## ■ Preface

The papers in this volume were presented at the 12th Innovations in Theoretical Computer Science (ITCS 2021) conference. The conference was held *online* from January 6–8, 2021. ITCS seeks to promote research that carries a strong conceptual message, for instance, introducing a new concept or model, opening a new line of inquiry within traditional or cross-interdisciplinary areas, introducing new techniques, or making novel connections between existing areas and ideas. The conference format is single-session and aims to promote the exchange of ideas between different areas of theoretical computer science and with other disciplines. A record 214 submissions were received and, of these, the program committee selected 89 papers. The submission pool was strong across the board, and it's very fulfilling to see the tradition of ITCS continue to grow.

The program committee consisted of 37 members (in addition to the chair): Andris Ambainis, University of Latvia; Nima Anari, Stanford; Elette Boyle, IDC Herzliya; Mark Braverman, Princeton; Sebastien Bubeck, Microsoft Research; Claire Mathieu, CNRS, Paris; Edith Cohen, Google; Anindya De, University of Pennsylvania; Uriel Feige, Weizmann Institute; Kira Goldner, Columbia; Monika Henzinger, University of Vienna; Maurice Herlihy, Brown; Sam Hopkins, UC Berkeley and MIT; Tali Kaufman, Bar-Ilan University; Adam Klivans, UT Austin; Gillat Kol, Princeton; Alexandra Kolla, University of Colorado, Boulder; Lap Chi Lau, University of Waterloo; Jamie Morgenstern, University of Washington; Anand Natajaran, MIT; Alantha Newman, Université Grenoble Alpes; Lorenzo Orecchia, University of Chicago; Debmalya Panigrahi, Duke University; Richard Peng, Georgia Tech; Ron Rothblum, Technion; Aviad Rubinstein, Stanford; Tselil Schramm, Stanford; Leonard Schulman, California Institute of Technology; Anastasios Sidiropoulos, University of Illinois at Chicago; Nikhil Srivastava, UC Berkeley; Ola Svensson, EPFL; Avishay Tal, UC Berkeley; Luca Trevisan, Bocconi University; Jan Vondrak, Stanford; Matt Weinberg, Princeton; Amir Yehudayoff, Technion; Mark Zhandry, Princeton and NTT Research.

Planning and execution of the conference were made more challenging by a global pandemic, and in this light I am especially grateful to the committee for agreeing to serve, and then investing substantial time and effort in producing a fantastic program. Similarly, I am thankful to the hundreds of subreviewers who assisted in the reviewing process. Special thanks are also due to Gautam Kamath from the University of Waterloo, and the Simons Institute for the Theory of Computing for their help in organizing the virtual conference. I'm grateful to the ITCS Steering Committee – and especially its chair Umesh Vazirani – for their advice and guidance in forming the program and, finally, to all the authors, presenters, and audience members for making ITCS a unique and innovative experience.

## Abstract

“Twenty questions” is a guessing game played by two players: Bob thinks of an integer between 1 and  $n$ , and Alice’s goal is to recover it using a minimal number of Yes/No questions. Shannon’s entropy has a natural interpretation in this context. It characterizes the average number of questions used by an optimal strategy in the distributional variant of the game: let  $\mu$  be a distribution over  $[n]$ , then the average number of questions used by an optimal strategy that recovers  $x \sim \mu$  is between  $H(\mu)$  and  $H(\mu) + 1$ .

We consider an extension of this game where at most  $k$  questions can be answered falsely. We extend the classical result by showing that an optimal strategy uses roughly  $H(\mu) + kH_2(\mu)$  questions, where  $H_2(\mu) = \sum_x \mu(x) \log \log \frac{1}{\mu(x)}$ . This also generalizes a result by Rivest et al. (1980) for the uniform distribution.

Moreover, we design near optimal strategies that only use comparison queries of the form “ $x \leq c$ ?” for  $c \in [n]$ . The usage of comparison queries lends itself naturally to the context of sorting, where we derive sorting algorithms in the presence of adversarial noise.

## 1 Introduction

The “twenty questions” game is a cooperative game between two players: Bob thinks of an integer between 1 and  $n$ , and Alice’s goal is to recover it using the minimal number of Yes/No questions. An optimal strategy for Alice is to perform binary search, using  $\log n$  queries in the worst case.

The game becomes more interesting when Bob chooses his number according to a distribution  $\mu$  known to both players, and Alice attempts to minimize the *expected* number of questions. In this case, the optimal strategy is to use a Huffman code for  $\mu$ , at an expected cost of roughly  $H(\mu)$ .

What happens when Bob is allowed to lie (either out of spite, or due to difficulties in the communication channel)? Rényi [20] and Ulam [25] suggested a variant of the (non-distributional) “twenty questions” game, in which Bob is allowed to lie  $k$  times. Rivest et al. [21], using ideas of Berlekamp [4], showed that the optimal number of questions in this setting is roughly  $\log n + k \log \log n$ . There are many other ways of allowing Bob to lie, some of which are described by Spencer and Winkler [24] in their charming work, and many others by Pelc [19] in his comprehensive survey on the topic.

### Distributional “twenty questions” with lies

This work addresses the distributional “twenty questions” game in the presence of lies. In this setting, Bob draws an element  $x$  according to a distribution  $\mu$ , and Alice’s goal is to recover the element using as few Yes/No questions as possible on average. The twist is that Bob, who knows Alice’s strategy, is allowed to lie up to  $k$  times. Both Alice and Bob are allowed to use randomized strategies, and the average is measured according to both  $\mu$  and the randomness of both parties.

Our main result shows that the expected number of questions in this case is

$$H(\mu) + kH_2(\mu), \quad \text{where } H_2(\mu) = \sum_x \mu(x) \log \log \frac{1}{\mu(x)},$$

up to an additive factor of  $O(k \log k + kH_3(\mu))$ , where  $H_3(\mu) = \sum_x \mu(x) \log \log \log(1/\mu(x))$  (here  $\mu(x)$  is the probability of  $x$  under  $\mu$ .) See Section 3 for a complete statement of this result.

When  $\mu$  is the uniform distribution, the expected number of queries that our algorithm makes is roughly  $\log n + k \log \log n$ , matching the performance of the algorithm of Rivest et al. However, the approach by Rivest et al. is tailored to their setting, and the distributional setting requires new ideas.

As in the work of Rivest et al., our algorithms use only *comparison queries*, which are queries of the form “ $x \prec c$ ?” (for some fixed value  $c$ ). Moreover, our algorithms are efficient, requiring  $O(n)$  preprocessing time and  $O(\log n)$  time per question. Our lower bounds, in contrast, apply to *arbitrary* Yes/No queries.

### Noisy sorting

One can apply binary search algorithms to implement insertion sort. While sorting an array typically requires  $\Theta(n \log n)$  *sorting queries* of the form “ $x_i \prec x_j$ ?”, there are situations where one has some prior knowledge about the correct ordering. This may happen, for example, when maintaining a sorted array: one has to perform consecutive sorts, where each sort is not expected to considerably change the locations of the elements. Assuming a distribution  $\Pi$  over the  $n!$  possible permutations, Moran and Yehudayoff [17] showed that sorting a  $\Pi$ -distributed array requires  $H(\Pi) + O(n)$  sorting queries on average. We extend this result to the case in which the answerer is allowed to lie  $k$  times, giving an algorithm which uses the following expected number of queries:<sup>1</sup>

$$H(\Pi) + O(nk).$$

This result is tight, and matches the optimal algorithms for the uniform distribution due to Bagchi [3] and Long [16], which use  $n \log n + O(nk)$  queries.

---

<sup>1</sup> Strictly speaking, this bound holds only under the mild condition that  $k$  is at most exponential in  $n$ .

■ **Table 1** Query complexities of searching and sorting in different settings, ignoring lower-order terms. All terms are exact upper and lower bounds except for those inside the  $O(\cdot)$  and  $\Theta(\cdot)$  notations.

Setting	Searching	Sorting
No lies; deterministic	$\log n$ [classical]	$n \log n$ [classical]
No lies; distributional	$H(\mu)$ [classical]	$H(\Pi) + O(n)$ [17]
$k$ lies; deterministic	$\log n + k \log \log n$ [21]	$n \log n + \Theta(nk)$ [3, 16, 15]
$k$ lies; distributional	$H(\mu) + kH_2(\mu)$ [this paper]	$H(\Pi) + \Theta(nk)$ [this paper]

Table 1 summarizes the query complexities of resilient and non-resilient searching and sorting algorithms, in both the deterministic and the distributional settings. To the best of our knowledge, we present the first resilient algorithms in the distributional setting.

## On randomness

All algorithms presented in the paper are randomized. Since they only employ public randomness which is known for both players, there exists a fixing of the randomness which yields a deterministic algorithm with the same (or possibly smaller) expected number of queries. However, this comes at the cost of possibly increasing the running time of the algorithm (since we need to find a good fixing of the randomness); it would be interesting to derive an explicit efficient deterministic algorithm with a similar running time.

## 1.1 Main ideas

### Upper bound

Before presenting the ideas behind our algorithms, we explore several other ideas which give suboptimal results. The first approach that comes to mind is simulating the optimal non-resilient strategy, asking each question  $2k + 1$  times and taking the majority vote, which results in an algorithm using  $\Theta(kH(\mu))$  queries on average.

A better approach is using *tree codes*, suggested by Schulman [22] as an approach for making interactive communication resilient to errors [11, 22, 14]. Tree codes are designed for a different error model, in which we are bounding the *fraction* of lies rather than their absolute number; for an  $\varepsilon$ -fraction of lies, the best known constructions suffer a multiplicative overhead of  $1 + O(\sqrt{\varepsilon})$  [13]. In contrast, we are aiming at an *additive* overhead of  $kH_2(\mu)$ .

Using a packing bound, one can prove that there exists a (non-interactive) code of expected length roughly  $H(\mu) + 2kH_2(\mu)$ , coming much closer to the bound that we are able to get (but off by a factor of 2 from our target  $H(\mu) + kH_2(\mu)$ ). The idea, which is similar to the proof of the Gilbert–Varshamov bound, is to construct a prefix code  $w_1, \dots, w_n$  in which the prefixes of  $w_i, w_j$  of length  $\min(|w_i|, |w_j|)$  are at distance at least  $2k + 1$  (whence the factor  $2k$  in the resulting bound); this can be done greedily. Apart from the inferior bound, two other disadvantages of this approach is that it is not efficient and uses arbitrary queries.

In contrast to these prior techniques, which do not achieve the optimal complexity, might ask arbitrary questions, and could result in strategies which cannot be implemented efficiently, in this paper we design an efficient and nearly optimal strategy, relying on comparison queries only, and utilizing simple observations on the behavior of binary search trees under the presence of lies.

■ **Figure 1** Representing items as centers of segments partitioning the interval  $[0, 1]$ .

■ **Figure 2** On the left, the operation of the algorithm without any lies. On the right, answerer lied on the first question. As a result, all future truthful answers are the same.

Following the footsteps of Rivest et al. [21], our upper bound is based on a binary search algorithm on the unit interval  $[0, 1]$ , first suggested in this context by Gilbert and Moore [12]: given  $x \in [0, 1]$ , the algorithm locates  $x$  by first asking “ $x < 1/2$ ?”; depending on the answer, asking “ $x < 1/4$ ?” or “ $x < 3/4$ ?”; and so on. If  $x \in [0, 1]$  is chosen uniformly at random then the answers behave like an infinite sequence of random and uniform coin tosses.

In order to apply this kind of binary search to the problem of identifying an unknown element (assuming truthful answers), we partition the unit interval  $[0, 1]$  into segments of lengths  $\mu(x_1), \dots, \mu(x_n)$ , and label the center of each segment with the corresponding item (see Figure 1). We then perform binary search until the current interval contains a single item. (In the proof, we use a slightly more sophisticated randomized placement of points which guarantees that the answers on *each* element behave like an infinite sequence of random and uniform coin tosses.)

The main observation is that if a question “ $x < a$ ?” is answered with a lie, this will be strongly reflected in subsequent answers (see Figure 2). Indeed, suppose that  $x < a$ , but Bob claimed that  $x > a$ . All subsequent questions will be of the form “ $x < b$ ?” for various  $b > a$ , the truthful answer to all of which is  $x < b$ . An observer taking notes of the proceedings will thus observe the following pattern of answers:  $>$  (the lie) followed by many  $<$ ’s (possibly interspersed with up to  $k - 1$  many  $>$ ’s, due to further lies). This is suspicious since it is highly unlikely to obtain many  $<$  answers in a row (the probability of getting  $r$  such answers is just  $2^{-r}$ ).

This suggests the following approach: for each question we will maintain a “confidence interval” consisting of  $r(d)$  further questions (where  $d$  is the index of the question). At the end of the interval, we will check whether the situation is suspicious (as described in the preceding paragraph), and if so, will ascertain by brute force the correct answer to the original question (by taking a majority of  $2k + 1$  answers), and restart the algorithm from that point.

The best choice for  $r(d)$  turns out to be roughly  $\log d$ . Each time Bob lies, our unrolling of the confidence interval results in a loss of  $r(d)$  questions. Since an item  $x$  requires roughly  $\log(1/\mu(x))$  questions to be discovered, the algorithm has an overhead of roughly  $kr(\log(1/\mu(x))) \approx k \log \log(1/\mu(x))$  questions on element  $x$ , resulting in an expected overhead of roughly  $kH_2(\mu)$ .

When implementing the algorithm, apart from the initial  $O(n)$  time needed to setup the partition of  $[0, 1]$  into segments, the costliest step is to convert the intervals encountered in the binary search to comparison queries. This can be done in  $O(\log n)$  time per query.

## Lower bound

The proof of our lower bound uses information theory: one can lower bound the expected number of questions by the amount of information that the questioner gains. There are two such types of information: first, the hidden object reveals  $H(\mu)$  information, as in the setting where no lies are allowed. Second, when the object is revealed, the positions of the lies are revealed as well. This reveals additional  $H_2(\mu)$  (conditional) information, as we explain below.

Let  $d_x$  denote the number of questions asked for element  $x$ . Kraft's inequality shows that any good strategy of the questioner satisfies  $d_x \gtrsim \log(1/\mu(x))$ . If the answerer chooses a randomized strategy in which the positions of the lies are chosen uniformly from the  $\binom{d_x}{k}$  possibilities, these positions reveal  $\log \binom{d_x}{k} \approx k \log d_x \gtrsim k \log \log(1/\mu(x))$  information given  $x$ . Taking expectation over  $x$ , the positions of the lies reveal at least  $kH_2(\mu)$  information beyond the identity of  $x$ .

## 1.2 Related work

Most of the literature on error-resilient search procedures has concentrated on the non-distributional setting, in which the goal is to give a worst case guarantee on the number of questions asked, under various error models. The most common error models are as follows:<sup>2</sup>

- Fixed number of errors. This is the error model we consider, and it is also the one suggested by Ulam [25]. This model was first studied by Berlekamp [4], who used an argument similar to the sphere-packing bound to give a lower bound on the number of questions. Rivest et al. [21] used this lower bound as a guiding principle in their almost matching upper bound using comparison queries.
- At most a fixed fraction  $p$  of the answers can be lies. This model is similar to the one considered in error-correcting codes. Pelc [18] and Spencer and Winkler [24] (independently) gave a non-adaptive strategy for revealing the hidden element when  $p \leq 1/4$ , and showed that the task is not possible (non-adaptively) when  $p > 1/4$ . Furthermore, when  $p < 1/4$  there is an algorithm using  $O(\log n)$  questions, and when  $p = 1/4$  there is an algorithm using  $O(n)$  questions, which are both optimal (up to constant factors). Spencer and Winkler also showed that if questions are allowed to be adaptive, then the hidden element can be revealed if and only if  $p < 1/3$ , again using  $O(\log n)$  questions.
- At most a fixed fraction  $p$  of any *prefix* of the answers can be lies. Pelc [18] showed that the hidden element can be revealed if and only if  $p < 1/2$ , and gave an  $O(\log n)$  strategy when  $p < 1/4$ . Aslam and Dhagat [2] and Spencer and Winkler gave an  $O(\log n)$  strategy for all  $p < 1/2$ .

<sup>2</sup> This section is heavily based on Pelc's excellent and comprehensive survey [19].

- Every question is answered erroneously with probability  $p$ , an error model common in information theory. Rényi [20] showed that the number of questions required to discover the hidden element with constant success probability is  $(1 + o(1)) \log n / (1 - h(p))$ .

The distributional version of the “twenty questions” game (without lies) was first considered by Shannon [23] in his seminal paper introducing information theory, where its solution was attributed to Fano (who published it later as [9]). The Shannon–Fano code uses at most  $H(\mu) + 1$  questions on average, but the questions can be arbitrary. The Shannon–Fano–Elias code (also due to Gilbert and Moore [12]), which uses only comparison queries, asks at most  $H(\mu) + 2$  questions on average. Dagan et al. [7] give a strategy, using only comparison and equality queries, which asks at most  $H(\mu) + 1$  questions on average.

### Sorting

The non-distributional version of sorting has also been considered in some of the settings considered above:

- At most  $k$  errors: Lakshmanan et al. [15] gave a lower bound of  $\Omega(n \log n + kn)$  on the number of questions, and an almost matching upper bound of  $O(n \log n + kn + k^2)$  questions. An optimal algorithm, using  $n \log n + O(kn)$  questions, was given independently by Bagchi [3] and Long [16].
- At most a  $p$  fraction of errors in every prefix: Aigner [1] showed that sorting is possible if and only if  $p < 1/2$ . Borgstrom and Kosaraju [5] had showed earlier that even *verifying* that an array is sorted requires  $p < 1/2$ .
- Every answer is correct with probability  $p$ : Feige et al. [10] showed in an influential paper that  $\Theta(n \log(n/\epsilon))$  queries are needed, where  $\epsilon$  is the probability of error.
- Braverman and Mossel [6] considered a different setting, in which an algorithm is given access to noisy answers to all possible  $\binom{n}{2}$  comparisons, and the goal is to find the most likely permutation. They gave a polynomial time algorithm which succeeds with high probability.

The distributional version of sorting (without lies) was considered by Moran and Yehudayoff [17], who gave a strategy using at most  $H(\mu) + 2n$  queries on average, based on the Gilbert–Moore algorithm.

### Paper organization

After a few preliminaries in Section 2, we describe our results in full in Section 3. The proofs are presented in the full version of this paper [8].

## 2 Definitions

We use the notation  $\binom{n}{\leq k} = \sum_{\ell=0}^k \binom{n}{\ell}$ . Unless stated otherwise, all logarithms are base 2. We define  $\overline{\log}(x) = \log(x + C)$  and  $\overline{\ln}(x) = \ln(x + C)$  for a fixed sufficiently large constant  $C > 0$  satisfying  $\log \log \log C > 0$ .

### Information theory

Given a probability distribution  $\mu$  with countable support, the entropy of  $\mu$  is given by the formula

$$H(\mu) = \sum_{x \in \text{supp } \mu} \mu(x) \log \frac{1}{\mu(x)}.$$

## Twenty questions game

We start with an intuitive definition of the game, played by a questioner (Alice) and an answerer (Bob). Let  $U$  be a finite set of elements, and let  $\mu$  be a distribution over  $U$ , known to both parties. The game proceeds as follows: first, an element  $x \sim \mu$  is drawn and revealed to the answerer but not to the questioner. The element  $x$  is called the *hidden* element. The questioner asks binary queries of the form “ $x \in Q?$ ” for subsets  $Q \subseteq U$ . The answerer is allowed to lie a fixed number of times, and the goal of the questioner is to recover the hidden element  $x$ , asking the minimal number of questions on expectation.

## Decision trees

Let  $U$  be a finite set of elements. A *decision tree*  $T$  for  $U$  is a binary tree formalizing the question asking strategy in the twenty questions game. Each internal node of  $T$  is labeled by a *query* (or *question*) – a subset of  $U$ , denoted by  $Q(v)$ ; and each leaf is labeled by the output of the decision tree, which is an element of  $U$ . The semantics of the tree are as follows: on input  $x \in U$ , traverse the tree by starting at the root, and whenever at an internal node  $v$ , go to the left child if  $x \in Q(v)$  and to the right child if  $x \notin Q(v)$ .

## Comparison tree

Given an ordered set of elements  $x_1 \prec x_2 \prec \dots \prec x_n$ , *comparison questions* are questions of the form  $Q = \{x_1, \dots, x_{i-1}\}$ , for some  $i = 1, \dots, n+1$ . In other words, the questions are “ $x \prec x_i?$ ” for some  $i = 1, \dots, n+1$ . An answer to a comparison question is one of  $\{\prec, \succeq\}$ . A *comparison tree* is a decision tree all of whose nodes are labeled by comparison questions.

## Adversaries

Let  $k \geq 0$  be a bound on the number of lies. An intuitive way to formalize the possibility of lying is via an adversary. The adversary knows the hidden element  $x$  and receives the queries from the questioner as the tree is being traversed. The adversary is allowed to lie at most  $k$  times, where each lie is a violation of the above stated rule. Formally, an adversary is a mapping that receives as input an element  $x \in X$ , a sequence of the previous queries and their answers, and an additional query  $Q \subseteq U$ , which represents the current query. The output of the adversary is a boolean answer to the current query; this answer is a *lie* if it differs from the truth value of “ $x \in Q$ ”.

We also allow the adversary and the tree to use randomness: a randomized decision tree is a distribution over decision trees and a randomized adversary is a distribution over adversaries.

## Computation and complexity

The responses of the adversary induce a unique root-to-leaf path in the decision tree, which results in the output of the tree. A decision tree is *k-valid* if it outputs the correct element against any adversary that lies at most  $k$  times.

Given a  $k$ -valid decision tree  $T$  and a distribution  $\mu$  on  $U$ , the *cost* of  $T$  with respect to  $\mu$ , denoted  $c(T, \mu)$ , is the maximum, over all possible adversaries that lie at most  $k$  times, of the expected<sup>3</sup> length of the induced root-to-leaf path in  $T$ . Finally, the *k-cost* of  $\mu$ , denoted  $c_k(\mu)$ , is the minimum of  $c(T, \mu)$  over all  $k$ -valid decision trees  $T$ .

<sup>3</sup> The expectation is also taken with respect to the randomness of the adversary and the tree when they are randomized.

### Basic facts

We will refer to the following well-known formula as *Kraft's identity*:

► **Fact 1** (Kraft's identity). *Fix a binary tree  $T$ , let  $L$  be its set of leaves and let  $d(\ell)$  be the depth of leaf  $\ell$ . The following applies:*

$$\sum_{\ell \in L(T)} 2^{-d(\ell)} \leq 1.$$

We will use the following basic lower bound on the expected depth by the entropy:

► **Fact 2.** *Let  $T$  be a binary tree and let  $\mu$  be a distribution over its leaves. Then*

$$H(\mu) \leq \mathbb{E}_{\ell \sim \mu} [d(\ell)].$$

In other words, for any distribution  $\mu$ ,  $c_0(\mu) \geq H(\mu)$ . In fact, it is also known that  $c_0(\mu) \leq H(\mu) + 1$ .

## 3 Main results

This section is organized as follows: The lower bound is presented in Section 3.1. Then, the two searching algorithms are presented in Section 3.2, and finally the application to sorting is presented in Section 3.3.

### 3.1 Lower bound

In this section we present the following lower bound on  $c_k(\mu)$ , namely, on the expected number of questions asked by *any*  $k$ -valid tree (not necessarily a comparison trees).

► **Theorem 3.** *For every non-constant distribution  $\mu$  and every  $k \geq 0$ ,*

$$c_k(\mu) \geq \left( \mathbb{E}_{x \sim \mu} \log \frac{1}{\mu(x)} \right) + k \left( \mathbb{E}_{x \sim \mu} \log \log \frac{1}{\mu(x)} \right) - (k \log k + k + 1).$$

### Proof overview

Consider a  $k$ -valid tree; we wish to lower bound the expected number of questions for  $x \sim \mu$ . Let  $d_x$  denote the number of questions asked when the secret element is  $x$ . Then, by the entropy lower bound when the number of mistakes is  $k = 0$ , it follows that *typically*,  $d_x \gtrsim \log(1/\mu(x))$ . Moreover, the transcript of the game (i.e. the list of questions and answers) determines both  $x$  and the positions of the  $k$  lies. This requires

$$d_x + k \log(d_x) \gtrsim \log(1/\mu(x)) + k \log \log(1/\mu(x))$$

bits of information. Taking expectation over  $x \sim \mu$  then yields the stated bound.

Our proof formalizes this intuition using standard and basic tools from information theory. One part that requires a subtler argument is showing that indeed one may assume that  $d_x \gtrsim \log(1/\mu(x))$  for all  $x$ . This is done by showing that any  $k$ -valid tree can be modified to satisfy this constraint without increasing the expected number of questions by too much.

### 3.2 Upper bounds

We introduce two algorithms. The first algorithm, presented in Section 3.2.1, is simpler, however, the second algorithm has a better query complexity. The expected number of questions asked by the first algorithm is at most

$$H(\mu) + (k+1)H_2(\mu) + O(k^2 H_3(\mu) + k^2 \log k), \quad \text{where } H_3(\mu) = \sum_x \mu(x) \log \log \log \frac{1}{\mu(x)}.$$

The second algorithm, presented in Section 3.2.2, removes the quadratic dependence on  $k$ , and has an expected complexity of:

$$H(\mu) + kH_2(\mu) + O(kH_3(\mu) + k \log k).$$

In Section 3.2.3 we robustify the guarantees of these algorithms and consider scenarios where the exact distribution  $\mu$  is not known but only some prior  $\eta \approx \mu$ , or where the actual number of lies is less than the bound  $k$  (whence the algorithm achieves better performance).

#### 3.2.1 First algorithm

Suppose that we are given a probability distribution  $\mu$  whose support is the linearly ordered set  $x_1 \prec \dots \prec x_n$ . In this section we overview the proof of the following theorem:

► **Theorem 4.** *There is a  $k$ -valid comparison tree  $T$  with*

$$c(T, \mu) \leq H(\mu) + (k+1) \sum_{i=1}^n \mu_i \log \log \frac{1}{\mu_i} + O\left(k^2 \sum_{i=1}^n \mu_i \log \log \log \frac{1}{\mu_i} + k^2 \log k\right),$$

where  $\mu_i = \mu(x_i)$ .

The question-asking strategy simulates a binary search to recover the hidden element. If, at some point, the answer to some question  $q$  is suspected as a lie then  $q$  is asked  $2k+1$  times to verify its answer. When is the answer to  $q$  suspected? The binary search tree is constructed in a manner that if no lies are told then roughly half of the questions are answered  $\prec$ , and half  $\succeq$ . However, if, for example, the lie “ $x \succeq x_{50}$ ” is told when in fact  $x = x_{10}$ , then all consecutive questions will be of the form “ $x \prec x_i$ ?” for  $i > 50$ , and the correct answer would always be  $\prec$ . Since no more than  $k$  lies can be told, almost all consecutive questions will be answered  $\prec$ , and the algorithm will suspect that some earlier question is a lie.

We start by suggesting a question-asking strategy using comparison queries which is valid as long as there are no lies, and then show how to make it resilient to lies. Each element  $x_i$  is mapped to a point  $p_i$  in  $[0, 1]$ , such that  $p_1 < p_2 < \dots < p_n$ . Then, a binary search on the interval  $[0, 1]$  is performed, for finding the point  $p_i$  corresponding to the hidden element. The search proceeds by maintaining a *Live* interval, which is initialized to  $[0, 1]$ . At any iteration, the questioner asks whether  $p_i$  lies in the left half of the *Live* interval. The interval is updated accordingly, and its length shrinks by a factor of 2. This technique was proposed by Gilbert–Moore [12], and is presented in AuxiliaryAlgorithm 1, as an algorithm which keeps asking questions indefinitely.

The points  $p_1, \dots, p_n$  are defined as follows: first, a number  $\theta \in [0, 1/2)$  is drawn uniformly at random. Now, for any element  $i$  define  $p_i = \frac{1}{2} \sum_{j=1}^{i-1} \mu_j + \frac{1}{4} \mu_i + \theta$ .<sup>4</sup> Given  $\theta$ , let  $T'_\theta$  denote the infinite tree generated by AuxiliaryAlgorithm 1. Note that whenever *Live* contains just

<sup>4</sup> In the original paper  $p_i$  was defined similarly but without the randomization:  $p_i = \sum_{j=1}^{i-1} \mu_j + \frac{1}{2} \mu_i$ .

---

**Algorithm 1** Randomized Gilbert–Moore.

---

```

1:  $Live \leftarrow [0, 1]$ 
2: loop
3:    $m \leftarrow \text{midpoint of } Live$ 
4:    $X \leftarrow \{i : p_i \geq m\}$ 
5:   if  $x \in X$  then
6:      $Live \leftarrow \text{right half of } Live$ 
7:   else
8:      $Live \leftarrow \text{left half of } Live$ 
9:   end if
10: end loop

```

---

one point  $p_i$ , then (as there are no lies) the hidden element must be  $x_i$ . Denote by  $T_\theta$  the finite tree corresponding to the algorithm which stops whenever that happens. We present two claims about these trees.

First, conditioned on any hidden element  $x_i$ , the answers to all questions (except, perhaps, for the first answer) are distributed uniformly and independently, where the distribution is over the random choice of  $\theta$ . This follows from the fact that all bits of  $p_i$  except for the most significant bit are i.i.d. unbiased coin flips.

▷ **Claim 5.** For any element  $x_i$ , let  $(A_t)$  be the random sequence of answers to the questions in AuxiliaryAlgorithm 1, containing all answers except for the first answer, assuming there are no lies. The distribution of the sequence  $(A_t)$  is the same as that of an infinite sequence of independent unbiased coin tosses, where the randomness stems from the random choice of  $p_i$ .

Second, since  $\min(p_i - p_{i-1}, p_{i+1} - p_i) \geq \mu_i/4$ , one can bound the time it takes to isolate  $x_i$  as follows.

▷ **Claim 6.** For any element  $x_i$  and any  $\theta$ , the leaf in  $T_\theta$  labeled by  $x_i$  is of depth at most  $\log(1/\mu_i) + 3$ . Hence, if  $x$  is drawn from a distribution  $\mu$ , the expected depth of the leaf labeled  $x$  is at most  $\sum_i \mu_i \log(1/\mu_i) + 3 = H(\mu) + 3$ .

We now describe the  $k$ -resilient algorithm: Algorithm 1 (the pseudocode appears as well). At the beginning, a number  $\theta$  is randomly drawn. Then, two concurrent simulations over  $T'_\theta$  are performed, and two pointers to nodes in this tree are maintained (recall that  $T'_\theta$  is the infinite binary search tree). The first pointer, *Current*, simulates the question-asking strategy according to  $T'_\theta$ , ignoring the possibility of lies. In particular, it may point on an incorrect node in the tree (reached as a result of a lie). Since *Current* ignores the possibility of lies, there is a different pointer, *LastVerified*, which verifies the answers to the questions asked in the simulation of *Current*. All answers in the path from the root to *LastVerified* are verified as correct, and *LastVerified* will always be an ancestor of *Current*. See Figure 3 for the basic setup.

The algorithm proceeds in iterations. In every iteration the question  $Q(\textit{Current})$  is asked and *Current* is advanced to the corresponding child accordingly. In some of the iterations also *LastVerified* is advanced. Concretely, this happens when the depth of *Current* in  $T'_\theta$  equals  $d + r(d)$ , where  $d$  is the depth of *LastVerified* and  $r(d) \approx \log d + k \log \log d$ . In these iterations, the answer given to  $Q(\textit{LastVerified})$  is being verified, as detailed next.

■ **Algorithm 1** Resilient-Tree.

```

1:  $\theta \leftarrow \text{Uniform}([0, 1/2])$ 
2:  $Current \leftarrow \text{root}(T'_\theta)$ 
3:  $LastVerified \leftarrow \text{root}(T'_\theta)$ 
4: while  $LastVerified$  is not a leaf of  $T_\theta$  do
5:   if  $x \in Q(Current)$  then
6:      $Current \leftarrow \text{left-child}(Current)$ 
7:   else
8:      $Current \leftarrow \text{right-child}(Current)$ 
9:   end if
10:   $d \leftarrow \text{depth}(LastVerified) + 1$ 
11:  if  $\text{depth}(Current) = d + r(d)$  then
12:     $Candidate \leftarrow$  child of  $LastVerified$  which is an ancestor of  $Current$ 
13:     $VerificationPath \leftarrow$  ancestors of  $Current$  up to and excluding  $Candidate$ 
14:    if  $Candidate$  is a left (right) child and at most  $k - 1$  vertices in  $VerificationPath$ 
are left (right) children then
15:      Ask  $2k + 1$  times the question  $x \in Q(LastVerified)$ 
16:      if majority answer is  $x \in Q(LastVerified)$  then
17:         $LastVerified \leftarrow \text{left-child}(LastVerified)$ 
18:      else
19:         $LastVerified \leftarrow \text{right-child}(LastVerified)$ 
20:      end if
21:       $Current \leftarrow LastVerified$ 
22:    else
23:       $LastVerified \leftarrow Candidate$ 
24:    end if
25:  end if
26: end while
27: return label of  $LastVerified$ 

```

■ **Figure 3** An illustration of Algorithm 1 just before the detection of a lie. The answer at *LastVerified* was a lie ( $<$  instead of  $>$ ), and so all answers below *Candidate* (except for any further lies) are  $>$ . This is noticed since *Current* is at depth  $d + r(d)$ . The answer at *Candidate* will be verified and found wrong, and so *LastVerified* would move to the sibling of *Candidate* (and so will *Current*), and the algorithm will continue from that point.

### The verification process

Next, we examine the verification process when *LastVerified* is advanced. There are two possibilities: first, when the answer to the question  $Q(\textit{LastVerified})$ , which was given when *Current* traversed it, is verified to be correct. In that case, *LastVerified* moves to its child which lies on the path towards *Current*. In the complementing case, when the the answer to the question  $Q(\textit{LastVerified})$  is detected as a lie, then *LastVerified* moves to the other child. In that case, *Current* is no longer a descendant of *LastVerified*, hence *Current* is moved up the tree and is set to *LastVerified*.

We now explain how the answer to  $Q(\textit{LastVerified})$  is verified. There are two verification steps: the first step uses no additional questions and the second step uses  $2k + 1$  additional questions. Usually, only the first step will be used and no additional questions will be spent during verification. In the first verification step one checks whether the following condition holds:

*The answer to  $Q(\textit{LastVerified})$  is identical to at least  $k$  of the answers along the path from  $\textit{LastVerified}$  to  $\textit{Current}$ .*

If this condition holds, then the answer is verified as correct. To see why this reasoning is valid, assume without loss of generality that the answer is  $\prec$ , and assume towards contradiction that it was a lie. Then, the correct answers to all following questions in the simulation of *Current* are  $\succeq$ . Since there can be at most  $k - 1$  additional lies, there can be at most  $k - 1$  additional  $\prec$  answers. Hence, if there are more  $\prec$  answers among the following questions then the previous answer to  $Q(\textit{LastVerified})$  is verified as correct.

Else, if the above condition does not hold then one proceeds to the second verification step and asks  $2k + 1$  times the question  $Q(\textit{LastVerified})$ . Here, the majority answer must be correct, since there can be at most  $k$  lies.

We add one comment: if the second verification step is taken, one sets  $\textit{Current} \leftarrow \textit{LastVerified}$  regardless of whether a lie had been revealed (this is performed to facilitate the proof). So, whenever the condition in the first verification step fails to hold then *Current* and *LastVerified* point to the same node in the tree.

The algorithm ends when *LastVerified* reaches a leaf of  $T_\theta$ , at which point the hidden element is recovered.

### Query complexity analysis

Fix an element  $x_i$ . We bound the expected number of questions asked when  $x_i$  is the hidden element as follows. Define  $d \approx \log(1/\mu(x_i))$  as the depth of the leaf labeled  $x_i$  in  $T_\theta$ . We divide the questions into the following five categories:

- Questions on the path  $P$  from the root to *Current* by the end of the algorithm, when *Current* reaches depth  $d + r(d)$ , *LastVerified* reaches depth  $d$ , and the algorithm terminates. Hence, there are at most  $d + r(d)$  such questions.
- Questions that were ignored due to the second verification step while *Current* was backtracked from a node outside  $P$ . This can only happen due to a lie between *Current* and *LastVerified* so there are at most  $k \cdot r(d)$  such questions.
- Questions asked  $2k + 1$  times during the second verification step when *Current* was pointing to a node outside  $P$ . This can only happen due to a lie between *Current* and *LastVerified* so there are at most  $k \cdot (2k + 1)$  such questions.
- Questions that were ignored due to the second verification step, when *Current* was being backtracked from a node in  $P$ . By the choice of  $r(d)$  there are at most  $O(1)$  such questions (on expectation).
- Questions asked  $2k + 1$  during the second verification step when *Current* was pointing to a node in  $P$ . By the choice of  $r(d)$  there are at most  $O(1)$  such questions (in expectation).

Summing these bounds up, one obtains a bound of

$$\begin{aligned} & (d + r(d)) + k \cdot r(d) + k \cdot (2k + 1) + O(1) + O(1) \\ & \approx \log(1/\mu_i) + (k + 1) \left( \log \log(1/\mu_i) + k \log \log \log(1/\mu_i) + O(k) \right). \end{aligned}$$

### 3.2.2 Second algorithm

In this section we overview the proof of the following theorem.

► **Theorem 7.** *For any distribution  $\mu$  there exists a  $k$ -valid comparison tree  $T$  with*

$$c(T, \mu) \leq H(\mu) + k \mathbb{E}_{x \sim \mu} [\log \log(1/\mu(x))] + O(k \mathbb{E}_{x \sim \mu} [\log \log \log(1/\mu(x))] + k \log k).$$

We explain the key differences with Algorithm 1.

- In Algorithm 1, an answer to a question  $Q$  at depth  $d$  was suspected as a lie if at most  $k$  of the  $r(d)$  consecutive questions received the same answer as  $Q$ . In the new algorithm, we suspect a question  $Q$  if *all* the  $r'(d)$  consecutive answers are different than  $Q$ . This change enables setting  $r'(d) \approx \log d$  rather than the previous value of  $r(d) \approx \log d + k \log \log d$ . Similarly to Algorithm 1, any time a lie is deleted,  $r'(d)$  questions are being deleted. Summing over the  $k$  lies, one obtains a total of  $kr'(d) \approx k \log d$  deleted questions, which is smaller than the corresponding value of  $kr(d) \approx k \log d + k^2 \log \log d$  in Algorithm 1.
- In Algorithm 1, the lies were detected in the same order they were told (i.e. in a *first-in-first-out* queue-like manner). This is due to the semantic of the pointer *LastVerified* which verifies the questions one-by-one, along the branching of the tree. In Algorithm 2 the pointer *LastVerified* is removed (only *Current* is used), and the lies are detected in a *last-in-first-out* stack-like manner: only the last lie can be deleted at any point in time. Indeed, as described in the previous paragraph, a lie will be deleted only if all consecutive answers are different (which is equivalent to them being non-lies).
- In Algorithm 1, when an answer is suspected as a lie, the corresponding question  $Q$  is repeated  $2k + 1$  times in order to verify its correctness. This happens after each lie, hence  $\Omega(k)$  redundant questions are asked per lie. In Algorithm 2, the suspected question  $Q$  will be asked again only *once*, and the algorithm will proceed accordingly. It may however be the case that this process will repeat itself and also the second answer to this question will be suspected as a lie and  $Q$  will be asked once again and so on. In order to avoid an infinite loop we add the condition that if the same answer is told  $k + 1$  times then it is guaranteed to be correct and will not be suspected any more.
- The removal of *LastVerified* forces finding a different method of verifying the correctness of an element  $x$  upon arriving at a leaf of  $T_\theta$ . One option is to ask the question “element =  $x$ ?”  $2k + 1$  times and take the majority vote, where each = question is implemented using one  $\preceq$  and one  $\succeq$ . This will, however, lead to asking  $\Omega(k)$  redundant questions each time  $x$  is not the correct element. Instead, one asks “element =  $x$ ?” multiple times, stopping either when the answer = is obtained  $k + 1$  times, or by the first the answer  $\neq$  has obtained more than the answer =. The total redundancy imposed by these verification questions throughout the whole search is  $O(k)$ .

To put the algorithm together, we exploit some simple combinatorial properties of paths containing multiple lies.

### 3.2.3 A fine-grained analysis of the guarantees

In this section, we present a stronger statement for the guarantees of our algorithms. First, the algorithms do not have to know *exactly* the distribution  $\mu$  from which the hidden element is drawn: an approximation suffices for getting a similar bound. Recall that the algorithm gets as an input some probability distribution  $\eta$ . This distribution might differ from the true distribution  $\mu$ . The cost of using  $\eta$  rather than  $\mu$  is related to  $D(\mu\|\eta)$ , the Kullback–Leibler divergence between the distributions.

Secondly, the algorithm has stronger guarantees when the actual number of lies is less than  $k$ . This is an improvement comparing to the algorithm of Rivest et al. [21] mentioned in the introduction. It will be utilized in the application of sorting, where the searching algorithm is invoked multiple times with a bound on the total number of lies (rather the number of lies per iteration). We present the general statement with respect to Algorithm 2.

► **Theorem 8.** *Assume that Algorithm 2 is invoked with the distribution  $(\eta_1, \dots, \eta_n)$ . Then, for any element  $x_i$ , the expected number of questions asked when  $x_i$  is the secret is at most*

$$\log(1/\eta_i) + \mathbb{E}[K'] \log \log \frac{1}{\eta_i} + O\left(\mathbb{E}[K'] \log \log \log \frac{1}{\eta_i} + \mathbb{E}[K'] \log k + k\right),$$

where  $K'$  is the expected number of lies. (The expectation is taken over the randomness of both parties.)

As a corollary, one obtains Theorem 7 and the following corollary, which corresponds to using a distribution different from the actual distribution.

► **Corollary 9.** *Assume that Algorithm 2 is invoked with  $(\eta_1, \dots, \eta_n)$  while  $(\mu_1, \dots, \mu_n)$  is the true distribution. Then, for a random hidden element drawn from  $\mu$ , the expected number of questions asked is at most*

$$\begin{aligned} H(\mu) + k \mathbb{E}_{x \sim \mu} [\log \log(1/\mu(x))] + O(k \mathbb{E}_{\mu} [\log \log \log(1/\mu(x))] + k \log k) \\ + D(\mu\|\eta) + O(k \log D(\mu\|\eta)), \end{aligned}$$

where  $D(\mu\|\eta) = \sum_{x \in \text{supp } \mu} \mu(x) \log \frac{\mu(x)}{\eta(x)}$  is the Kullback–Leibler divergence between  $\mu$  and  $\eta$ .

Corollary 9 follows from Theorem 8 by bounding  $K' \leq k$ , taking expectation over  $x_i \sim \mu$ , noting that  $\sum_i \mu_i \log(1/\eta_i) = H(\mu) + D(\mu\|\eta)$  and applying Jensen's inequality with the function  $x \mapsto \log x$ .

## 3.3 Sorting

One can apply Algorithm 2 to implement a stable version of the insertion sort using comparison queries. Let  $\Pi$  be a distribution over the set of permutations on  $n$  elements. Complementing with prior algorithms achieving a complexity of  $H(\Pi) + O(n)$  in the randomized setting with no lies [17], and  $n \log n + O(nk + n)$  in the deterministic setting with  $k$  lies [3, 16], we present an algorithm with a complexity of  $H(\Pi) + O(nk + n + k \log k)$  in the distributed setting with  $k$  lies. Note that  $k \log k = O(nk)$  unless the unlikely case that  $k = e^{w(n)}$ , hence the  $k \log k$  term can be ignored. Therefore, the guarantee of our algorithm matches the guarantees of the prior algorithms substituting either  $k = 0$  or  $\Pi = \text{Uniform}$ .

► **Theorem 10.** *Assume a distribution  $\Pi$  over the set of all permutations on  $n$  elements. There exists a sorting algorithm which is resistant to  $k$  lies and sorts the elements using  $H(\Pi) + O(nk + n + k \log k)$  comparisons on expectation.*

The randomized algorithms benefit from prior knowledge, namely, when one has information about the correct ordering. This is especially useful for maintaining a sorted list of elements, a procedure common in many sequential algorithms. In these settings, the values of the elements can change in time, hence, the elements have to be re-sorted regularly, however, their locations are not expected to change drastically.

The suggested sorting algorithm performs  $n$  iterations of insertion sort. By the end of each iteration  $i$ ,  $x_1, \dots, x_i$  are successfully sorted. Then, on iteration  $i + 1$ , one performs a binary search to find the location where  $x_{i+1}$  should be inserted, using conditional probabilities.

The guarantee of the algorithm is asymptotically tight: a lower bound of  $H(\Pi)$  follows from information theoretic reasons, and a lower bound of  $\Omega(nk)$  follows as well: the bound of Lakshmanan et al. [15] can be adjusted to the randomized setting.

## Abstract

Computational pseudorandomness studies the extent to which a random variable  $\mathbf{Z}$  looks like the uniform distribution according to a class of tests  $\mathcal{F}$ . Computational entropy generalizes computational pseudorandomness by studying the extent which a random variable looks like a *high entropy* distribution. There are different formal definitions of computational entropy with different advantages for different applications. Because of this, it is of interest to understand when these definitions are equivalent.

We consider three notions of computational entropy which are known to be equivalent when the test class  $\mathcal{F}$  is closed under taking majorities. This equivalence constitutes (essentially) the so-called *dense model theorem* of Green and Tao (and later made explicit by Tao-Zeigler, Reingold et al., and Gowers). The dense model theorem plays a key role in Green and Tao’s proof that the primes contain arbitrarily long arithmetic progressions and has since been connected to a surprisingly wide range of topics in mathematics and computer science, including cryptography, computational complexity, combinatorics and machine learning. We show that, in different situations where  $\mathcal{F}$  is *not* closed under majority, this equivalence fails. This in turn provides examples where the dense model theorem is *false*.

## 1 Introduction

Computational pseudorandomness is a central topic in theoretical computer science. In this scenario, one has a class  $\mathcal{F}$  of boolean functions  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  (which we’ll refer to as *tests*) and random variable  $\mathbf{Z}$  over  $\{0, 1\}^n$ . We say that  $\mathbf{Z}$  is  $\epsilon$ -pseudorandom with respect to  $\mathcal{F}$  if  $\max_{f \in \mathcal{F}} |\mathbb{E}[f(\mathbf{Z})] - \mathbb{E}[f(\mathbf{U})]| \leq \epsilon$  where  $\mathbf{U}$  is the uniform distribution over  $\{0, 1\}^n$  and  $\epsilon > 0$  is small. In this case, we think of  $\mathbf{Z}$  as “behaving like the uniform distribution” according to tests in  $\mathcal{F}$ . In general, say that two random variables  $\mathbf{X}, \mathbf{Y}$   $\epsilon$ -indistinguishable by  $\mathcal{F}$  if  $\max_{f \in \mathcal{F}} |\mathbb{E}[f(\mathbf{X})] - \mathbb{E}[f(\mathbf{Y})]| \leq \epsilon$  (and so  $\epsilon$ -pseudorandom distributions are exactly those which are  $\epsilon$ -indistinguishable from  $\mathbf{U}$ ). Constructing explicit  $\mathbf{Z}$ ’s which behave like the uniform distribution according to different test classes is among the central goals of complexity theory, with sufficiently strong constructions leading to, for example, derandomization of BPP. One way in which the theory of pseudo-randomness is rich is that there are multiple equivalent formulations of pseudo-randomness, such as Yao’s next bit test ([51]).

The various notions of pseudo-entropy and pseudo-density generalize pseudo-randomness to formalize how much randomness a distribution looks like it has as far as this class of tests can perceive. Many of these notions were first introduced as stepping stones towards

pseudo-randomness, giving properties of sub-routines within constructions of pseudo-random generators. However, measuring seeming randomness quantitatively is important in many other contexts, so these notions have found wider application. For example, in mathematical subjects such as combinatorics and number theory, there is a general phenomenon of “structure vs. randomness”, where a deterministically defined object such as a graph or set of integers can be decomposed into a structured part and a random part. Pseudo-entropy quantifies how much randomness the “random part” has. Notions of pseudo-density were used in this context by Green, Tao, and Ziegler [18, 48] to show that the primes contain arbitrarily long arithmetic progressions. We can also use pseudo-entropy notions to characterize the amount of seeming randomness remains in a cryptographic key after it has been compromised with a side-channel attack. A data set used in a machine learning algorithm might not have much randomness in itself, and might not be completely random looking, but is hopefully representative of the much larger set of inputs that the results of the algorithm will be applied to, so we can use notions of pseudo-entropy to say when such algorithms will generalize. There are many possible definitions of this intuitive idea, and as with pseudo-randomness, the power of pseudo-entropy is that many of these notions have been related or proven equivalent.

In particular, the dense model theorem provides such a basic equivalence. Here, the intuitive concept we are trying to capture is the density (or relative min-entropy) of the target distribution within a larger distribution, what fraction of the larger distribution is within the target. We say that  $\mathbf{Z}$  is  $\delta$ -dense if  $\mathbb{E}[\mu(x)] = 2^{-n} \sum_x \mu(x) \geq \delta$  where  $\mu : \{0, 1\}^n \rightarrow [0, 1]$  is density function defining  $\mathbf{Z}$  (in the sense that  $\Pr[\mathbf{Z} = z] = \mu(z)/(2^n \mathbb{E}[\mu(x)])$ ). One application of indistinguishability from a dense distribution is as a stepping stone to pseudorandomness: if  $\mathbf{Z}$  is indistinguishable from a distribution  $\mathbf{M}$  with density  $\delta$  within the uniform distribution, then applying a randomness extractor with min-entropy rate  $n - \log(1/\delta)$  to  $\mathbf{Z}$  is a pseudorandom distribution. A more sophisticated application comes from additive number theory. It is not hard to show that a *random* subset of  $[N] = \{1, 2, \dots, N\}$  (including each element with probability  $1/2$ , say) contains many arithmetic progressions (which are sets of the form  $\{a, a + b, a + 2b, a + 3b, \dots\}$ ). Szemerédi [45] showed that, in fact, sufficiently *dense* subsets of the integers also contain such arithmetic progressions: specifically, that for any  $k$ , the size of the largest subsets of  $[N]$  which *doesn't* contain an arithmetic progression grows like  $o(N)$ .

So we would like some technology to reason about random variables  $\mathbf{Z}$  which “behave like dense distributions”. It turns out, however, that formalizing what it means for  $\mathbf{Z}$  to “behave like a dense distribution” is subtle. Here are three perfectly legitimate candidates:

**Candidate 1:**  $\mathbf{Z}$  behaves like a  $\delta$ -dense distribution if it behaves like something that's  $\delta$ -dense.

Formally, this means that  $\mathbf{Z}$  is  $\varepsilon$ -indistinguishable from some  $\delta$ -dense distribution. In this case, we say that  $\mathbf{Z}$  has a  $\delta$ -dense  $\varepsilon$ -model.

**Candidate 2:**  $\mathbf{Z}$  behaves  $\delta$ -dense if it's  $\delta$ -dense inside of something that behaves like the uniform distribution. Formally this means there's an  $\varepsilon$ -pseudorandom distribution  $\mathbf{X}$  in which  $\mathbf{Z}$  is  $\delta$ -dense. In this case, we say that  $\mathbf{Z}$  is  $\delta$ -dense in an  $\varepsilon$ -pseudorandom set.

**Candidate 3:**  $\mathbf{Z}$  behaves  $\delta$ -dense if it appears to be the case that conditioning on  $\mathbf{Z}$  increases the size of any set by at most (roughly) a  $1/\delta$ -factor. This is an operational definition: conditioning on a (truly) dense set increases the set by at most a  $1/\delta$ -fraction, so we should expect the same behavior from things that behave like a dense set. Formally, this means that  $\delta \mathbb{E}[f(\mathbf{Z})] \leq \mathbb{E}[f(\mathbf{U})] + \varepsilon$  for any  $f$  in our test class  $\mathcal{F}$ . In this case, we say that  $\mathbf{Z}$  has  $(\varepsilon, \delta)$ -pseudodensity.

Precisely which definition you pick will depend on what you know about  $\mathbf{Z}$  and in what sense you would like it to behave like a  $\delta$ -dense distribution. Indeed, each of these definitions have appeared in different applications ([25], [18], [13], respectively), so there are scenarios where each of these types of behavior is desired. In general, the first candidate is the strongest (and, arguably, the most natural), but it is sometimes hard to establish that a distribution has the property. The following claim gives some simple relationships between the definitions:

▷ **Claim 1.** For any  $\mathcal{F}$ , the following hold:

1. If  $\mathbf{Z}$  has a  $\delta$ -dense  $\varepsilon$ -model, then  $\mathbf{Z}$  is  $\delta$ -dense in a  $\varepsilon$ -pseudorandom set.
2. If  $\mathbf{Z}$  is  $\delta$ -dense in an  $\varepsilon$ -pseudorandom set, then  $\mathbf{Z}$  has  $(\varepsilon, \delta)$ -pseudodensity.

Proof sketch.

1. Let  $\mathbf{M}$  be the  $\delta$ -dense  $\varepsilon$ -model for  $\mathbf{Z}$ . Note that  $\mathbf{U} = \delta\mathbf{M} + (1-\delta)\overline{\mathbf{M}}$ . So  $\mathbf{U}' = \delta\mathbf{Z} + (1-\delta)\overline{\mathbf{M}}$  is  $\varepsilon$ -pseudorandom and  $\mathbf{Z}$  is  $\delta$ -dense within it.
2. Suppose  $\mathbf{Z}$  is  $\delta$ -dense in  $\mathbf{Z}'$  which  $\varepsilon$ -pseudorandom for  $\mathcal{F}$ . Then for any  $f \in \mathcal{F}$ ,  $\delta\mathbb{E}[f(\mathbf{Z})] \leq \mathbb{E}[f(\mathbf{Z}')] \leq \mathbb{E}[f(\mathbf{U})] + \varepsilon$ .  $\triangleleft$

The marvelous quality of these three candidates in particular is that, for many natural  $\mathcal{F}$ , all of them are *equivalent*, and so establishing even  $(\varepsilon', \delta)$ -pseudodensity is enough to guarantee the existence of a  $\delta$ -dense  $\varepsilon$ -model.

This equivalence holds for  $\mathcal{F}$  which are *closed under majority*, meaning for any  $k$  (which we can think of as  $k = O(1)$  for now), if  $f_1, \dots, f_k \in \mathcal{F}$  then  $\text{MAJ}_k(f_1, \dots, f_k) \in \mathcal{F}$ , where  $\text{MAJ} : \{0, 1\}^n \rightarrow \{0, 1\}$  is 1 if at least half of its input bits are 1. In fact, it holds for more general  $\mathcal{F}$  if we allow the distinguishing parameter ( $\varepsilon'$  in  $(\varepsilon', \delta)$ -pseudodensity) to be exponentially small (as in the original formulation, which we'll discuss later on). In this case, the subtlety in defining what it means to behave like a dense set vanishes. These equivalences constitute (essentially) what is known as the *dense model theorem*, originating in the work of Green-Tao [18] and Tao-Zeigler [48], and independently in Barak et al. [8] (though in different guises). This result has been fruitfully applied in many seemingly unrelated areas of mathematics and computer science: additive number theory [18, 48] where  $\mathcal{F}$  encodes additive information about subsets of  $\{1, \dots, N\}$  (or possibly a more general group), graph theory [49, 38] where  $\mathcal{F}$  encodes cuts in a fixed graph, circuit complexity [49], Fourier analysis [29], machine learning [29] and leakage-resilient cryptography [14]. The ubiquity of the dense model theorem motivates a simple question: are there natural scenarios in which the dense model theorem is *false*?

We show that the answer to this question is *yes*. In particular, we show that for either implication from Claim 1 there is a class  $\mathcal{F}$  and a random variable  $\mathbf{Z}$  so that converse fails to hold. From the computational entropy perspective, we show that the three computational entropies we've discussed are inequivalent for certain test classes  $\mathcal{F}$ . Necessarily (with  $\varepsilon'$  not exponentially small) these classes are *not* closed under majority and so we will need to look “below” majority in order to find our counterexamples.

## 1.1 The dense model theorem

We turn to discuss the dense model theorem in some more detail to better contextualize our work. Restricting our attention to random variable over  $\{0, 1\}^n$ , the dense model theorem states the following:

► **Theorem 1.1** (Dense model theorem). *Let  $\mathcal{F}$  be a class of tests  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  and  $\mathbf{Z}$  a random variable over  $\{0, 1\}^n$  with  $(\varepsilon\delta, \delta)$ -pseudodensity with respect to  $\text{MAJ}_k \circ \mathcal{F}$  for  $k = O(\log(1/\delta)/\varepsilon^2)$ . Then  $\mathbf{Z}$  has a  $\delta$ -dense  $\varepsilon$ -model with respect to  $\mathcal{F}$ .*

We will generally also consider a parameter  $\varepsilon'$ , which in this case is  $\varepsilon\delta$ , the additive error in pseudodensity. To get an intuition for what this is saying, let's consider a setting where it's false but for trivial reasons. As a simple example given in [52], pick a set  $\mathbf{Z}$  some set as a  $(1 - \varepsilon)$  fraction of another set  $\mathbf{S}$  of size  $\delta 2^n$ . Then  $\mathbf{Z}$  doesn't have a  $\delta$ -dense  $\varepsilon$ -model (i.e.  $\mathbf{S}$ ) with respect to  $\mathbf{Z}$ 's indicator function, which we'll call  $f$ . On the other hand, the distribution  $\mathbf{W}$  obtained by sampling  $\mathbf{Z}$  with probability  $\delta$  and sampling from  $\mathbf{S}$ 's complement with probability  $1 - \delta$  is at most  $\varepsilon\delta$ -distinguishable from  $\mathbf{S}$  for any function, since  $\varepsilon\delta$  is simply the measure of the difference between  $\mathbf{S}$  and  $\mathbf{Z}$ . In particular  $\mathbf{Z}$  is  $\delta$ -dense in the  $\varepsilon\delta$ -pseudorandom  $\mathbf{W}$  (which implies, via Claim 1, that it is  $(\varepsilon\delta, \delta)$ -pseudodense). This means that the Theorem 1.1 is tight for the dependence on  $\varepsilon' = \varepsilon\delta$ , in that it becomes false for  $\Omega(\varepsilon\delta)$ . In many instances, we think of  $\varepsilon = 1/\text{poly}(n)$ ,  $\delta$  constant (or perhaps with mild dependences on  $n$ ) and  $\varepsilon' = \delta\varepsilon$ .

Originally, the dense model theorem was proved with a different (and stronger) assumption; namely, that  $\mathbf{Z}$  is dense in a pseudorandom set. Green and Tao, in proving that the primes contain arbitrarily long arithmetic progressions, used it to the following effect: if  $\mathbf{Z}$  are the prime numbers up to  $n$ , then its density is known to behave like  $\Theta(1/\log n)$ . On the other hand, Szemerédi [45] showed that sufficiently dense subsets of  $\mathbb{Z}$  contain arbitrarily long arithmetic progressions. The best bounds for Szemerédi's theorem require density  $\omega(1/\log \log n)$ , which is much larger than the primes (see [16] and the recent [9] for more on the rich history on this and related problems). Not all is lost, however: the only property of dense sets that we're interested in is that they contain arithmetic progressions. So Green and Tao construct a class  $\mathcal{F}$  of tests which can “detect” arithmetic progressions and under which the primes are dense inside of a  $\mathcal{F}'$ -pseudorandom set (more on  $\mathcal{F}'$  later). By applying the dense model theorem, we conclude that the primes “look like” a dense set (themselves having long arithmetic progressions) with respect to the class  $\mathcal{F}$ . As  $\mathcal{F}$  detects arithmetic progressions, it must be the case that the primes possess them. Of course, many details need to be filled in, but we hope this example shows the reader the “spirit” of the dense model theorem.

A primary source of interest in the dense model theorem is in the connections it shares with seemingly unrelated branches of mathematics and computer science. The original application was in additive number theory, but it was independently discovered and proved in the context of cryptography ([8, 14]). RTV [38] and Gowers [17] observed proofs of the dense model theorem which use linear programming duality, which is in turn related to Nisan's proof of the hardcore lemma from circuit complexity [28]. In fact, Impagliazzo [29] shows in unpublished work that optimal-density versions of the hardcore lemma due to Holenstein [26] actually *imply* the dense model theorem. Klivans and Servedio [32] famously observed the relationship between the hardcore lemma and *boosting*, a fundamental technique for aggregating weak learners in machine learning [15]. Together with the result of Impagliazzo, this connection means that dense model theorems can be proved by a particular type of boosting algorithm. A boosting argument for the existence of dense models also gives us *constructive* versions of the dense model theorem, which are needed for algorithmic applications. Zhang [52] (without using Impagliazzo's reduction from the dense model theorem to the hardcore lemma) used the boosting algorithm of [7] directly to prove the dense model theorem with optimal query complexity ( $k$ ).

In addition to its connections to complexity, machine learning, additive number theory and cryptography, the dense model theorem (and ideas which developed from the dense model theorem, chiefly the approximation theorem of [49]), have been used to understand the weak graph regularity lemma of Frieze and Kannan [29], notions of computational differential

privacy [36] and even generalization in generative adversarial networks (GANs) [5]. We now turn to discussing the complexity-theoretic aspects of the dense model theorem, specifically regarding our question of whether the  $\text{MAJ}_k$  from the statement is optimal.

As alluded to earlier, Green and Tao actually worked in a setting where  $\mathcal{F}'$  doesn't need to compute majorities but where  $\varepsilon\delta$  (that is, the distinguishing parameter in the pseudodensity assumption in the statement of Theorem 1.1) needs to be replaced by some  $\varepsilon' = \exp(-\text{poly}(1/\varepsilon, 1/\delta))$  (with  $k = \text{poly}(1/\delta, 1/\varepsilon)$  experiencing a small increase). We state this result, as proved in Tao and Zeigler [48] and stated this way in RTTV [38], for comparison. For a test class  $\mathcal{F}$ , let  $\prod_k \mathcal{F}$  be the set of tests of the form  $\prod_{i \in [k]} f_i$  for  $f_i \in \mathcal{F}$ .

► **Theorem 1.2** (Computationally simple dense-model theorem, strong assumption). *Let  $\mathcal{F}$  be a class of tests  $f : \{0, 1\}^n \rightarrow [0, 1]$  and  $\mathbf{Z}$  a random variable over  $\{0, 1\}^n$  which is  $\delta$ -dense in a set  $\varepsilon'$ -pseudorandom for  $\prod_k \mathcal{F}$  with  $k = \text{poly}(1/\delta, 1/\varepsilon)$  and  $\varepsilon' = \exp(-1/\delta, 1/\varepsilon)$ . Then  $\mathbf{Z}$  has a  $\delta$ -dense  $\varepsilon$ -model with respect to  $\mathcal{F}$ .*

RTTV [38] observe that this proof can be adapted to work for  $\varepsilon'$  have polynomial dependence on  $\varepsilon, \delta$  by restricting to the case of boolean-valued tests. Doing so, however, makes  $\mathcal{F}'$  much more complicated (essentially requiring circuits of size exponential in  $k$ ). In Theorem 1.1, we can obtain the best of both worlds:  $\varepsilon'$  has polynomial dependence on  $\varepsilon, \delta$  and the complexity blow-up is rather small. However, in this more picturesque circumstance, we need to be able to compute majorities. Is such a tradeoff necessary? Our results suggest that the answer is yes. Theorem 1.6 (stated in the following section) tells us that if the dense model theorem is true for  $\mathcal{F}$ , then there's a small, constant-depth circuit with  $\mathcal{F}$ -oracle gates approximating majority on  $O(1/\varepsilon^2)$  bits.

Another important aspect of the dense model theorem is how the different assumptions are related. As mentioned, the original assumption was that  $\mathbf{Z}$  is  $\delta$ -dense in an  $\varepsilon$ -pseudorandom set, but the proof can be extended to the case where  $\mathbf{Z}$  is  $(\varepsilon, \delta)$ -pseudodense. Claim 1 showed that the former assumption implies that latter assumption. When the dense model theorem is true, the latter also implies the former: simply apply the dense model theorem to  $\mathbf{Z}$  which is  $(\varepsilon, \delta)$ -dense to obtain a  $\delta$ -dense  $\varepsilon$ -model. Then, by the first part of Claim 1, we're done.

First, we give examples of situations where these two notions are distinct. For example, we show in Theorem 1.4 and Theorem 1.5 that they are inequivalent when  $\mathcal{F}$  is constant-depth polynomial size circuits or when  $\mathcal{F}$  is a low-degree polynomial over a finite field. Note that a separation between pseudodensity and being dense in a pseudorandom set also implies a separation between pseudodensity and having a dense model, as being dense in a pseudorandom set is a necessary condition for having a dense model.

Second, we show that the dense model theorem is false even when we make the stronger assumption that the starting distribution  $\mathbf{Z}$  is dense in a pseudorandom set. Specifically, in Theorem 1.3 we can show that some distributions  $\mathbf{Z}$  are dense in a pseudorandom set but fail to have a dense model when  $\mathcal{F}$  consists of constant-depth, polynomial size circuits.

Having contextualized our work some, we now turn to describe our contributions in more detail.

## 1.2 Contributions

We separate the previously described notions of computational entropy, giving examples where the dense model theorem is false. We are able to prove different separations when  $\mathcal{F}$  is constant-depth unbounded fan-in circuits, low-degree polynomials over a finite field, and, in one case, any test class  $\mathcal{F}$  which cannot efficiently approximate majority (in some sense made explicit later on). The only known separation prior was between pseudodensity and having a dense model for bounded-width read-once branching programs, due to Barak et al. [8].

Let  $\mathcal{C}(S, d)$  denote the class of unbounded fan-in, size  $S$ , depth  $d$  circuits. We are generally thinking of  $S = \text{poly}(n)$  and  $d = O(1)$ , which corresponds to the complexity class  $\text{AC}^0$ . Theorem 1.3 shows that  $\mathbf{Z}$  being  $\delta$ -dense in an  $\varepsilon$ -pseudorandom set need not imply that  $\mathbf{Z}$  has a  $\delta$ -dense  $\varepsilon$ -model when the test class is  $\mathcal{C}(S, d)$ :

► **Theorem 1.3.** *Let  $\varepsilon, \varepsilon' > 0$  be arbitrary,  $\delta \geq \varepsilon'/8$  and*

$$S \leq \exp\left(O\left(\frac{\sqrt{\varepsilon'}}{\varepsilon} \cdot \frac{\sqrt{\log(1/\delta)}}{\log(1/\varepsilon')}\right)^{1/(d-1)}\right).$$

*Then for  $\mathcal{F} = \mathcal{C}(S, d)$ , there is a random variable  $\mathbf{D}$  over  $\{0, 1\}^n$  with  $n = O(\log(1/\delta)/\varepsilon^2)$  so that  $\mathbf{D}$  is  $\delta$ -dense in an  $\varepsilon'$ -pseudorandom set but does not have a  $\delta$ -dense  $\varepsilon$ -model. In particular, the dense model theorem is false in this setting.*

Recall that the dense model theorem is false when  $\varepsilon' = \Omega(\varepsilon\delta)$ , which makes the restriction  $\delta \geq \varepsilon'/8$  extremely mild. A common regime is  $\varepsilon = 1/\text{poly}(n)$ ,  $\delta = O(1)$  and  $\varepsilon' = \delta\varepsilon = \Theta(\varepsilon)$ , in which case this gives us (essentially) a lower bound of weakly exponential in  $1/\sqrt{\varepsilon} \approx 1/\sqrt{\varepsilon'}$ .

Let  $\mathbf{N}_\alpha$  denote the product distribution of  $n$  Bernoulli random variables with success probability  $1/2 - \alpha$ . Recall that density in a pseudorandom set readily implies pseudodensity, and one can use the dense model theorem to show the converse. We show that  $(\varepsilon, \delta)$ -pseudodensity need not imply  $\delta$ -density in an  $\varepsilon$ -pseudorandom set when the test class is  $\mathcal{C}(S, d)$ :

► **Theorem 1.4.** *Fix  $\varepsilon, \varepsilon', \delta > 0$ ,  $d \in \mathbb{N}$ , and*

$$S \leq \exp\left(O\left(\frac{\sqrt{\delta}}{\sqrt{\varepsilon}} \cdot \frac{\log(1/\delta)}{\log(1/\varepsilon')}\right)^{1/(d-1)}\right).$$

*Then  $\mathbf{N}_{\sqrt{\varepsilon/\delta}}$  over  $\{0, 1\}^n$  with  $n = O(1/\varepsilon)$  is  $(\varepsilon', \delta)$ -pseudodense and yet  $\mathbf{N}_{\sqrt{\varepsilon/\delta}}$  is not  $\delta$ -dense inside of any  $\varepsilon$ -pseudorandom set.*

The dependence  $\varepsilon'$  means that we can take  $\varepsilon'$  exponentially smaller than  $\varepsilon$  and still obtain a separation. This case corresponds to  $\mathcal{F}$  being “very” fooled by  $\mathbf{N}_\alpha$  but still not being  $\delta$ -dense in a “mildly” pseudorandom set. This result draws on a recent line of work in the pseudorandomness literature – often referred to as “the coin problem” and studied in, e.g., [42, 12, 1, 46] – which concerns the ability of a test class  $\mathcal{F}$  unable to compute majority has in distinguishing  $\mathbf{N}_\alpha$  and  $\mathbf{U}$ . We will discuss this connection in more detail during the proof overviews.

We prove a similar separation for degree- $d$   $\mathbb{F}_p$ -polynomials (on  $n$  variables), which generalizes (and uses techniques from) a recent result of Srinivasan [44] in the case where  $\delta = 1$ . In this case, we think of a distribution  $\mathbf{Z}$  as being  $(\varepsilon', \delta)$ -pseudodense for degree- $d$   $\mathbb{F}_p$ -polynomials when  $\delta \Pr[P(\mathbf{Z}) \neq 0] - \varepsilon' \geq \Pr[P(\mathbf{U}) \neq 0]$  for any degree- $d$  polynomial  $P \in \mathbb{F}_p[X_1, \dots, X_n]$  (noting that we are only evaluating  $P$  over  $\{0, 1\}^n$ ).

► **Theorem 1.5.** *Fix a finite field  $\mathbb{F}$  with characteristic  $p = O(1)$ ,  $\varepsilon, \varepsilon' > 0$  and let  $c > \delta > 0$  where  $c \approx 1/200$  is an absolute constant. Suppose that*

$$d \leq O(\sqrt{\delta/\varepsilon}).$$

*Then when  $\mathcal{F}$  is the  $n$ -variate degree- $d$  polynomials over  $\mathbb{F}$  with  $n = 1/\varepsilon$ , and  $\alpha = O(\sqrt{\varepsilon/\delta})$ ,  $\mathbf{N}_\alpha$  is  $(\varepsilon', \delta)$ -pseudodense but is not  $\delta$ -dense inside of an  $\varepsilon$ -pseudorandom set.*

This implies lower bounds for constant-depth circuits with  $\text{MOD}_p$  gates by the classical lower bounds of Razborov [37] and Smolensky [43]. Perhaps more interestingly, this holds even over non-prime fields. Also notably, there is no dependence on  $\varepsilon' \leq \varepsilon\delta$ , so we can take it to be arbitrarily small.

We also prove a more general separation between pseudodensity and density in a pseudorandom set. This result, drawing from the work of [42], provides a more specific characterization of the sense in which dense model theorems are “required” to compute majority.

► **Theorem 1.6.** *Let  $\varepsilon, \delta > 0$ . Suppose  $\mathcal{F}$  is a test class of boolean functions  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  with the following property: there is no  $\text{AC}^0$   $\mathcal{F}$ -oracle circuit of size  $\text{poly}(n \cdot \frac{\sqrt{\delta}}{\varepsilon^{3/2}})$  computing majority on  $O(\sqrt{\delta/\varepsilon})$  bits.*

*Then  $\mathbf{N}_{\sqrt{\varepsilon/\delta}}$  is  $(\varepsilon\delta, \delta)$ -pseudodense and yet does not have a  $\delta$ -dense  $\varepsilon$ -model. In particular, when the hypotheses are met, the dense model theorem is false.*

Informally, this says that any  $\mathcal{F}$  which can refute the pseudodensity of  $\mathbf{N}_\alpha$  is only “a constant-depth circuit away” from computing majority.

### 1.3 Related work

#### Computational entropy

Computational entropy was studied systematically in [8] and is relevant to various problems in complexity and cryptography such as leakage-resilience [14], constructions of PRGs from one-way functions [25, 21, 20]. and derandomization [13].

There are a number of definitions of computational entropy which we *don't* consider in this work. For example, Yao pseudoentropy [51] (see also [8]), corresponding to random variables which are “compressible” by a class of tests  $\mathcal{F}$ , in the sense that  $\mathcal{F}$  can encode and decode the random variable by encoding into a small number of bits. Yao pseudoentropy was recently used in time-efficient hardness-to-randomness tradeoffs [13], where (randomness-efficient) samplers for pseudodense distributions were used with an appropriate extractor to construct a pseudorandom distribution. Another example is *inaccessible entropy* of Haitner et al. [21], corresponding to the entropy of a message at some round in a two-player protocol conditioned on the prior messages and the randomness of the players, which is used in efficient constructions of statistically hiding commitment schemes from one-way functions [20].

Separating notions of computational entropy has been studied before in [8], who prove a separation of pseudodensity and having a dense model for bounded-width read-once branching programs. Separating notions of *conditional* computational entropy was studied in [27], showing separations between conditional variants of Yao pseudoentropy and having a dense model.

As mentioned in [27], citing [49] and personal communication with Impagliazzo, another question of interest is whether Yao pseudoentropy (corresponding to efficient encoding/-decoding algorithms) implies having dense model. It is not hard to see that small Yao pseudoentropy implies small pseudodensity, with some mild restrictions on  $\mathcal{F}$ . It would be interesting to see if the techniques from this paper can be used to understand Yao pseudoentropy in more detail. We leave this to future work.

#### Complexity of dense model theorems and hardness amplification

Prior work on the complexity of dense model theorems has included a tight lower bound on the query complexity [52] and a lower bound on the advice complexity [50]. As far as we are aware, this is the first work to consider the computational complexity of dense model theorems.

There has also been prior work on the computational complexity of hardness amplification, establishing that various known strategies for hardness amplification require the computation of majority [34, 42, 19, 41]. It is known that a particular type of hardness amplification given by the *hardcore lemma* implies the dense model theorem [29].

Our results are stronger in the following sense: previous work [34, 42, 19] shows that *black-box hardness amplification proofs* require majority. This means that if you amplify the hardness of  $f$  in some black-box way, then this can be used to compute majority. In our case, we simply show (in different settings) that the dense model theorem is *false*, regardless of how we tried to prove it. By the connection between the hardcore lemma and the dense model theorem, our results also provide scenarios where the hardcore lemma is false. As far as we are aware, these are the first such scenarios recorded in the literature.

## 1.4 Technical overview

We discuss two general themes that appear consistently in the proofs and then discuss each of the main theorems in some more detail.

### 1.4.1 Dense distributions have mostly unbiased bits

A commonly-used observation in theoretical computer science is that most bit positions of a  $\delta$ -dense random variable over  $\{0, 1\}^n$  have bias  $O(\sqrt{\log(1/\delta)}/n)$  (see, for example, the introduction of [35]). Relevant to our purposes, it provides a *necessary* condition for having a  $\delta$ -dense  $\varepsilon$ -model with respect to any class  $\mathcal{F}$  containing the projections  $z \mapsto z_i$ .  $\mathbf{Z}$  has a  $\delta$ -dense  $\varepsilon$ -model, then most bits of  $\mathbf{Z}$  have bias  $\varepsilon + O(\sqrt{\log(1/\delta)}/n)$ . In particular, if all of the bits of  $\mathbf{Z}$  have *large* bias, then it can't have a dense model.

This is used directly in the proof of Theorem 1.3. In this case, we construct a distribution  $\mathbf{Z}$  which is  $\delta$ -dense in a set which is  $\varepsilon$ -pseudorandom for  $\text{AC}^0$  but where the each bit is noticeably biased away from  $1/2$ .

In order to prove separations between pseudodensity and being dense in a pseudorandom set – as in Theorem 1.4, Theorem 1.5 and Theorem 1.6 – we need to consider the bias of larger subsets of variables. Considering just two bits is sufficient to prove mild concentration bounds on the weight of pseudorandom strings. This implies that the tails of dense subsets of pseudorandom sets should not be too heavy.

### 1.4.2 Biased coin distribution

The *biased coin distribution*,  $\mathbf{N}_\alpha$  over  $\{0, 1\}^n$  is the product of  $n$  Bernoulli random variables with success probability  $1/2 - \alpha$ .  $\mathbf{N}_\alpha$  has recently garnered significant interest in the pseudorandomness literature (see [2, 12, 46, 10, 1]). Shaltiel and Viola [42] showed that if  $f$  is a test which  $\varepsilon$ -distinguishes  $\mathbf{N}_\alpha$  from  $\mathbf{U}$ , then there is a small, constant-depth circuit  $C$  with  $f$ -oracle gates which computes majority on  $O(1/\varepsilon)$  bits. A similar, but qualitatively different, connection due to Limaye et al [33] – extended to any choice of  $\varepsilon > 0$  by Srinivasan [44] – shows that any  $\mathbb{F}_p$ -polynomial with advantage  $1 - 2\varepsilon$  in distinguishing  $\mathbf{N}_\alpha$  from  $\mathbf{U}$  must have degree  $\Omega(\log(1/\varepsilon)/\alpha)$ . We extend some of these pseudorandomness results regarding  $\mathbf{N}_\alpha$  to *pseudodensity* results.

First, we extend the observation of Shaltiel and Viola to apply to tests  $f$  for which  $\mathbb{E}[f(\mathbf{Z})] \geq \delta \mathbb{E}[f(\mathbf{U})] + \varepsilon$  (which corresponds to pseudorandomness when  $\delta = 1$ ). This gives us unconditional pseudodensity for test classes  $\mathcal{F}$  which can't be used in small, constant-depth oracle circuits approximating majority. We also extend the observation of [33] to show lower bounds on the  $\mathbb{F}_p$ -degree for any function  $f$  which refutes the pseudodensity of  $\mathbf{N}_\alpha$ .

In Lemma 13, we show that  $\mathbf{N}_\alpha$  exhibits  $(\varepsilon, \delta)$ -pseudodensity for  $\varepsilon = (p \cdot O(\log S)^{d-1})^k$  and  $\delta = e^{-\alpha k/p}$ . This can be seen as a generalization of Tal's result, building on [12, 1, 42] that  $\mathbf{N}_\alpha$  is  $3\alpha \cdot O(\log S)^{d-1}$ -pseudorandom for  $\mathcal{C}(S, d)$ .

Tal uses a Fourier analytic proof which becomes very simple given tail bounds on the Fourier spectrum of  $\mathbf{AC}^0$  (the latter being the main contribution of [46]). More generally, any  $\mathcal{F}$  enjoying sufficiently strong tail bounds on the Fourier spectrum (in the  $\ell_1$  norm) cannot distinguish between  $\mathbf{N}_\alpha$  and uniform. It turns out, as proved by Tal and recorded in Agarwal [2], that if  $\mathcal{F}$  is closed under restrictions then even bounding the first level of the Fourier spectrum works. The proof of Lemma 13 based specifically on the switching lemma for constant-depth circuits. While switching lemmas can be used to show Fourier concentration, it would be interesting to find a proof which only uses the assumption of Fourier concentration (or some Fourier-analytic assumption).

### 1.4.3 Theorem 1.3

Our goal is to construct a random variable  $\mathbf{D}$  which is dense inside of an  $\mathbf{AC}^0$ -pseudorandom set but where each bit is biased away from 0. In this case,  $\mathbf{D}$  would be distinguishable from any dense set, since the average bit of a dense set is roughly unbiased. Doing so requires two steps.

The first step is constructing an appropriate distribution  $\mathbf{Z}$  that fools  $\mathbf{AC}^0$  circuits. For this we adopt a general strategy of Ajtai and Wigderson [3] (and applied in many contexts in pseudorandomness since; see, e.g., [40]): to fool a circuit  $C$ , we start by producing a random restriction to simplify  $C$  to a short decision tree (via the switching lemma), and then we fool the decision tree on the remaining bits using a  $k$ -wise independent distribution  $\mathbf{S}$ . If we wanted  $\mathbf{Z}$  to have small support size, we would need some way of producing random restrictions with a small amount randomness (which is precisely the approach of Ajtai-Wigderson and later work). Fortunately, we only care about the existence of  $\mathbf{Z}$  and are therefore content to use the “non-derandomized” switching lemma.

The second step is finding a dense subset  $\mathbf{D}$  of  $\mathbf{S}$  with biased bits. We do this by constructing  $\mathbf{S}$  so that each bit has bias roughly  $\sqrt{\log(1/\delta)/K}$ , where  $k \ll K \ll n$  is a parameter. This is achieved by randomly bucketing the indices into  $K$  buckets and assigning each bucket a random bit, which reduces the dimension of the problem from  $n$  to  $K$ . This means we can pick a  $\delta$ -dense event in  $\{0, 1\}^K$  with extremal bias – met (up to constants) by the function accepting all strings with weight less than  $K/2 - K\sqrt{\log(1/\delta)}$  – in order to find a dense subset of  $\mathbf{S}$  with large bias. The bucketing construction introduces some error when a small set  $I \subseteq [n]$  hits to distinct elements in some buckets.

### 1.4.4 Theorem 1.4

We will show  $\mathbf{N}_\alpha$  has  $(\delta, \varepsilon')$ -pseudodensity for  $\mathbf{AC}^0$  for  $\delta = \varepsilon' = O(1)$ ,  $\alpha = 1/\text{poly} \log(n)$ . The idea is that  $\mathbf{N}_\alpha$  can be sampled by first sampling a random restriction which leaves a  $p$  fraction of the bits unset (and is unbiased on the restricted bits) and then setting the remaining bits with bias  $\alpha/p$ . Applying the switching lemma, we conclude that  $\mathbb{E}[f(\mathbf{N}_\alpha)] \approx \mathbb{E}[f'(\mathbf{N}_{\alpha/p})]$  where  $f'$  is a short decision tree (which doesn't not depend on all of its inputs). A simple calculation reveals that acceptance probability of  $f'$  can increase by at a most a factor  $(1 + \alpha/p)^d \leq e^{\alpha d/p}$  when passing from the uniform distribution to  $\mathbf{N}_{\alpha/p}$ . By incorporating the error from the switching lemma (i.e. the advantage lost by conditioning on the switching lemma succeeding), we get  $(\delta, \epsilon)$ -pseudodensity.

To prove the separation, we use the fact that the Hamming weight of a random variable fooling  $\mathcal{C}(S, d)$  is concentrated around its expectation. This means in particular that if  $\mathbf{N}_\alpha$  were  $\delta$ -dense in a pseudorandom distribution, then the tails of  $\mathbf{N}_\alpha$  couldn't be too heavy and therefore  $\alpha$  couldn't be too large.

### 1.4.5 Theorem 1.5 and Theorem 1.6

Theorem 1.5 and Theorem 1.6 draw from related work of Srinivasan [44] and Shaltiel-Viola [42] respectively.

With  $\epsilon > 0$  and  $\mathcal{F}$  an arbitrary class of tests  $f : \{0, 1\}^n \rightarrow \{\pm 1\}$ , suppose that  $f \in \mathcal{F}$  witnesses that  $\mathbf{N}_\epsilon$  fails to have  $(\epsilon', \delta)$ -pseudo-density in the sense that

$$\mathbb{E}[f(\mathbf{U})] \leq \delta \mathbb{E}[f(\mathbf{N}_\beta)] - \gamma.$$

[44] and [42] both make use of the following simple observation. Given two strings  $u, v \in \{0, 1\}^m$  with  $\text{wt}(u) = (1/2 - \epsilon)m$  and  $\text{wt}(v) = m/2$ , a uniformly random index  $i \in [m]$  has  $u_i$  distributed as a  $(1/2 - \epsilon)$ -biased coin and  $v_i$  as an unbiased coin. In our case, applying  $f$  to sufficiently many random samples from  $u$  or  $v$  “distinguishes” the two of them, but in a weaker sense.

In the case of Theorem 1.6, we can amplify acceptance probabilities by increasing the size of the circuit by a factor  $1/\epsilon\delta$ , after which we can apply [42] saying that constant-error distinguishers between  $\mathbf{N}_\alpha$  and  $\mathbf{U}$  can be used to compute majority.

For Theorem 1.5, we apply a beautiful recent result of Srinivasan [44] showing that any  $m$ -variate polynomial (over a finite field) which vanishes on most points on the slice  $1/2 - \alpha$  and doesn't vanish on most points on the slice  $1/2$  must have high degree  $\Omega(\alpha m)$ . One way of interpreting this result is that low-degree polynomials can't approximately solve certain “promise” versions of majority.

In this latter case, we need to open up the error reduction procedure we use for Theorem 1.6 and show how to approximate it using low-degree polynomials. This will ultimately be achieved by approximating OR with a probabilistic polynomial, as in [37, 43]. The detailed proofs of these results are deferred to the full version of the paper.

## 2 Technical tools

We write  $[n] = \{1, \dots, n\}$  and use boldface to denote random variables. Let  $\mathcal{C}(S, d)$  be the set of size  $S$ , depth- $d$  unbounded fan-in circuits. For a boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ , let  $DT(f)$  denote the depth of the shortest decision tree computing  $f$ .

### 2.1 Biased coins

As before, let  $\mathbf{N}_\alpha$  denote the random variable corresponding to the product of  $n$  independent coins with bias  $(1/2 - \alpha)$ . That is,

$$\Pr[\mathbf{N}_\alpha = z] = (1/2 - \alpha)^{\text{wt}(z)} (1/2 + \alpha)^{n - \text{wt}(z)}$$

where  $\text{wt}(z)$  denotes the Hamming weight of  $z$ .

For a random variable  $\mathbf{Z}$  over  $\{0, 1\}^n$  and  $i \in [n]$ , let  $\text{bias}_i(\mathbf{Z}) = |\Pr[\mathbf{Z}_i = 1] - \Pr[\mathbf{Z}_i = 0]|/2$ . Let  $\mathcal{B} = \{z \mapsto z_i : i \in [n]\}$  be the set of monotone projections. A random variable  $\mathbf{Z} = (\mathbf{Z}_1, \dots, \mathbf{Z}_n)$  is  $\epsilon$ -pseudorandom with respect to  $\mathcal{B}$  precisely when each marginal  $\mathbf{Z}_i$  has the property that  $\text{bias}_i(\mathbf{Z}) = |\Pr[\mathbf{Z}_i = 1] - 1/2| \leq \epsilon$  for each  $i \in [n]$ . In particular,

▷ **Claim 2.** For any  $\epsilon > 0$ ,  $\mathbf{N}_\epsilon$  is  $\epsilon$ -pseudorandom with respect to  $\mathcal{B}$ .

## 2.2 Information theory

The (*Shannon*) *entropy* of a random variable is defined as

$$H(\mathbf{Z}) = - \sum_{x \in \{0,1\}^n} p_{\mathbf{Z}}(x) \log p_{\mathbf{Z}}(x),$$

where  $p_{\mathbf{Z}}$  is the probability density function corresponding to  $\mathbf{Z}$ . The Shannon entropy of random vector is sub-additive, in that  $H(\mathbf{Z}) \leq \sum_{i \in [n]} H(\mathbf{Z}_i)$ . When  $\mathbf{Z} \in \{0,1\}$  and  $\Pr[\mathbf{Z} = 1] = p$ , we use  $h(p) = H(\mathbf{Z}) = -(p \log p + (1-p) \log(1-p))$  to denote the binary entropy function.

The *min-entropy* is defined as

$$H_{\infty}(\mathbf{Z}) = - \min_{x \in \{0,1\}^n} \log p_{\mathbf{Z}}(x).$$

If  $\mathbf{Z}$  is  $\delta$ -dense inside of  $\mathbf{U}$ , then its min-entropy is  $n - \log(1/\delta)$  and for any random variable  $\mathbf{Z}$ ,  $H_{\infty}(\mathbf{Z}) \leq H(\mathbf{Z})$ .

By this latter inequality and subadditivity, the average entropy of  $\mathbf{Z}$ 's bits is at least  $1 - \log(1/\delta)/n$ . Appealing to a quadratic approximation of binary entropy, we learn that the bias must be at most  $\sqrt{\log(1/\delta)/n}$ . This result has been referred to as *Chang's inequality* and the *Level-1 inequality*, having been observed in different forms and with different proofs in, for example, [47, 11, 22, 31]. Because it is so simple, we provide a proof here:

▷ **Claim 3.** If  $\mathbf{Z}$  is  $\delta$ -dense in  $\mathbf{U}$ , then  $\mathbb{E}_i[\text{bias}_i(\mathbf{Z})] \leq \sqrt{\log(1/\delta)/n}$ .

Proof. As  $\delta$ -density is equivalent to  $n - \log(1/\delta)$  min-entropy,

$$n - \log(1/\delta) = H_{\infty}(\mathbf{Z}) \leq H(\mathbf{Z}) \leq \sum_{i \in [n]} H(\mathbf{Z}_i),$$

by subadditivity of entropy. The entropy of  $\mathbf{Z}_i$ 's bits, therefore, is at least  $1 - \log(1/\delta)/n$  on average. Taking the Taylor series, we can approximate the binary entropy function  $h(p)$  around  $1/2$  by a quadratic function as  $h(1/2 + \varepsilon) \leq 1 - (2/\ln 2)\varepsilon^2$ . Comparing this bound with the average, we get

$$1 - \log(1/\delta) \leq 1 - (2/\ln 2)\varepsilon^2,$$

meaning  $\varepsilon \leq \sqrt{(\ln 2/2) \cdot (\log(1/\delta)/n)} \leq \sqrt{\log(1/\delta)/n}$ . ◁

## 2.3 Random variables lacking computational entropy

It follows directly from Claim 3 that if  $\text{bias}_i(\mathbf{Z}_i)$  exceeds  $\varepsilon + \sqrt{\log(1/\delta)/n}$  for every  $i$ , then  $\mathbf{Z}$  does not have a  $\delta$ -dense  $\varepsilon$ -model with respect to the projections  $\mathcal{B}$ .

► **Lemma 4.** Let  $\mathbf{Z}$  be a random variable with  $\text{bias}_i(\mathbf{Z}) \leq \gamma$  for every  $i \in [n]$ . Then for any  $\delta > 0$  and  $\gamma \geq \varepsilon + \sqrt{\frac{\log(1/\delta)}{n}}$ ,  $\mathbf{Z}$  does not have a  $\delta$ -dense  $\varepsilon$ -model with respect to  $\mathcal{B}$ .

This is used for the separation in Theorem 1.3. We would also like a necessary condition for being dense in a pseudorandom set. Towards this end, we note that pseudorandom distributions for even very simple test classes have mild concentration properties.

▷ **Claim 5.** Suppose  $\mathcal{F}$  can compute  $x_i \oplus x_j$  for every  $i, j \in [n]$  and let  $\mathbf{Z}$  over  $\{0,1\}^n$  be  $\varepsilon$ -pseudorandom for  $\mathcal{F}$ . Then

$$\Pr \left[ \sum_i \mathbf{Z}_i \leq n/2 - \alpha n \right] \leq \frac{1}{4\alpha^2 n} + \frac{\varepsilon}{4\alpha^2}.$$

## 2:12 Comparing Computational Entropies Below Majority

*Proof.* We work over  $\{\pm 1\}$  instead of  $\{0, 1\}$  to make calculations easier. We can compute the second moment as

$$\mathbb{E}[(\sum_i \mathbf{Z}_i)^2] = \sum_i \mathbb{E}[\mathbf{Z}_i^2] + \sum_{i \neq j} \mathbb{E}[\mathbf{Z}_i \mathbf{Z}_j] \leq n + \varepsilon n^2.$$

Applying Markov's inequality to  $(\sum_i \mathbf{Z}_i)^2$ , we see that

$$\Pr \left[ \left| \sum_i \mathbf{Z}_i \right| \geq 2\alpha n \right] = \Pr \left[ (\sum_i \mathbf{Z}_i)^2 \geq (2\alpha n)^2 \right] \leq \mathbb{E}[(\sum_i \mathbf{Z}_i)^2] / (2\alpha n)^2.$$

We use  $2\alpha n$  because it maps back to  $n/2 - \alpha n$  in  $\{0, 1\}$ . Then the conclusion follows from our second moment calculation and converting back to  $\{0, 1\}$ .  $\triangleleft$

The tails of a dense subset can't be too much larger than the original distribution, by definition of density. This gives us a test for being dense in a pseudorandom set, which we specialize to  $\mathbf{N}_\alpha$ .

► **Lemma 6.** *Let  $\varepsilon, \delta > 0$  be arbitrary. Suppose  $\mathcal{F}$  can compute  $x_i \oplus x_j$  for any  $i, j \in [n]$  and  $\alpha \geq \sqrt{1/(8\delta) \cdot (1/n + \varepsilon)}$ . Then  $\mathbf{N}_\alpha$  is not  $\delta$ -dense in any set which is  $\varepsilon$ -pseudorandom for  $\mathcal{F}$ .*

**Proof.** Under  $\mathbf{N}_\alpha$ , the volume of the threshold  $\mathbf{1}[\sum_i \mathbf{Z}_i \leq n/2 - \alpha n]$  is  $1/2$ . Taking Claim 5 in the contrapositive, we reach the desired conclusion when

$$\begin{aligned} 1/2 &> \frac{1}{4\delta\alpha^2 n} + \frac{\varepsilon}{4\delta\alpha^2} \\ \alpha^2 &> \frac{1}{8\delta}(1/n + \varepsilon). \end{aligned} \quad \blacktriangleleft$$

## 2.4 Random restrictions and the switching lemma

A restriction over  $[n]$  is a function  $\rho : [n] \rightarrow \{0, 1, *\}$ . Indices in  $\rho^{-1}(*)$  can be thought of as *unset* and each other index as *set*. For another restriction  $z$  so that  $\rho^{-1}(*) \subseteq z^{-1}(\{0, 1\})$ , let  $\rho \circ z \in \{0, 1\}^n$  be defined by

$$(\rho \circ z)_i = \begin{cases} z_i & \text{if } i \in \rho^{-1}(*) \\ \rho_i & \text{otherwise.} \end{cases}$$

Define the restricted function  $f|_\rho : \{0, 1\}^{\rho^{-1}(*)} \rightarrow \{0, 1\}$  over  $\rho$ 's unset indices by

$$f|_\rho(z) = f(\rho \circ z).$$

Let  $R_p$  be the distribution on restrictions over  $[n]$  obtained by setting  $\rho(i) = *$  independently with probability  $p$ , and then setting each bit not assigned to  $*$  a random bit. The switching lemma we use is due to Rossman [39], building on a long line of work [3, 23, 24, 30]:

► **Theorem 2.1** (Rossman [39]). *Suppose  $f \in \mathcal{C}(S, d)$ . Then*

$$\Pr_{\rho \sim R_p} [DT(f|_\rho) \geq k] \leq (p \cdot O(\log S)^{d-1})^k.$$

By considering a random restriction  $\rho \sim R_p$  over  $[n]$  and a random variable  $\mathbf{Z}$  over  $\{0, 1\}^n$ , the definition of a restricted function implies that

$$\mathbb{E}[f(\rho \circ \mathbf{Z})] = \mathbb{E}[f|_{\rho}(\mathbf{Z})].$$

We make crucial use of two simple corollaries of the switching lemma, which allow us to reason about distinguishability for  $\text{AC}^0$  circuits in terms of distinguishability for short decision trees.

► **Lemma 7.** *Suppose  $f \in \mathcal{C}(S, d)$ . Then there is a distribution over depth  $k$  decision trees so that*

$$|\mathbb{E}[f(\rho \circ \mathbf{Z})] - \mathbb{E}[h_{\rho}(\mathbf{Z})]| \leq (p \cdot O(\log S)^{d-1})^k.$$

**Proof.** Let  $g_{\rho}$  denote the optimal decision tree for  $f|_{\rho}$ . Let  $E$  denote the event that  $g_{\rho}$  has depth at most  $k$  and  $\Pr[E] = 1 - q$ . Let  $h_{\rho}$  be the distribution over depth at most  $k$  decision trees obtained by sampling  $g_{\rho}$  conditioned on  $E$ . Then

$$\begin{aligned} \mathbb{E}[f(\rho \circ \mathbf{Z})] &= \mathbb{E}[f|_{\rho}(\mathbf{Z})] \\ &= (1 - q)\mathbb{E}[g_{\rho}(\mathbf{Z})|E] + q\mathbb{E}[g_{\rho}(\mathbf{Z})|\neg E] \\ &= (1 - q)\mathbb{E}[h_{\rho}(\mathbf{Z})] + q\mathbb{E}[g_{\rho}(\mathbf{Z})|\neg E] \\ &= \mathbb{E}[h_{\rho}(\mathbf{Z})] - q(\mathbb{E}[h_{\rho}(\mathbf{Z})] - \mathbb{E}[g_{\rho}(\mathbf{Z})|\neg E]). \end{aligned}$$

The right-hand term is bounded in absolute value by  $q$  because  $f$  is Boolean. By Theorem 2.1,  $q \leq (p \cdot O(\log S)^{d-1})^k$ . ◀

► **Lemma 8.** *Suppose  $f \in \mathcal{C}(S, d)$ . Then there's a depth  $k$  decision tree  $h$  so that*

$$|\mathbb{E}[f(\mathbf{U})] - \mathbb{E}[f(\rho \circ \mathbf{Z})]| \leq |\mathbb{E}[f'(\mathbf{U})] - \mathbb{E}[f'(\mathbf{Z})]| + (p \cdot O(\log S)^{d-1})^k.$$

**Proof.** Lemma 7 gives us the following upper bound.

$$\begin{aligned} |\mathbb{E}[f(\mathbf{U})] - \mathbb{E}[f(\rho \circ \mathbf{Z})]| &\leq |(\mathbb{E}[h_{\rho}(\mathbf{U})] \pm q) - (\mathbb{E}[h_{\rho}(\mathbf{Z})] \pm q)| && \text{(Lemma 7)} \\ &\leq |\mathbb{E}[h_{\rho}(\mathbf{U})] - \mathbb{E}[h_{\rho}(\mathbf{Z})]| + 2q. && \text{(triangle inequality)} \end{aligned}$$

We can continue to upper bound the right-hand term by

$$\begin{aligned} |\mathbb{E}[h_{\rho}(\mathbf{U})] - \mathbb{E}[h_{\rho}(\mathbf{Z})]| &= |\mathbb{E}_{\rho}[\mathbb{E}[h_{\rho}(\mathbf{U})] - \mathbb{E}[h_{\rho}(\mathbf{Z})]]| \\ &\leq \mathbb{E}_{\rho}[|\mathbb{E}[h_{\rho}(\mathbf{U})] - \mathbb{E}[h_{\rho}(\mathbf{Z})]|] && \text{(triangle inequality)} \\ &\leq |\mathbb{E}[h(\mathbf{U})] - \mathbb{E}[h(\mathbf{Z})]| \end{aligned}$$

where the last line holds for some  $h$  in the support of  $h_{\rho}$  by averaging. ◀

### 3 Proof of Theorem 1.3

We start by reducing the problem of constructing a pseudorandom  $\mathbf{Z}$  for  $\text{AC}^0$  to constructing a pseudorandom  $\mathbf{Z}$  for small-depth decision trees. This can be immediately achieved by applying Lemma 8.

▷ **Claim 9.** Let  $p \in [0, 1]$  be arbitrary and suppose  $\mathbf{Z}$  is a random variable over  $\{0, 1\}^n$  which is  $\epsilon$ -pseudorandom for depth- $k$  decision trees. Then for  $\rho \sim R_p$ ,  $\rho \circ \mathbf{Z}$  is  $\epsilon'$ -pseudorandom for  $\mathcal{C}(S, d)$  for

$$\epsilon' = \epsilon + (p \cdot O(\log S)^{d-1})^k.$$

The next lemma constructs a pseudorandom distribution for depth- $k$  decision trees with each bit having significant bias.

► **Lemma 10.** *For any  $k \in \mathbb{N}$ ,  $\delta > 0$  and  $K \geq 1/2\delta$ , there is a  $k$ -wise independent random variable  $\mathbf{S}$  over  $\{0, 1\}^n$  and a  $\delta$ -dense subset  $\mathbf{D}$  of  $\mathbf{S}$  with the property that*

1.  $\mathbf{D}$  is  $\delta$ -dense in  $\mathbf{S}$ .
2. For all  $i \in [n]$ ,  $\text{bias}_i(\mathbf{D}) = \Omega(\sqrt{\log(1/\delta)/8K})$ .
3.  $\mathbf{S}$  is  $k^2/K$ -pseudorandom for depth- $k$  decision trees.

We will use the following standard lower bound on the lower tail of a binomial distribution:

▷ **Claim 11** ([6]). For  $0 < \alpha < 1$  and let  $\mathbf{Z}_1, \dots, \mathbf{Z}_K$  be independent unbiased coins ( $\{0, 1\}$ -valued). Then any  $\gamma$  with  $1/2 - \gamma = r/K$  for some positive integer  $r$  satisfies

$$\frac{2^{-K(1-h(1/2-\gamma))}}{\sqrt{2K}} \leq \Pr \left[ \sum_{i \in [K]} \mathbf{Z}_i \leq K/2 - K\gamma \right].$$

**Proof of Lemma 10.** We sample  $\mathbf{S}$  in two stages. First, randomly partition  $[n]$  into  $K$  parts  $\mathbf{A}_1, \dots, \mathbf{A}_K$  for  $K > k^2$ . Second, assign to each  $A_i$  a uniformly random bit  $\mathbf{b}_i$ .

Let  $\mathbf{D}$  be  $\mathbf{S}$  conditioned on  $\mathbf{b} = (\mathbf{b}_1, \dots, \mathbf{b}_K)$  having weight less than  $K/2 - \sqrt{K \log(1/\delta)/8}$ . Since the  $\mathbf{b}_i$ 's are unbiased random bits, we can apply Claim 11 to lower bound  $\mathbf{D}$ 's density: for any  $\gamma$ ,

$$\Pr \left[ \sum_{i \in [k]} \mathbf{b}_i \leq \gamma K \right] \geq \frac{2^{-Kh(1/2-\gamma)}}{\sqrt{2K}}.$$

This is at least  $\delta$  when

$$\begin{aligned} \frac{2^{-K(1-h(1/2-\gamma))}}{\sqrt{2K}} &\geq \delta \\ 1 - h(1/2 - \gamma) &\geq \log(1/\delta)/K - \log(2K)/2K \\ 4\gamma^2 &\geq \log(1/\delta)/K - \log(2K)/2K \end{aligned}$$

with the upper bound in the last line following from  $h(1/2 - \gamma) \geq 1 - 4\gamma^2$ . Hence, if the set of strings with weight at most  $K/2 - \gamma K$  is  $\delta$ -dense, we have  $\gamma \geq \frac{1}{2} \sqrt{\log(1/\delta)/K - \log(2K)/2K}$ .  $\log(2K)/2K$  is at most  $\log(1/\delta)/2K$  when  $2K \leq 1/\delta$ , in which case  $\gamma \geq \sqrt{\log(1/\delta)/8K}$ . In particular, this lower bounds the bias of  $\mathbf{D}$ 's bits.

To see why it's  $k^2/K$ -pseudorandom for depth- $k$  decision trees, consider a depth- $k$  decision tree  $T$ . Over  $\mathbf{U}$ , we can imagine evaluating  $T$  “on-line” as follows: whenever  $T$  queries the  $i$ th bit, determine the value of  $z_i$  by flipping an unbiased coin. Over  $\mathbf{S}$ , we can imagine evaluating  $T$  similarly, where we determine the bucket  $A_j$  that  $i$  lives in and the value  $b_j$  of that bucket.

By conditioning  $\mathbf{S}$  on *not* placing two distinct indices  $i, j$  in the same bucket – call this conditioned random variable  $\mathbf{S}'$  – then  $T$  doesn't have *any* distinguish advantage over  $\mathbf{S}'$ , as all of the bits it queries are independent and uniform. By a union bound,  $\mathbf{S}$  places two distinct indices in the same bucket with probability at most  $k^2/K$ .  $T$ 's distinguishing advantage is therefore at most  $k^2/K$ . ◀

In principle, we could have used other pseudorandom distributions for decision trees such as the  $\varepsilon$ -almost  $k$ -wise independent distributions from [4]. The construction here is used to obtain better dependence on the parameters of interest. We will also need a claim to express the bias of the bits in  $\rho \circ \mathbf{Z}$ . The proof can be found in the full version of the paper.

▷ **Claim 12.** Fix  $p \in [0, 1]$  and a random variable  $\mathbf{Z}$ . Let  $E$  be an event which is independent from  $\rho$  (in that the conditional distribution of  $\rho$  is identical to the unconditioned distribution). Then

$$\Pr[(\rho \circ \mathbf{Z})_i = 1 | E] = p \Pr[\mathbf{Z}_i = 1 | E] + (1 - p)/2.$$

Theorem 1.3, which we restate here, is obtained by an appropriate setting of parameters.

► **Theorem 1.3.** Let  $\varepsilon, \varepsilon' > 0$  be arbitrary,  $\delta \geq \varepsilon'/8$  and

$$S \leq \exp\left(O\left(\frac{\sqrt{\varepsilon'}}{\varepsilon} \cdot \frac{\sqrt{\log(1/\delta)}}{\log(1/\varepsilon')}\right)^{1/(d-1)}\right).$$

Then for  $\mathcal{F} = \mathcal{C}(S, d)$ , there is a random variable  $\mathbf{D}$  over  $\{0, 1\}^n$  with  $n = O(\log(1/\delta)/\varepsilon^2)$  so that  $\mathbf{D}$  is  $\delta$ -dense in an  $\varepsilon'$ -pseudorandom set but does not have a  $\delta$ -dense  $\varepsilon$ -model. In particular, the dense model theorem is false in this setting.

**Proof.** Let  $n = \log(1/\delta)/\varepsilon^2$ ,  $k = \log(2/\varepsilon')$  and  $K = (2k^2)/\varepsilon'$ . We also need  $K \geq 1/2\delta$  by the restriction in Lemma 10, which explains the restriction  $8\delta k^2 \geq \varepsilon'$ , simplified by using  $8\delta \geq \varepsilon'$  (a stronger restriction) instead. Let  $\mathbf{S}$  and  $\mathbf{D}$  be the random variables from Lemma 10. By Claim 12, the bias of  $\rho \circ \mathbf{S}$  (where  $\rho \sim R_p$ ) is  $p\sqrt{\log(1/\delta)/8K}$ . By Claim 9 and Lemma 10,  $\rho \circ \mathbf{S}$  is  $\varepsilon' = k^2/K + (pO(\log S)^{d-1})^k$  pseudorandom. We can also ensure that  $\rho \circ \mathbf{S}$  does not have a  $\delta$ -dense  $\varepsilon$ -model when  $p\sqrt{\log(1/\delta)/8K} \geq \varepsilon + \sqrt{\log(1/\delta)/n}$ , by Lemma 4.

By substituting,  $p \geq 2\sqrt{K/n} = 2\sqrt{(k\varepsilon)^2/\varepsilon' \cdot \log(1/\delta)}$ . In comparison,  $\varepsilon' \geq k^2/K + (pO(\log S)^{d-1})^k$ . Recalling that  $k^2/K = \varepsilon'/2$ , we get that

$$\begin{aligned} \varepsilon'/2 &\geq (2\sqrt{K/n}O(\log S)^{d-1})^k \\ \frac{\sqrt{n}}{2\sqrt{K}}(\varepsilon'/2)^{1/k} &\geq O(\log S)^{d-1} \\ \frac{\sqrt{\log 1/\delta}}{\varepsilon} \cdot \frac{\sqrt{\varepsilon'}}{2\sqrt{2k}} \cdot (\varepsilon'/2)^{1/k} &\geq O(\log S)^{d-1} \\ \frac{\sqrt{\log 1/\delta}}{\varepsilon} \cdot \frac{\sqrt{\varepsilon'}}{\sqrt{32\log(1/\varepsilon')}} &\geq O(\log S)^{d-1}. \end{aligned}$$

The claim follows by solving for  $S$ . ◀

## 4 Proof of Theorem 1.4

Theorem 1.4 follows by combining Lemma 6 and the following lemma:

► **Lemma 13.**  $\mathbf{N}_\alpha$  has  $(\varepsilon, \delta)$ -pseudodensity for  $\mathcal{C}(S, d)$  for  $\varepsilon = (p \cdot O(\log S)^{d-1})^k$  and  $\delta = e^{-\alpha k/p}$ .

Of note, the only additive error depends on the error from the switching lemma. Compare this with the claim that  $\mathbf{N}_\alpha$  is  $(3\alpha \cdot O(\log S)^{d-1})$ -pseudorandom (and therefore has the same pseudodensity for  $\delta = 1$ ) for  $\mathcal{C}(S, d)$ , due to Tal [46].

To prove the lemma, we need a few claims.

## 2:16 Comparing Computational Entropies Below Majority

▷ **Claim 14.** Suppose  $f \in \mathcal{C}(S, d)$ . Then there is a depth- $k$  decision tree  $h$  with the property that:

$$\mathbb{E}[f(\mathbf{N}_\alpha)] \leq \mathbb{E}[h(\mathbf{N}_{\alpha/p})] + (p \cdot O(\log S)^{d-1})^k.$$

**Proof.** Take  $\mathbf{Z} = \mathbf{N}_{\alpha/p}$  in Lemma 7, so we have  $\rho \circ \mathbf{N}_{\alpha/p} = \mathbf{N}_\alpha$  and

$$\mathbb{E}[f(\mathbf{N}_\alpha)] \leq \mathbb{E}[h_\rho(\mathbf{N}_{\alpha/p})] + (p \cdot O(\log S)^{d-1})^k.$$

Averaging over  $\rho$  yields the fixed decision tree. ◁

Second, we can upper bound the extent to which the acceptance probability of a short decision tree increases when passing from the uniform distribution  $\mathbf{U}$  to the biased distribution  $\mathbf{N}_\gamma$ .

▷ **Claim 15.** Suppose  $f : \{0, 1\}^n \rightarrow \{-1, 1\}$  is a depth- $k$  decision tree. Then

$$\mathbb{E}[f(\mathbf{N}_\gamma)] \leq (1 + \gamma)^k \cdot \mathbb{E}[f(\mathbf{U})] \leq e^{\gamma k} \cdot \mathbb{E}[f(\mathbf{U})].$$

The proof is simple and can be found in the full version. We're now in a position to prove the lemma.

**Proof of Lemma 13.** Directly applying Claim 14, we get

$$\mathbb{E}[f(\mathbf{N}_\alpha)] \leq \mathbb{E}[f'(\mathbf{N}_{\alpha/p})] + (p \cdot O(\log S)^{d-1})^k.$$

Applying Claim 15 to  $\mathbb{E}[f'(\mathbf{N}_{\alpha/p})]$ , we get

$$\begin{aligned} \mathbb{E}[f(\mathbf{N}_\alpha)] &\leq (1 + \alpha/p)^k \mathbb{E}[f'(\mathbf{U})] \\ &\leq e^{\alpha k/p} \mathbb{E}[f'(\mathbf{U})]. \end{aligned}$$

Putting these together finishes the proof. ◀

We can now prove Theorem 1.4, restated here:

► **Theorem 1.4.** Fix  $\varepsilon, \varepsilon', \delta > 0$ ,  $d \in \mathbb{N}$ , and

$$S \leq \exp \left( O \left( \frac{\sqrt{\delta}}{\sqrt{\varepsilon}} \cdot \frac{\log(1/\delta)}{\log(1/\varepsilon')} \right)^{1/(d-1)} \right).$$

Then  $\mathbf{N}_{\sqrt{\varepsilon/\delta}}$  over  $\{0, 1\}^n$  with  $n = O(1/\varepsilon)$  is  $(\varepsilon', \delta)$ -pseudodense and yet  $\mathbf{N}_{\sqrt{\varepsilon/\delta}}$  is not  $\delta$ -dense inside of any  $\varepsilon$ -pseudorandom set.

**Proof of Theorem 1.4.** Let  $n = 1/(7\varepsilon)$ ,  $k = \log(1/\varepsilon')$  and  $\alpha = \sqrt{\varepsilon/\delta}$ . These choices satisfy  $\alpha \geq \sqrt{\frac{1}{8\delta}}(1/n + \varepsilon)$ , meaning  $\mathbf{N}_\alpha$  is not  $\delta$ -dense in any  $\varepsilon$ -pseudorandom set for  $\mathcal{C}(S, d)$ , by Lemma 6.

By Lemma 13,  $\mathbf{N}_\alpha$  has  $(\varepsilon', \delta)$ -pseudodensity for  $\delta = e^{-\alpha k/p}$  and  $\varepsilon' = (p \cdot O(\log S)^{d-1})^k$ . The constraint on the density implies

$$\delta = e^{-\alpha k/p}$$

$$\log(1/\delta) = \alpha k/p$$

$$\log(1/\delta) = \sqrt{\varepsilon/\delta} \log(1/\varepsilon')/p$$

$$p = \frac{\sqrt{\varepsilon/\delta} \log(1/\varepsilon')}{\log(1/\delta)}.$$

Plugging this value of  $p$  into the expression for  $\varepsilon'$ , we get

$$\begin{aligned}\varepsilon' &= (p \cdot O(\log S)^{d-1})^k \\ (\varepsilon')^{1/k}/p &= O(\log S)^{d-1} \\ (\varepsilon')^{1/\log(1/\varepsilon')} \cdot \frac{\sqrt{\delta} \log(1/\delta)}{\sqrt{\varepsilon} \log(1/\varepsilon')} &= O(\log S)^{d-1}.\end{aligned}$$

Note that  $(\varepsilon')^{1/\log(1/\varepsilon')} = 2^{-\log(1/\varepsilon')/\log(1/\varepsilon')} = 1/2$ . Solving for  $S$  gives the claimed bound.  $\blacktriangleleft$

## 5 Discussion of Theorem 1.5 and Theorem 1.6

This section briefly discusses Theorem 1.5 and Theorem 1.6, deferring a more detailed discussion to the full version of the paper. The basic idea underlying both proofs is to use tests which solve the coin problem to construct a test which “computes majority” in some problem-dependent sense.

Theorem 1.5 shows that the dense model theorem can fail for low-degree polynomials over finite fields.

► **Theorem 1.5.** *Fix a finite field  $\mathbb{F}$  with characteristic  $p = O(1)$ ,  $\varepsilon, \varepsilon' > 0$  and let  $c > \delta > 0$  where  $c \approx 1/200$  is an absolute constant. Suppose that*

$$d \leq O(\sqrt{\delta/\varepsilon}).$$

*Then when  $\mathcal{F}$  is the  $n$ -variate degree- $d$  polynomials over  $\mathbb{F}$  with  $n = 1/\varepsilon$ , and  $\alpha = O(\sqrt{\varepsilon/\delta})$ ,  $\mathbf{N}_\alpha$  is  $(\varepsilon', \delta)$ -pseudodense but is not  $\delta$ -dense inside of an  $\varepsilon$ -pseudorandom set.*

The main tool used in the proof is a special case of the robust Heg  dus lemma, discovered recently by Srinivasan [44].

► **Lemma 16** (Robust Heg  dus lemma (special case), [44]). *Let  $\mathbb{F}$  be a finite field. Let  $2^{-m/100} \leq \lambda \leq c$  where  $c < 1$  is a (small) absolute constant. Let  $\alpha^2 m$  be an integer so that  $2^{-2\alpha^2 m} \geq \lambda$ . Then if  $P : \mathbb{F}^n \rightarrow \mathbb{F}$  is a degree  $d$  polynomial for which:*

1.  $\Pr[P(\mathbf{Sp}_{m, \alpha m}) \neq 0] \leq \lambda$
2.  $\Pr[P(\mathbf{Sp}_{m, 0}) = 0] \leq 1 - e^{-\alpha^2 m/2}$ .

*Then  $d = \Omega(\alpha m)$ .*

The idea is to use a low-degree polynomial distinguishing the biased coin distribution from uniform to construct another low-degree polynomial satisfying the conditions in the above lemma. Our particular approach uses random sampling and the approximation of OR by low-degree probabilistic polynomials [37]. We defer the details to the full version.

Theorem 1.6 gives a generic condition under which the dense model theorem is false, being witnessed by biased coins.

► **Theorem 1.6.** *Let  $\varepsilon, \delta > 0$ . Suppose  $\mathcal{F}$  is a test class of boolean functions  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  with the following property: there is no  $\text{AC}^0$   $\mathcal{F}$ -oracle circuit of size  $\text{poly}(n \cdot \frac{\sqrt{\delta}}{\varepsilon^{3/2}})$  computing majority on  $O(\sqrt{\delta/\varepsilon})$  bits.*

*Then  $\mathbf{N}_{\sqrt{\varepsilon/\delta}}$  is  $(\varepsilon\delta, \delta)$ -pseudodense and yet does not have a  $\delta$ -dense  $\varepsilon$ -model. In particular, when the hypotheses are met, the dense model theorem is false.*

The approach is the same as Theorem 1.5, this time using a small circuit distinguishing biased from uniform to build an only-slightly-larger circuit computing majority. In this case, we use the following result of Shaltiel & Viola:

► **Theorem 5.1** ([42]). *Let  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  be a function that distinguishes between  $\mathbf{U}$  and  $\mathbf{N}_\alpha$  with constant distinguishing probability. Then there is an  $\text{AC}^0$ -circuit of size  $\text{poly}(n/\alpha)$  using  $f$ -oracle gates which computes majority on  $O(1/\alpha)$  bits.*

Once again, we defer the details to the full version.

## Abstract

We consider a game of persuasion with evidence between a sender and a receiver. The sender has private information. By presenting evidence on the information, the sender wishes to persuade the receiver to take a single action (e.g., hire a job candidate, or convict a defendant). The sender's utility depends solely on whether or not the receiver takes the action. The receiver's utility depends on both the action as well as the sender's private information. We study three natural variations. First, we consider sequential equilibria of the game without commitment power. Second, we consider a persuasion variant, where the sender commits to a signaling scheme and then the receiver, after seeing the evidence, takes the action or not. Third, we study a delegation variant, where the receiver first commits to taking the action if being presented certain evidence, and then the sender presents evidence to maximize the probability the action is taken. We study these variants through the computational lens, and give hardness results, optimal approximation algorithms, as well as polynomial-time algorithms for special cases. Among our results is an approximation algorithm that rounds a semidefinite program that might be of independent interest, since, to the best of our knowledge, it is the first such approximation algorithm for a natural problem in algorithmic economics.

## 1 Introduction

Persuasion is a fundamental challenge arising in diverse areas such as recommendation problems in the Internet, consulting and lobbying, employee hiring, and many more. Persuasion problems occupy a central role in economics and received significant interest over the last two decades. A prominent approach is *persuasion with evidence* as introduced by Glazer and Rubinstein [13, 14], which has attracted a lot of subsequent work. In this problem, a sender wishes to persuade a receiver to take a single action by presenting evidence. The sender's utility depends solely on whether or not the action is taken, while the receiver's utility

depends on both the action as well as the sender’s private information. Consider, for example, a prosecutor trying to convince a judge that a defendant is guilty and should be convicted, or a job candidate trying to convince a company that she has the best qualifications and should be hired. How should these pairs of agents interact?

The literature on persuasion games in economics and game theory is vast; see Sobel [27] for a survey. In sharp contrast, very little is known about *computation* in this domain, especially for the persuasion problem with evidence. How does the restriction to evidence impact the computational complexity of the problem? Our main contribution of this paper is to initiate the systematic study of *persuasion with evidence through a computational lens*. We examine three natural model variants that arise from the power to commit to certain behavior.

If there is no commitment power, the scenario is an extensive-form game. We prove that finding a sequential equilibrium is always possible in polynomial time. However, the sender and the receiver can significantly improve their utility when they enjoy commitment power.

If the sender has commitment power, then she can commit in advance which evidence is presented in each possible instantiation of her private information, and the receiver seeing the evidence then takes the action or not. We refer to this situation as *constrained persuasion*, since the sender with commitment power wants to persuade the rational receiver to take the action. The sender is constrained to providing concrete evidence instead of just making a recommendation as is the case in the so called Bayesian persuasion paradigm [19]. Constrained persuasion is a natural model in the example of prosecutor and judge, where the prosecutor (sender) with private information would first present evidence before the judge (receiver) makes a decision. Although this scenario seems structurally rather simple, we show that the sender’s task in constrained persuasion is computationally (highly) intractable. Unless  $P = NP$ , optimal persuasion can become hard to approximate within a polynomial factor of the input size.

If the receiver has commitment power, she commits to taking the action if and only if being faced with a specific set of evidence. We refer to this situation as *constrained delegation*, since we assume that the receiver with commitment power delegates inspection of the state of nature to a sender, whose incentive becomes to provide convincing evidence to support taking the action. Constrained delegation better fits the second example, where the company (receiver) can give the candidate (sender) a test to present evidence on the private information about qualifications, and commit to hiring her if she performs well. We show that the receiver’s task in delegation is also intractable – unless  $P = NP$ , optimal delegation can become hard to approximate within a factor of  $2 - \varepsilon$ , for any constant  $\varepsilon > 0$ .

These computational differences nicely reflect conceptual differences known from the economics literature. Namely, persuasion lacks a condition termed “credibility” that was shown for delegation. Formally, credibility implies that there is a deterministic optimal solution that does not require randomization, see Glazer and Rubinstein [14] for details. We proceed to study algorithms with matching approximation guarantees for constrained persuasion and delegation, as well as a number of exact and approximation algorithms for various special cases. This includes, in particular, an approximation algorithm for a class of delegation problems that solves and rounds a semidefinite program (SDP). This last result might be of independent interest and, to the best of our knowledge, it is the first natural problem in information structure design, as well as mechanism design, where the SDP toolbox is used.

## 2 Preliminaries

Following [13, 14, 25], we study the fundamental problem of persuasion with evidence. There are two players, a sender and a receiver. The receiver is tasked with either taking a specific action and “accept” (henceforth  $A$ ), or sticking to the status quo and “reject” (henceforth  $R$ ). The sender wants to convince the receiver to take action  $A$ . There is a state of nature  $\theta$  drawn from a distribution  $\mathcal{D}$  with support  $\Theta$  of size  $n$ . We denote the probability that  $\theta$  is drawn by  $q_\theta$ . The set  $\Theta$  is partitioned into the set of acceptable states  $\Theta_A$  and the set of rejectable ones  $\Theta_R = \Theta \setminus \Theta_A$ . We denote the total probability on acceptable states by  $q_A = \sum_{\theta \in \Theta_A} q_\theta$ , and the total probability on rejectable states by  $q_R = \sum_{\theta \in \Theta_R} q_\theta$ .

Both players know  $\mathcal{D}$ . The sender knows the realization of the state of nature, the receiver does not. The sender has utility 1 whenever the receiver takes action  $A$ , and 0 otherwise. Formally, for the sender utility we have  $u_s(A, \theta) = 1$  and  $u_s(R, \theta) = 0$ , for all  $\theta \in \Theta$ .

The utility of the receiver depends on the combination of the chosen action  $a \in \{A, R\}$  and the state of nature  $\theta$ . She has utility 1 if she makes the “right” decision – accept in an acceptable state of nature or reject in a rejectable state of nature – and 0 otherwise. Formally,  $u_r(a, \theta) = 1$  when (1)  $a = A$  and  $\theta \in \Theta_A$ , or (2)  $a = R$  and  $\theta \in \Theta_R$ . Otherwise,  $u_r(a, \theta) = 0$ .

The sender strives to send a message to the receiver according to a public signaling strategy. This message should persuade the receiver to accept. On the other hand, upon receiving the message, the receiver strives to infer the state of nature and make the right accept/reject decision. We focus on games with evidence, where the messages that can be sent are not arbitrary. Every state of nature has intrinsic characteristics (e.g., a candidate for a position has grades, degrees, or test scores) that *can* be (but don’t *have* to be) revealed to the receiver and cannot be forged.

More formally, there is a set  $\Sigma$  of  $m$  possible messages or *signals* that the sender can report to the receiver. We are given as input a bipartite graph  $H = (\Theta \cup \Sigma, E)$ , where an edge  $e = (\theta, \sigma) \in E$  implies that signal  $\sigma$  is allowed to be sent in state  $\theta$ . We use  $N(\theta) \subseteq \Sigma$  to denote the neighborhood of  $\theta$ , i.e., the set of allowed signals for state  $\theta$ . Similarly,  $N(\sigma) \subseteq \Theta$  is the set of states in which signal  $\sigma$  can be sent. To avoid trivialities, we assume that none of the neighborhoods  $N(\cdot)$  are empty, i.e., there are no isolated nodes in  $H$ .

We study the computational complexity of games with evidence for different forms of interaction between the sender and the receiver. In particular, in the case of *constrained persuasion*, the game starts with the sender committing to a *signaling scheme*. A signaling scheme  $\varphi$  is a mapping  $\varphi : E \rightarrow [0, 1]$ , where  $\varphi(\theta, \sigma)$  is the joint probability that state  $\theta$  is realized and signal  $\sigma$  is sent in state  $\theta$ . Clearly, for any signaling scheme we have  $\sum_{\sigma \in N(\theta)} \varphi(\theta, \sigma) = q_\theta$  for every state  $\theta \in \Theta$ . After the sender has committed to a scheme  $\varphi$ , nature draws  $\theta \in \Theta$  with probability  $q_\theta$ , and  $\theta$  is revealed to the sender. Then, the sender sends signal  $\sigma$  with probability  $\varphi(\theta, \sigma)/q_\theta$ . The receiver then decides on an action  $A$  or  $R$ . Finally, depending on the (state of nature, action)-pair, the sender and receiver get payoffs as described by the utilities above.

► **Problem 1 (CONSTRAINED PERSUASION).** *Find a signaling scheme  $\varphi^*$  for commitment of the sender such that, upon a best response of the receiver, the sender utility is as high as possible.*

In the case of *constrained delegation*, the game starts with the receiver committing to an action for every possible signal  $\sigma \in \Sigma$ , according to a *decision scheme*. A decision scheme  $\psi$  is a mapping  $\psi : \Sigma \rightarrow [0, 1]$ , where  $\psi(\sigma)$  is the probability to choose action  $A$ . After the receiver has committed to a scheme  $\psi$ , nature draws  $\theta \in \Theta$  with probability  $q_\theta$ , and  $\theta$  is revealed to the sender. Then, the sender decides which signal  $\sigma$  she will report (under the

constraint that  $\sigma \in N(\theta)$ ). The receiver then takes action A with probability  $\psi(\sigma)$ , and R otherwise. Finally, depending on the (state of nature, action)-pair, the sender and receiver get payoffs as described by the utilities above.

► **Problem 2 (CONSTRAINED DELEGATION).** *Find a decision scheme  $\psi^*$  for commitment of the receiver such that, upon a best response of the sender, the receiver utility is as high as possible.*

Finally, in the game without commitment power, we look for a pair  $(\varphi, \psi)$  of signaling and decision schemes that constitute a sequential equilibrium in the extensive-form game, where nature first determines the state of nature, the sender then picks  $\varphi$  to provide evidence, and then the receiver uses  $\psi$  to accept or reject based on the evidence provided. Given that the sender picks  $\varphi$ , the receiver shall pick  $\psi$  as a best response for every given evidence. Similarly, given that the receiver responds to evidence with  $\psi$ , the signaling scheme  $\varphi$  shall be a best response for the sender.

► **Problem 3 (CONSTRAINED EQUILIBRIUM).** *Find a pair of signaling scheme  $\varphi$  and decision scheme  $\psi$  that represents a sequential equilibrium in the persuasion game with evidence and without commitment power.*

## 2.1 Structural Properties

While the persuasion problem with evidence appears rather elementary, it turns out that both persuasion and delegation variants are NP-hard, and even NP-hard to approximate in polynomial time. Hence, even in this seemingly simple domain, it is necessary to identify additional structure to obtain positive results. We mostly consider structural properties of the neighborhoods of the states of nature.

**Unique Accepts and Rejects.** In an instance with *unique accepts*, there is a single acceptable state, i.e.,  $|\Theta_A| = 1$ . Similarly, for *unique rejects* we have  $|\Theta_R| = 1$ . This is equivalent to assuming that every acceptable (rejectable, resp.) state  $\theta$  has the same neighborhood  $N(\theta)$ .

**Degree-bounded States.** In an instance with *degree- $k$  states*, every state  $\theta \in \Theta$  has  $|N(\theta)| \leq k$ . Similarly, for *degree- $k$  accepts*, every acceptable state  $\theta \in \Theta_A$  has  $|N(\theta)| \leq k$ , and for *degree- $k$  rejects* every rejectable state  $\theta \in \Theta_R$  has  $|N(\theta)| \leq k$ .

**Foresight.** Sher [25] considers instances with *foresight* defined as follows. For an acceptable state  $\theta \in \Theta_A$ , a signal  $\sigma \in N(\theta)$  is called *minimally forgeable for  $\theta$*  if  $\sigma \in N(\theta')$  implies  $\sigma' \in N(\theta')$  for every other signal  $\sigma' \in N(\theta)$  and every rejectable state  $\theta' \in \Theta_R$ . In an instance *with foresight* every acceptable state has a minimally forgeable signal. Intuitively, in such a problem every acceptable state  $\theta$  has a (not necessarily unique) signal that is maximally informative about  $\theta$  with respect to the set of rejectable states. Foresight strictly generalizes other properties studied in previous work, e.g. normality [4]. Normality requires a signal for every state (not only the acceptable ones) that satisfies the condition of minimally forgeable, and it satisfies the condition w.r.t. all states (not only w.r.t. rejectable ones). In addition, foresight is a generalization of instances with unique rejects, as well as a generalization the class of degree-1 accepts.

■ **Table 1** Approximation results shown in this paper, as well as results shown or implied by [25].

Scenario	Constrained Delegation		Constrained Persuasion	
	Upper	Lower	Upper	Lower
General	2	$2 - \varepsilon$ ( $P \neq NP$ )	$O(n)$	$n^{1-\varepsilon}$ ( $P \neq NP$ )
Degree-2 States	1.1	APX-hard [25]	$O(n)$	$n^{1-\varepsilon}$ ( $P \neq NP$ )
Degree- $d$ States	$2 - 1/d^2$	APX-hard [25]	$O(n)$	$n^{1-\varepsilon}$ ( $P \neq NP$ )
Degree-1 Rejects	2	APX-hard [25]	$O(n)$	$n^{1-\varepsilon}$ ( $P \neq NP$ )
Degree-1 Accepts	1 [25]		$O(n)$	$n^{1-\varepsilon}$ ( $P \neq NP$ )
Foresight	1 [25]		$O(n)$	$n^{1-\varepsilon}$ ( $P \neq NP$ )
Unique Rejects	1 [25]		1	
Unique Accepts	1		PTAS	Strongly NP-hard

## 2.2 Results and Contribution

We provide polynomial-time exact and approximation algorithms as well as hardness results for the general problems and the domains with more structure described above.

We first consider the case of the constrained equilibrium problem. The existence of a sequential equilibrium is implied by [14]; we show that it can always be computed in polynomial time by repeatedly solving a maximum flow problem. We compare the utility obtained in an equilibrium with the one achievable with commitment power, for the sender and the receiver, respectively. Formally, we define and bound the ratio of the utilities for best and worst-case equilibria, in the spirit of prices of anarchy and stability. For the receiver, it is known that the price of stability is 1 [14]; we show that the price of anarchy is 2. For the sender we show that both ratios are unbounded. This substantial utility gain provides further motivation to study problems with commitment power.

Our results for constrained delegation and persuasion are summarized in Table 1. We discuss a selected subset of our most interesting contributions in the main part of the paper. All missing proofs are deferred to the full version of this paper. In addition, in the full version, we prove additional results that omitted from this version due to spatial constraints.

For the constrained delegation problem, we show two interesting non-trivial approximation results. For degree-2 states, we propose a semidefinite-programming algorithm to compute a 1.1-approximation. To the best of our knowledge, this is the first application of advanced results from the SDP toolbox in the context of information design, as well as mechanism design. For instances with degree- $d$  states we give a  $(2 - \frac{1}{d^2})$ -approximation algorithm via LP rounding.

For constrained persuasion, the strong hardness arises from deciding which action should be preferred by the receiver for each signal. It holds even in several seemingly special cases with degree-1 accepts, degree-1 rejects and degree-2 states. As a consequence, good approximation algorithms can be obtained only in significantly more limited scenarios than for delegation. For unique accepts, we prove strong NP-hardness (i.e. there is no FPTAS unless  $P = NP$ ) and provide a polynomial-time approximation scheme (PTAS).

## 2.3 Related Work

There is a large literature on strategic communication, see Sobel [27] for an extensive review. The works most closely related to ours are [14, 25]. Glazer and Rubinstein [14] introduce the problem of constrained delegation. They show, among other things, that the optimal decision scheme in constrained delegation is deterministic. Furthermore, they prove that there is

always a sequential equilibrium where the receiver plays the optimal decision scheme from constrained delegation, i.e., the price of stability for the receiver is 1. This condition is termed “credibility”. It is easy to see that this is not true when sender moves first. This conceptual difference between persuasion and delegation is reflected as a difference in the problems’ computational complexity. Deterministic optimal strategies and “credibility” hold also beyond the simple model with 2 actions – when receiver utility is a concave transformation of sender utility, see [24]. Sher [25] builds on the model of [14] and characterizes optimal rules for static as well as dynamic persuasion. Furthermore, and more relevant to our interest here, he proves an NP-hardness result for constrained delegation, as well as provides a polynomial-time algorithm for optimal delegation in instances with foresight. Here we strengthen this hardness result to a hardness of approximation within a factor of  $2 - \varepsilon$  (and provide a matching, alas trivial, approximation algorithm). While this subsumes NP-hardness in general, we observe that his hardness proof applies in case of degree-2 states and degree-1 rejects, and that it even implies APX-hardness for such instances.

Glazer and Rubinstein [13] study a related setting, where the state of nature is multi-dimensional, and the receiver can verify at most one dimension. The authors characterize the optimal mechanism as a solution to a particular linear programming problem, show that it takes a fairly simple form, and show that random mechanisms may be necessary to achieve the optimum. Carroll and Egorov [5] study the problem of fully revealing the sender’s information in a setting with multidimensional states, where the receiver can verify a single dimension. Importantly, the dimension the receiver chooses to reveal depends on the sender’s message.

A number of works in the algorithmic economics literature investigate the computational complexity of persuasion and information design. Computational aspects of the Bayesian persuasion model [19] are studied in, e.g., [10, 6, 9, 8, 11, 18, 17], but in these works there are no limits on the senders’ signals, i.e.,  $H$  is the complete bipartite graph. More closely related to our work are [7, 16] who study computational problems in Bayesian persuasion with limited signals, where the number of signals is smaller than the number of actions.

### 3 Sequential Equilibria

We first study the scenario without commitment power. Our interest here is to obtain a signaling scheme  $\varphi : E \rightarrow [0, 1]$  and a decision scheme  $\psi : \Sigma \rightarrow [0, 1]$ , such that the pair  $(\varphi, \psi)$  forms a sequential equilibrium.

► **Theorem 4.** *A sequential equilibrium can be computed in polynomial time.*

Our algorithm repeatedly sets up a flow network based on the graph  $H$ . In each iteration, it computes a maximum  $s$ - $t$  flow and identifies suitable regions of the graph where it fixes the equilibrium schemes of sender and receiver. Then it removes the fixed regions and repeats the construction on the graph with the remaining states and signals. After at most  $\min\{n, m\}$  iterations, the algorithm finishes the construction of the equilibrium.

How desirable is an equilibrium for the sender and the receiver? By how much can each player benefit when he or she enjoys commitment power? Towards this end, we bound the ratios of the optimal utility achievable with commitment power over the utilities in the worst and best equilibrium. Intuitively, commitment power might be interpreted as a form of control over the game, so we use the term *price of anarchy* and *price of stability* to refer to the ratios, respectively.

More formally, for the price of anarchy we bound the ratio of the optimal utility achievable with commitment over the *worst* utility in any sequential equilibrium. For the price of stability we bound the ratio of the optimal utility achievable with commitment over the *best* utility in any sequential equilibrium.

For the receiver, the optimal scheme with commitment leads to an equilibrium [14], so the price of stability is 1. The price of anarchy is 2 (c.f. Proposition 7 below). For the sender, both prices of anarchy and stability are unbounded.

► **Proposition 5.** *The price of anarchy for the receiver is 2 and this is tight. The prices of anarchy and stability for the sender are unbounded.*

## 4 Constrained Delegation

In constrained delegation, the game starts with the receiver committing to a decision scheme  $\psi : \Sigma \rightarrow [0, 1]$ , where  $\psi(\sigma)$  is the probability to choose action A if the sender reports signal  $\sigma$ . The first insight is due to [14, Proposition 1].

► **Lemma 6** (Glazer and Rubinstein [14]). *In constrained delegation, there is an optimal decision scheme  $\psi^*$  that is deterministic, i.e.,  $\psi^*(\sigma) \in \{0, 1\}$  for all  $\sigma \in \Sigma$ .*

Given a deterministic decision scheme  $\psi$ , the sender's problem is trivial: after learning  $\theta$ , report an arbitrary signal  $\sigma \in N(\theta)$  such that  $\psi(\sigma) = 1$  if one exists. Otherwise, report an arbitrary signal  $\sigma \in N(\theta)$ . In the following, we focus on the computational complexity of the receiver's problem: How hard is it to compute the optimal  $\psi$ ? What about a good approximation algorithm?

This problem turns out to be much easier than the sender's problem in constrained persuasion studied below. It readily admits a trivial 2-approximation algorithm. Let  $\psi_A$  be the scheme that accepts all signals, i.e.,  $\psi_A(\sigma) = 1$  for all  $\sigma$ , and  $\psi_R$  the scheme that rejects all signals. The better of  $\psi_A$  and  $\psi_R$  results in utility  $\max\{q_A, q_R\}$  for the receiver, which is at least  $1/2$ . Clearly, the receiver can obtain at most a utility of 1.

► **Proposition 7.** *For constrained delegation, the better of  $\psi_A$  and  $\psi_R$  is a 2-approximation to the optimal decision scheme  $\psi^*$ .*

In Section 4.1 we show that the factor 2 is essentially optimal in the worst case, unless  $P = NP$ . In Section 4.2 we present our results on approximation algorithms.

### 4.1 Hardness

Sher [25, Theorem 7] shows NP-hardness of constrained delegation, even in the special case with degree-1 rejects and degree-2 states. His construction can be extended easily to show APX-hardness (we provide the details in the full version of this paper). Our main result in this section is a stronger hardness result that matches the guarantee of the trivial algorithm in Proposition 7.

► **Theorem 8.** *For any constant  $\varepsilon \in (0, 1)$ , it is NP-hard to approximate constrained delegation within a factor of  $(2 - \varepsilon)$ .*

For simplicity, we sketch below an outline for a reduction that does *not* give the NP-hardness, but nonetheless encapsulates the main ideas of the proof. After the outline, we roughly explain the changes needed to achieve the NP-hardness; the full proof is deferred to the full version of this paper.

We reduce from the BIPARTITE VERTEX EXPANSION problem. In this problem, we are given a bipartite graph  $(U, V, E)$  and positive real number  $\beta$ . The goal is to select (at least)  $\beta|U|$  vertices from  $U$  such that their neighborhood (in  $V$ ) is as small as possible. Khot and Saket [20] show the following strong inapproximability result:

► **Theorem 9** ([20]). *Assuming  $\text{NP} \not\subseteq \bigcap_{\delta>0} \text{DTIME}(2^{n^\delta})$ , for any positive constants  $\tau, \gamma > 0$ , there exists  $\beta \in (0, 1)$  such that no polynomial-time algorithm can, given a bipartite graph  $(U, V, E)$ , distinguish between the following two cases:*

- (YES) *There exists  $S^* \subseteq U$  of size at least  $\beta|U|$  where  $|N(S^*)| \leq \gamma|V|$ .*
- (NO) *For any  $S \subseteq U$  of size at least  $\tau\beta|U|$ ,  $|N(S)| > (1 - \gamma)|V|$ .*

The main idea of our reduction is as follows. Roughly speaking, given a bipartite graph  $(U, V, E)$ , we set  $\Sigma = U$ ,  $\Theta_R = V$  and the edge set between them is exactly  $E$ . To get a high utility on  $\Theta_R$ , we must pick a signal set  $T \subseteq \Sigma$  such that  $|N(T)|$  is small, and set  $\psi(\sigma) = 1$  for all  $\sigma \in T$ ; this does not mean much so far, since we could just pick  $T = \emptyset$ . This is where the set of acceptable states comes in: we let  $\Theta_A$  be equal to  $U^\ell = \{(u_1, \dots, u_\ell) \mid u_i \in U\}$  for some appropriate  $\ell \in \mathbb{N}$ , and there is an edge between  $\theta = (u_1, \dots, u_\ell)$  and  $\sigma = u$  if  $u_i = u$  for some  $i \in [\ell]$ . Intuitively, this forces us to pick  $T$  that is not too small as otherwise  $\Theta_A$  won't contribute to the total utility. Finally, we need to pick a distribution  $\mathcal{D}$  over  $\Theta$  such that  $q_A = q_R$ , as otherwise the trivial algorithm already gets better than a 2-approximation.

As stated earlier, the above reduction does not yet give NP-hardness, because Theorem 9 relies on a stronger assumption<sup>1</sup> that  $\text{NP} \not\subseteq \bigcap_{\delta>0} \text{DTIME}(2^{n^\delta})$ . To overcome this, we instead use a “colored version” of the problem, where every vertex in  $U$  is colored and the subset  $S \subseteq U$  must only contain vertices of different colors (i.e., be “colorful”). It turns out that the above reduction can be adapted to work with such a variant as well, by changing the acceptable states  $\Theta_A$  to “test” this condition instead of the condition that  $|S|$  is small. Furthermore, we show, via a reduction from the Label Cover problem, that this colored version of BIPARTITE VERTEX EXPANSION is NP-hard to approximate. Together, these imply Theorem 8. Our proof formalizes this outline; see the full version for details.

## 4.2 Approximation Algorithms for Constrained Delegation

By Theorem 8 there is no hope for a  $(2 - \epsilon)$ -approximation algorithm for the constrained delegation problem. Proposition 7 provides a matching guarantee.

As a consequence, we examine in which way instance parameters influence the existence of polynomial-time approximation algorithms. In particular, the maximum degree  $d$  is a main force that drives the hardness result. For the case of degree at most  $d$ , we give a  $2 - \frac{1}{d^2}$  approximation algorithm via LP rounding. When  $d = 2$ , we improve upon this by giving a 1.1-approximation algorithm via SDP rounding.

### 4.2.1 Better than 2 via LP Rounding

For instances with degree- $d$ -states we take the better of (1) rounding the natural linear program for constrained delegation and (2) the trivial scheme of Proposition 7.

► **Theorem 10.** *For constrained delegation with degree- $d$  states there is a polynomial-time  $(2 - \frac{1}{d^2})$ -approximation algorithm.*

<sup>1</sup> We remark that it is entirely possible that Theorem 9 holds under NP-hardness (instead of under the assumption  $\text{NP} \not\subseteq \bigcap_{\delta>0} \text{DTIME}(2^{n^\delta})$ ) but this is not yet known.

**Proof.** Consider the following integer program for constrained delegation (c.f. [14, 25]).

$$\max \sum_{\theta \in \Theta} c_{\theta} q_{\theta} \quad (1a)$$

$$\text{s.t.} \quad \sum_{\sigma \in N(\theta)} \psi_{\sigma} \geq c_{\theta}, \quad \text{for all } \theta \in \Theta_A \quad (1b)$$

$$\sum_{\sigma \in N(\theta)} \psi_{\sigma} \leq |N(\theta)|(1 - c_{\theta}) \quad \text{for all } \theta \in \Theta_R \quad (1c)$$

$$\psi_{\sigma} \in \{0, 1\}, \text{ for all } \sigma \in \Sigma \quad \text{and} \quad c_{\theta} \in \{0, 1\}, \text{ for all } \theta \in \Theta \quad (1d)$$

The variable  $\psi_{\sigma}$  encodes whether the action is accept or reject for signal  $\sigma$ . The variable  $c_{\theta}$  encodes whether the receiver makes the correct choice when the state of nature is  $\theta$ . Constraint (1b) states that, if  $\theta \in \Theta_A$ , she can't make the correct choice when she rejects all signals available from  $\theta$ . Constraint (1c) states that, if  $\theta \in \Theta_R$ , making the correct choice means rejecting all signals available from  $\theta$ ; the  $|N(\theta)|$  term ensures that the constraint can still be satisfied even when  $c_{\theta} = 0$ .

Our algorithm first solves the linear relaxation of this integer program; let  $\hat{\psi}_{\sigma}$  and  $\hat{c}_{\theta}$  be the fractional optimum. We round this solution by setting  $\psi_{\sigma} = 1$  with probability  $\hat{\psi}_{\sigma}$ , and 0 otherwise. We can optimally pick  $c_{\theta}$  given the  $\psi_{\sigma}$ 's. The rounded solution is feasible by definition; we show that it is a good approximation to the optimal LP value, i.e.,  $\sum_{\theta \in \Theta} \hat{c}_{\theta} q_{\theta}$ .

Let  $G = \frac{1}{|\Theta_A|} \sum_{\theta \in \Theta_A} \hat{c}_{\theta} q_{\theta}$  and  $B = \frac{1}{|\Theta_R|} \sum_{\theta \in \Theta_R} \hat{c}_{\theta} q_{\theta}$  be the average contribution to the LP objective from the acceptable and rejectable states, respectively. The LP value is  $G|\Theta_A| + B|\Theta_R|$ . We start by showing the following lower bound on the expected value of the rounded solution.

► **Lemma 11.**  $\mathbb{E}[\sum_{\theta \in \Theta} c_{\theta} q_{\theta}] \geq \frac{G|\Theta_A|}{d} + q_R(1 - d) + dB|\Theta_R|$ .

**Proof.** First, consider a state  $\theta \in \Theta_A$ . The probability that  $c_{\theta} = 1$  is at least the probability that we rounded one of the  $\psi_{\sigma}$  variables to 1, for  $\sigma \in N(\theta)$ , i.e.,

$$\Pr[c_{\theta} = 1] \geq \max_{\sigma \in N(\theta)} \hat{\psi}_{\sigma} \geq \frac{\hat{c}_{\theta}}{|N(\theta)|} \geq \frac{\hat{c}_{\theta}}{d}, \quad (2)$$

where we used the fact that  $\hat{c}_{\theta}$  satisfies Constraint (1b). For a state  $\theta \in \Theta_R$ , the probability that  $c_{\theta} = 1$  is exactly the probability that none of its signals were selected, which is  $\prod_{\sigma \in N(\theta)} (1 - \hat{\psi}_{\sigma}) \geq 1 - \sum_{\sigma \in N(\theta)} \hat{\psi}_{\sigma}$ . Thus

$$\Pr[c_{\theta} = 1] \geq 1 - \sum_{\sigma \in N(\theta)} \hat{\psi}_{\sigma} \geq 1 - |N(\theta)|(1 - \hat{c}_{\theta}) \geq 1 - d + d\hat{c}_{\theta}, \quad (3)$$

where we used the fact that  $\hat{c}_{\theta}$  satisfies Constraint (1c). Adding up (2) and (3), the expected value of our rounded solution is

$$\mathbb{E}\left[\sum_{\theta \in \Theta} c_{\theta} q_{\theta}\right] \geq \sum_{\theta \in \Theta_A} \frac{q_{\theta} \hat{c}_{\theta}}{d} + \sum_{\theta \in \Theta_R} q_{\theta} (1 - d + d\hat{c}_{\theta}) \geq \frac{G|\Theta_A|}{d} + q_R(1 - d) + dB|\Theta_R|. \quad \blacktriangleleft$$

Our final algorithm, i.e., the better of the trivial scheme and the rounded LP solution, has expected value at least  $\max\{q_A, q_R, \mathbb{E}[\sum_{\theta \in \Theta} c_\theta q_\theta]\}$ . We have that

$$\begin{aligned} \left(2d - \frac{1}{d}\right) \max \left\{ q_A, q_R, \mathbb{E} \left[ \sum_{\theta \in \Theta} c_\theta q_\theta \right] \right\} &\geq \left(d - \frac{1}{d}\right) q_A + (d-1)q_R + \mathbb{E} \left[ \sum_{\theta \in \Theta} c_\theta q_\theta \right] \\ &\stackrel{\text{Lemma 11}}{\geq} \left(d - \frac{1}{d}\right) q_A + (d-1)q_R + \frac{G|\Theta_A|}{d} + q_R(1-d) + dB|\Theta_R| \\ &\stackrel{(G|\Theta_A| \leq q_A)}{\geq} dG|\Theta_A| + dB|\Theta_R|, \end{aligned}$$

which is  $d$  times the value of the optimum fractional value of the LP. The theorem follows.  $\blacktriangleleft$

#### 4.2.2 Better than 2 via Semidefinite Programming

In this subsection we give a 1.1-approximation algorithm for constrained delegation with degree-2 states, where every state of nature  $\theta$  has at most two allowed signals,  $\sigma_u$  and  $\sigma_v$ . The approach stems from an observation that the problem belongs to the class of *constraint satisfaction problems* (CSPs); we make use of the toolbox for semidefinite program (SDP) rounding in approximating CSPs (e.g. [15, 12, 21]).

