathbb{E}_{x \sim U_{2N}} [D(x, z)]$  of  $z$  is fooled by  $\mathcal{D}$ . Towards this, we will prove that it is fooled by  $p\mathcal{G}$  for small  $p$ . This approach was first used in [6] and is analogous to Claim 7.2 in [15].

► **Lemma 7.** *Let  $p \leq \frac{1}{2N}$  and let  $C(x, y)$  be any deterministic protocol of cost  $c \geq 1$  for the forrelation problem. As before, let  $D(x, z) : \mathbb{R}^{2N} \times \mathbb{R}^{2N} \rightarrow \mathbb{R}$  refer to the multilinear extension of  $C(x, x \cdot z)$ . Let  $P \in [-p, p]^{2N}$ . Then,*

$$\left| \mathbb{E}_{\substack{z \sim P \cdot \mathcal{G} \\ x \sim U_{2N}}} [D(x, z)] - \mathbb{E}_{z, x \sim U_{2N}} [D(x, z)] \right| \leq \frac{120\epsilon c^2 p^2}{\sqrt{N}} + p^4 N^3.$$

**Proof of Lemma 7.** We begin by observing some properties of the distribution  $P \cdot \mathcal{G}$ . The sample  $z \sim P \cdot \mathcal{G}$  is obtained by scaling the  $i$ -th coordinate of  $z' \sim \mathcal{G}$  by  $P_i$  for each  $i \in [2N]$ . This implies that for all  $S \subseteq [2N]$ ,

$$\mathbb{E}_{z \sim P \cdot \mathcal{G}} [\chi_S(z)] = \left( \prod_{i \in S} P_i \right) \mathbb{E}_{z \sim \mathcal{G}} [\chi_S(z)]. \quad (1)$$

Part (2.) of Claim 5 implies that the odd moments of  $\mathcal{G}$  are zero. Equation (1) implies that this is also true for  $P \cdot \mathcal{G}$ . That is, for all  $S \subseteq [2N]$ ,

$$|S| \text{ is odd} \implies \mathbb{E}_{z \sim P \cdot \mathcal{G}} [\chi_S(z)] = 0. \quad (2)$$

Part (3.) of Claim 5 implies that for  $S \subseteq [2N]$ ,  $|S| = 2k$ , the  $S$ -th moment  $\mathbb{E}_{z \sim \mathcal{G}} \chi_S(z)$  is at most  $\epsilon^k k! N^{-k/2}$  in magnitude. Along with equation (1), this implies that for  $k \in \mathbb{N}$ ,

$$|S| = 2k \implies \left| \mathbb{E}_{z \sim P \cdot \mathcal{G}} [\chi_S(z)] \right| \leq \left( \prod_{i \in S} P_i \right) \epsilon^k k! N^{-k/2} \leq p^{2k} \epsilon^k k! N^{-k/2}. \quad (3)$$

We now proceed with the proof of the lemma. Let

$$\Delta := \left| \mathbb{E}_{\substack{z \sim P \cdot \mathcal{G} \\ x \sim U_{2N}}} [D(x, z)] - \mathbb{E}_{z, x \sim U_{2N}} [D(x, z)] \right|.$$

Note that this is the quantity we wish to bound in the lemma. For ease of notation, let  $H : \{-1, 1\}^{2N} \rightarrow [-1, 1]$  be defined at every point  $z \in \{-1, 1\}^{2N}$  by

$$H(z) := \mathbb{E}_{x \sim U_{2N}} [D(x, z)].$$

We identify  $H(z)$  with its multilinear extension. Note that by uniqueness of multilinear extensions, the above equality holds even for  $z \in \mathbb{R}^{2N}$ . This implies that

$$\mathbb{E}_{\substack{z \sim P \cdot \mathcal{G} \\ x \sim U_{2N}}} [D(x, z)] = \mathbb{E}_{z \sim P \cdot \mathcal{G}} [H(z)] \quad \text{and} \quad \mathbb{E}_{z, x \sim U_{2N}} [D(x, z)] = \mathbb{E}_{z \sim U_{2N}} [H(z)].$$

This, along with the definition of  $\Delta$  implies that

$$\Delta = \left| \mathbb{E}_{z \sim P \cdot \mathcal{G}}[H(z)] - \mathbb{E}_{z \sim U_{2N}}[H(z)] \right|.$$

Note that  $H(z) = \sum_S \hat{H}(S) \chi_S(z)$  for all  $z \in \mathbb{R}^{2N}$ . This implies that for all distributions  $\mathcal{Z}$  on  $\mathbb{R}^{2N}$ , we have  $\mathbb{E}_{z \sim \mathcal{Z}}[H(z)] = \sum_S \hat{H}(S) \mathbb{E}_{z \sim \mathcal{Z}}[\chi_S(z)]$ . This implies that

$$\Delta = \left| \sum_{S \subseteq [2N]} \hat{H}(S) \left( \mathbb{E}_{z \sim P \cdot \mathcal{G}}[\chi_S(z)] - \mathbb{E}_{z \sim U_{2N}}[\chi_S(z)] \right) \right|.$$

For any probability distribution, the moment corresponding to the empty set is 1 by definition. For all non empty sets  $S$ , we have  $\mathbb{E}_{z \sim U_{2N}}[\chi_S(z)] = 0$ . Using this fact in the above equality, along with the triangle inequality, we have

$$\Delta = \left| \sum_{\emptyset \neq S \subseteq [2N]} \hat{H}(S) \mathbb{E}_{z \sim P \cdot \mathcal{G}}[\chi_S(z)] \right| \leq \sum_{\emptyset \neq S \subseteq [2N]} \left| \hat{H}(S) \right| \left| \mathbb{E}_{z \sim P \cdot \mathcal{G}}[\chi_S(z)] \right|.$$

We use the bounds from (2) and (3) on the moments of  $P \cdot \mathcal{G}$  to derive the following.

$$\begin{aligned} \Delta &\leq \sum_{\substack{|S|=2k \\ k \geq 1}} \left| \hat{H}(S) \right| p^{2k} \epsilon^k k! N^{-k/2} \\ &= \sum_{k \geq 1} L_{2k}(H) p^{2k} \epsilon^k k! N^{-k/2} \end{aligned}$$

We upper bound  $L_{2k}(H)$  by  $\binom{2N}{2k}$  when  $k \geq 2$ . This implies that

$$\begin{aligned} \Delta &\leq L_2(H) \frac{\epsilon p^2}{\sqrt{N}} + \sum_{k \geq 2} \binom{2N}{2k} p^{2k} \epsilon^k k! N^{-k/2} \\ &\leq L_2(H) \frac{\epsilon p^2}{\sqrt{N}} + \sum_{k \geq 2} \frac{2^{2k} N^{2k}}{(2k)!} p^{2k} \epsilon^k k! N^{-k/2} \\ &\leq L_2(H) \frac{\epsilon p^2}{\sqrt{N}} + \sum_{k \geq 2} N^{3k/2} p^{2k} 4^k \epsilon^k. \end{aligned}$$

In the summation  $\sum_{k \geq 2} N^{3k/2} p^{2k} 4^k \epsilon^k$ , we see that every successive term is smaller than the previous by a factor of at least  $1/4$ . This is because the assumption  $p \leq \frac{1}{2N}$  implies that  $p^2 N^{3/2} \leq p^2 N^2 \leq \frac{1}{4}$  and because  $4\epsilon \leq 1$ . Thus, we can bound this summation by twice the first term, which is  $16p^4 N^3 \epsilon^2$ . This implies that

$$\Delta \leq L_2(H) \frac{\epsilon p^2}{\sqrt{N}} + 32p^4 N^3 \epsilon^2.$$

Since  $\epsilon = \frac{1}{50 \ln N} \leq \frac{1}{32}$ , we may bound  $32p^4 N^3 \epsilon^2$  by  $p^4 N^3$ . This implies that

$$\Delta \leq L_2(H) \frac{\epsilon p^2}{\sqrt{N}} + p^4 N^3.$$

We restate Claim 1 which provides a bound on  $L_2(H)$ .

▷ **Claim 1.** Let  $C(x, y) : \{-1, 1\}^{2N} \times \{-1, 1\}^{2N} \rightarrow \{-1, 1\}$  be any deterministic protocol of cost  $c \geq 1$ , let  $D(x, z) : \mathbb{R}^{2N} \times \mathbb{R}^{2N} \rightarrow \mathbb{R}$  refer to the unique multilinear extension of  $C(x, x \cdot z)$  and  $H : \mathbb{R}^{2N} \rightarrow \mathbb{R}$  be defined by  $H(z) = \mathbb{E}_{x \sim U_{2N}} D(x, z)$ . Then,

$$L_2(H) \triangleq \sum_{|S|=2} |\widehat{H}(S)| \leq 120c^2.$$

This claim along with the preceding inequality implies that

$$\Delta \leq 120c^2 \frac{\epsilon p^2}{\sqrt{N}} + p^4 N^3.$$

This completes the proof of Lemma 7. ◀

**Proof of Claim 1.** In order to bound the level-2 Fourier mass of  $H$ , we will use the following lemma. Its statement and proof appear as “Level- $k$  Inequalities” on Page 259 of “Analysis of Boolean Functions” [12].

► **Lemma 8 (Level- $k$  Inequalities).** *Let  $F : \{-1, 1\}^n \rightarrow \{0, 1\}$  have mean  $\mathbb{E}[F] = \alpha$  and let  $k \in \mathbb{N}$  be at most  $2 \ln(1/\alpha)$ . Then,*

$$\sum_{|S|=k} \left( \widehat{F}(S) \right)^2 \leq \alpha^2 \left( \frac{2e}{k} \ln(1/\alpha) \right)^k.$$

We now show the desired bound on  $L_2(H)$ . Since  $C$  is a deterministic protocol of cost at most  $c$ , it induces a partition of the input space  $\{-1, 1\}^{2N} \times \{-1, 1\}^{2N}$  into at most  $2^c$  rectangles. Let  $\mathcal{P}$  be this partition and let  $A \times B$  index rectangles in  $\mathcal{P}$ , where  $A$  (respectively  $B$ ) is the set of Alice’s (respectively Bob’s) inputs compatible with the rectangle. Let  $C(A \times B) \in \{-1, 1\}$  be the output of the protocol on inputs from a rectangle  $A \times B \in \mathcal{P}$ . For all  $x, y \in \{-1, 1\}^{2N}$ , we have

$$C(x, y) = \sum_{A \times B \in \mathcal{P}} C(A \times B) \mathbb{1}_A(x) \mathbb{1}_B(y).$$

By definition,  $D(x, z) = C(x, x \cdot z)$ . This implies that

$$D(x, z) = \sum_{A \times B \in \mathcal{P}} C(A \times B) \mathbb{1}_A(x) \mathbb{1}_B(x \cdot z).$$

Taking an expectation over  $x \sim U_{2N}$  of the above identity implies that

$$H(z) \triangleq \mathbb{E}_{x \sim U_{2N}} [D(x, z)] = \sum_{A \times B \in \mathcal{P}} C(A \times B) (\mathbb{1}_A * \mathbb{1}_B)(z).$$

This implies that for any  $S \subseteq [n]$ , we have

$$\widehat{H}(S) = \sum_{A \times B \in \mathcal{P}} C(A \times B) \widehat{\mathbb{1}_A * \mathbb{1}_B}(S) = \sum_{A \times B \in \mathcal{P}} C(A \times B) \widehat{\mathbb{1}_A}(S) \widehat{\mathbb{1}_B}(S).$$

We thus obtain

$$\begin{aligned} L_2(H) &= \sum_{|S|=2} \left| \widehat{H}(S) \right| \\ &= \sum_{|S|=2} \left| \sum_{A \times B \in \mathcal{P}} C(A \times B) \widehat{\mathbb{1}_A}(S) \widehat{\mathbb{1}_B}(S) \right| \\ &\leq \sum_{A \times B \in \mathcal{P}} \sum_{|S|=2} |\widehat{\mathbb{1}_A}(S)| |\widehat{\mathbb{1}_B}(S)|. \end{aligned}$$

■ **Figure 1** Plot of the function  $y = x \left(\ln \frac{1}{x}\right)^2$ .

We apply Cauchy Schwarz to the term  $\sum_{|S|=2} |\widehat{\mathbb{1}_A}(S)| |\widehat{\mathbb{1}_B}(S)|$  to obtain

$$L_2(H) \leq \sum_{A \times B \in \mathcal{P}} \left( \sum_{|S|=2} \widehat{\mathbb{1}_A}(S)^2 \right)^{1/2} \left( \sum_{|S|=2} \widehat{\mathbb{1}_B}(S)^2 \right)^{1/2}.$$

For ease of notation, let  $\mu(A) = \frac{|A|}{2^{2N}}$  denote the measure of a set  $A \subseteq \{-1, 1\}^{2N}$  under  $U_{2N}$ . We first ensure that for each rectangle  $A \times B \in \mathcal{P}$ , we have  $\mu(A) \leq \frac{1}{e}$  and  $\mu(B) \leq \frac{1}{e}$ . We may do this by adding 2 extra bits of communication for each player. For  $k = 2$ , we have  $k = 2 \ln(e) \leq 2 \ln \frac{1}{\mu(A)}$  and  $k \leq 2 \ln \frac{1}{\mu(B)}$ . We apply Lemma 8 on the indicator functions  $\mathbb{1}_A$  and  $\mathbb{1}_B$  for  $k = 2$  to obtain

$$\sum_{|S|=2} \left( \widehat{\mathbb{1}_A}(S) \right)^2 \leq \mu(A)^2 \left( e \ln(1/\mu(A)) \right)^2 \quad \text{and} \quad \sum_{|S|=2} \left( \widehat{\mathbb{1}_B}(S) \right)^2 \leq \mu(B)^2 \left( e \ln(1/\mu(B)) \right)^2.$$

Substituting this in the bound for  $L_2(H)$ , we have

$$L_2(H) \leq e^2 \sum_{A \times B \in \mathcal{P}} \mu(A) \mu(B) \ln \frac{1}{\mu(A)} \ln \frac{1}{\mu(B)}.$$

Let  $\Delta := e^2 \sum_{A \times B \in \mathcal{P}} \mu(A) \mu(B) \ln \frac{1}{\mu(A)} \ln \frac{1}{\mu(B)}$  be the expression in the R.H.S. of the above.

Note that it suffices to upper bound  $\Delta$ . Consider the case when  $\mathcal{P}$  consists of  $2^c$  rectangles  $A \times B$ , each of which satisfies  $\mu(A) = \mu(B) = \frac{1}{2^{c/2}}$ . In this case,  $\Delta$  evaluates to  $e^2 \sum_{A \times B \in \mathcal{P}} \frac{1}{2^c} \left( \frac{c \ln 2}{2} \right)^2 = O(c^2)$ . This proves the lemma in this special case. A similar bound holds for the general case and the proof follows from a concavity argument that we describe now.

Since  $\mu(A), \mu(B) \leq 1$ , we have the following inequality.

$$\begin{aligned} \Delta &\triangleq e^2 \sum_{A \times B \in \mathcal{P}} \mu(A) \mu(B) \ln \frac{1}{\mu(A)} \ln \frac{1}{\mu(B)} \\ &\leq e^2 \sum_{A \times B \in \mathcal{P}} \mu(A) \mu(B) \ln \frac{1}{\mu(A) \mu(B)} \ln \frac{1}{\mu(A) \mu(B)} \\ &= e^2 \sum_{A \times B \in \mathcal{P}} \mu(A \times B) \left( \ln \frac{1}{\mu(A \times B)} \right)^2. \end{aligned}$$

Let  $f : [0, \infty) \rightarrow \mathbb{R}$  be defined by  $f(p) := p \ln(1/p)^2$ . A small calculation shows that  $f$  is a concave function in the interval  $[0, 0.3]$  (see Figure 7). Let  $\alpha_i \in [0, 0.3]$  for  $i \in [k]$ . Jensen's inequality applied to  $f$  states that for  $i \sim [k]$  drawn uniformly at random, we have  $\mathbb{E}_i[f(\alpha_i)] \leq f(\mathbb{E}_i[\alpha_i])$ . This implies that

$$\sum_{i=1}^k \alpha_i \ln(1/\alpha_i)^2 \leq \left( \sum_{i=1}^k \alpha_i \right) \ln \left( \frac{k}{\sum_{i=1}^k \alpha_i} \right)^2.$$

We apply this inequality to the terms in  $\Delta$  by substituting  $\alpha_i$  with  $\mu(A \times B)$ . We may do this since the assumption that  $\mu(A), \mu(B) \leq \frac{1}{e}$  implies that  $\mu(A \times B) \leq \frac{1}{e^2} \leq 0.3$ . This implies that

$$\Delta \leq e^2 \left( \sum_{A \times B \in \mathcal{P}} \mu(A \times B) \right) \ln \left( \frac{2^{c+4}}{\sum_{A \times B \in \mathcal{P}} \mu(A \times B)} \right)^2$$

Since  $\sum_{A \times B \in \mathcal{P}} \mu(A \times B) = 1$ , we have

$$\Delta \leq e^2 (c+4)^2 (\ln 2)^2 \leq 120c^2.$$

This completes the proof of Claim 1.  $\triangleleft$

We now show that an analogue of Lemma 7 holds for restricted protocols, similarly to Claim 7.3 in [15].

► **Lemma 9.** *Let  $p \leq \frac{1}{4N}$  and  $C(x, y)$  be any deterministic protocol of cost  $c \geq 1$  for the forrelation problem. As before, let  $D(x, z) : \mathbb{R}^{2N} \times \mathbb{R}^{2N} \rightarrow \mathbb{R}$  refer to the multilinear extension of  $C(x, x \cdot z)$ . Let  $z_0 \in [-1/2, 1/2]^{2N}$ . Then,*

$$\left| \mathbb{E}_{\substack{z \sim p\mathcal{G} \\ x \sim U_{2N}}} [D(x, z_0 + z)] - \mathbb{E}_{z, x \sim U_{2N}} [D(x, z_0 + z)] \right| \leq \frac{120\epsilon c^2 (2p)^2}{\sqrt{N}} + (2p)^4 N^3.$$

► **Corollary 10.** *Under the same hypothesis as in Lemma 9,*

$$\left| \mathbb{E}_{z \sim p\mathcal{G}} [D(0, z_0 + z)] - D(0, z_0) \right| \leq \frac{120\epsilon c^2 (2p)^2}{\sqrt{N}} + (2p)^4 N^3.$$

**Proof of Corollary 10 from Lemma 9.** Since  $D(x, z)$  is a multilinear polynomial, for all  $z \in \mathbb{R}^{2N}$ , we have  $\mathbb{E}_{x \sim U_{2N}} [D(x, z)] = D(0, z)$ . This implies that for all  $z_0 \in \mathbb{R}^{2N}$ ,

$$\mathbb{E}_{\substack{z \sim p\mathcal{G} \\ x \sim U_{2N}}} [D(x, z_0 + z)] = \mathbb{E}_{z \sim p\mathcal{G}} [D(0, z_0 + z)].$$

For all  $z_0 \in \mathbb{R}^{2N}$ , since  $\mathbb{E}_{z \sim U_{2N}} [D(0, z_0 + z)] = D(0, z_0)$ , we have

$$\mathbb{E}_{z, x \sim U_{2N}} [D(x, z_0 + z)] = D(0, z_0).$$

The proof of Corollary 10 follows from the above two equalities and Lemma 9.  $\blacktriangleleft$

**Proof of Lemma 9.** Similarly to the approach of [6, 15], we will express  $D(x, z_0 + z)$  as the average output of restricted protocols  $(C \circ \rho)(x, x \cdot z)$ , on which we can use Lemma 7 to derive the result. These restricted protocols roughly correspond to Alice and Bob fixing a common subset  $I \subseteq [2N]$  of their inputs in a predetermined way and then running the original protocol. We formalize this now.

A restriction  $\rho$  of  $\mathbb{R}^{2N}$  is an element of  $\{-1, 1, *\}^{2N}$ . It defines an action  $\rho : \mathbb{R}^{2N} \rightarrow \mathbb{R}^{2N}$  in the following natural way. For any  $z \in \mathbb{R}^{2N}$  and  $i \in [2N]$ ,

$$(\rho(z))(i) := \begin{cases} \rho(i) & \text{if } \rho(i) \in \{-1, 1\} \\ z(i) & \text{otherwise.} \end{cases}$$

Let  $\text{sign} : (\mathbb{R} \setminus 0) \rightarrow \{-1, 1\}$  be the function which maps real numbers to their sign. Given  $z_0 \in [-1/2, 1/2]^{2N}$ , let  $R_{z_0}$  be a distribution over restrictions of  $\mathbb{R}^{2N}$  defined as follows. For each  $i \in [2N]$ , independently, set<sup>1</sup>:

$$\rho(i) := \begin{cases} \text{sign}(z_0(i)) & \text{with probability } |z_0(i)| \\ * & \text{with probability } 1 - |z_0(i)|. \end{cases}$$

Let  $P \in \mathbb{R}^{2N}$  be such that  $P_i := \frac{1}{1-|z_0(i)|}$  for every  $i \in [2N]$ . Note that the assumption of  $z_0 \in [-1/2, 1/2]^{2N}$  ensures that  $P$  is a well defined element of  $[1, 2]^{2N}$ . For any  $z \in \mathbb{R}^{2N}$  and  $i \in [2N]$ , the expected value of the  $i$ th coordinate of  $\rho(z)$  when  $\rho \sim R_{z_0}$  can be computed as follows.

$$\mathbb{E}_{\rho \sim R_{z_0}} [(\rho(z))(i)] = |z_0(i)| \text{sign}(z_0(i)) + (1 - |z_0(i)|)z(i) = z_0(i) + \frac{1}{P_i}z(i)$$

This implies that for any fixed  $x, z \in \mathbb{R}^{2N}$  and  $z_0 \in [-1/2, 1/2]^{2N}$ , since  $D$  is a multilinear function, we have

$$\mathbb{E}_{\rho \sim R_{z_0}} [D(x, \rho(z))] = D(x, \mathbb{E}_{\rho \sim R_{z_0}} [\rho(z)]) = D(x, z_0 + P^{-1} \cdot z).$$

Replacing  $z$  with  $P \cdot z$  in the above equality implies that

$$\mathbb{E}_{\rho \sim R_{z_0}} [D(x, \rho(P \cdot z))] = D(x, z_0 + z).$$

This equality allows us to rewrite the L.H.S. of Lemma 9 as follows.

$$\begin{aligned} \Delta &:= \left| \mathbb{E}_{\substack{z \sim p\mathcal{G}, \\ x \sim U_{2N}}} [D(x, z_0 + z)] - \mathbb{E}_{z, x \sim U_{2N}} [D(x, z_0 + z)] \right| \\ &= \left| \mathbb{E}_{\substack{z \sim pP \cdot \mathcal{G}, \\ x \sim U_{2N}}} \mathbb{E}_{\rho \sim R_{z_0}} [D(x, \rho(z))] - \mathbb{E}_{\substack{z \sim P \cdot U_{2N}, \\ x \sim U_{2N}}} \mathbb{E}_{\rho \sim R_{z_0}} [D(x, \rho(z))] \right| \\ &= \left| \mathbb{E}_{\rho \sim R_{z_0}} \left[ \mathbb{E}_{\substack{z \sim pP \cdot \mathcal{G}, \\ x \sim U_{2N}}} [D(x, \rho(z))] - \mathbb{E}_{\substack{z \sim P \cdot U_{2N}, \\ x \sim U_{2N}}} [D(x, \rho(z))] \right] \right|. \end{aligned}$$

For a multilinear polynomial, its expectation over a product distribution depends only on the mean of that distribution. This allows us to replace the expectation of  $D(x, \rho(z))$  over  $z \sim P \cdot U_{2N}$  by an expectation over  $z \sim U_{2N}$ . We thus obtain

$$\Delta = \left| \mathbb{E}_{\rho \sim R_{z_0}} \left[ \mathbb{E}_{\substack{z \sim pP \cdot \mathcal{G}, \\ x \sim U_{2N}}} [D(x, \rho(z))] - \mathbb{E}_{\substack{z \sim U_{2N}, \\ x \sim U_{2N}}} [D(x, \rho(z))] \right] \right| \quad (4)$$

---

<sup>1</sup> If  $z_0(i)$  is zero, then  $\rho(i) = *$  with probability 1.

For any  $\rho \in \{-1, 1, *\}^{2N}$  and  $u \in \{-1, 1\}^{2N}$ , we define a substitution  $\rho^u : \mathbb{R}^{2N} \rightarrow \mathbb{R}^{2N}$  obtained from  $\rho$  and  $u$  as follows. For any  $x \in \mathbb{R}^{2N}$  and  $i \in [2N]$ ,

$$(\rho^u(x))(i) := \begin{cases} u(i) & \text{if } \rho(i) \in \{-1, 1\} \\ x(i) & \text{otherwise.} \end{cases}$$

This is an action on  $\mathbb{R}^{2N}$  which replaces the values of coordinates specified by  $\rho$ , with values from  $u$ . For every fixed  $\rho$ , as we vary over  $x, u \sim U_{2N}$  the distribution of  $\rho^u(x)$  is exactly  $U_{2N}$ . This implies that for all  $z \in \mathbb{R}^{2N}, \rho \in \{-1, 1, *\}^{2N}$ ,

$$\mathbb{E}_{x \sim U_{2N}} [D(x, \rho(z))] = \mathbb{E}_{x, u \sim U_{2N}} [D(\rho^u(x), \rho(z))].$$

Substituting this in equation (4), we have

$$\Delta = \left| \mathbb{E}_{\rho \sim R_{z_0}} \mathbb{E}_{u \sim U_{2N}} \left[ \mathbb{E}_{\substack{z \sim pP \cdot \mathcal{G}, \\ x \sim U_{2N}}} [D(\rho^u(x), \rho(z))] - \mathbb{E}_{z, x \sim U_{2N}} [D(\rho^u(x), \rho(z))] \right] \right|.$$

Applying Triangle Inequality on the above, we have

$$\Delta \leq \mathbb{E}_{\rho \sim R_{z_0}} \mathbb{E}_{u \sim U_{2N}} \left| \mathbb{E}_{\substack{z \sim pP \cdot \mathcal{G}, \\ x \sim U_{2N}}} [D(\rho^u(x), \rho(z))] - \mathbb{E}_{z, x \sim U_{2N}} [D(\rho^u(x), \rho(z))] \right|. \quad (5)$$

Fix any  $\rho \in \{-1, 1, *\}^{2N}$  and  $u \in \{-1, 1\}^{2N}$ . For every  $x, z \in \{-1, 1\}^{2N}$ , we have  $D(x, z) = C(x, x \cdot z)$ , furthermore,  $\rho^u(x), \rho(z) \in \{-1, 1\}^{2N}$ . This implies that for every  $x, z \in \{-1, 1\}^{2N}$ ,

$$D(\rho^u(x), \rho(z)) = C(\rho^u(x), \rho^u(x) \cdot \rho(z)). \quad (6)$$

This prompts us to define a communication protocol  $C \circ \rho^u$  where Alice and Bob first restrict their inputs and then run the original protocol  $C$ . The restriction is that for each coordinate  $i \in [2N]$  with  $\rho_i \in \{-1, 1\}$ , Alice overwrites her input  $x_i$  with  $u_i$  while Bob overwrites his input  $y_i$  with  $\rho_i u_i$ . The main property of this restricted protocol is that for all  $x, z \in \{-1, 1\}^{2N}$ ,

$$(C \circ \rho^u)(x, x \cdot z) = C(\rho^u(x), \rho^u(x) \cdot \rho(z)).$$

This, along with equation (6) implies that  $D(\rho^u(x), \rho(z))$  is the unique multilinear extension of  $(C \circ \rho^u)(x, x \cdot z)$ . The cost of  $C \circ \rho^u$  is at most that of  $C$  since Alice and Bob don't need to communicate to restrict their inputs. We now use Lemma 7 on  $C \circ \rho^u$  to argue that  $pP \cdot \mathcal{G}$  fools  $\mathbb{E}_{x \sim U_{2N}} [D(\rho^u(x), \rho(z))]$ . The conditions of the lemma are satisfied since  $pP \in [-2p, 2p]^{2N}$ ,  $p \leq \frac{1}{4N}$ , and  $C \circ \rho^u$  is a protocol of cost at most  $c$  and whose multilinear extension is  $D(\rho^u(x), \rho(z))$ . The lemma implies that

$$\left| \mathbb{E}_{\substack{z \sim pP \cdot \mathcal{G}, \\ x \sim U_{2N}}} [D(\rho^u(x), \rho(z))] - \mathbb{E}_{\substack{z \sim U_{2N}, \\ x \sim U_{2N}}} [D(\rho^u(x), \rho(z))] \right| \leq \frac{120\epsilon c^2 (2p)^2}{\sqrt{N}} + (2p)^4 N^3.$$

Substituting this in inequality (5) completes the proof of Lemma 9. ◀

**Proof of Theorem 3.** Since  $D(x, z)$  is the multilinear extension of  $C(x, x \cdot z)$  and since  $\mathcal{D}$  and  $U_{2N}$  are distributions over  $\{-1, 1\}^{2N}$ , we have

$$\mathbb{E}_{x \sim U_{2N}, z \sim \mathcal{D}}[C(x, x \cdot z)] = \mathbb{E}_{x \sim U_{2N}, z \sim \mathcal{D}}[D(x, z)] = \mathbb{E}_{z \sim \mathcal{D}}[D(0, z)].$$

When  $x \sim U_{2N}$  and  $y \sim U_{2N}$  are independently sampled, the distribution of  $(x, x \cdot y)$  is  $U_{4N}$ . This implies that

$$\mathbb{E}_{x, y \sim U_{2N}}[C(x, y)] = \mathbb{E}_{x, y \sim U_{2N}}[D(x, x \cdot y)] = D(0, 0).$$

The above two equations allow us to rewrite the quantity in the L.H.S. of Theorem 3 as follows.

$$\Delta := \left| \mathbb{E}_{\substack{x \sim U_{2N} \\ z \sim \mathcal{D}}} [C(x, x \cdot z)] - \mathbb{E}_{x, y \sim U_{2N}} [C(x, y)] \right| = \left| \mathbb{E}_{z \sim \mathcal{D}} [D(0, z)] - D(0, 0) \right|$$

Claim 3 applied on the multilinear polynomial  $D$  implies that  $\mathbb{E}_{z \sim \mathcal{D}} [D(0, z)] = \mathbb{E}_{z \sim \mathcal{G}} [D(0, \text{trnc}(z))]$ . Substituting this in the above equality implies that

$$\Delta = \left| \mathbb{E}_{z \sim \mathcal{G}} [D(0, \text{trnc}(z))] - D(0, 0) \right|.$$

Let  $t = 16N^4$ ,  $p = \frac{1}{\sqrt{t}} = \frac{1}{4N^2}$ . Let  $z^{(1)}, \dots, z^{(t)} \sim \mathcal{G}$  be independent samples and let  $Z$  refer to this collection of random variables. For  $i \in [t]$ , define  $z^{\leq(i)} := p(z^{(1)} + \dots + z^{(i)})$ . By convention,  $z^{\leq(0)} := 0$ . Note that for  $i \in [t]$ ,  $z^{\leq(i)}$  has a Gaussian distribution with mean 0 and covariance matrix as  $p^2 i$  times that of  $\mathcal{G}$ . Thus,  $z^{\leq(t)}$  is sampled according to  $\mathcal{G}$ . Substituting this in the previous equality implies that

$$\Delta = \left| \mathbb{E}_Z [D(0, \text{trnc}(z^{\leq t}))] - D(0, 0) \right|.$$

To bound the above quantity, for each  $0 \leq i \leq t-1$ , we show a bound on

$$\Delta_i := \left| \mathbb{E}_Z [D(0, \text{trnc}(z^{\leq(i+1)}))] - \mathbb{E}_Z [D(0, \text{trnc}(z^{\leq(i)}))] \right|.$$

Since  $z^{\leq(0)} = 0$ , the triangle inequality implies that  $\Delta \leq \sum_{i=0}^{t-1} \Delta_i$ .

Fix any  $i \in \{0, \dots, t-1\}$ . We now bound  $\Delta_i$ . Let  $E_i$  be the event that  $z^{\leq(i)} \notin [-1/2, 1/2]^{2N}$ . We first observe that  $E_i$  is a low probability event. Since each  $z^{\leq(i)}(j)$  is distributed as  $\mathcal{N}(0, p^2 i \epsilon)$ , where  $p^2 i \leq 1$  and  $\epsilon = 1/(50 \ln N)$ , we have

$$\mathbb{P}[z^{\leq(i)}(j) \notin [-1/2, 1/2]] \leq \mathbb{P}[|\mathcal{N}(0, \epsilon)| \geq 1/2] \leq \exp(-1/8\epsilon) \leq \exp(-6 \ln N) = \frac{1}{N^6}$$

Applying a Union bound over coordinates  $j \in [2N]$ , we have for each  $0 \leq i \leq t$ ,

$$\mathbb{P}[E_i] = \mathbb{P}[z^{\leq(i)} \notin [-1/2, 1/2]^{2N}] \leq 2N \frac{1}{N^6} \leq \frac{2}{N^5}. \quad (7)$$

When  $E_i$  does not occur, we have  $\text{trnc}(z^{\leq(i)}) = z^{\leq(i)} \in [-1/2, 1/2]^{2N}$ . For every fixed value of  $z^{\leq(i)}$  in this range, we apply Corollary 10 with parameters  $p = \frac{1}{4N^2}$ ,  $z_0 = z^{\leq(i)}$  and  $z = z^{\leq(i+1)} - z^{\leq(i)} = pz^{(i+1)}$ . Note that the conditions in the hypothesis are satisfied since  $z_0 \in [-1/2, 1/2]^{2N}$ ,  $p \leq 1/(4N)$  and the random variable  $pz^{(i+1)}$  is distributed as  $p\mathcal{G}$ . The corollary implies that for every  $z^{\leq(i)} \in [-1/2, 1/2]^{2N}$ ,

$$\left| \mathbb{E}_Z [D(0, z^{\leq(i+1)}) \mid z^{\leq(i)}] - \mathbb{E}_Z [D(0, z^{\leq(i)}) \mid z^{\leq(i)}] \right| \leq \frac{120\epsilon c^2 (2p)^2}{N^{1/2}} + (2p)^4 N^3.$$

Since  $\neg E_i$  implies that  $z^{\leq(i)} \in [-1/2, 1/2]^{2N}$ , we have

$$\left| \mathbb{E}_Z \left[ D(0, z^{\leq(i+1)}) \mid \neg E_i \right] - \mathbb{E}_Z \left[ D(0, z^{\leq(i)}) \mid \neg E_i \right] \right| \leq \frac{120\epsilon c^2 (2p)^2}{N^{1/2}} + (2p)^4 N^3.$$

We apply Claim 4 on the multilinear polynomial  $D(0, z) : [-1, 1]^{2N} \rightarrow [-1, 1]$  with the parameters  $p = \frac{1}{4N^2}$ ,  $z_0 = z^{\leq(i)}$  and  $z = z^{\leq(i+1)}$ . Note that the conditions are satisfied since  $z_0 \in [1/2, 1/2]^{2N}$  and  $p \leq \frac{1}{2}$ . The claim implies that

$$\left| \mathbb{E}_Z \left[ D(0, z^{\leq(i+1)}) \mid \neg E_i \right] - \mathbb{E}_Z \left[ D(0, \text{trnc}(z^{\leq(i+1)})) \mid \neg E_i \right] \right| \leq \frac{8}{N^5}.$$

The previous two inequalities, along with the triangle inequality, imply that

$$\left| \mathbb{E}_Z \left[ D(0, \text{trnc}(z^{\leq(i+1)})) \mid \neg E_i \right] - \mathbb{E}_Z \left[ D(0, z^{\leq(i)}) \mid \neg E_i \right] \right| \leq \frac{120\epsilon c^2 (2p)^2}{N^{1/2}} + (2p)^4 N^3 + \frac{8}{N^5}. \quad (8)$$

Note that for every possible values of  $z^{\leq(i+1)}$  and  $z^{\leq(i)}$ , the difference  $D(0, \text{trnc}(z^{\leq(i+1)})) - D(0, \text{trnc}(z^{\leq(i)}))$  is bounded in magnitude by 2, since  $D(0, \text{trnc}(z))$  maps  $\mathbb{R}^{2N}$  to  $[-1, 1]$ . This implies that

$$\left| \mathbb{E}_Z \left[ D(0, \text{trnc}(z^{\leq(i+1)})) \mid E_i \right] - \mathbb{E}_Z \left[ D(0, \text{trnc}(z^{\leq(i)})) \mid E_i \right] \right| \leq 2.$$

Thus, we have

$$\begin{aligned} \Delta_i &\leq \mathbb{P}[\neg E_i] \cdot \left| \mathbb{E}_Z[D(0, \text{trnc}(z^{\leq(i+1)})) \mid \neg E_i] - \mathbb{E}_Z[D(0, \text{trnc}(z^{\leq(i)})) \mid \neg E_i] \right| \\ &\quad + \mathbb{P}[E_i] \cdot \left| \mathbb{E}_Z[D(0, \text{trnc}(z^{\leq(i+1)})) \mid E_i] - \mathbb{E}_Z[D(0, \text{trnc}(z^{\leq(i)})) \mid E_i] \right| \\ &\leq \left| \mathbb{E}_Z[D(0, \text{trnc}(z^{\leq(i+1)})) \mid \neg E_i] - \mathbb{E}_Z[D(0, \text{trnc}(z^{\leq(i)})) \mid \neg E_i] \right| + 2\mathbb{P}[E_i] \\ &= \left| \mathbb{E}_Z[D(0, \text{trnc}(z^{\leq(i+1)})) \mid \neg E_i] - \mathbb{E}_Z[D(0, z^{\leq(i)}) \mid \neg E_i] \right| + 2\mathbb{P}[E_i] \\ &\leq \frac{120\epsilon c^2 (2p)^2}{N^{1/2}} + (2p)^4 N^3 + \frac{8}{N^5} + \frac{4}{N^5}. \end{aligned}$$

The equality in the fourth line follows from the fact that whenever  $E_i$  does not occur,  $\text{trnc}(z^{\leq(i)}) = z^{\leq(i)}$  by definition. The last inequality follows from inequalities (7) and (8). Along with the fact that  $t = \frac{1}{p^2} = 16N^4$ , and  $\epsilon \leq 1$ , this implies that

$$\begin{aligned} \Delta &\leq \sum_{i=0}^{t-1} \Delta_i \leq t \left( \frac{120\epsilon c^2 (2p)^2}{N^{1/2}} + (2p)^4 N^3 + \frac{12}{N^5} \right) \leq \frac{480\epsilon c^2}{N^{1/2}} + 16p^2 N^3 + \frac{192}{N} \\ &= O\left(\frac{c^2}{N^{1/2}} + \frac{1}{N}\right) = O\left(\frac{c^2}{N^{1/2}}\right). \end{aligned}$$

The last inequality follows from the assumption that  $c \geq 1$ . This completes the proof of Theorem 3.  $\blacktriangleleft$

## Abstract

Traditional learning approaches for classification implicitly assume that each mistake has the same cost. In many real-world problems though, the utility of a decision depends on the underlying context  $x$  and decision  $y$ ; for instance, misclassifying a stop sign is worse than misclassifying a road-side postbox. However, directly incorporating these utilities into the learning objective is often infeasible since these can be quite complex and difficult for humans to specify.