Consider the integer program (4a) for our problem below. We assume w.l.o.g. that every state has *exactly* two adjacent signals; if there is a state  $\theta$  with a single neighbor  $\sigma$ , we can add a parallel edge  $(\theta, \sigma)$  in  $H$  and the analysis remains valid. Note that the integer program here is *not* the same as the one used in the previous subsection. An intuitive reason for the change is that the variables  $c_\theta$  there are redundant: given  $\{\psi_\sigma\}_{\sigma \in \Sigma}$ , the values of  $\{c_\theta\}_{\theta \in \Theta}$  are already fixed. In particular, each  $c_\theta$  can be expressed as a degree- $d$  polynomial<sup>2</sup> in  $\{\psi_\sigma\}_{\sigma \in N(\theta)}$ , which is exactly how the integer program below is written.

$$\max_{x \in \{-1, 1\}^m} \quad \frac{1}{4} \sum_{\substack{\theta \in \Theta_A \\ \theta = (\sigma_i, \sigma_j)}} (3 - x_i - x_j - x_i x_j) q_\theta + \frac{1}{4} \sum_{\substack{\theta \in \Theta_R \\ \theta = (\sigma_i, \sigma_j)}} (1 + x_i + x_j + x_i x_j) q_\theta \quad (4a)$$

In the program above  $x_i = -1$  is interpreted as accepting when the signal is  $\sigma_i$ . One can check that  $\frac{1}{4}(3 - x_i - x_j - x_i x_j)$  is equal to 1 iff at least one of  $x_i, x_j$  is  $-1$  (and zero otherwise), i.e., a state of nature  $\theta \in \Theta_A$  contributes to the objective only when at least one of its allowed signals is accepted. Similarly,  $\frac{1}{4}(1 + x_i + x_j + x_i x_j)$  is equal to 1 if and only if both  $x_i$  and  $x_j$  are equal to 1.

We will solve the semidefinite relaxation of this program, and give a rounding algorithm. The SDP is the following, where we replaced  $x_i$  by  $w_i$ , to distinguish these vector variables from the variables of our integer program above.

<sup>2</sup> Note that linear functions do not suffice to express  $c_\theta$ . In particular, if we rewrite (1c) for  $\theta = (\sigma_i, \sigma_j)$  as  $c_\theta \leq 1 - \frac{\psi_{\sigma_i} + \psi_{\sigma_j}}{2}$ , then it is still possible to have  $c_\theta = 1/2$  when  $\psi_{\sigma_i} = 1, \psi_{\sigma_j} = 0$ .

$$\begin{aligned} \max \quad & \frac{1}{4} \sum_{\theta=(\sigma_i, \sigma_j) \in \Theta_A} (3 - w_i \cdot w_0 - w_j \cdot w_0 - w_i \cdot w_j) q_\theta \\ & + \frac{1}{4} \sum_{\theta=(\sigma_i, \sigma_j) \in \Theta_R} (1 + w_i \cdot w_0 + w_j \cdot w_0 + w_i \cdot w_j) q_\theta \end{aligned} \quad (5a)$$

$$\text{s.t.} \quad w_i \cdot w_i = 1 \quad \text{for all } i \in [m] \cup \{0\} \quad (5b)$$

$$w_i \cdot w_0 + w_j \cdot w_0 + w_i \cdot w_j \geq -1 \quad \text{for all } i, j \in [m] \quad (5c)$$

$$-w_i \cdot w_0 + w_j \cdot w_0 - w_i \cdot w_j \geq -1 \quad \text{for all } i, j \in [m] \quad (5d)$$

$$-w_i \cdot w_0 - w_j \cdot w_0 + w_i \cdot w_j \geq -1 \quad \text{for all } i, j \in [m] \quad (5e)$$

$$w_i \in \mathbb{R}^{m+1} \quad \text{for all } i \in [m] \cup \{0\}$$

Constraint (5b) is standard. Constraints (5c)-(5e) encode the triangle inequalities, which are satisfied by every valid solution to the original program; these strengthen the relaxation a bit (see [12, 21]). Let  $\mathcal{V}_{SDP}$  denote the optimal value of this semidefinite program (SDP). We generally cannot find the exact solution to an SDP, but it is possible to find a feasible solution with value at least  $\mathcal{V}_{SDP} - \epsilon$  in time polynomial in  $1/\epsilon$  (see [1]). In our analysis we will (as is typically the case) ignore the  $\epsilon$  factor as it can be made arbitrarily small given sufficient time.

It is known that the SDP written above provides the optimal approximation achievable in polynomial time for any 2-CSPs [22, 23] including our problem, assuming the Unique Games Conjecture (UGC). However, a generic rounding algorithm from this line of work (see e.g. [23]) does not give a concrete approximation ratio. Below, we describe a specific family of rounding algorithms for which we can provide the concrete approximation ratio of 1.1.

## Rounding Algorithm

Given solution vectors  $\{w_0, w_1, \dots, w_m\}$ ,  $w_i \in \mathbb{R}^{m+1}$ , for this SDP we produce a feasible solution  $x_i \in \{-1, 1\}$  (for  $i \in [m]$ ) to the original integer program as follows. Let  $\xi_i = w_0 \cdot w_i$ , and  $\tilde{w}_i = \frac{w_i - \xi_i w_0}{\sqrt{1 - \xi_i^2}}$  be the part of  $w_i$  orthogonal to  $w_0$ , normalized to a unit vector. Our rounding algorithm mostly follows the rounding procedure of [21], which they call  $\mathcal{THRESH}^-$ . First, pick a  $(m+1)$ -dimensional vector<sup>3</sup>  $r \sim \mathcal{N}(0, 1)$   $r \in \mathbb{R}^{m+1}$ . Then, set  $x_i = -1$  (which corresponds to accepting signal  $\sigma_i$ ) if and only if  $\tilde{w}_i \cdot r \leq T(\xi_i)$ , where  $T(\cdot)$  is a threshold function, and set  $x_i = 1$  otherwise. Specifically,  $T(x) = \Phi^{-1}(\frac{1-\nu(x)}{2})$ , where  $\Phi^{-1}(\cdot)$  is the inverse of the normal distribution function, and  $\nu : [-1, 1] \rightarrow [-1, 1]$  is a function. Later in the analysis – and this is essentially the point in which various SDP rounding methods diverge from each other, e.g. see [26] for the different choices for MAX-2-SAT and MAX-2-AND – we will optimize over a family of  $\nu(\cdot)$ , exploiting structure in our problem, in order to improve our approximation ratio.

## Generic Analysis

We now derive a generic analysis for  $\mathcal{THRESH}^-$  algorithms; note that these are similar arguments as in [21, 2]. However, in the end, we will pick a different function  $\nu$  than previous works, which results in better approximation ratios for our problem.

<sup>3</sup> In other words, the  $i$ -th dimension  $r_i$  is sampled independently from a Gaussian with zero mean and variance one.

First, notice that  $\tilde{w}_i \cdot r$  is a standard  $\mathcal{N}(0, 1)$  variable, and therefore by the choice of  $T(\cdot)$  we have that  $\Pr[x_i = -1] = \frac{1 - \nu(\xi_i)}{2}$ , which implies that

$$\mathbb{E}[x_i] = \nu(\xi_i) . \quad (6)$$

Now, we need to also analyze the quadratic terms. Let  $\Gamma_c(\mu_1, \mu_2) = \Pr[X_1 \leq t_1 \text{ and } X_2 \leq t_2]$ , where  $t_i = \Phi^{-1}(\frac{1 - \mu_i}{2})$ , and  $X_1, X_2 \in \mathcal{N}(0, 1)$  with covariance  $c$  (in other words,  $\Gamma_c$  is the bivariate normal distribution function with covariance  $c$ , with a transformation on the input).

Let  $\rho = w_i w_j$  and  $\tilde{\rho} = \tilde{w}_i \tilde{w}_j = \frac{\rho - \xi_i \xi_j}{\sqrt{1 - \xi_i^2} \sqrt{1 - \xi_j^2}}$ . Observe that the products  $\tilde{w}_i \cdot r$  and  $\tilde{w}_j \cdot r$  are  $\mathcal{N}(0, 1)$  random variables with covariance  $\tilde{\rho}$ . Thus, the probability that  $\tilde{w}_i \cdot r \leq T(\xi_i)$  and  $\tilde{w}_j \cdot r \leq T(\xi_j)$  (i.e., both  $x_i, x_j$  are set to  $-1$ ) is exactly  $\Gamma_{\tilde{\rho}}(\nu(\xi_i), \nu(\xi_j))$ . The probability that  $x_i = x_j = 1$  is equal to  $\Gamma_{\tilde{\rho}}(-\nu(\xi_i), -\nu(\xi_j))$ . Austrin [2, Proposition 2.1] shows that  $\Gamma_c(-\mu_1, -\mu_2) = \Gamma_c(\mu_1, \mu_2) + \mu_1/2 + \mu_2/2$ . Using this fact we can calculate the probability that  $x_i = x_j$ , which, in turn, gives that

$$\mathbb{E}[x_i x_j] = 4\Gamma_{\tilde{\rho}}(\nu(\xi_i), \nu(\xi_j)) + \nu(\xi_i) + \nu(\xi_j) - 1 . \quad (7)$$

With Equations (6) and (7) at hand we can calculate the expected value of our rounding algorithm (i.e., the expected value of (4a)) for every choice of  $\nu$ , and compare it against the value of the SDP in (5a). Specifically, we will aim for a term-by-term approximation. Define the following quantities:

$$\begin{aligned} \ell_\nu^{OR}(\xi_i, \xi_j, \rho) &= \frac{3 - \xi_i - \xi_j - \rho}{4 - 2\nu(\xi_i) - 2\nu(\xi_j) - 4\Gamma_{\tilde{\rho}}(\nu(\xi_i), \nu(\xi_j))} \\ \ell_\nu^{AND}(\xi_i, \xi_j, \rho) &= \frac{1 + \xi_i + \xi_j + \rho}{2\nu(\xi_i) + 2\nu(\xi_j) + 4\Gamma_{\tilde{\rho}}(\nu(\xi_i), \nu(\xi_j))} , \end{aligned}$$

and let

$$\ell^{OR}(\nu) = \min_{\xi_i, \xi_j, \rho} \ell_\nu^{OR}(\xi_i, \xi_j, \rho) \quad \text{and} \quad \ell^{AND}(\nu) = \min_{\xi_i, \xi_j, \rho} \ell_\nu^{AND}(\xi_i, \xi_j, \rho) ,$$

where the minimization is over all choices of  $\xi_i, \xi_j, \rho \in [-1, 1]$  that satisfy the triangle inequalities (Constraints (5c)-(5e)). It is now straightforward to see that the term-by-term analysis implies that, for any choice of  $\nu$ , our approximation ratio is at most  $\max\{\ell^{OR}(\nu), \ell^{AND}(\nu)\}$ .

### Choosing $\nu$ and Putting Things Together

We are left to choose the function  $\nu$  that results in the smallest approximation ratio  $\max\{\ell^{OR}(\nu), \ell^{AND}(\nu)\}$ . We consider a rounding function of the form  $\nu(y) = \alpha \cdot y + \beta$  for parameters  $\alpha, \beta$  to be chosen. Using extensive computational effort, we found that  $\alpha = 0.8825$  and  $\beta = 0.0384$  perform well. Once we have a choice for  $\alpha$  and  $\beta$ , it remains to prove the approximation ratio.

We have a computer-assisted proof showing that the approximation ratio is at most 1.1; our computer-based proof approach is similar to that of [26]. Roughly speaking, we divide the cube  $(\xi_i, \xi_j, \rho) \in [-1, 1]^3$  into a certain number of subcubes. For each subcube, we (numerically) compute an upper bound to  $\max\{\ell_\nu^{OR}(\xi_i, \xi_j, \rho), \ell_\nu^{AND}(\xi_i, \xi_j, \rho)\}$ . If this upper bound is already at most 1.1, then we are finished with the subcube. Otherwise, we divide it further into a certain number of subcubes. By continuing this process, we eventually manage to show that for the whole region  $[-1, 1]^3$  that satisfies the triangle inequalities, the ratio must be at most 1.1, as desired. (The smallest subcube our proof considers has edge length 0.00078.)

## Comparison to Prior Work

As stated earlier, our algorithm, with the exception of the choice of  $\nu$ , is similar to [21] and the follow-up works (e.g. [2, 26]). However, perhaps surprisingly, we end up with a better approximation ratio than the MAX 2-AND problem<sup>4</sup>, whose approximation ratio is known to be at least 1.143 assuming the UGC [3]. To understand the difference, recall that MAX 2-AND can be written as  $\max \frac{1}{4} \sum_{(i,j,b_i,b_j)} (1 + b_i x_i + b_j x_j + b_i b_j x_i x_j)$  where  $b_i, b_j \in \{\pm 1\}$  (representing whether the variable is negated in the clause). This is very similar to our problem (4a), except that MAX 2-AND has the aforementioned  $b_i, b_j$ -terms for negation. It turns out that this is also the cause that we can achieve better approximation ratio. Specifically, these negation terms led previous works [21, 2, 26, 3] to only consider  $\nu$  that is an odd function, i.e.,  $\nu(y) = \nu(-y)$  for all  $x \in [-1, 1]$ . For example, Austrin [2] considers a function of the form  $\nu(y) = \alpha \cdot y$ . We note here that, due to the aforementioned UGC-hardness of MAX 2-AND, we cannot hope to get an approximation ratio smaller than 1.143 using odd  $\nu$ . Nonetheless, since we do not have “negation” in our problem, we are not only restricted to odd  $\nu$ , allowing us to consider a more general family of the form  $\nu(y) = \alpha \cdot y + \beta$  for  $\beta \neq 0$ . This ultimately leads to our better approximation ratio.

## 5 Constrained Persuasion

Let us now turn to the constrained persuasion problem. The sender first commits to a signaling scheme  $\varphi$ , which she then uses to transmit information to the receiver, once the state of nature is revealed. Given that the sender has commitment power and the receiver knows  $\varphi$ , the receiver picks action A if and only if conditioned on receiving signal  $\sigma$ , the expected utility of A is more than R, i.e.,

$$\sum_{\theta \in N(\sigma) \cap \Theta_A} \varphi(\theta, \sigma) \geq \sum_{\theta \in N(\sigma) \cap \Theta_R} \varphi(\theta, \sigma)$$

or, equivalently,  $2 \cdot \sum_{\theta \in N(\sigma) \cap \Theta_A} \varphi(\theta, \sigma) \geq \sum_{\theta \in N(\sigma)} \varphi(\theta, \sigma)$ .

In this case, we say that  $\sigma$  is an *accept signal*, otherwise we call  $\sigma$  a *reject signal*. An optimal signaling scheme  $\varphi^*$  maximizes the expected utility of the sender, i.e., the total probability associated with accept signals. Note that if both accepting and rejecting are optimal actions for the receiver, we assume that she breaks ties in favor of the sender (so, in our case, accept). This mild assumption is standard in economic bilevel problems (e.g., when indifferent between buying and not buying, a potential customer is usually assumed to buy) and is often without loss of generality. This way we avoid obfuscating technicalities in the definition of optimal schemes  $\varphi^*$ .

We study the computational complexity of finding  $\varphi^*$  and polynomial-time approximation algorithms. In general, approximating  $\varphi^*$  can be an extremely hard problem, even in the constrained persuasion problem. Our first insight in Section 5.1 is that the main source of hardness in the problem is deciding the optimal set of accept signals. We then provide a simple  $2n$ -approximation algorithm and a  $n^{1-\epsilon}$ -hardness in Section 5.2. The PTAS and the matching strong NP-hardness for instances with unique accepts is discussed in Section 5.3.

<sup>4</sup> This is the problem where we are given a set of clauses, each of which is an AND of two literals. The goal is to assign the variables as to maximize the number of satisfied clauses.

### 5.1 Signal Partitions

A signaling scheme  $\varphi$  partitions the signal space  $\Sigma$  into  $(\Sigma_A, \Sigma_R)$ , in the sense that the receiver takes action  $A$  if and only if she gets signal  $\sigma \in \Sigma_A$  (and  $R$  for  $\Sigma_R$ ). Determining this partition of the signal set turns out to be the main source of computational hardness of finding  $\varphi^*$ : Given an optimal partition of the signal set, the reduced problem of computing appropriate optimal signaling probabilities is solved with a linear program.

We prove this result in a general case of the persuasion problem, in which the receiver has an arbitrary finite set  $\mathcal{A}$  of actions. Moreover, sender and receiver can have utilities  $u_s, u_r : \mathcal{A} \times \Theta \rightarrow \mathbb{R}$  that yield arbitrary positive or negative values for every (state of nature, action)-pair.

► **Proposition 12.** *Given a partition  $P = (\Sigma_a)_{a \in \mathcal{A}}$  of the signal space such that the receiver's best action for a signal  $\sigma \in \Sigma_a$  is action  $a$ , an optimal signaling scheme  $\varphi_P^*$  for the general persuasion problem that (1) implements these receiver preferences and (2) maximizes the sender utility, can be computed by solving a linear program of polynomial size.*

**Proof.** Given  $P = (\Sigma_a)_{a \in \mathcal{A}}$ , consider the following linear program (8).

$$\begin{aligned}
 \text{Max.} \quad & \sum_{a \in \mathcal{A}} \sum_{\sigma \in \Sigma_a} \sum_{\theta \in N(\sigma)} x_{\theta, \sigma} \cdot u_s(a, \theta) \\
 \text{s.t.} \quad & \sum_{\theta \in N(\sigma)} x_{\theta, \sigma} \cdot u_r(a, \theta) \geq \sum_{\theta \in N(\sigma)} x_{\theta, \sigma} \cdot u_r(a', \theta) \quad \text{for all } a \in \mathcal{A}, \sigma \in \Sigma_a, a' \in \mathcal{A} \\
 & \sum_{\sigma \in N(\theta)} x_{\theta, \sigma} = q_\theta \quad \text{for all } \theta \in \Theta \\
 & x_{\theta, \sigma} \geq 0 \quad \text{for all } \sigma \in \Sigma, \theta \in N(\sigma)
 \end{aligned} \tag{8}$$

For each  $\sigma \in \Sigma_a$  and every action  $a' \neq a$  we must satisfy that  $\mathbb{E}[u_r(a, \theta) \mid \sigma] \geq \mathbb{E}[u_r(a', \theta) \mid \sigma]$ , encoded by the first constraint. The other two constraints encode the feasibility of the scheme. Subject to these constraints, the objective is to maximize the expected utility of the sender. An optimal LP-solution  $x^*$  directly implies an optimal signaling scheme  $\varphi_P^*(\theta, \sigma) = x_{\theta, \sigma}^*$ . ◀

### 5.2 A $2n$ -Approximation Algorithm and Hardness

Going back to constrained persuasion with binary actions, we start by giving a simple  $2n$ -approximation algorithm. First, we give a useful benchmark for the optimal scheme.

► **Lemma 13.** *An optimal signaling scheme  $\varphi^*$  yields a sender utility of at most  $\min\{1, 2q_A\}$ .*

**Proof.** The upper bound of 1 is trivial.  $\varphi^*$  partitions the signal space into  $(\Sigma_A, \Sigma_R)$ , the accept and reject signals, respectively. The expected utility of the sender is

$$\sum_{\sigma \in \Sigma_A} \sum_{\theta \in N(\sigma)} \varphi^*(\theta, \sigma) \leq \sum_{\sigma \in \Sigma_A} \sum_{\theta \in N(\sigma) \cap \Theta_A} 2 \cdot \varphi^*(\theta, \sigma) \leq 2 \sum_{\theta \in \Theta_A} q_\theta = 2 \cdot q_A. \quad \blacktriangleleft$$

Our simple algorithm considers the  $m$  partitions with a single accept signal  $\Sigma_A = \{\sigma\}$ , for every  $\sigma \in \Sigma$ . For each such partition, the algorithm determines an optimal scheme and then picks the best one, among all  $m$  partitions. Instead of solving the LP of Proposition 12, given a proposed partition we proceed as follows. Assign as much probability mass from  $\Theta_A \cap N(\sigma)$  to  $\sigma$  and at most the same amount from  $\Theta_R \cap N(\sigma)$  – this ensures that  $\sigma$  is an accept signal. The remaining probability mass is assigned arbitrarily to other signals. Note that if this is impossible, there is no scheme that makes  $\sigma$  an accept signal.

► **Proposition 14.** *For constrained persuasion there is a  $2n$ -approximation algorithm that runs in polynomial time.*

**Proof.** Suppose  $\theta' \in \Theta_A$  is an acceptable state from which  $\varphi^*$  assigns the largest amount to accept signals, i.e.,  $\theta' = \arg \max_{\theta \in \Theta_A} \sum_{\sigma \in \Sigma_A \cap N(\theta)} \varphi^*(\theta, \sigma)$ . Clearly, the optimum accumulates on the accept signals at most  $n$  times this probability mass from the set of acceptable states, and at most the same from rejectable states. Hence,  $\sum_{\sigma \in \Sigma_A \cap N(\theta')} \varphi^*(\theta', \sigma) < q_{\theta'}$  is at least a  $1/(2n)$ -fraction of the optimal sender utility.

Consider the accept signals  $\Sigma_A$  in  $\varphi^*$  and any such signal  $\sigma' \in N(\theta') \cap \Sigma_A$ . When our algorithm checks the partition with  $\sigma'$  as the unique accept signal, it finds a feasible scheme, since the optimum scheme makes  $\sigma'$  an accept signal and the algorithm only assigns more probability from  $\Theta_A$  to  $\sigma'$ . The value of this solution is at least  $q_{\theta'}$ . ◀

In addition to this simple algorithm, we show a number of strong hardness results for constrained persuasion. The proofs of the following two theorems can be found in the full version.

► **Theorem 15.** *For any constant  $\varepsilon > 0$ , constrained persuasion is NP-hard to approximate within a factor of  $n^{1-\varepsilon}$ , even for instances with degree-2 states and degree-1 accepts.*

For instances with degree-1 rejects a similar result follows with a slightly different reduction.

► **Theorem 16.** *For any constant  $\varepsilon > 0$ , constrained persuasion is NP-hard to approximate within a factor of  $n^{1-\varepsilon}$ , even for instances with degree-1 rejects.*

### 5.3 Unique Accepts

In this section, we examine instances in which there is only a single acceptable state, for which we prove NP-hardness and give a PTAS. It will be convenient to state a lemma which allows us to get a better handle on the sender utility in an optimal signaling scheme for a given signal partition. This lemma will be helpful in both our hardness and algorithm analyses.

To state this lemma, we need some additional notation: for every subset  $\tilde{\Sigma} \subseteq \Sigma$ , we use  $\Theta_R(\tilde{\Sigma})$  to denote  $\{\theta \in \Theta_R \mid N(\theta) \subseteq \tilde{\Sigma}\}$ ; when  $\tilde{\Sigma} = \{\sigma\}$  is a singleton, we write  $\Theta_R(\sigma)$  in place of  $\Theta_R(\{\sigma\})$  for brevity. Moreover, let  $N(\tilde{\Sigma})$  denote  $\bigcup_{\sigma \in \tilde{\Sigma}} N(\sigma)$ . The lemma can now be stated as follows.

► **Lemma 17.** *Suppose that there exists a unique accept state  $\theta_a$ . For any partition  $P = (\Sigma_A, \Sigma_R)$  of the signal space such that  $\Sigma_A \neq \emptyset$ , we have*

1. *There exists a signaling scheme  $\varphi$  such that every signal in  $\Sigma_A$  is accepted and every signal in  $\Sigma_R$  is rejected by the receiver if and only if  $\Sigma_A \subseteq N(\theta_a)$  and  $\sum_{\theta \in \Theta_R(\Sigma_A)} q_\theta \leq q_{\theta_a}$ .*
2. *When the above condition holds, any optimal signaling scheme  $\varphi^*$  for the sender has utility equal to  $\min\{2q_{\theta_a}, \sum_{\theta \in N(\Sigma_A)} q_\theta\}$ , and, such a signaling scheme can be computed in polynomial time.*

We remark that the algorithm for finding  $\varphi^*$  in the above lemma is a simple greedy algorithm that tries to “put as much probability mass from rejectable states as possible” in  $\Sigma_A$  and then use the probability mass of the acceptable state  $\theta_a$  to “balance out” the mass from the rejectable states, so that eventually the signals in  $\Sigma_A$  are accepted. This is in contrast to the generic linear program-based algorithm in Proposition 12. The simpler greedy algorithm allows us to consider more concrete conditions and exactly compute the utility as stated in Lemma 17.

**Proof of Lemma 17.**

1. ( $\Rightarrow$ ) First, assume that there is such a signaling scheme  $\varphi$ . Clearly, every signal not in  $N(\theta_a)$  must be rejected, which implies that  $\Sigma_A \subseteq N(\theta_a)$ . Furthermore, for all  $\sigma \in \Sigma_A$ , we must have  $\varphi(\theta_a, \sigma) \geq \sum_{\theta \in N(\sigma) \cap \Theta_R} \varphi(\theta, \sigma)$ . Summing up over all  $\sigma \in \Sigma_A$  gives

$$\begin{aligned} q_{\theta_a} &\geq \sum_{\sigma \in \Sigma_A} \sum_{\theta \in N(\sigma) \cap \Theta_R} \varphi(\theta, \sigma) \\ &\geq \sum_{\sigma \in \Sigma_A} \sum_{\theta \in \Theta_R(\Sigma_A)} \varphi(\theta, \sigma) = \sum_{\theta \in \Theta_R(\Sigma_A)} \sum_{\sigma \in \Sigma_A} \varphi(\theta, \sigma) = \sum_{\theta \in \Theta_R(\Sigma_A)} q_{\theta}. \end{aligned}$$

- ( $\Leftarrow$ ) Assume that  $\emptyset \neq \Sigma_A \subseteq N(\theta_a)$  and  $\sum_{\theta \in \Theta_R(\Sigma_A)} q_{\theta} \leq q_{\theta_a}$ . We may construct a desired signaling scheme  $\varphi$  as follows. First, we assign  $\varphi(\theta, \sigma)$  arbitrarily for all  $\theta \in \Theta_R(\Sigma_A)$ . Then, we assign  $\varphi(\theta_a, \sigma)$  such that  $\varphi(\theta_a, \sigma) = 0$  for all  $\sigma \notin \Sigma_A$  and that  $\varphi(\theta_a, \sigma) \geq \sum_{\theta \in \Theta_R(\Sigma_A)} \varphi(\theta, \sigma)$  for all  $\sigma \in \Sigma_A$ . The former is possible because  $\Sigma_A \neq \emptyset$  and the latter possible because  $\sum_{\theta \in \Theta_R(\Sigma_A)} q_{\theta} \leq q_{\theta_a}$ . Finally, for each  $\theta \in \Theta_R \setminus \Theta_R(\Sigma_A)$ , assign  $\varphi(\theta, \sigma) = 0$  for all  $\sigma \in \Sigma_A$ . It is straightforward from the construction that this  $\varphi$  is a desired signaling scheme.
2. First, we will show that any signaling scheme  $\varphi$  has utility at most  $\min\{2q_{\theta_a}, \sum_{\theta \in N(\Sigma_A)} q_{\theta}\}$  for the sender. Observe that the upper bound  $2q_{\theta_a}$  follows trivially from Lemma 13. Thus, it suffices for us to prove that the utility is at most  $\sum_{\theta \in N(\Sigma_A)} q_{\theta}$ . To do so, let us rearrange the utility as follows:

$$\sum_{\sigma \in \Sigma_A} \sum_{\theta \in N(\sigma)} \varphi(\theta, \sigma) \leq \sum_{\theta \in N(\Sigma_A)} \sum_{\sigma \in N(\theta)} \varphi(\theta, \sigma) = \sum_{\theta \in N(\Sigma_A)} q_{\theta}.$$

Finally, we construct a signaling scheme  $\varphi^*$  with utility equal to  $\min\{2q_{\theta_a}, \sum_{\theta \in N(\Sigma_A)} q_{\theta}\}$ . The algorithm is a modification of the algorithm from the first part, and it works in four steps:

- For every  $\theta \in \Theta_R(\Sigma_A)$ , assign  $\varphi(\theta, \sigma)$  arbitrarily.
- For every  $\theta \in (N(\Sigma_A) \cap \Theta_R) \setminus \Theta_R(\Sigma_A)$ , assign  $\varphi(\theta, \sigma)$  so that

$$\sum_{\sigma \in \Sigma_A} \sum_{\theta \in N(\sigma) \cap \Theta_R} \varphi(\theta, \sigma) = \min\{q_{\theta_a}, \sum_{\theta \in N(\Sigma_A) \cap \Theta_R} q_{\theta}\}.$$

Note that this step is possible because  $\sum_{\theta \in \Theta_R(\Sigma_A)} q_{\theta} \leq q_{\theta_a}$ .

- Assign  $\varphi(\theta_a, \sigma)$  so that  $\varphi(\theta_a, \sigma) = 0$  for all  $\sigma \notin \Sigma_A$ , and that

$$\varphi(\theta_a, \sigma) \geq \sum_{\theta \in N(\sigma) \cap \Theta_R} \varphi(\theta, \sigma)$$

for all  $\sigma \in \Sigma_A$ . Note that this is possible because, from the previous step, we must have  $\sum_{\sigma \in \Sigma_A} \sum_{\theta \in N(\sigma) \cap \Theta_R} \varphi(\theta, \sigma) \leq q_{\theta_a}$ .

- All other remaining assignments are made arbitrarily in order to turn  $\varphi$  into a feasible signaling scheme.

It is straightforward to check that  $\varphi^*$  is the desired signaling scheme with utility equal to  $q_{\theta_a} + \min\{q_{\theta_a}, \sum_{\theta \in N(\Sigma_A) \cap \Theta_R} q_{\theta}\} = \min\{2q_{\theta_a}, \sum_{\theta \in N(\Sigma_A)} q_{\theta}\}$ .  $\blacktriangleleft$

With Lemma 17 ready, we now prove NP-hardness of the problem.

► **Theorem 18.** *Constrained persuasion with unique accepts is NP-hard.*

**Proof.** We reduce from the MAX-K-VERTEX-COVER problem, where we have a graph  $G = (V, E)$ . The goal is to choose a set  $V'$  of  $k$  vertices in order to maximize the number of edges incident to at least one vertex in  $V'$ . For every vertex  $v \in V$ , let  $E(v)$  be the set of incident edges, then we try to pick a subset  $V'$  of  $k$  vertices to maximize  $|\bigcup_{v \in V'} E(v)|$ .

For each edge  $e \in E$ , we introduce a rejectable state  $\theta_e$  with  $q_{\theta_e} = \frac{1}{(|V|+k)(|E|+1)+2|E|}$ . For each vertex  $v$  we introduce a signal  $\sigma_v$ . The graph  $H$  between states and signals expresses the incident property of edges and vertices. In addition, for each signal  $\sigma$ , we introduce an auxiliary rejectable states that have  $\sigma$  as their unique signal. Each auxiliary state  $\theta$  has  $q_\theta = \frac{|E|+1}{(|V|+k)(|E|+1)+2|E|}$ . Finally, the unique acceptable state  $\theta_a$  is incident to all signals and has probability

$$q_{\theta_a} = \frac{k(|E|+1) + |E|}{(|V|+k)(|E|+1) + 2|E|}.$$

From Lemma 17, the optimal signaling scheme has sender utility equal to

$$\max_{\Sigma_A} \min \left\{ 2q_{\theta_a}, \sum_{\theta \in N(\Sigma_A)} q_\theta \right\},$$

where the maximum is over non-empty  $\Sigma_A \subseteq \Sigma$  such that  $\sum_{\theta \in \Theta_R(\Sigma_A)} q_\theta \leq q_{\theta_a}$ . Notice that, in our construction, this condition is satisfied iff  $|\Sigma_A| \leq k$ . This means that  $\Sigma_A = \{\sigma_v\}_{v \in V'}$  for some subset  $V'$  of size at most  $k$ . It is also not hard to see that

$$\min \left\{ 2q_{\theta_a}, \sum_{\theta \in N(\Sigma_A)} q_\theta \right\} = \sum_{\theta \in N(\Sigma_A)} q_\theta = \frac{(|V'|+k)(|E|+1) + |\bigcup_{v \in V'} E(v)|}{(|V|+k)(|E|+1) + 2|E|}.$$

In other words, the utility is maximized iff  $V'$  is an optimal solution to the instance of MAX-K-VERTEX-COVER. Since the latter is NP-hard, we can conclude that constrained persuasion with unique accepts is also NP-hard.  $\blacktriangleleft$

We next give a PTAS for the problem. Before we formalize our PTAS, let us give an informal intuition. Observe that the condition in Lemma 17 implies that  $q_{\theta_a} \geq \sum_{\sigma \in \Sigma_A} \left( \sum_{\theta \in \Theta_R(\sigma)} q_\theta \right)$ . This latter constraint is a *knapsack constraint*. One generic strategy to solve knapsack problems is to first brute-force enumerate all possibilities of selecting “heavy items”, which in our case are the signals with large  $\sum_{\theta \in \Theta_R(\sigma)} q_\theta$ . Then, use a simple greedy algorithm for the remaining “light items”. Our PTAS follows this blueprint. However, since neither our constraints nor our objective function are exactly the same as in knapsack problems, we cannot use results from there directly and have to carefully argue the approximation guarantee ourselves.

► **Theorem 19.** *For constrained persuasion with unique accepts, for every fixed  $\varepsilon \in (0, 1]$ , Algorithm 1 runs in time  $m^{O(1/\varepsilon)} n^{O(1)}$  and outputs a  $(1 + \varepsilon)$  approximate solution.*

**Proof.** It is clear that our algorithm runs in time  $m^{O(1/\varepsilon)} n^{O(1)}$ . Let  $\varphi^*$  be any optimal signaling scheme, with utility OPT for the sender. We prove that the utility of  $\varphi_{\text{ALG}}$  is at least  $(1 - 0.5\varepsilon)\text{OPT}$ .

Without loss of generality we assume that the utility of  $\varphi^*$  is non-zero. Now, let  $(\Sigma_A^*, \Sigma_R^*)$  denote the signal partition of  $\varphi^*$ ; since the utility of  $\varphi^*$  is non-zero, we must have  $\Sigma_A^* \neq \emptyset$ . Furthermore, the first item of Lemma 17 implies that  $\Sigma_A^* \cap \Sigma_{\geq \varepsilon}$  must be of size at most  $1/\varepsilon$ . As a result, our algorithm must consider  $S = (\Sigma_A^* \cap \Sigma_{\geq \varepsilon})$  in the for-loop (3). For this particular  $S$ , let  $T'$  denote the largest  $T$  for which Line (6) is executed. We next consider two cases, based on whether or not we have  $T' = S \cup (\Sigma_{< \varepsilon} \cap N(\theta_a))$ .

■ **Algorithm 1** A PTAS for constrained persuasion with unique accepts.

---

**Input:** Graphs  $H$  with a single acceptable state  $\theta_a$ , and  $\varepsilon > 0$ .

- 1 Let  $\Sigma_{\geq \varepsilon}$  be the set of all signals  $\sigma \in \Sigma$  such that  $\sum_{\theta \in \Theta_R(\sigma)} q_\theta \geq \varepsilon q_{\theta_a}$ . Then, let  $\Sigma_{< \varepsilon} = \Sigma \setminus \Sigma_{\geq \varepsilon}$ ;
- 2 Let  $\varphi_{\text{ALG}}$  be an arbitrary signaling scheme;
- 3 **for** every (possibly empty) subset  $S \subseteq \Sigma_{\geq \varepsilon}$  of size at most  $1/\varepsilon$  **do**
- 4     Let  $T = S$ ;
- 5     **while**  $\sum_{\theta \in \Theta_R(T)} q_\theta \leq q_{\theta_a}$  **do**
- 6         If the utility of  $\varphi_{\text{ALG}}$  is less than  $\min\{2q_{\theta_a}, \sum_{\theta \in N(T)} q_\theta\}$ , then let  $\varphi_{\text{ALG}}$  be the optimal signaling scheme consistent with signaling partition  $\Sigma_A = T$ , which can be computed in polynomial time due to Lemma 17 ;
- 7         If  $T = \Sigma_{< \varepsilon} \cap N(\theta_a)$ , break from the loop;
- 8         Otherwise, add an arbitrary signal from  $(\Sigma_{< \varepsilon} \cap N(\theta_a)) \setminus T$  to  $T$ ;
- 9     **end**
- 10 **end**

**Output:**  $\varphi_{\text{ALG}}$ .

---

- Case I:  $T' = S \cup (\Sigma_{< \varepsilon} \cap N(\theta_a))$ . Notice that  $T' \supseteq \Sigma_A^*$ . Lemma 17, implies that the utility of  $\varphi_{\text{ALG}}$  must be at least OPT.
- Case II:  $T' \neq S \cup (\Sigma_{< \varepsilon} \cap N(\theta_a))$ . This means that there exists a signal  $\sigma^* \in (\Sigma_{< \varepsilon} \cap N(\theta_a))$  whose addition to  $T'$  breaks the condition of the while-loop (5), i.e.,  $q_{\theta_a} < \sum_{\theta \in \Theta_R(T' \cup \{\sigma^*\})} q_\theta$ . The right hand side of this inequality is equal to

$$\begin{aligned}
 \sum_{\substack{\theta \in \Theta_R \\ N(\theta) \subseteq (T' \cup \{\sigma^*\})}} q_\theta &\leq \sum_{\substack{\theta \in \Theta_R \\ N(\theta) \cap T' \neq \emptyset}} q_\theta + \sum_{\substack{\theta \in \Theta_R \\ N(\theta) = \{\sigma^*\}}} q_\theta \\
 &= \sum_{\theta \in N(T') \cap \Theta_R} q_\theta + \sum_{\theta \in \Theta_R(\sigma^*)} q_\theta \\
 &< \sum_{\theta \in N(T') \cap \Theta_R} q_\theta + \varepsilon q_{\theta_a} ,
 \end{aligned}$$

where the last inequality since  $\sigma$  belongs to  $\Sigma_{< \varepsilon}$ . Combining the two inequalities we have

$$\sum_{\theta \in N(T') \cap \Theta_R} q_\theta > (1 - \varepsilon) q_{\theta_a} . \tag{9}$$

On the other hand, from Lemma 17, when we execute line Line (6) for  $T = T'$ , it must result in a signaling scheme of utility

$$\min \left\{ 2q_{\theta_a}, \sum_{\theta \in N(T')} q_\theta \right\} = \min \left\{ 2q_{\theta_a}, q_{\theta_a} + \sum_{\theta \in N(T') \cap \Theta_R} q_\theta \right\} \stackrel{(9)}{>} (2 - \varepsilon) q_{\theta_a} ,$$

which is at least  $(1 - 0.5\varepsilon)\text{OPT}$  due to Lemma 13.

Hence, we can conclude that our algorithm always outputs a signaling scheme with sender utility at least  $(1 - 0.5\varepsilon)\text{OPT}$ . In other words, its approximation ratio is at most  $\frac{1}{1 - 0.5\varepsilon} \leq 1 + \varepsilon$ . ◀

# The Complexity of Finding Fair Independent Sets in Cycles

Ishay Haviv

---

## Abstract

Let  $G$  be a cycle graph and let  $V_1, \dots, V_m$  be a partition of its vertex set into  $m$  sets. An independent set  $S$  of  $G$  is said to *fairly represent* the partition if  $|S \cap V_i| \geq \frac{1}{2} \cdot |V_i| - 1$  for all  $i \in [m]$ . It is known that for every cycle and every partition of its vertex set, there exists an independent set that fairly represents the partition (Aharoni et al., A Journey through Discrete Math., 2017). We prove that the problem of finding such an independent set is PPA-complete. As an application, we show that the problem of finding a monochromatic edge in a Schrijver graph, given a succinct representation of a coloring that uses fewer colors than its chromatic number, is PPA-complete as well. The work is motivated by the computational aspects of the “cycle plus triangles” problem and of its extensions.

## 1 Introduction

In 1986, Du, Hsu, and Hwang [19] conjectured that if a graph on  $3n$  vertices is the disjoint union of a Hamilton cycle of length  $3n$  and  $n$  pairwise vertex-disjoint triangles then its independence number is  $n$ . The conjecture has become known as the “cycle plus triangles” problem and has been strengthened by Erdős [20], who conjectured that such a graph is 3-colorable. Fleischner and Stiebitz [26] confirmed these conjectures in a strong form and proved, using an algebraic approach of Alon and Tarsi [6], that such a graph is in fact 3-choosable. Their proof can also be viewed as an application of Alon’s Combinatorial Nullstellensatz technique [4]. Slightly later, an alternative elementary proof of the 3-coloring result was given by Sachs [39]. However, none of these proofs supplies an efficient algorithm that given a graph on  $3n$  vertices whose set of edges is the disjoint union of a Hamilton cycle and  $n$  pairwise vertex-disjoint triangles finds a 3-coloring of the graph or an independent set of size  $n$ . Questions on the computational aspects of the problem were posed in several works over the years (see, e.g., [27, 5, 9, 1]).

A natural extension of the problem of Du et al. [19] is the following. Let  $G$  be a cycle and let  $V_1, \dots, V_m$  be a partition of its vertex set into  $m$  sets. We are interested in an independent set of  $G$  that (almost) *fairly represents* the given partition, that is, an independent set  $S$  of  $G$  satisfying  $|S \cap V_i| \geq \frac{1}{2} \cdot |V_i| - 1$  for all  $i \in [m] = \{1, \dots, m\}$ . The existence of such an independent set was proved in a recent work of Aharoni, Alon, Berger, Chudnovsky, Kotlar, Loeb, and Ziv [1]. For the special case where all the sets  $V_i$  are of size 3, the proof technique of Aharoni et al. [1] allowed them to show that there are *two* disjoint independent

sets that fairly represent the partition, providing a new proof of a stronger form of the original conjecture of Du et al. [19]. The results of [1] were extended in a work of Alishahi and Meunier [3] who proved the following.

► **Theorem 1** ([3]). *Let  $G$  be a cycle on  $n$  vertices and let  $V_1, \dots, V_m$  be a partition of its vertex set into  $m$  sets. Suppose that  $n$  and  $m$  have the same parity. Then, there exist two disjoint independent sets  $S_1$  and  $S_2$  of  $G$  covering all vertices but one from each  $V_i$  such that for each  $j \in \{1, 2\}$ , it holds that  $|S_j \cap V_i| \geq \frac{1}{2} \cdot |V_i| - 1$  for all  $i \in [m]$ .*

As shown by Black et al. [10], analogues of Theorem 1 for paths and for partitions into sets of odd sizes can also be proved using the approach of Aharoni et al. [1].

It is interesting to mention that although the statements of Theorem 1 and of its aforementioned variants are purely combinatorial, all of their known proofs are based on tools from topology. The use of topological methods in combinatorics was initiated by Lovász [32] who applied the Borsuk-Ulam theorem [11] from algebraic topology to prove a conjecture of Kneser [31] on the chromatic number of Kneser graphs. For integers  $n \geq 2k$ , the *Kneser graph*  $K(n, k)$  is the graph whose vertices are all the  $k$ -subsets of  $[n]$  where two sets are adjacent if they are disjoint. It was proved in [32] that the chromatic number of  $K(n, k)$  is  $n - 2k + 2$ , a result that was strengthened and generalized by several researchers (see, e.g., [34, Chapter 3]). One such strengthening was obtained by Schrijver [40], who studied the subgraph of  $K(n, k)$  induced by the collection of all  $k$ -subsets of  $[n]$  with no two consecutive elements modulo  $n$ . This graph is denoted by  $S(n, k)$  and is commonly referred to as the *Schrijver graph*. It was proved in [40], again by a topological argument, that the chromatic number of  $S(n, k)$  is equal to that of  $K(n, k)$ . As for Theorem 1, the proof of Alishahi and Meunier [3] employs the Octahedral Tucker lemma that was applied by Matoušek [33] in an alternative proof of Kneser's conjecture and can be viewed as a combinatorial formulation of the Borsuk-Ulam theorem (see also [42]). The approach of Aharoni et al. [1] and of Black et al. [10], however, is based on a direct application of the chromatic number of the Schrijver graph. As before, these proofs are not constructive, in the sense that they do not suggest efficient algorithms for the corresponding search problems. Understanding the computational complexity of these problems is the main motivation for the current work.

In 1994, Papadimitriou [38] has initiated the study of the complexity of total search problems in view of the mathematical argument that lies at the existence proof of their solutions. Let TFNP be the complexity class, defined in [35], of total search problems in NP, that is, the class of search problems in which a solution is guaranteed to exist and can be verified in polynomial running-time. Papadimitriou has introduced in [38] several subclasses of TFNP, each of which consists of the total search problems that can be reduced to a problem that represents some mathematical argument. For example, the class PPA (Polynomial Parity Argument) corresponds to the simple fact that every graph with maximum degree 2 that has a vertex of degree 1 must have another degree 1 vertex. Hence, PPA is defined as the class of all problems in TFNP that can be efficiently reduced to the LEAF problem, in which given a succinct representation of a graph with maximum degree 2 and given a vertex of degree 1 in the graph, the goal is to find another such vertex. The class PPAD (Polynomial Parity Argument in Directed graphs) is defined similarly with respect to directed graphs. Another complexity class defined in [38] is PPP (Polynomial Pigeonhole Principle) whose underlying mathematical argument is the pigeonhole principle. Additional examples of complexity classes defined in this way are PLS (Polynomial Local Search) [30], CLS (Continuous Local Search) [15], and EOPL (End of Potential Line) [21].

The complexity class PPAD is known to perfectly capture the complexity of many important search problems. Notable examples of PPAD-complete problems are those associated with Sperner's lemma [38, 12], the Nash Equilibrium theorem [13, 14], the Envy-Free Cake

Cutting theorem [18], and the Hairy Ball theorem [29]. For PPA, the undirected analogue of PPAD, until recently there were not known complete problems that are “natural”, i.e., do not involve circuits and Turing machines in their definitions. In the last few years, the situation was changed following a breakthrough result of Filos-Ratsikas and Goldberg [23, 24], who proved that the Consensus Halving problem with inverse-polynomial precision parameter is PPA-complete (see also [25]) and used it to derive the PPA-completeness of the classical Splitting Necklace with two thieves and Discrete Sandwich problems. This was obtained building on the PPA-hardness, proved by Aisenberg, Bonet, and Buss [2], of the search problem associated with Tucker’s lemma. The variant of the problem that corresponds to the Octahedral Tucker lemma was suggested for study by Pálvölgyi [37] and proved to be PPA-complete by Deng, Feng, and Kulkarni [17]. Additional PPA-complete problems, related to the Combinatorial Nullstellensatz and the Chevalley-Waring theorem, were provided by Belovs et al. [8].

## 1.1 Our Contribution

The present work initiates the study of the complexity of finding independent sets that fairly represent a given partition of the vertex set of a cycle. It is motivated by the computational aspects of combinatorial existence statements, such as the “cycle plus triangles” conjecture of Du et al. [19] proved by Fleischner and Stiebitz [26] and its extensions by Aharoni et al. [1], Alishahi and Meunier [3], and Black et al. [10]. As mentioned before, the challenge of understanding the complexity of the corresponding search problems was explicitly raised by several authors, including Fleischner and Stiebitz [27], Alon [5], and Aharoni et al. [1]. In this work we demonstrate that this research avenue may illuminate interesting connections between this family of problems and the complexity class PPA.

We start by introducing the Fair Independent Set in Cycle Problem, which we denote by FAIR-IS-CYCLE and define as follows.

► **Definition 2** (Fair Independent Set in Cycle Problem). *In the FAIR-IS-CYCLE problem, the input consists of a cycle  $G$  and a partition  $V_1, \dots, V_m$  of its vertex set into  $m$  sets. The goal is to find an independent set  $S$  of  $G$  satisfying  $|S \cap V_i| \geq \frac{1}{2} \cdot |V_i| - 1$  for all  $i \in [m]$ .*

The existence of a solution to every input of FAIR-IS-CYCLE is guaranteed by a result of Aharoni et al. [1, Theorem 1.8]. Since such a solution can be verified in polynomial running-time, the total search problem FAIR-IS-CYCLE lies in the complexity class TFNP. We prove that the class PPA captures the complexity of the problem.

► **Theorem 3.** *The FAIR-IS-CYCLE problem is PPA-complete.*

In view of the “cycle plus triangles” problem of Du et al. [19], it would be interesting to understand the complexity of the FAIR-IS-CYCLE problem restricted to partitions into sets of size 3. While Theorem 3 immediately implies that this restricted problem lies in PPA, the question of determining its precise complexity remains open.

We proceed by considering the search problem associated with Theorem 1. In the Fair Splitting of Cycle Problem, denoted FAIR-SPLIT-CYCLE, we are given a cycle and a partition of its vertex set and the goal is to find *two* disjoint independent sets that fairly represent the partition and cover all vertices but one from every part of the partition. We define below an approximation version of this problem, in which the fairness requirement is replaced with the relaxed notion of  $\varepsilon$ -fairness, where the independent sets should include at least  $\frac{1}{2} - \varepsilon$  fraction of the vertices of every part.

► **Definition 4** (Approximate Fair Splitting of Cycle Problem). *In the  $\varepsilon$ -FAIR-SPLIT-CYCLE problem with parameter  $\varepsilon \geq 0$ , the input consists of a cycle  $G$  on  $n$  vertices and a partition  $V_1, \dots, V_m$  of its vertex set into  $m$  sets, such that  $n$  and  $m$  have the same parity. The goal is to find two disjoint independent sets  $S_1$  and  $S_2$  of  $G$  covering all vertices but one from each  $V_i$  such that for each  $j \in \{1, 2\}$ , it holds that  $|S_j \cap V_i| \geq (\frac{1}{2} - \varepsilon) \cdot |V_i| - 1$  for all  $i \in [m]$ . For  $\varepsilon = 0$ , the problem is denoted by FAIR-SPLIT-CYCLE.*

The existence of a solution to every input of  $\varepsilon$ -FAIR-SPLIT-CYCLE, already for  $\varepsilon = 0$ , is guaranteed by Theorem 1 proved in [3]. For  $\varepsilon = 0$ , it can be seen that FAIR-SPLIT-CYCLE is at least as hard as FAIR-IS-CYCLE. Yet, it turns out that FAIR-SPLIT-CYCLE lies in PPA and is thus also PPA-complete.

► **Theorem 5.** *The FAIR-SPLIT-CYCLE problem is PPA-complete.*

For the approximation version of the problem, we provide the following hardness result.

► **Theorem 6.** *There exists a constant  $\varepsilon > 0$  for which the  $\varepsilon$ -FAIR-SPLIT-CYCLE problem is PPAD-hard.*

We finally consider the complexity of the SCHRIJVER problem. In this problem we are given a succinct representation of a coloring of the Schrijver graph  $S(n, k)$  with  $n - 2k + 1$  colors, which is one less than its chromatic number [40], and the goal is to find a monochromatic edge (see Definition 16). The study of the SCHRIJVER problem is motivated by a question raised by Deng et al. [17] regarding the complexity of the analogue problem for Kneser graphs. Note that the latter is not harder than the SCHRIJVER problem, because  $S(n, k)$  is a subgraph of  $K(n, k)$  with the same chromatic number. As an application of our Theorem 3, we prove the following.

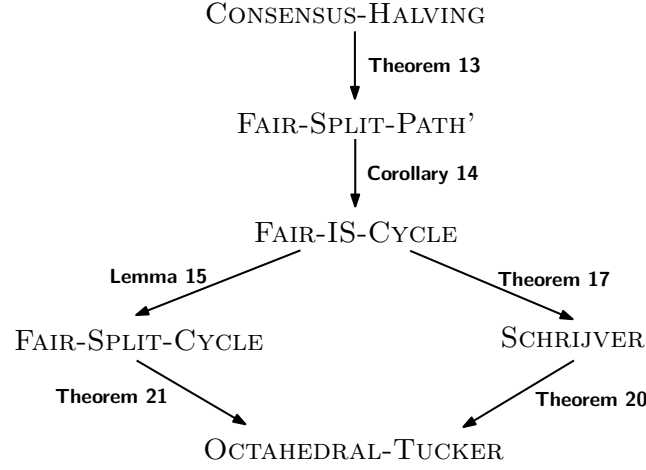

► **Theorem 7.** *The SCHRIJVER problem is PPA-complete.*

## 1.2 Overview of Proofs

To obtain our results we present a chain of reductions, as described in Figure 1. Our starting point is the Consensus Halving problem with precision parameter  $\varepsilon$ , in which given a collection of  $m$  probability measures on the interval  $[0, 1]$  the goal is to partition the interval into two pieces using relatively few cuts, so that each of the measures has the same mass on the two pieces up to an error of  $\varepsilon$  (see Definition 8). It is known that every input to this problem has a solution with at most  $m$  cuts even for  $\varepsilon = 0$  [41] (see also [28, 7]). The problem of finding a solution is PPA-hard when  $\varepsilon$  is inverse-polynomial in  $m$  [23, 24, 25] and PPAD-hard when  $\varepsilon$  is some positive constant [22].

In Section 2, we reduce the Consensus Halving problem to an intermediate variant of the  $\varepsilon$ -FAIR-SPLIT-CYCLE problem, which we call  $\varepsilon$ -FAIR-SPLIT-PATH' (see Definition 12). Then, we use this reduction to obtain our hardness results for the FAIR-IS-CYCLE and FAIR-SPLIT-CYCLE problems. The reduction borrows a discretization argument that was used in [23] to reduce the Consensus Halving problem to the Splitting Necklace problem with two thieves. This argument enables us to transform a Consensus Halving instance into a path and a partition of its vertex set, for which the goal is to partition the path using relatively few cuts into two parts, each of which contains roughly half of the vertices of every set in the partition. In order to relate this problem to independent sets that fairly represent the partition, we need an additional simple trick. Between every two consecutive vertices of the path we add a new vertex and put all the new vertices in a new set added to the partition

■ **Figure 1** Chain of reductions.

of the vertex set. We then argue, roughly speaking, that two disjoint independent sets in the obtained path, which fairly represent the partition and cover almost all of the vertices, can be used to obtain a solution to the original instance. The high-level idea is that those few vertices that are uncovered by the two independent sets can be viewed as cuts, and every path between two such vertices alternates between the two given independent sets. By construction, it means that only one of the two independent sets contains in such a path original vertices (that is, vertices that were not added in the last phase of the reduction), hence every such path can be naturally assigned to one of the two pieces required by the Consensus Halving problem. Combining our reduction with the known hardness results of Consensus Halving, we derive the PPA-hardness of FAIR-IS-CYCLE and FAIR-SPLIT-CYCLE and the PPAD-hardness of  $\varepsilon$ -FAIR-SPLIT-CYCLE for a constant  $\varepsilon > 0$ , as needed for Theorems 3, 5, and 6.

In Section 3, we introduce and study the SCHRIJVER problem. We reduce the FAIR-IS-CYCLE problem to the SCHRIJVER problem, implying that the latter is PPA-hard. The reduction follows an argument of Aharoni et al. [1] who used the chromatic number of the Schrijver graph [40] to prove the existence of the independent set required in FAIR-IS-CYCLE. Finally, employing arguments of Meunier [36] and Alishahi and Meunier [3], we reduce the SCHRIJVER and FAIR-SPLIT-CYCLE problems to the search problem associated with the Octahedral Tucker lemma (see Definition 18). Since it is known, already from [38], that this problem lies in PPA, we get that FAIR-IS-CYCLE, FAIR-SPLIT-CYCLE, and SCHRIJVER are all members of PPA, completing the proofs of Theorems 3, 5, and 7.

We remark that one could consider analogues of the FAIR-IS-CYCLE and FAIR-SPLIT-CYCLE problems for paths rather than for cycles and obtain similar results. We have chosen to focus here on the cycle setting, motivated by the computational aspects of the “cycle plus triangles” problem [19, 20, 26].

## 2 Fair Independent Sets in Cycles

In this section we prove our hardness results for the FAIR-IS-CYCLE and FAIR-SPLIT-CYCLE problems. We first recall the definition of the Consensus Halving problem and gather some of the hardness results known for it. Then, we present an efficient reduction from this problem to an intermediate problem, which is used to obtain the hardness results of Theorems 3, 5, and 6.

## 2.1 Consensus Halving

Consider the following variant of the Consensus Halving problem, denoted CON-HALVING.

► **Definition 8** (Consensus Halving Problem). *In the  $\varepsilon$ -CON-HALVING( $m, \ell$ ) problem with precision parameter  $\varepsilon = \varepsilon(m)$ , the input consists of  $m$  probability measures  $\mu_1, \dots, \mu_m$  on the interval  $I = [0, 1]$ , given by their density functions. The goal is to partition the interval  $I$  using at most  $\ell$  cuts into two (not necessarily connected) pieces  $I^+$  and  $I^-$ , so that for every  $i \in [m]$  it holds that  $|\mu_i(I^+) - \mu_i(I^-)| \leq \varepsilon$ .*

For  $\ell \geq m$ , every input of  $\varepsilon$ -CON-HALVING( $m, \ell$ ) has a solution even for  $\varepsilon = 0$  [41]. We state below two hardness results known for CON-HALVING. Here, a function on an interval is said to be *piecewise constant* if its domain can be partitioned into a finite set of intervals such that the function is constant on each of them. We refer to the intervals of the partition on which the function is nonzero as the *blocks* of the function.

► **Theorem 9** ([23, 24, 25]). *There exists an inverse-polynomial  $\varepsilon = \varepsilon(m)$  such that for every constant  $c \geq 0$ , the  $\varepsilon$ -CON-HALVING( $m, m + c$ ) problem, restricted to inputs with piecewise constant density functions with at most 2 blocks, is PPA-hard.*

► **Theorem 10** ([22]). *There exist an absolute constant  $\varepsilon > 0$  and a polynomial  $p$  such that for every constant  $c \geq 0$ , the  $\varepsilon$ -CON-HALVING( $m, m + c$ ) problem, restricted to inputs with piecewise constant density functions with at most  $p(m)$  blocks, is PPAD-hard.*

► **Remark 11.** We note that, as explained in [25], the constant  $c$  given in Theorems 9 and 10 can be replaced by  $m^{1-\alpha}$  for any constant  $\alpha > 0$ . This stronger hardness, however, is not required to obtain our results. We also note that our results do not rely on the fact that the hardness given in Theorem 9 holds for instances with density functions with at most 2 blocks, as proved in [25], rather than polynomially many blocks as was previously proved in [24].

## 2.2 The Main Reduction

To obtain our hardness results for the FAIR-IS-CYCLE and FAIR-SPLIT-CYCLE problems, we consider the following intermediate problem.

► **Definition 12.** *In the  $\varepsilon$ -FAIR-SPLIT-PATH' problem with parameter  $\varepsilon \geq 0$ , the input consists of a path  $G$  and a partition  $V_1, \dots, V_m$  of its vertex set into  $m$  sets such that  $|V_i|$  is odd for all  $i \in [m]$ . The goal is to find two disjoint independent sets  $S_1$  and  $S_2$  of  $G$  covering all but at most  $m$  of the vertices of  $G$  such that*

$$|S_1 \cap V_i| \in \left[ \left(\frac{1}{2} - \varepsilon\right) \cdot |V_i| - 1, \left(\frac{1}{2} + \varepsilon\right) \cdot |V_i| \right]$$

*for all  $i \in [m]$ . When  $\varepsilon = 0$ , the problem is denoted by FAIR-SPLIT-PATH'.*

Note that the  $\varepsilon$ -FAIR-SPLIT-PATH' problem differs from the  $\varepsilon$ -FAIR-SPLIT-CYCLE problem (see Definition 4) in the following respects: (a) The input graph is a path rather than a cycle, (b) an  $\varepsilon$ -fairness property is required only for the independent set  $S_1$  rather than for both  $S_1$  and  $S_2$ , (c) there is no requirement regarding the sets  $V_i$  to which the vertices that are uncovered by  $S_1$  and  $S_2$  belong, and (d) the sets  $V_i$  are required to be of odd sizes. Yet, it is easy to check that Theorem 1 implies that every instance of the  $\varepsilon$ -FAIR-SPLIT-PATH' problem has a solution already for  $\varepsilon = 0$ .

We turn to prove the following.

► **Theorem 13.** *Let  $p$  be a polynomial and suppose that  $\varepsilon = \varepsilon(m)$  is bounded from below by some inverse-polynomial in  $m$ . Then, the  $\varepsilon$ -CON-HALVING( $m, m+1$ ) problem, restricted to inputs with piecewise constant density functions with at most  $p(m)$  blocks, is polynomial-time reducible to the  $\frac{\varepsilon}{4}$ -FAIR-SPLIT-PATH' problem.*

**Proof.** Consider an instance of  $\varepsilon$ -CON-HALVING( $m, m+1$ ) consisting of  $m$  probability measures  $\mu_1, \dots, \mu_m$  on the interval  $I = [0, 1]$ , given by their piecewise constant density functions  $g_1, \dots, g_m$ , each of which has at most  $p(m)$  blocks. The reduction constructs an instance of  $\frac{\varepsilon}{4}$ -FAIR-SPLIT-PATH', namely, a path  $G$  and a partition  $V_1, \dots, V_{m+1}$  of its vertex set into  $m+1$  sets of odd sizes.

We start with a high-level description of the reduction. The reduction associates with every density function  $g_i$  a collection  $V_i$  of vertices located in the (at most  $p(m)$ ) intervals on which  $g_i$  is nonzero. To do so, we partition every block of  $g_i$  into sub-intervals such that the measure of  $\mu_i$  on each of them is  $\delta$ , where  $\delta > 0$  is some small parameter (assuming, for now, that the measure of  $\mu_i$  on every block is an integer multiple of  $\delta$ ). At the middle of every such sub-interval we locate a vertex and put it in  $V_i$ . Then, we construct a path  $G$  that alternates between the vertices of  $V_1 \cup \dots \cup V_m$  ordered according to their locations in  $I$  and additional vertices which we put in another set  $V_{m+1}$ . We also take care of the requirement that each  $|V_i|$  is odd.

The intuitive idea behind this reduction is the following. Suppose that we are given a solution to the constructed instance, i.e., two disjoint independent sets  $S_1$  and  $S_2$  of the path  $G$  covering all but  $m+1$  of the vertices such that  $S_1$  contains roughly half of the vertices of  $V_i$  for each  $i \in [m+1]$ . Observe that by removing from  $G$  the  $m+1$  vertices that *do not* belong to  $S_1 \cup S_2$ , we essentially get a partition of the vertices of  $S_1 \cup S_2$  into  $m+2$  paths. Since  $S_1$  and  $S_2$  are independent sets in  $G$ , it follows that each such path alternates between  $S_1$  and  $S_2$ . However, recalling that  $G$  alternates between  $V_1 \cup \dots \cup V_m$  and  $V_{m+1}$ , it follows that ignoring the vertices of  $V_{m+1}$ , each such path contains either only vertices of  $S_1$  or only vertices of  $S_2$ . Now, one can view the  $m+1$  locations of the vertices that do not belong to  $S_1 \cup S_2$  as cuts in the interval  $I$  which partition it into  $m+2$  sub-intervals, each of which includes vertices from either  $S_1$  or  $S_2$  (again, ignoring the vertices of  $V_{m+1}$ ). Let  $I^+$  and  $I^-$  be the pieces of  $I$  obtained from the sub-intervals that correspond to  $S_1$  and  $S_2$  respectively. Since the number of vertices from  $V_i$  in every path is approximately proportional to the measure of  $\mu_i$  in the corresponding sub-interval, it can be shown that the probability measure of  $\mu_i$  on  $I^+$  is approximately  $\frac{1}{2}$ . This yields that the probability measure  $\mu_i$  is approximately equal on the pieces  $I^+$  and  $I^-$ , as needed for the CON-HALVING( $m, m+1$ ) problem.

We turn to the formal description of the reduction. Define  $\delta = \frac{\varepsilon}{4 \cdot (2p(m) + m + 3)}$ . The reduction acts as follows.

1. For every  $i \in [m]$ , do the following:
  - We are given a partition of the interval  $I$  into intervals such that on at most  $p(m)$  of them the function  $g_i$  is equal to a nonzero value and is zero everywhere else. For every such interval, let  $\gamma$  denote the volume of  $g_i$  on it, and divide it into  $\lceil \gamma/\delta \rceil$  sub-intervals of volume  $\delta$  each, possibly besides the last one whose volume might be smaller. We refer to a sub-interval of volume smaller than  $\delta$  as an *imperfect* sub-interval. The number of imperfect sub-intervals associated with  $g_i$  is clearly at most  $p(m)$ . At the middle point of every sub-interval of  $g_i$ , locate a vertex and put it in the set  $V_i$ .
  - If the number of vertices in  $V_i$  is even, then add another vertex to  $V_i$  and locate it arbitrarily in  $I$ .
  - Note that, by  $\mu_i(I) = 1$ , we have
 
$$|V_i| \cdot \delta \in [1, 1 + (p(m) + 1) \cdot \delta]. \quad (1)$$

2. Consider the path on the vertices of  $V_1 \cup \dots \cup V_m$  ordered according to their locations in the interval  $I$ , breaking ties arbitrarily.
3. Add a new vertex before every vertex in this path, locate it at the middle of the sub-interval between its two adjacent vertices (where the first new vertex is located at 0), and put these new vertices in the set  $V_{m+1}$ . If the number of vertices in  $V_{m+1}$  is even then add one more vertex to the end of the path, locate it at 1, and put it in  $V_{m+1}$  as well. Denote by  $G$  the obtained path, and note that  $G$  alternates between  $V_1 \cup \dots \cup V_m$  and  $V_{m+1}$ .
4. The output of the reduction is the path  $G$  and the partition  $V_1, \dots, V_{m+1}$  of its vertex set  $V$  into  $m+1$  sets. By construction,  $|V_i|$  is odd for every  $i \in [m+1]$ .

It is easy to verify that the reduction can be implemented in polynomial running-time. Indeed, every density function  $g_i$  is piecewise constant with at most  $p(m)$  blocks, hence for every  $i \in [m]$  the number of vertices that the reduction defines for  $V_i$  is at most  $1/\delta + p(m) + 1$ , and the latter is polynomial in the input size because of the definition of  $\delta$  and the fact that  $\varepsilon$  is at least inverse-polynomial in  $m$ . The additional set  $V_{m+1}$  doubles the number of vertices, possibly with one extra vertex, preserving the construction polynomial in the input size.

We turn to prove the correctness of the reduction, that is, that a solution to the constructed instance of  $\frac{\varepsilon}{4}$ -FAIR-SPLIT-PATH' can be used to efficiently compute a solution to the original instance of  $\varepsilon$ -CON-HALVING( $m, m+1$ ). Suppose we are given a solution to  $\frac{\varepsilon}{4}$ -FAIR-SPLIT-PATH' for the path  $G$  and the partition  $V_1, \dots, V_{m+1}$  of its vertex set  $V$ . Such a solution consists of two disjoint independent sets  $S_1$  and  $S_2$  of  $G$  covering all but at most  $m+1$  of the vertices of  $G$  such that

$$|S_1 \cap V_i| \in \left[ \left( \frac{1}{2} - \frac{\varepsilon}{4} \right) \cdot |V_i| - 1, \left( \frac{1}{2} + \frac{\varepsilon}{4} \right) \cdot |V_i| \right] \quad (2)$$

for all  $i \in [m+1]$ . Put  $S_3 = V \setminus (S_1 \cup S_2)$ . It can be assumed that  $|S_3| = m+1$  (otherwise, remove some arbitrary vertices from  $S_2$ ). Denote the vertices of  $S_3$  by  $u_1, \dots, u_{m+1}$  ordered according to their order in  $G$ . Let  $P_1, \dots, P_{m+2}$  be the  $m+2$  paths obtained from  $G$  by removing the vertices of  $S_3$  (where some of the paths might be empty). Since  $S_1$  and  $S_2$  are independent sets, every path  $P_j$  alternates between  $S_1$  and  $S_2$ . By our construction, this implies that in every path  $P_j$  either the vertices of  $S_1$  are from  $V \setminus V_{m+1}$  and those of  $S_2$  are from  $V_{m+1}$ , or the vertices of  $S_2$  are from  $V \setminus V_{m+1}$  and those of  $S_1$  are from  $V_{m+1}$ . We define  $b_j = 1$  in the former case and  $b_j = 2$  in the latter. Thus, for every  $i \in [m]$ , the number of vertices of  $V_i$  that appear in the paths  $P_j$  with  $b_j = 1$  is precisely  $|S_1 \cap V_i|$ .

Now, let  $\beta_1, \dots, \beta_{m+1} \in I$  be the locations of the vertices  $u_1, \dots, u_{m+1}$  in the interval  $I$  as defined by the reduction. We interpret these locations as  $m+1$  cuts of the interval  $I$ . Set  $\beta_0 = 0$  and  $\beta_{m+2} = 1$ , and for every  $j \in [m+2]$ , let  $I_j$  denote the interval  $[\beta_{j-1}, \beta_j]$ . Consider the partition of  $I$  into two pieces  $I^+$  and  $I^-$ , where  $I^+$  includes all the parts  $I_j$  with  $b_j = 1$  and  $I^-$  includes all the parts  $I_j$  with  $b_j = 2$ . We claim that this partition, which is obtained using  $m+1$  cuts in  $I$ , forms a valid solution to the original instance of  $\varepsilon$ -CON-HALVING( $m, m+1$ ). To this end, we show that for every  $i \in [m]$  it holds that  $|\mu_i(I^+) - \frac{1}{2}| \leq \frac{\varepsilon}{2}$ , which is equivalent to  $|\mu_i(I^+) - \mu_i(I^-)| \leq \varepsilon$ .

Fix some  $i \in [m]$ . We turn to estimate the quantity  $\mu_i(I^+)$ , i.e., the total measure of  $\mu_i$  on the intervals  $I_j$  with  $b_j = 1$ . By our construction, every vertex of  $V_i$  corresponds to a sub-interval whose measure by  $\mu_i$  is  $\delta$  (except for at most  $p(m) + 1$  of them). Since the intervals of  $I^+$  correspond to the paths  $P_j$  whose vertices in  $V \setminus V_{m+1}$  are precisely the vertices of  $S_1 \setminus V_{m+1}$ , one would expect  $\mu_i(I^+)$  to measure the number of vertices in  $S_1 \cap V_i$ , with a contribution of  $\delta$  per every such vertex. This suggests an estimation of  $|S_1 \cap V_i| \cdot \delta$  for  $\mu_i(I^+)$ . However, several issues might prevent from this estimation to be accurate:

- The set  $V_i$  might include vertices that correspond to imperfect sub-intervals whose measure by  $\mu_i$  is smaller than  $\delta$ . Since there are at most  $p(m)$  such vertices in  $V_i$ , they can cause an error of at most  $p(m) \cdot \delta$  in the above estimation.
- To make sure that  $|V_i|$  is odd, the reduction might add one extra vertex to  $V_i$ . This might cause an error of at most  $\delta$  in the above estimation.
- The precise locations  $\beta_j$  of the cuts of  $I$  might fall inside sub-intervals that correspond to vertices of  $V_i$ . Since the sub-intervals that correspond to vertices of  $V_i$  are disjoint, every such cut can cause an error of at most  $\delta$  in the above estimation, and since there are  $m + 1$  cuts the error here is bounded by  $(m + 1) \cdot \delta$ .

We conclude that  $\mu_i(I^+)$  differs from the aforementioned estimation  $|S_1 \cap V_i| \cdot \delta$  by not more than  $(p(m) + m + 2) \cdot \delta$ . Combining (1) and (2), it can be verified that

$$\left| |S_1 \cap V_i| \cdot \delta - \frac{1}{2} \right| \leq \frac{\varepsilon}{4} + (p(m) + 1) \cdot \delta,$$

hence

$$\begin{aligned} \left| \mu_i(I^+) - \frac{1}{2} \right| &\leq \left| \mu_i(I^+) - |S_1 \cap V_i| \cdot \delta \right| + \left| |S_1 \cap V_i| \cdot \delta - \frac{1}{2} \right| \\ &\leq (p(m) + m + 2) \cdot \delta + \frac{\varepsilon}{4} + (p(m) + 1) \cdot \delta \\ &= \frac{\varepsilon}{4} + (2p(m) + m + 3) \cdot \delta = \frac{\varepsilon}{2}, \end{aligned}$$

where the last equality holds by the definition of  $\delta$ . This completes the proof.  $\blacktriangleleft$

### 2.3 Hardness of Fair-IS-Cycle and Fair-Split-Cycle

Equipped with Theorem 13, we are ready to derive the hardness of the FAIR-IS-CYCLE and FAIR-SPLIT-CYCLE problems (see Definitions 2 and 4).

► **Corollary 14.** *The FAIR-IS-CYCLE problem is PPA-hard.*

**Proof.** By Theorem 9, the  $\varepsilon$ -CON-HALVING( $m, m + 1$ ) problem is PPA-hard for input density functions that are piecewise constant with at most 2 blocks, where  $\varepsilon = \varepsilon(m)$  is inverse-polynomial. By Theorem 13, this problem is polynomial-time reducible to the  $\frac{\varepsilon}{4}$ -FAIR-SPLIT-PATH' problem, implying that FAIR-SPLIT-PATH', with  $\varepsilon = 0$ , is PPA-hard. Hence, to prove the corollary, it suffices to show that FAIR-SPLIT-PATH' is polynomial-time reducible to FAIR-IS-CYCLE.

Consider an instance of FAIR-SPLIT-PATH', that is, a path  $G$  on  $n$  vertices and a partition  $V_1, \dots, V_m$  of its vertex set into  $m$  sets such that  $|V_i|$  is odd for all  $i \in [m]$ . The reduction simply returns the cycle  $G'$ , obtained from the path  $G$  by connecting its endpoints by an edge, and the same partition  $V_1, \dots, V_m$  of its vertex set. For correctness, suppose that we are given a solution to this instance of FAIR-IS-CYCLE, i.e., an independent set  $S_1$  of  $G'$  satisfying  $|S_1 \cap V_i| \geq \frac{1}{2} \cdot |V_i| - 1$  for all  $i \in [m]$ . Since each  $|V_i|$  is odd, it can be assumed that  $|S_1 \cap V_i| = \frac{1}{2} \cdot (|V_i| - 1)$  for all  $i \in [m]$  (by removing some vertices from  $S_1$  if needed), implying that

$$|S_1| = \sum_{i=1}^m |S_1 \cap V_i| = \frac{1}{2} \cdot \sum_{i=1}^m (|V_i| - 1) = \frac{n - m}{2}.$$

For every vertex of  $S_1$  consider the vertex that follows it in the cycle  $G'$  (say, oriented clockwise), and let  $S_2$  be the set of vertices that follow those of  $S_1$ . Since  $S_1$  is an independent

## 4:10 The Complexity of Finding Fair Independent Sets in Cycles

set in  $G'$ , we get that  $S_2$  is another independent set in  $G'$  which is disjoint from  $S_1$  and has the same size. We obtain that

$$|S_1 \cup S_2| = |S_1| + |S_2| = 2 \cdot \frac{n-m}{2} = n-m,$$

hence  $S_1$  and  $S_2$  are two disjoint independent sets of  $G'$  covering all but  $m$  of its vertices. In particular,  $S_1$  and  $S_2$  are independent sets in the path  $G$ , and as such, they form a valid solution to the FAIR-SPLIT-PATH' instance. This solution can clearly be constructed in polynomial running-time given  $S_1$ , completing the proof. ◀

The following simple lemma allows us to derive the PPA-hardness of FAIR-SPLIT-CYCLE.

► **Lemma 15.** *The FAIR-IS-CYCLE problem is polynomial-time reducible to FAIR-SPLIT-CYCLE.*

**Proof.** Consider an instance of FAIR-IS-CYCLE, that is, a cycle  $G$  on  $n$  vertices and a partition  $V_1, \dots, V_m$  of its vertex set into  $m$  sets. If  $n$  and  $m$  have the same parity then the reduction returns the input as is. Otherwise, there exists some  $i \in [m]$  for which the size of  $V_i$  is even. In this case, the reduction adds to the cycle  $G$  a new vertex located between two arbitrary consecutive vertices and puts it in  $V_i$ . Now, the number of vertices and the number of sets in the partition have the same parity, so the reduction can output the obtained cycle and partition.

A solution to the constructed instance of FAIR-SPLIT-CYCLE involves two disjoint independent sets that fairly represent the partition. Clearly, at least one of the sets does not include the two neighbors of the vertex that was possibly added to  $G$ . Letting  $S$  denote the set of vertices of  $G$  in this set, we get that  $S$  is independent in  $G$ , and it is easy to check that  $|S \cap V_i| \geq \frac{1}{2} \cdot |V_i| - 1$  for all  $i \in [m]$ , so we are done. ◀

We end this section with a proof of Theorem 6.

**Proof of Theorem 6.** By Theorem 10, the  $\varepsilon$ -CON-HALVING( $m, m+1$ ) problem is PPAD-hard for input density functions that are piecewise constant with at most  $p(m)$  blocks, where  $p$  is a polynomial and  $\varepsilon$  is a positive constant. Applying Theorem 13, we get that the  $\frac{\varepsilon}{4}$ -FAIR-SPLIT-PATH' problem is PPAD-hard. To complete the proof, we show that for every  $\varepsilon \geq 0$  the  $\varepsilon$ -FAIR-SPLIT-PATH' problem is polynomial-time reducible to the  $\varepsilon$ -FAIR-SPLIT-CYCLE problem.

Consider again the reduction that given a path  $G$  and a partition  $V_1, \dots, V_m$  of its vertex set into sets of odd sizes returns the cycle  $G'$ , obtained from the path  $G$  by connecting its endpoints by an edge, and the same partition  $V_1, \dots, V_m$ . Since the sets of the partition have odd sizes, it follows that the number of vertices and the number of sets in the partition have the same parity, hence the reduction provides an appropriate instance of the  $\varepsilon$ -FAIR-SPLIT-CYCLE problem.

For correctness, consider a solution to the constructed instance, i.e., two disjoint independent sets  $S_1$  and  $S_2$  of  $G'$  covering all vertices but one from each part  $V_i$  such that for each  $j \in \{1, 2\}$ , it holds that  $|S_j \cap V_i| \geq (\frac{1}{2} - \varepsilon) \cdot |V_i| - 1$  for all  $i \in [m]$ . We claim that  $S_1$  and  $S_2$  form a valid solution to the original  $\varepsilon$ -FAIR-SPLIT-PATH' instance. Indeed, an independent set in  $G'$  is also an independent set in  $G$ . In addition, the set  $S_1$  satisfies  $|S_1 \cap V_i| \in [(\frac{1}{2} - \varepsilon) \cdot |V_i| - 1, (\frac{1}{2} + \varepsilon) \cdot |V_i|]$  for all  $i \in [m]$ , where the upper bound holds because

$$|S_1 \cap V_i| = |V_i| - |S_2 \cap V_i| - 1 \leq |V_i| - \left( (\frac{1}{2} - \varepsilon) \cdot |V_i| - 1 \right) - 1 = (\frac{1}{2} + \varepsilon) \cdot |V_i|.$$

This completes the proof. ◀

### 3 The Schrijver Problem

In this section we introduce and study the SCHRIJVER problem, a natural analogue of the Kneser problem defined by Deng et al. [17].

We start with some definitions. A set  $A \subseteq [n]$  is said to be *stable* if it does not contain two consecutive elements modulo  $n$  (that is, if  $i \in A$  then  $i + 1 \notin A$ , and if  $n \in A$  then  $1 \notin A$ ). In other words, a stable subset of  $[n]$  is an independent set in the cycle on  $n$  vertices with the numbering from 1 to  $n$  along the cycle. For integers  $n \geq 2k$ , let  $\binom{[n]}{k}_{\text{stab}}$  denote the collection of all stable  $k$ -subsets of  $[n]$ . Recall that the Schrijver graph  $S(n, k)$  is the graph on the vertex set  $\binom{[n]}{k}_{\text{stab}}$ , where two sets are adjacent if they are disjoint. We define the search problem SCHRIJVER as follows.

► **Definition 16** (Schrijver Graph Problem). *In the SCHRIJVER problem, the input consists of a Boolean circuit that represents a coloring*

$$c : \binom{[n]}{k}_{\text{stab}} \rightarrow [n - 2k + 1]$$

*of the Schrijver graph  $S(n, k)$  using  $n - 2k + 1$  colors, where  $n$  and  $k$  are integers satisfying  $n \geq 2k$ . The goal is to find a monochromatic edge, i.e., two disjoint sets  $S_1, S_2 \in \binom{[n]}{k}_{\text{stab}}$  such that  $c(S_1) = c(S_2)$ .*

As mentioned earlier, it was proved by Schrijver [40] that the chromatic number of  $S(n, k)$  is precisely  $n - 2k + 2$ . Therefore, every input to the SCHRIJVER problem has a solution.

#### 3.1 From Fair-IS-Cycle to Schrijver

The following theorem is used to obtain the hardness result for the SCHRIJVER problem. The proof applies an argument of [1] (see also [10]).

► **Theorem 17.** *The FAIR-IS-CYCLE problem is polynomial-time reducible to the SCHRIJVER problem.*

**Proof.** Consider an instance of the FAIR-IS-CYCLE problem, namely, a cycle  $G$  and a partition  $V_1, \dots, V_m$  of its vertex set into  $m$  sets. For every  $i \in [m]$ , let  $V'_i$  be the set obtained from  $V_i$  by removing one arbitrary vertex if  $|V_i|$  is even, and let  $V'_i = V_i$  otherwise. Since the size of every set  $V'_i$  is odd, we can write  $|V'_i| = 2r_i + 1$  for an integer  $r_i \geq 0$ . Let  $G'$  be the cycle obtained from  $G$  by removing the vertices that do not belong to the sets  $V'_i$  and connecting the remaining vertices according to their order in  $G$ . Letting  $n$  denote the number of vertices in  $G'$ , it can be assumed that its vertex set is  $[n]$  with the numbering from 1 to  $n$  along the cycle. Put  $k = \sum_{i=1}^m r_i$ , and notice that  $n = 2k + m$ . Define a coloring  $c$  of the Schrijver graph  $S(n, k)$  as follows. The color  $c(S)$  of a vertex  $S \in \binom{[n]}{k}_{\text{stab}}$  is defined as the smallest integer  $i \in [m]$  for which  $|S \cap V'_i| > r_i$  in case that such an  $i$  exists, and  $m + 1$  otherwise. This gives us a coloring of  $S(n, k)$  with  $n - 2k + 1$  colors, and thus an instance of the SCHRIJVER problem. It can be seen that a Boolean circuit that computes the coloring  $c$  can be constructed in polynomial running-time.

To prove the correctness of the reduction, consider a solution to the constructed SCHRIJVER instance, i.e., two disjoint sets  $S_1, S_2 \in \binom{[n]}{k}_{\text{stab}}$  with  $c(S_1) = c(S_2)$ . It is impossible that for some  $i \in [m]$  it holds that  $|S_1 \cap V'_i| > r_i$  and  $|S_2 \cap V'_i| > r_i$ , because  $S_1$  and  $S_2$  are disjoint and  $|V'_i| = 2r_i + 1$ . It follows that  $c(S_1) = c(S_2) = m + 1$ , meaning that  $|S_1 \cap V'_i| \leq r_i$  and  $|S_2 \cap V'_i| \leq r_i$  for all  $i \in [m]$ . Since  $|S_1| = |S_2| = k$ , it follows that

$|S_1 \cap V'_i| = r_i$  and  $|S_2 \cap V'_i| = r_i$  for all  $i \in [m]$ , hence  $S_1$  and  $S_2$  are two disjoint independent sets of  $G'$  covering all vertices but one from each  $V'_i$  and for each  $j \in \{1, 2\}$ , we have  $|S_j \cap V'_i| = \frac{1}{2} \cdot (|V'_i| - 1) \geq \frac{1}{2} \cdot |V_i| - 1$  for all  $i \in [m]$ . Since  $S_1$  and  $S_2$  are also independent sets of the original cycle  $G$ , each of them forms a valid solution to the FAIR-IS-CYCLE instance, completing the proof.  $\blacktriangleleft$

### 3.2 Membership in PPA

We now show that the SCHRIJVER and FAIR-SPLIT-CYCLE problems lie in PPA by reductions to the search problem associated with the Octahedral Tucker lemma. The reductions follow the proofs of the corresponding mathematical statements by Meunier [36] and by Alishahi and Meunier [3]. The proofs can be found in the full version of the paper.

We start with some notation (following [16, Section 2]). The partial order  $\preceq$  on the set  $\{+, -, 0\}$  is defined by  $0 \preceq +$  and by  $0 \preceq -$ , where  $+$  and  $-$  are incomparable. The definition is extended to vectors, so that for two vectors  $x, y$  in  $\{+, -, 0\}^n$ , we have  $x \preceq y$  if for all  $i \in [n]$  it holds that  $x_i \preceq y_i$  (equivalently,  $x_i = y_i$  whenever  $x_i \neq 0$ ). The Octahedral Tucker lemma, given implicitly in [33] and explicitly in [42], asserts that for every function  $\lambda : \{+, -, 0\}^n \setminus \{0\} \rightarrow \{\pm 1, \dots, \pm(n-1)\}$  satisfying  $\lambda(-x) = -\lambda(x)$  for all  $x$ , there exist vectors  $x, y$  such that  $x \preceq y$  and  $\lambda(x) = -\lambda(y)$ . This guarantees the existence of a solution to every input of the following search problem, denoted OCTAHEDRAL-TUCKER.

► **Definition 18** (Octahedral Tucker Problem). *In the OCTAHEDRAL-TUCKER problem, the input consists of a Boolean circuit that represents a function  $\lambda : \{+, -, 0\}^n \setminus \{0\} \rightarrow \{\pm 1, \pm 2, \dots, \pm(n-1)\}$  satisfying  $\lambda(-x) = -\lambda(x)$  for all  $x$ . The goal is to find vectors  $x, y$  such that  $x \preceq y$  and  $\lambda(x) = -\lambda(y)$ .*

The OCTAHEDRAL-TUCKER problem is known to be PPA-complete [17], where its membership in PPA follows already from [38] (see also [17, Appendix A]).

► **Proposition 19** ([38]). *The OCTAHEDRAL-TUCKER problem lies in PPA.*

The SCHRIJVER problem is reduced to OCTAHEDRAL-TUCKER, applying an argument of [36]. The proof is omitted.

► **Theorem 20.** *SCHRIJVER is polynomial-time reducible to OCTAHEDRAL-TUCKER.*

The FAIR-SPLIT-CYCLE problem (see Definition 4) is reduced to OCTAHEDRAL-TUCKER, applying an argument of [3]. The proof is omitted.

► **Theorem 21.** *FAIR-SPLIT-CYCLE is polynomial-time reducible to OCTAHEDRAL-TUCKER.*

### 3.3 Putting All Together

The presented reductions complete the proofs of our results. Indeed, the FAIR-IS-CYCLE problem is PPA-hard by Corollary 14, and is polynomial-time reducible to the FAIR-SPLIT-CYCLE and SCHRIJVER problems by Lemma 15 and Theorem 17 respectively. By Theorems 20 and 21, each of the two is efficiently reducible to the OCTAHEDRAL-TUCKER problem, which by Proposition 19 lies in PPA. It thus follows that all of these problems are PPA-complete (see Figure 1), confirming Theorems 3, 5, and 7.

## Abstract

Suppose that  $\mathcal{P}$  is a property that may be satisfied by a random code  $C \subset \Sigma^n$ . For example, for some  $p \in (0, 1)$ ,  $\mathcal{P}$  might be the property that there exist three elements of  $C$  that lie in some Hamming ball of radius  $pn$ . We say that  $R^*$  is the *threshold rate* for  $\mathcal{P}$  if a random code of rate  $R^* + \varepsilon$  is very likely to satisfy  $\mathcal{P}$ , while a random code of rate  $R^* - \varepsilon$  is very unlikely to satisfy  $\mathcal{P}$ . While random codes are well-studied in coding theory, even the threshold rates for relatively simple properties like the one above are not well understood.

We characterize threshold rates for a rich class of properties. These properties, like the example above, are defined by the inclusion of specific sets of codewords which are also suitably “symmetric.” For properties in this class, we show that the threshold rate is in fact *equal* to the lower bound that a simple first-moment calculation obtains. Our techniques not only pin down the threshold rate for the property  $\mathcal{P}$  above, they give sharp bounds on the threshold rate for *list-recovery* in several parameter regimes, as well as an efficient algorithm for estimating the threshold rates for list-recovery in general.

## 1 Introduction

Random codes are ubiquitous in the theory of error correcting codes: when thinking about the “right” trade-offs for a particular problem, a coding theorist’s first instinct may be to try a random code. A *random code* here is simply a random set. That is, let  $C \subseteq \Sigma^n$  be chosen so that each  $x \in \Sigma^n$  is included in  $C$  with probability  $|\Sigma|^{-n(1-R)}$  for some parameter  $R$ , which is called the (expected<sup>1</sup>) *rate* of the code  $C$ . Random codes are used in the proofs of the Gilbert-Varshamov bound, Shannon’s channel coding theorem, and the list-decoding capacity theorem, to name just a few. This success may lead to the intuition that random codes are “easy” to analyze, and that the hard part is finding explicit constructions that match (or in rare cases, exceed) the parameters of random codes. However, there is still much we do not know about random codes, especially if we want extremely precise answers.

In particular, the question of *threshold rates*, of broader interest in probability theory, is something that we do not understand well for random codes. In more detail, suppose that  $\mathcal{P}$  is a code property. For example, perhaps  $\mathcal{P}$  is the property that there is some pair of codewords  $c^{(1)}, c^{(2)} \in C$  that both lie in some Hamming ball of radius  $pn$ . Or perhaps  $\mathcal{P}$  is the property that there are three codewords  $c^{(1)}, c^{(2)}, c^{(3)} \in C$  that lie in such a Hamming ball. A value  $R^* \in (0, 1)$  is a *threshold rate* for  $\mathcal{P}$  if a random code of rate  $R^* + \varepsilon$  is very likely to satisfy  $\mathcal{P}$ , but a random code of rate  $R^* - \varepsilon$  is very unlikely to satisfy  $\mathcal{C}$ . For the first example above, about pairs of codewords, the property in question is just the property of the code having *minimum distance* less than  $2pn$ , and this is not too hard to understand. However, already for the second example above – called *list-of-two decoding* – the threshold rate was not known.

### 1.1 Contributions

In this paper, we characterize threshold rates for a rich class of natural properties of random codes. We apply our characterization to obtain threshold rates for list-of-two decoding, as well as to properties like *list-decoding* and *perfect hashing codes*, and more generally to *list-recovery*. We outline our contributions below.

#### A characterization of the threshold rate $R^*$ for symmetric properties

Suppose that  $\mathcal{P}$  is a property defined by the inclusion of certain “bad” sets. For example, the list-of-two decoding property described above is defined by the inclusion of three codewords that lie in a radius- $pn$  Hamming ball. For such properties that are also “symmetric enough,” our main technical result, Theorem 1, characterizes the threshold rate  $R^*$ . Moreover, we show that this threshold rate is exactly the same as the lower bound that one obtains from a simple first-moment calculation! This is in contrast to recent work of [13] for random *linear* codes, which shows that the corresponding first-moment calculation is not the correct answer in that setting.

Part of our contribution is formalizing the correct notion of “symmetric enough.” As we describe in the technical overview in Section 1.2, this definition turns out to be fairly subtle. We also show in the full version of the paper, that this definition is necessary.

---

<sup>1</sup> Throughout, we refer to  $R$  as the rate of the code, and drop the adjective “expected.”

### Estimates of $R^*$ for list-recovery

We give precise estimates of the threshold rate  $R^*$  for *list-recovery*. We say that a code  $C \subseteq \Sigma^n$  is  $(p, \ell, L)$ -list-recoverable if for all sets  $K_i \subseteq \Sigma$  (for  $1 \leq i \leq n$ ) with  $|K_i| \leq \ell$ ,

$$|\{c \in C : \Pr_{i \sim [n]}[c_i \notin K_i] \leq p\}| < L.$$

List-recovery is a useful primitive in list-decoding, algorithm design, and pseudorandomness (see, e.g., [15, 10, 16]). In particular, it generalizes the list-of-two decoding example above (when  $\ell = 1$  and  $L = 3$ ), as well as other interesting properties, such as list-decoding and perfect hashing codes, discussed below.

Our characterization allows us to estimate or even exactly compute the threshold rate for  $(p, \ell, L)$ -list-recovery in a wide variety of parameter regimes. To demonstrate this, we include several results along these lines. First, in Section 4 (Corollary 38), we give estimates that are quite sharp when  $\frac{q \log L}{L}$  is small. In Section 5 (Lemma 40), we give an exact formula for the case  $p = 0$ , which is relevant for perfect hashing codes. In Section 6 (Theorem 42(I)), we give an exact formula for the case that  $L = 3$  and  $\ell = 1$ , relevant for list-of-two decoding. Moreover, in Section 7 (Corollary 47) we use our characterization to develop an efficient algorithm to compute the threshold rate up to an additive error of  $\varepsilon > 0$ ; our algorithm runs in time  $O_p(L^q + \text{poly}(q, L, \log(1/\varepsilon)))$ .

### List-of-two decoding and a separation between random codes and random linear codes

We obtain new results for list-of-two decoding, the example discussed above. List-of-two decoding is a special case of *list-decoding*, which itself the special case of list-recovery where  $\ell = 1$ . We say that a code is  $(p, L)$ -list-decodable if there is no Hamming ball of radius  $pn$  containing  $L$  codewords; list-of-two decoding is the special case of  $L = 3$ .<sup>2</sup> We show in Section 6 (Theorem 42) that the threshold rate for this question, for random binary codes, is  $R^* = 1 - \frac{1-h_2(3p)+3p \log_2 3}{3}$ . That is, above this rate, a random binary code is very likely to have three codewords contained in a radius  $pn$  ball, while below this rate, the code most likely avoids all such triples.

This result is interesting for two reasons. First, it demonstrates that our techniques are refined enough to pin down the threshold rate in this parameter regime. Second, the particular value of  $R^*$  is interesting because it is *different* than the corresponding threshold rate for random *linear* codes. A *random linear code* over  $\mathbb{F}_q$  of rate  $R$  is a random linear subspace of  $\mathbb{F}_q^n$ , of dimension  $Rn$ . The list-decodability of random linear codes has been extensively studied, and it is known (e.g., [19, 7]) that the  $(p, L)$ -list-decoding threshold rate for both random linear codes and random codes is  $1 - h_q(p)$ , for sufficiently large list sizes  $L$ .<sup>3</sup>

### Limitations of random codes for perfect hashing

Another special case of list-recovery is *perfect hashing codes*. Suppose that  $|\Sigma| = q$ . A code  $C \subseteq \Sigma^n$  is said to be a  $q$ -hash code if, for any set of  $q$  distinct codewords  $c^{(1)}, c^{(2)}, \dots, c^{(q)} \in C$ , there is at least one  $i \in [n]$  so that  $\{c_i^{(1)}, c_i^{(2)}, \dots, c_i^{(q)}\} = \Sigma$ ; that is, if the set of symbols that

<sup>2</sup> It is called list-of-two decoding, even though  $L$  is *three*, because any Hamming ball contains at most *two* codewords.

<sup>3</sup> Here,  $h_q(x) = x \log_q(q-1) - x \log_q(x) - (1-x) \log_q(1-x)$  is the  $q$ -ary entropy.

appear in position  $i$  are all distinct. Thus,  $C$  is a  $q$ -hash code if and only if it is  $(0, q-1, q)$ -list-recoverable. As the name suggests,  $q$ -hash codes have applications in constructing small perfect hash families, and it is a classical question to determine the largest rate possible for a  $q$ -hash code.<sup>4</sup>

A simple random coding argument shows that a random code of rate  $R = \frac{1}{q} \log_q \frac{1}{1-q^{1/q^q}} - o(1)$  is a  $q$ -hash code with high probability [5, 12]. However, it is still an area of active research to do significantly better than this bound for any  $q$ . It is known that  $R < \frac{q^l}{q^q-1}$  for any  $q$ -hash code [5, 9], and for large  $q$ , there is a gap of a multiplicative factor of about  $q^2$  between these upper and lower bounds. Körner and Matron gave a construction that beats the random bound for  $q = 3$  [11], and recently Xing and Yuan gave a construction that beats the random bound for infinitely many  $q$ 's [18]. One might have hoped that a random code might in fact do better than the straightforward probabilistic argument (which follows from a union bound). Unfortunately, our results show that this is not the case.

### A broader view

Taking a broader view, threshold phenomena in other combinatorial domains, notably random graphs and Boolean functions, have been the subject of extensive study at least since Erdős and Rényi's seminal work [3]. Some of the deeper results in this field (e.g. [6]), deal simultaneously with a wide class of properties, rather than a specific one. Other works, such as the recent [4], are general enough to cover not only multiple properties, but also multiple domains. Our work (as with the work of [13], [8] on random linear codes, discussed below) is not as general as these, but we are able to get more precise results. It would be interesting to find a general framework that connects threshold phenomena in a variety of random code models, with analogues from random graphs and other natural combinatorial structures.

## 1.2 Technical Overview

As mentioned above, we study properties defined by the inclusion of bad subsets. We organize bad subsets of size  $b$  into matrices  $B \in \Sigma^{n \times b}$ , interpreting the columns of  $B$  as the elements of the set. We write " $B \subseteq C$ " to mean that the columns of  $B$  are all contained in the code  $C$ .

As a running example – and also our motivating example – consider list recovery, defined above. The property  $\mathcal{P}$  of *not* being  $(p, \ell, L)$ -list-recoverable is defined by the inclusion of "bad" matrices  $B \in \Sigma^{n \times L}$  so that for some sets  $K_1, \dots, K_n \subset \Sigma$  of size at most  $\ell$ ,  $\Pr_{i \sim [n]}[B_{ij} \notin K_i] \leq p$  for each  $j \in [L]$ . Moreover we require the columns of  $B$  to be distinct.

### Analyzing a property as a union of types

Following the approach of [13] for random linear codes, we group the bad matrices into *types* based on their row distributions. That is, for a bad matrix  $B \in \Sigma^{n \times b}$ , let  $\tau$  denote the row distribution

$$\tau(v) = \frac{|\{i \in [n] : B_{i,\star} = v\}|}{n},$$

where  $B_{i,\star}$  denotes the  $i$ 'th row of  $B$ . We say that  $B$  has *type*  $\tau$ . Consider the set  $\mathcal{B}$  of all of the matrices of type  $\tau$ ; equivalently,  $\mathcal{B}$  is the set of matrices obtained by permuting the

<sup>4</sup> A  $q$ -hash code naturally gives rise to a perfect hash family: suppose that  $C$  is a universe of items, and define a hash function  $h_i : C \rightarrow \Sigma$  given by  $h_i(c) = c_i$ . Then the property of being a  $q$ -hash code is equivalent to the property that, for any set of  $q$  items in the universe, there exists some hash function  $h_i$  for  $1 \leq i \leq n$  that maps each item to a different value.

rows of  $B$ . We note that possible types  $\tau$  depend on  $n$ , because of divisibility constraints. For simplicity, let us ignore these restrictions for now (we will deal with them later), and suppose that a single type  $\tau$  can appear for all  $n$ .

### First-moment bound and main theorem

We can use a simple first-moment approach to give a lower bound on the threshold rate. In more detail, the probability that a particular  $B$  is contained in  $C$  is  $q^{-nb(1-R)}$ , assuming that  $B$  has  $b$  distinct columns. Using the fact that  $|\mathcal{B}| \approx q^{H_q(\tau) \cdot n}$ , where  $H_q(\tau)$  is the base- $q$  entropy of  $\tau$  (see Section 2), and applying a union bound over all  $B \in \mathcal{B}$ , we see that the probability that any  $B \in \mathcal{B}$  is contained in  $C$  is at most

$$q^{nb(H_q(\tau)-(1-R))}.$$

Thus, if  $R \leq 1 - \frac{H_q(\tau)}{b} - \varepsilon$  for some small  $\varepsilon > 0$ , it is very unlikely that  $\tau$  will be represented in  $C$ .

Now suppose that our collection of bad sets, which define the property  $\mathcal{P}$ , is closed under row permutations. This means that  $\mathcal{P}$  can be represented as a collection  $T$  of types  $\tau$ ; note that the size of  $T$  is polynomial in  $n$ . Union bounding over all of these types, the computation above shows that a random code  $C$  of rate  $R < 1 - \max_{\tau \in T} \frac{H_q(\tau)}{b} - \varepsilon$  will, with high probability, not satisfy  $\mathcal{P}$ .

The question is, could the rate be larger? Might it be the case that  $\mathcal{P}$  still not satisfied (with high probability) by a random code of rate  $R$  significantly larger than  $1 - \max_{\tau} H_q(\tau)/b$ ? In [13], it was shown that the answer for random *linear* codes is “yes.” If  $\mathcal{P}$  exhibits certain linear structure, then it may be possible that a higher rate random linear code still does not satisfy  $\mathcal{P}$  with high probability. One may conjecture that something similar holds for random codes.

Our main technical result, Theorem 30, is that, for random codes, for sufficiently symmetric properties, the answer to this question is “no.” That is, the simple calculation above *does* give the right answer for random codes!

► **Theorem 1** (Informal; see Theorem 30 for the formal version). *Let  $\mathcal{P}$  be a “symmetric” property defined by the inclusion of a type among the types in  $T$ . Let*

$$R^* = 1 - \frac{\max_{\tau \in T} H_q(\tau)}{b}$$

*Then for all  $\varepsilon > 0$ , a random code of rate  $R \geq R^* + \varepsilon$  satisfies  $\mathcal{P}$  with probability  $1 - o(1)$ , while a random code of rate  $R^* - \varepsilon$  satisfies  $\mathcal{P}$  with probability  $o(1)$ .*

### Sketch of proof: second moment method

Below, we sketch the proof of Theorem 1, and explain what the assumption of “symmetry” means. As noted above, it is straightforward to show that the threshold rate  $R^*$  is at least  $1 - \max_{\tau \in T} \frac{H_q(\tau)}{b}$ , so the challenge is to show that it is not larger. The proof of Theorem 1 uses the second-moment method to show that for any *histogram type*  $\tau$  (we discuss histogram types more below), a random code  $C$  of rate  $1 - H_q(\tau)/b + \varepsilon$  is very likely to contain some matrix  $B$  with type  $\tau$ . Thus, the threshold rate is at most  $1 - \max_{\tau} H_q(\tau)/b$ , where the maximum is over all histogram types  $\tau$  that appear in  $T$ . Our eventual definition of “symmetric” will guarantee that it is legitimate to restrict our attention to histogram types.

### Histogram types and the meaning of “symmetry”

In order to apply the second moment method, we bound the variance of  $\sum_{B \sim \tau} \mathbf{1}[B \subset C]$ , where the sum is over all matrices  $B$  of type  $\tau$ . This turns out to be possible when  $\tau$  has the following symmetry property: for any  $u \in \Sigma^b$ , and for any permutation  $\pi : [b] \rightarrow [b]$ , it holds that  $\tau(u) = \tau(\pi(u))$ , where  $\pi(u)$  denotes the corresponding coordinate permutation of  $u$ . We call such a type  $\tau$  a *histogram-type* (Definition 27) because the probability of a particular vector  $u$  under  $\tau$  depends only on the histogram of  $u$ .

A first attempt to formulate a definition of “symmetry” for Theorem 1 is thus to require  $\mathcal{P}$  to be defined by histogram types. This results in a true statement, but unfortunately it is too restrictive: it is not hard to see that, for example, the property of not being list-decodable contains types  $\tau$  that are not histogram types. Fortunately, for the logic above to go through, it is enough to show that  $T$  contains a type  $\tau$  that is *both* a maximum entropy distribution in  $T$ , and is also a histogram type. Thus, the assumption of “symmetry” we will use is that  $T$ , the collection of types represented in the property  $\mathcal{P}$ , forms a convex set. Then, using the fact that  $\mathcal{P}$  is defined by the inclusion of bad sets (which do not care about the order of the columns in the corresponding matrices), we can always find a maximum entropy histogram type by “symmetrizing” and taking a convex combination of column permutations of some maximum entropy type  $\tau$ . One might wonder if this symmetrization step (and the resulting assumption about convexity) is necessary. In the full version of this paper show that it is.

### Taking a limit as $n \rightarrow \infty$

There is one more challenge to consider, which is that in the description above, we have ignored the fact that we would like our characterization to work for a sequence of values of  $n$ . However, a type  $\tau$  only works for certain values of  $n$  due to divisibility restrictions. To get around this, we work instead with a sequence of types  $\tau_n$  which tend to  $\tau$ . This leads us to our final definition of “symmetric” (Definition 20). Suppose that  $\mathcal{P}$  is a property defined by the inclusion of size- $b$  bad sets. Then for each  $n$ , there is some collection  $T^n$  of bad types  $\tau_n$ , each of which is a distribution on  $\Sigma^b$ . We say that  $\mathcal{P}$  is *symmetric* if the sets  $T^n$  approach some convex set  $T$  as  $n$  goes to infinity. The logic above then goes through to give Theorem 1.

### Applications to list-recovery

Finally, in order to apply Theorem 1, we need to understand the maximum entropy distribution  $\tau$  for our property  $\mathcal{P}$ . We do this for the property  $\mathcal{P}$  of not being  $(p, \ell, L)$ -list-recoverable in a variety of parameter regimes in Sections 4, 5 and 6, and along the way obtain our results about list-of-two decoding and perfect hashing codes. Finally, in Section 7, we use our framework to develop an algorithm to efficiently calculate the threshold rate for  $(p, \ell, L)$ -list-recovery.

## 1.3 Organization

In Section 2, we introduce notation, and also set up the definitions we need about types, thresholds, properties, and various notions of symmetry. We also introduce (non-)list-recoverability as a property, and prove in Corollary 24 that it is symmetric.

In Section 3, we state and prove Theorem 30, the formal version of the characterization theorem (Theorem 1 above). At the end of Section 3, we begin to apply Theorem 30 to list-recovery, and in particular define several notions we will need to analyze list recovery in the subsequent sections.

In the remaining sections, we specialize to list-recovery. Note that the proofs of the claims in the remaining sections are available in the full version. In Section 4, we develop bounds on the threshold rate  $R^*$  for list-recovery that are tight when  $(q \log L)/L$  is small. In Section 5, we compute the threshold rate  $R^*$  exactly for zero-error list-recovery (that is, when  $p = 0$ ), and use this to compute the threshold rate for perfect hashing. In Section 6, we compute the threshold rate  $R^*$  for list-of-two decoding (e.g., list-recovery when  $\ell = 1$  and  $L = 3$ ), and use this to quantify the gap between random codes and random linear codes for list-of-two decoding. Finally, in Section 7, we give an efficient algorithm to compute the threshold rate.

## 2 Preliminaries

First, we fix some basic notation. Throughout, we consider codes  $C \subseteq \Sigma^n$  of block length  $n$  over an alphabet  $\Sigma$ , where  $|\Sigma| = q$ . When we use  $\log(x)$  without an explicit base, we mean  $\log_2(x)$ . We use  $H_q$  to denote the base- $q$  entropy: for a distribution  $\tau$ ,

$$H_q(\tau) := - \sum_x \tau(x) \log_q(\tau(x)).$$

When  $q$  is clear from context, we will use  $H(\tau)$  to denote  $H_q(\tau)$ . If  $u$  is a random variable distributed according to  $\tau$ , then we abuse notation slightly and define  $H(u) := H(\tau)$ . We use  $h_q(x) := x \log_q(q-1) - x \log_q(x) - (1-x) \log_q(1-x)$  to denote the  $q$ -ary entropy of  $x \in (0, 1)$ . Again, when  $q$  is clear from context we will use  $h(x)$  to denote  $h_q(x)$ .

For a vector  $x \in \Sigma^k$  and  $I \subseteq [k]$ , we use  $x_I$  to refer to the vector  $(x_i)_{i \in I} \in \Sigma^I$ . Given a vector  $u \in \Sigma^k$  and a permutation  $\pi : [k] \rightarrow [k]$ , we let  $\pi(u) \in \Sigma^k$  denote the corresponding coordinate permutation of  $u$ .

Given distributions  $\tau, \mu$  on the same finite set, we define their  $\ell_\infty$ -distance by

$$d_\infty(\tau, \mu) := \max_x |\tau(x) - \mu(x)|.$$

Given a set of distributions  $T$ , we define the  $\ell_\infty$  distance from  $\mu$  to  $T$  by

$$d_\infty(\mu, T) := \inf_{\tau \in T} d_\infty(\mu, \tau).$$

### 2.1 Basic notions

As mentioned in the introduction, we will organize our “bad” sets into matrices. We formalize this with the following two definitions.

► **Definition 2** (Matrices with distinct columns). Let  $\Sigma_{\text{distinct}}^{n \times b}$  denote the collection of all matrices  $B \in \Sigma^{n \times b}$  such that each column of  $B$  is distinct.

► **Definition 3** (Subsets as matrices). Let  $C \subseteq \Sigma^n$  be a code, and let  $B \in \Sigma^{n \times b}$  be a matrix. We write  $B \subseteq C$  to mean that each column of  $B$  is an element of  $C$ . If  $A \subseteq \Sigma^n$ , let  $\mathcal{B}_A \subseteq \Sigma^{n \times |A|}$  denote the collection all matrices  $B \in \Sigma_{\text{distinct}}^{n \times |A|}$  such that the columns of  $B$  are the elements of  $A$ .

For completeness, we reiterate our definition of a random code from the introduction.

► **Definition 4** (Random code). Let  $\Sigma$  be a finite set with  $q := |\Sigma| \geq 2$ . For  $n \in \mathbb{N}$  and  $R \in [0, 1]$ , let  $C_{\text{RC}}^n(R)$  denote an expected-rate  $R$  random code (over the alphabet  $\Sigma$ )  $C \subseteq \Sigma^n$ . Namely, for each  $x \in \mathbb{F}_q^n$  we have  $\Pr[x \in C] = q^{-n(1-R)}$ , and these events are independent over all  $x$ .

## 5:8 Sharp Threshold Rates for Random Codes

We record a useful fact about random codes, which is the probability that any particular matrix  $B$  is contained in one.

► **Fact 5** (Probability that a random code contains a matrix). *Let  $B \in \Sigma^{n \times b}$ . Then,*

$$\Pr[B \subseteq C_{\text{RC}}^n(R)] = q^{-n(1-R)t},$$

where  $t$  is the number of distinct columns in  $B$ .

We study (noisy) list-recovery, which generalizes both the list-decoding and perfect hashing examples mentioned in the introduction. We repeat the definition, so that we may formally define a “bad” matrix for list-recovery.

► **Definition 6** (Noisy list-recovery). *Let  $p \in [0, 1]$ ,  $1 \leq \ell \leq q$ , and  $L \in \mathbb{N}$ . Say that a matrix  $B \in \Sigma_{\text{distinct}}^{L \times n}$  is  $(p, \ell, L)$ -bad for  $(p, \ell, L)$ -list-recovery if there exist sets  $K_i \subseteq \Sigma$  ( $1 \leq i \leq n$ ), each of size  $\ell$ , such that for every  $1 \leq j \leq L$ ,*

$$\Pr_{i \sim [n]} [B_{i,j} \notin K_i] \leq p.$$

*A code  $C \subseteq \Sigma^n$  is  $(p, \ell, L)$ -list-recoverable if it does not contain a  $(p, \ell, L)$ -bad matrix.*

### 2.2 Monotone-increasing properties and thresholds

We study the threshold rate  $R^*$  for random codes to satisfy certain properties. This was discussed informally in the introduction and the definitions below formalize what “threshold rate” means.

► **Definition 7** (Monotone-increasing property). *A code property  $\mathcal{P}$  is monotone-increasing if given a code  $C$  satisfying  $\mathcal{P}$ , it holds that every code  $C'$  such that  $C \subseteq C'$  also satisfies  $\mathcal{P}$ .*

For example, the property of being *not*  $(p, \ell, L)$ -list-recoverable (that is, the property of containing a  $(p, \ell, L)$ -bad matrix) is a monotone-increasing property.

► **Definition 8** (Minimal-set). *Let  $P_n$  be a monotone-increasing property of length- $n$  codes. A set  $A \subseteq \Sigma^n$  is a minimal element of  $P_n$  if  $A$  satisfies  $P_n$  but no strict subset of  $A$  satisfies  $P_n$ . The minimal set for  $P_n$  is the collection of matrices*

$$\bigcup_{A \text{ is a minimal element of } P_n} \mathcal{B}_A.$$

For example, the minimal set for the property  $P_n$  of being *not*  $(p, \ell, L)$ -list-recoverable is the set of  $(p, \ell, L)$ -bad matrices.

Note that a code satisfies  $P_n$  if and only if it contains some matrix belonging to the minimal set of  $P_n$ . If  $\mathcal{P}$  is a monotone-increasing property of codes, we define its associated *threshold rate* by

$$R_{\text{RC}}^n(\mathcal{P}) := \begin{cases} \sup \{R \in [0, 1] : \Pr[C_{\text{RC}}^n(R) \text{ satisfies } \mathcal{P}] \leq \frac{1}{2}\} & \text{if there is such an } R \\ 0 & \text{otherwise.} \end{cases}$$

► **Remark 9.** If  $\mathcal{P}$  is monotone-increasing then the function  $\Pr[C_{\text{RC}}^n(R) \text{ satisfies } \mathcal{P}]$  is monotone-increasing in  $R$ . This can be proved by a standard coupling argument, akin to [1, Thm. 2.1].

► **Definition 10** (Sharpness for random codes). *A monotone-increasing property  $\mathcal{P}$  is sharp for random codes if*

$$\lim_{n \rightarrow \infty} \Pr[C_{\text{RC}}^n(R_{\text{RC}}^n(\mathcal{P}) - \varepsilon) \text{ satisfies } \mathcal{P}] = 0$$

and

$$\lim_{n \rightarrow \infty} \Pr[C_{\text{RC}}^n(R_{\text{RC}}^n(\mathcal{P}) + \varepsilon) \text{ satisfies } \mathcal{P}] = 1$$

for every  $\varepsilon > 0$ .

### 2.3 Local and row-symmetric properties

As discussed in the introduction, we study properties that can be written as a union of “types,” where each type corresponds to a row distribution  $\tau$  of a matrix  $M$ . The following definitions make this notion precise.

► **Definition 11** (Row-permutation invariant collection of matrices). *A collection of matrices  $\mathcal{B} \subseteq \Sigma^{n \times b}$  is row-permutation invariant if, given a matrix  $B \in \mathcal{B}$ , every row permutation of  $B$  (that is, a matrix resulting from applying the same coordinate permutation to each column of  $B$ ) also belongs to  $\mathcal{B}$ .*

► **Definition 12** (Local and row-symmetric properties). *Let  $\mathcal{P} = \{P_n\}_{n \in \mathbb{N}}$  be a monotone-increasing property, and let  $M_n$  denote the minimal set of  $P_n$ .*

- *If there exists some  $b \in \mathbb{N}$  such that  $M_n \subseteq \Sigma^{n \times b}$  for every  $n$ , we say that  $\mathcal{P}$  is  $b$ -local.*
- *If every  $M_n$  is row-permutation invariant, we say that  $\mathcal{P}$  is row-symmetric.*

► **Remark 13.** Every monotone-increasing property is trivially *column-symmetric*, in the sense that permuting the columns of a matrix in  $M_n$  results in another matrix in  $M_n$ . This naturally reflects the fact that containment of a matrix does not depend on the ordering of the columns, and follows immediately from the definition of a minimal set.

Let  $B \in \Sigma^{n \times b}$ , and consider the collection  $\mathcal{B}$  of all row-permutations of  $B$ . Let  $\tau_B$  denote the *row-distribution* of  $B$ . That is,  $\tau$  is the probability distribution, over  $\Sigma^b$ , of the row  $B_{i,\star}$ , where  $i$  is sampled uniformly from  $[n]$ . Observe that every matrix in  $\mathcal{B}$  has the same row-distribution as  $B$ . Moreover,  $\mathcal{B}$  can be characterized as the set of all matrices with the row distribution  $\tau_B$ . These observations motivate the following definitions.

► **Definition 14** (Type of a matrix). *Let  $B \in \Sigma^{n \times b}$ . We define its type  $\tau_B$  as the distribution of a uniformly random row of  $B$ . That is,  $\tau_B$  is the distribution over  $\Sigma^b$ , such that*

$$\tau_B(x) = \frac{|\{i \in [n] \mid B_i = x\}|}{n}$$

for every  $x \in \Sigma^b$ . Let

$$\mathcal{T}_b^n = \{\tau_B \mid B \in \Sigma_{\text{distinct}}^{n \times b}\}$$

denote the set of all possible types of  $n \times b$  matrices with distinct columns. Given  $\tau \in \mathcal{T}_b^n$ , we denote

$$M_\tau = \{B \in \Sigma^{n \times b} \mid \tau_B = \tau\}.$$

## 5:10 Sharp Threshold Rates for Random Codes

► **Remark 15.** The type of a matrix  $B \in \Sigma^{n \times b}$  determines whether  $B \in \Sigma_{\text{distinct}}^{n \times b}$ . Therefore, for  $\tau \in \mathcal{T}_b^n$ ,

$$M_\tau = \{B \in \Sigma_{\text{distinct}}^{n \times b} \mid \tau_B = \tau\}.$$

The following fact now follows from the above discussion.

► **Fact 16** (Decomposition of a row-permutation invariant collection). *Let  $\mathcal{B} \subseteq \Sigma^{n \times b}$  be a row-permutation invariant collection. Then, there exists a set of types  $T \subseteq \mathcal{T}_{n,b}$  such that*

$$\mathcal{B} = \bigcup_{\tau \in T} M_\tau.$$

Note that a type in  $\mathcal{T}_b^n$  is defined by the number of occurrences of each of  $|\Sigma^b|$  possible rows, in a matrix consisting of  $n$  rows. In particular, each row occurs between 0 and  $n$  times. Thus,

$$|\mathcal{T}_b^n| \leq (n+1)^{|\Sigma^b|} = (n+1)^{q^b}.$$

Crucially for our purposes, this upper bound is polynomial in  $n$ .

### 2.4 Symmetric properties and convex approximations

► **Definition 17.** Let  $\mathcal{T}_b$  denote the simplex of all probability distributions over  $\Sigma^b$ .

It is generally more convenient to work in  $\mathcal{T}_b$  rather than  $\mathcal{T}_b^n$ , since the former is continuous, while the latter is discrete and involves certain divisibility conditions. This motivates the following definition.

► **Definition 18** (Permutation-closed type sets). *A set  $T \subseteq \mathcal{T}_b$  is called permutation-closed if for every  $\tau \in T$  and every permutation  $\pi : [b] \rightarrow [b]$ , the distribution of  $\pi(u)$  (where  $u \sim \tau$ ) also belongs to  $T$ .*

► **Definition 19** (Approximating sets of types). *Fix  $b \in \mathbb{N}$ . Let  $\{T^n\}_{n \in \mathbb{N}}$  be a sequence of sets of types, such that  $T^n \subseteq \mathcal{T}_b^n$ . A (topologically) closed and permutation-closed set  $T \subseteq \mathcal{T}_b$  is an approximation for  $\{T^n\}_{n \in \mathbb{N}}$  if  $T^n \subseteq T$  for every  $n$ , and*

$$\lim_{n \rightarrow \infty} \max_{\tau \in T^n} d_\infty(\tau, T^n) = 0.$$

► **Definition 20** (Symmetric property and convex approximation). *Let  $\mathcal{P} = \{P_n\}_{n \in \mathbb{N}}$  be a  $b$ -local, row-symmetric, monotone-increasing property. Due to Fact 16, for every  $n$  there exists a set  $T_n \subseteq \mathcal{T}_{n,b}$  such that the minimal set of  $P_n$  is  $\bigcup_{\tau \in T_n} M_\tau$ . If the sequence  $\{T_n\}_{n \in \mathbb{N}}$  has a convex approximation  $T$ , we say that  $T$  is a convex approximation for  $\mathcal{P}$ . In this case, we say that  $\mathcal{P}$  is symmetric.*

### 2.5 Non-list-recoverability as a property

Our motivating property is that of being *not* list-recoverable. In this section, we show that non- $(p, \ell, L)$ -list-recoverability is a symmetric property, and we define the convex set  $T_{p,\ell,L}$  that is a convex approximation for it.

Fix  $p \in [0, 1]$ ,  $1 \leq \ell \leq q$  and  $L \in \mathbb{N}$ . Let  $\mathcal{P} = (P_n)_{n \in \mathbb{N}}$  denote the property of being *not*  $(p, \ell, L)$ -list-recoverable. That is, a code  $C \subseteq \Sigma^n$  satisfies  $P_n$  if it contains a  $(p, \ell, L)$ -bad matrix. We now show that  $\mathcal{P}$  is a symmetric property.

Clearly,  $\mathcal{P}$  is monotone-increasing, and its minimal set is exactly the set of  $(p, \ell, L)$ -bad matrices, which we denote  $M_n \subseteq \Sigma_{\text{distinct}}^{n \times L}$ . It follows immediately that  $\mathcal{P}$  is  $L$ -local. Furthermore since the left-hand side of (6) is invariant to row-permutations of  $B$ , the collection  $M_n$  is row-permutation invariant, and so  $\mathcal{P}$  is row-symmetric.

Fact 16 says that we can write  $M_n = \bigcup_{\tau \in T_{p,\ell,L}^n} M_\tau$  for some  $T_{p,\ell,L}^n \subseteq \mathcal{T}_L^n$ . Indeed, (6) yields the following description of  $\mathcal{T}_{p,\ell,L}^n$ : A type  $\tau \in \mathcal{T}_L^n$  belongs to  $\mathcal{T}_{p,\ell,L}^n$  if and only if there exists a distribution  $\rho$  over  $\Sigma^L \times \binom{\Sigma}{\ell}$  such that, given  $(u, K) \sim \rho$ , the following holds:

1. The distribution of  $u$  is  $\tau$ .
2. For every  $1 \leq j \leq L$ , it holds that  $\Pr[u_j \notin K] \leq p$ .
3.  $n \cdot \rho((u, K)) \in \mathbb{N}$  for every  $u$  and  $K$ .

To see this, let  $\rho$  be the joint distribution  $(B_i, K_i)$  for  $i$  uniformly sampled from  $[n]$ , where  $B$  and  $K$  are as in (6). Note that  $\rho$  must satisfy the three conditions above. In the other direction, it is not hard to see that any such distribution  $\rho$  as above gives rise to a matrix of type  $\tau$ , satisfying (6).

We next construct a convex approximation for  $\mathcal{P}$ . Let  $T_{p,\ell,L}$  denote the set of all types  $\tau \in \mathcal{T}_L$  for which there exists a distribution  $\rho$  satisfying Conditions 1 and 2, but not necessarily Condition 3:

► **Definition 21.** Let  $1 \leq \ell \leq L$ ,  $L \in \mathbb{N}$  and  $0 \leq p \leq 1$ . Let  $\tau$  be a distribution over  $\Sigma^L$ . We say that  $\tau$  belongs to the set  $T_{p,\ell,L}$  if there exists a distribution  $\rho$  over  $\Sigma^L \times \binom{\Sigma}{\ell}$  such that:

1. If  $(u, K) \sim \rho$  then the vector  $u$  is  $\tau$ -distributed.
2. For every  $1 \leq j \leq L$  it holds that

$$\Pr_{(u,K) \sim \rho}[u_j \notin K] \leq p.$$

Clearly,  $T_{p,\ell,L}^n \subseteq T_{p,\ell,L}$  for all  $n \in \mathbb{N}$ . It is also immediate to verify that  $T_{p,\ell,L}$  is permutation-closed.

► **Lemma 22.** The set  $T_{p,\ell,L}$  is convex.

**Proof.** Let  $\tau_0, \tau_1 \in T_{p,\ell,L}$ . Let  $t \in [0, 1]$  and let  $\tau_t$  denote the mixture distribution  $(1-t)\tau_0 + t\tau_1$ . Let  $\rho_0$  and  $\rho_1$  be distributions over  $\Sigma^L \times \binom{\Sigma}{\ell}$ , satisfying Conditions 1 and 2 for  $\tau_0$  and  $\tau_1$ , respectively. Let  $\rho_t$  be the mixture distribution  $(1-t)\rho_0 + t\rho_1$ . It is straightforward to verify that  $\rho_t$  satisfies Conditions 1 and 2 with respect to  $\tau_t$ . Hence,  $\tau_t \in T_{p,\ell,L}$ . ◀

The following lemma, proven in the appendix of the full version of this paper, shows that  $T_{p,\ell,L}$  satisfies (19). Namely, every type in  $T_{p,\ell,L}$  can be realized with low error as a type from  $T_{p,\ell,L}^n$ , for large enough  $n$ .

► **Lemma 23.**

$$\lim_{n \rightarrow \infty} \sup_{\tau \in T_{p,\ell,L}} d_\infty(\tau, T_{p,\ell,L}^n) = 0.$$

We record the results of this section in the following corollary.

► **Corollary 24.** Being not  $(p, \ell, L)$ -list-recoverable is a symmetric property. Furthermore,  $T_{p,\ell,L}$  is a convex approximation for this property.

### 3 Characterization theorem

In this section, we prove our main characterization theorem, Theorem 1, which is formally stated below as Theorem 30. Before stating and proving the theorem, we record a few useful lemmas.

► **Lemma 25** ([2, Lemma 2.2]). *Let  $\tau \in \mathcal{T}_b^n$ . Then,*

$$q^{H(\tau)n} \cdot n^{-O_{q,b}(1)} \leq |M_\tau| \leq q^{H(\tau)n}.$$

► **Lemma 26.** *Let  $M \subseteq \Sigma^{n \times b}$ . Then,*

$$|M| \leq n^{q^b} \cdot q^{n \cdot \max_{B \in M} H(\tau_B)}.$$

**Proof.** Let  $T = \{\tau_B \mid B \in M\}$ . Note that

$$M \subseteq \bigcup_{\tau \in T} M_\tau.$$

Thus,

$$|M| \leq \sum_{\tau \in T} |M_\tau| \leq |T| \cdot \max_{\tau \in T} |M_\tau| \leq |\mathcal{T}_{n,b}| \cdot \max_{\tau \in T} |M_\tau|.$$

The claim follows from (2.3) and Lemma 25. ◀

We say that a type is a *histogram type* if it is indifferent to the ordering of a given vector's entries, and thus, only cares about the histogram of the vector. Formally, we make the following definition.

► **Definition 27** (Histogram type). *A type  $\tau \in T_b$  is called a histogram-type if  $\tau(u) = \tau(\pi(u))$  for every  $u \in \Sigma^b$  and every permutation  $\pi : [b] \rightarrow [b]$ .*

► **Lemma 28.** *Let  $T \subseteq T_b$  be a closed, permutation-closed, convex, set of types. Then there exists a histogram type  $\tau \in T$  such that  $H(\tau) = \max_{\tau' \in T} H(\tau')$ .*

**Proof.** Since  $T$  is closed and bounded, it is compact. Thus, there is some  $\tau' \in T$  such that  $H(\tau')$  is maximal. Given a permutation  $\pi : [b] \rightarrow [b]$ , let  $\pi(\tau')$  denote the distribution of the vector  $\pi(u)$ , where  $u \sim \tau'$ . Let

$$\tau = \frac{\sum_{\pi \in \text{Sym}_b} \pi(\tau')}{b!}.$$

Since  $T$  is permutation-closed and convex,  $\tau \in T$ . By concavity of entropy,

$$H(\tau) \geq \frac{\sum_{\pi \in \text{Sym}_b} H(\pi(\tau'))}{b!} = \frac{\sum_{\pi \in \text{Sym}_k} H(\tau')}{b!} = H(\tau').$$

Thus,  $\tau$  has maximum entropy in  $T$ , and is clearly a histogram-type. ◀

The following technical lemma, proven in the appendix of the full version, facilitates our use of an approximation for a set of types.

► **Lemma 29.** *Let  $\tau, \tau' \in T_b$  such that  $d_\infty(\tau, \tau') \leq \varepsilon$ . Then,*

$$|H_{u \sim \tau}(u \mid u_I) - H_{u \sim \tau'}(u \mid u_I)| \leq O_{b,q} \left( \varepsilon \cdot \log \frac{1}{\varepsilon} \right)$$

for any  $I \subseteq [b]$ .

We now prove that every monotone-increasing, local and row-symmetric property with a convex approximation is sharp for random codes. Furthermore, we identify the threshold rate as the maximal entropy in the approximating set.

► **Theorem 30.** Fix  $b \in \mathbb{N}$ . Let  $\mathcal{P} = \{P_n\}_{n \in \mathbb{N}}$  be a symmetric property with locality parameter  $b$ , and let  $T$  be a convex approximation for  $\mathcal{P}$ . Denote  $R^* = 1 - \frac{\max_{\tau \in T} H(\tau)}{b}$ . Fix  $\varepsilon > 0$  and let  $R \in [0, 1]$ . The following now holds.

1. If  $R \leq R^* - \varepsilon$  then

$$\lim_{n \rightarrow \infty} \Pr[C_{\text{RC}}^n(R) \text{ satisfies } \mathcal{P}] = 0.$$

2. If  $R \geq R^* + \varepsilon$  then

$$\lim_{n \rightarrow \infty} \Pr[C_{\text{RC}}^n(R) \text{ satisfies } \mathcal{P}] = 1.$$

**Proof.** For  $b \in \mathbb{N}$  and a matrix  $B \in \Sigma_{\text{distinct}}^{b \times n}$ , let  $X_B$  be an indicator variable for the event that  $B \in C_{\text{RC}}^n(R)$ . For a set  $M \subseteq \Sigma_{\text{distinct}}^{b \times n}$ , let  $X_M = \sum_{B \in M} X_B$ . By Fact 5,

$$\mathbb{E}[X_M] = |M| \cdot q^{-n(1-R)b}.$$

Let  $M_n$  denote the minimal set for  $P_n$  and let  $T_n = \{\tau_B \mid B \in M_n\}$ .

The first statement now follows from Markov's inequality, (3), and Lemma 26:

$$\begin{aligned} \Pr[C \text{ satisfies } \mathcal{P}] &= \Pr[\exists B \in M_n \ B \subseteq C_{\text{RC}}^n(R)] \\ &\leq \Pr[X_M \geq 1] \\ &\leq \mathbb{E}[X_M] \\ &= |M| \cdot q^{-n(1-R)b} \\ &\leq n^{q^b} \cdot q^{n \cdot \max_{\tau \in T_n} H(\tau)} \cdot q^{-n(1-R)b} \\ &\leq n^{q^b} \cdot q^{n \cdot \max_{\tau \in T} H(\tau)} \cdot q^{-n(1-R)b} \\ &\leq n^{q^b} \cdot q^{-nb\varepsilon} \leq e^{-\Omega(n)}. \end{aligned}$$

Above, we used the fact that  $T_n \subseteq T$ .

For the second statement, let  $\tau \in T$  have maximum entropy. By definition 19,  $T$  is closed and permutation-closed, in addition to being convex. Consequently, due to Lemma 28, we may assume that  $\tau$  is a histogram-type. Let  $\tau_n \in T_n$  such that  $d_\infty(\tau, \tau_n) = o_{n \rightarrow \infty}(1)$ . Our plan is to use a second-moment argument to show that  $C_{\text{RC}}^n(R)$  likely contains a matrix of type  $\tau_n$ .

By (3) and Lemma 25,

$$\mathbb{E}[X_{M_{\tau_n}}] = |M_{\tau_n}| q^{-n(1-R)b} \geq q^{(H(\tau_n) - (1-R)b) + o(1)} \geq q^{(H(\tau) - (1-R)b) + o(1)}.$$

We turn to bounding the variance of  $X_{M_{\tau_n}}$ . Fact 5 yields

$$\begin{aligned} \text{Var}[X_{M_{\tau_n}}] &= \sum_{B, B' \in M_{\tau_n}} (\Pr[X_B = X_{B'} = 1] - \Pr[X_B = 1] \Pr[X_{B'} = 1]) \\ &= \sum_{B, B' \in M_{\tau_n}} \left( q^{-n(1-R)(2b - \alpha(B, B'))} - q^{-2n(1-R)b} \right) \\ &\leq \sum_{\substack{B, B' \in M_{\tau_n} \\ \alpha(B, B') \geq 1}} q^{-n(1-R)(2b - \alpha(B, B'))} \end{aligned}$$

where  $\alpha(B, B')$  is the number of columns in  $B'$  that also appear in  $B$ .

## 5:14 Sharp Threshold Rates for Random Codes

In order to bound this sum, we need an estimate on the number of pairs  $B, B'$  with a given  $\alpha(B, B')$ . For  $0 \leq r \leq b$ , let

$$W_r = \{(B, B') \mid B, B' \in M_{\tau_n} \text{ and } \alpha(B, B') = r\}$$

and denote  $S_r = \{\tau_{B\|B'} \mid (B, B') \in W_r\}$ . Here,  $B\|B'$  is the  $n \times 2b$  matrix whose first (resp. last)  $b$  columns are  $B$  (resp.  $B'$ ). By Lemma 26,

$$|W_r| \leq n^{2q^b} \cdot q^{n \max_{\nu \in S_r} H(\nu)}.$$

Let  $(B, B') \in W_r$  and let  $\nu = \tau_{B\|B'}$ . Assume without loss of generality that the first  $r$  columns of  $B$  are identical to the first  $r$  columns of  $B'$ . Let  $u \sim \nu$ . Note that, since  $B, B' \in M_{\tau_n}$ , the random variables  $u_{[b]}$  and  $u_{[2b] \setminus [b]}$  are both  $\tau_n$ -distributed. Hence,

$$\begin{aligned} H(\nu) &= H(u) = H(u_{[2b] \setminus [b]}) + H(u_{[b]} \mid u_{[2b] \setminus [b]}) = H(\tau_n) + H(u_{[b]} \mid u_{[2b] \setminus [b]}) \\ &\leq H(\tau_n) + H(u_{[b]} \mid u_{[r]}) = H(\tau_n) + H(u_{[b] \setminus [r]} \mid u_{[r]}). \end{aligned}$$

Lemma 29 yields

$$\begin{aligned} H(u_{[b] \setminus [r]} \mid u_{[r]}) &\leq H_{v \sim \tau}(v_{[b] \setminus [r]} \mid v_{[r]}) + o(1) \\ &= \sum_{i=r+1}^b H_{v \sim \tau}(v_i \mid v_{[i-1]}) + o(1) \\ &= \sum_{i=r+1}^b H_{v \sim \tau}(v_b \mid v_{[i-1]}) + o(1), \end{aligned}$$

where the last equality is due to  $\tau$  being a histogram-type. Writing

$$f(r) = \sum_{i=r+1}^b H_{v \sim \tau}(v_b \mid v_{[i-1]}),$$

we conclude that

$$H(\nu) \leq f(r) + H(\tau) + o(1),$$

so that

$$|W_r| \leq q^{(f(r) + H(\tau))n + o(n)},$$

and

$$\begin{aligned} \text{Var}[X_{M_{\tau_n}}] &\leq \sum_{r=1}^b |W_r| \cdot q^{-n(1-R)(2b-r)} \leq \sum_{r=1}^b q^{(f(r) + H(\tau) - (1-R)(2b-r))n + o(n)} \\ &\leq \max_{1 \leq r \leq b} q^{(f(r) + H(\tau) - (1-R)(2b-r))n + o(n)}. \end{aligned}$$

By Chebyshev's inequality,

$$\Pr[X_{M_{\tau_n}} = 0] \leq \frac{\text{Var}[X_{M_{\tau_n}}]}{\mathbb{E}[X_{M_{\tau_n}}]^2} \leq \max_{1 \leq r \leq b} q^{(f(r) - H(\tau) + r(1-R))n + o_{b,q}(n)}.$$

We claim that  $(f(r))_{r=0}^b$  is a convex sequence. Indeed,

$$f(r-1) + f(r+1) - 2f(r) = H_{v \sim \tau}(v_b \mid v_{[r-1]}) - H_{v \sim \tau}(v_b \mid v_{[r]}) \geq 0.$$

Therefore, the maximum in the right-hand side of (3) is achieved either by  $r = 1$  or  $r = b$ . In the former case, note that

$$\begin{aligned} f(1) &= \sum_{i=2}^b H_{v \sim \tau}(v_b \mid v_{[i-1]}) = \sum_{i=2}^b H_{v \sim \tau}(v_i \mid v_{[i-1]}) = H_{v \sim \tau}(v \mid v_1) \\ &\leq H(\tau) - H_{v \sim \tau}(v_1) \leq H(\tau) \cdot \frac{b-1}{b}. \end{aligned}$$

In the last inequality above, we used the fact that  $H_{v \sim \tau} v_1 = H_{v \sim \tau} v_i$  for all  $i \in [b]$ , due to  $\tau$  being a histogram-type. Thus, for  $r = 1$ , the corresponding exponent in (3) is

$$(f(1) - H(\tau) + (1 - R))n \leq \left( (1 - R) - \frac{H(\tau)}{b} \right) n \leq -\varepsilon n.$$

In the latter case, since  $f(b) = 0$ , the exponent is

$$(-H(\tau) + (1 - R)b)n \leq -\varepsilon b n.$$

We conclude that

$$\Pr[C_{\text{RC}}^n(R) \text{ does not satisfy } \mathcal{P}] \leq \Pr(X_{M_p} = 0) \leq q^{-\varepsilon n + o(n)}.$$

### Applying the framework to list-recovery

In the rest of the paper, we use Theorem 30 to compute the threshold rate for  $(p, \ell, L)$  list-recovery in several different settings. In order to do that, we set up a few useful definitions.

► **Definition 31** ( $\beta(p, \ell, L)$  and  $\bar{T}_{p, \ell, L}$ ). *Given  $L \in \mathbb{N}$ ,  $\ell \leq L$  and  $p \in [0, 1]$ , let  $\bar{T}_{p, \ell, L}$  denote the set of all histogram-types in  $T_{p, \ell, L}$ . Let*

$$\beta(p, \ell, L) = \max_{\tau \in \bar{T}_{p, \ell, L}} H(\tau).$$

Theorem 30 allows us to characterize the threshold rate for  $(p, \ell, L)$ -list recovery in terms of  $\beta(p, \ell, L)$ :

► **Corollary 32.** *Fix  $L \in \mathbb{N}$ ,  $\ell \leq L$  and  $p \in [0, 1]$ . The threshold rate for  $(p, \ell, L)$  list-recovery is*

$$R^* = 1 - \frac{\beta(p, \ell, L)}{L}.$$

**Proof.** By Corollary 24 and Lemma 28,

$$\beta(p, \ell, L) = \max_{\tau \in T_{p, \ell, L}} H(\tau).$$

The claim now follows from Corollary 24 and Theorem 30. ◀

Finally, we introduce the following notation, which will be used for the rest of the paper.

► **Definition 33** ( $P_\ell(\cdot)$  and  $D_{d, \ell, L}$ ). *Fix  $\ell \leq L$ . Given a vector  $v \in \Sigma^L$  let*

$$P_\ell(v) = \min_{A \in \binom{[L]}{\ell}} |\{i \in [L] \mid v_i \notin A\}|$$

*We use the notation  $D_{d, \ell, L} = \{v \in \Sigma^L \mid P_\ell(v) = d\}$ .*

#### 4 Bounds on the threshold rate for noisy list-recovery

The main result in this section is an estimate of  $\beta(p, \ell, L)$  (Proposition 37 below), which leads to an estimate on the threshold rate for list-recovery (Corollary 38). This estimate is very sharp when  $\frac{q \log L}{L}$  is small; in subsequent sections we will derive estimates which are more precise for certain parameter regimes.

Before coming to these bounds, we begin with a few useful lemmas that bound  $|D_{d,\ell,L}|$  and characterize  $\bar{T}_{p,\ell,L}$ .

► **Lemma 34.** *Let  $r = 1 - \frac{\ell}{q}$  and  $s = \frac{d}{L}$ . Suppose that  $s < r$ . Then,*

$$\binom{q}{rq} \binom{L}{sL} \underbrace{\left( \frac{(1-s)L}{(1-r)q}, \dots, \frac{(1-s)L}{(1-r)q} \right)}_{\ell} \underbrace{\left( \frac{sL}{rq}, \dots, \frac{sL}{rq} \right)}_{q-\ell} \leq$$

$$|D_{d,\ell,L}| \leq \binom{q}{rq} \cdot \left( \sum_{i=0}^{sL} \binom{L}{i} \cdot ((1-r)q)^{L-i} \cdot (rq)^i \right).$$

Using Stirling's approximation, Lemma 34 immediately yields the following.

► **Corollary 35.** *In the setting of Lemma 34, suppose that  $s < r$ . Then,*

$$\log_q |D_{d,\ell,L}| = L(1 - D_{\text{KL}q}(s \parallel r)) \pm O(q \log L),$$

where the underlying constant is universal.

In order to compute  $\beta(p, \ell, L)$ , we will make use of the following characterization of  $\bar{T}_{p,\ell,L}$  (Definition 31). Intuitively, this lemma says that a histogram-type  $\tau$  is bad for  $(p, \ell, L)$ -list-recovery if and only if it has many symbols inside the most frequent  $\ell$  symbols in expectation.

► **Lemma 36.** *Let  $1 \leq \ell \leq q$ ,  $L \in \mathbb{N}$  and  $0 \leq p \leq 1$ . Let  $\tau$  be a distribution over  $\Sigma^L$  and suppose that  $\tau$  is a histogram-type. Then,  $\tau \in \bar{T}_{p,\ell,L}$  if and only if*

$$\mathbb{E}_{u \sim \tau} [P_\ell(u)] \leq pL.$$

Now, we come to our estimate on the threshold rate for  $(p, \ell, L)$  list-recovery in the regime where  $L \rightarrow \infty$  and  $q \leq o(\frac{\log L}{L})$ . We begin with the following proposition, which bounds the quantity  $\beta(p, \ell, L)$ .

► **Proposition 37.** *Let  $r = 1 - \frac{\ell}{q}$  and suppose that  $p \leq r$ . Then,*

$$\beta(p, \ell, L) = L(1 - D_{\text{KL}q}(p \parallel r)) \pm O(q \log L).$$

► **Corollary 38.** *The threshold rate for  $(p, \ell, L)$  list-recovery of a random code is*

$$R^* = \begin{cases} D_{\text{KL}q}(p \parallel r) \pm O\left(\frac{q \log L}{L}\right) & \text{if } p < r \\ 0 & \text{if } p \geq r, \end{cases}$$

where  $r = 1 - \frac{\ell}{q}$ .

► **Remark 39.** To make sense of the threshold in Corollary 38, one can verify the identity

$$D_{\text{KL}_q}(p \parallel 1 - \ell/q) = 1 - p \log_q \left( \frac{q - \ell}{p} \right) - (1 - p) \log_q \left( \frac{\ell}{1 - p} \right).$$

Substituting  $\ell = 1$ , we find  $D_{\text{KL}_q}(p \parallel 1 - 1/q) = 1 - h_q(p)$ , agreeing with the list decoding capacity theorem. For larger  $\ell$ , this expression agrees with the *list-recovery capacity theorem*, as stated in e.g. [14].

## 5 Zero-error list-recovery and perfect hashing codes

In this section we analyze the threshold rate for zero-error list-recovery (that is, when  $p = 0$ ), and give a more precise version of Corollary 38 in this setting.

► **Lemma 40.** *Let  $p^* = |D_{0,\ell,L}|/q^L$ . The threshold rate for  $(0, \ell, L)$  list-recovery of a random code is*

$$R^* = \frac{-\log_q(p^*)}{L}.$$

We use this to compute the threshold rate for a random code to be a perfect hash code, which is the same as being  $(0, q - 1, q)$  list-recoverable.

► **Corollary 41.** *The threshold rate for  $(0, q - 1, q)$  list-recovery of a random code is*

$$R^* = \frac{1}{q} \log_q \left( \frac{1}{1 - q!/q^q} \right).$$

The corollary follows from the lemma in a straightforward manner by verifying that  $|D_{0,q-1,q}| = q^q - q!$ .

## 6 List of two decoding of random and random linear codes

In this section, we study the list-of-2 decodability of two random ensembles of codes. In detail, we precisely compute the threshold rate for  $(p, 3)$ -list-decoding for random codes and for random *linear* codes. Denote by  $\mathcal{P}$  the monotone increasing property of *not* being  $(p, 3)$ -list-decodable. Note that we cannot immediately apply Corollary 38, as the error term of  $O\left(\frac{q \log L}{L}\right)$  is not negligible in this regime. We specialize to the case of  $q = 2$ , and recall our convention that  $\log$  denotes the base-2 logarithm. Recall from the introduction that whenever  $p < 1/4$  there exist  $(p, 3)$ -list-decodable codes with positive rate, but whenever  $p > 1/4$  the only  $(p, 3)$ -list-decodable codes are of bounded size, independent of  $n$ .

Our main result of this section is a demonstration that the list-of-2 decoding threshold rate for random *linear* codes is in fact greater than the corresponding threshold rate for random codes. This result demonstrates that our techniques are precise enough to allow us to sharply delineate between different natural ensembles of codes.

In the following,  $C_{\text{RLC}}^n(R)$  denotes a random linear code of block length  $n$  and rate  $R$ . We define the threshold rate for random linear codes in a manner analogous to the definition for random codes:

$$R_{\text{RLC}}^n(\mathcal{P}) := \begin{cases} \sup \{R \in [0, 1] : \Pr[C_{\text{RLC}}^n(R) \text{ satisfies } \mathcal{P}] \leq \frac{1}{2}\} & \text{if there is such an } R \\ 0 & \text{otherwise.} \end{cases}$$

■ **Figure 1** The threshold rate  $R_{RC}$  (red) for  $(p, 3)$ -list-decodability of random codes, and the threshold rate  $R_{RLC}$  (blue, dashed) for  $(p, 3)$ -list-decodability of random *linear* codes. Note that, uniformly over  $p$ , random linear codes have the greater threshold rate.

► **Theorem 42.** *Let  $p \in (0, 1/4)$ .*

1. *The threshold rate for  $(p, 3)$ -list-decoding for random codes satisfies*

$$\lim_{n \rightarrow \infty} R_{RC}^n(\mathcal{P}) = 1 - \frac{1 + h(3p) + 3p \log 3}{3}.$$

2. *The threshold rate for  $(p, 3)$ -list-decoding for random linear codes satisfies*

$$\lim_{n \rightarrow \infty} R_{RLC}^n(\mathcal{P}) = 1 - \frac{h(3p) + 3p \log 3}{2}.$$

Note that the threshold rate for random linear codes is greater than the threshold rate for random codes, uniformly over  $p \in (0, 1/4)$ . See Figure 1.

## 7 Computing the threshold rate for list-recovery efficiently

In the previous sections, we gave precise analytical expressions for the threshold rate for list-recovery in certain parameter regimes. However, there are some regimes where these bounds aren't precise. In this section, we consider the question of computing the threshold rate  $R^*$  algorithmically, given  $p, \ell$  and  $L$ . We use tools from the study of entropy-maximizing distributions to develop a simple binary-search-based procedure to pinpoint  $R^*$  up to arbitrarily small additive error.

We begin with a lemma that shows that we can compute the cardinality  $|D_{d,\ell,L}|$  efficiently; we will use this as a subroutine in our final algorithm.

► **Lemma 43.** *Given  $0 \leq d \leq L$  and  $1 \leq \ell \leq q$ , the cardinality  $|D_{d,\ell,L}|$  can be computed in time*

$$O((L+1)^q + \text{poly}(q, L)).$$

We recall the following standard facts from the theory of entropy-maximizing distributions.

► **Lemma 44** ([17, Sec. 3]). Let  $\Omega$  be a finite nonempty set,  $f : \Omega \rightarrow \mathbb{R}$  and  $t \in \mathbb{R}$ . Let  $S_t$  denote the set of all distributions  $\tau$  over  $\Omega$  such that  $\mathbb{E}_{\omega \sim \tau} [f(\omega)] = t$ . Let

$$F(t) = \max_{\tau \in S_t} H(\tau).$$

Then

$$F(t) = \inf_{\alpha \in \mathbb{R}} \left[ \log_q \left( \sum_{\omega \in \Omega} q^{\alpha \cdot f(\omega)} \right) - \alpha t \right].$$

Furthermore:

1. If  $\tau$  is the entropy maximizing distribution, then  $\tau(\omega) = \tau(\omega')$  for every  $\omega, \omega' \in \Omega$  such that  $f(\omega) = f(\omega')$ .
2. Let  $t^* = \mathbb{E}_{\omega \sim \text{Uniform}(\Omega)} [f(\omega)]$ . Then,  $F(t^*) = \log |\Omega|$ , and  $F(t)$  is nondecreasing (resp. nonincreasing) in the range  $t < t^*$  (resp.  $t > t^*$ ).
3. The function

$$\log_q \left( \sum_{\omega \in \Omega} q^{\alpha \cdot f(\omega)} \right) - \alpha t$$

is convex in  $\alpha$ .

► **Lemma 45.** Let  $\ell \leq q$ ,  $L \in \mathbb{N}$  and  $0 < p \leq 1$ , and let  $t^* = q^{-L} \cdot \sum_{d=0}^L d \cdot |D_{d,\ell,L}|$ . Then,

$$\beta(p, \ell, L) = \begin{cases} \inf_{\alpha \in \mathbb{R}} \left[ \log_q \left( \sum_{d=0}^L |D_{d,\ell,L}| \cdot q^{\alpha d} \right) - \alpha p L \right] & \text{if } pL < t^* \\ L & \text{if } pL \geq t^*. \end{cases}$$

► **Remark 46.** In general,  $\frac{t^*}{L}$  is slightly smaller than  $1 - \frac{\ell}{q}$ . Thus, Lemma 45 extends the range in which the threshold is 0 from  $\left[1 - \frac{\ell}{q}, 1\right]$  (Corollary 38) to  $[t^*, 1]$ .

► **Corollary 47.** There is an algorithm, that, given  $p, \ell, L$  and  $\varepsilon > 0$ , computes the threshold-rate for  $(p, \ell, L)$ -list-recovery, within an additive error of  $\varepsilon$ . The runtime of this algorithm is  $O((L+1)^q + \text{poly}(q, L, \log \frac{1}{\varepsilon}, \beta(p)))$ , where

$$\beta(p) = \begin{cases} \log \frac{1}{p} & \text{if } p > 0 \\ 1 & \text{if } p = 0. \end{cases}$$

## Abstract

In the *masked low-rank approximation problem*, one is given data matrix  $A \in \mathbb{R}^{n \times n}$  and binary mask matrix  $W \in \{0, 1\}^{n \times n}$ . The goal is to find a rank- $k$  matrix  $L$  for which:

$$\text{cost}(L) \stackrel{\text{def}}{=} \sum_{i=1}^n \sum_{j=1}^n W_{i,j} \cdot (A_{i,j} - L_{i,j})^2 \leq \text{OPT} + \epsilon \|A\|_F^2,$$

where  $\text{OPT} = \min_{\text{rank-}k \text{ } \hat{L}} \text{cost}(\hat{L})$  and  $\epsilon$  is a given error parameter. Depending on the choice of  $W$ , the above problem captures factor analysis, low-rank plus diagonal decomposition, robust PCA, low-rank matrix completion, low-rank plus block matrix approximation, low-rank recovery from monotone missing data, and a number of other important problems. Many of these problems are NP-hard, and while algorithms with provable guarantees are known in some cases, they either 1) run in time  $n^{\Omega(k^2/\epsilon)}$  or 2) make strong assumptions, for example, that  $A$  is incoherent or that the entries in  $W$  are chosen independently and uniformly at random.