We formally study this as *agnostic learning with unknown utilities*: given a dataset  $S = \{x_1, \dots, x_n\}$  where each data point  $x_i \sim \mathcal{D}_x$  from some unknown distribution  $\mathcal{D}_x$ , the objective of the learner is to output a function  $f$  in some class of decision functions  $\mathcal{F}$  with small excess risk. This risk measures the performance of the output predictor  $f$  with respect to the best predictor in the class  $\mathcal{F}$  on the *unknown* underlying utility  $u^* : \mathcal{X} \times \mathcal{Y} \mapsto [0, 1]$ . This utility  $u^*$  is not assumed to have any specific structure and is allowed to be any bounded function. This raises an interesting question whether learning is even possible in our setup, given that obtaining a generalizable estimate of utility  $u^*$  might not be possible from finitely many samples. Surprisingly, we show that estimating the utilities of only the sampled points  $S$  suffices to learn a decision function which generalizes well.

With this insight, we study mechanisms for eliciting information from human experts which allow a learner to estimate the utilities  $u^*$  on the set  $S$ . While humans find it difficult to directly provide utility values reliably, it is often easier for them to provide comparison feedback based on these utilities. We show that, unlike in the realizable setup, the vanilla comparison queries where humans compare a pair of decisions for a single input  $x$  are insufficient. We introduce a family of elicitation mechanisms by generalizing comparisons, called the  $k$ -comparison oracle, which enables the learner to ask for comparisons across  $k$  different inputs  $x$  at once. We show that the excess risk in our agnostic learning framework decreases at a rate of  $O\left(\frac{1}{k}\right)$  with such queries. This result brings out an interesting accuracy-elicitation trade-off – as the order  $k$  of the oracle increases, the comparative queries become harder to elicit from humans but allow for more accurate learning.

## 1 Introduction

Our focus is on learning predictive models for decision-making tasks. Current paradigms for classification tasks use datasets consisting of scenarios<sup>1</sup>  $x$  along with the decisions  $y$  taken by human experts to learn a decision function<sup>2</sup>  $f : \mathcal{X} \mapsto \mathcal{Y}$ . For instance, in economics such decisions correspond to whether buyers bought an item at a suggested price [2, 9], in robotics such feedback comprises expert demonstrations in imitation learning [1, 4], and in machine learning literature such supervision consists of labels selected by human annotators [10, 13].

When we optimize models to predict correctly on these datasets, we often implicitly assume that all mistakes are equally costly, and that each scenario  $x$  in the data is just as important. In reality though, this is rarely the case. For instance, the standard 0 – 1 loss for classification tasks assigns a unit of loss for each mistake, but misclassifying a stop sign is significantly more dangerous than misclassifying a road-side postbox. In Figure 1, we expand on this insight and illustrate how learning from such revealed decisions can often lead to suboptimal decision functions.

What is missing from this classical framework is that for most decision-making tasks there exists an underlying function  $u^* : \mathcal{X} \times \mathcal{Y} \mapsto [0, 1]$  which evaluates the utility of a decision  $y$  depending on the surrounding context  $x$ . Depending on the decision task, such utility functions can encode buyer preferences in economics, rewards for robotic skills, or misprediction costs for classification. However, these utility functions are a priori unknown to the learner since the dataset consists only of context-decision pairs  $(x, y)$ . Furthermore, asking human experts to write down these complex utility functions can be quite challenging and prone to serious errors [3].

One commonly studied approach, referred to as learning from revealed preferences in economics [9, 6] and inverse reinforcement learning (IRL) in the machine learning literature [19, 26], assumes that the utility function  $u^*$  belongs to some pre-specified class and uses the fact that decision  $y$  was the optimal decision for scenario  $x$  to learn estimates of these utilities. This setup is called the well-specified or realizable setup. However, this posited utility class can be misspecified in that the underlying utility  $u^*$  might not belong to this class. The correctness of such learning approaches crucially relies on the well specified assumption and offers no guarantees on how their performance degrades in the presence of class misspecifications.

We overcome this uncertainty in specifying the utility function  $u^*$  by proposing an *agnostic learning* framework which places no assumptions on the class of utility functions. Instead, we consider decision functions belonging to some class  $\mathcal{F} = \{f \mid f : \mathcal{X} \mapsto \mathcal{Y}\}$  and study the objective of obtaining the “best” decision rule in  $\mathcal{F}$  with respect to the unknown utility  $u^*$ . Formally, given the decision class  $\mathcal{F}$  and samples from a distribution  $\mathcal{D}_x$  over the feature space  $\mathcal{X}$ , the objective of the learner is to output a model  $\hat{f} \in \mathcal{F}$  with small excess risk or regret

$$\text{err}(\hat{f}, \mathcal{F}) := \sup_{f \in \mathcal{F}} \mathbb{E}_{x \sim \mathcal{D}_x} [u^*(x, f(x))] - \mathbb{E}_{x \sim \mathcal{D}_x} [u^*(x, \hat{f}(x))] . \quad (1)$$

Our proposed notion of excess risk measures the performance of an estimator  $\hat{f}$  by comparing its decisions with those of the best predictive model in the class  $\mathcal{F}$  under the utility  $u^*$ .

<sup>1</sup> We use the term scenario/context/feature for the vector  $x$  interchangeably.

<sup>2</sup> We consider finite decision spaces  $\mathcal{Y}$ .

**Figure 1** Consider a binary decision-task with decisions G(reen) and B(lue). The instance space comprises of three equiprobable clusters of datapoints  $x_1, x_2$  and  $x_3$ , and have associated utilities  $u^*$  for decisions B and G. The colour of the datapoints represents the decision with higher utility. The function class  $\mathcal{F}$  consists of linear predictors. In the traditional learning setups where the dataset consists of pairs  $(x, y)$ , no learner will have enough information to select between  $f_1$  and  $f_2$  since the 0 – 1 error for both is  $1/3$ . In contrast, using a 2-comparison oracle, a learner can ask a query of the form “Which of  $u^*(x_1, \text{G}) + u^*(x_3, \text{B})$  or  $u^*(x_1, \text{B}) + u^*(x_3, \text{G})$  is bigger?”. This allows them to infer that correctly predicting  $x_3$  gives a higher overall utility and output the optimal decision function  $f_2$ .

Contrast this with the classical agnostic learning framework [15] where the evaluation metric for classification measures what proportion of datapoints  $\hat{f}$  predicts correctly

$$\text{err}_{\text{cl}}(\hat{f}, \mathcal{F}) := \sup_{f \in \mathcal{F}} \mathbb{E}_{x \sim \mathcal{D}_x} [\mathbb{I}[f(x) \neq y_x]] - \mathbb{E}_{x \sim \mathcal{D}_x} [\mathbb{I}[\hat{f}(x) \neq y_x]], \quad (2)$$

where  $y_x = \arg\max_{y \in \mathcal{Y}} u^*(x, y)$  represents the expert decision (revealed decision) for scenario  $x$ . Our above framework generalizes the proper agnostic learning framework – we restrict our attention to proper learners which output models  $\hat{f} \in \mathcal{F}$  and the decision class  $\mathcal{F}$  is agnostic towards the unknown underlying utility  $u^*$ . Indeed, our agnostic framework allows for misspecification in the decision class  $\mathcal{F}$  and allows for situations where no predictive model  $f \in \mathcal{F}$  matches the expert predictions  $y_x$  for all instances  $x$ .

As highlighted by Figure 1, such a misspecification in the function class  $\mathcal{F}$  implies that no decision function  $f \in \mathcal{F}$  will be able to perfectly fit these optimal decisions  $y_x$  for all points  $x \in S$ . In order to solve the agnostic learning problem, it is necessary for the learner to understand the how costly these different mistakes are relative to each other. From the learners perspective, observing only the optimal decisions  $y_x$  for each instance  $x$ , such as revealed preferences or expert demonstrations, are clearly insufficient to obtain any information about these costs. One way to overcome this information-theoretic limit of revealed decisions is to directly elicit the utilities from humans – for scenarios  $x$  and decision  $y$ , ask an expert “What is the utility  $u^*(x, y)$  for taking the decision  $y$  given situation  $x$ ?”. However, since the underlying utility  $u^*$  can be quite complex, humans are inept at answering them reliably [17, 23]. For instance, it can be challenging for humans to correctly specify the costs of mispredicting, say, a stop sign as a red signal relative to that of predicting it as a post-box.

On the other hand, it is often easier for humans to provide comparative evaluations based on these utilities [24, 14] and allow the learner to obtain relative feedback. Using these, the learner can query an expert with comparison or preference queries asking “For instance  $x$ , which of the two utilities  $u^*(x, y_1)$  or  $u^*(x, y_2)$  is larger?”. Such vanilla comparisons can allow the learner to infer relative utilities for decisions  $y_1$  and  $y_2$  for a given context  $x$ ; the learner can conclude that mispredicting stop sign as post-box is worse than mispredicting it

as a red signal. However, such feedback still does not provide any information about the mistake costs across different examples – given a choice, should the learner correctly predict a stop-sign or correctly predict a post-box?

While vanilla comparisons are insufficient for the agnostic setup, let us consider the other extreme: suppose that we have access to an oracle which can provide us with comparisons of overall utilities for functions  $f_1, f_2 \in \mathcal{F}$ . That is, the oracle can answer question of the form “Which of the two overall utilities  $\mathbb{E}_x[u^*(x, f_1(x))]$  or  $\mathbb{E}_x[u^*(x, f_2(x))]$  is larger?”. Given access to such an oracle, we will be able to find the optimal classifier in the class  $\mathcal{F}$ . We call this the  $\infty$ -comparison oracle since such preferences requires a human to reason about the utilities over the entire feature space  $\mathcal{X}$  at once. Even for a small image classification task with a million images, this would require a human to compare the utility of a million simultaneous predictions! While this approach does allow for optimal estimation, the trade-off is that it puts the complete burden of learning on the human’s side. It is worth highlighting that the comparisons between lotteries used to establish the von Neumann-Morgenstern utility theorem [18] can be shown to be a special case of such an  $\infty$ -comparison oracle.

While comparison queries only allow comparison within a single instance, the  $\infty$ -comparison oracle takes the other extreme and requires a comparison along all instances. However, we need not restrict our self to either of these extremes; our key insight is that there is a natural spectrum of such comparisons, which we call  $k$ -comparisons which interpolate between the single or 1-comparison and the  $\infty$ -comparison oracle. Such comparison queries allow a learner to pick  $k$  instances  $\{x_1, \dots, x_k\}$  and two sets of corresponding decision,  $\{y_1, \dots, y_k\}$  and  $\{y'_1, \dots, y'_k\}$ , and ask “Which of the cumulative utilities  $\sum_i u^*(x_i, y_i)$  or  $\sum_i u^*(x_i, y'_i)$  is bigger?”. For instance, for the example in Figure 1, giving the learner access to a 2-comparison oracle allows the algorithm to output the optimal decision function.

These higher-order comparison oracles form a natural hierarchy of elicitation mechanisms for the learner with a  $k'$ -oracle being strictly more informative than a  $k$ -oracle for  $k' > k$ . They allow for a natural trade-off between accuracy and elicitation in the learning with unknown utilities framework. As we increase the order  $k$  of the oracle, the learner can obtain finer information about the utilities  $u^*$  and output functions with lower excess risk. However, this increase in information comes at the expense of asking for a harder elicitation from the human expert.

## Our Contributions

We propose a novel framework, which we call *agnostic learning with unknown utilities*, for studying decision problems wherein the learner is evaluated with respect to an unknown utility function. Within this framework, we show that standard approaches which work well in the realizable setup, such as revealed preferences as well as vanilla comparisons, can perform quite poorly in the face of misspecification and can have excess risk  $\Omega(1)$ . To overcome this, we propose a family of elicitation mechanisms, the  $k$ -comparisons, which allows the learner access to finer information from an human expert with increasing values of the order  $k$ . Our main results, detailed in Section 3, provide a tight characterization of the excess risk as a function of the order  $k$  of the comparison oracle available to the learner. These result brings out an interesting accuracy-elicitation trade-off – as the order  $k$  of the oracle increases, the comparative queries allow for more accurate learning in our setup but become harder to elicit from humans.

We would like to highlight that increasing the order  $k$  of the comparisons could lead to potentially biased and noisy responses from the human expert. As a consequence, there might be an additional trade-off involving the *quality of the information* obtained by increasing the order. While we do not focus on this aspect of elicitation, it is an interesting direction for future work.

## Paper Organization

The remainder of the paper is organized as follows: Section 2 introduces our agnostic learning with unknown utilities problem setup and the  $k$ -comparison elicitation mechanism, and Section 3 gives an overview of our main results and algorithmic contributions. In Section 4, we study excess risk bounds for the binary decision problem in our framework and propose our algorithm, Comptron, to learn from higher-order comparisons and in Section 5, we study adaptive estimators which are optimal for each instance of our problem. While these sections contain a formal statement of all our main results, due to space limitations, we defer some of the proofs to full version of the paper.

## 2 Problem formulation

In this section, we formally state our learning with unknown utilities problem and introduce the  $k$ -comparison oracle. Let  $\mathcal{X} \subseteq \mathbb{R}^d$  represent the space of feature vectors,  $\mathcal{Y}$  denote the corresponding decision space and  $\mathcal{F}$  denote a class of decision making functions, given as  $\mathcal{F} = \{f \mid f : \mathcal{X} \mapsto \mathcal{Y}\}$ . Our framework considers an underlying utility function  $u^* : \mathcal{X} \times \mathcal{Y} \mapsto [0, 1]$  which assigns a non-negative real value for making a decision  $y \in \mathcal{Y}$  given a situation  $x \in \mathcal{X}$ . Further, let us denote the set

$$\mathcal{U} = \{u \mid u : \mathcal{X} \times \mathcal{Y} \mapsto [0, 1]\} \quad (3)$$

of all possible such utility functions. For any distribution  $\mathcal{D}_x$  over the feature space  $\mathcal{X}$ , we define the expected utility of a decision function  $f \in \mathcal{F}$  as  $U(f; u^*) := \mathbb{E}_{x \sim \mathcal{D}_x}[u^*(x, f(x))]$ . Observe that such an expected utility model assumes that the utilities are additive across the different instances  $x$  and is a commonly studied model both in the machine learning, statistics and economics literature. We denote the excess risk of a function  $f$  with respect to the function class  $\mathcal{F}$  by

$$\text{err}(f, \mathcal{F}; u^*) := \max_{f' \in \mathcal{F}} U(f'; u^*) - U(f; u^*). \quad (4)$$

Further, we denote the optimal decision for any instance  $x$  with respect to the underlying utility  $u^*$  by  $y_x := \operatorname{argmax}_{y \in \mathcal{Y}} u^*(x, y)$ .

Similar to the classical agnostic learning setup [15], we assume that the learner does not know the underlying distribution  $\mathcal{D}_x$  of the instances. However, our setup differs from it in that we do not assume that the underlying utility function  $u^*$  is known to the learner. Instead, we provide the learner access to an oracle which allows the learner to elicit responses to higher-order preferences queries.

### Comparison Oracle

Since the utility function  $u^*$  is unknown to the learner, our framework allows the learner access to an oracle which provides comparative feedback based on the utilities  $u^*$ . We consider a family of such oracles  $\mathcal{O}_k$ , each indexed by its order  $k$  which determines the number of different instances the learner is allowed to specify in the comparison query. For an oracle  $\mathcal{O}_k$ , a learner is allowed to select a set of  $k$  situations  $\mathbf{x} \in \mathcal{X}^k$  and two pairs of corresponding decisions  $\mathbf{y}_1, \mathbf{y}_2 \in \mathcal{Y}^k$ . The oracle then compares, in a possibly noisy manner, the cumulative utilities of the pair  $(\mathbf{x}, \mathbf{y}_1)$  and  $(\mathbf{x}, \mathbf{y}_2)$  and responds with the feedback on which one is larger. As the order  $k$  of the oracle increases, the queries become more complex – an expert is required to evaluate a larger number of instances at once. This family of comparison oracles captures a natural hierarchy of elicitation mechanisms where with each increasing value of  $k$ , a learner has access to more information about the utility function  $u^*$ .

Formally, we represent a  $k$ -query by a tuple  $(\mathbf{x}, \mathbf{y}_1, \mathbf{y}_2)$  where the input  $\mathbf{x} = (x_1, \dots, x_k)$  comprises  $k$  feature vectors and the corresponding decision vectors  $\mathbf{y}_1 = (y_1, \dots, y_k)$  and  $\mathbf{y}_2 = (y'_1, \dots, y'_k)$ .<sup>3</sup> Given such a query  $q$ , the oracle  $\mathcal{O}_k$  provides the learner a binary response

$$\mathcal{O}_k(q = (\mathbf{x}, \mathbf{y}_1, \mathbf{y}_2)) = \begin{cases} \mathbb{I}[u^*(\mathbf{x}, \mathbf{y}_1) \geq u^*(\mathbf{x}, \mathbf{y}_2)] & \text{with prob. } 1 - \eta_q, \\ 1 - \mathbb{I}[u^*(\mathbf{x}, \mathbf{y}_1) \geq u^*(\mathbf{x}, \mathbf{y}_2)] & \text{otherwise} \end{cases}, \quad (5)$$

where the parameter  $0 \leq \eta_q < \frac{1}{2}$  represents the noise level corresponding to query  $q$ . Thus, the oracle<sup>4</sup>  $\mathcal{O}_k$  provides noisy comparisons of the cumulative utilities  $u^*(\mathbf{x}, \mathbf{y}_1)$  and  $u^*(\mathbf{x}, \mathbf{y}_2)$  with varying noise level  $\eta_q$ . Observe that we allow the noise levels  $\eta_q$  to be different for each query  $q$ .

### Problem Statement

We are interested in the *agnostic learning with unknown utilities* problem where a learner is provided  $n$  samples  $S = \{x_1, \dots, x_n\}$  with each  $x_i \sim \mathcal{D}_x$  and access to the  $k$ -comparison oracle described above, and is required to output a decision function  $\hat{f} \in \mathcal{F}$  such that error  $\text{err}(\hat{f}, \mathcal{F})$  is small. The caveat is to do so with a minimum number of calls, which we term the query complexity  $n_q$  of learning, to the comparison oracle  $\mathcal{O}_k$ . Quantitatively, we would like to characterize the excess risk from equation (4) in terms of the number of sampled instances  $n$ , the order  $k$  of the comparison oracle and properties of the decision function class  $\mathcal{F}$ , and the associated oracle query complexity  $n_q$  to obtain this bound.

Obtaining such bounds on the excess risk  $\text{err}(f, \mathcal{F}; u^*)$  in terms of the order  $k$  allow us to quantify the trade-offs in learning better decision functions at the expense of requiring more complex information from the human expert. Going forward, we focus on the binary decision making problem where the label space  $\mathcal{Y} = \{0, 1\}$  for clarity of exposition. Whenever our results can be extended to arbitrary decision sets, we provide a small remark about this extension.

## 3 Main results

With the formal problem setup in place, we discuss our main results for learning in this framework of unknown utilities. At a high level, our objective is to understand how the excess risk  $\text{err}(f, \mathcal{F}; u^*)$  defined in equation (4) behaves as a function of the oracle order  $k$  – specifically, at what rates does learning in our proposed framework get easier as we allow learner to elicit more complex information from the oracle?

For our main results, on the upper bound side, we design estimators for learning from the  $k$ -comparison oracle, and on the lower bound side, we study information-theoretic limits of learning with such higher-order comparisons. While we state our results for the binary decision problem where the label space  $\mathcal{Y} = \{0, 1\}$  for clarity, most of our results can be generalized to arbitrary outcome space  $\mathcal{Y}$ .

<sup>3</sup> We overload our notation and represent the cumulative utilities of the  $k$  inputs  $(\mathbf{x}, \mathbf{y})$  by  $u^*(\mathbf{x}, \mathbf{y}) = \sum_i u^*(x_i, y_i)$ .

<sup>4</sup> Note that while the oracle depends on the underlying utility function  $u^*$ , our notation suppresses this dependence for clarity. We use the notation  $\mathcal{O}_k(q; u^*)$  whenever we want to make this dependence explicit.

### 3.1 Excess risk with $k$ -comparison oracle (Section 4)

We study a class of *plug-in* estimators which are based on the following two-step procedure:

- i. Obtain estimate  $\hat{u}$  of the true utility  $u^*$  on the sampled datapoints.
- ii. Output utility maximizing function  $\hat{f}_{k,n}$  with respect to the estimated utility  $\hat{u}$ .

For learning the parameters  $\hat{u}$ , we introduce the Comptron (Algorithm 1) and Rob-Comptron (Algorithm 2) algorithms for the noiseless and noisy comparison oracles respectively. We show that when these estimates  $\hat{u}$  are combined with the two-step plug-in estimator, the excess risk of the function  $\hat{f}_{k,n}$  scales as  $O(\frac{1}{k})$  and an additive complexity term capturing uniform convergence of the decision class  $\mathcal{F}$  with respect to the true utility  $u^*$ .

► **Theorem 1** (Informal, noiseless comparisons). *Given  $n$  samples, the excess risk for the function  $\hat{f}_{k,n} \in \mathcal{F}$  output by the plug-in estimator using estimates  $\hat{u}$  from Comptron satisfies*

$$\text{err}(\hat{f}_{k,n}, \mathcal{F}; u^*) \leq \text{Complexity}_n(\mathcal{F}; u^*) + O\left(\frac{1}{k}\right) \cdot \left(\frac{1}{n} \sum_{i=1}^n \mathbb{I}[f_{\text{ERM}}(x_i) \neq y_i]\right),$$

where the ERM function  $f_{\text{ERM}} \in \arg\max_{f \in \mathcal{F}} \sum_{i=1}^n u^*(x_i, f(x_i))$ . Furthermore, Comptron makes only  $O(n \log k)$  queries to the oracle  $\mathcal{O}_k$ .

We make a few remarks on this result. First, observe that the complexity term depends on the true utility function  $u^*$  and not on the estimates  $\hat{u}$ . This ensures that the complexity term does not depend on the utility class  $\mathcal{U}$  but rather only on the specific utility  $u^*$  – indeed, the class  $\mathcal{U}$  consists of all bounded function and uniform convergence might not even be possible with finite sample for a large class of distributions  $\mathcal{D}_x$ . Second, the additional error of  $O(\frac{1}{k})$  accounts for the fact that the utilities  $u^*$  are unknown. One can learn better decision functions by increasing the order  $k$  of the comparison oracle but this comes at the cost of the human expert answering a more complex set of queries. Furthermore, this error is multiplied by the 0 – 1 prediction error of the optimal on-sample classifier  $f_{\text{ERM}} = \arg\max_{f \in \mathcal{F}} \sum_i u^*(x_i, f(x_i))$ . This implies that in the well-specified setup, where there exists an  $f \in \mathcal{F}$  such that  $f(x_i) = y_i$  on the sampled datapoints, the second term becomes 0 and the learner pays no additional error for not knowing the utilities  $u^*$ . Third, observe that our proposed algorithms, Comptron and Rob-Comptron, are query efficient; both require only  $O(n \log k)$  calls to the  $k$ -comparison oracle to produce “good” estimates  $\hat{u}$ .

The proof of the above theorem proceeds in two steps. First, we adapt the classical proof for upper bounding the risk of ERM procedures to show that the gap  $\text{err}(\hat{f}_{k,n}, \mathcal{F})$  decomposes into the complexity term and estimation error  $\|\hat{u} - u^*\|_{S, \infty}$ , evaluated on the dataset  $S$ . Next, we show that this estimation error scales as  $O(\frac{1}{k})$  for the Comptron and Rob-Comptron procedures.

Next, we address the optimality of the above plug-in procedure by studying the information-theoretic limits of learning with a  $k$ -comparison oracle. Specifically, in Theorem 9 we establish that the rate of  $\frac{1}{k}$  is indeed minimax optimal – for any  $k > 1$  and any predictor  $\hat{f}$  in some class  $\mathcal{F}$ , we can construct utility functions  $u^*$  such that excess risk  $\text{err}(\hat{f}, \mathcal{F}; u^*) = \Omega(\frac{1}{k})$ . These lower bounds imply that traditional comparison based learning, corresponding to  $k = 1$ , is insufficient for learning good decision rules in our framework.

### 3.2 Instance-optimal learning (Section 5)

While the previous results show that the error rate of  $O(\frac{1}{k})$  is optimal on worst-case instances, some instances of our learning with unknown utilities problem might be easier than these worst-case ones and one would expect the excess risk to be smaller for them. In this section, we study estimators whose error adapts to hardness of the specific problem instance.

To begin with, in Proposition 11 we establish that the plug-in estimator with Comptron estimates  $\hat{u}$  is not optimal for all instances – it does not adapt to these easier instances. Inspired from the robust optimization literature, we introduce a randomized estimator  $p_{\text{rob}}$  and show that it is instance-optimal. Informally, we establish in Theorem 13 that for any instance  $(\mathcal{D}_x, u^*, \mathcal{F})$  of the problem, the excess risk for  $p_{\text{rob}}$  is characterized by a local modulus of continuity; this modulus captures how quickly the optimal decision function in class  $\mathcal{F}$  can change in a small neighborhood around  $u^*$  for the distribution  $\mathcal{D}_x$ . In Theorem 12, we derive a lower bound on the *local minimax excess risk* and show that the local modulus is indeed the correct instance-dependent complexity measure for this problem.

However, note that such adaptivity to the hardness of the instance comes at the cost of query efficiency. Our estimator  $p_{\text{rob}}$  makes an exponential number  $O(n^k)$  of calls to the oracle  $\mathcal{O}_k$ .

## 4 Binary decision-making with $k$ -comparisons

In this section, we obtain upper and lower bounds on the excess risk for the binary prediction problem with unknown utilities where the learner can elicit utility information using a  $k$ -comparison oracle. In Section 4.1, we introduce algorithms which learn decision-making rules from higher-order preference queries and obtain upper bounds on the excess risk for such estimators. Then, in Section 4.2, we turn to the information-theoretic limits of learning from  $k$ -queries and obtain lower bounds on the minimax risk of any estimator.

Recall from Section 2, our setup gives the learner access to a dataset  $S = \{x_1, \dots, x_n\}$  comprising  $n$  points, each sampled i.i.d. from an underlying distribution  $\mathcal{D}_x$  and to a comparison oracle  $\mathcal{O}_k$ . Before proceeding to define the estimator, we introduce some notation. For any function  $f \in \mathcal{F}$ , let us denote the empirical cumulative utility with respect to utility function  $u^*$  and the corresponding empirical utility maximizer as

$$\hat{U}_n(f; u^*) = \frac{1}{n} \sum_i u^*(x_i, f(x_i)) \quad \text{and} \quad f_{\text{ERM}} \in \operatorname{argmax}_{f \in \mathcal{F}} \hat{U}_n(f; u^*), \quad (6)$$

where the subscript  $n$  encodes the dependence on the number of samples. If the underlying utility  $u^*$  were in fact known to the learner, it would have output the classifier  $f_{\text{ERM}}$ , which, from the classical learning theory literature, is known to have favorable generalization properties [22]. For the case of unknown utilities, we extend this ERM procedure to a natural two-stage plug-in estimator which outputs the minimizer with respect to an estimate  $\hat{u}_k$  of these utilities.

### 4.1 Excess-risk upper bounds for plug-in estimator

Building on the ERM estimator  $f_{\text{ERM}}$  described in equation (6), we design a two stage *plug-in* estimator  $\hat{f}_{k,n}$ , where the subscript  $k$  represents the order of the comparison oracle used to obtain the estimate.

In the first stage, we form estimates  $\hat{u}_k$  of the true utility function  $u^*$  on the sampled datapoints  $S$  using the  $k$ -comparison oracle. The predictor  $\hat{f}_{k,n} \in \mathcal{F}$  is then given by the empirical utility maximizer with respect to  $\hat{u}_k$ , that is,

$$\hat{f}_{k,n} \in \operatorname{argmax}_{f \in \mathcal{F}} \frac{1}{n} \sum_{i=1}^n \hat{u}_k(x_i, f(x_i)). \quad (7)$$

Before detailing out the procedures for producing utility estimates  $\hat{u}_k$ , we present our first main result which shows that the excess risk  $\text{err}(\hat{f}_{k,n}, \mathcal{F}; u^*)$  can be upper bounded as a sum of two terms: (i) a complexity term corresponding to the rate of uniform convergence of the

cumulative utility  $U(f; u^*)$  over the decision class  $\mathcal{F}$  and (ii) an estimation error term which denotes how well the estimates  $\hat{u}_k$  approximate  $u^*$  on the sampled datapoints. Our result measures this estimation error in terms of a data-dependent norm

$$\|u\|_{S, \infty} := \sup_{i \in [n]} \sup_{y \in \mathcal{Y}} |u(x_i, y)|. \quad (8)$$

Recall from equation (6) that the function  $f_{\text{ERM}}$  is the minimizer of the empirical utility  $\hat{U}_n(f; u^*)$ . While the following results hold for general decision spaces  $\mathcal{Y}$ , we later specialize this in Proposition 3 for the binary prediction setup.

► **Theorem 2** (Excess-risk upper bound). *Given datapoints  $S = \{x_1, \dots, x_n\}$  such that each  $x_i \sim \mathcal{D}_x$ , and an estimate  $\hat{u}_k$  of the true utility function  $u^*$ , the plug-in estimate  $\hat{f}_{k,n}$  from equation (7) satisfies*

$$\text{err}(\hat{f}_{k,n}, \mathcal{F}; u^*) \leq 2 \cdot \sup_{f \in \mathcal{F}} (|U(f; u^*) - \hat{U}_n(f; u^*)|) + 2\|u^* - \hat{u}_k\|_{S, \infty} \cdot \left( \frac{1}{n} \sum_{i=1}^n \mathbb{I}[f_{\text{ERM}}(x_i) \neq \hat{f}_{k,n}(x_i)] \right). \quad (9)$$

A few comments on Theorem 2 are in order. First, notice that the upper bound on the risk  $\text{err}(\hat{f}_{k,n}, \mathcal{F}; u^*)$  is a deterministic bound comprising two terms. The uniform convergence term captures how fast the empirical utility  $\hat{U}_n(f; u^*)$  converge to the population utility  $U(f; u^*)$  uniformly over the decision class  $\mathcal{F}$ . Using standard bounds [8], one can show that this term is upper bounded by the empirical Rademacher complexity of the class  $\mathcal{F}$  on the datapoints  $S$ , that is,

$$\sup_{f \in \mathcal{F}} (|U(f; u^*) - \hat{U}_n(f; u^*)|) \leq \mathbb{E}_\varepsilon \left[ \sup_{f \in \mathcal{F}} \left| \frac{1}{n} \sum_{i=1}^n \varepsilon_i u^*(x_i, f(x_i)) \right| \right] := \hat{\mathfrak{R}}_n(\mathcal{F} \circ u^*) \quad (10)$$

where each  $\varepsilon_i$  is an i.i.d. Rademacher random variable taking values  $\{-1, +1\}$  equiprobably. Such complexity measures are commonly studied in the learning theory literature and one can obtain sample complexity rates for a wide range of decision classes including parametric decision classes and non-parametric kernel classes amongst others.

The second term in equation (9) is given by a product of two terms. The first part  $\|u^* - \hat{u}_k\|_{S, \infty}$  captures the *on-sample approximation error* of the estimates  $\hat{u}_k$ . Notice that, in general, the problem of estimating  $u^*$  uniformly over the space  $\mathcal{X}$  is infeasible since the class  $\mathcal{U}$  contains the set of all bounded functions on  $\mathcal{X} \times \mathcal{Y}$ . However, the fact that we are required to estimate the utilities  $u^*$  only on the sampled datapoints  $S$  makes learning feasible in our framework. The second part,  $\frac{1}{n} \sum_{i=1}^n \mathbb{I}[f_{\text{ERM}}(x_i) \neq \hat{f}_{k,n}(x_i)] \leq 1$  the mismatch between the predictions of  $f_{\text{ERM}}$ , obtained with complete knowledge of  $u^*$ , and of  $\hat{f}_{k,n}$ , obtained from estimates  $\hat{u}_k$ . Notice that whenever the function class  $\mathcal{F}$  is correctly specified on  $S$ , that is, there exists a function  $f \in \mathcal{F}$  such that  $f(x_i) = y_i$ , then the predictions of  $\hat{f}_{k,n}$  and  $f_{\text{ERM}}$  will coincide. This follows since the labels  $y_i$  can be inferred using a 1-comparison. In such a well-specified setup, this second term vanishes and we recover the upper bound in terms of the uniform convergence term. Surprisingly, this exhibits that not knowing the utility  $u^*$  affects learnability only when the function class  $\mathcal{F}$  is misspecified.

**Proof.** We begin by decomposing the excess error  $\text{err}(\hat{f}_{k,n}, \mathcal{F}; u^*)$  and then handle each term in the decomposition separately. Recall that the function  $f_{\text{ERM}}$  is the maximizer of the empirical utility  $\hat{U}_n(f; u^*)$ . Then, for any decision function  $f \in \mathcal{F}$ , consider the error

$$\begin{aligned}
\text{err}(\hat{f}_{k,n}, f; u^*) &= U(f; u^*) - \hat{U}_n(f; u^*) + \hat{U}_n(f; u^*) - \hat{U}_n(f_{\text{ERM}}; u^*) + \hat{U}_n(f_{\text{ERM}}; u^*) - \hat{U}_n(\hat{f}_{k,n}; u^*) \\
&\quad + \hat{U}_n(\hat{f}_{k,n}; u^*) - U(\hat{f}_{k,n}; u^*) \\
&\stackrel{(i)}{\leq} 2 \sup_{f \in \mathcal{F}} (|U(f; u^*) - \hat{U}_n(f; u^*)|) + \underbrace{\hat{U}_n(f_{\text{ERM}}; u^*) - \hat{U}_n(\hat{f}_{k,n}; u^*)}_{\text{Term (I)}}, \tag{11}
\end{aligned}$$

where the inequality (i) follows by noting that  $f_{\text{ERM}}$  is the maximizer of  $\hat{U}_n(f; u^*)$ . We now focus our attention on Term (I) in the above expression.

$$\begin{aligned}
\hat{U}_n(f_{\text{ERM}}; u^*) - \hat{U}_n(\hat{f}_{k,n}; u^*) &= \hat{U}_n(f_{\text{ERM}}; u^*) - \hat{U}_n(f_{\text{ERM}}; \hat{u}) + \hat{U}_n(f_{\text{ERM}}; \hat{u}) - \hat{U}_n(\hat{f}_{k,n}; \hat{u}) \\
&\quad + \hat{U}_n(\hat{f}_{k,n}; \hat{u}) - \hat{U}_n(\hat{f}_{k,n}; u^*) \\
&\stackrel{(i)}{\leq} \frac{2}{n} \sum_{i=1}^n \mathbb{I}[f_{\text{ERM}}(x_i) \neq \hat{f}_{k,n}(x_i)] \cdot \sup_{y \in \mathcal{Y}} |u^*(x_i, y) - \hat{u}(x_i, y)| \\
&\leq 2 \|u^* - \hat{u}\|_{S, \infty} \cdot \left( \frac{1}{n} \sum_{i=1}^n \mathbb{I}[f_{\text{ERM}}(x_i) \neq \hat{f}_{k,n}(x_i)] \right),
\end{aligned}$$

where (i) follows by noting that  $\hat{f}_{k,n}$  maximizes the utility  $\hat{U}_n(f; \hat{u})$ . Plugging the bound above in equation (11) completes the proof.  $\blacktriangleleft$

We now specialize the result of Theorem 2 to the binary prediction setup where the label space  $\mathcal{Y} = \{0, 1\}$ . Recall that for each datapoint  $x_i$ , we denote the true label by  $y_i = \arg\max_y u^*(x_i, y)$ . We now introduce the notion of utility gaps  $u_{\text{gap}}(x_i)$  which measures the excess utility a learner gains by predicting a datapoint  $x_i$  correctly relative to an incorrect prediction. Formally, the gap  $u_{\text{gap}}(x_i)$  for datapoint  $x_i$  with respect to some utility function  $u \in \mathcal{U}$  is given as

$$u_{\text{gap}}(x_i) := u(x_i, y_i) - u(x_i, \bar{y}_i), \tag{12}$$

where we denote the incorrect label by  $\bar{y} = 1 - y$ . With this notation, the following proposition obtains an upper bound on the excess error of plug-in estimator  $\hat{f}_{k,n}$  for the binary prediction problem in terms of the estimation error in these gaps  $u_{\text{gap}}(x_i)$ .

► **Proposition 3** (Upper bounds for binary prediction). *Consider the binary decision making problem with label space  $\mathcal{Y} = \{0, 1\}$ . Given  $n$  datapoints  $\{x_1, \dots, x_n\}$  such that each datapoint  $x_i \sim \mathcal{D}_x$ , and an estimate  $\hat{u}_k$  of the utility function  $u^*$ , the plug-in estimator  $\hat{f}_{k,n}$  from equation (7) satisfies*

$$\begin{aligned}
\text{err}(\hat{f}_{k,n}, \mathcal{F}; u^*) &\leq 2 \cdot \sup_{f \in \mathcal{F}} (|U(f; u^*) - \hat{U}(f; u^*)|) \\
&\quad + 2 \max_i [u_{\text{gap}}^*(x_i) - \hat{u}_{\text{gap}}(x_i)] \cdot \left( \frac{1}{n} \sum_{i=1}^n \mathbb{I}[f_{\text{ERM}}(x_i) \neq y_i] \right). \tag{13}
\end{aligned}$$

The proof of the above proposition follows similar to Theorem 2 and is deferred to the full version. This specializes the result of Theorem 2 and shows that for the binary prediction problem, estimating the utility gaps  $u_{\text{gap}}$  well for each datapoint suffices

The upper bound on excess risk given by Proposition 3 shows that the function  $\hat{f}_{k,n}$  derived from estimates  $\hat{u}_k$  will have small error as long as the estimates  $\hat{u}_{\text{gap}}(x_i)$  approximate the true utility gaps  $u_{\text{gap}}^*(x_i)$  for each datapoint  $x_i$ . Therefore, in the following sections, we focus on procedures for obtaining the utility estimates  $\hat{u}_{\text{gap}}$  using the  $k$ -comparison oracle. we separate the presentation based on whether the oracle  $\mathcal{O}_k$  provides noiseless comparisons ( $\eta_q = 0$  for all  $q$ ) or whether the oracle evaluations are noisy.

■ **Algorithm 1** Comptron: Comparison based Coordinate-Perceptron for estimating  $u_{\text{gap}}^*$ .