In this work, we show that a common polynomial time heuristic, which simply sets  $A$  to 0 where  $W$  is 0, and then finds a standard low-rank approximation, yields bicriteria approximation guarantees for this problem. In particular, for rank  $k' > k$  depending on the *public coin partition number* of  $W$ , the heuristic outputs rank- $k'$   $L$  with  $\text{cost}(L) \leq \text{OPT} + \epsilon \|A\|_F^2$ . This partition number is in turn bounded by the randomized communication complexity of  $W$ , when interpreted as a two-player communication matrix. For many important cases, including all those listed above, this yields bicriteria approximation guarantees with rank  $k' = k \cdot \text{poly}(\log n/\epsilon)$ .

Beyond this result, we show that different notions of communication complexity yield bicriteria algorithms for natural variants of masked low-rank approximation. For example, multi-player number-in-hand communication complexity connects to masked tensor decomposition and non-deterministic communication complexity to masked Boolean low-rank factorization.

## 1 Introduction

The goal of low-rank approximation is to approximate an  $n \times n$  matrix  $A$  with a rank- $k$  matrix  $L$ .  $L$  can be written as the product  $L = U \cdot V$  of a “tall-and-thin” matrix  $U$  and a “short-and-wide” matrix  $V$  with  $k$  columns and rows respectively. For  $k \ll n$  this approximation can lead to computational speedups: one can store the factors  $U$  and  $V$  with less memory than storing  $A$  itself, and can compute the product  $U \cdot V \cdot x$  with a vector  $x$  faster than computing  $A \cdot x$ . Additionally, low-rank approximation is useful for denoising and can reveal low-dimensional structure in high-dimensional data (it is e.g., the basis behind principal component analysis). It thus serves as a preprocessing step in many applications, including clustering, data mining, and recommendation systems. The optimal low-rank approximation to  $A$  with distance measured in the Frobenius, spectral, or any unitarily invariant norm can be computed in polynomial time using a singular value decomposition (SVD). There are also extremely efficient approximation algorithms for finding a near optimal  $L$  under different measures, including the Frobenius norm, spectral norm, and various entrywise norms. For a comprehensive treatment, we refer the reader to the surveys [36, 47, 70].

Despite its wide applicability, in many situations standard low-rank approximation does not suffice. For example, it is common that certain entries in  $A$  either *don't obey underlying low-rank structure* or are *missing*. For example,  $A$  may be close to low-rank but with a small number of corrupted entries, or may be the sum of a low-rank matrix plus a high-rank, but still efficiently representable, diagonal or block diagonal matrix. In both cases, one must compute a low-rank approximation of  $A$  ignoring the outlying entries. One can formalize this problem, considering a binary matrix  $W$  with  $W_{i,j} = 0$  for each outlying entry  $(i, j)$  of  $A$  and  $W_{i,j} = 1$  otherwise.

► **Problem 1 (Masked Low-Rank Approximation).** *Given  $A \in \mathbb{R}^{n \times n}$ , binary  $W \in \{0, 1\}^{n \times n}$ , and rank parameter  $k$ , find rank- $k$   $L$  minimizing:*

$$\|W \circ (A - L)\|_F^2 = \sum_{i,j \in [n]} W_{i,j} \cdot (A_{i,j} - L_{i,j})^2,$$

where for two matrices  $M$  and  $N$  of the same size,  $M \circ N$  denotes the entrywise (Hadamard product): with  $(M \circ N)_{i,j} = M_{i,j} \cdot N_{i,j}$  and for integer  $n$ ,  $[n]$  denotes  $\{1, \dots, n\}$ .

As stated, Problem 1 minimizes the squared Frobenius norm of  $W \circ (A - L)$ . However any matrix norm can be used. In any case, is unclear how to extend standard low-rank approximation algorithms to solving Problem 1, since they optimize over the full matrix  $A$ , without the ability to take into account  $W$  encoding entries that should be ignored. We note that Problem 1 is equivalent to minimizing  $\|A - (L + S)\|_F^2$  where  $L$  is rank- $k$  and  $S$  is any matrix with support restricted to the 0 entries of  $W$ . If these zeros are on the diagonal, then  $S$  is diagonal. If they are sparse, then  $S$  is sparse, etc. This is how Problem 1 is traditionally stated in many applications.

### 1.1 Existing Work

A common approach to solving Problem 1 is to apply alternating minimization or the EM (Expectation-Maximization) algorithm. In fact, factor analysis, a slight variant of Problem 1 when  $W$  is 0 on its diagonal and 1 off the diagonal, was one of the original motivations of the EM algorithm [21, 56]. Much recent work studies when alternating minimization for Problem 1 converges in polynomial time under the assumptions that (1) there is a solution  $L = U \cdot V \approx A$  which is *incoherent*, meaning that the squared row norms of  $U$  and column

norms of  $V$  are small and (2) the entries of  $W$  are selected at random or have pseudorandom properties [73, 40, 51]. Under similar assumptions it can be shown that Problem 1 and the related problem of *robust PCA* can be solved via convex relaxation in polynomial time [13, 71, 12]. In many cases, these algorithms perform well in practice even when the above assumptions do not hold. Additionally, they can be proven to run in polynomial time in some common settings when the entries of  $W$  are not random – e.g., when  $W$  is zero only on its diagonal or at a few arbitrary locations. That is, when we want to approximate  $A$  as a low-rank plus diagonal component, or a low-rank matrix with arbitrary sparse corruptions respectively. However, these results still require assuming the existence of  $U \cdot V$  that is incoherent and further that is *exact* – with  $U \cdot V$

A natural question is if for common mask patterns, one can obtain provable algorithms without incoherence or other strong assumptions. This approach was taken in [54] in the context of *weighted low-rank approximation*, where  $W$  is a nonnegative matrix and the objective is still to minimize  $\|W \circ (A - L)\|_F^2$ . When  $W$  is binary, this reduces to Problem 1. In [54] it was shown that if  $W$  has at most  $r$  distinct columns, then it is possible to obtain a relative error guarantee in  $2^{\text{poly}(rk/\epsilon)} \cdot \text{poly}(n)$  time. More generally, if the rank of  $W$  over the reals is at most  $r$ , then  $n^{\text{poly}(rk/\epsilon)}$  time is achievable. Note that such algorithms are only polynomial time if  $k$ ,  $r$ , and  $1/\epsilon$  are very small. In many common use cases, such as when  $W$  is all 0s on the diagonal and 1 off-diagonal (corresponding to low-rank plus diagonal decomposition), or when  $W$  is all 0s above the diagonal and 1s on or beneath the diagonal,  $r$  is large: in fact  $\text{rank}(W) = r = n$  in these cases.

When  $A$  is low-rank with sparse corruptions, i.e., when  $W$  has at most  $t$  zero entries per row and column, the algorithms of [54] can be applied if there is an exact solution (with  $A = L$  on all non-corrupted entries). [54] referred to this problem as *adversarial matrix completion* and gave an  $n^{O(tk^2)}$  time algorithm. This is only polynomial time for constant values of  $t$  and  $k$ , and even for constant  $t$  and  $k$  is very large. Moreover, their method cannot be used in the approximate case since it requires creating a low-rank weight matrix  $W'$  whose support matches that of  $W$ . Since  $W$  may be far from low-rank, the non-zero entries of  $W$  and  $W'$  necessarily have very different values. This introduces significant error, unless  $A = L$  exactly on the support of  $W$ .

## 1.2 Our Contributions

With the goal of obtaining fast masked low-rank approximation algorithms, we consider *bicriteria approximation* with additive error. That is, we allow the rank  $k'$  of the output  $L$  to be slightly larger than  $k$ , but one still compares to the best rank- $k$  approximation. Formally, given  $A \in \mathbb{R}^{n \times n}$ ,  $W \in \{0, 1\}^{n \times n}$ , and an error parameter  $\epsilon$ , we would like to find a rank- $k'$  matrix  $L$  for which:

$$\|W \circ (A - L)\|_F^2 \leq OPT + \epsilon \|A\|_F^2, \quad (1)$$

where  $OPT = \min_{\text{rank-}k} \hat{L} \|W \circ (A - \hat{L})\|_F^2$  is the optimal value of Problem 1.

Assuming a variant of the Exponential Time Hypothesis, [54] shows a lower bound of  $2^{\Omega(r)}$  time for finding rank- $k$   $L$  achieving (1) with constant  $\epsilon$  when  $W$  is rank- $r$ . Thus the relaxation to bicriteria approximation seems necessary. In many applications it is not essential for the output rank  $k'$  to be exactly  $k$  – as long as  $k'$  is small, one still obtains significant compression. Indeed, bicriteria algorithms for low-rank matrix approximation are widely studied [22, 23, 18, 17, 63, 9]. The starting point of our work is the question:

*For which mask patterns  $W \in \{0, 1\}^{n \times n}$  can one obtain efficient bicriteria low-rank approximation algorithms with  $k' \leq k \cdot \text{poly}((\log n)/\epsilon)$  satisfying (1)?*

## Main Results

We show that the answer to this question is related to the *randomized communication complexity* of  $W$ .<sup>1</sup> If the rows and columns of  $W \in \{0, 1\}^{n \times n}$  are indexed by strings  $x \in \{0, 1\}^{\log n}$  and  $y \in \{0, 1\}^{\log n}$ , respectively, we can think of  $W$  as a two-player communication matrix for a Boolean function  $f$ , where  $f(x, y) = W_{x,y}$ . Here Alice has  $x$ , Bob has  $y$ , and the two parties want to exchange messages with as few bits as possible to compute  $f(x, y)$  with probability at least  $1 - \delta$ . The number of bits required is the randomized communication complexity  $R_\delta(f)$ . If we further require that the protocol never errs when  $f(x, y) = 1$ , but for any fixed pair  $(x, y)$  with  $f(x, y) = 0$ , it errs with probability at most  $\delta$ , then the number of bits required is the 1-sided randomized communication complexity  $R_\delta^{1\text{-sided}}(f)$ . We show:

► **Theorem 1.** *Letting  $f$  be the function computed by  $W \in \{0, 1\}^{n \times n}$  and  $\neg f$  be its negation, there is a bicriteria low-rank approximation  $L$  with rank  $k' = k \cdot 2^{R_\epsilon^{1\text{-sided}}(\neg f)}$  achieving:*

$$\|W \circ (A - L)\|_F^2 \leq OPT + 2\epsilon \|A \circ W\|_F^2,$$

where  $OPT = \min_{\text{rank-}k \hat{L}} \|W \circ (A - \hat{L})\|_F^2$ .  $L$  is computable in  $O(\text{nnz}(A)) + n \cdot \text{poly}(k'/\epsilon)$  time.

As we will see, for many common  $W$ ,  $R_\epsilon^{1\text{-sided}}(\neg f)$  is very small – with  $2^{R_\epsilon^{1\text{-sided}}(\neg f)}$  at most  $\text{poly}(\log n/\epsilon)$ . Note that our additive error is in terms of  $\|A \circ W\|_F^2$  which is only smaller than  $\|A\|_F^2$ , and may be much smaller, if e.g., the zeros in  $W$  correspond to corruptions in  $A$ . We also show a bound in terms of the communication complexity with 2-sided error.

► **Theorem 2.** *Letting  $f$  be the function computed by  $W \in \{0, 1\}^{n \times n}$ , there is a bicriteria low-rank approximation  $L$  with rank  $k' = k \cdot 2^{R_\epsilon(f)}$  achieving:*

$$\|W \circ (A - L)\|_F^2 \leq OPT + 2\epsilon \|A \circ W\|_F^2 + \epsilon \|L_{\text{opt}} \circ (1 - W)\|_F^2,$$

where  $OPT = \min_{\text{rank-}k \hat{L}} \|W \circ (A - \hat{L})\|_F^2$  and  $L_{\text{opt}}$  is any rank- $k$  matrix achieving  $OPT$ .  $L$  is computable in  $O(\text{nnz}(A)) + n \cdot \text{poly}(k'/\epsilon)$  time.

Further, the algorithm achieving Theorems 1 and 2 is extremely simple: just zero out the entries in  $A$  corresponding to entries in  $W$  that are 0 (i.e., compute  $A \circ W$ ), and then output a standard rank- $k'$  approximation of the resulting matrix. This is already a widely-used heuristic for solving Problem 1 [3, 74], and we obtain the first provable guarantees. An optimal low-rank approximation of  $A \circ W$  can be computed in polynomial time via an SVD. An approximation achieving relative error  $(1 + \epsilon)$  can be computed with high probability in  $O(\text{nnz}(A)) + n \cdot \text{poly}(k/\epsilon)$  time, giving the runtime bounds of Theorems 1 and 2 [19].

### 1.2.1 Applications

Theorems 1 and 2 provide the first bicriteria approximation algorithms for Problem 1 with small  $k'$  for a number of important special cases of the mask matrix  $W$ :

1. If  $W$  has at most  $t$  zero entries in each row, this is Low-Rank Plus Sparse (LRPS) matrix approximation, which captures the challenge of finding a low-rank approximation when a few entries are not known, or do not obey underlying low-rank structure. It has been studied in the context of adversarial matrix completion [58], robust matrix decomposition [31, 12], optics, system identification [7], and more [15].

<sup>1</sup> Our bounds actually hold for the public coin partition number of  $W$ , which is upper bounded by the randomized communication complexity [34]. See Section 1.2.4 for a more detailed discussion.

2. If  $W$  is zero exactly on the diagonal entries, this is Low-Rank Plus Diagonal (LRPD) matrix approximation. This problem arises since in practice, many matrices that are not close to low-rank are close to diagonal, or contain a mixture of diagonal and low-rank components [15]. This observation has been used e.g., to construct compact representations of kernel matrices [61, 69], weight matrices in neural networks [48, 74], and covariance matrices [66, 65]. LRPD approximation also arises in applications related to source separation [44] and variational inference [49] and is closely related to factor analysis [64, 57], which adds the additional constraints that  $L$  and  $A - L$  are PSD.
3. If  $W$  is the negation of a block-diagonal matrix with blocks of varying sizes, meaning that  $W$  is 0 on entries in the blocks and 1 on entries outside of the blocks, this is Low-Rank Plus Block-Diagonal (LRPBD) matrix approximation. This is a natural generalization of the LRPD problem and has been studied in the context of anomaly detection in networks [4], foreground detection [29], and robust principal component analysis [41]. We also consider the natural generalization of LRPS approximation discussed above, which we call the Low-Rank Plus Block-Sparse (LRPBS) matrix approximation problem.
4. If each row of  $W$  has a prefix of ones, followed by a suffix of zeros, this is the Monotone Missing Data Pattern (MMDP) problem. This is a common missing data pattern, arising in the event that when a variable is missing from a sample, all subsequent variables are also missing. Methods for handling this pattern are, e.g., included in the SAS/STAT package for statistical analyses [1]. We refer the reader to [68] for more examples of common missing data patterns, such as “connected” and “file matching” patterns.
5. If  $W$  is the negation of a banded matrix where  $W_{i,j} = 0$  iff  $|i - j| < p$  for some distance  $p$ , this is Low-Rank Plus Banded (LRPBand) matrix approximation. Variants of this problem arise in scientific computing and machine learning, in particular in the approximation of kernel matrices via fast multipole methods [55, 28, 72]. These methods approximate a kernel matrix using a low-rank “far-field” component, and a “near-field” component, which explicitly represents the kernel function between close points. If points are in one dimension and sorted, this corresponds to approximating  $A$  with a low-rank plus banded matrix. Many methods compute the low-rank component analytically (using polynomial approximations of the kernel function). A natural alternative is to seek an optimal decomposition via Problem 1. Many applications involve higher dimensional data. E.g., in the two-dimensional case, each  $i \in [n]$  can be mapped to  $(i_1, i_2) \in [\sqrt{n}] \times [\sqrt{n}]$  where  $i_1, i_2$  correspond to the first and second halves of  $i$ 's binary expansion.  $W_{i,j} = 0$  iff  $|i_1 - j_1| + |i_2 - j_2| < p$ . We give similar bounds for this multidimensional variant.

We summarize our results for the above weight patterns in Table 1. We detail the specific functions  $f$  used in these applications in Sections 2 and 3, but note that (1), (2), and (3) use variants of Equality, which has  $O(\log(1/\epsilon))$  randomized 1-sided error communication complexity, (4) and (5) use a variant of the Greater-Than problem with  $O(\log \log n + \log(1/\epsilon))$  randomized 2-sided error communication complexity for  $\log n$  bit inputs.

### 1.2.2 Relation to Matrix Completion

Masked low-rank approximation is closely related to the well-studied matrix completion problem [13, 32, 37], however the goal is different. In masked low-rank approximation, we want to approximate  $A$  as accurately as possible on the *non-masked entries* (i.e., where  $W_{ij} = 1$ ). In matrix completion, the support of  $W$  represents entries in  $A$  that are observed and the goal is to approximate  $A$  on the *missing entries* (i.e., where  $W_{ij} = 0$ ). The most common approach to solving this problem is in fact to find a low-rank approximation fitting the non-missing entries (i.e., to solve Problem 1), however the two problems are not equivalent.

■ **Table 1** Summary of applications of Theorems 1 and 2.

Mask Pattern	$k'$	Communication Problem	Ref.
LRPD/LRPBD	$O(k/\epsilon)$	Equality	Cor. 15 & 16
LRPBand	$k \cdot \text{poly}\left(\frac{\log n}{\epsilon}\right)$	Variant of Greater-Than	Cors. 17
LRPS/LRPBS (w/ sparsity $t$ )	$O(kt/\epsilon)$	Variant of equality	Full paper
MMDP	$k \cdot \text{poly}\left(\frac{\log n}{\epsilon}\right)$	Greater-Than	Cor. 18
Subsampled Toeplitz	$O(\min(pk, k/\epsilon))$	Equality mod $p$	Full paper

For example, it is not clear that a bicriteria solution to Problem 1, as given by Theorems 1 and 2, will give anything interesting for the matrix completion problem. In fact, our proof technique implies that it likely will not.

We further note that in matrix completion, the mask  $W$  is typically assumed to be random and the goal is to recover the missing entries of  $A$  when  $W$  has as few sampled ones as possible. We do not expect that a random matrix will have low-communication complexity, unless it has further structure (e.g., few zeros or ones per row).

### 1.2.3 Other Communication Models

Theorems 1 and 2 connect communication complexity to the analysis of a simple heuristic for masked low-rank approximation. A natural question is:

*Can other notions of communication complexity, such as multi-party communication complexity, non-deterministic communication complexity, and communication complexity of non-Boolean functions yield algorithms for masked low-rank approximation?*

We answer this question affirmatively. We first look at multi-party communication complexity, which we show corresponds to masked tensor low-rank approximation. Here we focus on order-3 tensors, though our results are proven for arbitrary order- $t$  tensors. A tensor is just an array  $A \in \mathbb{R}^{n \times n \times n}$ . In masked low-rank tensor approximation we are given such an  $A$  and a mask tensor  $W \in \{0, 1\}^{n \times n \times n}$  and the goal is to find rank- $k$  tensor  $L$  minimizing  $\|W \circ (A - L)\|_F^2$ . This problem has been widely studied in the context of low-rank tensor completion [25, 43, 50] and robust tensor PCA [42, 45], which corresponds to the setting where  $W$ 's zeros represent sparse corruptions of an otherwise low-rank tensor. Applications include color image and video reconstruction along with low-rank plus diagonal tensor approximation [8], where  $W$  is zero on its diagonal and one everywhere else. In the full paper we show:

► **Theorem 3** (Multipart Communication Complexity  $\rightarrow$  Tensor Low-Rank Approx). *Let  $f$  be the function computed by  $W \in \{0, 1\}^{n \times n \times n}$ ,  $\neg f$  be its negation, and  $R_{\epsilon}^{3,1\text{-sided}}(\neg f)$  be the randomized 3-party communication complexity of  $\neg f$  in the number-in-hand black-board model with 1-sided error. A bicriteria low-rank approximation  $L$  with rank  $k' = O\left((k/\epsilon)^2 \cdot 4^{R_{\epsilon}^{3,1\text{-sided}}(\neg f)}\right)$  achieving:*

$$\|W \circ (A - L)\|_F^2 \leq OPT + 2\epsilon \|A \circ W\|_F^2,$$

where  $OPT = \inf_{\text{rank-}k \hat{L}} \|W \circ (A - \hat{L})\|_F^2$ , can be computed in  $O(\text{nnz}(A)) + n \cdot \text{poly}(k/\epsilon)$  time.

We give applications of Theorem 3 to low-rank plus diagonal tensor approximation, achieving  $k' = O(k^2/\epsilon^4)$  and the low-rank plus sparse tensor approximation problem achieving  $k' = O\left(\frac{k^2 \cdot t^4}{\epsilon^6}\right)$ , where  $t$  is the maximum number of zeros on any face of  $W$ .

We also consider a common variant of low-rank approximation studied in data mining and information retrieval: *Boolean low-rank approximation* (binary low-rank approximation). Here one is given binary  $A \in \{0, 1\}^{n \times n}$  and seeks to find  $U \in \{0, 1\}^{n \times k}$  and  $V \in \{0, 1\}^{k \times n}$  minimizing  $\|A - U \cdot V\|_0$  where  $U \cdot V$  denotes Boolean matrix multiplication and  $\|\cdot\|_0$  is the entrywise  $\ell_0$  norm, equal to the squared Frobenius norm in this case. While Boolean low-rank approximation is NP-hard [20, 26], there is a large body of work studying heuristic algorithms and approximation schemes, when no entries of  $A$  are masked [46, 59, 67, 10, 24]. We show in the full paper that any black-box algorithm for standard Boolean low-rank approximation yields a bicriteria algorithm for masked Boolean low-rank approximation, with rank depending on the *nondeterministic communication complexity* of the mask  $W$ .

► **Theorem 4** (Nondeterministic Communication Complexity  $\rightarrow$  Boolean Low-Rank Approx).

Let  $f$  be the function computed by  $W$  and  $N(f)$  be the nondeterministic communication complexity of  $f$ . For any  $k' \geq k \cdot 2^{N(f)}$ , if one computes  $U, V \in \{0, 1\}^{n \times k'}$  satisfying  $\|A \circ W - U \cdot V\|_0 \leq \min_{\hat{U}, \hat{V} \in \{0, 1\}^{n \times k'}} \|A \circ W - \hat{U} \cdot \hat{V}\|_0 + \Delta$  then:

$$\|W \circ (A - U \cdot V)\|_0 \leq 2^{N(f)} \cdot OPT + \Delta,$$

where  $OPT = \min_{\hat{U}, \hat{V} \in \{0, 1\}^{k \times n}} \|W \circ (A - \hat{U} \cdot \hat{V})\|_0$  and  $U \cdot V$  denotes Boolean matrix multiplication.

We can apply Theorem 4 for example, to the low-rank plus diagonal Boolean matrix approximation problem, where  $W$  is zero on its diagonal and one everywhere else. In this case we have  $2^{N(f)} = \log n$  and correspondingly  $k' = k \log n$ .

## 1.2.4 Connections to Approximate Rank and Other Communication Lower Bounds

In Section 1.3 we sketch the proof of Theorem 1, which is very simple (Theorems 2, 3, and 4 are proved similarly.) The proof is based on covering  $W$  with  $2^{R_{\epsilon}^{1-sided}(\neg f)}$  disjoint monochromatic rectangles, which match  $W$  on all but a small random subset of its 1 entries. The existence of a 1-sided error randomized communication protocol for  $\neg f$  using  $R_{\epsilon}^{1-sided}(\neg f)$  bits of communication is well known to imply the existence of such a covering with  $2^{R_{\epsilon}^{1-sided}(\neg f)}$  rectangles. However, the optimal size of such a covering, which is known as the “public-coin partition bound” [34], may be lower than this. In fact, recent work has shown that it is provably smaller for some problems [27]. Thus, our algorithm can be stated in terms of this bound, giving improved results for these problems. However, as far as we are aware, this bound does not give any improvements for the communication problems we consider (corresponding to natural weight matrices  $W$ ).

The public coin partition bound is a strengthening of the well-studied partition bound [33] for randomized communication complexity, which is itself a strengthening of the smooth rectangle bound [33]. This logarithm of the smooth rectangle bound is equivalent to the log approximate nonnegative rank of  $W$  up to constants [38]. It has been shown that the randomized communication complexity can be polynomially larger than the log partition bound [27]. Additionally, recent work refuting the log approximate rank conjecture [16] has shown that the randomized communication complexity can be exponentially larger than the log approximate nonnegative rank. Thus, improving our results to depend on these communication complexity lower bounds rather than the communication complexity itself would lead to potential improvements for some weight matrices  $W$ . However, all known separations are for  $W$  with complex structure and relatively high communication complexity, and thus not relevant to common applications. Additionally, it is unclear how to extend

our techniques to these weaker notions, or to other related notations, such as information complexity [14]. Such extensions would be interesting, e.g., connecting the difficulty of masked low-rank approximation to the approximate rank of the mask.

### 1.2.5 Lower Bounds

Given our results, and the above discussion, a natural question to ask is:

*Is there a natural notion of the complexity of the mask  $W$  that characterizes the difficulty of the masked low-rank approximation problem?*

We give some initial results, focused on how communication complexity in particular relates to the best bicriteria approximation factor for masked low-rank approximation achievable in polynomial time. We note that, since our results actually hold with rank depending on the public-coin partition bound [34], which has been separated from the randomized communication complexity, the communication complexity itself certainly does not tightly characterize the difficulty of masked low-rank approximation. However, we view our lower bounds in terms of communication complexity as a step in understanding this difficulty.

We prove two bounds based on a conjecture of the hardness of approximate 3-coloring. We show that there is a class of masks  $W$  such that any polynomial time algorithm achieving guarantee (1) and small enough  $\epsilon$  requires bicriteria rank  $k' = \Omega\left(\frac{D(f)}{\log D(f)}\right)$  where  $D(f)$  is the deterministic communication complexity of  $f$ . Note that  $D(f)$  is only greater than  $R_\epsilon^{1-sided}(\neg f)$  and  $R_\epsilon(f)$ .

We strengthen this bound significantly for two natural variants of the masked low-rank approximation problem: when the low-rank approximation  $L$  is required to have a non-negative or binary factorization. We note that our techniques yield matching algorithmic results analogous to Theorems 1 and 2 for these variants. We show that for these variants on Problem 1, there is a class of masks  $W$  such that any polynomial time algorithm achieving guarantee (1) for small enough  $\epsilon$  requires bicriteria rank which is exponential in the deterministic communication complexity,  $k' = 2^{\Omega(D(\neg f))}$ . This bound matches our algorithmic results for these variants. We note that in the parameter regimes considered (we just require rank  $k = 3$ ), there exist polynomial time algorithms for the *non-masked* versions of binary and non-negative low-rank approximation. Thus, the hardness in terms of communication complexity comes from adding the mask to the low-rank cost function rather than the binary and non-negativity constraints themselves.

Our lower bounds are closely related to those of [30] on the hardness of bicriteria low-rank matrix completion. We note that for any  $n \times n$  mask matrix  $W$ , we can always bound  $D(f) = O(\log n)$ . Thus, achieving a  $2^{o(D(f))}$  bicriteria approximation factor means achieving an approximation factor sub-polynomial in  $n$ . [30] leaves open if achieving a  $\sqrt{n}$  bicriteria approximation to rank-3 matrix completion is hard (Question 4.3 in [30]), and more generally asks what bicriteria approximation is achievable in polynomial time (Question 4.2 in [30]).

## 1.3 Our Techniques

The key ideas behind Theorems 1 and 2 are similar. We focus on Theorem 1 for exposition. We want to argue that any near optimal rank- $k'$  approximation of  $A \circ W$ , gives a good bicriteria solution to the masked rank- $k$  approximation problem. For simplicity, here we focus on showing this for the actual optimal rank- $k'$  approximation,  $L = \arg \min_{\text{rank} = k'} \hat{L} \|(A \circ W) - \hat{L}\|_F^2$ . We show that  $\|W \circ (A - L)\|_F^2 \leq OPT + O(\epsilon) \|A \circ W\|_F^2$  via a comparison method. Namely, we exhibit a rank  $k'$  matrix  $\tilde{L}$  that:

1. Nearly matches how well the optimum rank- $k$  solution  $L_{opt}$  to Problem 1 approximates  $A$  on the support of  $W$ . In particular,  $\|(A - \bar{L}) \circ W\|_F^2 \leq \|(A - L_{opt}) \circ W\|_F^2 + O(\epsilon) \|A \circ W\|_F^2$ .
2. Places *no mass* outside the support of  $W$ . In particular,  $\|\bar{L} \circ (1 - W)\|_F^2 = 0$ .

Since  $L$  minimizes the distance to  $(A \circ W)$  among all rank- $k'$  matrices, we have  $\|(A \circ W) - L\|_F^2 \leq \|(A \circ W) - \bar{L}\|_F^2$ . However, by (2),  $\bar{L}$  *exactly matches*  $A \circ W$  outside the support of  $W$  – both matrices are 0 there. Thus  $L$  must have at least as large error outside the support of  $W$ , and in turn cannot have larger error on the support of  $W$ . That is, we must have  $\|(A - L) \circ W\|_F^2 \leq \|(A - \bar{L}) \circ W\|_F^2$ . Then by (1),  $L$  satisfies the desired bound.

### 1.3.1 From Communication Protocols to Low-Rank Approximations

The key question becomes how to exhibit  $\bar{L}$ , which we do using communication complexity. We view  $W$  as the communication matrix of some function  $f : \{0, 1\}^{\log n} \times \{0, 1\}^{\log n} \rightarrow \{0, 1\}$ , with  $W_{x,y} = f(x, y)$ , where in  $f$  we interpret  $x, y \in [n]$  as their binary representations. It is well-known that the existence of a deterministic communication protocol  $\Pi$  that computes  $f$  with  $D(f)$  total bits of communication implies the existence of a partition of  $W$  into  $2^{D(f)}$  *monochromatic combinatorial rectangles*. That is, there are  $2^{D(f)}$  non-overlapping sets  $R_i = S \times T$  for  $S, T \in [n]$  that partition  $W$  and that satisfy  $W(R_i)$  is either all 1 or all 0. We could construct  $\bar{L}$  by taking the best  $k$ -rank approximation of each  $A(R_i)$  where  $R_i$  is colored 1 (i.e., contains inputs with  $f(x, y) = 1$ ). We could then sum up these approximations to produce  $\bar{L}$  with rank  $\leq k \cdot 2^{D(f)}$ . Note that  $\bar{L}$  is 0 outside the rectangles colored 1 – i.e., outside the support of  $W$ . Thus condition (2) above is satisfied. Further,  $\bar{L}$  matches the optimal rank- $k$  approximation on each  $R_i$  colored 1. So it approximates  $A$  at least as well as  $L_{opt}$  on these rectangles, and since these rectangles fully cover the support of  $W$  we have  $\|(A - \bar{L}) \circ W\|_F^2 \leq \|(A - L_{opt}) \circ W\|_F^2$ , giving the requirement of (1).

Unfortunately, essentially none of the  $W$  that are of interest in applications admit efficient deterministic communication protocols.  $k' = k \cdot 2^{D(f)}$  will typically be larger than  $n$ , giving a vacuous bound. Thus we turn to randomized communication complexity with error probability  $\epsilon$ ,  $R_\epsilon(f)$ , which is much lower in these cases. A randomized protocol  $\Pi$  achieving this complexity corresponds to a distribution over partitions of  $W$  into  $2^{R_\epsilon(f)}$  rectangles. These rectangles are not monochromatic but are close to it – letting  $W_\Pi$  be the communication matrix of the (random) function computed by the protocol,  $W_\Pi$  is partitioned into  $2^{R_\epsilon(f)}$  monochromatic rectangles and further matches  $W$  on each  $(x, y)$  with probability at least  $1 - \epsilon$ . We prove that, even with this small error, constructing  $\bar{L}$  as above using the partition of  $W_\Pi$  instead of  $W$  itself gives a solution nearly matching  $L_{opt}$  up to small additive error. This error will involve  $\|A \circ W\|_F^2$  and  $\|L_{opt} \circ (1 - W)\|_F^2$ , depending on whether the protocol makes 1 or 2-sided error, as seen in Theorems 1 and 2.

### 1.3.2 Low-Rank Approximation to $W$ Does Not Suffice

A natural view of our argument above is that the existence of an efficient randomized protocol for  $W$  implies the existence of a distribution over low-rank matrices (induced by partitions into near monochromatic rectangles) that match  $W$  on each entry with good probability. We note that this distributional view is critical – simply having a low-rank approximation to  $W$  matching all but a small fraction of entries does not suffice. The mistaken entries could in the worst case align with very heavy entries of  $A$ , which must be approximated well to solve masked low-rank approximation to small error. An approximation with small entrywise error (in the  $\ell_\infty$  sense) would suffice. However, for important cases, e.g., when  $W$  is zero on the diagonal and one off the diagonal, such approximations provably require higher rank than  $2^{R_\epsilon(f)}$  and thus relying on them would lead to significantly weaker bounds [2].

### 1.3.3 Other Communication Models

In extending our results to other communication models, we first consider the connection between multiparty number-in-hand communication and tensor low-rank approximation. Protocols in this model correspond to a partition of the communication tensor  $W \in \{0, 1\}^{n \times n \times n}$  into  $2^{R_\epsilon^3(f)}$  monochromatic (or nearly monochromatic) rectangles of the form  $R_i = S \times T \times U$  for  $S, T, U \subseteq [n]$ , where  $R_\epsilon^3(f)$  is the randomized 3-player communication complexity of  $W$ . We can again argue the existence of a rank  $k' = k \cdot 2^{R_\epsilon^3(f)}$  tensor  $\bar{L}$ , obtained by taking a near optimal low-rank approximation to each rectangle colored 1 in  $W_\Pi$ , which is mostly 0 outside the support of  $W$  and at the same time competes with the best rank- $k$  tensor approximation  $L_{opt}$  on the support of  $W$ . There are different notions of rank for tensors; here we mostly discuss canonical or CP rank. This lets us argue, as in the two player case, that the best rank- $k'$  approximation of  $A \circ W$  also competes with  $L_{opt}$ . It is not known how to find this best rank- $k'$  approximation efficiently, however using an algorithm of [63] we can find a rank  $k'' = O((k'/\epsilon)^2)$  bicriteria approximation achieving relative error  $1 + \epsilon$ . Overall we have  $k'' = O\left((k/\epsilon)^2 \cdot 2^{2R_\epsilon^3(f)}\right)$ , giving Theorem 3.

We next consider the nondeterministic communication complexity. In a nondeterministic communication protocol for a function  $f$ , players can make “guesses” at any point during the protocol  $\Pi$ . The only requirement is that, (1) for every  $x, y$  with  $f(x, y) = 1$ , for some set of guesses made by the players, the protocol outputs  $\Pi(x, y) = 1$  and (2) the protocol never outputs  $\Pi(x, y) = 1$  for  $x, y$  with  $f(x, y) = 0$ . Such a protocol using  $N(f)$  bits of communication corresponds to covering the communication matrix  $W$  with  $2^{N(f)}$  *possibly overlapping* monochromatic rectangles. In many cases, the nondeterministic complexity is much lower than the randomized communication complexity. However, for low-rank approximation in the Frobenius norm, the overlap is a problem. We cannot construct  $\bar{L}$  simply by approximating each rectangle and adding these approximations together.  $\bar{L}$  will be too “heavy” where the rectangles overlap. However, for the Boolean low-rank approximation problem, the overlap is less of a problem. We simply construct  $\bar{L}$  in the same way, letting it be the AND of the approximations on each rectangle. In the end, we obtain an error bound of roughly  $2^{N(f)} \cdot OPT$ , owing to the fact that error may still build up on the overlapping sections. Since there are  $2^{N(f)}$  rectangles total, each entry is overlapped by at most  $2^{N(f)}$  of them. However, since  $N(f)$  can be very small, this result gives a tradeoff with Theorems 1 and 2 (which can also be extended to the Boolean case). For example, we show how to obtain error  $\approx O(\log n \cdot OPT)$  for the Boolean low-rank plus diagonal approximation problem, with rank  $k' = O(k \log n)$ . This is smaller than the  $O(k/\epsilon)$  achieved by Theorem 1 for small  $\epsilon$ , which may be required to achieve good error if, e.g.,  $\|A\|_F^2$  is large.

### 1.3.4 An Alternative Approach

In the important cases when  $W$  is zero on its diagonal and one elsewhere or has a few non-zeros per row (the low-rank plus diagonal and low-rank plus sparse approximation problems, respectively) the existence of  $\bar{L}$  satisfying the necessary conditions (1) and (2) above can be proven via a very different technique. The key idea is a structural result: that any low-rank matrix cannot concentrate too much weight on more than a few entries of its diagonal, or more generally, on a sparse support outside a few rows. Thus we can obtain  $\bar{L}$  from  $L_{opt}$  by explicitly zero-ing out these few large entries falling outside the support of  $W$  (e.g., on its diagonal when  $W$  has zeros just on its diagonal). We detail this approach in the full paper, giving a bound matching Theorem 1 in this case. We show that the same structural result can also be used to obtain a fixed-parameter-tractable, relative error, non-bicriteria

approximation algorithm for Problem 1 in the low-rank plus diagonal case, as well as for the closely related factor analysis problem. We are unaware of any formal connection between this structural result and our communication complexity framework; however, establishing one would be very interesting.

## 1.4 Road Map

In Section 2 we give preliminaries, defining the communication models we use and giving communication complexity bounds for common mask matrices in these models. In Section 3 we then prove our main results, Theorems 1 and 2. We instantiate these results for the common mask matrices shown in Table 1. We defer our results connecting masked tensor approximation to multiparty communication complexity and Boolean low-rank approximation to nondeterministic communication complexity to the full paper – available at <https://arxiv.org/abs/1904.09841>. We also defer our lower bound results to the full version.

## 2 Preliminaries

### 2.1 Notation and Conventions

Throughout we use  $\log z$  to denote the base-2 logarithm of  $z$ . For simplicity, so that we can associate any  $W \in \mathbb{R}^{n \times n}$  with a function  $f : \{0, 1\}^{\log n} \times \{0, 1\}^{\log n} \rightarrow \{0, 1\}$  we assume that  $n$  is a power of 2 and so  $\log n$  is an integer. Our results can be easily extended to general  $n$ . Given a matrix  $M \in \mathbb{R}^{n \times n}$  and a combinatorial rectangle  $R = S \times T$  for  $S, T \subseteq [n]$ , we let  $M_R$  denote the submatrix of  $M$  indexed by  $R$ . For matrix  $M$  we let  $1 - M$  denote the matrix  $N$  with  $N_{i,j} = 1 - M_{i,j}$ . E.g.,  $1 - I$  is the matrix with all zeros on diagonal and all ones off diagonal.

While in the introduction we focus on low-rank approximation in the Frobenius norm, many of our results will apply to any entrywise matrix norm of the form:

► **Definition 5.** An entrywise matrix norm  $\|\cdot\|_* : \mathbb{R}^{n \times n} \rightarrow \mathbb{R}$  is a function of the form:

$$\|M\|_* = \sum_{i=1}^n \sum_{j=1}^n g(|M_{i,j}|),$$

where  $g : \mathbb{R} \rightarrow \mathbb{R}$  is some monotonically increasing nonnegative function.

$g(x) = x^2$  gives the squared Frobenius norm,  $g(x) = x^p$  gives the entrywise  $\ell_p$  norm,  $g(x) = 1$  iff  $x \neq 0$  gives the entrywise  $\ell_0$  norm, etc. See [62, 10, 17, 5] for a discussion of standard low-rank approximation algorithms for these norms. As discussed, our bicriteria results will simply require applying one of these algorithms to compute a near-optimal low-rank approximation to  $A \circ W$  (i.e.,  $A$  with the masked entries zeroed out).

### 2.2 Communication Complexity Models

We give a brief introduction to the communication models we consider, and refer the reader to the textbooks [39, 53] for more background. We mostly consider two-party communication of Boolean functions, though in the full paper discuss extensions to more than two parties.

Consider two parties, Alice and Bob, holding inputs  $x \in \mathcal{X}$  and  $y \in \mathcal{Y}$  respectively. They exchange messages in order to compute a function  $f : \mathcal{X} \times \mathcal{Y} \rightarrow \{0, 1\}$  evaluated at  $(x, y)$ . They would like to do this while minimizing the total number of bits exchanged. The communication between the parties is determined by a possibly randomized protocol, which

specifies the message of the next player to speak as a function of previous messages received by that player and that player's input. For a given protocol  $\Pi$ , we let  $|\Pi(x, y)|$  denote the number of bits transmitted by the players on inputs  $x$  and  $y$ , and we let  $|\Pi| = \max_{x, y} |\Pi(x, y)|$ .

Let  $M$  be the communication matrix of  $f$ , that is, the matrix whose rows are indexed by elements of  $\mathcal{X}$  and columns by elements of  $\mathcal{Y}$ , and for which  $M_{x, y} = f(x, y)$ . A well known and useful property is that  $\Pi$  partitions  $M$  into rectangles  $R = S \times T$ , where  $S \subseteq \mathcal{X}$  and  $T \subseteq \mathcal{Y}$ , and every pair  $(x, y)$  of inputs with  $(x, y) \in S \times T$  has the same output when running protocol  $\Pi$ . The number of rectangles in the partition is equal to  $2^{|\Pi|}$ . We call the unique output of  $\Pi$  on a rectangle  $S \times T$  the *label* of the rectangle.

► **Definition 6** (Deterministic Communication Complexity). *The deterministic communication complexity  $D(f) = \min_{\Pi} |\Pi|$ , where the minimum is taken over all protocols  $\Pi$  for which  $\Pi(x, y) = f(x, y)$  for every pair  $(x, y)$  of inputs. Equivalently,  $D(f)$  is the minimum number so that  $M$  can be partitioned via a protocol  $\Pi$  into  $2^{D(f)}$  rectangles for which for every rectangle  $R$  and  $b \in \{0, 1\}$ , if  $R$  is labeled  $b$ , then for all  $(x, y) \in R$ ,  $f(x, y) = b$ .*

We next turn to randomized communication complexity. For the purposes of this paper, we will consider public coin randomized communication complexity, i.e., there is a shared random string  $r$  that both Alice and Bob have access to. In a randomized protocol  $\Pi$ , Alice and Bob see  $r$  and then run a deterministic protocol  $\Pi_r$ . We say a protocol  $\Pi$  is a  $(\delta_1, \delta_2)$ -error protocol if for all  $x, y \in \mathcal{X} \times \mathcal{Y}$ , with  $f(x, y) = 1$ ,  $\mathbb{P}_r[\Pi_r(x, y) = f(x, y)] \geq 1 - \delta_1$  and for all  $x, y \in \mathcal{X} \times \mathcal{Y}$  with  $f(x, y) = 0$ ,  $\mathbb{P}_r[\Pi_r(x, y) = f(x, y)] \geq 1 - \delta_2$ . We can then define a general notion of randomized communication complexity:

► **Definition 7** (Randomized Communication Complexity – General). *The  $(\delta_1, \delta_2)$ -error randomized communication complexity  $R_{\delta_1, \delta_2}(f) = \min_{\Pi} |\Pi|$ , where the minimum is taken over all  $(\delta_1, \delta_2)$ -error protocols  $\Pi$ . Equivalently,  $R_{\delta_1, \delta_2}(f)$  is the minimum number so that there is a distribution over protocols inducing partitions of  $M$ , each containing at most  $2^{R_{\delta_1, \delta_2}(f)}$  rectangles, such that (1) for every  $(x, y) \in \mathcal{X} \times \mathcal{Y}$  with  $f(x, y) = 1$ , with probability at least  $1 - \delta_1$ ,  $(x, y)$  lands in a rectangle which is labeled 1 and (2) for every  $(x, y) \in \mathcal{X} \times \mathcal{Y}$  with  $f(x, y) = 0$ , with probability at least  $1 - \delta_2$ ,  $(x, y)$  lands in a rectangle which is labeled 0.*

Definition 7 is typically specialized to two cases: the randomized communication complexity with 2-sided error and the randomized communication complexity with 1-sided error.

► **Definition 8** (Randomized Communication Complexity – 2-sided). *The  $\delta$ -error randomized communication complexity of  $f$  is  $R_{\delta}(f) \stackrel{\text{def}}{=} R_{\delta, \delta}(f)$ .*

► **Definition 9** (Randomized Communication Complexity – 1-Sided). *The  $\delta$ -error 1-sided randomized communication complexity of  $f$  is  $R_{\delta}^{1\text{-sided}}(f) \stackrel{\text{def}}{=} R_{0, \delta}(f)$ .*

In Theorem 1 we consider the 1-sided communication complexity of  $\neg f$ :  $R_{\delta, 0}(f)$ .

## 2.3 Specific Communication Bounds

We discuss a few problems that will be particularly useful for our applications. We only need communication upper bounds and in specific models. Note that in this section, as is standard, we state bounds for communication problems with  $n$ -bit inputs. In our applications to masked low-rank approximation, we will typically apply the bounds with input size  $\log n$ .

### Equality

In the Equality problem, denoted  $EQ$ , there are two players Alice and Bob, holding strings  $x, y \in \{0, 1\}^n$ , and the function  $EQ(x, y) = 1$  if  $x = y$ , and  $EQ(x, y) = 0$  otherwise.

► **Theorem 10** ([39], combining Corollaries 26 and 27 of [11]).  $R_\delta^{1-way}(EQ) \leq (1 - \delta) \log((1 - \delta)^2 / \delta) + 5$ , and  $R_\delta^{1-way, 1-sided}(EQ) \leq \log(1/\delta) + 5$ .

We also can bound the nondeterministic communication complexity of inequality, i.e., the function  $NEQ(x, y)$  with  $NEQ(x, y) = 1$  iff  $x \neq y$ .

► **Theorem 11.**  $N(NEQ) \leq \lceil \log n \rceil + 2$ .

**Proof.** Alice simply guesses an index at which  $x$  and  $y$  differ and sends this index (using  $\lceil \log n \rceil$  bits) along with the value of  $x$  at this index to Bob. Bob sends the value of  $y$  at this index and the players check if  $x$  and  $y$  differ at the index. ◀

Essentially the same protocol can be used to solve the negation of the disjointness problem, with  $\neg DISJ(x, y) = 1$  only if there is some  $k \in [n]$  with  $x(k) = y(k) = 1$ . We thus have:

► **Theorem 12** ([60]).  $N(\neg DISJ) \leq \lceil \log n \rceil + 2$ .

### Greater-Than

In Greater-Than, denoted  $GT$ , there are two players Alice and Bob, holding integers  $x, y \in \{0, 1, \dots, n-1\}$ , and the function  $GT(x, y) = 1$  if  $x > y$ , and  $GT(x, y) = 0$  otherwise.

► **Theorem 13** ([52]).  $R_\delta(GT) = O(\log(n/\delta))$ .

## 3 Bicriteria Approximation from Communication Complexity

In this section we prove our main results, Theorems 1 and 2, which connect the randomized communication complexity of the binary matrix  $W$  to the rank required to solve Problem 1 efficiently up to small additive error. We prove a general theorem connecting the rank to  $R_{\delta_1, \delta_2}(f)$ . Both Theorems 1 and 2 follow as corollaries if we consider the 1-sided error complexity  $R_\delta^{1-sided}(\neg f) = R_{\delta, 0}(f)$  and the 2-sided error complexity  $R_\delta(f) \stackrel{\text{def}}{=} R_{\delta, \delta}(f)$  respectively (Definitions 8 and 9).

► **Theorem 14** (Randomized Communication Complexity  $\rightarrow$  Bicriteria Approximation). *Consider  $W \in \{0, 1\}^{n \times n}$  and let  $f$  be the function computed by it. For  $k' \geq k \cdot 2^{R_{\epsilon_1, \epsilon_2}(f)}$ , and any entrywise norm  $\|\cdot\|_\star$  (Def. 5), for any  $L$  satisfying  $\|A \circ W - L\|_\star \leq \min_{\text{rank}-k'} \hat{L} \|A \circ W - \hat{L}\|_\star + \Delta$ :*

$$\|(A - L) \circ W\|_\star \leq OPT + \epsilon_1 \|A \circ W\|_\star + \epsilon_2 \|L_{opt} \circ (1 - W)\|_\star + \Delta,$$

where  $OPT = \min_{\text{rank}-k} \hat{L} \|(A - \hat{L}) \circ W\|_\star$  and  $L_{opt}$  is any rank- $k$  matrix achieving  $OPT$ .

**Proof.** As discussed (Def. 7),  $R_{\epsilon_1, \epsilon_2}(f)$  is the minimum number so that there is a distribution on protocols inducing partitions of  $W$ , each containing at most  $2^{R_{\epsilon_1, \epsilon_2}(f)}$  rectangles, such that (1) for every  $x, y \in \{0, 1\}^{\log n}$  with  $f(x, y) = 1$ ,  $(x, y)$  lands in a rectangle labeled 1 with probability  $\geq 1 - \epsilon_1$  and (2) for every  $x, y \in \{0, 1\}^{\log n}$  with  $f(x, y) = 0$ ,  $(x, y)$  lands in a rectangle labeled 0 with probability  $\geq 1 - \epsilon_2$ . In other words, letting  $W_\Pi$  be the (random) matrix corresponding to the function computed by the protocol: (1)  $W \circ (1 - W_\Pi)$  has each entry equal to 1 with probability  $\leq \epsilon_1$  and (2)  $W_\Pi \circ (1 - W)$  has each entry equal to 1 with probability  $\leq \epsilon_2$ . Thus, fixing some  $L_{opt}$ :

$$\begin{aligned} \mathbb{E}_{\text{protocol } \Pi} [\|A \circ W \circ (1 - W_\Pi)\|_* + \|L_{\text{opt}} \circ W_\Pi \circ (1 - W)\|_*] \\ \leq \epsilon_1 \|A \circ W\|_* + \epsilon_2 \|L_{\text{opt}} \circ (1 - W)\|_*. \end{aligned}$$

Thus, there is at least one protocol  $\Pi$  (inducing a partition with  $\leq 2^{R_{\epsilon_1, \epsilon_2}(f)}$  rectangles) with:

$$\|A \circ W \circ (1 - W_\Pi)\|_* + \|L_{\text{opt}} \circ W_\Pi \circ (1 - W)\|_* \leq \epsilon_1 \|A \circ W\|_* + \epsilon_2 \|L_{\text{opt}} \circ (1 - W)\|_*. \quad (2)$$

Let  $P_1$  be the set of rectangles on which the protocol achieving (2) returns 1 and  $P_0$  be the set on which it returns 0. For any  $R \in P_1$  let  $L^R = \arg \min_{\text{rank}-k} \hat{L} \|A_R \circ W_R - \hat{L}\|_*$  (note that  $L^R$  is the size of  $R$ ). Let  $\bar{L}^R$  be the  $n \times n$  matrix equal to  $L^R$  on  $R$  and 0 elsewhere. Let  $\bar{L} = \sum_{R \in P_1} \bar{L}^R$ . Note that  $\bar{L}$  has rank at most  $\sum_{R \in P_1} \text{rank}(\bar{L}^R) \leq k \cdot |P_1| \leq k \cdot 2^{R_{\epsilon_1, \epsilon_2}(f)}$ . Thus, by the assumption that  $L$  satisfies  $\|A \circ W - L\|_* \leq \min_{\text{rank}-k'} \hat{L} \|A \circ W - \hat{L}\|_* + \Delta$ :

$$\begin{aligned} \|(A - L) \circ W\|_* &\leq \|A \circ W - L\|_* \leq \|A \circ W - \bar{L}\|_* + \Delta \\ &= \|(A \circ W - \bar{L}) \circ W_\Pi\|_* + \|(A \circ W - \bar{L}) \circ (1 - W_\Pi)\|_* + \Delta \\ &= \|(A \circ W - \bar{L}) \circ W_\Pi\|_* + \|A \circ W \circ (1 - W_\Pi)\|_* + \Delta, \end{aligned} \quad (3)$$

where the third line follows since  $\bar{L}$  is 0 outside the support of  $W_\Pi$  (i.e., outside of the rectangles in  $P_1$ ). Since  $\bar{L}$  is equal to the best rank- $k$  approximation to  $A_R \circ W_R$  on each rectangle  $R$  in  $P_1$ , and since these rectangles partition the support of  $W_\Pi$ :

$$\begin{aligned} \|(A \circ W - \bar{L}) \circ W_\Pi\|_* &\leq \|(A \circ W - L_{\text{opt}}) \circ W_\Pi\|_* \\ &= \|(A - L_{\text{opt}}) \circ W \circ W_\Pi\|_* + \|L_{\text{opt}} \circ (1 - W) \circ W_\Pi\|_* \\ &\leq \text{OPT} + \|L_{\text{opt}} \circ (1 - W) \circ W_\Pi\|_*. \end{aligned}$$

Plugging back into (3) and applying (2):

$$\begin{aligned} \|(A - L) \circ W\|_* &\leq \text{OPT} + \|L_{\text{opt}} \circ (1 - W) \circ W_\Pi\|_* + \|A \circ W \circ (1 - W_\Pi)\|_* + \Delta \\ &\leq \text{OPT} + \epsilon_1 \|A \circ W\|_* + \epsilon_2 \|L_{\text{opt}} \circ (1 - W)\|_* + \Delta, \end{aligned}$$

which completes the theorem.  $\blacktriangleleft$

**Proof of Theorems 1 and 2.** Theorems 1 and 2 follow by applying Theorem 14 with  $\epsilon_1 = \epsilon_2 = \epsilon$  and  $\epsilon_1 = \epsilon$ ,  $\epsilon_2 = 0$  respectively, and noting that  $\|A \circ W\|_* \leq \|A\|_*$  and  $\|L_{\text{opt}} \circ (1 - W)\|_* \leq \|L_{\text{opt}}\|_*$ . When  $\|\cdot\|_*$  is the squared Frobenius norm,  $L$  satisfying  $\|A \circ W - L\|_* \leq \min_{\text{rank}-k'} \hat{L} \|A \circ W - \hat{L}\|_* + \Delta$  for  $\Delta = \epsilon \|(A \circ W) - (A \circ W)_{k'}\|_F^2 \leq \epsilon \|A \circ W\|_F^2$  can be computed with high probability in  $O(\text{nnz}(A)) + n \cdot \text{poly}(k'/\epsilon)$  time.  $\blacktriangleleft$

### 3.1 Applications of Main Theorem

We can instantiate Theorem 14 for a number of common mask patterns, yielding the results summarized in Table 1. Note that the additive error bounds achieved are stated in terms of  $\|A \circ W\|_*$  and  $\|L_{\text{opt}} \circ (1 - W)\|_*$ , which are only smaller than  $\|A\|_*$  and  $\|L_{\text{opt}}\|_*$  respectively.

We start with the case when  $W$  is the negation of a diagonal matrix or a block diagonal matrix, corresponding to the Low-Rank Plus Diagonal (LRPD) and Low-Rank Plus Block Diagonal (LRPBD) matrix approximation problems. The argument uses the communication complexity of Equality (EQ). A variant on this problem is also used when  $W$  has at most  $t$  nonzeros (or nonzero blocks) per row. This corresponds to the Low-Rank Plus Sparse (LRPS) and Low-Rank Plus Block Sparse (LRPBS) approximation problems, which strictly generalize the Low-Rank Plus (Block) Diagonal Problem. Proofs are given in the full paper.

► **Corollary 15** (Low-Rank Plus Diagonal Approximation). *Let  $W = 1 - I$  where  $I$  is the  $n \times n$  identity matrix. Then for  $k' = O\left(\frac{k}{\epsilon}\right)$  and  $L$  with  $\|A \circ W - L\|_* \leq \min_{\text{rank} - k'} \hat{L} \|A \circ W - \hat{L}\|_* + \epsilon \|A \circ W\|_*$ :*

$$\|(A - L) \circ W\|_* \leq OPT + 2\epsilon \|A \circ W\|_*.$$

*If  $\|\cdot\|_* = \|\cdot\|_F^2$ ,  $L$  can be computed with high probability in  $O(\text{nnz}(A)) + n \text{poly}(k/\epsilon)$  time.*

**Proof.** The function  $f$  corresponding to  $W$  is the inequality function  $NEQ$ . We have  $R_\epsilon^{1\text{-sided}}(\neg NEQ) = R_\epsilon^{1\text{-sided}}(EQ)$ , which by Theorem 10 is bounded by  $\log(1/\epsilon) + 5$ . Thus  $2^{R_\epsilon^{1\text{-sided}}(\neg NEQ)} \leq \frac{32}{\epsilon}$ . The corollary then follows directly from Theorem 14. ◀

► **Corollary 16** (Low-Rank Plus Block Diagonal Approximation). *Consider any partition  $B_1 \cup B_2 \cup \dots \cup B_b = [n]$  and let  $W$  be the matrix with  $W_{i,j} = 0$  if  $i, j \in B_k$  for some  $k$  and  $W_{i,j} = 1$  otherwise. Then for  $k' = O\left(\frac{k}{\epsilon}\right)$  and  $L$  with  $\|A \circ W - L\|_* \leq \min_{\text{rank} - k'} \hat{L} \|A \circ W - \hat{L}\|_* + \epsilon \|A \circ W\|_*$ :*

$$\|(A - L) \circ W\|_* \leq OPT + 2\epsilon \|A \circ W\|_*.$$

*If  $\|\cdot\|_* = \|\cdot\|_F^2$ ,  $L$  can be computed with high probability in  $O(\text{nnz}(A)) + n \text{poly}(k/\epsilon)$  time.*

**Proof.** The function  $f$  corresponding to  $W$  is the inequality function  $NEQ$  where  $x, y \in [n]$  are identified with  $j, k \in [b]$  if block  $B_j$  contains  $x$  and  $B_k$  contains  $y$ . The randomized communication complexity  $\neg f$  is thus bounded by the complexity of equality. By Theorem 10,  $R_\epsilon^{1\text{-sided}}(EQ) \leq \log(1/\epsilon) + 5$  and so  $2^{R_\epsilon^{1\text{-sided}}(f)} \leq \frac{32}{\epsilon}$ , which gives the corollary. ◀

Beyond equality, a number of common sparsity patterns are related to the communication complexity of Greater-Than (GT), which is bounded by Theorem 13. Since two-sided error is required to give efficient GT protocols, we incur an additional error term depending on  $L_{opt}$ . An interesting question is if this is necessary for efficient bicriteria approximation.

► **Corollary 17** (Low-Rank Plus Banded Approximation). *For any integer  $p \leq n$ , let  $W \in \{0, 1\}^{n \times n}$  be the banded Toeplitz matrix with  $W_{i,j} = 0$  iff  $|i - j| < p$ . Then for  $k' = k \cdot \min\left(\frac{p}{\epsilon}, \text{poly}\left(\frac{\log n}{\epsilon}\right)\right)$  and  $L$  with  $\|A \circ W - L\|_* \leq \min_{\text{rank} - k'} \hat{L} \|A \circ W - \hat{L}\|_* + \epsilon \|A \circ W\|_*$ :*

$$\|(A - L) \circ W\|_* \leq OPT + 2\epsilon \|A \circ W\|_* + \epsilon \|L_{opt} \circ (1 - W)\|_*.$$

*If  $\|\cdot\|_* = \|\cdot\|_F^2$ ,  $L$  can be computed with high probability in  $O(\text{nnz}(A)) + n \text{poly}(k'/\epsilon)$  time.*

**Proof.** The function  $f$  corresponding to  $W$  is the negation of the AND of  $i + p < j$  and  $j + p > i$ . Thus, it can be solved with two calls to a protocol for Greater-Than (GT). By Theorem 13, for  $\log n$  bit inputs,  $R_\epsilon(GT) = O\left(\log\left(\frac{\log n}{\epsilon}\right)\right)$ . Thus  $R_\epsilon(f) = O\left(\log\left(\frac{\log n}{\epsilon}\right)\right)$  and  $2^{R_\epsilon(f)} = \text{poly}\left(\frac{\log n}{\epsilon}\right)$ , giving  $k' = k \cdot \text{poly}\left(\frac{\log n}{\epsilon}\right)$ . When  $p$  is small, we can apply our result for  $W$  with sparse rows (see full paper), which gives  $k' = k \cdot \frac{p}{\epsilon}$ , completing the corollary. ◀

In the full paper, we also consider a “multi-dimensional” banded pattern. Here each  $i \in \{0, 1\}^{\log n}$  corresponds to a point  $(i_1, i_2)$  in a  $\sqrt{n} \times \sqrt{n}$  grid ( $i_1$  and  $i_2$  are determined by the first  $\frac{\log n}{2}$  and last  $\frac{\log n}{2}$  bits of  $i$  respectively). We focus on the two-dimensional case, achieving rank  $k' = k \cdot \text{poly}\left(\frac{\log n}{\epsilon}\right)$  as in the 1-dimensional case. This set up can easily be generalized to higher dimensions. We can also imagine generalizing to different distance measures over the points  $(i_1, i_2)$  using efficient sketching methods (which yield efficient communication protocols) for various distances [6, 35].

A similar result holds for low-rank approximation with monotone missing data.

► **Corollary 18** (Monotone Missing Data Problem (MMDP)). *Let  $W \in \{0, 1\}^{n \times n}$  be any matrix where each row of  $W$  has a prefix of an arbitrary number of ones, followed by a suffix of zeros. Then for  $k' = k \cdot \text{poly}\left(\frac{\log n}{\epsilon}\right)$  and  $L$  with  $\|A \circ W - L\|_* \leq \min_{\text{rank} - k'} \hat{L} \|A \circ W - \hat{L}\|_* + \epsilon \|A \circ W\|_*$ :*

$$\|(A - L) \circ W\|_* \leq OPT + 2\epsilon \|A \circ W\|_* + \epsilon \|L_{opt} \circ (1 - W)\|_*.$$

If  $\|\cdot\|_* = \|\cdot\|_F^2$ ,  $L$  can be computed with high probability in  $O(\text{nnz}(A)) + n \text{poly}(k'/\epsilon)$  time.

**Proof.** Let  $p_x$  be the length of the prefix of ones in the  $x^{\text{th}}$  row of  $W$ . Then the function  $f$  corresponding to  $W$  is  $f(x, y) = 1$  iff  $p_x \geq y$ . That is, it is just the Greater-Than function where Alice maps her input  $x$  to  $p_x$ . Thus by Theorem 13,  $R_\epsilon(f) \leq R_\epsilon(GT) = O\left(\log\left(\frac{\log n}{\epsilon}\right)\right)$ . So  $2^{R_\epsilon(f)} = \text{poly}\left(\frac{\log n}{\epsilon}\right)$ , which gives the corollary. ◀

## 4 Open Questions

By focusing on bicriteria approximation, we show how to solve masked low-rank approximation in polynomial time using a simple heuristic. A number of open questions remain. It would be very interesting to improve the bicriteria ranks we achieve for common masks (summarized in Table 1). It would also be interesting to give relative error bounds achieving error  $(1 + \epsilon) \cdot OPT$  instead of our additive error bounds. This is challenging since it requires achieving zero error when there is an exact masked low-rank factorization of  $A$ .

Relatedly, while we have connected bicriteria masked low-rank approximation to the randomized communication complexity of the mask matrix  $W$  (in fact, the public coin partition number of  $W$ ), it would be very interesting to find a notion of  $W$ 's complexity that tightly characterizes the bicriteria rank achievable in polynomial time. We make some initial steps via lower bounds in terms of the communication complexity in the full paper, however the question remains mostly unanswered.

Finally, a related problem is *weighted low-rank approximation* – when  $W$  is real valued and we seek to minimize  $\|W \circ (A - L)\|_F^2$ . Approximation algorithms depending exponentially on the rank  $k$ , error parameter  $\epsilon$ , and notions of  $W$ 's complexity, such as its rank or number of distinct columns are known [54]. However, it would be very interesting to give polynomial time bicriteria approximation algorithms as we have done in the special case of binary  $W$ .

## Abstract

We prove that the Impagliazzo-Nisan-Wigderson [9] pseudorandom generator (PRG) fools ordered (read-once) permutation branching programs of *unbounded width* with a seed length of  $\tilde{O}(\log d + \log n \cdot \log(1/\varepsilon))$ , assuming the program has only one accepting vertex in the final layer. Here,  $n$  is the length of the program,  $d$  is the degree (equivalently, the alphabet size), and  $\varepsilon$  is the error of the PRG. In contrast, we show that a randomly chosen generator requires seed length  $\Omega(n \log d)$  to fool such unbounded-width programs. Thus, this is an unusual case where an explicit construction is “better than random.”

Except when the program’s width  $w$  is very small, this is an improvement over prior work. For example, when  $w = \text{poly}(n)$  and  $d = 2$ , the best prior PRG for permutation branching programs was simply Nisan’s PRG [15], which fools general ordered branching programs with seed length  $O(\log(wn/\varepsilon) \log n)$ . We prove a seed length lower bound of  $\tilde{\Omega}(\log d + \log n \cdot \log(1/\varepsilon))$  for fooling these unbounded-width programs, showing that our seed length is near-optimal. In fact, when  $\varepsilon \leq 1/\log n$ , our seed length is within a constant factor of optimal. Our analysis of the INW generator uses the connection between the PRG and the derandomized square of Rozenman and Vadhan [20] and the recent analysis of the latter in terms of unit-circle approximation by Ahmadinejad et al. [1].

## 1 Introduction

Randomness, like time or space, is a computational resource. All else being equal, it is best to use as few random bits as possible. A *pseudorandom generator* (PRG) is a tool for reducing the number of random bits used by some computational process.

► **Definition 1.1.** Let  $\mathcal{F}$  be a class of functions  $B: [d]^n \rightarrow \{0, 1\}$ . An  $\epsilon$ -PRG for  $\mathcal{F}$  is a function  $G: \{0, 1\}^s \rightarrow [d]^n$  such that for every  $B \in \mathcal{F}$ ,

$$|\Pr[B(U_{[d]^n}) = 1] - \Pr[B(G(U_{\{0,1\}^s})) = 1]| \leq \epsilon,$$

where  $U_S$  is the uniform distribution over the set  $S$ . The value  $s$  is the **seed length** of the PRG.

Motivated by the goal of derandomizing small-space computation, a long line of research has studied PRGs for classes  $\mathcal{F}$  of functions computable by *branching programs*.

► **Definition 1.2.** An ordered **branching program**  $B$  of length  $n$ , width  $w$  and degree  $d$  computes a function  $B: [d]^n \rightarrow \{0, 1\}$ . At time step  $t \in [n]$ , the program maintains a state in  $[w]$ , reads the next symbol  $\sigma_t$  of the input  $\sigma \in [d]^n$  and updates its state according to a transition function  $W_t: [w] \times [d] \rightarrow [w]$ . We allow the transition function  $W_t$  to be different at each time step.

Moreover, there is an initial state  $v_{\text{start}} \in [w]$  and a single accept state  $v_{\text{end}} \in [w]$ . Let  $u$  be the final state of the branching program on input  $\sigma$ . If  $u = v_{\text{end}}$  the branching program accepts, denoted  $B(\sigma) = 1$ . For any other final state the program rejects, denoted  $B(\sigma) = 0$ .

We can represent a branching program as a graph, with  $n + 1$  layers and  $w$  vertices per layer corresponding to the states of the program at each step. For all  $t \in [n]$ , for state  $s$  in layer  $t - 1$  and  $s'$  in layer  $t$ , we add edge  $(s, s')$  with label  $\sigma_t \in [d]$  if  $W_t(s, \sigma_t) = s'$ . An ordered read-once branching program of length  $n$  and width  $w$  can compute the output of an algorithm that uses  $\log w$  bits of memory and  $n$  random bits, by taking the state at each layer as the contents of memory at that time. Unusually, we will consider branching programs where the width is unbounded (e.g., it can even be  $w = d^n$ ), albeit with the restriction of being a *permutation branching program*.

► **Definition 1.3.** A **permutation branching program** is an ordered branching program where for all  $t \in [n]$  and  $\sigma \in [d]$ ,  $W_t(\cdot, \sigma)$  is a permutation. This can be thought of as the computation being time-reversible.

Note that with this restriction the graph representation consists of  $n + 1$  layers where each layer is the union of  $d$  perfect matchings, with each matching corresponding to a distinct input symbol.

Restricted classes of branching programs, including permutation branching programs [22, 5, 10], have received attention largely because of the lack of progress on designing PRGs for general length- $n$  width- $n$  branching programs since the work of Nisan three decades ago [15]. There has also been work on permutation branching programs where the input is read in an arbitrary order [17, 3]. Our main theorem is that there is an explicit PRG fooling unbounded-width permutation branching programs with seed length that is nearly logarithmic in  $n$  and has no dependence on the width  $w$ :

► **Theorem 1.4 (Main Theorem).** For all  $n, d \in \mathbb{N}$  and  $\epsilon > 0$ , there is an explicitly computable  $\epsilon$ -PRG  $G: \{0, 1\}^s \rightarrow [d]^n$  for permutation branching programs of length  $n$ , degree  $d$ , and arbitrary width. This PRG has seed length

$$O(\log d + \log n \cdot (\log \log n + \log(1/\epsilon))).$$

In contrast, we show that a randomly chosen generator requires seed length  $\Omega(n \log d)$  to fool such unbounded-width programs. Thus, this is an unusual case where an explicit construction is “better than random.” (See Section 1.3 for more discussion.)

The PRG is an instantiation of the Impagliazzo-Nisan-Wigderson (INW) generator [9]. The proof uses the interpretation of the INW generator in terms of the derandomized square for consistently labeled graphs, introduced by Rozenman and Vadhan [20], and the analysis of the derandomized square in terms of unit-circle approximation by Ahmadinejad et al. [1].

We emphasize that our definition of permutation branching program only allows one accepting vertex. This assumption is crucial: a permutation branching program with unbounded width and an unbounded number of accepting vertices can compute any Boolean function on  $[d]^n$ , so nontrivial PRGs for that model do not exist. That being said, a program with  $a$  accepting vertices can be written as a sum of  $a$  programs with one accepting vertex each, so our PRG fools such a permutation branching program with seed length

$$O(\log d + \log n \cdot (\log \log n + \log(a/\varepsilon))).$$

## 1.1 Prior Work on the Derandomized Square

In the paper introducing the derandomized square [20], Rozenman and Vadhan showed how to use it to decide undirected connectivity in deterministic log space, giving another proof of Reingold’s famous theorem [16]. As another application, they showed how to take a (polynomially long) pseudorandom walk through a regular, aperiodic directed graph in such a way that the final vertex is distributed nearly uniformly (i.e., is close to the stationary distribution of a truly random walk), matching a result of Reingold, Trevisan, and Vadhan [18]. As mentioned previously, they observed that this pseudorandom walk is described by the INW generator, assuming the graph is “consistently labeled” (see Definition 3.4). However, their analysis does not show how to approximate short random walks (e.g., shorter than the mixing time).

In a pair of relatively recent works [13, 14], Murtagh et al. showed how to approximate (in some respects) random walks of any length  $n$ , even if  $n$  is much smaller than the graph’s mixing time. These algorithms are only for undirected graphs, but the recent work by Ahmadinejad et al. [1] handles the more general case of Eulerian digraphs (as well as getting stronger results for undirected graphs). Among other tools, all three of these papers [13, 14, 1] use the derandomized square.

Fooling branching programs amounts to approximating *bounded-length* random walks through *directed* graphs, which is why we rely on Ahmadinejad et al.’s results [1] for our theorem. One of their results is a deterministic non-black-box algorithm for estimating the acceptance probability of a given polynomial-width “regular” branching program in space  $\tilde{O}(\log n)$  to within error  $\varepsilon = 1/\text{poly}(n)$ . Our theorem solves the more challenging black-box derandomization problem, although it only works for permutation branching programs and we have a worse dependence on the error parameter  $\varepsilon$ .

## 1.2 Prior PRGs for Permutation Branching Programs

Our PRG is superior to prior generators for permutation branching programs<sup>1</sup> when the width of the branching program is not small. Previous work has focused on the constant-width case. In that regime, the best PRG for permutation branching programs is due to Steinke [22].

---

<sup>1</sup> In this discussion of prior work, we focus on the case  $d = 2$  for simplicity.

He achieves seed length  $O(w^4 \log w \log n + \log n \log(1/\varepsilon))$ , which is better than our seed length by a factor of  $\log \log n$ . For larger widths up to  $w = \text{poly}(n)$ , the best prior PRG for permutation branching programs is by Braverman et al. [2], who gave a PRG for regular branching programs with seed length

$$O(\log w \log n + \log n \cdot (\log \log n + \log(1/\varepsilon))).$$

Note that when  $w = \text{poly}(n)$  and  $\varepsilon = \Omega(1)$ , Braverman et al.'s PRG has seed length  $\Theta(\log^2 n)$ , just like Nisan's PRG [15], whereas our PRG has seed length  $\tilde{O}(\log n)$ . The case  $w = \text{poly}(n)$  is arguably the most important case, because polynomial-width ordered branching programs correspond to uniform randomized algorithms that always halt. Recall that low-error PRGs for polynomial-width regular branching programs suffice for derandomizing all of **RL** [18].

When the width is even larger than  $\text{poly}(n)$ , the best prior PRG is by De [5]. De's work is focused on the constant-width case, but he also gave a generator with seed length  $O(\log(n/\varepsilon) \log n)$  independent of  $w$ .

### 1.3 Failure of the Probabilistic Method

There is something counterintuitive about the superpolynomial-width regime. Recall that for typical models of computation, including polynomial-width degree-2 branching programs, it is straightforward to show that there exists a nonexplicit PRG with seed length  $O(\log(n/\varepsilon))$ , because a random function is a good PRG. Furthermore, it is typically fairly trivial to prove a matching  $\Omega(\log(n/\varepsilon))$  lower bound. The main challenge, in most cases, is to devise an explicit construction matching the parameters of the probabilistic existence proof.

However, the standard nonexplicit existence argument is not applicable to unbounded-width permutation branching programs, because they can compute doubly-exponentially many distinct functions; in particular, we show (Lemma 5.1) that they can compute every Boolean function  $B(x, y)$  that tests whether  $\pi(x) = y$  for a permutation  $\pi: [d]^{n/2} \rightarrow [d]^{n/2}$ . And indeed, as mentioned previously, for seed length less than  $(n \log d)/4$ , we show (Theorem 5.2) that a random function is *not* a good PRG for this model. The reason is that when a generator is chosen at random, with high probability, there is some permutation  $\pi$  such that every output  $(x, y)$  of the generator satisfies  $\pi(x) = y$ .

Since the probabilistic method fails here, it might be surprising that there even *exists* a PRG with near-logarithmic seed length, let alone our explicit construction. Intuitively, the INW generator manages to outperform the probabilistic method because the second half of the INW generator's output is *information-theoretically* unpredictable given the first half, and vice versa.

We remark that another family of unbounded-width ordered branching programs has been studied previously: "monotone" branching programs. From Meka and Zuckerman's work [12], it follows that a random function *is* a good PRG for unbounded-width monotone branching programs. In that respect, the model we study is more unusual.

### 1.4 The Optimal Seed Length

These considerations raise the question of what the optimal seed length is for our model. We prove (Theorem 6.1) that any PRG for unbounded-width permutation branching programs must have seed length at least  $\Omega(\log d + \log n \cdot \log(1/\varepsilon))$ , provided  $\varepsilon$  is not extremely small.<sup>2</sup> Thus, our explicit PRG's seed length is near-optimal. In fact, although the lower bound gets

<sup>2</sup> E.g., any  $\varepsilon \geq \exp(-(n \log d)^{0.99})$  is large enough.

slightly weaker when  $\varepsilon$  is extremely small, we give a matching refinement of our *upper* bound in that regime (see Corollary 4.9), providing an explicit PRG with asymptotically optimal seed length whenever  $\varepsilon \leq 1/\log n$ .

To the best of our knowledge, this is the first known case where, e.g., some seed length  $s$  is sufficient for a constant-error PRG, but seed length  $O(s + \log n)$  is not sufficient to achieve error  $1/n$ . In the context of fooling shallow circuits, similar lower bounds were proven previously for restricted classes of PRGs such as  $k$ -wise independent distributions [11] or small-bias distributions [6], but our lower bound holds for any PRG whatsoever. Our lower bound uses basic tools from matching theory and information theory.

On the other hand, we show (Theorem 7.1) that a random function is at least a good *hitting set* generator (HSG); the optimal seed length for nonexplicit HSGs for unbounded-width permutation branching programs is  $\Theta(\log(nd/\varepsilon))$ . This is the first case we are aware of where there is a large gap between the best possible PRGs and the best possible HSGs.

## 1.5 Organization

In Section 2, we introduce measures of spectral approximation for matrices and basic linear algebra facts. In Section 3, we introduce the derandomized square, and recall two theorems relating the square to unit-circle approximation, then prove repeated derandomized squaring provides a suitable quality approximation. In Section 4, we use the bounds on repeated derandomized squares to analyze the INW generator. In Section 5, we prove that a random function with seed length less than  $(n \log d)/4$  does not fool unbounded-width permutation branching programs. In Section 6, we prove our lower bound on the seed length of any PRG for these programs. Finally, in Section 7, we identify the optimal seed length for nonexplicit HSGs for these programs.

## 2 Spectral Approximation Preliminaries

We first introduce basic notation and recall two measures of closeness of approximation for matrices, complex spectral approximation and unit-circle approximation.

- For a complex number  $z \in \mathbb{C}$  we write  $z^*$  to denote the complex conjugate of  $z$  and  $|z|$  to denote the magnitude of  $z$ .
- For a matrix  $A \in \mathbb{C}^{N \times N}$  we write  $A^*$  to denote its conjugate transpose and write  $U_A = (A + A^*)/2$  to denote its **symmetrization**.
- We say a Hermitian matrix  $A$  is **positive semidefinite** (PSD) or write  $A \succeq 0$  if  $x^*Ax \geq 0$  for all  $x \in \mathbb{C}^N$ . For two Hermitian matrices  $A, B$ , we use  $A \succeq B$  to denote  $A - B \succeq 0$  and define  $\preceq$  analogously.

► **Definition 2.1** (Complex Spectral Approximation [1]). *For  $A, B \in \mathbb{C}^{N \times N}$  and  $\varepsilon > 0$ , we say  $A$  is a **complex  $\varepsilon$ -approximation** of  $B$ , denoted  $A \approx_\varepsilon B$ , if*

$$\forall x, y \in \mathbb{C}^N, \quad |x^*(B - A)y| \leq \frac{\varepsilon}{2}(|x|^2 + |y|^2 - x^*U_Bx - y^*U_By).$$

*For two  $N$ -vertex digraphs  $\tilde{\mathbf{G}}, \mathbf{G}$  with random walk matrices  $A, B$ , write  $\tilde{\mathbf{G}} \approx_\varepsilon \mathbf{G}$  if  $A \approx_\varepsilon B$ .*

We now recall the stronger notion that we will use for analyzing the generator.

► **Definition 2.2** (Unit-Circle Approximation [1]). *For  $A, B \in \mathbb{C}^{N \times N}$  and  $\varepsilon > 0$ , we say  $A$  is a **unit-circle  $\varepsilon$ -approximation** of  $B$ , denoted  $A \overset{\circ}{\approx}_\varepsilon B$ , if*

$$\forall x, y \in \mathbb{C}^N, \quad |x^*(B - A)y| \leq \frac{\varepsilon}{2}(|x|^2 + |y|^2 - |x^*Bx + y^*By|).$$

*For two  $N$ -vertex digraphs  $\tilde{\mathbf{G}}, \mathbf{G}$  with random walk matrices  $A, B$ , write  $\tilde{\mathbf{G}} \overset{\circ}{\approx}_\varepsilon \mathbf{G}$  if  $A \overset{\circ}{\approx}_\varepsilon B$ .*

Including the magnitude operation in the right hand side forces the approximation to be exact for all eigenspaces with eigenvalues of complex magnitude 1, and this property is essential for the preservation of approximation under high powers. The unit-circle approximation is developed in [1]. We rely on a convenient equivalence between unit-circle approximation and complex approximation:

► **Lemma 2.3** ([1] Lemma 3.8). *Let  $A, B \in \mathbb{C}^{N \times N}$  and  $\varepsilon > 0$ . Then  $A \overset{\circ}{\approx}_{\varepsilon} B$  if and only if for all  $z \in \mathbb{C}$  with  $|z| = 1$ ,  $zA \approx_{\varepsilon} zB$ .*

We will also use this basic result about complex approximation. Note that Cohen et al. [4] prove the analogous statement where complex numbers are replaced with reals.

► **Lemma 2.4.** *Let  $A, B \in \mathbb{C}^{N \times N}$  where  $A \approx_{\varepsilon} B$ . Then  $(1 - \varepsilon)U_{I-B} \preceq U_{I-A} \preceq (1 + \varepsilon)U_{I-B}$ .*

**Proof.** Let arbitrary  $x \in \mathbb{C}^N$ . Bounding the gap between the symmetrizations via the definition of complex approximation gives

$$\begin{aligned} |x^*U_{I-B}x - x^*U_{I-A}x| &= \left| \frac{1}{2}(x^*(B + B^*)x - x^*(A + A^*)x) \right| \\ &\leq \left| \frac{1}{2}x^*(B - A)x \right| + \left| \frac{1}{2}x^*(B^* - A^*)x \right| \\ &\leq \frac{1}{2}\varepsilon(\|x\|^2 - x^*U_Bx) + \frac{1}{2}\varepsilon(\|x\|^2 - x^*U_Bx) \\ &= \varepsilon \cdot x^*U_{I-B}x. \end{aligned}$$

This directly implies  $x^*U_{I-A}x - (1 - \varepsilon)x^*U_{I-B}x \geq 0$  and  $(1 + \varepsilon)x^*U_{I-B}x - x^*U_{I-A}x \geq 0$ . Since  $x$  was arbitrary we are done. ◀

We now state an approximate triangle inequality for unit-circle approximation, which will be a tool for bounding the error of the generator. Previously, Cohen et al. [4] proved a similar lemma regarding the real analogue of complex approximation.

► **Lemma 2.5** (Quasi-Triangle Inequality). *If  $C \overset{\circ}{\approx}_{\varepsilon_2} B \overset{\circ}{\approx}_{\varepsilon_1} A$  then  $C \overset{\circ}{\approx}_{\varepsilon_1 + \varepsilon_2 + \varepsilon_1\varepsilon_2} A$ .*

**Proof.** Let  $z \in \mathbb{C}$  satisfy  $|z| = 1$ , and let  $x, y \in \mathbb{C}^N$  be arbitrary. Since  $B \overset{\circ}{\approx}_{\varepsilon_1} A$ , by Lemma 2.3,  $zB \approx_{\varepsilon_1} zA$ , so

$$|x^*(A - B)y| \leq \frac{\varepsilon_1}{2}(x^*U_{I-zA}x + y^*U_{I-zA}y).$$

Similarly, since  $C \overset{\circ}{\approx}_{\varepsilon_2} B$ ,

$$\begin{aligned} |x^*(B - C)y| &\leq \frac{\varepsilon_2}{2}(x^*U_{I-zB}x + y^*U_{I-zB}y) \\ &\leq \frac{\varepsilon_2}{2} \cdot (1 + \varepsilon_1) \cdot (x^*U_{I-zA}x + y^*U_{I-zA}y) \end{aligned}$$

where the second inequality follows from Lemma 2.4. Therefore,

$$\begin{aligned} |x^*(A - C)y| &\leq |x^*(A - B)y| + |x^*(B - C)y| \\ &\leq \left( \frac{\varepsilon_1}{2} + \frac{\varepsilon_2}{2} + \frac{\varepsilon_1\varepsilon_2}{2} \right) \cdot (x^*U_{I-zA}x + y^*U_{I-zA}y). \end{aligned}$$

Since  $x$  and  $y$  were arbitrary, this shows that  $zC \approx_{\varepsilon_1 + \varepsilon_2 + \varepsilon_1\varepsilon_2} zA$ . Since  $z$  was arbitrary, we are done by Lemma 2.3. ◀

► **Corollary 2.6** (Iterated Quasi-Triangle Inequality). *Suppose  $\delta \leq 1$  and*

$$A_0 \overset{\circ}{\approx}_{\delta} A_1 \overset{\circ}{\approx}_{\delta} \dots \overset{\circ}{\approx}_{\delta} A_{\ell}.$$

*Then  $A_0 \overset{\circ}{\approx}_{\varepsilon} A_{\ell}$  with  $\varepsilon = \ell\delta/(1-\delta)^2$ .*

**Proof.** Applying Lemma 2.5 inductively, we get a bound of

$$\sum_{i=0}^{\ell} (\ell - i) \cdot \delta^{i+1} = \frac{\ell\delta - \delta^2 \cdot (\ell + 1 - \delta^{\ell})}{(1 - \delta)^2} \leq \frac{\ell\delta}{(1 - \delta)^2}. \quad \blacktriangleleft$$

Finally, we give a basic result used to relate unit-circle to entrywise approximation for the final generator analysis.

► **Proposition 2.7.** *Given  $A, B \in \mathbb{C}^{N \times N}$  so that  $A \overset{\circ}{\approx}_{\varepsilon} B$ , for all indices  $u, v \in [N]$ ,  $|A_{u,v} - B_{u,v}| \leq \varepsilon$ .*

**Proof.** Let  $e_u, e_v$  be the standard basis vectors with ones in coordinates  $u, v$  respectively and apply Definition 2.2:

$$|A_{u,v} - B_{u,v}| = |e_u^*(A - B)e_v| \leq \frac{\varepsilon}{2} (||e_u||^2 + ||e_v||^2 - |e_u^* B e_u + e_v^* B e_v|) \leq \varepsilon. \quad \blacktriangleleft$$

### 3 Repeated Derandomized Squaring

#### 3.1 Graph Labelings

Branching programs are closely related to graphs with *one-way labelings*.

► **Definition 3.1** (One-Way Labeling [20]). *A **one-way labeling** of a  $d$ -regular directed multigraph  $\mathbf{G}$  assigns a label in  $[d]$  to each edge  $(u, v)$  such that for every vertex  $u$ , the labels of the outgoing edges of  $u$  are distinct. If  $\mathbf{G}$  has a one-way labeling, let  $\mathbf{G}[u, i]$  denote the vertex  $v$  such that  $(u, v)$  is labeled  $i$ .*

One-way labelings are compatible with the operation of *powering* a graph. One step on  $\mathbf{G}^n$  corresponds to  $n$  steps in  $\mathbf{G}$ . The formal definition follows.

► **Definition 3.2** (Graph Powering). *Let  $\mathbf{G}$  be a  $d$ -regular directed multigraph with a one-way labeling. For  $n \geq 1$ , we recursively define  $\mathbf{G}^n$  to be a  $(d^n)$ -regular directed multigraph on the same vertex set with a one-way labeling given by*

$$\mathbf{G}^1 = \mathbf{G}$$

$$\mathbf{G}^{n+1}[v, (e_1, e_2)] = \mathbf{G}^n[\mathbf{G}[v, e_1], e_2],$$

*identifying  $[d^{n+1}] = [d] \times [d^n]$ .*

Derandomized squaring is a way of “approximating” the powers of a graph. The derandomized squaring operation is defined in terms of graphs with additional structure, namely, a *two-way labeling*.

► **Definition 3.3** (Two-Way Labeling [20]). *A **two-way labeling** of a  $d$ -regular directed multigraph  $\mathbf{G}$  assigns two labels in  $[d]$  to each edge  $(u, v)$ : one as an edge incident to  $u$  (the “outgoing label”) and one as an edge incoming to  $v$  (the “incoming label”). We require that for every vertex  $v$ , the outgoing labels of the outgoing edges of  $v$  are distinct, and the incoming labels of the incoming edges of  $v$  are distinct. If  $\mathbf{G}$  is an  $N$ -vertex graph with a two-way labeling, we define the rotation map [19, 20]  $\text{Rot}_{\mathbf{G}}: [N] \times [d] \rightarrow [N] \times [d]$  by letting  $\text{Rot}_{\mathbf{G}}(u, i) = (v, j)$  if there is an edge  $(u, v)$  with outgoing label  $i$  and incoming label  $j$ .*

Naturally, if  $\mathbf{G}$  has a two-way labeling, we think of  $\mathbf{G}$  as also having a one-way labeling given by the outgoing labels:  $\text{Rot}_{\mathbf{G}}(u, i) = (v, j) \implies \mathbf{G}[u, i] = v$ . Conversely, there is a natural way to extend any *consistent* one-way labeling (defined next) to a two-way labeling.

► **Definition 3.4** (Consistent One-Way Labeling [8]). *A **consistent one-way labeling** of a graph  $\mathbf{G}$  is a one-way labeling such that for every vertex  $v$ , the labels of the incoming edges of  $v$  are distinct. Equivalently,  $\mathbf{G}[u, i] = \mathbf{G}[v, i] \implies u = v$ . If  $\mathbf{G}$  has a consistent one-way labeling, then we can extend  $\mathbf{G}$  to a graph  $\overline{\mathbf{G}}$  that has a two-way labeling given by*

$$\text{Rot}_{\overline{\mathbf{G}}}(u, i) = (\mathbf{G}[u, i], i).$$

### 3.2 Derandomized Squaring

Now we are ready to define the derandomized square operation, introduced by Rozenman and Vadhan [20]. Let  $\mathbf{G} = (V, E)$  be a regular directed multigraph. In the true square  $\mathbf{G}^2$ , for each vertex  $v \in V$ , there is a complete bipartite graph from in-neighbors of  $v$  to outneighbors of  $v$ , equivalent to all two-step walks through  $v$ . A derandomized square picks out a pseudorandom subset of such walks by correlating the two steps via edges on an expander graph  $\mathbf{H}$ .

► **Definition 3.5** (Derandomized Square [20]). *Let  $\mathbf{G}$  be a directed  $d$ -regular multigraph on  $N$  vertices with a two-way labeling. Let  $\mathbf{H}$  be a directed  $c$ -regular multigraph on  $d$  vertices with a one-way labeling. We define the **derandomized square**  $\mathbf{G} \circledast \mathbf{H}$  to be a  $(cd)$ -regular directed multigraph on  $N$  vertices with a one-way labeling given by*

$$(\mathbf{G} \circledast \mathbf{H})[v, (i, j)] = \mathbf{G}[v', \mathbf{H}[i', j]],$$

where  $(v', i') = \text{Rot}_{\mathbf{G}}(v, i)$ .

Note that Definition 3.5 requires  $\mathbf{G}$  to have a two-way labeling, but the derandomized square  $\mathbf{G} \circledast \mathbf{H}$  itself only has a one-way labeling. If we wish to apply the derandomized squaring operation a second time to approximate  $\mathbf{G}^4$ , we must first assign incoming labels to the edges in  $\mathbf{G} \circledast \mathbf{H}$ . When they introduced the derandomized square operation, Rozenman and Vadhan studied two distinct approaches for assigning incoming edge labels [20]. The first approach is to assume that we start with a graph  $\mathbf{G}$  with a consistent one-way labeling. In this case,  $\overline{\mathbf{G}} \circledast \mathbf{H}$  has a consistent one-way labeling as well (see Lemma 4.2). This approach is closely connected to the INW generator [9], as we will discuss in Section 4. The second approach is to assume that  $\mathbf{H}$  has a two-way labeling. In this case, one can assign incoming edge labels to  $\mathbf{G} \circledast \mathbf{H}$  by setting  $\text{Rot}_{\mathbf{G} \circledast \mathbf{H}}(v_0, (i_0, j_0)) = (v_2, (i_3, j_1))$ , where

$$(v_1, i_1) = \text{Rot}_{\mathbf{G}}(v_0, i_0), \quad (i_2, j_1) = \text{Rot}_{\mathbf{H}}(i_1, j_0), \quad (v_2, i_3) = \text{Rot}_{\mathbf{G}}(v_1, i_2).$$

This is the approach taken in, e.g., the recent work of Ahmadi et al. [1]. Note that if  $\mathbf{G}$  has a consistent one-way labeling and  $\mathbf{H}$  has a two-way labeling, the two approaches for assigning incoming edge labels to  $\overline{\mathbf{G}} \circledast \mathbf{H}$  do not coincide.

Like previous work, we will use auxiliary graphs  $\mathbf{H}$  that are good *spectral expanders*, meaning that  $\lambda(\mathbf{H})$  (defined next) is small. For the purposes of this paper, an *undirected* graph is a symmetric directed graph, i.e., a directed graph such that for every edge  $(u, v)$ , the reverse edge  $(v, u)$  is also present.

► **Definition 3.6.** *Let  $\mathbf{H}$  be an undirected regular multigraph on  $N$  vertices with random walk matrix  $M$ . We define  $\lambda(\mathbf{H}) = \max_{x \in \mathbb{R}^N: \langle \mathbf{1}, x \rangle = 0} \|Mx\|_2 / \|x\|_2$ , where  $\mathbf{1}$  is the all-ones vector. This is equal to the second largest eigenvalue in absolute value of  $M$ .*

Ahmadinejad et al. showed that the derandomized square is a unit-circle approximation of the true square [1]. Since the conclusion of this theorem is only a statement about the random walk matrix of  $\mathbf{G} \circledast \mathbf{H}$ , the theorem is oblivious to any edge labels in  $\mathbf{G} \circledast \mathbf{H}$ .

► **Theorem 3.7** ([1] Theorem 5.9). *Let  $\mathbf{G}$  be a  $d$ -regular directed multigraph with a two-way labeling, and let  $\mathbf{H}$  be a  $c$ -regular undirected multigraph on  $d$  vertices with a one-way labeling. If  $\lambda(\mathbf{H}) \leq \varepsilon$ , then  $\mathbf{G} \circledast \mathbf{H} \overset{\circ}{\approx}_{2\varepsilon} \mathbf{G}^2$ .*

We now use the spectral approximation measures of Section 2 to bound the error introduced by repeated derandomized squares. In the theorem below, although  $\mathbf{G}_i$  has a two-way labeling, when we write  $\mathbf{G}_i = \mathbf{G}_{i-1} \circledast \mathbf{H}_i$ , we merely mean equality of one-way labelings. Thus, our bound applies *regardless* of how the incoming edge labels of  $\mathbf{G}_{i-1} \circledast \mathbf{H}_i$  are assigned, as long as they form a valid two-way labeling.

► **Theorem 3.8** (Repeated Derandomized Squaring). *Let  $\mathbf{G}_0, \mathbf{G}_1, \dots, \mathbf{G}_\ell$  be directed multigraphs on  $N$  vertices with two-way labelings, where  $\mathbf{G}_i$  is  $(d \cdot c^i)$ -regular. Let  $\varepsilon \in (0, 0.12)$ , and let  $\mathbf{H}_1, \dots, \mathbf{H}_\ell$  be undirected  $c$ -regular multigraphs with one-way labelings, where  $\mathbf{H}_i$  is on  $d \cdot c^{i-1}$  vertices and  $\lambda(\mathbf{H}_i) \leq \varepsilon$ . Assume that for every  $i \in [\ell]$ , we have  $\mathbf{G}_i = \mathbf{G}_{i-1} \circledast \mathbf{H}_i$ . Then  $\mathbf{G}_\ell \overset{\circ}{\approx}_{8\ell\varepsilon} \mathbf{G}_0^{2^\ell}$ .*

The proof of Theorem 3.8 relies on a result by Ahmadinejad et al. [1] saying that unit-circle approximations are preserved under arbitrary *true* powers.

► **Lemma 3.9** ([1] Corollary 4.9). *Let  $\tilde{\mathbf{G}}, \mathbf{G}$  be directed multigraphs. If  $\tilde{\mathbf{G}} \overset{\circ}{\approx}_\varepsilon \mathbf{G}$  then for all  $k \in \mathbb{N}$  we have  $\tilde{\mathbf{G}}^k \overset{\circ}{\approx}_{\varepsilon/(1-\frac{3}{2}\varepsilon)} \mathbf{G}^k$ .*

**Proof of Theorem 3.8.** By Theorem 3.7, for all  $j$ ,  $\mathbf{G}_{i+1} \overset{\circ}{\approx}_{2\varepsilon} \mathbf{G}_i^2$ . We then use Lemma 3.9 which states that we can take arbitrary powers and preserve unit-circle approximation. For arbitrary  $i \in [\ell]$ ,  $k_i \in \mathbb{N}$  we have  $\mathbf{G}_{i+1}^{k_i} \overset{\circ}{\approx}_{\frac{2\varepsilon}{1-3\varepsilon}} \mathbf{G}_i^{2k_i}$ . Then by choosing  $k_i = 2^{\ell-i}$  we obtain a chain

$$\mathbf{G}_\ell \overset{\circ}{\approx}_{\frac{2\varepsilon}{1-3\varepsilon}} \mathbf{G}_{\ell-1}^2 \overset{\circ}{\approx}_{\frac{2\varepsilon}{1-3\varepsilon}} \mathbf{G}_{\ell-2}^4 \overset{\circ}{\approx}_{\frac{2\varepsilon}{1-3\varepsilon}} \dots \overset{\circ}{\approx}_{\frac{2\varepsilon}{1-3\varepsilon}} \mathbf{G}_0^{2^\ell},$$

relating the final derandomized square to the true power via a sequence of unit-circle approximations. Applying Corollary 2.6 gives the bound  $\mathbf{G}_\ell \overset{\circ}{\approx}_C \mathbf{G}_0^{2^\ell}$  where  $C = 2\varepsilon\ell \cdot \frac{1-3\varepsilon}{(1-5\varepsilon)^2} \leq 8\varepsilon\ell$ . ◀

## 4 The Pseudorandom Generator

In this section, we present the PRG of Theorem 1.4. We first state the definition of the Impagliazzo-Nisan-Wigderson (INW) generator and relate it to the repeated derandomized square. For the remainder of the section, fix a sequence of  $c$ -regular undirected multigraphs  $\mathbf{H}_1, \mathbf{H}_2, \dots$  where  $\mathbf{H}_i$  has  $d \cdot c^{i-1}$  vertices and has a one way labeling. We define a sequence of generators  $\text{INW}_0, \text{INW}_1, \dots$  such that  $\text{INW}_i : [d] \times [c]^i \rightarrow [d]^{2^i}$ .

► **Definition 4.1** (INW Generator [9]). *Define  $\text{INW}_0(\sigma) = \sigma$  for  $\sigma \in [d]$  as the trivial PRG that outputs its input and  $\text{INW}_{i+1}(v, e) = (\text{INW}_i(v), \text{INW}_i(\mathbf{H}_{i+1}[v, e]))$ .*

This is the recursive definition of the INW generator [9]. However, in the context of graphs with consistent one-way labelings there exists an equivalent characterization in terms of the derandomized square [20], which we will use for our analysis. The following two lemmas follow from the reasoning in Rozenman and Vadhan's work [20, Theorem 5.8]. We repeat the proofs here for completeness.

► **Lemma 4.2.** *Let  $\mathbf{G}$  be a  $d$ -regular multigraph and  $\mathbf{H}$  a  $c$ -regular undirected multigraph on  $d$  vertices. If  $\mathbf{G}$  has a consistent one-way labeling, then  $\overline{\mathbf{G}} \circledast \mathbf{H}$  has a consistent one-way labeling.*

**Proof.** Let  $\tilde{\mathbf{G}} = \overline{\mathbf{G}} \circledast \mathbf{H}$ . By the definitions of  $\overline{\mathbf{G}}$  and  $\circledast$ , we have

$$\tilde{\mathbf{G}}[v, (i, j)] = \mathbf{G}[\mathbf{G}[v, i], \mathbf{H}[i, j]].$$

To prove that  $\tilde{\mathbf{G}}$  has a consistent one-way labeling, fix  $(i, j)$ , and suppose  $\tilde{\mathbf{G}}[u, (i, j)] = \tilde{\mathbf{G}}[v, (i, j)]$ . We must show that  $u = v$ . Indeed,  $\mathbf{G}[\mathbf{G}[u, i], \mathbf{H}[i, j]] = \mathbf{G}[\mathbf{G}[v, i], \mathbf{H}[i, j]]$ . Since  $\mathbf{G}$  has a consistent one-way labeling, this implies that  $\mathbf{G}[u, i] = \mathbf{G}[v, i]$ . Again using the fact that  $\mathbf{G}$  has a consistent one-way labeling, this implies that  $u = v$  as desired. ◀

► **Lemma 4.3.** *Let  $\mathbf{G}_0$  be a  $d$ -regular multigraph on any number of vertices with a consistent one-way labeling. For  $i \geq 0$ , inductively define  $\mathbf{G}_{i+1} = \overline{\mathbf{G}_i} \circledast \mathbf{H}_{i+1}$ . Then for all  $v$  and  $e$ ,  $\mathbf{G}_i[v, e] = \mathbf{G}_0^{2^i}[v, \text{INW}_i(e)]$ .*

**Proof.** First, note that inductively,  $\mathbf{G}_i$  has a consistent labeling by Lemma 4.2, so  $\mathbf{G}_{i+1}$  is well-defined. Now we show by induction on  $i$  that  $\mathbf{G}_i[v, e] = \mathbf{G}_0^{2^i}[v, \text{INW}_i(e)]$ . The case of  $\mathbf{G}_0$  is immediate. Assume the inductive hypothesis holds for  $i$ . Fix an arbitrary vertex  $v$  and end label  $e = (e_1, e_2) \in [d \cdot c^i] \times [c]$ . We have

$$\begin{aligned} \mathbf{G}_{i+1}[v, e] &= \mathbf{G}_i[\mathbf{G}_i[v, e_1], \mathbf{H}_{i+1}[e_1, e_2]] && \text{(Definitions)} \\ &= \mathbf{G}_0^{2^i}[\mathbf{G}_0^{2^i}[v, \text{INW}_i(e_1)], \text{INW}_i(\mathbf{H}_{i+1}[e_1, e_2])] && \text{(Induction hypothesis)} \\ &= \mathbf{G}_0^{2^{i+1}}[v, (\text{INW}_i(e_1), \text{INW}_i(\mathbf{H}_{i+1}[e_1, e_2]))] \\ &= \mathbf{G}_0^{2^{i+1}}[v, \text{INW}_{i+1}(e)]. \end{aligned} \quad \blacktriangleleft$$

Let  $\ell = \lceil \log(n) \rceil$ , and define  $G: [d] \times [c]^\ell \rightarrow [d]^n$  by letting  $G(x)$  be the  $n$ -symbol prefix of  $\text{INW}_\ell(x)$ . This will be the generator that proves Theorem 1.4.

## 4.1 Approximation Guarantee

To bridge the gap between regular graphs and branching programs, we now define the *execution graph* of a branching program, which is just like the standard graph representation of the program, but the length is padded to a power of two and edges are added to wrap around from the end to the beginning.

► **Definition 4.4** (Branching Program Execution Graph). *Let  $B$  be a permutation branching program of width  $w$ , degree  $d$  and length  $n$ , and let  $m$  be the smallest power of 2 greater than  $n$ . Define the **execution graph** of  $B$  to be a directed  $d$ -regular multigraph  $\mathbf{G}$  on the vertex set  $\{0, \dots, m\} \times [w]$  with a one-way labeling given by*

$$\mathbf{G}[(t, u), \sigma] = \begin{cases} (t+1, W_t(u, \sigma)) & t \in \{0, \dots, n-1\} \\ (t+1, u) & t \in \{n, \dots, m-1\} \\ (0, u) & t = m, \end{cases}$$

where  $W_t$  is the transition function of  $B$  at layer  $i$  as in Definition 1.3.

► **Remark 4.5.** Since  $B$  is a permutation branching program, the execution graph  $\mathbf{G}$  has a consistent one-way labeling. This is not true for general regular branching programs and is why our method does not generalize.

▷ **Claim 4.6.** Let  $\varepsilon > 0$ . If every  $\mathbf{H}_i$  satisfies  $\lambda(\mathbf{H}_i) \leq \varepsilon/(8\ell)$ , then  $G$  is an  $\varepsilon$ -PRG for permutation branching programs of degree  $d$ , length  $n$ , and arbitrary width.

*Proof.* Let  $B$  be an arbitrary permutation branching program of degree  $d$  and length  $n$ . Let  $\mathbf{G}_0$  be the execution graph of  $B$ . Let  $\mathbf{G}_1, \mathbf{G}_2, \dots$  be the graphs in Lemma 4.3. By Theorem 3.8 we have  $\mathbf{G}_\ell \overset{\circ}{\approx}_\varepsilon \mathbf{G}_0^m$ .

Let  $u = (0, v_{\text{start}})$  be the start vertex in the execution graph, and let  $v = (m, v_{\text{end}})$  be the accept vertex. By the definition of  $\mathbf{G}_0$ , for all  $\sigma \in [d]^m$ , we have  $\mathbf{G}_0^m[u, \sigma] = (m, a)$ , where  $a$  is the final state of  $B$  when it reads  $\sigma_{1\dots n}$ . Therefore,  $\mathbf{G}_0^m[u, \sigma] = v \iff B(\sigma_{1\dots n}) = 1$ .

Let  $M$  be the random walk matrix of  $\mathbf{G}_0$  and  $\widetilde{M}$  the random walk matrix of  $\mathbf{G}_\ell$ . Then

$$\begin{aligned} & \left| \Pr_{x \leftarrow U_{[d] \times [c]^\ell}} [B(G(x)) = 1] - \Pr_{\sigma \leftarrow U_{[d]^m}} [B(\sigma) = 1] \right| \\ &= \left| \Pr_{x \leftarrow U_{[d] \times [c]^\ell}} [\mathbf{G}_0^m[u, \text{INW}_\ell(x)] = v] - \Pr_{e \leftarrow U_{[d]^m}} [\mathbf{G}_0^m[u, e] = v] \right| \\ &= \left| \Pr_{e \leftarrow U_{[d] \times [c]^\ell}} [\mathbf{G}_\ell[u, e] = v] - \Pr_{e \leftarrow U_{[d]^m}} [\mathbf{G}_0^m[u, e] = v] \right| \\ &= \left| \widetilde{M}_{v,u} - M_{v,u}^m \right|, \end{aligned}$$

which is at most  $\varepsilon$  by Proposition 2.7.  $\triangleleft$

To complete the proof of Theorem 1.4 we recall a result giving the existence of explicit expanders of all sizes.

▷ **Lemma 4.7** ([14] Theorem 3.3, Definition 2.13). *For all  $n > 1$  and  $\lambda > 0$ , there is a  $c = \text{poly}(1/\lambda)$  and a  $c$ -regular undirected multigraph  $\mathbf{H}$  on  $n$  vertices with a one-way labeling such that  $\lambda(\mathbf{H}) \leq \lambda$ , and given  $\lambda$ ,  $v$ , and  $e$ , the vertex  $\mathbf{H}[v, e]$  can be computed in space  $O(\log(nc))$ .*

**Proof of Theorem 1.4.** Let  $\mathbf{H}_i$  be the expander given by Lemma 4.7 with  $\lambda = \varepsilon/(8\ell)$  and  $n = d \cdot c^{i-1}$ . This sequence  $\mathbf{H}_1, \mathbf{H}_2, \dots$  satisfies the requirements of Claim 4.6, so  $G$  constructed with this sequence is an  $\varepsilon$ -PRG. It remains to show the seed length and that the generator is explicit.

By construction the  $\ell$ th INW generator  $\text{INW}_\ell$  has domain  $[d] \times [c]^\ell$ . By definition  $\ell \leq \log(n) + 1$  and by Lemma 4.7 the degree of  $\mathbf{H}_i$  for all  $i$  is  $c = \text{poly}(\log(n)/\varepsilon)$ , which gives a seed length of  $s = O(\log d + \log n \cdot (\log \log n + \log(1/\varepsilon)))$ .

Finally,  $G$  is explicit, in that the output of the generator can be computed in working space  $O(s)$ . This follows directly from Definition 4.1 and the explicitness of the expanders.  $\blacktriangleleft$

## 4.2 Improved Seed Length for Tiny Error

So far, we have designed a PRG with seed length

$$O(\log d + \log n \cdot (\log \log n + \log(1/\varepsilon))). \quad (1)$$

In this section, we will present a simple reduction that yields an improved seed length when  $\varepsilon$  is extremely small.

▷ **Lemma 4.8.** *Suppose  $G: \{0, 1\}^s \rightarrow [d^m]^n$  is an  $\varepsilon$ -PRG for length- $n$  degree- $(d^m)$  permutation branching programs. Identify  $[d^m] = [d]^m$ , and think of  $G$  as a function  $G: \{0, 1\}^s \rightarrow [d]^{mn}$ . Then  $G$  is an  $\varepsilon$ -PRG for length- $(mn)$  degree- $d$  permutation branching programs.*

**Proof.** Let  $B$  be a length- $(mn)$  degree- $d$  permutation branching program. Define a length- $n$  degree- $(d^m)$  branching program  $B'$  where one step of  $B'$  simulates  $m$  steps of  $B$ . Then  $B'$  is a permutation branching program, and  $B'$  computes the same function as  $B$ , so fooling  $B'$  implies fooling  $B$ . ◀

► **Corollary 4.9.** *For all  $n, d \in \mathbb{N}$  and  $\varepsilon > d^{-n/2}$ , there is an explicitly computable  $\varepsilon$ -PRG  $G: \{0, 1\}^s \rightarrow [d]^n$  for permutation branching programs of length  $n$ , degree  $d$ , and arbitrary width. This PRG has seed length*

$$O\left(\log d + \log\left(\frac{n \log d}{\log(1/\varepsilon)}\right) \cdot (\log \log n + \log(1/\varepsilon))\right).$$

**Proof.** If  $\log(1/\varepsilon) < \log d$ , then the seed length of Equation 1 is already sufficient. Assume, therefore, that  $\log(1/\varepsilon) \geq \log d$ . Let  $m = \left\lceil \frac{\log(1/\varepsilon)}{\log d} \right\rceil$  and let  $n' = \lceil n/m \rceil$ . Plugging into Equation 1, we have constructed already a PRG for length- $n'$  degree- $(d^m)$  permutation branching programs with seed length  $s$ , where

$$\begin{aligned} s &\leq O(\log(d^m) + \log(n/m) \cdot (\log \log n + \log(1/\varepsilon))) \\ &= O\left(\log(1/\varepsilon) + \log\left(\frac{n \log d}{\log(1/\varepsilon)}\right) \cdot (\log \log n + \log(1/\varepsilon))\right) \\ &= O\left(\log\left(\frac{n \log d}{\log(1/\varepsilon)}\right) \cdot (\log \log n + \log(1/\varepsilon))\right), \end{aligned}$$

where the last step uses the assumption  $\varepsilon \geq d^{-n/2}$  which implies  $\log\left(\frac{n \log d}{\log(1/\varepsilon)}\right) \geq 1$ . By Lemma 4.8, that same PRG fools length- $(mn')$  degree- $d$  permutation branching programs. Since  $mn' > n$ , by truncating to the first  $n$  symbols, we get the desired PRG for length- $n$  degree- $d$  permutation branching programs. ◀

## 5 A Random Function is Not a Good PRG

In this section, we prove that a random generator does not fool unbounded-width permutation branching programs, unless the seed length is  $\Omega(n \log d)$ . The proof is based on the following family of exponential-width permutation branching programs.

► **Lemma 5.1.** *Let  $n$  be a multiple of two, and let  $\pi: [d]^{n/2} \rightarrow [d]^{n/2}$  be a permutation. There is a width- $(d^{n/2})$  length- $n$  degree- $d$  permutation branching program  $B$  such that*

$$B(x, y) = 1 \iff y = \pi(x).$$

**Proof.** Let  $\mathbb{Z}_d$  denote the ring of integers modulo  $d$ . We identify the state space  $[d^{n/2}]$  with the space  $\mathbb{Z}_d^{n/2}$ , a  $\mathbb{Z}_d$ -module. Let  $e_1, \dots, e_{n/2} \in \mathbb{Z}_d^{n/2}$  denote the standard “basis vectors,” i.e.,  $e_t$  has a 1 in coordinate  $t$  and 0 in all other coordinates. The transition function  $W_t: \mathbb{Z}_d^{n/2} \times \mathbb{Z}_d \rightarrow \mathbb{Z}_d^{n/2}$  is given by

$$W_t(v, \sigma) = \begin{cases} v + \sigma \cdot e_t & \text{if } t \leq n/2 \\ \pi^{-1}(\pi(v) - \sigma \cdot e_t) & \text{if } t > n/2. \end{cases}$$

These transition functions satisfy the permutation condition, because  $W_t(W_t(v, \sigma), -\sigma) = v$ . The start state of  $B$  is the zero element  $0 \in \mathbb{Z}_d^{n/2}$ , and the accepting state is  $\pi^{-1}(0)$ . By induction, when  $B$  reads an input  $(x, y) \in (\mathbb{Z}_d^{n/2})^2$ , it passes through the state  $x$  in layer  $n/2$ , and ultimately it arrives at the state  $\pi^{-1}(\pi(x) - y)$  in the final layer. Thus,  $B(x, y) = 1 \iff y = \pi(x)$ . ◀

► **Theorem 5.2** (Failure of the Probabilistic Method). *Let  $n$  be a multiple of 2. Let  $s = \left\lfloor \frac{n \log d}{4} \right\rfloor - 1$ , and sample a generator  $G$  uniformly at random from all functions  $G: \{0, 1\}^s \rightarrow [d]^n$ . With probability at least  $3/4$ , there is some length- $n$  degree- $d$  permutation branching program  $B$  such that*

$$\left| \Pr_{\sigma \leftarrow U_{[d]^n}} [B(\sigma) = 1] - \Pr_{x \leftarrow U_{\{0,1\}^s}} [B(G(x)) = 1] \right| = 1 - d^{-n/2}.$$

**Proof.** Let  $G_L, G_R: \{0, 1\}^s \rightarrow [d]^{n/2}$  be the left and right halves of  $G$  respectively, i.e.,  $G(x) = G_L(x) \circ G_R(x)$ . We claim that with high probability,  $G_L$  and  $G_R$  are both injective. Indeed, for each pair of distinct seeds  $x, x' \in \{0, 1\}^s$ , the strings  $G_L(x), G_L(x')$  are independent uniform  $(n/2)$ -symbol strings, so  $\Pr_G[G_L(x) = G_L(x')] = d^{-n/2}$ . The number of pairs  $(x, x')$  is at most  $\binom{2^s}{2} \leq \frac{1}{2} 2^{2s} \leq 2^{-3} d^{n/2}$ , where the last inequality is by our choice of  $s$ . Therefore, by the union bound,  $\Pr_G[G_L \text{ is not injective}] \leq 2^{-3}$ . The same argument applies to  $G_R$  as well, so except with probability  $2 \cdot 2^{-3} = \frac{1}{4}$ ,  $G_L$  and  $G_R$  are both injective. In this case, there exists a permutation  $\pi: [d]^{n/2} \rightarrow [d]^{n/2}$  such that for every seed  $x$ ,  $\pi(G_L(x)) = G_R(x)$ . By Lemma 5.1, there is a length- $n$  degree- $d$  permutation branching program  $B$  such that  $B(y, z) = 1 \iff z = \pi(y)$ . Therefore, for every seed  $x$ ,  $B(G(x)) = 1$ , so  $\Pr_x[B(G(x)) = 1] = 1$ . On the other hand, since  $\pi$  is a permutation,  $\Pr_\sigma[B(\sigma) = 1] = d^{-n/2}$ . ◀

## 6 Seed Length Lower Bound

In this section, we prove our lower bound on the seed length of any PRG for unbounded-width permutation branching programs, showing that our PRG's seed length is near-optimal. Except when  $\varepsilon$  is extremely small, the lower bound is  $\Omega(\log d + \log n \cdot \log(1/\varepsilon))$ .

► **Theorem 6.1.** *Let  $d \geq 2$  and  $n \geq 1$ . Let  $G: \{0, 1\}^s \rightarrow [d]^n$  be an  $\varepsilon$ -PRG for length- $n$  degree- $d$  permutation branching programs of unbounded width, where  $d^{-n/2} \leq \varepsilon \leq 0.49$ . Then*

$$s \geq \Omega \left( \log d + \log \left( \frac{n \log d}{\log(1/\varepsilon)} \right) \cdot \log(1/\varepsilon) \right).$$

The proof of Theorem 6.1 is based on the same family of exponential-width branching programs that we used to prove Theorem 5.2. At an intuitive level, we argue that either the first half of the PRG's output is information-theoretically unpredictable given the second half, or vice versa. After all, if each half is somewhat predictable given the other half, there ought to exist a permutation  $\pi$  such that the pseudorandom string  $(x, y)$  has a noticeable chance (say at least  $2\varepsilon$ ) of satisfying  $\pi(x) = y$ , whereas a truly random string is extremely unlikely to satisfy  $\pi(x) = y$ . It follows that the PRG must use  $\Omega(\log(1/\varepsilon))$  bits of seed above and beyond the seed length for sampling the first half or the second half individually.

To obtain a suitable permutation  $\pi$ , we rely on a version of the Kőnig-Egerváry theorem regarding maximum matchings in bipartite graphs. (In the lemma statement, think of  $p$  as a weight function on the edges of the complete bipartite graph  $K_{N,N}$ , and think of  $\pi$  as identifying a perfect matching.)

► **Lemma 6.2** (Kőnig-Egerváry theorem for fractional edge weights, [21, Theorem 17.1]). *For every integer  $N \geq 1$  and every function  $p: [N] \times [N] \rightarrow [0, \infty)$ , there exist a permutation  $\pi: [N] \rightarrow [N]$  and functions  $q, r: [N] \rightarrow [0, \infty)$  such that*

$$\forall x, y \in [N], p(x, y) \leq q(x) + r(y) \tag{2}$$

and

$$\sum_{x \in [N]} p(x, \pi(x)) = \sum_{x \in [N]} q(x) + \sum_{y \in [N]} r(y). \tag{3}$$

Note that Equations 2 and 3 immediately imply that  $\pi$  maximizes  $\sum_x p(x, \pi(x))$ . A proof of Lemma 6.2 can be found in Schrijver's text [21, Theorem 17.1]. Alternatively, Lemma 6.2 follows from strong linear programming duality and the fact that the integer matching polytope equals the fractional matching polytope.

As outlined previously, we would now like to show that if each of  $X$  and  $Y$  is somewhat predictable given the other, then there is a noticeable chance that  $\pi(X) = Y$ . To rigorously formulate and prove this statement, we use the notion of Shannon entropy.

► **Definition 6.3.** If  $X$  is a discrete random variable, the entropy of  $X$  is

$$H[X] = \mathbb{E}_{x \sim X} \left[ \log \left( \frac{1}{\Pr[X = x]} \right) \right].$$

If  $X$  and  $Y$  are jointly distributed discrete random variables, the joint entropy  $H[X, Y]$  is the entropy of the pair  $(X, Y)$ , and the conditional entropy of  $X$  given  $Y$  is

$$H[X | Y] = \mathbb{E}_{y \sim Y} [H[X | Y = y]] = \mathbb{E}_{\substack{x \sim X \\ y \sim Y}} \left[ \log \left( \frac{1}{\Pr[X = x | Y = y]} \right) \right].$$

► **Lemma 6.4.** Let  $N \geq 1$ , and let  $X$  and  $Y$  be jointly distributed random variables, each taking values in  $[N]$ . There exists a permutation  $\pi: [N] \rightarrow [N]$  such that

$$\Pr[\pi(X) = Y] \geq 2^{-H[X|Y] - H[Y|X]}.$$

Lemma 6.4 bears a resemblance to a well-known fact, which says that if we allow an *arbitrary* function  $\pi$  (not necessarily a permutation), the maximum possible value of  $\Pr[\pi(X) = Y]$  is precisely  $2^{-H_\infty(Y|X)}$ , where  $H_\infty(Y|X)$  is the “average min-entropy” of  $Y$  given  $X$  [7]. Our lemma is an interesting “symmetric” variant.

**Proof.** Let  $\pi, q, r$  be the functions guaranteed by Lemma 6.2 for the function  $p(x, y) = \Pr[(X, Y) = (x, y)]$ . Let  $\mathcal{X} = \text{Supp}(X)$  and  $\mathcal{Y} = \text{Supp}(Y)$ . Then

$$\begin{aligned} \Pr[\pi(X) = Y] &= \sum_{x \in [N]} q(x) + \sum_{y \in [N]} r(y) && \text{(Equation 3)} \\ &\geq \sum_{x \in \mathcal{X}} q(x) + \sum_{y \in \mathcal{Y}} r(y) \\ &= \sum_{\substack{x \in \mathcal{X} \\ y \in \mathcal{Y}}} \Pr[(X, Y) = (x, y)] \cdot \left( \frac{q(x)}{\Pr[X = x]} + \frac{r(y)}{\Pr[Y = y]} \right) \\ &\geq \sum_{\substack{x \in \mathcal{X} \\ y \in \mathcal{Y}}} \Pr[(X, Y) = (x, y)]^2 \cdot \frac{q(x) + r(y)}{\Pr[X = x] \cdot \Pr[Y = y]} \\ &\geq \sum_{\substack{x \in \mathcal{X} \\ y \in \mathcal{Y}}} \frac{\Pr[(X, Y) = (x, y)]^3}{\Pr[X = x] \cdot \Pr[Y = y]} && \text{(Equation 2)} \\ &= \mathbb{E}_{(x, y) \sim (X, Y)} [\Pr[X = x | Y = y] \cdot \Pr[Y = y | X = x]] \\ &\geq 2^{\mathbb{E}_{(x, y) \sim (X, Y)} [\log(\Pr[X = x | Y = y] \cdot \Pr[Y = y | X = x])]} && \text{(Jensen)} \\ &= 2^{-H[X|Y] - H[Y|X]}. \end{aligned}$$

To apply Lemma 6.4 to analyze pseudorandom distributions for permutation branching programs, we will use the standard *chain rule* for Shannon entropy.

▷ **Claim 6.5 (Chain Rule).** If  $X$  and  $Y$  are discrete random variables, then  $H[X, Y] = H[X] + H[Y | X]$ .

► **Lemma 6.6.** Let  $n$  be a multiple of two, let  $X$  and  $Y$  be random variables distributed over  $[d]^{n/2}$ , and let  $\varepsilon \geq d^{-n/2}$ . Assume that for every length- $n$  degree- $d$  permutation branching program  $B$ ,

$$|\Pr[B(U_{[d]^n}) = 1] - \Pr[B(X, Y) = 1]| \leq \varepsilon. \quad (4)$$

Then

$$H[X, Y] \geq \frac{1}{2} \left( H[X] + H[Y] + \log \left( \frac{1}{2\varepsilon} \right) \right).$$

**Proof.** Let  $\pi$  be the permutation of Lemma 6.4. By Lemma 5.1, there is some length- $n$  degree- $d$  permutation branching program  $B$  such that  $B(x, y) = 1 \iff \pi(x) = y$ . Since  $\pi$  is a permutation,  $\Pr[B(U_{[d]^n}) = 1] = d^{-n/2}$ . Therefore, by Equation 4,

$$2^{-H[X|Y] - H[Y|X]} \leq d^{-n/2} + \varepsilon \leq 2\varepsilon.$$

Therefore,

$$\begin{aligned} H[X, Y] &= \frac{1}{2} (H[X] + H[Y | X] + H[Y] + H[X | Y]) && \text{(Chain Rule)} \\ &\geq \frac{1}{2} \left( H[X] + H[Y] + \log \left( \frac{1}{2\varepsilon} \right) \right). && \blacktriangleleft \end{aligned}$$

To complete the proof of Theorem 6.1, we use the following standard fact about Shannon entropy.

▷ **Claim 6.7.** If  $X$  is a discrete random variable and  $f$  is a function, then  $H[f(X)] \leq H[X]$ .

**Proof of Theorem 6.1.** The seed length must be  $\Omega(\log d)$  simply because the program can compute any arbitrary function of its first symbol. For  $i \geq 0$ , let

$$n_i = \left\lceil \frac{\log(1/\varepsilon)}{\log d} \right\rceil \cdot 2^i.$$

We will prove by induction on  $i$  that if a distribution  $X$  over  $[d]^{n_i}$  fools length- $n_i$  degree- $d$  permutation branching programs with error  $\varepsilon$ , then

$$H[X] \geq \frac{i}{2} \cdot \log \left( \frac{1}{2\varepsilon} \right).$$

The base case  $i = 0$  is trivial. For the inductive step, consider a distribution  $(X, Y)$  over strings of length  $n_i$ , where  $|X| = |Y| = n_{i-1}$ . Since a permutation branching program can elect to ignore some of its input symbols,  $X$  and  $Y$  must each individually fool length- $n_{i-1}$  degree- $d$  permutation branching programs with error  $\varepsilon$ . Therefore, by induction,

$$\frac{1}{2} (H[X] + H[Y]) \geq \frac{(i-1)}{2} \cdot \log \left( \frac{1}{2\varepsilon} \right).$$

Furthermore, since  $n_i \geq 2 \log(1/\varepsilon) / \log d$ , we have  $\varepsilon \geq d^{-n_i/2}$ , so we may apply Lemma 6.6 to complete the inductive step.

Now consider

$$i = \left\lfloor \log \left( \frac{n}{\lceil \log(1/\varepsilon) / \log d \rceil} \right) \right\rfloor.$$

Since  $\varepsilon \geq d^{-n/2}$ , we have  $n/2 \leq n_i \leq n$ . Let  $X$  be the truncation of  $G(U_{\{0,1\}^s})$  to the first  $n_i$  symbols. Then

$$s = H[U_{\{0,1\}^s}] \geq H[G(U_{\{0,1\}^s})] \geq H[X] \geq \frac{i}{2} \log \left( \frac{1}{2\varepsilon} \right),$$

where the first two inequalities follow from Claim 6.7. If  $\log(1/\varepsilon) > \log d$ , then  $i = \Omega \left( \log \left( \frac{n \log d}{\log(1/\varepsilon)} \right) \right)$ , so we are done. Meanwhile, if  $\log d = \lambda \cdot \log(1/\varepsilon)$  for some  $\lambda \geq 1$ , then  $i = \lfloor \log n \rfloor$ , so we have shown

$$s \geq \frac{\lfloor \log n \rfloor}{2} \cdot \log \left( \frac{1}{2\varepsilon} \right).$$

We also have

$$s \geq \Omega(\log d) = \Omega(\lambda \cdot \log(1/\varepsilon)) \geq \Omega(\log \lambda \cdot \log(1/\varepsilon)).$$

Combining, we get

$$\begin{aligned} s &\geq \Omega((\log n + \log \lambda) \cdot \log(1/\varepsilon)) \\ &= \Omega(\log(n\lambda) \cdot \log(1/\varepsilon)) \\ &= \Omega \left( \log \left( \frac{n \log d}{\log(1/\varepsilon)} \right) \cdot \log(1/\varepsilon) \right). \end{aligned}$$

◀

## 7 The Optimal Seed Length for Hitting Set Generators

Let  $\mathcal{F}$  be a class of functions  $B: [d]^n \rightarrow \{0,1\}$ . Recall that an  $\varepsilon$ -HSG for  $\mathcal{F}$  is a function  $G: \{0,1\}^s \rightarrow [d]^n$  such that

$$\forall B \in \mathcal{F}, \Pr[B(U_{[d]^n}) = 1] \geq \varepsilon \implies \exists x \in \{0,1\}^s, B(G(x)) = 1.$$

Thus, an HSG is a “one-sided” variant of a PRG.

In this section, we prove that any HSG for polynomial-width permutation branching programs is an HSG for unbounded-width permutation branching programs. As a corollary, we will show that the optimal (nonexplicit) seed length for an HSG for unbounded-width permutation branching programs is  $O(\log(nd/\varepsilon))$ .

► **Theorem 7.1.** *Let  $n$  be a positive integer, let  $G: \{0,1\}^s \rightarrow [d]^n$  be a function, and let  $\varepsilon > 0$ .*

1. *There is a value  $w = O(n/\varepsilon)$  such that if  $G$  is an  $(\varepsilon/2)$ -HSG for width- $w$  length- $n$  ordered branching programs, then  $G$  is an  $\varepsilon$ -HSG for unbounded-width length- $n$  permutation branching programs.*
2. *There is a value  $w = O(n^2/\varepsilon)$  such that if  $G$  is an  $(\varepsilon/2)$ -HSG for width- $w$  length- $n$  permutation branching programs, then  $G$  is an  $\varepsilon$ -HSG for unbounded-width length- $n$  permutation branching programs.*

Item 2 is not necessary for the purpose of establishing the optimal seed length for HSGs for unbounded-width permutation branching programs. We include the proof because we find it interesting.

**Proof.** Let  $B$  be a length- $n$  permutation branching program. We will define a function  $f: [d]^n \rightarrow \{0, 1\}$  such that  $f(x) = 1 \implies B(x) = 1$  and  $\Pr_{x \in [d]^n}[B(x) \neq f(x)] \leq \varepsilon/2$ . Furthermore, we will show that  $f$  can be computed by an ordered branching program of width  $O(n/\varepsilon)$ , as well as by a permutation branching program of width  $O(n^2/\varepsilon)$ .

Think of  $B$  as a directed graph. Let  $V_0, \dots, V_n$  be the layers of the graph. For each vertex  $v$ , let  $p_{\rightarrow v}$  denote the probability that  $B$  passes through  $v$  when it reads a random input. Let  $q = \lceil 2n/\varepsilon \rceil$ . If the width of  $B$  is less than  $q$ , we can just let  $f = B$ , so assume the width of  $B$  is at least  $q$ . For each  $t \in \{0, 1, \dots, n\}$ , define  $S_t$  to be the set of  $q$  vertices  $v \in V_t$  with the largest values of  $p_{\rightarrow v}$ . Let  $f(x) = 1$  if the path through  $B$  described by  $x$  stays within  $S_0, S_1, \dots, S_n$  and ends at the accepting vertex.

Clearly,  $f(x) = 1 \implies B(x) = 1$ . Now consider sampling  $x = (x_1, \dots, x_n) \in [d]^n$  uniformly at random. For each  $t \in [n]$  and each vertex  $v \in V_t$ , let  $B_{v \rightarrow}$  denote the permutation branching program that ignores the first  $t$  symbols of its inputs and then simulates the last  $(n - t)$  layers of  $B$  starting at vertex  $v$ . By the definition of  $S_t$ , each  $v \in V_t \setminus S_t$  satisfies  $p_{\rightarrow v} < 1/q$ . Therefore,

$$\begin{aligned} \Pr_x[B(x) \neq f(x)] &\leq \sum_{t=1}^n \sum_{v \in V_t \setminus S_t} p_{\rightarrow v} \cdot \Pr_x[B_{v \rightarrow}(x) = 1] \\ &< \frac{1}{q} \cdot \sum_{t=1}^n \sum_{v \in V_t \setminus S_t} \Pr_x[B_{v \rightarrow}(x) = 1] \\ &\leq \frac{1}{q} \cdot \sum_{t=1}^n \mathbb{E}_x \left[ \sum_{v \in V_t} B_{v \rightarrow}(x) \right]. \end{aligned}$$

Consider any fixed  $t$  and  $x$ . By the permutation condition, it is possible to work backward from the accepting vertex to find the unique vertex  $v \in V_t$  such that  $B_{v \rightarrow}(x) = 1$ . Therefore,  $\sum_{v \in V_t} B_{v \rightarrow}(x) = 1$ . Thus,

$$\Pr_x[B(x) \neq f(x)] \leq \frac{1}{q} \cdot \sum_{t=1}^n 1 \leq \frac{\varepsilon}{2}.$$

An ordered branching program for  $f$  can be obtained from  $B$  by deleting all the vertices in  $V_t \setminus S_t$  and redirecting all their incoming edges to a new  $\perp$  vertex. All outgoing edges from the  $\perp$  vertex in layer  $t$  point to the  $\perp$  vertex in layer  $t + 1$ , and finally in layer  $n$ , the  $\perp$  vertex is a reject vertex. Clearly, the width of this program is  $q + 1$ .

Now let us define a permutation branching program computing  $f$  of width  $w = q \cdot (n + 1)$ . Let  $w_0$  be the width of  $B$ , and number the states so that  $S_t$  corresponds to  $[q] \subseteq [w_0]$ . Let  $W_t: [w_0] \times [d] \rightarrow [w_0]$  be the transition function of  $B$ . Let  $A_{t,\sigma}$  be the set of  $v \in [q]$  such that  $W_t(v, \sigma) \in [q]$ . By the permutation condition, for each fixed  $t$  and  $\sigma$ , the function  $W_t(\cdot, \sigma)$  is a permutation on  $[w_0]$ . Therefore, there exists a permutation  $\pi_{t,\sigma}: [w_0] \setminus A_{t,\sigma} \rightarrow [w_0] \setminus W_t(A_{t,\sigma}, \sigma)$ .

Let  $\mathbb{Z}_n$  denote the additive group of integers modulo  $n$ , and identify  $[w] = [q] \times \mathbb{Z}_{n+1}$ . The new branching program's transition function  $W'_t: [q] \times \mathbb{Z}_{n+1} \times [d] \rightarrow [q] \times \mathbb{Z}_{n+1}$  is given by

$$W'_t(v, i, \sigma) = \begin{cases} (W_t(v, \sigma), i) & \text{if } v \in A_{t,\sigma} \\ (\pi_{t,\sigma}(v), i + 1) & \text{otherwise.} \end{cases}$$

Clearly, this satisfies the permutation condition. The start state is  $(v_{\text{start}}, 0)$  and the accept state is  $(v_{\text{end}}, 0)$ , where  $v_{\text{start}}$  and  $v_{\text{end}}$  are the start and accept states of  $B$ . If  $f(\sigma) = 1$ , then inductively, when our permutation branching program reads  $\sigma$ , it simulates  $B$  and ultimately

accepts without ever incrementing  $i$ . Conversely, if our permutation branching program accepts  $\sigma$ , then  $i$  must never be incremented. Therefore, when  $B$  reads  $\sigma$ , it stays within the sets  $S_0, \dots, S_n$  and accepts, and hence  $f(\sigma) = 1$ .

Finally, if  $\Pr[B(U_{[d]^n}) = 1] \geq \varepsilon$ , then  $\Pr[f(U_{[d]^n}) = 1] \geq \varepsilon/2$ . Therefore, under either of the two assumptions of the theorem,  $G$  hits  $f$ , and since  $f \leq B$ , this implies that  $G$  hits  $B$  as well.  $\blacktriangleleft$

► **Corollary 7.2.** *For every  $n, d, \varepsilon$ , there exists an  $\varepsilon$ -HSG  $G: \{0, 1\}^s \rightarrow [d]^n$  for unbounded-width length- $n$  degree- $d$  permutation branching programs with seed length  $s = O(\log(nd/\varepsilon))$ .*

**Proof.** It is standard that there exists a nonexplicit  $\varepsilon$ -HSG for width- $w$  length- $n$  degree- $d$  ordered branching programs with seed length  $O(\log(wnd/\varepsilon))$ . (Indeed, a random function is an HSG with these parameters with high probability.)  $\blacktriangleleft$

The next claim shows that the seed length in Corollary 7.2 is optimal.

▷ **Claim 7.3.** Let  $d \geq 2$  and  $n \geq 1$ . Let  $G: \{0, 1\}^s \rightarrow [d]^n$  be an  $\varepsilon$ -HSG for length- $n$  degree- $d$  permutation branching programs of unbounded width, where  $d^{-n} \leq \varepsilon \leq 1/3$ . Then  $s \geq \Omega(\log(nd/\varepsilon))$ .

*Proof sketch.* The seed length needs to be at least  $\Omega(\log d)$  because the program can compute any function of the first input symbol. The seed length needs to be at least  $\Omega(\log(1/\varepsilon))$  because unbounded-width permutation branching programs can check whether a prefix of the input is equal to a fixed arbitrary string. Finally, let  $G: \{0, 1\}^s \rightarrow [d]^n$  with  $s < \log n$ ; we will show that  $G$  is not a  $(1/3)$ -HSG for degree- $d$  permutation branching programs. Let  $b: [d] \rightarrow \mathbb{F}_2$  be as close to balanced as possible. Since  $2^s < n$ , there is some nonzero vector  $z \in \mathbb{F}_2^n$  such that for every seed  $x$ ,

$$\sum_{i=1}^n z_i \cdot b(G(x)_i) = 0.$$

The function  $B(x) = \sum_{i=1}^n z_i \cdot b(x_i)$  can be computed by a width-2 degree- $d$  permutation branching program, and  $\Pr_x[B(x) = 1] \geq 1/3$ .  $\triangleleft$

## 8 Directions for Further Research

The obvious challenge is to obtain optimal PRGs for unbounded-width permutation branching programs in the large-error regime. We conjecture that our seed length lower bound is tight, i.e., there is a PRG construction that eliminates the  $\log \log n$  factor from our PRG's seed length.

We showed that there is a nonexplicit HSG with seed length  $O(\log(n/\varepsilon))$  for unbounded-width permutation branching programs. A natural problem is to match the seed length with an explicit construction. In the constant-width case, Braverman et al. [2] presented a simple HSG for the more general model of regular branching programs with seed length  $O(\log n)$ , independent of  $\varepsilon$ .

We wonder what PRGs can be constructed for the more challenging model of *arbitrary-order* permutation branching programs. Reingold, Steinke, and Vadhan [17] and Chattopadhyay et al. [3] have constructed PRGs for the small-width case. By using one generator for large  $\varepsilon$  and the other for small  $\varepsilon$ , one can achieve seed length  $\tilde{O}(\log n \cdot \log(1/\varepsilon))$  when the width is a constant. For the unbounded-width case, explicit constructions or bounds for nonexplicit PRGs would be interesting.

Finally, we wonder whether our results can be generalized to the case of unbounded-width regular branching programs. Our HSG existence proof (Theorem 7.1 and Corollary 7.2) does generalize to the regular case<sup>3</sup>, but the PRG situation is unclear.

## Abstract

We introduce the *pipeline intervention* problem, defined by a layered directed acyclic graph and a set of stochastic matrices governing transitions between successive layers. The graph is a stylized model for how people from different populations are presented opportunities, eventually leading to some reward. In our model, individuals are born into an initial position (i.e. some node in the first layer of the graph) according to a fixed probability distribution, and then stochastically progress through the graph according to the transition matrices, until they reach a node in the final layer of the graph; each node in the final layer has a *reward* associated with it. The pipeline intervention problem asks how to best make costly changes to the transition matrices governing people's stochastic transitions through the graph, subject to a budget constraint. We consider two objectives: social welfare maximization, and a fairness-motivated maximin objective that seeks to maximize the value to the population (starting node) with the *least* expected value. We consider two variants of the maximin objective that turn out to be distinct, depending on whether we demand a deterministic solution or allow randomization. For each objective, we give an efficient approximation algorithm (an additive FPTAS) for constant width networks. We also tightly characterize the “price of fairness” in our setting: the ratio between the highest achievable social welfare and the social welfare consistent with a maximin optimal solution. Finally we show that for polynomial width networks, even approximating the maximin objective to any constant factor is NP hard, even for networks with constant depth. This shows that the restriction on the width in our positive results is essential.

## 1 Introduction

Inequality can be difficult to correct by the time it manifests itself in consequential domains. For example, faculty in computer science departments are disproportionately male (Way et al. [21]), and although the reasons for this are varied and complex, it seems difficult to correct *only* by intervening in the process of faculty hiring (although the solution likely involves some intervention at this stage). The problem is that interventions at the final stage of a long pipeline may not be enough (or the best way) to address inequities that compound starting from earlier stages in the pipeline such as graduate school, college, high school, enrichment programs, all the way back to birth circumstances. Because each stage of, for example, employment pipelines feeds into the next, interventions that are isolated to any one stage can have difficulty controlling effects on final outcomes – and although in practice it is difficult to fully understand such a system, we would ideally like to design proposed interventions at a system-wide level, rather than myopically.

Thus motivated, we study an optimization problem within a stylized (and highly simplified) model of such a pipeline. Our model is a layered directed acyclic graph. The vertices in the first layer represent a coarse partitioning of possible birth circumstances into a small number of types – each vertex representing one of these types. There is a probability vector over these vertices and individuals are “born” into some vertex with these probabilities. The graph represents a Markov process that determines how individuals progress through the pipeline. From every vertex there is a stochastic transition matrix specifying the probability that an individual will progress to each vertex in the next layer of the pipeline. We might imagine, for example, that the proportion of children that enroll in each of several elementary schools (the second layer of such a pipeline) varies according to the neighborhood that they are raised in (the first layer). The proportion of children that then go on to enroll in each of several high schools may then vary according to the elementary school they attend, and so on. Finally, vertices at the last layer of the pipeline are associated with payoffs. One may then calculate the expected payoff of an individual as a function of their initial position. These payoffs may vary widely depending on this position.

We are concerned with the problem of how best to invest limited resources so as to *modify* the transition matrices governing different layers of this pipeline to achieve some goal. In the main body of the paper, we focus on a stylized model where the costs of modifying transition matrices are linear, for simplicity of exposition; we extend our results to more complex and realistic cost functions in the Appendix. We consider two goals: the first is simply maximizing social welfare – the expected payoff for an individual chosen according to the given probability vector for the first layer. Although this is a natural objective, it can easily lead to solutions that are “unfair” in the sense that they will prioritize investments that lead to improvements for majority populations over minority populations, simply because majority populations, by their sheer numbers, contribute more to social welfare. The second goal we study is therefore to maximize the *minimum* expected payoff of individuals, where the minimum is taken over all of the initial positions, i.e., layer 1 vertices. This “maximin” objective is a standard fairness-motivated objective in allocation problems [See Barman and Krishnamurthy [2], Procaccia and Wang [19], Budish [5]]. In fact, we study two different variants of this objective, that can be distinguished by the timing with which one wants to evaluate fairness. The *ex-ante* maximin objective asks for a *distribution* over budget-feasible modifications of the transition matrices, that maximize the minimum expected payoff over all initial positions. The *ex-post* maximin objective asks for a single (i.e. deterministic) budget-feasible modification to the transition matrices. Because the problem we study is non-convex, these two goals are distinct – which is preferred depends on *when* one wants to evaluate the fairness of a solution: before or after the randomization.

## 1.1 Overview of Our Results

Briefly, our main contributions are the following:

1. We define and formalize the *pipeline intervention problem* with the social welfare, ex-ante maximin, and ex-post maximin objectives. We also prove a separation between the ex-post and ex-ante maximin solutions.
2. We give an additive fully polynomial-time approximation scheme (FPTAS) for both the social welfare and ex-post maximin objectives for networks of constant width (but arbitrarily long depth).
3. We give an efficient reduction from the ex-ante maximin objective problem to the ex-post maximin objective problem via equilibrium computation in two-player zero-sum games. Combined with our results from 2, this yields an additive FPTAS for the ex-ante maximin objective problem for constant width networks as well.
4. We define and prove tight bounds on the “price of fairness”, which compares the optimal social welfare that can be achieved with a given budget to the social welfare of ex-post maximin optimal solutions.
5. Finally, we show that the pipeline intervention problem is NP hard even to approximate in the general case when the width  $w$  is not bounded – and hence that our efficient approximation algorithms cannot be extended to the general case (or even the case of constant depth, polynomial width networks).

## 1.2 Related Work

There is an enormous literature in “algorithmic fairness” that has emerged over the last several years, that we cannot exhaustively summarize here – but see Chouldechova and Roth [6] for a recent survey. Most of this literature is focused on the myopic effects of a single intervention, but what is more conceptually related to our paper is work focusing on the longer-term effects of algorithmic interventions.

Dwork and Ilvento [9] and Bower et. al. [4] study the effects of imposing fairness constraints on machine learning algorithms that might be composed together in various ways to reach an eventual outcome. They show that generally fairness constraints imposed on constituent algorithms in a pipeline or other composition do not guarantee that the same fairness constraints will hold on the entire mechanism as a whole. (They also study conditions under which fairness guarantees *are* well behaved under composition). Two recent papers (Liu et al. [15], Mouzannar et al. [17]) study parametric models by which classification interventions in an earlier stage can have effects on the data distribution at later stages, and show that for many commonly studied fairness constraints, their effects can either be positive or negative in the long term, depending on the functional form of the relationship between classification decisions and changes in the agent type distribution.

There is also a substantial body of work studying game theoretic models for how interventions affect “fairness” goals. This work dates back to Coate and Loury [7], Foster and Vohra [10] in the economics literature, who propose game theoretic models to rationalize how unequal outcomes might emerge despite two populations being symmetrically situated. More recently, in the computer science literature, several papers consider more complicated models that are similar in spirit to Coate and Loury [7], Foster and Vohra [10]. Hu and Chen [12] propose a two-stage model of a labor market with a “temporary” (i.e. internship) and “permanent” stage, and study the equilibrium effects of imposing a fairness constraint on the temporary stage. Liu et al. [16] consider a model of the labor market with higher dimensional signals, and study equilibrium effects of subsidy interventions which can lessen

the cost of exerting effort. Kannan et al. [14] study the effects of admissions policies on a two-stage model of education and employment, in which a downstream employer makes rational decisions. Jung et al. [13] study a model of criminal justice in which crime rates are responsive to the classifiers used to determine criminal guilt, and study which fairness constraints are consistent with the goal of minimizing crime.

## 2 Model

The *pipeline intervention* problem is defined by a layered directed acyclic graph  $G = (V, E)$ , where  $V$  is the set of vertices (or nodes), and  $E$  is the set of edges. The vertices are partitioned into  $k$  layers  $L_1, L_2, \dots, L_k$ , each consisting of  $w$  vertices. We say that  $w$  is the *width* of the graph. For every  $t \in [k - 1]$ , there is a directed edge from every  $u \in L_t$  to every  $v \in L_{t+1}$ ; the graph contains no other edge. In turn, every path from layer  $L_1$  to layer  $L_k$  must go through exactly one vertex in each layer  $L_2, \dots, L_{k-1}$  in this order. Intuitively, such a layered graph represents a pipeline, in which individuals start at initial positions in layer 1, and transition through the graph to final positions in layer  $k$ , stochastically according to transition matrices which we define next. This layered model can be used to abstractly represent real-life pipelines; such a pipeline, that has received attention in previous work (e.g. Kannan et al. [14]), is the education and job market one. Nodes in the initial layer represent a coarse partitioning of the population based on family income levels and educational background. The second layer could represent pre-K experience. For example, one could have 3 nodes in the second layer representing no pre-K, Headstart, and private pre-K. See for example Barnum [3] for a general discussion of as well as pointers to recent studies on the efficacy of Headstart programs. At the next level or two, nodes can represent different qualities of K-12 schools, based on a coarse partitioning of their performance under one of several widely-available metrics, such as the ones provided by U.S. News [20], Niche [18].

The layer after that could be a coarse partitioning where nodes represent, for example, no college, technical or vocational school, and 2 and 4-year colleges coarsely grouped together based on perceived quality according to one of several college rankings. A subsequent layer could encode the details of a student's performance in college, such as their major and GPA, again under a coarse bucketing. The last layer, with numerical rewards could represent different types of employment with rewards determined by starting salaries and prospects for advancement.

In a more accurate model, we might perhaps condition the probability of transition from node  $u$  in layer  $i$  to node  $v$  in layer  $i + 1$  on the entire path taken by an individual leading up to node  $u$ . However, for mathematical tractability, we make the simplifying assumption that the process is Markovian, and this transition probability from  $u$  is independent of prior history.

Let  $\mathcal{M}$  be the set of left stochastic matrices in  $\mathbb{R}^{w \times w}$ : i.e.,  $M \in \mathcal{M}$  if and only if for all  $j \in [w]$ ,  $\sum_{i \in [w]} M(i, j) = 1$ , and for all  $(i, j) \in [w]^2$ ,  $M(i, j) \geq 0$ . Let  $\mathcal{D} \triangleq \{x \in [0, 1]^w : \sum_{k=1}^w x(k) = 1\}$  be the set of probability distributions over  $[w]$ . An instance of the pipeline intervention problem is defined by three elements:

1. A set of initial transition matrices  $M_t^0 \in \mathcal{M}$  between layers  $L_t$  and  $L_{t+1}$ , for all  $t \in [k - 1]$ , such that for all  $u \in L_t$ ,  $v \in L_{t+1}$ ,  $M_t^0(v, u)$  denotes the probability of transitioning from node  $u$  to node  $v$ . Note that we will multiply any input distribution to the right of any transition matrix we use in the paper.

2. An input distribution  $D_1$  over the vertices in layer 1, where  $D_1(u)$  denotes the fraction of the population that starts at  $u$  in  $L_1$  as their initial position. Without loss of generality we assume  $D_1(u) > 0$  for all initial positions  $u \in L_1$ .
3. Finally, a reward  $R(v) \geq 0$  corresponding to each vertex  $v \in L_k$  in the final layer. We let  $R = (v)_{v \in L_k}^\top$  denote the vector of all rewards on layer  $k$ . We assume without loss of generality that the rewards on any two vertices in the final layer are distinct: for all  $v, v' \in L_k$ ,  $R(v) \neq R(v')$ . We can also assume without loss of generality (up to renaming) that  $R(1) > \dots > R(w)$ .

In our model, each vertex  $u$  in the *starting layer*  $L_1$  represents the initial position of some population; abusing notation, we refer to this population also as  $u$ . An individual in population  $u$  transitions to a node in layer  $L_2$ , then a node in layer  $L_3$ , up until they reach a node  $v$  in *destination layer*  $L_k$ , and obtains a reward of  $R(v)$ , with probability given by the transition matrices  $M_1^0$  to  $M_{k-1}^0$ . The expected reward of an individual from population  $u$  is therefore given by  $R^\top M_{k-1} \dots M_1 e_u$ , where  $e_u$  represents the  $w$ -dimensional standard basis vector corresponding to index  $u$ . The aim of the pipeline intervention problem is to *modify* the transition matrices between pairs of adjacent layers so as to improve these expected rewards in some way (we study several objectives) given a finite resource constraint.