---

**Input:** Datapoints  $S = \{x_1, \dots, x_n\}$ ,  $k$ -comparison oracle  $\mathcal{O}_k$   
**Initialize:** Set  $T = \log_2 k - 1$   
 Obtain  $y_i = \operatorname{argmax}_y u^*(x_i, y)$  for each  $i$  using 1-comparison.  
 Obtain index  $i_{\max}$  using 2-comparisons such that  $i_{\max} = \operatorname{argmax}_i u_{\text{gap}}^*(x_i)$ .  
 Set initial estimates  $\hat{u}_{\text{gap}}^0 = [\hat{u}_{\text{gap}}^0(x_1), \dots, \hat{u}_{\text{gap}}^0(x_n)] = u_{\max}^* := u_{\text{gap}}^*(x_{i_{\max}})$ .  
 (Note that exact value of  $u_{\max}^*$  is not required since comparison queries are relative)  
**for**  $t = 1, \dots, T$  **do**  
   **for**  $i = 1, \dots, n$  **do**  
     Denote by  $\lambda = \frac{k}{2u_{\max}^*} \left( \hat{u}_{\text{gap}}^{t-1}(x_i) - \frac{u_{\max}^*}{2^t} \right)$  and query  $q_{i,t} = (\mathbf{x}, \mathbf{y}_1, \mathbf{y}_2)$  where  
        $\mathbf{x} = (\underbrace{x_i, \dots, x_i}_{\frac{k}{2} \text{ times}}, \underbrace{x_{i_{\max}}, \dots, x_{i_{\max}}}_{\lambda \text{ times}}), \quad \mathbf{y}_1 = (\underbrace{y_i, \dots, y_i}_{\frac{k}{2} \text{ times}}, \underbrace{1 - y_{i_{\max}}, \dots, 1 - y_{i_{\max}}}_{\lambda \text{ times}}), \quad \mathbf{y}_2 = 1 - \mathbf{y}_1$ .  
       Query oracle  $\mathcal{O}_k$  with  $q_{i,t}$  and receive response  $r_{i,t}$ .  
       Update  $\hat{u}_{\text{gap}}^t(x_i) = \hat{u}_{\text{gap}}^{t-1}(x_i) - \mathbb{I}[r_{i,t} = 0] \cdot \frac{u_{\max}^*}{2^t}$ .  
**Output:** Gap estimates  $\hat{u}_{\text{gap}}^T$

---

#### 4.1.1 Estimating $u_{\text{gap}}^*$ with noiseless oracle

In this section, we propose our algorithm for estimating the gaps  $u_{\text{gap}}^*$  when the  $k$ -comparison oracle is noiseless. Recall from equation (5), for a query  $q = (\mathbf{x}, \mathbf{y}_1, \mathbf{y}_2)$  comprising  $k$  feature vectors  $\mathbf{x} = (x_1, \dots, x_k)$ , and two decision vectors  $\mathbf{y}_1 = (y_1, \dots, y_k)$  and  $\mathbf{y}_2 = (y'_1, \dots, y'_k)$ , such a noiseless oracle deterministically outputs

$$\mathcal{O}_k(q = (\mathbf{x}, \mathbf{y}_1, \mathbf{y}_2)) = \mathbb{I}[u^*(\mathbf{x}, \mathbf{y}_1) \geq u^*(\mathbf{x}, \mathbf{y}_2)] ,$$

where recall that  $u^*(\mathbf{x}, \mathbf{y}) = \sum_{i \in [k]} u^*(x_i, y_i)$  is the sum of the utilities under  $u^*$  for the tuple  $(\mathbf{x}, \mathbf{y})$ . In the binary prediction setup, such queries allow a learner to specify a set of  $k$  instances  $\mathbf{x}$  and a subset  $S_q \subset \mathbf{x}$  and ask the oracle “whether correctly predicting instances in  $S_q$  has higher utility or the instances in the complement  $\mathbf{x} \setminus S_q$ ?”

Recall that Proposition 3 shows that excess risk for the plug-in estimator can be bounded by the worst-error  $|u_{\text{gap}}^*(x_i) - \hat{u}_{\text{gap}}(x_i)|$  over the set of sampled datapoints  $S$ . To obtain such estimates, we introduce *Comptron* in Algorithm 1 which is a coordinate-wise variant of the classical perceptron algorithm [20]. At a high level, Comptron is an iterative procedure which estimates the utility gaps  $u_{\text{gap}}^*(x_i)$  for each  $x_i$  relative to the largest gap

$$u_{\max}^* := \max_{i \in [n]} u_{\text{gap}}^*(x_i) \leq 1. \tag{14}$$

At each iteration  $t$ , the queries  $q_{i,t}$  are selected such that  $\hat{u}_{\text{gap}}^{t-1}(\mathbf{x}, \mathbf{y}_1) > \hat{u}_{\text{gap}}^{t-1}(\mathbf{x}, \mathbf{y}_2)$  under the current estimates  $\hat{u}_{\text{gap}}^{t-1}$ . If the oracle’s response is  $r_{i,t} = 1$ , the estimates are consistent with the response and it keeps the current estimate. On the other hand, if the response  $r_{i,t} = 0$ , the algorithm decreases its current estimate of the  $i^{\text{th}}$  datapoint in order to be consistent with this query. Comptron repeats the above procedure for  $T = \log_2 k - 1$  timesteps and finally outputs the estimates  $\hat{u}_{\text{gap}}^T$ .

It is worth highlighting here that Comptron initializes all the estimates as the largest gap, that is,  $\hat{u}_{\text{gap}}^0(x_i) = u_{\max}^*$ . Such an initialization is purely symbolic in nature and the algorithm *does not* require knowledge of this value. This is because the comparison queries  $q_{i,t}$  allows

the algorithm to compare the estimates  $\hat{u}_{\text{gap}}$  with  $u_{\text{max}}^*$  and the algorithm maintains its estimates  $\hat{u}_{\text{gap}}^t$  as a multiplicative factor of  $u_{\text{max}}^*$  for iterations  $t$ . Further, we can use symbolic estimates to output the plug-in estimator since it is invariant to scaling the utility gaps by a positive constant,

$$\begin{aligned} \operatorname{argmax}_{f \in \mathcal{F}} \sum_{i=1}^n \hat{u}(x_i, f(x_i)) &\equiv \operatorname{argmax}_{f \in \mathcal{F}} \sum_{i=1}^n \hat{u}_{\text{gap}}(x_i) \cdot \mathbb{I}[f(x_i) = y_i] \\ &\equiv \operatorname{argmax}_{f \in \mathcal{F}} \sum_{i=1}^n \frac{\hat{u}_{\text{gap}}(x_i)}{u_{\text{max}}^*} \cdot \mathbb{I}[f(x_i) = y_i]. \end{aligned}$$

The following lemma provides an upper bound on the estimation error of Comptron and shows that the output estimates  $\hat{u}_{\text{gap}}(x_i)$  are within a factor  $O(\frac{u_{\text{max}}^*}{k})$  of the true gaps  $u_{\text{gap}}^*(x_i)$ .

► **Lemma 4** (Estimation error of Algorithm 1). *Given access to datapoints  $S = \{x_1, \dots, x_n\}$  and  $k$ -comparison oracle  $\mathcal{O}_k$ , Comptron (Algorithm 1) uses  $O(n \log k)$  queries to the oracle and produces estimates  $\hat{u}_{\text{gap}}$  such that*

$$\max_{i \in [n]} |\hat{u}_{\text{gap}}(x_i) - u_{\text{gap}}^*(x_i)| \leq \frac{2u_{\text{max}}^*}{k}. \quad (15)$$

We defer the proof of the lemma to the full version. The proof proceed via an inductive argument where we show that the confidence interval around  $u_{\text{gap}}^*(x_i)$  shrinks by a factor of  $\frac{1}{2}$  in each iteration for every datapoint  $x_i$ . Given the above estimation error guarantee for Comptron, the following corollary combines these with the excess risk bounds of Proposition 3 to obtain an upper bound on the excess risk of  $\hat{f}_{k,n}$ .

► **Corollary 5.** *Consider the binary decision making problem with label space  $\mathcal{Y} = \{0, 1\}$ . Given  $n$  datapoints  $\{x_1, \dots, x_n\}$  such that each  $x_i \sim \mathcal{D}_x$ , the plug-in estimate  $\hat{f}_{k,n}$  from equation (7), when instantiated with the output of Comptron (Algorithm 1), satisfies*

$$\operatorname{err}(\hat{f}_{k,n}, \mathcal{F}; u^*) \leq 2 \cdot \sup_{f \in \mathcal{F}} (|U(f; u^*) - \hat{U}(f; u^*)|) + \frac{2u_{\text{max}}^*}{k} \cdot \left( \frac{1}{n} \sum_{i=1}^n \mathbb{I}[f_{\text{ERM}}(x_i) \neq y_i] \right).$$

Corollary 5 exhibits the advantage of using higher-order comparisons for the learning with unknown utilities problem – as the order  $k$  increases, the error of the plug-in estimate decreases additively as  $O(\frac{1}{k})$ . It is worth noting here that while the higher-order comparisons allow the learner to better estimate the underlying utilities, the problem gets harder from the side of the human expert. Indeed, with higher values of  $k$ , the expert is required to compare utilities across  $k$  different possible situations which can make the elicitation a harder task.

While the results in this section exhibit how the excess risk  $\operatorname{err}(\hat{f}_{k,n}; \mathcal{F})$  varies as a function of  $k$ , they rely on the oracle responses being noiseless. In the next section, we consider the setup where the oracle responses can be noisy and propose a robust version of the Comptron algorithm for learning in this scenario.

#### 4.1.2 Estimating $u_{\text{gap}}^*$ with noisy oracle

In contrast to the deterministic noiseless oracle of the previous section, here, we consider learning with unknown utilities when the oracle  $\mathcal{O}_k$  can output noisy responses to each query. Recall from equation (5), for any query  $q$ , the noisy  $k$ -comparison oracle the correct response with probability  $1 - \eta_q$  and flips the response with probability  $\eta_q$  for some value of  $\eta_q < \frac{1}{2}$ . While we allow this error probability to vary across different queries, we assume that this error is bounded uniformly across all queries by some constant  $\eta < \frac{1}{2}$ .

■ **Algorithm 2** Rob-Comptron: Robust Comptron for estimating  $u_{\text{gap}}^*$  with noisy oracle.

---

**Input:** Datapoints  $S = \{x_1, \dots, x_n\}$ ,  $k$ -comparison oracle  $\mathcal{O}_k$ , noise level  $\eta$ , confidence  $\delta$

**Initialize:**  $T = \log_2 k - 1$ ,  $J = \frac{8}{(1-2\eta)^2} \log\left(\frac{nT}{\delta}\right)$

Obtain  $y_i = \operatorname{argmax}_y u^*(x_i, y)$  for each  $i$  using 1-comparison.

Obtain index  $i_{\max}$  using 2-comparisons such that  $i_{\max} = \operatorname{argmax}_i u_{\text{gap}}^*(x_i)$ .

Set initial estimates  $\hat{u}_{\text{gap}}^0 = [\hat{u}_{\text{gap}}^0(x_1), \dots, \hat{u}_{\text{gap}}^0(x_n)] = u_{\max}^*$  symbolically

**for**  $t = 1, \dots, T$  **do**

**for**  $i = 1, \dots, n$  **do**

Denote by  $\lambda = \frac{k}{2u_{\max}^*} \left( \hat{u}_{\text{gap}}^{t-1}(x_i) - \frac{u_{\max}^*}{2^t} \right)$

Set query  $q_{i,t} = (\mathbf{x}, \mathbf{y}_1, \mathbf{y}_2)$  where

$\mathbf{x} = (\underbrace{x_i, \dots, x_i}_{\frac{k}{2} \text{ times}}, \underbrace{x_{i_{\max}}, \dots, x_{i_{\max}}}_{\lambda \text{ times}}), \quad \mathbf{y}_1 = (\underbrace{y_i, \dots, y_i}_{\frac{k}{2} \text{ times}}, \underbrace{1 - y_{i_{\max}}, \dots, 1 - y_{i_{\max}}}_{\lambda \text{ times}}), \quad \mathbf{y}_2 = 1 - \mathbf{y}_1.$

**for**  $j = 1, \dots, J$  **do**

Query oracle  $\mathcal{O}_k$  with  $q_{i,t}$  and receive response  $r_{i,j,t}$ .

Update  $\hat{u}_{\text{gap}}^t(x_i) = \hat{u}_{\text{gap}}^{t-1}(x_i) - \mathbb{I}[\frac{1}{J} \sum_j r_{i,j,t} < \frac{1}{2}] \cdot \frac{u_{\max}^*}{2^t}.$

**Output:** Gap estimates  $\hat{u}_{\text{gap}}^T$

---

► **Assumption 6.** For the noisy  $k$ -comparison oracle described in equation (5), we have that  $\eta_q \leq \eta < \frac{1}{2}$  for all queries  $q$ .

From an algorithmic perspective, it is well known that the perceptron algorithm itself is not noise-stable and can oscillate if there are datapoints  $x$  which have noisy labels. In order to overcome this limitation, several noise-robust perceptron variants have been proposed in the literature; see [16] for an extensive review.

We build on this line of work and present Rob-Comptron (Algorithm 2), a noise-robust variant of the deterministic Comptron algorithm. The main difference is the presence of an additional inner-loop with index  $j$  which repeatedly queries  $q_{i,t}$  for  $J = \tilde{O}\left(\frac{1}{(1-2\eta)^2}\right)$  times. In each iteration, the update is again a coordinate-wise perceptron update which matches the prediction of the current estimate with the average of the oracle responses. Such an averaging has been previously used in the context of learning halfspaces from noisy data both in a passive [11] and active [25] framework.

The following lemma provides an upper bound on the estimation error of the gap estimates produced by Rob-Comptron.

► **Lemma 7** (Estimation error of Algorithm 2). Given access to datapoints  $S = \{x_1, \dots, x_n\}$  and noisy  $k$ -comparison oracle  $\mathcal{O}_k$  satisfying Assumption 6 with parameter  $\eta$ , Rob-Comptron (Algorithm 2) uses  $O\left(\frac{n}{(1-2\eta)^2} \cdot \log k \cdot \log \frac{n \log k}{\delta}\right)$  queries and produces estimates  $\hat{u}_{\text{gap}}$  such that

$$\max_{i \in [n]} |\hat{u}_{\text{gap}}(x_i) - u_{\text{gap}}^*(x_i)| \leq \frac{2u_{\max}^*}{k}, \quad (16)$$

with probability at least  $1 - \delta$ .

In comparison to Comptron which requires  $O(n \log k)$  queries to the comparison oracle, the robust variant Rob-Comptron requires a fraction  $\frac{1}{(1-2\eta)^2}$  more queries to achieve a similar estimation error. Such an increase in query complexity is typical of learning with such noisy oracles in the binary classification setup [5, 7, 12, 25].

Similar to Corollary 5 in the previous section, we can combine the above high-probability bound on the estimation error to obtain a bound on the excess risk which scales as  $\frac{1}{k}$  with the order  $k$  of the comparison oracle.

► **Corollary 8.** *Consider the binary decision making problem with label space  $\mathcal{Y} = \{0, 1\}$ . Given  $n$  datapoints  $\{x_1, \dots, x_n\}$  such that each  $x_i \sim \mathcal{D}_x$ , the plug-in estimate  $\hat{f}_{k,n}$  from equation (7), when instantiated with the output of Comptron (Algorithm 1), satisfies*

$$\text{err}(\hat{f}_{k,n}, \mathcal{F}; u^*) \leq 2 \cdot \sup_{f \in \mathcal{F}} \left( |U(f; u^*) - \hat{U}(f; u^*)| \right) + \frac{2u_{\max}^*}{k} \cdot \left( \frac{1}{n} \sum_{i=1}^n \mathbb{I}[f_{\text{ERM}}(x_i) \neq y_i] \right).$$

with probability at least  $1 - \delta$ .

We omit the proof of this corollary since it essentially follows the same steps as that for Corollary 5. This corollary establishes that by increasing the query complexity by a factor of  $O(1/(1-2\eta)^2)$ , one can recover the same additive  $\frac{1}{k}$  excess risk bound of the deterministic setup. Combined, Corollaries 5 and 8 establish the trade-offs in the reduction of the excess risk while eliciting more complex information about the underlying utility  $u^*$  through the  $k$ -comparison oracle.

## 4.2 Information-theoretic lower bounds

In the previous section, we studied the learning with unknown utility problem from an algorithmic perspective and showed that the plug-in estimator with Comptron estimates  $\hat{u}$  achieve an excess risk bound which scales as  $O(\frac{1}{k})$  with the order  $k$  of the comparison. In this section, we ask whether such a scaling of the error term is optimal and study this lower bound question from an information-theoretic perspective.

Recall from Theorem 2 that the excess risk decomposes into two terms: (i) a uniform convergence term for the decision class  $\mathcal{F}$  with respect to utility function  $u^*$  and (ii) an estimation error term corresponding to how well  $\hat{u}_k$  approximates  $u^*$  on the sampled datapoints. When the underlying utility function  $u^*$  is known, classical results from the learning theory literature the uniform convergence complexity term is in general unavoidable [21]. With this, we take the infinite-data limit, where the learner is assumed to have access to the distribution  $\mathcal{D}_x$ , and study whether the excess error of  $O(\frac{1}{k})$  is necessary.

Our notion of minimax risk is based on the subset of utility functions which cannot be distinguished by any learner with access to a  $k$ -comparison oracle. Formally, given any oracle  $\mathcal{O}_k(\cdot; u^*)$ , where we have made the dependence on the utility  $u^*$  explicit, we denote by  $\mathcal{U}_{k,u^*}$  the subset of utility functions in the class  $\mathcal{U}$  which are consistent with the responses of  $\mathcal{O}_k(\cdot; u^*)$ . With this, we define the information-theoretic minimax risk  $\mathfrak{M}_k(\mathcal{F}, \mathcal{D}_x)$  with respect to the function class  $\mathcal{F}$  and distribution  $\mathcal{D}_x$  as

$$\mathfrak{M}_k(\mathcal{F}, \mathcal{D}_x) := \sup_{\mathcal{O}_k(\cdot; u^*)} \inf_{p \in \Delta_{\mathcal{F}}} \sup_{u \in \mathcal{U}_{k,u^*}} \mathbb{E}_{f \sim p} [\text{err}(f, \mathcal{F}; u)], \quad (17)$$

where the infimum is taken over all procedures which take as input the distribution  $\mathcal{D}_x$  over the instances and access to a  $k$ -comparison oracle, and output a possibly randomized estimate  $p \in \Delta_{\mathcal{F}}$ . The above notion of minimax risk can be viewed as a three-stage game

between the learner and the environment. The sequence of supremum and infimum depicts the order in which information is revealed in this game. The environment first selects a  $k$ -query oracle  $\mathcal{O}(\cdot; u^*)$  with underlying utility  $u^*$ . The learner is then provided access to the underlying distribution  $\mathcal{D}_x$ , function class  $\mathcal{F}$  and the oracle  $\mathcal{O}(\cdot; u^*)$  based on which it outputs a possibly randomized decision function given by  $p \in \Delta_{\mathcal{F}}$ . The environment is then allowed to select the worst-case utility  $u$  such that it is consistent with the  $k$ -oracle  $\mathcal{O}(\cdot; u^*)$  and the learner is evaluated in expectation over this chosen utility. We call this the minimax risk of learning with respect to class  $\mathcal{F}$  and distribution  $\mathcal{D}_x$ .

Our next main result shows that there exist instances of the binary prediction problem  $(\mathcal{F}, \mathcal{D}_x)$  such that the minimax risk  $\mathfrak{M}_k(\mathcal{F}, \mathcal{D}_x)$  is lower bounded by  $\frac{1}{k}$  for any  $k \geq 2$  up to some universal constants. Observe that this matches the corresponding upper bounds obtained in Corollaries 5 and 8 exhibiting that the proposed plug-in estimator in equation (7) with Comptron (Rob-Comptron for noisy oracle) utilities is indeed minimax optimal for the binary prediction setup.

► **Theorem 9.** *There exists a universal constant  $c > 0$  such that for any  $k \geq 2$ , there exist a binary prediction problem instance  $(\mathcal{F}, \mathcal{D}_x)$  such that*

$$\mathfrak{M}_k(\mathcal{F}, \mathcal{D}_x) \geq \frac{c}{k}.$$

A few comments on Theorem 9 are in order. First, the above result shows a family of lower bounds for our learning with unknown utilities framework – one for each value of the order  $k$ . Specifically, it shows that for every  $k \geq 2$ , there exists a worst-case instance such that any algorithm will incur an error of  $\Omega(\frac{1}{k})$ . Compare this with the upper bounds on excess risk from the previous section. In the limit of infinite data, Corollaries 5 and 8 exhibit that the excess risk  $\text{err}(\hat{f}_{k,n}, \mathcal{F}; u^*) = O(\frac{1}{k})$  for the plug-in estimator  $\hat{f}_{k,n}$ . This establishes that the plug-in estimator with Comptron and Rob-Comptron utility estimates is indeed minimax optimal.

**Proof.** In order to establish a lower bound on the minimax risk  $\mathfrak{M}_k$ , we will construct two utility functions  $u_1, u_2 \in \mathcal{U}$  such that the  $k$ -comparison oracle has identical responses for both these utility functions. For the purpose of our construction, we will consider noiseless oracle; the problem only becomes harder for the learner if the oracle responses are noisy. Given these two utility functions, we next show that their maximizers  $f_1$  and  $f_2$  are different for some function class  $\mathcal{F}$ . We then combine these two insights to obtain the final minimax bound.

For our lower bound construction, we will focus on a setup where the features are one dimensional with  $\mathcal{X} = \mathbb{R}$  and the linear decision function class

$$\mathcal{F}_{\text{lin}} = \{f_a \mid f_a(x) = \text{sign}(ax), a \in [-1, 1]\}.$$

Recall that for any point  $x$ , we represent by  $u_{\text{gap}}(x) = u(x, y_x) - u(x, \bar{y}_x)$  the utility gain corresponding to the function  $u$ . Before constructing the explicit example, we present a technical lemma which highlights a limitation of a  $k$ -comparison oracle – it establishes that a  $k$ -oracle will not be able to distinguish utility functions for which the utility gaps are in the range  $(1 - \frac{1}{k}, 1)$ .

► **Lemma 10.** *Consider any utility functions  $u_1, u_2 \in \mathcal{U}$ . Let datapoints  $x$  have utility gain  $u_{\text{gap}}^i(x)$  for  $i = \{1, 2\}$ . For any two points  $x_1, x_2$  such that*

$$u_{\text{gap}}^1(x_1) = u_{\text{gap}}^2(x_1) = u_{\text{gap}}(x_1) \quad \text{and} \quad \left(1 - \frac{1}{k}\right) \cdot u_{\text{gap}}(x_1) \leq u_{\text{gap}}^i(x_2) \leq u_{\text{gap}}(x_1),$$

*the oracle responses for any query  $q = (\mathbf{x}, \mathbf{y}_1, \mathbf{y}_2)$  comprising points  $x_1$  and  $x_2$  are identical for  $u^* = u_1$  or  $u^* = u_2$ .*

We defer the proof of the above lemma to the full version. Taking this as given, we proceed with our lower bound construction.

**Utility functions  $u_1$  and  $u_2$ .** Our construction considers two datapoints  $x_+ = +1$  and  $x_- = -1$  and two utility functions  $u$  and  $\tilde{u}$  satisfying

$$\begin{aligned} u_1(x_+, 1) &> u_1(x_+, 0) \quad \text{and} \quad u_1(x_-, 1) > u_1(x_-, 0), \\ u_2(x_+, 1) &> u_2(x_+, 0) \quad \text{and} \quad u_2(x_-, 1) > u_2(x_-, 0). \end{aligned}$$

Observe that under these utilities, any function  $f_a \in \mathcal{F}_{\text{lin}}$  can make a correct decision for either point  $x_+$  or point  $x_-$  but not for both simultaneously. Given these datapoints, the two utility functions are given by

$$\begin{aligned} u_1(x_+, 1) &= 1, \quad u_1(x_-, 1) = 1 - \gamma_1 \quad \text{where} \quad \gamma_1 = \frac{1}{2(3k+1)} \\ u_2(x_+, 1) &= 1, \quad u_2(x_-, 1) = 1 - \gamma_2 \quad \text{where} \quad \gamma_2 = \frac{2}{(3k+1)}, \end{aligned}$$

and  $u_i(x, 0) = 0$  for both  $i = \{1, 2\}$ . Observe that both  $\gamma_1, \gamma_2$  have been set to satisfy the conditions of Lemma 10, that is,

$$\left(1 - \frac{1}{k}\right) \cdot u_{\text{gap}}(x_+) \leq u_{\text{gap}}^i(x_-) \leq u_{\text{gap}}(x_+) \quad \text{for } i = \{1, 2\}.$$

**Distribution  $\mathcal{D}_x$ .** For any  $k > 2$ , consider the distribution  $\mathcal{D}_x$  over the points  $\{x_+, x_-\}$  such that

$$\Pr(x = x_+) = \frac{3k}{6k+1} \quad \text{and} \quad \Pr(x = x_-) = \frac{3k+1}{6k+1}.$$

By Lemma 10, we have that using the  $k$ -comparison oracle, no learner can distinguish between the utility functions  $u_1$  and  $u_2$  on the distribution  $\mathcal{D}_x$ . Further, recall that any classifier  $f_a \in \mathcal{F}_{\text{lin}}$  can either predict  $x_+$  or  $x_-$  correctly. We now obtain a bound on the excess risk  $\text{err}(f_a, \mathcal{F}; u)$  for both these cases separately.

**Case 1:**  $f_a(x_+) = 1$ . In this case, the utility gap is maximized by setting the utility  $u = u_1$  in the minimax risk. The corresponding excess risk is given by

$$\text{err}(f_a, \mathcal{F}; u_1) = \frac{(3k+1)(1-\gamma_1)}{6k+1} - \frac{3k}{6k+1} = \frac{1}{2(6k+1)}. \quad (18)$$

**Case 2:**  $f_a(x_-) = 1$ . In this case, the utility gap is maximized by setting the utility  $u = u_2$  and the excess risk is given by

$$\text{err}(f_a, \mathcal{F}; u_2) = \frac{3k}{6k+1} - \frac{(3k+1)(1-\gamma_2)}{6k+1} = \frac{1}{(6k+1)}. \quad (19)$$

Noting that any predictor  $\hat{f}$  will output a function corresponding to one of the two cases above and combining equations (18) and (19) establishes the desired claim.  $\blacktriangleleft$

While the information theoretic results of this section showed that the plug-in estimator is minimax optimal, the next section focuses on whether this estimator is able to *adapt* to easier problem instances – specifically, whether our estimation procedures Comptron and Rob-Comptron are optimal for every problem instance? We answer this in the negative and introduce a new estimator which is instance optimal. However, such an adaptivity to easier instances comes at the cost of an exponential query complexity.

## 5 Instance-optimal guarantees for binary prediction

In the previous section, we proposed query-efficient algorithms, Comptron and Rob-Comptron, for learning a function  $\hat{f}_{k,n}$  with small excess risk using only  $\tilde{O}(n \log k)$  queries to the  $k$ -comparison oracle. Further, the upper bounds in Corollaries 5 and 8 along with the lower bound of Theorem 9 establish that our proposed algorithms are indeed minimax optimal over the class of utility functions  $\mathcal{U}$ . Given this, it is natural to ask whether our proposed algorithms are instance wise-optimal, that is, do they achieve the best possible excess-risk bounds for *all*  $u^* \in \mathcal{U}$ ?

To simplify our presentation, we study this question at the population level,<sup>5</sup> where we assume that the learner has access to the underlying distribution  $\mathcal{D}_x$ . This allows us to focus on the excess risk as a function of the order  $k$  of the comparison oracle and ignore the uniform convergence term. We also restrict our attention to the deterministic noiseless oracle since one can reduce the noisy oracle to the noiseless oracle by using the averaging technique presented in Section 4.1.

The following proposition shows that the plug-in estimator with Comptron utilities are *not instance-optimal*, that is, it does not adapt to the hardness of the learning with unknown utilities problem instance. Specifically, it constructs a problem instance  $(\mathcal{F}, \mathcal{D}_x)$  with a noiseless oracle and shows that the estimate<sup>6</sup>  $\hat{f}_k$  from equation (7) with Comptron utility estimates has an excess risk of  $\frac{1}{k}$  while there exists an estimator, which uses all  $k$ -queries and is able to achieve zero excess risk.

Recall that for any utility  $u^* \in \mathcal{U}$ , we denote by  $\mathcal{U}_{k,u^*}$  the subset of utility functions in the class  $\mathcal{U}$  which are indistinguishable from  $u^*$  under the  $k$ -comparison oracle  $\mathcal{O}(\cdot; u^*)$ .

► **Proposition 11** (Plug-in with Comptron estimates is not instance-optimal). *For every  $k > 2$ , there exists a binary prediction instance  $(\mathcal{F}, \mathcal{D}_x)$  along with an oracle  $\mathcal{O}_k$  such that*

a) *The error of the plug-in estimate  $\hat{f}_k$  from equation (7) with estimated utilities  $\hat{u}_k$  from Comptron (Algorithm 1) is non-zero, that is,*

$$\text{err}(\hat{f}_k, \mathcal{F}; u^*) = \frac{1}{k}.$$

b) *There exists an optimal predictor  $\tilde{f}$  with zero excess-risk, that is,*

$$\sup_{u \in \mathcal{U}_{k,u^*}} \text{err}(\tilde{f}, \mathcal{F}; u) = 0.$$

We make a few remarks about the proposition. While the first part of the proposition shows that the excess risk  $\text{err}(\hat{f}_k, \mathcal{F}; u^*) = \frac{1}{k}$ , the second part makes a stronger claim about the performance of  $\tilde{f}$  on all utilities  $u \in \mathcal{U}_{k,u^*}$ . This shows that the predictor  $\tilde{f}$  performs well when evaluated on an entire neighborhood around the true utility  $u^*$ .

Having established that our estimators from the previous section are not adaptive, we introduce a notion of *local minimax risk* and study estimators which are instance-optimal. We begin by precisely defining this notion of instance-wise minimax optimality. Recall from Section 4.2, our notion of minimax risk  $\mathfrak{M}_k(\mathcal{F}, \mathcal{D}_x)$  was a worst-case notion – the minimax risk was defined as a supremum over all oracles  $\mathcal{O}_k(\cdot; u^*)$ . We extend this global minimax notion to a local minimax one. In particular, for any  $u^* \in \mathcal{U}$ , we define the local minimax risk around  $u^*$  as

<sup>5</sup> Our analysis could be extended to the finite sample setup using the bound obtained in Theorem 2.

<sup>6</sup> Since we are working at the population level, we have dropped the subscript  $n$  from  $\hat{f}_{k,n}$ .

$$\mathfrak{M}_k(\mathcal{F}, \mathcal{D}_x; u^*) := \inf_{\hat{f}} \sup_{u \in \mathcal{U}_{|u^*}} \left[ \text{err}(\hat{f}, \mathcal{F}; u) \right], \quad (20)$$

where the infimum is again over the set of all estimators which output a function  $\hat{f} \in \mathcal{F}$  given access to distribution  $\mathcal{D}_x$  and  $k$ -comparison oracle  $\mathcal{O}_k$ . Observe that this local notion of minimax risk concerns the performance of an algorithm  $\hat{f}$  around a specific instance  $u^*$  as compared to the worst-case instance.

For any utility function  $u \in \mathcal{U}$ , we define its population maximizer  $f_u \in \text{argmax}_{f \in \mathcal{F}} U(f; u)$ . With this notation, our next theorem provides a lower bound on this local minimax risk in terms of a local modulus of continuity with respect to the set  $\mathcal{U}_{k, u^*}$ .

► **Theorem 12** (Local minimax lower bound). *For any distribution  $\mathcal{D}_x$  over feature space  $\mathcal{X}$ , utility function  $u^* \in \mathcal{U}$ , function class  $\mathcal{F}$  and order  $k$  of the comparison oracle, the local minimax risk*

$$\mathfrak{M}_k(\mathcal{F}, \mathcal{D}_x; u^*) \geq \frac{1}{2} \cdot \sup_{u_1, u_2 \in \mathcal{U}_{k, u^*}} \left( U(f_{u_1}; u_1) - U(f_{\frac{u_1+u_2}{2}}; u_1) \right). \quad (21)$$

**Proof.** Consider any two utility functions  $u_1, u_2 \in \mathcal{U}_{k, u^*}$  and let  $\bar{u} = \frac{u_1+u_2}{2}$ . We can then lower bound the minimax risk as

$$\begin{aligned} \mathfrak{M}_k(\mathcal{F}, \mathcal{D}_x; u^*) &\geq \inf_{f \in \mathcal{F}} \left( \frac{1}{2} \text{err}(f, \mathcal{F}; u_1) + \frac{1}{2} \text{err}(f, \mathcal{F}; u_2) \right) \\ &= \frac{1}{2} \text{err}(f_{\bar{u}}, \mathcal{F}; u_1) + \frac{1}{2} \text{err}(f_{\bar{u}}, \mathcal{F}; u_2) \\ &\geq \frac{1}{2} (U(f_{u_1}; u_1) - U(f_{\bar{u}}; u_1)), \end{aligned}$$

where the last equality follows by noting that  $\text{err}(f_{\bar{u}}, \mathcal{F}; u_2) \geq 0$ . Since the above holds for any choice of  $u_1, u_2$ , the desired bound follows by taking a supremum over these values. ◀

A few comments on Theorem 12 are in order. The theorem establishes that the local minimax risk  $\mathfrak{M}_k(\mathcal{F}, \mathcal{D}_x)$  is lower bounded by a local modulus of continuity,

$$\sup_{u_1, u_2 \in \mathcal{U}_{k, u^*}} \left( U(f_{u_1}; u_1) - U(f_{\frac{u_1+u_2}{2}}; u_1) \right), \quad (22)$$

which captures the worst-case variation in the performance of utility maximizers of utility in a neighborhood of  $u^*$ . For any two utilities  $u_1, u_2 \in \mathcal{U}_{k, u^*}$ , it measures the performance drop in the utility of a learner uses the maximizer  $f_{\frac{u_1+u_2}{2}}$  in place of  $f_{u_1}$  when the underlying utility is  $u_1$ .

Given this lower bound on the local minimax risk  $\mathfrak{M}_k(\mathcal{F}, \mathcal{D}_x)$ , it is natural to ask whether this local modulus of continuity exactly captures the instance-specific hardness of the problem. To this end, our next result answers this in the affirmative. In particular, it shows that for any  $u^*$ , the randomized minimax robust estimator  $p_{\text{rob}} \in \Delta_{\mathcal{F}}$ , given by

$$p_{\text{rob}} \in \text{argmin}_{p \in \Delta_{\mathcal{F}}} \sup_{u \in \mathcal{U}_{k, u^*}} \mathbb{E}_{f \sim p} [\text{err}(f, \mathcal{F}; u)], \quad (23)$$

(nearly-)obtains the same excess-risk bound as that given by the lower bound in Theorem 12.

► **Theorem 13** (Upper bounds for  $p_{\text{rob}}$ ). *For any distribution  $\mathcal{D}_x$  over feature space  $\mathcal{X}$ , utility function  $u^* \in \mathcal{U}$  and function class  $\mathcal{F}$ , the expected excess risk of the randomized estimator given by the distribution  $p_{\text{rob}} \in \Delta_{\mathcal{F}}$  is*

$$\begin{aligned} \mathbb{E}[\text{err}(p_{\text{rob}}, \mathcal{F}; u^*)] &= \sup_{p_u} (\mathbb{E}_{u' \sim p_u} [U(f_{u'}; u') - U(f_{p_u}; u')]) \\ &\leq \sup_{u_1, u_2 \in \mathcal{U}_{k, u^*}} (U(f_{u_1}; u_1) - U(f_{u_2}; u_1)), \end{aligned} \quad (24)$$

where the distribution  $p_u \in \Delta_{\mathcal{U}_{k, u^*}}$  is over the space of utility functions consistent with  $u^*$ .

We defer the proof of Theorem 13 to the full version. Compared with the lower bound of Theorem 12, the bound in (24) shows that the local minimax risk can indeed be upper bounded by a similar local modulus of continuity. Observe that while the lower bound evaluates the performance loss of the maximizer  $f_{\frac{u_1+u_2}{2}}$ , the upper bound is evaluated on  $f_{u_2}$ . While the minimax estimator  $p_{\text{rob}}$  in equation (23) is defined at the population level, we can naturally extend it to the finite sample regime as

$$\hat{p}_{\text{rob}, n} \in \underset{p \in \Delta_{\mathcal{F}}}{\text{argmin}} \sup_{u \in \hat{\mathcal{U}}_{k, u^*}} \mathbb{E}_{f \sim p} [\hat{U}(f_u; u) - \hat{U}(f; u)] \quad (25)$$

where the class of utilities  $\hat{\mathcal{U}}_{k, u^*}$  represents the set of all  $n$ -dimensional vectors in  $[0, 1]^n$  which are consistent with responses to all  $k$ -queries on the set of sampled datapoints  $S$ . Using a similar analysis as in Theorem 2, one can then upper bound the excess risk of this estimator in terms of the local modulus on the dataset  $S$  and an additional uniform convergence term.

In comparison to the Comptron procedure which uses  $O(n \log k)$  queries to the comparison oracle for estimating utilities, the estimator  $\hat{p}_{\text{rob}, n}$  uses  $O(n^k)$  queries to construct the set  $\hat{\mathcal{U}}_{k, u^*}$ . Thus, while this estimator adapts to the problem hardness, such an adaptation comes at the cost of an exponential increase in query complexity. Achieving instance-optimality by using fewer queries is an interesting question for future research.

## Abstract

We study the setup where each of  $n$  users holds an element from a discrete set, and the goal is to count the number of distinct elements across all users, under the constraint of  $(\epsilon, \delta)$ -differentially privacy:

- In the non-interactive *local* setting, we prove that the additive error of any protocol is  $\Omega(n)$  for any constant  $\epsilon$  and for any  $\delta$  inverse polynomial in  $n$ .
- In the *single-message shuffle* setting, we prove a lower bound of  $\tilde{\Omega}(n)$  on the error for any constant  $\epsilon$  and for some  $\delta$  inverse quasi-polynomial in  $n$ . We do so by building on the moment-matching method from the literature on distribution estimation.
- In the *multi-message shuffle* setting, we give a protocol with at most one message per user in expectation and with an error of  $\tilde{O}(\sqrt{n})$  for any constant  $\epsilon$  and for any  $\delta$  inverse polynomial in  $n$ . Our protocol is also robustly shuffle private, and our error of  $\sqrt{n}$  matches a known lower bound for such protocols.

Our proof technique relies on a new notion, that we call *dominated protocols*, and which can also be used to obtain the first non-trivial lower bounds against multi-message shuffle protocols for the well-studied problems of selection and learning parity.

Our first lower bound for estimating the number of distinct elements provides the first  $\omega(\sqrt{n})$  separation between global sensitivity and error in local differential privacy, thus answering an open question of Vadhan (2017). We also provide a simple construction that gives  $\tilde{\Omega}(n)$  separation between global sensitivity and error in *two-party* differential privacy, thereby answering an open question of McGregor et al. (2011).

## 1 Introduction

Differential privacy (DP) [20, 19] has become a leading framework for private-data analysis, with several recent practical deployments [25, 39, 28, 3, 16, 1]. The most commonly studied DP setting is the so-called central (aka curator) model whereby a single authority (sometimes referred to as the analyst) is trusted with running an algorithm on the raw data of the users and the privacy guarantee applies to the algorithm’s output.

The absence, in many scenarios, of a clear trusted authority has motivated the study of *distributed* DP models. The most well-studied such setting is the *local* model [31] (also [44]), denoted henceforth by  $\text{DP}_{\text{local}}$ , where the privacy guarantee is enforced at each user’s output (i.e., the protocol transcript). While an advantage of the local model is its very strong privacy guarantees and minimal trust assumptions, the noise that has to be added can sometimes be quite large. This has stimulated the study of “intermediate” models that seek to achieve accuracy close to the central model while relying on more distributed trust assumptions. One such middle-ground is the so-called *shuffle* (aka *anonymous*) model [29, 8, 12, 24], where the users send messages to a *shuffler* who randomly shuffles these messages before sending them to the analyzer; the privacy guarantee is enforced on the shuffled messages (i.e., the input to the analyzer). We study both the local and the shuffle models in this work.

### 1.1 Counting Distinct Elements

A basic function in data analytics is estimating the number of distinct elements in a domain of size  $D$  held by a collection of  $n$  users, which we denote by  $\text{CountDistinct}_{n,D}$  (and simply by  $\text{CountDistinct}_n$  if there is no restriction on the universe size). Beside its use in database management systems, it is a well-studied problem in sketching, streaming, and communication complexity (e.g., [30, 9] and the references therein). In central DP, it can be easily solved with constant error using the Laplace mechanism [20]; see also [36, 15, 38, 14].

We obtain new results on  $(\epsilon, \delta)$ -DP protocols for  $\text{CountDistinct}$  in the local and shuffle settings<sup>2</sup>.

#### 1.1.1 Lower Bounds for Local DP Protocols

Our first result is a lower bound on the additive error of  $\text{DP}_{\text{local}}$  protocols<sup>3</sup> for counting distinct elements.

► **Theorem 1.** *For any  $\epsilon = O(1)$ , no public-coin  $(\epsilon, o(1/n))$ - $\text{DP}_{\text{local}}$  protocol can solve<sup>4</sup>  $\text{CountDistinct}_{n,n}$  with error  $o(n)$ .*

The lower bound in Theorem 1 is asymptotically tight<sup>5</sup>. Furthermore, it answers a question of Vadhan [42, Open Problem 9.6], who asked if there is a function with a gap of  $\omega(\sqrt{n})$  between its (global) sensitivity and the smallest achievable error by any  $\text{DP}_{\text{local}}$

<sup>2</sup> For formal definitions, please refer to Section 2. We remark that, throughout this work, we consider the *non-interactive* local model where all users apply the *same* randomizer (see Definition 15). We briefly discuss in Section 1.4 possible extensions to interactive local models. See the full version for how to generalize our results to the relaxed setting where each user can apply different randomizers to their inputs.

<sup>3</sup> See Section 2 for the formal (standard) definition of public-coin DP protocols. Note that private-coin protocols are a sub-class of public-coin protocols, so all of our lower bounds apply to private-coin protocols as well.

<sup>4</sup> Throughout this work, we say that a randomized algorithm solves a problem with error  $e$  if with probability 0.99 it incurs error at most  $e$ .

<sup>5</sup> The trivial algorithm that always outputs 0 incurs an error  $n$ .

protocol.<sup>6</sup> As the global sensitivity of the number of distinct elements is 1, Theorem 1 exhibits a (natural) function for which this gap is as large as  $\Omega(n)$ . While Theorem 1 applies to the constant  $\varepsilon$  regime, it turns out we can prove a lower bound for much less private protocols (i.e., having a much larger  $\varepsilon$  value) at the cost of polylogarithmic factors in the error:

► **Theorem 2.** *For some  $\varepsilon = \ln(n) - O(\ln \ln n)$  and  $D = \Theta(n / \text{polylog}(n))$ , no public-coin  $(\varepsilon, n^{-\omega(1)})$ -DP<sub>local</sub> protocol can solve  $\text{CountDistinct}_{n,D}$  with error  $o(D)$ .*

To prove Theorem 2, we build on the *moment matching* method from the literature on (non-private) distribution estimation, namely [43, 45], and tailor it to  $\text{CountDistinct}$  in the DP<sub>local</sub> setting (see Section 3.1 for more details on this connection). The bound on the privacy parameter  $\varepsilon$  in Theorem 2 turns out to be very close to tight: the error drops quadratically when  $\varepsilon$  exceeds  $\ln n$ . This is shown in the next theorem:

► **Theorem 3.** *There is a  $(\ln(n) + O(1))$ -DP<sub>local</sub> protocol solving  $\text{CountDistinct}_{n,n}$  with error  $O(\sqrt{n})$ .*

### 1.1.2 Lower Bounds for Single-Message Shuffle DP Protocols

In light of the negative result in Theorem 2, a natural question is whether  $\text{CountDistinct}$  can be solved in a weaker distributed DP setting such as the shuffle model. It turns out that this is not possible using any shuffle protocol where each user sends no more than 1 message (for brevity, we will henceforth denote this class by  $\text{DP}_{\text{shuffle}}^1$ , and more generally denote by  $\text{DP}_{\text{shuffle}}^k$  the variant where each user can send up to  $k$  messages). Note that the class  $\text{DP}_{\text{shuffle}}^1$  includes any method obtained by taking a DP<sub>local</sub> protocol and applying the so-called *amplification by shuffling* results of [24, 6].

In the case where  $\varepsilon$  is any constant and  $\delta$  is inverse quasi-polynomial in  $n$ , the improvement in the error for  $\text{DP}_{\text{shuffle}}^1$  protocols compared to DP<sub>local</sub> is at most polylogarithmic factors:

► **Theorem 4.** *For all  $\varepsilon = O(1)$ , there are  $\delta = 2^{-\text{polylog}(n)}$  and  $D = n / \text{polylog}(n)$  such that no public-coin  $(\varepsilon, \delta)$ -DP<sub>shuffle</sub><sup>1</sup> protocol can solve  $\text{CountDistinct}_{n,D}$  with error  $o(D)$ .*

We note that Theorem 4 essentially answers a more general variant of Vadhan’s question: it shows that even for  $\text{DP}_{\text{shuffle}}^1$  protocols (which include DP<sub>local</sub> protocols as a sub-class) the gap between sensitivity and the error can be as large as  $\tilde{\Omega}(n)$ .

The proof of Theorem 4 follows by combining Theorem 2 with the following connection between DP<sub>local</sub> and  $\text{DP}_{\text{shuffle}}^1$ :

► **Lemma 5.** *For any  $\varepsilon = O(1)$  and  $\delta \leq \delta_0 \leq 1/n$ , if the randomizer  $R$  is  $(\varepsilon, \delta)$ -DP<sub>shuffle</sub><sup>1</sup> on  $n$  users, then  $R$  is  $(\ln n - \ln(\Theta_\varepsilon(\log \delta_0^{-1} / \log \delta^{-1})), \delta_0)$ -DP<sub>local</sub>.*

We remark that Lemma 5 provides a stronger quantitative bound than the qualitatively similar connections in [12, 27]; specifically, we obtain the term  $\ln(\Theta_\varepsilon(\log \delta_0^{-1} / \log \delta^{-1}))$ , which was not present in the aforementioned works. This turns out to be crucial for our purposes, as this term gives the  $O(\ln \ln n)$  term necessary to apply Theorem 2.

<sup>6</sup> To the best of our knowledge, the largest previously known gap between global sensitivity and error was  $O(\sqrt{n})$ , which is achieved, e.g., by binary summation [11]. For  $\text{CountDistinct}$ , the lower bound of [21] on pan-private algorithms against two intrusions along with the equivalence shown by [2] between this model and sequential local DP, imply a lower bound of  $\Omega(n)$  against *pure* DP protocols. A lower bound against approximate DP protocols can then be obtained via the transformation of [10]; however, this lower bound would only hold for an  $\varepsilon$  bounded strictly below one (e.g.,  $1/4$ ), whereas our lower bound in Theorem 1 holds for  $\varepsilon$  an arbitrarily large constant.

### 1.1.3 A Communication-Efficient Shuffle DP Protocol

In contrast with Theorem 4, Balcer et al. [5] recently gave a  $\text{DP}_{\text{shuffle}}$  protocol for  $\text{CountDistinct}_{n,D}$  with error  $O(\sqrt{D})$ . Their protocol sends  $\Omega(D)$  messages per user. We instead show that an error of  $\tilde{O}(\sqrt{D})$  can still be guaranteed with each user sending *in expectation* at most one message each of length  $O(\log D)$  bits.

► **Theorem 6.** *For all  $\varepsilon \leq O(1)$  and  $\delta \leq 1/n$ , there is a public-coin  $(\varepsilon, \delta)$ - $\text{DP}_{\text{shuffle}}$  protocol that solves  $\text{CountDistinct}_n$  with error  $\sqrt{\min(n, D)} \cdot \text{poly}(\log(1/\delta)/\varepsilon)$  where the expected number of messages sent by each user is at most one.*

In the special case where  $D = o(n / \text{poly}(\varepsilon^{-1} \log(\delta^{-1})))$ , we moreover obtain a *private-coin*  $\text{DP}_{\text{shuffle}}$  protocol achieving the same guarantees as in Theorem 6 (see the full version for a formal statement). Note that Theorem 6 is in sharp contrast with the lower bound shown in Theorem 4 for  $\text{DP}_{\text{shuffle}}^1$  protocols. Indeed, for  $\delta$  inverse quasi-polynomial in  $n$ , the former implies a public-coin protocol with less than one message per-user *in expectation* having error  $\tilde{O}(\sqrt{n})$  whereas the latter proves that no such protocol exists, even with error as large as  $\tilde{\Omega}(n)$ , if we restrict each user to send one message *in the worst case*.

A strengthening of  $\text{DP}_{\text{shuffle}}$  protocols called *robust  $\text{DP}_{\text{shuffle}}$  protocols*<sup>7</sup> was studied by [5], who proved an  $\Omega(\sqrt{\min(D, n)})$  lower bound on the error of any protocol solving  $\text{CountDistinct}_{n,D}$ . Our protocols are robust  $\text{DP}_{\text{shuffle}}$  and, therefore, achieve the optimal error (up to polylogarithmic factors) among all robust  $\text{DP}_{\text{shuffle}}$  protocols, while only sending at most one message per user in expectation.

## 1.2 Dominated Protocols and Multi-Message Shuffle DP Protocols

The technique underlying the proof of Theorem 1 can be extended beyond  $\text{DP}_{\text{local}}$  protocols for  $\text{CountDistinct}$ . It applies to a broader category of protocols that we call *dominated*, defined as follows:

► **Definition 7.** *We say that a randomizer  $R: \mathcal{X} \rightarrow \mathcal{M}$  is  $(\varepsilon, \delta)$ -dominated, if there exists a distribution  $\mathcal{D}$  on  $\mathcal{M}$  such that for all  $x \in \mathcal{X}$  and all  $E \subseteq \mathcal{M}$ ,*

$$\Pr[R(x) \in E] \leq e^\varepsilon \cdot \Pr_{\mathcal{D}}[E] + \delta.$$

*In this case, we also say  $R$  is  $(\varepsilon, \delta)$ -dominated by  $\mathcal{D}$ . We define  $(\varepsilon, \delta)$ -dominated protocols in the same way as  $(\varepsilon, \delta)$ - $\text{DP}_{\text{local}}$ , except that we require the randomizer to be  $(\varepsilon, \delta)$ -dominated instead of being  $(\varepsilon, \delta)$ -DP.*

Note that an  $(\varepsilon, \delta)$ - $\text{DP}_{\text{local}}$  randomizer  $R$  is  $(\varepsilon, \delta)$ -dominated: we can fix a  $y^* \in \mathcal{X}$  and take  $\mathcal{D} = R(y^*)$ . Therefore, our new definition is a relaxation of  $\text{DP}_{\text{local}}$ .

We show that *multi-message*  $\text{DP}_{\text{shuffle}}$  protocols are dominated, which allows us to prove the first non-trivial lower bounds against  $\text{DP}_{\text{shuffle}}^{O(1)}$  protocols.

Before formally stating this connection, we recall why known lower bounds against  $\text{DP}_{\text{shuffle}}^1$  protocols [12, 27, 4] do not extend to  $\text{DP}_{\text{shuffle}}^{O(1)}$  protocols.<sup>8</sup> These prior works use the connection stating that any  $(\varepsilon, \delta)$ - $\text{DP}_{\text{shuffle}}^1$  protocol is also  $(\varepsilon + \ln n, \delta)$ - $\text{DP}_{\text{local}}$  [12,

<sup>7</sup> Roughly speaking, they are  $\text{DP}_{\text{shuffle}}$  protocols whose transcript remains private even if a constant fraction of users drop out from the protocol.

<sup>8</sup> We remark that [26] developed a technique for proving lower bounds on the *communication complexity* (i.e., the number of bits sent per user) for multi-message protocols. Their techniques do not apply to our setting as our lower bounds are in terms of the number of messages, and do not put any restriction on the message length. Furthermore, their technique only applies to *pure*-DP where  $\delta = 0$ , whereas ours applies also to *approximate*-DP where  $\delta > 0$ .

Theorem 6.2]. It thus suffices for them to prove lower bounds for  $\text{DP}_{\text{local}}$  protocols with low privacy requirement (i.e.,  $(\varepsilon + \ln n, \delta)\text{-DP}_{\text{local}}$ ), for which lower bound techniques are known or developed. For  $\varepsilon\text{-DP}_{\text{shuffle}}^1$  protocols, [4] showed that they are also  $\varepsilon\text{-DP}_{\text{local}}$ ; therefore, lower bounds on  $\text{DP}_{\text{local}}$  protocols automatically translate to lower bounds on pure- $\text{DP}_{\text{shuffle}}^1$  protocols. To apply this proof framework to  $\text{DP}_{\text{shuffle}}^{O(1)}$  protocols, a natural first step would be to connect  $\text{DP}_{\text{shuffle}}^{O(1)}$  protocols to  $\text{DP}_{\text{local}}$  protocols. However, as observed by [4, Section 4.1], there exists an  $\varepsilon\text{-DP}_{\text{shuffle}}^{O(1)}$  protocol that is not  $\text{DP}_{\text{local}}$  for any privacy parameter. That is, there is no analogous connection between  $\text{DP}_{\text{local}}$  protocols and multi-message  $\text{DP}_{\text{shuffle}}$  protocols, even if the latter can only send  $O(1)$  messages per user.

In contrast, the next lemma captures the connection between multi-message  $\text{DP}_{\text{shuffle}}$  and dominated protocols.

► **Lemma 8.** *If  $R$  is  $(\varepsilon, \delta)\text{-DP}_{\text{shuffle}}^k$  on  $n$  users, then it is  $(\varepsilon + k(1 + \ln n), \delta)\text{-dominated}$ .*

By considering dominated protocols and using Lemma 8, we obtain the first lower bounds for *multi-message*  $\text{DP}_{\text{shuffle}}$  protocols for two well-studied problems: **Selection** and **ParityLearning**.

### 1.2.1 Lower Bounds for Selection

The **Selection** problem on  $n$  users is defined as follows. The  $i$ th user has an input  $x_i \in \{0, 1\}^D$  and the goal is to output an index  $j \in [D]$  such that  $\sum_{i=1}^n x_{i,j} \geq \left( \max_{j^*} \sum_{i=1}^n x_{i,j^*} \right) - n/10$ .

**Selection** is well-studied in DP (e.g., [17, 40, 41]) and its variants are useful primitives for several statistical and algorithmic problems including feature selection, hypothesis testing and clustering. In central DP, the exponential mechanism of [35] yields an  $\varepsilon\text{-DP}$  algorithm for **Selection** when  $n = O_\varepsilon(\log D)$ . On the other hand, it is known that any  $(\varepsilon, \delta)\text{-DP}_{\text{local}}$  protocol for **Selection** with  $\varepsilon = O(1)$  and  $\delta = O(1/n^{1.01})$  requires  $n = \Omega(D \log D)$  users [41]. Moreover, [12] obtained a  $(\varepsilon, 1/n^{O(1)})\text{-DP}_{\text{shuffle}}^D$  protocol for  $n = \tilde{O}_\varepsilon(\sqrt{D})$ . By contrast, for  $\text{DP}_{\text{shuffle}}^1$  protocols, a lower bound of  $\Omega(D^{1/17})$  was obtained in [12] and improved to  $\Omega(D)$  in [27].

The next theorem give a lower bounds for **Selection** that holds against approximate- $\text{DP}_{\text{shuffle}}^k$  protocols. To the best of our knowledge, this is the first lower bound even for  $k = 2$  (and even for the special case of pure protocols, where  $\delta = 0$ ).

► **Theorem 9.** *For any  $\varepsilon = O(1)$ , any public-coin  $(\varepsilon, o(1/D))\text{-DP}_{\text{shuffle}}^k$  protocol that solves **Selection** requires  $n \geq \Omega\left(\frac{D}{k}\right)$ .*

We remark that combining the advanced composition theorem for DP and known  $\text{DP}_{\text{shuffle}}$  aggregation algorithms, one can obtain a  $(\varepsilon, 1/\text{poly}(n))\text{-DP}_{\text{shuffle}}^k$  protocol for **Selection** with  $\tilde{O}(D/\sqrt{k})$  samples for any  $k \leq D$  (see the full version for details).

### 1.2.2 Lower Bounds for Parity Learning

In **ParityLearning**, there is a hidden random vector  $s \in \{0, 1\}^D$ , each user gets a random vector  $x \in \{0, 1\}^D$  together with the inner product  $\langle s, x \rangle$  over  $\mathbb{F}_2$ , and the goal is to recover  $s$ . This problem is well-known for separating PAC learning from the Statistical Query (SQ) learning model [32]. In DP, it was studied by [31] who gave a central DP protocol (also based on the exponential mechanism) computing it for  $n = O(D)$ , and moreover proved a lower bound of  $n = 2^{\Omega(D)}$  for any  $\text{DP}_{\text{local}}$  protocol, thus obtaining the first exponential separation between the central and local settings.

We give a lower bound for ParityLearning that hold against approximate- $\text{DP}_{\text{shuffle}}^k$  protocols:

► **Theorem 10.** *For any  $\varepsilon = O(1)$ , if  $P$  is a public-coin  $(\varepsilon, o(1/n))$ - $\text{DP}_{\text{shuffle}}^k$  protocol that solves ParityLearning with probability at least 0.99, then  $n \geq \Omega(2^{D/(k+1)})$ .*

Our lower bounds for ParityLearning can be generalized to the Statistical Query (SQ) learning framework of [32] (see the full version for more details).

### Independent Work

In a recent concurrent work, Cheu and Ullman [13] proved that robust  $\text{DP}_{\text{shuffle}}$  protocols solving Selection and ParityLearning require  $\Omega(\sqrt{D})$  and  $\Omega(2^{\sqrt{D}})$  samples, respectively. Their results have no restriction on the number of messages sent by each user, but they only hold against the special case of *robust* protocols. Our results provide stronger lower bounds when the number of messages per user is less than  $\sqrt{D}$ , and apply to the most general  $\text{DP}_{\text{shuffle}}$  model without the robustness restriction.

### 1.3 Lower Bounds for Two-Party DP Protocols

Finally, we consider another model of distributed DP, called the *two-party* model [33], denoted  $\text{DP}_{\text{two-party}}$ . In this model, there are two parties, each holding part of the dataset. The DP guarantee is enforced on the view of each party (i.e., the transcript, its private randomness, and its input). See the full version for a formal treatment.

McGregor et al. [33] studied the  $\text{DP}_{\text{two-party}}$  and proved an interesting separation of  $\Omega_\varepsilon(n)$  between the global sensitivity and  $\varepsilon$ -DP protocol in this model. However, this lower bound does not extend to the approximate-DP case (where  $\delta > 0$ ); in this case, the largest known gap (also proved in [33]) is only  $\tilde{\Omega}_\varepsilon(\sqrt{n})$ , and it was left as an open question if this can be improved<sup>9</sup>. We answer this question by showing that the gap of  $\tilde{\Omega}_\varepsilon(n)$  holds even against approximate-DP protocols:

► **Theorem 11.** *For any  $\varepsilon = O(1)$  and any sufficiently large  $n \in \mathbb{N}$ , there is a function  $f: \{0, 1\}^{2n} \rightarrow \mathbb{R}$  whose global sensitivity is one and such that no  $(\varepsilon, o(1/n))$ - $\text{DP}_{\text{two-party}}$  protocol can compute  $f$  to within an error of  $o(n/\log n)$ .*

The above bound is tight up to a logarithmic factors in  $n$ , as it is trivial to achieve an error of  $n$ .

The proof of Theorem 11 is unlike others in the paper; in fact, we only employ simple reductions starting from the hardness of inner product function already shown in [33]. Specifically, our function is a sum of blocks of inner product modulo 2. While this function is not symmetric, we show that it can be easily symmetrized (see the full version for details).

### 1.4 Discussions and Open Questions

In this work, we study DP in distributed models, including the local and shuffle settings. By building on the moment matching method and using the newly defined notion of dominated protocols, we give novel lower bounds in both models for three fundamental problems: CountDistinct, Selection, and ParityLearning. While our lower bounds are (nearly) tight in a large setting of parameters, there are still many interesting open questions, three of which we highlight below:

<sup>9</sup> The conference version of the paper [33] actually claimed to also have a lower bound  $\Omega_\varepsilon(n)$  for the approximate-DP case as well. However, it was later found to be incorrect; see [34] for more discussions.

- **DP<sub>shuffle</sub> Lower Bounds for Protocols with Unbounded Number of Messages.** Our connection between DP<sub>shuffle</sub> and dominated protocols becomes weaker as  $k \rightarrow \infty$  (Lemma 8). As a result, it cannot be used to establish lower bounds against DP<sub>shuffle</sub> protocols with a possibly unbounded number of messages. In fact, we are not aware of any separation between central DP and DP<sub>shuffle</sub> without a restriction on the number of messages and without the robustness restriction. This remains a fundamental open question. (In contrast, separations between central DP and DP<sub>local</sub> are well-known, even for basic functions such as binary summation [11].)
- **Lower Bounds against Interactive Local/Shuffle Model.** Our lower bounds hold in the *non-interactive* local and shuffle DP models, where all users send their messages simultaneously in a single round. While it seems plausible that our lower bounds can be extended to the *sequentially interactive* local DP model [17] (where each user speaks once but not simultaneously), it is unclear how to extend them to the fully interactive local DP model.  
The situation for DP<sub>shuffle</sub> however is more complicated. We remark that certain definitions could lead to the model being as powerful as the central model (in terms of achievable accuracy and putting aside communication constraints); see e.g., [29] on how to perform secure computations under a certain definition of the shuffle model. A very recent work provides a formal treatment of an interactive setting for the shuffle model [7].
- **DP<sub>shuffle</sub><sup>1</sup> Lower Bounds for CountDistinct with Larger  $\delta$ .** All but one of our lower bounds hold as long as  $\delta = n^{-\omega(1)}$ , which is a standard assumption in the DP literature. The only exception is that of Theorem 4, which requires  $\delta = 2^{-\Omega(\log^c n)}$  for some constant  $c > 0$ . It is interesting whether this can be relaxed to  $\delta = n^{-\omega(1)}$ .

## 2 Preliminaries

### 2.1 Notation

For a function  $f: \mathcal{X} \rightarrow \mathbb{R}$ , a distribution  $\mathcal{D}$  on  $\mathcal{X}$ , and an element  $z \in \mathcal{X}$ , we use  $f(\mathcal{D})$  to denote  $\mathbb{E}_{x \leftarrow \mathcal{D}} [f(x)]$  and  $\mathcal{D}_z$  to denote  $\Pr_{x \leftarrow \mathcal{D}} [x = z]$ . For a subset  $E \subseteq \mathcal{X}$ , we use  $\mathcal{D}_E$  to denote  $\sum_{z \in E} \mathcal{D}_z = \Pr_{x \leftarrow \mathcal{D}} [x \in E]$ . We also use  $\mathcal{U}_D$  to denote the uniform distribution over  $\{0, 1\}^D$ .

For two distributions  $\mathcal{D}_1$  and  $\mathcal{D}_2$  on sets  $\mathcal{X}$  and  $\mathcal{Y}$  respectively, we use  $\mathcal{D}_1 \otimes \mathcal{D}_2$  to denote their product distribution over  $\mathcal{X} \times \mathcal{Y}$ . For two random variables  $X$  and  $Y$  supported on  $\mathbb{R}^D$  for  $D \in \mathbb{N}$ , we use  $X + Y$  to denote the random variable distributed as a sum of two independent samples from  $X$  and  $Y$ . For any set  $\mathcal{S}$ , we denote by  $\mathcal{S}^*$  the set consisting of sequences on  $\mathcal{S}$ , i.e.,  $\mathcal{S}^* = \cup_{n \geq 0} \mathcal{S}^n$ . For  $x \in \mathbb{R}$ , let  $[x]_+$  denote  $\max(x, 0)$ . For a predicate  $P$ , we use  $\mathbb{K}[P]$  to denote the corresponding Boolean value of  $P$ , that is,  $\mathbb{K}[P] = 1$  if  $P$  is true, and 0 otherwise.

For a distribution  $\mathcal{D}$  on a finite set  $\mathcal{X}$  and an event  $\mathcal{E} \subseteq \mathcal{X}$  such that  $\Pr_{z \leftarrow \mathcal{D}} [z \in \mathcal{E}] > 0$ , we use  $\mathcal{D}|\mathcal{E}$  to denote the conditional distribution such that

$$(\mathcal{D}|\mathcal{E})_z = \begin{cases} \frac{\mathcal{D}_z}{\Pr_{z \leftarrow \mathcal{D}} [z \in \mathcal{E}]} & \text{if } z \in \mathcal{E}, \\ 0 & \text{otherwise.} \end{cases}$$

Slightly overloading the notation, we also use  $\alpha \cdot \mathcal{D}_1 + (1 - \alpha) \cdot \mathcal{D}_2$  to denote the mixture of distributions  $\mathcal{D}_1$  and  $\mathcal{D}_2$  with mixing weights  $\alpha$  and  $(1 - \alpha)$  respectively. Whether  $+$  means mixture or convolution will be clear from the context unless explicitly stated.

## 2.2 Differential Privacy

We now recall the basics of differential privacy that we will need. Fix a finite set  $\mathcal{X}$ , the space of user reports. A *dataset*  $X$  is an element of  $\mathcal{X}^*$ , namely a tuple consisting of elements of  $\mathcal{X}$ . Let  $\text{hist}(X) \in \mathbb{N}^{|\mathcal{X}|}$  be the *histogram* of  $X$ : for any  $x \in \mathcal{X}$ , the  $x$ th component of  $\text{hist}(X)$  is the number of occurrences of  $x$  in the dataset  $X$ . We will consider datasets  $X, X'$  to be *equivalent* if they have the same histogram (i.e., the ordering of the elements  $x_1, \dots, x_n$  does not matter). For a multiset  $\mathcal{S}$  whose elements are in  $\mathcal{X}$ , we will also write  $\text{hist}(\mathcal{S})$  to denote the histogram of  $\mathcal{S}$  (so that the  $x$ th component is the number of copies of  $x$  in  $\mathcal{S}$ ).

Let  $n \in \mathbb{N}$ , and consider a dataset  $X = (x_1, \dots, x_n) \in \mathcal{X}^n$ . For an element  $x \in \mathcal{X}$ , let  $f_X(x) = \frac{\text{hist}(X)_x}{n}$  be the *frequency* of  $x$  in  $X$ , namely the fraction of elements of  $X$  that are equal to  $x$ . Two datasets  $X, X'$  are said to be *neighboring* if they differ in a single element, meaning that we can write (up to equivalence)  $X = (x_1, x_2, \dots, x_n)$  and  $X' = (x'_1, x_2, \dots, x_n)$ . In this case, we write  $X \sim X'$ . Let  $\mathcal{Z}$  be a set; we now define the differential privacy of a randomized function  $P: \mathcal{X}^n \rightarrow \mathcal{Z}$  as follows.

► **Definition 12** (Differential privacy (DP) [20, 19]). *A randomized algorithm  $P: \mathcal{X}^n \rightarrow \mathcal{Z}$  is  $(\varepsilon, \delta)$ -DP if for every pair of neighboring datasets  $X \sim X'$  and for every set  $\mathcal{S} \subseteq \mathcal{Z}$ , we have*

$$\Pr[P(X) \in \mathcal{S}] \leq e^\varepsilon \cdot \Pr[P(X') \in \mathcal{S}] + \delta,$$

where the probabilities are taken over the randomness in  $P$ . Here,  $\varepsilon \geq 0$  and  $\delta \in [0, 1]$ .

If  $\delta = 0$ , then we use  $\varepsilon$ -DP for brevity and informally refer to it as *pure-DP*; if  $\delta > 0$ , we refer to it as *approximate-DP*. We will use the following post-processing property of DP.

► **Lemma 13** (Post-processing, e.g., [22]). *If  $P$  is  $(\varepsilon, \delta)$ -DP, then for every randomized function  $A$ , the composed function  $A \circ P$  is  $(\varepsilon, \delta)$ -DP.*

## 2.3 Shuffle Model

We briefly review the *shuffle model* of DP [8, 24, 12]. The input to the model is a dataset  $(x_1, \dots, x_n) \in \mathcal{X}^n$ , where item  $x_i \in \mathcal{X}$  is held by user  $i$ . A protocol  $P: \mathcal{X} \rightarrow \mathcal{Z}$  in the shuffle model consists of three algorithms:

- The *local randomizer*  $R: \mathcal{X} \rightarrow \mathcal{M}^*$  takes as input the data of one user,  $x_i \in \mathcal{X}$ , and outputs a sequence  $(y_{i,1}, \dots, y_{i,m_i})$  of *messages*; here  $m_i$  is a positive integer.  
To ease discussions in the paper, we will further assume that the randomizer  $R$  pre-shuffles its messages. That is, it applies a random permutation  $\pi: [m_i] \rightarrow [m_i]$  to the sequence  $(y_{i,1}, \dots, y_{i,m_i})$  before outputting it.<sup>10</sup>
- The *shuffler*  $S: \mathcal{M}^* \rightarrow \mathcal{M}^*$  takes as input a sequence of elements of  $\mathcal{M}$ , say  $(y_1, \dots, y_m)$ , and outputs a random permutation, i.e., the sequence  $(y_{\pi(1)}, \dots, y_{\pi(m)})$ , where  $\pi \in S_m$  is a uniformly random permutation on  $[m]$ . The input to the shuffler will be the concatenation of the outputs of the local randomizers.
- The *analyzer*  $A: \mathcal{M}^* \rightarrow \mathcal{Z}$  takes as input a sequence of elements of  $\mathcal{M}$  (which will be taken to be the output of the shuffler) and outputs an answer in  $\mathcal{Z}$  that is taken to be the output of the protocol  $P$ .

<sup>10</sup>Therefore, for every  $x \in \mathcal{X}$  and any two tuples  $z_1, z_2 \in \mathcal{M}^*$  that are equivalent up to a permutation,  $R(x)$  outputs them with the same probability.

We will write  $P = (R, S, A)$  to denote the protocol whose components are given by  $R$ ,  $S$ , and  $A$ . The main distinction between the shuffle and local model is the introduction of the shuffler  $S$  between the local randomizer and the analyzer. As in the local model, the analyzer is untrusted in the shuffle model; hence privacy must be guaranteed with respect to the input to the analyzer, i.e., the output of the shuffler. Formally, we have:

► **Definition 14** (DP in the Shuffle Model, [24, 12]). *A protocol  $P = (R, S, A)$  is  $(\varepsilon, \delta)$ -DP if, for any dataset  $X = (x_1, \dots, x_n)$ , the algorithm*

$$(x_1, \dots, x_n) \mapsto S(R(x_1), \dots, R(x_n))$$

*is  $(\varepsilon, \delta)$ -DP.*

Notice that the output of  $S(R(x_1), \dots, R(x_n))$  can be simulated by an algorithm that takes as input the *multiset* consisting of the union of the elements of  $R(x_1), \dots, R(x_n)$  (which we denote as  $\bigcup_i R(x_i)$ , with a slight abuse of notation) and outputs a uniformly random permutation of them. Thus, by Lemma 13, it can be assumed without loss of generality for privacy analyses that the shuffler simply outputs the multiset  $\bigcup_i R(x_i)$ . For the purpose of analyzing the accuracy of the protocol  $P = (R, S, A)$ , we define its *output* on the dataset  $X = (x_1, \dots, x_n)$  to be  $P(X) := A(S(R(x_1), \dots, R(x_n)))$ . We also remark that the case of *local DP*, formalized in Definition 15, is a special case of the shuffle model where the shuffler  $S$  is replaced by the identity function:

► **Definition 15** (Local DP [31]). *A protocol  $P = (R, A)$  is  $(\varepsilon, \delta)$ -DP in the local model (or  $(\varepsilon, \delta)$ -locally DP) if the function  $x \mapsto R(x)$  is  $(\varepsilon, \delta)$ -DP.*

We say that the *output* of the protocol  $P$  on an input dataset  $X = (x_1, \dots, x_n)$  is  $P(X) := A(R(x_1), \dots, R(x_n))$ .

We denote DP in the shuffle model by  $\text{DP}_{\text{shuffle}}$ , and the special case where each user can send at most<sup>11</sup>  $k$  messages by  $\text{DP}_{\text{shuffle}}^k$ . We denote DP in the local model by  $\text{DP}_{\text{local}}$ .

## Public-Coin DP

The default setting for local and shuffle models is private-coin, i.e., there is no randomness shared between the randomizers and the analyzer. We will also study the public-coin variants of the local and shuffle models. In the public-coin setting, each local randomizer also takes a public random string  $\alpha \leftarrow \{0, 1\}^*$  as input. The analyzer is also given the public random string  $\alpha$ . We use  $R_\alpha(x)$  to denote the local randomizer with public random string being fixed to  $\alpha$ . At the start of the protocol, all users jointly sample a public random string from a publicly known distribution  $\mathcal{D}_{\text{pub}}$ .

Now, we say that a protocol  $P = (R, A)$  is  $(\varepsilon, \delta)$ -DP in the *public-coin local model*, if the function

$$x \xrightarrow{\alpha \leftarrow \mathcal{D}_{\text{pub}}} (\alpha, R_\alpha(x))$$

is  $(\varepsilon, \delta)$ -DP.

<sup>11</sup> We may assume w.l.o.g. that each user sends *exactly*  $k$  messages; otherwise, we may define a new symbol  $\perp$  and make each user send  $\perp$  messages so that the number of messages becomes exactly  $k$ .

Similarly, we say that a protocol  $P = (R, S, A)$  is  $(\varepsilon, \delta)$ -DP in the public-coin shuffle model, if for any dataset  $X = (x_1, \dots, x_n)$ , the algorithm

$$(x_1, \dots, x_n) \xrightarrow{\alpha \leftarrow \mathcal{D}_{\text{pub}}} (\alpha, S(R_\alpha(x_1), \dots, R_\alpha(x_n)))$$

is  $(\varepsilon, \delta)$ -DP.

## 2.4 Useful Divergences

We will make use of two important divergences between distributions, the KL-divergence and the  $\chi^2$ -divergence, defined as

$$KL(P||Q) = \mathbb{E}_{z \leftarrow P} \log \left( \frac{P_z}{Q_z} \right) \quad \text{and} \quad \chi^2(P||Q) = \mathbb{E}_{z \leftarrow Q} \left[ \frac{P_z - Q_z}{Q_z} \right]^2.$$

We will also use Pinsker's inequality, whereby the total variation distance lower-bounds the KL-divergence:

$$KL(P||Q) \geq \frac{2}{\ln 2} \|P - Q\|_{TV}^2.$$

## 2.5 Fourier Analysis

We now review some basic Fourier analysis and then introduce two inequalities that will be heavily used in our proofs. For a function  $f: \{0, 1\}^D \rightarrow \mathbb{R}$ , its Fourier transform is given by the function  $\hat{f}(S) := \mathbb{E}_{x \leftarrow \mathcal{U}_D} [f(x) \cdot (-1)^{\sum_{i \in S} x_i}]$ . We also define  $\|f\|_2^2 = \mathbb{E}_{x \leftarrow \mathcal{U}_D} [f(x)^2]$ . For  $k \in \mathbb{N}$ ,

we define the *level- $k$  Fourier weight* as  $\mathbf{W}^k[f] := \sum_{S \subseteq [D], |S|=k} \hat{f}(S)^2$ . For convenience, for

$s \in \{0, 1\}^D$ , we will also write  $\hat{f}(s)$  to denote  $f(\chi_s)$ , where  $\chi_s$  is the set  $\{i: i \in [D] \wedge s_i = 1\}$ . One key technical lemma is the Level-1 Inequality from [37], which was also used in [27].

► **Lemma 16** (Level-1 Inequality). *Suppose  $f: \{0, 1\}^D \rightarrow \mathbb{R}_{\geq 0}$  is a non-negative-valued function with  $f(x) \in [0, L]$  for all  $x \in \{0, 1\}^D$ , and  $\mathbb{E}_{x \sim \mathcal{U}_D} [f(x)] \leq 1$ . Then,  $\mathbf{W}^1[f] \leq 6 \ln(L + 1)$ .*

We also need the standard Parseval's identity.

► **Lemma 17** (Parseval's Identity). *For all functions  $f: \{0, 1\}^D \rightarrow \mathbb{R}$ ,*

$$\|f\|_2^2 = \sum_{S \subseteq [D]} \hat{f}(S)^2.$$

## 3 Overview of Techniques

In this section, we describe the main intuition behind our lower bounds. As alluded to in Section 1, we give two different proofs of the lower bounds for **CountDistinct** in the  $\text{DP}_{\text{local}}$  and  $\text{DP}_{\text{shuffle}}$  settings, each with its own advantages:

- **Proof via Moment Matching.** Our first proof is technically the hardest in our work. It applies to the much more challenging low-privacy setting (i.e.,  $(\ln n - O(\ln \ln n), \delta)$ - $\text{DP}_{\text{local}}$ ), and shows an  $\Omega(n / \text{polylog}(n))$  lower bound on the additive error (Theorem 2). Together with our new improved connection between  $\text{DP}_{\text{shuffle}}^1$  and  $\text{DP}_{\text{local}}$  (Lemma 5), it also implies the same lower bound for protocols in the  $\text{DP}_{\text{shuffle}}^1$  model. The key ideas behind the first proof will be discussed in Section 3.1.

- **Proof via Dominated Protocols.** Our second proof has the advantage of giving the optimal  $\Omega(n)$  lower bound on the additive error (Theorem 1), but only in the constant privacy regime (i.e.,  $(O(1), \delta)$ -DP<sub>local</sub>), and it is relatively simple compared to the first proof.

Moreover, the second proof technique is very general and is a conceptual contribution: it can be applied to show lower bounds for other fundamental problems (i.e., **Selection** and **ParityLearning**; Theorems 9 and 10) against multi-message DP<sub>shuffle</sub> protocols. We will highlight the intuition behind the second proof in Section 3.2.