We will take the point of view of a centralized designer, who can invest money into modifying the transition matrices between layers. We assume some edges can be modified, while some edges cannot; the edges that can be modified are called *malleable*, and the edges that cannot be modified are called *non-malleable*. We denote the set of malleable edges between layers  $t$  and  $t+1$  by  $E_{mal}^t$  and the set of non-malleable edges by  $\overline{E_{mal}^t}$  its complement. Further, we assume that modifying these transitions matrices comes at a cost, and that on a given layer  $t$ , the cost of transforming  $M_t^0$  to some alternative  $M_t \in \mathcal{M}$  is given by:

$$c(M_t, M_t^0) \triangleq \sum_{(i,j) \in [w]^2} |M_t(i,j) - M_t^0(i,j)|.$$

► **Remark 1.** A critique of such cost functions is that they may not be rich enough to model the cost of improving transitions and opportunities between different stages of, say, the education pipeline.

To address this, we note that while we focus on these simple cost functions in the main body of the paper for simplicity of exposition, our algorithmic results (of Sections 4, 5 and 6) extend to more general and possibly more realistic cost functions – so long as they are convex and increase at least linearly as the distance  $\sum_{(i,j) \in [w]^2} |M_t(i,j) - M_t^0(i,j)|$  between modified transition matrix  $M_t$  and initial transition matrix  $M_t^0$  increases. We discuss this extension in more detail in the full version [1].

This extension allows us to model more realistic situations such as those where the cost functions are not linear, but also those where different edges have different costs – as motivated by the fact that real-life interventions often become more expensive the later they happen.

The designer has a total budget of  $B$ , and can select target transition matrices  $(M_1, \dots, M_{k-1})$  so long as the cost of modifying the initial transition matrices to his targets does not exceed his budget, and only malleable edges have been modified. That is, he must select target transition matrices subject to the constraint:

$$\sum_{t=1}^{k-1} c(M_t, M_t^0) \leq B.$$

We let

$$\begin{aligned} & \mathcal{F}(B, M_1^0, \dots, M_{k-1}^0) \\ &= \left\{ (M_1, \dots, M_{k-1}) : \sum_{t=1}^{k-1} c(M_t, M_t^0) \leq B, M_t \in \mathcal{M} \forall t, M_t(i, j) = M_t^0(i, j) \forall (i, j) \in \overline{E_t^{mal}} \right\} \end{aligned}$$

be the set of feasible sets of transition matrices, given initial matrices  $M_1^0, \dots, M_{k-1}^0$  and budget  $B$ . We will consider several objectives that we may wish to optimize. The first is simply to maximize the overall social welfare (i.e. the expected reward of an individual chosen according to  $D_1$ ), which is given by

$$W(M_1, \dots, M_{k-1}) \triangleq R^\top M_{k-1} \dots M_1 D_1.$$

The second objective aims to compute a “fair” outcome in the sense that it evaluates a solution according to the expected payoff of the worst-off members of society (here interpreted as individuals starting at the pessimal initial position), rather than according to the average. This is the classic maximin objective. It turns out that there are two distinct variants of this problem, depending on whether one wishes to allow randomized solutions (i.e. distributions over matrices) or not. We will elaborate on this distinction in the next section, but in the deterministic variant we wish to optimize

$$\min_{j \in [w]} R^\top M_{k-1} \dots M_1 e_j,$$

where  $e_j \in \mathbb{R}^w$  is the unit vector with  $e_j(j) = 1$ , and  $e_j(i) = 0$  for all  $i \neq j$ .

► **Remark 2.** We have assumed that each layer has *exactly*  $w$  vertices. In fact, all of our results generalize to the case in which each layer has  $\leq w$  vertices.

## 2.1 Optimization Problems of Interest

In this paper, we will provide algorithms to solve the following three optimization problems. We note at the outset that these optimization problems are non-convex, due to the fact that our objective values are not convex for  $k \geq 2$ . Hence we should not expect efficient algorithms in the fully general setting; we will give efficient algorithms for networks of constant width  $w$  (i.e. algorithms whose running time is polynomial in the depth of the network  $k$ ), and show that outside of this class, the problem is NP hard even to approximate.

- **Social welfare maximization** The first optimization problem we aim to solve is that of maximizing the social welfare of our network, under our budget constraint:

$$\begin{aligned} OPT_{SW} &= \max_{M_1, \dots, M_{k-1}} R^\top M_{k-1} \dots M_1 D_1^0 \\ \text{s.t. } & (M_1, \dots, M_{k-1}) \in \mathcal{F}(B, M_1^0, \dots, M_{k-1}^0) \end{aligned} \quad (1)$$

- **Ex-post maximin problem** The second optimization problem aims to maximize the minimum expected reward that a population can obtain, where the minimum is taken over all initial positions:

$$\begin{aligned} OPT_{MM} &= \max_{M_1, \dots, M_{k-1}} \min_{j \in [w]} R^\top M_{k-1} \dots M_1 e_j \\ \text{s.t. } & (M_1, \dots, M_{k-1}) \in \mathcal{F}(B, M_1^0, \dots, M_{k-1}^0) \end{aligned} \quad (2)$$

- **Ex-ante maximin problem** The third optimization problem has the same objective as Program 2, but allows randomization over sets of transition matrices that satisfy the budget constraint. Note that the budget constraint must be satisfied *ex-post*, for *any realization* of the set of transition matrices. To define this optimization problem, we let  $\Delta\mathcal{F}(B, M_1^0, \dots, M_{k-1}^0)$  the set of probability distributions with support  $\mathcal{F}(B, M_1^0, \dots, M_{k-1}^0)$ . The optimization program is given by:

$$\begin{aligned} OPT_{RMM} = \max_{\Delta M} \quad & \min_{j \in [w]} R^\top \mathbb{E}_{M \sim \Delta M} [M_{k-1} \dots M_1] e_j \\ \text{s.t.} \quad & \Delta M \in \Delta\mathcal{F}(B, M_1^0, \dots, M_{k-1}^0), \end{aligned} \quad (3)$$

where the expectation is taken over the randomness of distribution  $\Delta M$ . Note that where Program 3 can be viewed as optimizing an *ex-ante* notion of fairness, in which we are evaluated on the minimum expected value of individuals starting at any initial position, *before the coins of  $\Delta M$  are flipped*. In contrast, Program 2 evaluates the minimum expected value of individuals starting at any initial position for an already established set of transition matrices.

► **Remark 3.** Programs (1), (2) and (3) all have solutions, and as such the use of maxima instead of suprema is well defined. To see this, first note that the feasible sets are non-empty since  $(M_1^0, \dots, M_{k-1}^0) \in \mathcal{F}(B, M_1^0, \dots, M_{k-1}^0)$  for all  $B \geq 0$ . For Program (1), the existence of a maximum is an immediate consequence of the fact that the objective function is continuous in  $(M_1, \dots, M_{k-1})$  and  $\mathcal{F}$  and  $\mathcal{M}$  are compact sets. For Program (2), note that no solution can have  $R^\top M_{k-1} \dots M_1 e_j \geq \|R\|_\infty$  for any  $j$ , as  $M_{k-1} \dots M_1 e_j$  is a probability distribution. Hence, we can rewrite the program as

$$\begin{aligned} \max_{v, M_1, \dots, M_{k-1}} \quad & v \\ \text{s.t.} \quad & 0 \leq v \leq \|R\|_\infty, \\ & R^\top M_{k-1} \dots M_1 e_j \geq v \quad \forall j \in [w], \\ & (M_1, \dots, M_{k-1}) \in \mathcal{F}(B, M_1^0, \dots, M_{k-1}^0). \end{aligned}$$

This is an optimization problem with a continuous objective function over a compact set, so it admits a solution. A similar argument follows for Program (3).

### 3 Algorithmic Preliminaries

Our paper uses a dynamic programming approach for solving programs (1) and (2). (Our solution to program (3) is a game-theoretic reduction to our solution to program (2)). Our algorithms will search over possible input distributions in  $\mathcal{D}$  starting from layer  $L_t$  for all  $t \in \{2, \dots, k-2\}$ , and over possible ways of splitting the total budget  $B$  and allocating budget  $B_t$  to the transition from layer  $L_t$  to layer  $L_{t+1}$ , for all  $t \in [k-1]$ . To do so, we will need to discretize both the budget space  $[0, B]$  and the probability space  $\mathcal{D}$ .

#### 3.1 Cost of Discretizing the Budget

To discretize the budget space, we define  $\mathcal{B}(\varepsilon) = \{k\varepsilon, \forall k \in \mathcal{N}\}$  to be the set of numbers on the real line that are multiples of  $\varepsilon$ . We consider the following discretized version of Program 1:

$$\begin{aligned}
OPT_{SW}^\varepsilon &= \max_{M_1, \dots, M_{k-1}} R^\top M_{k-1} \dots M_1 D_1 \\
\text{s.t. } &c(M_t, M_t^0) \leq B_t \quad \forall t \in [k-1] \\
&B_t \in \mathcal{B}(\varepsilon) \quad \forall t \in [k-1], \quad \sum_{t=1}^{k-1} B_t \leq B \\
&M_t(i, j) = M_t^0(i, j) \quad \forall (i, j) \in \overline{E_t^{mal}}, \quad M_t \in \mathcal{M} \quad \forall t
\end{aligned} \tag{4}$$

Program 2 needs an analogous modification. (We do not need to explicitly consider Program (3), since our solution for this one will be a reduction to our solution to Program (2).)

We show that this discretization does not affect the optimal value of our problems by much:

► **Claim 4.** There exists a feasible solution  $(M_1^\varepsilon, \dots, M_{k-1}^\varepsilon)$  to Program (4) (resp. for the analogous modification of Program ) with objective value at least  $OPT_{SW} - (k-1)\varepsilon \|R\|_\infty$  (resp.  $OPT_{MM} - (k-1)\varepsilon \|R\|_\infty$ ).

We provide a brief proof sketch below, and defer the full proof to the full version [1].

*Proof Sketch.* We prove this result by constructing transition matrices  $M_t^\varepsilon$  that use roughly  $\varepsilon$  budget less than  $M_t^*$ . We show that we can do so so as to only lose welfare of the order of  $\varepsilon$  in each of the  $k-1$  layer transitions we consider, and that this loss composes additively.  $\triangleleft$

► **Definition 5.** Let  $K \subseteq [0, 1]^w$ . We call a subset  $S$  of  $K$  an  $\varepsilon$ -net for  $K$  with respect to the  $\ell_1$ -norm if and only if for every  $D \in K$ , there exists  $D' \in S$  such that

$$\|D - D'\|_1 \leq \varepsilon.$$

► **Claim 6** ( $\varepsilon$ -nets in  $\ell_1$ -distance for  $\mathcal{D}$ ). Take  $\varepsilon > 0$ . There exists an  $\varepsilon$ -net  $\mathcal{D}(\varepsilon)$  of  $\mathcal{D}$  with respect to the  $\ell_1$ -norm that has size  $\left(\frac{1}{\varepsilon}\right)^w$ .

This is a standard proof, which can be found in the full version of this paper [1].

## 4 Social Welfare Maximization

We want to solve the following optimization problem:

$$\begin{aligned}
&\max_{M_1, \dots, M_{k-1}} R^\top M_{k-1} \dots M_1 D_1 \\
\text{s.t. } &\sum_{t=1}^{k-1} c(M_t, M_t^0) \leq B, \\
&M_t \in \mathcal{M} \quad \forall t \in [k-1],
\end{aligned} \tag{5}$$

### 4.1 A Dynamic Programming Algorithm for Social Welfare Maximization

In this section, we describe a dynamic programming algorithm for approximately solving the problem above on long skinny networks. The algorithm will run in polynomial time when the width  $w$  of the network is small; its running time is polynomial in the depth  $k$  of the network, but exponential in the width  $w$ . The formal description can be found in the full version. Our

algorithm works backwards, starting from the final transition matrix from layer  $L_{k-1}$  to  $L_k$ . It builds up the solutions to sub-problems parameterized by three parameters – a layer  $t$ , a starting distribution over the vertices in layer  $t$ , and a budget  $B_{\geq t}$  that can be used at layers  $\geq t$ . For each sub-problem, it computes an approximately welfare-optimal solution. Once all of these sub-problems have been solved, the optimal solution to the original problem can be read off from the “sub-problem” in which  $t = 1$ , the starting distribution is the distribution on initial positions, and  $B_{\geq 1} = B$ . Here is the informal description of the algorithm:

1. For  $t$  going backwards from  $k - 1$  to 1, the algorithm does the following exploration over budget splits and probability distributions  $D_t, D_{t+1} \in \mathcal{D}(\varepsilon)$  (an  $\varepsilon$ -net for the  $w$ -dimensional simplex in  $\ell_1$  norm) on  $L_t$ :
  - a. The algorithm explores all discretized splits of a budget  $B_{\geq t}$  to be used for layers  $t$  to  $k - 1$  into a budget  $B_t$  to expend on layer  $t$  and a budget  $B_{\geq t+1}$  to expend on the remaining layers  $t + 1$  to  $k - 1$ , as well as all choices of target output probability distribution  $D_{t+1} \in \mathcal{D}(\varepsilon)$  on layer  $L_{t+1}$  and the starting probability distribution  $D_t \in \mathcal{D}(\varepsilon)$ . Informally, we can think of these “target” and “initial” probability distributions as guesses for what the distribution on vertices in layer  $t + 1$  and layer  $t$  look like in the optimal solution. Recall that for each  $D_{t+1}$  and  $B_{\geq t+1}$ , our algorithm has already computed a near-optimal solution for a smaller sub-problem, which we will utilize in the next step.
  - b. The algorithm then finds a transition matrix from  $L_t$  to  $L_k$  that maximizes welfare when the starting distribution on layer  $t$  is  $D_t$  and the remaining transition matrices are fixed as in the solution to the corresponding sub-problem. Although the overall welfare-maximization problem is non-convex, this sub-problem can be solved as a linear program (Program 6) because all transition matrices except for one have been fixed as the solution to our sub-problem.
  - c. Finally, the algorithm picks and stores the recovered transition matrices from layer  $L_t$  to  $L_k$  that yield the highest reward, among all the transition matrices recovered from step 1b.

We remark that while (for notational simplicity) our algorithm is written as if all layers have size exactly  $w$ , it can easily be extended to the case in which all layers have size *at most*  $w$ .

We briefly note why Program (6) is a linear program. The objective is linear because only the matrix  $M_t$  represents variables. Thus we simply need to verify that the constraint on the cost is linear.

► **Definition 7.** We say that a transition matrix  $M_t \in \mathcal{M}$  is feasible with respect to a budget split  $B_{\geq t}, B_{\geq t+1}$  if and only if

$$c(M_t, M_t^0) \leq B_{\geq t+1} - B_{\geq t}.$$

and  $M_t(i, j) = M_t^0(i, j)$  for every non-malleable edge  $(i, j)$ .

Note that saying that  $M_t$  feasible with respect to  $B_{\geq t}, B_{\geq t+1}$  is equivalent to saying that  $M_t$  is a feasible solution to Program (6) with parameters  $B_{\geq t}, B_{\geq t+1}, D_t, D_{t+1}$  for any  $D_t, D_{t+1} \in \mathcal{D}(\varepsilon)$ . The constraint  $c(M_t, M_t^0) \leq B_{\geq t+1} - B_{\geq t}$  can be equivalently replaced by  $2w^2 + 1$  linear constraints. To do so, we introduce  $w^2$  variables -  $a_1, a_2, \dots, a_{w^2}$ . The constraint can then be rewritten in the form  $\sum_{i=1}^{w^2} |f_i| \leq B_{\geq t+1} - B_{\geq t}$ , where each  $f_i$  is a linear combination of the variables. We can thus express the budget constraint of Program 6 by the following set of linear constraints:

■ **Algorithm 1** Dynamic Program for (Approximate) Social Welfare Maximization.

---

**Input:** Input distribution  $D_1$ , reward vector  $R$ , initial transition matrices  $M_1^0, \dots, M_{k-1}^0$ , budget  $B$ , discretization parameter  $\varepsilon$ .

**Output:** Transition  $M(B^\varepsilon, D_1^0)$  from  $L_1$  to  $L_k$ .

**Initialization:** Let  $B_{\geq k} = 0$ ,  $M(B_{\geq k}, D_k) = I$ ,  $B^\varepsilon = \max\{x \in \mathcal{B}(\varepsilon) : x \leq B\}$ .

**for** layer  $t = k - 1, \dots, 1$  **do**

**for** all distributions  $D_t \in \mathcal{D}(\varepsilon)$  if  $t \neq 1$  ( $D_t = D_1^0$  if  $t = 1$ ) and budgets  $B_{\geq t} \in \mathcal{B}(\varepsilon)$  with  $B_{\geq t} \leq B$  **do**

**for** all distributions  $D_{t+1} \in \mathcal{D}(\varepsilon)$  and budgets  $B_{\geq t+1} \leq B_{\geq t}$  such that  $B_{\geq t+1} \in \mathcal{B}(\varepsilon)$  **do**

Solve linear program

$$M_t(B_{\geq t}, B_{\geq t+1}, D_t, D_{t+1}) = \arg \max_{M_t} R^\top M(B_{\geq t+1}, D_{t+1}) M_t D_t$$

s.t.  $c(M_t, M_t^0) \leq B_{\geq t} - B_{\geq t+1}$ ,

$$M_t(i, j) = M_t^0(i, j) \quad \forall (i, j) \in \overline{E_t^{mal}}$$

$$M_t \in \mathcal{M} \tag{6}$$

**end**

Pick  $B_{\geq t+1}, D_{t+1}$  leading to the highest objective value in Program 6, and set  $M(B_{\geq t}, D_t) = M(B_{\geq t+1}, D_{t+1}) M_t(B_{\geq t}, B_{\geq t+1}, D_t, D_{t+1})$ .

**end**

**end**

**Return**  $M(B^\varepsilon, D_1)$ .

---

1.  $f_i \leq a_i \quad \forall i \in [w^2]$
2.  $-f_i \leq a_i \quad \forall i \in [w^2]$
3.  $\sum_{i=1}^{w^2} a_i \leq B_{\geq t+1} - B_{\geq t}$ .

Thus, Program 6 can be written as a linear program with the number of constraints and variables being polynomial in  $w$ .

## 4.2 Running Time and Social Welfare Guarantees

We provide the running time and social welfare guarantees of Algorithm 8 below.

► **Theorem 8.** *Algorithm 1 instantiated with discretization parameter  $\varepsilon$  yields a solution achieving social welfare at least  $OPT - 3(k-1)\varepsilon\|R\|_\infty$ , and has running time  $O\left(k\frac{B}{\varepsilon}\left(\frac{1}{\varepsilon}\right)^{w^2}f(w)\right)$ , where  $f(w)$  is any upper-bound on the running time for solving linear Program 6, which is always polynomial in  $w$ .*

This immediately yields the following corollary:

► **Corollary 9.** *Algorithm 1 with discretization parameter  $\varepsilon' = \frac{\varepsilon}{3(k-1)}$  yields social welfare at least  $OPT - \varepsilon\|R\|_\infty$ , and has running time  $O\left(k^2\frac{B}{\varepsilon}\left(\frac{k}{\varepsilon}\right)^{w^2}f(w)\right)$ , where  $f(w)$  is any upper-bound on the running time for solving linear Program 6, which is always polynomial in  $w$ .*

We observe that this running time is polynomial in  $k$  (the depth of the network) and  $1/\varepsilon$  (the inverse additive error tolerance), but exponential in  $w$  (the width of the network). Hence our algorithm runs in polynomial time for the class of constant width networks.

► **Remark 10.** We note that our additive near-optimality guarantee can be translated into a multiplicative guarantee. In the case where *all edges are malleable*, this follows from noting that given budget  $B$ ,  $OPT \geq \frac{B}{2w} \|R\|_\infty$ : this can be reached by investing the totality of the budget into transitioning every node in the second-to-last layer to the highest reward node in the last layer, with probability  $\frac{B}{2w}$  for each such node. Taking  $\varepsilon = \delta \cdot \frac{B}{6(k-1)w}$  for some constant  $\delta < 1$  gives a multiplicative approximation to the optimal social welfare with approximation factor  $1 - \delta$ .

For the case in which non-malleable edges are allowed, a lower bound on  $OPT$  is given by  $OPT \geq W_0$ . Taking  $\varepsilon = \delta \cdot \frac{W_0}{3(k-1)\|R\|_\infty}$  yields a multiplicative  $1 - \delta$  approximation still.

### Proof of Theorem 8

The proof of Theorem 8 relies on the following lemma, and its corollary:

► **Lemma 11.** *Let  $M \in \mathbb{R}^{w \times w}$  be a left stochastic matrix, and let  $D, D' \in \mathcal{D}$  be probability distributions.*

$$\|MD - MD'\|_1 \leq \|D - D'\|_1.$$

**Proof.** Note that

$$\begin{aligned} \|M(D - D')\|_1 &= \sum_{i=1}^w |(M(D - D'))(i)| = \sum_{i=1}^w \left| \sum_{j=1}^w M(i, j)(D(j) - D'(j)) \right| \\ &\leq \sum_{i=1}^w \sum_{j=1}^w |M(i, j)(D(j) - D'(j))| \\ &= \sum_{j=1}^w |D(j) - D'(j)| \sum_{i=1}^w |M(i, j)| \\ &= \sum_{j=1}^w |D(j) - D'(j)| \\ &= \|D - D'\|_1, \end{aligned}$$

where the inequality follows from the triangle inequality, and the second-to-last equality from the fact that

$$\sum_{i=1}^w |M(i, j)| = \sum_{i=1}^w M(i, j) = 1 \quad \forall j \in [w]$$

as  $M$  is a left stochastic matrix. ◀

► **Corollary 12.** *Let  $R \in \mathbb{R}^w$  be a real vector and  $D, D' \in \mathcal{D}$  be probability distributions such that  $\|D - D'\|_1 \leq \varepsilon$ , and  $M \in \mathbb{R}^{w \times w}$  a left stochastic matrix. Then*

$$R^\top MD \geq R^\top MD' - \|R\|_\infty \cdot \varepsilon.$$

**Proof of Corollary 12.**  $\|R^\top M(D' - D)\|_1 \leq \|R\|_\infty \|M(D' - D)\|_1 \leq \|R\|_\infty \|D' - D\|_1 \leq \|R\|_\infty \cdot \varepsilon$ , where the first step follows from Holder's inequality. ◀

We are now ready to prove Theorem 8:

**Proof of Theorem 8.** Let us denote by  $B_1^\varepsilon, \dots, B_{k-1}^\varepsilon$  a split of the budget for the discretized problem with  $B_{\geq t}^\varepsilon = B_t^\varepsilon + \dots + B_{k-1}^\varepsilon$ . Let  $M_1^\varepsilon, \dots, M_{k-1}^\varepsilon$  a set of transition matrices achieving welfare  $R^\top M_{k-1}^\varepsilon \dots M_1^\varepsilon D_1^0 \geq OPT^\varepsilon \triangleq OPT - (k-1)\varepsilon \|R\|_\infty$  that is feasible with respect to budget split  $B_1^\varepsilon, \dots, B_{k-1}^\varepsilon$ . Note that such a budget split and matrices exist by Claim 4. Let  $D_t^\varepsilon$  the probability distribution on layer  $t$  defined by these transition matrices, i.e.

$$D_t^\varepsilon = M_{t-1}^\varepsilon \dots M_1^\varepsilon D_1^0.$$

To prove the result, we will show by induction that for all  $B_{\geq t} \geq B_{\geq t}^\varepsilon$ , and for  $D_t \in \mathcal{D}(\varepsilon)$  such that  $\|D_t - D_t^\varepsilon\|_1 \leq \varepsilon$ ,

$$R^\top M(B_{\geq t}, D_t) D_t \geq OPT^\varepsilon - 2(k-t)\varepsilon \|R\|_\infty.$$

This will directly imply that as  $B^\varepsilon$  is one of the possible values of  $B_{\geq 1}$ ,

$$R^\top M(B^\varepsilon, D_1) D_1 \geq OPT^\varepsilon - 2(k-1)\varepsilon \|R\|_\infty.$$

Combined with Claim 4 that states  $OPT^\varepsilon \geq OPT - (k-1)\varepsilon \|R\|_\infty$ , we will obtain the result.

Let us now provide our inductive proof. First, consider the transition from layer  $L_{k-1}$  to layer  $L_k$ . Note that

$$OPT^\varepsilon \leq R^\top M_{k-1}^\varepsilon \dots M_1^\varepsilon D_1^0 = R^\top M_{k-1}^\varepsilon D_{k-1}^\varepsilon.$$

Let  $D_{k-1} \in \mathcal{D}(\varepsilon)$  be such that  $\|D_{k-1} - D_{k-1}^\varepsilon\|_1 \leq \varepsilon$ . Note then that by Corollary 12,

$$R^\top M_{k-1}^\varepsilon D_{k-1} \geq R^\top M_{k-1}^\varepsilon D_{k-1}^\varepsilon - \varepsilon \|R\|_\infty.$$

Further,  $M_{k-1}^\varepsilon$  is feasible for Program (6) with respect to  $B_{\geq k-1}, B_{\geq k} = 0$ , given  $B_{\geq k-1} \geq B_{\geq k-1}^\varepsilon$ . As such, for  $B_{\geq k-1} \geq B_{\geq k-1}^\varepsilon$ , we have that

$$R^\top M(B_{\geq k-1}, D_{k-1}) D_{k-1} \geq R^\top M_{k-1}^\varepsilon D_{k-1},$$

and in turn

$$R^\top M(B_{\geq k-1}, D_{k-1}) D_{k-1} \geq OPT^\varepsilon - \varepsilon \|R\|_\infty.$$

Now, suppose the induction hypothesis holds at layer  $t+1$ . I.e., for all  $B_{\geq t+1} \geq B_{\geq t+1}^\varepsilon$ , for  $D_{t+1} \in \mathcal{D}(\varepsilon)$  such that  $\|D_{t+1} - D_{t+1}^\varepsilon\|_1 \leq \varepsilon$ ,

$$R^\top M(B_{\geq t+1}, D_{t+1}) D_{t+1} \geq OPT^\varepsilon - 2(k-t-1)\varepsilon \|R\|_\infty.$$

For any  $B_{\geq t} \geq B_{\geq t}^\varepsilon$ , note that one can set  $B_{\geq t+1} = B_{\geq t+1}^\varepsilon$  and  $B_t \geq B_t^\varepsilon$ ; hence,  $M_t^\varepsilon$  is feasible for Program (6) with respect to  $B_t \geq B_t^\varepsilon, B_{\geq t+1}^\varepsilon$ . Since  $\|D_t - D_t^\varepsilon\|_1 \leq \varepsilon$  and  $\|D_{t+1} - M_t^\varepsilon D_t^\varepsilon\|_1 \leq \varepsilon$ , we have that by Corollary 12,

$$\begin{aligned} R^\top M(B_{\geq t+1}, D_{t+1}) M_t^\varepsilon D_t &\geq R^\top M(B_{\geq t+1}, D_{t+1}) M_t^\varepsilon D_t^\varepsilon - \varepsilon \|R\|_\infty \\ &\geq R^\top M(B_{\geq t+1}, D_{t+1}) D_{t+1} - 2\varepsilon \|R\|_\infty. \end{aligned}$$

Using the induction hypothesis, we obtain that  $R^\top M(B_{\geq t+1}, D_{t+1}) M_t^\varepsilon D_t \geq OPT^\varepsilon - 2(k-t)\varepsilon \|R\|_\infty$ . In particular, we get

$$R^\top M(B_{\geq t}, D_t) D_t \geq OPT^\varepsilon - 2(k-t)\varepsilon \|R\|_\infty,$$

which concludes the proof of the social welfare guarantee. For the running time, we note that at each time step  $t$ , we solve one instance of Program 6 for each of the (at most)  $\frac{B}{\varepsilon}$  possible budget splits of  $B_{\geq t}$  and for each of the  $\left(\frac{1}{\varepsilon}\right)^w$  (by Claim 6) probability distributions in  $\mathcal{D}(\varepsilon)$  in layer  $L_t$  and layer  $L_{t+1}$ ; i.e., for each  $t$ , the algorithm solves  $O\left(\frac{B}{\varepsilon} \left(\frac{1}{\varepsilon}\right)^{w^2}\right)$  optimization programs. Then, the algorithm finds the solution of all of these programs with the best objective value, which can be done in time linear in the number of such solutions, i.e.  $O\left(\frac{B}{\varepsilon} \left(\frac{1}{\varepsilon}\right)^{w^2}\right)$ . This is repeated for  $k-1$  values of  $t$ .  $\blacktriangleleft$

## 5 (Ex-post) Maximin Value Maximization

Although social welfare maximization is a natural objective, it is well-known that it can be “unfair” in the sense that it explicitly prioritizes the welfare of larger populations (here represented as initial positions that have larger probability mass) over smaller populations. We can alternately evaluate a solution according to the welfare of the *least-well-off* population (here represented by the initial position with the smallest expected value) and ask to optimize *that* objective. We show how to optimize this objective in this section, when one demands a deterministic solution.

### 5.1 A Dynamic Programming Algorithm for Computing an Ex-post Maximin Allocation

In this subsection, we adapt the dynamic programming approach in Section 4.1 to give an approximation algorithm for the problem of maximizing the minimum expected reward over all initial positions. Recall that  $\mathcal{D}$ , the probability simplex, denotes the set of all possible probability distributions on a layer. Intuitively, our algorithm for maximizing social welfare kept track of a single probability distribution in each subproblem: the overall probability of arriving at each vertex in the layer *over both the randomness of an individual’s initial position, and the randomness of the transition matrix*. In order to optimize the *minimum* expected value over all initial positions, we will need to keep track of more state. At every layer  $L_t$ , we will keep track of the probability of reaching each vertex in that layer *from each initial position in the starting layer*. So, we will now keep track of collections of  $w$  probability distributions in  $\mathcal{D}^w$ , one for each starting position. We call the elements of  $\mathcal{D}^w$  *population-wise distributions*.

We introduce a discretization  $\mathcal{A}(\varepsilon)$  of  $\mathcal{D}^w$ , as follows:  $\mathcal{A}(\varepsilon) \triangleq (\mathcal{D}(\varepsilon))^w$ , where  $\mathcal{D}(\varepsilon)$  denotes a  $\varepsilon$ -net of  $\mathcal{D}$  (of size  $(\frac{1}{\varepsilon})^w$ ). Given a population-wise probability distribution  $A_t \in \mathcal{A}(\varepsilon)$  at layer  $t$ , we write  $A_t^j$  for the probability distribution corresponding to population  $j$ . The algorithm works as follows, just as before, running backwards from the final layer to the first layer. We describe the algorithm below informally, a formal presentation may be found in the full version [1].

#### 5.1.1 Algorithm

1. For  $t$  going backwards from  $k - 1$  to 1, the algorithm does the following, for every population-wise distribution  $A_t \in \mathcal{A}(\varepsilon)$  on  $L_t$ :
  - a. The algorithm explores all splits of the budget  $B_{\geq t}$  for layers  $t$  to  $k$  into a budget  $B_t$  for the transition from  $L_t$  to  $L_{t+1}$  and a budget  $B_{\geq t+1}$  for  $L_{t+1}$  to  $L_k$ , as well as all choices of output population-wise probability distributions  $A_{t+1} \in \mathcal{A}(\varepsilon)$  on layer  $L_{t+1}$ .
  - b. The algorithm then finds a near-optimal transition matrix from  $L_t$  to  $L_k$  for every budget decomposition, by using the previously computed near-optimal solution for layers  $L_{t+1}$  to  $L_k$ , and solving a program similar to Program 6. The program maximizes the *minimum reward obtained from any initial position*, assuming the population-wise distribution of individuals at layer  $L_t$  is given by  $A_t$ .
  - c. Finally, the algorithm picks and stores the best recovered transition matrices from layer  $L_t$  to  $L_k$  that yield the highest reward, among all the transition matrices recovered from step 1b.

The input population-wise probability distribution  $A_1 \in \mathcal{D}^w$  on the first layer is defined in the following manner,  $A_1^j := e_j$  (the  $j$ -th basis vector in the usual orthonormal basis of  $\mathbb{R}^w$ ) for all  $j \in [w]$ .

Note that the Program in step 1b can be written as a linear program of size polynomial in  $w$ , using the same method that was employed to write Program (6) as a linear program.

## 5.2 Running Time and Ex-Post Maximin Value Guarantees

Remember that we let  $OPT_{MM}$  denote the maximin value of the given network. The running time and accuracy guarantees of the described Algorithm are provided below:

► **Theorem 13.** *The Algorithm described in Section 5.1.1 with discretization parameter  $\varepsilon$  yields maximin value at least  $OPT_{MM} - 3(k-1)\varepsilon\|R\|_\infty$ , and has running time  $O\left(k\frac{B}{\varepsilon}\left(\frac{1}{\varepsilon}\right)^{w^4}g(w)\right)$ , where  $g(w)$  is any upper-bound on the running time for solving the linear Program in Step 1b, which is always polynomial in  $w$ .*

This immediately implies the following corollary:

► **Corollary 14.** *The algorithm described in 5.1.1 with discretization parameter  $\varepsilon' = \frac{\varepsilon}{3(k-1)}$  yields maximin value at least  $OPT_{MM} - \varepsilon\|R\|_\infty$ , and has running time  $O\left(k^2\frac{B}{\varepsilon}\left(\frac{k}{\varepsilon}\right)^{w^4}g(w)\right)$ , where  $g(w)$  is a polynomial upper-bound on the running time of the linear Program in Step 1b.*

The proof of Theorem 13 is almost identical to that of Theorem 8. We provide a complete proof in the full version [1].

## 6 (Ex-ante) Maximin Value Maximization

In this section, we consider the problem of optimizing the *ex-ante* minimum expected value over all initial positions: in other words, we allow ourselves to find a *distribution* over solutions, and take expectations over the randomness of this distribution, solving:

$$\begin{aligned} \max_{\Delta M} \quad & \min_{j \in [w]} R^\top \mathbb{E}_{M \sim \Delta M} [M_{k-1} \dots M_1] e_j \\ \text{s.t.} \quad & \Delta M \in \Delta \mathcal{F}(B, M_1^0, \dots, M_{k-1}^0) \end{aligned} \quad (7)$$

We show in the full version [1] that this can yield strictly higher utility than optimizing the ex-post minimum value. We then give an algorithm for solving the ex-ante problem by exhibiting a game theoretic reduction to the ex-post problem.

### 6.1 Solving the Ex-ante Maximization Problem Using Algorithm 1

Because Program 3 is a max min problem over a polytope, we can view it as a zero-sum game, and the solution that we want corresponds to a maximin equilibrium strategy of this game. As first shown by Freund and Schapire[11], it is possible to compute an approximate equilibrium of a zero-sum game if we can implement a *no-regret* learning algorithm for one of the players, and an approximate best-response algorithm for the other player: if we simply simulate repeated play of the game between a no-regret player and a best-response player, then the empirical average of player actions in this simulation converges to the Nash equilibrium of the game.

This forms the basis of our algorithm. One player plays the “multiplicative weights” algorithm over the initial positions in layer 1 of the graph. This induces at every round a distribution over initial positions. The best response problem, which must be solved by the other player, corresponds to solving a welfare-maximization problem given the distribution over initial positions represented by the multiplicative weights distribution. Fortunately, this

is exactly the problem that we have already given a dynamic programming solution for. The solution in the end corresponds to the uniform distribution over the solutions computed by the best-response player over the course of the dynamics. The algorithm is described formally in the full version [1].

■ **Algorithm 2** 2-Player Dynamics for the Ex-Ante Maximin Problem.

---

**Input:** Time horizon  $T$ , reward vector  $R$  on layer  $L_k$ , initial transition matrices  $M_1^0, \dots, M_{k-1}^0$ , budget  $B$ , discretization parameter  $\varepsilon$ .

**Output:**  $M^1, \dots, M^T \in \mathcal{F}(B, M_1^0, \dots, M_{k-1}^0)$ .

**Initialization:** The no-regret player picks  $D^1 = (\frac{1}{w}, \dots, \frac{1}{w}) \in \mathcal{D}$ , the uniform distribution over  $[w]$ .

**for**  $t = 1, \dots, T$  **do**

The no-regret player plays distribution  $D^t \in \mathcal{D}$ .

The best-response player chooses  $M^t \in \mathcal{F}(B, M_1^0, \dots, M_{k-1}^0)$  such that

$$R^\top M_{k-1}^t \dots M_1^t D^t \geq \max_{M \in \mathcal{F}} R^\top M_{k-1} \dots M_1 D^t - \varepsilon \|R\|_\infty,$$

using Algorithm 1.

The no-regret player observes  $u_i^t = \frac{R^\top M_{k-1}^t \dots M_1^t e_i}{\|R\|_\infty}$  for all  $i \in [w]$ , and picks  $D^{t+1}$  via multiplicative weight update, as follows:

$$D^{t+1}(i) = \frac{D^t(i) \beta^{u_i^t}}{\sum_{j=1}^w D^t(j) \beta^{u_j^t}} \quad \forall i \in [w],$$

with  $\beta = \frac{1}{1 + \sqrt{2 \frac{\ln w}{T}}} \in [0, 1)$ .

**end**

---

► **Lemma 15.** *Let  $T > 0$ ,  $\overline{\Delta M}$  be the probability distribution that picks  $(M_1, \dots, M_{k-1}) \in \mathcal{F}(B, M_1^0, \dots, M_{k-1}^0)$  with probability*

$$\frac{1}{T} \sum_{t=1}^T \mathbb{1} \{ (M_1, \dots, M_{k-1}) = (M_1^t, \dots, M_{k-1}^t) \},$$

*where  $M^1, \dots, M^T$  are the outputs of Algorithm 2. Then  $\overline{\Delta M} \left( \varepsilon + \sqrt{2 \frac{\ln w}{T}} + \frac{\ln w}{T} \right) \|R\|_\infty$ -approximately optimizes Program 3.*

The proof of Lemma 15 follows from interpreting Program 3 as zero-sum game, noting that the best response problem for the maximization player corresponds to the welfare-maximization problem for which we have an efficient algorithm, and then applying the no-regret dynamic analysis from Freund and Schapire [11]. The details are provided in the full version [1].

## 7 Price of Fairness

In this section, we compute lower bounds on a notion of “price of fairness”, and we show these lower bounds are tight when restricting attention to pipelines whose edges are *all* malleable. Specifically, we compare the optimal welfare achievable with the welfare that is

achievable if we instead use our budget to maximize the *minimum* value over initial positions – i.e. if we solve the maximin problem. We focus on the ex-post maximin problem – i.e. we prove our bounds with respect to *deterministic* solutions. We note that there may be many different maximin optimal solutions that differ in their overall welfare, and so we consider two variants of the price of fairness in our setting – comparing with both the *maximum* welfare consistent with a maximin optimal solution, and the *minimum* welfare consistent with a maximin optimal solution.

Let  $OPT_{SW}$  the optimal value of Program (1) (the optimal social welfare). Let  $S^f$  be the set of solutions to Program (2) (the deterministic maximin problem). Further, define

$$W(M_1, \dots, M_{k-1}) \triangleq R^\top M_{k-1} \dots M_1 D_1^0$$

to be the social welfare achieved by transition matrices  $M_1, \dots, M_{k-1}$ , and

$$W_{fair}^+ \triangleq \max_{(M_1, \dots, M_{k-1}) \in S^f} W(M_1, \dots, M_{k-1}),$$

$$W_{fair}^- \triangleq \min_{(M_1, \dots, M_{k-1}) \in S^f} W(M_1, \dots, M_{k-1})$$

to be the maximum and minimum social welfare respectively that are consistent with maximin optimal solutions. We define two variants of “the price of fairness” in our setting as:  $P_f^+ \triangleq \frac{OPT_{SW}}{W_{fair}^+} \geq 1$ , and

$$P_f^- \triangleq \frac{OPT_{SW}}{W_{fair}^-} \geq 1.$$

Note that  $P_f^+ \leq P_f^-$  always, as  $P_f^+$  compares the optimal social welfare with the solution of Program 2 with highest social welfare, while  $P_f^-$  considers the solution that has the lowest social welfare. We provide matching lower bounds on  $P_f^+$  and upper bounds on  $P_f^-$ . This, in turn, provides tight bounds on the price of fairness with respect to *any* choice of maximin solution.

## 7.1 Lower Bounds on $P_f^+$

Our lower bounds are based on the following construction:

► **Example 16.** Consider a network with only two layers,  $L_1$  and  $L_2$ , such that  $L_1$  has  $w$  nodes and  $L_2$  has 2 nodes. Suppose the starting distribution is given by  $D_1^0 = (1 - (w-1)\varepsilon, \varepsilon, \dots, \varepsilon)^\top$  for  $\varepsilon > 0$  small enough, the reward vector is given by  $R = (1, 0)^\top$ , and the initial transition matrix  $M_1^0$  is given by

$$M_1^0 = \begin{pmatrix} 0 & \dots & 0 \\ 1 & \dots & 1 \end{pmatrix}.$$

I.e., in the initial transition matrix, every starting node transitions to the destination node that has reward 0, and the welfare of the initial network is 0. We assume all edges are malleable.

► **Theorem 17.** *For all  $w \in \mathbb{N}$ , for any  $\delta > 0$ , there exists a network with  $k = 2$  with price of fairness*

$$P_f \geq \begin{cases} w - \delta & \text{if } 0 < B \leq 2 \\ \frac{2w}{B} - \delta & \text{if } 2 < B \leq 2w \\ 1 & \text{if } B \geq 2w \end{cases}.$$

The proof follows from solving the social welfare maximization problem and the maximin value problem on Example 16. The complete proof is provided in the full version [1].

## 7.2 Upper Bounds on $P_f^-$

Importantly, in this section, we restrict ourselves to pipelines such that *all* edges are malleable. In this case, we show upper bounds that tightly match the lower bounds of Section 7.1.

Our upper bounds will make use of the following claim, which bounds the maximum social welfare that can be achieved under budget  $B$ .

► **Lemma 18.**

$$OPT_{SW} \leq \|R\|_\infty \text{ and } OPT_{SW} \leq W^0 + \frac{B}{2} \|R\|_\infty,$$

where  $W^0 = R^\top M_{k-1}^0 \dots M_1^0 D_1^0$  is the initial welfare.

The proof of this lemma is straightforward and is deferred to the full version [1]. We will also need lower bounds on the social welfare achieved by any optimal solution to the maximin program. The first lower bound is a function of  $B$  and  $w$ , but is independent of  $W^0$ .

► **Lemma 19.** *When all edges are malleable, for any  $(M_1^f, \dots, M_{k-1}^f) \in S^f$ ,*

$$W(M_1^f, \dots, M_{k-1}^f) \geq \min\left(1, \frac{B}{2w}\right) \|R\|_\infty.$$

The proof of Lemma 19 is deferred to the full version [1]. The second lower bound we need shows that the social welfare achieved by a solution to Program (2) is lower-bounded by the initial social welfare  $W^0 = R^\top M_{k-1}^0 \dots M_1^0 D_1^0$ .

► **Lemma 20.** *When all edges are malleable, for any  $(M_1^f, \dots, M_{k-1}^f) \in S^f$ ,*

$$W(M_1^f, \dots, M_{k-1}^f) \geq W^0.$$

We defer the full proof of Lemma 20 to the full version [1]. We can now use Lemmas 18, 19 and 20 to derive nearly tight upper bounds on the price of fairness with respect to the worst maximin solution:

► **Theorem 21.** *For every instance of the problem in which edges are malleable, we have that*

$$P_f^- \leq \begin{cases} w + 1 & \text{if } 0 < B \leq 2 \\ \frac{2w}{B} & \text{if } 2 < B \leq 2w \\ 1 & \text{if } B \geq 2w \end{cases}.$$

**Proof.** We divide the proof in three cases:

1.  $B \geq 2w$ . By Lemma 19, it must be the case that any optimal solution to Program (2) has welfare at least  $\min(1, \frac{B}{2w}) \|R\|_\infty = \|R\|_\infty$ . It is then immediately the case that  $OPT_{SW} = \|R\|_\infty$  by Lemma 18 and  $P_f^- = 1$ .
2.  $2 < B \leq 2w$ . By Lemma 18, we have  $OPT_{SW} \leq \|R\|_\infty$ . Further, by Lemma 19, we have that any solution to Program (2) has welfare at least  $\frac{B}{2w} \|R\|_\infty$ . This immediately yields the result.

3.  $0 < B \leq 2$ . By Lemma 18, we have  $OPT_{SW} \leq W^0 + \frac{B}{2} \|R\|_\infty$ . By Lemmas 19 and 20, we have that the social welfare of any maximin solution is at least  $W^0$  and at least  $\frac{B}{2w} \|R\|_\infty$ . Therefore, the price of fairness is upper-bounded on the one hand by

$$P_f^- \leq \frac{W^0 + \frac{B}{2} \|R\|_\infty}{W^0} = 1 + \frac{\frac{B}{2} \|R\|_\infty}{W^0}$$

and on the other hand by

$$P_f^- \leq \frac{W^0 + \frac{B}{2} \|R\|_\infty}{\frac{B}{2w} \|R\|_\infty} = w + \frac{W^0}{\frac{B}{2w} \|R\|_\infty}.$$

When  $W^0 \geq \frac{B}{2w} \|R\|_\infty$ , the first bound gives  $P_f^- \leq 1 + \frac{\frac{B}{2} \|R\|_\infty}{\frac{B}{2w} \|R\|_\infty} = w + 1$ ,

and when  $W^0 \leq \frac{B}{2w} \|R\|_\infty$ , the second bound yields  $P_f^- \leq w + \frac{\frac{B}{2w} \|R\|_\infty}{\frac{B}{2w} \|R\|_\infty} = w + 1$ , which concludes the proof.  $\blacktriangleleft$

## 8 Hardness of Approximation

In this section, we show that the problem of finding the ex-post maximin value of a pipeline intervention problem instance within an approximation factor of 2 is NP-hard in the general case, where the width  $w$  of the network is not bounded. More specifically, we show that no algorithm that has a time bound polynomial in  $w, k$  and  $B$  can give a 2-approximation to the maximin value unless  $P = NP$ . This hardness result holds for  $k$  as small as 17. We remark that our result and proof can be immediately extended to show hardness of  $C$ -approximation, for any constant  $C$ , for an appropriate choice of constant depth  $k$ .

We show this hardness result via a reduction from a gap version of the vertex cover problem. The result of Dinur and Safra [8] shows that it is NP-hard to approximate the minimum vertex cover by a factor smaller than 1.306. In particular, their result shows that the following gap version of vertex cover is NP-hard: given  $(\mathcal{G}, \kappa)$ , we wish to either know if the graph  $\mathcal{G}$  has a vertex cover of size  $\kappa$ , or has no vertex cover smaller than size  $1.306\kappa$ .

We provide a description of our reduction below, and defer a formal statement along with a complete proof to the full version [1].

### 8.1 The Reduction

Our reduction works as follows: we construct a pipeline intervention instance of constant width (17 layers) from the given graph. The first layer has a node corresponding to each edge  $(u, v)$  of the original graph, and is connected by edges to nodes corresponding to vertices  $u$  and  $v$  on the second layer. We set up the instance so that positive probability mass is only ever added to a set of edge disjoint paths, where each path corresponds to a vertex in the original graph. These paths are shown by the dark, solid lines in Figure 1. The main idea behind the reduction is the following - by observing how allocations finding the maximin value split the budget over these edge disjoint paths, we can find out which vertices would form a small vertex cover of the original graph.

Formally, let the given graph  $\mathcal{G} = (\mathcal{V}, \mathcal{E})$  we reduce from have  $n$  vertices ( $|\mathcal{V}| = n$ ) and  $m$  edges ( $|\mathcal{E}| = m$ ). We construct a pipeline intervention problem instance  $\mathcal{I}'$  with  $k+2$  layers and width  $w$ , where  $k = 15$  and  $w$  is polynomial in  $n$ . The instance  $\mathcal{I}'$  has an associated budget  $B(\kappa, \varepsilon) = 2k\kappa\varepsilon$  where  $\varepsilon < \frac{1}{2}$ . For the sake of clarity, we refer to the set of vertices  $\mathcal{V}$  in the vertex cover instance as “vertices” and the vertices in the instance  $\mathcal{I}'$  as “nodes”. A complete description of instance  $\mathcal{I}'$  is as follows:

■ **Figure 1** Constructed Instance of the Pipeline Intervention problem.

1. The first layer,  $L_1$ , has exactly  $m$  nodes, with each edge  $(u, v)$  in graph  $\mathcal{G}$  having a unique corresponding node of the same label in layer  $L_1$ .
2. The second layer has exactly  $n$  nodes, with each vertex  $v$  in graph  $\mathcal{G}$ , having a unique corresponding node in layer  $L_2$  with label  $v^2$ .
3. The next  $k - 1$  layers are of the following form - layer  $L_i$ , for  $i = 3$  to  $k + 1$ , has  $n + 1$  nodes. The first  $n$  nodes have labels from the set  $\{v^i\}_{v \in V}$ , i.e., each vertex  $v$  in the original graph  $\mathcal{G}$  has a corresponding node  $v^i$  in layer  $L_i$ . The last node is indexed by  $x^i$  and exists to capture the “leftover” outward probability from the nodes  $\{v^{i-1}\}_{v \in V}$  in layer  $L_{i-1}$ .
4. The final layer  $L_{k+2}$  has two reward nodes -  $y$ , of reward 1 and  $z$ , of reward 0.

We now describe the initial transition matrices.

1. From layer  $L_1$  to layer  $L_2$ : for every node  $(u, v)$  in layer  $L_1$ , the outgoing probability is equally split between edges to nodes  $u^1$  and  $v^1$  in layer  $L_2$ , i.e., edges  $((u, v), u^1)$  and  $((u, v), v^1)$  each have probability  $\frac{1}{2}$ .
2. From layer  $L_i$  to layer  $L_{i+1}$  for  $i = 2$  to  $k$ : For all vertices  $v \in \mathcal{V}$  (i.e., the original graph), the corresponding edge  $(v^i, v^{i+1})$  (in our construction) has probability  $\epsilon$ . The remaining outgoing probability out of node  $v^i$  goes to the leakage node  $x^{i+1}$ . We call edges of the form  $(v^i, x^{i+1})$  “leakage” edges. For  $i \geq 3$ , the edge  $(x^i, x^{i+1})$  has all the outward probability, i.e., 1, from node  $x^i$ .
3. From layer  $L_{k+1}$  to layer  $L_{k+2}$ : each node in layer  $L_{k+1}$  is connected to  $z$ , the zero reward node, with probability 1.

We let  $P_v$  be the path going through nodes  $v^2, v^3 \dots v^{k+1}, y$  in our construction. We will refer to  $\{P_v\}_{v \in \mathcal{V}}$  as vertex paths. Let  $E'$  be the set of edges found on paths  $\{P_v\}_{v \in \mathcal{V}}$ . Let  $E''$  contain all the “leakage” edges in the instance  $\mathcal{I}'$ , i.e., edges of the form  $(v^i, x^{i+1})$  as well as all edges of the form  $(v^{k+1}, z)$ . We stipulate, as part of the description of the instance, that  $E' \cup E''$  is the set of malleable edges in  $\mathcal{I}'$  and that the probability mass on any other edge cannot be changed. This completes the description of instance  $\mathcal{I}'$ .

## Abstract

We show that there is an equation of degree at most  $\text{poly}(n)$  for the (Zariski closure of the) set of the non-rigid matrices: that is, we show that for every large enough field  $\mathbb{F}$ , there is a non-zero  $n^2$ -variate polynomial  $P \in \mathbb{F}[x_{1,1}, \dots, x_{n,n}]$  of degree at most  $\text{poly}(n)$  such that every matrix  $M$  which can be written as a sum of a matrix of rank at most  $n/100$  and a matrix of sparsity at most  $n^2/100$  satisfies  $P(M) = 0$ . This confirms a conjecture of Gesmundo, Hauenstein, Ikenmeyer and Landsberg [8] and improves the best upper bound known for this problem down from  $\exp(n^2)$  [11, 8] to  $\text{poly}(n)$ .

We also show a similar polynomial degree bound for the (Zariski closure of the) set of all matrices  $M$  such that the linear transformation represented by  $M$  can be computed by an algebraic circuit with at most  $n^2/200$  edges (without any restriction on the depth). As far as we are aware, no such bound was known prior to this work when the depth of the circuits is unbounded.

Our methods are elementary and short and rely on a polynomial map of Shpilka and Volkovich [17] to construct low degree “universal” maps for non-rigid matrices and small linear circuits. Combining this construction with a simple dimension counting argument to show that any such polynomial map has a low degree annihilating polynomial completes the proof.

As a corollary, we show that any derandomization of the polynomial identity testing problem will imply new circuit lower bounds. A similar (but incomparable) theorem was proved by Kabanets and Impagliazzo [10].

## 1 Introduction

### 1.1 Equations for varieties in algebraic complexity theory

Let  $V \subseteq \mathbb{F}^n$  be a (not necessarily irreducible) affine variety and let  $\mathbf{I}(V)$  denote its ideal.<sup>2</sup> A non-zero polynomial  $P \in \mathbf{I}(V)$  is called an *equation* for  $V$ . An equation for  $V$  may serve as a “proof” that a point  $\mathbf{x} \in \mathbb{F}^n$  is *not* in  $V$ , by showing that  $P(\mathbf{x}) \neq 0$ .

A fundamental observation of the Geometric Complexity Theory program is that many important circuit lower bounds problems in algebraic complexity theory fit naturally into the setting of showing that a point  $\mathbf{x}$  lies outside a variety  $V$  [15, 5]. In this formulation, one considers  $V$  to be the closure of a class of polynomials of low complexity, and  $\mathbf{x}$  is the coefficient vector of the candidate hard polynomial.

---

<sup>1</sup> A part of this work was done while at the Center for the Mathematics of Information, California Institute of Technology, USA.

<sup>2</sup> For completeness, we provide the formal (standard) definitions for these notions in Subsection 1.4.

Let  $\Delta(V) := \min_{0 \neq P \in \mathcal{I}(V)} \{\deg(P)\}$ . The quantity  $\Delta(V)$  can be thought of as a measure of complexity for the geometry of the variety  $V$ . The quantity  $\Delta(V)$  is a very coarse complexity measure. A recent line of work regarding *algebraic natural proofs* [7, 9] suggests to study the arithmetic circuit complexity of equations for varieties  $V$  that correspond to polynomials with small circuit complexity. Having  $\Delta(V)$  growing like a polynomial in  $n$  is a necessary (but not a sufficient) condition for a variety  $V$  to have an algebraic natural proof for non-containment.

## 1.2 Rigid matrices

A matrix  $M$  is  $(r, s)$ -rigid if  $M$  cannot be written as a sum  $R + S$  where  $\text{rank}(R) \leq r$  and  $S$  contains at most  $s$  non-zero entries. Valiant [18] proved that if  $A$  is  $(\varepsilon n, n^{1+\delta})$ -rigid for some constants  $\varepsilon, \delta > 0$  then  $A$  cannot be computed by arithmetic circuits of size  $O(n)$  and depth  $O(\log n)$ , and posed the problem of *explicitly* constructing rigid matrices with these parameters, which is still open. It is easy to prove that most matrices have much stronger rigidity parameters: over algebraically closed fields a generic matrix is  $(r, (n-r)^2)$ -rigid for any target rank  $r$ .

Let  $\mathbb{F}$  be an algebraically closed field. Let  $A_{r,s} \subseteq \mathbb{F}^{n \times n}$  denote the set of matrices which are not  $(r, s)$ -rigid. Let  $V_{r,s} = \overline{A_{r,s}}$  denote the Zariski closure of  $A_{r,s}$ . A geometric study of  $V_{r,s}$  was initiated by Kumar, Lokam, Patankar and Sarma [11]. Among other results, they prove that for every  $s < (n-r)^2$ ,  $\Delta(V_{r,s}) \leq n^{4n^2}$ . A slightly improved (but still exponential) upper bound was obtained by Gesmundo, Hauenstein, Ikenmeyer and Landsberg [8], who also conjectured that for some  $\varepsilon, \delta > 0$ ,  $\Delta(V_{\varepsilon n, n^{1+\delta}})$  grows like a polynomial function in  $n$ . The following theorem which we prove in this note confirms this conjecture.

► **Theorem 1.** *Let  $\varepsilon < 1/25$ , and let  $\mathbb{F}$  be a field of size at least  $n^2$ . For every large enough  $n$ , there exists a non-zero polynomial  $Q \in \mathbb{F}[x_{1,1}, \dots, x_{n,n}]$ , of degree at most  $n^3$ , which is a non-trivial equation for matrices which are not  $(\varepsilon n, \varepsilon n^2)$ -rigid. That is, for every such matrix  $M$ ,  $Q(M) = 0$ .*

In fact, the conjecture of [8] was slightly weaker: they conjectured that  $\Delta(U)$  is polynomial in  $n$  for every irreducible component  $U$  of  $V_{\varepsilon n, n^{1+\delta}}$ . As shown by [11], the irreducible components are in one-to-one correspondence with subsets of  $[n] \times [n]$  of size  $n^{1+\delta}$  corresponding to possible supports of the sparse matrix  $S$ .

As we observe in Remark 6, it is somewhat simpler to show that each of these irreducible components has an equation with a polynomial degree bound. However, since the number of such irreducible components is exponentially large, it is not clear if there is a single equation for the whole variety which is of polynomially bounded degree. We do manage to reverse the order of quantifiers and prove such an upper bound in Theorem 1. This suggests that the set of non-rigid matrices is much less complex than what one may suspect given the results of [11, 8].

## 1.3 Circuits for linear transformations

The original motivation for defining rigidity was in the context of proving lower bounds for algebraic circuits [18]. If  $A \in \mathbb{F}^{n \times n}$  is an  $(\varepsilon n, n^{1+\delta})$ -rigid matrix, for any  $\varepsilon, \delta > 0$ , then the linear transformation represented by  $A$  cannot be computed by an algebraic circuit of depth  $O(\log n)$  and size  $O(n)$ .

Every algebraic circuit computing a linear transformation is without loss of generality a *linear* circuit. A linear circuit is a directed acyclic graph that has  $n$  inputs labeled  $X_1, \dots, X_n$  and  $n$  output nodes. Each edge is labeled by a scalar  $\alpha \in \mathbb{F}$ . Each node computes a linear

function in  $X_1, \dots, X_n$  defined inductively. An internal node  $u$  with children,  $v_1, \dots, v_k$ , connected to it by edges labeled  $\alpha_1, \dots, \alpha_k$ , computes the linear function  $\sum_i \alpha_i \ell_{v_i}$ , where  $\ell_{v_i}$  is the linear function computed by  $v_i$ ,  $1 \leq i \leq k$ . The size of the circuit is the number of edges in the circuit.

It is possible to use similar techniques to those used in the proof of Theorem 1 in order to prove a polynomial upper bound on an equation for a variety containing all matrices  $A \in \mathbb{F}^{n \times n}$  whose corresponding linear transformation can be computed by an algebraic circuit of size at most  $n^2/200$  (even without restriction on the depth). Note that this is nearly optimal as any such linear transformation can be computed by a circuit of size  $n^2$ . More formally, we show the following.

► **Theorem 2.** *Let  $\mathbb{F}$  be a field of size at least  $n^2$ . For every large enough  $n$ , there exists a non-zero polynomial  $Q \in \mathbb{F}[x_{1,1}, \dots, x_{n,n}]$ , of degree at most  $n^3$ , which is a non-trivial equation for matrices which are computed by algebraic circuit of size at most  $n^2/200$ .*

Our proofs are based on a dimension counting arguments, and are therefore non-constructive and do not give explicit equations for the relevant varieties. It thus remains a very interesting open problem to provide explicit low-degree equations for any of the varieties considered in this paper. Here “explicit” means a polynomial which has arithmetic circuits of size  $\text{poly}(n)$ .<sup>3</sup> The question of whether such equations exists has a win-win flavor: if they do, this can aid in explicit constructions of rigid matrices, and on the other hand, if all equations are hard, we have identified a family of polynomials which requires super-polynomial arithmetic circuits. Assuming the existence of a polynomial time algorithm for polynomial identity testing, we are able to make this connection formal.

Let PIT denote the set of strings which describe arithmetic circuits (say, over  $\mathbb{C}$ ) which compute the zero polynomial. It is well known that  $\text{PIT} \in \text{coRP}$ . Kabanets and Impagliazzo [10] proved that certain circuit lower bounds follow from the assumption that  $\text{PIT} \in \text{P}$ . As a corollary to Theorem 2, we are able to prove theorem of a similar kind.

► **Corollary 3.** *Suppose  $\text{PIT} \in \text{P}$ . Then at least one of the following is true:*

1. *There exists a family of  $n$ -variate polynomials of degree  $\text{poly}(n)$  over  $\mathbb{C}$ , which can be computed (as its list of coefficients, given the input  $1^n$ ) in PSPACE, which does not have polynomial size constant free arithmetic circuits.*
2. *there exists a family of matrices, constructible in polynomial time with an NP oracle (given the input  $1^n$ ), which requires linear circuits of size  $\Omega(n^2)$ .*

A *constant free arithmetic circuit* is an arithmetic circuit which is only allowed to use the constants  $\{0, \pm 1\}$ .

A different way to interpret Corollary 3 is as saying that at least one of the following three lower bound results hold: either  $\text{PIT} \notin \text{P}$ , or (at least) one of the two circuit lower bounds stated in the corollary. We emphasize that the result holds under *any* (even so-called *white box*) derandomization of PIT.

Our statement is similar to, but incomparable with the result of Kabanets and Impagliazzo [10] who proved that if  $\text{PIT} \in \text{P}$  then either the permanent does not have polynomial size constant free arithmetic circuits, or  $\text{NEXP} \not\subseteq \text{P}/\text{poly}$ .

Since  $(\varepsilon n, \varepsilon n^2)$ -rigid matrices have linear circuit of size  $3\varepsilon n^2$ , the last item of Corollary 3 in particular implies a conditional construction of  $(\Omega(n), \Omega(n^2))$ -rigid matrices (it is also possible to directly use Theorem 1 instead of Theorem 2 to deduce this result). Unconditional

<sup>3</sup> Although one may consider other, informal notions of explicitness which could nevertheless be helpful.

constructions of rigid matrices in polynomial time with an NP oracle were recently given in [2, 3]. However, the rigidity parameters in these papers are not enough to imply circuit lower bounds (furthermore, even optimal rigidity parameters are not enough to imply  $\Omega(n^2)$  lower bounds for general linear circuits).

Since it is widely believed that  $\text{PIT} \in \text{P}$ , the answer to which of the last two items of Corollary 3 holds boils down to the question of whether there exists an equation for non-rigid matrices of degree  $\text{poly}(n)$  and circuit size  $\text{poly}(n)$ . If determining if a matrix is rigid is  $\text{coNP}$ -hard (as is known for some restricted ranges of parameters [13]), it is tempting to also believe that the equations should not be easily computable, as they provide “proof” for rigidity which can be verified in randomized polynomial time. However, it could still be the case that those equations that have polynomial size circuits only prove the rigidity of “easy” instances.

## 1.4 Some basic notions in algebraic geometry

For completeness, in this section we define some basic notions in algebraic geometry. A reader who is familiar with this topic may skip to the next section.

Let  $\mathbb{F}$  be an algebraically closed field. A set  $V \subseteq \mathbb{F}^n$  is called an *affine variety* if there exist polynomials  $f_1, \dots, f_t \in \mathbb{F}[x_1, \dots, x_n]$  such that  $V = \{\mathbf{x} : f_1(\mathbf{x}) = f_2(\mathbf{x}) = \dots = f_t(\mathbf{x}) = 0\}$ . For convenience, in this paper we often refer to affine varieties simply as varieties.

For each variety  $V$  there is a corresponding ideal  $\mathbf{I}(V) \subseteq \mathbb{F}[x_1, \dots, x_n]$  which is defined as

$$\mathbf{I}(V) := \{f \in \mathbb{F}[x_1, \dots, x_n] : f(\mathbf{x}) = 0 \text{ for all } \mathbf{x} \in V\}.$$

Conversely, for an ideal  $I \subseteq \mathbb{F}[x_1, \dots, x_n]$  we may define the variety

$$\mathbf{V}(I) = \{\mathbf{x} : f(\mathbf{x}) = 0 \text{ for all } f \in I\}.$$

Given a set  $A \subseteq \mathbb{F}^n$  we may similarly define the ideal  $\mathbf{I}(A)$ . The (Zariski) *closure* of a set  $A$ , denoted  $\overline{A}$ , is the set  $\mathbf{V}(\mathbf{I}(A))$ . In words, the closure of  $A$  is the set of common zeros of all the polynomials that vanish on  $A$ . It is also the smallest variety with respect to inclusion which contains  $A$ . By construction,  $\overline{A}$  is a variety, and a polynomial which vanishes everywhere on  $A$  is also vanishes on  $\overline{A}$ .

Over  $\mathbb{C}$ , it is instructive to think of the Zariski closure of  $A$  as the usual Euclidean closure. In fact, for the various sets  $A$  we consider in this paper (which correspond to sets of “low complexity” objects, e.g., non-rigid matrices or matrices which can be computed with a small circuit), it can be shown that these two notions of closure coincide (see, e.g., Section 4.2 of [4]).

A variety  $V$  is called *irreducible* if it cannot be written as a union  $V = V_1 \cup V_2$  of varieties  $V_1, V_2$  that are properly contained in  $V$ . Every variety can be uniquely written as a union  $V = V_1 \cup V_2 \cup \dots \cup V_m$  of irreducible varieties. The varieties  $V_1, \dots, V_m$  are then called the *irreducible components* of  $V$ .

## 2 Degree Upper Bound for Non-Rigid Matrices

In this section, we prove Theorem 1. A key component of the proof is the use of the following construction, due to Shpilka and Volkovich, which provides an explicit low-degree polynomial map on a small number of variables, which contains all sparse matrices in its image. For completeness, we provide the construction and prove its basic property.

► **Lemma 4** ([17]). *Let  $\mathbb{F}$  be a field such that  $|\mathbb{F}| > n$ . Then for all  $k \in \mathbb{N}$ , there exists an explicit polynomial map  $\text{SV}_{n,k}(\mathbf{x}, \mathbf{y}) : \mathbb{F}^{2k} \rightarrow \mathbb{F}^n$  of degree at most  $n$  such that for any subset  $T = \{i_1, \dots, i_k\} \subseteq [n]$  of size  $k$ , there exists a setting  $\mathbf{y} = \boldsymbol{\alpha}$  such that  $\text{SV}(\mathbf{x}, \boldsymbol{\alpha})$  is identically zero on every coordinate  $j \notin T$ , and equals  $x_j$  in coordinate  $i_j$  for all  $j \in [k]$ .*

**Proof.** Arbitrarily pick distinct  $\alpha_1, \dots, \alpha_n \in \mathbb{F}$ , and let  $u_1, \dots, u_n$  be their corresponding Lagrange's interpolation polynomials, i.e., polynomials of degree at most  $n-1$  such that  $u_i(\alpha_j) = 1$  if  $j = i$  and 0 otherwise (more explicitly,  $u_i(z) = \frac{\prod_{j \neq i} (z - \alpha_j)}{\prod_{j \neq i} (\alpha_i - \alpha_j)}$ ).

Let  $P_i(x_1, \dots, x_k, y_1, \dots, y_k) = \sum_{j=1}^k u_i(y_j) \cdot x_j$ , and finally let

$$\text{SV}_{n,k}(\mathbf{x}, \mathbf{y}) = (P_1(\mathbf{x}, \mathbf{y}), \dots, P_n(\mathbf{x}, \mathbf{y})).$$

It readily follows that given  $T = \{i_1, \dots, i_k\}$  as in the statement of the lemma, we can set  $y_j = \alpha_{i_j}$  for  $j \in [k]$  to derive the desired conclusion. The upper bound on the degree follows by inspection. ◀

As a step toward the proof of Theorem 1, we show there is a polynomial map on much fewer than  $n^2$  variables with degree polynomially bounded in  $n$  such that its image contains every non-rigid matrix. In the next step, we show that the image of every such polynomial map has an equation of degree  $\text{poly}(n)$ .

► **Lemma 5.** *There exists an explicit polynomial map  $P : \mathbb{F}^{4\epsilon n^2} \rightarrow \mathbb{F}^{n \times n}$ , of degree at most  $n^2$ , such that every matrix  $M$  which is not  $(\epsilon n, \epsilon n^2)$  rigid lies in its image.*

**Proof.** Let  $k = \epsilon n^2$  and let  $\mathbf{u}, \mathbf{v}, \mathbf{x}, \mathbf{y}$  denote disjoint tuples of  $k$  variables each.

Let  $U$  be a symbolic  $n \times \epsilon n$  matrix whose entries are labeled by the variables  $\mathbf{u}$ , and similarly let  $V$  be a symbolic  $\epsilon n \times n$  matrix labeled by  $\mathbf{v}$ . Let  $UV(\mathbf{u}, \mathbf{v}) : \mathbb{F}^{2k} \rightarrow \mathbb{F}^{n \times n}$  be the degree 2 polynomial map defined by the matrix multiplication  $UV$ .

Finally, let  $P : \mathbb{F}^{4k} \rightarrow \mathbb{F}^{n \times n}$  be defined as

$$P(\mathbf{u}, \mathbf{v}, \mathbf{x}, \mathbf{y}) = UV(\mathbf{u}, \mathbf{v}) + \text{SV}_{n^2,k}(\mathbf{x}, \mathbf{y}),$$

where  $\text{SV}_{n^2,k}$  is as defined in Lemma 4.

Suppose now  $M$  is a non-rigid matrix, i.e.,  $M = R + S$  for  $R$  of rank  $\epsilon n$  and  $S$  which is  $\epsilon n^2$ -sparse. Decompose  $R = U_0 V_0$  for  $n \times \epsilon n$  matrix  $U_0$  and  $\epsilon n \times n$  matrix  $V_0$ . Let  $T$  denote the support of  $S$ . For convenience we may assume  $|T| = k$  (otherwise, pad with zeros arbitrarily). Let  $\boldsymbol{\alpha} \in \mathbb{F}^k$  denote the setting for  $\mathbf{y}$  in  $\text{SV}_{n^2,k}$  which maps  $x_1, \dots, x_k$  to  $T$ , and let  $\mathbf{s} = (s_1, \dots, s_k)$  denote the non-zero entries of  $S$ . Then

$$P(U_0, V_0, \mathbf{s}, \boldsymbol{\alpha}) = U_0 V_0 + S = R + S = M. \quad \blacktriangleleft$$

To complete the proof of Theorem 1, we now argue that the image of any polynomial map with parameters as in Lemma 5 has an equation of degree at most  $n^3$ .

**Proof of Theorem 1.** Let  $V_1$  denote the subspace of polynomials over  $\mathbb{F}$  in  $n^2$  variables of degree at most  $n^3$ . Let  $V_2$  denote the subspace of polynomials over  $\mathbb{F}$  in  $4\epsilon n^2$  variables of degree at most  $n^5$ . Let  $P$  be as in Lemma 5, and consider the linear transformation  $T : V_1 \rightarrow V_2$  given by  $Q \mapsto Q \circ P$ , where  $Q \circ P$  denotes the composition of the polynomial  $Q$  with the map  $P$ , i.e.,  $(Q \circ P)(\mathbf{x}) = Q(P(\mathbf{x}))$  (indeed, observe that since  $\deg(Q) \leq n^3$  and  $\deg(P) \leq n^2$ , it follows that  $\deg(Q \circ P) \leq n^5$ ).

We have that  $\dim(V_1) = \binom{n^3+n^2}{n^2} \geq n^{n^2}$ , whereas  $\dim(V_2) = \binom{4\epsilon n^2+n^5}{4\epsilon n^2} \leq (2n^5)^{4\epsilon n^2} < \dim(V_1)$  by the choice of  $\epsilon$ , so that there exists a non-zero polynomial in the kernel of  $T$ , that is,  $0 \neq Q_0 \in V_1$  such that  $Q_0 \circ P \equiv 0$ .

It remains to be shown that for any non-rigid matrix  $M$ ,  $Q_0(M) = 0$ . Indeed, let  $M$  be a non-rigid matrix. By Lemma 5, there exist  $\beta \in \mathbb{F}^{4\epsilon n^2}$  such that  $P(\beta) = M$ . Thus,  $Q_0(M) = Q_0(P(\beta)) = Q_0 \circ P(\beta) = 0$ , as  $Q_0 \circ P \equiv 0$ .  $\blacktriangleleft$

► **Remark 6.** If the support of the sparse matrix is fixed a-priori to some set  $S \subseteq [n] \times [n]$  of cardinality at most  $\epsilon n^2$ , then it is easier to come up with a universal map  $\tilde{P}$  from  $\mathbb{F}^{3\epsilon n^2} \mapsto \mathbb{F}^{n \times n}$  such that every matrix  $M$  whose rank can be reduced to at most  $\epsilon n$  by changing entries in the set  $S$  is contained in the image of  $\tilde{P}$ . Just consider  $\tilde{P}(\mathbf{w}, \mathbf{x}, \mathbf{y}) = UV(\mathbf{u}, \mathbf{v}) + W$ , where  $W$  is a matrix such that for all  $(i, j) \in [n] \times [n]$ , if  $(i, j) \in S$ , then  $W(i, j) = w_{i,j}$  and  $W(i, j)$  is zero otherwise. Here, each  $w_{i,j}$  is a distinct formal variable. Combined with the dimension comparison argument we used in the proof of Theorem 1, it can be seen that there is a non-zero low degree polynomial  $\tilde{Q}$  such that  $\tilde{Q} \circ \tilde{P} \equiv 0$ . This argument provides a (different) equation of polynomial degree for each irreducible component of the variety of non-rigid matrices.

► **Remark 7.** It is possible to use the equation given in Theorem 1, and using the methods of [11], to construct “semi-explicit”  $(\epsilon n, \epsilon n^2)$ -rigid matrices. These are matrices whose entries are algebraic numbers (over  $\mathbb{Q}$ ) with short description, which are non-explicit from the computational complexity point of view. However, such constructions are also known using different methods (see Section 2.4 of [12]).

### 3 Degree Upper bound for Other Models

The proof of Theorem 2 is omitted from this version and appears in the full version of the paper. The strategy, as before, is to observe that all matrices with a small circuit lie in the image of a polynomial map  $P$  on a small number of variables and small degree. Circuits of size  $s$  can have many different topologies and thus we first construct a “universal” linear circuit, of size  $s' \leq s^4$ , that contains as subcircuits all linear circuits of size  $s$ . Importantly,  $s'$  will affect the degree of  $P$  but not its number of variables. We note that this construction of universal circuits is slightly different from similar constructions in earlier work, e.g., in [16]; the key difference being that a naive use of ideas in [16] to obtain the map  $P$  seems to incur an asymptotic increase in the number of variables of  $P$ , which is unacceptable in our current setting.

Analogous to the proof of Theorem 1, we then observe via a dimension counting argument that the image of the polynomial map  $P$  has an equation of degree at most  $n^3$ . This completes the proof of Theorem 2.

Another algebraic object which is closely related to proving circuit lower bounds is the set of three dimensional tensors of high rank. A three dimensional tensor of rank at least  $r$  implies a lower bound of  $r$  on an arithmetic circuit computing the bi-linear function associated with the tensor. Our arguments also provide polynomial degree upper bounds for the set of tensors of (border) rank at most  $n^2/300$ . We again omit the details, which appear in the full version of the paper.

A similar method can be used to prove the existence of an equation of degree  $\text{poly}(n)$  for three dimensional tensors of *slice rank* (see, e.g., [5]) at most, say,  $n/1000$ . The existence of such an equation was proved (using different techniques) in [5].

## 4 Applications to Circuit Lower Bounds

In this section we prove Corollary 3. The strategy of the proof is simple: the proof of Theorem 2 implies a PSPACE algorithm which produces a sequence of polynomials which are equations for the set of matrices with small linear circuits. If those equations require large circuits, we are done, and if not, then there exists an equation with small circuits which (assuming  $\text{PIT} \in \text{P}$ ) can be found using an NP-oracle. Using, once again, the assumption that  $\text{PIT} \in \text{P}$ , we can also find deterministically a matrix on which the equation evaluates to non-zero, which implies the matrix requires large linear circuits.

There are some technical difficulties involved with this plan which we now describe. The first problem is that even arithmetic circuits of small size can have large description as bit strings, due to the field constants appearing in the circuits. To prevent this issue, we only consider *constant free* arithmetic circuits, which are only allowed inputs labeled by  $\{0, \pm 1\}$  (but can still compute other constants in the circuit using arithmetic operations).

The second problem is that, in order to be able to find a non-zero of the equation in the last step of the algorithm (using the mere assumption that  $\text{PIT} \in \text{P}$ ), we need not only the size of the circuit but also its *degree* to be bounded by  $\text{poly}(n)$ . Of course, by Theorem 2 there exists such a circuit, but we need to be able to prevent a malicious prover from providing us with a  $\text{poly}(n)$  size circuit of exponential degree, and it is not known how to compute the degree of a circuit in deterministic polynomial time, even assuming  $\text{PIT} \in \text{P}$ . To solve this issue, we use an idea of Malod and Portier [14], who showed that any polynomial with circuit of size  $\text{poly}(n)$  and degree  $d$  also has a *multiplicatively disjoint* (MD) circuit of size  $\text{poly}(n, d)$ . An MD circuit is a circuit in which any multiplication gate multiplies two disjoint subcircuits. This is a syntactic notion which is easy to verify efficiently and deterministically, and an MD circuit of size  $s$  is guaranteed to compute a polynomial of degree at most  $s$ .

A final technical issue is that the notion of MD circuits does not fit perfectly within the framework of constant free circuits. Therefore we use the notion of “almost MD” circuits, which allow for the case which the inputs to a multiplication gates are not disjoint, as long as at least one of them is the root of a subcircuit in which only constants appear.

► **Definition 8.** We say a gate  $v$  in a circuit is *constant producing (CP)* if in the subcircuit rooted at  $v$ , all input nodes are field constants.

An *almost-MD circuit* is a circuit where every multiplication gate either multiplies two disjoint subcircuits, or at least one of its children is constant producing.

► **Lemma 9.** Suppose  $f$  is an  $n$ -variate polynomial of degree  $\text{poly}(n)$  which has a constant free arithmetic circuit of degree  $\text{poly}(n)$ . Then  $f$  has a constant free almost-MD circuit of size  $\text{poly}(n)$ .

The proof of Lemma 9 appears in the full version of the paper.

For circuits which compute low-degree polynomials, the mere existence of an algorithm for the decision version of PIT allows one to construct an algorithm for the search version. The following lemma is standard, and its proof appears in the full version of the paper.

► **Lemma 10.** Suppose  $\text{PIT} \in \text{P}$ . Then there is a polynomial time algorithm that given a non-zero almost-MD arithmetic circuit  $C$  of size  $s$  computing an  $n$ -variate polynomial, finds in time  $\text{poly}(n, s)$  an element  $\mathbf{a} \in \mathbb{C}^n$  such that  $C(\mathbf{a}) \neq 0$ .

As we noted above, the assumption that  $C$  is almost-MD was used in Lemma 10 to bound the degree of the circuit. It is also useful because it is easy to decide in deterministic polynomial time whether a circuit is almost-MD. We now complete the proof of Corollary 3.

**Proof of Corollary 3.** For every  $n$ , the proof of Theorem 2 provides an equation  $Q_n$  for the set of  $n \times n$  matrices with small linear circuits. This polynomial can be found by solving a linear system of equations in a linear space whose dimension is  $\exp(\text{poly}(n))$ . Using standard, small space algorithm for linear algebra [6, 1], this implies that there exists a fixed PSPACE algorithm which, on input  $1^n$ , outputs the list of coefficients of the polynomial  $Q_n$ .

Consider now the family  $\{Q_n\}_{n \in \mathbb{N}}$ . If for any constant  $k \in \mathbb{N}$  there exist infinitely many  $n \in \mathbb{N}$  such that  $Q_n$  requires circuits of size at least  $n^k$ , it follows (by definition) that the PSPACE algorithm above outputs a family of polynomials with super-polynomial constant-free arithmetic circuits.

We are thus left to consider the case that there exists a constant  $k \in \mathbb{N}$  such that for all large enough  $n \in \mathbb{N}$ ,  $Q_n$  can be computed by circuits of size  $n^k$ . By Lemma 9, we may assume without loss of generality that these circuits are almost-MD circuits. Further suppose  $\text{PIT} \in \text{P}$ . We will show how to construct a matrix in polynomial time with an NP oracle which requires large linear circuits.

Consider the language  $L$  of pairs  $(1^n, x)$  such that there exists a string  $y$  of length at most  $n^k$  such that  $xy$  describes an almost-MD circuit  $C$  such that  $C$  is non-zero, and  $C \circ U \equiv 0$ , where  $U$  is the polynomial map given in the proof of Theorem 2.

Assuming  $\text{PIT} \in \text{P}$ , the language  $L$  is in NP, and by assumption for every large enough  $n$  there exists such a circuit. Thus, we can use the NP oracle to construct such a circuit  $C$  bit by bit. Finally, using Lemma 10 we can output a matrix  $M$  such that  $C(M) \neq 0$ .

By the properties of the circuit  $C$  and the map  $U$ ,  $M$  does not have linear circuits of size less than  $n^2/200$ . ◀

Many variations of Corollary 3 can be proved as well, with virtually the same proof. By slightly modifying the language  $L$  used in the proof, it is possible to prove the same result even under the assumption  $\text{PIT} \in \text{NP}$  (recall that  $\text{PIT} \in \text{coRP}$ ). A similar statements also holds over finite fields of size  $\text{poly}(n)$ , in which case the proof is simpler since there are no issues related to the bit complexity of the first constants. Finally, an analog of Corollary 3 also holds for tensor rank: that is, assuming  $\text{PIT} \in \text{P}$ , either there exists a construction of a hard polynomial in PSPACE, or an efficient construction with an NP oracle of a 3-dimensional tensor of rank  $\Omega(n^2)$ . We remark that for tensors of large rank there are no analogs of [2, 3], i.e., there do not exist even constructions with an NP oracle of tensors with slightly super-linear rank.

## Abstract

We formulate a new hardness assumption, the *Strongish Planted Clique Hypothesis (SPCH)*, which postulates that any algorithm for planted clique must run in time  $n^{\Omega(\log n)}$  (so that the state-of-the-art running time of  $n^{O(\log n)}$  is optimal up to a constant in the exponent).

We provide two sets of applications of the new hypothesis. First, we show that SPCH implies (nearly) tight inapproximability results for the following well-studied problems in terms of the parameter  $k$ : Densest  $k$ -Subgraph, Smallest  $k$ -Edge Subgraph, Densest  $k$ -Subhypergraph, Steiner  $k$ -Forest, and Directed Steiner Network with  $k$  terminal pairs. For example, we show, under SPCH, that no polynomial time algorithm achieves  $o(k)$ -approximation for Densest  $k$ -Subgraph. This inapproximability ratio improves upon the previous best  $k^{o(1)}$  factor from (Chalermsook et al., FOCS 2017). Furthermore, our lower bounds hold even against fixed-parameter tractable algorithms with parameter  $k$ .

Our second application focuses on the complexity of graph pattern detection. For both induced and non-induced graph pattern detection, we prove hardness results under SPCH, improving the running time lower bounds obtained by (Dalirrooyfard et al., STOC 2019) under the Exponential Time Hypothesis.

## 1 Introduction

The last couple of decades have seen dramatic advances in our understanding of parameterized, fine-grained, and average-case complexity. To a large extent, this progress has been enabled by bolder computational hardness assumptions, beyond the classical  $P \neq NP$ . Two notable assumptions in these fields are the Exponential Time Hypothesis and the Planted Clique Hypothesis. In this paper we propose a new hypothesis, the *Strongish Planted Clique*

*Hypothesis*, which strengthens the Planted Clique Hypothesis in the style of the Exponential Time Hypothesis. We show that this hypothesis has interesting implications in the parameterized complexity of both approximation problems and graph pattern detection.

**Exponential Time Hypothesis.** The Exponential Time Hypothesis (ETH) [69] is a pessimistic version of  $P \neq NP$  which postulates that solving 3-SAT on  $n$  variables requires time  $2^{\Omega(n)}$ . In other words, the running times of the state-of-the-art (and the brute-force) algorithms for 3-SAT are optimal up to a constant factor in the exponent. ETH has important applications in parameterized complexity (e.g. [30, 82, 80, 46, 48]) and hardness of approximation (e.g. [26, 25, 92, 84, 87, 52]). In the past several years, further progress was achieved by assuming stronger variants of ETH such as the Strong ETH (SETH) in fine-grained complexity [70, 95], Gap-ETH in parameterized complexity [31, 23, 83], and ETH for PPAD in Algorithmic Game Theory [9, 91].

**Planted Clique Hypothesis.** In the Planted  $\kappa$ -Clique Problem, the goal is to distinguish (with high probability) between graphs sampled from one of the following distributions: Uniformly at random<sup>1</sup>; and uniformly at random, with an added  $\kappa$ -clique. While statistically it is easy to distinguish the two distributions for  $\kappa$  as little as  $2.1 \log(n)$ , the *Planted Clique Hypothesis* (PCH) postulates that no polynomial time algorithm can solve this problem, even for  $\kappa$  as large as  $o(\sqrt{n})$ . The history of this problem goes back to Karp [73] and Jerrum [71], and in the past decade it has been popular as a hardness assumption for both worst-case [8, 68, 3, 10, 20] and average-case [17, 66, 18, 63, 29, 27] problems. A simple  $n^{\Theta(\log(n))}$ -time algorithm for the planted- $\kappa$ -clique problem non-deterministically guesses  $\ell = \Theta(\log(n))$  vertices from the clique, and then checks whether all of their common neighbors form a clique. There are several other algorithms that also solve this problem in time  $n^{\Theta(\log(n))}$  [60, 59, 86, 13], but no faster algorithm is known for  $\kappa = O(n^{0.49})$ .

## Strongish Planted Clique Hypothesis

In analogy to the Exponential Time Hypothesis for 3-SAT, we propose the following hypothesis, which postulates that the state-of-the-art algorithms for the Planted Clique Problem are optimal up to a constant factor in the exponent. A *Strong* Planted Clique Hypothesis, in analogy with SETH, would specify a precise constant in the exponent – our hypothesis is merely Strong-ish. We let  $\mathcal{G}(n, p)$  denote the Erdős-Rényi distribution with parameter  $p$ , and  $\mathcal{G}(n, p, \kappa)$  denote the Erdős-Rényi distribution with a planted  $\kappa$ -clique.

► **Hypothesis 1** (Strongish Planted Clique Hypothesis (SPCH)). *There exists a constant  $\delta \in (0, \frac{1}{2})$  such that no  $n^{o(\log n)}$ -time algorithm  $\mathcal{A}$  satisfies both of the following:*

- (Completeness)  $\Pr_{G \sim \mathcal{G}(n, \frac{1}{2}, \lceil n^\delta \rceil)}[\mathcal{A}(G) = 1] \geq 2/3$ .
- (Soundness)  $\Pr_{G \sim \mathcal{G}(n, \frac{1}{2})}[\mathcal{A}(G) = 1] \leq 1/3$ .

In addition to the lack of algorithmic progress toward refuting this hypothesis, we note that  $n^{\Theta(\log(n))}$  is in fact provably optimal for the Sum-of-Squares hierarchy [11], which captures the state-of-the-art algorithmic techniques for a number of average-case problems. It is also known to be tight for statistical algorithms [62, 28].

<sup>1</sup> I.e. from the *Erdős-Rényi* (ER) distribution over  $n$ -vertex graphs where each edge appears independently with probability  $1/2$ .

## 1.1 Our Contributions: Hardness results from Strongish Planted Clique Hypothesis

Our main technical contributions are in exploring the implications of our new SPCH in parameterized complexity. We prove two types of hardness results: hardness of approximation, and hardness of (exact) graph pattern detection. Due to the rich literature for each problem we consider, we will only mention the most relevant results here and defer a more comprehensive discussion to Section 1.4.

### 1.1.1 Hardness of approximation from SPCH

At the heart of our work is the study of the *Densest  $k$ -Subgraph* problem, in which we are given an undirected graph  $G = (V, E)$  and a positive integer  $k$ . The goal is to output a subset  $S \subseteq V$  of  $k$  vertices that induces as many edges as possible. There is a trivial  $O(k)$ -approximation for the problem: return an arbitrary set of  $\lfloor k/2 \rfloor$  edges. We show that assuming SPCH, this algorithm is optimal:

► **Theorem 2.** *Assuming the Strongish Planted Clique Hypothesis (Hypothesis 1), there is no  $f(k) \cdot \text{poly}(n)$ -time algorithm that can approximate Densest  $k$ -Subgraph on  $n$ -vertex graphs to within a factor  $o(k)$  for any function  $f$ . Furthermore, this holds even in the perfect completeness case where the input graph is promised to contain a  $k$ -clique.*

Theorem 2 improves upon the inapproximability ratio of  $k^{o(1)}$  shown in [31] under Gap-ETH.

The approximability of Densest  $k$ -Subgraph is known to be intimately related to that of numerous other problems. As such, our tight hardness of approximation for Densest  $k$ -Subgraph immediately implies several tight approximability results as corollaries, which we list below.

- *Smallest  $k$ -Edge Subgraph*: given an undirected graph  $G = (V, E)$  and a positive integer  $k$ , find a smallest subset  $S \subseteq V$  that induces at least  $k$  edges. For this problem, the trivial solution that chooses  $k$  edges arbitrarily is an  $O(\sqrt{k})$ -approximation since even the optimum requires at least  $\sqrt{k}$  vertices. We show that this is tight (Corollary 11): no fixed-parameter tractable (FPT) (in  $k$ ) algorithm can achieve  $o(\sqrt{k})$  approximation ratio.
- *Steiner  $k$ -Forest* (aka  *$k$ -Forest*): given an edge-weighted undirected graph  $G = (V, E)$ , a set  $\{(s_1, t_1), \dots, (s_\ell, t_\ell)\}$  of demand pairs and a positive integer  $k$ , the goal is to find a (not necessarily induced) subgraph of  $G$  with smallest total edge weight that connects at least  $k$  demand pairs. In Corollary 12, we show that no FPT (in  $k$ ) algorithm can achieve  $o(\sqrt{k})$  approximation ratio. This matches the  $O(\sqrt{k})$ -approximation algorithm by Gupta et al. [65].
- *Directed Steiner Network* (aka *Directed Steiner Forest*): given an edge-weighted directed graph  $G = (V, E)$  and a set  $\{(s_1, t_1), \dots, (s_k, t_k)\}$  of  $k$  demand pairs, the goal is to find a (not necessarily induced) subgraph of  $G$  with smallest total edge weight in which  $t_i$  is reachable from  $s_i$  for all  $i = 1, \dots, k$ . We prove that no FPT (in  $k$ ) algorithm achieves  $o(\sqrt{k})$ -approximation (Corollary 14). This nearly matches the best known polynomial algorithms by Chekuri et al. [35] and Feldman et al. [61], both of which achieve a  $O(k^{1/2+\epsilon})$ -approximation for any constant  $\epsilon > 0$ . Our bound improves upon a  $k^{1/4-o(1)}$  ratio from [52] under Gap-ETH.
- *Densest  $k$ -Subhypergraph*: given a hypergraph  $G = (V, E)$  and a positive integer  $k$ , output a  $k$ -size subset  $S \subseteq V$  that maximizes the number of hyperedges fully contained in  $S$ . The trivial algorithm that outputs any hyperedge (of size at most  $k$ ) obtains a  $2^k$ -approximation. We prove a matching lower bound (Theorem 15): no  $2^{o(k)}$ -approximation FPT (in  $k$ ) algorithm exists. This resolves an open question posed by Cygan et al. [45], assuming SPCH.

### 1.1.2 Hardness of graph pattern detection from SPCH

*Graph Pattern Detection*, also known as *Subgraph Isomorphism* and closely related to *Motif Discovery*, is a fundamental problem in graph algorithms: Given a host graph  $G$  and a pattern graph  $H$ , decide whether  $G$  contains a subgraph  $S$  isomorphic to  $H$ . There are two main variants of this problem, where  $S$  is either required to be *induced* or *not-necessarily-induced*. For both variants, there is a brute-force  $n^{O(k)}$ -time algorithm. We prove matching SPCH-hardness for both variants. In addition to beating the ETH-based state-of-the-art for these results, we highlight that our reductions to graph pattern detection problems are extremely simple (in contrast to the prior work).

For induced subgraph detection, we prove the following:

► **Theorem 3.** *Assuming the Strongish Planted Clique Hypothesis (Hypothesis 1), for every  $k$ -node pattern  $H$ , there is no algorithm that solves the induced pattern detection problem on  $n$ -vertex graphs in time  $f(k) \cdot n^{o(k)}$  for any function  $f$ .*

Our  $n^{\Omega(k)}$  lower bound for all patterns can be compared to recent work of [48], who proved: (i)  $n^{\Omega(\log(k))}$  lower bound for every pattern assuming ETH; (ii)  $n^{\Omega(\sqrt{k})}$  lower bound for every pattern assuming ETH and the Hadwiger conjecture; and (iii)  $n^{\Omega(k/\log(k))}$  lower bound for most patterns.<sup>2</sup>

For not-necessarily-induced subgraph detection, it is no longer true that every pattern is hard (e.g. it is trivial to find a not-necessarily-induced subgraph isomorphic to an independent set). But we prove (Corollary 10) that for most patterns<sup>3</sup> detection requires  $n^{\Omega(k)}$  time assuming SPCH. For comparison, [48] proved that under ETH, not-necessarily-induced subgraph detection requires  $n^{\Omega(\omega(H))}$  time, where  $\omega(H)$  denotes the clique number of the pattern  $H$ . (Note that  $\omega(H) = \Theta(\log k)$  for most patterns.)

**$k$ -biclique detection.** For the special case where the pattern is a  $k$ -biclique, our aforementioned  $n^{\Omega(k)}$  hardness for non-induced subgraph detection rules out even constant factor approximations (Corollary 9). This improves over  $n^{\Omega(\sqrt{k})}$  lower bounds under ETH for the exact case [80] or Gap-ETH for approximation [31].

**Densest  $k$ -Subgraph.** We obtain our pattern detection result by first showing a  $n^{\Omega(k)}$  running time bound for  $O(1)$ -approximating Densest  $k$ -Subgraph (Theorem 8). This improves upon the previous lower bound who give a running time lower bound of  $n^{\Omega(\log k)}$  assuming Gap-ETH [31]. The aforementioned lower bounds for pattern detection follow almost trivially from our running time lower bound for Densest  $k$ -Subgraph; see Sections 3.2 and 3.3 for more detail.

## 1.2 Techniques

The starting point for all of our reductions is a *randomized graph product*: starting with an instance  $G$  of the planted clique problem on  $n$  vertices and any integers  $\ell \leq n$  and  $N$ , we produce a graph  $G'$  by taking its vertices to be  $N$  randomly sampled subsets  $S_1, \dots, S_N$  of  $\ell$  vertices each, and we add an edge on  $S_i, S_j$  if and only if their union induces a clique in  $G$ .

<sup>2</sup> In the sense of a pattern sampled randomly from  $\mathcal{G}(k, 1/2)$ .

<sup>3</sup> In particular any pattern with a constant fraction of the  $\binom{k}{2}$  possible edges.

The randomized graph product [16] (and its derandomized variant [4]) has a long history in proving hardness of approximating Maximum Clique. While not stated explicitly, it was also used to prove parameterized inapproximability of Densest  $k$ -Subgraph in [31]. As we will explain in more detail below, the main difference between our proof and previous works lie in the soundness, where we appeal to the fact that  $G \sim \mathcal{G}(n, 1/2)$  to achieve tighter bounds.

Since we would like to prove hardness of approximating Densest  $k$ -Subgraph in the perfect completeness case, our goal is to show (for appropriately chosen values of  $N, \ell$ ) that

- (Completeness) if  $G$  contains a large clique, then with high probability so does  $G'$ , and,
- (Soundness) if  $G$  is random, then  $G'$  does not have small dense subgraphs (with high probability).

For the completeness, if the starting graph  $G$  has a  $\kappa$ -clique, then the set of  $S_i$  that fall entirely within the  $\kappa$ -clique will form a clique in  $G'$  (the expected size is  $(\frac{\kappa}{n})^\ell \cdot N$ ). This part of the proof is exactly the same as that in the aforementioned previous works.

To prove soundness, we calculate the probability that a specific  $\gamma k$ -dense  $k$ -subgraph appears in  $G'$ , then take a union bound over all  $\leq \binom{N}{k} \cdot 2^{\binom{k}{2}}$  possible such subgraphs. Our simple argument hinges on showing that a  $k$ -subgraph with  $\gamma k^2$  edges in  $G'$  induces (with high probability) at least  $\Omega(\gamma k^2 \ell^2)$  edges in  $G$ , and since any such set of edges appears in  $G$  with probability at most  $2^{-\Omega(\gamma k^2 \ell^2)}$ , by choosing  $\ell$  sufficiently large we can beat this union bound. To argue that small subgraphs with  $m$  edges in  $G'$  induce small subgraphs with  $\Omega(m \ell^2)$  edges in  $G$ , we use that the randomly chosen  $S_i$  (for an appropriate choice of  $N \ll n^\ell$  and  $k_*$  sufficiently small) form a *dispenser*: the union of *any*  $t \leq k_*$  of the  $S_i$  contains  $\Omega(t\ell)$  vertices of  $G$  with high probability.<sup>4</sup> This implies that for  $k \leq k_*$ , each  $k$ -subgraph of  $G'$  corresponds to a union of  $k$  *pairwise* mostly-non-overlapping subsets of  $\ell$  vertices. Now, since each edge between mostly non-overlapping sets in  $G'$  corresponds to a  $\Omega(\ell)$ -clique in  $G$ , this in turn can be used to show that any  $k$ -subgraph of  $G'$  with density  $\gamma k$  corresponds to a subgraph of  $G$  with  $\Omega(\gamma k^2 \ell^2)$  edges. In this way we rule out the existence of  $\gamma k$ -dense  $k$ -subgraphs in  $G'$  (with high probability).

By carefully choosing the parameters  $N, \ell, \gamma$ , to control the completeness, soundness, and reduction size, we get a fine-grained reduction from Planted  $\kappa$ -Clique to Densest  $k$ -Subgraph. Our results for other problems are obtained via direct reductions from the Densest  $k$ -Subgraph problem.

We end by stressing that our new soundness proof gives a strong quantitative improvement over prior results, which is what enables us to achieve  $k^{\Omega(1)}$  inapproximability. Specifically, the previous soundness proof from [31] – in turn adapted from [84] – relies on showing that the graph is  $t$ -biclique-free for some  $t \in \mathbb{N}$ ; they then apply the so-called Kovari-Sos-Turan theorem [77] to deduce that any  $k$ -subgraph contains at most  $O(k^{2-1/t})$  edges. Notice that this gap is only  $O(k^{1/t})$ , and  $t$  cannot be a constant as otherwise the completeness and soundness case can be distinguished in time  $n^{O(t)} = \text{poly}(n)$ . As a result, their technique cannot yield an  $k^{\Omega(1)}$ -factor inapproximability for Densest  $k$ -Subgraph. Similarly, the techniques from [31] cannot give a running time lower bound of the form  $n^{\omega(\log k)}$  for  $O(1)$ -approximation of Densest  $k$ -Subgraph. The reason is that, to get a constant gap bounded from one, they need to select  $t = O(\log k)$ . Once again, this is in contrast to our technique which yields a tight running time lower bound of  $n^{\Omega(k)}$  in this setting, although our proof requires a different starting hardness result (from SPCH).

<sup>4</sup> The fact that the randomized graph product yields a dispenser has been used in previous works as well, see e.g. [16, 98, 31].

### 1.3 Discussion and Open Questions

In this work, we have proposed the Strongish Planted Clique Hypothesis, and used it prove several tight hardness of approximation or running time lower bound results. One direction for future investigation is to use SPCH to derive other interesting lower bounds.

Another intriguing question directly related to our hardness of approximation results is whether we can strengthen the inapproximability factors from  $k^{\Omega(1)}$  to  $n^{\Omega(1)}$ . Whether it is hard to approximate Densest  $k$ -Subgraph to within a  $n^{\Omega(1)}$  factor is a well-known open problem and is related to some other conjectures, such as the Sliding-Scaling Conjecture [14]<sup>5</sup>. As such, it would be interesting if one can prove this hardness under some plausible assumption. We remark that an attempt has been made in this direction, using the so-called “Log-Density Threshold” approach [21], which posits a heuristic for predicting which average-case Densest- $k$ -Subgraph problems are hard. The approach has also been applied to other related questions [39, 40, 42]. Nonetheless, there is still little evidence that these average-case DkS problems are indeed hard; not even lower bounds against strong SDP relaxations are known, although there are some matching lower bounds against LP hierarchies [22, 41].

Finally, it is of course interesting to either refute or find more evidence supporting the Strongish Planted Clique Hypothesis. As stated earlier, the current best supporting evidence is the Sum-of-Squares lower bound from [11]. Can such a lower bound be extended to, e.g., rule out any semi-definite programs of size  $n^{o(\log n)}$  (à la [79] for CSPs)?

### 1.4 Other Related Works

Historically, postulating hardness for average-case problems has been helpful in illuminating the landscape for hardness of approximation, beginning with Feige’s seminal random-3-SAT hypothesis [57] and its numerous consequences (e.g. [50]). See also [49, 2, 7, 12].

As discussed briefly above, the Planted Clique Hypothesis (PCH), which states that there is no polynomial-time algorithm for planted clique, has many known consequences for hardness of approximation. We draw attention in particular to the work of [3], which also obtains hardness of approximation results based on PCH. But even assuming the SPCH, their results can only rule out  $n^{\text{polylog}(\kappa)}$ -time algorithms for  $2^{\log(\kappa)^{2/3}}$ -approximating densest- $\kappa$ -subgraph for  $\kappa = n^{\Omega(1)}$ . Their reduction also uses a graph product, but the set of vertices of their new graph  $G'$  contains all  $\ell$ -size subsets of vertices of  $G$ . In contrast, we employ the *randomized* graph product, where we only randomly pick some  $\ell$ -size subsets – this allows us to better control the instance size blowup, which turns out to be crucial for obtaining our tight inapproximability and running time results.

Below we discuss in more detail the previous works for each of the problems studied here.

**Densest  $k$ -Subgraph.** The problem is well-studied in the approximation algorithms literature (e.g. [58, 76, 21]). The best known polynomial time algorithm [21] achieves an approximation ratio of  $O(n^{1/4+\epsilon})$  for any  $\epsilon > 0$ . Even though the NP-hardness of Densest  $k$ -Subgraph follows immediately from that of  $k$ -Clique [74], no NP-hardness of approximation of Densest  $k$ -Subgraph even for a small factor of 1.001 is known. Nonetheless, several hardness of approximation results are known under stronger assumptions [57, 75, 90, 3, 12, 25, 84].

<sup>5</sup> Specifically, from a reduction of [34],  $n^{\Omega(1)}$ -factor hardness of approximation of Densest  $k$ -Subgraph also implies that of the Label Cover problem.

Among these, only [3, 12] and [84] yield super-constant inapproximability ratios. Specifically, [3] rules out  $2^{O((\log n)^{2/3})}$ -approximation in polynomial time under a hypothesis similar to SPCH, [84] rules out  $n^{o(1/\text{poly log log } n)}$ -approximation under ETH, and [12] rules out  $n^{O(1)}$  approximations under a strong conjecture regarding the optimality of semidefinite programs for solving every random CSP.

Our hardness result holds even in the so-called *perfect completeness* case, where we are promised that the graph  $G$  contains a  $k$ -clique. In this case, a quasi-polynomial time approximation scheme exists [60]. Braverman et al. [25] showed that this is tight: there exists a constant  $\epsilon > 0$  for which  $(1 + \epsilon)$ -approximation of Densest  $k$ -Subgraph in the perfect completeness case requires  $n^{\Omega(\log n)}$ -time assuming ETH. We remark that the hardness from [84] also applies in the perfect completeness case, but it only rules out polynomial time algorithms.

For the parameterized version of the problem, its W[1]-hardness follows immediately from that of  $k$ -Clique [54]. Chalermsook et al. [31] showed that no  $k^{o(1)}$ -approximation is achievable in FPT time, unless Gap-ETH is false. This hardness also holds in the perfect completeness case, and yields a running time lower bound of  $n^{\Omega(\log k)}$  for any constant factor approximation.

**$k$ -Biclique.** Similar to Densest  $k$ -Subgraph, while the NP-hardness for the exact version of  $k$ -Biclique has long been known (e.g. [72]), even 1.001-factor NP-hardness of approximation has not yet been proved although inapproximability results under stronger assumptions are known [57, 75, 19, 85]. Specifically, under strengthened variants of the Unique Games Conjecture, the problem is hard to approximate to within a factor of  $n^{1-\epsilon}$  for any  $\epsilon > 0$  [19, 85].

On the parameterized complexity front, whether  $k$ -Biclique is FPT (in  $k$ ) was a well-known open question (see e.g. [55]). This was resolved by Lin [80] who showed that the problem is W[1]-hard and further provided a running time lower bound of  $n^{\Omega(\sqrt{k})}$  under ETH. As stated above, this running time lower bound was extended to rule out any constant factor approximation in [31] under Gap-ETH. Furthermore, [31] showed that no  $o(k)$ -approximation exists in FPT time.

**Smallest  $k$ -Edge Subgraph.** Most of the hardness of approximation for Densest  $k$ -Subgraph easily translates to Smallest  $k$ -Edge Subgraph as well, with a polynomial loss in the factor of approximation. For example, the hardness from [84] implies that Smallest  $k$ -Edge Subgraph cannot be approximated to within a factor of  $n^{1/\text{poly log log } n}$  in polynomial time, assuming ETH. On the other hand, Chlamtac et al. [39] devised an  $O(n^{3-2\sqrt{2}+\epsilon})$ -approximation algorithm for any constant  $\epsilon > 0$  for the problem; this remains the best known approximation algorithm for the problem.

**Densest  $k$ -Subhypergraph.** Apart from the hardness results inherited from Densest  $k$ -Subgraph, not much is known about Densest  $k$ -Subhypergraph. Specifically, the only new hardness is that of Applebaum [6], who showed that the problem is hard to approximate to within  $n^\epsilon$  for some constant  $\epsilon > 0$ , assuming a certain cryptographic assumption; this holds even when each hyperedge has a constant size. On the other hand, the only (non-trivial) approximation algorithm is that of Chlamtac et al. [37] which achieves  $O(n^{0.698})$ -approximation when the hypergraph is 3-uniform.

**Steiner  $k$ -Forest.** The Steiner  $k$ -Forest problem is a generalization of several well-known problems, including the Steiner Tree problem and the  $k$ -Minimum Spanning Tree problem. This problem was first explicitly defined in [67] and subsequently studied in [93, 65, 51].

In terms of the number of vertices  $n$  of the input graph, the best known approximation ratio achievable in polynomial time is  $O(\sqrt{n})$  [65] (assuming that  $k \leq \text{poly}(n)$ ); furthermore, when edge weights are uniform, a better approximation ratio of  $O(n^{0.449})$  is achievable in polynomial time [51]. On the other hand, as stated earlier, in terms of  $k$ , the best known approximation ratio is  $O(\sqrt{k})$  [65].

A reduction in [67] together with W[1]-hardness of  $k$ -Clique [54] implies that Steiner  $k$ -Forest is W[1]-hard with respect to the parameter  $k$ . We are not aware of any further parameterized complexity study of this problem (with respect to parameter  $k$ ).

**Directed Steiner Network.** Several polynomial time approximation algorithms have been proposed for the Directed Steiner Network problem [33, 35, 61, 15, 38, 1]; in terms of the number of vertices  $n$  of the input graph the best known approximation ratio is  $O(n^{2/3+\epsilon})$  [15] and in terms of  $k$  the best known ratio is  $O(k^{1/2+\epsilon})$  for any constant  $\epsilon > 0$  [35, 61]. On the hardness front, Dodis and Khanna [53] shows that the problem is quasi-NP-hard to approximate to within a factor of  $2^{(\log n)^{1-\epsilon}}$  for any constant  $\epsilon > 0$ . Furthermore, Guo et al. [64] show that the exact version of the problem is W[1]-hard with respect to parameter  $k$ . Later, [52] rules out even  $k^{1/4-o(1)}$ -approximation in FPT time, under Gap-ETH.

**Graph Pattern Detection.** As discussed earlier, [48] give ETH-based hardness results for graph pattern detection, both in the induced and non-induced case. The complexity for many special patterns has also been considered, e.g.  $k$ -cliques,  $k$ -bicliques (mentioned above), and  $k$ -cycles (e.g. [5, 97, 47, 48, 81]). A  $k$ -clique can be detected in time  $O(n^{\lceil k/3 \rceil \omega})$  using fast matrix multiplication [89], and the  $k$ -Clique Conjecture in Fine-Grained Complexity postulates that this is essentially optimal [95]. Any other pattern over  $k$  vertices can be detected in time  $O(n^{k-1})$ , without using fast matrix multiplication [24]. There is also an extensive body of work on *counting* the number of occurrences of a pattern in a host graph (e.g. [88, 78, 94, 96, 44, 43]).

## Preliminaries and Notation

For a natural number  $n \in \mathbb{N}$ , we use  $[n]$  to denote the set of integers up to  $n$ ,  $[n] = \{1, \dots, n\}$ . We will use the abbreviation “w.h.p.” to mean “with high probability.”

For an undirected graph  $G = (V, E)$ , we use  $\deg_G(v)$  to denote the degree of a vertex  $v \in V$ , and  $\min\text{-deg}(G)$  to denote  $\min_{v \in V(G)} \deg_G(v)$ . For a subset  $S \subseteq V$ , we use  $G[S] = (V, E[S])$  to denote the induced subgraph of  $G$  on subset  $S$ .

The *density* of  $G$ , denoted by  $\text{den}(G)$ , is defined as  $|E|/|V|$ . We use  $\text{den}_{\leq k}(G)$  to denote  $\max_{S \subseteq V, |S| \leq k} \text{den}(G[S])$ , the maximum density of subgraphs of  $G$  of at most  $k$  vertices.

## 2 Randomized Graph Product

In this section we formally define our reduction, and analyze its soundness and completeness in terms of the reduction parameters (in later sections we instantiate the parameters differently for each target bound). Our reduction takes as input a graph and applies the *randomized graph product* [16], described in Figure 1. We use  $\text{RP}_{N,\ell}(G)$  to denote the distribution of outputs of the above reduction on input graph  $G$ .

We will show that for well-chosen  $N$  and  $\ell$ , the randomized graph product  $\text{RP}_{N,\ell}$  reduces the planted  $n^\delta$ -clique problem to densest- $k$  subgraph for  $k = k(N, \ell, \delta, n)$ . That is, a sample from  $\text{RP}_{N,\ell} \circ \mathcal{G}(n, \frac{1}{2})$  has no dense  $k$ -subgraph with probability close to 1, and if on the other hand  $G$  is a graph with an  $n^\delta$ -clique, then a sample from  $\text{RP}_{N,\ell}(G)$  has a dense  $k$ -subgraphs with probability close to 1.

**Input:**  $n$ -vertex Graph  $G = (V, E)$ , positive integers  $N, \ell$ .  
**Output:** Graph  $G' = (V', E')$ .  
The graph  $G'$  is constructed as follows.

1. For each  $i \in [N]$ , sample  $S_i \subseteq V$  by independently sampling  $\ell$  vertices uniformly from  $V$ .
2. Let  $V' = \{S_1, \dots, S_N\}$ .
3. For every distinct  $i, j \in [N]$ , include  $(S_i, S_j)$  in  $E'$  iff  $S_i \cup S_j$  induces a clique in  $G$ .

■ **Figure 1** Randomized Graph Product [16].

## 2.1 Completeness

We first prove that applying the randomized graph product to a graph with a large clique results in a graph with a large clique.

► **Lemma 4 (Completeness).** *Suppose that  $\delta \in (0, 1)$ ,  $N, \ell, k \in \mathbb{N}$  are such that  $N \geq 10k \cdot n^{(1-\delta)\ell}$  and  $k \geq 20$ . If  $G$  contains a clique of size  $\lceil n^\delta \rceil$ , then*

$$\Pr_{G' \sim \text{RP}_{N, \ell}(G)} [G' \text{ contains a } k\text{-clique}] \geq 0.9.$$

**Proof.** Let  $C \subseteq V$  be the  $\lceil n^\delta \rceil$ -size clique in  $G$ . For each  $i \in [N]$ ,  $\Pr[S_i \subseteq C] = \left(\frac{\lceil n^\delta \rceil}{n}\right)^\ell \geq n^{-(1-\delta)\ell}$ . By our lower bound on  $N$ , the expected number of indices  $i \in [N]$  such that  $S_i \subseteq C$  is at least  $10k$ , and thus a Chernoff bound implies that with probability  $1 - \exp(-4k) \geq 0.9$ , there exists at least  $k$  indices  $i \in [N]$  such that  $S_i \subseteq C$ . By definition of the randomized graph product  $\text{RP}_{N, \ell}$ , these subsets form a clique in  $G'$ . ◀

## 2.2 Soundness

We now prove that if we apply the randomized graph product to a graph drawn from  $\mathcal{G}(n, \frac{1}{2})$ , with high probability the resulting graph has no small subgraphs which are too dense.

► **Lemma 5 (Soundness).** *Suppose that  $\delta \in (0, 1)$ ,  $N, \ell, k \in \mathbb{N}$  are such that  $N \leq 1000k \cdot n^{(1-\delta)\ell}$ ,  $\ell \geq k \geq 20$  and  $n^{0.99\delta} \geq k\ell$ . If  $G$  is drawn from  $\mathcal{G}(n, \frac{1}{2})$ , then*

$$\Pr_{\substack{G \sim \mathcal{G}(n, \frac{1}{2}) \\ G' \sim \text{RP}_{N, \ell}(G)}} \left[ \text{den}_{\leq k}(G') \leq \frac{10^7 \log n}{\ell \delta^2} \right] \geq 0.9.$$

We will use the following observation that allows us to translate a large-density graph to a subgraph with large minimum degree. This observation is folklore and appears e.g. in [32].

► **Observation 6.** *For any  $H = (V_H, G_H)$ , there exists  $S' \subseteq V_H$  such that  $\min\text{-deg}(H[S']) \geq \text{den}(H)$ .*

Another auxiliary lemma that is useful for us is that for any subset  $M \subseteq [N]$  not too large, the size of the union  $|\cup_{j \in M} S_j|$  is not too small relative to  $|M| \cdot \ell$ . This lemma is also standard and has been used in prior works (e.g. [16, 98, 31]).

► **Lemma 7.** *Suppose  $N \leq 1000\ell n^{(1-\delta)\ell}$ ,  $20 \leq \ell$ . Then with probability at least 0.95 over a sample  $G' \sim \text{RP}_{N, \ell} \circ \mathcal{G}(n, \frac{1}{2})$ ,  $G' = (\{S_i\}_{i \in [N]}, E')$ , the following event occurs: for every  $M \subseteq [N]$  with  $|M| \leq n^{0.99\delta}/\ell$ , we have  $|\cup_{i \in M} S_i| \geq 0.01\delta|M|\ell$ .*

## 10:10 The Strongish Planted Clique Hypothesis and Its Consequences

The proofs of both Observation 6 and Lemma 7 are included in the full version. We now prove the soundness guarantee.

**Proof of Lemma 5.** We will assume that the event in Lemma 7 occurs and show that conditioned on this event, under the randomness of  $G$ , with probability 0.95 all  $k$ -subgraphs of  $G'$  have density at most  $d := 10^7 \log n / (\ell \delta^2)$ . Lemma 5 then follows immediately since  $(0.95)^2 > 0.9$ .

Consider any  $J \subseteq [N]$  of size  $k' \leq k$ . For brevity, let  $\mathcal{F}(J)$  denote the set of all graphs whose vertices are  $S_j$  for  $j \in J$  and the minimum degree is at least  $d$ . For each  $F = (\{S_j\}_{j \in J}, E_F) \in \mathcal{F}(J)$ , let  $\mathcal{E}^G(F)$  denote  $\bigcup_{\{S_j, S_{j'}\} \in E_F} \{\{u, v\} \mid u \in S_j, v \in S_{j'} \text{ and } u \neq v\}$ , or in words, the set of edges of  $G$  which have one endpoint in  $S_j$  and one endpoint in  $S_{j'}$  for an edge  $(S_j, S_{j'}) \in E_F$ . Observe that

$$\Pr_G[G'[\{S_j\}_{j \in J}] = F] \leq \Pr_G[\mathcal{E}^G(F) \subseteq E] = 2^{-|\mathcal{E}^G(F)|}, \quad (1)$$

where the inequality follows by definition of the randomized graph product – since  $(S_i, S_j)$  is an edge if and only if  $S_i \cup S_j$  is a clique in  $G$ , the event  $G'[\{S_j\}_{j \in J}] = F$  contains the event  $\mathcal{E}^G(F) \subseteq E$  – and the final equality follows because  $G \sim \mathcal{G}(n, \frac{1}{2})$ . To bound  $|\mathcal{E}^G(F)|$ , let  $\mathcal{V}^G(F) := \bigcup_{j \in J} S_j$ .

Since we have conditioned on the event in Lemma 7 occurring,<sup>6</sup> we have  $|\mathcal{V}^G(F)| \geq 0.01\delta k' \ell$ . Now, consider any  $v \in \mathcal{V}^G(F)$ ; from definition of  $\mathcal{V}^G(F)$ ,  $v \in S_j$  for some  $j \in J$ . Since  $F \in \mathcal{F}(J)$ ,  $S_j$  must have at least  $d$  neighbors in  $F$ . Let  $S_{j_1}, \dots, S_{j_{d'}}$  denote  $S_j$ 's neighbors in  $F$ , with  $d' \geq d$ . By applying the bound in Lemma 7, we have  $|S_{j_1} \cup \dots \cup S_{j_{d'}}| \geq 0.01\delta d' \ell \geq 0.01\delta d \ell$ . In other words,  $v$  has degree at least  $0.01\delta d \ell - 1 \geq 0.005\delta d \ell$  in the graph  $(\mathcal{V}^G(F), \mathcal{E}^G(F))$ . This implies that

$$|\mathcal{E}^G(F)| \geq \frac{1}{2} (0.01\delta k' \ell) (0.005\delta d \ell) \geq 10^{-5} \delta^2 k' d \ell^2.$$

Plugging the above bound back into (1), we have

$$\Pr_G[G'[\{S_j\}_{j \in J}] = F] \leq 2^{-10^{-5} \delta^2 k' d \ell^2} \quad (2)$$

We can use the above inequality to bound the probability that  $\{S_j\}_{j \in J}$  induces a subgraph with minimum degree at least  $d$  as follows:

$$\begin{aligned} \Pr[\min\text{-deg}(G'[\{S_j\}_{j \in J}]) \geq d] &= \sum_{F \in \mathcal{F}(J)} \Pr_G[G'[\{S_j\}_{j \in J}] = F] \stackrel{(2)}{\leq} 2^{(k')^2} \cdot 2^{-10^{-5} \delta^2 k' d \ell^2} \\ &\leq 2^{-10^{-6} \delta^2 k' d \ell^2}. \end{aligned}$$

where the first inequality follows because there are at most  $2^{(k')^2}$  subgraphs of an  $k'$ -vertex graph, and to obtain the final inequality we have applied that  $\ell \geq k \geq k'$  and  $d \geq 10^7 / (\delta^2 \ell)$ .

Applying Observation 6, the existence of a  $k$ -subgraph with density at least  $d$  would imply the existence of some  $J \subseteq [N]$  with  $|J| \leq k$  and minimum degree at least  $d$ . Taking union bound over all  $J \subseteq [N]$  of size at most  $k$  and applying our above bound, we have

$$\Pr[\text{den}_{\leq k}(G)] \leq \sum_{k'=1}^k N^{k'} \cdot 2^{-10^{-6} \delta^2 k' d \ell^2} = \sum_{k'=1}^k \left( N \cdot 2^{-10^{-6} \delta^2 d \ell^2} \right)^{k'}$$

<sup>6</sup> Note that  $|J| = k' \leq k \leq n^{0.99\delta} / \ell$  by our assumption and hence  $J$  satisfies the condition in Lemma 7.

$$\begin{aligned}
&\leq \sum_{k'=1}^k \left( 8 \cdot n \cdot 2^{-10^{-6}\delta^2 d \ell} \right)^{k' \ell} \\
&\leq \sum_{k'=1}^k 0.01^{k' \ell} \leq 0.95,
\end{aligned}$$

where to obtain the second line we use that  $N \leq 1000kn^{(1-\delta)\ell}$  and that  $\ell \geq k \geq 20$ , and in the final line we use that  $d \geq 10^7 \log n / (\ell\delta)^2$ . This completes our proof.  $\blacktriangleleft$

### 3 Tight Running Time Lower Bounds

In this section, we prove our tight running time lower bounds for  $O(1)$ -approximating Densest  $k$ -Subgraph,  $O(1)$ -approximating  $k$ -Biclique and (exact) Graph Pattern Detection.

#### 3.1 Constant Approximation for Densest $k$ -Subgraph

We start with the  $n^{\Omega(k)}$  running time lower bound for  $O(1)$ -approximating Densest  $k$ -Subgraph, from which the remaining results easily follow. We remark that this running time lower bound improves upon that of  $n^{\Omega(\log k)}$ , which is implicit in [31].

**► Theorem 8.** *Assuming Hypothesis 1, for any constant  $C > 0$ , there is no  $f(k) \cdot n^{o(k)}$ -time algorithm that can approximate Densest  $k$ -Subgraph to within a factor  $C$  for any function  $f$ . Furthermore, this holds even in the perfect completeness case where the input graph is promised to contain a  $k$ -clique.*

We will prove Theorem 8 by simply selecting an appropriate setting of parameters for the randomized graph product. Specifically, we will let  $\ell = O(C \log n / k)$  and  $N = n^{O(\ell)} = n^{o(\log n)}$ ; the generic soundness lemma (Lemma 5) then implies that the density of any  $k$ -subgraph in the soundness case is at most  $O(k/C)$  which yields the desired  $C$  inapproximability factor.

**Proof of Theorem 8.** We will reduce the problem of distinguishing samples from  $\mathcal{G}(n, \frac{1}{2})$  vs.  $\mathcal{G}(n, \frac{1}{2}, \lceil n^\delta \rceil)$  to approximating Densest  $k$ -subgraph.

For  $C$  the constant specified in the statement of the theorem, choose  $\ell = \lceil \frac{10^8 C \log n}{\delta^2 k} \rceil$  and  $N = \lceil 100kn^{(1-\delta)\ell} \rceil$ , so that  $d = \frac{10^7 \log n}{\ell \delta^2} \leq \frac{k}{10C}$ . Given a graph  $G$ , we sample  $G' \sim \text{RP}_{N,\ell}(G)$ .

**Completeness:** If  $G \sim \mathcal{G}(n, \frac{1}{2}, \lceil n^\delta \rceil)$ , then by Lemma 4 and since  $N \geq 10kn^{(1-\delta)\ell}$ , we have that with probability at least  $1 - \exp(-4k) \geq 0.9$ ,  $G' = \text{RP}_{N,\ell}(G)$  has a  $k$ -clique, and so  $\text{den}_{\leq k}(G') \geq k - 1$ .

**Soundness:** For any  $20 \leq k \leq \ell$  and any  $\delta$  bounded away from 0, we clearly satisfy the requirement of Lemma 5 that  $k\ell \leq n^{0.99\delta}$  and that  $N \leq 1000kn^{(1-\delta)\ell}$  for any sufficiently large  $n$ . Hence, if  $G \sim \mathcal{G}(n, \frac{1}{2})$ , applying the Lemma to  $G' \sim \text{RP}_{N,\ell}(G)$  we have that with probability at least 0.9,  $\text{den}_{\leq k}(G') \leq d \leq \frac{k}{10C}$ .

Thus, any algorithm which approximates Densest  $k$ -subgraph up to a factor of  $C$  in time  $f(k)N^{\epsilon k}$  can solve the planted  $\lceil n^\delta \rceil$ -clique problem in time  $f(k)(100kn^{(1-\delta)\ell})^{\epsilon k} = g(k)n^{\frac{(1-\delta)\delta^2 C}{10^8} \epsilon \log n}$  for  $g(k) = f(k)(100k)^{\epsilon k}$ . This contradicts Hypothesis 1 whenever  $\lim_{n \rightarrow \infty} \epsilon = 0$ . Choosing  $k$  to be a sufficiently slowly growing function of  $n$ , for any  $\epsilon$  decreasing in  $k$  we have a contradiction of the Hypothesis. This concludes the proof.  $\blacktriangleleft$

### 3.2 $O(1)$ -Approximation for $k$ -Biclique

Recall that a  $k$ -biclique, denoted by  $K_{k,k}$ , is a complete bipartite graph where each side has exactly  $k$  vertices. In the  $k$ -Biclique problem, we are given an undirected graph  $G$  and a positive integer  $k$ . Further, we are promised that  $G$  contains a  $K_{k,k}$  as a subgraph. Our goal is to output a balanced biclique in  $G$  of size as large as possible. (Note that we say that an algorithm achieves  $\alpha$ -approximation if the output biclique has size at least  $k/\alpha$ .)

We prove the following tight running time lower bound for  $O(1)$ -approximation of  $k$ -Biclique:

► **Corollary 9.** *Assuming Hypothesis 1, for any constant  $C > 0$ , there is no  $f(k) \cdot n^{o(k)}$ -time algorithm that can approximate  $k$ -Biclique to within a factor  $C$  for any function  $f$ . Furthermore, this holds even when we are promised that the input graph contains a  $2k$ -clique.*

**Proof.** Suppose contrapositively that there is an  $f(k) \cdot n^{o(k)}$ -time algorithm  $\mathbb{A}$  that can approximate  $k$ -Biclique to within a factor of  $C$  for some function  $f$ . We may use it to approximate Densest  $k$ -Subgraph with perfect completeness as follows. On a given instance  $(G, k)$  of Densest  $k$ -Subgraph with perfect completeness, we run our algorithm  $\mathbb{A}$  on  $(G, \lfloor k/2 \rfloor)$ . From the approximation guarantee of  $\mathbb{A}$ , we will find a  $t$ -Biclique for  $t \geq \lfloor k/2 \rfloor / C \geq \frac{k}{4C}$ . By taking this biclique together with arbitrary  $(k - 2t)$  additional vertices, we find a subset of size  $k$  that induces at least  $t^2 \geq \frac{k^2}{16C^2}$  edges. Hence, we have found a  $16C^2$ -approximation for Densest  $k$ -Subgraph in time  $f(k) \cdot n^{o(k)}$ , which by Theorem 8 violates Hypothesis 1. ◀

### 3.3 Pattern detection

Theorem 8 also yields the following corollary for the running time of pattern detection:

► **Corollary 10.** *Assuming Hypothesis 1, for almost all  $k$ -node patterns  $H$ , the not necessarily induced pattern detection problem cannot be solved in time  $f(k) \cdot n^{o(k)}$ .*

In the statement of Corollary 10, by “almost all  $k$ -node patterns” we mean w.h.p. over  $H \sim \mathcal{G}(k, 1/2)$ .<sup>7</sup>

**Proof.** By standard concentration inequalities, most  $H \sim \mathcal{G}(k, \frac{1}{2})$  have average degree  $\frac{k}{2} \pm o(k)$ . For such a pattern  $H$ , an algorithm that solves the not necessarily induced pattern detection problem also gives  $O(1)$ -approximation for Densest  $k$ -Subgraph. Hence, the corollary immediately follows from Theorem 8. ◀

► **Theorem (Restatement of Theorem 3).** *Assuming the Strongish Planted Clique Hypothesis (Hypothesis 1), for every  $k$ -node pattern  $H$ , there is no algorithm that solves the induced pattern detection problem on  $n$ -vertex graphs in time  $f(k) \cdot n^{o(k)}$  for any function  $f$ .*

**Proof.** We assume that  $H$  is at least  $\frac{k}{4}$ -dense (that is, has average degree at least  $\frac{k}{2}$ ). This is without loss of generality as otherwise, we may take the complement of  $H$  – for induced pattern detection the complexity is the same.

We start our reduction from an instance  $G$  of Densest  $k$ -Subgraph as in Theorem 8. We randomly color all the vertices of  $G$  in  $k$  colors, one for each vertex of  $H$ . We construct a graph  $G'$  from  $G$  by keeping edge  $(u, v) \in G$  if and only if  $u, v$  have different colors, and the vertices in  $H$  corresponding to those colors share an edge. (Note that we do not add any edges.)

<sup>7</sup> It may be more natural to sample uniformly from all *unlabeled*  $k$ -node patterns, but w.h.p. a graph drawn from  $\mathcal{G}(k, 1/2)$  has no non-trivial automorphisms [56], so the two notions of “almost all  $k$ -node patterns” are in fact equivalent.

**Completeness:** If  $G$  has a  $k$ -clique, with probability at least  $k^{-k}$  it has  $k$  different colors. In this case, the same vertices in  $G'$  will form an induced copy of  $H$ .

**Soundness:** If  $G$  does not have a  $\frac{k}{4}$ -dense  $k$ -subgraph, this remains true after removing edges.

Hence  $G'$  also does not contain any  $\frac{k}{4}$ -dense  $k$ -subgraph – and in particular no copy of  $H$ . As a result, if we can solve the induced pattern detection problem in time  $f(k) \cdot n^{o(k)}$ , we can achieve 4-approximation for Densest  $k$ -Subgraph with probability  $k^{-k}$  in time  $f(k) \cdot n^{o(k)}$ . By repeating this construction  $100 \cdot k^k$  times, we can achieve 4-approximation for Densest  $k$ -Subgraph with probability 0.99 in time  $O(f(k) \cdot k^k) \cdot n^{o(k)}$ . Together with Theorem 8, this concludes our proof. ◀

## 4 Tight Inapproximability Results

In this section, we prove tight inapproximability results for Densest  $k$ -Subgraph, Smallest  $k$ -Edge Subgraph, Steiner  $k$ -Forest, Directed Steiner Network, and Densest  $k$ -Subhypergraph.

### 4.1 Densest $k$ -Subgraph

We start with the  $o(k)$ -factor hardness of Densest  $k$ -Subgraph (Theorem 2), from which our other results follow. The proof of Theorem 2 is once again via selecting an appropriate setting of parameters for the randomized graph product. Specifically, we will select  $\ell = O((\log n) \cdot g(k)/k)$  where  $g(k) = o(k)$  is the assumed approximation ratio and  $N = n^{O(\ell)} = n^{o(\log n)}$ ; the generic soundness lemma (Lemma 5) then implies that the density of any  $k$ -vertex subgraph in the soundness case is at most  $k/g(k)$  as desired. The arguments are formalized below.

**Proof of Theorem 2.** We will reduce the problem of distinguishing samples from  $\mathcal{G}(n, \frac{1}{2})$  vs.  $\mathcal{G}(n, \frac{1}{2}, \lceil n^\delta \rceil)$  to approximating Densest  $k$ -subgraph on an  $N$  vertex graph.

Let  $g(k) \leq k$  be any function growing with  $k$ . Choose  $\ell = \lceil \frac{10^8 g(k) \log n}{\delta^2 k} \rceil$  and  $N = \lceil 100kn^{(1-\delta)\ell} \rceil$ , so that  $d = \frac{10^7 \log n}{\ell \delta^2} \leq \frac{k}{10g(k)}$ . Given a graph  $G$ , we sample  $G' \sim \text{RP}_{N,\ell}(G)$ .

**Completeness:** If  $G \sim \mathcal{G}(n, \frac{1}{2}, \lceil n^\delta \rceil)$ , then just as in the proof of Theorem 8, Lemma 4 implies that with probability at least 0.9,  $G' = \text{RP}_{N,\ell}(G)$  has a  $k$ -clique.

**Soundness:** For any  $20 \leq k \leq \ell$  and  $\delta$  bounded away from 0, we satisfy the requirements of Lemma 5 (just as in the proof of Theorem 8). Applying the lemma, if  $G \sim \mathcal{G}(n, \frac{1}{2})$ , we conclude that with probability at least 0.9,  $\text{den}_{\leq k}(G') \leq d \leq \frac{k}{10g(k)}$ . This means that

any  $k$ -vertex subgraph of  $G'$  contains at most  $\frac{k^2}{10g(k)} < \frac{\binom{k}{2}}{g(k)}$  edges.

Hence, any algorithm which approximates Densest  $k$ -subgraph within  $g(k)$  in time  $f(k)\text{poly}(N)$  can solve the planted  $\lceil n^\delta \rceil$ -clique problem in time  $f(k) \cdot \text{poly}(100kn^{(1-\delta)\ell}) = h(k) \cdot \text{poly}\left(n^{\frac{(1-\delta)\delta^2}{10^8} \frac{g(k)}{k} \log n}\right)$  for  $h(k) = f(k)\text{poly}(100k)$ . Choosing  $k$  to be a sufficiently slowly growing function of  $n$ , for any function  $g(k)$  with  $\lim_{n \rightarrow 0} \frac{g(k)}{k} = 0$  we have a contradiction of Hypothesis 1, as desired. ◀

### 4.2 Smallest $k$ -Edge Subgraph

► **Corollary 11.** *Assuming Hypothesis 1, there is no  $f(k) \cdot \text{poly}(n)$ -time algorithm that can approximate Smallest  $k$ -Edge Subgraph to within a factor  $o(\sqrt{k})$  for any function  $f$ .*

We prove the above corollary by reducing from Densest  $k$ -Subgraph; we remark here that similar reductions between the two problems are folklore and have appeared before in literature, e.g. in [67]. Hence, we defer the proof to the full version of the paper.

### 4.3 Steiner $k$ -Forest

► **Corollary 12.** *Assuming Hypothesis 1, there is no  $f(k) \cdot \text{poly}(n)$ -time algorithm that can approximate Steiner  $k$ -Forest to within a factor  $o(\sqrt{k})$  for any function  $f$ .*

Corollary 12 immediately follows from Corollary 11 via the following reduction:

► **Theorem 13** ([67, Theorem 6.2]). *If there is an  $f(k) \cdot \text{poly}(n)$ -time  $g(k)$ -approximation algorithm for Steiner  $k$ -Forest, then there is an  $f(k) \cdot \text{poly}(n)$ -time  $g(k)$ -approximation algorithm for Smallest  $k$ -Edge Subgraph.*

### 4.4 Directed Steiner Network

► **Corollary 14.** *Assuming Hypothesis 1, there is no  $f(k) \cdot \text{poly}(n)$ -time algorithm that can approximate Directed Steiner Network with  $k$  terminal pairs to within a factor  $o(\sqrt{k})$  for any function  $f$ .*

Corollary 14 is shown via a reduction from Smallest  $p$ -Edge Subgraph, which is similar to the reduction from the Label Cover problem by Dodis and Khanna [53] that was also used in subsequent works [36, 52]. The proof is deferred to the full version.

### 4.5 Densest $k$ -Subhypergraph

► **Theorem 15.** *Assuming Hypothesis 1, there is no  $f(k) \cdot \text{poly}(n)$ -time algorithm that can approximate Densest  $k$ -Subhypergraph to within a factor  $2^{o(k)}$  for any function  $f$ .*

The proof of our inapproximability for Densest  $k$ -Subhypergraph (Theorem 15) is unlike the others in this section: instead of starting from the inapproximability of Densest  $k$ -Subgraph (Theorem 2), we will start from the tight running time lower bound for  $O(1)$ -approximate  $k$ -Biclique (Corollary 9).

#### 4.5.1 A Combinatorial Lemma

Before we describe our reduction, let us prove the following lemma, which bounds the number of (induced) copies of  $K_{\ell,\ell}$  in a  $K_{t,t}$ -free graph for  $\ell < t$ . This is a generalized setting of the classic Kovari-Sos-Turan (KST) theorem [77], which applies only to the case  $\ell = 1$ . Note that, due to the parameters of interest in our reduction, we only prove a good bound for large  $\ell$ ; for  $\ell = 1$ , the bound in our lemma is trivial (and hence weaker than the KST theorem).

► **Lemma 16.** *Let  $\kappa, t, \ell$  be positive integers such that  $\ell < t \leq \kappa/16$ . Then, for any  $\kappa$ -vertex  $K_{t,t}$ -free graph  $H$ , the number of (not necessarily induced) copies of  $K_{\ell,\ell}$  in  $H$  is at most  $\left(2 \cdot e^{-\frac{\ell^2}{16t}}\right) \cdot \binom{\kappa}{\ell} \binom{\kappa-\ell}{\ell}$ .*

**Proof.** Let  $V$  denote the vertex set of  $H$ . We will count the number of copies of  $K_{\ell,t}$  in  $H$  in two ways. First, for every subset  $S \in \binom{V}{\ell}$ , the number of  $(\ell, t)$ -bicliques of the form  $(S, T)$  where  $T \in \binom{V}{t}$  is  $\binom{|N(S)|}{t}$  where  $N(S)$  denote the set of common neighbors of  $S$ . Hence, in total the number of  $(\ell, t)$ -bicliques in  $H$  is  $\sum_{S \in \binom{V}{\ell}} \binom{|N(S)|}{t}$ . On the other hand, for every set  $T \in \binom{V}{t}$ , we must have  $|N(T)| \leq t - 1$  since  $H$  does not contain  $K_{t,t}$ . As a result, the number of  $(\ell, t)$ -bicliques of the form  $(S, T)$  for a fixed  $T$  is at most  $\binom{t-1}{\ell}$ . That is, in total, there can be at most  $\binom{\kappa}{t} \binom{t-1}{\ell}$  copies of  $K_{\ell,t}$  in the graph. This implies that

$$\binom{\kappa}{t} \binom{t-1}{\ell} \geq \sum_{S \in \binom{V}{\ell}} \binom{|N(S)|}{t}. \quad (3)$$

For brevity, let  $\lambda$  denote  $(\kappa - \ell)/t$ ,  $\gamma$  denote  $\lambda^{-\ell/(2t)}$  and let  $x$  denote  $\gamma \cdot \kappa + (1 - \gamma) \cdot t$  (note  $x$  is chosen so that  $\frac{x-t}{\kappa-t} = \gamma$ ). Let us now classify  $S \in \binom{V}{\ell}$  into two groups: those with  $|N(S)| \geq x$  and those with  $|N(S)| < x$ . That is, we define

$$\mathcal{S}_{\geq x} := \left\{ S \in \binom{V}{\ell} \mid |N(S)| \geq x \right\}, \quad \text{and} \quad \mathcal{S}_{< x} := \left\{ S \in \binom{V}{\ell} \mid |N(S)| < x \right\}.$$

From (3), we have  $\binom{\kappa}{t} \binom{t-1}{\ell} \geq \sum_{S \in \mathcal{S}_{\geq x}} \binom{|N(S)|}{t} \geq |\mathcal{S}_{\geq x}| \cdot \binom{\lceil x \rceil}{t}$ . Rearranging, we have

$$\begin{aligned} |\mathcal{S}_{\geq x}| &\leq \frac{\binom{t-1}{\ell} \binom{\kappa}{t}}{\binom{\lceil x \rceil}{t}} \leq \binom{t-1}{\ell} \left( \frac{\kappa-t}{x-t} \right)^t = \binom{t-1}{\ell} \gamma^{-t} \leq \binom{\kappa}{\ell} \left( \frac{t-1}{\kappa} \right)^\ell \gamma^{-t} \\ &\leq \binom{\kappa}{\ell} \lambda^{-\ell} \gamma^{-t} \\ &= \binom{\kappa}{\ell} \lambda^{-\ell/2} \leq \binom{\kappa}{\ell} 2^{-\ell/2}, \end{aligned} \quad (4)$$

where the last line follows because  $t, \ell \leq \frac{1}{3}\kappa$ .

Let us now count the number of  $K_{\ell, \ell}$  in  $H$ . For each fixed  $S \in \binom{V}{\ell}$ , the number of  $K_{\ell, \ell}$  of the form  $(S, T)$  where  $T \in \binom{V}{\ell}$  is exactly  $\binom{|N(S)|}{\ell}$ . Thus, the total number of  $K_{\ell, \ell}$  in  $G$  is  $\sum_{S \in \binom{V}{\ell}} \binom{|N(S)|}{\ell}$ . This term can be further bounded by

$$\begin{aligned} \sum_{S \in \binom{V}{\ell}} \binom{|N(S)|}{\ell} &= \sum_{S \in \mathcal{S}_{\geq x}} \binom{|N(S)|}{\ell} + \sum_{S \in \mathcal{S}_{< x}} \binom{|N(S)|}{\ell} \\ &\leq |\mathcal{S}_{\geq x}| \binom{\kappa - \ell}{\ell} + |\mathcal{S}_{< x}| \binom{x}{\ell} \\ &\stackrel{(4)}{\leq} 2^{-\ell/2} \binom{\kappa}{\ell} \binom{\kappa - \ell}{\ell} + \binom{\kappa}{\ell} \binom{\lfloor x \rfloor}{\ell} \\ &\leq 2^{-\ell/2} \binom{\kappa}{\ell} \binom{\kappa - \ell}{\ell} + \binom{\kappa}{\ell} \binom{\kappa - \ell}{\ell} \cdot \left( \frac{x}{\kappa - \ell} \right)^\ell \\ &\leq 2^{-\ell/2} \binom{\kappa}{\ell} \binom{\kappa - \ell}{\ell} + \binom{\kappa}{\ell} \binom{\kappa - \ell}{\ell} \cdot \left( 1 - \frac{(1 - \gamma)(\kappa - t) - \ell}{\kappa - \ell} \right)^\ell \\ &= 2^{-\ell/2} \binom{\kappa}{\ell} \binom{\kappa - \ell}{\ell} + \binom{\kappa}{\ell} \binom{\kappa - \ell}{\ell} \cdot \left( 1 - \frac{(1 - \gamma - \frac{\ell}{\kappa - t})(\kappa - t)}{\kappa - \ell} \right)^\ell \\ (\text{From } \ell < t \leq \kappa/2) &\leq 2^{-\ell/2} \binom{\kappa}{\ell} \binom{\kappa - \ell}{\ell} + \binom{\kappa}{\ell} \binom{\kappa - \ell}{\ell} \cdot (1 - 0.5(1 - \gamma - 2\ell/\kappa))^\ell \\ &\leq 2^{-\ell/2} \binom{\kappa}{\ell} \binom{\kappa - \ell}{\ell} + \binom{\kappa}{\ell} \binom{\kappa - \ell}{\ell} \cdot e^{-0.5\ell(1 - \gamma - 2\ell/\kappa)} \end{aligned} \quad (5)$$

Consider the term  $(1 - \gamma - 2\ell/\kappa)$ . We can bound it as follows:

$$\begin{aligned} (1 - \gamma - 2\ell/\kappa) &= \left( 1 - \frac{1}{\lambda^{\ell/2t}} - \frac{2\ell}{\kappa} \right) \\ (\text{From } \lambda = (\kappa - \ell)/t \geq 2) &\geq \left( 1 - 0.5^{\ell/2t} - \frac{2\ell}{\kappa} \right) \\ (\text{Bernoulli inequality}) &\geq \left( 1 - \left( 1 - \frac{\ell}{4t} \right) - \frac{2\ell}{\kappa} \right) = \left( \frac{\ell}{4t} - \frac{2\ell}{\kappa} \right) \geq \frac{\ell}{8t}. \end{aligned}$$

Plugging this back into (5), we have

$$\sum_{S \in \binom{A}{\ell}} \binom{|N(S)|}{\ell} \leq \binom{\kappa}{\ell} \binom{\kappa - \ell}{\ell} \cdot \left(2^{-\ell/2} + e^{-\frac{\ell^2}{16t}}\right) \stackrel{(\text{From } \ell < t)}{\leq} \binom{\kappa}{\ell} \binom{\kappa - \ell}{\ell} \cdot \left(2 \cdot e^{-\frac{\ell^2}{16t}}\right),$$

which concludes our proof.  $\blacktriangleleft$

#### 4.5.2 Proof of Theorem 15

**Proof of Theorem 15.** Suppose contrapositively that there is an  $f(\rho) \cdot \text{poly}(n)$ -time  $2^{\rho/g(\rho)}$ -approximation algorithm  $\mathbb{A}$  for Densest  $\rho$ -Subhypergraph where  $g = \omega(1)$ . We will construct an algorithm  $\mathbb{B}$  that achieves  $O(1)$ -approximation for  $k$ -Biclique with the promise that a  $2k$ -Clique exists in time  $h(k) \cdot n^{o(k)}$  for some function  $h$ . Theorem 15 then follows from Corollary 9.

We define  $\mathbb{B}$  on input  $(G = (V, E), k)$  as follows:

- Let  $\rho = 2k$  and  $\ell = \lceil \rho/g(\rho)^{0.1} \rceil$ .
- Construct a hypergraph  $G'$  with the same vertex set as  $G$ , and we add a hyperedge  $e = \{u_1, \dots, u_{2\ell}\}$  to  $G'$  for all distinct  $u_1, \dots, u_{2\ell} \in V$  that induce a  $2\ell$ -clique in  $G$ .
- Run  $\mathbb{A}$  on  $(G', \rho)$ . Let  $S$  be  $\mathbb{A}$ 's output.
- Use brute force to find a maximum balanced biclique in  $S$  and output it.

Notice that algorithm  $\mathbb{B}$  runs in time  $(f(2k) + 2^{O(k)}) \cdot n^{O(\ell)} = (f(2k) + 2^{O(k)}) \cdot n^{o(k)}$  as desired, where the term  $2^{O(k)}$  comes from the last step.

Next, we claim that, when  $k$  is sufficiently large, the output biclique has size at least  $t := \lfloor k/8 \rfloor$ , which would give us the desired  $O(1)$ -approximation ratio. Suppose for the sake of contradiction that this is not true, i.e. that the induced graph  $G[S]$  is  $K_{t,t}$ -free.

For any sufficiently large  $k$ , we have  $\ell < t$ . Hence, we may apply Lemma 16, which gives the following upper bound on the number of not-necessarily induced copies of  $K_{\ell,\ell}$  in  $G[S]$ :

$$\left(2 \cdot e^{-\frac{\ell^2}{16t}}\right) \cdot \binom{2k}{\ell} \binom{2k - \ell}{\ell} \leq e^{-\Omega(k/g(k)^{0.2})} \cdot \binom{2k}{\ell} \binom{2k - \ell}{\ell}.$$

However, since each hyperedge  $e = \{u_1, \dots, u_{2\ell}\}$  corresponds to  $\binom{2\ell}{\ell}$  copies of  $K_{\ell,\ell}$ , the number of hyperedges fully contained in  $S$  is thus at most

$$e^{-\Omega(k/g(k)^{0.2})} \cdot \binom{2k}{\ell} \binom{2k - \ell}{\ell} / \binom{2\ell}{\ell} = e^{-\Omega(k/g(k)^{0.2})} \cdot \binom{2k}{2\ell},$$

which is less than  $2^{-\rho/g(\rho)} \cdot \binom{2k}{2\ell}$  for any sufficiently large  $k$ . This contradicts the approximation guarantee of  $\mathbb{A}$  since the optimal solution (i.e. the  $2k$ -clique) contains  $\binom{2k}{2\ell}$  hyperedges.  $\blacktriangleleft$

---

## Abstract

In this paper, we study the quantum identity testing problem, i.e., testing whether two given quantum states are identical, and quantum independence testing problem, i.e., testing whether a given multipartite quantum state is in tensor product form. For the quantum identity testing problem of  $\mathcal{D}(\mathbb{C}^d)$  system, we provide a deterministic measurement scheme that uses  $\mathcal{O}(\frac{d^2}{\epsilon^2})$  copies via independent measurements with  $d$  being the dimension of the state and  $\epsilon$  being the additive error. For the independence testing problem  $\mathcal{D}(\mathbb{C}^{d_1} \otimes \mathbb{C}^{d_2} \otimes \dots \otimes \mathbb{C}^{d_m})$  system, we show that the sample complexity is  $\tilde{\Theta}(\frac{\sum_{i=1}^m d_i}{\epsilon^2})$  via collective measurements, and  $\mathcal{O}(\frac{\sum_{i=1}^m d_i^2}{\epsilon^2})$  via independent measurements. If randomized choice of independent measurements are allowed, the sample complexity is  $\Theta(\frac{d^{3/2}}{\epsilon^2})$  for the quantum identity testing problem, and  $\tilde{\Theta}(\frac{\sum_{i=1}^m d_i^{3/2}}{\epsilon^2})$  for the quantum independence testing problem.

We are grateful for the reviewer to point out that using random independent measurement can provide a tight bound for quantum state certification.

## 1 Introduction

### 1.1 Classical Property Testing

The ability to test whether an unknown object satisfies a hypothetical model based on observed data plays a particularly important role in science [50]. Initially proposed by Rubinfeld and Sudan [60, 61] to test algebraic properties of polynomials, the concept of property testing has been extended to many objects of computer science: graphs, Boolean functions, and so on [41, 40]. Property testing and distribution testing are intricately connected. At the beginning of this century, Batu *et al.* introduced the problem of testing properties associated with discrete probability distributions [14, 15]. In other words, how many samples from a collection of probability distributions are needed to determine whether those distributions satisfy a particular property with high confidence? Over the past two decades, this area has become an extremely well-studied and successful branch of property testing due in part to

the ongoing data science revolution. Never have computationally-efficient algorithms, a.k.a., testers, that can identify and/or classify properties using as few samples as possible been in higher demand.

A direct approach to distribution property testing is to reconstruct the given distributions from sufficiently many samples. It is well known that, after taking  $\Theta(\epsilon^{-2} \cdot d)$  samples from a  $d$ -dimensional probability distribution  $p$ , the empirical distribution is, with high probability,  $\epsilon$ -close to  $p$  in total variance distance [29, pages 10 and 31]. Therefore, finding algorithms that use  $o(d)$  samples for testing problems is highly desirable. Surprisingly, algorithms using less number of samples than  $\Theta(\epsilon^{-2} \cdot d)$  exist for many important properties.

The equality, or identity, of distributions is a central problem in this branch of study, and one that is frequently revisited with different approaches due to its importance. In an important work [40], Goldreich and Ron found that the  $\ell_2$  norm can be estimated from  $O(\epsilon^{-2} \cdot \sqrt{d})$  samples. This led to an algorithm for uniformity testing, *i.e.*, to determine whether a probability distribution is a uniform using  $O(\epsilon^{-4} \cdot \sqrt{d})$  samples. Paninski [58] and Valiant and Valiant [63] showed that the complexity of uniformity is  $\Theta(\epsilon^{-2} \cdot \sqrt{d})$ . If one distribution is an arbitrary known distribution, Batu *et al.* [14, 13] presented an  $\ell_2$ -identity tester and used it to build an  $\ell_1$  estimator using  $O(\epsilon^{-2} \cdot \sqrt{d} \log d)$  samples; later in [65], Valiant and Valiant showed the sample complexity of this problem is  $\Theta(\epsilon^{-2} \cdot \sqrt{d})$ . If both distributions are unknown, Batu *et al.* provided a tester in [14] using  $O(\epsilon^{-8/3} \cdot d^{2/3} \log d)$  samples; In 2014, Chan *et al.*, in [23], showed the complexity of the identity testing is  $\Theta(\max(\epsilon^{-2} \cdot \sqrt{d}, \epsilon^{-4/3} \cdot d^{2/3}))$ .

The idea of identity testing has been extensively explored in studying other property testing problems. Independence testing and conditional independence testing are among the most important ones. In [13], Batu *et al* presented an independence tester for bipartite independence testing over  $[d_1] \times [d_2]$  with a sample complexity of  $\tilde{O}(d_1^{2/3} d_2^{1/3}) \cdot \text{Poly}(\epsilon^{-1})$ , for  $d_1 \geq d_2$ . Levi, Ron and Rubinfeld in [51] showed a lower bound  $\Omega(\sqrt{d_1 d_2})$  for all  $d_1 \geq d_2$  and  $\Omega(d_1^{2/3} d_2^{1/3})$  for  $d_1 = \Omega(d_2 \log d_2)$ . Acharya *et al.* [6] introduced a tester for multipartite independence testing over  $\times_{j=1}^m [d_j]$  with sample complexity  $O(\epsilon^{-2} \cdot \sqrt{\prod_{j=1}^m d_j} + \epsilon^{-2} \cdot \sum_{j=1}^m d_j)$ . In their important work [31], Diakonikolas and Kane demonstrated a unified approach to resolve the sample complexity of a wide variety of testing problems based on their alternative proof for identity testing. In particular, they showed that the sample complexity of independence testing is  $\Theta(\max_k \{\epsilon^{-2} \sqrt{\prod_{j=1}^m d_j}, \epsilon^{-4/3} \cdot d_k^{2/3} \cdot \prod_{j=1}^m d_j^{1/3}\})$ . Canonne *et al.* [22] initiated the study of the conditional independence within property testing framework. Notably, for the very important  $[2] \times [2] \times [n]$ , they showed that the sample complexity for this problem is  $\Theta(\max\{\epsilon^{-2} \cdot \sqrt{n}, \min\{\epsilon^{-1} \cdot n^{7/8}, \epsilon^{-8/7} \cdot n^{6/7}\}\})$ .

Besides the mentioned works, a very incomplete list of works of distributional property testing includes [12, 15, 68, 5, 64, 51, 46, 26, 32, 48, 66, 70, 30, 67, 28, 39, 33, 7, 21, 27, 34, 24], and two excellent surveys include more [59, 20].

## 1.2 Quantum Property Testing

Quantum property testing has been extensively studied. At this stage of development of quantum computation, testing the properties of new devices as they are built is a basic problem as illustrated in Montanaro and de Wolf's comprehensive survey [53]. A standard quantum device outputs some known  $d$ -dimensional (mixed) state  $\sigma \in \mathcal{D}(\mathbb{C}^d)$  but inevitably, the results are noisy such that the actual output state  $\rho \in \mathcal{D}(\mathbb{C}^d)$  is not equal  $\sigma$ , maybe not even close to. Similar to property testing with classical distributions, properties of  $\rho$  need to be verified by accessing the device, say,  $m$  times, to derive  $\rho^{\otimes m}$ .

Starting from the very basic problem of quantum state tomography, a fundamental problem is to decide how many copies of an unknown mixed quantum state  $\rho \in \mathcal{D}(\mathbb{C}^d)$  is necessary and sufficient to output a good approximation of  $\rho$  in trace distance, with high probability. This problem has been studied extensively since the birth of quantum information theory. The main-stream approach is through independent measurement, i.e., measurement on each copy of the state. A sequence of work [42, 36, 69, 49] is dedicated to showing that  $O(\epsilon^{-2} \cdot d^3)$  copies are sufficient in an  $\ell_1$  distance of no more than  $\epsilon$ . Haah *et al.* [44] showed that this is tight for independent measurement. For joint measurement, Haah *et al.* [44] proved that  $O(\epsilon^{-1} \cdot d^2 \log(\epsilon^{-1} \cdot d))$  copies are sufficient to obtain an infidelity of no more than  $\epsilon$ , which can be regarded as a quantum generalization of Sanov's theorem [62]. By combining the lower bound of [44] and upper bound of [56, 57], the sample complexity of state tomography with joint measurement is  $\tilde{\Theta}(\epsilon^{-2} \cdot d^2)$  in a  $\ell_1$  distance error of less than  $\epsilon$  with high probability.

A more direct approach to quantum property testing is to estimate  $\rho$  by sampling from  $\rho^{\otimes m}$ , which also means one could check any property of interest. However, like classical property testing, this idea is not optimal for a general property. One problem that has received much attention is quantum identity testing. Suppose we are given query access to two states  $\rho, \sigma \in \mathcal{D}(\mathbb{C}^d)$ , and we want to test whether they are equal or have a large  $\ell_1$  distance. For practical purposes, the results from cases where  $\sigma$  is a known pure state have been extensively studied, in the independent measurement setting [37, 25, 10]. [55] solved the problem, in the joint measurement setting, where  $\sigma$  is a maximally mixed state case by showing that  $\Theta(\epsilon^{-2} \cdot d)$  copies are necessary and sufficient. Importantly, the sample complexity of the general problem was proven to be  $\Theta(\epsilon^{-2} \cdot d)$  in [18] by providing an efficient  $\ell_2$  distance estimator between two unknown quantum states.

In [4], Aaronson initialized the study of the learnability of quantum state, whose goal is to output good estimations of a set of measurements simultaneously. In [1], Aaronson provided an efficient procedure of the quantum shadow tomography. A connection between quantum learning and differential privacy was established in [3]. In [2], the online learning of quantum states was studied.

Entanglement is a ubiquitous phenomenon in quantum information theory. A multipartite pure state  $|\psi\rangle \in (\mathbb{C}^d)^{\otimes m}$  is not entangled if it can be written as  $|\psi\rangle = \bigotimes_{j=1}^m |\psi_j\rangle$  for some  $|\psi_j\rangle \in \mathbb{C}^d$ . Pure entanglement testing was first discussed by Mintert *et al.* [52]. Harrow and Montanaro [45] subsequently proved that  $O(\epsilon^{-2})$  copies are sufficient and used that to study the quantum complexity theory. In [17], it was proved that  $\Omega(d^2/\epsilon^2)$  copies are necessary to test separability of quantum states in  $\mathbb{C}^d \otimes \mathbb{C}^d$  for not small  $\epsilon$ .

Acharya *et al.* [8] estimated the von Neumann entropy of general quantum states. Gross *et al.* [43] showed that “stabilizerness” can be tested efficiently. One research direction is to study the potential speed-up of distributional property testing using quantum algorithms where the distribution is given in the form of a quantum oracle [16, 38].

### 1.3 Measurement Schemes

A significant difference between quantum property testing and classical property testing is the way the objects are sampled. In classical property testing, each sample is output with a classical index according to the probability distribution and given a fixed number of samples, the output string obeys the product probability distribution. However, with quantum property testing, the sampling methods have much richer structures. This difference together with others prevents the potential to design algorithms for quantum property testing from ingenious ideas and techniques of distribution testing.

Measurement	Complexity	Dimension	Implementation
Joint	Low	$d^m$	Hard even in the future
Independent	Medium	$d$	Available in the future

Among the many available sampling methods for quantum property testing (given a fixed number of copies, says  $k$ , of the states  $\rho \in \mathcal{D}(\mathbb{C}^d)$ ), the two listed in Table 1 are of particular interests, i.e., joint measurement, and independent measurement. Joint measurement, the most general, allows arbitrary measurements of  $\mathbb{C}^{d^m}$ . Independent measurement only allows non-adaptive measurements on each copy of  $\rho$ , which results in,  $n$  measurements of  $\mathbb{C}^d$ .

Joint measurement has the potential to provide the optimal number of samples, but there are two caveats. “Optimal” joint measurement algorithms usually require an *exponential* number of copies of the quantum state to produce optimal results. They are also based on the assumption of noiseless, universal quantum computation on the *exponential* number of copies of the quantum state. For instance, the optimal tomography algorithms of  $k$ -qubit quantum state in [44, 56, 57] require a joint measurement on  $\Theta(\epsilon^{-2} \cdot k 2^{2k})$  qubits. Even in the future when quantum computers become a reality, implementing optimal joint measurement would be extremely hard given these conditions. General independent measurements are not feasible with currently-available technology. To implement a two-outcome measurement on the  $k$ -qubit system, one needs to implement a  $k + 1$  qubit unitary. Implementing a general  $k + 1$  qubit unitary requires a circuit consisting of at least  $\Omega(4^k)$  elementary gates, which could also be hard.

In this paper, we study the quantum identity testing problem, i.e., testing whether two given quantum states are identical, and the quantum independence testing problem, i.e., testing whether a given multipartite quantum state is in tensor product form. For the quantum identity testing problem of  $\mathcal{D}(\mathbb{C}^d)$  system, we provide a measurement scheme that uses  $\mathcal{O}(\frac{d^2}{\epsilon^2})$  copies via independent measurements with  $d$  being the dimension of the state and  $\epsilon$  being the additive error. For the independence testing problem  $\mathcal{D}(\mathbb{C}_1^d \otimes \mathbb{C}^{d_2} \otimes \dots \otimes \mathbb{C}^{d_m})$  system, we show that the sample complexity is  $\tilde{\Theta}(\frac{\sum_{i=1}^m d_i}{\epsilon^2})$  via collective measurements, and  $\mathcal{O}(\frac{\sum_{i=1}^m d_i^2}{\epsilon^2})$  via independent measurements. Further, we initialize the study of the property testing problems of classical-quantum states, motivated by the potential applications of classical-quantum states. Our main tool is a measurement that “preserves” the  $\ell_2$  distance, which invokes an immediate connection between quantum and classical property testing.

## 1.4 Our contributions

Identify whether two quantum states are equal or not is called *quantum identity testing problem*.

► **Problem 1.** *Given two unknown quantum mixed states  $\rho, \sigma \in \mathcal{D}(\mathbb{C}^d)$ , they satisfy either  $\rho = \sigma$  or  $\|\rho - \sigma\|_1 > \epsilon$  for a given  $\epsilon > 0$ . How many copies of  $\rho$  and  $\sigma$  are needed to distinguish these two cases, with high probability?*

This problem under joint measurement setting is solved in [18]. In this paper, we study this problem using independent measurement. To reach this goal, we observe the following lemma. It maintains interesting relations between the  $\ell_2$  distance of quantum states and the  $\ell_2$  distance of the generated corresponding probability distributions. Given that  $\ell_2$  distance plays a central role in classical property testing [31], our approach invokes an immediate connection between quantum and classical property testing. Previous research into quantum property testing has always been in isolation of classical property testing, whereas this scheme

opens up the potential to design quantum property tester from ingenious ideas and techniques of distribution testing. Further, this is a fixed measurement scheme that does not depend on the property to be tested, which makes our algorithms a perfect fit for implementation with current experiments.

► **Lemma 2.** *For  $d$  being power of 2, there is a measurement*

$$\mathcal{M} = (M_1, M_2, \dots, M_{d(d+1)}) : \mathcal{D}(\mathbb{C}^d) \mapsto \Delta(d(d+1))$$

*whose outcome lies in  $\Delta(d(d+1))$ , the  $d(d+1)$ -dimensional probability simplex, such that, for any quantum states  $\rho, \sigma \in \mathcal{D}(\mathbb{C}^d)$*

$$\|p - q\|_2 = \frac{\|\rho - \sigma\|_2}{d+1}, \quad \|p\|_2, \|q\|_2 \leq \frac{\sqrt{2}}{d+1}, \quad (1)$$

*where  $p = (p_1, p_2, \dots, p_{d(d+1)})$  and  $q = (q_1, q_2, \dots, q_{d(d+1)})$  with  $p_i = \text{Tr}(\rho M_i)$  and  $q_i = \text{Tr}(\sigma M_i)$ .*

We employ mutually unbiased bases (MUB) to construct such measurement. MUB in Hilbert space  $\mathbb{C}^d$  are two orthonormal bases  $\{|e_1\rangle, \dots, |e_d\rangle\}$  and  $\{|f_1\rangle, \dots, |f_d\rangle\}$  such that the square of the magnitude of the inner product between any basis states  $|e_j\rangle$  and  $|f_k\rangle$  equals the inverse of the dimension  $d$ . These bases are unbiased in the following sense: if a system is prepared in a state belonging to one of the bases, then all outcomes of the measurement with respect to the other basis are predicted to occur with equal probability.

For  $d = 2^n$ , there are  $2^n + 1$  mutually unbiased bases in  $\mathbb{C}^d$ . Therefore, the density matrices of these MUBs form a linear basis of  $\mathcal{D}(\mathbb{C}^d)$  in this case. Each measurement operator  $M_i$  is proportional to a density matrix of a MUB element. Therefore, after the measurement, there is no more information left because applying measurement in other MUB basis would output uniform distribution.

The upper bound of  $\ell_2$  norms of the output probability distribution is essential in designing an efficient quantum tester by lifting classical property tester because a small  $\ell_2$  norms ensures that the tester could use a smaller number of samples for the distributional identity testing problem as illustrated in [31], and distributional independence testing problem studied in [22].

Using Lemma 2 and the result of classical property testing, a tester using independent measurement for Problem 2 can be obtained as follows.

► **Theorem 3.** *For  $\rho, \sigma \in \mathcal{D}(\mathbb{C}^d)$ ,  $O(\epsilon^{-2} \cdot d^2)$  copies are sufficient to distinguish via deterministic independent measurements, with at least a  $\frac{2}{3}$  probability of success, the cases where  $\rho = \sigma$  from the cases where  $\|\rho - \sigma\|_1 > \epsilon$ .*

This is better than directly using the SWAP test which uses  $O(\frac{d^2}{\epsilon^4})$  copies, although the SWAP test is already a joint measurement.

Entanglement is a central feature in quantum information science. Certification of entanglement has received great amount of effort. This motivates us to study the following quantum independence testing problem.

► **Problem 4.** *Given an unknown quantum mixed states  $\rho \in \mathcal{D}(\mathbb{C}^{d_1} \otimes \mathbb{C}^{d_2} \otimes \dots \otimes \mathbb{C}^{d_n})$ , they satisfy either  $\rho = \sigma_1 \otimes \sigma_2 \otimes \dots \otimes \sigma_n$  for some  $\sigma_i \in \mathcal{D}(\mathbb{C}^{d_i})$  or for all  $\sigma_i \in \mathcal{D}(\mathbb{C}^{d_i})$ ,  $\|\rho - \sigma_1 \otimes \sigma_2 \otimes \dots \otimes \sigma_n\|_1 > \epsilon$  for a given  $\epsilon > 0$ . How many copies of  $\rho$  are needed to distinguish these two cases, with high probability?*

The above  $\ell_1$  identity testers for independent measurement together with the  $\ell_1$  identity tester of [18] for joint measurement enable us to derive the following result.

► **Theorem 5.** *The sample complexity of quantum independence testing problem for  $n$ -qubit quantum state is  $\Theta(\epsilon^{-2} \cdot 2^n)$ .*

*For general  $n$ -partite system  $\mathcal{D}(\mathbb{C}^{d_1} \otimes \mathbb{C}^{d_2} \otimes \dots \otimes \mathbb{C}^{d_n})$  with  $d_1 \geq d_2 \geq \dots \geq d_n$ , the sample complexity of quantum independence testing problem is  $\tilde{\Theta}(\epsilon^{-2} \cdot \prod_{i=1}^n d_i)$  with joint measurements; and  $O(\epsilon^{-2} \cdot \prod_{i=1}^n d_i^2)$  with deterministic independent measurements, where  $\tilde{\Theta}$  hides a factor between  $(\log^3 d_1 \cdot \log \log d_1)^{-1}$  and 1.*

In  $n$ -qubit system, the lower bound of the quantum independence for joint measurement comes from a reduction from determining whether a given state is a maximally mixed state.

In a general system, the lower bound is derived using an additional technique called dimension splitting which regards a  $d_1$ -dimensional system as  $\log d_1$  qubits system.

## 1.5 Other Results

It is widely believed that the fully-fledged quantum computer will be controlled through a classical system. Therefore, the data generated by quantum computers would be modeled by classical-quantum states, e.g., classical collections of quantum states. The importance of classical-quantum states also comes from its central role in studying quantum communication complexity [47, 9]. In classical property testing, Levi, Ron, and Rubinfeld initialized the study of property testing of collections of distributions in their pioneering work [51]. This motivates us to study the property testing problems of classical-quantum states.

In the query model, there are  $m$  states  $\rho_1, \rho_2, \dots, \rho_m$ . We can choose  $1 \leq i \leq n$  to obtain a copy of  $\rho_i$ . A motivation of studying this model is the quantum state preparation. Suppose there are different ways of generating a quantum state. We want to know whether these methods all work well. This problem can be formulated as *the independence testing of collections of quantum states*.

► **Problem 6.** *Given unknown quantum mixed states  $\rho_1, \rho_2, \dots, \rho_m \in \mathcal{D}(\mathbb{C}^{d_1} \otimes \mathbb{C}^{d_2} \otimes \dots \otimes \mathbb{C}^{d_n})$  and a given distribution  $p = (p_1, p_2, \dots, p_m)$ , they satisfy either there exist  $\sigma_{k,i} \in \mathcal{D}(\mathbb{C}^{d_k})$  for  $1 \leq k \leq n$  such that for all  $1 \leq i \leq m$   $\rho_i = \otimes_{k=1}^n \sigma_{k,i}$ , or for any  $\sigma_{k,i} \in \mathcal{D}(\mathbb{C}^{d_k})$ ,  $\sum_{i=1}^m p_i \|\rho_i - \otimes_{k=1}^n \sigma_{k,i}\|_1 > \epsilon$ , for a given  $\epsilon > 0$ . How many queries are needed to distinguish these two cases, with high probability?*

Combing the framework in [31] and our independence testers, we obtain

► **Theorem 7.** *The sample complexity of the independence testing of collections of quantum states is  $\tilde{\Theta}(\epsilon^{-2} \cdot d)$  with joint measurement;  $O(\epsilon^{-2} \cdot d^2)$  with deterministic independent measurement.*

Like their classical counterparts, the complexity does not depend on the number of states  $n$ . Similarly, this idea can be used for the independence testing of collections of quantum states.

In further work, we explore the problem of testing conditional independence with classical-quantum-quantum states. This question naturally arises in studying distributed quantum computing. One typical example is environment assisted entanglement distribution. Suppose  $\rho_{ABC}$  is a tripartite state. We want to reach the goal of sharing a bipartite state  $\sigma_{AB}$ .  $C$  should perform a measurement on its system, now the state becomes classical-quantum-quantum.

► **Problem 8.** *Given an unknown classical-quantum-quantum mixed states*

$$\rho_{ABC} = \sum_{i=1}^m p_m \rho_{AB,i} \otimes |i\rangle\langle i| \in \mathcal{D}(\mathbb{C}^{d_1} \otimes \mathbb{C}^{d_2}) \otimes \Delta(C)$$

with  $\Delta(C)$  being the probabilistic simplex of  $C$  and  $|C| = m$  and  $|i\rangle$  being a basis of  $C$ , we want to distinguish whether  $\rho_{ABC}$  is conditional independence, that is  $\rho = \sum_{i=1}^m p_m \rho_{A,i} \otimes \rho_{B,i} \otimes |i\rangle\langle i|$ , or for any conditional independent classical-quantum-quantum state  $\sigma_{ABC}$   $\|\rho - \sigma\|_1 > \epsilon$ , for a given  $\epsilon > 0$ . How many queries are needed to distinguish these two cases, with high probability?

This problem is a generalization of the independence testing of collections of quantum states in the sense that the prior coefficient of the  $\ell_1$  distance is not given explicitly but may be approximated through sampling. One motivation for studying this problem is a simplified version of the conditional independence of general tripartite quantum states, which a fundamental concept in theoretical physics and quantum information theory.

More specifically, we modify the  $\ell_2$  estimator developed in [18] for joint measurement and develop a finer  $\ell_2$  estimator for independent measurement. Then we plug that estimator into the classical conditional independence testing framework developed in [22].

► **Theorem 9.** *For classical-quantum-quantum state  $\rho_{ABC} \in \mathcal{D}(\mathbb{C}^{d_1} \otimes \mathbb{C}^{d_2}) \otimes \Delta(C)$ , the sample complexity of testing whether  $A$  and  $B$  are conditionally independent given  $C$  is*

- $O(\max\{\frac{\sqrt{nd_1d_2}}{\epsilon^2}, \min\{\frac{d_1^{\frac{4}{7}}d_2^{\frac{4}{8}}n^{\frac{6}{7}}}{\epsilon^{\frac{6}{7}}}, \frac{\sqrt{d_1d_2}n^{\frac{7}{8}}}{\epsilon}\}\})$  with joint measurement; and
- $O(\max\{\frac{\sqrt{nd_1^2d_2^2}}{\epsilon^2}, \min\{\frac{d_1^{\frac{6}{7}}d_2^{\frac{6}{8}}n^{\frac{6}{7}}}{\epsilon^{\frac{6}{7}}}, \frac{d_1^{\frac{3}{4}}d_2^{\frac{3}{4}}n^{\frac{7}{8}}}{\epsilon}\}\})$  with independent measurement.

## 1.6 Organization of this paper

Section 2 recalls the basic definitions of distance with discrete distributions and quantum states and presents some formal tools from earlier work that are used here. In Section 3, we state technical lemmata about the independence and conditional independence of quantum states. Section 4 demonstrates Lemma 2. Section 5 contains the results of identity testing and Theorems 3. In Section 6, we discuss the advantage of using random choice of independent measurements. Detail proofs of Lemmata, Theorem 7 and Theorem 9 can be found in the full version [71].

## 2 Preliminaries

This section begins with some standard notations and definitions used throughout the paper.

### 2.1 Basic facts for probability distributions

For  $m \in \mathbb{N}$ ,  $[m]$  denotes the set  $\{1, \dots, m\}$ , and  $\log$  denotes the binary logarithm. A probability distribution over discrete domain  $\Omega$  is a function  $p : \Omega \mapsto [0, 1]$  such that  $\sum_{\omega \in \Omega} p(\omega) = 1$ .  $|\Omega|$  is the cardinality of set  $\Omega$ .  $\Delta(\Omega)$  denotes the set of probability distributions over  $\Omega$ , i.e., the probability simplex of  $\Omega$ . The marginal distributions  $p_1 \in \Delta(A)$  and  $p_2 \in \Delta(B)$  of a bipartite distribution  $p_{1,2} \in \Delta(A \times B)$  can be defined as  $p_1(a) = \sum_{b \in B} p_{1,2}(a, b)$ ,  $p_1(b) = \sum_{a \in A} p_{1,2}(a, b)$ . The product distribution  $q_1 \otimes q_2$  of distributions  $q_1 \in \Delta(A)$  and  $q_2 \in \Delta(B)$  can be defined as  $[q_1 \otimes q_2](a, b) = q_1(a)q_2(b)$ , for every  $(a, b) \in A \times B$ .

The  $\ell_1$  distance between two distributions  $p, q \in \Delta(\Omega)$  is  $\|p - q\|_1 = \sum_{\omega \in \Omega} |p(\omega) - q(\omega)|$ , and their  $\ell_2$  distance is  $\|p - q\|_2 = \sqrt{\sum_{\omega \in \Omega} (p(\omega) - q(\omega))^2}$ .

## 2.2 Basic quantum mechanics

An isolated physical system is associated with a Hilbert space, which is called the *state space*. A *pure state* of a quantum system is a normalized vector in its state space, and a *mixed state* is represented by a density operator on the state space. Here, a density operator  $\rho$  on  $d$ -dimensional Hilbert space  $\mathbb{C}^d$  is a semi-definite positive linear operator such that  $\text{Tr}(\rho) = 1$ . We let

$$\mathcal{D}(\mathbb{C}^d) = \{\rho : \rho \text{ is } d\text{-dimensional density operator of } \mathbb{C}^d\}$$

denote the set of quantum states.

The reduced quantum state of a bipartite mixed state  $\rho_{1,2} \in \mathcal{D}(\mathbb{C}^{d_1} \otimes \mathbb{C}^{d_2})$  on the second system is the density operators  $\rho_2 := \text{Tr}_1 \rho_{1,2} = \sum_i \langle i|A|i\rangle$ , where  $\{|i\rangle\}$  is the orthonormal basis of  $\mathbb{C}^{d_1}$ . The partial trace of  $\rho_1 := \text{Tr}_2 \rho_{1,2}$  can be similarly defined, note that partial trace functions are also independent of the selected orthonormal basis. This definition can be directly generalized into multipartite quantum states.

## 2.3 Quantum measurement

A positive-operator valued measure (POVM) is a measure whose values are non-negative self-adjoint operators in a Hilbert space  $\mathbb{C}^d$ , which is described by a collection of matrices  $\{M_i\}$  with  $M_i \geq 0$  and  $\sum_i M_i = I_d$ . If the state of a quantum system was  $\rho$  immediately before measurement  $\{M_i\}$  was performed on it, then the probability of that result  $i$  recurring is  $p(i) = \text{Tr}(M_i \rho)$ .

## 2.4 $\ell_1$ distance

$\ell_1$  distance is used to characterize the difference between quantum states. The  $\ell_1$  distance between  $\rho$  and  $\sigma$  is defined as  $\|\rho - \sigma\|_1 \equiv \text{Tr}|\rho - \sigma|$  where  $|A| \equiv \sqrt{A^\dagger A}$  is the positive square root of  $A^\dagger A$ .

Given a general operator  $A$ , the  $\ell_1$  norm is defined as  $\|A\|_1 = \text{Tr}|A|$ . And Lemma 10 always applies:

► **Lemma 10** ([54]). *The  $\ell_1$  distance is decreasing under partial trace. That is*

$$\|\rho_1 - \sigma_1\|_1, \|\rho_2 - \sigma_2\|_1 \leq \|\rho_{1,2} - \sigma_{1,2}\|_1.$$

Their  $\ell_2$  distance is defined as  $\|\rho - \sigma\|_2 = \sqrt{\text{Tr}(\rho - \sigma)^2}$ . For  $\rho, \sigma \in \mathcal{D}(\mathbb{C}^d)$ , we have the following relation between  $\ell_1$  and  $\ell_2$  distances,  $\|\rho - \sigma\|_2 \leq \|\rho - \sigma\|_1 \leq \sqrt{d} \|\rho - \sigma\|_2$ . Given a subset  $\mathcal{P} \subsetneq \mathcal{D}(\mathbb{C}^d)$ , the  $\ell_1$  distance between  $\rho$  and  $\mathcal{P}$  is defined as  $\|\rho - \mathcal{P}\|_1 = \inf_{\sigma \in \mathcal{P}} \|\rho - \sigma\|_1$ . If  $\|\rho - \mathcal{P}\|_1 > \epsilon$ , we say that  $\rho$  is  $\epsilon$ -far from  $\mathcal{P}$ ; otherwise, it is  $\epsilon$ -close.

## 2.5 Mutually unbiased bases

In quantum information theory, mutually unbiased bases (MUB) in  $d$ -dimensional Hilbert space are two orthonormal bases  $\{|e_1\rangle, \dots, |e_d\rangle\}$  and  $\{|f_1\rangle, \dots, |f_d\rangle\}$  such that the square of the magnitude of the inner product between any basis states  $|e_j\rangle$  and  $|f_k\rangle$  equals the inverse of the dimension  $d$ :

$$|\langle e_j | f_k \rangle|^2 = \frac{1}{d}, \quad \forall j, k \in \{1, \dots, d\}.$$

These bases are unbiased in the following sense: if a system is prepared in a state belonging to one of the bases, then all outcomes of the measurement with respect to the other basis will occur with equal probability. It is known that, for  $d = p^n$  with prime  $p$ , there exists  $d + 1$  MUBs [35].

## 2.6 Quantum property testing

Let  $\mathcal{D}(\mathbb{C}^d)$  denote the set of mixed states in Hilbert space  $\mathbb{C}^d$ , and let a known  $\mathcal{T} \subset \mathcal{D}(\mathbb{C}^d)$  be the working domain of the quantum states. In a standard of property testing scenario, a testing algorithm for a property  $\mathcal{P} \subset \mathcal{T}$  would be an algorithm that, when granted access to independent samples from an unknown quantum state  $\rho \in \mathcal{T}$  as well as an  $\ell_1$  distance parameter of  $0 < \epsilon \leq 1$ , outputs either “Yes” or “No”, with the following guarantees:

- If  $\rho \in \mathcal{P}$ , then it outputs “Yes” with a probability of at least  $\frac{2}{3}$ .
- If  $\rho$  is  $\epsilon$ -far from  $\mathcal{P}$ , then it outputs “No” with a probability of at least  $\frac{2}{3}$ .

Our interest is in designing computational efficient algorithms with the smallest sample complexity (i.e., the smallest number of samples drawn of  $\rho$ ).

Confidence of  $\frac{2}{3}$  is not essential here, it could be replaced by any constant greater than  $\frac{1}{2}$ . This would only change the sample complexity by a multiplicative constant. According to the Chernoff bound, the probability of success becomes  $1 - 2^{-\Omega(k)}$ , after repeating the algorithm  $k$  times.

## 2.7 Tools from earlier work

The following results were established in earlier work, and are used within this paper.

► **Theorem 11** ([11]). *The Pauli group  $\mathcal{P}_k = \{I, X, Y, Z\}^{\otimes n}$  of order  $4^n$  can be divided into  $2^n + 1$  Abelian subgroups with an order of  $2^n$ , say,  $G_0, \dots, G_{2^n}$  such that  $G_i \cap G_j = \{I_2^{\otimes n}\}$  for  $i \neq j$ . Each subgroup can be simultaneously diagonalizable by a corresponding basis. All these  $2^n + 1$  bases form  $2^n + 1$  MUBs.*

► **Theorem 12** ([55, 18]).  *$100 \frac{d}{\epsilon^2}$  copies are sufficient and  $0.15 \frac{d}{\epsilon^2}$  copies are necessary to test whether  $\rho \in \mathcal{D}(\mathbb{C}^d)$  is the maximally mixed state  $\frac{I_d}{d}$  or  $\|\rho - \frac{I_d}{d}\|_1 > \epsilon$  with at least a  $2/3$  probability of success. Generally,  $O(\frac{d}{\epsilon^2})$  copies of  $\rho$  and  $\sigma$  are sufficient to test whether  $\rho = \sigma$  or  $\|\rho - \sigma\|_1 > \epsilon$*

### ■ Algorithm 1 A Mixness Test.

---

**Input:**  $100 \frac{d}{\epsilon^2}$  copies of  $\rho \in \mathcal{D}(\mathbb{C}^d)$

**Output:** “Yes” with a probability of at least  $\frac{2}{3}$  if  $\rho = \frac{I_d}{d}$ ; and “No” with a probability of at least  $\frac{2}{3}$  if  $\|\rho - \frac{I_d}{d}\|_1 > \epsilon$ .

---

### ■ Algorithm 2 A Identity Test with Joint Measurement.

---

**Input:**  $O(\frac{d}{\epsilon^2})$  copies of  $\rho \in \mathcal{D}(\mathbb{C}^d)$  and  $O(\frac{d}{\epsilon^2})$  copies of  $\sigma \in \mathcal{D}(\mathbb{C}^d)$

**Output:** “Yes” with a probability of at least  $\frac{2}{3}$  if  $\rho = \sigma$ ; and “No” with a probability of at least  $\frac{2}{3}$  if  $\|\rho - \sigma\|_1 > \epsilon$ .

---

► **Theorem 13** ([23]). *For  $n$ -dimensional probability distributions of  $p$  and  $q$ ,  $O(\frac{b}{\epsilon^2})$  samples are sufficient to distinguish, with at least a  $\frac{2}{3}$  probability, the cases where  $p = q$  from the cases where  $\|p - q\|_2 > \epsilon$ , where  $b \geq \|p\|_2, \|q\|_2$ .*

### ■ Algorithm 3 An $\ell_2$ norm Identity Test.

---

**Input:**  $O(\frac{b}{\epsilon^2})$  copies of  $p$  and  $O(\frac{b}{\epsilon^2})$  copies of  $q$

**Output:** “Yes” with probability at least  $\frac{2}{3}$  if  $p = q$ , “No” with probability at least  $\frac{2}{3}$  if  $\|p - q\|_2 > \epsilon$ .

---

### 3 Quantum Independence and Technical Lemmata

#### 3.1 Bipartite independence and approximate independence

We say that  $\rho_{1,2} \in \mathcal{D}(\mathbb{C}^d \otimes \mathbb{C}^{d_2})$  is independent if  $\rho_{1,2} = \sigma_1 \otimes \sigma_2$  for some  $\sigma_i \in \mathcal{D}(\mathbb{C}^{d_i})$ . One can directly verify that, if  $\rho_{1,2}$  is independent, then  $\rho = \rho_1 \otimes \rho_2$  with  $\rho_1$  and  $\rho_2$  being the reduced density matrices of  $\rho_{1,2}$ .

We say that  $\rho$  is  $\epsilon$ -independent with respect to the  $\ell_1$  distance if there is an independent state  $\sigma$  such that  $\|\rho - \sigma\|_1 \leq \epsilon$ . We say that  $\rho$  is  $\epsilon$ -far from being independent with respect to the  $\ell_1$  distance if  $\|\rho - \sigma\|_1 > \epsilon$  for any independent state  $\sigma$ .

► **Proposition 14.** *Let  $\rho$  and  $\sigma$  be bipartite states of  $\mathcal{D}(\mathbb{C}^d \otimes \mathbb{C}^{d_2})$ . If  $\|\rho - \sigma\|_1 \leq \epsilon/3$  and  $\sigma$  is independent, then  $\|\rho - \rho_1 \otimes \rho_2\|_1 \leq \epsilon$ .*

► **Lemma 15.**  $\|\rho_1 \otimes \rho_2 - \sigma_1 \otimes \sigma_2\|_1 \leq \|\rho_1 - \sigma_1\|_1 + \|\rho_2 - \sigma_2\|_1$ .

#### 3.2 Multipartite independence and approximate independence

We say that  $\rho \in \mathcal{D}(\mathbb{C}^d \otimes \mathbb{C}^{d_2} \otimes \dots \otimes \mathbb{C}^{d_n})$  is  $n$ -partite independent if  $\rho = \rho_1 \otimes \rho_2 \otimes \dots \otimes \rho_n$ , and that  $\rho$  is  $\epsilon$ -independent with respect to the  $\ell_1$  distance if there is a state  $\sigma$  that is  $m$ -partite independent and  $\|\rho - \sigma\|_1 \leq \epsilon$ . We say that  $\rho$  is  $\epsilon$ -far from being independent with respect to the  $\ell_1$  distance if  $\|\rho - \sigma\|_1 > \epsilon$  for any  $m$ -partite independent state  $\sigma$ .

► **Proposition 16.** *Let  $\rho$  and  $\sigma$  be  $n$ -partite states, if  $\|\rho - \sigma\|_1 \leq \epsilon$ , and  $\sigma$  is  $m$ -partite independent, then  $\|\rho - \rho_1 \otimes \rho_2 \otimes \dots \otimes \rho_n\|_1 \leq (n+1)\epsilon$ .*

► **Lemma 17.**  $\|\rho_1 \otimes \rho_2 \otimes \dots \otimes \rho_n - \sigma_1 \otimes \sigma_2 \otimes \dots \otimes \sigma_n\|_1 \leq \sum_{i=1}^n \|\rho_i - \sigma_i\|_1$ .

Proposition 18 establishes a connection between bipartite independence and multipartite independence. Specifically, it shows that if an  $n$ -partite state is close to bipartite independence in any 1 versus  $n-1$  cut, it is close to being  $n$  partite independent.

► **Proposition 18.** *Let  $\rho$  be an  $n$ -partite states. If for any  $1 \leq i \leq n$ , there exists a state  $\sigma_i^{(i)}$  of party  $i$ , and a state  $\psi_{[n] \setminus \{i\}}$  of parties  $[n] \setminus \{i\}$  such that  $\|\rho - \sigma_i^{(i)} \otimes \psi_{[n] \setminus \{i\}}\|_1 \leq \epsilon$ , then  $\|\rho - \rho_1 \otimes \rho_2 \otimes \dots \otimes \rho_n\|_1 \leq 5n\epsilon$ .*

### 4 Connections between Quantum Property Testing and Distribution Testing

Mutually unbiased bases (MUBs) are used to map the quantum states of  $\mathcal{D}(\mathbb{C}^d)$  into  $d(d+1)$  dimensional probability distributions. Without loss of generality, assume  $d = 2^n$ , and we let the Pauli group  $\mathcal{P}_k = \{I, X, Y, Z\}^{\otimes n}$  be to the order of  $4^n$ . According to Theorem 11, any state  $\rho \in \mathcal{D}(\mathbb{C}^d)$  can be written as

$$\rho = \sum_{P \in \mathcal{P}_n} \eta_P P = \frac{I_d}{d} + \sum_{a=0}^d \sum_{\substack{P \in G_a, \\ P \neq I_d}} \eta_P P = \frac{I_d}{d} + \sum_{i,j} \mu_{i,j} |\beta_{i,j}\rangle \langle \beta_{i,j}|,$$

where  $G_a$  are the Abelian subgroups with an order of  $2^n = d$  such that  $\cup G_a = \mathcal{P}_n$  and  $G_a \cap G_b = \{I_2^{\otimes n}\}$  for  $a \neq b$ . The equation is due to the simultaneous spectrum decomposition of  $G_a$  through the MUBs bases. That is, for  $0 \leq i \neq s \leq d, 1 \leq j, t \leq d$ ,

$$|\langle \beta_{i,j}, \beta_{s,t} \rangle| = \frac{1}{\sqrt{d}}.$$

In addition, it is verifiable that  $\sum_{j=1}^d \mu_{i,j} = 0$  for all  $i$  by the traceless property of  $P \neq I_d$ . Therefore, we can obtain the following constraint on  $\mu_{i,j}$  using  $\sum_{j=1}^d \mu_{i,j} = 0$  for all  $i$ ,

$$\text{Tr } \rho^2 = \text{Tr } \frac{I_d}{d^2} + \sum_{i,j,s,t} \mu_{i,j} \mu_{s,t} |\langle \beta_{i,j}, \beta_{s,t} \rangle|^2 = \frac{1}{d} + \sum_{i,j} \mu_{i,j}^2 \leq 1.$$

$\mathcal{M} = \{M_{ij} = \frac{|\beta_{i,j}\rangle\langle\beta_{i,j}|}{d+1} : 0 \leq i \leq d, 1 \leq j \leq d\}$  can be used to map the  $d$ -dimensional quantum state  $\rho$  into a  $d(d+1)$  dimensional probabilistic distribution. The corresponding probability distribution  $p = (p(0,1), \dots, p(d,d))$  satisfies

$$p(i,j) = \frac{\text{Tr}(\rho |\beta_{i,j}\rangle\langle\beta_{i,j}|)}{d+1} = \frac{\mu_{i,j} + \frac{1}{d}}{d+1},$$

note that other terms are orthogonal or cancel out due to the property of MUBs and the equations  $\sum_{j=1}^d \mu_{i,j} = 0$  for all  $i$ .

Then the  $\ell_2$  norm of  $p$  can be bounded with

$$\frac{\sqrt{\sum_{i,j} (\mu_{i,j} + \frac{1}{d})^2}}{d+1} = \frac{\sqrt{\sum_{i,j} \mu_{i,j}^2 + \frac{d(d+1)}{d^2} + \frac{2 \sum_{i,j} \mu_{i,j}}{d}}}{d+1} = \frac{\sqrt{\sum_{i,j} \mu_{i,j}^2 + \frac{d+1}{d}}}{d+1} \leq \frac{\sqrt{2}}{d+1}.$$

More importantly, this map preserves the  $\ell_2$  distance, in the sense that the  $\ell_2$  distance between the image probability distributions is exactly the same as the  $\ell_2$  distance between the pre-image quantum states with a scaling of  $\frac{1}{d+1}$ .

For any two states  $\rho = \frac{I_d}{d} + \sum_{i,j} \mu_{i,j} |\beta_{i,j}\rangle\langle\beta_{i,j}|$  and  $\sigma = \frac{I_d}{d} + \sum_{i,j} \nu_{i,j} |\beta_{i,j}\rangle\langle\beta_{i,j}|$ , we have that

$$\|\rho - \sigma\|_2 = \left\| \sum_{i,j} (\mu_{i,j} - \nu_{i,j}) |\beta_{i,j}\rangle\langle\beta_{i,j}| \right\|_2 = \sqrt{\sum_{i,j} (\mu_{i,j} - \nu_{i,j})^2},$$

where the other terms are orthogonal or cancel out due to the property of MUBs and the equation  $\sum_{j=1}^d \mu_{i,j} = 0$  for all  $i$ .

Using the measurement  $\mathcal{M}$ , the corresponding probability distributions can be obtained:  $p = (p(0,1), \dots, p(d,d))$  and  $q = (q(0,1), \dots, q(d,d))$  with

$$p(i,j) = \frac{\text{Tr}(\rho |\beta_{i,j}\rangle\langle\beta_{i,j}|)}{d+1} = \frac{\mu_{i,j} + \frac{1}{d}}{d+1}, \quad q(i,j) = \frac{\text{Tr}(\sigma |\beta_{i,j}\rangle\langle\beta_{i,j}|)}{d+1} = \frac{\nu_{i,j} + \frac{1}{d}}{d+1}.$$

The following equality proves Lemma 2.  $\|p - q\|_2 = \frac{\sqrt{\sum_{i,j} (\mu_{i,j} - \nu_{i,j})^2}}{d+1} = \frac{\|\rho - \sigma\|_2}{d+1}.$

## 5 Quantum State Certification

The connections developed in Section 4, together with the  $\ell_2$ -identity tester of probability distributions provided in [23], also make efficient identity testing of quantum states possible.

**Proof of Theorem 3.** First map the state into probability distributions, say  $p$  and  $q$ , through independent measurement with Theorem 2, and follow by executing Algorithm 4.

■ **Algorithm 4** A Identity Test with Independent Measurement.

---

**Input:**  $O(\frac{d^2}{\epsilon^2})$  copies of  $\rho \in \mathcal{D}(\mathbb{C}^d)$  and  $O(\frac{d}{\epsilon^2})$  copies of  $\sigma \in \mathcal{D}(\mathbb{C}^d)$   
**Output:** “Yes” with a probability of at least  $\frac{2}{3}$  if  $\rho = \sigma$ ; and “No” with a probability of at least  $\frac{2}{3}$  if  $\|\rho - \sigma\|_1 > \epsilon$ .  
1 Run Algorithm 3 to distinguish between  $p = q$  and  $\|p - q\|_2 \geq \frac{\epsilon}{\sqrt{d(d+1)}}$ ;  
/\*  $p$  and  $q$  are the probability distributions obtained by measuring  $\rho$   
and  $\sigma$  through the independent measurement with Theorem 2,  
respectively. \*/

---

According to  $\|p - q\|_2 = \frac{\|\rho - \sigma\|_2}{\sqrt{d+1}}$ , we only need to distinguish cases where  $p = q$  from cases where  $\|p - q\|_2 \geq \frac{\|\rho - \sigma\|_1}{\sqrt{d(d+1)}} \geq \frac{\epsilon}{\sqrt{d(d+1)}}$ . Choosing  $b = \frac{\sqrt{2}}{d+1} \geq \|p\|_2, \|q\|_2$  and invoking Theorem 13, we have

$$O\left(\frac{b}{\left(\frac{\epsilon}{\sqrt{d(d+1)}}\right)^2}\right) = O\left(\frac{d^2}{\epsilon^2}\right)$$

which is a sufficient number of copies. ◀

According to [44], the sample complexity for tomography is  $\rho \in \mathcal{D}(\mathbb{C}^d)$  is  $\Theta(\frac{d^3}{\epsilon^2})$ , which makes Algorithm 4 a better choice for identity testing after tomography.

As mentioned in the introduction, Algorithm 4 should be significantly easier to implement because it does not demand noiseless, universal quantum computation with an *exponential* number of qubits.

## 6 Independence Testing

The goal of independence testing is to determine whether a fixed multipartite state  $\rho$  is independent, i.e., in tensor product form, or far from being independent. Hence, in this section, we outline a series of testing algorithms and almost matching lower bounds in joint measurement setting, and independent measurement setting.

We start with an algorithm for the bipartite case of Theorem 5.

■ **Algorithm 5** A Bipartite Independence Testing with Joint Measurement.

---

**Input:**  $n = O(\frac{d_1 d_2}{\epsilon^2})$  copies of  $\rho \in \mathcal{D}(\mathbb{C}^{d_1} \otimes \mathbb{C}^{d_2})$   
**Output:** “Yes” with a probability of at least  $\frac{2}{3}$  if  $\rho$  is independent; and “No” with a probability of at least  $\frac{2}{3}$  if  $\|\rho - \sigma\|_1 > \epsilon$  for any independent  $\sigma$ .

- 1 Use  $\frac{n}{3}$  copies of  $\rho$  to generate  $\rho_1$ ;  
 /\* Trace out system 2 \*/
- 2 Use  $\frac{n}{3}$  copies of  $\rho$  to generate  $\rho_2$ ;  
 /\* Trace out system 1 \*/
- 3 Run Algorithm 2 on  $\frac{n}{3}$  copies of  $\rho$  and  $\frac{n}{3}$  copies of  $\rho_1 \otimes \rho_2$  with the parameter  $\epsilon/3$ ;

---

**Proof.** The correctness of this algorithm accords with Theorem 1 by note that

- If  $\rho$  is independent, then  $\rho = \rho_1 \otimes \rho_2$ , and this algorithm will output “Yes” with high probability.
- If  $\|\rho - \sigma\|_1 > \epsilon$  for any independent  $\sigma$ , then  $\|\rho - \rho_1 \otimes \rho_2\|_1 > \epsilon/3$  by Proposition 14, and this algorithm will output “No” with high probability.

We can derive an independent measurement tester by replacing the identity tester in Algorithm 2 with Algorithm 4. From a similar analysis to the above,  $O(\frac{d_1^2 d_2^2}{\epsilon^2})$  is a sufficient number of copies. ◀

The obvious generalization of the bipartite independence testing to  $m$ -partite would work using bipartite independence in any  $n - 1$  parties versus 1 party. Our goal is to test independence in this scenario with an accuracy of  $O(\frac{\epsilon}{n})$  and at least a  $1 - \frac{1}{n^2}$  probability of success. The correctness of the algorithm follows from Proposition 18, and the generalization incurs an  $O(n^3 \log n)$  factor. For constant  $n$ ,  $O(n^3 \log n)$  is still constant. Thus, the complexity of the different algorithm variants would be  $O(\frac{\prod_{i=1}^n d_i}{\epsilon^2})$  with joint measurement, and  $O(\frac{\prod_{i=1}^n d_i^2}{\epsilon^2})$  with independent measurement. With a super-constant  $n$ , algorithms could be built that achieve the same complexity using Diakonikolas and Kane’s [31] recursion idea coupled with our previous bipartite independence tester.

We only prove the lower bound part of Theorem 5 for bipartite systems here. The general version can be proved similarly. In cases where  $d_1$  and  $d_2$  are both very large, the bound is derived from the mixness test of Theorem 12 in [55], where the constant 2000 comes from the upper and lower bound of the constant in that theorem. To deal with “unbalanced” cases where only  $d_1$  or  $d_2$  is small—here, let us say  $d_2$ —we split the  $d_1$  system into many systems of dimension  $d_2$ , which transforms the original unbalance of a bipartite problem into a problem of “balanced” multipartite independence testing. Then, we use Proposition 18.

**Proof.** First, note that it suffices to consider cases where  $d_1 d_2$  are sufficiently large. To show the lower bound for a general  $d_1$  and  $d_2$ , assume there is an algorithm, Algorithm A, that uses  $f(d_1, d_2, \epsilon)$  copies to decide whether a given  $\rho \in \mathcal{D}(\mathbb{C}^{d_1} \otimes \mathbb{C}^{d_2})$  is independent or  $\epsilon$ -far from being independent with at least a  $2/3$  probability of successful. By using Algorithm A as an oracle, the following algorithm can distinguish cases where  $\rho = \frac{I_{d_1}}{d_1} \otimes \frac{I_{d_2}}{d_2}$  from cases where  $\|\rho - \frac{I_{d_1}}{d_1} \otimes \frac{I_{d_2}}{d_2}\|_1 > \epsilon$  for any  $t > 1$ .

To see this algorithm to succeed at detecting whether  $\rho$  is maximally mixed with high probability, note that: If  $\rho = \frac{I_{d_1}}{d_1} \otimes \frac{I_{d_2}}{d_2}$ , in Line 1, the algorithm will output  $\rho_1 = \frac{I_{d_1}}{d_1}$  with a probability of at least  $\frac{20}{27}$ ; in Line 5, the algorithm will output  $\rho_2 = \frac{I_{d_2}}{d_2}$  with a probability of at least  $\frac{27}{28}$ ; in Line 9,  $\rho$  will be independent with a probability of at least  $\frac{28}{30}$ . Overall, Algorithm 6 will output “Yes” with a probability of at least  $\frac{2}{3}$ .

## 11:14 Quantum Identity Testing and Independence Testing

If  $\|\rho - \frac{I_{d_1}}{d_1} \otimes \frac{I_{d_2}}{d_2}\|_1 > \epsilon$ , then one of the following three statements will be true:  $\rho_1$  is  $\epsilon/t$ -far from  $\frac{I_{d_1}}{d_1}$ ; or  $\rho_2$  is  $\frac{(t-1)\epsilon}{4t}$ -far from  $\frac{I_{d_2}}{d_2}$ ; or  $\rho$  is  $\frac{(t-1)\epsilon}{4t}$ -far from being independent. Otherwise, assume that there exists an  $\sigma_1$  and an  $\sigma_2$ , such that  $\|\rho - \sigma_1 \otimes \sigma_2\|_1 < \frac{(t-1)\epsilon}{4t}$ ,  $\|\rho_1 - \frac{I_{d_1}}{d_1}\|_1 < \frac{\epsilon}{t}$  and  $\|\rho_2 - \frac{I_{d_2}}{d_2}\|_1 < \frac{(t-1)\epsilon}{4t}$ . According to Proposition 14, we have  $\|\rho - \rho_1 \otimes \rho_2\|_1 < \frac{3(t-1)\epsilon}{4t}$ . Then by the triangle inequality and Lemma 15, we have

$$\|\rho - \frac{I_{d_1}}{d_1} \otimes \frac{I_{d_2}}{d_2}\|_1 \leq \|\rho - \rho_1 \otimes \rho_2\|_1 + \|\frac{I_{d_1}}{d_1} \otimes \frac{I_{d_2}}{d_2} - \rho_1 \otimes \rho_2\|_1 < \epsilon.$$

Contradiction! Therefore, in this case, the algorithm outputs “No” with a probability of at least  $\min\{\frac{20}{27}, \frac{27}{28}, \frac{28}{30}\} > \frac{2}{3}$ .

■ **Algorithm 6** A Bipartite Identity test A for a maximally mixed state.

---

**Input:**  $n = 100f(d_1, d_2, \frac{(t-1)\epsilon}{4t}) + 300t^2 \frac{d_1}{\epsilon^2} + \Theta(\frac{d_2}{t^2(t-1)^2\epsilon^2})$  copies of  $\rho \in \mathcal{D}(\mathbb{C}^{d_1} \otimes \mathbb{C}^{d_2})$

**Output:** “Yes” with a probability of at least  $\frac{2}{3}$  if  $\rho = \frac{I_{d_1}}{d_1} \otimes \frac{I_{d_2}}{d_2}$ ; and “No” with a probability of at least  $\frac{2}{3}$  if  $\|\rho - \frac{I_{d_1}}{d_1} \otimes \frac{I_{d_2}}{d_2}\|_1 > \epsilon$ .

- 1 Repeat Algorithm 1, with  $100t^2 \frac{d_1}{\epsilon^2}$  copies of  $\rho$ , three times to test whether  $\rho_1 = \frac{I_{d_1}}{d_1}$  or  $\|\rho_1 - \frac{I_{d_1}}{d_1}\|_1 > \epsilon/t$  with at least a  $\frac{20}{27}$  probability of success;
- 2 **if** “No” **then**
- 3     Return “No”;
- 4 **else**
- 5     Employ Algorithm 1 with  $\Theta(\frac{t^2 d_2}{(t-1)^2 \epsilon^2})$  copies of  $\rho$  to test whether  $\rho_2 = \frac{I_{d_2}}{d_2}$  or  $\|\rho_2 - \frac{I_{d_2}}{d_2}\|_1 > \frac{(t-1)\epsilon}{4t}$  with at least a  $\frac{27}{28}$  probability of success;
- 6     **if** “No” **then**
- 7         Return “No”;
- 8     **else**
- 9         Run Algorithm A 100 times to test whether  $\rho$  is independent or is  $\frac{(t-1)\epsilon}{4t}$ -far from being independent with at least a  $\frac{28}{30}$  probability of success;
- 10        **if** “Yes” **then**
- 11            Return “Yes”;
- 12        **else**
- 13            Return “No”;

---

This algorithm uses  $n = 100f(d_1, d_2, \frac{(t-1)\epsilon}{4t}) + 300t^2 \frac{d_1}{\epsilon^2} + \Theta(\frac{t^2 d_2}{(t-1)^2 \epsilon^2})$  copies of  $\rho$ . Invoking Theorem 12, we know that  $0.15 \frac{d_1 d_2}{\epsilon^2}$  copies are necessary to test, with at least a  $2/3$  probability of success, whether  $\rho$  is the maximally mixed state or whether it is  $\epsilon$ -far.

We must have

$$100f(d_1, d_2, \frac{(t-1)\epsilon}{4t}) + 300t^2 \frac{d_1}{\epsilon^2} + \Theta(t^2 \frac{d_2}{(t-1)^2 \epsilon^2}) \geq 0.15 \frac{d_1 d_2}{\epsilon^2}.$$

If  $d_1$  and  $d_2$  are both sufficiently large, we can choose a constant  $t$  such that  $300t^2 \frac{d_1}{\epsilon^2} + \Theta(t^2 \frac{d_2}{(t-1)^2 \epsilon^2}) = o(\frac{d_1 d_2}{\epsilon^2})$ , which implies

$$f(d_1, d_2, \epsilon) \geq \Omega(\frac{16t^2 d_1 d_2}{(t-1)^2 \epsilon^2}) = \Omega(\frac{d_1 d_2}{\epsilon^2}).$$

If  $d_1$  is sufficiently large and  $d_2$  is not sufficiently large but  $d_2 > 2000$ , we can choose  $t = \sqrt{\frac{2000.5}{2000}}$ , then

$$f(d_1, d_2, c\epsilon) \geq 0.15 \frac{d_1 d_2}{\epsilon^2} - 300t^2 \frac{d_1}{\epsilon^2} + \Omega(t^2 \frac{d_2}{(t-1)^2 \epsilon^2}) = \Omega(\frac{d_1}{\epsilon^2}) = \Omega(\frac{d_1 d_2}{\epsilon^2}),$$

with the constant  $c = \frac{t-1}{4t}$ . Thus, for  $d_2 > 2000$ ,

$$f(d_1, d_2, \epsilon) \geq \Omega(\frac{d_1 d_2}{\epsilon^2}).$$

The above technique does not work with a small  $d_2$ , because the number of copies required to test a  $d_1$  system  $300t^2 \frac{d_1}{\epsilon^2}$  and the number of copies required to test a total system of  $0.15 \frac{d_1 d_2}{\epsilon^2}$  are of the same order.

To deal with this unbalanced case, we developed a dimension splitting technique that transforms bipartite independence into  $k$ -partite independence. First observe that the sample complexity for independence testing in  $\mathcal{D}(\mathbb{C}^{d_1} \otimes \mathbb{C}^{d_2})$  is no less than the sample complexity for an independence test of  $\mathcal{D}(\mathbb{C}^d \otimes \mathbb{C}^2)$  for  $d = 2^{\lceil \log d_1 \rceil} \leq d_1$ . Therefore, without loss of generality, assume that  $d_2 = 2$  and  $d_1 = 2^k$  instead of  $d_2 \leq 2000$ , and that  $d_1$  is sufficiently large.

We still assume that there is an Algorithm A that uses  $f(2^k, 2, \epsilon)$  copies to decide, with at least a  $2/3$  probability of success, whether a given  $\rho \in \mathcal{D}(\mathbb{C}^{2^k \times 2^k} \otimes \mathbb{C}^{2 \times 2})$  is independent or  $\epsilon$ -far from independent in the  $2^k$  and 2 bipartitions. Any such  $\rho$  can be regarded as a  $k+1$  qubit state, and the qubit systems will be labeled as  $S = \{1, 2, \dots, k, k+1\}$ .  $\rho_i$  denotes the reduced density matrix of the  $i$ -th qubit of  $\rho$ . Algorithm A is a bipartite independence tester for a  $k+1$  qubit system in the bipartition of  $k$  qubits and 1 qubit. In the following, Algorithm A is applied as a black box to the bipartition  $i$  and  $S \setminus \{i\}$  for any  $i$  to test the identity of  $\rho$  and  $\frac{I_{d_1}}{d_1} \otimes \frac{I_{d_2}}{d_2}$ .

■ **Algorithm 7** A Bipartite Identity Test B for a maximally mixed state.

**Input:**  $n = \Theta[(k+1) \log k f(2^k, 2, \frac{\epsilon}{6(k+1)})] + \Theta[(k+1) \log k \frac{(k+1)^2}{\epsilon^2}]$  copies of  $\rho$ .

**Output:** “Yes” with a probability of at least  $\frac{2}{3}$  if  $\rho = \otimes_{i=1}^{k+1} \frac{I_2}{2}$ ; and “No” with a probability of at least  $\frac{2}{3}$  if  $\|\rho - \otimes_{i=1}^{k+1} \frac{I_2}{2}\|_1 > \epsilon$ .

```

1 for  $i \leftarrow 1$  to  $k+1$  do
2   Repeat Algorithm 1, with  $\Theta(\frac{(k+1)^2}{\epsilon^2})$  copies of  $\rho$  each time,  $\Theta(\log k)$  times to test
   whether  $\rho_i = \frac{I_2}{2}$  or  $\|\rho_i - \frac{I_2}{2}\|_1 > \frac{\epsilon}{6(k+1)}$  at least a  $1 - \frac{1}{k^2}$  probability of success;
3   if No then
4     Return “No”;
5   else
6     Run Algorithm A  $\Theta(\log k)$  times, with  $f(2^k, 2, \frac{\epsilon}{6(k+1)})$  copies each time, to
     test whether  $\rho$  is independent or  $\frac{\epsilon}{6(k+1)}$ -far from being independent in the
     bipartition  $\{i\}$  and  $S \setminus \{i\}$  with at least a  $1 - \frac{1}{k^2}$  probability of success;
7     if No then
8       Return “No”;
9 Return “Yes”;
```

To see this algorithm succeed in detecting whether  $\rho$  is maximally mixed with high probability, we note that

## 11:16 Quantum Identity Testing and Independence Testing

If  $\rho = \frac{I_{d_1}}{d_1} \otimes \frac{I_{d_2}}{d_2}$ , then  $\rho_i = \frac{I_2}{2}$  when  $\rho$  is regarded as a  $k+1$  qubit state. It is independent in any bipartition  $\{i\}$  and  $S \setminus \{i\}$ . For each  $i$ , the passing probability of the test  $\rho_i = \frac{I_2}{2}$  is at least  $1 - \frac{1}{k^2}$ . For each  $i$ , the passing probability of the independence test in the bipartition  $\{i\}$  and  $S \setminus \{i\}$  is at least  $1 - \frac{1}{k^2}$ . In total, Algorithm 7 will accept with a probability of at least  $(1 - \frac{1}{k^2})^{O(k)} = 1 - o(1) > \frac{2}{3}$ .

If  $\|\rho - \frac{I_{d_1}}{d_1} \otimes \frac{I_{d_2}}{d_2}\|_1 > \epsilon$ , at least one of the following two statements is true:

- $\|\rho_i - \frac{I_2}{2}\|_1 > \frac{\epsilon}{6(k+1)}$  for some  $1 \leq i \leq k+1$ ; and/or
- $\rho$  is  $\frac{\epsilon}{6(k+1)}$ -far from independent in the bipartition  $\{i\}$  and  $S \setminus \{i\}$  for some  $1 \leq i \leq k+1$ .

Otherwise,  $\|\rho_i - \frac{I_2}{2}\|_1 \leq \frac{\epsilon}{6(k+1)}$  and  $\rho$  is  $\frac{\epsilon}{6(k+1)}$  close to being independent in the bipartition  $\{i\}$  and  $S \setminus \{i\}$  for all  $1 \leq i \leq k+1$ .

According to Proposition 18, we have

$$\|\rho - \rho_1 \otimes \rho_2 \otimes \cdots \otimes \rho_{k+1}\|_1 \leq 5(k+1) \frac{\epsilon}{6(k+1)} = \frac{5\epsilon}{6}.$$

By Lemma 17, we have

$$\begin{aligned} & \|\rho - \frac{I_{d_1}}{d_1} \otimes \frac{I_{d_2}}{d_2}\|_1 \\ &= \|\rho - \frac{I_2}{2} \otimes \frac{I_2}{2} \otimes \cdots \otimes \frac{I_2}{2}\|_1 \\ &\leq \|\rho - \rho_1 \otimes \rho_2 \otimes \cdots \otimes \rho_{k+1}\|_1 + \|\frac{I_2}{2} \otimes \frac{I_2}{2} \otimes \cdots \otimes \frac{I_2}{2} - \rho_1 \otimes \rho_2 \otimes \cdots \otimes \rho_{k+1}\|_1 \\ &\leq \frac{5\epsilon}{6} + \sum_{i=1}^{k+1} \|\rho_i - \frac{I_2}{2}\|_1 \\ &\leq \epsilon. \end{aligned}$$

Contradiction! Therefore, the algorithm outputs “No” with a probability of at least  $1 - \frac{1}{k^2} > \frac{2}{3}$  in this case.

Invoking Theorem 12, we know that  $\Theta(\frac{d_1 d_2}{\epsilon^2}) = \Theta(\frac{2^{k+1}}{\epsilon^2})$  copies are necessary to test whether  $\rho$  is a maximally mixed state or  $\epsilon$ -far with at least a  $2/3$  probability of success. Algorithm 7 uses  $\Theta[(k+1) \log k f(2^k, 2, \frac{\epsilon}{6(k+1)})] + \Theta[(k+1) \log k \frac{(k+1)^2}{\epsilon^2}]$  copies of  $\rho$ . We must have

$$\begin{aligned} & \Theta[(k+1) \log k f(2^k, 2, \frac{\epsilon}{6(k+1)})] + \Theta[(k+1) \log k \frac{(k+1)^2}{\epsilon^2}] \geq \Theta(\frac{2^{k+1}}{\epsilon^2}) \\ \Rightarrow & f(2^k, 2, \frac{\epsilon}{6(k+1)}) \geq \Theta(\frac{2^k}{k \log k \epsilon^2}) \\ \Rightarrow & f(2^k, 2, \epsilon) \geq \Theta(\frac{2^k}{k^3 \log k \epsilon^2}) \\ \Rightarrow & f(d_1, d_2, \epsilon) = \Omega(\frac{d_1}{\log^3 d_1 \log \log d_1 \epsilon^2}) = \Omega(\frac{d_1 d_2}{\log^3 d_2 \log \log d_1 \epsilon^2}) \end{aligned}$$

That is, if  $d_2$  is a small constant,  $\Omega(\frac{d_1 d_2}{\epsilon^2 \log^3 d_1 \log \log d_1})$  copies are necessary to test the independence of  $\rho \in \mathcal{D}(\mathbb{C}^{d_1} \otimes \mathbb{C}^{d_2})$ . ◀

## 7 Discussion

If we can use random measurements, a fewer number of copies are needed for quantum identity testing and independence testing.

In [19], it is proved that using non-adaptive independent measurements, to test whether a quantum state  $\rho \in \mathcal{D}(\mathbb{C}^d)$  is equal to or  $\epsilon$ -far in trace distance from the maximally mixed state,  $\Omega(\frac{d^{3/2}}{\epsilon^2})$ , and this complexity can be achieved via Haar-random orthogonal POVMs. The measurement can be implemented by randomly choosing a unitary  $U$  applied on  $\rho$  and measuring  $U\rho U^\dagger$  in computational basis many times. The last step is to test whether the resulting  $d$ -dimensional probability distribution  $p_U$  is equal to or  $\frac{\epsilon}{\sqrt{d}}$ -far from uniform distribution  $u$ . The correctness of this algorithm comes from the concentration of measure and

$$\mathbb{E}_U \|p_U - u\|_2^2 = \frac{\|\rho - \frac{I}{d}\|_2^2}{d+1}.$$

This method can be used to the general quantum identity testing problem: Randomly choosing a unitary  $U$  applied on  $\rho$  and  $\sigma$  respectively, then measuring  $U\rho U^\dagger$  and  $U\sigma U^\dagger$  in computational basis many times. The last step is to test whether the resulting  $d$ -dimensional probability distributions  $p_U$  and  $q_U$  are equal or  $\frac{\epsilon}{\sqrt{d}}$ -far. One can verify

$$\mathbb{E}_U \|p_U - q_U\|_2^2 = \frac{\|\rho - \sigma\|_2^2}{d+1},$$

and

$$\mathbb{E}_U \|p_U\|_2^2, \|q_U\|_2^2 \leq O\left(\frac{1}{d+1}\right).$$

Using concentration of measure, we know that  $\|p_U - q_U\|_2^2 \geq \frac{\|\rho - \sigma\|_2^2}{2d+1}$  and  $\|p_U\|_2^2, \|q_U\|_2^2 \leq O(\frac{1}{d+1})$  are valid with high probability. The rest is to run Algorithm 3 from [23] with  $O(\frac{d^{3/2}}{\epsilon^2})$  samples. We can conclude that

► **Theorem 19.** *The sample complexity of quantum identity testing is  $\Theta(\frac{d^{3/2}}{\epsilon^2})$  for non-adaptive independent measurements.*

This continuous randomness can be discretized by randomly choosing the MUB basis presented in Section 4.

Plug in our method of quantum independence testing, we know that

► **Theorem 20.** *The sample complexity of quantum independence testing of  $\mathcal{D}(\mathbb{C}^{d_1} \otimes \mathbb{C}^{d_2} \otimes \dots \otimes \mathbb{C}^{d_m})$  is  $\tilde{\Theta}(\frac{\prod_{i=1}^m d_i^{3/2}}{\epsilon^2})$  for non-adaptive independent measurements.*

## Abstract

QBF solvers implementing the QCDCL paradigm are powerful algorithms that successfully tackle many computationally complex applications. However, our theoretical understanding of the strength and limitations of these QCDCL solvers is very limited.

In this paper we suggest to formally model QCDCL solvers as proof systems. We define different policies that can be used for decision heuristics and unit propagation and give rise to a number of sound and complete QBF proof systems (and hence new QCDCL algorithms). With respect to the standard policies used in practical QCDCL solving, we show that the corresponding QCDCL proof system is incomparable (via exponential separations) to Q-resolution, the classical QBF resolution system used in the literature. This is in stark contrast to the propositional setting where CDCL and resolution are known to be p-equivalent.

This raises the question what formulas are hard for standard QCDCL, since Q-resolution lower bounds do not necessarily apply to QCDCL as we show here. In answer to this question we prove several lower bounds for QCDCL, including exponential lower bounds for a large class of random QBFs.

We also introduce a strengthening of the decision heuristic used in classical QCDCL, which does not necessarily decide variables in order of the prefix, but still allows to learn asserting clauses. We show that with this decision policy, QCDCL can be exponentially faster on some formulas.

We further exhibit a QCDCL proof system that is p-equivalent to Q-resolution. In comparison to classical QCDCL, this new QCDCL version adapts both decision and unit propagation policies.

## 1 Introduction

SAT solving has revolutionised the way we perceive and approach computationally complex problems. While traditionally, NP-hard problems were considered computationally intractable, today SAT solvers routinely and successfully solve instances of NP-hard problems from virtually all application domains, and in particular problem instances of industrial relevance [53]. Starting with the classic DPLL algorithm from the 1960s [25, 26], there have been a number of milestones in the evolution of SAT solving, but clearly one of the breakthrough achievements was the introduction of clause learning in the late 1990s, leading to the paradigm of *conflict-driven clause learning* (CDCL) [43, 55], the predominant technique

of modern SAT solving. CDCL ingeniously combines a number of crucial ingredients, among them variable decision heuristics, unit propagation, clause learning from conflicts, and restarts (cf. [42] for an overview).

Inspired by the success of SAT solving, many researchers have concentrated on the task to extend the reach of these technologies to computationally even more challenging settings with *quantified Boolean formulas* (QBF) receiving key attention. As a PSPACE-complete problem, the satisfiability problem for QBFs encompasses all problems from the polynomial hierarchy and allows to encode many problems far more succinctly than in propositional logic (cf. [51] for applications).

One of the main techniques in QBF solving is the propositional CDCL technique, lifted to QBF in the form of QCDCL [56]. However, solving QBFs presents additional challenges as the quantifier type of variables (existential and universal) needs to be taken into account as well as the variable dependencies stemming from the quantifier prefix.<sup>1</sup> This particularly impacts the variable selection heuristics and details of the unit propagation within QCDCL. In addition to QCDCL there are further QBF solving techniques, exploiting QBF features absent in SAT, such as expanding universal variables in expansion solving [36] and dependency schemes in dependency-aware solving [40, 47, 52]. Compared to SAT solving, QBF solving is still at an earlier stage. However, QBF solving has seen huge improvements during the past 15 years [49], and there are problems of practical relevance where QBF solvers outperform SAT solvers [28].

The enormous success of SAT and QBF solving of course raises theoretical questions of utmost importance: why are these solvers so successful and what are their limitations? The main approach through understanding these questions comes from proof complexity [20, 46]. The central problem in proof complexity is to determine the size of the smallest proof for a given formula in a specified proof system, typically defined through a set of axioms and inference rules. Traces of runs of SAT/QBF solvers on unsatisfiable instances yield proofs of unsatisfiability, whereby each solver implicitly defines a proof system. In particular, SAT solvers implementing the DPLL and CDCL paradigms are based on resolution [46], which is arguably the most studied proof system in proof complexity.

*Propositional resolution* operates on clauses and uses the resolution rule

$$\frac{C \vee x \quad D \vee \bar{x}}{C \vee D} \quad (1)$$

as its only inference rule to derive a new clause  $C \vee D$  from the two parent clauses  $C \vee x$  and  $D \vee \bar{x}$ .<sup>2</sup> There is a host of lower bounds and lower bound techniques available for propositional resolution (cf. [5, 38, 50] for surveys).

While it is relatively easy to see that the classic DPLL branching algorithm [25, 26] exactly corresponds to tree-like resolution (where resolution derivations are in form of a tree), the *relation between CDCL and resolution* is far more complex. On the one hand, resolution proofs can be generated efficiently from traces of CDCL runs on unsatisfiable formulas [4], a crucial observation being that learned clauses are derivable by resolution [4, 43]. The opposite simulation is considerably more difficult, with a series of works [1, 4, 33, 48] culminating in the result that CDCL can efficiently simulate arbitrary resolution proofs, i.e., resolution and CDCL are equivalent. This directly implies that all known lower bounds for proof size in resolution translate into lower bounds for CDCL running time. In addition, other measures such as proof space model memory requirements of SAT solvers, thereby implying lower bounds on memory consumption, in particular when considering time-space tradeoffs [45].

<sup>1</sup> In this paper we focus on prenex QBFs with a CNF matrix.

<sup>2</sup> We denote such a resolution inference with pivot  $x$  by  $(C \vee x) \stackrel{x}{\bowtie} (D \vee \bar{x})$  throughout the paper.

Exciting as this equivalence between CDCL and resolution is from a theoretical point of view, it has to be interpreted with care. Proof systems are inherently non-deterministic procedures, while CDCL algorithms are largely deterministic (some randomisation might occasionally be used). To overcome this discrepancy, the simulations of resolution by CDCL [4, 48] use arbitrary decision heuristics and perform excessive restarts, both of which diverge from practical CDCL policies. Indeed, in very recent work [54] it was shown that CDCL with practical decision heuristics such as VSIDS [55] is exponentially weaker than resolution, and similar results have been obtained for further decision heuristics [44]. Regarding restarts there is intense research aiming to determine the power of CDCL without restarts from a proof complexity perspective (cf. [19, 21]).

On the QBF level, this naturally raises the question *what proof system corresponds to QCDCL*. As in propositional proof complexity, QBF resolution systems take a prominent place in the QBF proof system landscape, with the basic and historically first **Q-resolution** system [37] receiving key attention. **Q-resolution** is a refutational system that proves the falsity of fully quantified prenex QBFs with a CNF matrix (QCNFs). The system allows to use the propositional resolution rule (1) under the conditions that the pivot  $x$  is an existential variable and the resolvent  $C \vee D$  is non-tautological. In addition, **Q-resolution** uses a *universal reduction rule*

$$\frac{C \vee u}{C}, \quad (2)$$

where  $u$  is a universal literal that in the quantifier prefix is quantified right of all variables in  $C$ , i.e., none of the literals in  $C$  depends on  $u$ . For **Q-resolution** we have a number of lower bounds [3, 8, 12] as well as lower bound techniques, some of them lifted from propositional proof complexity [13, 15], but more interestingly some of them genuine to the QBF domain [8, 10] that unveil deep connections between proof size and circuit complexity [11, 16], unparalleled in the propositional domain.

Unlike in the relation between SAT and CDCL, it has been open whether QCDCL runs can be efficiently translated into **Q-resolution**. Instead, QCDCL runs can be simulated by the stronger QBF resolution system of **long-distance Q-resolution** [2, 56]. In fact, this system originates from solving, where it was noted that clauses learned from QCDCL conflicts can be derived in **long-distance Q-resolution** [56]. **Long-distance Q-resolution** implements a more liberal use of the resolution rule (1), which allows to derive certain tautologies. In general, allowing to derive tautologies with (1) is unsound. However, the tautologies allowed in **long-distance Q-resolution** do not present problems for soundness and are exactly those clauses needed when learning clauses in QCDCL. Hence **long-distance Q-resolution** simulates QCDCL [2, 56]. However, it is known that **long-distance Q-resolution** allows exponentially shorter proofs than **Q-resolution** for some QBFs [8, 9, 27].

We also remark that there are further QBF resolution systems (cf. [18] for an overview) and even stronger QBF calculi [11, 14, 23, 34]. Some of these correspond to other solving approaches in QBF, such as the system  $\forall\text{Exp}+\text{Res}$  [36] that captures expansion QBF solving [6].

In summary, it is fair to say that the relations between QCDCL solving and QBF resolution (either **Q-resolution** or **long-distance Q-resolution**) are *currently not well understood*. In particular, an analogue of the equivalence of CDCL SAT solving and propositional resolution [1, 4, 48] is currently absent in the QBF domain. This brings us to the topic of this paper. However, rather than giving an overview of our results in this introduction, we will describe our results in Sections 3 to 7, after stating some preliminaries in Section 2. Most proofs will be omitted in this extended abstract due to space constraints.

## 2 Preliminaries

### 2.1 Propositional and quantified formulas

We will consider propositional and quantified formulas over a countable set of variables. Variables and negations of variables are called *literals*, i.e., for a variable  $x$  we can form two literals:  $x$  and its negation  $\bar{x}$ . Sometimes we write  $x^1$  instead of  $x$  and  $x^0$  instead of  $\bar{x}$ . We denote the corresponding variable as  $\text{var}(x) := \text{var}(\bar{x}) := x$ .

A *clause* is a disjunction  $\ell_1 \vee \dots \vee \ell_m$  of some literals  $\ell_1, \dots, \ell_m$ . We will sometimes view a clause as a set of literals, i.e., we will use the notation  $\ell \in C$  if the literal  $\ell$  is one of the literals in the clause  $C$ . If  $m = 1$ , we will often write  $(\ell_1)$  to emphasize the difference between literals and clauses. The *empty clause* is the clause consisting of zero literals, denoted by  $(\perp)$ . For reasons of consistency it is helpful to define an *empty literal*, denoted by  $\perp$  in our case. As a consequence, we have  $\perp \in (\perp)$ , although we define the empty clause as a clause with zero literals.

The negation of a clause  $C = \ell_1 \vee \dots \vee \ell_m$  is called a *term*, i.e., terms are conjunctions  $\bar{\ell}_1 \wedge \dots \wedge \bar{\ell}_m$  of literals. Similarly terms can be considered as sets of literals. A *CNF* (*conjunctive normal form*) is a conjunction of clauses.

Let  $C = \ell_1 \vee \dots \vee \ell_m$ . We define  $\text{var}(C) := \{\text{var}(\ell_1), \dots, \text{var}(\ell_m)\}$ . For a CNF  $\phi = C_1 \wedge \dots \wedge C_n$  we define  $\text{var}(\phi) := \bigcup_{i=1}^n \text{var}(C_i)$ .

A clause or a set  $C$  of literals is called *tautological*, if there is a variable  $x$  with  $x, \bar{x} \in C$ .

An *assignment*  $\sigma$  of a set of variables  $X$  is a non-tautological set of literals, such that for all  $x \in X$  there is  $\ell \in \sigma$  with  $\text{var}(\ell) = x$ . The restriction of a clause  $C$  by an assignment  $\sigma$  is defined as

$$C|_\sigma := \begin{cases} \top \text{ (true)} & \text{if } C \cap \sigma \neq \emptyset, \\ \bigvee_{\substack{\ell \in C \\ \ell \notin \sigma}} \ell & \text{otherwise.} \end{cases}$$

For example, let  $C = t \vee x \vee y \vee \bar{z}$  and define the assignment  $\sigma := \{\bar{x}, z, w\}$ . Then we have  $C|_\sigma = t \vee y$ . Note that the set of assigned variables might differ from  $\text{var}(C)$ . In our case,  $\sigma$  is an assignment of the set  $X := \{x, z, w\}$ .

One can interpret  $\sigma$  as an operator that sets all literals from  $\sigma$  to the Boolean constant 1. We denote the set of assignments of  $X$  by  $\langle X \rangle$ . A CNF  $\phi$  *entails* another CNF  $\psi$  if each assignment that satisfies  $\phi$  also satisfies  $\psi$  (denoted by  $\phi \models \psi$ ).

A *QBF* (*quantified Boolean formula*)  $\Phi = Q \cdot \phi$  is a propositional formula  $\phi$  (also called *matrix*) together with a *prefix*  $Q$ . A prefix  $Q_1 x_1 Q_2 x_2 \dots Q_k x_k$  consists of variables  $x_1, \dots, x_k$  and quantifiers  $Q_1, \dots, Q_k \in \{\exists, \forall\}$ . We obtain an equivalent formula if we unite adjacent quantifiers of the same type. Therefore we can always assume the prefix to be in the form

$$Q = Q'_1 X_1 Q'_2 X_2 \dots Q'_s X_s$$

with nonempty sets of variables  $X_1, \dots, X_s$  and quantifiers  $Q'_1, \dots, Q'_s \in \{\exists, \forall\}$  such that  $Q'_i \neq Q'_{i+1}$  for  $i \in [s-1]$ . For a variable  $x$  in  $Q$  we denote the *quantifier level* with respect to  $Q$  by  $\text{lv}(x) = \text{lv}_\Phi(x) = i$ , if  $x \in X_i$ . Variables from  $\Phi$  are called *existential*, if the corresponding quantifier is  $\exists$ , and *universal* if the quantifier is  $\forall$ . We denote the set of existential variables from  $\Phi$  by  $\text{var}_\exists(\Phi)$ , and the set of universal variables by  $\text{var}_\forall(\Phi)$ .

A QBF with CNF matrix is called a *QCNF*. We require that all clauses from a matrix of a QCNF are non-tautological, otherwise we just delete these clauses. This requirement is crucial for the correctness of the derivation rules we define later for QBF proof systems. Since we will only discuss refutational proof systems, we will always assume that all QCNFs we consider are false.

A QBF can be interpreted as a game between two players: The  $\exists$ -player and the  $\forall$ -player. These players have to assign the respective variables one by one along the quantifier order from left to right. The  $\forall$ -player wins the game if and only if the matrix of the QBF gets falsified by this assignment. It is well known that for every false QBF  $\Phi = \mathcal{Q} \cdot \phi$  there exists a winning strategy for the  $\forall$ -player.

## 2.2 Q-resolution and long-distance Q-resolution

Let  $C_1$  and  $C_2$  be two clauses of a QCNF  $\Phi$  and let  $\ell$  be an existential literal with  $\text{var}(\ell) \notin \text{var}(C_1) \cup \text{var}(C_2)$ . The *resolvent* of  $C_1 \vee \ell$  and  $C_2 \vee \bar{\ell}$  over  $\ell$  is defined as

$$(C_1 \vee \ell) \overset{\ell}{\bowtie} (C_2 \vee \bar{\ell}) := C_1 \vee C_2.$$

Let  $C := u_1 \vee \dots \vee u_m \vee x_1 \vee \dots \vee x_n \vee v_1 \vee \dots \vee v_s$  be a clause from  $\Phi$ , where  $u_1, \dots, u_m, v_1, \dots, v_s$  are universal literals,  $x_1, \dots, x_n$  are existential literals and

$$\{v \in C : v \text{ is universal and } \text{lv}(v) > \text{lv}(x_i) \text{ for all } i \in [n]\} = \{v_1, \dots, v_s\}.$$

Then we can perform a *reduction* step and obtain

$$\text{red}(C) := u_1 \vee \dots \vee u_m \vee x_1 \vee \dots \vee x_n.$$

For a CNF  $\phi = \{C_1, \dots, C_k\}$  we define  $\text{red}(\phi) := \{\text{red}(C_1), \dots, \text{red}(C_k)\}$ .

Q-resolution [37] is a refutational proof system for false QCNFs. A Q-resolution proof  $\pi$  of a clause  $C$  from a QCNF  $\Phi = \mathcal{Q} \cdot \phi$  is a sequence of clauses  $\pi = C_1, \dots, C_m$  with  $C_m = C$ . Each  $C_i$  has to be derived by one of the following three rules:

- *Axiom*:  $C_i \in \phi$ ;
- *Resolution*:  $C_i = C_j \overset{x}{\bowtie} C_k$  for some  $j, k < i$  and  $x \in \text{var}_{\exists}(\Phi)$ , and  $C_i$  is non-tautological;
- *Reduction*:  $C_i = \text{red}(C_j)$  for some  $j < i$ .

Note that none of our axioms are tautological by definition. A *refutation* of a QCNF  $\Phi$  is a proof of the empty clause  $(\perp)$ .

For the simulating QCDCL runs, long-distance Q-resolution was introduced in [2, 56]. This extension of Q-resolution allows to derive universal tautologies under certain conditions. As in Q-resolution, there are three rules by which a clause  $C_i$  can be derived. The axiom and reduction rules are identical to Q-resolution, but the resolution rule is changed to

- *Resolution (long-distance)*:  $C_i = C_j \overset{x}{\bowtie} C_k$  for some  $j, k < i$  and  $x \in \text{var}_{\exists}(\Phi)$ . The resolvent  $C_i$  is allowed to contain a tautology  $u \vee \bar{u}$  if  $u$  is a universal variable. If  $u \in \text{var}(C_j) \cap \text{var}(C_k)$ , then we additionally require  $\text{lv}(u) > \text{lv}(x)$ .

Note that a long-distance Q-resolution proof without tautologies is just a Q-resolution proof.

Creating universal tautologies without any assumptions is unsound in general. For example, consider the true QCNF  $\Psi := \forall u \exists x \cdot (u \vee \bar{x}) \wedge (\bar{u} \vee x)$ . There is a winning strategy for the  $\exists$ -player by assigning  $x$  equal to  $u$ . Hence, the step  $\text{red}((u \vee \bar{x}) \overset{x}{\bowtie} (\bar{u} \vee x)) = (\perp)$  is unsound since we resolved over an existential literal  $x$  with  $\text{lv}_{\Psi}(x) > \text{lv}_{\Psi}(u)$  while generating  $u \vee \bar{u}$ .

### 3 Our framework: versions of QCDCL as formal proof systems

We now start to describe the framework for our results. Technically, this paper hinges on the formalisation of QCDCL solving as precisely defined proof systems, which can subsequently be analysed from a proof-complexity perspective. For this we need to formally define central ingredients of QCDCL solving, including trails, decision policies, unit propagation, and clause learning (cf. [18] for background). For decisions and unit propagation we will consider different policies: those corresponding to QCDCL solving in practice and new policies, yet unexplored. We will show that the corresponding QCDCL proof systems are all sound and complete.

We start with defining trails, decisions, unit propagations and our collection of policies.

► **Definition 1** (trails and policies for decision/unit propagation). *Let  $\Phi = \mathcal{Q} \cdot \phi$  be a QCNF in  $n$  variables. A trail  $\mathcal{T}$  for  $\Phi$  is a sequence of literals (or  $\perp$ ) of variables from  $\Phi$  with specific properties. We distinguish two types of literals in  $\mathcal{T}$ : decision literals, that can be both existential and universal, and propagated literals, that are either existential or  $\perp$ . Most of the time we write a trail  $\mathcal{T}$  as*

$$\mathcal{T} = (p_{(0,1)}, \dots, p_{(0,g_0)}; \mathbf{d}_1, p_{(1,1)}, \dots, p_{(1,g_1)}; \dots; \mathbf{d}_r, p_{(r,1)}, \dots, p_{(r,g_r)}).$$

We typically denote decision literals by  $d_i$  and propagated literals by  $p_{(i,j)}$ . To emphasize decisions, we will set decision literals in the trail in **boldface** and put a semicolon at the end of each decision level. The literal  $p_{(i,j)}$  represents the  $j^{\text{th}}$  propagated literal at the  $i^{\text{th}}$  decision level, determined by the corresponding decision  $d_i$ . The decision level 0 is the only level without a decision literal. Similarly as with clauses, we can view  $\mathcal{T}$  as a set of literals or as an assignment and use the notation  $x \in \mathcal{T}$  if the literal  $x$  is contained in  $\mathcal{T}$ .

Let  $s \in \{0, \dots, r\}$  and  $t \in \{0, \dots, g_s\}$ . The subtrail of  $\mathcal{T}$  at time  $(s, t)$  is the trail consisting of all literals from the leftmost literal in  $\mathcal{T}$  up to (and including)  $p_{(s,t)}$ , if  $t \neq 0$ , or  $d_s$  otherwise. We denote this subtrail by  $\mathcal{T}[s, t]$ . The subtrail  $\mathcal{T}[0, 0]$  is the empty trail.

We impose some further requirements for  $\mathcal{T}$  to be a trail for a QCNF  $\Phi$ . The decisions have to be non-tautological and non-repeating, i.e., we require  $\text{var}(d_i) \neq \text{var}(d_k)$  for each  $i \neq k \in \{0, \dots, r\}$ . If  $\perp \in \mathcal{T}$ , then this must be the last (rightmost) literal in  $\mathcal{T}$ . In this case we say that  $\mathcal{T}$  has run into a conflict.

We define four policies, concerning the decision of literals, from which we can choose exactly one at a time:

- **LEV-ORD** - For each  $d_i \in \mathcal{T}$  we have  $lv(d_i) \leq lv(x)$  for all  $x \in \text{var}(\phi) \setminus \text{var}(\mathcal{T}[i-1, g_{i-1}])$ . This means that we have to decide the variables along the quantification order.
- **ASS-ORD** - We can decide a literal  $d_k$  if it is existential, or if it is universal and  $lv(d_1) \leq \dots \leq lv(d_k)$ .
- **ASS-R-ORD** - We can only decide an existential variable  $x$  next, if and only if we already decided all universal variables  $u$  with  $lv(u) < lv(x)$  before.
- **ANY-ORD** - We can choose any remaining literal as the next decision.

We define two more policies concerning unit propagation. Again, we have to choose exactly one:

- **RED** - For each  $p_{(i,j)} \in \mathcal{T}$  there has to be a clause  $C \in \phi$  such that  $\text{red}(C|_{\mathcal{T}[i,j-1]}) = (p_{(i,j)})$ .
- **NO-RED** - For each  $p_{(i,j)} \in \mathcal{T}$  there has to be a clause  $C \in \phi$  with  $C|_{\mathcal{T}[i,j-1]} = (p_{(i,j)})$ .

These clauses  $C$  as described in the unit-propagation policies are called antecedent clauses and will be denoted by  $\text{ante}_{\mathcal{T}}(p_{(i,j)}) := C$ . There could be more than one such suitable clause, in which case we will just choose one of them arbitrarily. The antecedent clauses clearly depend on the unit propagation policy we use.

The size of a trail  $\mathcal{T}$  is measured by  $|\mathcal{T}|$  (i.e., the cardinality of  $\mathcal{T}$  as a set). Because each trail can at most contain all variables, we have  $|\mathcal{T}| \in \mathcal{O}(n)$ .

We remark that QCDCL as used in practice employs the policies LEV-ORD and RED, and the decision policy ANY-ORD originates from CDCL.

The policies RED and NO-RED determine the notion of unit clauses, which are important for unit propagation.

► **Definition 2** (unit clauses). *Let  $C$  be a clause. In the policy RED, we call  $C$  a unit clause if  $\text{red}(C) = (x)$  for an existential literal  $x$  or  $x = \perp$ . Otherwise, for NO-RED, we call  $C$  a unit clause if  $C = (x)$  for an existential literal  $x$  or  $x = \perp$ .*

Note that  $(u)$  is not a unit clause under the policy NO-RED for a universal literal  $u$ .

In (Q)CDCL, whenever a trail  $\mathcal{T}$  runs into a conflict, i.e., a clause  $C$  from  $\Phi$  is falsified, we perform conflict analysis in the form of *clause learning*. This results in a clause  $D$  that follows from  $\Phi$  and describes a reason for the conflict. Such conflict clauses are obtained by performing resolution (for CDCL) and long-distance Q-resolution (for QCDCL), starting from the conflict clause  $C$  and resolving along the propagated variables in  $\mathcal{T}$  in reverse order (skipping resolution steps when the pivot is missing).

► **Definition 3** (learnable clauses). *Let  $\Phi = \mathcal{Q} \cdot \phi$  be a QCNF and let*

$$\mathcal{T} = (p_{(0,1)}, \dots, p_{(0,g_0)}; \mathbf{d}_1, p_{(1,1)}, \dots, p_{(1,g_1)}; \dots; \mathbf{d}_r, p_{(r,1)}, \dots, p_{(r,g_r)})$$

*be a trail with  $p_{(r,g_r)} = \perp$  that follows policies  $P \in \{\text{LEV-ORD}, \text{ASS-ORD}, \text{ASS-R-ORD}, \text{ANY-ORD}\}$  and  $R \in \{\text{RED}, \text{NO-RED}\}$ . We call a clause learnable from  $\mathcal{T}$  if it appears in the sequence*

$$\mathcal{L}_{\mathcal{T}} := (C_{(r,g_r)}, \dots, C_{(r,1)}, \dots, C_{(1,g_1)}, \dots, C_{(1,1)}, C_{(0,g_0)}, \dots, C_{(0,1)})$$

*where  $C_{(r,g_r)} := \text{red}(\text{ante}(p_{(r,g_r)}))$ ,*

$$C_{(i,j)} := \begin{cases} \text{red}\left(C_{(i,j+1)} \stackrel{p_{(i,j)}}{\boxtimes} \text{red}(\text{ante}(p_{(i,j)}))\right) & \text{if } \bar{p}_{(i,j)} \in C_{(i,j+1)}, \\ C_{(i,j+1)} & \text{otherwise} \end{cases}$$

*for  $i \in \{0, \dots, r\}$ ,  $j \in [g_i - 1]$ , and*

$$C_{(i,g_i)} := \begin{cases} \text{red}\left(C_{(i+1,1)} \stackrel{p_{(i,g_i)}}{\boxtimes} \text{red}(\text{ante}(p_{(i,g_i)}))\right) & \text{if } \bar{p}_{(i,g_i)} \in C_{(i+1,1)}, \\ C_{(i+1,1)} & \text{otherwise} \end{cases}$$

*for  $i \in \{0, \dots, r-1\}$ .*

Note that clause learning works independently from the used policy. Even if we choose the policy NO-RED, we might have to make reduction steps in this process. After the construction of each trail  $\mathcal{T}$  we will choose to learn exactly one clause from  $\mathcal{L}_{\mathcal{T}}$ . The actual choice represents a kind of nondeterminism in the learning process.

Next we formalise natural trails, where we are not allowed to skip unit propagations.

► **Definition 4** (natural trails). *We call a trail  $\mathcal{T}$  natural, if the following holds: For any time  $(s, t)$ ,  $s \in \{0, \dots, r\}$  and  $t \in [g_s]$ , if  $\{D_1, \dots, D_h\}$  are all clauses from the corresponding QCNF that become unit clauses  $(\ell_1), \dots, (\ell_h)$  under the assignment  $\mathcal{T}[s, t-1]$ , then the next propagated literal has to be one of the  $\ell_i$  together with  $D_i$  as antecedent clause. If one of the  $\ell_i$  is  $\perp$ , then we have to choose this  $\ell_i$ . I.e., conflicts have higher priority.*

The next definition presents the main framework for this paper. Having defined trails in a general sense, we specify how a trail can be generated during a QCDCL run. We introduce the notion of QCDCL-based proofs consisting of three components: the naturally created trails, the clauses learned from each trail, and the proof of each learned clause.

► **Definition 5** (QCDCL proof systems). *Let  $\Phi = \mathcal{Q} \cdot \phi$  be a QCNF in  $n$  variables. We call a triple of sequences*

$$\iota = (\underbrace{(\mathcal{T}_1, \dots, \mathcal{T}_m)}_{=: \theta(\iota)}, \underbrace{(C_1, \dots, C_m)}_{=: \lambda(\iota)}, \underbrace{(\pi_1, \dots, \pi_m)}_{=: \rho(\iota)})$$

a QCDCL $_R^P$  proof from  $\Phi$  of a clause  $C$  for  $P \in \{\text{LEV-ORD}, \text{ASS-ORD}, \text{ASS-R-ORD}, \text{ANY-ORD}\}$  and  $R \in \{\text{RED}, \text{NO-RED}\}$ , if for all  $i \in [m]$  the trail  $\mathcal{T}_i$  follows the policies  $P$  and  $R$  and uses the QCNF  $\mathcal{Q} \cdot (\phi \cup \{C_1, \dots, C_{i-1}\})$ , where  $C_j \in \mathcal{L}_{\mathcal{T}_j}$  is a clause learnable from  $\mathcal{T}_j$  and  $C_m = C$ . Each  $\pi_i$  is the derivation of the clause  $C_i$  from  $\mathcal{Q} \cdot (\phi \cup \{C_1, \dots, C_{i-1}\})$  as defined recursively in Definition 3. We will denote  $(\mathcal{T}_1, \dots, \mathcal{T}_m)$  by  $\theta(\iota)$ ,  $(C_1, \dots, C_m)$  by  $\lambda(\iota)$  and  $(\pi_1, \dots, \pi_m)$  by  $\rho(\iota)$ . Note that all these trails need to run into a conflict in order to start clause learning. If  $C = (\perp)$  we call  $\iota$  a refutation.

We also require that  $\mathcal{T}_1$  is natural and for each  $i \in \{2, \dots, m\}$  there exist indices  $(s, t)$  such that the following holds:

- $\mathcal{T}_i[s, t] = \mathcal{T}_{i-1}[s, t]$ .
- For each subtrail  $\mathcal{T}_i[a, b]$  with  $\mathcal{T}_i[s, t] \subseteq \mathcal{T}_i[a, b]$  and  $\perp \notin \mathcal{T}_i[a, b]$  let  $D_1, \dots, D_h$  be all the clauses in  $\phi \cup \{C_1, \dots, C_{i-1}\}$  such that under the assignment  $\mathcal{T}_i[a, b]$  these clauses get unit (under the policy  $R$ ) with corresponding literals  $\ell_1, \dots, \ell_h$ . Then we have to propagate one of these literals next, i.e.,  $\ell_j \in \mathcal{T}_i[a, b+1]$  for some  $j \in [h]$ , and take the corresponding clause  $D_j$  as antecedent.
- In the situation above, if  $\perp \in \{\ell_1, \dots, \ell_h\}$ , then  $\perp \in \mathcal{T}_i[a, b+1]$ . I.e., we have to run into a conflict as soon as we find one.

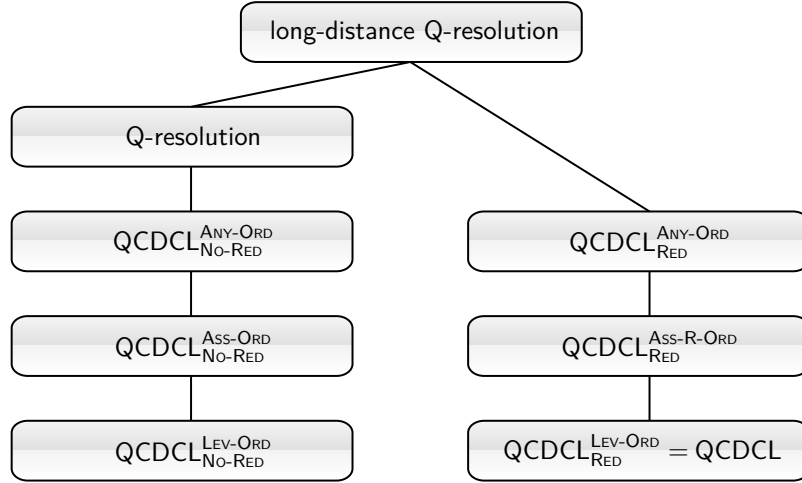

We call this process backtracking to  $\mathcal{T}_i[s, t]$ . Backtracking to  $\mathcal{T}_i[0, 0]$  is called restarting. The size of a proof  $\iota$  is measured by  $|\iota| := \sum_{j=1}^m |\mathcal{T}_j| \in \mathcal{O}(mn)$ .

The corresponding (refutational) proof system for false QCNFs is denoted QCDCL $_R^P$ . We will refer to these systems as QCDCL proof systems. A trail  $\mathcal{T}$  that follows the policies  $P$  and  $R$  is a QCDCL $_R^P$  trail.

Note that the first trail  $\mathcal{T}_1$  of each proof  $\iota$  is always natural.

Combining the two policies RED and NO-RED for unit propagation and the four policies ANY-ORD, LEV-ORD, ASS-ORD, and ASS-R-ORD, we obtain six QCDCL systems. These are depicted in Figure 1 (we are not interested in the systems QCDCL $_{\text{RED}}^{\text{ASS-ORD}}$  and QCDCL $_{\text{NO-RED}}^{\text{ASS-R-ORD}}$  since ASS-ORD and ASS-R-ORD would not be beneficial in these combinations). As mentioned, combining LEV-ORD with RED yields the standard QCDCL system, and we will also write QCDCL for QCDCL $_{\text{RED}}^{\text{LEV-ORD}}$ . The other five variants are introduced here for the first time.

The decision policies ASS-ORD and ASS-R-ORD might seem slightly unintuitive at first sight. We show that these policies guarantee the learning of so-called asserting clauses (Definition 6) in association with NO-RED resp. RED.

■ **Figure 1** Overview of the defined QCDCL proof systems. Lines denote p-simulations and follow by definition and Theorem 8.

A proof system  $P$  p-simulates a proof system  $S$  if each  $S$  proof can be efficiently transformed into a  $P$  proof of the same formula [24]. If the systems p-simulate each other, they are p-equivalent.

It will turn out that  $\pi_1, \dots, \pi_m$  in Definition 5 are in fact valid long-distance Q-resolution proofs. To prove this, we will argue that in proof systems with NO-RED we cannot derive any tautologies, while with RED we can at most derive universal tautologies.

Next we introduce *asserting learning schemes*. These are commonly used in practice since they guarantee a kind of progression in a run. These learning schemes are important to prevent a trail from backtracking too often.

► **Definition 6** (asserting clauses and asserting learning schemes). Let  $\Phi := \mathcal{Q} \cdot \phi$  be a QCNF in any of the defined QCDCL systems. Let

$$\mathcal{T} = (p_{(0,1)}, \dots, p_{(0,g_0)}; \mathbf{d}_1, p_{(1,1)}, \dots, p_{(1,g_1)}; \dots; \mathbf{d}_r, p_{(r,1)}, \dots, p_{(r,g_r)} = \perp)$$

be a trail which follows the corresponding policies and  $\mathcal{L}_{\mathcal{T}}$  the sequence of learnable clauses. A nonempty clause  $C \in \mathcal{L}_{\mathcal{T}}$  is called an asserting clause, if it becomes unit after backtracking, i.e., there exists a time  $(s, t)$  with  $s \in \{0, \dots, r-1\}$  and  $t \in [g_s]$  such that  $C|_{\mathcal{T}_{[s,t]}}$  is a unit clause under the corresponding system.

Let  $\mathbb{T}$  be the set of trails  $\mathcal{T}$  for  $\Phi$  such that  $\perp \in \mathcal{T}$ . A learning scheme  $\xi$  is a map with domain  $\mathbb{T}$ , which maps each  $\mathcal{T}$  to a clause  $\xi(\mathcal{T}) \in \mathcal{L}_{\mathcal{T}}$ .

A learning scheme  $\xi$  is called asserting if it maps to asserting clauses or  $(\perp)$  as long as  $\mathcal{L}_{\mathcal{T}}$  contains such.

It is not guaranteed that we will always find asserting clauses for trails. For example consider the false QCNF  $\forall u \exists x \cdot (u \vee x) \wedge (u \vee \bar{x}) \wedge (\bar{u} \vee x) \wedge (\bar{u} \vee \bar{x})$  and the trail  $\mathcal{T} = (\mathbf{x}; \mathbf{u}, \perp)$  under the system  $\text{QCDCL}_{\text{NO-RED}}^{\text{ANY-ORD}}$ . We can only learn the clause  $(\bar{u} \vee \bar{x})$ , which is non-unit under  $\mathcal{T}[0, 0] = \emptyset$ .

However, we can always learn asserting clauses when using one of the policies ASS-ORD or ASS-R-ORD, which is the reason why we introduced these policies.

► **Lemma 7.**

- Let  $\mathcal{T}$  be a trail under the policies ASS-ORD and NO-RED. If  $(\perp) \notin \mathcal{L}_{\mathcal{T}}$ , then there exists an asserting clause  $D \in \mathcal{L}_{\mathcal{T}}$ .
- Let  $\mathcal{T}$  be a trail under the policies ASS-R-ORD and RED. If  $(\perp) \notin \mathcal{L}_{\mathcal{T}}$ , then there exists an asserting clause  $D \in \mathcal{L}_{\mathcal{T}}$ .

We establish that all systems depicted in Figure 1 are sound and complete.

► **Theorem 8.** *All defined QCDCL proof systems are sound and complete QBF proof systems. In particular, all QCDCL calculi are  $p$ -simulated by long-distance Q-resolution and the proof systems with NO-RED are even  $p$ -simulated by Q-resolution.*

Soundness is shown via efficiently constructing long-distance Q-resolution proofs from QCDCL proofs. Crucially, when using the unit-propagation policy NO-RED, then no long-distance steps are actually needed and we just construct Q-resolution proofs. The resulting simulations are depicted in Figure 1. Simulations between the QCDCL calculi follow by definition. We remark already here that this simulation order simplifies further due to our results in the following sections (cf. Figure 2).

Proving that QCDCL decisions do not necessarily need to follow the order of quantification (as is done in practical QCDCL with policy LEV-ORD), might be a somewhat surprising discovery. It seems to us that inside the QBF community there is the wide-spread belief that following the quantification order in decisions is needed for soundness (cf. e.g. [30, 41, 56]).<sup>3</sup> While this is true for QDPLL [22, 30],<sup>4</sup> it is actually not needed in QCDCL: the quantification order is immaterial for the decisions as long as the quantification order is correctly taken into account when deriving learned clauses (Theorem 8).<sup>5</sup> Hence our theoretical work also opens the door towards *new solving approaches in practice* (cf. the discussion in Section 8).

From a theoretical point of view, formalising the QCDCL ingredients into proof systems enables a precise proof-theoretic analysis of the QCDCL systems and their comparison to Q-resolution. This will be the underlying feature of our results in the following two sections, showing the incomparability of Q-resolution and QCDCL (Section 4) and the lower bounds for QCDCL (Section 5). We will use it further to obtain a version of QCDCL that is even  $p$ -equivalent to Q-resolution (Section 6).

## 4 QCDCL and Q-resolution are incomparable

This section establishes that QCDCL and Q-resolution are incomparable by exponential separations, i.e., there exist QBFs that are easy for QCDCL, but require exponential-size Q-resolution refutations, and vice versa. As explained above, this is in stark contrast to the propositional setting, where CDCL and resolution are equivalent.

► **Theorem 9.** *The systems Q-resolution and QCDCL are incomparable.*

Proving Theorem 9 requires two families of QBFs. For the first we take the parity formulas.

► **Definition 10** ([12]). *The QCNF QParity<sub>n</sub> consists of the prefix  $\exists x_1 \dots x_n \forall z \exists t_2 \dots t_n$  and the matrix*

$$\begin{aligned} & x_1 \vee x_2 \vee \bar{t}_2, \quad x_1 \vee \bar{x}_2 \vee t_2, \quad \bar{x}_1 \vee x_2 \vee t_2, \quad \bar{x}_1 \vee \bar{x}_2 \vee \bar{t}_2, \\ & x_i \vee t_{i-1} \vee \bar{t}_i, \quad x_i \vee \bar{t}_{i-1} \vee t_i, \quad \bar{x}_i \vee t_{i-1} \vee t_i, \quad \bar{x}_i \vee \bar{t}_{i-1} \vee \bar{t}_i, \\ & t_n \vee z, \quad \bar{t}_n \vee \bar{z} \end{aligned}$$

for  $i \in \{2, \dots, n\}$ .

<sup>3</sup> In fact we thought so too, prior to this paper.

<sup>4</sup> The fact that the earlier QDPLL algorithm [22] needs to obey the quantifier order might have been the reason why this policy was adopted in QCDCL as well [56].

<sup>5</sup> We note, however, that the approach of *dependency learning* [47] starts with an empty set of dependency conditions (cf. [7, 52] for background on dependencies) and incrementally learns new dependencies. As decisions only need to respect the learned dependencies, they can initially be made out of order [47].

The formulas assert that there is an input  $x_1, \dots, x_n$  such that the parity  $\bigoplus_{i \in [n]} x_i$  is not equal to  $z$ . Since  $z$  is universally quantified, this means that  $\bigoplus_{i \in [n]} x_i$  should be neither 0 nor 1, an obvious contradiction. The parity computation is encoded by using variables  $t_i$  for the prefix sums  $\bigoplus_{j \in [i]} x_j$ . Using strategy extraction for Q-resolution [2, 12] and the result that the parity function is hard for bounded-depth circuits [29, 32], one can show that the  $\text{QParity}_n$  formulas require exponential-size Q-resolution refutations [12].

Here we show that  $\text{QParity}_n$  is easy for QCDCL.

► **Proposition 11.**  *$\text{QParity}_n$  has polynomial-size proofs in QCDCL.*

This requires to construct specific trails and clauses learned from these trails that together comprise a short QCDCL proof of the formulas.

For the opposite separation we consider the following QBFs:

► **Definition 12.** *Let  $\text{PHP}_n^{n+1}$  be the set of clauses for the pigeonhole principle with  $n$  holes and  $n + 1$  pigeons using variables  $x_1, \dots, x_{s_n}$ . Let  $\text{Trapdoor}_n$  be the QCNF with the prefix  $\exists y_1, \dots, y_{s_n} \forall w \exists t, x_1, \dots, x_{s_n} \forall u$  and the matrix*

$$\text{PHP}_n^{n+1}(x_1, \dots, x_{s_n}) \tag{3}$$

$$\bar{y}_i \vee x_i \vee u, \quad y_i \vee \bar{x}_i \vee u \tag{4}$$

$$y_i \vee w \vee t, \quad y_i \vee w \vee \bar{t}, \quad \bar{y}_i \vee w \vee t, \quad \bar{y}_i \vee w \vee \bar{t} \tag{5}$$

for  $i = 1, \dots, s_n$ .

We show that these formulas  $\text{Trapdoor}_n$  require exponential-size QCDCL refutations. In QCDCL, variables have to be decided in order of the quantifier prefix, hence each QCDCL trail for  $\text{Trapdoor}_n$  has to start with the  $y$  variables, which by unit propagation (used together with universal reduction) propagates  $x_i = y_i$  for  $i \in [s_n]$  by clauses (4). Therefore the trail runs into a conflict on the PHP clauses (3). This happens repeatedly, forcing QCDCL to produce a resolution refutation of the clauses (3), which by the propositional resolution lower bound by Haken [31] has to be of exponential size.

► **Proposition 13.** *The QCNFs  $\text{Trapdoor}_n$  require exponential-size  $\text{QCDCL}_{\text{RED}}^{\text{LEV-ORD}}$  refutations.*

On the other hand, it is easy to obtain short Q-resolution refutations of  $\text{Trapdoor}_n$  by just using the clauses (5).

► **Proposition 14.** *The QCNFs  $\text{Trapdoor}_n$  have constant-size Q-resolution refutations.*

This establishes the separation of QCDCL and Q-resolution. We remark that in earlier work, Janota [35] showed that QCDCL with a specific asserting learning scheme requires large running time on some class of QBFs, whereas the same formulas are easy for Q-resolution. Of course, this raises the question whether another learning scheme might produce short QCDCL runs. In contrast, our Theorem 9 rules out any simulation of Q-resolution by QCDCL (or vice versa), regardless of the learning scheme used.

## 5 Lower bounds for QCDCL

The incomparability of Q-resolution and QCDCL raises the immediate question of what formulas are hard for QCDCL. Previous research has largely concentrated on showing lower bounds for Q-resolution (e.g. [8, 12, 37]). However, by our results from the last section, these lower bounds do not necessarily apply to QCDCL, and prior to this paper no dedicated lower bounds for QCDCL (with arbitrary learning schemes) were known.

Here we show that several formulas from the QBF literature, including the equality formulas and a large class of random QBFs [8] are indeed hard for QCDCL.

We start by defining a proof system in which we can analyse hardness in classical QCDCL.

► **Definition 15.** *We call a long-distance Q-resolution proof  $\pi$  of a clause  $C$  from a QCNF  $\Phi$  a long-distance QCDCL resolution proof of  $C$  from  $\Phi$ , if there exists a  $\text{QCDCL}_{\text{RED}}^{\text{LEV-ORD}}$  proof  $\iota$  of  $C$  from  $\Phi$  such that the long-distance Q-resolution proof  $\pi$  is obtained by pasting together the sub-proofs  $(\pi_1, \dots, \pi_m)$  from  $\iota$  (cf. Definition 5).*

The system long-distance QCDCL resolution identifies a fragment of long-distance Q-resolution, which collects all long-distance Q-resolution proofs that appear in  $\text{QCDCL}_{\text{RED}}^{\text{LEV-ORD}}$  derivations. By definition therefore, long-distance QCDCL resolution and  $\text{QCDCL}_{\text{RED}}^{\text{LEV-ORD}}$  are p-equivalent proof systems.

Our next goal is to identify a whole class of QCNFs that witness the hardness of QCDCL.

The equality formulas from [8] are arguably one of the simplest families of QBFs that are interesting from a proof complexity perspective. The formula  $\text{Equality}_n$  is defined as the QCNF

$$\exists x_1 \dots x_n \forall u_1 \dots u_n \exists t_1 \dots t_n \cdot (\bar{t}_1 \vee \dots \vee \bar{t}_n) \wedge \bigwedge_{i=1}^n ((\bar{x}_i \vee \bar{u}_i \vee t_i) \wedge (x_i \vee u_i \vee t_i)).$$

These formulas are of the type  $\Sigma_3^b$ , i.e., they have two quantifier alternations starting with  $\exists$ .

Inspired by this construction, [8] considered a class of randomly generated QCNFs, again of type  $\Sigma_3^b$ .

► **Definition 16 ([8]).** *For each  $1 \leq i \leq n$  let  $C_i^{(1)}, \dots, C_i^{(cn)}$  be clauses picked uniformly at random from the set of clauses containing 1 literal from the set  $U_i = \{u_i^{(1)}, \dots, u_i^{(m)}\}$  and 2 literals from  $X_i = \{x_i^{(1)}, \dots, x_i^{(n)}\}$ . Define the randomly generated QCNF  $Q(n, m, c)$  as:*

$$Q(n, m, c) := \exists X_1, \dots, X_n \forall U_1, \dots, U_n \exists t_1, \dots, t_n \cdot \bigwedge_{i=1}^n \bigwedge_{j=1}^{cn} (\bar{t}_i \vee C_i^{(j)}) \wedge (t_1 \vee \dots \vee t_n).$$

Suitably choosing the parameters  $c$  and  $m$ , we obtain false QBFs with high probability.

Both the equality and the random formulas require exponential-size proofs in Q-resolution (the random formulas whp) [8]. This is shown in [8] via the size-cost-capacity technique, a semantically grounded QBF lower-bound technique that infers Q-resolution hardness for formulas  $\Phi_n$  (and in fact hardness for even stronger systems) from lower bounds for the size of countermodels for  $\Phi_n$ .

It is not clear how to directly apply this technique to QCDCL. Instead, we identify a property, which we term the *XT-property*, that we can use to lift hardness from Q-resolution to QCDCL.

► **Definition 17.** *Let  $\Phi$  be a QCNF of the form  $\exists X \forall U \exists T \cdot \phi$  with sets of variables  $X = \{x_1, \dots, x_a\}$ ,  $U = \{u_1, \dots, u_b\}$  and  $T = \{t_1, \dots, t_c\}$ .*

*We call a clause  $C$  in the variables of  $\Phi$*

- *T-clause, if  $\text{var}(C) \cap X = \emptyset$ ,  $\text{var}(C) \cap U = \emptyset$  and  $\text{var}(C) \cap T \neq \emptyset$ ,*
- *XT-clause, if  $\text{var}(C) \cap X \neq \emptyset$ ,  $\text{var}(C) \cap U = \emptyset$  and  $\text{var}(C) \cap T \neq \emptyset$ ,*
- *XUT-clause, if  $\text{var}(C) \cap X \neq \emptyset$ ,  $\text{var}(C) \cap U \neq \emptyset$  and  $\text{var}(C) \cap T \neq \emptyset$ .*

*We say that  $\Phi$  fulfils the XT-property if  $\phi$  contains no XT-clauses as well as no unit T-clauses and there do not exist two T-clauses  $C_1, C_2 \in \phi$  that are resolvable.*

Intuitively, this says that in a  $\Sigma_3^b$  formula  $\Phi$  with quantifier prefix of the form  $\exists X \forall U \exists T$  with blocks of variables  $X, U, T$ , there is no direct connection between the  $X$  and  $T$  variables, i.e.,  $\Phi$  does not contain clauses with  $X$  and  $T$  variables, but no  $U$  variables.

We can then prove that QCDCL runs on formulas with this  $XT$ -property can be efficiently transformed into Q-resolution refutations, not only into long-distance Q-resolution refutations.

We first show that under the  $XT$ -property we cannot derive any  $XT$ -clauses.

► **Lemma 18.** *It is not possible to derive  $XT$ -clauses by long-distance Q-resolution from a QCNF  $\Phi$  that fulfils the  $XT$ -property.*

**Proof.** Assume that we can derive an  $XT$ -clause  $C$  by a long-distance Q-resolution proof  $\pi$  from  $\Phi$ . Let  $D$  be the first  $XT$ -clause in  $\pi$  ( $D$  might be equal to  $C$ ). Since  $\Phi$  contains no  $XT$ -clauses as axioms, the last step before  $D$  has to be a resolution or reduction. A reduction is not possible since the reduced universal literal would have been blocked by a  $T$ -literal in  $D$ .

Therefore  $D$  is the resolvent of two preceding clauses  $D_1$  and  $D_2$ . If we resolve over an  $X$ -literal, then one of these clauses has to be an  $XT$ -clause. The same is true for a resolution over a  $T$ -literal. However, this contradicts the fact that  $D$  was the first  $XT$ -clause in  $\pi$ . ◀

The next lemma shows that under the  $XT$ -property it is also not possible to derive any non-axiomatic  $T$ -clauses.

► **Lemma 19.** *Let  $\Phi$  be a QCNF with the  $XT$ -property and let  $C$  be a  $T$ -clause derived by long-distance Q-resolution from  $\Phi$ . Then  $C$  is an axiom from  $\Phi$ .*

We will show later that we need to resolve two  $XUT$ -clauses over an  $X$ -literal in order to introduce tautologies. Now we prove that this is not possible in long-distance QCDCL resolution under the  $XT$ -property.

► **Lemma 20.** *It is not possible to resolve two  $XUT$ -clauses over an  $X$ -literal in a long-distance QCDCL resolution proof of a QCNF  $\Phi$  that fulfils the  $XT$ -property.*

**Proof.** Assume there is a long-distance QCDCL resolution proof  $\pi$  that contains such a resolution step over an  $X$ -literal  $x$ . Let  $C_1$  and  $C_2$  be the corresponding  $XUT$ -clauses. One of these clauses, say  $C_1$ , had to be an antecedent clause in a  $\text{QCDCL}_{\text{RED}}^{\text{LEV-ORD}}$  trail  $\mathcal{T}$  that implied  $x$ . Since our decisions in the trail are level-ordered and we did not skip any decisions, either  $x$  was propagated at decision level 0, or at a decision level in which we decided another  $X$ -literal.

Because  $C_1$  is an  $XUT$ -clause, we can find a  $T$ -literal  $t \in C_1$ . The literal  $\bar{t}$  must have been propagated before we implied  $x$  ( $\bar{t}$  could not have been decided because the decisions are level-ordered). That means that for the same trail we can find  $E := \text{ante}_{\mathcal{T}}(\bar{t})$ . Now,  $E$  cannot be a unit  $T$ -clause by the  $XT$ -property and Lemma 19. Hence  $E$  must contain further  $X$ -,  $U$ -, or  $T$ -literals. If  $E$  contains a  $U$ -literal, then we would have had to decide this  $U$ -literal before we use  $E$  as an antecedent clause, contradicting the level-order of our decisions. Also, this  $U$ -literal cannot be reduced since we want to imply a  $T$ -literal with the help of  $E$ . Therefore we conclude that  $E$  contains an  $X$ -literal or a  $T$ -literal. If  $E$  contains an  $X$ -literal, then  $E$  is an  $XT$ -clause, which is not possible by Lemma 18.

Therefore  $E$  contains at least another  $T$ -literal  $\ell \in E$ . As before, the literal  $\bar{\ell}$  was propagated before we implied  $\bar{t}$  and  $x$ . We set  $E' := \text{ante}_{\mathcal{T}}(\bar{\ell})$  and argue in the same way as with  $E$ . This process would repeat endlessly, which is a contradiction since we only have finitely many  $T$ -variables. ◀

Thus for formulas with the  $XT$ -property we can lift Q-resolution lower bounds to QCDCL, yielding the next theorem.

► **Theorem 21.** *If  $\Phi$  fulfils the  $XT$ -property and requires Q-resolution refutations of size  $s$ , then each QCDCL refutation of  $\Phi$  has size at least  $s$  as well.*

**Proof.** Let  $\pi$  be a long-distance QCDCL resolution refutation of  $\Phi$ . We show that  $\pi$  does not contain any tautological clause  $C$  and hence  $\pi$  is in fact a Q-resolution proof.

Assume that  $\pi$  contains some tautological clause  $C$ . W.l.o.g. let  $C$  be the first tautological clause in  $\pi$ . Clearly,  $C$  has to be derived by a resolution step over an  $X$ -literal. Let  $C_1$  and  $C_2$  be the parent clauses of  $C$ . Both of them contain some  $X$ -literals and some  $U$ -literals. They also have to contain  $T$ -literals, otherwise we would reduce all  $U$ -literals (in the learning process we reduce as soon as possible). Therefore  $C_1$  and  $C_2$  are both  $XUT$ -clauses that are resolved over an  $X$ -literal, which is not possible by Lemma 20.

Therefore such a clause  $C$  cannot exist. Hence each long-distance QCDCL resolution refutation of  $\Phi$  is even a Q-resolution refutation and the result follows. ◀

It is quite easy to check that both the equality formulas as well as the random formulas above have the  $XT$ -property. Thus we obtain:

► **Corollary 22.**

- Equality <sub>$n$</sub>  requires QCDCL refutations of size  $2^n$ .
- Let  $1 < c < 2$  be a constant and  $m \leq (1 - \epsilon) \log_2 n$  for some constant  $\epsilon > 0$ . With probability  $1 - o(1)$  the random QCNF  $Q(n, m, c)$  is false and requires QCDCL refutations of size  $2^{\Omega(n^\epsilon)}$ .

Our findings so far reveal an interesting picture on QCDCL hardness. Firstly, Proposition 11 and Corollary 22 imply that *not all Q-resolution hardness results lift to QCDCL*: the lower bounds for equality and random formulas shown via size-cost-capacity [8] *do*, but the lower bounds for parity shown via circuit complexity [12] *do not*.

Secondly, it is worth to compare the QCDCL hardness results for **Trapdoor** from the previous section to the QCDCL hardness results shown here for equality and random formulas. The hardness of **Trapdoor** lifts from propositional hardness for PHP, while the hardness of equality and random formulas lifts from Q-resolution hardness. In fact, this can be made formal by using a model of QBF proof systems with access to an NP oracle [17], which allows to collapse propositional subderivations of arbitrary size into just one oracle inference step. Hardness under the NP-oracle version of Q-resolution guarantees that the hardness is “genuine” to QBF and not lifted from propositional resolution. We show here that this notion of “genuine” QBF hardness, tailored towards QCDCL, also holds for the QCDCL lower bounds for equality and the random QBFs.

► **Proposition 23.** *The number of reduction steps in each long-distance QCDCL resolution refutation (and also each QCDCL<sup>LEV-ORD</sup><sub>RED</sub> refutation) of Equality <sub>$n$</sub>  is at least  $2^n$ . The analogous result holds for the false formulas  $Q(n, m, c)$  with  $2^{\Omega(n^\epsilon)}$  reduction steps.*

On the other hand, the parity formulas also exhibit “genuine” QBF hardness, as they are hard in the NP-oracle version of Q-resolution [10]. Since they are easy for QCDCL (Proposition 11), this means that not all genuine Q-resolution lower bounds lift to QCDCL.

Thirdly, hardness for QCDCL can of course also stem from hardness for long-distance Q-resolution, since the latter system p-simulates the former. However, there are only very few hardness results for long-distance Q-resolution known in the literature [3, 12, 13], hence

our hardness results shown here should be also valuable for practitioners, in particular the hardness results for the large class of random QCNFs. It is also worth noting that the equality formulas are easy for long-distance Q-resolution [9], hence our results imply an exponential separation between QCDCL and long-distance Q-resolution.

► **Proposition 24.** *Long-distance Q-resolution is exponentially stronger than QCDCL, i.e., long-distance Q-resolution  $p$ -simulates QCDCL and there are QCNFs that require exponential-size proofs in QCDCL, but admit polynomial-size proofs in long-distance Q-resolution.*

## 6 A QCDCL system that characterises Q-resolution

In one of our main results we obtain a QCDCL characterisation of Q-resolution. Of course, given that Q-resolution and QCDCL are incomparable (Section 4), we cannot hope to achieve such a characterisation by simply strengthening some of the QCDCL policies.<sup>6</sup> As explained in the previous section, traditional QCDCL is using the decision policy LEV-ORD and the unit-propagation policy RED. To obtain a QCDCL system equivalent to Q-resolution, we will have to change both policies. We will *strengthen* the decision policy and replace LEV-ORD by ANY-ORD (we could also replace it with the intermediate version ASS-ORD). In addition, we will somewhat *weaken* the unit propagation policy from RED to NO-RED.<sup>7</sup>

This leads to the following characterisation of Q-resolution.

► **Theorem 25.** *Q-resolution,  $\text{QCDCL}_{\text{NO-RED}}^{\text{ANY-ORD}}$ , and  $\text{QCDCL}_{\text{NO-RED}}^{\text{ASS-ORD}}$  are  $p$ -equivalent proof systems.*

*In particular, each Q-resolution refutation  $\pi$  of a QCNF in  $n$  variables can be transformed into a  $\text{QCDCL}_{\text{NO-RED}}^{\text{ASS-ORD}}$ -refutation of size  $\mathcal{O}(n^3 \cdot |\pi|)$  that uses an arbitrary asserting learning scheme.*

One part of the simulation above was already shown in Theorem 8, where we proved that all QCDCL systems with NO-RED are  $p$ -simulated by Q-resolution. The technically most challenging part is the reverse simulation where we need to construct  $\text{QCDCL}_{\text{NO-RED}}^{\text{ASS-ORD}}$  trails from Q-resolution proofs. The main conceptual notion we use is that of *reliable* clauses.

► **Definition 26.** *Let  $\Phi = \mathcal{Q} \cdot \phi$  be a QCNF and  $C$  be a non-tautological clause. If there is a  $\text{QCDCL}_{\text{NO-RED}}^{\text{ASS-ORD}}$  trail  $\mathcal{T}$ , an existential literal  $\ell \in C$  and a set of literals  $\alpha \subseteq \bar{C} \setminus \{\bar{\ell}\}$  such that  $\alpha$  is the set of decision literals in  $\mathcal{T}$  and  $\ell \in \mathcal{T}$ , then  $C$  is called *unreliable* with respect to  $\Phi$ . Alternatively, we say that the decisions  $\bar{C}$  are blocking each other.*

*If  $C$  is not unreliable, we call  $C$  reliable.*

Intuitively, a reliable clause  $C$  can be used to form a  $\text{QCDCL}_{\text{NO-RED}}^{\text{ASS-ORD}}$  trail by using all negated literals from  $C$  as decisions. This way we progress through the Q-resolution proof, successively learning clauses and making all clauses  $C$  in the Q-resolution proof unreliable until we obtain the empty clause.

This construction bears some similarities to the simulation of Q-resolution by CDCL [48], but poses further technical challenges due to quantification and the additional rules of Q-resolution. In the inductive argument for Theorem 25 we therefore need to distinguish three cases on whether  $C$  is an axiom or derived by resolution or reduction, each requiring its own lemma (Lemmas 27, 28, and 29). For the following lemmas, let  $\xi$  be an arbitrary, but fixed asserting learning scheme.

<sup>6</sup> Such hope might not have seemed totally implausible prior to this paper, e.g. [35] states that ‘CDCL QBF solving appears to be quite weak compared to general Q-resolution.’

<sup>7</sup> While intuitively NO-RED might indeed appear weaker than RED (it produces fewer unit propagations), we show in the next section that they are in fact incomparable, cf. Figure 2.

► **Lemma 27.** Let  $\Phi := \mathcal{Q} \cdot \phi$  be a QCNF in  $n$  variables and  $C \in \phi$ . If  $C$  is reliable with respect to  $\Phi$ , there exists a  $\text{QCDCL}_{\text{No-RED}}^{\text{Ass-ORD}}$ -proof  $\iota$  with trails  $\mathcal{T}_1, \dots, \mathcal{T}_{f_n}$  from  $\Phi$  of some clause  $E$  that uses the learning scheme  $\xi$  such that  $|\iota| \in \mathcal{O}(n^3)$ . If  $E \neq (\perp)$ , then  $C$  is unreliable with respect to  $\mathcal{Q} \cdot (\phi \cup \{\xi(\mathcal{T}_1), \dots, \xi(\mathcal{T}_{f_n})\})$ .

► **Lemma 28.** Let  $\Phi := \mathcal{Q} \cdot \phi$  be a QCNF in  $n$  variables. Also let  $C_1 \vee x$  be a clause that is unreliable with respect to  $\Psi := \mathcal{Q} \cdot \psi$  with  $\psi \subseteq \phi$  and  $C_2 \vee \bar{x}$  unreliable with respect to  $\Upsilon := \mathcal{Q} \cdot \tau$  with  $\tau \subseteq \phi$ , such that  $C_1 \vee C_2$  is non-tautological. Let  $\xi$  be an asserting learning scheme. If  $C_1 \vee C_2$  is reliable with respect to  $\Phi$ , there exists a  $\text{QCDCL}_{\text{No-RED}}^{\text{Ass-ORD}}$ -proof  $\iota$  with  $\theta(\iota) = \mathcal{T}_1, \dots, \mathcal{T}_{f_n}$  from  $\Phi$  of some clause  $E$  that uses the learning scheme  $\xi$  such that  $|\iota| \in \mathcal{O}(n^3)$ . If  $E \neq (\perp)$ , then  $C_1 \vee C_2$  is unreliable with respect to  $\mathcal{Q} \cdot (\phi \cup \{\xi(\mathcal{T}_1), \dots, \xi(\mathcal{T}_{f_n})\})$ .

► **Lemma 29.** Let  $\Phi := \mathcal{Q} \cdot \phi$  be a QCNF in  $n$  variables, let  $D := C \vee u_1 \vee \dots \vee u_m$  be a non-tautological clause with universal literals  $u_1, \dots, u_m$  and  $\text{red}(D) = C$ , such that  $D$  is unreliable with respect to a QCNF  $\Psi = \mathcal{Q} \cdot \psi$  with  $\psi \subseteq \phi$ . Let  $\xi$  be an asserting learning scheme. If  $C$  is reliable with respect to  $\Phi$ , there exists a  $\text{QCDCL}_{\text{No-RED}}^{\text{Ass-ORD}}$ -proof  $\iota$  with  $\theta(\iota) = \mathcal{T}_1, \dots, \mathcal{T}_{f_n}$  from  $\Phi$  of some clause  $E$  that uses the learning scheme  $\xi$  such that  $|\iota| \in \mathcal{O}(n^3)$ . If  $E \neq (\perp)$ , then  $C$  is unreliable with respect to  $\mathcal{Q} \cdot (\phi \cup \{\xi(\mathcal{T}_1), \dots, \xi(\mathcal{T}_{f_n})\})$ .

We also point out that in comparison to the notion of 1-empowering clauses from [48], our argument via reliability yields somewhat better bounds on the simulation, thereby implying a slight quantitative improvement by a factor of  $n$  in the simulation in [48]:

► **Theorem 30.** Let  $\phi$  be a CNF in  $n$  variables and let  $\pi$  be a resolution refutation of  $\phi$ . Then  $\phi$  has a CDCL refutation of size  $\mathcal{O}(n^3|\pi|)$ .

## 7 The simulation order of QCDCL proof systems

We can now analyse the simulation order of the defined QCDCL and QBF resolution systems, cf. Figure 2 which almost completely determines the simulations and separations between the systems involved (cf. Section 8 for the open cases).

We highlight the most interesting findings (in addition to the results already described).

Firstly, we show that the unit-propagation policies RED and NO-RED are incomparable when fixing the decision policy LEV-ORD used in practical QCDCL.

► **Theorem 31.** The systems  $\text{QCDCL}_{\text{No-RED}}^{\text{LEV-ORD}}$  and  $\text{QCDCL}_{\text{RED}}^{\text{LEV-ORD}}$  are incomparable.

For the separations we use the QBFs  $\text{QParity}_n$  and  $\text{Trapdoor}_n$ . For practice, this results means that it is a priori not clear that the unit-propagation policy as used in practical QCDCL is actually preferable to the simpler unit-propagation policy from CDCL (which would work in QCDCL as well).

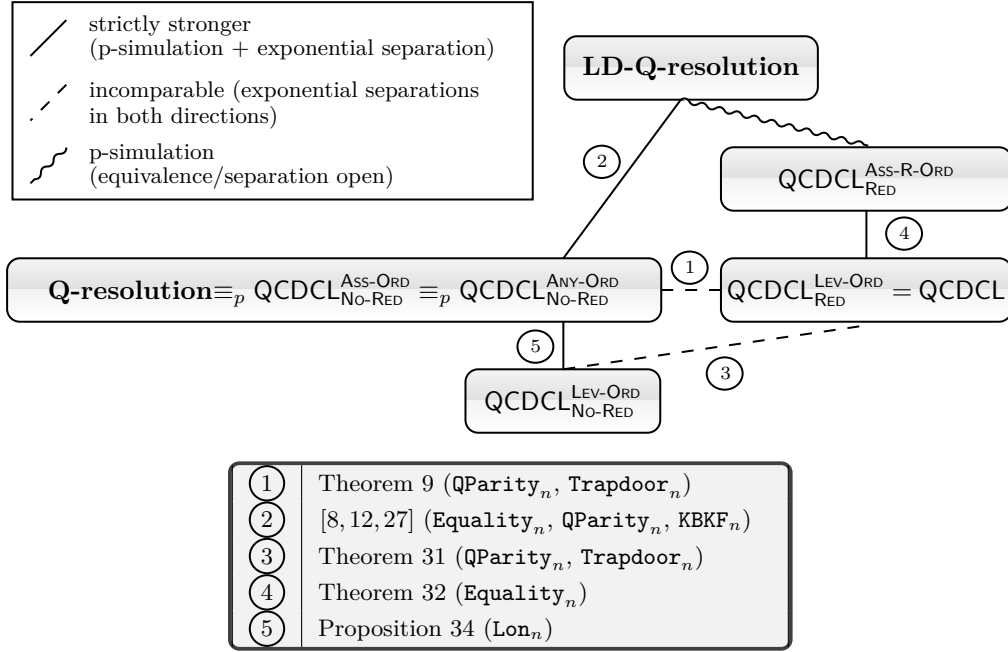

Secondly, we show that replacing the decision policy LEV-ORD in QCDCL with the more liberal decision policy ASS-R-ORD yields exponentially shorter QCDCL runs, which we demonstrate on the  $\text{Equality}_n$  formulas.

► **Theorem 32.**  $\text{QCDCL}_{\text{RED}}^{\text{ASS-R-ORD}}$  is exponentially stronger than  $\text{QCDCL}_{\text{RED}}^{\text{LEV-ORD}}$ .

Again, this theoretical result identifies potential for improvements in practical solving (cf. also the discussion in the concluding Section 8).

Thirdly, we recall the formulas  $\text{Lon}_n$  that were introduced by Lonsing in [39]. Originally, these QCNFs were constructed to separate QBF solvers that differ in the implemented dependency schemes (we do not consider these concepts here, though).

■ **Figure 2** The simulation order of QCDCL and QBF resolution systems. The table contains pointers to the separating formulas.

► **Definition 33** (Lonsing [39]). Let  $\text{Lon}_n$  be the QCNF

$$\exists a, b, b_1, \dots, b_{s_n} \forall x, y \exists c, d \cdot (a \vee x \vee c) \wedge (a \vee b \vee b_1 \vee \dots \vee b_{s_n}) \wedge (b \vee y \vee d) \wedge (x \vee c) \wedge (x \vee \bar{c}) \wedge \text{PHP}_n^{n+1}(b_1, \dots, b_{s_n}) .$$

It was shown in [39] that these formulas become easy to refute by choosing the standard dependency scheme. However,  $\text{Lon}_n$  serve as witnesses for separating our systems as well.

► **Proposition 34.** *The QCNFs  $\text{Lon}_n$  require exponential-size proofs in the proof systems  $\text{QCDCL}_{\text{RED}}^{\text{LEV-ORD}}$  and  $\text{QCDCL}_{\text{NO-RED}}^{\text{LEV-ORD}}$ , but have constant-size proofs in  $\text{QCDCL}_{\text{RED}}^{\text{ASS-R-ORD}}$  and Q-resolution.*

## 8 Conclusion

In this paper we performed a formal, proof-theoretic analysis of QCDCL. In particular, we focused on the relation of QCDCL and Q-resolution, showing both the incomparability of practically-used QCDCL to Q-resolution as well as the equivalence of a new QCDCL version to Q-resolution.

In addition to the theoretical contributions of this paper, we believe that our findings will also be interesting for practitioners. Firstly, because we have shown the first rigorous dedicated hardness results for QCDCL, not only in terms of formula families with at most one instance per input size (as is typical in proof complexity), but also in terms of a large family of random QBFs.

Secondly, we believe that it would be interesting to test the potential of our new QCDCL variants for practical solving. Though we have formulated these as proof systems, it should be fairly straightforward to incorporate our new policies into actual QCDCL implementations.

In particular, the insight that decisions do not need to follow the order of quantification in the prefix should be a welcome discovery. Of course, when just using the policy ANY-ORD, it is not clear that asserting clauses can always be learnt. Therefore, we suggest that for practical implementations, the most interesting new systems should be  $\text{QCDCL}_{\text{RED}}^{\text{ASS-ORD}}$  and  $\text{QCDCL}_{\text{RED}}^{\text{ASS-ORD}}$ . Both facilitate liberal decision policies, not necessarily following the prefix order, while still allowing to learn asserting clauses. Since both systems are incomparable, it is a priori not clear which one to prefer in practice. However, we would suggest that  $\text{QCDCL}_{\text{RED}}^{\text{ASS-ORD}}$  should be the more interesting system, since it uses the same unit propagation as QCDCL, but provides an exponential strengthening of QCDCL (as shown in Theorem 32) via the decision policy ASS-R-ORD.

We close with some open questions that are triggered by the results presented here:

- Can we find an alternative formula instead of  $\text{Trapdoor}_n$  for the separation between Q-resolution and QCDCL (easy for Q-resolution, hard for QCDCL)? I.e., we are primarily interested in formulas whose hardness does not depend on propositional resolution.
- Can we find a separation between  $\text{QCDCL}_{\text{RED}}^{\text{ASS-ORD}}$  and long-distance Q-resolution?
- Can we even find a separation between  $\text{QCDCL}_{\text{RED}}^{\text{ANY-ORD}}$  and long-distance Q-resolution, or are the systems possibly even equivalent?

## Abstract

A leading proposal for verifying near-term quantum supremacy experiments on noisy random quantum circuits is linear cross-entropy benchmarking. For a quantum circuit  $C$  on  $n$  qubits and a sample  $z \in \{0, 1\}^n$ , the benchmark involves computing  $|\langle z|C|0^n \rangle|^2$ , i.e. the probability of measuring  $z$  from the output distribution of  $C$  on the all zeros input. Under a strong conjecture about the classical hardness of estimating output probabilities of quantum circuits, no polynomial-time classical algorithm given  $C$  can output a string  $z$  such that  $|\langle z|C|0^n \rangle|^2$  is substantially larger than  $\frac{1}{2^n}$  (Aaronson and Gunn, 2019). On the other hand, for a random quantum circuit  $C$ , sampling  $z$  from the output distribution of  $C$  achieves  $|\langle z|C|0^n \rangle|^2 \approx \frac{2}{2^n}$  on average (Arute et al., 2019).

In analogy with the Tsirelson inequality from quantum nonlocal correlations, we ask: can a polynomial-time quantum algorithm do substantially better than  $\frac{2}{2^n}$ ? We study this question in the query (or black box) model, where the quantum algorithm is given oracle access to  $C$ . We show that, for any  $\varepsilon \geq \frac{1}{\text{poly}(n)}$ , outputting a sample  $z$  such that  $|\langle z|C|0^n \rangle|^2 \geq \frac{2+\varepsilon}{2^n}$  on average requires at least  $\Omega\left(\frac{2^{n/4}}{\text{poly}(n)}\right)$  queries to  $C$ , but not more than  $O(2^{n/3})$  queries to  $C$ , if  $C$  is either a Haar-random  $n$ -qubit unitary, or a canonical state preparation oracle for a Haar-random  $n$ -qubit state. We also show that when  $C$  samples from the Fourier distribution of a random Boolean function, the naive algorithm that samples from  $C$  is the optimal 1-query algorithm for maximizing  $|\langle z|C|0^n \rangle|^2$  on average.

## 1 Introduction

A team based at Google has claimed the first experimental demonstration of quantum computational supremacy on a programmable device [9]. The experiment involved *random circuit sampling*, where the task is to sample (with nontrivial fidelity) from the output distribution of a quantum circuit containing random 1- and 2-qubit gates. To verify their experiment, they used the so-called *Linear Cross-Entropy Benchmark*, or Linear XEB. Specifically, for an  $n$ -qubit quantum circuit  $C$  and samples  $z_1, \dots, z_k \in \{0, 1\}^n$ , the benchmark is given by:

$$b = \frac{2^n}{k} \cdot \sum_{i=1}^k |\langle z_i|C|0^n \rangle|^2.$$

## 13:2 The Quantum Supremacy Tsirelson Inequality

The goal is for  $b$  to be large with high probability over the choice of the random circuit and the randomness of the sampler, as this demonstrates that the observations tend to concentrate on the outputs that are more likely to be measured under the ideal distribution for  $C$  (i.e. the noiseless distribution in which  $z$  is measured with probability  $|\langle z|C|0^n \rangle|^2$ ). We formalize this task as the  $b$ -XHOG task:

► **Problem 1** ( $b$ -XHOG, or Linear Cross-Entropy Heavy Output Generation). *Given a quantum circuit  $C$  on  $n$  qubits, output a sample  $z \in \{0, 1\}^n$  such that  $\mathbb{E} [|\langle z|C|0^n \rangle|^2] \geq \frac{b}{2^n}$ , where the expectation is over an implicit distribution over circuits  $C$  and over the randomness of the algorithm that outputs  $z$ .*

Here,  $b$  “large” means  $b$  bounded away from 1, as outputting  $z$  uniformly at random achieves  $b = 1$  on average for any  $C$ . On the other hand, if  $z$  is drawn from the ideal noiseless distribution for  $C$ , and if the random circuits  $C$  empirically exhibit the *Porter-Thomas* distribution on output probabilities, then sampling from  $C$  achieves  $b \approx 2$  [9, 2].

Under a strong complexity-theoretic conjecture about the classical hardness of nontrivially estimating output probabilities of quantum circuits, Aaronson and Gunn showed that no classical polynomial-time algorithm can solve  $b$ -XHOG for any  $b \geq 1 + \frac{1}{\text{poly}(n)}$  on random quantum circuits of polynomial size [2]. Thus, a physical quantum computer that solves  $b$ -XHOG for  $b \geq 1 + \Omega(1)$  is considered strong evidence of quantum computational supremacy.

In this work, we ask: can an efficient quantum algorithm for  $b$ -XHOG do substantially better than  $b = 2$ ? That is, what is the largest  $b$  for which a polynomial-time quantum algorithm can solve  $b$ -XHOG on random circuits? Note that the largest  $b$  we could hope for is achieved by the optimal sampler that always outputs the string  $z$  maximizing  $|\langle z|C|0^n \rangle|^2$ . If the random circuits induce a Porter-Thomas distribution on output probabilities, then this solves  $b$ -XHOG for  $b = \Theta(n)$ , because the probabilities of a Porter-Thomas distribution approach i.i.d. exponential random variables (see Fact 10 below). However, finding the largest output probability might be computationally difficult even on a quantum computer, which is why we restrict our attention to *efficient* quantum algorithms.

We refer to our problem as the “quantum supremacy Tsirelson inequality” in reference to the Bell [11] and Tsirelson [18] inequalities for quantum nonlocal correlations (for a modern overview, see [20]). Under this analogy, the quantity  $b$  in XHOG plays a similar role as the probability  $p$  of winning some nonlocal game. For example, the Bell inequality for the CHSH game [19] states that no classical strategy can win the game with probability  $p > \frac{3}{4}$ ; we view this as analogous to the conjectured inability of efficient classical algorithms to solve  $b$ -XHOG for any  $b > 1$ . By contrast, a quantum strategy with pre-shared entanglement allows players to win the CHSH game with probability  $p = \cos^2(\frac{\pi}{8}) \approx 0.854 > \frac{3}{4}$ . An experiment that wins the CHSH game with probability  $p > \frac{3}{4}$ , a violation of the Bell inequality, is analogous to an experimental demonstration of  $b$ -XHOG for  $b > 1$  on a quantum computer that establishes quantum computational supremacy. Finally, the Tsirelson inequality for the CHSH game states that any quantum strategy involving arbitrary pre-shared entanglement wins with probability  $p \leq \cos^2(\frac{\pi}{8})$ . Hence, an upper bound on  $b$  for efficient quantum algorithms is the quantum supremacy counterpart to the Tsirelson inequality. We emphasize that our choice to refer to this as a “Tsirelson inequality” is purely by analogy; we do not claim that the question involving quantum supremacy or the techniques one might use to answer it are otherwise related to quantum nonlocal correlations.

### 1.1 Our Results

We study the quantum supremacy Tsirelson inequality in the quantum query (or black box) model. That is, we consider distributions over quantum circuits that make queries to a randomized quantum or classical oracle, and ask how many queries to the oracle are needed

to solve  $b$ -XHOG, in terms of  $b$ . Our motivation for studying this problem in the query model is twofold. First, quantum query results often give useful intuition for what to expect in the real world, and can provide insight into why naive algorithmic approaches fail. Second, we view this as an interesting quantum query complexity problem in its own right. Whereas most other quantum query lower bounds involve decision problems [5] or relation problems [12], XHOG is more like a weighted, average-case relation problem, because we only require that  $|\langle z|C|0^n\rangle|^2$  be large *on average*. Contrast this with the relation problem considered in [1], where the task is to output a  $z$  such that  $|\langle z|C|0^n\rangle|^2$  is greater than some threshold.

Note that there are known quantum query complexity lower bounds for relation problems [9], and even relation problems where the output is a quantum state [6, 25]. Yet, it is unclear whether existing quantum query lower bound techniques are useful here. Whereas the adversary method tightly characterizes the quantum query complexity of decision problems and state conversion problems [24], it is not even known to characterize the query complexity of relation problems (unless they are efficiently verifiable) [12]. The adversary method appears to be essentially useless for saying anything about XHOG, which is not efficiently verifiable and is not a relation problem in the traditional sense.<sup>1</sup>

The XHOG task is well-defined for any distribution of random quantum circuits, so this gives us a choice in selecting the distribution. We focus on three classes of oracle circuits that either resemble random circuits used in practical experiments, or that were previously studied in the context of quantum supremacy.

### Canonical State Preparation Oracles

Because the linear cross-entropy benchmark for a circuit  $C$  depends only on the state  $|\psi\rangle := C|0^n\rangle$  produced by the circuit on the all zeros input, it is natural to consider an oracle  $\mathcal{O}_\psi$  that prepares a random state  $|\psi\rangle$  without leaking additional information about  $|\psi\rangle$ . Formally, we choose a Haar-random  $n$ -qubit state  $|\psi\rangle$ , and fix a canonical state  $|\perp\rangle$  orthogonal to all  $n$ -qubit states.<sup>2</sup> Then, we take the oracle  $\mathcal{O}_\psi$  that acts as  $\mathcal{O}_\psi|\perp\rangle = |\psi\rangle$ ,  $\mathcal{O}_\psi|\psi\rangle = |\perp\rangle$ , and  $\mathcal{O}_\psi|\varphi\rangle = |\varphi\rangle$  for any state  $|\varphi\rangle$  that is orthogonal to both  $|\perp\rangle$  and  $|\psi\rangle$ . Equivalently,  $\mathcal{O}_\psi$  is the reflection about the state  $\frac{|\psi\rangle - |\perp\rangle}{2}$ . Finally, we let  $C$  be the composition of  $\mathcal{O}_\psi$  with any unitary that sends  $|0^n\rangle$  to  $|\perp\rangle$ , so that  $C|0^n\rangle = |\psi\rangle$ . This model is often chosen when proving lower bounds for quantum algorithms that query state preparation oracles (see e.g. [7, 3, 13]), in part because the ability to simulate  $\mathcal{O}_\psi$  follows in a completely black box manner from the ability to prepare  $|\psi\rangle$  unitarily without garbage (see Lemma 7 below). Hence, the oracle  $\mathcal{O}_\psi$  is “canonical” in the sense that it is uniquely determined by  $|\psi\rangle$  and is not any more powerful than any other oracle that prepares  $|\psi\rangle$  without garbage.

### Haar-Random Unitaries

A random polynomial-size quantum circuit  $C$  does not behave like a canonical state preparation oracle:  $C|x\rangle$  looks like a random quantum state for *any* computational basis state  $|x\rangle$ , not just  $x = 0^n$ . Indeed, random quantum circuits are known to information-theoretically approximate the Haar measure in certain regimes [14, 21], and it seems plausible that they are also computationally difficult to distinguish from the Haar measure. Thus, one could alternatively model random quantum circuits by Haar-random  $n$ -qubit unitaries.

<sup>1</sup> As we will see later, however, the polynomial method [10] plays an important role in one of our results.

<sup>2</sup> We can always assume that a convenient  $|\perp\rangle$  exists by extending the Hilbert space, if needed. For example, if  $|\psi\rangle$  is an  $n$ -qubit state, a natural choice is to encode  $|\psi\rangle$  by  $|\psi\rangle|1\rangle$  and to choose  $|\perp\rangle = |0^n\rangle|0\rangle$ .

### Fourier Sampling Circuits

Finally, we consider quantum circuits that query a random *classical* oracle. For this, we use FOURIER SAMPLING circuits, which Aaronson and Chen [1] previously studied in the context of proving oracular quantum supremacy for a problem related to XHOG. FOURIER SAMPLING circuits are defined as  $H^{\otimes n} U_f H^{\otimes n}$ , where  $U_f$  is a phase oracle for a uniformly random Boolean function  $f : \{0, 1\}^n \rightarrow \{-1, 1\}$ . On the all-zeros input, FOURIER SAMPLING circuits output a string  $z \in \{0, 1\}^n$  with probability proportional to the squared Fourier coefficient  $\hat{f}(z)^2$ . This model has the advantage that in principle, one can prove the corresponding quantum supremacy Bell inequality for classical algorithms given query access to  $f$ , and that in some cases one can replace  $f$  by a pseudorandom function to base quantum supremacy on cryptographic assumptions [1].