While our lower bounds also work for the public-coin DP<sub>shuffle</sub> models, throughout this section, we focus on private-coin models in order to simplify the presentation. The full proofs extending to public-coin protocols are given in the full version.

### 3.1 Lower Bounds for CountDistinct via Moment Matching

To clearly illustrate the key ideas behind the first proof, we will focus on the pure-DP case where each user can only send  $O(\log n)$  bits. In the full version, we generalize the proof to approximate-DP and remove the restriction on communication complexity.

► **Theorem 18** (A Weaker Version of Theorem 2). *For  $\varepsilon = \ln(n/\log^7 n)$  and  $D = n/\log^5 n$ , no  $\varepsilon$ -DP<sub>local</sub> protocol where each user sends  $O(\log n)$  bits can solve **CountDistinct** <sub>$n, D$</sub>  with error  $o(D)$ .*

Throughout our discussion, we use  $R : [D] \rightarrow \mathcal{M}$  to denote a  $\ln(n/\log^7 n)$ -DP<sub>local</sub> randomizer. By the communication complexity condition of Theorem 18, we have that  $|\mathcal{M}| \leq \text{poly}(n)$ .

Our proof is inspired by the lower bounds for estimating distinct elements in the property testing model, e.g., [43, 45]. In particular, we use the so-called *Poissonization* trick. To discuss this trick, we start with some notation. For a vector  $\vec{\lambda} \in \mathbb{R}^D$ , we use  $\vec{\text{Poi}}(\vec{\lambda})$  to denote the joint distribution of  $D$  independent Poisson random variables:

$$\vec{\text{Poi}}(\vec{\lambda}) := (\text{Poi}(\vec{\lambda}_1), \text{Poi}(\vec{\lambda}_2), \dots, \text{Poi}(\vec{\lambda}_n)).$$

For a distribution  $\vec{U}$  on  $\mathbb{R}^D$ , we define the corresponding mixture of multi-dimensional Poisson distributions as follows:

$$\mathbb{E}[\vec{\text{Poi}}(\vec{U})] := \mathbb{E}_{\vec{\lambda} \leftarrow \vec{U}} \vec{\text{Poi}}(\vec{\lambda}).$$

For two random variables  $X$  and  $Y$  supported on  $\mathbb{R}^{\mathcal{M}}$ , we use  $X + Y$  to denote the random variable distributed as a sum of two independent samples from  $X$  and  $Y$ .

**Shuffling the Outputs of the Local Protocol.** Our first observation is that the analyzer for any local protocol computing **CountDistinct** should achieve the same accuracy if it only sees the histogram of the randomizers' outputs. This holds because only seeing the histogram of the outputs is equivalent to shuffling the outputs by a uniformly random permutation, which is in turn equivalent to shuffling the users in the dataset uniformly at random. Since shuffling the users in a dataset does not affect the number of distinct elements, it follows that only seeing the histogram does not affect the accuracy. Therefore, we only have to consider the histogram of the outputs of the local protocol computing **CountDistinct**. For a dataset  $W$ , we use  $\text{Hist}_R(W)$  to denote the distribution of the histogram with randomizer  $R$ .

**Poissonization Trick.** Given a distribution  $\mathcal{D}$  on  $\mathcal{M}$ , suppose we draw a sample  $m \leftarrow \text{Poi}(\lambda)$ , and then draw  $m$  samples from  $\mathcal{D}$ . If we use  $N$  to denote the random variable corresponding to the histogram of these  $m$  samples, it follows that each coordinate of  $N$  is independent, and  $N$  is distributed as  $\vec{\text{Poi}}(\lambda \vec{\mu})$ , where  $\vec{\mu}_i = \mathcal{D}_i$  for each  $i \in \mathcal{M}$ .

We can now apply the above trick to the context of local protocols (recall that by our first observation, we can focus on the histogram of the outputs). Suppose we build a dataset by drawing a sample  $m \leftarrow \text{Poi}(\lambda)$  and then adding  $m$  users with input  $z$ . By the above discussion, the corresponding histogram of the outputs with randomizer  $R$  is distributed as  $\vec{\text{Poi}}(\lambda \cdot R(z))$ , where  $R(z)$  is treated as an  $|\mathcal{M}|$ -dimensional vector corresponding to its probability distribution.

**Moment-Matching Random Variables.** Our next ingredient is the following construction of two moment-matching random variables used in [45]. Let  $L \in \mathbb{N}$  and  $\Lambda = \Theta(L^2)$ . There are two random variables  $U$  and  $V$  supported on  $\{0\} \cup [1, \Lambda]$ , such that  $\mathbb{E}[U] = \mathbb{E}[V] = 1$  and  $\mathbb{E}[U^j] = \mathbb{E}[V^j]$  for every  $j \in [L]$ . Moreover  $U_0 - V_0 > 0.9$ . That is,  $U$  and  $V$  have the same moments up to degree  $L$ , while the probabilities of them being zero differs significantly. We will set  $L = \log n$  and hence  $\Lambda = \Theta(\log^2 n)$ .

**Construction of Hard Distribution via Signal/Noise Decomposition.** Recalling that  $D = n/\log^5 n$ , we will construct two input distributions for  $\text{CountDistinct}_{n,D}$ .<sup>12</sup> A sample from both distributions consists of two parts: a signal part with  $D$  many users in expectation, and a noise part with  $n - D$  many users in expectation.

Formally, for a distribution  $W$  over  $\mathbb{R}^{\geq 0}$  and a subset  $E \subseteq [D]$ , the dataset distributions  $\mathcal{D}_{\text{signal}}^W$  and  $\mathcal{D}_{\text{noise}}^E$  are constructed as follows:

- $\mathcal{D}_{\text{signal}}^W$ : for each  $i \in [D]$ , we independently draw  $\lambda_i \leftarrow W$ , and  $n_i \leftarrow \text{Poi}(\lambda_i)$ , and add  $n_i$  many users with input  $i$ .
- $\mathcal{D}_{\text{noise}}^E$ : for each  $i \in E$ , we independently draw  $n_i \leftarrow \text{Poi}((n - D)/|E|)$ , and add  $n_i$  many users with input  $i$ .

We are going to fix a “good” subset  $E$  of  $[D]$  such that  $|E| \leq 0.02 \cdot D$  (we will later specify the other conditions for being “good”). Therefore, when it is clear from the context, we will use  $\mathcal{D}_{\text{noise}}$  instead of  $\mathcal{D}_{\text{noise}}^E$ .

Our two hard distributions are then constructed as  $\mathcal{D}^U := \mathcal{D}_{\text{signal}}^U + \mathcal{D}_{\text{noise}}$  and  $\mathcal{D}^V := \mathcal{D}_{\text{signal}}^V + \mathcal{D}_{\text{noise}}$ . Using the fact that  $\mathbb{E}[U] = \mathbb{E}[V] = 1$ , one can verify that there are  $D$  users in each of  $\mathcal{D}_{\text{signal}}^U$  and  $\mathcal{D}_{\text{signal}}^V$  in expectation. Similarly, one can also verify there are  $n - D$  users in  $\mathcal{D}_{\text{noise}}$  in expectation. Hence, both  $\mathcal{D}^U$  and  $\mathcal{D}^V$  have  $n$  users in expectation. In fact, the number of users from both distributions concentrates around  $n$ .

We now justify our naming of the signal/noise distributions. First, note that the number of distinct elements in the signal parts  $\mathcal{D}_{\text{signal}}^U$  and  $\mathcal{D}_{\text{signal}}^V$  concentrates around  $(1 - \mathbb{E}[e^{-U}]) \cdot D$  and  $(1 - \mathbb{E}[e^{-V}]) \cdot D$  respectively. By our condition that  $U_0 - V_0 > 0.9$ , it follows that the signal parts of  $\mathcal{D}^U$  and  $\mathcal{D}^V$  separates their numbers of distinct elements by at least  $0.4D$ . Second, note that although  $\mathcal{D}_{\text{noise}}$  has  $n - D \gg D$  many users in expectation, they are from the subset  $E$  of size less than  $0.02 \cdot n$ . Therefore, these users collectively cannot change the number of distinct elements by more than  $0.02 \cdot n$ , and the numbers of distinct elements in  $\mathcal{D}^U$  and  $\mathcal{D}^V$  are still separated by  $\Omega(D)$ .

<sup>12</sup> In fact, in our presentation the number of inputs in each dataset from our hard distributions will not be exactly  $n$ , but only concentrated around  $n$ . This issue can be easily resolved by throwing “extra” users in the dataset; we refer the reader to the full version for the details.

**Decomposition of Noise Part.** To establish the desired lower bound, it now suffices to show for the local randomizer  $R$ , it holds that  $\text{Hist}_R(\mathcal{D}^U)$  and  $\text{Hist}_R(\mathcal{D}^V)$  are very close in statistical distance. For  $W \in \{U, V\}$ , we can decompose  $\text{Hist}_R(\mathcal{D}^W)$  as

$$\text{Hist}_R(\mathcal{D}^W) = \sum_{i \in [D]} \vec{\text{Poi}}(W \cdot R(i)) + \sum_{i \in [E]} \vec{\text{Poi}}((n-D)/|E| \cdot R(i)).$$

By the additive property of Poisson distributions, letting  $\vec{v} = (n-D)/|E| \cdot \sum_{i \in [E]} R(i)$ , we have that  $\sum_{i \in [E]} \vec{\text{Poi}}((n-D)/|E| \cdot R(i)) = \vec{\text{Poi}}(\vec{v})$ .

Our key idea is to decompose  $\vec{v}$  carefully into  $D+1$  nonnegative vectors  $\vec{v}^{(0)}, \vec{v}^{(1)}, \dots, \vec{v}^{(D)}$ , such that  $\vec{v} = \sum_{i=0}^D \vec{v}^{(i)}$ . Then, for  $W \in \{U, V\}$ , we have

$$\text{Hist}_R(\mathcal{D}^W) = \vec{\text{Poi}}(\vec{v}^{(0)}) + \sum_{i \in [D]} \vec{\text{Poi}}(W \cdot R(i) + \vec{v}^{(i)}).$$

To show that  $\text{Hist}_R(\mathcal{D}^U)$  and  $\text{Hist}_R(\mathcal{D}^V)$  are close, it suffices to show that for each  $i \in [D]$ , it is the case that  $\vec{\text{Poi}}(U \cdot R(i) + \vec{v}^{(i)})$  and  $\vec{\text{Poi}}(V \cdot R(i) + \vec{v}^{(i)})$  are close. We show that they are close when  $\vec{v}^{(i)}$  is sufficiently large on every coordinate compared to  $R(i)$ .

► **Lemma 19.** *For each  $i \in [D]$ , and every  $\vec{\lambda} \in (\mathbb{R}^{\geq 0})^{\mathcal{M}}$ , if  $\vec{\lambda}_z \geq 2\Lambda^2 \cdot R(i)_z$  for every  $z \in \mathcal{M}$ , then<sup>13</sup>*

$$\|\mathbb{E}[\vec{\text{Poi}}(U \cdot R(i) + \vec{\lambda})] - \mathbb{E}[\vec{\text{Poi}}(V \cdot R(i) + \vec{\lambda})]\|_{TV} \leq \frac{1}{n^2}.$$

To apply Lemma 19, we simply set  $\vec{v}^{(i)} = (2\Lambda^2) \cdot R(i)$  and  $\vec{v}^{(0)} = \vec{v} - \sum_{i \in [D]} \vec{v}^{(i)}$ . Letting  $\vec{\mu} = \sum_{i \in [D]} R(i)$ , the requirement that  $\vec{v}^{(0)}$  has to be nonnegative translates to  $\vec{v}_z \geq 2\Lambda^2 \cdot \vec{\mu}_z$ , for each  $z \in \mathcal{M}$ .

**Construction of a Good Subset  $E$ .** So we want to pick a subset  $E \subseteq [D]$  of size at most  $0.02 \cdot D$  such that the corresponding  $\vec{v}^E = (n-D)/|E| \cdot \sum_{i \in [E]} R(i)$  satisfies  $\vec{v}_z^E \geq 2\Lambda^2 \cdot \vec{\mu}_z$  for each  $z \in \mathcal{M}$ . We will show that a simple random construction works with high probability: i.e., one can simply add each element of  $[D]$  to  $E$  independently with probability 0.01.

More specifically, for each  $z \in \mathcal{M}$ , we will show that with high probability  $\vec{v}_z^E \geq 2\Lambda^2 \cdot \vec{\mu}_z$ . Then the correctness of our construction follows from a union bound (and this step crucially uses the fact that  $|\mathcal{M}| \leq \text{poly}(n)$ ).

Now, let us fix a  $z \in \mathcal{M}$ . Let  $m^* = \max_{i \in [D]} R(i)_z$ . Since  $R$  is  $\ln(n/\log^7 n)$ -DP, it follows that  $\vec{v}_z \geq \frac{n-D}{n/\log^7 n} \cdot m^* \geq \frac{\log^7 n}{2} \cdot m^*$ . We consider the following two cases:

1. If  $m^* \geq \vec{\mu}_z / \log^2 n$ , we immediately get that  $\vec{v}_z \geq \log^5 n / 2 \cdot \vec{\mu}_z \geq 2\Lambda^2 \cdot \vec{\mu}_z$  (which uses the fact that  $\Lambda = \Theta(\log^2 n)$ ).
2. If  $m^* < \vec{\mu}_z / \log^2 n$ , then in this case, the mass  $\vec{\mu}_z$  is distributed over at least  $\log^2 n$  many components  $R(i)_z$ . Applying Hoeffding's inequality shows that with high probability over  $E$ , it is the case that  $\vec{v}_z^E \geq \Theta(n/D) \cdot \vec{\mu}_z \geq \Lambda^2 \cdot \vec{\mu}_z$  (which uses the fact that  $D = n/\log^5 n$ ).

See the full version for a formal argument and how to get rid of the assumption that  $|\mathcal{M}| \leq \text{poly}(n)$ .

<sup>13</sup> We use  $\|\mathcal{D}_1 - \mathcal{D}_2\|_{TV}$  to denote the total variation (aka statistical) distance between two distributions  $\mathcal{D}_1, \mathcal{D}_2$ .

**The Lower Bound.** From the above discussions, we get that

$$\|\text{Hist}_R(\mathcal{D}^U) - \text{Hist}_R(\mathcal{D}^V)\|_{TV} \leq \sum_{i=1}^D \|\mathbb{E}[\vec{\text{Poi}}(U \cdot R(i) + \vec{v}^{(i)})] - \mathbb{E}[\vec{\text{Poi}}(V \cdot R(i) + \vec{v}^{(i)})]\|_{TV} \leq 1/n.$$

Hence, the analyzer of the local protocol with randomizer  $R$  cannot distinguish  $\mathcal{D}^U$  and  $\mathcal{D}^V$ , and thus it cannot solve  $\text{CountDistinct}_{n,D}$  with error  $o(D)$  and 0.99 probability. See the full version for a formal argument and how to deal with the fact that there may not be exactly  $n$  users in dataset from  $\mathcal{D}^U$  or  $\mathcal{D}^V$ .

**Single-Message  $\text{DP}_{\text{shuffle}}^1$  Lower Bound.** To apply the above lower bound to  $\text{DP}_{\text{shuffle}}^1$  protocols, the natural idea is to resort to the connection between the  $\text{DP}_{\text{shuffle}}^1$  and  $\text{DP}_{\text{local}}$  models. In particular, [12] showed that  $(\varepsilon, \delta)$ - $\text{DP}_{\text{shuffle}}^1$  protocols are also  $(\varepsilon + \ln n, \delta)$ - $\text{DP}_{\text{local}}$ .

It may seem that the  $\ln n$  privacy guarantee is very close to the  $\ln n - O(\ln \ln n)$  one in Theorem 2. But surprisingly, it turns out (as was stated in Theorem 3) that there is a  $(\ln n + O(1))$ - $\text{DP}_{\text{local}}$  protocol solving  $\text{CountDistinct}_{n,n}$  (hence also  $\text{CountDistinct}_{n,D}$ ) with error  $O(\sqrt{n})$ . Hence, to establish the  $\text{DP}_{\text{shuffle}}^1$  lower bound (Theorem 4), we rely on the following stronger connection between  $\text{DP}_{\text{shuffle}}^1$  and  $\text{DP}_{\text{local}}$  protocols.

► **Lemma 20** (Simplification of Lemma 5). *For every  $\delta \leq 1/n^{\omega(1)}$ , if the randomizer  $R$  is  $(O(1), \delta)$ - $\text{DP}_{\text{shuffle}}^1$  on  $n$  users, then  $R$  is  $(\ln(n \log^2 n / \log \delta^{-1}), n^{-\omega(1)})$ - $\text{DP}_{\text{local}}$ .*

Setting  $\delta = 2^{-\log^k n}$  for a sufficiently large  $k$  and combining Lemma 20 and Theorem 2 gives us the desired lower bound against  $\text{DP}_{\text{shuffle}}^1$  protocols.

### 3.2 Lower Bounds for $\text{CountDistinct}$ and Selection via Dominated Protocols

We will first describe the proof ideas behind Theorem 1, which is restated below. Then, we apply the same proof technique to obtain lower bounds for **Selection** (the lower bound for **ParityLearning** is established similarly; see the full version for details).

► **Lemma 21** (Detailed Version of Theorem 1). *For  $\varepsilon = o(\ln n)$ , no  $(\varepsilon, o(1/n))$ -dominated protocol can solve  $\text{CountDistinct}$  with error  $o(n/e^\varepsilon)$ .*

**Hard Distributions for  $\text{CountDistinct}_{n,n}$ .** We now construct our hard instances for  $\text{CountDistinct}_{n,n}$ . For simplicity, we assume  $n = 2^D$  for an integer  $D$ , and identify the input space  $[n]$  with  $\{0, 1\}^D$  by a fixed bijection. Let  $\mathcal{U}_D$  be the uniform distribution over  $\{0, 1\}^D$ . For  $(\ell, s) \in [2] \times \{0, 1\}^D$ , we let  $\mathcal{D}_{\ell,s}$  be the uniform distribution on  $\{x \in \{0, 1\}^D : \langle x, s \rangle = \ell\}$ .

We also use  $\mathcal{D}_{\ell,s}^\alpha$  to denote the mixture of  $\mathcal{D}_{\ell,s}$  and  $\mathcal{U}_D$  which outputs a sample from  $\mathcal{D}_{\ell,s}$  with probability  $\alpha$  and a sample from  $\mathcal{U}_D$  with probability  $1 - \alpha$ .

For a parameter  $\alpha > 0$ , we consider the following two dataset distributions with  $n$  users:

- $\mathcal{W}^{\text{uniform}}$ : each user gets an i.i.d. input from  $\mathcal{U}_D$ . That is,  $\mathcal{W}^{\text{uniform}} := \mathcal{U}_D^{\otimes n}$ .
- $\mathcal{W}^\alpha$ : to sample a dataset from  $\mathcal{W}^\alpha$ , we first draw  $(\ell, s)$  from  $[2] \times \{0, 1\}^D$  uniformly at random, then each user gets an i.i.d. input from  $\mathcal{D}_{\ell,s}^\alpha$ . Formally,  $\mathcal{W}^\alpha := \mathbb{E}_{(\ell,s) \leftarrow [2] \times \{0,1\}^D} (\mathcal{D}_{\ell,s}^\alpha)^{\otimes n}$ .

Since for every  $\ell, s$ , it holds that  $|\text{supp}(\mathcal{D}_{\ell,s}^1)| \leq n/2$ , the number of distinct elements from any dataset in  $\mathcal{W}^1$  is at most  $n/2$ . On the other hand, since  $\mathcal{U}_D$  is a uniform distribution over  $n$  elements, a random dataset from  $\mathcal{W}^{\text{uniform}} = \mathcal{W}^0$  has roughly  $(1 - e^{-1}) \cdot n > n/2$  distinct

elements with high probability. Hence, the expected number of distinct elements of datasets from  $\mathcal{W}^\alpha$  is controlled by the parameter  $\alpha$ . A simple but tedious calculation shows that it is approximately  $(1 - e^{-1} \cdot \cosh(\alpha)) \cdot n$ , which can be approximated by  $(1 - e^{-1} \cdot (1 + \alpha^2)) \cdot n$  for  $n^{-0.1} < \alpha < 0.01$ . Hence, any protocol solving **CountDistinct** with error  $o(\alpha^2 n)$  should be able to distinguish between the above two distributions. Our goal is to show that this is impossible for  $(\varepsilon, o(1/n))$ -dominated protocols.

**Bounding KL Divergence for Dominated Protocols.** Our next step is to upper-bound the statistical distance  $\|\text{Hist}_R(\mathcal{W}^{\text{uniform}}) - \text{Hist}_R(\mathcal{W}^\alpha)\|_{TV}$ . As in previous work [41, 27, 23], we may upper-bound the KL divergence instead. By the convexity and chain-rule properties of KL divergence, it follows that

$$\begin{aligned} \text{KL}(\text{Hist}_R(\mathcal{W}^\alpha) \parallel \text{Hist}_R(\mathcal{W}^{\text{uniform}})) &\leq \mathbb{E}_{(\ell,s) \leftarrow [2] \times \{0,1\}^D} \text{KL}(R(\mathcal{D}_{\ell,s}^\alpha)^{\otimes n} \parallel R(\mathcal{U}_D)^{\otimes n}) \\ &= n \cdot \mathbb{E}_{(\ell,s) \leftarrow [2] \times \{0,1\}^D} \text{KL}(R(\mathcal{D}_{\ell,s}^\alpha) \parallel R(\mathcal{U}_D)). \end{aligned} \quad (1)$$

**Bounding the Average KL Divergence between a Family and a Single Distribution.** We are now ready to introduce our general tool for bounding average KL divergence quantities like (1). We first set up some notation. Let  $\mathcal{I}$  be an index set and  $\{\lambda_v\}_{v \in \mathcal{I}}$  be a family of distributions on  $\mathcal{X}$ , let  $\pi$  be a distribution on  $\mathcal{I}$ , and  $\mu$  be a distribution on  $\mathcal{X}$ . For simplicity, we assume that for every  $x \in \mathcal{X}$  and  $v \in \mathcal{I}$ , it holds that  $(\lambda_v)_x \leq 2 \cdot \mu_x$  (which is true for  $\{\mathcal{D}_{\ell,s}^\alpha\}_{(\ell,s) \in [2] \times \{0,1\}^D}$  and  $\mathcal{U}_D$ ).

► **Theorem 22.** *Let  $W: \mathbb{R} \rightarrow \mathbb{R}$  be a concave function such that for all functions  $\psi: \mathcal{X} \rightarrow \mathbb{R}^{\geq 0}$  satisfying  $\psi(\mu) \leq 1$ , it holds that*

$$\mathbb{E}_{v \leftarrow \pi} [(\psi(\lambda_v) - \psi(\mu))^2] \leq W(\|\psi\|_\infty).$$

*Then for an  $(\varepsilon, \delta)$ -dominated randomizer  $R$ , it follows that*

$$\mathbb{E}_{v \leftarrow \pi} [\text{KL}(R(\lambda_v) \parallel R(\mu))] \leq O(W(2e^\varepsilon) + \delta).$$

Similar theorems are proved in the previous work [17, 18, 41, 23] but only for locally private randomizers. Theorem 22 can be seen as a generalization of these previous results to dominated protocols.

**Bounding (1) via Fourier Analysis.** To apply Theorem 22, for  $f: \mathcal{X} \rightarrow \mathbb{R}^{\geq 0}$  with  $f(\mathcal{U}_D) = \mathbb{E}_{x \in \{0,1\}^D} [f(x)] \leq 1$ , we want to bound

$$\mathbb{E}_{(\ell,s) \leftarrow [2] \times \{0,1\}^D} [(f(\mathcal{D}_{\ell,s}^\alpha) - f(\mathcal{U}_D))^2] = \mathbb{E}_{s \in \{0,1\}^D} \alpha^2 \cdot \hat{f}(s)^2.$$

By Parseval's Identity (see Lemma 17),

$$\sum_{s \in \{0,1\}^D} \hat{f}(s)^2 = \mathbb{E}_{x \in \{0,1\}^D} f(x)^2 \leq f(\mathcal{U}_D) \cdot \|f\|_\infty \leq \|f\|_\infty.$$

Therefore, we can set  $W(L) := \alpha^2 \cdot \frac{L}{2^D}$ , and apply Theorem 22 to obtain

$$\mathbb{E}_{(\ell,s) \leftarrow [2] \times \{0,1\}^D} \text{KL}(R(\mathcal{D}_{\ell,s}^\alpha) \parallel R(\mathcal{U}_D)) \leq O(\alpha^2 \cdot e^\varepsilon / n + \delta).$$

We set  $\alpha$  such that  $\alpha^2 = c/e^\varepsilon$  for a sufficiently small constant  $c$  and note that  $\delta = o(1/n)$ . It follows that

$$\text{KL}(\text{Hist}_R(\mathcal{W}^\alpha) \parallel \text{Hist}_R(\mathcal{W}^{\text{uniform}})) \leq 0.01,$$

and therefore

$$\|\text{Hist}_R(\mathcal{W}^\alpha) - \text{Hist}_R(\mathcal{W}^{\text{uniform}})\|_{TV} \leq 0.1$$

by Pinsker's inequality. Hence, we conclude that  $(\varepsilon, o(1/n))$ -dominated protocols cannot solve  $\text{CountDistinct}_{n,n}$  with error  $o(n/e^\varepsilon)$ , completing the proof of Lemma 21. Now Theorem 1 follows from Lemma 21 and the fact that  $(\varepsilon, \delta)$ - $\text{DP}_{\text{local}}$  protocols are also  $(\varepsilon, \delta)$ -dominated.

**Lower Bounds for Selection against Multi-Message  $\text{DP}_{\text{shuffle}}$  Protocols.** Now we show how to apply Theorem 22 and Lemma 20 to prove lower bounds for Selection. For  $(\ell, j) \in [2] \times [D]$ , let  $\mathcal{D}_{\ell,j}$  be the uniform distribution on all length- $D$  binary strings with  $j$ th bit being  $\ell$ . Recall that  $\mathcal{U}_D$  is the uniform distribution on  $\{0, 1\}^D$ . Again we aim to upper-bound the average-case KL divergence  $\mathbb{E}_{(\ell,j) \leftarrow [2] \times [D]} \text{KL}(R(\mathcal{D}_{\ell,j}) \parallel R(\mathcal{U}_D))$ .

To apply Theorem 22, for  $f: \mathcal{X} \rightarrow \mathbb{R}^{\geq 0}$  with  $f(\mathcal{U}_D) = \mathbb{E}_{x \in \{0,1\}^D} [f(x)] \leq 1$ , we want to bound

$$\mathbb{E}_{(\ell,j) \leftarrow [2] \times [D]} [(f(\mathcal{D}_{\ell,j}) - f(\mathcal{U}_D))^2] = \mathbb{E}_{j \in [D]} \hat{f}(\{j\})^2.$$

By Lemma 16, it is the case that

$$\sum_{j \in [D]} \hat{f}(\{j\})^2 \leq O(\log \|f\|_\infty).$$

Therefore, we can set  $W(L) := c_1 \cdot \frac{\log L}{D}$  for an appropriate constant  $c_1$ , and apply Theorem 22 to obtain

$$\mathbb{E}_{(\ell,j) \leftarrow [2] \times [D]} \text{KL}(R(\mathcal{D}_{\ell,j}) \parallel R(\mathcal{U}_D)) \leq O\left(\frac{\varepsilon}{D} + \delta\right).$$

Combining this with Lemma 20 completes the proof (see the full version for the details).

## Abstract

The goal in *reconfiguration problems* is to compute a *gradual transformation* between two feasible solutions of a problem such that all intermediate solutions are also feasible. In the *Matching Reconfiguration Problem* (MRP), proposed in a pioneering work by Ito et al. from 2008, we are given a graph  $G$  and two matchings  $M$  and  $M'$ , and we are asked whether there is a sequence of matchings in  $G$  starting with  $M$  and ending at  $M'$ , each resulting from the previous one by either adding or deleting a single edge in  $G$ , without ever going through a matching of size  $< \min\{|M|, |M'|\} - 1$ . Ito et al. gave a polynomial time algorithm for the problem, which uses the Edmonds-Gallai decomposition.

In this paper we introduce a natural generalization of the MRP that depends on an integer parameter  $\Delta \geq 1$ : here we are allowed to make  $\Delta$  changes to the current solution rather than 1 at each step of the transformation procedure. There is always a valid sequence of matchings transforming  $M$  to  $M'$  if  $\Delta$  is sufficiently large, and naturally we would like to minimize  $\Delta$ . We first devise an optimal transformation procedure for unweighted matching with  $\Delta = 3$ , and then extend it to weighted matchings to achieve asymptotically optimal guarantees. The running time of these procedures is linear.

We further demonstrate the applicability of this generalized problem to dynamic graph matchings. In this area, the number of changes to the maintained matching per update step (the *recourse bound*) is an important quality measure. Nevertheless, the *worst-case* recourse bounds of almost all known dynamic matching algorithms are prohibitively large, much larger than the corresponding update times. We fill in this gap via a surprisingly simple black-box reduction: Any dynamic algorithm for maintaining a  $\beta$ -approximate maximum cardinality matching with update time  $T$ , for any  $\beta \geq 1$ ,  $T$  and  $\varepsilon > 0$ , can be *transformed* into an algorithm for maintaining a  $(\beta(1 + \varepsilon))$ -approximate maximum cardinality matching with update time  $T + O(1/\varepsilon)$  and worst-case recourse bound  $O(1/\varepsilon)$ . This result generalizes for approximate maximum weight matching, where the update time and worst-case recourse bound grow from  $T + O(1/\varepsilon)$  and  $O(1/\varepsilon)$  to  $T + O(\psi/\varepsilon)$  and  $O(\psi/\varepsilon)$ , respectively;  $\psi$  is the graph *aspect-ratio*. We complement this positive result by showing that, for  $\beta = 1 + \varepsilon$ , the worst-case recourse bound of any algorithm produced by our reduction is optimal. As a corollary, several key dynamic approximate matching algorithms – with poor worst-case recourse bounds – are strengthened to achieve near-optimal worst-case recourse bounds with no loss in update time.

## 1 Introduction

The study of graph algorithms is mostly concerned with the measure of *(static) runtime*. Given a graph optimization problem, the standard objective is to design a fast (possibly approximation) algorithm, and ideally complement it with a matching lower bound on the runtime of any (approximation) algorithm for solving the problem. As an example, computing (from scratch) a 2-approximate minimum vertex cover (VC) can be done trivially in linear time, whereas a better-than-2 approximation for the minimum VC cannot be computed in polynomial time under the unique games conjecture [46].

The current paper is motivated by a natural need arising in networks that are prone to temporary or permanent changes. Such changes are sometimes part of the normal behavior of the network, as in *dynamic networks*, but changes could also be the result of unpredictable failures of nodes and edges, particularly in *faulty networks*. Consider a large-scale network  $G = (V, E, w)$  for which we need to solve, perhaps approximately, some graph optimization problem, and the underlying solution (e.g., a maximum matching) is being used for some practical purpose (e.g., scheduling in packet switches) throughout a long time span. If the network changes over time, the quality of the used solution may degrade until it is too poor to be used in practice and it may even become infeasible.

Instead of the standard objectives of optimization, the questions that arise here concern *reoptimization*: Can we “efficiently” transform one given solution (the *source*) to another one (the *target*) under “real-life constraints”? The efficiency of the *transformation procedure* could be measured in terms of running time, but in some applications making even small changes to the currently used solution may incur huge costs, possibly much higher than the runtime cost of computing (from scratch) a better solution; we shall use “procedure” and “process” interchangeably. In particular, this is often the case whenever the edges of the currently used solution are “hard-wired” in some physical sense, as in road networks. Various real-life constraints or objectives may be studied; the one we focus on in this work is that at any step (or every few steps) throughout the transformation process the current solution should be both feasible and of quality no worse (by much) than that of either the source or target solutions. This constraint is natural as it might be prohibitively expensive or even impossible to carry out the transformation process *instantaneously*. Instead, the transformation can be broken into *phases* each performing  $\leq \Delta$  changes to the transformed solution, where  $\Delta \geq 1$  is some parameter, so that the solution obtained at the end of each phase – to be used instead of the source solution – is both feasible and of quality no (much) worse than either the source or target. The transformed solution is to eventually coincide with the target solution.

The arising *reoptimization* meta-problem generalizes the well-studied framework of *reconfiguration problems*, which we discuss in Section 1.1. It is interesting from both practical and theoretical perspectives, since even the most basic and well-understood optimization problems become open in this setting. E.g., for the VC problem, *given* a better-than-2 approximate target VC, can we transform to it from any source VC subject to the above constraints? This is an example for a problem that is computationally hard in the standard sense but might be easy from a reoptimization perspective. In contrast, perhaps computationally easy problems, such as approximate maximum matching, are hard from a reoptimization perspective?

This meta-problem captures tension between (1) the *global* objective of transforming one global solution to another, and (2) the *local* objective of transforming *gradually* while having a feasible and high quality solution throughout the process. A similar tension is captured by various models of computation that involve locality, including dynamic graph algorithms,

distributed computing, property testing and local computation algorithms (LCA). The study of the meta-problem presented here could borrow from these related research fields, but, more importantly, we anticipate that it will also contribute to them; indeed, we present here an application of this meta-problem to dynamic graph algorithms.

## 1.1 Graph Reconfiguration

The framework of *reconfiguration problems* has been subject to growing interest in recent years. The term *reconfiguration* was coined in the work of Ito et al. [41], which unified earlier related problems and terminology (see, e.g., [40, 31, 22]) into a single framework. The general goal is to compute a *transformation* between two feasible solutions of a problem such that all intermediate solutions are also feasible, where each pair of consecutive solutions need to be *adjacent* under a fixed polynomially testable symmetric adjacency relation on the set of feasible solutions. Such a transformation arises naturally in many contexts, such as solving puzzles, motion planning, questions of evolvability (can genotype evolve into another one via individual “adjacent” mutations?), and similarity of DNA sequences in computational genomics and particularly gene editing, which is among the hottest scientific topics these days; see the surveys of [58, 51] for further details. In most previous work, two solutions are called adjacent if their symmetric difference has size 1. The most well-studied problem under this framework is graph matching. For brevity, we shall only discuss here papers on graph matching; see the surveys [58, 51] for discussions on other problems.

In the *Matching Reconfiguration Problem* (MRP), proposed in [41], we are given a graph  $G$  and two matchings  $M$  and  $M'$ , and we are asked whether there is a sequence of matchings in  $G$  starting with  $M$  and ending at  $M'$ , each resulting from the previous one by either adding or deleting a *single edge* in  $G$ , without ever going through a matching of size  $< \min\{|M|, |M'|\} - 1$ . Ito et al. gave a polynomial time algorithm for the problem, which uses the Edmonds-Gallai decomposition. In particular, in some cases such a transformation does not exist, and much of the difficulty is in the decision problem (decide if exists or not). The problem of generalizing this algorithm for weighted matchings was proposed as an open problem in [41], and remained open to date, partially since the algorithm of [41] for unweighted matchings already relies on a rather intricate decomposition. The work of [41] triggered interesting followups on MRP [44, 42, 39, 43, 21, 27]. In all these followups, the symmetric difference between two adjacent matchings is rather strict: it is fixed by either 1 or 2 in [44, 42, 39, 27], whereas in the context of perfect matchings the symmetric difference is an alternating cycle of length 4 [21, 43]. Perhaps since the symmetric difference in all the previous work is so strict, the goal was polynomial-time algorithms and hardness for the problem. The natural generalization of parameterizing the symmetric difference by an arbitrary  $\Delta, \Delta \geq 1$  – as in our *reoptimization meta-problem*, was not studied in prior work.

## 1.2 Our contribution

We study two fundamental graph matching problems under the aforementioned meta-problem: (approximate) maximum cardinality matching (MCM) and maximum weight matching (MWM). Our meta-problem is, in fact, inherently different than the original MRP. We are not interested in the decision version of the problem – we take  $\Delta$  to be large enough so that a transformation is *guaranteed* to exist. Thus we shift the focus from per-instance optimization to *existential optimization*, and our goal is to optimize  $\Delta$  so that any source matching can be transformed to any target matching by performing at most  $\Delta$  changes per step, while never reaching a *much worse* matching than either the source or the target along the way.

By “worse” we mean either in terms of size or weight, and we must indeed do a bit worse in some cases even for large  $\Delta$ ; the original MRP formulation for unweighted matchings allows to go down by 1 unit of size, and this slack is required also for large  $\Delta$ . For weighted graphs, naturally, a bigger slack is required. For both unweighted and weighted matchings, we provide transformation procedures with near-optimal guarantees and linear running time. Our results are summarized next; the transformation for approximate MWM (Theorem 2) is the most technically challenging part of this work.

► **Theorem 1 (MCM).** *For any source and target matchings  $\mathcal{M}$  and  $\mathcal{M}'$ , one can transform  $\mathcal{M}$  into (a possibly superset of)  $\mathcal{M}'$  via a sequence of phases consisting of  $\leq 3$  operations each (i.e.,  $\Delta = 3$ ), such that the matching at the end of each phase throughout this transformation is a valid matching for  $G$  of size  $\geq \min\{|\mathcal{M}|, |\mathcal{M}'| - 1\}$ . The runtime of this transformation procedure is  $O(|\mathcal{M}| + |\mathcal{M}'|)$ .*

► **Theorem 2 (MWM).** *For any source and target matchings  $\mathcal{M}$  and  $\mathcal{M}'$  with  $w(\mathcal{M}') > w(\mathcal{M})$ , and any  $\varepsilon > 0$ , one can transform  $\mathcal{M}$  into (a possibly superset of)  $\mathcal{M}'$  via a sequence of phases consisting of  $O(\frac{1}{\varepsilon})$  operations each (i.e.,  $\Delta = O(\frac{1}{\varepsilon})$ ), such that the matching obtained at the end of each phase throughout this transformation is a valid matching for  $G$  of weight  $\geq \max\{w(\mathcal{M}) - W, (1 - \varepsilon)w(\mathcal{M})\}$ , where  $W = \max_{e \in \mathcal{M}} w(e)$ . The runtime of this transformation procedure is  $O(|\mathcal{M}| + |\mathcal{M}'|)$ .*

► **Remark.** Theorem 2 assumes that  $w(\mathcal{M}') > w(\mathcal{M})$ . This assumption is made without loss of generality, since, if  $w(\mathcal{M}') \leq w(\mathcal{M})$ , we can apply a reversed transformation, so that the matching will always be of weight  $\geq \max\{w(\mathcal{M}') - W', (1 - \varepsilon)w(\mathcal{M}')\}$ , where  $W' = \max_{e \in \mathcal{M}'} w(e)$ .

In Section 5, we show that the guarantees provided by Theorems 1 and 2 are tight and asymptotically tight, respectively. Although our results may lead to the impression that there exists an efficient gradual transformation process to any graph optimization problem, we briefly discuss in Section 7 two trivial hardness results for the minimum VC and maximum independent set problems.

### 1.2.1 Application: A worst-case recourse bound for dynamic matching algorithms

In the standard *fully dynamic* setting we start from an empty graph  $G_0$  on  $n$  fixed vertices, and at each time step  $i$  a single edge  $(u, v)$  is either inserted to the graph  $G_{i-1}$  or deleted from it, resulting in graph  $G_i$ . In the *vertex update* setting we have vertex updates instead of edge updates; this setting was mostly studied for bipartite graphs [24, 25, 14].

The problem of maintaining a large matching in fully dynamic graphs was subject to intensive interest recently [52, 10, 50, 38, 53, 56, 18, 14, 29, 3, 32, 13]. The basic goal is to devise an algorithm for maintaining a large matching while keeping a tab on the *update time*, i.e., the time required to update the matching at each step. One may try to optimize the *amortized* (average) update time of the algorithm or its *worst-case* (maximum) update time, but both measures are defined with respect to a *worst-case* sequence of graphs.

“Maintaining” a matching with update time  $u_T$  translates into maintaining a data structure with update time  $u_T$ , which answers queries regarding the matching with a low, ideally constant, *query time*  $q_T$ . For a queried vertex  $v$  the answer is the only matched edge incident on  $v$ , or NULL if  $v$  is free, while for a queried edge  $e$  the answer is whether edge  $e$  is matched or not. All queries made following the same update step  $i$  should be answered *consistently* with respect to the same matching, hereafter the *output matching (at step  $i$ )*,

but queries made in the next update step  $i + 1$  may be answered with respect to a completely different matching. Thus even if the worst-case update time is low, the output matching may change significantly from one update step to the next; some natural scenarios where the output matching changes significantly per update step are discussed in Section 2.

The number of changes (or replacements) to the output matching per update step is an important measure of quality, sometimes referred to as the *recourse bound*, and the problem of optimizing it has received growing attention recently [33, 30, 37, 25, 26, 14, 15, 2, 47]. In applications such as job scheduling, web hosting, streaming content delivery, data storage and hashing, a replacement of a matched edge by another one may be costly, possibly much more than the runtime of computing these replacements. Moreover, when the recourse bound is low, one can efficiently *output* all the changes to the matching following every update step, which could be important in practical scenarios. In particular, a low recourse bound is important when the matching algorithm is used as a black-box subroutine inside a larger data structure or algorithm [17, 1]; see Section 2.3 for more details. We remark that the recourse bound (generally defined as the number of changes to some underlying structure per update step) has been well studied in the areas of dynamic and online algorithms for a plethora of optimization problems besides graph matching, such as MIS, set cover, Steiner tree, flow and scheduling; see [34, 36, 37, 9, 48, 6, 28, 35, 54], and the references therein.

There is a strong separation between the state-of-the-art amortized versus worst-case bounds for dynamic matching algorithms, in terms of both the time and the recourse bounds. A similar separation exists for numerous other problems, such as dynamic minimum spanning forest. In various practical scenarios, particularly in systems designed to provide real-time responses, a strict tab on the *worst-case update time* or on the *worst-case recourse bound* is crucial, thus an algorithm with a low amortized guarantee but a high worst-case guarantee is useless.

Despite the importance of the recourse bound measure, all known algorithms but one in the area of dynamic matchings (described in detail in the full version [55]; see Appendix C therein) provide no nontrivial worst-case recourse bounds whatsoever! The sole exception is an algorithm for maintaining a maximal matching with a worst-case update time  $O(\sqrt{m})$  and a constant recourse bound [50]. In this paper we fill in this gap via a surprisingly simple yet powerful black-box reduction (throughout  $\beta$ -MCM is a shortcut for  $\beta$ -approximate MCM):

► **Theorem 3.** *Any dynamic algorithm maintaining a  $\beta$ -MCM with update time  $T$ ,<sup>1</sup> for any  $\beta \geq 1$ ,  $T$  and  $\varepsilon > 0$ , can be transformed into an algorithm maintaining a  $(\beta(1 + \varepsilon))$ -MCM with update time  $T + O(1/\varepsilon)$  and worst-case recourse bound  $O(1/\varepsilon)$ . If the original time bound  $T$  is amortized/worst-case, so is the resulting time bound of  $T + O(1/\varepsilon)$ , while the recourse bound  $O(1/\varepsilon)$  always holds in the worst-case. This applies to the fully dynamic setting under edge and/or vertex updates.*

The proof of Theorem 3 is carried out in two steps. First we prove Theorem 1 by showing a simple transformation process for any two matchings  $\mathcal{M}$  and  $\mathcal{M}'$  of the same *static* graph. The second step of the proof, which is the key insight behind it, is that the gradual transformation process can be used *essentially as is* in fully dynamic graphs, while incurring a negligible loss to the size and approximation guarantee of the transformed matching.

In Section 6 we complement the positive result provided by Theorem 3 by proving that the recourse bound  $O(1/\varepsilon)$  is optimal (up to a constant factor) in the regime  $\beta = 1 + \varepsilon$ . In fact, the lower bound  $\Omega(1/\varepsilon)$  on the recourse bound holds even in the amortized sense

<sup>1</sup> Besides answering queries, we naturally assume that at any update step the entire matching can be output within time (nearly) linear in its size. All known algorithms satisfy this assumption.

and even in the incremental (insertion only) and decremental (deletion only) settings. For larger values of  $\beta$ , taking  $\varepsilon$  to be a sufficiently small constant gives rise to an approximation guarantee arbitrarily close to  $\beta$  with a constant recourse bound.

**A corollary of Theorem 3.** As a corollary of Theorem 3, all previous algorithms [38, 16, 53, 29, 3, 13, 59] with low worst-case update time are strengthened to achieve a worst-case recourse bound of  $O(1/\varepsilon)$  with only an additive overhead of  $O(1/\varepsilon)$  to the update time. (Some of these results were already strengthened in this way by using a previous version of the current work, which was posted to arXiv in 2018.) Since the update time of all these algorithms is larger than  $O(1/\varepsilon)$ , we get a recourse bound of  $O(1/\varepsilon)$  with no loss whatsoever in the update time! Moreover, all known algorithms with low amortized update time can be strengthened in the same way; e.g., in SODA'19 [32] (cf. [24]) it was shown that one can maintain a  $(1 + \varepsilon)$ -MCM in the incremental edge update setting with a constant (depending exponentially on  $\varepsilon$ ) amortized update time. While this algorithm yields a constant amortized recourse bound, no nontrivial (i.e.,  $o(n)$ ) worst-case recourse bound was known for this problem. Theorem 3 strengthens the result of [32] to maintain a  $(1 + \varepsilon)$ -MCM with a constant amortized update time and the optimal worst-case recourse bound of  $O(1/\varepsilon)$ . Since the recourse bound is an important measure of quality, this provides a significant contribution to the area of dynamic matching algorithms.

**Weighted matchings.** The result of Theorem 3 can be generalized for approximate MWM in graphs with bounded aspect ratio  $\psi$ , by using the much more intricate transformation provided by Theorem 2 (compared to Theorem 1), as summarized in the next theorem. (The *aspect ratio*  $\psi = \psi(G)$  of a weighted graph  $G = (V, E, w)$  is defined as  $\psi = \frac{\max_{e \in E} w(e)}{\min_{e \in E} w(e)}$ .)

► **Theorem 4.** *Any dynamic algorithm for maintaining a  $\beta$ -approximate MWM (shortly,  $\beta$ -MWM) with update time  $T$  in a dynamic graph with aspect ratio always bounded by  $\psi$ , for any  $\beta \geq 1$ ,  $T, \varepsilon > 0$  and  $\psi$ , can be transformed into an algorithm for maintaining a  $(\beta(1 + \varepsilon))$ -MWM with update time  $T + O(\psi/\varepsilon)$  and worst-case recourse bound  $O(\psi/\varepsilon)$ . If the original time bound  $T$  is amortized/worst-case, so is the resulting time bound of  $T + O(\psi/\varepsilon)$ , while the recourse bound  $O(\psi/\varepsilon)$  always holds in the worst-case. This applies to the fully dynamic setting under edge and/or vertex updates.*

**Scenarios with high recourse bounds.** There are various scenarios where high recourse bounds may naturally arise. In such scenarios our reductions (Theorems 3 and 4) can come into play to achieve low worst-case recourse bounds. Furthermore, although a direct application of our reductions may only hurt the update time, we demonstrate the usefulness of these reductions in achieving low update time bounds in some natural settings (where we might not care at all about recourse bounds); this, we believe, provides another strong motivation for our reductions. The details are provided in Section 2.

### 1.3 Related work

We discussed in Section 1.1 prior work on graph reconfiguration problems. Other than this line of work, there are also inherently different lines of work on “reoptimization”, which indeed can be interpreted broadly – there is an extensive and diverse body of research devoted to various notions of reoptimization; see [57, 8, 23, 20, 7, 11, 12, 54, 19], and the references therein. The common goal in all previous work on reoptimization (besides the one discussed in Section 1.1 on reconfiguration) is to (efficiently) compute an exact or approximate solution

to a new problem instance by using the solution for the old instance, where typically the solution for the new instance should be close to the original one under certain distance measure. Our work is inherently different than all such previous work, since our starting point is that *some solution to the new problem instance is given*, and the goal is to compute a *gradual transformation process* (subject to some constraints) between the two given solutions. Also, our work is inherently different than previous work on reconfiguration, as explained in Section 1.2.

## 1.4 Organization

We start (Section 2) with discussing some scenarios where high recourse bounds may naturally arise. We continue (Section 3) by describing a basic scheme for dynamic approximate matchings that was introduced in [38]. In Section 4.1 we present a simple transformation process for MCM in static graphs, thus proving Theorem 1. This result is generalized for MWM via a more intricate transformation process that proves Theorem 2, which is deferred to the full version [55] (see Appendix D therein) due to space constraints. These transformations, which apply to static graphs, are adapted to the fully dynamic setting in Sections 4.2 and 4.3, thus proving Theorems 3 and 4, respectively. The optimality of these transformations is discussed in Section 5. Our lower bound of  $\Omega(1/\varepsilon)$  on the recourse bound of  $(1 + \varepsilon)$ -MCMs is provided in Section 6. We conclude with a discussion in Section 7.

## 2 Scenarios with high recourse bounds

In this section we discuss some scenarios where high recourse bounds may naturally arise. In all such scenarios our reductions (Theorems 3 and 4) can come into play to achieve low worst-case recourse bounds; for clarity we focus in this discussion, sometimes implicitly, on large (unweighted) matching, but the entire discussion carries over with very minor changes to the generalized setting of weighted matchings.

Section 2.3 demonstrates that, although we *may not care at all about recourse bounds*, maintaining a large (weight) matching with a low update time requires in some cases the use of a dynamic matching algorithm with a low recourse bound; this is another situation where our reductions can come into play, but more than that, we believe that it provides an additional strong motivation for our reductions.

### 2.1 Randomized algorithms

**Multiple matchings.** Given a randomized algorithm for maintaining a large matching in a dynamic graph, it may be advantageous to run multiple instances of the algorithm (say  $\text{polylog}(n)$ ), since this may increase the chances that at least one of those instances provides a large matching with high probability (w.h.p.) at any point in time. Notice, however, that it is not the same matching that is guaranteed to be large throughout the entire update sequence, hence the ultimate algorithm (or data structure), which outputs the largest among the  $\text{polylog}(n)$  matchings, may need to switch between a pool of possibly very different matchings when going from one update step to the next. Thus even if the recourse bound of the given randomized algorithm is low, and so each of the maintained matchings changes gradually over time, we do not get any nontrivial recourse bound for the ultimate algorithm.

**Large matchings.** Sometimes the approximation guarantee of the given randomized algorithm holds w.h.p. only when the matching is sufficiently large. This is the case with the algorithm of [29] that achieves  $\text{polylog}(n)$  worst-case update time, where the approximation

guarantee of  $2 + \varepsilon$  holds w.h.p. only when the size of the matching is  $\Omega(\log^5 n / \varepsilon^4)$ . To perform efficiently, [29] also maintains a matching that is guaranteed to be maximal (and thus provide a 2-MCM) when the maximum matching size is smaller than  $\delta = O(\log^5 n / \varepsilon^4)$ , via a deterministic procedure with a worst-case update time of  $O(\delta)$ . The ultimate algorithm of [29] switches between the matching given by the randomized algorithm and that by the deterministic procedure, taking the larger of the two. Thus even if the recourse bounds of both the randomized algorithm and the deterministic procedure are low, the worst-case recourse bound of the ultimate algorithm, which might be of the order of the “large matching” threshold, could be very high. (The large matching threshold is the threshold on the matching size above which a high probability bound on the approximation guarantee holds.) In [29] the large matching threshold is  $\delta = O(\log^5 n / \varepsilon^4)$ , so the recourse bound is reasonably low. (This is not the bottleneck for the recourse bound of [29], as discussed next.) In general, however, the large matching threshold may be significantly higher than  $\text{polylog}(n)$ .

**Long update sequences.** For the probabilistic guarantees of a randomized dynamic algorithm to hold w.h.p., the update sequence must be of bounded length. In particular, polylogarithmic guarantees on the update time usually require that the length of the update sequence will be polynomially bounded. This is the case with numerous dynamic graph algorithms also outside the scope of graph matchings (cf. [45, 1]), and the basic idea is to partition the update sequence into sub-sequences of polynomial length each and to run a fresh instance of the dynamic algorithm in each sub-sequence. In the context of matchings, the algorithm of [29] uses this approach. Notice, however, that an arbitrary sub-sequence (other than the first) does not start from an empty graph. Hence, for the ultimate algorithm of [29] to provide a low worst-case update time, it has to gradually construct the graph at the beginning of each sub-sequence from scratch and maintain for it a new gradually growing matching, while re-using the “old” matching used for the previous sub-sequence throughout this gradual process. Once the gradually constructed graph coincides with the true graph, the ultimate algorithm switches from the old matching to the new one. (See [29] for further details.) While this approach guarantees that the worst-case update time of the algorithm is in check, it does not provide any nontrivial worst-case recourse bound.

## 2.2 From amortized to worst-case

There are techniques for transforming algorithms with low amortized bounds into algorithms with similar worst-case bounds. For approximate matchings, such a technique was first presented in [38]. Alas, the transformed algorithms do not achieve any nontrivial worst-case recourse bound; see Section 3 for details.

## 2.3 When low update time requires low recourse bound

When a dynamic matching algorithm is used as a black-box subroutine inside a larger data structure or algorithm, a low recourse bound of the algorithm used as a subroutine is needed for achieving a low update time for the larger algorithm. We next consider a natural question motivating this need; one may refer to [17, 1] for additional motivation.

► **Question 1.** *Given  $k$  dynamic matchings of a dynamic graph  $G$ , whose union is guaranteed to contain a large matching for  $G$  at any time, for an arbitrary parameter  $k$ , can we combine those  $k$  matchings into a large dynamic matching for  $G$  efficiently?*

This question may arise when there are physical limitations, such as memory constraints, e.g., as captured by MapReduce-style computation, where the edges of the graph are partitioned into  $k$  parties. More specifically, consider a fully dynamic graph  $G$  of huge scale, for which we want to maintain a large matching with low update time. The edges of the graph are dynamically partitioned into  $k$  parties due to memory constraints, each capable of maintaining a large matching for the graph induced by its own edges with low update time, and the only guarantee on those  $k$  dynamically changing matchings is the following global one: The *union* of the  $k$  matchings at any point in time *contains* a large matching for the entire dynamic graph  $G$ . (E.g., if we maintain at each update step the invariant that the edges of  $G$  are partitioned across the  $k$  parties uniformly at random, such a global guarantee can be provided via the framework of *composable randomized coresets* [49, 5, 4].)

This question may also arise when the input data set is noisy. Coping with noisy input usually requires *randomization*, which may lead to high recourse bounds as discussed in Section 2.1. Let us revisit the scenario where we run multiple instances of a randomized dynamic algorithm with low update time; denote the number of such instances by  $k$ . If the input is noisy, we may not be able to guarantee that at least one of the  $k$  maintained matchings is large w.h.p. at any point in time, as suggested in Section 2.1. A weaker, more reasonable assumption is that the union of those  $k$  matchings contains a large matching.

The key observation is that it is insufficient to maintain each of the  $k$  matchings with low update time, even in the worst-case, as each such matching may change significantly following a single update step, thereby changing significantly the union of those matchings. “Feeding” this union to *any* dynamic matching algorithm would result with poor update time bounds, even in the amortized sense. Consequently, to resolve Question 1, each of the  $k$  maintained matchings must change *gradually* over time, or in other words, the underlying algorithm(s) needed for maintaining those matchings should guarantee a low recourse bound. A low amortized/worst-case recourse bound of the underlying algorithm(s) translates into a low amortized/worst-case update time of the ultimate algorithm, provided of course that the underlying algorithm(s) for maintaining those  $k$  matchings, as well as the dynamic matching algorithm to which their union is fed, all achieve a low amortized/worst-case update time.

### 3 The scheme of [38]

This section provides a short overview of a basic scheme for dynamic approximate matchings from [38]. Although such an overview is not required for proving Theorems 3 and 4, it is instructive to provide it, as it shows that the scheme of [38] is insufficient for providing any nontrivial worst-case recourse bound. Also, the scheme of [38] exploits a basic *stability* property of matchings, which we use for proving Theorems 3 and 4, thus an overview of this scheme may facilitate the understanding of our proof.

#### 3.1 The amortization scheme of [38]

The *stability* property of matchings used in [38] is that the maximum matching size changes by at most 1 following each update step. Thus if we have a  $\beta$ -MCM, for any  $\beta \geq 1$ , the approximation guarantee of the matching will remain close to  $\beta$  throughout a long update sequence. Formally, the following lemma is a simple adaptation of Lemma 3.1 from [38]; its proof is given in Appendix E of the full version [55]. (Lemma 3.1 of [38] is stated for approximation guarantee  $1 + \varepsilon$  and for edge updates, whereas Lemma 5 here holds for any approximation guarantee and also for vertex updates.)

► **Lemma 5.** *Let  $\varepsilon' \leq 1/2$ . Suppose  $\mathcal{M}_t$  is a  $\beta$ -MCM for  $G_t$ , for any  $\beta \geq 1$ . For  $i = t, t+1, \dots, t + \lfloor \varepsilon' \cdot |\mathcal{M}_t| \rfloor$ , let  $\mathcal{M}_t^{(i)}$  denote the matching  $\mathcal{M}_t$  after removing from it all edges that got deleted during updates  $t+1, \dots, i$ . Then  $\mathcal{M}_t^{(i)}$  is a  $(\beta(1+2\varepsilon'))$ -MCM for  $G_i$ .*

For concreteness, we shall focus on the regime of approximation guarantee  $1 + \varepsilon$ , and sketch the argument of [38] for maintaining a  $(1 + \varepsilon)$ -MCM in fully dynamic graphs. (As Lemma 5 applies to any approximation guarantee  $\beta \geq 1 + \varepsilon$ , it is readily verified that the same argument carries over to any approximation guarantee.)

One can compute a  $(1 + \varepsilon/4)$ -MCM  $\mathcal{M}_t$  at a certain update step  $t$ , and then re-use the same matching  $\mathcal{M}_t^{(i)}$  throughout all update steps  $i = t, t+1, \dots, t' = t + \lfloor \varepsilon/4 \cdot |\mathcal{M}_t| \rfloor$  (after removing from it all edges that got deleted from the graph between steps  $t$  and  $i$ ). By Lemma 5, assuming  $\varepsilon \leq 1/2$ ,  $\mathcal{M}_t^{(i)}$  provides a  $(1 + \varepsilon)$ -MCM for all graphs  $G_i$ . Next compute a fresh  $(1 + \varepsilon/4)$ -MCM  $\mathcal{M}_{t'}$  following update step  $t'$  and re-use it throughout all update steps  $t', t'+1, \dots, t' + \lfloor \varepsilon/4 \cdot |\mathcal{M}_{t'}| \rfloor$ , and repeat. In this way the static time complexity of computing a  $(1 + \varepsilon)$ -MCM  $\mathcal{M}$  is *amortized* over  $1 + \lfloor \varepsilon/4 \cdot |\mathcal{M}| \rfloor = \Omega(\varepsilon \cdot |\mathcal{M}|)$  update steps. Note that the static computation time of an approximate matching is  $O(|\mathcal{M}| \cdot \alpha/\varepsilon^2)$ , where  $\alpha$  is the arboricity bound; refer to Appendix F in the full version [55]. (This bound on the static computation time was established in [53]; it reduces to  $O(|\mathcal{M}| \cdot \sqrt{m}/\varepsilon^2)$  and  $O(|\mathcal{M}| \cdot \Delta/\varepsilon^2)$  for general graphs and graphs of degree bounded by  $\Delta$ , respectively, which are the bounds provided by [38].)

### 3.2 A Worst-Case Update time

In the amortization scheme of [38] described above, a  $(1 + \varepsilon/4)$ -MCM  $\mathcal{M}$  is computed *from scratch*, and then being re-used throughout  $\lfloor \varepsilon/4 \cdot |\mathcal{M}| \rfloor$  additional update steps. The worst-case update time is thus the static computation time of an approximate matching, namely,  $O(|\mathcal{M}| \cdot \alpha/\varepsilon^2)$ . To improve the worst-case guarantee, the tweak used in [38] is to simulate the static approximate matching computation within a “time window” of  $1 + \lfloor \varepsilon/4 \cdot |\mathcal{M}| \rfloor$  consecutive update steps, so that following each update step the algorithm simulates only  $O(|\mathcal{M}| \cdot \alpha/\varepsilon^2)/(1 + \lfloor \varepsilon/4 \cdot |\mathcal{M}| \rfloor) = O(\alpha \cdot \varepsilon^{-3})$  steps of the static computation. During this time window the gradually-computed matching, denoted by  $\mathcal{M}'$ , is useless, so the previously-computed matching  $\mathcal{M}$  is re-used as the output matching. This means that each matching is re-used throughout a time window of twice as many update steps, hence the approximation guarantee increases from  $1 + \varepsilon$  to  $1 + 2\varepsilon$ , but we can reduce it back to  $1 + \varepsilon$  by a straightforward scaling argument. Note that the gradually-computed matching does not include edges that got deleted from the graph during the time window.

### 3.3 Recourse bounds

Consider an arbitrary time window used in the amortization scheme of [38], and note that the same matching is being re-used throughout the entire window. Hence there are no changes to the matching in the “interior” of the window except for those triggered by adversarial deletions, which may trigger at most one change to the matching per update step. On the other hand, at the start of any time window (except for the first), the output matching is switched from the old matching  $\mathcal{M}$  to the new one  $\mathcal{M}'$ , which may require  $|\mathcal{M}| + |\mathcal{M}'|$  replacements to the output matching at that time. Note that the amortized number of replacements per update step is quite low, being upper bounded by  $(|\mathcal{M}| + |\mathcal{M}'|)/(1 + \lfloor \varepsilon/4 \cdot |\mathcal{M}| \rfloor)$ . In the regime of approximation guarantee  $\beta = O(1)$ , we have  $|\mathcal{M}| = O(|\mathcal{M}'|)$ , hence the amortized recourse bound is bounded by  $O(1/\varepsilon)$ . For a general approximation guarantee  $\beta$ , the naive amortized recourse bound is  $O(\beta/\varepsilon)$ .

On the negative side, the worst-case recourse bound may still be as high as  $|\mathcal{M}| + |\mathcal{M}'|$ , even after performing the above tweak. Indeed, that tweak only causes the time windows to be twice longer, and it does not change the fact that once the computation of  $\mathcal{M}'$  finishes, the output matching is switched from the old matching  $\mathcal{M}$  to the new one  $\mathcal{M}'$  *instantaneously*, which may require  $|\mathcal{M}| + |\mathcal{M}'|$  replacements to the output matching at that time.

## 4 Proofs of Theorems 3 and 4

This section is mostly devoted (see Sections 4.1 and 4.2) to the proof of Theorem 3. At the end of this section (Section 4.3) we sketch the adjustments needed for deriving the result of Theorem 4, whose proof follows along similar lines to those of Theorem 3.

### 4.1 A simple transformation in static graphs

This section is devoted to the proof of Theorem 1, which provides the first step in the proof of Theorem 3. We remark that this proof can be viewed as a “warm up” to that of Theorem 2 for MWM, which is deferred to the full version [55] (see Appendix D therein), and is considerably more technically involved.

Let  $\mathcal{M}$  and  $\mathcal{M}'$  be two matchings for the same graph  $G$ . Our goal is to gradually transform  $\mathcal{M}$  into (a possibly superset of)  $\mathcal{M}'$  via a sequence of constant-time operations to be described next, each making at most 3 changes to the matching, such that the matching obtained at any point throughout this transformation process is a valid matching for  $G$  of size at least  $\min\{|\mathcal{M}|, |\mathcal{M}'| - 1\}$ . It is technically convenient to denote by  $\mathcal{M}^*$  the *transformed* matching, which is initialized as  $\mathcal{M}$  at the outset, and being gradually transformed into  $\mathcal{M}'$ ; we refer to  $\mathcal{M}$  and  $\mathcal{M}'$  as the *source* and *target* matchings, respectively. Each operation starts by adding a single edge of  $\mathcal{M}' \setminus \mathcal{M}^*$  to  $\mathcal{M}^*$  and then removing from  $\mathcal{M}^*$  the at most two edges incident on the newly added edge; thus at most 3 changes to the matching are made per operation. It is instructive to assume that  $|\mathcal{M}'| > |\mathcal{M}|$ , as the motivation for applying this transformation, which will become clear in Section 4.2, is to increase the matching size; in this case the size  $|\mathcal{M}^*|$  of the transformed matching  $\mathcal{M}^*$  never goes below the size  $|\mathcal{M}|$  of the source matching  $\mathcal{M}$ .

We say that an edge of  $\mathcal{M}' \setminus \mathcal{M}^*$  that is incident on at most one edge of  $\mathcal{M}^*$  is *good*, otherwise it is *bad*, being incident on two edges of  $\mathcal{M}^*$ . Since  $\mathcal{M}^*$  has to be a valid matching throughout the transformation process, adding a bad edge to  $\mathcal{M}^*$  must trigger the removal of two edges from  $\mathcal{M}^*$ . Thus if we keep adding bad edges to  $\mathcal{M}^*$ , the size of  $\mathcal{M}^*$  may halve throughout the transformation process. The following lemma shows that if all edges of  $\mathcal{M}' \setminus \mathcal{M}^*$  are bad, the transformed matching  $\mathcal{M}^*$  is at least as large as the target matching  $\mathcal{M}'$ .

► **Lemma 6.** *If all edges of  $\mathcal{M}' \setminus \mathcal{M}^*$  are bad, then  $|\mathcal{M}^*| \geq |\mathcal{M}'|$ .*

**Proof.** Consider a bipartite graph  $L \cup R$ , where each vertex in  $L$  corresponds to an edge of  $\mathcal{M}' \setminus \mathcal{M}^*$  and each vertex in  $R$  corresponds to an edge of  $\mathcal{M}^* \setminus \mathcal{M}'$ , and there is an edge between a vertex in  $L$  and a vertex in  $R$  iff the corresponding matched edges share a common vertex in the original graph. If all edges of  $\mathcal{M}' \setminus \mathcal{M}^*$  are bad, then any edge of  $\mathcal{M}' \setminus \mathcal{M}^*$  is incident on two edges of  $\mathcal{M}^*$ , and since  $\mathcal{M}'$  is a valid matching, those two edges cannot be in  $\mathcal{M}'$ . In other words, the degree of each vertex in  $L$  is exactly 2. Also, the degree of each vertex in  $R$  is at most 2, as  $\mathcal{M}'$  is a valid matching. It follows that  $|R| \geq |L|$ , or in other words  $|\mathcal{M}^* \setminus \mathcal{M}'| \geq |\mathcal{M}' \setminus \mathcal{M}^*|$ , yielding  $|\mathcal{M}^*| \geq |\mathcal{M}'|$ . ◀

The transformation process is carried out as follows. At the outset we initialize  $\mathcal{M}^* = \mathcal{M}$  and compute the sets  $\mathcal{G}$  and  $\mathcal{B}$  of good and bad edges in  $\mathcal{M}' \setminus \mathcal{M}^* = \mathcal{M}' \setminus \mathcal{M}$  within time  $O(|\mathcal{M}| + |\mathcal{M}'|)$  in the obvious way, and store them in doubly-linked lists. We keep mutual pointers between each edge of  $\mathcal{M}^*$  and its at most two incident edges in the corresponding linked lists  $\mathcal{G}$  and  $\mathcal{B}$ . Then we perform a sequence of operations, where each operation starts by adding an edge of  $\mathcal{M}' \setminus \mathcal{M}^*$  to  $\mathcal{M}^*$ , giving precedence to good edges (i.e., adding a bad edge to  $\mathcal{M}^*$  only when there are no good edges to add), and then removing from  $\mathcal{M}^*$  the at most two edges incident on the newly added edge. Following each such operation, we update the lists  $\mathcal{G}$  and  $\mathcal{B}$  of good and bad edges in  $\mathcal{M}' \setminus \mathcal{M}^*$  within constant time in the obvious way. This process is repeated until  $\mathcal{M}' \setminus \mathcal{M}^* = \emptyset$ , at which stage we have  $\mathcal{M}^* \supseteq \mathcal{M}'$ . Note that the number of operations performed before emptying  $\mathcal{M}' \setminus \mathcal{M}^*$  is bounded by  $|\mathcal{M}'|$ , since each operation removes at least one edge from  $\mathcal{M}' \setminus \mathcal{M}^*$ . It follows that the total runtime of the transformation process is bounded by  $O(|\mathcal{M}| + |\mathcal{M}'|)$ .

It is immediate that  $\mathcal{M}^*$  remains a valid matching throughout the transformation process, as we pro-actively remove from it edges that share a common vertex with new edges added to it. To complete the proof of Theorem 1 it remains to prove the following lemma.

► **Lemma 7.** *At any moment in time we have  $|\mathcal{M}^*| \geq \min\{|\mathcal{M}|, |\mathcal{M}'| - 1\}$ .*

**Proof.** Suppose for contradiction that the lemma does not hold, and consider the first time step  $t^*$  throughout the transformation process in which  $|\mathcal{M}^*| < \min\{|\mathcal{M}|, |\mathcal{M}'| - 1\}$ . Since initially  $|\mathcal{M}^*| = |\mathcal{M}|$  and as every addition of a good edge to  $\mathcal{M}^*$  triggers at most one edge removal from it, time step  $t^*$  must occur after an addition of a bad edge. Recall that a bad edge is added to  $\mathcal{M}^*$  only when there are no good edges to add. Just before this addition we have  $|\mathcal{M}^*| \geq |\mathcal{M}'|$  by Lemma 6, thus we have  $|\mathcal{M}^*| \geq |\mathcal{M}'| - 1$  after adding that edge to  $\mathcal{M}^*$  and removing the two edges incident on it from there, yielding a contradiction. ◀

► **Remark 8.** When  $|\mathcal{M}| < |\mathcal{M}'|$ , it is possible to gradually transform  $\mathcal{M}$  to  $\mathcal{M}'$  without ever being in deficit compared to the initial value of  $\mathcal{M}$ , i.e.,  $|\mathcal{M}^*| \geq |\mathcal{M}|$  throughout the transformation process. However, if  $|\mathcal{M}'| \leq |\mathcal{M}|$ , this no longer holds true; refer to Section 5.1 for more details.

## 4.2 The Fully Dynamic Setting

In this section we provide the second step in the proof of Theorem 3, showing that the simple transformation process described in Section 4.1 for static graphs can be generalized for the fully dynamic setting, thus completing the proof of Theorem 3.

Consider an arbitrary dynamic algorithm, Algorithm  $\mathcal{A}$ , for maintaining a  $\beta$ -MCM with an update time of  $T$ , for any  $\beta \geq 1$  and  $T$ . The matching maintained by Algorithm  $\mathcal{A}$ , denoted by  $\mathcal{M}_i^{\mathcal{A}}$ , for  $i = 1, 2, \dots$ , may change significantly following a single update step. All that is guaranteed by Algorithm  $\mathcal{A}$  is that it can update the matching following every update step within a time bound of  $T$ , either in the worst-case sense or in the amortized sense, following which queries regarding the matching can be answered in (nearly) constant time. Recall also that we assume that, for any update step  $i$ , the matching  $\mathcal{M}_i^{\mathcal{A}}$  provided by Algorithm  $\mathcal{A}$  at step  $i$  can be output within time (nearly) linear in the matching size.

Our goal is to output a matching  $\hat{\mathcal{M}} = \hat{\mathcal{M}}_i$ , for  $i = 1, 2, \dots$ , possibly very different from  $\mathcal{M}^{\mathcal{A}} = \mathcal{M}_i^{\mathcal{A}}$ , which changes very slightly from one update step to the next. To this end, the basic idea is to use the matching  $\mathcal{M}^{\mathcal{A}}$  provided by Algorithm  $\mathcal{A}$  at a certain update step, and then re-use it (gradually removing from it edges that get deleted from the graph) throughout a sufficiently long window of  $\Theta(\varepsilon \cdot |\mathcal{M}^{\mathcal{A}}|)$  consecutive update steps, while gradually transforming it into a larger matching, provided again by Algorithm  $\mathcal{A}$  at some later step.

The *gradual transformation process* is obtained by adapting the process described in Section 4.1 for static graphs to the fully dynamic setting. Next, we describe this adaptation. We assume that  $\beta = O(1)$ ; the case of a general  $\beta$  is addressed in Section 4.2.1.

Consider the beginning of a new time window, at some update step  $t$ . Denote the matching provided by Algorithm  $\mathcal{A}$  at that stage by  $\mathcal{M}' = \mathcal{M}_t^A$  and the matching output by our algorithm by  $\mathcal{M} = \tilde{\mathcal{M}}_t$ . Recall that the entire matching  $\mathcal{M}' = \mathcal{M}_t^A$  can be output in time (nearly) linear in its size, and we henceforth assume that  $\mathcal{M}'$  is given as a list of edges. (For concreteness, we assume that the time needed for storing the edges of  $\mathcal{M}'$  in an appropriate list is  $O(|\mathcal{M}'|)$ .) While  $\mathcal{M}'$  is guaranteed to provide a  $\beta$ -MCM at any update step, including  $t$ , the approximation guarantee of  $\mathcal{M}$  may be worse. Nevertheless, we will show (Lemma 9) that  $\mathcal{M}$  provides a  $(\beta(1 + 2\varepsilon'))$ -MCM for  $G_t$ . Under the assumption that  $\beta = O(1)$ , we thus have  $|\mathcal{M}| = O(|\mathcal{M}'|)$ . The length of the time window is  $W = \Theta(\varepsilon \cdot |\mathcal{M}|)$ , i.e., it starts at update step  $t$  and ends at update step  $t' = t + W - 1$ . During this time window, we gradually transform  $\mathcal{M}$  into (a possibly superset of)  $\mathcal{M}'$ , using the transformation described in Section 4.1 for static graphs; recall that the matching output throughout this transformation process is denoted by  $\mathcal{M}^*$ . We may assume that  $|\mathcal{M}|, |\mathcal{M}'| = \Omega(1/\varepsilon)$ , where the constant hiding in the  $\Omega$ -notation is sufficiently large; indeed, otherwise  $|\mathcal{M}| + |\mathcal{M}'| = O(1/\varepsilon)$  and there is no need to apply the transformation process, as the trivial worst-case recourse bound is  $O(1/\varepsilon)$ .

We will show (Lemma 9) that the output matching  $\tilde{\mathcal{M}}_i$  provides a  $(\beta(1 + O(\varepsilon)))$ -MCM at any update step  $i$ . Two simple adjustments are needed for adapting the transformed matching  $\mathcal{M}^*$  of the static setting to the fully dynamic setting:

- To achieve a low worst-case recourse bound and guarantee that the overhead in the update time (with respect to the original update time) is low in the worst-case, we cannot carry out the entire computation at once (i.e. following a single update step), but should rather *simulate it gradually* over the entire time window of the transformation process. Specifically, recall that the transformation process for static graphs consists of two phases, a preprocessing phase in which the matching  $\mathcal{M}' = \mathcal{M}_t^A$  and the sets  $\mathcal{G}$  and  $\mathcal{B}$  of good and bad edges in  $\mathcal{M}' \setminus \mathcal{M}$  are computed, and the actual transformation phase that transforms  $\mathcal{M}^*$ , which is initialized as  $\mathcal{M}$ , into (a possibly superset of)  $\mathcal{M}'$ . Each of these phases requires time  $O(|\mathcal{M}| + |\mathcal{M}'|) = O(|\mathcal{M}|)$ . The first phase does not make any replacements to  $\mathcal{M}^*$ , whereas the second phase consists of a sequence of at most  $|\mathcal{M}'|$  constant-time operations, each of which may trigger a constant number of replacements to  $\mathcal{M}^*$ . The computation of the first phase is simulated in the first  $W/2$  update steps of the window, performing  $O(|\mathcal{M}| + |\mathcal{M}'|)/(W/2) = O(1/\varepsilon)$  computation steps and zero replacements to  $\mathcal{M}^*$  following every update step. The computation of the second phase is simulated in the second  $W/2$  update steps of the window, performing  $O(|\mathcal{M}| + |\mathcal{M}'|)/(W/2) = O(1/\varepsilon)$  computation steps and replacements to  $\mathcal{M}^*$  following every update step.
- Denote by  $\mathcal{M}_i^*$  the matching output at the  $i$ th update step by the resulting gradual transformation process, which simulates  $O(1/\varepsilon)$  computation steps and replacements to the output matching following every update step. While  $\mathcal{M}_i^*$  is a valid matching for the (static) graph  $G_t$  at the beginning of the time window, some of its edges may get deleted from the graph in subsequent update steps  $i = t + 1, t + 2, \dots, t'$ . Consequently, the matching that we shall output for graph  $G_i$ , denoted by  $\tilde{\mathcal{M}}_i$ , is the one obtained from  $\mathcal{M}_i^*$  by removing from it all edges that got deleted from the graph between steps  $t$  and  $i$ .

Once the current time window terminates, a new time window starts, and the same transformation process is repeated, with  $\tilde{\mathcal{M}}_{t'}$  serving as  $\mathcal{M}$  and  $\mathcal{M}_{t'}^A$  serving as  $\mathcal{M}'$ . Since all time windows are handled in the same way, it suffices to analyze the output matching of the current time window, and this analysis would carry over to the entire update sequence.

It is immediate that the output matching  $\tilde{\mathcal{M}}_i$  is a valid matching for any  $i = t, t+1, \dots, t'$ . Moreover, since we make sure to simulate  $O(1/\varepsilon)$  computation steps and replacements following every update step, the worst-case recourse bound of the resulting algorithm is bounded by  $O(1/\varepsilon)$  and the update time is bounded by  $T + O(1/\varepsilon)$ , where this time bound is worst-case/amortized if the time bound  $T$  of Algorithm  $\mathcal{A}$  is worst-case/amortized.