### Summary of Results

Our first result is an exponential lower bound on the number of quantum queries needed to solve  $(2 + \varepsilon)$ -XHOG given either of the two types of quantum oracles that we consider:

► **Theorem 2** (Informal version of Theorem 14 and Theorem 17). *For any  $\varepsilon \geq \frac{1}{\text{poly}(n)}$ , any quantum query algorithm for  $(2 + \varepsilon)$ -XHOG with query access to either:*

- (1) *a canonical state preparation oracle  $\mathcal{O}_\psi$  for a Haar-random  $n$ -qubit state  $|\psi\rangle$ , or*
- (2) *a Haar-random  $n$ -qubit unitary,*

*requires at least  $\Omega\left(\frac{2^{n/4}}{\text{poly}(n)}\right)$  queries.*

We do not know if Theorem 2 is optimal, but we show in Theorem 15 that a simple algorithm based on the quantum collision finding algorithm [16] solves  $(2 + \Omega(1))$ -XHOG using  $O(2^{n/3})$  queries to either oracle.

Finally, we show that for FOURIER SAMPLING circuits, the naive algorithm of simply running the circuit is optimal among all 1-query algorithms:

► **Theorem 3** (Informal version of Theorem 19). *Any 1-query quantum algorithm for  $b$ -XHOG with FOURIER SAMPLING circuits achieves  $b \leq 3$ .<sup>3</sup>*

## 1.2 Our Techniques

The starting point for our proof of the Tsirelson inequality with a canonical state preparation oracle  $\mathcal{O}_\psi$  is a result of Ambainis, Rosmanis, and Unruh [7], which shows that any algorithm that queries  $\mathcal{O}_\psi$  can be approximately simulated by a different algorithm that makes no queries, but starts with copies of a resource state that depends on  $|\psi\rangle$ . This resource state consists of polynomially many (in the number of queries to  $\mathcal{O}_\psi$ ) states of the form  $\alpha|\psi\rangle + \beta|\perp\rangle$ , i.e. copies of  $|\psi\rangle$  in superposition with  $|\perp\rangle$ . Our strategy is to show that if any algorithm solves  $b$ -XHOG given this resource state, then a similar algorithm solves  $b$ -XHOG given copies of  $|\psi\rangle$  alone. Then, we prove a lower bound on the number of copies of  $|\psi\rangle$  needed to solve  $b$ -XHOG. To do so, we argue that if  $|\psi\rangle$  is Haar-random, then the best algorithm

<sup>3</sup> Note that the value of  $b$  achieved by the naive quantum algorithm for XHOG depends on the class of circuits used. In contrast to Haar-random circuits that achieve  $b \approx 2$ , FOURIER SAMPLING circuits achieve  $b \approx 3$  (see Proposition 18). This stems from the fact that the amplitudes of a Haar-random quantum state are approximately distributed as *complex* normal random variables, whereas the amplitudes of a state produced by a random FOURIER SAMPLING circuit are approximately distributed as *real* normal random variables.

for  $b$ -XHOG given copies of  $|\psi\rangle$  is a simple collision-finding algorithm: measure all copies of  $|\psi\rangle$  in the computational basis, and output whichever string  $z \in \{0,1\}^n$  appears most frequently in the measurement results. For a Haar-random  $n$ -qubit state, the chance of seeing any collisions is exponentially unlikely (unless the number of copies of  $|\psi\rangle$  is exponentially large in  $n$ ), and so this does not do much better than measuring a single copy of  $|\psi\rangle$  and outputting the result.

To prove the analogous lower bound for  $b$ -XHOG with a Haar-random unitary oracle, we show more generally that the canonical state preparation oracles and Haar-random unitary oracles are essentially equivalent as resources, which may be of independent interest. More specifically, we show that for an  $n$ -qubit state  $|\psi\rangle$ , given query access to  $\mathcal{O}_\psi$ , one can approximately simulate (to exponential precision) a random oracle that prepares  $|\psi\rangle$ . By “random oracle that prepares  $|\psi\rangle$ ,” we mean an  $n$ -qubit unitary  $U_\psi$  that acts as  $U_\psi|0^n\rangle = |\psi\rangle$  but Haar-random everywhere else. We can construct such a  $U_\psi$  by taking an arbitrary  $n$ -qubit unitary that maps  $|0^n\rangle$  to  $|\psi\rangle$ , then composing it with a Haar-random unitary on the  $(2^n - 1)$ -dimensional subspace orthogonal to  $|0^n\rangle$ .

Our lower bound for FOURIER SAMPLING circuits uses an entirely different technique. We use the polynomial method of Beals et al. [10], which shows that for any quantum algorithm that makes  $T$  queries to a classical oracle, the output probabilities of the algorithm can be expressed as degree- $2T$  polynomials in the variables of the classical oracle. Our key observation is that the average linear XEB score achieved by such a quantum query algorithm can *also* be expressed as a polynomial in the variables of the classical oracle. We further observe that this polynomial is constrained by the requirement that the polynomials representing the output probabilities must be nonnegative and sum to 1. This allows us to upper bound the largest linear XEB score achievable by the maximum value of a certain linear program, whose variables are the coefficients of the polynomials that represent the output probabilities of the algorithm. To upper bound this quantity, we exhibit a solution to the dual linear program.

Due to space constraints, we defer the proofs to the full version of this paper, available at <https://arxiv.org/abs/2008.08721>.

## 2 Preliminaries

### 2.1 Notation

We use  $[N]$  to denote the set  $\{1, 2, \dots, N\}$ . We use  $\mathbb{1}$  to denote the identity matrix (of implicit size). We let  $\text{TD}(\rho, \sigma)$  denote the trace distance between density matrices  $\rho$  and  $\sigma$ , and let  $\|A\|_\diamond$  denote the diamond norm of a superoperator  $A$  acting on density matrices (see [4] for definitions). For a unitary matrix  $U$ , we use  $U \cdot U^\dagger$  to denote the superoperator that maps  $\rho$  to  $U\rho U^\dagger$ . In a slight abuse of notation, if  $A$  denotes a quantum algorithm (which may consist of unitary gates, measurements, oracle queries, and initialization of ancilla qubits), then we also use  $A$  to denote the superoperator corresponding to the action of  $A$  on input density matrices.

### 2.2 Oracles for Quantum States

We frequently consider quantum algorithms that query quantum oracles. In this model, a query to a unitary matrix  $U$  consists of a single application of either  $U$ ,  $U^\dagger$ , or controlled versions of  $U$  or  $U^\dagger$ . We also consider quantum algorithms that make queries to *random* oracles. In analogue with the classical random oracle model, such calls are not randomized

at each query. Rather, a unitary  $U$  is chosen randomly (from some distribution) at the start of the execution of the algorithm, and thereafter all queries for the duration of the algorithm are made to  $U$ .

We now define several types of unitary oracles that we will use. These definitions (and associated lemmas giving constructions of them) have appeared implicitly or explicitly in prior work, e.g. [7, 3, 13, 8]. For completeness, we provide proofs of the constructions in the full version.

► **Definition 4.** For an  $n$ -qubit quantum state  $|\psi\rangle$ , the reflection about  $|\psi\rangle$ , denoted  $\mathcal{R}_\psi$ , is the  $n$ -qubit unitary  $\mathcal{R}_\psi := \mathbb{1} - 2|\psi\rangle\langle\psi|$ .

In other words,  $|\psi\rangle$  is a  $-1$  eigenstate of  $\mathcal{R}_\psi$ , and all states orthogonal to  $|\psi\rangle$  are  $+1$  eigenstates. Note that some authors define the reflection about  $|\psi\rangle$  to be the negation of this operator (e.g. [26, 28, 8]), while others follow our convention (e.g. [15, 23, 3]). This makes little difference, as these definitions are equivalent up to a global phase (or, if using the controlled versions, equivalent up to a Pauli  $Z$  gate).

The following lemma shows that  $\mathcal{R}_\psi$  can be simulated given any unitary that prepares  $|\psi\rangle$  from the all-zeros state, possibly with unentangled garbage.

► **Lemma 5.** Let  $U$  be a unitary that acts as  $U|0^n\rangle|0^m\rangle = |\psi\rangle|\varphi\rangle$ , where  $|\psi\rangle$  and  $|\varphi\rangle$  are  $n$ - and  $m$ -qubit states, respectively. Then one can simulate  $T$  queries to the reflection  $\mathcal{R}_\psi$  using  $2T + 1$  queries to  $U$ .

► **Definition 6.** For a quantum state  $|\psi\rangle$ , the canonical state preparation oracle for  $|\psi\rangle$ , denoted  $\mathcal{O}_\psi$ , is the reflection about the state  $\frac{|\psi\rangle - |\perp\rangle}{\sqrt{2}}$ , where  $|\perp\rangle$  is some canonical state orthogonal to  $|\psi\rangle$ .

Unless otherwise specified, we generally assume that if  $|\psi\rangle$  is an  $n$ -qubit state, then  $|\perp\rangle$  is orthogonal to the space of  $n$ -qubit states under a suitable encoding (see Footnote 2).

The next lemma shows that  $\mathcal{O}_\psi$  can be simulated from *any* oracle that prepares  $|\psi\rangle$  without garbage:

► **Lemma 7.** Let  $U$  be an  $n$ -qubit unitary that satisfies  $U|0^n\rangle = |\psi\rangle$ . Then one can simulate  $T$  queries to  $\mathcal{O}_\psi$  using  $4T + 2$  queries to  $U$ .

We introduce the notion of a *random* state preparation oracle, which, to our knowledge, is new.

► **Definition 8.** For an  $n$ -qubit state  $|\psi\rangle$  we define a random state preparation oracle for  $|\psi\rangle$ , denoted  $U_\psi$ , as follows. We fix an arbitrary  $n$ -qubit unitary  $V$  that satisfies  $V|0^n\rangle = |\psi\rangle$ , then choose a Haar-random unitary  $W$  that acts on the  $(2^n - 1)$ -dimensional subspace orthogonal to  $|0^n\rangle$  in the space of  $n$ -qubit states. Finally, we set  $U_\psi = VW$ .

The invariance of the Haar measure guarantees that this distribution over  $U_\psi$  is independent of the choice of  $V$ , and hence this is well-defined. Note that while we often refer to  $U_\psi$  as a single unitary matrix,  $U_\psi$  really refers to a *distribution* over unitary matrices. Notice also that if  $|\psi\rangle$  is distributed as a Haar-random  $n$ -qubit state, then  $U_\psi$  is distributed as a Haar-random  $n$ -qubit unitary.

## 2.3 Other Useful Facts

We use the following formula for the distance between unitary superoperators in the diamond norm.

► **Fact 9** ([4]). Let  $V$  and  $W$  be unitary matrices, and suppose  $d$  is the distance between 0 and the polygon in the complex plane whose vertices are the eigenvalues of  $VW^\dagger$ . Then

$$\|V \cdot V^\dagger - W \cdot W^\dagger\|_\diamond = 2\sqrt{1-d^2}.$$

Finally, we observe that for a Haar-random  $n$ -qubit quantum state, the information-theoretically largest linear XEB achievable is  $O(n)$ .

► **Fact 10.** Let  $|\psi\rangle$  be a Haar-random  $n$ -qubit quantum state. Then:

$$\mathbb{E}_{|\psi\rangle} \left[ \max_{z \in \{0,1\}^n} |\langle z|\psi\rangle|^2 \right] \leq \frac{O(n)}{2^n}.$$

### 3 Canonical State Preparation Oracles

In this section, we prove the quantum supremacy Tsirelson inequality for XHOG with a canonical state preparation oracle for a Haar-random state. We first sketch the important ideas in the proof. At the heart of our proof is the following lemma, due to Ambainis, Rosmanis, and Unruh [7]. It shows that any quantum algorithm that makes queries to a canonical state preparation oracle  $\mathcal{O}_\psi$  can be approximately simulated by a quantum algorithm that makes no queries to  $\mathcal{O}_\psi$ , and instead receives various copies of  $|\psi\rangle$  and superpositions of  $|\psi\rangle$  with some canonical orthogonal state.

► **Lemma 11** ([7]). Let  $A$  be a quantum query algorithm that makes  $T$  queries to  $\mathcal{O}_\psi$ . Then for any  $k$ , there is a quantum algorithm  $B$  that makes no queries to  $\mathcal{O}_\psi$ , and a quantum state  $|R\rangle$  of the form:

$$|R\rangle := \bigotimes_{j=1}^k \alpha_j |\psi\rangle + \beta_j |\perp\rangle$$

such that for any state  $|\varphi\rangle$ :

$$\text{TD}(A(|\varphi\rangle\langle\varphi|), B(|R\rangle\langle R|, |\varphi\rangle\langle\varphi|)) \leq O\left(\frac{T}{\sqrt{k}}\right).$$

So long as  $k \gg T^2$ , the output of  $B$  will be arbitrarily close to the output of  $A$  in trace distance. We will use this and Fact 10 to show that if  $A$  solves  $b$ -XHOG for some  $b > 2$ , then so does  $B$ . Then, to prove a lower bound on the number of queries  $T$  to  $\mathcal{O}_\psi$  needed to solve  $b$ -XHOG, it suffices to instead lower bound  $k$ , the number of states of the form  $\alpha_j |\psi\rangle + \beta_j |\perp\rangle$  needed to solve  $b$ -XHOG.

When  $|\psi\rangle$  is a Haar-random state, notice that the linear XEB depends only on the *magnitude* of the amplitudes in  $|\psi\rangle$ ; the phases are irrelevant. So, when considering algorithms that attempt to solve  $b$ -XHOG given only a state  $|R\rangle$  of the form used in Lemma 11, we might as well assume that the algorithm randomly reassigns the phases on  $|\psi\rangle$ . More formally, define the mixed state  $\sigma_R$  as

$$\sigma_R := \mathbb{E}_{\text{diagonal } U} [U^{\otimes k} |R\rangle\langle R| U^{\dagger \otimes k}], \quad (1)$$

where the expectation is over the diagonal unitaries  $U$  such that the entries  $\langle i|U|i\rangle$  are i.i.d. uniformly random complex phases (and by convention,  $\langle \perp|U|\perp\rangle = 1$ ). Then, the algorithm's average linear XEB score on  $\sigma_R$  is identical to its average linear XEB score on  $|R\rangle$ , because of the invariance of the Haar measure with respect to phases.

## 13:8 The Quantum Supremacy Tsirelson Inequality

Next, we observe that one can prepare  $\sigma_R$  by measuring  $k$  copies of  $|\psi\rangle$  in the computational basis. We prove this in Lemma 12. So, when considering algorithms for XHOG that start with  $|R\rangle$ , it suffices to instead consider algorithms that simply measure  $k$  copies of  $|\psi\rangle$  in the computational basis. Such algorithms are much easier to analyze, because once we have measured the  $k$  copies of  $|\psi\rangle$ , we can assume (by convexity) that any optimal such algorithm for XHOG outputs a string  $z$  deterministically given the  $k$  measurement results. And in that case, clearly the optimal strategy is to output whichever  $z$  maximizes the posterior expectation of  $|\langle z|\psi\rangle|^2$  given the measurement results. We analyze this strategy in Lemma 13, and show that roughly  $2^{n/2}$  copies of  $|\psi\rangle$  are needed to solve  $b$ -XHOG for  $b$  bounded away from 2. The intuition is that the posterior expectation of  $|\langle z|\psi\rangle|^2$  increases only when we see  $z$  at least twice in the measurement results. However, the probability that any two measurement results are the same is tiny – on the order of  $2^{-n}$  – and so we need to measure at least  $2^{n/2}$  copies of  $|\psi\rangle$  to see any collisions with decent probability.

We now proceed to proving the necessary lemmas.

► **Lemma 12.** *Let  $|\psi\rangle = \sum_{i=1}^N \psi_i |i\rangle$  be an unknown quantum state, and consider a state  $|R\rangle$  of the form:*

$$|R\rangle := \bigotimes_{j=1}^k \alpha_j |\psi\rangle + \beta_j |\perp\rangle,$$

where  $\alpha_j, \beta_j$  are known for  $j \in [k]$ , and the vectors  $\{|1\rangle, |2\rangle, \dots, |N\rangle, |\perp\rangle\}$  form an orthonormal basis. Define the mixed state  $\sigma_R$  as above. Then there exists a protocol to prepare  $\sigma_R$  by measuring  $k$  copies of  $|\psi\rangle$  in the computational basis.

To give some intuition, we note that it is simpler to prove Lemma 12 in the case where  $\alpha_j = 1$  for all  $j$ . In that case,  $\sigma_R$  can be viewed as an  $N^k \times N^k$  density matrix where both the rows and columns are indexed by strings in  $[N]^k$ . Then, the averaging over diagonal unitaries implies that  $\sigma_R$  is obtained from  $(|R\rangle\langle R|)^{\otimes k}$  by zeroing out all entries where the index corresponding to the row is not a reordering of the index corresponding to the column. In fact, one can show that  $\sigma_R$  is expressible as a mixture of pure states, where each pure state is a uniform superposition over basis states that are reorderings of each other. Moreover, the probability associated with each pure state in this mixture is precisely the probability that one of the reorderings is observed when we measure  $k$  copies of  $|\psi\rangle$  in the computational basis. So, to prepare  $\sigma_R$ , it suffices to measure  $|\psi\rangle^{\otimes k}$  and then output the uniform superposition over reorderings of the measurement result.

The proof of Lemma 12 is similar, but we instead have to randomly set some of the measurement results to  $\perp$  with probability  $|\beta_j|^2$ .

Combining Lemma 11 and Lemma 12, we have reduced the problem of lower bounding the number of  $\mathcal{O}_\psi$  queries needed to solve  $b$ -XHOG, to lower bounding the number of copies of  $|\psi\rangle$  needed to solve  $b$ -XHOG. The next lemma lower bounds this latter quantity.

► **Lemma 13.** *Let  $|\psi\rangle$  be a Haar-random  $n$ -qubit quantum state. Consider a quantum algorithm that receives as input  $|\psi\rangle^{\otimes k}$  and outputs a string  $z \in \{0, 1\}^n$ . Then:*

$$\mathbb{E}_{|\psi\rangle, z} [|\langle z|\psi\rangle|^2] \leq \frac{2}{2^n} + \frac{O(k^2)}{4^n}.$$

We note that one should not expect Lemma 13 to be tight for large  $k$  (say,  $k = \Omega(2^{n/2})$ ). For example, to achieve  $b = 4$ , we need at least enough samples to see  $m \geq 3$  with good probability. But  $\Pr[m \geq 3]$  is negligible unless  $k = \Omega(2^{2n/3})$ . More generally, a tight bound

on the number of copies of  $|\psi\rangle$  needed to achieve a particular value of  $b$  seems closely related to the number of measurements of  $|\psi\rangle$  needed to see  $m \geq b - 1$ . This is like a sort of “balls into bins” problem [22, 27] with  $k$  balls and  $2^n$  bins, but where the probabilities associated to each bin follow a Dirichlet prior rather than being uniform.

We finally have the tools to prove the main result of this section.

► **Theorem 14.** *Any quantum query algorithm for  $(2 + \varepsilon)$ -XHOG with query access to  $\mathcal{O}_\psi$  for a Haar-random  $n$ -qubit state  $|\psi\rangle$  requires  $\Omega\left(\frac{2^{n/4} \varepsilon^{5/4}}{n}\right)$  queries.*

Lastly, we give an upper bound on the number of queries needed to nontrivially beat the naive algorithm for XHOG with  $\mathcal{O}_\psi$ . In fact, the following algorithm works with *any* oracle that prepares a Haar-random state (including a Haar-random unitary), because the algorithm only needs copies of  $|\psi\rangle$  and the ability to perform the reflection  $\mathcal{R}_\psi$ . We thank Scott Aaronson for suggesting this approach based on quantum collision-finding.

► **Theorem 15.** *There is a quantum algorithm for  $(2 + \Omega(1))$ -XHOG that makes  $O(2^{n/3})$  queries to a state preparation oracle for a Haar-random  $n$ -qubit state  $|\psi\rangle$ .*

## 4 Random State Preparation Oracles

In this section, we show that a canonical state preparation oracle and a random state preparation oracle are essentially equivalent, and use it to prove the quantum supremacy Tsirelson inequality for XHOG with a Haar-random oracle.

By Lemma 7, for a state  $|\psi\rangle$ , query access to a random state preparation oracle  $U_\psi$  implies query access to the canonical state preparation oracle  $\mathcal{O}_\psi$  with constant overhead. The reverse direction is less obvious. We know from the definition of  $U_\psi$  (Definition 8) that one can simulate  $U_\psi$  given *any*  $n$ -qubit unitary  $V$  that prepares  $|\psi\rangle$  from  $|0^n\rangle$ . So, it is tempting to let  $V = \mathcal{O}_\psi$  with  $|\perp\rangle = |0^n\rangle$  to argue that  $\mathcal{O}_\psi$  allows simulating  $U_\psi$ . However, this is only possible if  $|0^n\rangle$  is orthogonal to  $|\psi\rangle$ . And while we previously argued that we can always find a canonical state  $|\perp\rangle$  that is orthogonal to  $|\psi\rangle$  (Footnote 2), this requires extending the Hilbert space, so that  $\mathcal{O}_\psi$  no longer acts on  $n$  qubits!

To address this, imagine that we knew an explicit  $n$ -qubit state  $|\psi^\perp\rangle$  orthogonal to  $|\psi\rangle$ . Notice that we could perfectly swap  $|\psi\rangle$  and  $|\psi^\perp\rangle$ : the composition  $\mathcal{O}_\psi \mathcal{O}_{\psi^\perp} \mathcal{O}_\psi$  sends  $|\psi\rangle$  to  $|\psi^\perp\rangle$ ,  $|\psi^\perp\rangle$  to  $|\psi\rangle$ , and acts trivially on all states orthogonal to  $|\psi\rangle$  and  $|\psi^\perp\rangle$ . In particular, this swaps  $|\psi\rangle$  and  $|\psi^\perp\rangle$  while acting only on the space of  $n$ -qubit states. Next, if we know  $|\psi^\perp\rangle$  explicitly, we can certainly come up with an  $n$ -qubit unitary that sends  $|0^n\rangle$  to  $|\psi^\perp\rangle$ . By composing such a unitary with  $\mathcal{O}_\psi \mathcal{O}_{\psi^\perp} \mathcal{O}_\psi$ , we are left with an  $n$ -qubit unitary that sends  $|0^n\rangle$  to  $|\psi\rangle$ . This is sufficient to construct  $U_\psi$ , by Definition 8.

While we do not necessarily have such a state  $|\psi^\perp\rangle$ , a *random*  $n$ -qubit state  $|\varphi\rangle$  will be exponentially close to such a  $|\psi^\perp\rangle$  with overwhelming probability. The next theorem shows that we can use this observation to *approximately* simulate  $U_\psi$  given  $\mathcal{O}_\psi$ , by going through the steps above and keeping track of deviation from the ideal construction in terms of  $\langle\psi|\varphi\rangle$ .

► **Theorem 16.** *Let  $|\psi\rangle$  be an  $n$ -qubit state. Consider a quantum query algorithm  $A$  that makes  $T$  queries to  $U_\psi$ . Then there is a quantum query algorithm  $B$  that makes  $2T$  queries to  $\mathcal{O}_\psi$  such that:*

$$\left\| \mathbb{E}_{U_\psi} [A] - B \right\|_{\diamond} \leq \frac{10T + 4}{2^{n/2}}.$$

The above theorem implies that the oracle  $\mathcal{O}_\psi$  in Theorem 14 can be replaced by a Haar-random  $n$ -qubit unitary.

## 13:10 The Quantum Supremacy Tsirelson Inequality

► **Theorem 17.** *Any quantum query algorithm for  $(2 + \varepsilon)$ -XHOG with query access to  $U_\psi$  for a Haar-random  $n$ -qubit state  $|\psi\rangle$  (i.e. a Haar-random  $n$ -qubit unitary) requires  $\Omega\left(\frac{2^{n/4}\varepsilon^{5/4}}{n}\right)$  queries.*

### 5 Fourier Sampling Circuits

In this section, we prove the quantum supremacy Tsirelson inequality for single-query algorithms over FOURIER SAMPLING circuits.

Throughout this section, we let  $N = 2^n$ , and let  $\mathcal{F}_n := \{f : \{0, 1\}^n \rightarrow \{-1, 1\}\}$  denote the set of all  $n$ -bit Boolean functions. Given a function  $f \in \mathcal{F}_n$ , we define the Fourier coefficient

$$\hat{f}(z) := \frac{1}{2^n} \sum_{x \in \{0, 1\}^n} f(x)(-1)^{x \cdot z}$$

for each  $z \in \{0, 1\}^n$ . We also define the characters  $\chi_z : \{0, 1\}^n \rightarrow \{-1, 1\}$  for each  $z \in \{0, 1\}^n$ :

$$\chi_z(x) := (-1)^{x \cdot z}.$$

Given oracle access to a function  $f \in \mathcal{F}_n$ , the FOURIER SAMPLING quantum circuit for  $f$  consists of a layer of Hadamard gates, then a single query to  $f$ , then another layer of Hadamard gates, so that the resulting circuit samples a string  $z \in \{0, 1\}^n$  with probability  $\hat{f}(z)^2$ . In the context of XHOG, we consider the distribution of FOURIER SAMPLING circuits where the oracle  $f$  is chosen uniformly at random from  $\mathcal{F}_n$ .

► **Proposition 18.** *FOURIER SAMPLING circuits over  $n$  qubits solve  $(3 - \frac{2}{2^n})$ -XHOG.*

The following theorem shows the optimality of the 1-query algorithm for XHOG with FOURIER SAMPLING circuits:

► **Theorem 19.** *Any 1-query algorithm for  $b$ -XHOG over  $n$ -qubit FOURIER SAMPLING circuits satisfies  $b \leq 3 - \frac{2}{2^n}$ .*

To prove Theorem 19, we use the polynomial method of Beals et al. [10]. Consider a quantum query algorithm that makes  $T$  queries to  $f \in \mathcal{F}_n$  and outputs a string  $z \in \{0, 1\}^n$ . The polynomial method implies that for each  $z \in \{0, 1\}^n$ , the probability that the algorithm outputs  $z$  can be expressed as a real multilinear polynomial of degree  $2T$  in the bits of  $f$ . We write such a polynomial as:

$$p_z(f) = \sum_{S \subset \{0, 1\}^n, |S| \leq 2T} c_{z,S} \cdot \prod_{x \in S} f(x).$$

Then, the expected XEB score of this quantum query algorithm is given by:

$$\frac{1}{2^N} \sum_{f \in \mathcal{F}_n} \sum_{z \in \{0, 1\}^n} p_z(f) \cdot \hat{f}(z)^2. \quad (2)$$

Our key observation is that the quantity (2) is linear in the coefficients  $c_{z,S}$ . This allows us to express the largest XEB score achievable by polynomials of degree  $2T$  as a linear program, with the constraints that the polynomials  $\{p_z(f) : z \in \{0, 1\}^n\}$  must represent a probability distribution. Then, the objective value of the linear program can be upper bounded by giving a solution to the dual linear program.

## 6 Discussion

The most natural question left for future work is whether our bounds could be improved. Our lower bounds for  $b$ -XHOG with  $\mathcal{O}_\psi$  or  $U_\psi$  show that for constant  $\varepsilon$ ,  $(2 + \varepsilon)$ -XHOG requires  $\Omega\left(\frac{2^{n/4}}{\text{poly}(n)}\right)$  queries to either oracle, while the best upper bound we know of solves  $(2 + \varepsilon)$ -XHOG in  $O(2^{n/3})$  queries. We conjecture that this upper bound is tight.

One possible approach towards improving the lower bound for  $b$ -XHOG with  $\mathcal{O}_\psi$  (and by extension,  $U_\psi$ ) is to use the polynomial method, as we did for the FOURIER SAMPLING lower bound. Indeed, the output probabilities of an algorithm that makes  $T$  queries to  $\mathcal{O}_\psi$  can be expressed as degree- $2T$  polynomials in the entries of  $\mathcal{O}_\psi$ . If we write  $|\psi\rangle = \sum_{i=1}^N \alpha_i |i\rangle$ , then these are polynomials in the amplitudes  $\alpha_1, \dots, \alpha_N$  and the conjugates of the amplitudes  $\alpha_1^*, \dots, \alpha_N^*$ . Because of the invariance of the Haar measure with respect to phases, and because the linear XEB score depends only on the magnitudes of the amplitudes, we can further assume without loss of generality that the output probabilities are polynomials in the variables  $|\alpha_1|^2, \dots, |\alpha_N|^2$ , which are equivalently the measurement probabilities of  $|\psi\rangle$  in the computational basis. We can also assume that these polynomials are homogeneous, because the input variables satisfy  $\sum_{i=1}^N |\alpha_i|^2 = 1$ . Like in our FOURIER SAMPLING lower bound, the polynomials are constrained to represent a probability distribution for all valid inputs. However, unlike the FOURIER SAMPLING lower bound, this introduces uncountably many constraints in the primal linear program. It may still be possible to exhibit a solution to the dual linear program if only finitely many of the constraints are relevant (such an approach was used in [17], for example).

Our  $b$ -XHOG bound for FOURIER SAMPLING circuits is tight, but it only applies to single-query algorithms. In principle, our lower bound approach via the polynomial method could be generalized to algorithms that make additional queries, by increasing the degree of the polynomials in the linear program and exhibiting another dual solution. The challenge seems to be that the parity constraint on the monomials with nonzero coefficients becomes unwieldy when working with higher degree polynomials.

Beyond possible improvements to the query complexity bounds, it would be interesting to give some evidence that beating the naive XHOG algorithm is hard in the real world. Aaronson and Gunn [2] showed that  $(1 + \varepsilon)$ -XHOG is *classically* hard, assuming the classical hardness of nontrivially estimating the output probabilities of random quantum circuits. It is not clear whether a similar argument could work for quantum algorithms, though, because sampling from a random quantum circuit gives a better-than-trivial algorithm for estimating its output probabilities.

## Abstract

We consider the manipulability of tournament rules which map the results of  $\binom{n}{2}$  pairwise matches and select a winner. Prior work designs simple tournament rules such that no pair of teams can manipulate the outcome of their match to improve their probability of winning by more than  $1/3$ , and this is the best possible among any Condorcet-consistent tournament rule (which selects an undefeated team whenever one exists) [14, 15]. These lower bounds require the manipulators to know precisely the outcome of all future matches.

We take a beyond worst-case view and instead consider tournaments which are “close to uniform”: the outcome of all matches are independent, and no team is believed to win any match with probability exceeding  $1/2 + \varepsilon$ . We show that Randomized Single Elimination Bracket [14] and a new tournament rule we term Randomized Death Match have the property that no pair of teams can manipulate the outcome of their match to improve their probability of winning by more than  $\varepsilon/3 + 2\varepsilon^2/3$ , for all  $\varepsilon$ , and this is the best possible among any Condorcet-consistent tournament rule.

Our main technical contribution is a recursive framework to analyze the manipulability of certain forms of tournament rules. In addition to our main results, this view helps streamline previous analysis of Randomized Single Elimination Bracket, and may be of independent interest.

## 1 Introduction

A tournament consists of  $n$  teams competing to win a championship via pairwise matches, and a tournament rule (possibly randomly) selects a single winner as a result of these matches. Tournament rules have been studied within Social Choice Theory for decades [6, 12, 16, 3, 7, 10, 11], see also [4] for a survey, and have gained attention from a few angles within TCS more recently [2, 1, 18, 17, 9, 8, 14, 15]. Our work follows the model studied in [2, 1, 14, 15] and seeks to design tournaments which are both fair (in that they select a reasonable winner, based on the match outcomes), and “as strategyproof as possible” subject to this.

More specifically, these works acknowledge that an undefeated team, if one exists, should surely win any reasonable tournament format. Formally, this property is termed *Condorcet-consistent* (Definition 4). These works also consider the possibility of two teams strategically manipulating the match between them to improve the probability that one of them wins. The situation to have in mind is that perhaps two teams sponsored by the same company enter an eSports tournament, and wish to maximize the probability that either of them take home the prize money. A rule is 2-Strongly Non-Manipulable (2-SNM, Definition 7) if no pair of teams can manipulate it to improve the probability that one of them wins.

Initial works quickly established that no tournament rule exists which is both Condorcet-consistent and 2-SNM [2, 1]. More recent works study the extent to which tournament rules can be Condorcet-consistent and *approximately* 2-SNM. Specifically, a rule is 2-SNM- $\alpha$  if no pair of teams can improve the probability that one of them wins by more than  $\alpha$  (Definition 7). [14, 15] design simple Condorcet-consistent tournament rules (defined in Section 3) which are 2-SNM-1/3, and also show this is the best possible *worst-case* guarantee.

### 1.1 Our Results: Probabilistic Tournaments

The lower bounds in previous works assume that the *deterministic future outcome* of all matches is known at the time of manipulation. While this is certainly a plausible scenario, most competitions worth watching have some element of uncertainty, even for matches between strong and weak teams. Indeed, [14, Open Problem 2] explicitly asks whether improved guarantees are possible if instead the teams have a common Bayesian prior about the possible outcomes of future matches which is *bounded away from deterministic*.

For example, consider the case where the outcome of all matches are uniformly at random. Then it is not hard to design a Condorcet-consistent tournament rule which is 2-SNM in this case. One example is a simple single-elimination bracket: when two manipulating teams face each other, each of them is equally likely to continue on and win the tournament, so manipulating doesn't help.

What if instead the outcome of all matches are not uniformly random, but close? More specifically, what if the match results are independent, and no team wins any match with probability more than  $1/2 + \varepsilon$ ? When  $\varepsilon = 0$ , the previous paragraph establishes that rules exist where profitable manipulation is impossible. When  $\varepsilon = 1/2$ , [14, 15] establish that 2-SNM-1/3 tournaments exist, but no better. What about when  $\varepsilon \in (0, 1/2)$ ? How do the achievable guarantees vary as a function of  $\varepsilon$ ?

Our main result resolves this question, and nails down the guarantees precisely as a function of  $\varepsilon$ . Moreover, we show that *the same tournament rule achieves the optimal guarantee for all  $\varepsilon$* . Below, Randomized Single Elimination Bracket (Definition 12, henceforth RSEB) randomly seeds all teams, then runs a single-elimination bracket to determine the winner, and was shown to be 2-SNM-1/3 in [14]. Randomized Death Match (Definition 14, henceforth RDM) repeatedly picks two uniformly random teams to play a match, and eliminates the loser (and is first analyzed in this paper).

► **Informal Theorem 1** (See Theorems 30, 31). *For all  $\varepsilon \in [0, 1/2]$ , Randomized Death Match and Randomized Single Elimination Bracket are 2-SNM- $(\varepsilon/3 + 2\varepsilon^2/3)$  when match outcomes are independent, and no team wins any match with probability more than  $1/2 + \varepsilon$ . Moreover, for all  $\varepsilon \in [0, 1/2]$ , no Condorcet-consistent tournament rule is 2-SNM- $\alpha$  for any  $\alpha < \varepsilon/3 + 2\varepsilon^2/3$ , on the set of all tournaments with independent match outcomes that no team wins with probability more than  $1/2 + \varepsilon$ .*

### 1.2 Technical Highlights

We prove our main result by finding a strong structural similarity between tournaments like RDM and RSEB: they can be defined recursively. Specifically, RDM could be alternatively defined as “Pick two teams uniformly at random, and eliminate the loser of their match. Then, recurse on the remaining teams.” Similarly, RSEB can be alternatively defined as “Pick a uniformly random perfect matching between the teams, and eliminate all teams which

lose their match. Then, recurse on the remaining teams.” Even the Randomized King of the Hill rule (Definition 13, henceforth RKotH) defined by [15] fits this framework as well: “Pick a uniformly random team to play all other teams. Eliminate all teams who lose a match, and recurse on the remaining teams.”

In Section 3, we give a formal definition of what it means to be a recursive tournament rule. And in Section 4 (specifically, Theorem 21), we provide a general framework to analyze the manipulability of recursive tournament rules on probabilistic tournaments. This provides a fairly clean outline to analyze recursive tournament rules, and our main result then applies this framework to RDM and RSEB. In the  $\varepsilon = 1/2$  case, our analysis of RSEB in isolation is perhaps not much simpler than that of [14], but our proof is arguably more structured. Indeed, a substantial fraction of our proof can be applied verbatim to other tournament rules like RDM, or applied verbatim to the  $\varepsilon < 1/2$  case.

It is worth noting that our framework does face some technical barriers in accommodating RKotH (and we leave open whether RKotH achieves the same guarantees as RDM and RSEB). But, the technical barrier is easy to describe: the matches played in each round of RDM and RSEB form a matching – no team plays more than one match. In RKotH, some team plays multiple matches. It seems likely that our analysis would extend (perhaps with messier calculations) to any recursive rule where each round’s matches form a matching. But we highlight the aspects of our analysis which rely on this aspect of RDM/RSEB (and therefore don’t hold for RKotH), and believe this is a genuine barrier.

### 1.3 Further Related Work

We’ve already discussed the most related work [2, 1, 14, 15]. The model is first posed in [2], and [1] design tournaments which are 2-SNM and approximately Condorcet-consistent (e.g. pick a uniformly random match and declare the winner of that match to win the tournament). [14] first proposed to instead consider rules which are Condorcet-consistent and approximately strategyproof, and establishes that RSEB is 2-SNM-1/3 and that this is optimal. [15] considers larger manipulating sets (not relevant to this paper) and also designs RKotH, showing that it too is 2-SNM-1/3 and satisfies a stronger notion of fairness termed “cover-consistent”. In relation to these works, our main contribution is going beyond the worst-case to derive improved bounds when match outcomes are more uncertain. A technical contribution is our framework of recursive tournament rules.

Other recent works within TCS focus specifically on single-elimination brackets and manipulation in the form of a bracket designer trying to get a certain team to win [18, 17, 9, 8], or manipulability of particular tournament rules such as the World Cup qualifying procedure [13, 5]. Aside from being thematically related, there is no significant technical overlap with our work.

### 1.4 Roadmap

Section 2 immediately follows with definitions and preliminaries. Section 3 provides definitions concerning recursive tournament rules, and formally defines RDM and RSEB. Section 4 provides our framework for analyzing the manipulability of recursive tournament rules. Section 5 applies this framework, as a warmup, to rederive the main result of [14] and analyze RDM/RSEB in the deterministic case. Section 6 proves our main results, and Section 7 provides a brief conclusion.

## 2 Preliminaries

### 2.1 Tournament Rule Basics

In this section, we introduce notation consistent with prior work [1, 14, 15].

► **Definition 2** (Deterministic Tournament). *A (round robin) tournament  $T$  on  $n$  teams is a complete, directed graph on  $n$  vertices whose edges denote the outcome of a match between two teams. Team  $i$  beats team  $j$  if the edge between them points from  $i$  to  $j$ .*

► **Definition 3** (Tournament Rule). *A tournament rule  $r$  is a function that maps (deterministic) tournaments  $T$  to a distribution over teams, where  $r_i(T) := \Pr[r(T) = i]$  denotes the probability that team  $i$  is declared the winner of tournament  $T$  under rule  $r$ . We use the shorthand  $r_S(T) := \sum_{i \in S} r_i(T)$  to denote the probability that a team in  $S$  is declared the winner of tournament  $T$  under rule  $r$ .*

Finally, we are interested in tournament rules which satisfy basic notions of fairness. Importantly, note that Condorcet-consistence is a minimal notion of fairness, and in particular does not constrain the behavior of  $r$  on any tournament without a Condorcet winner.

► **Definition 4** (Condorcet-Consistent). *Team  $i$  is a Condorcet winner of a tournament  $T$  if  $i$  beats every other team (under  $T$ ). A tournament rule  $r$  is Condorcet-consistent if for every tournament  $T$  with a Condorcet winner  $i$ ,  $r_i(T) = 1$  (whenever  $T$  has a Condorcet winner, that team wins with probability 1).*

### 2.2 Independent Probabilistic Tournaments

In this work, we study probabilistic tournaments. That is, we are interested in tournaments where the outcome of each match is not known to teams “in advance”, but teams share a Bayesian prior about the likelihood of each possible outcome. In particular, we consider when match outcomes are independent.

► **Definition 5** (Independent Probabilistic Tournament). *A probabilistic tournament  $T$  is just a distribution over deterministic tournaments. For notational convenience, we slightly abuse notation and refer by  $r_i(T)$  to  $\mathbb{E}[r_i(T)]$  (that is,  $r_i(T)$  is the probability that team  $i$  wins when rule  $r$  is applied to  $T$ , over the randomness in  $r$  and the randomness in drawing  $T$ ). A probabilistic tournament  $T$  is independent if all match outcomes in  $T$  are independent events. Observe that a probabilistic tournament  $T$  is fully defined by probabilities  $p_{ij}^T$  for all  $i < j$ , where  $p_{ij}^T$  denotes the probability that  $i$  beats  $j$  in tournament  $T$ .*

Observe that deterministic tournaments are also independent probabilistic tournaments, with each  $p_{ij}^T \in \{0, 1\}$ . Like prior work, we study tournament rules which are “as strategyproof as possible”. Because of our focus on independent probabilistic tournaments, we first refine previous definitions of non-manipulability.

► **Definition 6** ( $S$ -adjacent). *Two independent probabilistic tournaments  $T, T'$  are  $S$ -adjacent if  $p_{ij}^T = p_{ij}^{T'}$  whenever  $\{i, j\} \not\subseteq S$ . That is, two independent probabilistic tournaments are  $S$ -adjacent when all (probabilistic) match outcomes are identical, except possibly for matches between two teams in  $S$ .*

Intuitively, two tournaments  $T, T'$  are  $S$ -adjacent if the set of teams  $S$  can manipulate the outcomes of matches between them in advance and cause the resulting (probabilistic) tournament to go from  $T$  to  $T'$ .

► **Definition 7** (Manipulating a Tournament). *For a set  $S$  of teams, independent probabilistic tournament  $T$ , and tournament rule  $r$ , we define  $\alpha_S^r(T)$  to be the maximum winning probability that  $S$  can possibly gain by manipulating  $T$  to an  $S$ -adjacent  $T'$ . That is:  $\alpha_S^r(T) := \max_{T': T' \text{ is } S\text{-adjacent to } T} \{r_S(T') - r_S(T)\}$ .*

*For a class  $\mathcal{T}$  of (independent probabilistic) tournaments, we also define  $\alpha_k^r(\mathcal{T}) := \max_{T \in \mathcal{T}, S: |S| \leq k} \{\alpha_S^r(T)\}$ . If  $\alpha_k^r(\mathcal{T}) \leq \alpha$ , we say  $r$  is  $k$ -Strongly Non-Manipulable at probability  $\alpha$  with respect to  $\mathcal{T}$  ( $k$ -SNM $_{\mathcal{T}-\alpha}$ ). To match notation of prior work, we also say a tournament is  $k$ -SNM- $\alpha$  if it is  $k$ -SNM $_{S^{1/2}-\alpha}$ .<sup>1</sup>*

*Finally, we also define  $\alpha_k(\mathcal{T}) = \inf_{\text{Condorcet consistent } r} \{\alpha_k^r(\mathcal{T})\}$ .*

Intuitively,  $r$  is  $k$ -SNM $_{\mathcal{T}-\alpha}$  if no colluding set of  $\leq k$  teams can manipulate a tournament in  $\mathcal{T}$  to improve the probability the winner is in  $S$  by more than  $\alpha$ . The refinement over prior work is that the condition only holds for tournaments in  $\mathcal{T}$  – prior work only considers guarantees that hold over *all* tournaments. The additional notation in Definition 7 are just terms that will be helpful for later exposition.

We focus on independent probabilistic tournaments that are close to uniformly random.

► **Definition 8** ( $\varepsilon$ -Bounded Tournaments). *An independent probabilistic tournament  $T$  is weakly  $\varepsilon$ -bounded if for all  $i, j$ ,  $p_{ij}^T \in [1/2 - \varepsilon, 1/2 + \varepsilon]$ . We refer to  $\mathcal{T}^\varepsilon$  as the set of all  $\varepsilon$ -bounded tournaments.*

*An independent probabilistic tournament  $T$  is strictly  $\varepsilon$ -bounded if for all  $i, j$ ,  $p_{ij}^T \in \{1/2 - \varepsilon, 1/2 + \varepsilon\}$ . We refer to  $\mathcal{S}^\varepsilon$  as the set of all strictly  $\varepsilon$ -bounded tournaments. It will be helpful to define the notation  $\mathcal{T}_{\leq n}^\varepsilon$  (respectively,  $\mathcal{S}_{\leq n}^\varepsilon$ ) as the set of all weakly- (respectively, strictly-) bounded tournaments on  $\leq n$  teams.*

For example, every deterministic tournament is  $1/2$ -bounded, and the uniformly random tournament is  $0$ -bounded. Our main results study  $\alpha_k(\mathcal{T}^\varepsilon)$  as a function of  $\varepsilon$ . We conclude with a brief lemma relating  $\alpha_k(\mathcal{T}^\varepsilon)$  to  $\alpha_k(\mathcal{S}^\varepsilon)$ , as direct analysis of  $\alpha_k(\mathcal{S}^\varepsilon)$  is significantly simpler than direct analysis of  $\alpha_k(\mathcal{T}^\varepsilon)$ .

► **Proposition 9.** *For all rules  $r$ , and all  $\varepsilon, k$ ,  $\alpha_k^r(\mathcal{T}^\varepsilon) = \alpha_k^r(\mathcal{S}^\varepsilon)$ . Therefore, for all  $\varepsilon, k$ ,  $\alpha_k(\mathcal{T}^\varepsilon) = \alpha_k(\mathcal{S}^\varepsilon)$ .*

While the proof is deferred to Appendix A, the high-level outline is fairly intuitive. First, the “Therefore, . . .” statement follows trivially from the first portion of the lemma. Also, it is trivial to see that  $\alpha_k^r(\mathcal{T}^\varepsilon) \geq \alpha_k^r(\mathcal{S}^\varepsilon)$ , as  $\mathcal{S}^\varepsilon \subseteq \mathcal{T}^\varepsilon$ . So the interesting step is establishing  $\alpha_k^r(\mathcal{T}^\varepsilon) \leq \alpha_k^r(\mathcal{S}^\varepsilon)$ . Intuitively, this follows because all (independent probabilistic) tournaments in  $\mathcal{T}^\varepsilon$  can be written as convex combinations of tournaments in  $\mathcal{S}^\varepsilon$ , and one might expect that any particular tournament rule is most manipulable on extreme points (indeed this is true). With Proposition 9, we may restrict our study to  $\alpha_k(\mathcal{S}^\varepsilon)$ .

### 3 Recursive Tournament Rules

In this section, we formalize a class of tournament rules which have a recursive aspect to them. This will help us streamline previous analysis of [14], and also easily design a new tournament rule with matching guarantees. In addition, this view will help give us a clean outline to analyze the performance of these rules on tournaments in  $\mathcal{T}^\varepsilon$ , rather than just in the worst case.

<sup>1</sup> Note that  $\mathcal{S}^{1/2}$  is the set of all deterministic tournaments, defined shortly below.

► **Definition 10** (Elimination Rule). *An elimination rule  $E$  takes as input a number  $n$  of teams and selects (possibly randomly) a set  $M := E(n)$  of matches to play, with  $|M| \in [1, n - 1]$ .*

*An elimination rule is matching if  $M$  is a (not necessarily perfect) matching with probability one.*

► **Definition 11** (Recursive Tournament Rule). *A recursive tournament rule is fully defined by its elimination rule  $E$ . The recursive tournament rule  $r^E$  takes as input a tournament  $T$ , samples matches  $M := E(n)$  to play, and then eliminates any team which loses a match in  $M$ .<sup>2</sup> Specifically,  $T|_M$  denotes the induced subgraph of  $T$  on teams not eliminated by the matches in  $M$ . The tournament then recursively executes  $r^E(T|_M)$  to select a winner. As a base case, when there is only one team left, that team is the winner.*

We now give three examples of elimination rules, and the resulting tournament rule. Randomized Single Elimination Bracket was first studied in [14], Randomized King of the Hill was first studied in [15], and Randomized Death Match is first studied in this paper.

► **Definition 12** (Randomized Single Elimination Bracket). *For a tournament  $T$  on  $n$  teams, let  $n' := 2^{\lceil \log_2 n \rceil}$ . Create  $n' - n$  dummy players who all lose to the original  $n$  teams. Let  $M$  be matches corresponding to a uniformly random perfect matching (i.e. exactly  $n'/2$  matches are played, and every team plays in exactly one match). Eliminate the losers and recurse on the remaining (non-dummy) teams.*

► **Definition 13** (Randomized King of the Hill). *Pick a uniformly random team  $i$ , to play all others. Observe that if  $i$  is a Condorcet winner, then  $i$  will be the only remaining team. Otherwise,  $i$  and every team it beats will be eliminated. Recurse on the remaining teams.*

► **Definition 14** (Randomized Death Match). *Pick two uniformly random teams (without replacement) and play their match. Eliminate the loser and recurse on the remaining teams.*

Observe that our definition of Randomized Single Elimination Bracket (RSEB) differs semantically from that given in [14], where the  $n'$  teams are uniformly permuted into  $n'$  seeds, and then the resulting bracket is played (without re-randomizing at each round). Observe that the two definitions are equivalent (identically distributed), however, as our definition simply produces the seeding by first figuring out the first-round matches, then the second-round matches, etc. Our definition of Randomized King of the Hill (RKotH) is identical (semantically) to that given in [15].

Randomized Death Match (RDM) is similar to Randomized Voting Caterpillar (RVC) [14]. Like RDM, RVC picks two uniformly random teams (without replacement) and eliminates the loser. However, rather than a “pure recursion”, RVC proceeds by picking *one* uniformly random remaining team to play the previous winner. This subtle distinction causes RDM to be 2-SNM-1/3 (Theorem 23), but not RVC ([14, Theorem 3.14]). Observe also that RSEB and RDM have matching elimination rules, but RKotH doesn’t (this is the main technical barrier in extending our analysis to RKotH).

Finally, observe that all three rules above are *anonymous*: relabeling the teams simply relabels the distribution over winners. This will play a role in our analysis.

► **Definition 15** (Anonymous). *A tournament rule  $r$  is anonymous if for every tournament  $T$ , and every permutation  $\sigma$ , and all  $i$ ,  $r_{\sigma(i)}(\sigma(T)) = r_i(T)$ .*

<sup>2</sup> Observe that because  $|M| \in [1, n - 1]$  that at least one team is eliminated, but not all teams are eliminated.

## 4 Key Framework

In this section, we propose an outline to analyze the manipulability of recursive tournament rules for independent probabilistic tournaments. For notational convenience, if a team  $i$  is not present in tournament  $T$  (e.g. because they were eliminated in an earlier round), we abuse notation and denote by  $r_i(T) := 0$ . Additionally, we let  $M(T)$  denote the outcome of matches  $M$  for tournament  $T$  (i.e. for all  $(u, v) \in M$ , whether  $u$  or  $v$  wins in tournament  $T$ ). Note that if  $T$  is probabilistic,  $M(T)$  is a random variable, even after conditioning on  $M$ .

Our first step simply observes that recursive tournament rules can be analyzed recursively due to linearity of expectation. A (short) proof of Lemma 16 appears in Appendix B.

► **Lemma 16.** *Let  $r^E$  be any recursive tournament rule. Let  $T, T'$  be independent probabilistic tournaments on  $n > 1$  teams, and let  $S$  be any subset of teams. Then:*

$$r_S^E(T') - r_S^E(T) = \mathbb{E}_{M \leftarrow E(n)}[r_S^E(T'|_M) - r_S^E(T|_M)].$$

To help parse notation: recall that if  $T, T'$  are not deterministic, then the notation  $r_S^E(T')$  (respectively,  $r_S^E(T), r_S^E(T'|_M), r_S^E(T|_M)$ ) is taking an expectation over  $T'$  (respectively,  $T, T'|_M, T|_M$ ), as per Definition 5.<sup>3</sup> On the right-hand side, we are taking an expectation first over the matches  $M$  which are played. Inside the expectation, the teams in  $T|_M$  and  $T'|_M$  are still random variables (because they depend on the *outcome* of matches in  $M$  in  $T$ , which are still random after conditioning on  $M$ ). And after the teams are determined by  $M(T), M(T')$ , the tournaments  $T'|_M, T|_M$  are still probabilistic tournaments.

Importantly, observe that when  $S = \{u, v\}$  and  $T, T'$  are  $S$ -adjacent, the tournaments  $T|_M$  and  $T'|_M$  may differ for two reasons. First, perhaps  $(u, v) \in M$ . In this case, perhaps  $M(T) \neq M(T')$  (because  $T$  and  $T'$  can differ on the  $(u, v)$  match), and then  $T|_M, T'|_M$  may have different sets of teams. Second, perhaps  $(u, v) \notin M$ , implying that  $M(T) = M(T')$  (because  $T$  and  $T'$  are identically distributed outside of the  $(u, v)$  match).  $T|_M$  and  $T'|_M$  therefore have the same sets of teams, but it can still be that  $p_{uv}^T \neq p_{uv}^{T'}$ , so the tournaments  $T|_M$  and  $T'|_M$  can still differ due to this match (if both  $u$  and  $v$  are not eliminated).

The second step in our framework simply splits the recursive analysis into cases based on  $M$ , and the results of the matches  $M(T)$ . We define these cases clearly below, and then state our main framework.

► **Definition 17 (Base Case).** *We say that tournament  $T$  is a base case if  $\alpha_S^r(T) = 0$ . That is, it is not possible for  $S$  to gain by manipulating tournament  $T$  under rule  $r$ .*

One clear base case occurs if  $S = \{u, v\}$ , but  $u$  is not even in  $T$ . Lemma 22 later identifies another for anonymous tournament rules (if relabeling  $u$  and  $v$  doesn't change  $T$  except for the  $(u, v)$  match, then  $\{u, v\}$  cannot gain by manipulating an anonymous tournament rule).

► **Definition 18 (Bad Terminal Event).**  *$M$  is a bad terminal event if  $(u, v) \in M$ . That is, a bad terminal event occurs when the  $(u, v)$  match is played this round. We denote the occurrence of this event by  $B$ .*

► **Definition 19 (Good Terminal Event).**  *$M, M(T)$  is a good terminal event if  $(u, v) \notin M$ , and  $M(T)$  is such that  $T|_M$  is a base case.<sup>4</sup> That is, the  $(u, v)$  match is not played now (so no gains from manipulation are possible), and no future gains are possible either. We denote the occurrence of this event by  $G$ .*

<sup>3</sup> In particular, note that  $T|_M$  and  $T'|_M$  are not independent probabilistic tournaments, but are still probabilistic tournaments, as they are distributions over independent probabilistic tournaments.

<sup>4</sup> Observe that because  $(u, v) \notin M$ , that if  $T'$  is  $S$ -adjacent to  $T$  then  $M(T)$  and  $M(T')$  are identically distributed.

► **Definition 20** (Recursive Event).  $M, M(T)$  is a recursive event if  $(u, v) \notin M$ , but  $M(T)$  is not such that  $T|_M$  is a base case. That is, a recursive event occurs when the  $(u, v)$  match is not played now, but may be played later (and manipulating it may be beneficial). We denote the occurrence of this event by  $R$ .

We now state the theorem which drives our analysis. Observe that the bound claimed by Theorem 21 could in principle be (very) loose, but our subsequent sections show that this framework suffices to nail down  $\alpha_2^r(\mathcal{T}^\varepsilon)$  for RDM and RSEB, and also that these are the best possible guarantees for any Condorcet-consistent tournament rule.

► **Theorem 21.** Let  $r^E$  be a recursive tournament rule,  $\varepsilon \in [0, 1/2]$ , and  $S := \{u, v\}$ . Let  $b, g, c \geq 0$  (with  $b + g > 0$ ) be so that for any  $T \in \mathcal{S}^\varepsilon$ , and any  $T'$  which is  $S$ -adjacent to  $T$ :

- $\Pr_{M \leftarrow E(n)}[B] \leq b.$
- $\Pr_{M \leftarrow E(n), M(T)}[G] \geq g.$
- $\mathbb{E}_{M \leftarrow E(n)}[r_S^E(T'|_M) - r_S^E(T|_M)|B] \leq c.$

Then:  $\alpha_2^{r^E}(\mathcal{T}^\varepsilon) \leq \frac{bc}{b+g}.$

**Proof.** We prove the theorem by induction, and focus on  $\mathcal{S}^\varepsilon$  first (extending to  $\mathcal{T}^\varepsilon$  using Proposition 9). As a base case, observe that when there are at most two teams remaining, no gains from manipulation are possible and therefore  $\alpha_2^{r^E}(\mathcal{S}_{\leq 2}^\varepsilon) \leq 0 \leq \frac{bc}{b+g}$  as desired.

For the inductive hypothesis, assume that  $\alpha_2^{r^E}(\mathcal{S}_{\leq n-1}^\varepsilon) \leq \frac{bc}{b+g}$  and consider now any tournament  $T \in \mathcal{S}^\varepsilon$  on  $n$  teams, and an  $S$ -adjacent  $T'$ . We have the following chain of equalities, which essentially just breaks down  $r_S^E(T') - r_S^E(T)$  based on the three events  $R, B, G$  (below,  $I(X)$  denotes the indicator random variable for event  $X$ , which is 1 when event  $X$  occurs and 0 otherwise):

$$\begin{aligned}
 r_S^E(T') - r_S^E(T) &= \mathbb{E}_{M \leftarrow E(n)}[r_S^E(T'|_M) - r_S^E(T|_M)] \\
 &= \mathbb{E}_{M \leftarrow E(n), M(T)}[(r_S^E(T'|_M) - r_S^E(T|_M)) \cdot (I(R) + I(B) + I(G))] \\
 &= \Pr_{M \leftarrow E(n), M(T)}[R] \cdot \mathbb{E}_{M \leftarrow E(n), M(T)}[r_S^E(T'|_M) - r_S^E(T|_M)|R] \\
 &\quad + \Pr_{M \leftarrow E(n)}[B] \cdot \mathbb{E}_{M \leftarrow E(n)}[r_S^E(T'|_M) - r_S^E(T|_M)|B] \\
 &\quad + \Pr_{M \leftarrow E(n), M(T)}[G] \cdot \mathbb{E}_{M \leftarrow E(n), M(T)}[r_S^E(T'|_M) - r_S^E(T|_M)|G]
 \end{aligned}$$

The first line restates Lemma 16. The second line simply observes that exactly one of the events  $R, B, G$  occur, and also uses linearity of expectation to take an expectation also over  $M(T)$ . The third line just observes that  $\mathbb{E}[Y \cdot I(X)] = \Pr[X] \cdot \mathbb{E}[Y|X]$  for any random variable  $Y$  and event  $X$ , breaks the sum into three parts (again using linearity of expectation), and observes that the event  $B$  is determined entirely by  $M$  and is independent of  $M(T)$ .

We now want to analyze the three terms separately. First, observe that by bullet three:

$$\mathbb{E}_{M \leftarrow E(n)}[r_S^E(T'|_M) - r_S^E(T|_M)|B] \leq c. \quad (1)$$

Next, observe that in either a good terminal event or a recursive event,  $(u, v) \notin M$ . Because  $T, T'$  are  $S$ -adjacent, this means that  $M(T), M(T')$  are identically distributed (and can therefore be coupled so that  $M(T) = M(T')$  with probability one), so the teams in  $T|_M$  and  $T'|_M$  are therefore the same. Finally, because  $T$  is an *independent* probabilistic tournament, and at least one team that participates in every match in  $M$  is eliminated,  $p_{ij}^{T|_M} = p_{ij}^T$  for all teams  $i, j$  which are present in  $T|_M$  (and also  $p_{ij}^{T'|_M} = p_{ij}^{T'}$ ). This means that  $T|_M \in \mathcal{S}_{\leq n-1}^\varepsilon$ , and also that  $T'|_M, T|_M$  are  $S$ -adjacent.

In a good terminal event, because  $\alpha_2^E(T|M) = 0$  by definition, we must therefore have:

$$\mathbb{E}_{M \leftarrow E(n), M(T)}[r_S^E(T'|M) - r_S^E(T|M)|G] \leq 0. \quad (2)$$

In a recursive event, we instead have:

$$\mathbb{E}_{M \leftarrow E(n), M(T)}[r_S^E(T'|M) - r_S^E(T|M)|R] \leq \alpha_2^E(\mathcal{S}_{\leq n-1}). \quad (3)$$

Finally, we may now use our inductive hypothesis and Equations (1), (2), (3) to conclude:

$$\begin{aligned} r_S^E(T') - r_S^E(T) &= \Pr_{M \leftarrow E(n), M(T)}[R] \cdot \mathbb{E}_{M \leftarrow E(n), M(T)}[r_S^E(T'|M) - r_S^E(T|M)|R] \\ &\quad + \Pr_{M \leftarrow E(n)}[B] \cdot \mathbb{E}_{M \leftarrow E(n)}[r_S^E(T'|M) - r_S^E(T|M)|B] \\ &\quad + \Pr_{M \leftarrow E(n), M(T)}[G] \cdot \mathbb{E}_{M \leftarrow E(n), M(T)}[r_S^E(T'|M) - r_S^E(T|M)|G] \\ &\leq \Pr_{M \leftarrow E(n), M(T)}[R] \cdot \frac{bc}{b+g} + \Pr_{M \leftarrow E(n)}[B] \cdot c + \Pr_{M \leftarrow E(n), M(T)}[G] \cdot 0 \\ &= \frac{bc}{b+g} + \Pr_{M \leftarrow E(n)}[B] \cdot \left(c - \frac{bc}{b+g}\right) + \Pr_{M \leftarrow E(n), M(T)}[G] \cdot \left(0 - \frac{bc}{b+g}\right) \\ &\leq (1 - b - g) \cdot \frac{bc}{b+g} + b \cdot c + g \cdot 0 = \frac{bc}{b+g} \end{aligned}$$

The first inequality just combines the work of Equations (1), (2), (3), and upper bounds the expected gains in all three cases using either the inductive hypothesis ( $R$ ), direct hypothesis ( $B$ ), or definition of good terminal event ( $G$ ). The final inequality observes that  $c \geq \frac{bc}{b+g} \geq 0$ , so the bound is maximized when  $B$  occurs as often as possible, while  $G$  occurs as little as possible (consistent with the hypotheses).

We have now shown that for any  $T \in \mathcal{S}^\varepsilon$ , and any  $T'$  which is  $S$ -adjacent, that  $r_S^E(T') - r_S^E(T) \leq \frac{bc}{b+g}$ . This establishes that  $\alpha_2^E(\mathcal{S}^\varepsilon) \leq \frac{bc}{b+g}$ . Proposition 9 extends this to  $\mathcal{T}^\varepsilon$ . ◀

Theorem 21 is our main framework for analysis. The remainder of this paper now computes the bounds required for the three bullets for the two tournament rules of interest as a function of  $\varepsilon$ , and substitutes to obtain tight bounds. Finally, it is worth briefly noting that the definition of  $\alpha_2^E(\mathcal{T}^\varepsilon)$  semantically assumes that teams must decide how to manipulate the outcome of their match *in advance*, before any matches are played. Still, any analysis that follows from Theorem 21 applies *even to manipulations which are decided upon as the match is played*. This is because the bound in bullet three of Theorem 21 must hold over *all*  $S$ -adjacent  $T'$ , not just one which was decided in advance. This claim is not central to our main results, and making it formal would be notationally cumbersome, so we provide only this brief discussion.

## 5 Warmup: Rederiving Bounds for Deterministic Tournaments

In this section, we rederive the main result of [14] (RSEB is 2-SNM-1/3), and analyze a novel tournament rule (RDM is 2-SNM-1/3) using a simple application of Theorem 21. This will require one further lemma about anonymous tournament rules to find additional base cases. The proof is in Appendix C.

► **Lemma 22.** *Let  $r$  be any anonymous tournament rule,  $S := \{u, v\}$ , and  $T, T'$  be independent probabilistic tournaments which are  $S$ -adjacent and satisfy  $p_{uw}^T = p_{vw}^T$  for all  $w \notin \{u, v\}$ . Then  $r_S(T) = r_S(T')$ .*

## 14:10 Approximately Strategyproof Tournament Rules in the Probabilistic Setting

We now prove that RDM is 2-SNM-1/3. Recall that  $\alpha_2(\mathcal{S}^{1/2}) = 1/3$ , so this is optimal.

► **Theorem 23.** *RDM is 2-SNM-1/3. Or in our language,  $\alpha_2^{RDM}(\mathcal{T}^{1/2}) = 1/3$ .*

**Proof.** Recall that we need to lower bound the probability of a good terminal event, upper bound the probability of a bad terminal event, and upper bound the gains from manipulation in case of a bad terminal event. For the deterministic case, the latter bound is particularly simple, and we will just observe that clearly  $\mathbb{E}_{M \leftarrow E(n)}[r_S^E(T'|_M) - r_S^E(T|_M)|B] \leq 1$ . This is simply because the maximum probability that any coalition can win in any tournament is 1, and the minimum is 0. So we have established that RDM satisfies  $c = 1$ .

To bound the probability of a bad terminal event, observe that a bad terminal event occurs only when  $u$  plays  $v$  in this round, which happens with probability exactly  $1/\binom{n}{2}$ . So RDM satisfies  $b = 1/\binom{n}{2}$ .

For the good terminal events, we claim that  $\Pr[G] \geq 2/\binom{n}{2}$ . First, observe that once we show this, we can plug into Theorem 21 and conclude  $\alpha_2^{RDM}(\mathcal{T}^{1/2}) \leq \frac{1 \cdot 1/\binom{n}{2}}{1/\binom{n}{2} + 2/\binom{n}{2}} = 1/3$ .

To see this bound, let  $\ell_u$  denote the number of teams which beat  $u$  but not  $v$ , and  $\ell_v$  denote the number of teams which beat  $v$  but not  $u$ . Without loss of generality let  $\ell_u \geq \ell_v$ .

If  $\ell_u + \ell_v = 0$ , then Lemma 22 already establishes that  $u$  and  $v$  can gain nothing by manipulating. If  $\ell_u + \ell_v \geq 2$ , then whenever  $u$  or  $v$  play a team which beat them, we have a good terminal event (because  $u$  or  $v$  is already eliminated before having ever played the  $(u, v)$  match, resulting in a base case). This happens with probability at least  $2/\binom{n}{2}$ , as desired.

If  $\ell_u + \ell_v = 1$ , then  $\ell_u = 1, \ell_v = 0$ . Let  $w$  be the unique team which beats  $u$  but not  $v$ . We claim that if  $w$  plays *either*  $u$  or  $v$  that we are in a good terminal event. Indeed, if  $w$  plays  $u$ , then  $u$  is eliminated having never played the  $(u, v)$  match. If instead  $w$  plays  $v$ , then  $w$  is eliminated, but now there are no remaining teams which beat  $u$  but not  $v$  (or vice versa) and Lemma 22 asserts that there are no further gains from manipulation. The probability that  $w$  plays  $u$  or  $v$  is  $2/\binom{n}{2}$ , as desired.

This handles all possible cases, and establishes that  $g \geq 2/\binom{n}{2}$  in all cases. Plugging into Theorem 21 as described above completes the proof. ◀

The analysis of RSEB is extremely similar to RDM, and requires only slightly more calculations to bound the probability of a good terminal event. This proof structure is fairly different than the original analysis in [14], and highlights the similarities to other recursive tournament rules. A complete proof of Theorem 24 appears in Appendix C.

► **Theorem 24** ([14]). *RSEB is 2-SNM-1/3. Or in our language,  $\alpha_2^{RSEB}(\mathcal{T}^{1/2}) = 1/3$ .*

We wrap up our warmup by highlighting key points of the analysis which will be relevant for our main results. First, observe that our analysis of both rules succeeded by simply upper-bounding  $c$  by 1. Improving this as a function of  $\varepsilon$  is the biggest technical difference between our warmup and main results. Second, observe that our analysis required Lemma 22 in case  $\ell_u < 2$ . In particular, we needed good terminal events *even when both  $u$  and  $v$  were not eliminated* (and this need continues in main results).

## 6 Optimal Bounds for Independent Probabilistic Tournaments

Before analyzing our two tournament rules, we extend the simple 3-team lower bound of [14] for  $\alpha_2(\mathcal{T}^{1/2})$  to  $\alpha_2(\mathcal{T}^\varepsilon)$ . The proof is in Appendix D.

► **Lemma 25.**  $\alpha_2(\mathcal{T}^\varepsilon) \geq \frac{1}{3}\varepsilon + \frac{2}{3}\varepsilon^2$ .

## 6.1 Gauntlets: Upper Bounding Gains from Bad Terminal Events

As previously noted, the main difference between our warmup and main results is bounding gain from bad terminal events. We provide a short, but key, structural insight about recursive tournament rules. Intuitively, a team  $u$  wins under rule  $r^E$  as long as they survive all elimination matches. Our key observation is that this defines a *gauntlet* of teams such that  $u$  wins if and only if they defeat every team in the gauntlet.

► **Definition 26 (Gauntlet).** *For deterministic tournament  $T$ , recursive tournament rule  $r$ , and team  $u$ , let  $T'$  be such that the outcome of the  $(v, w)$  match is the same for all  $v, w \neq u$ , but  $u$  is a Condorcet winner. The gauntlet for  $u$  in tournament  $T$  under recursive rule  $r$ ,  $G_u^r(T)$ , is the set of teams that  $u$  plays in elimination matches when  $r$  is executed on  $T'$ . If  $r$  is randomized, then  $G_u^r(T)$  is a random variable.*

*If  $T$  is a probabilistic tournament, we extend the notation  $G_u^r(T)$  to be the random variable which first samples  $T$ , then outputs  $G_u^r(T)$  (again over randomness in  $r$ ).*

For intuition, consider RSEB.  $u$  wins RSEB if and only if they win each of their  $\lceil \log_2(n) \rceil$  matches, so their gauntlet is a list of  $\lceil \log_2(n) \rceil$  teams, one per round. For RDM, however, the set of matches that  $u$  plays is itself a random variable (depending on how many times  $u$  is selected to play), but  $u$  still must win all these matches in order to win. For RKotH, the size of the gauntlet is a random variable as well. Importantly, however, observe that for all three rules (and any elimination rule), as soon as  $u$  loses a match, they are eliminated, so their gauntlet opponents can be set assuming that  $u$  won all previous matches.

Importantly, observe that  $u$ 's gauntlet does *not* depend on the outcome of any of its own matches (because  $T'$  immediately causes  $u$  to win all its matches anyway). This lets us make the following key observation, which requires  $E$  to be a matching elimination rule.

► **Lemma 27.** *Let  $r^E$  be an anonymous recursive tournament rule with a matching elimination rule,  $T$  be an independent probabilistic tournament on  $n$  teams,  $M \leftarrow E(n)$ , and  $u, v$  be two teams. Let also  $(u, v) \in M$  and  $w$  denote the winner of the  $(u, v)$  match. Then the random variable  $G_w^{r^E}(T|_M)$  is independent of  $w$ .*

**Proof.** Observe first that because  $M$  is a matching which contains  $(u, v)$ , that exactly one of  $\{u, v\}$  (namely,  $w$ ) is present in  $T|_M$ . Moreover, because  $T$  is independent probabilistic, the remaining teams in  $T|_M$  are independent of  $w$ . Because the definition of  $w$ 's gauntlet immediately considers a tournament  $T'$  which replaces the outcome of all matches involving  $w$  by having  $w$  be a Condorcet winner, the tournament  $T'$  is independent of  $w$  *except for whether  $w$  is labeled as “ $u$ ” or “ $v$ ”*. But because  $r^E(\cdot)$  is anonymous, its behavior on  $T'$  is independent of  $w$ 's label. This completes the proof. ◀

Note that Lemma 27 fails when  $M$  is not a matching. This is because: (a) perhaps both  $u$  and  $v$  are eliminated, and  $w$  is undefined, but also (b) even conditioned on  $w$  being defined, the set of teams in  $T|_M$  can depend on  $w$ . This is the main technical challenge in extending beyond matching elimination rules.<sup>5</sup>

<sup>5</sup> For example, in RKotH: conditioned on  $w := u$ , we know either that  $u$  was a Condorcet winner, or that  $v$  was selected to play everyone, so all teams which lose to  $v$  are eliminated. If instead  $w := v$ , we know either that  $v$  was a Condorcet winner, or that  $u$  was selected to play everyone. The teams which lose to  $u$  vs.  $v$  could be different, so the Lemma fails to hold.

► **Corollary 28.** Let  $r^E$  be an anonymous tournament rule with a matching elimination rule,  $T \in \mathcal{T}^\varepsilon$ ,  $S = \{u, v\}$  be any two teams, and  $T'$  be  $S$ -adjacent to  $T$ . Then:

$$\mathbb{E}_{M \leftarrow E(n)}[r_S^E(T'|M) - r_S^E(T|M)|B] \leq 2\varepsilon(\frac{1}{2} + \varepsilon).$$

**Proof.** Because we are in a bad terminal event, this means that  $(u, v) \in M$ . If we let  $w$  denote the winner of the  $(u, v)$  match in  $T$ , and  $w'$  denote the winner in  $T'$ , then we know that  $G_w^{r^E}(T|M)$  and  $G_{w'}^{r^E}(T'|M)$  are identically distributed by Lemma 27. This means that:

$$\begin{aligned} r_S^E(T|M) &= \mathbb{E}_{G_w^{r^E}(T|M)} \left[ \prod_{x \in G_w^{r^E}(T|M)} p_{wx}^T \right] \\ r_S^E(T'|M) &= \mathbb{E}_{G_{w'}^{r^E}(T'|M)} \left[ \prod_{x \in G_{w'}^{r^E}(T'|M)} p_{w'x}^{T'} \right] = \mathbb{E}_{G_w^{r^E}(T|M)} \left[ \prod_{x \in G_w^{r^E}(T|M)} p_{w'x}^T \right] \\ \Rightarrow r_S^E(T'|M) - r_S^E(T|M) &= \mathbb{E}_{G_w^{r^E}(T|M)} \left[ \prod_{x \in G_w^{r^E}(T|M)} p_{w'x}^T - \prod_{x \in G_w^{r^E}(T|M)} p_{wx}^T \right] \\ &\leq \mathbb{E}_{G_w^{r^E}(T|M)} \left[ \prod_{x \in G_w^{r^E}(T|M)} (\frac{1}{2} + \varepsilon) - \prod_{x \in G_w^{r^E}(T|M)} (\frac{1}{2} - \varepsilon) \right] \\ &= \mathbb{E}_{G_w^{r^E}(T|M)} \left[ (\frac{1}{2} + \varepsilon)^{|G_w^{r^E}(T|M)|} - (\frac{1}{2} - \varepsilon)^{|G_w^{r^E}(T|M)|} \right] \\ &\leq 2\varepsilon \end{aligned}$$

The first two lines follow by definition of the gauntlet, and Lemma 27. The third line is basic algebra. The fourth line follows as  $T \in \mathcal{T}^\varepsilon$ . The fifth line is again basic algebra, and the final line invokes Lemma 29, which is stated below (proof omitted from this version). The above calculations hold for any  $T|M, T'|M$ .

► **Lemma 29.** For all  $n \in \mathbb{N}_{\geq 0}$ , and  $\varepsilon \in [0, 1/2]$ :  $(\frac{1}{2} + \varepsilon)^n - (\frac{1}{2} - \varepsilon)^n \leq 2\varepsilon$ .

To see where the additional factor of  $(\frac{1}{2} + \varepsilon)$  comes from, recall that  $p_{uv}^T \in [1/2 - \varepsilon, 1/2 + \varepsilon]$ . Therefore,  $p_{uv}^{T'} - p_{uv}^T \leq \frac{1}{2} + \varepsilon$ . Consider now coupling the tournaments  $T$  and  $T'$  so the the result of every match except for the one between  $u$  and  $v$  is identical (this is possible because  $T$  and  $T'$  are independent probabilistic). Under this coupling,  $T$  and  $T'$  are identical with probability at least  $\frac{1}{2} - \varepsilon$  (and gains from manipulation are clearly only possible when  $T \neq T'$ , which occurs with probability at most  $\frac{1}{2} + \varepsilon$ , and independently of  $M$ ). Therefore,  $T \neq T'$  with probability at most  $(\frac{1}{2} + \varepsilon)$  and conditioned on this,  $r_S^E(T'|M) - r_S^E(T|M) \leq 2\varepsilon$ . ◀

## 6.2 RDM and RSEB

Corollary 28 is the main technical lemma to extend from  $\mathcal{T}^{1/2}$  to  $\mathcal{T}^\varepsilon$ . We begin with RDM.

► **Theorem 30.**  $\alpha_2^{RDM}(\mathcal{T}^\varepsilon) = \alpha_2(\mathcal{T}^\varepsilon) = \frac{1}{3}\varepsilon + \frac{2}{3}\varepsilon^2$ .

**Proof.** Let  $T \in \mathcal{S}^\varepsilon$ . Recall that we need to lower bound the probability of a good terminal event, upper bound the probability of a bad terminal event, and upper bound the gains from manipulation in case of a bad terminal event. We have already upper bounded the gains from a bad terminal event using Corollary 28 and can therefore take  $c = 2\varepsilon(\frac{1}{2} + \varepsilon)$ .

To bound the probability of a bad terminal event, observe that a bad terminal event occurs only when  $u$  plays  $v$  in this round, which happens with probability exactly  $1/\binom{n}{2}$ . So RDM satisfies  $b = 1/\binom{n}{2}$ .

For the good terminal events, we claim that  $\Pr[G] \geq 2/\binom{n}{2}$ . First, observe that once we show this, we can plug into Theorem 21 and conclude  $\alpha_2^{\text{RDM}}(\mathcal{T}^\varepsilon) \leq \frac{2\varepsilon(\frac{1}{2}+\varepsilon) \cdot 1/\binom{n}{2}}{1/\binom{n}{2} + 2/\binom{n}{2}} = \frac{1}{3}\varepsilon + \frac{2}{3}\varepsilon^2$ .

To see this bound, let  $\ell_u$  denote the number of teams which beat  $u$  with probability  $(1/2 + \varepsilon)$  but  $v$  with probability  $(1/2 - \varepsilon)$ , and  $\ell_v$  denote the number of teams which beat  $v$  with probability  $(1/2 + \varepsilon)$  but  $u$  with probability  $(1/2 - \varepsilon)$ . Without loss of generality let  $\ell_u \geq \ell_v$ .

If  $\ell_u = 0$ , then Lemma 22 already establishes that  $u$  and  $v$  can gain nothing by manipulating. If  $\ell_u + \ell_v \geq 2$ , then whenever  $u$  or  $v$  plays a team (not in  $\{u, v\}$ ) which beats them, we have a good terminal event (because  $u$  or  $v$  is already eliminated before having ever played the  $(u, v)$  match, so manipulating the match has no impact). Observe that any team which beats  $u$  (respectively,  $v$ ) with probability  $(1/2 + \varepsilon)$  beats  $v$  (respectively,  $u$ ) with probability at least  $(1/2 - \varepsilon)$ . Therefore, we have a good terminal event with probability at least  $2(1/2 + \varepsilon)/\binom{n}{2} + 2(1/2 - \varepsilon)/\binom{n}{2} = 2/\binom{n}{2}$ , as desired.<sup>6</sup>

If  $\ell_u = 1, \ell_v = 0$ , then let  $w$  be the unique team which beats  $u$  with probability  $(1/2 + \varepsilon)$  but  $v$  with probability  $(1/2 - \varepsilon)$ . We claim that if  $w$  plays *either*  $u$  or  $v$  that we have a good terminal event. Indeed, if  $w$  wins, then either  $u$  or  $v$  are eliminated having never played the  $(u, v)$  match. If instead  $w$  loses this match, then  $w$  is eliminated, but now  $p_{ux}^T = p_{vx}^T$  for all remaining teams  $x$ , and Lemma 22 asserts that there are no further gains from manipulation. The probability that  $w$  plays  $u$  or  $v$  is  $2/\binom{n}{2}$ , as desired.

This handles all possible cases, and establishes that  $g \geq 2/\binom{n}{2}$  in all cases. Plugging into Theorem 21 as described above completes the proof.  $\blacktriangleleft$

The analysis for RSEB is again similar to RDM, but some calculations are more involved.

► **Theorem 31.**  $\alpha_2^{\text{RSEB}}(\mathcal{T}^\varepsilon) = \alpha_2(\mathcal{T}^\varepsilon) = \frac{1}{3}\varepsilon + \frac{2}{3}\varepsilon^2$ .

**Proof.** Let  $T \in \mathcal{S}^\varepsilon$ . We have already upper bounded the gains from a bad terminal event using Corollary 28 and can therefore take  $c = 2\varepsilon(\frac{1}{2} + \varepsilon)$ .

To bound the probability of a bad terminal event, observe that a bad terminal event occurs only when  $u$  plays  $v$  this round, which happens with probability exactly  $1/(n' - 1)$ .<sup>7</sup> So RSEB satisfies  $b = 1/(n' - 1)$ .

For the good terminal events, we claim that  $\Pr[G] \geq 2/(n' - 1)$ . First, observe that once we show this, we can plug into Theorem 21 and conclude  $\alpha_2^{\text{RSEB}}(\mathcal{T}^\varepsilon) \leq \frac{2\varepsilon(\frac{1}{2}+\varepsilon) \cdot 1/(n'-1)}{1/(n'-1) + 2/(n'-1)} = \frac{1}{3}\varepsilon + \frac{2}{3}\varepsilon^2$ .

To see this bound (which requires more calculations than previous proofs), let  $\ell_u$  denote the number of teams which beat  $u$  with probability  $(1/2 + \varepsilon)$  but  $v$  with probability  $(1/2 - \varepsilon)$ , and  $\ell_v$  denote the number of teams which beat  $v$  with probability  $(1/2 + \varepsilon)$  but  $u$  with probability  $(1/2 - \varepsilon)$ . Without loss of generality let  $\ell_u \geq \ell_v$ .

**Case One:**  $\ell_u + \ell_v \leq 1$ . If  $\ell_u = 0$ , then Lemma 22 already establishes that  $u$  and  $v$  can gain nothing by manipulating. If  $\ell_u = 1, \ell_v = 0$ , then let  $w$  be the unique team which beats  $u$  with probability  $(1/2 + \varepsilon)$  but  $v$  with probability  $(1/2 - \varepsilon)$ . We claim that if  $w$

<sup>6</sup> To be extra clear, the two matches  $(w, u)$ ,  $(w, v)$  together contribute probability  $1/\binom{n}{2}$  to the probability of a good terminal event, as long as  $w$  beats either  $u$  or  $v$  with probability  $(1/2 + \varepsilon)$ . Because there are two such teams, we get this twice.

<sup>7</sup> Recall in RSEB that  $n'$  denotes the total number of teams plus dummy teams, and is  $2^{\lceil \log_2(n) \rceil}$

plays *either*  $u$  or  $v$  that we are in a good terminal event. Indeed, if  $w$  wins this match, then either  $u$  or  $v$  are eliminated having never played the  $(u, v)$  match. If instead  $w$  loses this match, then  $w$  is eliminated, but now  $p_{ux}^T = p_{vx}^T$  for all remaining teams  $x$ , and Lemma 22 asserts that there are no further gains from manipulation. The probability that  $w$  plays  $u$  or  $v$  is  $2/(n' - 1)$ , as desired.

**Case Two:**  $\ell_u + \ell_v = 2$ . Next, consider the case where  $\ell_u + \ell_v = 2$ , and call the two relevant teams  $x, w$ . Observe first that if  $u$  plays  $x$  and  $v$  plays  $w$ , or if  $u$  plays  $w$  and  $v$  plays  $x$ , then we are surely in a good terminal event. This is because either (a)  $u$  or  $v$  is eliminated without having played the  $(u, v)$  match, or (b) *both*  $x$  and  $w$  are eliminated (allowing us to invoke Lemma 22). This occurs with probability  $\frac{2}{(n'-1)(n'-3)}$ . There are also the cases where exactly one of  $\{w, x\}$  plays a team in  $\{u, v\}$ . For any given pair  $(a, b)$ , with  $a \in \{w, x\}$  and  $b \in \{u, v\}$ , this case occurs with probability  $\frac{(n'-4)}{(n'-1)(n'-3)}$ .<sup>8</sup> Two of these cases contribute at least a  $(1/2 + \varepsilon)$  probability of eliminating the team in  $\{u, v\}$ , and the other two contribute at least a  $(1/2 - \varepsilon)$  probability. So in total, all four cases contribute at least  $\frac{2(n'-4)}{(n'-1)(n'-3)}$ , and together we get that a good terminal event occurs with probability at least:

$$\frac{2}{(n'-1)(n'-3)} + \frac{2(n'-4)}{(n'-1)(n'-3)} = \frac{2(n'-3)}{(n'-1)(n'-3)} = \frac{2}{n'-1}.$$

**Case Three:**  $\ell_u + \ell_v \geq 3$ . Next, consider the case where  $\ell_u + \ell_v \geq 3$  (observe that this implies  $n \geq 5$ ). We will show that either  $u$  or  $v$  are eliminated with probability at least  $2/(n' - 1)$ . Indeed, let  $L_u$  denote the set of teams which beat  $u$  with probability  $(1/2 + \varepsilon)$  (but not  $v$ ), and  $L_v$  denote the set of teams which beat  $v$  with probability  $(1/2 + \varepsilon)$  (but not  $u$ ). Then consider the case where  $u$  plays a team in  $L_u$ , or  $v$  plays a team in  $L_v$ . Conditioned on this, *both*  $u$  and  $v$  survive with probability at most  $(1/2 + \varepsilon)(1/2 - \varepsilon) \leq 1/4$ , so one of  $\{u, v\}$  is eliminated with probability at least  $3/4$ . So one sufficient condition would be to establish that  $u$  plays a team in  $L_u$  or  $v$  plays a team in  $L_v$  with probability at least  $\frac{8/3}{n'-1}$  (because conditioned on this, one of  $\{u, v\}$  is eliminated with probability  $3/4$ , for a total probability of at least  $\frac{2}{n'-1}$  that one of  $\{u, v\}$  is eliminated). In the subcase that  $\ell_u \geq 3$ , then the probability is in fact at least  $3/(n' - 1)$ , as desired. Clearly, this probability is monotone in  $\ell_u, \ell_v$ , so this leaves the only remaining subcase as  $\ell_u = 2, \ell_v = 1$ .

**Subcase Three-A:**  $\ell_u = 2, \ell_v = 1, n \geq 9$ . For the subcase of  $\ell_u = 2, \ell_v = 1$ , the probability that  $u$  plays a team in  $L_u$  or  $v$  plays a team in  $L_v$  is  $\frac{2}{n'-1} + \frac{(n'-5)}{(n'-1)(n'-3)}$ .<sup>9</sup> As  $n' \geq 16$  (because  $n \geq 9$  and  $n'$  is a power of 2), we have that  $(n' - 5)/(n' - 3) \geq 11/13$ , meaning that  $\frac{2}{n'-1} + \frac{(n'-5)}{(n'-1)(n'-3)} \geq \frac{37/13}{n'-1} > \frac{8/3}{n'-1}$ , which resolves this case by the work above.

**Subcase Three-B:**  $\ell_u = 2, \ell_v = 1, \varepsilon \geq \frac{1}{2\sqrt{13}}, n \in [5, 8]$ . When  $n \in [5, 8]$ , we have  $n' = 8$ .

This means that  $(n' - 5)/(n' - 3) = 3/5$ , and therefore  $\frac{2}{n'-1} + \frac{(n'-5)}{(n'-1)(n'-3)} = \frac{13/5}{n'-1}$ .

Unfortunately, this is  $< \frac{8/3}{n'-1}$ , meaning that this case doesn't immediately resolve by the method above. In this range, we do an explicit case analysis. First, observe that  $u$  and  $v$  are *least* likely to be eliminated when there are more dummy teams (because  $u$  and  $v$

<sup>8</sup> Because the probability that  $a$  plays  $b$  is  $1/(n' - 1)$ , and the probability that the other two teams do not play, conditioned on this, is  $(n' - 4)/(n' - 3)$ .

<sup>9</sup> To see this, observe that the probability that  $u$  plays a team in  $L_u$  is  $2/(n' - 1)$ . The probability that  $u$  plays a team not in  $L_u \cup L_v \cup \{v\}$  is  $(n' - 5)/(n' - 1)$ . Conditioned on this, the probability that  $v$  plays the team in  $L_v$  is  $1/(n' - 3)$  (and this is the only way that  $v$  can possibly play the team in  $L_v$  without  $u$  playing  $L_u$ ).

beat dummy teams with probability one, but real teams with probability at most  $1/2 + \varepsilon$ ). So the worst case to consider is when  $n = 5$ : two real teams beat only  $u$ , one beats only  $v$ , and there are three dummy teams. We just have to compute several cases:

- Perhaps  $u$  plays one of the  $\ell_u$  teams, and  $v$  plays one of the  $\ell_v$  teams. This occurs with probability  $\frac{2}{7} \cdot \frac{1}{5}$ , and eliminates  $u$  or  $v$  with probability  $1 - (1/2 - \varepsilon)^2 = 3/4 + \varepsilon - \varepsilon^2$ .
- Perhaps  $u$  plays one of the  $\ell_u$  teams, and  $v$  plays the other. This occurs with probability  $\frac{2}{7} \cdot \frac{1}{5}$ , and eliminates  $u$  or  $v$  with probability  $1 - (1/2 + \varepsilon)(1/2 - \varepsilon) = 3/4 + \varepsilon^2$ .
- Perhaps  $u$  plays one of the  $\ell_u$  teams, and  $v$  plays a dummy team. This occurs with probability  $\frac{2}{7} \cdot \frac{3}{5}$ , and eliminates  $u$  with probability  $1/2 + \varepsilon$ .
- Perhaps  $u$  plays one of the  $\ell_v$  teams, and  $v$  plays one of the  $\ell_u$  teams. This occurs with probability  $\frac{1}{7} \cdot \frac{2}{5}$ , and eliminates  $u$  or  $v$  with probability  $1 - (1/2 + \varepsilon)^2 = 3/4 - \varepsilon - \varepsilon^2$ .
- Perhaps  $u$  plays one of the  $\ell_v$  teams, and  $v$  plays a dummy team. This occurs with probability  $\frac{1}{7} \cdot \frac{3}{5}$ , and eliminates  $u$  with probability  $1/2 - \varepsilon$ .
- Perhaps  $u$  plays a dummy team, and  $v$  plays one of the  $\ell_v$  teams. This occurs with probability  $\frac{3}{7} \cdot \frac{1}{5}$ , and eliminates  $v$  with probability  $1/2 + \varepsilon$ .
- Perhaps  $u$  plays a dummy team, and  $v$  plays one of the  $\ell_u$  teams. This occurs with probability  $\frac{3}{7} \cdot \frac{2}{5}$ , and eliminates  $v$  with probability  $1/2 - \varepsilon$ .
- Perhaps both  $u$  and  $v$  play dummy teams. This happens with probability  $\frac{3}{7} \cdot \frac{2}{5}$ , but eliminates neither team.

So either  $u$  or  $v$  is eliminated (without playing each other) with probability:

$$\begin{aligned} & \frac{2}{35} \cdot (3/4 + \varepsilon - \varepsilon^2) + \frac{2}{35} \cdot (3/4 + \varepsilon^2) + \frac{6}{35} \cdot (1/2 + \varepsilon) + \frac{2}{35} \cdot (3/4 - \varepsilon - \varepsilon^2) \\ & + \frac{3}{35} \cdot (1/2 - \varepsilon) + \frac{3}{35} \cdot (1/2 + \varepsilon) + \frac{6}{35} \cdot (1/2 - \varepsilon) \\ & = \frac{27}{70} - \frac{2}{35}\varepsilon^2 \geq \frac{26}{70} > 2/7. \end{aligned}$$

Note that when  $n \in [5, 8]$ , the probability of a bad event is exactly  $1/7$ , and the above work establishes that in case Three-B, the probability of a good terminal event is at least twice that of a bad terminal event.

The arguments above handle all possible cases, and establishes that  $g \geq 2/(n' - 1)$  in all cases. Plugging into Theorem 21 as described above completes the proof. ◀

## 7 Conclusion and Open Problems

We take a beyond worst-case view on manipulability of tournament rules, and nail down optimal guarantees as a function of the uncertainty of match outcomes. Specifically, our main result shows that  $\alpha_2(\mathcal{T}^\varepsilon) = \varepsilon/3 + 2\varepsilon^2/3$ , and this is achieved *for all*  $\varepsilon$  by Randomized Death Match and Randomized Single Elimination Bracket. Our main technical contribution is a framework to analyze recursive tournament rules.

There are two natural directions for future work. The first concerns further work in the probabilistic setting: does  $\alpha_2^{\text{RKotH}}(\mathcal{T}^\varepsilon) = \varepsilon/3 + 2\varepsilon^2/3$ ? The main technical barrier is replacing Lemma 27, which only holds for matching elimination rules.<sup>10</sup> In addition, it is interesting to analyze probabilistic tournaments which are not independent. Here there are technical barriers to overcome (many of our steps do require independence), but also conceptual

<sup>10</sup>There are other barriers to using our precise definitions, but these barriers seem semantic rather than substantial.

ones: if tournament match outcomes are correlated, should we consider manipulations which are correlated with external outcomes as well? If so, is there a natural way to consider manipulations which are “not more correlated than the original tournament itself”?

A second direction concerns applications of our recursive framework towards other problems in approximately strategy-proof tournament design. For example, it is still an open question following [15] what is  $\alpha_k(\mathcal{T}^{1/2})$  for *any*  $k > 2$ . Our recursive framework may prove useful for analyzing this, or at least determining achievable guarantees for recursive rules.

## A Omitted Proofs from Section 2

**Proof of Proposition 9.** The second statement of the lemma clearly follows from the first. It is trivial to see that  $\alpha_k^r(\mathcal{T}^\varepsilon) \geq \alpha_k^r(\mathcal{S}^\varepsilon)$ , as  $\mathcal{S}^\varepsilon \subseteq \mathcal{T}^\varepsilon$ . To get intuition for why  $\alpha_k^r(\mathcal{T}) \leq \alpha_k^r(\mathcal{S}^\varepsilon)$ , observe that every probabilistic tournament in  $\mathcal{T}^\varepsilon$  can be written as a convex combination of probabilistic tournaments in  $\mathcal{S}^\varepsilon$ . Indeed, this intuition drives the proof.

To see this formally, let  $T$  be an arbitrary (independent probabilistic) tournament in  $\mathcal{T}^\varepsilon$ , and let  $T'$  be any  $S$ -adjacent (independent probabilistic) tournament for some  $|S| \leq k$ . Then  $p_{ij}^T \in [1/2 - \varepsilon, 1/2 + \varepsilon]$  for all  $i, j$ , by definition. Consider the following procedure to jointly sample tournaments from  $T, T'$ . The procedure first constructs another pair of probabilistic tournaments  $U, U'$ , and then samples from these.

1. For all  $(i, j)$ , set  $q_{ij} := \frac{p_{ij}^T - (1/2 - \varepsilon)}{2\varepsilon}$ . Observe that  $q_{ij} \cdot (1/2 + \varepsilon) + (1 - q_{ij}) \cdot (1/2 - \varepsilon) = p_{ij}^T$ , and that  $q_{ij} \in [0, 1]$  as  $p_{ij}^T \in [1/2 - \varepsilon, 1/2 + \varepsilon]$ .
2. For each  $(i, j)$ , independently, set  $p_{ij}$  equal to  $(1/2 + \varepsilon)$  with probability  $q_{ij}$  and equal to  $(1/2 - \varepsilon)$  with probability  $(1 - q_{ij})$ .
3. For all  $(i, j)$ , set  $p_{ij}^U := p_{ij}$ .
4. For all  $(i, j)$  such that  $\{i, j\} \not\subseteq S$ , set  $p^{U'} := p^U$ . For other  $(i, j)$ , set  $p_{ij}^{U'} := p_{ij}^{T'}$ .
5. Draw a pair of tournaments according to  $U, U'$  (independently, say).

Observe that this procedure correctly draws two tournament according to  $T, T'$ . Indeed, it is easy to see for each output tournament that the outcome of each match is independent, simply because they are independent in  $U$  (resp.  $U'$ ), and because the random variables  $p_{ij}^U$  (resp.  $p_{ij}^{U'}$ ) are independent. Moreover, we claim that the probability that  $i$  beats  $j$  is exactly  $p_{ij}^T$ . Indeed, the probability that  $i$  beats  $j$  in  $U$  is:  $\mathbb{E}[p_{ij}^U] = q_{ij} \cdot (1/2 + \varepsilon) + (1 - q_{ij}) \cdot (1/2 - \varepsilon) = p_{ij}^T$ . In  $U'$ , when  $\{i, j\} \subseteq S$ , the probability that  $i$  beats  $j$  in  $U'$  is clearly  $p_{ij}^{T'}$  by definition. When  $\{i, j\} \not\subseteq S$ , the probability that  $i$  beats  $j$  is also  $p_{ij}^T$ , which is equal to  $p_{ij}^{T'}$  as  $T, T'$  are  $S$ -adjacent. Additionally, observe that: (a)  $U \in \mathcal{S}^\varepsilon$  and (b)  $U$  and  $U'$  are  $S$ -adjacent. Now, consider any tournament rule  $r(\cdot)$ :

$$\begin{aligned} \text{For all } i: r_i(T) &= \mathbb{E}[r_i(U)], \text{ and } r_i(T') = \mathbb{E}[r_i(U')] \\ \Rightarrow r_S(T') - r_S(T) &= \mathbb{E}[r_S(U') - r_S(U)] \leq \alpha_k^r(\mathcal{S}^\varepsilon) \end{aligned}$$

Indeed, the first line is simply linearity of expectation, once the previous work confirms that going through  $U, U'$  is a valid way to draw tournaments from  $T, T'$ . The third line then also follows by linearity of expectation. The final line follows as  $U \in \mathcal{S}^\varepsilon$ , and  $U, U'$  are  $S$ -adjacent. This completes the proof, as we have now shown that  $\alpha_k^r(\mathcal{T}^\varepsilon) \leq \alpha_k^r(\mathcal{S}^\varepsilon)$ .  $\blacktriangleleft$

## B

 Omitted Proofs from Section 3

**Proof of Lemma 16.** This follows immediately from linearity of expectation. For all  $i$ , the probability that  $i$  wins in tournament  $T$  under rule  $r^E(\cdot)$  is the expected probability that  $i$  wins in  $T|_M$ . Summing over  $i \in S$ , and repeating this for  $T'$  yields the lemma. ◀

## C

 Omitted Proofs from Section 5

**Proof of Lemma 22.** Let  $\sigma(\cdot)$  denote the permutation which swaps  $u$  and  $v$ . Consider any two deterministic tournaments  $U, \sigma(U)$ . Then because  $r(\cdot)$  is anonymous, we have:

$$\begin{aligned} r_u(U) + r_v(U) &= r_{\sigma(u)}(\sigma(U)) + r_{\sigma(v)}(\sigma(U)) = r_v(\sigma(U)) + r_u(\sigma(U)) \\ &\Rightarrow r_S(U) = r_S(\sigma(U)) \end{aligned}$$

Indeed, the first line simply applies anonymity, and the second line simply applies  $\sigma$ . Now let's return to  $T, T'$  (which are independent probabilistic tournaments, rather than deterministic). Consider the following process to draw  $T$  and  $T'$  jointly:

1. To emphasize that  $p_{uw}^T = p_{vw}^T$ , for all  $w \notin \{u, v\}$ , denote by  $p_w^T := p_{uw}^T$ .
2. Without loss of generality, let  $p_{uv}^T \leq p_{uv}^{T'}$ .
3. Draw the outcome of all matches involving two teams both  $\notin \{u, v\}$ . Set the outcome of these matches the same for  $T$  and  $T'$ .
4. For all  $w \notin \{u, v\}$ , draw  $q_{w1}$  and  $q_{w2}$  iid and uniformly from  $[0, 1]$ . Draw  $q_{uv}$  independently and uniformly from  $[0, 1]$ .
5. For all  $w \notin \{u, v\}$ , have  $u$  beat  $w$  if and only if  $q_{w1} < p_w^T$ . Have  $v$  beat  $w$  if and only if  $q_{w2} < p_w^T$ . Have  $u$  beat  $v$  if and only if  $q_{uv} < p_{uv}^T$ .
6. If  $q_{uv} \notin [p_{uv}^T, p_{uv}^{T'}]$ , set  $T' := T$ .
7. If  $q_{uv} \in [p_{uv}^T, p_{uv}^{T'}]$ , then set  $T' := \sigma(T)$ .

This process clearly satisfies that with probability one, either  $T' = T$  or  $T' = \sigma(T)$ . By the work above, this means that  $r_S(T) = r_S(T')$  as desired, as long as we confirm that this process validly samples both  $T$  and  $T'$ . It is easy to see that the process is valid for  $T$ : the match outcomes are clearly independent, and any team  $w$  beats  $x$  if and only if a uniformly random draw from  $[0, 1]$  is  $< p_{wx}^T$  (which happens with probability  $p_{wx}^T$ , as desired).

To see that the process is valid for  $T'$ , observe first that  $u$  beats  $v$  with probability exactly  $p_{uv}^{T'}$ , because  $u$  beats  $v$  whenever  $q_{uv} < p_{uv}^{T'}$ . Moreover, after conditioning on  $q_{uv}$ , the outcome of each  $(u, w)$  match is either set according to  $q_{w1}$  (an independent, uniform draw from  $[0, 1]$ ), or  $q_{w2}$  (also an independent, uniform draw from  $[0, 1]$ ). In either case, these match results are all set independently and with the correct probability (because  $T, T'$  are  $S$ -adjacent, and because  $q_{w1}, q_{w2}$  are iid because  $p_{uw}^T = p_{vw}^T$  for all  $w$ ). This completes the proof. ◀

**Proof of Theorem 24.** We again simply let  $c = 1$  and take the trivial bound on the gain in bad terminal events.

To bound the probability of a bad terminal event, observe that a bad terminal event occurs only when  $u$  plays  $v$  this round, which happens with probability exactly  $1/(n' - 1)$ .<sup>11</sup> So RSEB satisfies  $b = 1/(n' - 1)$ .

For the good terminal events, we claim that  $\Pr[G] \geq 2/(n' - 1)$ . First, observe that once we show this, we can plug into Theorem 21 and conclude  $\alpha_2^{\text{RSEB}}(\mathcal{T}^{1/2}) \leq \frac{1 \cdot 1/(n' - 1)}{1/(n' - 1) + 2/(n' - 1)} = 1/3$ .

<sup>11</sup> Recall that in RSEB,  $n' := 2^{\lceil \log_2(n) \rceil}$ .

To establish this bound, let  $\ell_u$  denote the number of teams which beat  $u$  but not  $v$ ,  $\ell_v$  denote the number of teams which beat  $v$  but not  $u$ . Without loss of generality let  $\ell_u \geq \ell_v$ .

If  $\ell_u + \ell_v = 0$ , then Lemma 22 already establishes that  $u$  and  $v$  gain nothing by manipulating. If  $\ell_u \geq 2$ , then whenever  $u$  plays a team which beats them, we have a good terminal event (because  $u$  is already eliminated before having ever played the  $(u, v)$  match, so manipulating the match has no impact). This happens with probability at least  $2/(n' - 1)$ .

If  $\ell_u = 1, \ell_v = 0$ , then let  $w$  denote the unique team which beats  $u$  but not  $v$ . We now claim that if  $w$  plays *either*  $u$  or  $v$  that we are in a good terminal event. Indeed, if  $w$  plays  $u$ , then  $u$  is eliminated having never played the  $(u, v)$  match. If instead  $w$  plays  $v$ , then  $w$  is eliminated, but now there are no remaining teams which beat  $u$  but not  $v$  (or vice versa) and Lemma 22 asserts that there are no further gains from manipulation. The probability that  $w$  plays  $u$  or  $v$  is  $2/(n' - 1)$ , as desired.

Finally, if  $\ell_u = \ell_v = 1$ , let  $w$  denote the unique team which beats  $u$  but not  $v$ , and  $x$  denote the unique team which beats  $v$  but not  $u$  (this case requires slightly more calculations than RDM). If  $u$  plays  $w$ , or  $v$  plays  $x$ , then at least one of  $u, v$  is eliminated before the  $(u, v)$  match is played, and therefore no gains are possible. This happens with probability  $2/(n' - 1) - \frac{1}{(n' - 1)(n' - 3)}$ . In addition, if  $u$  plays  $x$  and  $v$  plays  $w$ , then both  $x$  and  $w$  will be eliminated, and Lemma 22 asserts that there are no further gains from manipulation. This occurs with probability  $\frac{1}{(n' - 1)(n' - 3)}$ . Therefore, a good terminal event happens with probability at least  $2/(n' - 1)$ , as desired. This handles all possible cases, and establishes that  $g \geq 2/(n' - 1)$  in all cases. Plugging into Theorem 21 as described completes the proof. ◀

## D Omitted Proofs from Section 6

**Proof of Lemma 25.** Consider a 3-player tournament  $T$  with teams  $u, v$ , and  $w$ ,  $p_{uv}^T = p_{vw}^T = p_{wu}^T = \frac{1}{2} + \varepsilon$ .<sup>12</sup> Noting that  $T$  is randomized, there are two possible types of deterministic outcomes: outcomes where there is a Condorcet winner, and outcomes which form a cycle (either  $v$  beats  $u$ ,  $u$  beats  $w$ , and  $w$  beats  $v$ , or vice versa).

In  $T$ , each of the three players has probability  $(\frac{1}{2} + \varepsilon)(\frac{1}{2} - \varepsilon)$  of being a Condorcet winner.

Call the cycle where  $v$  beats  $u$  “cycle 1”; this occurs with probability  $(\frac{1}{2} + \varepsilon)^3$ . Call the opposing cycle (where  $u$  beats  $v$ ) “cycle 2”; this occurs with probability  $(\frac{1}{2} - \varepsilon)^3$ .

Let  $r$  be any Condorcet-consistent tournament rule. Denote by  $\gamma_x$  the probability that the rule selects  $x$  as the winner when cycle 1 occurs (for any  $x \in \{u, v, w\}$ ). Denote by  $\beta_x$  the probability that the rule selects  $x$  as the winner when cycle 2 occurs. Recall that  $r$  must select  $x$  as the winner with probability 1 when  $x$  is the Condorcet winner.

Suppose that  $u$  and  $v$  collude so that  $u$  throws their match to  $v$ . Specifically, let  $T^{uv}$  denote the  $\{u, v\}$ -adjacent tournament to  $T$  where  $p_{uv}^{T^{uv}} = 0$  (instead of  $1/2 + \varepsilon$ ). In  $T^{uv}$ ,  $v$  is a Condorcet winner with probability  $\frac{1}{2} + \varepsilon$  (they need only beat  $w$ ), cycle 2 occurs with probability  $(\frac{1}{2} - \varepsilon)^2$  ( $v$  must lose to  $w$ , who must lose to  $u$ ), and  $w$  is a Condorcet winner with probability  $(\frac{1}{2} + \varepsilon)(\frac{1}{2} - \varepsilon)$ . No other outcomes are possible. We then have:

$$\begin{aligned} r_u(T^{uv}) + r_v(T^{uv}) - r_u(T) - r_v(T) &= (\tfrac{1}{2} + \varepsilon) + (\beta_u + \beta_v) \cdot (\tfrac{1}{2} - \varepsilon)^2 \\ &\quad - 2(\tfrac{1}{2} + \varepsilon)(\tfrac{1}{2} - \varepsilon) - (\beta_u + \beta_v) \cdot (\tfrac{1}{2} - \varepsilon)^3 - (\gamma_u + \gamma_v)(\tfrac{1}{2} + \varepsilon)^3 \\ &= 2\varepsilon \cdot (\tfrac{1}{2} + \varepsilon) + (\beta_u + \beta_v) \cdot ((\tfrac{1}{2} - \varepsilon)^2 - (\tfrac{1}{2} - \varepsilon)^3) - (\gamma_u + \gamma_v)(\tfrac{1}{2} + \varepsilon)^3 \end{aligned}$$

<sup>12</sup>That is, if  $\varepsilon = 1/2$ , this is the same 3-cycle example from [14].

**14:20    Approximately Strategyproof Tournament Rules in the Probabilistic Setting**

Identical calculations hold for  $T^{vw}, T^{wu}$ . We can sum these three together to achieve:

$$\begin{aligned} & (r_u(T^{uv}) + r_v(T^{uv}) - r_u(T) - r_v(T)) + (r_v(T^{vw}) + r_w(T^{vw}) - r_v(T) - r_w(T)) \\ & \quad + (r_w(T^{wu}) + r_u(T^{wu}) - r_w(T) - r_u(T)) \\ &= 6\varepsilon \cdot (\tfrac{1}{2} + \varepsilon) + 2(\beta_u + \beta_v + \beta_w) \cdot ((\tfrac{1}{2} - \varepsilon)^2 - (\tfrac{1}{2} - \varepsilon)^3) - 2(\gamma_u + \gamma_v + \gamma_w)(\tfrac{1}{2} + \varepsilon)^3 \\ &= 6\varepsilon \cdot (\tfrac{1}{2} + \varepsilon) + 2 \cdot (\tfrac{1}{2} - \varepsilon)^2 \cdot (\tfrac{1}{2} + \varepsilon) - 2(\tfrac{1}{2} + \varepsilon)^3 \\ &= 6\varepsilon \cdot (\tfrac{1}{2} + \varepsilon) + 2 \cdot (\tfrac{1}{2} + \varepsilon) \cdot ((\tfrac{1}{2} - \varepsilon)^2 - (\tfrac{1}{2} + \varepsilon)^2) \\ &= 6\varepsilon \cdot (\tfrac{1}{2} + \varepsilon) + 2 \cdot (\tfrac{1}{2} + \varepsilon) \cdot (-2\varepsilon) = 2\varepsilon \cdot (\tfrac{1}{2} + \varepsilon) \end{aligned}$$

This means that one of the three coalitions can gain at least  $\frac{2}{3}\varepsilon(\frac{1}{2} + \varepsilon) = \frac{1}{3}\varepsilon + \frac{2}{3}\varepsilon^2$ . ◀

## Abstract

We study a graph coloring problem that is otherwise easy in the RAM model but becomes quite non-trivial in the one-pass streaming model. In contrast to previous graph coloring problems in streaming that try to find an assignment of colors to vertices, our main work is on estimating the number of conflicting or monochromatic edges given a coloring function that is streaming along with the graph; we call the problem CONFLICT-EST. The coloring function on a vertex can be read or accessed only when the vertex is revealed in the stream. If we need the color on a vertex that has streamed past, then that color, along with its vertex, has to be stored explicitly. We provide algorithms for a graph that is streaming in different variants of the vertex arrival in one-pass streaming model, viz. the VERTEX ARRIVAL (VA), Vertex Arrival With Degree Oracle (VADEG), VERTEX ARRIVAL IN RANDOM ORDER (VARAND) models, with special focus on the random order model. We also provide matching lower bounds for most of the cases. The mainstay of our work is in showing that the properties of a random order stream can be exploited to design efficient streaming algorithms for estimating the number of monochromatic edges. We have also obtained a lower bound, though not matching the upper bound, for the random order model. Among all the three models vis-a-vis this problem, we can show a clear separation of power in favor of the VARAND model.

## 1 Introduction

The *chromatic number*  $\chi(G)$  of an  $n$ -vertex graph  $G = (V, E)$  is the minimum number of colors needed to color the vertices of  $V$  so that no two adjacent vertices get the same color. The *chromatic number* problem is NP-hard and even hard to approximate within a factor of  $n^{1-\varepsilon}$  for any constant  $\varepsilon > 0$  [14, 28, 20]. For any connected undirected graph  $G$  with maximum degree  $\Delta$ ,  $\chi(G)$  is at most  $\Delta + 1$  [27]. This existential coloring scheme can be made constructive across different models of computation. A seminal result of recent vintage is that the  $\Delta + 1$  coloring can be done in the streaming model [3]. Of late, there has been interest

in graph coloring problems in the sub-linear regime across a variety of models [1, 3, 4, 8, 6]. Keeping with the trend of coloring problems, these works look at assigning colors to vertices. Since the size of the output will be as large as the number of vertices, researchers study the semi-streaming model [22] for streaming graphs. In the semi-streaming model,  $\tilde{O}(n)^1$  space is allowed.

In a marked departure from the above works that look at the classical coloring problem, the starting point of our work is (inarguably?) the simplest question one can ask in graph coloring – given a coloring function  $f : V \rightarrow \{1, \dots, C\}$  on the vertex set  $V$  of a graph  $G = (V, E)$ , is  $f$  a valid coloring, i.e., for any edge  $e \in E$ , do both the endpoints of  $e$  have different colors? This is the problem one encounters while proving that the problem of chromatic number belongs to the class NP [15]. CONFLICT-EST, the problem of estimating the number of monochromatic (or, conflicting) edges for a graph  $G$  given a coloring function  $f$ , remains a simple problem in the RAM model; it even remains simple in the one-pass streaming model if the coloring function  $f$  is marked on a *public board*, readable at all times. We show that the problem throws up interesting consequences if the coloring function  $f$  on a vertex is revealed only when the vertex is revealed in the stream. For a streaming graph, if the vertices are assigned colors arbitrarily or randomly on-the-fly while it is exposed, our results can also be used to estimate the number of conflicting edges. These problems also find their use in estimating the number of conflicts in a job schedule and verifying a given job schedule in a streaming setting. This can also be extended to problems in various domains like frequency assignment in wireless mobile networks and register allocation [13]. As the problem, by its nature, admits an estimate or a yes-no answer, we can try for space efficient algorithms in the conventional graph streaming models like VERTEX ARRIVAL [11]. We also note in passing that many of the trend setting problems in streaming, like frequency moments, distinct elements, majority, etc. have been simple problems in the ubiquitous RAM model as the coloring problem we solve here.

## 2 Preliminaries

### 2.1 Notations and the streaming models

**Notations.** We denote the set  $\{1, \dots, n\}$  by  $[n]$ .  $G(V(G), E(G))$  denotes a graph where  $V(G)$  and  $E(G)$  denote the set of vertices and edges of  $G$ , respectively;  $|V| = n$  and  $|E| = m$ . We will write only  $V$  and  $E$  for vertices and edges when the graph is clear from the context. We denote  $E_M \subseteq E$  as the set of monochromatic edges. The set of neighbors of a vertex  $u \in V(G)$  is denoted by  $N_G(u)$  and the degree of a vertex  $u \in V(G)$  is denoted by  $d_G(u)$ . Let  $N_G(u) = N_G^-(u) \uplus N_G^+(u)$  where  $N_G^-(u)$  and  $N_G^+(u)$  denote the set of neighbors of  $u$  that have been exposed already and are yet to be exposed, respectively in the stream. Also,  $d_G(u) = d_G^-(u) + d_G^+(u)$  where  $d_G^-(u) = |N_G^-(u)|$  and  $d_G^+(u) = |N_G^+(u)|$ . For a monochromatic edge  $(u, v) \in E_M$ , we refer to  $u$  and  $v$  as monochromatic neighbors of each other. We define  $d_M(u)$  to be the number of monochromatic neighbors of  $u$  and hence, the monochromatic degree of  $u$ .

Let  $\mathbb{E}[X]$  denote the expectation of the random variable  $X$ . For an event  $\mathcal{E}$ ,  $\bar{\mathcal{E}}$  denotes the complement of  $\mathcal{E}$ .  $\mathbb{P}(\mathcal{E})$  denotes the probability of an event  $\mathcal{E}$ . The statement “event  $\mathcal{E}$  occurs with high probability” is equivalent to  $\mathbb{P}(\mathcal{E}) \geq 1 - \frac{1}{n^c}$ , where  $c$  is an absolute constant. The statement “ $a$  is a  $1 \pm \varepsilon$  multiplicative approximation of  $b$ ” means  $|b - a| \leq \varepsilon \cdot b$ . For  $x \in \mathbb{R}$ ,  $\exp(x)$  denotes the standard exponential function, that is,  $e^x$ . By polylogarithmic, we mean  $\mathcal{O}((\log n / \varepsilon)^{\mathcal{O}(1)})$ . The notation  $\tilde{O}(\cdot)$  hides a polylogarithmic term in  $\mathcal{O}(\cdot)$ .

---

<sup>1</sup>  $\tilde{O}(\cdot)$  hides a polylogarithmic factor.

**Streaming models for graphs.** As alluded to earlier, the crux of the problem depends on the way the coloring function  $f$  is revealed in the stream. The details follow.

- (i) **VERTEX ARRIVAL (VA):** The vertices of  $V$  are exposed in an arbitrary order. After a vertex  $v \in V$  is exposed, all the edges between  $v$  and pre-exposed neighbors of  $v$ , are revealed. This set of edges are revealed one by one in an arbitrary order. Along with the vertex  $v$ , only the color  $f(v)$  is exposed, and not the colors of any pre-exposed vertices. So, we can check the monochromaticity of an edge  $(v, u)$  only if  $u$  and  $f(u)$  are explicitly stored.
- (ii) **VERTEX ARRIVAL WITH DEGREE ORACLE (VADEG)** [23, 7]: This model works same as the VA model in terms of exposure of the vertex  $v$  and the coloring on it; but we are allowed to know the degree  $d_G(v)$  of the currently exposed vertex  $v$  from a degree oracle on  $G$ .
- (iii) **VERTEX ARRIVAL IN RANDOM ORDER (VARAND)** [25, 26]: This model works same as the VA model but the vertex sequence revealed is equally likely to be any one of the permutations of the vertices.
- (iv) **EDGE ARRIVAL (EA):** The stream consists of edges of  $G$  in an arbitrary order. As the edge  $e$  is revealed, so are the colors on its endpoints. Thus the conflicts can be easily checked.
- (v) **ADJACENCY LIST (AL):** The vertices of  $V$  are exposed in an arbitrary order. When a vertex  $v$  is exposed, all the edges that are incident to  $v$ , are revealed one by one in an arbitrary order. Note that in this model each edge is exposed twice, once for each exposure of an incident vertex. As in the VA model, here also only  $v$ 's color  $f(v)$  is exposed.

As the conflicts can be checked easily in the EA model in  $O(1)$  space, a logarithmic counter is enough to count the number of monochromatic edges. The AL model works almost the same as the VADEG model. So, we focus on the three models – VA, VADEG and VARAND in this work and show that they have a clear separation in their power vis-a-vis the problem we solve. A crucial takeaway from our work is that the random order assumption on exposure of vertices has huge improvements in space complexity.

## 2.2 Problem definitions, results and the ideas

**Problem definition.** Let the vertices of  $G$  be colored with a function  $f : V(G) \rightarrow [C]$ , for  $C \in \mathbb{N}$ . An edge  $(u, v) \in E(G)$  is said to be *monochromatic* or *conflicting* with respect to  $f$  if  $f(u) = f(v)$ . A coloring function  $f$  is called *valid* if no edge in  $E(G)$  is monochromatic with respect to  $f$ . For a given parameter  $\varepsilon \in (0, 1)$ ,  $f$  is said to be  $\varepsilon$ -far from being *valid* if at least  $\varepsilon \cdot |E(G)|$  edges are monochromatic with respect to  $f$ . We study the following problems.

► **Problem 2.1 (CONFLICT ESTIMATION aka CONFLICT-EST).** A graph  $G = (V, E)$  and a coloring function  $f : V(G) \rightarrow [C]$  are streaming inputs. Given an input parameter  $\varepsilon > 0$ , the objective is to estimate the number of monochromatic edges in  $G$  within a  $(1 \pm \varepsilon)$ -factor.

► **Problem 2.2 (CONFLICT SEPARATION aka CONFLICT-SEP).** A graph  $G = (V, E)$  and a coloring function  $f : V(G) \rightarrow [C]$  are streaming inputs. Given an input parameter  $\varepsilon > 0$ , the objective is to distinguish if the coloring function  $f$  is valid or is  $\varepsilon$ -far from being valid.

► Remark 2.3. Problem 2.1 is our main focus, but we will mention a result on Problem 2.2 in Section 5. Notice that the problem CONFLICT-EST is at least as hard as CONFLICT-SEP.

**The results and the ideas involved.** All our upper and lower bounds on space are for one-pass streaming algorithms. Table 1 states our results for the CONFLICT-EST problem, the main problem we solve in this paper, across different variants of the VA model. The main thrust of our work is on estimating monochromatic edges under random order stream. For random order stream, we present both upper and lower bounds in Sections 3 and 4. There is a gap between the upper and lower bounds in the VARAND model, though we have a strong hunch that our upper bound is tight. Apart from the above, using a structural result on graphs, we show in Section 5 that the CONFLICT-SEP problem admits an easy algorithm in the VARAND model. To give a complete picture across different variants of VA models, we show matching upper and lower bounds for constant  $\varepsilon > 0$  in the VA and VADEG models in [9]<sup>2</sup>.

■ **Table 1** This table shows our results on CONFLICT-EST on a graph  $G(V, E)$  across different VERTEX ARRIVAL models. Here,  $T > 0$  denotes the promised lower bound on the number of monochromatic edges. This paper discusses the results mentioned in the middle column corresponding to VARAND. The other results are discussed in the full version of the paper [9].

Model	VA	VARAND	VADEG
Upper Bound	$\tilde{O}\left(\min\{ V , \frac{ V ^2}{T}\}\right)$ (Thm. 3.1 in [9])	$\tilde{O}\left(\frac{ V }{\sqrt{T}}\right)$ (Sec. 3, Thm. 3.1)	$\tilde{O}\left(\min\{ V , \frac{ E }{T}\}\right)$ (Thm. 3.2 in [9])
Lower Bound	$\Omega\left(\min\{ V , \frac{ V ^2}{T}\}\right)$ (Thm. E.1 in [9])	$\Omega\left(\frac{ V }{T^2}\right)$ (Sec. 4, Thm. 4.1)	$\Omega\left(\min\{ V , \frac{ E }{T}\}\right)$ (Thm. E.2 in [9])

The promise  $T$  on the number of monochromatic edges is a very standard assumption for estimating substructures in the world of graph streaming algorithm [17, 19, 18, 23, 5].<sup>3</sup>

We now briefly mention the salient ideas involved. For the simpler variant of CONFLICT-EST in VA model, we first check if  $|V| \geq T$ . If yes, we store all the vertices and their colors in the stream to determine the exact value of the number of monochromatic edges. Otherwise, we sample each pair of vertices  $\{u, v\}$  in  $\binom{V}{2}$ <sup>4</sup>, with probability  $\tilde{O}(1/T)$  independently<sup>5</sup> before the stream starts. When the stream comes, we compute the number of monochromatic edges from this sample. The details are in Section 3 of [9]. Though the algorithm looks extremely simple, it matches the lower bound result for CONFLICT-EST in VA model, presented in Appendix E of [9]. The VADEG model with its added power of a degree oracle, allows us to know  $d_G(u)$  for a vertex  $u$  and as edges to pre-exposed vertices are revealed, we also know  $d_G^-(u)$  and  $d_G^+(u)$ . This allows us to use sampling to store vertices and to use a technique which we call *sampling into the future* where indices of random neighbors, out of  $d_G^+(u)$  neighbors, are selected for future checking. The upper bound result for CONFLICT-EST in VADEG model, presented in Section 3 of [9], is tight as we also prove a matching lower bound in Appendix E of [9].

<sup>2</sup> The reference [9] is the full version of this submission.

<sup>3</sup> Here we have cited a few. However, there are huge amount of relevant literature.

<sup>4</sup>  $\binom{V}{2}$  denotes the set of all size 2 subsets of  $V(G)$ .

<sup>5</sup> Note that we might sample some pairs that are not forming edges in the graph.

The algorithm for CONFLICT-EST in VARAND model is the mainstay of our work and is presented in Section 3. We redefine the degree in terms of the number of monochromatic neighbors a vertex has in the randomly sampled set. Here, we estimate the high monochromatic degree and low monochromatic degree vertices separately by sampling a random subset of vertices. While the monochromatic degree for the high degree vertices can be extrapolated from the sample, handling low monochromatic degree vertices individually in the same way does not work. To get around, we group such vertices having similar monochromatic degree and treat them as an entity. We also provide a lower bound for the VARAND model, in Section 4, using a reduction from *multi-party set disjointness*; though there is a gap in terms of the exponent in  $T$ .

The highlights of our work are as follows:

- We show that possibly the easiest graph coloring problem is worth studying over streams.
- For researchers working in streaming, the *gold standard* is the EA model as most problems are non-trivial in this model. We point out a problem that is harder to solve in the VA model as compared to the EA model.
- We show that the three VA related models have a clear separation in their space complexities vis-a-vis the problem we solve. We could exploit the random order of the arrival of the vertices to get substantial improvements in space complexity.
- We could obtain lower bounds for all the three models and the lower bounds are matching for the VA and VADEG models.

### 2.3 Prior works on graph coloring in semi-streaming model.

Bera and Ghosh [8] commenced the study of vertex coloring in the semi-streaming model. They devise a randomized one pass streaming algorithm that finds a  $(1 + \varepsilon)\Delta$  vertex coloring in  $\tilde{O}(n)$  space. Assadi et al. [3] find a proper vertex coloring using  $\Delta + 1$  colors via various classes of sublinear algorithms. Their state of the art contributions can be attributed to a key result called the *palette-sparsification theorem* which states that for an  $n$ -vertex graph with maximum degree  $\Delta$ , if  $O(\log n)$  colors are sampled independently and uniformly at random for each vertex from a list of  $\Delta + 1$  colors, then with a high probability a proper  $\Delta + 1$  coloring exists for the graph. They design a randomized one-pass dynamic streaming algorithm for the  $\Delta + 1$  coloring using  $\tilde{O}(n)$  space. The algorithm takes post-processing  $\tilde{O}(n\sqrt{\Delta})$  time and assumes a prior knowledge of  $\Delta$ . Alon and Assadi [2] improve the palette sparsification result of [3]. They consider situations where the number of colors available is both more than and less than  $\Delta + 1$  colors. They show that sampling  $O_\varepsilon(\sqrt{\log n})$  colors per vertex is sufficient and necessary for a  $(1 + \varepsilon)\Delta$  coloring. Bera et al. [6] give a new graph coloring algorithm in the semi-streaming model where the number of colors used is parameterized by the degeneracy  $\kappa$ . The key idea is a *low degeneracy partition*, also employed in [8]. The numbers of colors used to properly color the graph is  $\kappa + o(\kappa)$  and post-processing time of the algorithm is improved to  $\tilde{O}(n)$ , without any prior knowledge about  $\kappa$ . Behnezhad et al. [4] were the first to give one-pass W-streaming algorithms (streaming algorithms where outputs are produced in a streaming fashion as opposed to outputs given finally at the end) for edge coloring both when the edges arrive in a random order or in an adversarial fashion.

### 3 CONFLICT-EST in VARAND model

In this Section, we show that the power of randomness can be used to design a better solution for the CONFLICT-EST problem in the VARAND model. The CONFLICT-EST problem is the main highlight of our work. We feel that the crucial use of randomness in the input that is used to estimate a substructure (here, monochromatic edges) in a graph, will be of independent interest.

In this variant, we are given an  $\varepsilon \in (0, 1)$  and a promised lower bound  $T$  on  $|E_M|$ , the number of monochromatic edges in  $G$ , as input and our objective is to determine a  $(1 \pm \varepsilon)$ -approximation to  $|E_M|$ .

► **Theorem 3.1.** *Given any graph  $G = (V, E)$  and a coloring function  $f : V(G) \rightarrow [C]$  as input in the stream, the CONFLICT-EST problem in the VARAND model can be solved with high probability in  $\tilde{O}\left(\frac{|V|}{\sqrt{T}}\right)$  space, where  $T$  is a lower bound on the number of monochromatic edges in the graph.*

#### The proof idea

##### A random sample comes for free – pick the first few vertices

Let  $v_1, \dots, v_n$  be the random ordering in which the vertices of  $V$  are revealed. Let  $R$  be a random subset of  $\Gamma = \tilde{O}\left(\frac{n}{\sqrt{T}}\right)$  many vertices of  $G$  sampled without replacement<sup>6</sup>. As we are dealing with a random order stream, consider the first  $\Gamma$  vertices in the stream; they can be treated as  $R$ , the random sample. We start by storing all the vertices in  $R$  as well as their colors. Observe that if the monochromatic degree of any vertex  $v_i$  is *large* (say roughly more than  $\sqrt{T}$ ), then it can be well approximated by looking at the number of monochromatic neighbors that  $v_i$  has in  $R$ . As a vertex  $v_i$  streams past, there is no way we can figure out its monochromatic degree, unless we store its monochromatic neighbors that appear before it in the stream; if we could, we were done. Our only savior is the stored random subset  $R$ .

##### Classifying the vertices of the random sample $R$ based on its monochromatic degree

Our algorithm proceeds by figuring out the influence of the color of  $v_i$  on the monochromatic degrees of vertices in  $R$ . To estimate this, let  $\kappa_{v_i}$  denote the number of monochromatic neighbors that  $v_i$  has in  $R$ . We set a threshold  $\tau = \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}$ , where  $t = \lceil \log_{1+\frac{\varepsilon}{10}} n \rceil$ . The significance of  $t$  will be clear from the discussion below. Any vertex  $v_i$  will be classified as a high- $m_R$  or low- $m_R$  degree vertex depending on its monochromatic degree within  $R$ , i.e., if  $\kappa_{v_i} \geq \tau$ , then  $v_i$  is a high- $m_R$  vertex, else it is a low- $m_R$  vertex, respectively. (We use the subscripts  $m_R$  to stress the fact that the monochromatic degrees are induced by the set  $R$ .) Let  $H$  and  $L$  be the partition of  $V$  into the set of high- $m_R$  and low- $m_R$  degree vertices in  $G$ . Let  $H_R$  and  $L_R$  denote the set of high- $m_R$  and low- $m_R$  degree vertices in  $R$ . Notice that, because of the definition of high- $m_R$  and low- $m_R$  degree vertices, not only the sets  $H_R, L_R$  are subsets of  $R$ , but they are determined by the vertices of  $R$  only.

Let  $m_h$  and  $m_\ell$  denote the sum of the monochromatic degrees of all the high- $m_R$  degree vertices and low- $m_R$  degree vertices in  $G$ , respectively. So,  $m_h = \sum_{v \in H} d_M(v)$  and  $m_\ell = \sum_{v \in L} d_M(v)$ . Note that  $\hat{m} = |E_M| = \frac{1}{2} \sum_{v \in V} d_M(v) = \frac{1}{2} (m_h + m_\ell)$ . We will describe how to approximate  $m_h$  and  $m_\ell$  separately. The formal algorithm is described in Algorithm 1

<sup>6</sup>  $\tilde{O}(\cdot)$  hides a polynomial factor of  $\log n$  and  $\frac{1}{\varepsilon}$  in the upper bound.

as  $\text{RANDOM-ORDER-EST}(\varepsilon, T)$  (in Appendix D) that basically executes steps to approximate  $m_h$  and  $m_\ell$  in parallel.

### To approximate $m_h$ , the random sample $R$ comes to rescue

We can find  $\widehat{m}_h$ , that is, a  $(1 \pm \frac{\varepsilon}{10})$  approximation of  $m_h$  as described below. For each vertex  $v_i \in R$  and each monochromatic edge  $(u, v_i)$ ,  $u \in R$ , we see in the stream, we increase the value of  $\kappa_u$  for  $u$  and  $\kappa_{v_i}$  for  $v_i$ . After all the vertices in  $R$  are revealed, we can determine  $H_R$  by checking whether  $\kappa_{v_i} \geq \tau$  for each  $v_i \in R$ . For each vertex  $v_i \in H_R$ , we set its approximate monochromatic degree  $\widehat{d}_{v_i}$  to be  $\frac{n}{|R|}\kappa_{v_i}$ . We initialize the estimated sum of the monochromatic degree of high degree vertices as  $\widehat{m}_h = \sum_{v_i \in H_R} \widehat{d}_{v_i}$ . For each vertex  $v_i \notin R$  in the stream, we can determine  $\kappa_{v_i}$ , as we have stored all the vertices in  $R$  along with their colors, and hence we can also determine whether  $v_i$  is a high- $m_R$  degree vertex in  $G$ . If  $v_i \notin R$  is a high- $m_R$  degree vertex, we determine  $\widehat{d}_{v_i} = \frac{n}{|R|}\kappa_{v_i}$  and update  $\widehat{m}_h$  by  $\widehat{m}_h + \widehat{d}_{v_i}$ . Observe that, at the end,  $\widehat{m}_h$  is  $\sum_{v_i \in H} \widehat{d}_{v_i}$ . Recall that  $H$  is the set of all high- $m_R$  degree vertices in  $G$ . For each  $v_i \in H$ , we will show, as in Claim 3.3, that  $\widehat{d}_{v_i}$  is a  $(1 \pm \frac{\varepsilon}{10})$ -approximation to  $d_M(v_i)$  with high probability. This implies that

$$\left(1 - \frac{\varepsilon}{10}\right) m_h \leq \widehat{m}_h \leq \left(1 + \frac{\varepsilon}{10}\right) m_h \quad (1)$$

### To approximate $m_\ell$ , group the vertices in $L$ based on similar monochromatic degree

Recall that  $m_\ell = \sum_{v_i \in L} d_M(v_i)$ . Unlike the high- $m_R$  degree vertices, it is not possible to approximate the monochromatic degree of  $v_i \in L$  from  $\kappa_{v_i}$ . To cope up with this problem, we partition the vertices of  $L$  into  $t$  buckets  $B_1, \dots, B_t$  such that all the vertices present in a bucket have *similar* monochromatic degrees, where  $t = \lceil \log_{1+\frac{\varepsilon}{10}} n \rceil$ . The bucket  $B_j$  is defined as follows:  $B_j = \{v_i \in L : (1 + \frac{\varepsilon}{10})^{j-1} \leq d_M(v_i) < (1 + \frac{\varepsilon}{10})^j\}$ .

Note that our algorithm will not find the buckets explicitly. It will be used for the analysis only. Observe that  $\sum_{j \in [t]} |B_j| (1 + \frac{\varepsilon}{10})^{j-1} \leq m_\ell < \sum_{j \in [t]} |B_j| (1 + \frac{\varepsilon}{10})^j$ . We can surely approximate  $m_\ell$  by approximating  $|B_j|$ s suitably. We estimate  $|B_j|$ s as follows. After the stream of the vertices in  $R$  has gone past, we have the set of low- $m_R$  degree vertices  $L_R$  in  $R$  and  $\widehat{d}_{v_i} = \kappa_{v_i}$  for each  $v_i \in L_R$ . For each  $v_i \notin R$  in the stream, we determine the monochromatic neighbors of  $v_i$  in  $L_R$ . It is possible as we have stored all the vertices in  $R$  and their colors. For each monochromatic neighbor  $v_{i'} \in L_R$  of  $v_i$ , we increase the value of  $\widehat{d}_{v_{i'}}$  of  $v_{i'}$ . Observe that, at the end of the stream,  $\widehat{d}_{v_{i'}} = d_M(v_{i'})$  for each  $v_{i'} \in L_R$ , i.e., we can accurately estimate the monochromatic degree of each  $v_{i'} \in L_R$ . So, we can determine the bucket where each vertex in  $L_R$  belongs. Let  $A_j (= L_R \cap B_j)$  be the bucket  $B_j$  projected onto  $L_R$  in the random sample; note that as  $B_j \subseteq L$  and  $L_R = L \cap R$ ,  $A_j = R \cap B_j$  also. We determine  $\widehat{m}_\ell = \frac{n}{|R|} \sum_{j \in [t]} |A_j| (1 + \frac{\varepsilon}{10})^j$ . We can show that  $\frac{n}{|R|} |A_j|$  is a  $(1 + \frac{\varepsilon}{10})$ -approximation of  $|B_j|$ , with high probability, if  $|B_j| \geq \frac{\sqrt{\varepsilon T}}{10t}$ . Also, we can show that, if  $|B_j| < \frac{\sqrt{\varepsilon T}}{10t}$ , then  $|A_j| \leq \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}$  with high probability. Now using the fact that we consider bucketing of only low- $m_R$  degree vertices ( $L_R$ ), we can show that

$$\left(1 - \frac{\varepsilon}{10}\right) \left(m_\ell - \frac{\varepsilon T}{63t}\right) \leq \widehat{m}_\ell \leq \left(1 + \frac{\varepsilon}{10}\right)^2 \left(m_\ell + \frac{\varepsilon T}{56t}\right). \quad (2)$$

Note that  $\varepsilon \in (0, 1)$  and  $t = \lceil \log_{1+\frac{\varepsilon}{10}} n \rceil$ . Assuming  $T \geq 63t^2$ , Equations 1 and 2 imply that  $\widehat{m} = \frac{1}{2}(\widehat{m}_h + \widehat{m}_\ell)$  is a  $(1 \pm \varepsilon)$ -approximation to  $|E_M|$ . If  $T < 63t^2$ , then note that

## 15:8 Even the Easiest(?) Graph Coloring Problem Is Not Easy in Streaming!

$n = \tilde{O}\left(\frac{n}{\sqrt{T}}\right)$ . So, in that case, we store all the vertices along with their colors and compute the exact value of  $|E_M|$ .

### Proof of correctness

The correctness of the algorithm follows trivially if  $T < 63t^2$ . So, let us assume that  $T \geq 63t^2$ . In the VARAND model, we consider the first  $\tilde{\Theta}\left(\frac{n}{\sqrt{T}}\right)$  vertices as the random sample  $R$  without replacement. Using the Chernoff bound for sampling without replacement (See Lemma A.2 in Appendix A), we can have the following lemma (The proof is in Appendix B), which will be useful for the correctness proof of Algorithm 1 (RANDOM-ORDER-EST( $\varepsilon, T$ )) in case of  $T \geq 63t^2$ .

#### ► Lemma 3.2.

- (i) For each  $j \in [t]$  with  $|B_j| \geq \frac{\sqrt{\varepsilon T}}{10t}$ ,  $\mathbb{P}\left(\left|B_j \cap R\right| - \frac{|R||B_j|}{n} \geq \frac{\varepsilon}{10} \frac{|R||B_j|}{n}\right) \leq \frac{1}{n^{10}}.$
- (ii) For each  $j \in [t]$  with  $|B_j| < \frac{\sqrt{\varepsilon T}}{10t}$ ,  $\mathbb{P}\left(|B_j \cap R| \geq \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}\right) \leq \frac{1}{n^{10}}.$
- (iii) For each vertex  $v_i$  with  $d_M(v_i) \geq \frac{\sqrt{\varepsilon T}}{10t}$ ,  $\mathbb{P}\left(\left|\kappa_{v_i} - \frac{|R|d_M(v_i)}{n}\right| \geq \frac{\varepsilon}{10} \frac{|R|d_M(v_i)}{n}\right) \leq \frac{1}{n^{10}}.$
- (iv) For each vertex  $v_i$  with  $d_M(v_i) < \frac{\sqrt{\varepsilon T}}{10t}$ ,  $\mathbb{P}\left(\kappa_{v_i} \geq \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}\right) \leq \frac{1}{n^{10}}.$

The correctness proof of the algorithm is divided into the following two claims.

▷ Claim 3.3.  $(1 - \frac{\varepsilon}{10})m_h \leq \widehat{m}_h \leq (1 + \frac{\varepsilon}{10})m_h$  with probability at least  $1 - \frac{1}{n^9}.$

▷ Claim 3.4.  $(1 - \frac{\varepsilon}{10})(m_\ell - \frac{\varepsilon T}{63t}) \leq \widehat{m}_\ell \leq (1 + \frac{\varepsilon}{10})^2(m_\ell + \frac{\varepsilon T}{56t})$  with probability at least  $1 - \frac{1}{n^7}.$

Assuming the above two claims hold and taking  $\varepsilon \in (0, 1)$ ,  $t = \lceil \log_{1+\frac{\varepsilon}{10}} n \rceil$  and  $T \geq 63t^2$ , observe that  $\widehat{m} = \frac{1}{2}(\widehat{m}_h + \widehat{m}_\ell)$  is a  $(1 \pm \varepsilon)$  approximation of  $|E_M| = m_h + m_\ell$  with high probability. Thus, it remains to prove Claims 3.3 and 3.4.

Proof of Claim 3.3. Note that  $m_h = \sum_{v_i: \kappa_{v_i} \geq \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}} d_M(v_i)$  and  $\widehat{m}_h = \sum_{v_i: \kappa_{v_i} \geq \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}} \widehat{d}_{v_i}.$

From Lemma 3.2 (iv) and (iii),  $\kappa_{v_i} \geq \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}$  implies that  $\widehat{d}_{v_i}$  is an  $(1 \pm \frac{\varepsilon}{10})$  approximation to  $d_M(v_i)$  with probability at least  $1 - \frac{1}{n^{10}}$ . Hence, we have  $(1 - \frac{\varepsilon}{10})m_h \leq \widehat{m}_h \leq (1 + \frac{\varepsilon}{10})m_h$  with probability at least  $1 - \frac{1}{n^9}.$  ◁

Proof of Claim 3.4. Note that  $m_\ell = \sum_{v_i \in L} d_M(v_i) = \sum_{v_i: \kappa_{v_i} < \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}} d_M(v_i)$  and

$\widehat{m}_\ell = \frac{n}{|R|} \sum_{j \in [t]} |A_j| (1 + \frac{\varepsilon}{10})^j.$  Recall that the vertices in  $L$  are partitioned into  $t$  buckets as follows:

$B_j = \{v_i \in L : (1 + \frac{\varepsilon}{10})^{j-1} \leq d_M(v_i) < (1 + \frac{\varepsilon}{10})^j\}$ , where  $j \in [t]$ . By Lemma 3.2 (iv),  $\kappa_{v_i} < \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}$  implies that  $d_M(v_i) \leq \frac{\sqrt{\varepsilon T}}{7t}$  with probability  $1 - \frac{1}{n^{10}}$ . So, we have the following observation.

► **Observation 3.5.** Let  $j \in [t]$  be such that  $|A_j| \neq 0$  ( $|B_j| \neq 0$ ). Then, with probability at least  $1 - \frac{1}{n^{10}}$ , the monochromatic degree of each vertex in  $A_j$  as well as  $B_j$  is at most  $\frac{\sqrt{\varepsilon T}}{7t}$ , that is,  $(1 + \frac{\varepsilon}{10})^j \leq \frac{\sqrt{\varepsilon T}}{7t}.$

To upper and lower bound  $\widehat{m}_\ell$  in terms of  $m_\ell$ , we upper and lower bound  $m_\ell$  in terms of  $|B_j|$ 's as follows; for the upper bound, we break the sum into two parts corresponding to large and small sized buckets:

$$\begin{aligned} \sum_{j \in [t]} |B_j| \left(1 + \frac{\varepsilon}{10}\right)^{j-1} &\leq m_\ell < \sum_{j \in [t]} |B_j| \left(1 + \frac{\varepsilon}{10}\right)^j \\ \sum_{j \in [t]} |B_j| \left(1 + \frac{\varepsilon}{10}\right)^{j-1} &\leq m_\ell < \sum_{j \in [t]: |B_j| \geq \frac{\sqrt{\varepsilon T}}{9t}} |B_j| \left(1 + \frac{\varepsilon}{10}\right)^j + \sum_{j \in [t]: |B_j| < \frac{\sqrt{\varepsilon T}}{9t}} |B_j| \left(1 + \frac{\varepsilon}{10}\right)^j \end{aligned}$$

By Observation 3.5, we bound  $m_\ell$  in terms of  $|B_j|$ 's with probability  $1 - \frac{1}{n^9}$ .

$$\sum_{j \in [t]} |B_j| \left(1 + \frac{\varepsilon}{10}\right)^{j-1} \leq m_\ell < \sum_{j \in [t]: |B_j| \geq \frac{\sqrt{\varepsilon T}}{9t}} |B_j| \left(1 + \frac{\varepsilon}{10}\right)^j + t \cdot \frac{\sqrt{\varepsilon T}}{9t} \frac{\sqrt{\varepsilon T}}{7t}$$

This implies the following Observation:

► **Observation 3.6.**  $\sum_{j \in [t]} |B_j| \left(1 + \frac{\varepsilon}{10}\right)^{j-1} \leq m_\ell < \sum_{j \in [t]: |B_j| \geq \frac{\sqrt{\varepsilon T}}{9t}} |B_j| \left(1 + \frac{\varepsilon}{10}\right)^j + \frac{\varepsilon T}{63t}$  holds with probability at least  $1 - \frac{1}{n^9}$ .

Now, we have all the ingredients to show that  $\widehat{m}_\ell$  is a  $(1 \pm \varepsilon)$  approximation of  $m_\ell$ . To get to  $\widehat{m}_\ell$ , we need to focus on low- $m_R$  vertices of  $R$ , i.e.,  $A_j$ 's. Breaking  $\widehat{m}_\ell = \frac{n}{|R|} \sum_{j \in [t]} |A_j| \left(1 + \frac{\varepsilon}{10}\right)^j$  depending on small and large values of  $|A_j|$ 's (recall  $A_j = L_R \cap B_j = R \cap B_j$ ), we have

$$\widehat{m}_\ell = \frac{n}{|R|} \left[ \sum_{j \in [t]: |A_j| \geq \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}} |A_j| \left(1 + \frac{\varepsilon}{10}\right)^j + \sum_{j \in [t]: |A_j| < \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}} |A_j| \left(1 + \frac{\varepsilon}{10}\right)^j \right] \quad (3)$$

Note that  $A_j = B_j \cap R$ . By Lemma 3.2 (ii),  $|A_j| \geq \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}$  implies  $|B_j| \geq \frac{\sqrt{\varepsilon T}}{10t}$  with probability at least  $1 - \frac{1}{n^{10}}$ . Also, applying Lemma 3.2 (i),  $|B_j| \geq \frac{\sqrt{\varepsilon T}}{10t}$  implies  $|A_j|$  is an  $(1 \pm \frac{\varepsilon}{10})$ -approximation to  $\frac{|R||B_j|}{n}$  with probability at least  $1 - \frac{1}{n^{10}}$ . So, we have the following observation.

► **Observation 3.7.** Let  $j \in [t]$  be such that  $|A_j| \geq \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}$ . Then  $|A_j|$  is an  $(1 \pm \frac{\varepsilon}{10})$ -approximation to  $\frac{|R||B_j|}{n}$  with probability at least  $1 - \frac{2}{n^{10}}$ , that is,  $\frac{n}{|R|} |A_j|$  is an  $(1 \pm \frac{\varepsilon}{10})$ -approximation to  $|B_j|$  with probability at least  $1 - \frac{2}{n^{10}}$ .

By the above observation along with Equation 3, we have the following upper bound on  $\widehat{m}_\ell$  with probability at least  $1 - \frac{1}{n^9}$ .

$$\begin{aligned} \widehat{m}_\ell &\leq \sum_{j \in [t]: |A_j| \geq \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}} \left(1 + \frac{\varepsilon}{10}\right) |B_j| \left(1 + \frac{\varepsilon}{10}\right)^j + \sum_{j \in [t]: |A_j| < \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}} \frac{n}{|R|} |A_j| \left(1 + \frac{\varepsilon}{10}\right)^j \\ &\leq \left(1 + \frac{\varepsilon}{10}\right)^2 \left[ \sum_{j \in [t]: |A_j| \geq \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}} |B_j| \left(1 + \frac{\varepsilon}{10}\right)^{j-1} + \sum_{j \in [t]: |A_j| < \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}} \frac{\sqrt{\varepsilon T}}{8t} \left(1 + \frac{\varepsilon}{10}\right)^{j-2} \right] \end{aligned}$$

Now by Observations 3.6 and 3.5, we have the following with probability at least  $1 - \frac{1}{n^8}$ .

$$\begin{aligned} \widehat{m}_\ell &\leq \left(1 + \frac{\varepsilon}{10}\right)^2 \left( m_\ell + t \cdot \frac{\sqrt{\varepsilon T}}{8t} \frac{\sqrt{\varepsilon T}}{7t} \right) \\ &= \left(1 + \frac{\varepsilon}{10}\right)^2 \left( m_\ell + \frac{\varepsilon T}{56t} \right) \end{aligned}$$

## 15:10 Even the Easiest(?) Graph Coloring Problem Is Not Easy in Streaming!

Now, we will lower bound  $\widehat{m}_\ell$ . From Equation 3, we have

$$\widehat{m}_\ell \geq \frac{n}{|R|} \sum_{j \in [t]: |A_j| \geq \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}} |A_j| \left(1 + \frac{\varepsilon}{10}\right)^j$$

By Observation 3.7,  $|A_j| \geq \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}$  implies  $\frac{n}{|R|} |A_j|$  is an  $(1 \pm \frac{\varepsilon}{10})$ -approximation to  $|B_j|$  with probability at least  $1 - \frac{2}{n^{10}}$ . So, the following lower bound on  $\widehat{m}_\ell$  holds with probability at least  $1 - \frac{1}{n^9}$ .

$$\widehat{m}_\ell \geq \left(1 - \frac{\varepsilon}{10}\right) \sum_{j \in [t]: |A_j| \geq \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}} |B_j| \left(1 + \frac{\varepsilon}{10}\right)^j$$

By Lemma 3.2 (i), if  $|B_j| \geq \frac{\sqrt{\varepsilon T}}{9t}$ , then  $|A_j| \geq \frac{\sqrt{\varepsilon T}}{8t}$  with probability at least  $1 - \frac{1}{n^{10}}$ . Hence, we have the following lower bound on  $\widehat{m}_\ell$  with probability at least  $1 - \frac{1}{n^8}$ .

$$\widehat{m}_\ell \geq \left(1 - \frac{\varepsilon}{10}\right) \sum_{j \in [t]: |B_j| \geq \frac{\sqrt{\varepsilon T}}{9t}} |B_j| \left(1 + \frac{\varepsilon}{10}\right)^j$$

Now by Observation 3.6, we have the following with probability at least  $1 - \frac{1}{n^7}$ .

$$\widehat{m}_\ell \geq \left(1 - \frac{\varepsilon}{10}\right) \left(m_\ell - \frac{\varepsilon T}{63t}\right). \quad \triangleleft$$

### 4 Lower bound for CONFLICT-EST in VARAND model

In this Section, we show a lower bound of  $\Omega\left(\frac{n}{T^2}\right)$  for CONFLICT-EST in VERTEX ARRIVAL IN RANDOM ORDER via a reduction from a variation of MULTIPARTY SET DISJOINTNESS problem called DISJOINTNESS<sub>R</sub>( $t, n, p$ ), played among  $p$  players: Consider a matrix of order  $t \times n$  having  $t$  (rows) vectors  $M_1, \dots, M_t \in \{0, 1\}^n$  such that each entry of matrix  $M$  is given to one of the  $p$  players chosen uniformly at random. The objective is to determine whether there exists a column where all the entries are 1s. If  $t \geq 2$  and  $p = \Omega(t^2)$ , Chakrabarti et al. showed that any randomized protocol requires  $\Omega\left(\frac{n}{t}\right)$  bits of communication [10]. They showed that the lower bound holds under a promise called the UNIQUE INTERSECTION PROMISE which states that there exists at most a single column where all the entries are 1s and every other column of the matrix has Hamming weight either 0 or 1. Moreover, the lower bound holds even if all the  $p$  players know the random partition of the entries of matrix  $M$ .

► **Theorem 4.1.** *Let  $n, T \in \mathbb{N}$  be such that  $4 \leq T \leq \binom{n}{2}$ . Any constant pass streaming algorithm that takes the vertices and edges of a graph  $G(V, E)$  (with  $|V| = \Theta(n)$  and  $|E| = \Theta(m)$ ) and a coloring function  $f: V \rightarrow [C]$  in the VARAND model, and determines whether the monochromatic edges in  $G$  is 0 or  $\Omega(T)$  with probability  $2/3$ , requires  $\Omega\left(\frac{n}{T^2}\right)$  bits of space.*

**Proof.** Without loss of generality, assume that  $\sqrt{T} \in \mathbb{N}$ . Consider the DISJOINTNESS<sub>R</sub> $\left(\sqrt{T}, \frac{n}{\sqrt{T}}, p\right)$  problem with UNIQUE INTERSECTION PROMISE when all of the  $p$  players know the random partition of the entries of the relevant matrix  $M$ . Note that  $M$  is of order  $\left[\sqrt{T}\right] \times \left[\frac{n}{\sqrt{T}}\right]$  and  $p = AT$  for some suitable constant  $A \in \mathbb{N}$ . Also, consider a graph  $G$ , with  $V(G) = \{v_{ij} : i \in [\sqrt{T}], j \in [\frac{n}{\sqrt{T}}]\}$ , having  $\frac{n}{\sqrt{T}}$  many vertex disjoint cliques such that  $\{v_{1j}, \dots, v_{\sqrt{T}j}\}$  forms a clique for each  $j \in [n]$ , i.e., a column of  $M$  forms a clique. Also, notice

that each clique has  $\Theta(T)$  edges. Let us assume that there is an  $r$ -pass streaming algorithm  $\mathcal{S}$ , with space complexity  $s$  bits, that solves CONFLICT-EST for the above graph  $G$  in the VARAND model. Now, we give a protocol  $\mathcal{A}$  for  $\text{DISJOINTNESS}_R\left(\sqrt{T}, \frac{n}{\sqrt{T}}, p\right)$  with communication cost  $O(rsp)$ . Using the fact that the lower bound of  $\text{DISJOINTNESS}\left(\sqrt{T}, \frac{n}{\sqrt{T}}, p\right)$  is  $\Omega\left(\frac{n/\sqrt{T}}{\sqrt{T}}\right)$  along with the fact that  $p = AT$  and  $r$  is a constant, we get  $s = \Omega\left(\frac{n}{T^2}\right)$ .

### Protocol $\mathcal{A}$ for $\text{DISJOINTNESS}_R\left(\sqrt{T}, \frac{n}{\sqrt{T}}, p\right)$

Let  $P_1, \dots, P_p$  denote the set of  $p$  players. For  $k \in [p]$ ,  $V_k = \{v_{ij} : M_{ij} \text{ is with } P_k\}$ , where  $M_{ij}$  denotes the element present in the  $i$ -th row and  $j$ -th column of matrix  $M$ . Note that there is a one-to-one correspondence between the entries of  $M$  and the vertices in  $V(G)$ . Furthermore, there is a one-to-one correspondence between the columns of matrix  $M$  and the cliques in graph  $G$ . We assume that all the  $p$  players know the graph structure completely as well as both the one-to-one correspondences. The protocol proceeds as follows: for each  $k \in [p]$ , player  $P_k$  determines a random permutation  $\pi_k$  of the vertices in  $V_k$ . Also, for each  $k \in [p]$ , player  $P_k$  determines the colors of the vertices in  $V_k$  by the following rule: if  $M_{ij} = 1$ , then color vertex  $v_{ij}$  with color  $C_*$ . Otherwise, for  $M_{ij} = 0$ , color vertex  $v_{ij}$  with color  $C_i$ . Player  $P_1$  initiates the streaming algorithm and it goes over  $r$ -rounds.

**Rounds 1 to  $r - 1$ :** For  $k \in [p]$ , each player resumes the streaming algorithm by exposing the vertices in  $V_k$ , along with their colors, in the order dictated by  $\pi_k$ . Also,  $P_k$  adds the respective edges to previously exposed vertices when the current vertex is exposed to satisfy the basic requirement of VA model. This is possible because all players know the graph  $G$  and the random partition of the entries of matrix  $M$  among  $p$  players. After exposing all the vertices in  $V_k$ , as described,  $P_k$  sends the current memory state to player  $P_{k+1}$ . Assume that  $P_1 = P_{p+1}$ .

**Round  $r$ :** All the players behave similarly as in the previous rounds, except that, the player  $P_p$  does not send the current memory state to  $P_1$ . Rather,  $P_p$  decides whether there is a column in  $M$  with all 1s if the streaming algorithm  $\mathcal{S}$  decides that there are  $\Omega(T)$  many monochromatic edges in  $G$ . Otherwise, if  $\mathcal{S}$  decides that there is no monochromatic edge in  $G$ , then  $P_p$  decides that all the columns of  $M$  have weight either 0 or 1. Then  $P_p$  sends the output to all other players.

The vertices of graph  $G$  are indeed exposed randomly to the streaming algorithm. It is because the entries of matrix  $M$  are randomly partitioned among the players and each player also generates a random permutation of the vertices corresponding to the entries of matrix  $M$  available to them. From the description of the protocol  $\mathcal{A}$ , the memory state of the streaming algorithm (of space complexity  $s$ ) is communicated  $(r - 1)p + (p - 1)$  times and  $p - 1$  bits is communicated at the end by player  $P_p$  to broadcast the output. Hence, the communication cost of the protocol  $\mathcal{A}$  is at most  $O(rsp)$ .

Now we are left to prove the correctness of the protocol  $\mathcal{A}$ . If there is a column in  $M$  with all 1s, then all the vertices corresponding to entries of that column are colored with color  $C_*$ . Recall that there is a one-to-one correspondence between the columns in matrix  $M$  and cliques in the graph  $G$ . So, all the vertices of the clique, corresponding to the column having all 1s, are colored with the color  $C_*$ . As the size of each clique in the graph  $G$  is  $\sqrt{T}$ , there are at most  $\Omega(T)$  monochromatic edges. To prove the converse, assume that there is no column in the matrix  $M$  having all 1s. By UNIQUE INTERSECTION PROMISE, all the

## 15:12 Even the Easiest(?) Graph Coloring Problem Is Not Easy in Streaming!

columns have hamming weight at most 1. We will argue that there is no monochromatic edge in  $G$ . Consider an edge  $e$  in  $G$ . By the structure of  $G$ , the two vertices of  $e$  must be in the same clique, say the  $j$ -th clique, that is, let  $e = \{v_{i_1j}, v_{i_2j}\}$ . By the coloring scheme used by the protocols,  $v_{i_1j}$  and  $v_{i_2j}$  are colored according to the values of  $M_{i_1j}$  and  $M_{i_2j}$ , respectively. Note that both  $M_{i_1j}$  and  $M_{i_2j}$  belong to  $j$ -th column. As the hamming weight of every column is at most 1, there are three possibilities:

- (i)  $M_{i_1j} = M_{i_2j} = 0$ , that is,  $v_{i_1j}$  and  $v_{i_2j}$  are colored with color  $C_{i_1}$  and  $C_{i_2}$ , respectively;
- (ii)  $M_{i_1j} = 0$  and  $M_{i_2j} = 1$ , that is,  $v_{i_1j}$  and  $v_{i_2j}$  are colored with color  $C_{i_1}$  and  $C_*$ , respectively;
- (iii)  $M_{i_1j} = 1$  and  $M_{i_2j} = 0$ , that is,  $v_{i_1j}$  and  $v_{i_2j}$  are colored with color  $C_*$  and  $C_{i_2}$ , respectively.

In any case, the edge  $e = \{v_{i_1j}, v_{i_2j}\}$  is not monochromatic. This establishes the correctness of protocol  $\mathcal{A}$  for  $\text{DISJOINTNESS}_R\left(\sqrt{T}, \frac{n}{\sqrt{T}}, p\right)$ . ◀

### 5 CONFLICT-SEP in VARAND model

Using a structural property of the graph, we design a simple algorithm to solve the CONFLICT-SEP problem in the VARAND model.

► **Theorem 5.1.** *Given any graph  $G = (V, E)$  and a coloring function  $f : V(G) \rightarrow [C]$  and a parameter  $\varepsilon > 0$  as input, there exists an algorithm that solves the CONFLICT-SEP problem in the VARAND streaming model using space  $\tilde{O}\left(\frac{|V|}{\sqrt{\varepsilon|E|}}\right)$  with high probability.*

Let  $G'$  denote the subgraph of  $G$  consisting of only monochromatic edges in  $G$ . The lemma stated below guarantees that either there exists a large matching of size at least  $\sqrt{\varepsilon m}$  in  $G'$  or there exists a vertex of degree at least  $\sqrt{\varepsilon m}$  in  $G'$ .

► **Lemma 5.2** ([16]). *Let  $G = (V, E)$  be a graph and  $f : V(G) \rightarrow [C]$  be a coloring function such that at least  $\varepsilon$  fraction of the edges of  $E(G)$  are known to be monochromatic. Then, either there is a matching of size at least  $\sqrt{\varepsilon m}$  or there exists a vertex of degree at least  $\sqrt{\varepsilon m}$  in the subgraph  $G'$  defined on the monochromatic edges of  $G$ .*

The algorithm is as simple as it can get. We sample independently and uniformly at random the vertices in stream with probability  $p = \min\{1, \frac{10 \log n}{\sqrt{m}}\}$ <sup>7</sup> and store these vertices along with their colors. Let  $S \subseteq V$  be the set of sampled vertices. When a vertex appears in a stream, we check if it forms a monochromatic edge with one of the stored vertices in  $S$ . At the end of the stream, the algorithm declares the graph to be properly colored (valid) if it can not find a monochromatic edge, else it declares the instance to be  $\varepsilon$ -far from being monochromatic.

We show that Theorem 5.1 follows easily using Lemma 5.2.

<sup>7</sup> For simplicity of presentation, we assumed that, the number of edges  $m$  in graph  $G$  is known before the stream starts. However, this assumption can be removed by a simple tweak of starting with a value of  $m$  and increasing it in stages and adjusting the random sample accordingly. This is common in streaming algorithms.

**Proof.** We consider the following two cases.

- Case 1 – There exists a matching of size at least  $\sqrt{\varepsilon m}$ : Note that all these matched edges are monochromatic. Let  $(u, v)$  denote an arbitrary matched edge where  $u$  appears in the stream before  $v$ . Now, the edge  $(u, v)$  will be detected as monochromatic if vertex  $u$  has been sampled by the algorithm. The probability that vertex  $u$  is sampled is  $\frac{10 \log n}{\sqrt{m}}$ . Since, there are  $\sqrt{\varepsilon m}$  matched monochromatic edges, the algorithm will detect at least one of these matched monochromatic edges with probability at least  $(1 - 1/n^2)$ .
- Case 2 – There exists a vertex of degree at least  $\sqrt{\varepsilon m}$ : In this case most of the monochromatic edges may be incident on very few high degree vertices. To detect these edges, we want to store either the high degree vertices or one of its neighbours. But, if these high degree vertices appear at the beginning of the stream and we fail to sample them, then we may not detect a monochromatic edge. This is where the *random order* of vertices arriving in the stream comes into play. Now, assuming random order of vertices in the stream, at least  $\frac{1}{5}\sqrt{\varepsilon m}$  neighbors of  $v$  should appear before  $v$  in the stream with probability at least  $(1 - e^{-\frac{9}{50}\sqrt{\varepsilon m}})$ . Since we sample every vertex with probability  $\frac{10 \log n}{\sqrt{m}}$ , with high probability at least  $(1 - 1/n^2)$  one of its neighbors will be stored. ◀

## 6 Conclusion and Discussion

In this paper, we introduced a graph coloring problem to streaming setting with a different flavor – the coloring function streams along with the graph. We study the problem of CONFLICT-EST (estimating the number of monochromatic edges) and CONFLICT-SEP (detecting a separation between the number of valid edges) in VA, VADEG, and VARAND models. Our algorithms for VA and VADEG are tight upto polylogarithmic factors. However, a matching lower bound on the space complexity for VARAND model is still elusive. There is a gap between our upper and lower bound results for VARAND model in terms of the exponent in  $T$ . Our hunch is that the upper bound is tight. Specifically, we obtained an upper bound of  $\tilde{O}\left(\frac{n}{\sqrt{T}}\right)$  and the lower bound is  $\Omega\left(\frac{n}{T^2}\right)$ . Here we would like to note that the lower bound also holds in AL and VADEG model when the vertices are exposed in a random order. However, we feel that our algorithm for CONFLICT-EST in VARAND model is tight upto polylogarithmic factors. We leave this problem open.

We feel the *edge coloring* counterpart of the vertex coloring problem proposed in the paper will be worthwhile to study. Let the edges of  $G$  be colored with a function  $f : E(G) \rightarrow [C]$ , for  $C \in \mathbb{N}$ . A vertex  $u \in V(G)$  is said to be a *validly* colored vertex if no two edges incident on  $u$  have the same color. An edge coloring is valid if all vertices are validly colored. Consider the AL model for the edge coloring problem. As all edges incident on an exposed vertex  $u$  are revealed in the stream, if we can solve a duplicate element finding problem on the colors of the edges incident on  $u$ , then we are done! It seems at a first glance that all the three models of VA, AL and EA will be difficult to handle for the edge coloring problem on streams of graph and edge colors. It would be interesting to see if the edge coloring variant of the problems we considered in this paper, admit efficient streaming algorithms. We plan to look at this problem next.

---

**A** Some probability results

► **Lemma A.1** ([12], Chernoff-Hoeffding bound). *Let  $X_1, \dots, X_n$  be independent random variables such that  $X_i \in [0, 1]$ . For  $X = \sum_{i=1}^n X_i$  and  $\mu = \mathbb{E}[X]$ , the following holds for any  $0 \leq \delta \leq 1$ :*

$$\mathbb{P}(|X - \mu| \geq \delta\mu) \leq 2 \exp\left(-\frac{\mu\delta^2}{3}\right)$$

► **Lemma A.2** ([24]). *Let  $I = \{1, \dots, N\}$ ,  $r \in [N]$  be a given parameter. If we sample a subset  $R$  without replacement, then the following holds for any  $J \subset I$  and  $\delta \in (0, 1)$ .*

- (i)  $\mathbb{P}(|J \cap R| \geq (1 + \delta)|J| \frac{r}{N}) \leq \exp\left(-\frac{\delta^2 |J| r}{3N}\right);$
- (ii)  $\mathbb{P}(|J \cap R| \leq (1 - \delta)|J| \frac{r}{N}) \leq \exp\left(-\frac{\delta^2 |J| r}{3N}\right);$
- (iii) *Further more, we have the following if  $|J| \leq k$ , then the following holds.*

$$\mathbb{P}(|J \cap R| \geq (1 + \delta)k \frac{r}{N}) \leq \exp\left(-\frac{\delta^2 k r}{3N}\right)$$

**B** Proof of Lemma 3.2

► **Lemma B.1** (Restatement of Lemma 3.2).

- (i) *For each  $j \in [t]$  with  $|B_j| \geq \frac{\sqrt{\varepsilon T}}{10t}$ ,  $\mathbb{P}\left(\left||B_j \cap R| - \frac{|R||B_j|}{n}\right| \geq \frac{\varepsilon}{10} \frac{|R||B_j|}{n}\right) \leq \frac{1}{n^{10}}.$*
- (ii) *For each  $j \in [t]$  with  $|B_j| < \frac{\sqrt{\varepsilon T}}{10t}$ ,  $\mathbb{P}\left(|B_j \cap R| \geq \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}\right) \leq \frac{1}{n^{10}}.$*
- (iii) *For each vertex  $v_i$  with  $d_M(v_i) \geq \frac{\sqrt{\varepsilon T}}{10t}$ ,  $\mathbb{P}\left(\left|\kappa_{v_i} - \frac{|R|d_M(v_i)}{n}\right| \geq \frac{\varepsilon}{10} \frac{|R|d_M(v_i)}{n}\right) \leq \frac{1}{n^{10}}.$*
- (iv) *For each vertex  $v_i$  with  $d_M(v_i) < \frac{\sqrt{\varepsilon T}}{10t}$ ,  $\mathbb{P}\left(\kappa_{v_i} \geq \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}\right) \leq \frac{1}{n^{10}}.$*

**Proof.** Let us take  $N = n, r = |R| = \Gamma = \tilde{\Theta}\left(\frac{n}{\sqrt{T}}\right)$ ,  $I = \{v_1, \dots, v_n\}$  in Lemma A.2.

- (i) Setting  $J = B_j$  and  $\delta = \frac{\varepsilon}{10}$  in Lemma A.2 (i) and (ii), we have

$$\mathbb{P}\left(\left||B_j \cap R| - \frac{|R||B_j|}{n}\right| \geq \frac{\varepsilon}{10} \frac{|R||B_j|}{n}\right) \leq 2 \exp\left(-\frac{(\varepsilon/10)^2 |B_j| \Gamma}{3n}\right) \leq \frac{1}{n^{10}}.$$

The last inequality holds as  $|B_j| \geq \frac{\sqrt{\varepsilon T}}{10t}$ ,  $t = \lceil \log_{1+\frac{\varepsilon}{10}} n \rceil = \Theta\left(\frac{\log n}{\varepsilon}\right)$  and  $\Gamma = \tilde{\Theta}\left(\frac{n}{\sqrt{T}}\right)$ .

- (ii) Set  $J = B_j$ ,  $k = \frac{\sqrt{\varepsilon T}}{10t}$ ,  $\delta = \frac{1}{4}$  in Lemma A.2 (iii). As  $|B_j| \leq \frac{\sqrt{\varepsilon T}}{10t}$ ,  $|J| \leq k$ . Hence,

$$\mathbb{P}\left(|B_j \cap R| \geq \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}\right) \leq \exp\left(-\frac{(1/4)^2 (\sqrt{\varepsilon T}/10t) \Gamma}{3n}\right) \leq \frac{1}{n^{10}}.$$

- (iii) Setting  $J$  as the set of monochromatic neighbors of  $v_i$  in  $R$  and  $\delta = \frac{\varepsilon}{10}$  in Lemma A.2 (i) and (ii), we get

$$\mathbb{P}\left(\left|\kappa_{v_i} - \frac{|R|d_M(v_i)}{n}\right| \geq \frac{\varepsilon}{10} \frac{|R|d_M(v_i)}{n}\right) \leq \exp\left(-\frac{(\varepsilon/10)^2 |J| \Gamma}{3n}\right) \leq \frac{1}{n^{10}}.$$

The last inequality holds as  $|J| = d_M(v_i) \geq \frac{\sqrt{\varepsilon T}}{10t}$ ,  $t = \lceil \log_{1+\frac{\varepsilon}{10}} n \rceil = \Theta\left(\frac{\log n}{\varepsilon}\right)$  and  $\Gamma = \tilde{\Theta}\left(\frac{n}{\sqrt{T}}\right)$ .

- (iv) Set  $J$  as the set of monochromatic neighbors of  $v_i$  in  $R$ ,  $k = \frac{\sqrt{\varepsilon T}}{10t}$ ,  $\delta = \frac{1}{4}$  in Lemma A.2 (iii). Note that  $|J| = d_M(v_i) \leq \frac{\sqrt{\varepsilon T}}{10t} = k$ . Hence,

$$\mathbb{P}\left(\kappa_{v_i} \geq \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}\right) \leq \exp\left(-\frac{(1/4)^2(\sqrt{\varepsilon T}/10t)\Gamma}{3n}\right) \leq \frac{1}{n^{10}}. \quad \blacktriangleleft$$

## C Communication Complexity

Communication Complexity [21] deals with finding the minimum amount of space that is needed to communicate in order to compute a function when the input to the function is distributed among multiple parties. For the purpose of our work, we are concerned with two player games with one-way communication protocol. The players are traditionally called Alice and Bob. Both of them have a  $n$ -bit input string and are unaware of each other's input. The goal is to minimize the bits Alice needs to communicate to Bob so that he can compute a function on both their inputs. No assumption is made on their computational powers and there is no restriction on the amount of time needed for computing the function.

### C.1 INDEX problem in the communication complexity model

Lower bound results in the streaming model of computation are proved by reduction from a problem in communication complexity model. We determine our lower bounds by considering a reduction from the INDEX problem in the one-way communication protocol for two players to the specific problem in graphs in the VA model. The INDEX problem is defined as follows: There are two parties, Alice and Bob. Alice has a  $N$ -bit input string  $X \in \{0, 1\}^N$  and Bob has an integer  $j \in [N]$ . Both are unaware of each other's input and the goal is to compute  $X_j$ , the  $j^{\text{th}}$  bit of  $X$ . The lower bound for space complexity to solve the INDEX problem in the one-way deterministic communication model is  $\Omega(N)$ .

► **Lemma C.1** ([21]). *The deterministic communication complexity of INDEX is  $\Omega(N)$*

## D Algorithm for CONFLICT-EST in VARAND model

- $\Gamma = \tilde{\Theta}\left(\frac{n}{\sqrt{T}}\right)$ ;  $v_1, \dots, v_n$  be the random ordering in which vertices are revealed and  $R = \{v_1, \dots, v_\Gamma\}$ ;
- $\kappa_{v_i}, i \in [n]$ , denotes the number of monochromatic neighbors of  $v_i$  in  $R$ ,
- $\widehat{d}_{v_i}, i \in [n]$ , denotes the (estimated) monochromatic neighbors of vertices in  $G$ .
- $H$  denotes the set of *high* degree vertex in  $R$ , i.e.,  $H = \{v_i : \kappa_{v_i} \geq \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}\}$  and  $L = V \setminus H$ ;  $L_R = L \cap R$  and  $H_R = H \cap R$ ;
- The vertices in  $L$  are partitioned into  $t$  buckets as follows:  
 $B_j = \{v_i \in L : (1 + \frac{\varepsilon}{10})^{j-1} \leq d_M(v_i) < (1 + \frac{\varepsilon}{10})^j\}$ , where  $j \in [t]$ .

■ **Algorithm 1** RANDOM-ORDER-EST( $\varepsilon, T$ ): CONFLICT-EST in VARAND model.

---

**Input:**  $G = (V, E)$  and a coloring function  $f$  on  $V$  in the VARAND model, parameters  $T$  and  $\varepsilon$ .

**Output:**  $\widehat{m}$ , that is, a  $(1 \pm \varepsilon)$  approximation to  $|E_M|$ .

Set  $t = \lceil \log_{1+\frac{\varepsilon}{10}} n \rceil$ . If  $T < 63t^2$ , then store all the vertices in  $G$  along with their colors. At the end, report the exact value of  $|E_M|$ . Otherwise, we proceed through via three building blocks described below and marked as (1),(2), (3) and (4). Refer to the notations described above this pseudocode.

(1) Processing the vertices in  $R$ , the first  $\Gamma$  vertices, in the stream:

**for** (each vertex  $v_i \in R$  exposed in the stream) **do**  
 | Store  $v_i$  as well as its color  $f(v_i)$ .  
 | For each edge  $(v_{i'}, v_i)$  that arrives in the stream, increase the values of  $\kappa_{v_{i'}}$  and  $\kappa_{v_i}$ .  
**end**

(2) Computation of some parameters based on vertices in  $R$  and their colors:

**for** (each  $v_i \in R$  with  $\kappa_{v_i} \geq \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}$ ) **do**  
 | Add  $v_i$  to  $H_R$ , and set  $\widehat{d}_{v_i} = \frac{n}{|R|} \kappa_{v_i}$ .  
**end**  
 $\widehat{m}_h = \sum_{v_i \in H} \widehat{d}_{v_i}$ .  
 Let  $L_R = R \setminus H_R$ .  
**for** (each  $v_i \in L_R$ ) **do**  
 | Set  $\widehat{d}_{v_i} = \kappa_{v_i}$ .  
**end**

(3) Processing the vertices in  $V(G) \setminus R$  in the stream:

**for** (each vertex  $v_i \notin R$  exposed in the stream) **do**  
 | Determine the value of  $\kappa_{v_i}$ . If  $\kappa_{v_i} \geq \frac{|R|}{n} \frac{\sqrt{\varepsilon T}}{8t}$ , find  $\widehat{d}_{v_i} = \frac{n}{|R|} \kappa_{v_i}$  and add  $\widehat{d}_{v_i}$  to the current  $\widehat{m}_h$ .  
 | Also, for each  $v_{i'} \in L_R$ , increase the value of  $\widehat{d}_{v_{i'}}$  if  $(v_{i'}, v_i)$  is an edge.  
**end**

(4) Post processing, after the stream ends, to return the output:

From the values of  $\widehat{d}_{v_i}$  for all  $v_i \in L_R$ , determine the buckets for each vertex in  $L_R$ . Also, for each  $j \in [t]$ , find  $|A_j| = |L_R \cap B_j|$ . Then determine

$$\widehat{m}_\ell = \frac{n}{|R|} \sum_{j \in [t]} |A_j| \left(1 + \frac{\varepsilon}{10}\right)^j.$$

Report  $\widehat{m} = \frac{\widehat{m}_h + \widehat{m}_\ell}{2}$  as the final OUTPUT.

---

**E** Algorithm for CONFLICT-SEP in VARAND model**Algorithm 2** Algorithm: CONFLICT-SEP in VERTEX ARRIVAL IN RANDOM ORDER model**Input:**  $G = (V, E)$  and a coloring function  $f$  on  $V$  in the VARAND model**Output:** The algorithm verifies if  $f$  is  $\varepsilon$ -far from valid or notLet  $S$  be the set of stored vertices and their colors. Initially,  $S$  is empty. **for**  $i \leftarrow 1$  **to**  $|V|$  **do**    let  $u$  be the  $i^{th}$  vertex of the stream    Store  $u$  and its color  $f(u)$  in  $S$  with probability  $\mathcal{O}\left(\frac{\log n}{\sqrt{m}}\right)$     **for every vertex**  $v$  **in**  $S$  **do**        Check if  $(v, u)$  is an edge and  $f(v) = f(u)$     **end****end**Output  $f$  is valid if none of the edges sampled are conflicting, else output that  $f$  is  $\varepsilon$ -far from being valid.

# The Variable-Processor Cup Game

## Abstract

The problem of scheduling tasks on  $p$  processors so that no task ever gets too far behind is often described as a game with cups and water. In the  $p$ -processor cup game on  $n$  cups, there are two players, a filler and an emptier, that take turns adding and removing water from a set of  $n$  cups. In each turn, the filler adds  $p$  units of water to the cups, placing at most 1 unit of water in each cup, and then the emptier selects  $p$  cups to remove up to 1 unit of water from. The emptier's goal is to minimize the backlog, which is the height of the fullest cup.

The  $p$ -processor cup game has been studied in many different settings, dating back to the late 1960's. All of the past work shares one common assumption: that  $p$  is fixed. This paper initiates the study of what happens when the number of available processors  $p$  varies over time, resulting in what we call the *variable-processor cup game*.

Remarkably, the optimal bounds for the variable-processor cup game differ dramatically from its classical counterpart. Whereas the  $p$ -processor cup has optimal backlog  $\Theta(\log n)$ , the variable-processor game has optimal backlog  $\Theta(n)$ . Moreover, there is an efficient filling strategy that yields backlog  $\Omega(n^{1-\epsilon})$  in quasi-polynomial time against any deterministic emptying strategy.

We additionally show that straightforward uses of randomization cannot be used to help the emptier. In particular, for any positive constant  $\Delta$ , and any  $\Delta$ -greedy-like randomized emptying algorithm  $\mathcal{A}$ , there is a filling strategy that achieves backlog  $\Omega(n^{1-\epsilon})$  against  $\mathcal{A}$  in quasi-polynomial time.

## 1 Introduction

A fundamental challenge in processor scheduling is how to perform load balancing, that is, how to share processors among tasks in order to keep any one task from getting too far behind. Consider  $n$  tasks executing in time slices on  $p < n$  processors. During each time slice,

Leibniz International Proceedings in Informatics  
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

a scheduler must select  $p$  (distinct) tasks that will be executed during the slice; up to one unit of work is completed on each executed task. During the same time slice, however, up to  $p$  units of *new work* may be allocated to the tasks, with different tasks receiving different amounts of work. The goal of a load-balancing scheduler is to bound the backlog of the system, which is defined to be the maximum amount of uncompleted work for any task.

As a convention, the load balancing problem is often described as a game involving water and cups. The  **$p$ -processor cup game** is a multi-round game with two players, an **emptier** and a **filler**, that takes place on  $n$  initially empty cups. At the beginning of each round, the filler adds up to  $p$  units of water to the cups, subject to the constraint that each cup receives at most 1 unit of water. The emptier then selects up to  $p$  distinct cups and removes up to 1 unit of water from each of them. The emptier's goal is to minimize the amount of water in the fullest cup, also known as the **backlog**. In terms of processor scheduling, the cups represent tasks, the water represents work assigned to each task, and the emptier represents a scheduling algorithm.

Starting with the seminal paper of Liu [31], work on the  $p$  processor cup game has spanned more than five decades [7, 21, 8, 30, 28, 34, 6, 24, 31, 32, 17, 10, 26, 1, 16, 29]. In addition to processor scheduling [7, 21, 8, 30, 28, 34, 6, 24, 31, 32, 1, 29, 17], applications include network-switch buffer management [22, 4, 36, 20], quality of service guarantees [7, 1, 29], and data structure deamortization [2, 17, 16, 3, 35, 23, 18, 25, 9].

The game has also been studied in many different forms. Researchers have studied the game with a fixed-filling-rate constraint [7, 21, 8, 30, 28, 34, 6, 24, 31, 32], with various forms of resource augmentation [10, 26, 29, 17], with both oblivious and adaptive adversaries [1, 7, 31, 10, 26, 11], with smoothed analysis [26, 10], with a semi-clairvoyant emptier [29], with competitive analysis [5, 19, 15], etc.

For the plain form of the  $p$ -processor cup game, the greedy emptying algorithm (i.e., always empty from the fullest cups) is known to be asymptotically optimal [1, 10, 26], achieving backlog  $O(\log n)$ . The optimal backlog for randomized emptying algorithms remains an open question [17, 10, 26] and is known to be between  $\Omega(\log \log n)$  and  $O(\log \log n + \log p)$  [26].

### This paper: varying resources

Although cup games have been studied in many forms, all of the prior work on cup games shares one common assumption: the number  $p$  of processors is fixed.

In modern computing, however, computers are often shared among multiple applications, users, and even virtual OS's. The result is that the amount of resources (e.g., memory, processors, cache, etc.) available to a given application may fluctuate over time. The problem of handling cache fluctuations has received extensive attention in recent years (see work on cache-adaptive analysis [33, 12, 13, 14, 27]), but the problem of handling a varying number of processors remains largely unstudied.

This paper introduces the **variable-processor cup game**, in which the filler is allowed to *change*  $p$  (the total amount of water that the filler adds, and the emptier removes, from the cups per round) at the beginning of each round. Note that we do not allow the resources of the filler and emptier to vary separately. That is, as in the standard game, we take the value of  $p$  for the filler and emptier to be identical in each round. This restriction is crucial since, if the filler is allowed more resources than the emptier, then the filler could trivially achieve unbounded backlog.

A priori having variable resources offers neither player a clear advantage. When the number  $p$  of processors is fixed, the greedy emptying algorithm (i.e., always empty from the fullest cups), is known to achieve backlog  $O(\log n)$  [1, 10, 26] regardless of the value of  $p$ .

This seems to suggest that, when  $p$  varies, the correct backlog should remain  $O(\log n)$ . In fact, when we began this project, we hoped for a straightforward reduction between the two versions of the game.

## Results

We show that the variable-processor cup game is *not* equivalent to the standard  $p$ -processor game. By strategically controlling the number  $p$  of processors, the filler can achieve substantially larger backlog than would otherwise be possible.

We begin by constructing filling strategies against deterministic emptying algorithms. We show that for any positive constant  $\varepsilon$ , there is a filling strategy that achieves backlog  $\Omega(n^{1-\varepsilon})$  within  $2^{\text{polylog}(n)}$  rounds. Moreover, if we allow for  $n!$  rounds, then there is a filling strategy that achieves backlog  $\Omega(n)$ . In contrast, for the  $p$ -processor cup game with any fixed  $p$ , the backlog never exceeds  $O(\log n)$ .

Our lower-bound construction is asymptotically optimal. By introducing a novel set of invariants, we deduce that the greedy emptying algorithm never lets backlog exceed  $O(n)$ .

A natural question is whether *randomized* emptying algorithms can do better. In particular, when the emptier is randomized, the filler is taken to be **oblivious**, meaning that the filler cannot see what the emptier does at each step. Thus the emptier can potentially use randomization to obfuscate their behavior from the filler, preventing the filler from being able to predict the heights of cups.

When studying randomized emptying strategies, we restrict ourselves to the class of **greedy-like emptying strategies**. This means that the emptier never chooses to empty from a cup  $c$  over another cup  $c'$  whose fill is more than  $\omega(1)$  greater than the fill of  $c$ . All of the known randomized emptying strategies for the classic  $p$ -processor cup game are greedy-like [10, 26].

Remarkably, the power of randomization does not help the emptier very much in the variable-processor cup game. For any constant  $\varepsilon > 0$ , we give an oblivious filling strategy that achieves backlog  $\Omega(n^{1-\varepsilon})$  in quasi-polynomial time (with probability  $1 - 2^{-\text{polylog } n}$ ), no matter what (possibly randomized) greedy-like strategy the emptier follows.

Our results combine to tell a surprising story. They suggest that the problem of varying resources poses a serious theoretical challenge for the design and analysis of load-balancing scheduling algorithms. There are many possible avenues for future work. Can techniques from beyond worst-case analysis (e.g., smoothing, resource augmentation, etc.) be used to achieve better bounds on backlog? What about placing restrictions on the filler (e.g., bounds on how fast  $p$  can change), allowing the emptier to be able to be semi-clairvoyant, or making stochastic assumptions on the filler? We believe that all of these questions warrant further attention.

## Paper outline

In Section 2 we establish the conventions and notations that we will use to discuss the variable-processor cup game. In Section 3 we analyze the greedy emptying algorithm, showing that it achieves backlog  $O(n)$ . We then turn our attention to designing (both oblivious and adaptive) filling strategies that achieve large backlog. Section 4 gives a technical overview of the filling strategies and their analyses. Section 5 then gives a full treatment of the filling strategies in the case where the filler is adaptive; the full treatment of the case where the filler is oblivious is deferred to the extended version of this paper.

## 2 Preliminaries

The cup game consists of a sequence of rounds. Let  $S_t$  denote the state of the cups at the start of round  $t$ . At the beginning of the round, the filler chooses the number of processors  $p_t$  for the round. Next, the filler distributes  $p_t$  units of water among the cups (with at most 1 unit of water to any particular cup). Now the game is at the **intermediate state** for round  $t$ , which we call state  $I_t$ . Finally the emptier chooses  $p_t$  cups to empty at most 1 unit of water from, which marks the conclusion of round  $t$ . The state is then  $S_{t+1}$ .

If the emptier empties from a cup  $c$  on round  $t$  such that the fill of  $c$  is less than 1 in state  $I_t$ , then  $c$  now has 0 fill (not negative fill); we say that the emptier **zeroes out**  $c$  on round  $t$ . Note that on any round where the emptier zeroes out a cup the emptier has removed less total fill from the cups than the filler has added to the cups; hence the average fill of the cups has increased.

We denote the fill of a cup  $c$  at state  $S$  by  $\text{fill}_S(c)$ . Let the **mass** of a set of cups  $X$  at state  $S$  be  $m_S(X) = \sum_{c \in X} \text{fill}_S(c)$ . Denote the average fill of a set of cups  $X$  at state  $S$  by  $\mu_S(X)$ .<sup>1</sup> Note that  $\mu_S(X)|X| = m_S(X)$ . Let the **backlog** at state  $S$  be  $\max_c \text{fill}_S(c)$ , let the **anti-backlog** at state  $S$  be  $\min_c \text{fill}_S(c)$ . Let the **rank** of a cup at a given state be its position in the list of the cups sorted by fill at the given state, breaking ties arbitrarily but consistently. For example, the fullest cup at a state has rank 1, and the least full cup has rank  $n$ . Let  $[n] = \{1, 2, \dots, n\}$ , let  $i + [n] = \{i + 1, i + 2, \dots, i + n\}$ . For a state  $S$ , let  $S(r)$  denote the rank  $r$  cup at state  $S$ , and let  $S(\{r_1, r_2, \dots, r_m\})$  denote the set of cups of ranks  $r_1, r_2, \dots, r_m$ .

As a tool in the analysis we define a new variant of the cup game: the **negative-fill** cup game. In the negative-fill cup game, when the emptier empties from a cup, the cup's fill always decreases by exactly 1, i.e. there is no zeroing out. We refer to the standard version of the cup game where cups can zero out as the **standard-fill** cup game.

The notion of negative fill will be useful in our lower-bound constructions, in which we want to construct a strategy for the filler that achieves large backlog. By analyzing a filling strategy on the negative-fill game, we can then reason about what happens if we apply the same filling strategy recursively to a set of cups  $S$  whose average fill  $\mu$  is larger than 0; in the recursive application, the average fill  $\mu$  acts as the “new 0”, and fills less than  $\mu$  act as negative fills.

Note that it is strictly easier for the filler to achieve high backlog in the standard-fill cup game than in the negative-fill cup game; hence a lower bound on backlog in the negative-fill cup game also serves as a lower bound on backlog in the standard-fill cup game. On the other hand, during the upper bound proof we use the standard-fill cup game: this makes it harder for the emptier to guarantee its upper bound.

### Other Conventions

When discussing the state of the cups **at a round  $t$** , we will take it as given that we are referring to the starting state  $S_t$  of the round. Also, when discussing sets, we will use  $XY$  as a shorthand for  $X \cup Y$ . Finally, when discussing the average fill  $\mu_{S_t}(X)$  of a set of cups, we will sometimes omit the subscript  $S_t$  when the round number is clear.

<sup>1</sup> For both mass and average fill, in cases where  $S$  is clear from context, we may omit the subscript, writing  $m(X)$  or  $\mu(X)$ .

### 3 Upper Bound

In this section we analyze the **greedy emptier**, which always empties from the  $p$  fullest cups. We prove in Corollary 2 that the greedy emptier prevents backlog from exceeding  $O(n)$ . In order to analyze the greedy emptier, we establish a system of invariants that hold at every step of the game.

The main result of the section is the following theorem.

► **Theorem 1.** *In the variable-processor cup game on  $n$  cups, the greedy emptier maintains, at every step  $t$ , the invariants*

$$\mu_{S_t}(S_t([k])) \leq 2n - k \quad (1)$$

for all  $k \in [n]$ .

By applying Theorem 1 to the case of  $k = 1$ , we arrive at a bound on backlog:

► **Corollary 2.** *In the variable-processor cup game on  $n$  cups, the greedy emptying strategy never lets backlog exceed  $O(n)$ .*

**Proof of Theorem 1.** We prove the invariants by induction on  $t$ . The invariants hold trivially for  $t = 1$  (the base case for the inductive proof): the cups start empty so  $\mu_{S_1}(S_1([k])) = 0 \leq 2n - k$  for all  $k \in [n]$ .

Fix a round  $t \geq 1$ , and any  $k \in [n]$ . We assume the invariant for all values of  $k' \in [n]$  for state  $S_t$  (we will only explicitly use two of the invariants for each  $k$ , but the invariants that we need depend on the choice of  $p_t$  by the filler) and show that the invariant on the  $k$  fullest cups holds on round  $t + 1$ , i.e. that

$$\mu_{S_{t+1}}(S_{t+1}([k])) \leq 2n - k.$$

Note that because the emptier is greedy it always empties from the cups  $I_t([p_t])$ . Let  $A$ , with  $a = |A|$ , be  $A = I_t([\min(k, p_t)]) \cap S_{t+1}([k])$ ;  $A$  consists of the cups that are among the  $k$  fullest cups in  $I_t$ , are emptied from, and are among the  $k$  fullest cups in  $S_{t+1}$ . Let  $B$ , with  $b = |B|$ , be  $B = I_t([\min(k, p_t)]) \setminus A$ ;  $B$  consists of the cups that are among the  $k$  fullest cups in state  $I_t$ , are emptied from, and are not among the  $k$  fullest cups in  $S_{t+1}$ . Let  $C = I_t(a + b + [k - a])$ , with  $c = k - a = |C|$ ;  $C$  consists of the cups with ranks  $a + b + 1, \dots, k + b$  in state  $I_t$ . The set  $C$  is defined so that  $S_{t+1}([k]) = AC$ , since once the cups in  $B$  are emptied from, the cups in  $B$  are not among the  $k$  fullest cups, so cups in  $C$  take their places among the  $k$  fullest cups.

Note that  $k - a \geq 0$  as  $a + b \leq k$ , and also  $|ABC| = k + b \leq n$ , because by definition the  $b$  cups in  $B$  must not be among the  $k$  fullest cups in state  $S_{t+1}$  so there are at least  $k + b$  cups. Note that  $a + b = \min(k, p_t)$ . We also have that  $A = I_t([a])$  and  $B = I_t(a + [b])$ , as every cup in  $A$  must have higher fill than all cups in  $B$  in order to remain above the cups in  $B$  after 1 unit of water is removed from all cups in  $AB$ .

We now establish the following claim, which we call the **interchangeability of cups**:

► **Claim 3.** There exists a cup state  $S'_t$  such that: (a)  $S'_t$  satisfies the invariants (1), (b)  $S'_t(r) = I_t(r)$  for all ranks  $r \in [n]$ , and (c) the filler can legally place water into cups in order to transform  $S'_t$  into  $I_t$ .

**Proof.** Fix  $r \in [n]$ . We will show that  $S_t$  can be transformed into a state  $S'_t$  by relabelling only cups with ranks in  $[r]$  such that (a)  $S'_t$  satisfies the invariants (1), (b)  $S'_t([r]) = I_t([r])$  and (c) the filler can legally place water into cups in order to transform  $S'_t$  into  $I_t$ .

## 16:6 The Variable-Processor Cup Game

Say there are cups  $x, y$  with  $x \in S_t([r]) \setminus I_t([r]), y \in I_t([r]) \setminus S_t([r])$ . Let the fills of cups  $x, y$  at state  $S_t$  be  $f_x, f_y$ ; note that

$$f_x > f_y. \quad (2)$$

Let the amount of fill that the filler adds to these cups be  $\Delta_x, \Delta_y \in [0, 1]$ ; note that

$$f_x + \Delta_x < f_y + \Delta_y. \quad (3)$$

Define a new state  $S'_t$  where cup  $x$  has fill  $f_y$  and cup  $y$  has fill  $f_x$ . Note that the filler can transform state  $S'_t$  into state  $I_t$  by placing water into cups as before, except changing the amount of water placed into cups  $x$  and  $y$  to be  $f_x - f_y + \Delta_x$  and  $f_y - f_x + \Delta_y$ , respectively.

In order to verify that the transformation from  $S'_t$  to  $I_t$  is a valid step for the filler, one must check three conditions. First, the amount of water placed by the filler is unchanged: this is because  $(f_x - f_y + \Delta_x) + (f_y - f_x + \Delta_y) = \Delta_x + \Delta_y$ . Second, the fills placed in cups  $x$  and  $y$  are at most 1: this is because  $f_x - f_y + \Delta_x < \Delta_y \leq 1$  (by (3)) and  $f_y - f_x + \Delta_x < \Delta_x \leq 1$  (by (2)). Third, the fills placed in cups  $x$  and  $y$  are non-negative: this is because  $f_x - f_y + \Delta_x > \Delta_x \geq 0$  (by (2)) and  $f_y - f_x + \Delta_y > \Delta_y \geq 0$  (by (3)).

We can repeatedly apply this process to swap each cup in  $I_t([r]) \setminus S_t([r])$  into being in  $S'_t([r])$ . At the end of this process we will have some state  $S'_t$  for which  $S'_t([r]) = I_t([r])$ . Note that  $S'_t$  is simply a relabeling of  $S_t$ , hence it must satisfy the same invariants (1) satisfied by  $S_t$ . Further,  $S'_t$  can be transformed into  $I_t$  by a valid filling step.

Now we repeatedly apply this process, in descending order of ranks. In particular, we have the following process: create a sequence of states by starting with  $S_t^{n-1}$ , and to get to state  $S_t^r$  from state  $S_t^{r+1}$  apply the process described above. Note that  $S_t^{n-1}$  satisfies  $S_t^{n-1}([n-1]) = I_t([n-1])$  and thus also  $S_t^{n-1}(n) = I_t(n)$ . If  $S_t^{r+1}$  satisfies  $S_t^{r+1}(r') = I_t(r')$  for all  $r' > r+1$  then  $S_t^r$  satisfies  $S_t^r(r') = I_t(r')$  for all  $r' > r$ , because the transition from  $S_t^{r+1}$  to  $S_t^r$  has not changed the labels of any cups with ranks in  $(r+1, n]$ , but the transition does enforce  $S_t^r([r]) = I_t([r])$ , and consequently  $S_t^r(r+1) = I_t(r+1)$ . We continue with the sequential process until arriving at state  $S_t^1$  in which we have  $S_t^1(r) = I_t(r)$  for all  $r$ . Throughout the process each  $S_t^r$  has satisfied the invariants (1), so  $S_t^1$  satisfies the invariants (1). Further, throughout the process from each  $S_t^r$  it is possible to legally place water into cups in order to transform  $S_t^r$  into  $I_t$ .

Hence  $S_t^1$  satisfies all the properties desired, and the proof of Claim 3 is complete.  $\triangleleft$

Claim 3 tells us that we may assume without loss of generality that  $S_t(r) = I_t(r)$  for each rank  $r \in [n]$ . We will make this assumption for the rest of the proof.

In order to complete the proof of the theorem, we break it into three cases.

$\triangleright$  **Claim 4.** If some cup in  $A$  zeroes out in round  $t$ , then the invariant  $\mu_{S_{t+1}}(S_{t+1}([k])) \leq 2n-k$  holds.

**Proof.** Say a cup in  $A$  zeroes out in step  $t$ . Of course

$$m_{S_{t+1}}(I_t([a-1])) \leq (a-1)(2n-(a-1))$$

because the  $a-1$  fullest cups must have satisfied the invariant (with  $k = a-1$ ) on round  $t$ . Moreover, because  $\text{fill}_{S_{t+1}}(I_{t+1}(a)) = 0$

$$m_{S_{t+1}}(I_t([a])) = m_{S_{t+1}}(I_t([a-1])).$$

Combining the above equations, we get that

$$m_{S_{t+1}}(A) \leq (a-1)(2n-(a-1)).$$

Furthermore, the fill of all cups in  $C$  must be at most 1 at state  $I_t$  to be less than the fill of the cup in  $A$  that zeroed out. Thus,

$$\begin{aligned}
 m_{S_{t+1}}(S_{t+1}([k])) &= m_{S_{t+1}}(AC) \\
 &\leq (a-1)(2n-(a-1)) + k - a \\
 &= a(2n-a) + a - 2n + a - 1 + k - a \\
 &= a(2n-a) + (k-n) + (a-n) - 1 \\
 &< a(2n-a)
 \end{aligned}$$

as desired. As  $k$  increases from 1 to  $n$ ,  $k(2n-k)$  strictly increases (it is a quadratic in  $k$  that achieves its maximum value at  $k = n$ ). Thus  $a(2n-a) \leq k(2n-k)$  because  $a \leq k$ . Therefore,

$$m_{S_{t+1}}(S_{t+1}([k])) \leq k(2n-k). \quad \triangleleft$$

▷ **Claim 5.** If no cups in  $A$  zero out in round  $t$  and  $b = 0$ , then the invariant  $\mu_{S_{t+1}}(S_{t+1}([k])) \leq 2n - k$  holds.

Proof. If  $b = 0$ , then  $S_{t+1}([k]) = S_t([k])$ . During round  $t$  the emptier removes  $a$  units of fill from the cups in  $S_t([k])$ , specifically the cups in  $A$ . The filler cannot have added more than  $k$  fill to these cups, because it can add at most 1 fill to any given cup. Also, the filler cannot have added more than  $p_t$  fill to the cups because this is the total amount of fill that the filler is allowed to add. Hence the filler adds at most  $\min(p_t, k) = a + b = a + 0 = a$  fill to these cups. Thus the invariant holds:

$$m_{S_{t+1}}(S_{t+1}([k])) \leq m_{S_t}(S_t([k])) + a - a \leq k(2n-k). \quad \triangleleft$$

The remaining case, in which no cups in  $A$  zero out and  $b > 0$  is the most technically interesting.

▷ **Claim 6.** If no cups in  $A$  zero out on round  $t$  and  $b > 0$ , then the invariant  $\mu_{S_{t+1}}(S_{t+1}([k])) \leq 2n - k$  holds.

Proof. Because  $b > 0$  and  $a + b \leq k$  we have that  $a < k$ , and  $c = k - a > 0$ . Recall that  $S_{t+1}([k]) = AC$ , so the mass of the  $k$  fullest cups at  $S_{t+1}$  is the mass of  $AC$  at  $S_t$  plus any water added to cups in  $AC$  by the filler, minus any water removed from cups in  $AC$  by the emptier. The emptier removes exactly  $a$  units of water from  $AC$ . The filler adds no more than  $p_t$  units of water to  $AC$  (because the filler adds at most  $p_t$  total units of water per round) and the filler also adds no more than  $k = |AC|$  units of water to  $AC$  (because the filler adds at most 1 unit of water to each of the  $k$  cups in  $AC$ ). Thus, the filler adds no more than  $a + b = \min(p_t, k)$  units of water to  $AC$ . Combining these observations we have:

$$m_{S_{t+1}}(S_{t+1}([k])) \leq m_{S_t}(AC) + b. \quad (4)$$

The key insight necessary to bound this is to notice that larger values for  $m_{S_t}(A)$  correspond to smaller values for  $m_{S_t}(C)$  because of the invariants; the higher fill in  $A$  **pushes down** the fill that  $C$  can have. By capturing the pushing-down relationship combinatorially we will achieve the desired inequality.

We can upper bound  $m_{S_t}(C)$  by

$$\begin{aligned}
 m_{S_t}(C) &\leq \frac{c}{b+c} m_{S_t}(BC) \\
 &= \frac{c}{b+c} (m_{S_t}(ABC) - m_{S_t}(A))
 \end{aligned}$$

## 16:8 The Variable-Processor Cup Game

because  $\mu_{S_t}(C) \leq \mu_{S_t}(B)$  without loss of generality by the interchangeability of cups. Thus we have

$$m_{S_t}(AC) \leq m_{S_t}(A) + \frac{c}{b+c} m_{S_t}(BC) \quad (5)$$

$$= \frac{c}{b+c} m_{S_t}(ABC) + \frac{b}{b+c} m_{S_t}(A). \quad (6)$$

Note that the expression in (6) is monotonically increasing in both  $\mu_{S_t}(ABC)$  and  $\mu_{S_t}(A)$ . Thus, by numerically replacing both average fills with their extremal values,  $2n - |ABC|$  and  $2n - |A|$ . At this point the claim can be verified by straightforward (but quite messy) algebra (and by combining (4) with (6)). We instead give a more intuitive argument, in which we examine the right side of (5) combinatorially.

Consider a new configuration of fills  $F$  achieved by starting with state  $S_t$ , and moving water from  $BC$  into  $A$  until  $\mu_F(A) = 2n - |A|$ .<sup>2</sup> This transformation increases (strictly increases if and only if we move a non-zero amount of water) the right side of (5). In particular, if mass  $\Delta \geq 0$  fill is moved from  $BC$  to  $A$ , then the right side of (5) increases by  $\frac{b}{b+c} \Delta \geq 0$ . Note that the fact that moving water from  $BC$  into  $A$  increases the right side of (5) formally captures the way the system of invariants being proven forces a tradeoff between the fill in  $A$  and the fill in  $BC$  – that is, higher fill in  $A$  pushes down the fill that  $BC$  (and consequently  $C$ ) can have.

Since  $\mu_F(A)$  is above  $\mu_F(ABC)$ , the greater than average fill of  $A$  must be counter-balanced by the lower than average fill of  $BC$ . In particular we must have

$$(\mu_F(A) - \mu_F(ABC))|A| = (\mu_F(ABC) - \mu_F(BC))|BC|.$$

Note that

$$\begin{aligned} & \mu_F(A) - \mu_F(ABC) \\ &= (2n - |A|) - \mu_F(ABC) \\ &\geq (2n - |A|) - (2n - |ABC|) \\ &= |BC|. \end{aligned}$$

Hence we must have

$$\mu_F(ABC) - \mu_F(BC) \geq |A|.$$

Thus

$$\mu_F(BC) \leq \mu_F(ABC) - |A| \leq 2n - |ABC| - |A|. \quad (7)$$

Combining (5) with the fact that the transformation from  $S_t$  to  $F$  only increases the right side of (5), along with (7), we have the following bound:

$$\begin{aligned} m_{S_t}(AC) &\leq m_F(A) + c\mu_F(BC) \\ &\leq a(2n - a) + c(2n - |ABC| - a) \\ &\leq (a + c)(2n - a) - c(a + c + b) \\ &\leq (a + c)(2n - a - c) - cb. \end{aligned} \quad (8)$$

---

<sup>2</sup> Note that whether or not  $F$  satisfies the invariants is irrelevant.

By (4) and (8), we have that

$$\begin{aligned}
 m_{S_{t+1}}(S_{t+1}([k])) &\leq m_{S_t}(AC) + b \\
 &\leq (a + c)(2n - a - c) - cb + b \\
 &= k(2n - k) - cb + b \\
 &\leq k(2n - k),
 \end{aligned}$$

where the final inequality uses the fact that  $c \geq 1$ . This completes the proof of the claim.  $\triangleleft$

We have shown the invariant holds for arbitrary  $k$ , so given that the invariants all hold at state  $S_t$  they also must all hold at state  $S_{t+1}$ . Thus, by induction we have the invariant for all rounds  $t \in \mathbb{N}$ .  $\blacktriangleleft$

## 4 Technical overview of lower bounds

The rest of the paper is devoted to the construction of filler strategies that match (or nearly match) the upper bound in Section 3.

This section gives a technical overview of the main technical ideas used in the filler constructions. Full versions of the constructions are given in Section 5 (for adaptive fillers) and in the extended version of this paper (for oblivious fillers).

### 4.1 Adaptive Lower Bound

In Section 5 we provide an adaptive filling strategy that achieves backlog  $\Omega(n^{1-\epsilon})$ ; in this subsection we sketch the proof of the result.

First we note that there is a trivial algorithm, that we call **trivalg**, for achieving backlog at least  $1/2$  on at least 2 cups in time  $O(1)$ .

The essential ingredient in our lower-bound construction is what we call the **Amplification Lemma**. The lemma takes as input a filling strategy that achieves some backlog curve  $f$  (i.e., on  $n$  cups, the strategy achieves backlog  $f(n)$ ), and outputs a new filling strategy that achieves a new amplified backlog curve  $f'$ .

► **Lemma 7** (Lemma 12). *Let  $\text{alg}(f)$  be a filling strategy that achieves backlog  $f(n)$  on  $n$  cups (in the negative-fill cup game). There exists a filling strategy  $\text{alg}(f')$ , the **amplification** of  $\text{alg}(f)$ , that achieves backlog at least*

$$f'(n) \geq (1 - \delta)f(\lfloor (1 - \delta)n \rfloor) + f(\lceil \delta n \rceil).$$

**Proof Sketch.** The filler designates an **anchor set**  $A$  of size  $\lceil \delta n \rceil$  and a **non-anchor set**  $B$  of size  $\lfloor (1 - \delta)n \rfloor$ .

The filler's strategy begins with  $M$  phases, for some parameter  $M$  to be determined later. In each phase, the filler applies  $\text{alg}(f)$  to the non-anchor set  $B$ , while simultaneously placing 1 unit of water into each cup of  $A$  on each step. If there is ever a step during the phase in which the emptier does not remove water from every cup in  $A$ , then the phase is said to be **emptier neglected**. On the other hand, if a phase is not emptier neglected, then at the end of the phase, the filler swaps the cup in  $B$  with largest fill with the cup in  $A$  whose fill is smallest.

After the  $M$  phases are complete, the filler then recursively applies  $\text{alg}(f)$  to the cups  $A$ . This completes the filling strategy  $\text{alg}(f')$ .

The key to analyzing  $\text{alg}(f')$  is to show that, at the end of the  $M$ -th phase, the average fill of the cups  $A$  satisfies  $\mu(A) \geq (1 - \delta)f(|B|)$ . This, in turn, means that the recursive application of  $\text{alg}(f)$  to  $A$  will achieve backlog  $(1 - \delta)f(|B|) + f(|A|)$ , as desired.

Now let us reason about  $\mu(A)$ . If a phase is emptier neglected, then the total amount of water placed into  $A$  during the phase is at least 1 greater than the total amount of water removed. Hence  $\mu(A)$  increases by at least  $1/|A|$ . On the other hand, if a phase is not emptier neglected, then  $\text{alg}(f)$  will successfully achieve backlog  $\mu(B) + f(|B|)$  on the cups  $B$  during the phase. At the end of the phase, the filler will then swap a cup from  $B$  with large fill with a cup from  $A$ . Thus, in each phase, we either have that  $\mu(A)$  increases by  $1/|A|$ , or that a cup with large fill gets swapped into  $A$ . After sufficiently many phases, one can show that  $\mu(A)$  is guaranteed to become at least  $(1 - \delta)f(|B|) + f(|A|)$ . ◀

We use the Amplification Lemma to give two lower bounds on backlog: one with reasonable running time, the other with slightly better backlog.

► **Theorem 8** (Theorem 13). *There is an adaptive filling strategy for achieving backlog  $\Omega(n^{1-\varepsilon})$  for constant  $\varepsilon \in (0, 1/2)$  in running time  $2^{O(\log^2 n)}$ .*

**Proof Sketch.** We construct a sequence of filling strategies with  $\text{alg}(f_{i+1})$  the amplification of  $\text{alg}(f_i)$  using  $\delta = \Theta(1)$  determined as a function of  $\varepsilon$ , and  $\text{alg}(f_0) = \text{trivalg}$ . Choosing  $\delta$  appropriately as a function of  $\varepsilon$ , and letting  $c$  be some (small) positive constant, we show by induction on  $i$  that, for all  $k \leq 2^{ci}$ ,  $\text{alg}(f_i)$  achieves backlog  $\Omega(k^{1-\varepsilon})$  on  $k$  cups in running time  $2^{O(\log^2 k)}$ . Taking  $i = \Theta(\log n)$  completes the proof. ◀

► **Theorem 9** (Theorem 15). *There is an adaptive filling strategy for achieving backlog  $\Omega(n)$  in running time  $O(n!)$ .*

**Proof Sketch.** We construct a sequence of filling strategies with  $\text{alg}(f_{i+1})$  the amplification of  $\text{alg}(f_i)$  using  $\delta = 1/(i+1)$ , and  $\text{alg}(f_0)$  a filling strategy for achieving backlog 1 on  $O(1)$  cups in  $O(1)$  time (this is a slight modification of  $\text{trivalg}$ ). We show by induction that  $\text{alg}(f_{\Theta(n)})$  achieves backlog  $\Omega(n)$  in running time  $O(n!)$ . ◀

## 4.2 Oblivious Lower Bound

We now consider what happens if the filler is an **oblivious** adversary, meaning that the filler cannot see what the emptier does at each step. The emptier, in turn, is permitted to use randomization in order to make its behavior unpredictable to the filler. We focus on randomized emptying algorithms that satisfy the so-called  **$\Delta$ -greedy-like** property: the emptier never empties from a cup  $c$  over another cup  $c'$  whose fill is more than  $\Delta$  greater than the fill of  $c$ .

The next theorem gives an oblivious filling strategy that achieves backlog  $\Omega(n^{1-\varepsilon})$  against any  $\Delta$ -greedy-like emptier for any  $\Delta \in \Omega(1)$  (or, more precisely, any  $\Delta \leq \frac{1}{128} \log \log \log n$ ).

► **Theorem 10.** *There is an oblivious filling strategy for the variable-processor cup game on  $N$  cups that achieves backlog at least  $\Omega(N^{1-\varepsilon})$  for any constant  $\varepsilon > 0$  in running time  $2^{\text{polylog}(N)}$  with probability at least  $1 - 2^{-\text{polylog}(N)}$  against a  $\Delta$ -greedy-like emptier with  $\Delta \leq \frac{1}{128} \log \log \log N$ .*

Note that Theorem 10 uses  $N$  for the number of cups rather than using  $n$ . When describing the recursive strategy that the filler uses, we will use  $N$  to denote the true total number of cups, and  $n$  to denote the number of cups within the recursive subproblem currently being discussed.

The filling strategy used in Theorem 10 is closely related the adaptive filling strategy described in Section 4.1. The fact that the filling strategy must now be *oblivious*, however, introduces several new technical obstacles.

### Problem 1: Distinguishing between neglected and non-neglected phases

Recall that the Amplification Lemma in Section 4.1 proceeds in phases, where the filler behaves differently at the end of each phase depending on whether or not the emptier ever neglected the anchor set  $A$  during that phase. If the filler is oblivious, however, then it cannot detect which phases are neglected.

To solve this problem, the first thing to notice is that the *total* number of times that the emptier can neglect the anchor set (within a given recursive subproblem of the Amplification Lemma) is, without loss of generality, at most  $N^2$ . Indeed, if the emptier neglects the anchor set more than  $N^2$  times, then the total amount of water in cups  $A$  will be at least  $N^2$ . Since the amount of water in the system as a whole is non-decreasing, there will subsequently always be at least one cup in the system with fill  $N$  or larger, and thus the filler's strategy trivially achieves backlog  $N$ .

Assume that there are at most  $N^2$  phases that the emptier neglects. The filler does not know which phases these are, and the filler does not wish to ever move a cup from the non-anchor set to the anchor set during a phase that the emptier neglected (since, during such a phase, there is no guarantee on the amount of water in the cup from  $B$ ). To solve this problem, we increase the total number of phases in the Amplification Lemma to be some very large number  $M = 2^{\text{polylog } N}$ , and we have the filler select  $|A|$  random phases at the end of which to move a cup from the non-anchor set to the anchor set. With high probability, none of the  $|A|$  phases that the filler selects are neglected by the emptier.

### Problem 2: Handling the probability of failure

Because the filler is now oblivious (and the emptier is randomized) the guarantee offered by the filling strategy is necessarily probabilistic. This makes the Amplification Lemma somewhat more difficult, since each application of  $\text{alg}(f)$  now has some probability of failure.

We ensure that the applications of  $\text{alg}(f)$  succeed with such high probability that we can ignore the possibility of any of them failing on phases when we need them to succeed. This necessitates making sure that the base-case construction  $\text{alg}(f_0)$  succeeds with very high probability.

Fortunately, we can take a base-case construction  $\text{alg}_0$  that succeeds with only constant (or even sub-constant) probability, and perform an Amplification-Lemma-like construction in order to obtain a new filling strategy  $\text{alg}_1$  that achieves slightly *smaller* backlog, but that has a very high probability of succeeding.

To construct  $\text{alg}_1$ , we begin by performing the Amplification-Lemma construction on  $\text{alg}_0$ , but without recursing after the final phase. Even though many of the applications of  $\text{alg}_0$  may fail, with high probability at least one application succeeds. This results in some cup  $c_*$  in  $A$  having high fill. Unfortunately, the filler does not know which cup has high fill, so it cannot simply take  $c_*$ . What the filler can do, however, is select some cup  $c$ , decrease the number of processors to 1, and then spend a large number of steps simply placing 1 unit of water into cup  $c$  in each step. By the  $\Delta$ -greediness of the emptier, the emptier is guaranteed to focus on emptying from cup  $c_*$  (rather than cup  $c$ ) until  $c$  attains large fill. This allows for the filler to obtain a cup  $c$  that the filler *knows* contains a large amount of water (with high probability). We use this approach to construct a base-case filling strategy  $\text{alg}(f'_0)$  that succeeds with high probability.

**Problem 3: Non-flat starting states**

The next problem that we encounter is that, at the beginning of any given phase, the cups in the non-anchor set may not start off with equal heights. Instead, some cups may contain very large amounts of water while others contain very small (and even negative) amounts of water<sup>3</sup>. This is not a problem for an adaptive filler, since the filler knows which cups contain small/large amounts of water, but it is a problem for an oblivious filler.

To avoid the scenario in which the cups in  $B$  are highly unequal, we begin each phase by first performing a **flattening construction** on the cups  $B$ , which causes the cups in  $B$  to all have roughly equal fills (up to  $\pm O(\Delta)$ ). The flattening construction uses the fact that the emptier is  $\Delta$ -greedy-like to ensure that cups which are overly full get flattened out by the emptier.

**Putting the pieces together**

By combining the ideas above, as well as handling other issues that arise (e.g., one must be careful to ensure that the average fills of  $A$  and  $B$  do not drift apart in unpredictable ways), one can prove Theorem 10.

**5 Adaptive Filler Lower Bound**

In this section we give a  $2^{\text{polylog } n}$ -time filling strategy that achieves backlog  $n^{1-\varepsilon}$  for any positive constant  $\varepsilon$ . We also give a  $O(n!)$ -time filling strategy that achieves backlog  $\Omega(n)$ . These results formalize the ideas described in Section 4.1.

We begin with a trivial filling strategy that we call **trivalg** that gives backlog at least  $1/2$  when applied to at least 2 cups.

► **Proposition 11.** *Consider an instance of the negative-fill 1-processor cup game on  $n$  cups, and let the cups start in any state with average fill is 0. If  $n \geq 2$ , there is an  $O(1)$ -step adaptive filling strategy **trivalg** that achieves backlog at least  $1/2$ . If  $n = 1$ , **trivalg** achieves backlog 0 in running time 0.*

**Proof.** If  $n = 1$ , **trivalg** does nothing and achieves backlog 0; for the rest of the proof we consider the case  $n \geq 2$ .

Let  $a$  and  $b$  be the fullest and second fullest cups in the in the starting configuration, and let their initial fills be  $\text{fill}(a) = \alpha, \text{fill}(b) = \beta$ . If  $\alpha \geq 1/2$  the filler need not do anything, the desired backlog is already achieved. Otherwise, if  $\alpha \in [0, 1/2]$ , the filler places  $1/2 - \alpha$  fill into  $a$  and  $1/2 + \alpha$  fill into  $b$  (which is possible as both fills are in  $[0, 1]$ , and they sum to 1). Since  $\alpha + \beta \geq 0$  we have  $\beta \geq -\alpha$ . Clearly  $a$  and  $b$  now both have fill at least  $1/2$ . The emptier cannot empty from both  $a$  and  $b$  as  $p = 1$ , so even after the emptier empties from a cup we still have backlog  $1/2$ , as desired. ◀

Next we prove the **Amplification Lemma**, which takes as input a filling strategy  $\text{alg}(f)$  and outputs a new filling strategy  $\text{alg}(f')$  that we call the **amplification** of  $\text{alg}(f)$ .  $\text{alg}(f')$  is able to achieve higher fill than  $\text{alg}(f)$ ; in particular, we will show that by starting with a filling strategy  $\text{alg}(f_0)$  for achieving constant backlog and then forming a sufficiently long sequence of filling strategies  $\text{alg}(f_0), \text{alg}(f_1), \dots, \text{alg}(f_{i_*})$  with  $\text{alg}(f_{i+1})$  the amplification of  $\text{alg}(f_i)$ , we get a filling strategy for achieving  $\text{poly}(n)$  backlog.

<sup>3</sup> Recall that, in order for our lower-bound construction to be able to call itself recursively, we must analyze the construction in the negative-fill version of the variable-processor cup game.

► **Lemma 12** (Adaptive Amplification Lemma). *Let  $\delta \in (0, 1/2]$  be a parameter. Let  $\text{alg}(f)$  be an adaptive filling strategy that achieves backlog  $f(n) < n$  in the negative-fill variable-processor cup game on  $n$  cups in running time  $T(n)$  starting from any initial cup state where the average fill is 0.*

*Then there exists an adaptive filling strategy  $\text{alg}(f')$  that achieves backlog  $f'(n)$  satisfying*

$$f'(n) \geq (1 - \delta)f(\lfloor (1 - \delta)n \rfloor) + f(\lceil \delta n \rceil)$$

*and  $f'(n) \geq f(n)$  in the negative-fill variable-processor cup game on  $n$  cups in running time*

$$T'(n) \leq n \lceil \delta n \rceil \cdot T(\lfloor (1 - \delta)n \rfloor) + T(\lceil \delta n \rceil)$$

*starting from any initial cup state where the average fill is 0.*

**Proof.** Let  $n_A = \lceil \delta n \rceil$ ,  $n_B = n - n_A = \lfloor (1 - \delta)n \rfloor$ .

The filler defaults to using  $\text{alg}(f)$  if

$$f(n) \geq (1 - \delta)f(n_B) + f(n_A).$$

In this case using  $\text{alg}(f)$  achieves the desired backlog in the desired running time. In the rest of the proof, we describe our strategy for the case where we cannot simply use  $\text{alg}(f)$  to achieve the desired backlog.

Let  $A$ , the **anchor set**, be initialized to consist of the  $n_A$  fullest cups, and let  $B$  the **non-anchor set** be initialized to consist of the rest of the cups (so  $|B| = n_B$ ). Let  $h = (1 - \delta)f(n_B)$ .

The filler's strategy can be summarized as follows:

**Step 1:** Make  $\mu(A) \geq h$  by using  $\text{alg}(f)$  repeatedly on  $B$  to achieve cups with fill at least  $\mu(B) + f(n_B)$  in  $B$  and then swapping these into  $A$ . While doing this the filler always places 1 unit of fill in each anchor cup.

**Step 2:** Use  $\text{alg}(f)$  once on  $A$  to obtain some cup with fill  $\mu(A) + f(n_A)$ .

Note that in order to use  $\text{alg}(f)$  on subsets of the cups the filler will need to vary  $p$ .

We now describe how to achieve Step 1, which is complicated by the fact that the emptier may attempt to prevent the filler from achieving high fill in a cup in  $B$ .

The filling strategy always places 1 unit of water in each anchor cup. This ensures that no cups in the anchor set ever have their fill decrease. If the emptier wishes to keep the average fill of the anchor cups from increasing, then emptier must empty from every anchor cup on each step. If the emptier fails to do this on a given round, then we say that the emptier has **neglected** the anchor cups.

We say that the filler **applies**  $\text{alg}(f)$  to  $B$  if it follows the filling strategy  $\text{alg}(f)$  on  $B$  while placing 1 unit of water in each anchor cup. An application of  $\text{alg}(f)$  to  $B$  is said to be **successful** if  $A$  is never neglected during the application of  $\text{alg}(f)$  to  $B$ . The filler uses a series of phases that we call **swapping-processes** to achieve the desired average fill in  $A$ . In a swapping-process, the filler repeatedly applies  $\text{alg}(f)$  to  $B$  until a successful application occurs, and then takes the cup generated by  $\text{alg}(f)$  within  $B$  on this successful application with fill at least  $\mu(B) + f(|B|)$  and swaps it with the least full cup in  $A$  so long as the swap increases  $\mu(A)$ . If the average fill in  $A$  ever reaches  $h$ , then the algorithm immediately halts (even if it is in the middle of a swapping-process) and is complete.

We give pseudocode for the filling strategy in Algorithm 1.

## 16:14 The Variable-Processor Cup Game

■ **Algorithm 1** Adaptive Amplification (Step 1).

**Input:**  $\text{alg}(f), \delta$ , set of  $n$  cups

**Output:** Guarantees that  $\mu(A) \geq h$

$A \leftarrow n_A$  fullest cups,  $B \leftarrow$  rest of the cups

Always place 1 fill in each cup in  $A$

**while**  $\mu(A) < h$  **do**

▷ Swapping-Processes

Immediately **exit** this loop if ever  $\mu(A) \geq h$

successful  $\leftarrow$  false

**while** not successful **do**

Apply  $\text{alg}(f)$  to  $B$ ,  $\text{alg}(f)$  gives cup  $c$

**if**  $\text{fill}(c) \geq h$  **then**

successful  $\leftarrow$  true

Swap  $c$  with least full cup in  $A$

Note that

$$\mu(A) \cdot |A| + \mu(B) \cdot |B| = \mu(AB) \geq 0,$$

as  $\mu(AB)$  starts as 0, but could become positive if the emptier skips emptyings. Thus we have

$$\mu(A) \geq -\mu(B) \cdot \frac{\lfloor (1-\delta)n \rfloor}{\lceil \delta n \rceil} \geq -\frac{1-\delta}{\delta} \mu(B).$$

Thus, if at any point  $B$  has average fill lower than  $-h \cdot \delta / (1-\delta)$ , then  $A$  has average fill at least  $h$ , so the algorithm is finished. Thus we can assume in our analysis that

$$\mu(B) \geq -h \cdot \delta / (1-\delta). \quad (9)$$

We will now show that the filler applies  $\text{alg}(f)$  to  $B$  at most  $hn_A$  total times. Each time the emptier neglects the anchor set, the mass of the anchor set increases by 1. If the emptier neglects the anchor set  $hn_A$  times, then the average fill in the anchor set increases by  $h$ . Since  $\mu(A)$  started as at least 0, and since  $\mu(A)$  never decreases (note in particular that cups are only swapped into  $A$  if doing so will increase  $\mu(A)$ ), an increase of  $h$  in  $\mu(A)$  implies that  $\mu(A) \geq h$ , as desired.

Consider the fill of a cup  $c$  swapped into  $A$  at the end of a swapping-process. Cup  $c$ 's fill is at least  $\mu(B) + f(n_B)$ , which by (9) is at least

$$-h \cdot \frac{\delta}{1-\delta} + f(n_B) = (1-\delta)f(n_B) = h.$$

Thus the algorithm for Step 1 succeeds within  $|A|$  swapping-processes, since at the end of the  $|A|$ -th swapping process either every cup in  $A$  has fill at least  $h$ , or the algorithm halted before  $|A|$  swapping-processes because it already achieved  $\mu(A) \geq h$ .

After achieving  $\mu(A) \geq h$ , the filler performs Step 2, i.e. the filler applies  $\text{alg}(f)$  to  $A$ , and hence achieves a cup with fill at least

$$\mu(A) + f(|A|) \geq (1-\delta)f(n_B) + f(n_A),$$

as desired.

Now we analyze the running time of the filling strategy  $\text{alg}(f')$ . First, recall that in Step 1  $\text{alg}(f')$  calls  $\text{alg}(f)$  on  $B$ , which has size  $n_B$ , as many as  $hn_A$  times. Because we mandate that  $h < n$ , Step 1 contributes no more than  $(n \cdot n_A) \cdot T(n_B)$  to the running time. Step 2 requires applying  $\text{alg}(f)$  to  $A$ , which has size  $n_A$ , once, and hence contributes  $T(n_A)$  to the running time. Summing these we have

$$T'(n) \leq n \cdot n_A \cdot T(n_B) + T(n_A). \quad \blacktriangleleft$$

We next show that by recursively using the Amplification Lemma we can achieve backlog  $n^{1-\varepsilon}$ .

► **Theorem 13.** *There is an adaptive filling strategy for the variable-processor cup game on  $n$  cups that achieves backlog  $\Omega(n^{1-\varepsilon})$  for any constant  $\varepsilon > 0$  of our choice in running time  $2^{O(\log^2 n)}$ .*

**Proof.** Take constant  $\varepsilon \in (0, 1/2)$ . Let  $c, \delta$  be constants that will be chosen (later) as functions of  $\varepsilon$  satisfying  $c \in (0, 1), 0 < \delta \ll 1/2$ . We show how to achieve backlog at least  $cn^{1-\varepsilon} - 1$ .

Let  $\text{alg}(f_0) = \text{trivalg}$ , the algorithm given by Proposition 11; recall  $\text{trivalg}$  achieves backlog  $f_0(k) \geq 1/2$  for all  $k \geq 2$ , and  $f_0(1) = 0$ . Next, using the Amplification Lemma we recursively construct  $\text{alg}(f_{i+1})$  as the amplification of  $\text{alg}(f_i)$  for  $i \geq 0$ . Define a sequence  $g_i$  with

$$g_i = \begin{cases} \lceil 16/\delta \rceil, & i = 0, \\ \lfloor g_{i-1}/(1-\delta) \rfloor & i \geq 1. \end{cases}$$

We claim the following regarding this construction:

▷ **Claim 14.** For all  $i \geq 0$ ,

$$f_i(k) \geq ck^{1-\varepsilon} - 1 \quad \text{for all } k \in [g_i]. \quad (10)$$

**Proof.** We prove Claim 14 by induction on  $i$ . For  $i = 0$ , the base case, (10) can be made true by taking  $c$  sufficiently small; in particular, taking  $c < 1$  makes (10) hold for  $k = 1$ , and, as  $g_0 > 2$ , taking  $c$  small enough to make  $cg_0^{1-\varepsilon} - 1 \leq f_0(g_0) = 1/2$  makes (10) hold for  $k \in [2, g_0]$  by monotonicity of  $k \mapsto ck^{1-\varepsilon} - 1$ .

As our inductive hypothesis we assume (10) for  $f_i$ ; we aim to show that (10) holds for  $f_{i+1}$ . Note that, by design of  $g_i$ , if  $k \leq g_{i+1}$  then  $\lfloor k \cdot (1-\delta) \rfloor \leq g_i$ . Consider any  $k \in [g_{i+1}]$ . First we deal with the trivial case where  $k \leq g_0$ . In this case

$$f_{i+1}(k) \geq f_i(k) \geq \dots \geq f_0(k) \geq ck^{1-\varepsilon} - 1.$$

Now we consider the case where  $k \geq g_0$ . Since  $f_{i+1}$  is the amplification of  $f_i$  we have

$$f_{i+1}(k) \geq (1-\delta)f_i(\lfloor (1-\delta)k \rfloor) + f_i(\lceil \delta k \rceil).$$

By our inductive hypothesis, which applies as  $\lceil \delta k \rceil \leq g_i, \lfloor k \cdot (1-\delta) \rfloor \leq g_i$ , we have

$$f_{i+1}(k) \geq (1-\delta)(c \cdot \lfloor (1-\delta)k \rfloor^{1-\varepsilon} - 1) + c \lceil \delta k \rceil^{1-\varepsilon} - 1.$$

---

<sup>4</sup> Note that it is important here that  $\varepsilon$  and  $\delta$  are constants, that way  $c$  is also a constant.

## 16:16 The Variable-Processor Cup Game

Dropping the floor and ceiling, incurring a  $-1$  for dropping the floor, we have

$$f_{i+1}(k) \geq (1-\delta)(c \cdot ((1-\delta)k - 1)^{1-\varepsilon} - 1) + c(\delta k)^{1-\varepsilon} - 1.$$

Because  $(x-1)^{1-\varepsilon} \geq x^{1-\varepsilon} - 1$ , as  $x \mapsto x^{1-\varepsilon}$  is a sub-linear sub-additive function, we have

$$f_{i+1}(k) \geq (1-\delta)c \cdot (((1-\delta)k)^{1-\varepsilon} - 2) + c(\delta k)^{1-\varepsilon} - 1.$$

Moving the  $ck^{1-\varepsilon}$  to the front we have

$$f_{i+1}(k) \geq ck^{1-\varepsilon} \cdot \left( (1-\delta)^{2-\varepsilon} + \delta^{1-\varepsilon} - \frac{2(1-\delta)}{k^{1-\varepsilon}} \right) - 1.$$

Because  $(1-\delta)^{2-\varepsilon} \geq 1 - (2-\varepsilon)\delta$ , a fact called Bernoulli's Identity, we have

$$f_{i+1}(k) \geq ck^{1-\varepsilon} \cdot \left( 1 - (2-\varepsilon)\delta + \delta^{1-\varepsilon} - \frac{2(1-\delta)}{k^{1-\varepsilon}} \right) - 1.$$

Of course  $-2(1-\delta) \geq -2$ , so

$$f_{i+1}(k) \geq ck^{1-\varepsilon} \cdot \left( 1 - (2-\varepsilon)\delta + \delta^{1-\varepsilon} - \frac{2}{k^{1-\varepsilon}} \right) - 1.$$

Because

$$\frac{-2}{k^{1-\varepsilon}} \geq \frac{-2}{g_0^{1-\varepsilon}} \geq -2(\delta/16)^{1-\varepsilon} \geq -\delta^{1-\varepsilon}/2,$$

which follows from our choice of  $g_0 = \lceil 16/\delta \rceil$  and the restriction  $\varepsilon < 1/2$ , we have

$$f_{i+1}(k) \geq ck^{1-\varepsilon} \cdot (1 - (2-\varepsilon)\delta + \delta^{1-\varepsilon} - \delta^{1-\varepsilon}/2) - 1.$$

Finally, combining terms we have

$$f_{i+1}(k) \geq ck^{1-\varepsilon} \cdot (1 - (2-\varepsilon)\delta + \delta^{1-\varepsilon}/2) - 1.$$

Because  $\delta^{1-\varepsilon}$  dominates  $\delta$  for sufficiently small  $\delta$ , there is a choice of  $\delta = \Theta(1)$  such that

$$1 - (2-\varepsilon)\delta + \delta^{1-\varepsilon}/2 \geq 1.$$

Taking  $\delta$  to be this small we have,

$$f_{i+1}(k) \geq ck^{1-\varepsilon} - 1,$$

completing the proof. We remark that the choices of  $c, \delta$  are the same for every  $i$  in the inductive proof, and depend only on  $\varepsilon$ .  $\triangleleft$

To complete the proof, we will show that  $g_i$  grows exponentially in  $i$ . This implies that there exists  $i_* \leq O(\log n)$  such that  $g_{i_*} \geq n$ , and hence we have an algorithm  $\text{alg}(f_{i_*})$  that achieves backlog  $cn^{1-\varepsilon} - 1$  on  $n$  cups, as desired.

We lower bound the sequence  $g_i$  with another sequence  $g'_i$  defined as

$$g'_i = \begin{cases} 4/\delta, & i = 0 \\ g'_{i-1}/(1-\delta) - 1, & i > 0. \end{cases}$$

Solving this recurrence, we find

$$g'_i = \frac{4 - (1 - \delta)^2}{\delta} \frac{1}{(1 - \delta)^i} \geq \frac{1}{(1 - \delta)^i},$$

which clearly exhibits exponential growth. In particular, let  $i_* = \lceil \log_{1/(1-\delta)} n \rceil$ . Then,  $g_{i_*} \geq g'_{i_*} \geq n$ , as desired.

Let the running time of  $f_i(n)$  be  $T_i(n)$ . From the Amplification Lemma we have following recurrence bounding  $T_i(n)$ :

$$\begin{aligned} T_i(n) &\leq n \lceil \delta n \rceil \cdot T_{i-1}(\lfloor (1 - \delta)n \rfloor) + T_{i-1}(\lceil \delta n \rceil) \\ &\leq 2n^2 T_{i-1}(\lfloor (1 - \delta)n \rfloor). \end{aligned}$$

It follows that  $\text{alg}(f_{i_*})$ , recalling that  $i_* \leq O(\log n)$ , has running time

$$T_{i_*}(n) \leq (2n^2)^{O(\log n)} \leq 2^{O(\log^2 n)},$$

as desired. ◀

Now we provide a construction that can achieve backlog  $\Omega(n)$  in very long games. The construction can be interpreted as the same argument as in Theorem 13 but with an extremal setting of  $\delta$  to  $\Theta(1/n)^5$ .

► **Theorem 15.** *There is an adaptive filling strategy that achieves backlog  $\Omega(n)$  in time  $O(n!)$ .*

**Proof.** First we construct a slightly stronger version of  $\text{trivalg}$  that achieves backlog 1 on  $n \geq n_0 = 8$  cups, instead of just backlog  $1/2$ ; this simplifies the analysis.

▷ **Claim 16.** There is a filling algorithm  $\text{trivalg}_2$  that achieves backlog at least 1 on  $n_0 = 8$  cups.

**Proof.** Let  $\text{trivalg}_1$  be the amplification of  $\text{trivalg}$  using  $\delta = 1/2$ . On 4 cups  $\text{trivalg}_1$  achieves backlog at least  $(1/2)(1/2) + 1/2 = 3/4$ . Let  $\text{trivalg}_2$  be the amplification of  $\text{trivalg}_1$  using  $\delta = 1/2$ . On 8 cups  $\text{trivalg}_2$  achieves backlog at least  $(1/2)(3/4) + 3/4 \geq 1$ . ◁

Let  $\text{alg}(f_0) = \text{trivalg}_2$ ; we have  $f_0(k) \geq 1$  for all  $k \geq n_0$ . For  $i > 0$  we construct  $\text{alg}(f_i)$  as the amplification of  $\text{alg}(f_{i-1})$  using the Amplification Lemma with parameter  $\delta = 1/(i+1)$ .

We claim the following regarding this construction:

▷ **Claim 17.** For all  $i \geq 0$ ,

$$f_i((i+1)n_0) \geq \sum_{j=0}^i \left(1 - \frac{j}{i+1}\right). \quad (11)$$

**Proof.** We prove Claim 17 by induction on  $i$ . When  $i = 0$ , the base case, (11) becomes  $f_0(n_0) \geq 1$  which is true. Assuming (11) for  $f_{i-1}$ , we now show (11) holds for  $f_i$ . Because  $f_i$  is the amplification of  $f_{i-1}$  with  $\delta = 1/(i+1)$ , we have by the Amplification Lemma

$$f_i((i+1) \cdot n_0) \geq \left(1 - \frac{1}{i+1}\right) f_{i-1}(i \cdot n_0) + f_{i-1}(n_0).$$

<sup>5</sup> Or more precisely, setting  $\delta$  in each level of recursion to be  $\Theta(1/n)$ , where  $n$  is the subproblem size; note in particular that  $\delta$  changes between levels of recursion, which was not the case in the proof of Theorem 13.

## 16:18 The Variable-Processor Cup Game

Since  $f_{i-1}(n_0) \geq f_0(n_0) \geq 1$  we have

$$f_i((i+1) \cdot n_0) \geq \left(1 - \frac{1}{i+1}\right) f_{i-1}(i \cdot n_0) + 1.$$

Using the inductive hypothesis we have

$$f_i((i+1) \cdot n_0) \geq \left(1 - \frac{1}{i+1}\right) \sum_{j=0}^{i-1} \left(1 - \frac{j}{i}\right) + 1.$$

Note that

$$\left(1 - \frac{1}{i+1}\right) \cdot \left(1 - \frac{j}{i}\right) = \frac{i}{i+1} \cdot \frac{i-j}{i} = \frac{i-j}{i+1} = 1 - \frac{j+1}{i+1}.$$

Thus we have the desired bound:

$$f_i((i+1) \cdot n_0) \geq \sum_{j=1}^i \left(1 - \frac{j}{i+1}\right) + 1 = \sum_{j=0}^i \left(1 - \frac{j}{i+1}\right). \quad \triangleleft$$

Let  $i_* = \lfloor n/n_0 \rfloor - 1$ , which by design satisfies  $(i_* + 1)n_0 \leq n$ . By Claim 17 we have

$$f_{i_*}((i_* + 1) \cdot n_0) \geq \sum_{j=0}^{i_*} \left(1 - \frac{j}{i_* + 1}\right) = i_*/2 + 1.$$

As  $i_* = \Theta(n)$ , we have thus shown that  $\text{alg}(f_{i_*})$  can achieve backlog  $\Omega(n)$  on  $n$  cups.

Let  $T_i$  be the running time of  $\text{alg}(f_i)$ . The recurrence for the running time of  $f_{i_*}$  is

$$T_i(n) \leq n \cdot n_0 T_{i-1}(n - n_0) + O(1).$$

Clearly  $T_{i_*}(n) \leq O(n!)$ . ◀

# Comparison Graphs: A Unified Method for Uniformity Testing

Uri Meir

Tel Aviv University, Israel

---

## Abstract

Distribution testing can be described as follows:  $q$  samples are being drawn from some unknown distribution  $P$  over a known domain  $[n]$ . After the sampling process, a decision must be made about whether  $P$  holds some property, or is far from it. The most studied problem in the field is arguably *uniformity testing*, where one needs to distinguish the case that  $P$  is uniform over  $[n]$  from the case that  $P$  is  $\epsilon$ -far from being uniform (in  $\ell_1$ ). It is known that for this task  $\Theta(\sqrt{n}/\epsilon^2)$  samples are necessary and sufficient. This problem was recently considered in various restricted models that pose, for example, communication or memory constraints. In more than one occasion, the known optimal solution boils down to counting collisions among the drawn samples (each two samples that have the same value add one to the count). This idea dates back to the first uniformity tester, and was coined the name “collision-based tester”.

In this paper, we introduce the notion of *comparison graphs* and use it to formally define a generalized collision-based tester. Roughly speaking, the edges of the graph indicate the tester which pairs of samples should be compared (that is, the original tester is induced by a clique, where all pairs are being compared). We prove a structural theorem that gives a sufficient condition for a comparison graph to induce a good uniformity tester. As an application, we develop a generic method to test uniformity, and devise nearly-optimal uniformity testers under various computational constraints. We improve and simplify a few known results, and introduce a new constrained model in which the method also produces an efficient tester.

The idea behind our method is to translate computational constraints of a certain model to ones on the comparison graph, which paves the way to finding a good graph: a set of comparisons allowed by the model that suffice to test for uniformity. We believe that in future consideration of uniformity testing in new models, our method can be used to obtain efficient testers with minimal effort.

## 1 Introduction

The field of property testing was initiated by [10, 25, 20] and concerns with fast probabilistic algorithms that use query access to some large structure (such as graphs, functions, distribution, etc.) in order to determine whether a specific instance belongs to a subclass of possible instances (e.g., connected graphs or monotone functions) or in some sense far from it. Specifically for distributions, as formulated in [9], we are given random samples from some unknown distribution, and we wish to decide with high probability (over the random samples) whether it has some property, or it is far from any distribution that does (typically

we use  $\ell_1$  as a distance measure). Properties of distributions were excessively studied through the years (see [18, 11] for excellent surveys). Until recently, the vast majority of results were limited to the classic setting, where a *single* processor is given an oracle access, and performs the testing procedure. The measure of complexity is based solely on the number of samples, as typically the running time is polynomial in this number.

However, distribution testing can be very useful in different frameworks as well. For example, suppose we have a sensor network taking some measurements that need to be combined in order to make a decision about the subject of these measurements, be it volcanic activity, seismic movements, or any form of radiation.

Another framework where testing is useful, is under constrained memory. One might try testing an object so big, that the number of samples needed is very large. In that scenario, even if one might endure a lengthy sampling process, storing all past samples at one given moment can be too costly. For example, imagine a large telescope collecting data on infrared radiation in a pursuit to discover new planets. These types of questions can be translated to a *streaming model*, where samples come as a stream, and one wish to store only a small amount of data while reliably test for a property of the underlying distribution.

When considering the relatively similar motivations for these cases, one might even wonder about a combination of the two models, where multiple sensors spread out in some area collect samples, each of which has bounded memory. They will then need to process all available data within their memory constraints, such that by the end of each time period - they are able to report their individual findings concisely to some data center that aggregates all information in order to make an important decision.

All of these questions are inherently multi-dimensional, in the sense that many incomparable resources are in play: the number of players, the number of samples, the memory space of each sensor, and even the amount of bits communicated. Here, we focus our efforts, for the most part, on minimizing the *sample complexity* (or amount of samples per player, when multiple players are involved), with other resources given as parameters.

This specification is well-motivated by the case where we have no shortage of data we can sample from, and we wish to understand how long a sampling process should take, as a parameter of the number of sensors we use and their computational strength. Throughout the text, we focus on the task of uniformity testing, a key problem in the field of distribution testing.

**Uniformity testing.** The most studied family of problems in distribution testing is arguably *identity testing*, where we want to test whether the input distribution  $P$  is equal to some fixed distribution  $p$ , or  $\epsilon$ -far from it (in  $\ell_1$ ), where  $\epsilon$  is the proximity parameter of the problem. In the heart of these problems stands the problem of *uniformity testing*, where  $p = U_\Omega$ . One evidence for the importance of uniformity testing was shown in [15] and made more robust in [19]: it is actually complete for identity testing, in the sense that testing identity to any fixed distribution  $p$  can be reduced to testing uniformity instead. On the other hand, uniformity testing is a specific case of other problems such as closeness testing and independence testing, so showing lower bounds for uniformity testing would imply lower bounds for these problems. The classic version of testing uniformity was settled for the case  $\epsilon = \Omega(n^{-1/4})$  in [24], showing that  $\Theta(\sqrt{n}/\epsilon^2)$  samples are in fact sufficient and necessary. [26] later showed this holds for all values of  $\epsilon$ .

**Collision-based testers.** The problem of uniformity testing was implicitly introduced in [21], as a way to test the expansion of a graph: when simulating multiple short random walks, and observing the distribution of the endpoint, one can connect a uniform distribution over these

endpoint to good expansion of the graph. To solve uniformity, the *collision-based* tester was introduced, where one simply counts the number of pairs of samples that have the same value. This tester was shown to have sample complexity of  $\Theta(\sqrt{n} \cdot \text{poly}(1/\epsilon))$ , which is turned out to be sub-optimal in terms of  $\epsilon$ . However, several years after the question was settled, it was shown in [14] that the original collision-based tester also achieves optimal sample complexity, using a finer analysis.

The idea behind the collision-based tester is rather straightforward: when comparing two samples from a distribution, the chance of both having the same value (also referred as *collision probability*) relates to the  $\ell_2$  norm of the distribution. It is a well-known fact that over a fixed set  $\Omega$ , the uniform distribution has the minimal  $\ell_2$  norm. It is also rather easy to show that any distribution that is somewhat far from uniform (in statistical distance), has a significantly larger  $\ell_2$  norm. This means that each comparison of two samples is an unbiased estimator of the collision probability (having the right expectation), but with very high variance. One would need to average over many such comparisons in order to reduce the variance.

**Other methods to test for uniformity.** Over the years, numerous methods to test for uniformity have been proposed. Some of them had different goals in mind, such as testing with very high confidence, or in a multiparty model where each player gets a single sample (sometimes even wishing to keep it private). These methods include counting unique element [24], modified  $\chi^2$  test [26], using the empirical distance to uniformity [13], randomly hashing samples to a smaller domain [6] and more. In both [12, 16], testers that aim to overcome different constraints relied strongly on collision counting<sup>1</sup>. Considering it is also optimal in the classic setting, this makes collision-based testing a prime candidate for a more generic method to test uniformity, and hopefully adjust itself to different models easily.

**Comparison graphs.** The original version of the collision-based tester takes a set of samples, and use comparisons between *all pairs of samples*. This is well-suited for the classic model, where one processor sees all the samples, and can easily perform all comparisons.

However, in more constrained models, this simple task is inherently impossible. For example, a memory-constrained tester cannot store all previous samples in order to compare them with new ones. In the simultaneous model, where each processor holds its own set of samples, a lot of communication might be needed to compare samples that are held by different processors. In distributed models, such as CONGEST and LOCAL (see [16]), the problem is defined where each player in a network holds a single sample from a distribution (replacing one sample by a constant amount produces similar behaviour). In these models, it is much cheaper for player to compare their samples with those of a neighboring player, than it is to make such a comparison with players that are far away (on the network topology).

To this end, we introduce the notion of *comparison graphs*. A comparison graph is linked to a collision-based tester (or algorithm) as follows: the vertices of the graph are the samples given as input, and the edges are pairs of samples that are being compared. As stated above: in the classic model this graph is typically the complete clique (all pairs of samples are compared). Under constrained models, however, very specific edges (comparisons) are allowed, whereas others are not. For example, if the sample  $s_1$  is given to one player, and the sample  $s_2$  is given to another player in the simultaneous model, no algorithm can presume to compare the two samples.

---

<sup>1</sup> These testers do not count collisions per se, they use additional crucial steps.

Equipped with the notion of comparison graphs, one can define a *collision-based* tester as a couple  $(G, \tau)$ , where  $G = (V, E)$  is the comparison graph that defines which comparisons are being made, and  $\tau$  is a threshold parameter. The algorithm is defined as follows: it counts the amount of collisions observed,  $Z$ , and compares it to a threshold  $T$  that depends on  $\tau$  and the amount of comparisons made (which is  $|E|$ ).

**Reliable collisions-based testers** In this work we introduce a structural theorem concerning with which sets of comparisons are able to inspire a reliable test for uniformity based solely on counting collisions. This is done by observing the comparison graph  $G$ . We formulate sufficient conditions in terms of the graph  $G$ , that guarantee it induces a good tester (when paired with the right threshold parameter  $\tau$ ). It turns out that two properties of a comparison graph  $G$  are key: the first is the number of edges, which represents the amount of comparisons being made; the second one, somewhat surprisingly, is the number of 2-paths in the graph  $G$ , which encapsulates the amount of dependencies between different comparisons being made.

Few of our testers rely on the same type of graph, that pops up multiple times, for different reasons. To this end, we formulate Lemma 4, that specifies the required parameters for a comparison graph of this type to induce a good tester.

## 1.1 Examples of comparison graphs

It is interesting that the number of samples (the measure we usually wish to minimize) does *not* appear as a condition on our comparison graph directly. However, it does play a role indirectly, as simple inequalities connect the three graph quantities (see Section 4.1).

Our structural theorem basically shows that any comparison graph with enough edges, but not-too-many 2-paths induces a good uniformity tester. To better understand the meaning of this, we fix the amount of edges,  $|E|$ , and review a short list of examples for potential comparison graphs. We are interested in the interplay between the amount of vertices (samples), edges (comparisons made) and 2-paths (dependencies created).

**The clique graph.** The standard tester is actually the full clique, comparing each possible pair of samples. In this dense graph we only need  $\sqrt{|E|}$  vertices in order to have  $|E|$  edges. However, many 2-paths (and dependencies) are created along the way as well,  $\Theta(|E|^{3/2})$ . For this specific case, it is already known the two affects can be balanced to obtain optimal (asymptotic) sample complexity.

**Disjoint cliques.** Another interesting graph (used in some sense in [16]) is actually a union of disjoint cliques. This graph turns out to be quite useful. For once, it makes perfect sense in a simultaneous model, where each player process her own samples, sending a short summary to the referee. Surprisingly, it arises in other models as well.

**A perfect matching.** This graph relates to taking a fresh pair of samples each time we wish to make a new comparison, which leaves us with a set of completely independent collision indicators. Indeed, in this graph there are no 2-paths at all. Not only this tester minimizes the dependencies – it actually overdoes it. Doing so, it pays a price in sample complexity: the number of vertices we have is  $2|E|$ , much larger than the clique, for instance.

**The star graph.** With a fixed number of edges, this graph is actually the way to *maximize* the amount of 2-paths and dependencies – which makes it a very poor comparison graph. Indeed, the tester it induces is equivalent to drawing one element from  $P$ , and comparing it to many other samples, assessing the probability of this element. This test is indeed ill-advised against distributions where  $3/4$  of the elements have mass  $1/n$ .

**The full bipartite graph.** Another graph that could be considered is the full bipartite graph,  $G = (V_1 \sqcup V_2, V_1 \times V_2)$ . Here again we have a free parameter (the size  $|V_1|$ , which determines  $|V_2| = |E| / |V_1|$ ). It ranges from a star-graph (for  $|V_1| = 1$ ) to a balanced graph (for  $|V_1| = |V_2| = \sqrt{E}$ ), where the last one functions asymptotically similarly to the clique. It appears that Theorem 3 only gets optimal testers (minimizing the number of comparisons) from these graphs when they are balanced. To some extent, the test of [12] in the streaming model is based on such a graph. However, they use additional steps that seem crucial for the analysis. more details are given in 3.2, where it is also shown that one can test uniformity in the streaming model solely via collisions counting, using a whole different comparison graph.

## 1.2 Models and Results

Our main result is a method that produces well-performing uniformity testers in various models. In this paper we show a list of uniformity testers in different models, specified below. We also show limitations of our method for most of these models, which point towards a conclusion that no better comparison graphs could have been chosen (up to constant factors in the sample complexity of the induced tester). These limitations rely on a conjecture that no matter the shape of the graph, enough comparisons always must be made.

We emphasize that for any model in which a lower bound is known (for any method, not necessarily collision-based testing), the testers produced by our method are optimal, up to  $\text{poly}(1/\epsilon)$  factors. As far as we know, no testers in the literature are tight with the current lower bounds for these specific cases. Thus, it could be the case that collision-based testing achieves optimal results (even in terms of  $\epsilon$ ) for all the models we consider. A more thorough discussion is given in Section 4.2.

Equipped with the structural theorem, we consider various models and devise a uniformity tester in each one. The key idea here is to translate the constraints of each model into the comparisons we are able to perform, or differently put: a structural limitation on the comparison graph. Doing so will guide us how to choose a “good” comparison graph for this specific model. Having a structure in mind, two formalities are left: (i) Prove that calculation of  $Z, T$  (the number of collisions, and the threshold value) can be done in the model; (ii) Calculate our desired complexity measure (which changes from model to model), and optimize the parameters of the chosen graph (e.g., if the graph is a clique, determine the size of the clique).

**Standard processors.** In Section 3.1, we deal with the classic and the simultaneous model. First we use the classic model as a warm-up. Since this is done in [14], we add to the mix a small insight: our framework (which allows adjusting the threshold) actually provides slightly better constants when placing the threshold much lower than  $1/2$  (at roughly  $\tau = 1/9$ ).

For this model, it was shown by [13] that testing with high precision can be done faster than it would have using standard amplification. However, they use estimation of the empirical distance from uniform over the sample set. It is unclear whether collision-based testing is fit for this task. We do not pursue this direction here.<sup>2</sup>

<sup>2</sup> One reason is that our work focuses on the regime that uses new and different comparison graphs, other than the clique graph. This direction would probably involve analysis that is specific for the clique graph, where all samples can be compared with one another.

We then move to the simultaneous case where multiple players each send a short message to the referee, based on their own samples. The referee then needs to output a decision about the underlying distribution. In this model we want to find a good exchange for the number of players, the number of samples each player gets, and the length of the messages. For example, if the messages can be arbitrarily long, each player can send her entire sample set and the problem becomes trivial. For this reason, the two papers to first consider (independently) testing in this model, had a very different focus. In a preliminary version of [5, 6], only the case of a *single sample* per player was considered, and their algorithms indeed rely on different and interesting strategies, but not collision counting – as this strategy is irrelevant for this regime. In [16] a different approach was taken, where all messages were fixed to a *single bit*, but each player gets multiple samples (and in fact, their algorithm does rely on collisions in some sense, but it does not count them accurately, and does not fall under the umbrella of our definition for collision-based testers).

For our use, as oppose to both these view, we allow both parameters to be larger. We allow multiple samples per player, and show that using a short message (not a single bit, but not much longer), one can devise an efficient tester.

We also consider the asymmetric cost variant of this model, which aims to model the case where not all players have the same sampling capabilities (say, one player might gather samples much faster than another). As we measure our complexity by number of samples, we might as well think of the sampling process as being the bottleneck which we wish to hasten. When trying to minimize the sampling *time* instead, it is only natural to generalize the model to the case where some players are more efficient than others. Other than this motivation, a more technical motivations exists: a natural reduction from the LOCAL model. The LOCAL model is a standard interactive model. Uniformity testing in this model was first considered in [16], which gave a very natural reduction to a simultaneous model where players have different sampling rates.

We remark that many works in the simultaneous model consider communication trade-offs, when assigning only a *single sample* for each party. Our method does not currently extend to this framework, although one might consider integrating it with other methods. For example, one method (e.g., in [6]) uses random hash to a smaller domain. One might consider collisions on this domain instead of the original one. these meta-collisions can be counted within the communication constraints.

Some works in this regime (single sample) focus on privacy aspects of testing (e.g., [2, 7]). This line of research should be irrelevant for our method (and even the extension mentioned above), as any detection of a collision (even on a smaller domain) would immediately give away non-trivial information about the sample.

**Memory-constrained processors.** In Section 3.2, we deal with a different type of processors: *memory-constrained* processors. When observing a single processor of this type, we end up with the streaming model (as described in [12]). At least one scenario which motivates the simultaneous model is seemingly very coherent with such constrained processors. Thinking of a network of sensors, or remote devices, gathering samples – it is quite comprehensible that these processors are not only limited by their ability to communicate with the data center, but also by their ability to store the entire data observed between consecutive reports (in this scenario, the data center is the referee performing the test periodically to detect anomalies). For this reason, we also consider the case of a simultaneous model, where each processor has a small memory budget. In this new model, we easily devise again an efficient uniformity tester.

**Testing in an interactive model.** Lastly, in the full version of this paper, we use the structural theorem to show how on certain graphs one can solve uniformity in the CONGEST model faster than what was previously known to be possible. Specifically, if the communication network has  $k$  players and diameter  $D$ , and each players start with one sample, the best known algorithm runs in  $O(D + n/(k\epsilon^4))$  rounds [16]. The improvement we suggest is an algorithm that takes  $O(D)$  rounds, and works in specific networks that have a certain topological characteristics. Moreover, we show a simple detection procedure of  $O(D)$  rounds, that can be used to recognize such a good topology. This means that *any* network can use the detection procedure first, and then either proceed as in [16], or switch to the faster ( $O(D)$ ) algorithm whenever it is guaranteed to perform well.

### 1.3 Related Work

The task of uniformity testing, as well as the collision-based tester for it, were introduced in [9] (and implicitly in [21]). Later on, upper and lower bounds on the sample complexity of the problem were given by [24] (for most values of  $\epsilon$ ), showing that the optimal sample complexity is in fact  $s = \Theta(\sqrt{n}/\epsilon^2)$ , where  $n$  is the world size, and  $\epsilon$  is a proximity parameter. A preliminary version of [26] giving a tester that achieves this complexity for any value of  $\epsilon$ . The last two papers used two different testers: the first relied on the number of *distinct* elements in the sample set (this test is somewhat dual to counting collisions), and the second on a modified  $\chi^2$  tester. It was then shown by [14] that the collision-based tester does in fact achieve optimal sample complexity too.

In the past few years there has been a growing interest in distribution testing under various computational models, including collaborative testing in multiparty model, the streaming model, privacy aspects of testing, and others ([5, 6, 16, 8, 2, 22, 3, 4, 1, 23, 17, 7] and more). We mention in more details the works concerning uniformity testers in models we pursue.

In a preliminary version of [5, 6] and [16] each, independently, the task of uniformity testing was considered in a simultaneous communication model. In this model, all players receive samples from the same global distribution  $P$ , and all players report to a referee based on their own samples. The referee in turn uses the reports to output (with high probability) whether  $P$  holds some property.

In both lines of work, the focus was uniformity testing, but using two different perspectives: the former zeroes in on one sample per player, where the trade-off in question is between the number of bits each player is allowed in his report, and the number of players needed to the testing process. We think of the number of bits as too small to describe the sampled element fully. In this setting, a full description of two samples is never available to a single player (not even the referee). We do note that the tester given there relies on a looser notion of collisions (Taking a coarser division of  $[n]$  into subsets).

In the later, the focus is different: one now fixes instead the communication to *one* bit per player. Now, the trade-off is between the number of players and the number of samples each one of them takes. The upper bound devised there discuss each player taking the right amount of samples, and notifying the referee 0 if no collision occurred, and 1 otherwise. In some sense, the referee ends up counting collisions (notice the count is trimmed, as one player might see more than 1 collision, but is only able to report 0 or 1). This tester is then used as a black-box to solve uniformity testing in the classic distributed models (CONGEST and LOCAL), in a setting where each player initially draws one sample.

One other paper to specifically discuss uniformity testing is [12], in which a streaming version of the problem is defined, as well as another distributed version, in a blackboard model, where all players are privy to the messages sent by others. As opposed to the

simultaneous models mentioned above – here several rounds of communication are allowed. As it turns out, the streaming algorithm, as well as another algorithm for the distributed version, boil down yet again to counting collisions under the limitations of the model.

In addition to these, quite a few works had the focus of showing impossibility results both in the classic and the entire variety of models. For our interest, we mention [15, 24] for the classic version, as well as [22] for the simultaneous model (with multiple samples per machine), and [12, 3] for the streaming model.

## 2 Preliminaries

Throughout this text, we discuss uniformity testing using collision-based testers.

We let  $[n] := \{1, 2, \dots, n\}$ , and use  $\Delta([n])$  to denote the set of distributions over the set  $[n]$ . As we only care about the support size (rather than the values), it is enough to consider  $P \in \Delta([n])$  as possible input distributions. For a distribution  $P$  over  $[n]$ , we write  $P_i$  for the probability of the  $i^{\text{th}}$  element.

An  $(n, \epsilon)$ -uniformity tester is an algorithm  $\mathcal{A}$  that given oracle access to some unknown distribution  $P \in \Delta([n])$ , takes  $q = q(n, \epsilon)$  samples from  $P$  and satisfy the following:

- If the input distribution is  $P = U_n$ , the uniform distribution over  $[n]$ , then  $\mathcal{A}$  outputs YES with probability at least  $3/4$ .
- If  $\|P - U_n\| \geq \epsilon$ , which means the distribution  $P$  is  $\epsilon$ -far from uniform, then  $\mathcal{A}$  outputs NO with probability at least  $3/4$ .

The distance used here is  $L_1$ . Meaning, for two distribution  $P, Q$ , the distance is  $\|P - Q\| = \sum_{i=1}^n |P_i - Q_i|$ .

To formalize our notion of a *collision-based* tester, we take a fresh point of view of the sampling process. The key object in our analysis is the *comparison graph*, which is simply an undirected graph  $G = (V, E)$ , where we think about  $V$  as a set of placeholders for samples and  $E$  as the pairs of samples which are chosen to be compared with one another.

► **Definition 1** (Sampling process, collision indicators). *Given a comparison graph  $G = (V, E)$  and an input distribution  $P \in \Delta([n])$ , the sampling procedure  $S_P$  is described as a random labeling of the vertices according to  $P$ . We denote by  $S_P : V \rightarrow [n]$ , the process for which  $\forall i. S_P(v_i) \sim P$ , independently from one another. We end up with  $S_P(v_1), \dots, S_P(v_{|V|})$  which is a set of  $|V|$  i.i.d samples from  $P$ .*

Moreover, we define for any edge  $e = (u, v)$  in  $E$ , the collision indicator  $\mathbb{1}_e^P := \mathbb{1}_{S_P(u)=S_P(v)}$ .

When  $P$  is clear from context, we simply write  $S(u)$  for the sample sitting in vertex  $u$ , and  $\mathbb{1}_e$  for the collision indicator.

We are now ready to give a formal definition for a collision-based tester, which relies on a set of comparisons (not necessarily between all pairs of samples), and compares  $Z$  - the amount of collisions, with some threshold value  $T$ .

► **Definition 2** (Collision-based tester). *Fix  $n, \epsilon$ . For any comparison graph  $G = (V, E)$  and real number  $0 \leq \tau \leq 1$ , we define the algorithm  $\mathcal{A} = (G, \tau)$  as follows: upon receiving as input  $|V|$  i.i.d samples from  $P$  (given by  $S_P(v_1), \dots, S_P(v_{|V|})$ ), it computes the following:*

$$Z := \sum_{e \in E} \mathbb{1}_e, \quad T := |E| \cdot \left( \frac{1 + \tau \epsilon^2}{n} \right),$$

and outputs YES if  $Z < T$ , and NO otherwise.

The restriction  $\tau \in [0, 1]$  will help us deal with technicalities, but we note that it is rather intuitive. Indeed, as we will see later, only for these values the expectation of  $Z$  is lower than  $T$  for the good input (uniform distribution), and higher than  $T$  for *all* bad inputs.

Throughout, we will focus on properties of the graph and of our input distribution. We denote by  $|E_G|$ ,  $|V_G|$  the number of edges and vertices in  $G$ , and by  $c(G)$  the number of times a 2-path appears as a subgraph in  $G$ . We count each 2-path twice, for its 2 automorphisms, and so we need to count “directed” 2-paths (so  $e_1, e_2$  and  $e_2, e_1$  are both counted). Formally, we can write  $c(G) = \left| \left\{ (u, v, w) \in \binom{V}{3} \mid (u, v), (v, w) \in E \right\} \right|$ .

For the distribution  $P$  over  $[n]$ , with  $P_i$  for the probability of the  $i^{\text{th}}$  element, we denote the collision probability  $\mu_P = \sum_{i=1}^n P_i^2$ , and the three-way collision probability  $\gamma_P = \sum_{i=1}^n P_i^3$ . For brevity, whenever  $G$  or  $P$  are clear from context, we simply write  $|V|$ ,  $|E|$ ,  $\mu$ ,  $\gamma$ .

## 2.1 Models of Computation

In all our results we are concerned with distribution testing (and specifically uniformity testing), and we deal with various models. Therefore, in the following lines we specify in which way samples are taken in each model, and in what way the answer of the algorithm needs to be declared (where a good tester is the one that outputs YES (resp. NO) with high probability whenever the samples are taken from a YES (resp. NO) distribution).

**The centralized model.** The centralized model is the classic model. In this model one processor receives all samples  $s_1, \dots, s_q$  (in comparison graph notations, we think of  $s_i = S(v_i)$ , and  $q = |V|$ ), and is tasked with outputting a proper answer according to the underlying input distribution. The complexity measure we wish to minimize in this model is  $q$ , the number of samples.

**The simultaneous model.** The second model we consider is the simultaneous model, where  $k$  players (processors) each draw individual samples unseen by all other players. Each player sends a short message to the referee. The referee then aggregates the messages and outputs the answer. Formally, each player is tasked with  $V_i$  where the whole set of vertices in  $G$  is  $V = \sqcup_{i=1}^k V_i$ . The samples of processor  $i$  are then  $\{S(v)\}_{v \in V_i}$ . Each processor can send a message  $a_i$  which is a function of its samples, and a referee receives all messages  $a_1, \dots, a_k$  and outputs the answer. The simultaneous first appeared in the context of testing independently in [16] and preliminary version of [5, 6], where in the first  $|a_i| = 1$  meaning each player is allowed to send one bit, and in the latter  $|V_i| = 1$  meaning each player gets exactly one sample. We take the same point of view as in [16], but we remove the restriction of 1 bit and allow a longer (but still short) message instead.

The number of players  $k$  is given as a parameter, and our goal is to minimize the number of samples *per player*, where all players get the same amount of samples:  $q/k$  (we think of it as sort of parallelization of the sampling process). We also consider the asymmetric-cost variant, where each player has an individual cost for each sample it draws (we think of this cost as the time it takes to draw each sample), and we wish to minimize the cost (or time) of the entire sampling process.

We also discuss the case of memory-constrained processors, also referred to as the streaming model, where this distribution testing was recently considered in [12].

**Memory-constrained processor.** In the memory-constrained model, each processor receives its samples as a stream, and once a sample is dealt with it is gone forever (this is the one-pass variant of the streaming model). A processor can only use a limited amount at each given moment, denote by  $m$  (and measured by memory bits). We think of  $m' = \lfloor m/(2 \log n) \rfloor$  as the number of samples we can store with half the memory (we leave the other half for other calculations). The complexity measure of this model is the number of samples needed to complete the testing task.

We also consider a simultaneous model where each processor is memory-constrained, receiving its samples as a stream, and using its  $m$  bits of memory it needs to come up with a message  $a_i$  to send to the referee once all samples are seen. The referee then receives all messages and outputs an answer. We stick to the case where all processors are of the same type and therefore have the same constraints of  $m$  bits.

### 3 Results

In this section we go over numerous applications of our method. For each model we go over the same phases: we start with intuition as to which comparison graph  $G$  is fit to this model, and we go on to show how one can simulate a collision-based algorithm  $\mathcal{A} = (G, \tau)$ . By simulating the algorithm we mean that by the end of the calculation, some processor will be able to compute both the number of collisions ( $Z$ ) and the fitting threshold ( $T$ ), so it is able to output the answer. The last part is optimizing parameters, where first order parameters are those of  $G$ , and in some application we also give focus to second order parameters (choosing  $\tau$ ).

The strength of the method comes from the following structural theorem that gives sufficient conditions for a comparison graph inducing a good uniformity tester:

► **Theorem 3.** *Fix a domain size  $n$  and a proximity parameter  $\epsilon$ . If the following hold for an algorithm  $\mathcal{A} := (G, \tau)$ :*

1.  $|E| \geq \frac{4n}{\tau^2 \epsilon^4}$ ,
2.  $|E| \geq \frac{16n}{(1-\tau)^2 \epsilon^4}$ , and
3.  $\frac{c(G)}{|E|^2} \leq \frac{(1-\tau)^2 \epsilon^2}{16\sqrt{n}}$ ,

*then  $\mathcal{A}$  is an  $\epsilon$ -uniformity tester.*

We direct the reader to the full version for the proof. For the most part, it is a generalization of the one used in [14] to show the original collision-based tester is optimal (in our notations, the original tester over  $q$  samples is simply the algorithm  $\mathcal{A} = (K_q, 1/2)$ ). While generalizing the proof we leave not one, but *three* separate conditions on a general comparison graph, that together guarantee it induces an  $(n, \epsilon)$ -uniformity tester. This supplies a better, multi-dimensional understanding of how well a collision-based algorithm is guaranteed to perform. We note that if one is willing to ignore constants, one could simply fix  $\tau = 1/2$  and merge the first two conditions into one. However, interestingly for our method other values of  $\tau$  (usually smaller) guarantee slightly better constants. We leave all 3 conditions separate to maintain maximum flexibility when proving application of the theorem.

A specific comparison graph that is key to our algorithms is the one of *disjoint cliques*. Indeed, our strategy will be “perform any comparison you can” which sometimes simply means we have several bulks of samples, where in each bulk all pairs can be compared. To this end, we also give a more specific version of Theorem 3, for graphs that have this structure:

► **Lemma 4.** Fix  $n, \epsilon$ . Fix a comparison graph  $G = \bigsqcup_{i=1}^{\ell} G_i$ , where each  $G_i$  is isomorphic to  $K_q$ , for some  $q \geq 3$ . If the following hold for an algorithm  $\mathcal{A} := (G, \tau)$ :

1.  $q\sqrt{\ell} \geq \frac{\sqrt{12}\sqrt{n}}{\tau\epsilon^2}$
2.  $q\sqrt{\ell} \geq \frac{\sqrt{48}\sqrt{n}}{(1-\tau)\epsilon^2}$
3.  $q\ell \geq \frac{24\sqrt{n}}{(1-\tau)^2\epsilon^2}$

then  $\mathcal{A}$  is an  $\epsilon$ -uniformity tester that uses  $|V|$  samples.

Here again we leave the 3-conditions version in order to be able to adjust the threshold parameter for optimizations. However, here all 3 conditions are quite similar, pointing to the following simple corollary:

► **Corollary 5.** Fix  $n, \epsilon$ . Fix a comparison graph  $G = \bigsqcup_{i=1}^{\ell} G_i$ , where each  $G_i$  is isomorphic to  $K_q$ , for some  $q \geq 3$ . For each constant  $\tau$ , the algorithm  $\mathcal{A} := (G, \tau)$  is an  $\epsilon$ -uniformity tester, if it holds that

$$q\sqrt{\ell} \geq 35\sqrt{n}/\epsilon^2$$

The proofs of these are also omitted, and appear in the full version of the paper. We go on to show how these statements are used to devise testers in various models.

## 3.1 Standard Processors

### 3.1.1 Centralized Model

As a warm up, we re-prove the original collision-based tester works, in term of the comparison graph, and using 4. To add a small twist, we show that under our analysis, better sample complexity is guaranteed when using a biased threshold (meaning, taking  $\tau \neq 1/2$ ). Let us denote  $q := |V|$ , which is the number of samples drawn, and our complexity measure for the model. The following is rather straightforward:

► **Corollary 6.** One can test uniformity using  $q = \Theta\left(\frac{\sqrt{n}}{\epsilon^2}\right)$ .

**Proof.** We simply use the lemma for  $\ell = 1$  (one big clique), and we get 3 conditions of similar form, and in particular:

$$q \geq \max \left\{ \frac{\sqrt{12}}{\tau}, \frac{\sqrt{48}}{1-\tau}, \frac{24}{(1-\tau)^2} \right\} \cdot \frac{\sqrt{n}}{\epsilon^2}$$

Which means that choosing e.g.,  $q = \frac{100\sqrt{n}}{\epsilon^2}$  with  $\tau = 1/2$ . We note that the tester can easily compute  $Z, T$  and therefore execute the collision-based algorithm  $(G, \tau)$ , for any value of  $\tau$ .

An added perk here, is that one can optimize  $\tau$  over the three conditions to reduce sample complexity by a constant factor. Even though the guaranteed constant is somewhat of an artifact of the proof, it is still interesting to see that  $\tau = 1/9$  would reduce the constant from 100 to roughly 35 (while simple optimization over  $\tau$  would reduce it even a bit more, for some irrational threshold value). ◀

### 3.1.2 Simultaneous Model

In the simultaneous model,  $k$  players are each given oracle access to the distribution  $P$ . After taking samples, each player is allowed to send a short message to a referee, who then needs to output the right classification for  $P$  (with high probability).

We give our focus to the variant posed in [16]: what is the number of *samples per player* needed to test uniformity? The “single collision” algorithm devised for that question only requires *one bit* from each player, and indeed it was shown to be optimal in [22]. However, this algorithm is somewhat delicate: first, the range of the parameter  $k$  is limited (it cannot be too high or too low, with regards to  $n, \epsilon$ ); second, if the number of players  $k$  is not accurately known to all players, the algorithm breaks. This is because unlike most results in the classic setting, the analysis here actually requires each player to use a specific amount of samples, but not more than that. Because the players can only communicate a single bit, everything else must be set in advance given the problem’s parameters.

To that end, we relax the model, and allow each player to send more than a single bit, but still only a small number of bits is allowed. These would allow each player to send the number of collisions she saw (rather than *whether* a collision occurred). Our algorithm works for any parameter  $k$ , and can adjust to the case where each player is not exposed to the exact value of  $k$ , but rather to an approximation of it.

The model at hand imposes very concrete limitations on our comparison graph: one cannot compare a sample from one process to a sample of the another process. This means having  $k$  players solving the problem in a parallel way, is equivalent to having a comparison graph whose number of connected components is *at least*  $k$ . Followed by the intuition of “compare every pair you have”, the graph we use is the disjoint cliques graph, with  $k$  disjoint cliques. Our measure of complexity is the number of samples each player used,  $q'$ , which is translated to be the size of each one of our cliques.

► **Corollary 7.** *In the simultaneous model, one can test uniformity using  $q' = \Theta\left(\frac{\sqrt{n}}{\sqrt{k}\epsilon^2}\right)$  samples per player, where each player is allowed to send  $\Theta(\log(1/\epsilon))$  bits to the referee.*

**Proof.** We use Lemma 4, where each player has an independent sample set of size  $q'$  and compares all the pairs. We have  $k$  players in total doing so.

Our first goal is to show how to simulate a collision-based tester  $(G, \tau)$  in this model. This will be possible whenever  $G$  is made of at least  $k$  vertex-disjoint connected components  $G = \bigsqcup_{i \in [k]} G_i$ .

Now, we can write  $Z = \sum_i Z_i$  where  $Z_i := \sum_{e \in E_i} \mathbb{1}_e$ , and each  $Z_i$  is calculated by the  $i$ th player and then sent to the referee who simply sums them up to produce  $Z$ . Computing  $T$  is easy: the algorithm is known to all, and specifically the values  $\tau, |E|$  are known to the referee. Now she simply needs to output the decision  $\mathbb{1}_{Z < T}$ .

Our next step is to quantify the communication and sampling cost of said algorithm. We aim at a communication cost of roughly  $\log(1/\epsilon)$  bits per player. We note that  $Z_i$  can theoretically be very large, however if it surpasses  $T$ , then obviously  $Z > T$ , and the referee can reject. To this end we designate a specific string to say “too large” and instead each player sends  $Z_i$  only up to a value of  $T$ . This amount can be communicated using merely  $\log(T)$  bits by each player.

We now calculate the sample complexity, measured in samples *per player*. We use Lemma 4 with  $q'$  and  $\ell = k$ , to know that it is enough if we satisfy:

1.  $q' \geq \frac{\sqrt{12}\sqrt{n}}{\tau \cdot \sqrt{k}\epsilon^2}$
2.  $q' \geq \frac{\sqrt{48}\sqrt{n}}{(1-\tau) \cdot \sqrt{k}\epsilon^2}$
3.  $q' \geq \frac{24\sqrt{n}}{(1-\tau)^2 k \epsilon^2}$

Which is enough to show the asymptotic sample complexity we desire.<sup>3</sup>

<sup>3</sup> Assuming large enough  $k$ , the third condition pose asymptotically weaker requirement, and so optimizing  $\tau$  on the first two would yield the optimal guarantee for  $\tau = 1/3$ , getting us to  $q' = \left\lceil \frac{\sqrt{108}\sqrt{n}}{\sqrt{k}\epsilon^2} \right\rceil$  samples per player.

Since the third condition is looser than the first two, we actually choose the number of samples per player,  $q'$ , such that  $|E| = \Theta(n/\epsilon^4)$ . Since  $\tau\epsilon^2 \leq 1$ , this means that our threshold is not too large

$$T = \Theta\left(\frac{n}{\epsilon^4}\right) \cdot \left(\frac{1 + \tau\epsilon^2}{n}\right) = \Theta(1/\epsilon^4),$$

and so the simulation of the tester only requires each player to send  $\log(\Theta(1/\epsilon^4))$  bits to describe the number of collisions she saw.  $\blacktriangleleft$

► **Remark 8.** As apparent from [5, 6, 22], when messages are  $r$  bits long, the correct value to look for in the sample complexity is  $2^r$  (and sometimes  $\sqrt{2^r}$ ). For this reason, when discussing communication, we explicitly write expressions such as  $\log(\Theta(1/\epsilon^4))$  instead of a more general  $\Theta(\log(1/\epsilon))$ . This would prove useful when comparing our results to known lower bounds, as is done in Section 4.2.

### 3.1.3 Asymmetric-Cost Model

This variant is best described and motivated as follows: we think of the sampling process as time consuming, and each of the  $k$  players now has her own sampling rate, meaning that some players are able to draw samples faster than others. We describe the sampling rate vector  $R = (R_1, \dots, R_k)$ , and we let each player draw her own number of samples  $(s_1, \dots, s_k)$ . The complexity measure is the time dedicated for the sampling process, denoted  $t$ . Within  $t$  time, player  $i$  collects exactly  $q_i := \lfloor R_i \cdot t \rfloor$  samples.

Simulating the tester (calculations of  $Z, T$ ) works just as before. The big difference is that now each player has a different amount of samples (depending on her rate  $R_i$ ) and thus a different clique size. We omit the calculations which can be found in the full version, and merely state the result we obtain:

► **Corollary 9.** *In the simultaneous model, one can test uniformity in time  $t = \Theta\left(\frac{\sqrt{n}}{\epsilon^2 \|R\|_2}\right)$ , where  $\|R\|_2 = \sqrt{R_1^2 + \dots + R_k^2}$ , and each player sends  $\Theta(\log(1/\epsilon))$  bits to the referee.*

It is interesting that this tester actually generalizes the previous two. Indeed, taking rate vectors  $R = (1, \dots, 1)$  gives the symmetric model, and  $R = (1, 0, \dots, 0)$  the centralized one.

## 3.2 Memory-Constrained Processors

### 3.2.1 Centralized Model with Memory Constraints

In the streaming version of the problem, introduced in [12], the samples from the distribution  $P$  arrive in a stream, and our processor can only store  $m$  bits of memory. We wish to stream as few samples as possible and still output with high probability whether  $P$  is uniform or  $\epsilon$ -far. For our purposes, we use  $m' = \lfloor m/2(\log(n)) \rfloor$ , the number of *samples* that can be stored with half of the memory space (the other half will be used to perform calculations).

The restriction this model imposes is that when a certain sample is being processed, it can only be compared with the  $O(m')$  samples that are currently stored. This intuition can be formalized, showing that any comparison graph used in the streaming model must have a bounded *average* degree (the maximal degree can be arbitrarily high: store the first sample and compare with all others). Indeed, we later quantify this statement (see Claim 16, in Section 4.1.2). For now, we just use it as intuition for the right comparison graph.

In [12] the full bipartite graph was used (with few modifications): they store a batch of samples  $V_1$  and compare the rest of the stream ( $V_2$ ) while comparing each new samples to all samples in  $V_1$ . For a partial range of  $m$ , they achieve sample complexity of  $\Theta(n/(m'\epsilon^4))$ , which is shown to be optimal for an even more limited range parameter  $m$ . It was left as an open question whether this sample complexity can be attained for a wider range of values for  $m$ . For the upper bound, we answer this question in the positive. We use not only a different analysis, but rather a whole different comparison graph, one that also has a low average degree. For simpler representation, we again turn to the disjoint cliques graph used before. The induced algorithm is this: we allocate half the memory for samples and half for calculations. for the first half we take batches of  $m'$  samples, and make all comparisons in between them. We then delete them entirely and make room for a new batch. The number of comparisons is a compact information, that can be easily calculated and stored on the second half of our memory tape.

Once again we leave the full details in the full version of this paper and sum up the differences. The calculations are somewhat similar to before. The one major difference (that results with a different-looking result) is the fact we now express the sample complexity with respect to parameter  $m$  (the size of each clique), whereas before we used  $k$  (the number of cliques) as a parameter.

Since the first half of the tape must store samples, and the second half must count collisions all the way up to the threshold  $T = \Theta(1/\epsilon^4)$ , the result only applies for  $m = \Omega(\log(1/\epsilon))$ . Whenever  $m' \geq c\sqrt{n}/\epsilon^2$  there is not need (nor a possibility) to split our samples to batches, and instead we use one large batch to test uniformity such as in the centralized (standard) model. Combining all the above, we obtain the following result:

► **Corollary 10.** *In the streaming model with memory  $m$ , one can test uniformity using*

$$q = \Theta\left(\max\left\{\frac{n \cdot \log(n)}{m\epsilon^4}, \sqrt{n}/\epsilon^2\right\}\right)$$

*samples, as long as we have  $m = \Omega(\log(1/\epsilon))$ .*

Note that our result has similar complexity as in [12], but it widens the range of acceptable values for  $m$ . They had the requirement of  $m = \Omega(\log(n)/\epsilon^6)$ , which is far larger than the humble requirement posed on our tester. We leave open an interesting question posed also in [12]: is it possible to test for uniformity in the scarce regime, and if so – what is the sample complexity required to do so? (The scarce regime is essentially  $m = o(\log(n))$ ). Though, to comply with our result - e.g., for absurdly small values of  $\epsilon$  - it can be redefined to  $m = o(\max\{\log(1/\epsilon), \log n\})$

### 3.2.2 Simultaneous Model with Memory Constraints

The main difficulty in this section seems to be handling the multiple parameters: on top of  $n, \epsilon$ , we use  $k$  processors, each of which can store at most  $m$  bits of memory (or  $m'$  samples), and is allowed a short one-sided communication to the referee.

We state the result and omit the proof (which is given in the full version).

► **Corollary 11.** *In the memory-constrained simultaneous model, whenever  $m = \Omega(\log(1/\epsilon))$  bits of memory are allowed for each player, and  $\log(1/\epsilon^4)$  bits of communication are allowed for each player, uniformity can be tested using*

$$\Theta\left(\frac{n}{k\epsilon^4} \cdot \max\left\{\frac{\log(n)}{m}, \frac{\sqrt{k}\epsilon^2}{\sqrt{n}}\right\}\right)$$

*samples per player.*

Note that in the regime of very small memory constraint, the problem suddenly “parallelize” perfectly: imagine taking  $k \leq \Theta((n/\epsilon^4) \cdot (\log^2(n)/m^2))$  machines with memory  $m$  per machine. In this case, each machine needs only a  $1/k$  fraction of the amount of samples required for a single machine with memory  $m$ . This phenomena is explained by the observation that the real barrier (or scarce resource) in this regime is the overall storage, which indeed grows linearly with the number of machines used.

## 4 Limitations of the Method

In this section our goal is to better understand the possibilities (and impossibilities) of collision-based testing, in comparison to arbitrary testing methods (many of which were developed for specific testing task, as mentioned earlier in the text).

Here, we use Definition 2 to shift the discussion to graph terminology, focusing on the comparison graph. We leverage simple graph properties to show some limitations that apply when generating testers, such as done in Section 3.

The results hereinafter apply to testers where correctness is proven via our structural theorem. However, we next formulate a simple conjecture (regarding the necessity of making enough comparisons) that implies these results are true for any tester that answers Definition 2. In matter of fact, we will formally show that under the framework of Theorem 3, the comparison graphs we have chosen are essentially the best to answer the requirements. If the conjecture is proven to be true, we get the stronger results that this graphs are indeed optimal with respect to any tester from Definition 2).

In the discussion at the end of this section, we compare these results with known lower bounds (for arbitrary testers) under the same constraints. This section aims to both show optimality (or near-optimality) of the testers we develop, and more importantly: give a better understanding of collision-based testing and how strong it is, compared to an arbitrary tester.

We first go on to show some basic inequalities that hold in any simple graph (and in our comparison graphs as well). These will serve us for the rest of this section. The goal is to establish the inherent connection between the 3 sizes:  $|V|, |E|, c(G)$  in any simple graph  $G$ .

### 4.1 Conditional Impossibility Results

We start by stating the following easy lemma that connects our quantities of interest in any simple graph.

► **Lemma 12.** *For any simple graph  $G$ , it holds that:*

1.  $|E| \leq \frac{|V|^2}{2}$
2.  $|V| \geq \frac{4|E|^2}{2|E|+c(G)}$
3. *if  $|V| \leq |E|$  then  $c(G) \geq 2|E|$*
4. *Whenever  $|V| \leq |E|$ , we have  $|V| \cdot c(G) \geq 2|E|^2$*

We omit the proof here (it appears in the full version), and proceed to put these properties into use.

In order to understand the scope of possible applications of Theorem 3, we stick to graph notations, and combine the 3 different types of assertions concerning our comparison graph:

1. The requirements needed to apply Theorem 3.
2. The basic graph properties of Lemma 12.
3. Individual assertions that apply for the model at hand.

We note that all the results below only use the first requirement of Theorem 3, which asks for the total number of comparisons to be large enough. We believe this requirement to be inherent for *any* collision-based tester (rather than an artifact of our analysis). We formulate this belief as the following conjecture, which would strengthen the impossibility results of this section to be independent of the analysis (instead of limitation of Theorem 3, we get a lower bound for all collision-based testers as defined in Definition 2).

► **Conjecture 13.** *Any collision-based tester as in Definition 2 that tests uniformity with error at most  $1/4$  must have  $|E| = \Omega\left(\frac{n}{\epsilon^4}\right)$*

Note that it holds in two extremes: for maximum amount of dependencies (clique graph) it follows from any lower bound in the classic version of the task. On the other side, the perfect matching has no dependencies at all, and it induces a tester that draws a new pair of samples each time. As the collision probability is either  $1/n$  or larger than  $(1 + \epsilon^2)/n$ , each comparison is like an independent coin toss with this biased (as observed by [6]). It is known for this problem that at least  $\Theta(n/\epsilon^4)$  tosses are needed to decide the bias, which shows correctness of the conjecture for this comparison graph.

#### 4.1.1 Standard Processors

**Centralized model.** As a warm-up, we turn to the classic model, where no constraints are involved. We easily see that Conjecture 13 helps. Using the first bullet in Lemma 12 gives the known lower bound in the classic version of the problem:  $q = |V| \geq \sqrt{2|E|} = \Omega(\sqrt{n}/\epsilon^2)$ .

**Simultaneous model.** In the simultaneous case, the main restriction is that of each player has her own comparison graph, as no comparisons can be made between two different players. This leads us to the following:

► **Corollary 14.** *Assuming Conjecture 13 holds, the number of samples per player of any collision-based uniformity tester in the simultaneous model is  $q' = \Omega\left(\frac{\sqrt{n}}{\sqrt{k} \cdot \epsilon^2}\right)$ .*

**Proof.** We recall the sample complexity here is the maximum amount of samples one player draws. Formally, we write the comparison graph as the union of  $k$  disjoint parts:  $G = \bigsqcup_{i \in [k]} G_i$ , where  $G_i = (V_i, E_i)$ , and so the complexity measure is simply  $q' = \max_{i \in [k]} |V_i|$ .

We note, however, that  $|E_i| \leq |V_i|^2/2$  for each component  $G_i$ , and therefore:

$$|E| = \sum_{i \in [k]} |E_i| \leq \sum_{i \in [k]} |V_i|^2/2 \leq k \cdot \max_{i \in [k]} |V_i|^2/2 = k \cdot q'^2/2.$$

Plugging in Conjecture 13, we get

$$q' \geq \sqrt{\frac{2|E|}{k}} = \Omega\left(\frac{\sqrt{n}}{\sqrt{k} \cdot \epsilon^2}\right),$$

which ends the proof. ◀

**Asymmetric cost model.** The more elaborate version of the asymmetric-cost model also impose similar limitations, where the difference comes from the generalized definition of the complexity measure.

► **Corollary 15.** *We observe the asymmetric-cost simultaneous model, with sampling rate vector  $(R_1, \dots, R_k)$ . If Conjecture 13 holds, then any collision-based uniformity tester in this model must use sampling time of  $t = \Omega\left(\frac{\sqrt{n}}{\epsilon^2 \|R\|_2}\right)$ .*

**Proof.** We again use  $G = \bigsqcup_{i \in [k]} G_i$ , where  $G_i = (V_i, E_i)$ . However, the complexity measure is the time  $t$  in which player  $i$  with rate  $R_i$  can obtain  $|V_i| = q_i = t \cdot R_i$  samples.

Again, using the trivial edges-vertices inequality over each component  $G_i$ , we get

$$\forall i. |E_i| \leq |V_i|^2 / 2 = t^2 \cdot R_i^2 / 2$$

and summing all together, we get

$$|E| = \sum_{i \in [k]} |E_i| \leq \sum_{i \in [k]} t^2 \cdot R_i^2 / 2 \leq t^2 \|R\|_2^2 / 2.$$

Joined with Conjecture 13, it concludes the proof

$$t \geq \sqrt{\frac{2|E|}{\|R\|_2^2}} = \Omega\left(\frac{\sqrt{n}}{\epsilon^2 \|R\|_2}\right). \quad \blacktriangleleft$$

### 4.1.2 Memory-Constrained Processors

Here we use a slightly more sophisticated argument, to show that the memory constraint can also be translated to graph notation. We emphasize that our desire is to show limitations of our framework, and so we relax the model and assume that comparisons are made on designated memory cells, in which we can only store  $m'$  element names. In order to count collisions *accurately*, we cannot expect to compress this data further. For example,  $m' = o(\sqrt{n})$  and samples are drawn from the uniform distribution  $P = U_n$ , with 99% we need to write in our memory  $m'$  different elements, and this information cannot be compressed.

We go on to show how the memory constraint translates well:

▷ **Claim 16.** Let us assume a constrained machine can only store  $m'$  elements at a time, and it is able to accurately count collisions on a comparison graph  $G = (V, E)$ . Then it must be the case that  $|E| \leq m' \cdot |V|$ .

*Proof.* w.l.o.g let us name the vertices, or samples, by their order in the stream  $V = \{v_1, v_2, \dots, v_s\}$ , and w.l.o.g let us think of the edges in  $E$  as ordered pairs (We only write  $(i, j) \in E$  for pairs where  $i < j$ ).

Now, we note that at time  $t$ , upon processing the sample  $v_t$ , the memory can only store  $m'$  samples from the set  $s(v_1), \dots, s(v_{t-1})$ . This means that the number of edges in  $E$  of the form  $(v_i, v_t)$  is at most  $m'$ . Now, we can count our (ordered) edges using the second item:

$$|E| = \sum_{v_j \in V} |\{(u, v_j) \in E \mid u \in V\}| \leq \sum_{v_t \in V} m' = |V| \cdot m'$$

which completes the proof. ◀

**Centralized model with memory constraints.** We next apply this claim to give similar lower bounds in the following models.

► **Corollary 17.** Assume Conjecture 13 holds. Any collision-based uniformity tester that can only store at most  $m' = \Theta(m/\log(n))$  samples at any given time, must take at least  $q \geq \Omega\left(\frac{n \log(n)}{m \epsilon^4}\right)$  samples.

**Proof.** As our measure complexity is the total amount of samples,  $q = |V|$ , we can combine the claim above with Conjecture 13 to get:

$$q = |V| \geq \frac{|E|}{m'} = \Omega\left(\frac{n \log(n)}{m \epsilon^4}\right),$$

which ends the proof. ◀

**Simultaneous model with memory constraints.** We observe the combined model of simultaneous model with memory-constrained machines. We again restrict ourselves to a specific framework: each player uses her own graph  $G_i = (V_i, E_i)$ , where memory is allocated for sampled elements, and then all players send a short message to the referee. The entire comparison graph the algorithm is based on is  $G = \bigsqcup_i G_i$ .

► **Corollary 18.** *Any collision-based uniformity tester in a simultaneous model of  $k$  machines that can store up to  $m'$  samples each, must use*

$$q' = \Omega \left( \frac{n}{k\epsilon^4} \cdot \max \left\{ \frac{\log(n)}{m}, \frac{\sqrt{k}\epsilon^2}{\sqrt{n}} \right\} \right)$$

*samples per player, assuming Conjecture 13 holds .*

**Proof.** We start by re-writing the desired expression:

$$q' = \Omega \left( \max \left\{ \frac{\sqrt{n}}{\sqrt{k}\epsilon^2}, \frac{n \log(n)}{mk\epsilon^4} \right\} \right)$$

We show the two lower bounds separately. Indeed, the first lower bound can be derived directly from Corollary 14:

$$q' = \Omega \left( \sqrt{n/(k\epsilon^2)} \right)$$

For the second lower bound, we extend Corollary 17 instead. As each  $G_i$  is done by a machine with memory constraints, we apply Claim 16 to player  $i$  and get  $|V_i| \geq |E_i|/m'$ . We recall that our measure complexity is in fact  $q' := \max_i |V_i|$ , and as the maximum is greater than the average, we get:

$$q' \geq \frac{\sum_i |V_i|}{k} \geq \frac{\sum_i |E_i|}{m' \cdot k} = \frac{|E|}{m' \cdot k}$$

And plugging in Conjecture 13 on the entire graph  $G = (V, E)$ , we get

$$q' = \Omega \left( \frac{n}{m' \cdot k\epsilon^4} \right) = \Omega \left( \frac{n \log(n)}{m \cdot k\epsilon^4} \right),$$

concluding the proof. ◀

## 4.2 Discussion

We point out to the fact that in all 4 models (as well as the classic model), the limitation of this method coincide with the upper bounds we obtained in the previous section. This does not come as a surprise, as choosing the “right” comparison graph is easily made once the constraints of the model are understood. The rule of thumb is simply to compare all pairs that can be compared.

It is more interesting, though, to compare the collection of possible testers with the sub-collection of collision-based testers. We next brief through known impossibility results (for an arbitrary tester. It turns out for the most part, collision-based testers compete well with others. For the classical model, as already established in [13], collision-based testing is in fact optimal. For the two simultaneous models (with no memory constraints), the collision-based testers perform optimally in terms of  $n, k$  (or  $n, (R_1, \dots, R_k)$  in the asymmetric case). To the best of our knowledge, the only testers for these models to consider *multiple* samples

per processor are the ones of [16]. For both models, the two papers show similar sample complexity, but there are two non-trivial differences. On one hand, the new testers use  $\log(\Theta(1/\epsilon^4))$  bits per communication, instead of a single one used in [16]. On the other hand, the new testers work for the full range of the parameter  $k$  (the number of players), whereas the previous results excluded extreme values: e.g., in the symmetric case it only works for  $c/\epsilon^4 \leq k \leq c'n\epsilon^4$ .

Lower bounds for both models are shown in [22], even for the case of  $r$ -bit messages. While the tester of [16] is an optimal one-bit protocol, ours is not known to be optimal  $r$ -bit protocol. This is true as the aforementioned lower bound weakens by a factor  $2^r$  for the longer  $r$ -bit messages. In our case, we have  $2^r = \Theta(1/\epsilon^4)$ , which means there is a gap of  $\epsilon^4$  between the general lower bound, and the optimal collision-based tester we obtain. Despite the gap, no better tester is known for this amount of bits and  $q > 1$  samples per player.

In the streaming model our tester attain the same sample complexity as the best known tester (that of [12]), but for a wider range for the parameter  $m$ . A matching lower bound can also be found in [12], but only for a more restricted range of the parameter  $m$ , whereas for the general case they give a weaker lower bound, which leaves an  $\epsilon^2$  gap between the general case and the optimal collision-based tester.

To the best of our knowledge, the simultaneous model with memory constraints was never considered in the context of distribution testing, and therefore there are no prior results. However, we conjecture that similarly to before, the collision-based tester achieves optimal sample complexity in parameters  $n, k, m$ , with a possible  $\text{poly}(\epsilon)$  gap that would pop, as before, due to the use of longer messages.

## Abstract

*Trace reconstruction* is the problem of learning an unknown string  $x$  from independent traces of  $x$ , where traces are generated by independently deleting each bit of  $x$  with some deletion probability  $q$ . In this paper, we initiate the study of *Circular trace reconstruction*, where the unknown string  $x$  is circular and traces are now rotated by a random cyclic shift. Trace reconstruction is related to many computational biology problems studying DNA, which is a primary motivation for this problem as well, as many types of DNA are known to be circular.

Our main results are as follows. First, we prove that we can reconstruct arbitrary circular strings of length  $n$  using  $\exp(\tilde{O}(n^{1/3}))$  traces for any constant deletion probability  $q$ , as long as  $n$  is prime or the product of two primes. For  $n$  of this form, this nearly matches what was the best known bound of  $\exp(O(n^{1/3}))$  for standard trace reconstruction when this paper was initially released. We note, however, that Chase very recently improved the standard trace reconstruction bound to  $\exp(\tilde{O}(n^{1/5}))$ . Next, we prove that we can reconstruct random circular strings with high probability using  $n^{O(1)}$  traces for any constant deletion probability  $q$ . Finally, we prove a lower bound of  $\tilde{\Omega}(n^3)$  traces for arbitrary circular strings, which is greater than the best known lower bound of  $\tilde{\Omega}(n^{3/2})$  in standard trace reconstruction.

**Acknowledgements** The first author thanks Professor Piotr Indyk for many helpful discussions and feedback, Mehtaab Sawhney for pointers to some references, and Professor Bjorn Poonen for a helpful discussion on sums of roots of unity. The second author thanks Professor Joe Gallian for running the Duluth REU at which part of this research was conducted, as well as program advisors Amanda Burcroff, Colin Defant, and Yelena Mandelshtam for providing a supportive environment. The authors also thank Amanda Burcroff for helpful edits on the paper's writeup.

## 1 Introduction

The trace reconstruction problem asks one to recover an unknown string  $x$  of length  $n$  from independent noisy samples of the string. In the original setting,  $x$  is a binary string in  $\{0, 1\}^n$ , and a random subsequence  $\tilde{x}$  of  $x$ , called a *trace*, is generated by sending  $x$  through a deletion channel with deletion probability  $q$ , which removes each bit of  $x$  independently with some fixed probability  $q$ . The main question is to determine how many independent traces are needed to recover the original string with high probability. This question has become very well studied over the past two decades [26, 27, 7, 24, 23, 38, 30, 19, 32, 35, 20, 21, 22, 13, 15, 14],

■ **Figure 1** An example of a circular trace. We start with an unknown circular string (top left). Each bit of the string is randomly deleted (red bits are deleted, black bits are retained) and the order of the retained bits is preserved, so we are left with the smaller circular string. However, since there is no beginning or end of the circular string, we assume the string is seen in clockwise order starting from a randomly chosen bit.

with many results over various settings. For instance, people have studied the case where we wish to reconstruct  $x$  for any arbitrarily chosen  $x \in \{0, 1\}^n$  (worst-case) or the case where we just wish to reconstruct a randomly chosen string  $x$  (average-case). People have also studied the trace reconstruction problem for various values of the deletion probability  $q$ , such as if  $q$  is a fixed constant between 0 and 1 or decays as some function of  $n$ . People have also studied variants where the traces allow for insertions of random bits, rather than just deletions, and variants where the string is no longer binary but from a larger alphabet.

Finally, various generalizations or variants of the trace reconstruction problem have also been developed. These include error-correcting codes over the deletion channel (i.e., “coded” trace reconstruction) [16, 11], reconstructing matrices [25] and trees [18] from traces, and reconstructing mixtures of strings from traces [3, 4, 31].

In this paper, we develop and study a new variant of trace reconstruction that we call *Circular trace reconstruction*. In this variant, there is again an unknown string  $x \in \{0, 1\}^n$  that we can sample traces from, but this time, the string  $x$  is a cyclic string, meaning that there is no beginning or end to the string. Equivalently, one can imagine a linear string that undergoes a random cyclic shift before a trace is returned. See Figure 1 for an example. Our goal, like in the normal trace reconstruction, is to reconstruct the original circular string using as few random traces as possible.