It is left to bound the approximation guarantee of the output matching  $\tilde{\mathcal{M}}_i$ . Recall that  $W = \Theta(\varepsilon \cdot |\mathcal{M}|)$ , and write  $W = \varepsilon' \cdot |\mathcal{M}|$ , with  $\varepsilon' = \Theta(\varepsilon)$ . (We assume that  $\varepsilon$  is sufficiently small so that  $\varepsilon' \leq 1/2$ . We need this restriction on  $\varepsilon'$  to apply Lemma 5.)

► **Lemma 9.**  *$\tilde{\mathcal{M}}_t$  and  $\tilde{\mathcal{M}}_{t'}$  provide a  $(\beta(1+2\varepsilon'))$ -MCM for  $G_t$  and  $G_{t'}$ , respectively. Moreover,  $\tilde{\mathcal{M}}_i$  provides a  $(\beta((1+2\varepsilon')^2))$ -MCM for  $G_i$ , for any  $i = t, t+1, \dots, t'$ .*

**Proof.** First, we bound the approximation guarantee of the matching  $\tilde{\mathcal{M}}_{t'}$ , which is obtained from  $\mathcal{M}_{t'}^*$  by removing from it all edges that got deleted from the graph throughout the time window. By the description of the transformation process,  $\mathcal{M}_{t'}^*$  is a superset of  $\mathcal{M}'$ , hence  $\tilde{\mathcal{M}}_{t'}$  is a superset of the matching obtained from  $\mathcal{M}'$  by removing from it all edges that got deleted throughout the time window. Since  $\mathcal{M}'$  is a  $\beta$ -MCM for  $G_t$ , Lemma 5 implies that  $\tilde{\mathcal{M}}_{t'}$  is a  $(\beta(1+2\varepsilon'))$ -MCM for  $G_{t'}$ . More generally, this argument shows that the matching obtained at the end of any time window is a  $(\beta(1+2\varepsilon'))$ -MCM for the graph at that step.

Next, we argue that the matching obtained at the start of any time window (as described above) is a  $(\beta(1+2\varepsilon'))$ -MCM for the graph at that step. This assertion is trivially true for the first time window, where both the matching and the graph are empty. For any subsequent time window, this assertion follows from the fact that the matching at the start of a new time window is the one obtained at the end of the old time window, for which we have already shown that the required approximation guarantee holds. It follows that  $\tilde{\mathcal{M}}_t = \mathcal{M}$  is a  $(\beta(1+2\varepsilon'))$ -MCM for  $G_t$ .

Finally, we bound the approximation guarantee of the output matching  $\tilde{\mathcal{M}}_i$  in the entire time window. (It suffices to consider the interior of the window.) Lemma 7 implies that  $|\mathcal{M}_i^*| \geq \min\{|\mathcal{M}|, |\mathcal{M}'| - 1\}$ , for any  $i = t, t+1, \dots, t'$ . We argue that  $\mathcal{M}_i^*$  is a  $(\beta(1+2\varepsilon'))$ -MCM for  $G_t$ . If  $|\mathcal{M}_i^*| \geq |\mathcal{M}|$ , then this assertion follows from the fact that  $\mathcal{M}$  provides such an approximation guarantee. We henceforth assume that  $|\mathcal{M}_i^*| \geq |\mathcal{M}'| - 1$ . Recall that  $|\mathcal{M}'| = \Omega(1/\varepsilon) = \Omega(1/\varepsilon')$ , where the constants hiding in the  $\Omega$ -notation are sufficiently large, hence removing a single edge from  $\mathcal{M}'$  cannot hurt the approximation guarantee by more than an additive factor of, say  $\varepsilon'$ , i.e., less than  $\beta(2\varepsilon')$ . Since  $\mathcal{M}'$  provides a  $\beta$ -MCM for  $G_t$ , it follows that  $\mathcal{M}_i^*$  is indeed a  $(\beta(1+2\varepsilon'))$ -MCM for  $G_t$ , which completes the proof of the above assertion. Consequently, Lemma 5 implies that  $\tilde{\mathcal{M}}_i$ , which is obtained from  $\mathcal{M}_i^*$  by removing from it all edges that got deleted from the graph between steps  $t$  and  $i$ , is a  $(\beta((1+2\varepsilon')^2))$ -MCM for  $G_i$ . ◀

#### 4.2.1 A general approximation guarantee

In this section we consider the case of a general approximation parameter  $\beta \geq 1$ . The bound on the approximation guarantee of the output matching provided by Lemma 9, namely  $(\beta((1+2\varepsilon')^2))$ , remains unchanged. Recalling that  $\varepsilon' \leq 1/2$ , it follows that the size of  $\mathcal{M}'$  cannot be larger than that of  $\mathcal{M}$  by more than a factor of  $(\beta((1+2\varepsilon')^2)) \leq 2\beta$ . Consequently, the number of computation steps and replacements performed per update step, namely,  $O(|\mathcal{M}| + |\mathcal{M}'|)/(W/2)$ , is no longer bounded by  $O(1/\varepsilon)$ , but rather by  $O(\beta/\varepsilon)$ . To achieve a bound of  $O(1/\varepsilon)$  for a general  $\beta$ , we shall use a matching  $\mathcal{M}''$  different from  $\mathcal{M}'$ , which includes a possibly small fraction of the edges of  $\mathcal{M}'$ . Recall that we can output  $\ell$  arbitrary edges of the matching  $\mathcal{M}' = \mathcal{M}_t^A$  in time (nearly) linear in  $\ell$ , for any integer

$\ell = 1, 2, \dots, |\mathcal{M}'|$ . Let  $\mathcal{M}''$  be a matching that consists of (up to)  $2|\mathcal{M}|$  arbitrary edges of  $\mathcal{M}'$ ; that is, if  $|\mathcal{M}'| > 2|\mathcal{M}|$ ,  $\mathcal{M}''$  consists of  $2|\mathcal{M}|$  arbitrary edges of  $\mathcal{M}'$ , otherwise  $\mathcal{M}'' = \mathcal{M}'$ . We argue that  $\mathcal{M}''$  is a  $\beta$ -MCM for  $G_t$ . Indeed, if  $|\mathcal{M}'| > 2|\mathcal{M}|$  the approximation guarantee follows from the approximation guarantee of  $\mathcal{M}$  and the fact that  $\mathcal{M}''$  is twice larger than  $\mathcal{M}$ , whereas in the complementary case the approximation guarantee follows from that of  $\mathcal{M}'$ . In any case it is immediate that  $|\mathcal{M}''| = O(|\mathcal{M}|)$ . (For concreteness, we assume that the time needed for storing the edges of  $\mathcal{M}''$  in an appropriate list is  $O(|\mathcal{M}''|) = O(|\mathcal{M}|)$ .) We may henceforth carry out the entire transformation process with  $\mathcal{M}''$  taking the role of  $\mathcal{M}'$ , and in this way guarantee that the number of computation steps and replacements to the output matching performed per update step is reduced from  $O(\beta/\varepsilon)$  to  $O(1/\varepsilon)$ .

### 4.3 Proof of Theorem 4

The proof of Theorem 4 is very similar to the one of Theorem 3. Specifically, we derive Theorem 4 by making a couple of simple adjustments to the proof of Theorem 3 given above, which we sketch next. First, instead of using the transformation of Theorem 1, we use the one of Theorem 2, whose proof appears in Appendix D of the full version [55]. Second, the *stability* property of unweighted matchings used in the proof of Theorem 3 is that the maximum matching size changes by at most 1 following each update step. This stability property enables us in the proof of Theorem 3 to consider a time window of  $W = \Theta(\varepsilon \cdot |\mathcal{M}|)$  update steps, so that any  $\beta$ -MCM computed at the beginning of the window will provide (after removing from it all the edges that get deleted from the graph) a  $(\beta(1 + \varepsilon))$ -MCM throughout the entire window, for any  $\beta \geq 1$ . It is easy to see that this stability property generalizes for weighted matchings, where the maximum matching weight may change by an additive factor of at most  $\psi$ . (Recall that the aspect ratio of the dynamic graph is always bounded by  $\psi$ ; also, we may assume by scaling that the minimum edge weight is 1.) In order to obtain a  $(\beta(1 + \varepsilon))$ -MWM throughout the entire time window, it suffices to consider a time window of  $W' = W/\psi = \Theta(\varepsilon \cdot |\mathcal{M}|/\psi)$ , i.e., a time window shorter than that used for unweighted matchings by a factor of  $\psi$ , and as a result the update time of the resulting algorithm will grow from  $T + O(1/\varepsilon)$  to  $T + O(\psi/\varepsilon)$  and the worst-case recourse bound will grow from  $O(1/\varepsilon)$  to  $O(\psi/\varepsilon)$ .

## 5 Optimality of our Transformations

### 5.1 Unweighted matchings

In the unweighted case, when  $|\mathcal{M}| < |\mathcal{M}'|$ , Theorem 1 states that  $\mathcal{M}$  can gradually transform into  $\mathcal{M}'$  without ever being in deficit compared to the initial value of  $\mathcal{M}$ , i.e.,  $|\mathcal{M}^*| \geq |\mathcal{M}|$  throughout the entire transformation process. If  $|\mathcal{M}'| \leq |\mathcal{M}|$ , however, this no longer holds; in this case the theorem states that we'll reach a deficit of at most 1 unit. To see that this bound is tight, consider the case when  $|\mathcal{M}| = |\mathcal{M}'|$  and  $H = \mathcal{M} \oplus \mathcal{M}'$  is a simple alternating cycle that consists of all edges in  $\mathcal{M}$  and  $\mathcal{M}'$ , and thus of length  $2|\mathcal{M}|$ . Throughout any transformation process and until handling the last edge of the cycle, it must be that  $|\mathcal{M}^*| < |\mathcal{M}|$  if  $\Delta < 2|\mathcal{M}|$ .

► **Remark.** In fact, the same situation will occur if  $\Delta = 2$ . In the particular case of  $\Delta = 1$ , we'll be in deficit of up to 2 throughout the process – adding the first edge of  $\mathcal{M}'$  requires us to delete its two incident edges in  $\mathcal{M}$ , which already leads to a deficit of 2 units.

## 5.2 Weighted matchings

In the weighted case, quantifying this deficit throughout the process is more subtle, but the worst-case scenario remains essentially the same:  $|\mathcal{M}| = |\mathcal{M}'|$ , all edges have weight  $W$  and  $H = \mathcal{M} \oplus \mathcal{M}'$  is a simple alternating cycle that consists of all edges in  $\mathcal{M}$  and  $\mathcal{M}'$ . Throughout any transformation process and until handling the last edge of the cycle, it must be that  $w(\mathcal{M}^*) \leq w(\mathcal{M}) - W$  if  $\Delta < 2|\mathcal{M}|$ . In general, the deficit to the weight of the matching is inverse linear in  $\Delta$ , hence taking  $\Delta$  to be  $\Theta(1/\varepsilon)$  ensures that the weight of the matching throughout the process never goes below  $(1 - \varepsilon)w(\mathcal{M})$ . Interestingly, here a similar situation occurs also when  $w(\mathcal{M}') > w(\mathcal{M})$ . Specifically, consider the same example as above but add  $\eta$  to each edge weight of  $\mathcal{M}'$ , i.e., assume that the edge weights of  $\mathcal{M}$  and  $\mathcal{M}'$  are now  $W$  and  $W' = W + \eta$ , respectively. Then the deficit is no longer  $W$  as before (for  $1 < \Delta < 2|\mathcal{M}|$ ), but rather  $W - \lfloor \Delta/2 \rfloor \cdot \eta$  (for  $1 < \Delta < 2|\mathcal{M}|$ ). Indeed, adding the first edge of  $\mathcal{M}'$  requires the deletion of its two incident edges in  $\mathcal{M}$ , at which stage the deficit is  $W - \eta$ ; from that moment onwards, a single edge of  $\mathcal{M}$  is deleted so that another edge of  $\mathcal{M}'$  can be added, which reduces  $\eta$  from the deficit each time. Therefore, if  $\Delta \cdot \eta = W$ , the deficit is always at least  $W/2$ , while  $w(\mathcal{M}') > w(\mathcal{M}) + W/2$ . This scenario shows that the bound of Theorem 2 is asymptotically tight.

► **Remark.** If  $\Delta = 1$ , we'll be in deficit of  $2W$  (rather than  $W$ ) throughout the process, similarly to the unweighted case. In the degenerate case that  $\mathcal{M}$  and  $\mathcal{M}'$  consist of a single edge each and  $\Delta = 1$ , the weight after the first edge deletion reduces to 0.

## 6 Optimality of the Recourse Bound

In this section we show that an approximation guarantee of  $(1 + \varepsilon)$  requires a recourse bound of  $\Omega(1/\varepsilon)$ , even in the amortized sense and even in the incremental (insertion only) and decremental (deletion only) settings. We only consider edge updates, but the argument extends seamlessly to vertex updates. This lower bound of  $\Omega(1/\varepsilon)$  on the recourse bound does not depend on the update time of the algorithm in any way. Let us fix  $\varepsilon$  to be any parameter satisfying  $\varepsilon = \Omega(1/n)$ ,  $\varepsilon \ll 1$ , where  $n$  is the (fixed) number of vertices.

Consider a simple path  $P_\ell = (v_1, v_2, \dots, v_{2\ell})$  of length  $2\ell - 1$ , for an integer  $\ell = c(1/\varepsilon)$  such that  $\ell \geq 1$  and  $c$  is a sufficiently small constant. (Thus  $P_\ell$  spans at least two but no more than  $n$  vertices.) There is a single maximum matching  $\mathcal{M}_\ell^{OPT}$  for  $P_\ell$ , of size  $\ell$ , which is also the only  $(1 + \varepsilon)$ -MCM for  $P_\ell$ . After adding the two edges  $(v_0, v_1)$  and  $(v_{2\ell}, v_{2\ell+1})$  to  $P_\ell$ , the maximum matching  $\mathcal{M}_\ell^{OPT}$  for the old path  $P_\ell$  does not provide a  $(1 + \varepsilon)$ -MCM for the new path,  $(v_0, v_1, \dots, v_{2\ell+1})$ , which we may rewrite as  $P_{\ell+1} = (v_1, v_2, \dots, v_{2(\ell+1)})$ . The only way to restore a  $(1 + \varepsilon)$ -approximation guarantee is by removing all  $\ell$  edges of  $\mathcal{M}_\ell^{OPT}$  and adding the remaining  $\ell + 1$  edges instead, which yields  $\mathcal{M}_{\ell+1}^{OPT}$ . One may carry out this argument repeatedly until the length of the path reaches, say,  $4\ell - 1$ . The amortized number of replacements to the matching per update step throughout this process is  $\Omega(1/\varepsilon)$ . Moreover, the same amortized bound, up to a small constant factor, holds if we start from an empty path instead of a path of length  $2\ell - 1$ . We then delete all  $4\ell - 1$  edges of the final path and start again from scratch, which may reduce the amortized bound by another small constant. In this way we get an amortized recourse bound of  $\Omega(1/\varepsilon)$  for the fully dynamic setting.

To adapt this lower bound to the incremental setting, we construct  $n' = \Theta(\varepsilon \cdot n)$  vertex-disjoint copies  $P^1, P^2, \dots, P^{n'}$  of the aforementioned incremental path, one after another, in the following way. Consider the  $i$ th copy  $P^i$ , from the moment its length becomes  $2\ell - 1$  and until it reaches  $4\ell - 1$ . If at any moment during this gradual construction of  $P^i$ , the matching

restricted to  $P^i$  is not the (only) maximum matching for  $P^i$ , we *halt* the construction of  $P^i$  and move on to constructing the  $(i + 1)$ th copy  $P^{i+1}$ , and then subsequent copies, in the same way. A copy whose construction started but was halted is called *incomplete*; otherwise it is *complete*. (There are also *empty* copies, whose construction has not started yet.) For any incomplete copy  $P^j$ , the matching restricted to it is not the maximum matching for  $P^j$ , hence its approximation guarantee is worse than  $1 + \varepsilon$ ; more precisely, the approximation guarantee provided by any matching other than the maximum matching for  $P^j$  is at least  $1 + c' \cdot \varepsilon$ , for a constant  $c'$  that can be made as large as we want by decreasing the aforementioned constant  $c$ , or equivalently,  $\ell$ . (Recall that  $\ell = c(1/\varepsilon)$ .) If the matching restricted to  $P^j$  is changed to the maximum matching for  $P^j$  at some later moment in time, we return to that incomplete copy and resume its construction from where we left off, thereby *temporarily suspending* the construction of some other copy  $P_{j'}$ . The construction of  $P^j$  may get halted again, in which case we return to handling the temporarily suspended copy  $P_{j'}$ , otherwise we return to handling  $P_{j'}$  only after the construction of  $P^j$  is complete, and so forth. In this way we maintain the invariant that the approximation guarantee of the matching restricted to any incomplete copy (whose construction is not temporarily suspended) is at least  $1 + c' \cdot \varepsilon$ , for a sufficiently large constant  $c'$ . While incomplete copies may get completed later on, a complete copy remains complete throughout the entire update sequence. At the end of the update sequence no copy is empty or temporarily suspended, i.e., any copy at the end of the update sequence is either incomplete or complete. The above argument implies that any complete copy has an amortized recourse bound of  $\Omega(1/\varepsilon)$ , over the update steps restricted to that copy. Observe also that at least a constant fraction of the  $n'$  copies must be complete at the end of the update sequence, otherwise the entire matching cannot provide a  $(1 + \varepsilon)$ -MCM for the entire graph, i.e., the graph obtained from the union of these  $n'$  copies. It follows that the amortized recourse bound over the entire update sequence is  $\Omega(1/\varepsilon)$ .

The lower bound for the incremental setting can be extended to the decremental setting using a symmetric argument to the one given above.

## 7 Discussion

This paper introduces a natural generalization of the MRP, and provides near-optimal transformations for the problems of MCM and MWM.

One application of this meta-problem is to dynamic graph algorithms. In particular, by building on our transformation for maximum cardinality matching we have shown that any algorithm for maintaining a  $\beta$ -MCM can be transformed into an algorithm for maintaining a  $\beta(1 + \varepsilon)$ -MCM with essentially the same update time as that of the original algorithm and with a worst-case recourse bound of  $O(1/\varepsilon)$ , for any  $\beta \geq 1$  and  $\varepsilon > 0$ . This recourse bound is optimal for the regime  $\beta = 1 + \varepsilon$ . We also extended this result for weighted matchings, but there is a linear dependence on the aspect-ratio of the graph in the update time and recourse bounds. It would be interesting to improve this dependency to be polylogarithmic in the aspect-ratio.

A natural direction for future work is to study additional basic graph problems under this generalized framework. Although our positive results may lead to the impression that there exists an efficient gradual transformation process to any optimization graph problem, we conclude with a sketch of two trivial hardness results.

For the *maximum independent set problem* any gradual transformation process cannot provide any nontrivial approximation guarantee, regardless of the approximation guarantees of the source and target independent sets. To see this, denote the source approximate

maximum independent set (the one we start from) by  $\mathcal{S}$  and the target approximate maximum independent set (the one we gradually transform into) by  $\mathcal{S}'$ , and suppose there is a complete bipartite graph between  $\mathcal{S}$  and  $\mathcal{S}'$ . Since we cannot add even a single vertex of  $\mathcal{S}'$  to the output independent set  $\mathcal{S}^*$  (which is initialized as  $\mathcal{S}$ ) before removing from it all vertices of  $\mathcal{S}$  and assuming each step of the transformation process makes only  $\Delta$  changes to  $\mathcal{S}^*$ , the approximation guarantee of the output independent set must reach  $\Omega(|\mathcal{S}'|/\Delta)$  at some moment throughout the transformation process. In other words, the approximation guarantee may be arbitrarily large.

As another example, an analogous argument shows that for the *minimum vertex cover problem*, any gradual transformation process cannot provide an approximation guarantee better than  $\frac{|\mathcal{C}|+|\mathcal{C}'|}{|\mathcal{C}'|} > 2$ , where  $\mathcal{C}$  and  $\mathcal{C}'$  are the source and target vertex covers, respectively. On the other hand, one can easily see that the approximation guarantee throughout the entire transformation process does not exceed  $\frac{|\mathcal{C}|+|\mathcal{C}'|}{|\mathcal{C}^{OPT}|}$ , where  $\mathcal{C}^{OPT}$  is a minimum vertex cover for the graph, by gradually adding all vertices of the target vertex cover  $\mathcal{C}'$  to the output vertex cover  $\mathcal{C}^*$  (which is initialized as  $\mathcal{C}$ ), and later gradually removing the vertices of  $\mathcal{C}$  from the output vertex cover  $\mathcal{C}^*$ .

These examples demonstrate a basic limitation of our generalized framework, and suggest that further research of this framework is required. One interesting direction for further research is studying the maximum independent set and minimum vertex cover problems for bounded degree graphs; note that the trivial hardness results mentioned above do not apply directly to bounded degree graphs. More generally, studying additional combinatorial optimization problems under this framework may contribute to a deeper understanding of its inherent limitations and strengths, and in particular, to finding additional applications of this framework, possibly outside the area of dynamic matching algorithms.

## Abstract

We consider the *sensitivity* of algorithms for the maximum matching problem against edge and vertex modifications. When an algorithm  $A$  for the maximum matching problem is deterministic, the sensitivity of  $A$  on  $G$  is defined as  $\max_{e \in E(G)} |A(G) \Delta A(G - e)|$ , where  $G - e$  is the graph obtained from  $G$  by removing an edge  $e \in E(G)$  and  $\Delta$  denotes the symmetric difference. When  $A$  is randomized, the sensitivity is defined as  $\max_{e \in E(G)} d_{\text{EM}}(A(G), A(G - e))$ , where  $d_{\text{EM}}(\cdot, \cdot)$  denotes the earth mover's distance between two distributions. Thus the sensitivity measures the difference between the output of an algorithm after the input is slightly perturbed. Algorithms with low sensitivity, or *stable* algorithms are desirable because they are robust to edge failure or attack.

In this work, we show a randomized  $(1 - \epsilon)$ -approximation algorithm with *worst-case* sensitivity  $O_\epsilon(1)$ , which substantially improves upon the  $(1 - \epsilon)$ -approximation algorithm of Varma and Yoshida (SODA'21) that obtains *average* sensitivity  $n^{O(1/(1+\epsilon^2))}$  sensitivity algorithm, and show a deterministic  $1/2$ -approximation algorithm with sensitivity  $\exp(O(\log^* n))$  for bounded-degree graphs. We then show that any deterministic constant-factor approximation algorithm must have sensitivity  $\Omega(\log^* n)$ . Our results imply that randomized algorithms are strictly more powerful than deterministic ones in that the former can achieve sensitivity independent of  $n$  whereas the latter cannot. We also show analogous results for vertex sensitivity, where we remove a vertex instead of an edge.

Finally, we introduce the notion of normalized weighted sensitivity, a natural generalization of sensitivity that accounts for the weights of deleted edges. For a graph with weight function  $w$ , the normalized weighted sensitivity is defined to be the sum of the weighted edges in the symmetric difference of the algorithm normalized by the altered edge, i.e.,  $\max_{e \in E(G)} \frac{1}{w(e)} w(A(G) \Delta A(G - e))$ . Hence the normalized weighted sensitivity measures the weighted difference between the output of an algorithm after the input is slightly perturbed, normalized by the weight of the perturbation. We show that if all edges in a graph have polynomially bounded weight, then given a trade-off parameter  $\alpha > 2$ , there exists an algorithm that outputs a  $\frac{1}{4\alpha}$ -approximation to the maximum weighted matching in  $O(m \log_\alpha n)$  time, with normalized weighted sensitivity  $O(1)$ .

## 1 Introduction

The problem of finding the maximum matching in a graph is a fundamental problem in graph theory with a wide range of applications in computer science. For example, the maximum matching problem on a bipartite graph  $G$  captures a typical example where a number of possible clients want to access content distributed across multiple providers. Each client can download their specific content from a specific subset of the possible providers, but each provider can only connect to a limited number of clients. A maximum matching between clients and providers would ensure that the largest possible number of clients receive their content.

However in many modern applications, the underlying graph  $G$  represents some large dataset that is often dynamic or incomplete. In the above example, the content preference of clients may change, which alters the set of suppliers that provide their desired content. Connections between specific providers and clients may become online or offline, effectively adding or removing edges in the underlying graph. Providers and clients may themselves join or leave the network, adding or removing entire vertices from the graph. Thus, it is reasonable to assume that our knowledge of important properties of  $G$  may also change or be incomplete. Nevertheless, we must extract information from our current knowledge of  $G$  either for pre-processing or to perform tasks on the current infrastructure. At the same time, we would like to maintain as much consistency as possible when updates to  $G$  are revealed.

Motivated by a formal definition of consistency of algorithms across graph updates, Varma and Yoshida [12] first defined the *average sensitivity* of a deterministic algorithm  $A$  to be the Hamming distance<sup>1</sup> between the output of  $A$  on graphs  $G$  and  $G - e$ , where  $G'$  is the graph formed by deleting a random edge of  $G$ . Then, they defined *average sensitivity* for randomized algorithms as

$$\mathbb{E}_{e \sim E(G)} [d_{\text{EM}}(A(G), A(G - e))],$$

where  $d_{\text{EM}}(\cdot, \cdot)$  denotes the earth mover's distance and  $G - e$  is the graph obtained from  $G$  by deleting an edge  $e \in E(G)$ . For the maximum matching problem, they showed a randomized  $1/2$ -approximation algorithm with average sensitivity  $O(1)$  and a randomized  $(1 - \epsilon)$ -approximation algorithm with average sensitivity  $O(n^{1/(1+\epsilon^2)})$ .

**Worst case sensitivity.** In this work, we continue the study of sensitivity for the maximum matching problem. Instead of average sensitivity as in [12], we consider a stronger notion of (worst-case) sensitivity. Specifically, the *sensitivity* of a deterministic algorithm  $A$  is the maximum Hamming distance between the output of  $A$  on graphs  $G$  and  $G'$ , where  $G'$  is the graph formed by deleting an edge of  $G$ . Then, the *sensitivity* of a randomized algorithm  $A$  is

$$\max_{e \in E(G)} d_{\text{EM}}(A(G), A(G - e)).$$

Clearly, the sensitivity of an algorithm is no smaller than its average sensitivity. As a natural variant, we also consider *vertex sensitivity*, where we delete a vertex instead of an edge. To avoid confusion, sensitivity with respect edge deletion will be sometimes called *edge sensitivity*.

---

<sup>1</sup> Here we regard the output as a binary string so we can think of the Hamming distance between outputs.

## 1.1 Our Contributions

We first show that, for any  $\epsilon > 0$ , there exists a randomized  $(1 - \epsilon)$ -approximation algorithm whose sensitivity solely depends on  $\epsilon$  (Section 2).

► **Theorem 1.** *For any  $\epsilon > 0$ , there exists an algorithm that outputs a  $(1 - \epsilon)$ -approximation to the maximum matching problem with probability at least 0.99, using time complexity  $O((n + m) \cdot K)$  and edge/vertex sensitivity  $O(3^K)$ , where  $K = (1/\epsilon)^{2^{O(1/\epsilon)}}$ .*

This result improves upon the previous  $(1 - \epsilon)$ -approximation algorithm [12] in that (1) the sensitivity is constant instead of  $O(n^{1/(1+\epsilon^2)})$  and (2) it bounds worst-case sensitivity instead of average sensitivity.

We observe that approximation is necessary to achieve a small sensitivity. For example, consider an  $n$ -cycle for an even  $n$ , and let  $M_1$  and  $M_2$  be the two maximum matchings of size  $n/2$  in the graph. Consider a deterministic algorithm that always outputs a maximum matching, say,  $M_1$  for the  $n$ -cycle. Then, it must output  $M_2$  after removing an edge in  $M_1$ , and hence the sensitivity is  $\Omega(n)$ . With a similar reasoning, we can show a lower bound of  $\Omega(n)$  for randomized algorithms. Also as we show in Section 4.3, the dependency on  $\epsilon$  in Theorem 1 is necessary.

Next, we show a deterministic algorithm for finding a maximal matching on bounded degree graphs that has low sensitivity (Section 3). Note that it has approximation ratio  $1/2$  because the size of any maximal matching is a  $1/2$ -approximation to the maximum matching.

► **Theorem 2.** *There exists a deterministic algorithm that finds a maximal matching with edge/vertex sensitivity  $\Delta^{O(6^\Delta + \log^* n)}$ , where  $\Delta$  is the maximum degree of a vertex in the graph.*

Then, we show that randomness is necessary to achieve sensitivity independent of  $n$  (Section 4):

► **Theorem 3.** *Any deterministic constant-factor approximation algorithm for the maximum matching problem has edge sensitivity  $\Omega(\log^* n)$ .*

Namely, we show in Section 4.2 that we cannot obtain sublinear sensitivity just by derandomizing the randomized greedy algorithm. Theorems 1 and 3 imply that randomized algorithms are strictly more powerful than deterministic ones in that the former can achieve sensitivity independent of  $n$  whereas the latter cannot for the maximum matching problem.

We then introduce the idea of *weighted sensitivity*, which is a natural generalization of sensitivity for both the average and worst cases. For the problems that we consider, the sensitivity of a deterministic graph algorithm is the number of edges that changes in the output induced by the alteration of a single vertex/edge in the input. Thus for a weighted graph, the weighted sensitivity is the total weight of the edges that are changed in the output, following the deletion of a vertex/edge. For randomized algorithms, the definition extends naturally to the earth mover's distance between the distributions with the corresponding weighted loss function. Finally, we can also normalize by the weight of the edge that is deleted.

The motivation for studying weighted sensitivity is natural; in many applications with evolving data, the notion of sensitivity arises in the context of recourse, a quantity that measures the change in the underlying topology of the optimal solution. For example in the facility location problem, the goal is to construct a set of facilities to minimize the sum of

the costs of construction and service to a set of consumers. As the information about the set of consumers evolves, it would be ideal to minimize the number of relocations for the facilities, due to the construction costs, which is measured by the sensitivity of the algorithm. However, as construction costs may not be uniform, a more appropriate quantity to minimize would be the total cost of the relocations for the facilities, which is measured by the weighted sensitivity.

Similarly, matchings are often used to maximize flow across a bipartite graph, but the physical structures that support the flow may incur varying costs to construct or demolish, corresponding to the amount of flow that the structures support. In this case, we note that it may not be possible for the worst case weighted sensitivity to be small. For example, if a single edge has weight  $n^C$  for some large constant  $C$  and the remaining edges have weight 1, any constant factor approximation to the maximum weighted matching must include the heavy edge. But if the heavy edge is then removed from the graph, the weighted sensitivity of any constant factor approximation algorithm is  $\Omega(n^C)$ . This issue is circumvented by the normalized weighted sensitivity, which scales the sensitivity by the weight of the deleted edge. We give approximation algorithms for maximum weighted matching with low normalized weighted worst-case sensitivity.

► **Theorem 4.** *Let  $G = (V, E)$  be a weighted graph with  $\frac{1}{n^c} \leq w(e) \leq n^c$  for some constant  $c > 0$  and all  $e \in E$ . For a trade-off parameter  $\alpha > 2$ , there exists an algorithm that outputs a  $\frac{1}{4\alpha}$ -approximation to the maximum weighted matching in  $O(m \log_\alpha n)$  time and has normalized weighted sensitivity  $O(1)$ .*

Our results also extend to  $\alpha = 2$  and general worst-case weighted sensitivity, i.e., weighted sensitivity that is not normalized. We detail these algorithms in Section 5.

## 1.2 Proof Sketch

We explain the idea behind the algorithm of Theorem 1. For simplicity, we focus on edge sensitivity. We note that if we only sought a  $1/2$ -approximation to the maximum matching, then it would suffice to find any maximal matching. Although the well-known greedy algorithm produces a maximal matching, the output of the algorithm is highly sensitive to the ordering of the edges in the input. One may hope that, if we choose an ordering of the edges uniformly at random, then the resulting output will be stable against edge deletions to the underlying graph. This is not immediately obvious because the deleted edge will appear about halfway through the ordering (of the edges in the original graph) in expectation, so it seems possible that it can impact about the remaining half of the edges. Luckily, we show that the edges at the beginning of the ordering are significantly more important, so that even if the deleted edge appears about halfway through the ordering, the sensitivity of the maximal matching is  $O(1)$  (Section 2.3.1). Our analysis is similar to [2], who show that the vertices at the beginning of an ordering are significantly more important in maintaining a maximal independent set in the dynamic distributed model.

Adapting this idea to a  $(1 - \epsilon)$ -approximation is more challenging. The natural approach is to take a maximal matching and repeatedly find a large number of augmenting paths, but the change of even a single edge in a maximal matching can potentially impact a large number of edges if the augmenting paths are found in a sequential manner. We instead adapt a layered graph of [9] that is used to randomly find a large number of augmenting paths in a small number of passes in the streaming model. Crucially, we instead find a large number of disjoint augmenting paths in a small number of parallel rounds, which results in low sensitivity.

Now we turn to explaining the idea behind Theorem 2. Again we focus on edge sensitivity. Our algorithm first uses a deterministic local computation algorithm (LCA) of [4] for  $6^\Delta$ -coloring a graph  $G$  with maximum degree  $\Delta$ , using  $O(\Delta \log^* n)$  probes to an adjacency list oracle. Here we want to design an algorithm that answer queries about the colors of vertices by making a series of probes to the oracle. The answers of the algorithm must be consistent so that there exists at least one proper coloring that is consistent with the answers. In our case, each probe to the oracle is a query  $(v, i)$  with  $v \in V$  and a positive integer  $i$ . If the degree of  $v$  is at least  $i$ , the oracle responds with the  $i$ -th neighbor of  $v$  to the probe. Otherwise, the oracle outputs a special symbol  $\perp$ . In particular, the deterministic  $6^\Delta$ -coloring LCA only probes vertices that are within a “small” neighborhood of the query.

Given a coloring for  $G$ , we then give a local distributed algorithm that takes a coloring of a graph and outputs a maximal matching. It follows from a framework of [10] that our local distributed algorithm can actually be simulated by a deterministic LCA that again only probes a “small” neighborhood of the query. Thus to bound the sensitivity of the algorithm, we bound the number of queries for which a deleted edge would be probed. Since only a small number of queries probes the deleted edge, then the output of the algorithm only has a small number of changes and thus low worst-case sensitivity.

Our lower bound of Theorem 3 considers the set of length- $t$  cycles on a graph with  $n$  vertices. Any matching on length- $t$  cycles can be represented as a series of indicator variables denoting whether edge  $i \in [t]$  is in the matching. We can then interpret the indicator variables as an integer encoding from 0 to  $2^t - 1$  through the natural binary representation. Ramsey theory claims that for  $t = O(\log^* n)$ , there exists a set  $S$  of  $t + 1$  nodes of  $n$  so that any subset of  $t$  nodes has the same encoding. We then choose  $G$  and  $G'$  to be the cycle graphs consisting of the first  $t$  nodes of  $S$  and the last  $t$  nodes of  $S$ , respectively. Since the encodings of the matchings of  $G$  and  $G'$  are the same, but the edge indices are shifted by one, it follows that  $\Omega(t)$  edges must be in the symmetric difference between  $G$  and  $G'$ , which implies from  $t = O(\log^* n)$  that the worst-case sensitivity of the algorithm must be  $\Omega(\log^* n)$ .

### 1.3 Related Work

Varma and Yoshida [12] introduced the notion of sensitivity and performed a systematic study of average sensitivity on many graph problems. Namely, they gave efficient approximation algorithms with low average sensitivities for the minimum spanning forest problem, the global minimum cut problem, the minimum  $s$ - $t$  cut problem, and the maximum matching problem. They also introduced a low-sensitivity algorithm for linear programming, and proved many fundamental properties of average sensitivity, such as sequential or parallel composition. Peng and Yoshida [11] gave an algorithm for the problem of spectral clustering with average sensitivity  $\frac{\lambda_2}{\lambda_3}$ , where  $\lambda_i$  is the  $i$ -th smallest eigenvalue of the normalized Laplacian, which is small when there are exactly two clusters in the graph.

The effects of graph updates have also been studied significantly in the dynamic/online model, where updates to the graph arrive in a stream, and the goal is to maintain some data structure to answer queries on the underlying graph so that both the update time and query time are efficient. Consequently, most of the literature for dynamic algorithms focuses on optimizing these quantities, rather than the changes in the output as the data evolves. Sensitivity analysis is more relevant when the goal of the dynamic/offline model is to minimize the number of changes between successive outputs of the algorithm over the stream.

Lattanzi and Vassilvitski [8] studied the problem of consistent  $k$ -clustering, where the goal is to maintain a constant-factor approximation to some underlying  $k$ -clustering problem, such as  $k$ -center,  $k$ -median, or  $k$ -means, while minimizing the total number of changes to the

set of centers as the stream evolves. In this setting, each change to the set of center is known as a *recourse*. Whereas the model of [8] allows only insertions of new points, algorithms with low sensitivity are robust against both insertions and deletions. Cohen-Addad *et. al.* [3] further considered the facility location problem in this model of maintaining a constant-factor approximation while minimizing the total recourse. Although the algorithm of [3] addresses both the insertions and deletions of points, their total recourse across the stream is  $O(n)$ , where  $n$  is the length of the stream; this is inherent to the difficulty of their problem in the model. Whereas their work already provides an amortized  $O(1)$  recourse per update, we also study the worst-case sensitivity in our work.

## 1.4 Preliminaries

For a positive integer  $n$ , let  $[n]$  denote the set  $\{1, 2, \dots, n\}$ . For a positive integer  $n$  and  $p \in [0, 1]$ , let  $\mathcal{B}(n, p)$  be the binomial distribution with  $n$  trials and success probability  $p$ . We use the notation  $O_\epsilon(\cdot)$  to omit dependencies on  $\epsilon$ .

Let  $G = (V, E)$  be a graph. For an edge  $e \in E$ , let  $N_G(e)$  be the “neighboring” edges of  $e$  in  $G$ , that is,  $N_G(e) = \{e' \in E \mid e' \neq e, |e' \cap e| \geq 1\}$ . We omit the subscript if it is clear from the context.

For two (vertex or edge) sets  $S$  and  $S'$ , let  $d_H(S, S') = |S \Delta S'|$ , where  $\Delta$  denotes the symmetric difference. Abusing the notation, for set of paths  $\mathcal{P}$  and  $\mathcal{P}'$ , we write  $d_H(\mathcal{P}, \mathcal{P}')$  to denote  $d_H(\cup_{P \in \mathcal{P}} V(P), \cup_{P \in \mathcal{P}'} V(P))$ . For two random sets  $X$  and  $X'$ , let  $d_{EM}(X, X')$  be the earth mover’s distance between  $X$  and  $X'$ , where the distance between two sets is measured by  $d_H$ , that is,

$$d_{EM}(X, X') = \min_{\mathcal{D}} \mathbf{E}_{(S, S') \sim \mathcal{D}} d_H(S, S'),$$

where  $\mathcal{D}$  is a distribution such that its marginal on the first and second coordinates are  $X$  and  $X'$ , respectively. For a real-valued function  $\beta$  on graphs, we say that the *sensitivity* of a (randomized) algorithm  $A$  that outputs a set of edges is at most  $\beta$  if

$$d_{EM}(A(G), A(G - e)) \leq \beta(G)$$

holds for every  $e \in E(G)$ .

Given a matching  $M$  in a graph  $G = (V, E)$ , we call a vertex *free* if it does not appear as the endpoint of any edge in  $M$ . A path  $(v_1, v_2, \dots, v_{2\ell+2})$  of length  $2\ell + 1$  is an *augmenting path* if  $v_1$  and  $v_{2\ell+2}$  are free vertices and  $(v_i, v_{i+1}) \in M$  for even  $i$  and  $(v_i, v_{i+1}) \in E \setminus M$  for odd  $i$ .

## 2 Randomized $(1 - \epsilon)$ -Approximation

In this section, we prove Theorem 1. Our algorithm, which we describe in Section 2.1, is a slight modification of the multi-pass streaming algorithm due to McGregor [9]. We discuss its approximation guarantee and sensitivity in Sections 2.2 and 2.3, respectively.

### 2.1 Algorithm Description

A key step of McGregor’s algorithm is to find a large set of augmenting paths of a specified length in a batch manner using the *layered graph*, given below. Given a graph  $G = (V, E)$ , a matching  $M \subseteq E$ , and a positive integer  $\ell$ , the layered graph  $H = H(G)$  consists of  $\ell + 2$  layers  $L_0, L_1, \dots, L_{\ell+1}$ , where  $L_0 = L_{\ell+1} = V$  and  $L_1 = L_2 = \dots = L_\ell = V \times V$ .

For each vertex  $v \in V$ , we sample  $i_v \in \{0, \ell + 1\}$  uniformly at random independently from others. We say that the copy of  $v$  in the  $L_{i_v}$ -th layer is *active* and that the other copy is *inactive*. For each edge  $\{u, v\} \in M$ , with probability half, we sample a value  $i_{(u,v)} \in \{1, \dots, \ell\}$  uniformly at random and set  $i_{(v,u)} = \perp$ , where  $\perp$  is a special symbol, and with the remaining probability half, we sample a value  $i_{(v,u)} \in \{1, \dots, \ell\}$  uniformly at random and set  $i_{(u,v)} = \perp$ . For each edge  $\{u, v\} \in E \setminus M$ , we set  $i_{(u,v)} = i_{(v,u)} = \perp$ . We say that the copy of  $(u, v)$  in the  $L_{i_{(u,v)}}$ -th is *active* if  $i_{(u,v)} \neq \perp$  and is *inactive* otherwise. Intuitively, some orientation of each edge  $\{u, v\}$  in the matching  $M$  is assigned to a random internal layer in  $H$  and edges of  $G$  that are not in the matching are not initially assigned to any layer in  $H$ . For  $i = 0, \dots, \ell + 1$ , we denote by  $\tilde{L}_i$  the set of active vertices in  $L_i$ . Let  $L = \bigcup_{i=0}^{\ell+1} L_i$  be the vertex set of  $H$ , and let  $\tilde{L} = \bigcup_{i=0}^{\ell+1} \tilde{L}_i$  be the set of active vertices in  $H$ .

The edges in the layered graph  $H$  are those between active vertices that can be a part of an augmenting path in  $G$ . More specifically,

- We add an edge between  $t \in \tilde{L}_0$  and  $(u, v) \in \tilde{L}_1$  if  $t$  is free in  $M$  and  $t$  is adjacent to  $v$ .
- We add an edge between  $(u, v) \in \tilde{L}_\ell$  and  $s \in \tilde{L}_{\ell+1}$  if  $s$  is free in  $M$  and  $s$  is adjacent to  $u$ .
- We add an edge between  $(u, v) \in \tilde{L}_i$  and  $(u', v') \in \tilde{L}_{i+1}$  for  $i \in [\ell - 1]$  if  $v$  is adjacent to  $u'$ .

Note that inactive vertices are isolated in  $H$ .

■ **Figure 1** Example of an active layered graph with respect to a matching  $M$ , in solid lines. The free vertex  $5$  appears in  $L_0$  and the free vertex  $6$  appears in  $L_3$ . The augmenting path found by the layered graph is represented by a dashed purple line.

We introduce the following definition to handle augmenting paths for a matching  $M$  in a graph  $G$  via paths in its corresponding layered graph.

► **Definition 5.** We say that a path  $v_i, v_{i-1}, \dots, v_0$  with  $v_j \in \tilde{L}_j$  ( $j \in \{0, 1, \dots, i\}$ ) is an  $i$ -path. Note that an  $(\ell + 1)$ -path in  $H$  corresponds to an augmenting path of length  $2\ell + 1$  in  $G$ .

The layered graph defined above is slightly different from the original one due to McGregor [9] in that he did not include inactive vertices in  $H$ , as they are irrelevant to find augmenting paths. However as we consider sensitivity of algorithms, it is convenient to fix the vertex set so that it is independent of the current matching  $M$ .

We briefly define the randomized greedy subroutine **RANDOMIZEDGREEDY** on a graph  $G = (V, E)$  as follows. The subroutine first chooses a random ordering  $\pi$  over edges and then starting with an empty matching  $M$ , the procedure iteratively adds the  $i$ -th edge in the ordering  $\pi$  to  $M$  if the edge is not adjacent to any edge in  $M$ , until it has processed all edges. See Algorithm 1 for the full details.

■ **Algorithm 1** Randomized Greedy Algorithm.

---

```

1 Procedure RANDOMIZEDGREEDY(Graph  $G = (V, E)$ )
2   Generate a permutation  $\pi$  of  $E$  uniformly at random;
3   Greedily add edges to a maximal matching  $M$ , in the order of  $\pi$ ;
4   Output  $M$ ;

```

---

Algorithm 2 shows our algorithm for finding a large set of augmenting paths of length  $2\ell + 1$  given a matching  $M$  in a graph  $G$ . For a matching  $M$  and a vertex  $v$  belonging to an edge  $e$  in  $M$ , let  $\Gamma_M(v)$  denote the other endpoint of  $e$ . Similarly, for a vertex set  $S$  such that each edge in  $M$  uses at most one vertex in  $S$ , let  $\Gamma_M(S)$  denote the set of other endpoints. For subsets  $L$  and  $R$  of adjacent layers in  $H$ , let **RANDOMIZEDGREEDY**( $L, R$ ) denote the randomized greedy on the induced bipartite graph  $H[L \cup R]$ . **FINDPATHS** tries to find a large set of vertex disjoint  $i$ -paths from  $S \subseteq L_i$  to  $L_0$ . The result is stored as a tag function  $t : V(H) \rightarrow V(H) \cup \{\text{untagged}, \text{dead end}\}$ . Here,  $t(v)$  is initialized to **untagged**, and it will represent the next vertex in the  $i$ -path found. If we could not find any  $i$ -path starting from  $v$ ,  $t(v)$  is set to **deadend**.

The difference from McGregor's algorithm is that we run the loop in **FINDPATHS**  $1/\delta$  times instead of running it until  $|M'| \leq \delta|M|$ . This makes sure that we compute a maximal matching the same number of times no matter what  $G$  and  $M$  are, and it is more convenient when analyzing the sensitivity.

Our algorithm for the maximum matching problem (Algorithm 3) simply runs **AUGMENTINGPATHS** sufficiently many times for various choice of  $\ell$  and then keep applying the obtained augmenting paths. Before analyzing its approximation ratio and sensitivity, we analyze its running time.

► **Lemma 6.** *The total running time of Algorithm 3 is  $O(n + m)K$ , where  $K = (1/\epsilon)^{2^{O(1/\epsilon)}}$ .*

**Proof.** Observe that the outer loop of Algorithm 3 runs for  $r$  iterations and the inner loop runs for  $k$  iterations, where  $k = \lceil \epsilon^{-1} + 1 \rceil$  and  $r = 4k^2(16k + 20)(k - 1)(2k)^k$ . Each inner loop runs an instance of **AUGMENTINGPATHS** with parameters  $\ell \leq k$  and  $\delta = \frac{1}{r(2k+2)}$ , which creates a layered graph with  $O(\ell)$  layers in  $O((n + m)k)$  time, and then calls **FINDPATHS**. For each time that **FINDPATHS** is called, the value of  $\delta$  is squared and the value of  $\ell$  is decremented, starting at  $\ell = k$  until  $\ell = 1$ . Thus, the loop in **FINDPATHS** is run at most  $\frac{1}{\delta} = O\left((r(2k + 2))^{2^k}\right)$  times and each loop uses time  $O(n + m)$ . Hence, the total runtime is  $O(n + m)K$ , where  $K = (1/\epsilon)^{2^{O(1/\epsilon)}}$ . ◀

## 2.2 Approximation Ratio

In this section, we analyze the approximation ratio of Algorithm 3.

► **Lemma 7** ([9]). *Suppose **FINDPATHS**( $\cdot, \cdot, j, \cdot$ ) is called  $\delta^{-2^{i-j+1}+1}$  times in the recursion for **FINDPATHS**( $H, S, i, \delta$ ). Then at most  $2\delta|L_i|$  paths are removed from consideration as being  $(i + 1)$ -paths.*

9        $M \leftarrow M \oplus M'_{\ell,i}$ .
10  return  $M$ .

```

---

Let  $\mathcal{L}_i$  be the set of graphs whose vertices are partitioned into  $i + 2$  layers,  $L_0, \dots, L_{i+1}$  and whose edges are a subset of  $\bigcup_{j=1}^{i+1} (L_j \times L_{j-1})$ . Then we immediately have the following lemma, analogous to Lemma 2 in [9]:

► **Lemma 8.** For a graph  $G \in \mathcal{L}_i$ ,  $\text{FINDPATHS}(H, S, i, \delta)$  finds at least  $(\gamma - \delta)|M|$  of the  $(i + 1)$ -paths among some maximal set of  $(i + 1)$ -paths of size  $\gamma|M|$ .

We require the following structural property relating maximal and maximum matchings through the set of connected components in the symmetric difference.

► **Lemma 9** (Lemma 1 in [9]). Let  $M$  be a maximal matching and  $M^*$  be a maximum matching. Let  $\mathcal{C}$  be the set of connected components in  $M^* \triangle M$ . Let  $\alpha_\ell$  be the constant so that  $\alpha_\ell|M|$  is the number of connected components in  $\mathcal{C}$  with  $\ell$  edges from  $M$ , excluding those with  $\ell$  edges from  $M^*$ . If  $\max_{\ell \in [k]} \alpha_\ell \leq \frac{1}{2k^2(k+1)}$ , then  $|M| \geq \frac{|M^*|}{1+1/k}$ .

We also require the following result by [9] bounding the number of augmenting paths found by  $\text{AUGMENTINGPATHS}$ .

► **Lemma 10** (Theorem 1 in [9]). If  $G$  has  $\alpha_\ell|M|$  augmenting paths of length  $2\ell + 1$ , then the number of augmenting paths of length  $2\ell + 1$  found by  $\text{AUGMENTINGPATHS}$  is at least  $(b_\ell\beta_\ell - \delta)|M|$ , where  $b_\ell = \frac{1}{2\ell+1}$  and  $\beta_\ell \sim \mathcal{B}\left(\alpha_\ell|M|, \frac{1}{2(2\ell)^\ell}\right)$ .

We now show that Algorithm 3 outputs a  $(1 - \epsilon)$ -approximation to the maximum matching.

► **Theorem 11.** Algorithm 3 finds a  $(1 - \epsilon)$ -approximation to the maximum matching with probability at least 0.99.

**Proof.** We say the algorithm enters *phase*  $\ell$  when the number of layers in the layered graph has been incremented to  $\ell$ , i.e., each invocation of the outer for loop corresponds to a separate phase. We say the algorithm enters *round*  $i$  in phase  $\ell$  after the subroutine  $\text{AUGMENTINGPATHS}$  has completed  $i - 1$  iterations within phase  $\ell$ . Let  $M_{\ell,i}$  be the matching  $M$  prior to the call to  $\text{AUGMENTINGPATHS}$  in round  $i$  of phase  $\ell$ . Let  $\alpha_{\ell,i}|M_{\ell,i}|$  be the number of length  $2\ell + 1$  augmenting paths of  $M_{\ell,i}$ . Thus by Lemma 10, the subroutine  $\text{AUGMENTINGPATHS}$  augments  $M_{\ell,i}$  by at least  $(b_\ell\beta_{\ell,i} - \delta)|M_{\ell,i}|$  edges in round  $i$  of phase  $\ell$ , where  $b_\ell = \frac{1}{2\ell+2}$ ,  $\delta$  is a parameter that we choose later, and  $\beta_{\ell,i}$  is a random variable distributed according to  $\mathcal{B}\left(\alpha_{\ell,i}|M_{\ell,i}|, \frac{1}{2(2\ell)^\ell}\right)$ . Let  $M$  be the output matching. Then by Bernoulli's inequality, we have

$$\begin{aligned} \Pr[|M| \geq 2|M_{1,1}|] &\geq \Pr\left[|M_{1,1}| \prod_{\ell \in [k], i \in [r]} (1 + \max(0, b_\ell\beta_{\ell,i} - \delta)) \geq 2|M_{1,1}|\right] \\ &\geq \Pr\left[\sum_{\ell \in [k]} \max_{i \in [r]} b_\ell\beta_{\ell,i} \geq 2 + r\delta\right]. \end{aligned}$$

We would like to analyze  $\sum_{\ell \in [k]} \max_{i \in [r]} b_\ell\beta_{\ell,i}$ , but the analysis is challenging due to dependencies between multiple rounds and phases. We thus define independent variables  $X_1, \dots, X_k$  and use a coupling argument.

We define  $A_\ell = \max_{i \in [r]} b_\ell\beta_{\ell,i}|M_{\ell,i}|$  to be an upper bound on the maximum number of augmented edges during phase  $\ell$  of the algorithm. Suppose by way of contradiction that  $\max_{i \in [r]} \alpha_{\ell,i} < \alpha_0 := \frac{1}{2k^2(k-1)}$  for each of the phases  $1 \leq \ell \leq k$ . Then Lemma 9 would imply that at some point  $M_{\ell,i}$  is sufficiently large. Thus we have  $\max_{i \in [r]} \alpha_{\ell,i} \geq \alpha_0$ .

We have  $A_\ell = \max_{i \in [r]} b_\ell\beta_{\ell,i}|M_{\ell,i}|$ ,  $b_\ell = \frac{1}{2\ell+2}$ , and  $\beta_{\ell,i}|M_{\ell,i}| \sim \mathcal{B}\left(\alpha_{\ell,i}|M_{\ell,i}|, \frac{1}{2(2\ell)^\ell}\right)$ . Now for  $\ell \leq k$ , we have that  $\frac{1}{2(2\ell)^\ell} \geq \frac{1}{2(2k)^k}$ . Thus  $\max_{i \in [r]} \alpha_{\ell,i} \geq \alpha_0$  and  $|M_{\ell,i}| \geq |M_{\ell,1}|$  implies that the distribution of  $A_\ell$  statistically dominates the distribution of  $b_\ell \cdot \mathcal{B}\left(\alpha_0|M_{\ell,1}|, \frac{1}{2(2k)^k}\right)$ .

Hence if we define  $X_\ell$  to be independent random variables distributed as  $\mathcal{B}\left(\alpha_0|M_{\ell,1}|, \frac{1}{2(2k)^k}\right)$  for each  $\ell \in [r]$ , then the distribution of  $A_\ell$  statistically dominates the distribution of  $b_\ell \cdot X_\ell$ . Thus,

$$\begin{aligned} \Pr \left[ \sum_{\ell \in [k]} \max_{i \in [r]} b_\ell \beta_{\ell,i} \geq 2 + r\delta \right] &\geq \Pr \left[ \sum_{\ell \in [k]} \max_{i \in [r]} b_\ell \beta_{\ell,i} |M_{\ell,i}| \geq (2 + r\delta)|M_{k,r}| \right] \\ &= \Pr \left[ \sum_{\ell \in [k]} A_\ell \geq (2 + r\delta)|M_{k,r}| \right] \\ &\geq \Pr \left[ \sum_{\ell \in [k]} X_\ell \geq \frac{4 + 2r\delta}{b_k} \cdot |M_{1,1}| \right], \end{aligned}$$

where the final inequality results from  $M_{1,1}$  being a maximal matching and  $b_\ell \geq b_k$  for  $\ell \in [k]$ .

Now the variables  $X_\ell$  are independent but not identically distributed. Nevertheless, we can write  $Y = \sum_{\ell \in [k]} X_\ell$  and note that the distribution of  $Y$  statistically dominates the distribution of  $Z \sim \mathcal{B}\left(\alpha_0|M_{1,1}|r, \frac{1}{2(2k)^k}\right)$  since  $|M_{\ell,i}| \geq |M_{1,1}|$  for all  $\ell \in [k]$  and  $i \in [r]$ . Thus for  $b_k = \frac{1}{2k+2}$  and  $\delta = \frac{b_k}{r}$ ,

$$\begin{aligned} \Pr \left[ \sum_{\ell \in [k]} X_\ell \geq \frac{4 + 2r\delta}{b_k} \cdot |M_{1,1}| \right] &\geq \Pr \left[ Z \geq \frac{4 + 2b_k}{b_k} |M_{1,1}| \right] \\ &= \Pr[Z \geq |M_{1,1}|(8k + 10)]. \end{aligned}$$

For  $r = \frac{2(2k)^k(16k+20)}{\alpha_0}$ , we have that  $\mathbf{E}[Z] = (16k + 20)|M_{1,1}|$ . Thus from a simple Chernoff bound,

$$\Pr[Z \geq |M_{1,1}|(8k + 10)] = 1 - \Pr \left[ Z < \frac{\mathbf{E}[Z]}{2} \right] > 1 - e^{-2(16k+20)|M_{1,1}|} \geq 0.99.$$

Putting things together, we have  $\Pr[|M| \geq 2|M_{1,1}|] \geq 0.99$ , which implies that there exists a maximum matching with more than double the number of edges of a maximal matching and is a contradiction. Therefore, our assumption that  $\max_{i \in [r]} \alpha_{\ell,i} \geq \alpha_0 := \frac{1}{2k^2(k-1)}$  for each of the phases  $1 \leq \ell \leq k$  must have been invalid. However, if  $\alpha_{\ell,i} < \frac{1}{2k^2(k-1)}$  for some  $i \in [r]$  and  $\ell \in [k]$ , then by Lemma 9, we have for  $k = \lceil \epsilon^{-1} + 1 \rceil$  and sufficiently small  $\epsilon > 0$  that

$$|M_{\ell,i}| \geq \frac{|M^*|}{1 + 1/k} \geq \frac{|M^*|}{1 + \epsilon} \geq (1 - \epsilon)|M^*|,$$

with probability at least 0.99. Thus, Algorithm 3 outputs a  $(1 - \epsilon)$  approximation the maximum matching with probability at least 0.99.  $\blacktriangleleft$

**Boosting the Success Probability.** To increase the probability of success to  $1 - p$  for any  $p \in (0, 1)$ , a naïve approach would be to run  $O\left(\log \frac{1}{p}\right)$  iterations of Algorithm 3 in parallel. However, the sensitivity analysis becomes considerably more challenging. Instead, we note that the  $\frac{1}{e}$  probability of failure is actually a significant weakening of the  $e^{-2(16k+20)|M_{1,1}|}$  probability of failure. Thus, increasing  $k$  by a factor of  $O\left(\log \frac{1}{p}\right)$  increases the probability of success to  $1 - p$ . However, for subconstant  $p$ , it also substantially increases the asymptotic sensitivity of Algorithm 3.

### 2.3 Sensitivity of the Randomized Greedy and Algorithm 3

To analyze the sensitivity of Algorithm 3, we first analyze the sensitivity of the randomized greedy algorithm.

#### 2.3.1 Sensitivity of the Randomized Greedy

In this section, we study the sensitivity of the randomized greedy with respect to vertex deletions. Recall that given a graph  $G = (V, E)$ , the randomized greedy works as follows. First, it chooses a random ordering  $\pi$  over edges. Then starting with an empty matching  $M$ , it iteratively adds the  $i$ -th edge in the ordering  $\pi$  to  $M$  if it is not adjacent to any edge in  $M$ . The main result of this section is the following.

► **Theorem 12.** *Let  $A$  be the randomized greedy for the maximum matching problem. Then, for any graph  $G = (V, E)$  and a vertex  $v \in V$ , we have  $d_{\text{EM}}(A(G), A(G - v)) \leq 1$ .*

We need to consider deleting vertices to analyze the sensitivity of our randomized  $(1 - \epsilon)$ -approximation algorithm for the maximum matching problem in Section 2. Our analysis is a slight modification of a similar result for the maximal independent set problem [2]. Hence, we defer the proof to the full version of the paper.

#### 2.3.2 Sensitivity of Algorithm 3

We first analyze the sensitivity of AUGMENTINGPATHS. Let us fix the graphs  $G = (V, E)$  and  $G' = (V, E')$ , and matchings  $M \subseteq E$  and  $M' \subseteq E'$ , a positive integer  $\ell$ , and  $\delta > 0$ . Let  $H$  and  $H'$  be the layered graphs constructed using  $G, M, \ell$  and  $G', M', \ell$ , respectively, and let  $\tilde{L}$  and  $\tilde{L}'$  be the set of active vertices in  $H$  and  $H'$ , respectively.

► **Lemma 13.** *We have  $d_H(\tilde{L}, \tilde{L}') \leq 3d_H(E, E') + 3d_H(M, M')$ .*

**Proof.** Each edge modification in the graph or the matching may cause activate/inactivate at most three vertices in the layered graph (two of them are in the first and last layers, and the remaining one is in one of the middle layers), and hence the lemma follows. ◀

For two tag functions  $t, t': V(H) \rightarrow V(H) \cup \{\text{untagged}, \text{deadend}\}$ , we define  $d_H(t, t') = |\{v \in V(H) \mid t(v) \neq t'(v)\}|$ . We will use symbols  $t$  and  $t'$  to denote tag functions for  $H$  and  $H'$ , respectively. Note that the supposed domain of  $t'$  is  $V(H')$ , but it is equal to  $V(H)$ .

► **Lemma 14.** *Let  $\mathcal{P} = \text{AUGMENTINGPATHS}(G, M, \ell, \delta)$  and  $\mathcal{P}' = \text{AUGMENTINGPATHS}(G', M', \ell, \delta)$ . Then, we have*

$$d_{\text{EM}}(\mathcal{P}, \mathcal{P}') \leq (d_H(E, E') + d_H(M, M')) \cdot 3^K,$$

where  $K = (1/\epsilon)^{2^{O(1/\epsilon)}}$ .

**Proof.** Let  $A$  and  $A'$  denote  $\text{AUGMENTINGPATHS}(G, M, \delta, \ell)$  and  $\text{AUGMENTINGPATHS}(G', M', \delta, \ell)$ , respectively. Let  $M_1, M_2, \dots, M_K$  and  $M'_1, M'_2, \dots, M'_K$  be the sequences of matchings constructed during the process of  $A$  and  $A'$ , respectively. Note that  $A$  and  $A'$  construct the same number of matchings, and that  $K \leq (1/\epsilon)^{2^{O(1/\epsilon)}}$ , which follows by a similar argument to that in the proof of Lemma 6. For  $i \in [K]$ , let  $S_i$  and  $S'_i$  be the vertex sets on which  $M_i$  and  $M'_i$ , respectively, are constructed, that is, the vertex set passed on to RANDOMIZEDGREEDY, and let  $t_i$  and  $t'_i$  be the tag functions right before constructing  $M_i$  and  $M'_i$ , respectively. By Lemma 13, we have  $d_{\text{EM}}(S_1, S'_1) \leq c$ , where  $c = 3d_H(M, M') + 3d_H(E, E')$ . First, because each difference between  $M_{i-1}$  and  $M'_{i-1}$  increases the Hamming distance between  $t_i$  and  $t'_i$  by one, we have

$$\begin{aligned}
d_{\text{EM}}(t_i, t'_i) &\leq d_{\text{EM}}(M_{i-1}, M'_{i-1}) + d_{\text{EM}}(t_{i-1}, t'_{i-1}) \\
&\leq \sum_{j=1}^{i-1} d_{\text{EM}}(M_j, M'_j) + d_{\text{EM}}(t_1, t'_1) = \sum_{j=1}^{i-1} d_{\text{EM}}(M_j, M'_j).
\end{aligned}$$

Then we have

$$d_{\text{EM}}(S_i, S'_i) \leq d_{\text{EM}}(M_{i-1}, M'_{i-1}) + d_{\text{EM}}(t_i, t'_i) \leq 2 \sum_{j=1}^{i-1} d_{\text{EM}}(M_j, M'_j) \leq 2 \sum_{j=1}^{i-1} d_{\text{EM}}(S_j, S'_j),$$

where the last inequality is due to Theorem 12. Solving this recursion, we get

$$\sum_{j=1}^i d_{\text{EM}}(S_j, S'_j) \leq c \cdot 3^{i-1},$$

and hence we have  $d_{\text{EM}}(S_K, S'_K) = 2 \cdot 3^{K-2}c$ , and the claim follows.  $\blacktriangleleft$

We now show that the sensitivity of Algorithm 3 is  $O_\epsilon(1)$ .

► **Theorem 15.** *The sensitivity of Algorithm 3 is at most  $3^K$ , where  $K = (1/\epsilon)^{2^{O(1/\epsilon)}}$ .*

**Proof.** Let  $G = (V, E)$  be a graph and  $G' = (V, E') = G - e$  for some  $e \in E$ . Let  $M_0, M_1, \dots, M_{kr}$  be the sequence of matchings we construct in Algorithm 3 on  $G$ , where  $M_0$  is the matching constructed at Line 3, and  $M_j$  is the matching constructed at Line 3 in the round  $i$  of the phase  $\ell$  such that  $j = (\ell - 1)r + i$ . We define  $M'_0, M'_1, \dots, M'_{kr}$  similarly using  $G'$ . Then, we have by Theorem 12

$$d_{\text{EM}}(M_0, M'_0) \leq 1,$$

and we have by Lemma 14

$$\begin{aligned}
d_{\text{EM}}(M_i, M'_i) &\leq d_{\text{EM}}(M_{i-1}, M'_{i-1}) + (d_{\text{EM}}(E, E') + d_{\text{EM}}(M_{i-1}, M'_{i-1})) \cdot 3^K \\
&= d_{\text{EM}}(M_{i-1}, M'_{i-1})(3^K + 1) + 3^K
\end{aligned}$$

for  $i \in [kr]$ , where  $K = (1/\epsilon)^{2^{O(1/\epsilon)}}$ . Solving the recursion, we get

$$d_{\text{EM}}(M_{kr}, M'_{kr}) \leq 2(1 + 3^K)^{kr} - 1,$$

and we have the desired bound.  $\blacktriangleleft$

The proof of Theorem 1 then follows from Theorem 11 and Theorem 15.

### Sensitivity to Vertex Deletions

We remark that Algorithm 3 also has sensitivity  $O(3^K)$ , for  $K = (1/\epsilon)^{2^{O(1/\epsilon)}}$ , to vertex deletions. Recall that Lemma 13 crucially relies on each edge deletion changing at most three vertices in the layered graph. That is, due to the construction of the layered graph, each edge deletion changes at most two altered vertices in the first and last layers, and at most one altered vertex in one of the middle layers. This is because the first layer and the last layer encode the vertex set  $V$ , while each matched edge is assigned to one of the middle layers.

Observe that when we delete a vertex  $v$ , at most one vertex in the vertex set  $V$  is altered, so that the first and last layer of the layered graph each have one change. Moreover, at most one matched edge is incident to  $v$ , so at most one vertex in one of the middle layers is altered as well. Thus, at most three vertices in the layered graph are changed as a result of the vertex deletion, so the sensitivity of Algorithm 3 to vertex deletions is again  $O(3^K)$ , for  $K = (1/\epsilon)^{2^{O(1/\epsilon)}}$ .

### 3 Deterministic Maximal Matching for Bounded-Degree Graphs

In this section, we give a deterministic algorithm for computing a maximal matching that has low sensitivity on bounded-degree graphs. The main idea is to use deterministic local computation algorithms with a small number of probes to find a maximal matching. Our algorithm uses two main ingredients. The first ingredient is a deterministic LCA of [4] for  $6^\Delta$ -coloring a graph with maximum degree  $\Delta$ , using  $O(\Delta \log^* n)$  probes. The second ingredient is a framework of [10] that simulates local distributed algorithms using a deterministic LCA. In particular, we use the framework to simulate an algorithm that takes a coloring of a graph and outputs a maximal matching. We give the details for the local distributed algorithm in Algorithm 5.

To bound the sensitivity of the algorithm, it suffices to analyze the number of queries for which a deleted edge would be probed. Crucially, both the deterministic LCA of [4] and the framework of [10] only probe edges (incident to vertices) within a small radius of the query. Thus, only a small number of queries will probe the edge that is altered, so that the output of the algorithm only has a small number of changes.

We first require a deterministic LCA of [4] for  $6^\Delta$ -coloring a graph with degree  $\Delta$ , using a small number of probes within distance  $O(\Delta \log^* n)$  of the query. We give the full details in Algorithm 4, which has the following guarantee.

► **Lemma 16** ([4]). *There exists a deterministic LCA  $\text{COLORINGLCA}$  for  $6^\Delta$ -coloring a graph with degree  $\Delta$ , using  $O(\Delta \log^* n)$  probes.*

We now describe a local distributed algorithm that takes a coloring of a graph and outputs a maximal matching. The algorithm iterates over all colors and adds any edge adjacent to a vertex of a particular color to the greedy matching if there is no other adjacent edge already present in the matching. We give the algorithm in full in Algorithm 5.

Putting things together, we obtain a deterministic maximal matching algorithm in Algorithm 6.

We next require the following framework of [10] that simulates local distributed algorithms using a deterministic LCA. In particular, we will implement Algorithm 5.

► **Lemma 17** ([7, 10]). *Given access to an oracle that takes vertices of an underlying graph as queries and outputs a color for the queried vertex, there exists a deterministic LCA that can implement  $\text{COLORING-TO-MM}$  using  $\Delta^{O(c)}$  probes.*

Given a  $\text{COLORINGLCA}$  for  $6^\Delta$ -coloring, the LCA for maximal matching in Lemma 17 uses the following idea. For a query edge  $e$ , we first call  $\text{COLORINGLCA}$  for every vertex with distance roughly  $6^\Delta$  from  $e$ . Parnas and Ron [10] then shows it suffices to run Algorithm 5 locally on the graph of radius roughly  $6^\Delta$  from  $e$ .

We now show that our deterministic LCA based algorithm outputs a maximal matching with low worst case sensitivity for low-degree graphs.

■ **Algorithm 4** LCA Algorithm COLORINGLCA for  $6^\Delta$ -coloring with  $O(\Delta \log^* n)$  probes.

13        Let  $v$  be the parent of  $u$  in  $G_i$ ;
14        Let  $a_u$  be the index of the least significant bit with  $\phi_u \neq \phi_v$ ;
15        Let  $b_u$  be the value of the  $a_u$ -th bit of  $v$ ;
16         $\phi_u \leftarrow a_u \circ b_u$ .
```

---

■ **Algorithm 5** Maximal Matching Algorithm COLORING-TO-MM.

---

```

1 Procedure COLORING-TO-MM( $G$  colored with  $c$  colors)
2    $M \leftarrow \emptyset$ ;
3   for color  $i = 1$  to  $i = c$  do
4     if edge  $(u, v)$  has either  $\phi_u = i$  or  $\phi_v = i$  then
5       Add  $(u, v)$  to  $M$  if no adjacent edge is in  $M$ .
```

---

■ **Algorithm 6** Maximal Matching Algorithm.

---

```

1 Procedure COLORING-TO-MM(Graph  $G$ )
2   Coloring  $G_C = \text{COLORINGLCA}(G, \Delta)$ ;
3   Output COLORING-TO-MM( $G_C$ );
```

---

**Proof of Theorem 2.** Consider running the deterministic LCA from Lemma 17 that simulates COLORING-TO-MM on a graph  $G$  and a graph  $G' := G - e$ , for some  $e \in E$ . Let  $S$  be the set of vertices that are assigned different colors in  $G$  and  $G'$  by COLORINGLCA. First observe that  $e$  is within distance  $\Theta(\log^* n)$  from at most  $\Delta^{\Theta(\log^* n)}$  other vertices. Hence, from Lemma 16 we have  $|S| \leq \Delta^{\Theta(\log^* n)}$ . Moreover, each vertex  $u \in S$  is within distance  $O(6^\Delta)$  from at most  $\Delta^{O(6^\Delta)}$  other vertices. Thus the total number of edges that differ between the matchings  $M$  and  $M'$  output by COLORING-TO-MM for  $G$  and  $G'$  respectively is at most

$$\Delta^{\Theta(\log^* n)} \cdot \Delta^{O(6^\Delta)} = \Delta^{O(6^\Delta + \log^* n)}.$$

◀

It is clear that an almost identical analysis goes through for vertex sensitivity.

## 4 Lower Bounds for Maximum Matching

In this section, we show lower bounds for deterministic and randomized algorithms for the maximum matching problem.

### 4.1 Deterministic Lower Bound

In this section, we prove Theorem 3, which claims that *any* deterministic algorithm for the maximum matching problem has edge sensitivity  $\Omega(\log^* n)$ . Our proof relies on Ramsey's theorem. First we introduce some definitions. Let  $Y$  be a finite set. We say that  $X$  is a  $k$ -subset of  $Y$  if  $X \subseteq Y$  and  $|X| = k$ . Let  $Y^{(k)} = \{X \subseteq Y \mid |X| = k\}$  be the collection of all  $k$ -subsets of  $Y$ . A  $c$ -labeling of  $Y^{(k)}$  is an arbitrary function  $f : Y^{(k)} \rightarrow [c]$ . Then we say that  $X \subseteq Y$  is *monochromatic* in  $f$  if  $f(A) = f(B)$  for all  $A, B \in X^{(k)}$ . Let  $R_c(n; k)$  be the smallest integer  $N$  such that the following holds: for any set  $Y$  with at least  $N$  elements, and for any  $c$ -labeling  $f$  of  $Y^{(k)}$ , there is an  $n$ -subset of  $Y$  that is monochromatic in  $f$ . If no such  $N$  exists,  $R_c(n; k) = \infty$ . Define  $\text{twr}(k)$  as the tower of twos of height  $k$ , that is,  $\text{twr}(1) = 2$  and  $\text{twr}(k+1) = 2^{\text{twr}(k)}$ . We will use the following formulation of Ramsey's theorem.

► **Theorem 18** (Special case of Theorem 1 in [6]). *For any positive integer  $t$ ,  $R_{2^t}(t+1; t) \leq \text{twr}(O(t))$ .*

We now show that any deterministic constant-factor approximation algorithm for the maximum matching problem has edge sensitivity  $\Omega(\log^* n)$ .

**Proof of Theorem 3.** Let  $A$  be an arbitrary deterministic algorithm that outputs a maximal matching, let  $t$  be a positive integer, which will be determined later. Let  $\mathcal{G}$  be a class of graphs on the vertex set  $[n]$  consisting of a cycle  $v_1, \dots, v_t$  with  $v_1 < v_2 < \dots < v_t$  and  $n-t$  isolated vertices. Given a matching  $M$  on the cycle  $v_1, \dots, v_t$ , we encode it to an integer  $0 \leq k \leq 2^t - 1$  so that the  $i$ -th bit of  $k$  is 1 if and only if the edge  $\{v_i, v_{i+1}\}$  belongs to  $M$ , where we regard  $v_{t+1} = v_1$ . Then, we can regard the algorithm  $A$  as a function  $f : \binom{[n]}{t} \rightarrow \{0, 1, \dots, 2^t - 1\}$ , that is, given a set  $\{v_1, \dots, v_t\} \subseteq [n]$  with  $v_1 < v_2 < \dots < v_t$ , we compute a matching on the cycle  $v_1, \dots, v_t$ , and encode it to an integer. Then if  $n \geq R_{2^t}(t+1; t)$ , which holds when  $t = O(\log^* n)$  by Theorem 18, there exists a set  $S = \{s_0, s_1, \dots, s_t\} \subseteq [n]$  with  $s_0 < s_1 < \dots < s_t$  such that  $f(T)$  is constant whenever  $T \subseteq S$  with  $|T| = t$ . Let  $G, G' \in \mathcal{G}$  be the graph with cycles  $s_0, \dots, s_{t-1}$  and  $s_1, \dots, s_t$ , respectively, and let  $M$  and  $M'$  be the matching output by  $A$  on  $G$  and  $G'$ , respectively. As  $M$  and  $M'$  have the same encoding,  $\{s_i, s_{i+1 \bmod t}\} \in M$  if and only if  $\{s_{i+1}, s_{i+2}\} \in M'$ , where we regard  $s_{t+2} = s_1$ . Note that, however, if  $\{s_i, s_{i+1 \bmod t}\} \in M$  then  $\{s_{i+1 \bmod t}, s_{i+2 \bmod t}\} \notin M'$ . It follows that  $d_H(M, M') = \Omega(|M|) = \Omega(t)$ , where the last equality holds because  $A$  has a constant approximation ratio. ◀

### 4.2 Lower Bounds for Deterministic Greedy Algorithm

As we have seen in Section 2.3.1, the randomized greedy algorithm has  $O(1)$  sensitivity even for vertex deletion. Can we derandomize it without increasing the sensitivity? To make the question more precise, let  $V$  be a set of  $n$  vertices and  $\pi$  be a permutation over  $\binom{V}{2}$ . Then, let  $A_\pi$  denote the greedy algorithm such that, starting with an empty matching  $M$ , it iteratively adds the  $i$ -th edge with respect to  $\pi$  to  $M$  if and only if the edge does not share an endpoint with any edge in  $M$ . We now show that the answer to the question is negative.

► **Theorem 19.** *For any permutation  $\pi$  over  $\binom{V}{2}$ , the algorithm  $A_\pi$  has sensitivity  $\Omega(n)$ .*

**Proof.** We say that an element  $e$  of a poset *covers* another element  $e'$  if  $e > e'$ , where  $>$  is the order relation of the poset, and there is no other element  $e''$  such that  $e > e'' > e'$ . Then, we construct a poset  $P$  on the element set  $\binom{V}{2}$  in which a pair  $e \in \binom{V}{2}$  covers another pair  $e' \in \binom{V}{2}$  if  $\pi(e) > \pi(e')$  and  $|e \cap e'| \geq 1$ . Note that the size of any antichain in  $P$  is at most  $n/2$ : A set of elements of size more than  $n/2$  must have two elements  $e, e'$  with  $|e \cap e'| \geq 1$ , which form a chain of length two. Hence, we need at least  $\binom{n}{2}/(n/2) = n - 1$  antichains to cover all the elements in  $P$ . Then by Mirsky's theorem, there exists a chain, say,  $e_1, \dots, e_{n-1}$ , of size  $n - 1$  in  $P$ . From the construction of  $P$ ,  $e_1, \dots, e_{n-1}$  forms a path of length  $n - 1$ . Then,  $A_\pi$  on the path  $e_1, \dots, e_{n-1}$  outputs edges with odd indices, whereas  $A_\pi$  on the path  $e_2, \dots, e_{n-1}$  outputs edges with even indices, and hence the sensitivity of  $A_\pi$  is  $\Omega(n)$ . ◀