## 1.1 Main Results and Comparison to Linear Trace Reconstruction

Perhaps the first natural question about circular trace reconstruction is the following: how does the sample complexity of circular trace reconstruction compare to the sample complexity of standard (linear) trace reconstruction? Intuitively, one should expect circular trace reconstruction to be at least as difficult as standard trace reconstruction, since given any trace of a linear string, we can randomly rotate it to get a trace of the corresponding circular string. This reasoning, however, is slightly flawed. For instance, perhaps the hardest instance of linear trace reconstruction comes from distinguishing between two strings  $x$  and  $y$  which are different as linear strings but equivalent up to a cyclic shift. In this case, the circular trace reconstruction problem does not even need to distinguish between  $x$  and  $y$ , because they are equivalent! However, by padding the trace with extra bits before randomly rotating, one can show that circular trace reconstruction is at least as hard as linear trace reconstruction in both the worst-case and average-case. Indeed, we have the following proposition. As its proof is quite simple, we defer it to Appendix A in the full version of this paper on arXiv.

► **Proposition 1.** *Suppose that we can solve worst-case (resp., average case) circular trace reconstruction over length  $m$  strings with deletion probability  $q$  using  $T(m, q)$  traces. Then, we can solve worst-case (resp., average case) linear trace reconstruction over length  $n$  strings with deletion probability  $q$  using  $\min_{m \geq 2n} T(m, q)$  traces.*

Given Proposition 1, any upper bounds for circular trace reconstruction imply nearly equivalent upper bounds for the linear trace reconstruction, and any lower bounds for linear trace reconstruction imply nearly equivalent lower bounds for circular trace reconstruction. This raises two natural questions. First, can we match or nearly match the best linear trace reconstruction upper bounds for circular trace reconstruction? Second, can we beat the best linear trace reconstruction lower bounds for circular trace reconstruction?

The first main result we prove is for worst-case circular strings. At the time of the initial release of this paper, the best known upper bound for worst-case linear trace reconstruction with deletion probability  $q$ , where  $q$  is a fixed constant between 0 and 1, is  $\exp(O(n^{1/3}))$ , where the unknown string has length  $n$  [19, 32]. Shortly afterwards, the upper bound was improved to  $\exp(\tilde{O}(n^{1/5}))$  [14]. Our first main result, which we prove in Section 3, provides an upper bound for the circular trace reconstruction problem that nearly matches the results of [19, 32], but only if the length  $n$  has at most 2 prime factors.

► **Theorem 2.** *Let  $x$  be an unknown, arbitrary circular string of length  $n$ , let  $q$  be the deletion probability of each element in the string, and let  $p = 1 - q$  be the retention probability. Then, if  $n$  is either a prime or a product of two (possibly equal) primes, using  $\exp(O(n^{1/3}(\log n)^{2/3}p^{-2/3}))$  random traces, we can determine  $x$  with failure probability at most  $2^{-n}$ .*

The primary reason why our theorem fails for  $n$  having 3 or more prime factors is that we prove the following number theoretic result which is crucial in our algorithm.

► **Theorem 3.** *For any fixed integer  $n \geq 2$ , the following statement is true **if and only if**  $n$  has at most 2 prime factors, counting multiplicity.*

*Define  $\omega := e^{2\pi i/n}$ , and suppose that  $a_0, \dots, a_{n-1}, b_0, \dots, b_{n-1}$  are all integers in  $\{0, 1\}$ . Also, suppose that for all  $0 \leq k \leq n-1$ , there is some integer  $c_k$  such that  $\sum_{i=1}^n a_i \omega^{i \cdot k} = \omega^{c_k} \cdot \sum_{i=1}^n b_i \omega^{i \cdot k}$ . Then, the sequences  $\{a_i\}$  and  $\{b_i\}$  are cyclic shifts of each other.*

In this conference version, we only prove the above theorem in the special case that  $n$  is prime. For the full proof of this theorem, please see the arXiv version of this paper at <https://arxiv.org/abs/2009.01346>.

The next main result we prove is for average-case circular strings: we show that a random circular string can be recovered using a polynomial number of traces. Formally, we prove the following theorem in Section 4.

► **Theorem 4.** *Let  $x$  be an unknown but randomly chosen circular string of length  $n$  and let  $0 < q < 1$  be the deletion probability of each element. Then, there exists a constant  $C_q$  depending only on  $q$  such that we can determine  $x$  with failure probability at most  $n^{-10}$  using  $O(n^{C_q})$  traces.*

The main lemma we need to prove Theorem 4 is actually a result that is true for worst-case strings. Specifically, we show how to recover the multiset of all consecutive substrings of length  $O(\log n)$  using a polynomial number of traces. While this does not guarantee that we can recover an arbitrary circular string, it does allow us to recover what we will call *regular strings*, which we show comprise the majority of circular strings. The following lemma may be of independent interest for studying worst-case strings as well, as it allows one to gain information about all “consecutive chunks” of the unknown string using only a polynomial number of queries.

► **Lemma 5.** *Let  $x = x_1 \cdots x_n$  be an arbitrary circular string of length  $n$  and let  $0 < q < 1$  be the deletion probability of each element. Then, for  $k = 100 \log n$ , we can recover the multiset of all substrings  $\{x_i x_{i+1} \cdots x_{i+k-1}\}_{i=1}^n$ , where indices are modulo  $n$ , using  $O(n^{C_q})$  traces with failure probability  $n^{-10}$ , where  $C_q$  is a constant that only depends on  $q$ .*

The best upper bound for average-case linear trace reconstruction is  $\exp(O((\log n)^{1/3}))$  [22]. Unfortunately, we were not able to adapt their argument to circular strings. One major reason why we are unable to do so is that in the argument of [22] (as well as [35], which provides an  $\exp(O((\log n)^{1/2}))$  sample algorithm), the authors recover the  $(k+1)^{\text{st}}$  bit of the string assuming the first  $k$  bits are known using a small number of traces, and by reusing traces, they inductively recover the full string. However, since we are dealing with circular strings, even recovering the “first” bit does not make much sense. However, we note that even a polynomial-sample algorithm is quite nontrivial. In the linear case, a polynomial-sample algorithm for average-case strings was first proven by [23], and their algorithm only worked as long as the deletion probability  $q$  was at most some small constant, which when optimized is only about 0.07 [35].

Our final main result regards lower bounds for worst-case strings. For linear worst-case strings, the best known lower bound for trace reconstruction is  $\tilde{\Omega}(n^{3/2})$  [13]. For circular trace reconstruction, we show an improved lower bound of  $\tilde{\Omega}(n^3)$ . Moreover, the proof of our lower bound is actually much simpler and cleaner than those of the known lower bounds for standard trace reconstruction [13, 21]. Specifically, we prove the following theorem, done in Section 5:

► **Theorem 6.** *Let  $x$  be the string  $10^n 10^{n+1} 10^{n+k} = 1 \underbrace{0 \dots 0}_{n \text{ times}} 1 \underbrace{0 \dots 0}_{n+1 \text{ times}} 1 \underbrace{0 \dots 0}_{n+k \text{ times}}$ , where  $n \geq 1$  and  $2 \leq k \leq 4$ . Likewise, let  $y$  be the string  $y = 10^n 10^{n+k} 10^{n+1}$ . Then, the strings  $x, y$  are not equivalent up to cyclic rotations, but for any constant deletion probability  $q$ , one requires  $\Omega(n^3 / \log^3 n)$  random traces to distinguish between the original string being  $x$  or  $y$ . Thus, for all integers  $n$ , worst-case circular trace reconstruction requires at least  $\tilde{\Omega}(n^3)$  random traces.*

### 1.1.1 Concurrent Work

We note that a very similar statement to Lemma 5, but for linear strings, was proven in independent concurrent work by Chen et. al. [15, Theorem 2], which provides a polynomial-sample algorithm for a “smoothed” variant of worst-case linear trace reconstruction. Many ideas in our proof of Lemma 5 and their proof appear to overlap, though our proof is substantially shorter. We discuss the relation between our work and [15] further at the end of Section 4.

## 1.2 Motivation and Relation to Other Work

From a theoretical perspective, circular trace reconstruction can bring many novel insights to the theory of reconstruction algorithms, some of which may be useful even in the standard trace reconstruction problem. For instance, the proof of Theorem 2 combines analytic, statistical, and combinatorial approaches as in previous trace reconstruction papers, but now also uses ideas from number theory and results about cyclotomic integers. To the best of our knowledge, this paper is the first paper on trace reconstruction to utilize number theoretic ideas, though there is work on other problems about cyclic strings that uses ideas from number theory. Also, Lemma 5 shows a way to recover all contiguous sequences in the

original string of length  $O(\log n)$  for arbitrary circular strings, which is a new result even in the linear case (concurrent with [15]) and has applications to problems in linear trace reconstruction as well (as done in [15]).

From an applications perspective, trace reconstruction is closely related to the multiple sequence alignment problem in computational biology. In the multiple sequence alignment problem, one is given DNA sequences from several related organisms, and the goal is to align the sequences to determine what mutations each descendant underwent from their common ancestor: the trace reconstruction problem is analogous to actually recovering the common ancestor. One can learn more about trace reconstruction's relation to the multiple sequence alignment problem (as well as to various other problems in computational biology) via the recent survey [8].

The multiple sequence alignment problem is also a key motivation for studying circular trace reconstruction. Many important types of DNA, such as mitochondrial DNA in humans and other eukaryotes, chloroplast DNA, bacterial DNA, and DNA in plasmids, are predominantly circular (see, e.g., [37, pp. 313, 397, 516-517], or [1]). Therefore, understanding circular trace reconstruction could prove useful in reconstructing ancestral sequences for mitochondrial or bacterial DNA. Another problem in computational biology that trace reconstruction may be applicable to is the DNA Data Storage problem, where data is stored in DNA and can be recovered through sequencing, though the stored DNA may mutate over time [17, 34]. Recently, long-term DNA data storage in plasmids has been successfully researched [33], which further motivates the study of circular trace reconstruction.

Besides the linear trace reconstruction problem, circular trace reconstruction is also closely related to the problem of population recovery from the deletion channel [3, 4, 31], where the goal is to recover an unknown mixture of  $\ell$  strings from random traces. Indeed, receiving traces from a circular string is equivalent to receiving traces from a uniform mixture of a linear string along with all of its cyclic shifts, so circular trace reconstruction can be thought of as an instance of population recovery from the deletion channel with mixture size  $\ell = n$ .

Unfortunately, the best known algorithm for population recovery over worst-case strings requires  $\exp(\tilde{O}(n^{1/3}) \cdot \ell^2)$  traces [31], which is not useful if  $\ell = n$ . However, to prove our worst-case upper bound, we will use ideas based on [19, 32, 31] to estimate certain polynomials that depend on the unknown circular string  $x$ . For the average case problem, i.e., if given a mixture over  $\ell$  random strings, population recovery can be done with  $\text{poly}(\ell, \exp((\log n)^{1/3}))$  random traces. While this seemingly implies a  $\text{poly}(n)$ -sample algorithm for average-case circular trace reconstruction, the  $n$  cyclic shifts of the circular string are quite similar to each other and thus do not behave like a collection of  $n$  independent random strings. Indeed, our techniques for average-case circular trace reconstruction are very different from those developed in [4].

While circular strings have not been studied before in the context of trace reconstruction, people have studied circular strings and cyclic shifts in the context of edit distance [28, 2], multi-reference alignment [5, 6, 36], and other pattern matching problems [12]. We note that [2] also applies results from number theory and about cyclotomic polynomials, though their techniques overall are not very similar to ours.

### 1.3 Proof Overview

In this subsection, we highlight some of the ideas used in Theorems 2, 4, and 6.

The proof of Theorem 2 is partially based on ideas from [19, 32, 31]. The authors of [19, 32] consider two strings  $x, y \in \{0, 1\}^n$  and show how to distinguish between random traces of  $x$  and random traces of  $y$ . To do so, they construct an unbiased estimator for the

polynomial  $P(z; x) := \sum_{i=1}^n x_i z^i$  (or  $P(z; y) = \sum_{i=1}^n y_i z^i$ ) solely based on the random trace of either  $x$  or  $y$ , for some  $z \in \mathbb{C}$ . By showing that the unbiased estimator is never “too” large and that  $P(z; x)$  and  $P(z; y)$  differ enough for an appropriate choice of  $z$ , they can estimate this quantity using random traces to distinguish between  $x$  and  $y$ . In our case, applying the same estimator will give us an unbiased estimator for  $P'(z; x) := \mathbb{E}_i[P(z; x^{(i)})]$ , where  $x^{(i)}$  is the  $i$ th cyclic shift of  $x$ . Unfortunately, it turns out that  $P'(z; x) = P'(z; y)$  as polynomials in  $z$  as long as  $x, y$  have the same number of 1’s, even if  $x$  and  $y$  are vastly different as circular strings. Our goal will then be to establish some other polynomial  $Q(z; x)$  such that we can construct a good unbiased estimator, but at the same time  $Q'(z; x) := \mathbb{E}_i[Q(z; x^{(i)})]$  and  $Q'(z; y) := \mathbb{E}_i[Q(z; y^{(i)})]$  are distinct polynomials for any distinct cyclic strings  $x, y$ . We show that the polynomial  $Q(z; x) := z^{kn} P(z; x)^k P(z^{-k}; x)$  will do the job, for some small integer  $k$ . We provide a (significantly more complicated) unbiased estimator of  $Q(z; x)$  using a random trace: the construction is similar to that of [31], which shows how to estimate  $P(z; x)^k$  for some integer  $k$ . To show that  $Q(z; x) \neq Q(z; y)$  as polynomials, we first show that  $Q(z; x)$  has the special property that if  $z$  is a cyclotomic  $n$ th root of unity, this polynomial is invariant under cyclic shifts of  $x$ ! Thus, it just suffices to show that if  $x, y \in \{0, 1\}^n$  are not cyclic shifts of each other, there is some  $n$ th root of unity  $z = e^{2\pi i r/n}$  for some  $0 \leq r \leq n-1$  such that  $P(z; x)^k P(z^{-k}; x) \neq P(z; y)^k P(z^{-k}; y)$ . This will require significant number theoretic computation, and will be true as long as  $n$  is a prime or a product of two primes.

The bulk of the proof of Theorem 4 will be proving Lemma 5, which reconstructs all consecutive substrings of length  $100 \log n$  in the unknown circular string  $x$ . For a random string  $x$ , these substrings will all be sufficiently different, so once we know the substrings, we can reconstruct the full string because there will only be one way to “glue” together the substrings. Therefore, we focus on explaining the ideas for Lemma 5. Our goal will be to determine how many times a string  $s$  appears consecutively in  $x$  for each string  $s$  of length  $100 \log n$ . For an unknown string  $x$  and  $i$  between 0 and  $n - 100 \log n$ , we let  $c_i$  be the number of times  $s$  appears (possibly non-contiguously) in some contiguous block of length  $i + 100 \log n$  in  $x$ . Then, a basic enumerative argument shows that for a random (cyclically shifted) trace  $\tilde{x} = \tilde{x}_1 \tilde{x}_2 \cdots \tilde{x}_m$ , the probability that  $\tilde{x}_1 \cdots \tilde{x}_{100 \log n} = s$  can be written as  $\sum_{i \geq 0} c_i (1 - q)^{100 \log n} q^i$ , and we wish to recover  $c_0$ . The  $(1 - q)^{100 \log n}$  term is a constant that equals  $1/\text{poly}(n)$ , so it is easy to recover an approximation to  $\sum_{i \geq 0} c_i q^i$ . We truncate this polynomial at an appropriate degree (approximately  $C \log n$  for some large  $C$ ) and show that the truncated polynomial  $\sum_{i=0}^{C \log n} c_i x^i$  is very close to the original polynomial, but differs from  $\sum_{i=0}^{C \log n} c'_i x^i$  for some  $x \in [q, (1 - q)/2]$  by a significant amount, if  $c'_0 \neq c_0$ , using ideas based on [10]. We can also simulate a trace with deletion probability  $x > q$  by taking a “trace of the trace.” This will be sufficient in determining  $c_0$ , and therefore, the (multi)-set of all consecutive substrings of length  $100 \log n$ .

The proof of Theorem 6 proceeds by showing that the laws of the traces of  $x = 10^n 10^{n+1} 10^{n+k}$  and  $y = 10^n 10^{n+k} 10^{n+1}$  are close to each other in the sense of Hellinger distance and concluding by a lemma in [21] that was used in a similar fashion to show a lower bound for linear trace reconstruction. It is first shown that conditioned on a 1 being deleted, a trace from  $x$  is equidistributed as a trace from  $y$ . Then explicit expressions for the probabilities that the trace is  $10^a 10^b 10^c$  are computed and compared, yielding an upper bound on the Hellinger distance. The difference between the probabilities for  $x$  and  $y$  is proportional to the product of  $(a - b)(b - c)(a - c)$  and a symmetric polynomial in  $a, b, c$ . Both  $x$  and  $y$  consist of three 1’s separated by runs of 0’s of approximate length  $n$ , so with high probability we have that  $a, b, c$  are approximately  $np$ , with square root fluctuations. The contribution of the  $(a - b)(b - c)(a - c)$  term allows us to recover a  $\tilde{\Omega}(n^3)$  bound.

## 1.4 Outline

In Section 2, we go over some preliminary definitions and results. In Section 3, we prove Theorem 2. In Section 4, we prove Theorem 4. In Section 5, we prove Theorem 6. Finally, in Section 6, we conclude by discussing open problems and avenues for further research. Some proofs, such as the proof of Proposition 1 and the full proof of Theorem 3, are deferred to Appendix A in the full version of this paper on arXiv.

## 2 Preliminaries

First, we explain a basic definition we will use involving complex numbers.

► **Definition 7.** For  $z \in \mathbb{C}$ , let  $|z|$  be the magnitude of  $z$ , and if  $z \neq 0$ , let  $\arg z$  be the argument of  $z$ , which is the value of  $\theta \in (-\pi, \pi]$  such that  $\frac{z}{|z|} = e^{i\theta}$ .

Next, we state a Littlewood-type result about bounding polynomials on arcs of the unit circle.

► **Theorem 8 ([9]).** Let  $f(z) = \sum_{j=0}^n a_j z^j$  be a nonzero polynomial of degree  $n$  with complex coefficients. Suppose there is some positive integer  $M$  such that  $|a_0| \geq 1$  and  $|a_j| \leq M$  for all  $0 \leq j \leq n$ . Then, if  $A$  is an arc of the unit circle  $\{z \in \mathbb{C} : |z| = 1\}$  with length  $0 < a < 2\pi$ , there exists some absolute constant  $c_1 > 0$  such that

$$\sup_{z \in A} |f(z)| \geq \exp\left(\frac{-c_1(1 + \log M)}{a}\right).$$

Next, we state two well known results about roots of unity in cyclotomic fields.

► **Lemma 9 ([29]).** Let  $\omega = e^{2\pi i/n}$ . Then, the set of  $\{\omega^k\}$  for  $k \in \mathbb{Z}, \gcd(k, n) = 1$  are all Galois conjugates. This means that if  $P(x)$  is an integer polynomial, then  $P(\omega^k) = 0$  if and only if  $P(\omega) = 0$  for any  $k \in \mathbb{Z}$  with  $\gcd(k, n) = 1$ . Moreover,  $P(\omega) = 0$  if and only if  $P$  is a multiple of the  $n$ th Cyclotomic polynomial.

► **Lemma 10 ([29]).** Let  $\omega = e^{2\pi i/n}$  be an  $n$ th root of unity, and let  $\mathbb{Q}[\omega]$  be the  $n$ th degree cyclotomic field. Then, if  $z \in \mathbb{Q}[\omega]$  is such that  $z^r = 1$  for some integer  $r \geq 1$ ,  $z$  must equal  $\omega^k$  or  $-\omega^k$  for some integer  $k$ .

Finally, we define the Hellinger distance between two probability measures and state a folklore bound on distinguishing between distributions based on samples in terms of the Hellinger distance.

► **Definition 11.** Let  $\mu$  and  $\nu$  be discrete probability measures over some set  $\Omega$ . In other words, for  $x \in \Omega$ ,  $\mu(x)$  is the probability of selecting  $x$  when drawing from the measure  $\mu$ . Then, the Hellinger distance is defined as

$$d_H(\mu, \nu) = \left( \sum_{x \in \Omega} \left( \sqrt{\mu(x)} - \sqrt{\nu(x)} \right)^2 \right)^{1/2}.$$

The following proposition is quite well-known (see for instance, [21, Lemma A.5]).

► **Proposition 12.** If  $\mu, \nu$  are discrete probability measures, then if given i.i.d. samples from either  $\mu$  or  $\nu$ , one must see at least  $\Omega(d_H(\mu, \nu)^{-2})$  i.i.d. samples to determine whether the distribution is  $\mu$  or  $\nu$  with at least  $2/3$  success probability.

### 3 Worst Case: Upper Bound

In this section, we prove Theorem 2, i.e., we provide an  $\exp(\tilde{O}(n^{1/3}))$ -sample algorithm for circular trace reconstruction when the length  $n$  is a prime or product of two primes.

For a (linear) string  $x \in \{0, 1\}^n$  and  $z \in \mathbb{C}$ , we define  $P(z; x) := \sum_{i=1}^n x_i z^i$ . The first lemma we require creates an unbiased estimator for  $\prod_{i=1}^m P(z_i; x)$  for some complex numbers  $z_1, \dots, z_m$ , using only random traces of  $x$ . The proof of the following lemma greatly resembles the proof of [31, Lemma 4.1], so we defer the proof to Appendix A in the full version of this paper on arXiv.

► **Lemma 13.** *Let  $x$  be a linear string of length  $n$ . Fix  $q$  as the deletion probability and  $p = 1 - q$  as the retention probability. Then, for any integer  $m \geq 1$  and any  $Z = (z_1, \dots, z_m)$  for  $z_1, \dots, z_m \in \mathbb{C}$ , there exists some function  $g_m(\tilde{x}, Z)$  such that*

$$\mathbb{E}_{\tilde{x}}[g_m(\tilde{x}, Z)] = \prod_{k=1}^m \left( \sum_{i=1}^n x_i z_k^i \right),$$

where the expectation is over traces drawn from  $x$ . Moreover, for any  $L \geq 1$ , and for all  $\tilde{x} \in \{0, 1\}^n$  and all  $Z$  such that  $|z_1|, \dots, |z_m| = 1$  and  $|\arg z_i| \leq \frac{1}{L}$  for all  $1 \leq i \leq m$ ,

$$|g_m(\tilde{x}, Z)| \leq (p^{-1}mn)^{O(m)} \cdot e^{O(m^2 n / (p^2 L^2))}.$$

For  $x \in \{0, 1\}^n$  and  $z \in \mathbb{C}$ , let  $P(z; x) := \sum_{i=1}^n x_i z^i$ . Our main goal will be to determine the value of  $f_t(z; x) := P(z; x)^t \cdot P(z^{-t}; x)$  for some integer  $t$ , where  $z$  is an  $n$ th root of unity. Importantly, we note that  $f_t(z; x)$  is invariant under rotations of  $x$ , since for  $z = e^{2\pi i k/n}$ ,

$$\sum_{i=1}^n x_{(i+1) \bmod n} z^i = \sum_{i=1}^n x_i z^{i-1} = P(z; x) \cdot z^{-1}$$

whereas

$$\sum_{i=1}^n x_{(i+1) \bmod n} z^{-t \cdot i} = \sum_{i=1}^n x_i z^{-t(i-1)} = P(z^{-t}; x) \cdot z^t.$$

Therefore, if we define  $x^{(j)}$  as the string  $x$  rotated by  $j$  places (so  $x_i^{(j)} = x_{(i+j) \bmod n}$ ), then  $f(z; x) = f(z; x^{(j)})$  for all  $z = e^{2\pi i k/n}$  and  $0 \leq j \leq n-1$ .

Now, choose some  $z$  with  $|z| = 1$  and  $|\arg z| \leq \frac{1}{L}$ . Also, fix some integer  $t$ , let  $m = t+1$ , and let  $Z = (\underbrace{z, \dots, z}_{t \text{ times}}, z^{-t})$ . Then, if  $j$  is randomly chosen in  $\{0, 1, \dots, n-1\}$  and  $\tilde{x}$  is a random trace,

$$\begin{aligned} \mathbb{E}_{\tilde{x}}[n z^{tn} \cdot g_m(\tilde{x}, Z)] &= (n \cdot z^{tn}) \cdot \left( \frac{1}{n} \cdot \sum_{j=0}^{n-1} P(z; x^{(j)})^t \cdot P(z^{-t}; x^{(j)}) \right) \\ &= \sum_{j=0}^{n-1} z^{tn} \cdot P(z; x^{(j)})^t \cdot P(z^{-t}; x^{(j)}), \end{aligned}$$

where  $g_m(\tilde{x}, Z)$  is defined in Lemma 13. Note that  $\sum_{j=0}^{n-1} z^{tn} \cdot P(z; x^{(j)})^t \cdot P(z^{-t}; x^{(j)})$  is a polynomial of  $z$  of degree at most  $3tn$  and all coefficients bounded by  $n^{t+1}$ . We write this polynomial as  $Q_t(z; x)$ . Thus, if we define  $h_t(\tilde{x}, z) := n z^{tn} g_m(\tilde{x}, Z)$ , we have that  $\mathbb{E}_{\tilde{x}}[h_t(\tilde{x}, z)] = Q_t(z; x)$  for  $\tilde{x}$  a trace of a randomly shifted  $x$ , and that  $|h_t(\tilde{x}; z)| \leq (p^{-1}tn)^{O(t)} \cdot e^{O(t^2 n / (p^2 L^2))}$  whenever  $|z| = 1$  and  $|\arg z| \leq \frac{1}{L}$  for  $L \geq 2$  and  $m = t+1$ , by Lemma 13.

Now, we will state two important results that will lead to the proof of the main result.

► **Lemma 14.** *Let  $n \geq 2$ , and suppose that  $x, x'$  are strings in  $\{0, 1\}^n$  such that  $Q_t(z; x) \neq Q_t(z; x')$  as polynomials in  $z$ . Then, there is an absolute constant  $c_2$  such that for any  $L \geq 2$ , there exists  $z$  such that  $|z| = 1$ ,  $|\arg z| \leq \frac{1}{L}$ , and*

$$|Q_t(z; x) - Q_t(z; x')| \geq n^{-c_2 t L}.$$

**Proof.** Note that  $Q_t(z; x) - Q_t(z; x')$  is a nonzero polynomial in  $z$  of degree at most  $(t+1)n$  and with all coefficients bounded by  $2n^{t+1}$ . Therefore, by Theorem 8,

$$\begin{aligned} \sup_{|z|=1, |\arg z| \leq 1/L} |Q_t(z; x) - Q_t(z; x')| &\geq \exp\left(-\frac{c_1(1 + \log(2n^{t+1}))}{2/L}\right) \\ &\geq \exp(-c_2 \cdot L \cdot t \cdot \log n) \\ &= n^{-c_2 t L}, \end{aligned}$$

where we note that the arc  $\{z : |z| = 1, |\arg z| \leq \frac{1}{L}\}$  has length  $\frac{2}{L}$ . ◀

The next important result we need will be Theorem 3. We defer the full proof of Theorem 3 to the full version of this paper on arXiv, but as the proof of the case where  $n$  is prime is simpler, we prove this special case here. Using this, we can get an  $\exp(\tilde{O}(n^{1/3}))$  sample upper bound at least for  $n$  prime. As a note, we will define  $\omega = e^{2\pi i/n}$  from now on, where  $n$  will be clear from context.

► **Proposition 15.** *Suppose that  $n = p$  is prime, and  $a_0, \dots, a_{p-1}, b_0, \dots, b_{p-1} \in \{0, 1\}$  are such that for all  $0 \leq k < p$ , there is some integer  $c_k$  such that  $\sum_{i=0}^{p-1} a_i = \omega^{c_k} \cdot \sum_{i=0}^{p-1} b_i$ . Then, the sequences  $\{a_1, \dots, a_p\}$  and  $\{b_1, \dots, b_p\}$  are equivalent up to a cyclic permutation.*

**Proof.** First,  $\sum_{i=0}^{p-1} a_i = \omega^{c_0} \cdot \sum_{i=0}^{p-1} b_i$ . Since  $\sum_{i=0}^{p-1} a_i$  and  $\sum_{i=0}^{p-1} b_i$  are both nonnegative real numbers, and since  $\omega^{c_0}$  is a root of unity, we must have that  $\sum_{i=0}^{p-1} a_i = \sum_{i=0}^{p-1} b_i$ .

Next, we have that  $\sum_{i=0}^{p-1} a_i \omega^i = \omega^{c_1} \cdot \sum_{i=0}^{p-1} b_i \omega^i$ . Letting  $b'_i = b_{(i-c_1) \pmod p}$ , we have that  $b'$  is a cyclic shift of  $b$ , and  $\sum_{i=0}^{p-1} a_i = \sum_{i=0}^{p-1} b'_i$  and  $\sum_{i=0}^{p-1} a_i \omega^i = \sum_{i=0}^{p-1} b'_i \omega^i$ . Letting  $Q(x) = \sum_{i=0}^{p-1} (a_i - b'_i) x^i$ , we have that  $\omega$  and 1 are both roots of  $Q(x)$ . Since  $Q(x)$  is an integer-valued polynomial, this implies that all Galois conjugates of  $\omega$  are roots, so  $1, \omega, \omega^2, \dots, \omega^{p-1}$  are roots of  $Q(x)$ . Thus,  $x^p - 1$  divides  $Q(x)$ . But since  $Q(x)$  has degree at most  $p-1$ ,  $Q(x)$  must equal 0, so  $a_i = b'_i$  for all  $i$ . Since the sequence  $b'$  is just a shift of  $b$ , we are done. ◀

By using Theorem 3 (or Proposition 15 in the case of  $n$  prime), we obtain the following number theoretic result.

► **Lemma 16.** *Let  $n$  be a prime or a product of two primes, and let  $a = a_1 a_2 \dots a_n$  and  $b = b_1 b_2 \dots b_n$  be distinct  $n$ -bit strings (even up to cyclic shift). Then, for some  $0 \leq \ell \leq n-1$  with  $z = \omega^\ell$ , and for some  $2 \leq t \leq 5$ , we have that  $P(z; a)^t P(z^{-t}; a) \neq P(z; b)^t P(z^{-t}; b)$ .*

**Proof.** First choose  $k$  such that  $\sum_{i=1}^n a_i \omega^{i \cdot k} \neq \omega^{c_k} \cdot \sum_{i=1}^n b_i \omega^{i \cdot k}$  for all integers  $c_k$ , which exists by Theorem 3. If  $k = 0$ , then  $P(\omega^k; a) = P(1; a)$  and  $P(\omega^k; b) = P(1; b)$  are distinct nonnegative integers, so we trivially have  $P(1; a)^t P(1; a) \neq P(1; b)^t P(1; b)$ . Otherwise, let  $t$  be the smallest prime that doesn't divide  $\frac{n}{\gcd(n, k)}$  (so  $t \leq 5$  as  $n$  has at most 2 prime factors). If  $\sum_{i=1}^n a_i \omega^{i \cdot k} = 0$ , then  $\sum_{i=1}^n b_i \omega^{i \cdot k} \neq 0$ . Now, since  $\omega^{-tk}$  is a Galois conjugate of  $\omega^k$  (since  $t \nmid n$ ), we also have that  $\sum_{i=1}^n b_i \omega^{-ti \cdot k} \neq 0$ . This means that  $P(\omega^k; a) = 0$  so  $P(\omega^k; a)^t P((\omega^k)^{-t}; a) = 0$ , but  $P(\omega^k; b)^t P((\omega^k)^{-t}; b) \neq 0$ . Likewise, if  $\sum_{i=1}^n b_i \omega^{i \cdot k} = 0$ , we'll have  $P(\omega^k; a)^t P((\omega^k)^{-t}; a) \neq 0$ , but  $P(\omega^k; b)^t P((\omega^k)^{-t}; b) = 0$ . This means the result follows if either  $P(\omega^k; a) = 0$  or  $P(\omega^k; b) = 0$ .

## 18:10 Circular Trace Reconstruction

Otherwise,  $P(\omega^k; a) = \sum_{i=1}^n a_i \omega^{i \cdot k}$  and  $P(\omega^k; b) = \sum_{i=1}^n b_i \omega^{i \cdot k}$  are both nonzero. This means that for all  $r \geq 0$ ,  $P(\omega^{(-t)^r \cdot k}; a)$  and  $P(\omega^{(-t)^r \cdot k}; b)$  are both nonzero, since  $\omega^{(-t)^r \cdot k}$  and  $\omega^k$  are Galois conjugates. This means that if  $P(z; a)^t P(z^{-t}; a) = P(z; b)^t P(z^{-t}; b)$  for all  $z = \omega^{(-t)^r \cdot k}$ , then

$$\frac{P(\omega^{(-t)^{r+1} \cdot k}; a)}{P(\omega^{(-t)^r \cdot k}; a)^{-t}} = \frac{P(z^{-t}; a)}{P(z; a)^{-t}} = \frac{P(z^{-t}; b)}{P(z; b)^{-t}} = \frac{P(\omega^{(-t)^{r+1} \cdot k}; b)}{P(\omega^{(-t)^r \cdot k}; b)^{-t}}$$

for all  $r \geq 0$ , so we inductively have that

$$\frac{P(\omega^{(-t)^r \cdot k}; a)}{P(\omega^k; a)^{(-t)^r}} = \frac{P(\omega^{(-t)^r \cdot k}; b)}{P(\omega^k; b)^{(-t)^r}}.$$

Now, letting  $r = \varphi\left(\frac{n}{\gcd(n, k)}\right)$ , we know that  $k \cdot (-t)^r \equiv k \pmod{n}$  by Euler's theorem, which means that  $\omega^{(-t)^r \cdot k} = \omega^k$ . Thus,

$$P(\omega^k; a)^{1-(-t)^r} = P(\omega^k; b)^{1-(-t)^r}.$$

Since  $k \neq 0$ , we have that  $\frac{n}{\gcd(n, k)} > 1$  so  $r \geq 1$ . Thus, since  $t \geq 2$ ,  $1 - (-t)^r \neq 0$ . Now, since  $P(\omega^k; a), P(\omega^k; b)$  are nonzero, we have that  $\frac{P(\omega^k; a)}{P(\omega^k; b)}$  is a  $|1 - (-t)^r|^{\text{th}}$  root of unity. Also,  $P(\omega^k; a), P(\omega^k; b) \in \mathbb{Q}[\omega]$ , which means  $\frac{P(\omega^k; a)}{P(\omega^k; b)} \in \mathbb{Q}[\omega]$ . However, all roots of unity in  $\mathbb{Q}[\omega]$  are of the form  $\pm \omega^i$  for some  $i$ , and since  $(-t)^r - 1$  is odd if  $n$  is odd (since  $t = 2$ ), we must have that  $\frac{P(\omega^k; a)}{P(\omega^k; b)} = \omega^{c_k}$  for some integer  $c_k$ . This is a contradiction, so we must have that  $P(z; a)^t P(z^{-t}; a) \neq P(z; b)^t P(z^{-t}; b)$ , for some  $z = \omega^{(-t)^r \cdot k}$ ,  $r \geq 0$ .  $\blacktriangleleft$

Finally, we are ready to prove Theorem 2.

**Proof of Theorem 2.** Suppose that we are trying to distinguish between the original circular string being  $a = a_1 a_2 \dots a_n$  or  $b = b_1 b_2 \dots b_n$ , where  $a, b$  are distinct, even up to cyclic shifts.

We choose  $\ell, t$  based on Lemma 16, so that  $P(\omega^\ell; a)^t P((\omega^\ell)^{-t}; a) \neq P(\omega^\ell; b)^t P((\omega^\ell)^{-t}; b)$ . As we have already noted, if  $z$  is an  $n^{\text{th}}$  root of unity, then  $P(z; a)^t P(z^{-t}; a)$  is invariant under rotation of  $a$ , and  $P(z; b)^t P(z^{-t}; b)$  is invariant under rotation of  $b$ . By our definition of  $Q_t(z; x)$ , we have that  $Q_t(\omega^\ell; a) \neq Q_t(\omega^\ell; b)$ , so  $Q_t(z; a) \neq Q_t(z; b)$  as polynomials in  $z$ . Therefore, by Lemma 14, there is some  $z$  such that  $|z| = 1, |\arg z| \leq \frac{1}{L}$ , and

$$|Q_t(z; a) - Q_t(z; b)| \geq n^{-c_2 t L} \geq n^{-5c_2 L}.$$

So, for  $L = \lceil n^{1/3} (\log n)^{-1/3} p^{-2/3} \rceil$ , there exists  $z$  with  $|z| = 1$  and  $|\arg z| \leq \frac{1}{L}$  and some  $2 \leq t \leq 5$  such that

$$|Q_t(z; a) - Q_t(z; b)| \geq n^{-5c_2 L} \geq \exp\left(-c_3 \cdot n^{1/3} (\log n)^{2/3} p^{-2/3}\right),$$

but

$$|h_t(\tilde{x}, z)| \leq (p^{-1} n)^{O(1)} \cdot \exp\left(O\left(\frac{n}{p^2 L^2}\right)\right) \leq \exp\left(c_4 \cdot n^{1/3} (\log n)^{2/3} p^{-2/3}\right)$$

for any trace  $\tilde{x}$  of either  $a$  or  $b$ . Sample  $R = \exp\left(O\left(n^{1/3} (\log n)^{2/3} p^{-2/3}\right)\right)$  traces  $\tilde{x}^{(1)}, \dots, \tilde{x}^{(R)}$  and choose  $z$  and  $t$  based on Lemma 16. Then, if we define  $h_t(z)$  to be the average of  $h_t(\tilde{x}^{(i)}, z)$  over  $i$  from 1 to  $R$ , the Chernoff bound tells us that with failure probability at most  $10^{-n}$ ,  $|h_t(z) - Q_t(z; a)| \leq \frac{1}{3} \cdot \exp\left(c_4 \cdot n^{1/3} (\log n)^{2/3} p^{-2/3}\right)$  if the original string were  $a$ ,

and  $|h(z) - Q_t(z; b)| \leq \frac{1}{3} \cdot \exp(c_4 \cdot n^{1/3}(\log n)^{2/3}p^{-2/3})$  if the original string were  $b$ . Thus, by returning  $a$  if  $h(z)$  is closer to  $Q_t(z; a)$  and returning  $b$  otherwise, we can distinguish between the original string being  $a$  or  $b$  using  $\exp(O(n^{1/3}(\log n)^{2/3}p^{-2/3}))$  traces, with  $1 - 10^{-n}$  failure probability.

Thus, to reconstruct the original string  $x$ , we simply run the distinguishing algorithm for all pairs  $a, b \in \{0, 1\}^n$  such that  $a \neq b$ , using the same  $R$  traces  $\tilde{x}^1, \dots, \tilde{x}^R$ . With probability at least  $1 - (4/10)^n \geq 1 - 2^{-n}$ , the true string  $x$  will be the only string such that the distinguishing algorithm will successfully choose  $x$  over all other strings. Thus, for  $n$  a prime or a product of two primes, the circular trace reconstruction problem can be solved using  $\exp(O(n^{1/3}(\log n)^{2/3}p^{-2/3}))$  traces. ◀

## 4 Average Case: Upper Bound

We now consider the situation in which the unknown circular string  $x$  is random. For the sake of simplicity, we will assume that we may sample  $x$  by sampling a uniform random linear binary string of length  $n$  and applying a uniform random cyclic shift. Note that the resulting distribution on  $x$  is not uniform over all possible circular strings, as strings with nontrivial cyclic symmetries are more likely to appear. However, such strings form a negligible fraction of all strings, and our arguments can easily be modified to handle the situation in which the distribution is uniform over all possible circular strings. We use the randomness to rule out certain problematic strings with high probability, and this can be done for uniform random circular strings as well as other distributions, for example if in the sampling procedure each bit is independently biased towards 0 or 1.

► **Theorem 17.** *Let  $x$  be a random (in the sense described above) unknown circular string of length  $n$  and let  $q$  be the deletion probability of each element. Then there exists a constant  $C_q$  depending only on  $q$  such that we can determine  $x$  with failure probability at most  $n^{-10}$  using  $O(n^{C_q})$  traces.*

In what follows, we will let  $x = x_1 \cdots x_n$  and take indices of bits in  $x$  modulo  $n$ . Let  $k = 100 \log n$ . We first note that with high probability, all of the consecutive substrings of  $x$  of length  $k$  and  $k - 1$  are pairwise distinct. We will refer to such strings  $x$  as *regular* strings. Indeed, the probability that  $x_i \cdots x_{i+k-1} = x_j \cdots x_{j+k-1}$  for  $i \neq j$  is  $2^{-k}$  (where indices are taken modulo  $n$ ), and union bounding over all  $i, j$  as well as both  $k$  and  $k - 1$  gives a failure probability of at most  $O(n^2 2^{-k}) \ll n^{-10}$ .

If we assume that  $x$  is regular, the length  $k$  consecutive substrings of  $x$  uniquely determine  $x$ . Indeed, given  $x_i \cdots x_{i+k-1}$ , we can uniquely determine  $x_{i+k}$  as there is a unique length  $k$  consecutive substring of  $x$  that begins with  $x_{i+1} \cdots x_{i+k-1}$ . Iteratively applying this allows us to recover the entire string  $x$ . Thus, to prove Theorem 17, it suffices to prove Lemma 5, i.e., to determine how many times each length  $k$  substring appears consecutively in any string  $x$  using  $O(n^{C_q})$  traces, which will allow us to recover  $x$  if  $x$  is regular.

**Proof of Lemma 5.** For a circular string  $x$ , let  $S_x = \{x_i x_{i+1} \cdots x_{i+k-1}\}_{i=1}^n$  be the  $k$ -deck of  $x$ , which is the multiset of contiguous substrings of  $x$  of length  $k$ . Let  $S$  and  $T$  be the  $k$ -decks of some circular strings of length  $n$  such that  $S \neq T$ . Suppose that given  $O(n^{C_q})$  traces of a circular string, we are able to distinguish between whether its  $k$ -deck is  $S$  or  $T$  correctly with failure probability  $10^{-n}$ . Then, by union bounding over all possible pairs of distinct  $k$ -decks (note that there are at most  $2^n$  different  $k$ -decks), we can with high probability correctly determine the  $k$ -deck of the string, showing the lemma.

The key property we will use is that given two distinct  $k$ -decks  $S$  and  $T$  that come from circular strings  $x$  and  $y$ , there exists some string  $s$  of length  $k$  such that the number of consecutive occurrences of  $s$  in  $x$  and in  $y$  are different. We will show the existence of  $C_q$  so that for any string  $s$  of length  $k$  satisfying this property, we can distinguish between  $x$  and  $y$  correctly using  $O(n^{C_q})$  samples with failure probability  $10^{-n}$ , from which the result follows.

Let  $\alpha$  denote a sufficiently large positive integer only depending on  $q$  that we will determine later. For  $0 \leq i \leq n-k$ , let  $c_i$  denote the number of (not necessarily consecutive) occurrences of  $s$  in  $x$  contained in a consecutive substring of  $x$  of length at most  $i+k$ . Similarly, let  $d_i$  denote the number of (not necessarily consecutive) occurrences of  $s$  in  $y$  contained in a consecutive substring of  $y$  of length at most  $i+k$ . By assumption, we have that  $c_0 \neq d_0$ . By casework on the last bit of the occurrence of  $s$ , we have that  $c_i, d_i \leq n \binom{i+k}{k}$ . Let  $P(t) = \sum_{i=0}^{\alpha k} c_i t^i$  and  $Q(t) = \sum_{i=0}^{\alpha k} d_i t^i$ . Moreover, the following is true:

► **Lemma 18.** *The probability that a trace of  $x$  starts with  $s$  (where a random bit in the string is chosen as the beginning before bits are deleted) is  $\frac{1}{n}(1-q)^k P(q) + O(q^{\alpha k}(\alpha+1)^k e^k)$ . Similarly, the probability that a trace of  $y$  starts with  $s$  is  $\frac{1}{n}(1-q)^k Q(q) + O(q^{\alpha k}(\alpha+1)^k e^k)$ .*

**Proof.** To compute the probability that a trace of  $x$  starts with  $s$ , we do casework on how many bits are deleted before the last bit in the occurrence of  $s$ . If  $i$  bits are deleted, then note that there are  $c_i$  ways for it to be done by definition. Each such way has a probability of  $\frac{1}{n}(1-q)^k q^i$  to occur. Indeed, for each way there is a  $\frac{1}{n}$  probability that the correct starting bit is chosen, and the probability that only the bits corresponding to the specific instance of  $s$  are kept is  $(1-q)^k q^i$ . It follows that the probability is exactly  $\frac{1}{n}(1-q)^k \sum_{i=0}^{n-k} c_i q^i$ .

It remains to show that  $\frac{1}{n}(1-q)^k \sum_{i=\alpha k}^{n-k} c_i q^i = O(q^{\alpha k}(\alpha+1)^k e^k)$ . As mentioned before, we have that  $c_i \leq n \binom{i+k}{k}$ . Thus, this sum is at most  $\sum_{i>\alpha k} \binom{i+k}{k} q^i \leq \binom{\alpha k+k}{k} q^{\alpha k} \sum_{i \geq 0} \left(\frac{q(\alpha+1)}{\alpha}\right)^i$ . Indeed, the ratio of consecutive terms in the sequence  $\binom{i+k}{k} q^i$  is equal to  $q \frac{i+k}{i} \leq \frac{q(\alpha+1)}{\alpha}$ . For a sufficiently large choice of  $\alpha$ ,  $\frac{q(\alpha+1)}{\alpha} < 1$ , so  $\sum_{i>\alpha k} \binom{i+k}{k} q^i = O\left(\binom{\alpha k+k}{k} q^{\alpha k}\right) = O(q^{\alpha k}(\alpha+1)^k e^k)$  by Stirling's approximation.

The argument for  $y$  is analogous. ◀

Lemma 18 allows us to estimate  $P(q)$  and  $Q(q)$  up to an  $O(n(1-q)^{-k} q^{\alpha k}(\alpha+1)^k e^k)$  error by looking at how often traces of  $x$  or  $y$  begin with  $s$ , and then dividing by  $\frac{1}{n}(1-q)^k$ . So long as  $P(q)$  and  $Q(q)$  are sufficiently far apart, a Chernoff bound allows us to determine with high probability if the traces came from  $x$  or  $y$ . However, it may be the case that  $P(q)$  and  $Q(q)$  are quite close. To remedy this, we observe that it is possible to *simulate higher deletion probabilities*  $q' > q$ . Indeed, this can be achieved by deleting each bit in traces received independently with probability  $\frac{q'-q}{1-q}$ . Thus, it suffices to find  $q' \in [q, r]$  with  $P(q')$  and  $Q(q')$  far apart for some  $q < r < 1$ . The existence of such a  $q'$  is proven by the following Littlewood-type result of Borwein, Erdélyi, and Kós.

► **Theorem 19** ([10], Theorem 5.1). *There exist absolute constants  $c_1 > 0$  and  $c_2 > 0$  such that if  $f$  is a polynomial with coefficients in  $[-1, 1]$  and  $a \in (0, 1]$ , then*

$$|f(0)|^{c_1/a} \leq \exp\left(\frac{c_2}{a}\right) \sup_{z \in [1-a, 1]} |f(z)|.$$

Let  $r = \frac{q+1}{2}$ . We first apply Theorem 19 to  $\binom{\alpha k+k}{k}^{-1}(P(rx) - Q(rx))$  and  $a = 1 - q/r$ . Here, we are using the fact that the coefficients of  $P$  and  $Q$  are bounded in magnitude by  $\binom{\alpha k+k}{k}$  by previous observations, and that  $|P(0) - Q(0)| \geq 1$ . Theorem 19 tells us that

$$\begin{aligned}
\binom{\alpha k + k}{k}^{-c_1/a} &\leq \exp\left(\frac{c_2}{a}\right) \binom{\alpha k + k}{k}^{-1} \sup_{z \in [1-a, 1]} |P(rz) - Q(rz)| \\
&= \exp\left(\frac{c_2}{a}\right) \binom{\alpha k + k}{k}^{-1} \sup_{q' \in [q, r]} |P(q') - Q(q')|,
\end{aligned}$$

or

$$\sup_{q' \in [q, r]} |P(q') - Q(q')| \geq c_3 \binom{\alpha k + k}{k}^{-c_4}$$

for some constants  $c_3$  and  $c_4$  that only depend on  $q$ .

In particular, this is much larger than  $10^k n(1-r)^{-k} r^{\alpha k} (\alpha+1)^k e^k$  for sufficiently large values of  $\alpha$  ( $\alpha$  may depend on  $q$ ). Indeed, after taking  $k$ th roots and using Stirling's approximation this reduces to showing that  $(e(\alpha+1))^{-c_5} > 10n^{1/k}(1-r)^{-1} r^\alpha (\alpha+1)e$  for sufficiently large  $\alpha$  where  $c_5$  is some constant that only depends on  $q$ , which is clear (since  $0 < r < 1$  is fixed and  $n^{1/k} < 2$ ). Thus, for any  $q' \in [q, r]$ , the error term  $\frac{1}{n}(1-q')^k \sum_{\alpha k+1}^{n-k} c_i(q')^i = O((q')^{\alpha k} (\alpha+1)^k e^k)$  is at most  $10^{-k}$  times  $\frac{1}{n}(1-q')^k \cdot \sup_{q' \in [q, r]} |P(q') - Q(q')|$ .

Hence, for some  $q' \in [q, r]$ , the probability that a trace begins with  $s$  under bit deletion with probability  $q'$  differs between  $x$  and  $y$  by  $\Omega(10^k n(1-r)^{-k} r^{\alpha k} (\alpha+1)^k e^k) = \Omega(n^{-c_6})$  for some constant  $c_6$  that only depends on  $q$ . By a standard Chernoff bound, for some constant  $C_q$  only depending on  $q$ , we can distinguish between  $x$  and  $y$  using  $O(n^{C_q})$  traces with failure probability at most  $\exp(-\Omega(n))$ , so Lemma 5 follows. ◀

By the previous discussions, Theorem 4 is also proven.

As mentioned before, Chen et. al. independently proved the analogue of Lemma 5 for linear strings in [15, Theorem 2]. The ideas behind their result and ours are similar: both are proved by considering a polynomial encoding the  $k$ -deck and using complex analysis to bound the corresponding polynomials for different  $k$ -decks away from each other on  $[q, 1]$ . Here, we directly apply the Littlewood-type result from [10], while Chen et. al. prove their own result for this bound. This idea of reconstructing the  $k$ -deck of the unknown string may be useful in other variants of trace reconstruction, though the sample complexity it achieves is only polynomial and in order to apply it, we must be able to reconstruct the string from its  $k$ -deck. For worst case trace reconstruction, we must be able to reconstruct strings not uniquely determined by their  $k$ -decks, and for average case trace reconstruction, a subpolynomial sample complexity has already been achieved for constant deletion probabilities. Thus, these ideas are not directly applicable to worst case and average case trace reconstruction, though they may be helpful for variants in which it suffices to construct  $k$ -decks and a polynomial sample complexity is not known, such as the ones considered in this paper and in [15].

One difference between our result and that of Chen et. al. is that while we only addressed the sample complexity, they also give a polynomial time algorithm for reconstructing the string via a linear program. Their approach can be modified to give a polynomial time algorithm for average case circular trace reconstruction as well. For more details on their algorithm, see [15, Section 6]. Moreover, while we do not address the smoothed complexity model as in Chen et. al., our proof of Theorem 4 easily generalizes to a polynomial sample (or time) algorithm for circular trace reconstruction in the smoothed complexity model. This is because one can show that a circular string drawn from Chen et. al.'s smoothed model is regular with very high probability, in a similar way to how we showed an average string is regular. For more details, see [15, Section 3].

## 5 Worst Case: Lower Bound

In this section, we prove Theorem 6 and demonstrate that worst-case circular trace reconstruction requires  $\tilde{\Omega}(n^3)$  traces. We first record the following lemma from [21] expressing the number of independent samples required to distinguish between two probability measures  $\mu$  and  $\nu$  in terms of their Hellinger distance  $d_H(\mu, \nu)$ , defined to be  $\left( \sum_{x \in X} \left( \sqrt{\mu(\{x\})} - \sqrt{\nu(\{x\})} \right)^2 \right)^{1/2}$  where the sum is over all events in some discrete sample space  $X$ . Let  $d_{TV}(\mu, \nu)$  denote the total variation distance between  $\mu$  and  $\nu$  and  $\mu^n$  denote the law of  $n$  independent samples from  $\mu$ .

► **Lemma 20** ([21], Lemma A.5). *If  $\mu$  and  $\nu$  are probability measures satisfying  $d_H(\mu, \nu) \leq 1/2$ , then  $1 - d_{TV}(\mu^m, \nu^m) \geq \varepsilon$  if  $m \leq \frac{\log(1/\varepsilon)}{9d_H^2(\mu, \nu)}$ .*

Given  $m$  traces, we cannot determine if they came from  $\mu^m$  or  $\nu^m$  with probability higher than  $\frac{1}{2}(1 + d_{TV}(\mu^m, \nu^m))$ . Thus, it requires  $\Omega(d_H^{-2}(\mu, \nu))$  samples to distinguish between two probability measures  $\mu$  and  $\nu$  with probability greater than  $\frac{3}{4}$ .

**Proof of Theorem 6.** We specialize to the case of distinguishing between  $x = 10^n 10^{n+1} 10^{n+k}$  and  $y = 10^n 10^{n+k} 10^{n+1}$  from independent traces. Let  $\mu$  and  $\nu$  respectively denote the laws of traces from  $x$  and  $y$ . We will show that  $d_H^2(\mu, \nu) = O((\log n/n)^3)$ , which establishes the result by Lemma 20.

First, we note that conditional on the first 1 in  $x$  being deleted, the resulting trace is equidistributed as a trace from  $y$  conditioned on the second 1 being deleted, as in both cases we obtain a trace from the circular string  $10^{n+1} 10^{2n+k}$ . Similar arguments for other cases show that conditioned on any 1 being deleted, traces from  $x$  and  $y$  are equal in law. Thus, the resulting string must have three 1's to contribute to the Hellinger distance. We will henceforth assume that the resulting trace is of the form  $10^a 10^b 10^c$  for some nonnegative integers  $a, b, c$ .

We now compute the ratio  $\frac{\mu(\{10^a 10^b 10^c\})}{\nu(\{10^a 10^b 10^c\})}$  and show that it is typically  $1 + O((\log n/n)^{3/2})$ . We have that

$$\begin{aligned} \frac{\mu(\{10^a 10^b 10^c\})}{q^{3n+k+1-a-b-c}(1-q)^{a+b+c}} &= \binom{n}{a} \binom{n+1}{b} \binom{n+k}{c} + \binom{n}{b} \binom{n+1}{c} \binom{n+k}{a} + \binom{n}{c} \binom{n+1}{a} \binom{n+k}{b}, \\ \frac{\nu(\{10^a 10^b 10^c\})}{q^{3n+k+1-a-b-c}(1-q)^{a+b+c}} &= \binom{n}{a} \binom{n+k}{b} \binom{n+1}{c} + \binom{n}{b} \binom{n+k}{c} \binom{n+1}{a} + \binom{n}{c} \binom{n+k}{a} \binom{n+1}{b}. \end{aligned}$$

It follows that

$$\frac{\mu(\{10^a 10^b 10^c\})}{\nu(\{10^a 10^b 10^c\})} = \frac{\frac{1}{(n+1-b)(n+1-c)\cdots(n+k-c)} + \frac{1}{(n+1-c)(n+1-a)\cdots(n+k-a)} + \frac{1}{(n+1-a)(n+1-b)\cdots(n+k-b)}}{\frac{1}{(n+1-c)(n+1-b)\cdots(n+k-b)} + \frac{1}{(n+1-a)(n+1-c)\cdots(n+k-c)} + \frac{1}{(n+1-b)(n+1-a)\cdots(n+k-a)}}.$$

Multiplying the numerator and denominator by  $\prod_{i=1}^k (n+i-a)(n+i-b)(n+i-c)$  results in

$$S_1 = \prod_{i=1}^k (n+i-a) \prod_{i=2}^k (n+i-b) + \prod_{i=1}^k (n+i-b) \prod_{i=2}^k (n+i-c) + \prod_{i=1}^k (n+i-c) \prod_{i=2}^k (n+i-a)$$

and

$$S_2 = \prod_{i=1}^k (n+i-b) \prod_{i=2}^k (n+i-a) + \prod_{i=1}^k (n+i-c) \prod_{i=2}^k (n+i-b) + \prod_{i=1}^k (n+i-a) \prod_{i=2}^k (n+i-c),$$

respectively. We have that  $S_1 - S_2 = (a - b) \prod_{i=2}^k (n + i - a)(n + i - b) + (b - c) \prod_{i=2}^k (n + i - b)(n + i - c) + (c - a) \prod_{i=2}^k (n + i - c)(n + i - a)$ . This is an alternating polynomial in  $a, b, c$ , i.e., applying a permutation  $\sigma$  to  $a, b, c$  changes the sign of the polynomial by the sign of  $\sigma$ . Hence, it can be written in the form  $(a - b)(b - c)(a - c)P_k(n, a, b, c)$ , where  $P_k$  is a polynomial in  $n, a, b, c$  of degree  $2k - 4$  since  $S_1$  and  $S_2$  have degree  $2k - 1$ .

By a standard Chernoff bound, there exists a constant  $C$  such that with probability at least  $1 - n^{-100}$ ,  $a, b, c \in [np - C\sqrt{n \log n}, np + C\sqrt{n \log n}]$ . When this occurs, we have that  $S_2 = \Omega(n^{2k-1})$  and  $|S_1 - S_2| = O((n \log n)^{3/2} n^{2k-4})$ , so  $\frac{\mu(\{10^a 10^b 10^c\})}{\nu(\{10^a 10^b 10^c\})} \in [1 - (c \log n/n)^{3/2}, 1 + (c \log n/n)^{3/2}]$  for some constant  $c$ . We thus have that

$$\begin{aligned} d_H^2(\mu, \nu) &= \sum_{a, b, c \geq 0} \left( \sqrt{\mu(\{10^a 10^b 10^c\})} - \sqrt{\nu(\{10^a 10^b 10^c\})} \right)^2 \\ &\leq 2n^{-100} + \sum_{a, b, c \in [np - C\sqrt{n \log n}, np + C\sqrt{n \log n}]} \nu(\{10^a 10^b 10^c\}) \left( 1 - \sqrt{\frac{\mu(\{10^a 10^b 10^c\})}{\nu(\{10^a 10^b 10^c\})}} \right)^2 \\ &= O((\log n/n)^3). \end{aligned}$$

It follows by Lemma 20 that it requires  $\Omega(n^3 / \log^3 n)$  samples to distinguish between traces from  $x$  and  $y$ , as desired.  $\blacktriangleleft$

## 6 Conclusion and Future Work

We note that our work leaves several open problems, including the following:

1. As noted in the introduction, Chase [14] very recently improved the worst-case linear trace reconstruction bound to  $\exp(\tilde{O}(n^{1/5}))$ . Is it possible to get a matching circular trace reconstruction bound, even just for certain lengths of strings?
2. For worst-case strings, can one get an upper bound of  $\exp(\tilde{O}(n^{1/3}))$  or even a subexponential bound for  $n$  with an arbitrary prime factorization?
3. Can one get a subpolynomial (i.e.,  $n^{o(1)}$ ) upper bound for the average case?
4. Can one improve our current lower bound for worst-case strings, perhaps even to  $n^{\omega(1)}$ ?
5. All of the work we have done in this paper has primarily focused on traces with constant deletion probability  $q$ . However, if  $q = o(1)$ , the implied results are no better than the bounds we get for fixed  $0 < q < 1$ . Can better bounds be obtained for circular trace reconstruction with small deletion probability (for instance,  $q = 1/(\log n)^2$ , or even  $q = n^{-2/3}$ )? In the linear case, there exist much better trace reconstruction algorithms in the low deletion probability regime (e.g., [7, 24]), so perhaps these results can be extended to circular strings.

For answering open problem 2, one method we attempted for getting a  $\exp(\tilde{O}(n^{1/2}))$  upper bound was to look at the polynomial  $P(y)P(z)P(y^{-1}z^{-1})$  for cyclotomic  $n$ th roots of unity  $y, z$ . One can establish a ‘‘Bivariate Littlewood’’-type result and the same argument as ours to show the following. Suppose that for any  $a, b \in \{0, 1\}^n$ ,  $P(y; a)P(z; a)P(y^{-1}z^{-1}; a) = P(y; b)P(z; b)P(y^{-1}z^{-1}; b)$  for all cyclotomic  $n$ th roots of unity  $y, z$  implies that  $a, b$  are equivalent up to cyclic rotation. Then, one can solve circular trace reconstruction using  $\exp(\tilde{O}(n^{1/2}))$  traces. This result may in fact look obvious, as if  $P(\omega_n; a) = \alpha \cdot P(\omega_n; b)$ , one should expect via a simple induction argument that  $P(\omega_n^k; a) = \alpha^k \cdot P(\omega_n^k; b)$  which implies that  $\alpha = e^{2\pi i r/n}$  for some  $r$  (by looking at  $k = n$ ). Thus, by rotating  $a$  by  $r$  elements, we will get that  $P(\omega_n^k; a) = P(\omega_n^k; b)$  for all  $k$ , which implies  $a = b$ . Unfortunately, one can have

cases where  $P(z; a) = P(z; b) = 0$  for several choices of  $z = e^{2\pi i k/n}$ , which can cause this induction argument to fail. Indeed, we believe that if such a result were true, proving it would again be a challenging number theoretic task.

We already noted some reasons in the introduction for why modifying the results of [35, 22] to answer open problem 3 is difficult. The main reason was that one cannot efficiently find the “start” of the string.

Finally, we note that a potential way of answering open problem 4 is via strings based on [21, 13]. One cannot use their strings directly, as their strings are equivalent up to a cyclic rotation, but perhaps an appropriate modification may improve upon our  $\tilde{\Omega}(n^3)$  lower bound.

## Abstract

Self-testing is a method to characterise an arbitrary quantum system based only on its classical input-output correlations, and plays an important role in device-independent quantum information processing as well as quantum complexity theory. Prior works on self-testing require the assumption that the system's state is shared among multiple parties that only perform local measurements and cannot communicate. Here, we replace the setting of *multiple non-communicating* parties, which is difficult to enforce in practice, by a *single computationally bounded* party. Specifically, we construct a protocol that allows a classical verifier to robustly certify that a single computationally bounded quantum device must have prepared a Bell pair and performed single-qubit measurements on it, up to a change of basis applied to both the device's state and measurements. This means that under computational assumptions, the verifier is able to certify the presence of entanglement, a property usually closely associated with two separated subsystems, inside a single quantum device. To achieve this, we build on techniques first introduced by Brakerski et al. (2018) and Mahadev (2018) which allow a classical verifier to constrain the actions of a quantum device assuming the device does not break post-quantum cryptography.

## 1 Introduction

The *device-independent* approach to quantum information processing treats quantum devices as black boxes which we can interact with classically to observe their input-output correlations. Based solely on these correlations and the assumption that quantum mechanics is correct,

the goal is to prove statements about the devices, e.g., to show that they can be used for secure quantum key distribution (see e.g. [24]) or delegated quantum computation (see e.g. [32]). At a fundamental level, this provides a theory-of-computation approach to the study of classical signatures of quantum mechanics and their use as a “leash” to control and characterize quantum devices.

*Self-testing* is arguably the most effective method in device-independent quantum information processing. The goal in self-testing is to characterise the quantum state and measurements of multiple black-box quantum devices using only their classical input-output correlations. In analogy to the setting of interactive proof systems, the classical party observing the input-output correlations is sometimes called the *verifier*, and the black-box quantum devices are called *provers*. More specifically, the verifier can interact with multiple quantum provers by sending (classical) questions as inputs and receiving (classical) answers as outputs. The provers can share any (finite-dimensional) entangled quantum state at the start of the interaction and are computationally unbounded; however, it is assumed that after having received the verifier’s questions, the provers can no longer communicate. Based on the question-answer correlations, the verifier would like to deduce that the provers must have shared a certain initial state and performed certain measurements on it, up to a local change of basis on each prover’s Hilbert space. We will describe this scenario in more detail in Section 1.1. We emphasize that self-testing is a uniquely quantum phenomenon: for classical devices, there is simply a function that is implemented by the device, and it is not meaningful to ask *how* the function is implemented “on the inside”. In contrast, for quantum devices, in certain cases knowledge of the function (the observed input-output behaviour) implies an essentially unique realization in terms of a quantum state and measurements on it.

The term *self-testing* was introduced by Mayers and Yao in [24] in the context of proofs of security for quantum key distribution, but the notion was already present in earlier works [34, 29]. For a review covering a large number of different self-testing protocols, as well as applications such as randomness expansion and delegated quantum computation, see [35]. In addition to more practical applications, self-testing has also proved to be a powerful tool in quantum complexity theory for the study of multi-prover interactive proof systems in the quantum setting and is at the heart of the recent characterisation of the complexity class  $\text{MIP}^*$  [21].

The starting point for our work is the observation that, while the model of non-communicating quantum provers used in existing self-testing results is appealing in theory, it is difficult to enforce this non-communication assumption in practice. Motivated by the many applications of self-testing in quantum cryptography (e.g. device-independent quantum key distribution) and complexity theory, we are compelled to search for protocols that allow for a self-testing-like certification of a *single* untrusted quantum device.

Self-testing protocols in the multi-prover setting are typically based on the violation of Bell inequalities [3], for which the non-communication assumption is necessary.<sup>1</sup> Hence, different techniques or additional assumptions are necessary when considering the single-device scenario. What could a “computational Bell inequality” look like?

In this paper we give an answer to this question by constructing a self-testing protocol for a *single computationally bounded* quantum device. Specifically, the only assumptions required are the correctness of quantum mechanics and that the prover does not have the

---

<sup>1</sup> Another approach is to base the self-testing statement on non-contextuality inequalities [5, 6]. The violation of non-contextuality inequalities is a uniquely quantum phenomenon that is similar to the violation of Bell inequalities, with the advantage that it only requires a single quantum device and therefore no non-communication assumption. The downside of this approach is that it places additional assumptions, such as memory constraints and compatibility relations between measurements, on the quantum device, limiting its suitability for practical cryptographic applications.

ability to break the Learning with Errors (LWE) assumption [31], a common assumption in post-quantum cryptography, *during* the protocol execution (whereas breaking the LWE assumption *after* the end of the protocol is allowed). Our protocol is a three-round interaction between a classical verifier and a quantum prover, at the end of which the verifier decides to either “accept” or “reject” the prover. Informally, the guarantee provided by the protocol is the following:

► **Theorem (Informal).** *A prover’s strategy in the protocol is described by a quantum state and the measurements that the prover makes on the state to obtain the (classical) answers received by the verifier. If a computationally bounded prover is accepted by the verifier with probability  $1 - \varepsilon$ , then there exists an isometry  $V$  such that for a universal constant  $c > 0$  and under the isometry  $V$ :*

1. *the prover’s state is  $O(\varepsilon^c)$ -close (in trace distance) to a Bell pair,*
2. *(a subset of) the prover’s measurements are  $O(\varepsilon^c)$ -close to single-qubit measurements in the computational or Hadamard basis, where the measurement bases are chosen by the verifier. Here, “closeness” is measured in a distance measure suitable for measurements acting on a state.*

We emphasize that the theorem not only guarantees the preparation of an entangled state by the prover, but also the implementation of specific measurements on it. As such, it provides a complete analogue of foundational self-testing results for the CHSH inequality [34, 25].

The proof of our main result builds on techniques introduced in recent works [23, 8, 19] to allow a classical verifier to leverage post-quantum cryptography to control a computationally bounded quantum prover. Because they are relevant for understanding the proof of our results, we now give a brief overview of these works and explain their relation to self-testing.

In [23], Mahadev gives the first protocol to classically verify a delegated quantum computation with a single untrusted quantum prover. The central ingredient in Mahadev’s verification protocol is a “measurement protocol” that allows the verifier to force the prover to report classical outcomes obtained by performing certain measurements on a quantum state that the prover has “committed to” using classical information. The main guarantee of the measurement protocol is this: if the prover is accepted in the protocol, *there exists* a quantum state such that the distribution over the prover’s answers could have been produced by performing the requested measurements on this state. In other words, all of the prover’s answers must be self-consistent in the sense that they could have originated from performing different measurements on (copies of) the same quantum state.

To verify a quantum computation, the statement that the prover’s answers are *consistent* with measurements on a quantum state is sufficient, as the *existence* of a quantum state with the right properties can certify the outcome of the quantum computation (this is due to Kitaev’s “circuit-to-Hamiltonian” construction, which we do not explain here). However, in this work we seek to make a stronger statement: we want to certify that the prover *actually constructed* the desired quantum state *and performed the desired measurements* on it (up to an isometry). While the honest prover in Mahadev’s protocol does indeed construct the desired quantum state, the protocol does not guarantee that an arbitrary prover must do, too. Hence, our self-testing protocol is stronger in the sense that it allows for a more stringent characterisation of the prover’s actions, namely its actual states and measurements.<sup>2</sup> To emphasize the difference, we note that the guarantee of Mahadev’s protocol *does not* directly

<sup>2</sup> This comes at the cost that we are only able to certify Bell pairs, while Mahadev’s measurement protocol works for measurements on any state.

imply that a successful prover must have performed any quantum computation; the guarantee is only that, if the correct state preparation and measurements were to be performed, the outcome would be as claimed by the prover.

Another closely related work is that of Brakerski et al. [8], who give a protocol between a classical verifier and a quantum prover that allows the verifier to generate certified information-theoretic randomness, again assuming that the prover does not break the LWE assumption; in other words, their protocol generates information-theoretic randomness from a computational assumption. For this, the authors show that two of the prover’s measurements must be maximally incompatible, as defined by a quantity that they call the “overlap”. Informally, one can think of two maximally incompatible measurements as being close to a computational and Hadamard basis measurement, up to some global change of basis. Hence, this result already resembles self-testing in the sense that the verifier can make a statement about the actual measurements used by the prover. In particular, it does serve as a “test of quantumness” for the prover.

Building on [8] and using techniques from [23], Gheorghiu and Vidick construct a protocol for a task that they call verifiable remote state preparation (RSP) [19]. They consider a set of single-qubit pure states  $\{|\psi_1\rangle, \dots, |\psi_n\rangle\}$ .<sup>3</sup> Under the same LWE assumption as before, the protocol enables the verifier to certify that the prover has prepared one of these states, up to a global change of basis (i.e., some isometry  $V$  that is applied to all  $|\psi_i\rangle$ ). More precisely, the verifier cannot decide beforehand on a particular  $|\psi_i\rangle$ , but after executing the protocol, the verifier knows which  $|\psi_i\rangle$  the prover has prepared, and the distribution over  $i$  can be made uniform. The prover, on the other hand, does not know which  $|\psi_i\rangle$  he has prepared.

This result resembles a self-testing statement even more than that of [8] because it explicitly characterises a family of single-qubit quantum states, one of which is certified to be present in the prover’s space. However, it differs from a standard self-testing statement in that it is defined for a family of states, not an individual state: because the prover’s isometry  $V$  is arbitrary, any individual state  $|\psi_i\rangle$  can be mapped to another arbitrary state. Hence, what is certified in RSP is not any individual state, but the relationships (e.g., orthogonality) between different states in some family. Alternatively, one can also take the view that RSP characterises the relationships between the prover’s states and measurements. We return to this issue in more detail in Section 1.1. The idea of certifying a family of states has also been considered by Cojocaru et al. [12], who call this notion “blind self-testing”. They analyze a different protocol under a restricted adversarial model and conjecture that their protocol yields similar guarantees as [19] for single-qubit states and tensor products of single-qubit states.

This lengthy overview of previous works makes explicit a progression towards the task that we tackle here, that of genuine self-testing of a single quantum device. We note that this presentation clearly benefits from hindsight, and that none of the cited works mentions any relation to self-testing; indeed, the results are too weak to be used in this setting. In particular, none of the previous works provides a sufficiently strong guarantee on the measurements performed by the quantum device and goes beyond the setting of a single qubit, which is arguably the main technical challenge. Indeed, moving from a single-qubit state to an entangled two-qubit state means that the verifier has to enforce a tensor product structure on the prover’s space, which is one of the main difficulties in our soundness proof ([27, Section 4]). On a technical level, it requires the certification of compatibility relations

---

<sup>3</sup> The protocol in [19] is designed for a specific set of ten pure states that are useful for delegated quantum computation, but for the purposes of this overview it is not important which specific states these are.

between different measurements meant to act on different qubits. Additionally, having two qubits instead of one prevents us from using Jordan’s lemma, a standard tool in self-testing also used in [19], to characterise the prover’s measurements; in [27, Section 4.7], we show how to characterise the prover’s measurements using a different method starting with a *partial* characterisation of the prover’s measurements, using that to partially characterise the prover’s states, which in turn is used for a stronger partial characterisation of the measurements, etc., until we reach the full statement that shows that the prover makes single-qubit measurements on a Bell pair.

## 1.1 Self-testing in the multi- and single-prover settings

In this section, we give a brief overview of the standard multi-prover self-testing scenario, and explain how it can be extended to a single prover. For more details on the multi-prover scenario, see [35] or [33, Chapter 7]. For simplicity, let us consider the case of two provers  $A$  and  $B$ , with Hilbert spaces  $\mathcal{H}_A$  and  $\mathcal{H}_B$ , respectively. Hence, the total Hilbert space is  $\mathcal{H}_A \otimes \mathcal{H}_B$ . The verifier interacts with  $A$  and  $B$  by sending questions and receiving answers. The question-answer correlations can be described by a family of probability distributions  $\{p(a, b|x, y)\}_{x, y}$ , where for each choice of questions  $x$  and  $y$  sent to  $A$  and  $B$ , respectively,  $p(a, b|x, y)$  is a probability distribution over their answers  $a$  and  $b$ . We say that a quantum state  $|\psi\rangle_{AB} \in \mathcal{H}_A \otimes \mathcal{H}_B$  is *compatible* with the correlations  $p(a, b|x, y)$  if there are local measurements  $\{P_x^{(a)}\}_a$  on  $\mathcal{H}_A$  for every input  $x$ , and  $\{Q_y^{(b)}\}_b$  on  $\mathcal{H}_B$  for every input  $y$ , that realise the correlations  $p(a, b|x, y)$ , i.e.,  $p(a, b|x, y) = \langle \psi | P_x^{(a)} \otimes Q_y^{(b)} | \psi \rangle_{AB}$  for all  $x, y, a, b$ .

► **Definition 1** (Self-testing of states, informal). *The correlations  $p(a, b|x, y)$  self-test a state  $|\phi\rangle_{AB}$  if for any state  $|\psi\rangle_{AB}$  compatible with these correlations, there exists a local isometry  $V = V_A \otimes V_B$  (with  $V_A$  only acting on  $\mathcal{H}_A$ , and  $V_B$  only acting on  $\mathcal{H}_B$ ) such that  $V|\psi\rangle_{AB} = |\phi\rangle_{AB}|AUX\rangle$  for some ancillary state  $|AUX\rangle$ .*

A more operational view of this statement is that it must be possible to “extract” the state  $|\phi\rangle_{AB}$  from  $|\psi\rangle_{AB}$  only by performing local operations. The condition that the isometry must be local is crucial: if we would allow a global isometry, we could map any state  $|\psi\rangle_{AB}$  to the desired state  $|\phi\rangle_{AB}$ . In the two-prover case, the notion of a *local* isometry is natural, since the separation between the two provers induces a tensor product structure  $\mathcal{H} = \mathcal{H}_A \otimes \mathcal{H}_B$  on the global Hilbert space  $\mathcal{H}$ . In contrast, for a single prover no such tensor product structure exists and we cannot define *local* isometries in a meaningful way.

In Definition 1, we only dealt with the provers’ state, not his measurements. A stronger notion of self-testing is to characterise both the provers’ state and measurements. This is the version of self-testing originally considered by Mayers and Yao [24], and we will see that it can be meaningfully extended to the single-prover setting.

► **Definition 2** (Self-testing of states and measurements, informal). *The correlations  $p(a, b|x, y)$  self-test a state  $|\phi\rangle_{AB}$  and measurements  $\{M_x^{(a)}\}, \{N_y^{(b)}\}$  if for any state  $|\psi\rangle_{AB}$  and measurements  $\{P_x^{(a)}\}, \{Q_y^{(b)}\}$  that realise the correlations  $p(a, b|x, y)$ , there exists a local isometry  $V = V_A \otimes V_B$  such that*

1.  $V|\psi\rangle_{AB} = |\phi\rangle_{AB}|AUX\rangle$ ,
2.  $V(P_x^{(a)} \otimes Q_y^{(b)})|\psi\rangle_{AB} = ((M_x^{(a)} \otimes N_y^{(b)})|\phi\rangle_{AB})|AUX\rangle$ , for some ancillary state  $|AUX\rangle$ .

The first condition is the same as in Definition 1. The second condition roughly says that the “physical” measurements  $\{P_x^{(a)}\}$  and  $\{Q_y^{(b)}\}$  used by  $A$  and  $B$ , respectively, act on the state  $|\psi\rangle_{AB}$  in the same way that the desired measurements  $\{M_x^{(a)}\}$  and  $\{N_y^{(b)}\}$  act on the desired state  $|\phi\rangle_{AB}$ .

Self-testing of states and measurements still has meaning in the single-prover setting. In this setting, one can imagine that the verifier sends both questions  $x$  and  $y$  to the same prover, and the prover replies with two answers  $a$  and  $b$ . To compute his answers, the prover prepares a quantum state  $|\psi\rangle$  and, on inputs  $x, y$ , performs a measurement  $\{P_{x,y}^{(a,b)}\}_{a,b}$  to obtain answers  $a, b$ .

► **Definition 3** (Self-testing for a single prover, informal). *The correlations  $p(a, b|x, y)$  self-test a state  $|\phi\rangle$  and measurements  $\{K_{x,y}^{(a,b)}\}_{a,b}$  if for any state  $|\psi\rangle$  and measurements  $\{P_{x,y}^{(a,b)}\}_{a,b}$  that realise the correlations  $p(a, b|x, y)$ , there exists an isometry  $V$  such that*

1.  $V|\psi\rangle = |\phi\rangle|AUX\rangle$ ,
2.  $VP_{x,y}^{(a,b)}|\psi\rangle = \left(K_{x,y}^{(a,b)}|\phi\rangle\right)|AUX\rangle$ , for some ancillary state  $|AUX\rangle \in \mathcal{H}'$ .

This definition is rather informal because whenever the number of possible questions and answers is fixed and independent of the security parameter (as is the case in this paper), single-round question-answer correlations  $p(a, b|x, y)$  alone cannot be sufficient: a prover can always succeed in the protocol simply by answering the verifier's questions according to a look-up table; such a prover is classical and does not actually perform any computation. Therefore, our protocol will have multiple rounds of interaction between the verifier and the prover: the questions and answers in the initial “setup rounds” will involve a public key that scales with the security parameter; then, in the last round, the verifier observes question-answer correlations  $p(a, b|x, y)$  similar to standard self-testing, i.e., with a fixed question and answer length. Instead of using multi-round interaction, one could also try to build a single-round protocol with questions that depend on the security parameter (e.g., the question would include a public key). A number of recent works have shown that under the (quantum) random oracle assumption, the protocol for certifying the quantumness of a prover from [8] and the verification protocol from [23] can be adapted to this single-round setting [2, 11, 9]. We leave it for future work to investigate whether the interaction in our protocol can also be removed with the random oracle assumption.

To obtain a statement that is more similar to the two-prover scenario, we consider the stronger constraint that the desired measurements have a tensor product form  $K_{x,y}^{(a,b)} = M_x^{(a)} \otimes N_y^{(b)}$ . In particular, this means that answer  $a$  only depends on question  $x$  and  $b$  only depends on  $y$ , and it enforces a natural tensor product structure on the prover's space. Specifically, we define Hilbert spaces  $\mathcal{H}_A, \mathcal{H}_B$  and  $\mathcal{H}'$  and deduce the existence of an isometry  $V$  from the prover's physical space  $\mathcal{H}$  to  $\mathcal{H}_A \otimes \mathcal{H}_B \otimes \mathcal{H}'$  such that under the isometry, the measurements operators  $P_{x,y}^{(a,b)}$  act on  $|\psi\rangle$  in the same way that tensor product measurement operators of the form  $M_x^{(a)} \otimes N_y^{(b)}$  act on  $|\phi\rangle_{AB}$ , where  $M_x^{(a)}$  acts only on  $\mathcal{H}_A$ ,  $N_y^{(b)}$  acts only on  $\mathcal{H}_B$ , and  $|\phi\rangle_{AB}$  is the state that we are self-testing for (e.g., a Bell state).

► **Definition 4** (Self-testing of tensor product strategies for a single prover, informal). *The correlations  $p(a, b|x, y)$  self-test a state  $|\phi\rangle_{AB}$  and measurements  $\{M_x^{(a)}\}$  on system  $A$  and  $\{N_y^{(b)}\}$  on system  $B$  if for any state  $|\psi\rangle \in \mathcal{H}$  and measurements  $\{P_{x,y}^{(a,b)}\}_{a,b}$  on  $\mathcal{H}$  that realise the correlations  $p(a, b|x, y)$ , there exists an isometry  $V : \mathcal{H} \rightarrow \mathcal{H}_A \otimes \mathcal{H}_B \otimes \mathcal{H}'$  such that*

1.  $V|\psi\rangle = |\phi\rangle_{AB}|AUX\rangle$ ,
2.  $VP_{x,y}^{(a,b)}|\psi\rangle = \left((M_x^{(a)} \otimes N_y^{(b)})|\phi\rangle_{AB}\right)|AUX\rangle$ , for some ancillary state  $|AUX\rangle \in \mathcal{H}'$ .

Again, this definition is informal for the same reason as for Definition 3. A formal statement of such a single-prover self-testing result with a tensor product structure is given in [27, Theorem 4.38], the main result of our work.

## 1.2 Cryptographic primitives

The main cryptographic primitive underlying our self-testing protocol is a so-called extended noisy trapdoor claw-free function family (ENTCF family). ENTCF families were introduced by Mahadev in [23], building on the construction of noisy trapdoor claw-free function families by Brakerski et al. in [8]. Here, we only give a brief informal description of the main properties of an ENTCF family (see [27, Section 2.2] for references and details).

An ENTCF family consists of two families  $\mathcal{F}$  and  $\mathcal{G}$  of function pairs. A function pair  $(f_{k,0}, f_{k,1}) \in \mathcal{F}$  is called a *claw-free pair* and is indexed by a public key  $k$ . Similarly, an *injective pair* is a pair of functions  $(f_{k,0}, f_{k,1}) \in \mathcal{G}$ , also indexed by a public key  $k$ . Informally, the most important properties are the following:

1. For fixed  $k \in \mathcal{K}_{\mathcal{F}}$ ,  $f_{k,0}$  and  $f_{k,1}$  are bijections with the same image, i.e., for every  $y$  in their image there exists a unique pair  $(x_0, x_1)$ , called a *claw*, such that  $f_{k,0}(x_0) = f_{k,1}(x_1) = y$ .
2. Given a key  $k \in \mathcal{K}_{\mathcal{F}}$  for a claw-free pair, it is quantum-computationally intractable (without access to trapdoor information) to compute both a preimage  $x_i$  and a single generalised bit of  $x_0 \oplus x_1$  (i.e.,  $d \cdot (x_0 \oplus x_1)$  for any non-trivial bit string  $d$ ), where  $(x_0, x_1)$  forms a valid claw. This is called the *adaptive hardcore bit property*.
3. For fixed  $k \in \mathcal{K}_{\mathcal{G}}$ ,  $f_{k,0}$  and  $f_{k,1}$  are injective functions with disjoint images.
4. Given a key  $k \in \mathcal{K}_{\mathcal{F}} \cup \mathcal{K}_{\mathcal{G}}$ , it is quantum-computationally hard (without access to trapdoor information) to determine the “function type”, i.e., to decide whether  $k$  is a key for a claw-free or an injective pair. This is called *injective invariance*.
5. For every key  $k \in \mathcal{K}_{\mathcal{F}} \cup \mathcal{K}_{\mathcal{G}}$ , there exists a trapdoor  $t_k$ , which can be sampled together with  $k$  and with which (ii) and (iv) are computationally easy.

## 2 Our self-testing protocol

We now give an informal description of our self-testing protocol with the honest prover behaviour and provide some intuition for its soundness. A full description of the protocol is given in [27, Figure 1].

On a very high level, one can view the protocol as first executing the RSP protocol from [19] twice in parallel to prepare two qubits in the provers space. Then, the prover is asked to perform an entangling operation on these two qubits. Because the prover does not know which states the qubits are in, and the entangling operation acts differently on different states, to pass the checks in the protocol the prover has to apply the entangling operation honestly.

In more detail, the protocol begins with the verifier sampling two uniformly random bits  $\theta_1, \theta_2$ , each bit denoting a *basis choice* (either the computational or the Hadamard basis). The case where both bits denote the Hadamard basis will be the one where the prover prepares a Bell pair, whereas the other basis choices serve as tests that prevent the prover from cheating. Depending on these basis choices, the verifier then samples two key-trapdoor pairs  $(k_1, t_{k_1})$  and  $(k_2, t_{k_2})$  from the ENTCF family: for the computational basis, it samples an injective pair, and for the Hadamard basis a claw-free pair. The verifier sends the keys to the prover and keeps the trapdoors private.

The honest prover treats the two keys separately. For each key  $k_i$ , he prepares the state

$$|\psi_i\rangle = \frac{1}{\sqrt{2|\mathcal{X}|}} \sum_{x \in \mathcal{X}, b \in \{0,1\}} |b\rangle |x\rangle |f_{k_i,b}(x)\rangle. \quad (1)$$

Here,  $\mathcal{X}$  is the domain of the ENTCF family. Note that even though the prover does not know which kind of function (claw-free or injective) he is dealing with, the definition of ENTCF families still allows him to construct this state. The prover now measures both

image registers (i.e., the registers storing “ $f_{k_i,b}(x)$ ”), obtains images  $y_1, y_2$ , and sends these to the verifier. (In the terminology of [23], this is called a “commitment”.) Depending on the choice of function family by the verifier, the prover’s post-measurement state has one of two forms: if the verifier sampled the key  $k_i$  from the injective family, the post-measurement state is a computational basis state:

$$|\psi'_i\rangle = |b\rangle|x_b\rangle, \quad (2)$$

where  $x_b$  is the unique preimage of  $y_i$ . If the key  $k_i$  belongs to a claw-free family, the post-measurement state is a superposition over a claw:

$$|\psi'_i\rangle = \frac{1}{\sqrt{2}}(|0\rangle|x_0\rangle + |1\rangle|x_1\rangle), \quad (3)$$

where  $(x_0, x_1)$  form a claw, i.e.,  $f_{k,0}(x_0) = f_{k,1}(x_1) = y$ .

At this point, the verifier selects a round type, either a “preimage round” or a “Hadamard round”, uniformly at random and sends the round type to the prover. For a preimage round, the honest prover measures his entire state in the computational basis and returns the result; the verifier checks that the prover has indeed returned correct preimages for the submitted  $y_1, y_2$ . The preimage round is an additional test that is required for us to leverage the adaptive hardcore bit property, but we do not discuss this further in this overview.

For a Hadamard round, the honest prover measures both of his preimage registers (i.e., the registers containing “ $x_b$ ”) in the Hadamard basis, obtains two bit strings  $d_1, d_2$ , and sends these to the verifier. This results in the following states (using the notation from above):

$$|\psi''_i\rangle = \begin{cases} |b\rangle & \text{if } k_i \text{ belongs to an injective family,} \\ \frac{1}{\sqrt{2}}(|0\rangle + (-1)^{d_i \cdot (x_0 \oplus x_1)}|1\rangle) & \text{if } k_i \text{ belongs to a claw-free family.} \end{cases} \quad (4)$$

Note that the phase in the second case is exactly the adaptive hardcore bit from the definition of ENTFC families. At this point, the verifier selects two additional bases  $q_1, q_2$  uniformly at random (again from either the computational or Hadamard basis), and sends these to the prover. In analogy to self-testing, we call these bases “questions”. The honest prover now applies a  $CZ$  gate (an entangling two-qubit gate that applies a  $\sigma_Z$  operation to the second qubit if the first qubit is in state  $|1\rangle$ ) to its state  $|\psi''_1\rangle|\psi''_2\rangle$ . In the case where both  $\theta_1$  and  $\theta_2$  specify the Hadamard basis, this results in a Bell state (rotated by a single-qubit Hadamard gate). The prover measures the individual qubits of the resulting state in the bases specified by  $q_1, q_2$ . The outcomes  $v_1, v_2$  are returned to the verifier.

The verifier can use the prover’s answers  $y_1, y_2, d_1, d_2$  and her trapdoor information  $t_{k_1}, t_{k_2}$  to determine which state  $CZ|\psi''_1\rangle|\psi''_2\rangle$  the prover should have prepared. The verifier accepts the prover if his answers  $v_1, v_2$  are consistent with making the measurements specified by  $q_1, q_2$  on the honest prover’s state  $CZ|\psi''_1\rangle|\psi''_2\rangle$ .

## 2.1 Soundness proof

We now give a brief intuition for the soundness of the protocol; the full soundness proof is given in [27, Section 4]. Let us first consider a version of the protocol where the prover is not supposed to perform a  $CZ$  operation. As noted before, this would be (a simplified version of) the RSP protocol [19], executed twice in parallel. For the purposes of this overview, let us assume that the only way for the prover to pass these two parallel executions of the RSP protocol is to treat each execution separately, i.e., use a tensor product Hilbert space  $\mathcal{H}_1 \otimes \mathcal{H}_2$  and execute each instance of the RSP protocol on a different part of the space

(enforcing such a tensor product structure is reminiscent of the classic question of parallel repetition [30] and is actually one of the main difficulties in our soundness proof, but we leave the details of this for [27, Section 4]). It now follows from the security of the RSP protocol that the prover must have prepared one of  $\{|0\rangle, |1\rangle, |+\rangle, |-\rangle\}$  in each part of his space (up to a “local” change of basis for each space), but he does not know which one.

Now consider how a  $CZ$  operation acts on these different states: if both states are Hadamard basis states (e.g.,  $|+\rangle|-\rangle$ ), the  $CZ$  operation will entangle them and produce a Bell state (rotated by a single-qubit Hadamard gate); in contrast, if at least one of the states is a computational basis state (e.g.,  $|1\rangle|-\rangle$ ), the resulting state will still be a product state of computational and Hadamard basis states (albeit a different one). This means that in the latter case, the  $CZ$  operation essentially only relabels the states. Therefore, if the verifier adapts her checks to account for the relabelling, in the latter case the guarantees from the RSP protocol still hold. Because the prover does not know which bases the verifier has selected, we can extend these guarantees to the case of two Hadamard basis states, too.

We stress that this only provides a rough intuition, and that the actual proof proceeds quite differently from this because we cannot just assume the existence of a tensor product structure on the prover’s Hilbert space. Deducing this tensor product structure poses technical difficulties. In two-prover self-testing proofs, the first step is to show that the measurement operators used by each prover approximately satisfy certain relations, e.g. anti-commutation. Because the measurement operators of different provers act on different Hilbert spaces, they exactly commute. Combining the approximate relations from the first step with the exact commutation relations, one can show that the prover’s measurement operators must be close to some desired operators, e.g. the Pauli operators. This last “rounding step” typically uses Jordan’s lemma or a stability theorem for approximate group representations [20]. In our case, we cannot show exact commutation relations between operators – commutation can only be enforced via the protocol, which tolerates a small failure probability. Hence, we are only able to show approximate commutation relations, which prevents us from applying Jordan’s lemma or the result of [20]. We therefore develop an alternative approach to “rounding” the prover’s operators that only requires approximate commutation and leverages the cryptographic assumptions. This method might also be useful for other applications that require a very tight “cryptographic leash” on a quantum prover.

### 3 Discussion

Self-testing has developed into a versatile tool for quantum information processing and quantum complexity theory and presents one of the strongest possible black-box certification techniques of quantum devices. The standard self-testing setting involves multiple non-communicating quantum provers, which is difficult to enforce in practice. The main contribution of this paper is the construction of a self-testing protocol that allows a classical verifier to certify that a single computationally bounded quantum prover has prepared a Bell state and measured the individual qubits of the state in the computational or Hadamard basis, up to a global change of basis applied to both the state and measurements. This means that we are able to certify the existence of entanglement in a single quantum device.<sup>4</sup>

<sup>4</sup> The freedom of applying a global change of basis means that the entangled Bell state can be mapped to a product state. However, then the prover’s measurements are mapped to entangling measurements, so entanglement is still present.

Due to the interactive nature of our protocol, this certification remains valid even if it turned out that any quantum computation is classically simulable, i.e.,  $\text{BQP} = \text{BPP}$ .<sup>5</sup> It therefore constitutes a “test of quantumness” in the sense of [8] and differs from proposals for testing quantum supremacy such as [7], which only certify the “quantumness” of a device under the assumption that  $\text{BQP} \neq \text{BPP}$ .<sup>6</sup>

Existing multi-prover self-testing protocols are typically based on non-local games, e.g., the CHSH game [25]. Our self-testing protocol follows a more “custom” approach guided by the available cryptographic primitives. While this enables us to construct a single-prover self-test for single-qubit measurements on a Bell state, arguably the most important quantum state for many applications, it does not allow us to extend the result to other states for which multi-prover self-tests are known [13]. To better make use of the extensive existing self-testing literature, it would be desirable to construct a procedure that allows for the “translation” of multi-prover non-local games to single-prover games with computational assumptions. In classical cryptography, similar attempts have been made to construct single-prover argument systems from multi-prover proof systems using fully homomorphic encryption [1, 22, 18].

Another approach to constructing single-prover self-tests for a larger class of states might be to strengthen Mahadev’s measurement protocol [23] from guaranteeing the existence of a state compatible with the measurement results to certifying that the prover actually has prepared this state. As a step in this direction, the second author and Zhang recently showed that Mahadev’s protocol is a classical proof of quantum knowledge [37]. The concept of a proof of quantum knowledge, first introduced in [10, 15] for the setting of a quantum verifier and extended to the setting of a classical verifier in [37], is still less stringent than a self-test and in particular lacks the strong characterisation of the prover’s measurements that we obtain in self-testing.

Beyond the conceptual appeal of gaining more fine-grained control over untrusted quantum devices, our self-testing protocol presents a first step towards translating multi-prover protocols for applications such as delegated computation [32, 14], randomness expansion [16, 36, 28], or secure multi-party quantum computation [17, 4] to a single-prover setting. There are already computationally secure single-prover protocols for delegated quantum computation [23] and randomness expansion [8]; however, establishing a more general link between self-testing-based multi-prover protocols and computationally secure single-prover protocols is still desirable: it might lead to conceptually simpler single-prover protocols and will be useful for constructing single-prover protocols for other applications without resorting to a low-level cryptographic analysis.

For example, using our self-testing theorem in a black-box way, the first author and others have recently constructed a protocol for device-independent quantum key distribution (DIQKD) [26]. In contrast to previous DIQKD protocols, which rely on a non-communication similar to the one in standard self-testing, this new DIQKD protocol requires no non-communication assumption and more closely models how DIQKD protocols are expected to be implemented experimentally. Crucially, the security analysis of this DIQKD protocol can be reduced to our self-testing theorem without any intricate cryptographic analysis involving computational hardness assumptions.

<sup>5</sup> Note that the LWE assumption is independent of whether  $\text{BQP} = \text{BPP}$  or not, since LWE is assumed to be hard for both quantum and classical computers.

<sup>6</sup> Intuitively, the reason for this is the following: in our protocol and in [8], the quantum prover has to be able to compute either a preimage or a pair  $(u, d)$  such that  $u = d \cdot (x_0 \oplus x_1)$ , where  $(x_0, x_1)$  forms a claw. If a classical prover was able to correctly compute a preimage or a pair  $(u, d)$ , it could be rewound to compute both at the same time, contradicting the adaptive hardcore bit property. In a quantum prover, the collapsing nature of quantum measurements prevents us from rewinding the prover.

We believe that, in a similar vein, our protocol will also serve as a useful building block for other future protocols for computationally bounded quantum devices, in the same way that self-testing for EPR pairs in the multi-prover scenario has proved to be a versatile tool in physics, cryptography, and complexity theory.

## Abstract

In the *trace reconstruction problem*, an unknown source string  $x \in \{0, 1\}^n$  is transmitted through a probabilistic *deletion channel* which independently deletes each bit with some fixed probability  $\delta$  and concatenates the surviving bits, resulting in a *trace* of  $x$ . The problem is to reconstruct  $x$  given access to independent traces. Trace reconstruction of arbitrary (worst-case) strings is a challenging problem, with the current state of the art for  $\text{poly}(n)$ -time algorithms being the 2004 algorithm of Batu et al. [2]. This algorithm can reconstruct an arbitrary source string  $x \in \{0, 1\}^n$  in  $\text{poly}(n)$  time provided that the deletion rate  $\delta$  satisfies  $\delta \leq n^{-(1/2+\varepsilon)}$  for some  $\varepsilon > 0$ .

In this work we improve on the result of [2] by giving a  $\text{poly}(n)$ -time algorithm for trace reconstruction for any deletion rate  $\delta \leq n^{-(1/3+\varepsilon)}$ . Our algorithm works by alternating an alignment-based procedure, which we show effectively reconstructs portions of the source string that are not “highly repetitive”, with a novel procedure that efficiently determines the length of highly repetitive subwords of the source string.

## 1 Introduction

The *trace reconstruction* problem was proposed almost twenty years ago in works of [10, 11, 2], though some earlier variants of the problem were already considered in the 1970s [9]. This problem deals with the *deletion channel*, which works as follows: when an  $n$ -bit string (the source string) is passed through a deletion channel of rate  $\delta$ , each coordinate is independently deleted with probability  $\delta$ . The surviving  $n' \leq n$  coordinates are concatenated to form the output of the channel, which is referred to as a *trace* of the original source string; we write “ $\mathbf{z} \sim \text{Del}_\delta(x)$ ” to indicate that  $\mathbf{z}$  is a trace generated from source string  $x$  according to this probabilistic process. As discussed in [13], this channel provides an elegant formalization for the theoretical study of problems involving synchronization errors.

In the *trace reconstruction problem*, independent traces are generated from an unknown and arbitrary source string  $x \in \{0, 1\}^n$ , and the task of the algorithm is to reconstruct (with high probability)  $x$  from its traces. The trace reconstruction problem is motivated by applications in several domains, including sensor networks and biology [13, 1, 16, 15]. It is also attractive because it is a clean and natural “first problem” which already seems to capture much of the difficulty of dealing with the deletion channel.

The problem of trace reconstruction for an arbitrary (worst-case) source string  $x$  has proved to be quite challenging.<sup>1</sup> [2] gave an algorithm that runs in  $\text{poly}(n)$  time, uses  $\text{poly}(n)$  traces, and with high probability reconstructs an arbitrary source string  $x \in \{0, 1\}^n$  provided that the deletion rate  $\delta$  is at most  $n^{-(1/2+\varepsilon)}$  for some constant  $\varepsilon > 0$ . Unfortunately, the trace reconstruction problem seems to quickly become intractable at higher deletion rates. Holenstein et al. [8] gave an algorithm that runs in time  $\exp(O(n^{1/2}))$  and uses  $\exp(O(n^{1/2}))$  traces for any deletion rate  $\delta$  that is bounded away from 1 by a constant, and this result was subsequently improved in simultaneous and independent works by [4, 14], both of which gave algorithms with time and sample complexity  $\exp(O(n^{1/3}))$ . On the lower bounds side, for  $\delta = \Theta(1)$  successively stronger lower bounds on the required sample complexity were given by [12] and [5], with the current state of the art being a  $\tilde{\Omega}(n^{3/2})$  lower bound due to Chase [3].

**The low deletion rate regime.** The positive result of [4] actually gives an algorithm that is faster than  $\exp(O(n^{1/3}))$  if the deletion rate is sufficiently low: [4] shows that for  $O(\log^3 n)/n \leq \delta \leq 1/2$ , their algorithm runs in time  $\exp(O(\delta n)^{1/3})$ . Consequently, for the specific deletion rate  $\delta = n^{-(1/2+\varepsilon)}$ , the [4] algorithm runs in time essentially  $\exp(O(n^{1/6}))$ , and [4] shows that no faster running time or better sample complexity is possible for any “mean-based” algorithm, a class of algorithms which includes those of [4, 14, 8].

Algorithmic approaches other than mean-based algorithms can provably do better at low deletion rates. This is witnessed by the algorithm of Batu et al. [2] which, as described earlier, runs in  $\text{poly}(n)$  time and uses  $\text{poly}(n)$  samples at deletion rate  $\delta = n^{-(1/2+\varepsilon)}$ . The main algorithmic component of [2] is a “*Bitwise Majority Alignment*” (BMA for short) procedure, which is further augmented with a simple procedure to determine the length of long “runs” (subwords of  $x$  of the form  $0^\ell$  or  $1^\ell$  with  $\ell \geq \sqrt{n}$ ). Roughly speaking, the BMA algorithm maintains a pointer in each trace and increments those pointers in successive time steps, attempting to always keep almost all of the pointers correctly aligned together. The analysis of [2] shows that the BMA algorithm succeeds if the source string  $x$  does not contain any

---

<sup>1</sup> We note that the average-case problem, in which the reconstruction algorithm is only required to succeed for a  $1 - o(1)$  fraction of all possible source strings in  $\{0, 1\}^n$ , is much more tractable, with the current state of the art [6, 7] being an algorithm that uses  $\exp(O(\log^{1/3} n))$  traces and runs in  $\text{poly}(n)$  time for any deletion rate  $\delta$  that is bounded away from 1.

long runs, but a challenge for the BMA algorithm is that the pointers in different traces will inevitably become misaligned if  $x$  does contain a long run  $0^\ell$  or  $1^\ell$ ; this is why the [2] algorithm must interleave BMA with a procedure to handle long runs separately. Intuitively, deletion rate  $\delta = n^{-1/2}$  is a barrier for the [2] analysis because if  $\delta = \omega(n^{-1/2})$ , then each trace is likely to have multiple locations where more than one consecutive bit of  $x$  is “dropped,” which is problematic for the analysis of BMA given in [2].

To summarize: given this state of the art from prior work, it is clear that alignment-based approaches can outperform mean-based algorithms at low deletion rates, but it is not clear whether, or how far, alignment-based approaches can be extended beyond the [2] results. Further incentive for studying the low deletion rate regime comes from potential applications in areas such as computer networks, where it may be natural to model deletions as occurring at relatively low rates. These considerations motivate the results of the present paper, which we now describe.

### 1.1 This work: An improved algorithm for the low deletion rate regime

The main result of this paper is an efficient algorithm that can handle significantly higher deletion rates than the [2] algorithm. We prove the following:

► **Theorem 1** (Efficient trace reconstruction at deletion rate  $\delta \geq n^{-(1/3+\varepsilon)}$ ). *Fix any constant  $\varepsilon > 0$  and let  $\delta = n^{-(1/3+\varepsilon)}$ . There is an algorithm **Reconstruct** that uses  $O(n^{4/3})$  independent traces drawn from  $\text{Del}_\delta(x)$  (where  $x \in \{0,1\}^n$  is arbitrary and unknown to **Reconstruct**), runs in  $O(n^{7/3})$  time, and outputs the unknown source string  $x$  with probability at least  $9/10$ .*

Note that any deletion rate  $\delta < n^{-(1/3+\varepsilon)}$  can of course be handled, given Theorem 1, by simply deleting additional bits to reduce to the  $\delta = n^{-(1/3+\varepsilon)}$  case. Note further that any desired success probability  $1 - \kappa$  can easily be achieved from Theorem 1 by running **Reconstruct**  $O(\log(1/\kappa))$  times and then taking a majority vote.

At a high level, the **Reconstruct** algorithm works by interleaving two different subroutines.

- The first subroutine is (essentially) the BMA algorithm, for which we provide an improved analysis, showing that BMA successfully reconstructs any string that does not contain a long subword (of length at least  $M = 2m + 1$  with  $m = n^{1/3}$ ) that is a prefix of  $s^\infty$  for some short (constant-length) bitstring  $s$ . We refer to long and “highly-repetitive” subwords of  $x$  of this form as “ $s$ -deserts” of  $x$ ; see Definition 2 for a detailed definition.
- The second subroutine is a new algorithm which we show efficiently determines the length of an  $s$ -desert in the source string  $x$ .

Thus, two novel aspects of this work that go beyond [2] are (i) our improved analysis of BMA, and (ii) our new procedure for efficiently measuring deserts (the analogous component of the [2] algorithm could only measure runs, which correspond to  $s$ -deserts with  $|s| = 1$ ).

We believe that it may be possible to further extend the kind of “hybrid” approach that we employ in this paper to obtain efficient trace reconstruction algorithms that can handle even larger deletion rates  $\delta$ . However, there are some significant technical challenges that would need to be overcome in order to do so. We describe some of these challenges at the end of the next section, which gives a more detailed overview of our approach.

## 2 Overview of our approach

As alluded to in the introduction, at a high level our algorithm carries out a careful interleaving of two procedures, which we call **BMA** and **FindEnd**. In this section we first give a high-level overview of the procedure BMA as well as our improved analysis. Then we give a high-level overview of **FindEnd**, and finally we explain how these two procedures are interleaved. We close with a brief discussion of possibilities and barriers to further progress.

## 2.1 Overview of BMA

The procedure **BMA** is exactly the same as the bitwise majority alignment algorithm of [2]; our new contribution regarding **BMA** is in giving a more general analysis. To explain the high level idea, let us fix the deletion rate  $\delta = n^{-(1/3+\varepsilon)}$  and a constant  $C = \lceil 100/\varepsilon \rceil$ . Let

$$m = n^{1/3} \quad \text{and} \quad M = 2m + 1.$$

The **BMA** procedure operates on a sample of some  $N = O(\log n)$  traces  $\mathbf{y}^1, \dots, \mathbf{y}^N$  drawn independently from  $\text{Del}_\delta(x)$  before the procedure begins its execution. Note that for any  $i \in [N]$  and any position  $\ell$  in the trace  $\mathbf{y}^i$ , there is a position  $f_i(\ell)$  satisfying  $\ell \leq f_i(\ell) \leq n-1$  in the target string  $x = (x_0, \dots, x_{n-1})$  that maps to  $\ell$  under the deletion process.<sup>2</sup> The high level idea of **BMA** is to maintain pointers  $\text{current}_1, \dots, \text{current}_N$ , with  $\text{current}_i$  pointing to a position in  $\mathbf{y}^i$ , such that *most of them are correctly aligned* – i.e., at the beginning of each time step  $t$ ,  $t = 0, 1, \dots$ , as we try to determine  $x_t$ , we have  $f_i(\text{current}_i) = t$  for most  $i \in [N]$ . Note that if this alignment guarantee were to hold for more than half of the traces for all  $t = 0, 1, \dots, n-1$ , then we could reconstruct the unknown string  $x$  by taking a majority vote of  $\mathbf{y}_{\text{current}_i}^i$  in each time step. Indeed we show that this happens with high probability over the randomness of  $\mathbf{y}^1, \dots, \mathbf{y}^N$  when  $x$  does not contain an  $s$ -desert for any string  $s \in \{0, 1\}^{\leq C}$  (i.e. a subword of length at least  $M = 2m + 1$  that is a prefix of  $s^\infty$ ). In contrast, the analysis of [2] requires the deletion rate to be  $n^{-(1/2+\varepsilon)}$  but works as long as  $x$  does not contain a run of 0's or 1's (or  $s$ -deserts with  $|s| = 1$  in our notation) of length at least  $\sqrt{n}$ .

To explain **BMA** in more detail, let us initialize  $t = 0$  and pointers  $\text{current}_1(0), \dots, \text{current}_N(0)$  to position 0. (Note that most pointers are correctly aligned as desired given that  $\delta = n^{-(1/3+\varepsilon)}$  and thus,  $x_0$  is not deleted in most traces and  $f_i(\text{current}_i(0)) = f_i(0) = 0$  for most  $i$ .) The way the pointers are updated is as follows: At each time step  $t$ , we let  $w_t$  be the majority element of the  $N$ -element multiset  $\{\mathbf{y}_{\text{current}_i(t)}^i\}_{i \in [N]}$ . For those traces  $\mathbf{y}^i$  with  $\mathbf{y}_{\text{current}_i(t)}^i = w_t$  (i.e., the bit of  $\mathbf{y}^i$  at the current pointer is the majority bit), we move the pointer to the right by 1, i.e. we set  $\text{current}_i(t+1) \leftarrow \text{current}_i(t) + 1$ ; otherwise the pointer stays the same, i.e., we set  $\text{current}_i(t+1) \leftarrow \text{current}_i(t)$ . Next we increment  $t$  and start the next round, repeating until  $t = n$  when **BMA** outputs the string  $(w_0, \dots, w_{n-1})$ .

For intuition we observe that if most of the pointers were aligned at the beginning of time step  $t$  (i.e.,  $f_i(\text{current}_i(t)) = t$  for most  $i \in [N]$ ), then  $w_t = x_t$  is indeed the next bit in  $x$ . Moreover, if  $\text{current}_i(t)$  is aligned and  $w_t = x_t$ , then moving  $\text{current}_i$  to the right by 1 is justified by noting that most likely  $x_{t+1}$  is not deleted in  $\mathbf{y}^i$  (with probability  $1 - \delta$ ), and when this happens  $f_i(\text{current}_i(t+1)) = t+1$  so  $\text{current}_i$  remains aligned at the beginning of the next time step.

In more detail, our analysis shows that when  $x$  does not contain an  $s$ -desert for any  $s \in \{0, 1\}^{\leq C}$  **BMA** maintains the following invariants at the beginning of time step  $t = 0, 1, \dots, n$ :

1. At time  $t$ , **BMA** has reconstructed  $x_0, \dots, x_{t-1}$  correctly as  $w_0, \dots, w_{t-1}$ .
2. For every trace  $\mathbf{y}^i$ ,  $i \in [N]$ , it holds that  $f_i(\text{current}_i(t)) \geq t$ .
3. Finally,  $\sum_{i \in [N]} (f_i(\text{current}_i(t)) - t) \leq 2N/C$ .

The intuitive meaning behind conditions (2) and (3) is as follows: while (2) says that the “original position” of  $\text{current}_i(t)$  never falls behind  $t$ , condition (3) ensures that on average, the original positions of these pointers do not surpass  $t$  by too much. In fact, since  $C$  is a large constant, most of the pointers are perfectly aligned, i.e., they satisfy  $f_i(\text{current}_i(t)) = t$ .

<sup>2</sup> It will be convenient for us to index a binary string  $x \in \{0, 1\}^\ell$  using  $[0 : \ell - 1]$  as  $x = (x_0, \dots, x_{\ell-1})$ .

We now discuss how the invariants (1), (2) and (3) are maintained. First, we observe that invariant (1) for time step  $t + 1$ , i.e.,  $w_t = x_t$ , follows immediately from (3) at time step  $t$ . Invariant (2) for time step  $t + 1$  follows almost immediately from (2) at  $t$  and  $w_t = x_t$ . (If  $f_i(\text{current}_i(t)) > t$ , then  $f_i(\text{current}_i(t + 1)) \geq f_i(\text{current}_i(t)) \geq t + 1$  given that both  $f_i$  and  $\text{current}_i$  are nondecreasing; if  $f_i(\text{current}_i(t)) = t$  is aligned at time step  $t$ , then  $w_t = x_t$  implies  $\text{current}_i(t + 1) = \text{current}_i(t) + 1$  and thus,  $f_i(\text{current}_i(t + 1)) \geq t + 1$ .) The main challenge is to show that invariant (3) is maintained. While this is not true for a general string  $x$ , we show that this holds with high probability (over  $\mathbf{y}^1, \dots, \mathbf{y}^N \sim \text{Del}_\delta(x)$ ) for any string  $x$  which does not have an  $s$ -desert for any  $s \in \{0, 1\}^{\leq C}$ . (We note here that the value of  $m$  is selected so as to satisfy  $m\delta \ll 1$ ; on the other hand, when we discuss the **FindEnd** procedure below, we will see that we also require  $m$  to satisfy  $m \gg \sqrt{\delta n}$ .)

In a nutshell, the main proof idea for (3) is to exploit the fact that when we draw  $\mathbf{y}^1, \dots, \mathbf{y}^N \sim \text{Del}_\delta(x)$ , with high probability they satisfy two properties: (i) for every  $\mathbf{y}^i$  and every subword of roughly  $C^2 m$  consecutive positions in the original string  $x$ , no more than  $C$  positions within the subword are deleted in the generation of  $\mathbf{y}^i$ ; (ii) for every subword of roughly  $m$  consecutive positions in  $x$ , the number of  $\mathbf{y}^i$  that have at least one deletion in the subword is no more than  $N/C^3$ . These two properties can be shown using straightforward probabilistic arguments by taking advantage of the aforementioned  $m\delta \ll 1$ . Using these two properties, a detailed (non-probabilistic) argument shows that **BMA** can reconstruct the string  $x$  with high probability if  $x$  contains no  $s$ -desert.

The above discussion sketches our argument that if the target string  $x$  does not have an  $s$ -desert, then **BMA** correctly reconstructs  $x$ . More generally, our arguments show that if  $x$  does have an  $s$ -desert, then **BMA** correctly reconstructs the prefix of  $x$  up to the position when an  $s$ -desert shows up: Let  $r$  be the first position in  $x$  that is “deep in an  $s$ -desert”; this is the first position in  $x$  such that  $x_{[r-m:r+m]}$ <sup>3</sup>, the length- $M$  subword of  $x$  centered at  $r$ , is an  $s$ -desert. Then **BMA** correctly reconstructs the prefix of  $x$  up to position  $r + m$ . Having reached such a position, it is natural to now ask – “how do we determine the *end* of this desert?”. This naturally leads us to the next procedure **FindEnd**.

## 2.2 Overview of FindEnd

Suppose that  $x$  has an  $s$ -desert with  $|s| = k \leq C$ , so **BMA** reconstructs the length- $(r + m + 1)$  prefix of  $x$ , where  $r$  is the first position that is “deep in the  $s$ -desert” (note that it is easy to determine the position  $r$  from the output of **BMA**). The algorithm **FindEnd** takes as input the prefix  $x_{[0:r+m]}$  of  $x$  and the location  $r$ , and its task is to compute the end of the  $s$ -desert: the first position  $\text{end} \geq r + m$  such that  $x_{\text{end}+1} \neq x_{\text{end}-k+1}$ . The **FindEnd** algorithm is rather involved but at a high level it consists of two stages: an initial *coarse estimation* of the end of the desert followed by *alignments* of traces from  $\text{Del}_\delta(x)$  with the end of the desert (using the coarse estimate).

**Coarse estimation:** The goal of the coarse estimation stage is to identify an integer  $\hat{\beta}$  that is close to  $(1 - \delta)\text{end}$ :  $|\hat{\beta} - (1 - \delta)\text{end}| \leq 2\sigma$ , where  $\sigma := \tilde{O}(\sqrt{\delta n}) \ll m$  is basically how far an entry  $x_i$  of  $x$  can deviate from its expected location  $(1 - \delta)i$  in a typical trace  $\mathbf{y} \sim \text{Del}_\delta(x)$ . Intuitively,  $\hat{\beta}$  is an estimation of the location of  $x_{\text{end}}$  in a trace  $\mathbf{y} \sim \text{Del}_\delta(x)$  that contains it, i.e., when  $x_{\text{end}}$  is not deleted in  $\mathbf{y}$ . To do this, we draw  $\alpha = O(1/\varepsilon)$  many traces  $\mathbf{y}^1, \dots, \mathbf{y}^\alpha \sim \text{Del}_\delta(x)$ . Roughly speaking, we split each trace  $\mathbf{y}^i$  into overlapping intervals of

<sup>3</sup> For a string  $x \in [0 : n - 1]$  integers  $0 \leq a < b \leq n - 1$ , we write  $x_{[a:b]}$  to denote the *subword*  $(x_a, x_{a+1}, \dots, x_b)$ .

length  $4\sigma$ . The first interval starts at  $(1 - \delta)r$  and each successive interval shifts to the right by  $\sigma$  (so it overlaps with the previous interval by  $3\sigma$ ). Since  $m \gg \sigma = \tilde{O}(\sqrt{\delta n})$  (which is one of the bottlenecks that requires  $\delta \ll n^{-1/3}$ ), the  $s$ -desert is unlikely to end before  $(1 - \delta)r$  in a trace  $\mathbf{y} \sim \text{Del}_\delta(x)$  and must end in one of constantly many intervals with high probability, by the choice of  $\sigma$ . To identify one such interval, we make the following observation. Let  $\text{Cyc}_s$  be the set of all  $k$ -bit strings that can be obtained as cyclic shifts of  $s$ . Given  $\text{end}$  as the end of the  $s$ -desert that starts at  $x_{r-m}$ , every  $k$ -bit subword of  $x_{[r-m:\text{end}]}$  is in  $\text{Cyc}_s$  but  $(x_{\text{end}-k+2}, \dots, x_{\text{end}+1}) \notin \text{Cyc}_s$ , and these  $k \leq C$  bits will most likely remain in a trace given the low deletion rate. This motivates us to look for the leftmost interval  $I^*$  such that in at least half of  $\mathbf{y}^1, \dots, \mathbf{y}^\alpha$ , it holds that  $\mathbf{y}_{I^*}^i$  contains a  $k$ -bit subword not in  $\text{Cyc}_s$ . We show that with high probability, setting  $\hat{\beta}$  to be the right endpoint of  $I^*$  gives us a coarse estimate of  $(1 - \delta)\text{end}$  up to an accuracy of  $\pm 2\sigma$ .

In addition to obtaining  $\hat{\beta}$ , the coarse estimation stage recovers the following  $8\sigma$ -bit subword of  $x$ :  $(x_{\text{end}-k+2}, \dots, x_{\text{end}-k+8\sigma+1})$ , which we will refer to as the *tail string* of the  $s$ -desert and denote by  $\text{tail} \in \{0, 1\}^{8\sigma}$ . To this end, we draw another  $\alpha = O(1/\varepsilon)$  fresh traces  $\mathbf{y}^1, \dots, \mathbf{y}^\alpha$  and examine the subword of each  $\mathbf{y}^i$  of length  $6\sigma$  centered at location  $\hat{\beta}$ . Each  $\mathbf{y}^i$  looks for the first  $k$ -bit subword in this interval that is not in  $\text{Cyc}_s$  and votes for its  $8\sigma$ -bit subword that starts at this non-cyclic shift as its candidate for  $\text{tail}$ . We show that with high probability, the string with the highest votes is exactly  $\text{tail}$ . (We note that both parts of this coarse estimation procedure require that with high probability, any fixed interval of length  $O(\sigma)$  in  $x$  does not get any deletions in a random trace, i.e.,  $\sigma\delta \ll 1$ . This follows from the two constraints  $m\delta \ll 1$  and  $m \gg \sigma$ .)

**Alignments:** Suppose the first stage succeeds in computing  $\hat{\beta}$  and  $\text{tail} \in \{0, 1\}^{8\sigma}$ . The second stage is based on a procedure called **Align** which satisfies two crucial criteria. These criteria are as follows: if **Align** is given an input trace  $\mathbf{y} \sim \text{Del}_\delta(x)$ , then (a) with *fairly high* probability (by which we mean  $1 - n^{-\Theta(\varepsilon)}$  for the rest of the overview) it returns a location  $\ell$  in  $\mathbf{y}$  such that  $\mathbf{y}_\ell$  corresponds to  $x_{\text{end}}$  in  $x$ , and moreover (b) the expectation of  $\ell$  (over the randomness of  $\mathbf{y}$ ) is a “sharp estimate” of  $(1 - \delta)\text{end}$  that is accurate up to an additive  $\pm 0.1$  error.<sup>4</sup> To pin down the exact end of the  $s$ -desert, **FindEnd** simply draws  $\tilde{O}(n^{2/3-\varepsilon})$  many traces, runs **Align** on each of them and computes the average  $\hat{\ell}$  of the locations it returns. It is easy to show that rounding  $\hat{\ell}/(1 - \delta)$  to the nearest integer gives  $\text{end}$  with high probability.

The case when  $k = |s| = 1$  (so the desert is a long subword consisting either of all 0's or of all 1's) is significantly easier (and was implicitly handled in [2]), so in the following discussion we focus on the case when  $k = |s| \geq 2$  and the desert has a more challenging structure. For this case our **Align** procedure uses a new idea, which is that of a “signature.” A *signature* is a subword of  $x$ , denoted  $\text{sig}$ , of length between  $2k$  and  $8\sigma$  that starts at the same location  $x_{\text{end}-k+2}$  as  $\text{tail}$  (so  $\text{sig}$  is contained in  $\text{tail}$ , since  $|\text{tail}| = 8\sigma$ ) and either ends at a location  $d$  which is the smallest integer  $d \in [\text{end} + k + 1 : \text{end} + 8\sigma - k + 1]$  such that the  $k$ -bit subword that ends at  $d$  is not in  $\text{Cyc}_s$ , or has length  $8\sigma$  if no such  $d$  exists (in this case  $\text{sig}$  is the same as  $\text{tail}$ ). We remind the reader that the first  $k$ -bits of  $\text{tail}$ , and hence also of  $\text{sig}$ , is a string not in  $\text{Cyc}_s$ , and the same is true of the last  $k$  bits of  $\text{sig}$  if its length is less than  $8\sigma$ .

<sup>4</sup> We note that item (b) is not an immediate consequence of item (a). In more detail, the failure probability of (a) is roughly  $1/n^{\Theta(\varepsilon)}$ , but if when **Align** fails in (a) it returns a location that is inaccurate by  $\gg n^{\Theta(\varepsilon)}$  positions, then (b) would not follow from (a). Indeed significantly more effort is required in our analysis to ensure (b).

Given a trace  $\mathbf{y} \sim \text{Del}_\delta(x)$ , **Align** (roughly speaking) attempts to locate the image of  $x_{\text{end}}$  in  $\mathbf{y}$  by locating the image of **sig** within an interval in  $\mathbf{y}$  of length  $O(\sigma)$  around  $\hat{\beta}$ . In a bit more detail, it checks whether the restriction of  $\mathbf{y}$  to a certain interval  $J$  around  $\hat{\beta}$  is of the form  $w \circ \text{sig} \circ v$ , such that the first  $k$  bits of **sig** is the leftmost  $k$ -bit subword of  $\mathbf{y}_J$  that is not in  $\text{Cyc}_s$ . If  $\mathbf{y}$  does not satisfy this condition then **Align** discards that trace and outputs nil. We note that if the only goal of **Align** were to locate a position  $\ell$  in  $\mathbf{y}$  such that with fairly high probability  $\mathbf{y}_\ell$  corresponds to  $x_{\text{end}}$  (i.e. item (a) above), then in all other cases (i.e. whenever  $\mathbf{y}$  does satisfy the above condition) **Align** could return the index of the  $(k-1)$ -th bit of **sig** in  $\mathbf{y}_J$ . (By doing this, **Align** always returns the correct position whenever the subword of  $x$  of length  $O(\sigma)$  centered at **end** has no deletion in  $\mathbf{y}$  and  $x_{\text{end}}$  deviates from its expected location in a trace by at most  $\sigma$  in  $\mathbf{y}$ , which happens with probability  $O(\sigma\delta) = n^{-\Theta(\varepsilon)}$ .) However, it turns out that **Align** must proceed in a slightly (but crucially) different way in order to additionally satisfy item (b) above (i.e., have the expected value of its output locations provide an accurate “sharp estimate” of  $(1-\delta)\text{end}$ ). The actual execution of **Align** is that in the case when  $\mathbf{y}_J$  does satisfy the above condition, **Align** returns the index of the  $(k-1)$ -th bit of **sig** in  $\mathbf{y}_J$  with high probability and with some small remaining probability (the precise value of which depends on the location of **sig** within  $\mathbf{y}_J$ ), **Align** opts to still output nil. A detailed analysis, which we provide in Section 6.2.2, shows that this **Align** procedure satisfies both criteria (a) and (b) described above.

### 2.3 The overall algorithm

The overall algorithm works by alternately running **BMA** and **FindEnd**. It starts with **BMA**, which draws  $N = O(\log n)$  traces of  $x$  and returns the first position  $r$  in  $x$  that is deep in a desert as well as the prefix  $w = x_{[0:r+m]}$  of the target string  $x$ . Then the algorithm runs **FindEnd** to compute **end**, the right end of the desert. Note that the execution of **BMA** will misalign some small fraction of the traces it uses, but these errors do not affect **FindEnd** as **FindEnd** is run using fresh traces.

With **end** from **FindEnd**, the algorithm has now reconstructed the prefix  $x_{[0:\text{end}]}$  by extending  $x_{[0:r+m]}$ . Next the algorithm runs **BMA** again on  $N$  traces that are, ideally, drawn from  $x_{[\text{end}+1:n-1]}$ , in order to reconstruct the next segment of  $x$  until a new desert shows up (at which point the algorithm repeats). These traces are obtained by running the **Align** procedure used by **FindEnd** on  $N$  fresh traces  $\mathbf{y}^1, \dots, \mathbf{y}^N$  of  $x$ . Let  $\ell_i$  be the output of **Align** running on  $\mathbf{y}^i$ . As noted in (a) earlier, all but a small fraction of  $\ell_i$ 's are such that the desert ends at  $\mathbf{y}_{\ell_i}^i$  in  $\mathbf{y}^i$ . We then run **BMA** on  $\mathbf{z}^1, \dots, \mathbf{z}^N$ , where  $\mathbf{z}^i$  is the suffix of  $\mathbf{y}^i$  starting at  $\ell_i + 1$  for each  $i$ . Even though  $\mathbf{z}^1, \dots, \mathbf{z}^N$  are *not* exactly  $N$  fresh traces of  $x_{[\text{end}+1:n-1]}$  (since a small and arbitrary fraction of  $\mathbf{y}^i$  might be misaligned), **BMA** is able to succeed because of a crucial *robustness* property. This property is that the correctness guarantee of **BMA** holds even when a small and “adversarially” picked constant fraction of the  $N$  traces given to it are misaligned; intuitively, **BMA** enjoys this robustness because it works in each time step by taking a majority vote over its input traces, so as long as a substantial majority of the traces are correctly aligned, even a small constant fraction of adversarial traces cannot affect its correctness. The algorithm continues alternating between **BMA** and **FindEnd**, and is thereby able to reconstruct the entire target string  $x$ .

## 3 Preliminaries

**Notation.** Given a positive integer  $n$ , we write  $[n]$  to denote  $\{1, \dots, n\}$ . Given two integers  $a \leq b$  we write  $[a : b]$  to denote  $\{a, \dots, b\}$ . We write  $\ln$  to denote natural logarithm and  $\log$  to denote logarithm to the base 2. We denote the set of non-negative integers by  $\mathbb{Z}_{\geq 0}$ . We write “ $a = b \pm c$ ” to indicate that  $b - c \leq a \leq b + c$ .

**Subword.** It will be convenient for us to index a binary string  $x \in \{0, 1\}^n$  using  $[0 : n - 1]$  as  $x = (x_0, \dots, x_{n-1})$ . Given such a string  $x \in \{0, 1\}^n$  and integers  $0 \leq a \leq b \leq n - 1$ , we write  $x_{[a:b]}$  to denote the *subword*  $(x_a, x_{a+1}, \dots, x_b)$  of  $x$ . An  $\ell$ -*subword* of  $x$  is a subword of  $x$  of length  $\ell$ , given by  $(x_a, x_{a+1}, \dots, x_{a+\ell-1})$  for some  $a \in [0 : n - \ell]$ .

**Distributions.** When we use bold font such as  $\mathbf{D}, \mathbf{y}, \mathbf{z}$ , etc., it is to emphasize that the entity in question is a random variable. We write “ $\mathbf{x} \sim \mathcal{D}$ ” to indicate that random variable  $\mathbf{x}$  is distributed according to distribution  $\mathcal{D}$ .

**Deletion channel and traces.** Throughout this paper the parameter  $\delta : 0 < \delta < 1$  denotes the *deletion probability*. Given a string  $x \in \{0, 1\}^n$ , we write  $\text{Del}_\delta(x)$  to denote the distribution of the string that results from passing  $x$  through the  $\delta$ -deletion channel (so the distribution  $\text{Del}_\delta(x)$  is supported on  $\{0, 1\}^{\leq n}$ ), and we refer to a string in the support of  $\text{Del}_\delta(x)$  as a *trace* of  $x$ . Recall that a random trace  $\mathbf{y} \sim \text{Del}_\delta(x)$  is obtained by independently deleting each bit of  $x$  with probability  $\delta$  and concatenating the surviving bits.<sup>5</sup>

**A notational convention.** In several places we use sans serif font for names such as *tail* (which is a subword of the target string  $x$ ), *end* (which is a location in the target string  $x$ ), and so on. To aid the reader, whenever we use this font the corresponding entity is an “ $x$ -entity,” i.e. a location, subword, etc. that is associated with the source string  $x$  rather than with a trace of  $x$ .

## 4 The main algorithm

In this section we describe the main algorithm **Reconstruct**. We begin by giving a precise definition of the notion of an *s-desert*. To do this, here and throughout the paper we fix

$$C := \lceil 100/\varepsilon \rceil, \quad \text{and we recall that } m = n^{1/3} \quad \text{and} \quad M = 2m + 1.$$

► **Definition 2.** For  $s \in \{0, 1\}^{\leq C}$ , a binary string  $z \in \{0, 1\}^*$  is said to be an *s-desert* if  $z$  is a prefix of  $s^\infty$  and  $|z| \geq M$ . A string is said to be a *desert* if it is an *s-desert* for some  $s \in \{0, 1\}^{\leq C}$ . Given a string  $x \in \{0, 1\}^n$ , we say that a location  $i \in [0 : n - 1]$  is *deep* in a desert if the length- $M$  subword  $x_{[i-m:i+m]}$  centered at  $i$  is a desert. We say a string  $x$  has *no desert* if no subword of  $x$  is a desert (or equivalently, no location  $i \in [0 : n - 1]$  is deep in a desert in  $x$ ); otherwise we say that it has *at least one desert*.

### 4.1 The preprocessing step

Before stating the main algorithm, we first describe a simple preprocessing step.

► **Lemma 3.** There is a randomized algorithm **Preprocess** which satisfies the following with probability  $1 - n^{-\omega(1)}$  (over its internal randomness):

1. It outputs a string  $v \in \{0, 1\}^{n/2}$ .
2. For any unknown string  $x \in \{0, 1\}^n$ , given access to a sample from  $\text{Del}_\delta(x)$ , it can output a sample from  $\text{Del}_\delta(z)$ , where  $z = x \circ v$ , in linear time.
3. For any  $s \in \{0, 1\}^{\leq C}$ , the string  $v$  does not have a *s-desert*. Consequently, any desert in the string  $z = x \circ v$  ends at least  $n/2 - (2m + 1)$  bits before the end of  $z$ .

<sup>5</sup> For simplicity in this work we assume that the deletion probability  $\delta$  is known to the reconstruction algorithm. We note that it is possible to obtain a high-accuracy estimate of  $\delta$  simply by measuring the average length of traces received from the deletion channel.

■ **Algorithm 1** Algorithm **Reconstruct** for  $\delta = n^{-(1/3+\varepsilon)}$ .

---

**Input:** Length  $n$  of an unknown  $x \in \{0, 1\}^n$  and access to  $\text{Del}_\delta(x)$  where  $\delta = n^{-(1/3+\varepsilon)}$

**Output:** A string  $u$ , where the algorithm succeeds if  $u = x$

```

1 Set  $N := O(\log n)$ 
2 Draw  $N$  fresh traces  $z^1, \dots, z^N$  independently from  $\text{Del}_\delta(x)$ 
3 Run  $\text{BMA}(n, \{z^1, \dots, z^N\})$  and let  $w$  be its output
4 if  $w$  has no desert then return  $w$ 
5 else
6   | Let  $r$  be the first location that is deep in a desert in  $w$  and let  $u = w_{[0:r+m]}$ 
   // Main loop
7 for  $n/m$  rounds do
8   | Draw  $N$  fresh traces  $y^1, \dots, y^N$  independently from  $\text{Del}_\delta(x)$ 
9   | Run  $\text{FindEnd}(r, u, \{y^1, \dots, y^N\})$  and let  $b$  and  $\ell_i, i \in [N]$ , be its output
10  | Set  $r = b$  and extend  $u$  to be a string of length  $b$  such that  $u_{[r-m:b]}$  is a desert
11  | if  $b = n - 1$  then output "FAILURE"
12  | Let  $z^i$  be the suffix of  $y^i$  starting at  $y_{\ell_i+1}^i$  for each  $i \in [N]$ 
13  | Run  $\text{BMA}(n - b - 1, \{z^1, \dots, z^N\})$  and let  $w$  be its output
14  | if  $w$  has no desert then
15  |   | return  $u \circ w$ 
16  | else
17  |   | Let  $r^*$  be the first location that is deep in a desert in  $w$  and set  $r \leftarrow r + r^*$ 
18  |   | and  $u \leftarrow u \circ w_{[r^*+m]}$ 
19  |   | return  $u$  if  $u$  is of length  $n$ 
19 return  $u$ 

```

---

The algorithm chooses  $v$  to be a random string of length  $n/2$ . In order to obtain the original  $n$ -bit string  $x$  it suffices for us to reconstruct the  $(3n/2)$ -bit string  $z$ . The proof of correctness involves standard probabilistic arguments and is deferred to the full version.

For convenience of notation, we rename  $z$  as  $x$  and rename  $n$  to be the length of this string  $z$ , so we still have  $x = (x_0, \dots, x_{n-1})$ . Now  $x$  is an  $n$ -bit string that has the following property: any desert in  $x$  ends at least  $n/4$  bits before the right end of  $x$ . With this preprocessing accomplished, we now describe Algorithm **Reconstruct** in Algorithm 1.

## 4.2 The high level idea of the Reconstruct algorithm

At a high level the algorithm works as follows. It starts (lines 1-3) by drawing

$$N = O(\log n)$$

independent traces  $z^1, \dots, z^N$  from  $\text{Del}_\delta(x)$  and using them to run **BMA**. An important component of our analysis is the following new result about the performance of **BMA** (note that later we require, and will give, a more robust version of the theorem below; see Theorem 6):

► **Theorem 4.** Let  $\delta = n^{-(1/3+\varepsilon)}$  for some fixed constant  $\varepsilon > 0$ . Given  $N$  traces drawn independently from  $\text{Del}_\delta(x)$  for some unknown string  $x \in \{0,1\}^n$ , BMA runs in  $\tilde{O}(n)$  time and returns a string  $w$  of length  $n$  with the following performance guarantees:

1. If  $x$  has no desert, then  $w = x$  with probability at least  $1 - 1/n^2$ ;
2. If  $x$  has at least one desert, then  $w$  and  $x$  share the same  $(r + m + 1)$ -bit prefix with probability at least  $1 - 1/n^2$ , where  $r$  is the first location that is deep in a desert of  $x$ .

Let  $w$  be the string BMA returns. By Theorem 4, we have the following two cases:

1. If  $w$  has no desert, then also  $x$  has no desert and the algorithm can just return  $w$  (line 4);
2. If  $w$  has at least one desert, then writing  $r$  to denote the first location that is deep in a desert in  $w$ , it is safe to assume that  $w_{[0:r+m]} = x_{[0:r+m]}$  and  $r$  is also the first location that is deep in a desert in  $x$  (line 6).

Suppose that we are in the second case with  $w_{[0:r+m]} = x_{[0:r+m]}$ . Then  $w_{[r-m:r+m]}$  is an  $s$ -desert for some string  $s \in \{0,1\}^k$  of some length  $k \leq C$ . We let  $s$  be the shortest such string and let  $k$  be its length (so if  $w_{[r-m:r+m]}$  were, for example, a subword of the form 001001001001... of length a multiple of 12, we would take  $s = 001$  and  $k = 3$ ).

Next (lines 8-9) we run **FindEnd** to figure out where this repetition of  $s$  ends in  $x$ . We use **end** to denote the end of the desert, where  $\text{end} \geq r + m$  is the smallest integer such that  $x_{\text{end}+1} \neq x_{\text{end}-k+1}$ . By the preprocessing step we may assume that **end** exists and satisfies  $\text{end} \leq 3n/4$ . (We note that **FindEnd** has access to  $\text{Del}_\delta(x)$  to draw fresh traces by itself; we send  $N$  fresh traces  $\mathbf{y}^1, \dots, \mathbf{y}^N$  to **FindEnd** so that it can help align them to the end of the desert, which are used to run BMA later.) The performance guarantee for **FindEnd** is given below:

► **Theorem 5.** Let  $\delta = n^{-(1/3+\varepsilon)}$  for some fixed constant  $\varepsilon > 0$ . There is an algorithm **FindEnd** with the following input and output:

- **Input:** (i) a location  $r \in [0 : 3n/4]$ , (ii) a string  $u \in \{0,1\}^{r+m+1}$ , (iii) a multiset of strings  $\{\mathbf{y}^1, \dots, \mathbf{y}^N\}$  from  $\{0,1\}^{\leq n}$  where  $N = O(\log n)$ , and (iv) sample access to  $\text{Del}_\delta(x)$  for some unknown string  $x \in \{0,1\}^n$ .
- **Output:** An integer  $b$ , and an integer  $\ell_i$  for each  $i \in [N]$ .

The algorithm **FindEnd** draws  $\tilde{O}(n^{2/3-\varepsilon})$  many independent traces from  $\text{Del}_\delta(x)$ , runs in  $O(n^{5/3})$  time and has the following performance guarantee. Suppose that  $r$  is the first location that is deep in some desert of  $x$ ;  $u = x_{[0:r+m]}$ ; the unknown **end** of the desert to which  $x_r$  belongs is at most  $3n/4$ ; and  $\mathbf{y}^1 = \mathbf{y}^1, \dots, \mathbf{y}^N = \mathbf{y}^N$  are independent traces drawn from  $\text{Del}_\delta(x)$ . Then the integers  $b$  and  $\ell_i$  that **FindEnd** outputs satisfy the following properties with probability at least  $1 - 1/n^2$ :  $b = \text{end}$ , and  $\ell_i = \text{last}(\mathbf{y}^i)$  for at least 0.9 fraction of  $i \in [N]$ . Here  $\text{last}(y)$  for a trace  $y$  denotes the location  $\ell$  in  $y$  such that  $y_\ell$  corresponds to the last bit of  $x_{[0:\text{end}]}$  that survives in  $y$  (and we set  $\text{last}(y) = -1$  by default if all of  $x_{[0:\text{end}]}$  gets deleted in  $y$ ).

Line 9 runs **FindEnd** with fresh independent traces  $\mathbf{y}^1, \dots, \mathbf{y}^N$  drawn from  $\text{Del}_\delta(x)$ . By Theorem 5, with high probability **FindEnd** returns the correct location  $b = \text{end}$ , from which we can then recover  $x_{[0:b]}$  as the unique extension of  $w_{[0:r+m]}$  in which the pattern  $s$  keeps repeating until (and including) location  $b$ . Moreover, we have from Theorem 5 that, for at least a 9/10-fraction of all  $i \in [N]$ , the suffix  $\mathbf{z}^i$  of  $\mathbf{y}^i$  starting from  $\mathbf{y}_{\ell_i+1}^i$  is a trace drawn from  $\text{Del}_\delta(x_{[b+1:n-1]})$ . We further note that our preprocessing ensures  $b \leq 3n/4$  and thus, the algorithm does not halt on line 11.

To continue, we would like to run BMA again on  $\mathbf{z}^1, \dots, \mathbf{z}^N$  (the suffixes of  $\mathbf{y}^1, \dots, \mathbf{y}^N$ ) to recover  $x_{[b+1:n-1]}$  (or a prefix of  $x_{[b+1:n-1]}$  if it contains a desert). However, observe that now we need BMA to be robust against some noise in its input traces because by Theorem 5, up to

$1/10$  of  $z^1, \dots, z^N$  might have been obtained from an incorrect alignment of  $y^1, \dots, y^N$ . Thus we require the following more robust performance guarantee from **BMA**, given by Theorem 6 below. (To state this we need a quick definition: we say two multisets of strings of the same size are  $\eta$ -close if one can be obtained from the other by substituting no more than  $\eta$ -fraction of its strings. One should also consider  $x'$  in the statement below as  $x_{[b+1:n-1]}$  and  $n'$  as  $n - b - 1$ .)

► **Theorem 6.** *Let  $\delta = n^{-(1/3+\varepsilon)}$  for some fixed constant  $\varepsilon > 0$ . Suppose  $\tilde{z}^1, \dots, \tilde{z}^N$  are  $N$  independent traces drawn from  $\text{Del}_\delta(x')$  for some unknown string  $x' \in \{0, 1\}^{n'}$  with  $n' \leq n$ . The following holds with probability at least  $1 - 1/n^2$  over the randomness of  $\tilde{z}^1, \dots, \tilde{z}^N \sim \text{Del}_\delta(x')$ :*

1. *If  $x'$  has no desert, then **BMA** running on  $n'$  and any multiset  $\{z^1, \dots, z^N\}$  that is  $(1/10)$ -close to  $\{\tilde{z}^1, \dots, \tilde{z}^N\}$  returns  $w = x'$ ;*
2. *If  $x'$  has at least one desert, then **BMA** running on  $n'$  and any multiset  $\{z^1, \dots, z^N\}$  that is  $(1/10)$ -close to  $\{\tilde{z}^1, \dots, \tilde{z}^N\}$  returns a string  $w$  that shares the same  $(r' + m + 1)$ -bit prefix with  $x'$ , where  $r'$  is the first location that is deep in a desert in  $x'$ .*

Given Theorem 6, we can indeed successfully run **BMA** on  $z^1, \dots, z^N$  and with high probability, it correctly recovers a prefix of  $x_{[b+1:n-1]}$  up to the first point deep in the next desert (if any exists), in which case the algorithm repeats (if there is no next desert, then with high probability **BMA** will correctly recover the rest of  $x$ ).

### 4.3 Correctness of Reconstruct

The case when  $x$  has no desert is handled by Theorem 6. Assuming that  $x$  has at least one desert, it follows from Theorem 6 that  $r, u$  together satisfy the following property with probability at least  $1 - 1/n^2$  at the beginning of the main loop (lines 7-18):  $r$  is the first location that is deep in a desert in  $x$  and  $u = x_{[0:r+m]}$ . This gives the base case for the following invariant that the algorithm maintains with high probability:

**Invariant:** *At the beginning of each loop,  $r$  is the first location deep in some desert in  $x$  and  $u = x_{[0:r+m]}$ .*

Assume that the invariant is met at the beginning of the current loop. Let **end** denote the end of the current desert (i.e., the smallest value  $\text{end} \geq r + m$  such that  $x_{\text{end}+1} \neq x_{\text{end}-k+1}$ ; we observe that  $\text{end} \leq 3n/4$  always exists by the guarantee of the preprocessing step). Let  $y^1, \dots, y^N$  be fresh traces drawn at the beginning of this loop. For each  $i \in [N]$ , we write  $\tilde{z}^i$  to denote the suffix of  $y^i$  starting at  $\text{last}(y^i) + 1$ . Given that  $y^1, \dots, y^N \sim \text{Del}_\delta(x)$ ,  $\tilde{z}^1, \dots, \tilde{z}^N$  are indeed independent traces drawn from  $\text{Del}_\delta(x')$ , where  $x' = x_{[\text{end}+1:n-1]}$ . Then we note that, for the algorithm to deviate from the invariant in the current round, one of the following two events must hold for  $y^1, \dots, y^N$ :

1. **FindEnd**( $r, u, \{y^1, \dots, y^N\}$ ) fails Theorem 5; or
2.  $\{\tilde{z}^1, \dots, \tilde{z}^N\}$  fails Theorem 6, i.e., there is a multiset  $\{z^1, \dots, z^N\}$  that is  $(1/10)$ -close to  $\{\tilde{z}^1, \dots, \tilde{z}^N\}$  but **BMA**( $n - \text{end} - 1, \{z^1, \dots, z^N\}$ ) violates the condition in Theorem 6.

This is because whenever **FindEnd** succeeds, the strings  $\{z^1, \dots, z^N\}$  on which we run **BMA** on line 13 must be  $(1/10)$ -close to  $\{\tilde{z}^1, \dots, \tilde{z}^N\}$ . Theorem 5 ensures that item 1 happens with probability at most  $1/n^2$ ; Theorem 6 ensures that item 2 happens with probability at most  $1/n^2$ , given that  $\tilde{z}^1, \dots, \tilde{z}^N$  are independent traces from  $\text{Del}_\delta(x')$  as required in the assumption of Theorem 6.

---

**Algorithm 2** Algorithm BMA.

---

**Input:** A length  $n'$  and a multiset  $\{z^1, \dots, z^N\}$  of strings, each of length at most  $n'$   
**Output:** A string  $w = (w_0, \dots, w_{n'-1}) \in \{0, 1\}^{n'}$

- 1 For each  $i \in [N]$  pad each  $z^i$  to be a string  $u^i$  of length  $n'$  by adding 0's to the end
- 2 Set  $t = 0$  and  $\text{current}_i(t) = 0$  for each  $i \in [N]$
- 3 **while**  $t \leq n' - 1$  **do**
- 4     Set  $w_t \in \{0, 1\}$  to be the majority of the  $N$  bits  $u_{\text{current}_1(t)}^1, \dots, u_{\text{current}_N(t)}^N$
- 5     For each  $i \in [N]$ , set  $\text{current}_i(t+1)$  to  $\text{current}_i(t) + 1$  if  $u_{\text{current}_i(t)}^i = w_t$ ;  
       otherwise set  $\text{current}_i(t+1)$  to  $\text{current}_i(t)$
- 6     Increment  $t$ .
- 7 **return**  $w$ .

---

By a union bound, the invariant holds with high probability in every round given that we only repeat for  $n/m$  rounds. Finally, observe that we only need to repeat for  $n/m$  rounds to reconstruct the entire  $n$ -bit string  $x$ , since in each round the pointer  $r$  increases by at least  $2m$ .

This concludes the proof of correctness of **Reconstruct** and the proof of Theorem 1, modulo the proofs of Theorem 6 and Theorem 5. In the rest of the paper we prove those two theorems.

## 5 Improved analysis of the Bitwise Majority Algorithm: Proof of Theorem 6

The bitwise majority algorithm was first described and analyzed in [2]. The analysis given in [2] established that **BMA** successfully reconstructs any unknown source string  $x \in \{0, 1\}^n$  that does not contain any “long runs” (i.e., subwords of the form  $0^{n^{1/2+\varepsilon}}$  or  $1^{n^{1/2+\varepsilon}}$ ) provided that the deletion rate  $\delta$  is at most  $n^{-(1/2+\varepsilon)}$ . We describe the **BMA** algorithm in Algorithm 2. As the main result of this section we establish an improved performance guarantee for **BMA**. Our discussion and notation below reflects the fact that we will in general be running **BMA** “in the middle” of a string  $x$  for which we have already reconstructed a  $(b+1)$ -bit prefix of  $x$  (this is why Theorem 6 is stated in terms of a source string  $x'$  of length  $n' \leq n$ , which should be thought of as a suffix of  $x$ ). Our goal is to prove Theorem 6.

We break the proof of Theorem 6 into two steps (Lemma 8 and Lemma 14 below). For ease of exposition, in the rest of this section if  $x'$  has at least one desert then as stated in item (2) of the theorem, we let  $r'$  be the first location that is deep in a desert in  $x'$ . If  $x'$  has no desert, then we let  $r' = n' - m - 1$ . Note that with this definition of  $r'$ , it is guaranteed that there is no desert in  $x'_{[0:r'+m-1]}$  and the goal of **BMA** is to return a string that shares the same  $(r' + m + 1)$ -prefix with  $x$ .

Let  $R = 9N/10$ . We first prove in Lemma 8 that if a multiset of  $R$  traces  $Z = \{z^1, \dots, z^R\}$  of  $x'$  satisfies a certain sufficient “goodness” condition (see Definition 7 for details), then **BMA**( $n', Z$ ) not only returns a string  $w = (w_0, \dots, w_{n'-1}) \in \{0, 1\}^n$  that satisfies  $w_{[0:r'+m]} = x'_{[0:r'+m]}$  as desired but moreover, the bitwise majority during each of the first  $r' + m + 1$  rounds of **BMA** is “robust” in the following sense: for each one of those rounds, at least  $9R/10 = 81N/100$  of the  $R$  strings  $z^i$ 's agree with each other. This immediately implies that when  $Z$  satisfies this condition, adding any multiset of  $N/10$  strings to  $Z$  and running **BMA** on the resulting multiset of size  $N$  cannot affect the output of **BMA** during the first  $r' + m + 1$  rounds, so its output  $w$  still satisfies  $w_{[0:r'+m]} = x'_{[0:r'+m]}$ . The next lemma,

Lemma 14, shows that if  $\tilde{\mathbf{Z}} = \{\tilde{z}^1, \dots, \tilde{z}^N\}$  is a multiset of  $N$  traces drawn independently from  $\text{Del}_\delta(x')$  (as in the assumption part of Theorem 6), then with high probability *every*  $R$ -element subset of  $\tilde{\mathbf{Z}}$  satisfies the sufficient condition (Definition 7) for BMA to succeed robustly. Theorem 6 follows easily by combining Lemma 8 and Lemma 14. Due to lack of space, we defer most proofs in this section to the full version.

## 5.1 Notation for traces

We start with some useful notation for analyzing traces of  $x'$ . When a trace  $\mathbf{y}$  is drawn from  $\text{Del}_\delta(x')$  we write  $\mathbf{D}$  to denote the set of *locations deleted* when  $x'$  goes through the deletion channel, i.e.,  $\mathbf{D}$  is obtained by including each element in  $[0 : n' - 1]$  independently with probability  $\delta$ , and  $\mathbf{y}$  is set to be  $x'_{[0:n'-1] \setminus \mathbf{D}}$ . In the analysis of BMA when it is given as input  $R$  traces  $Z = \{z^1, \dots, z^R\}$ , our analysis will sometimes refer to the set  $D_i \subseteq [0 : n' - 1]$  of locations that was deleted when generating  $z^i$ .

Note that in the execution of BMA we pad each trace  $z^i$  to a string  $u^i$  of length  $n'$  by adding 0's to its end. In the rest of the section it will be convenient for us to view  $x'$  as a string of infinite length by adding infinitely many 0's to its end. We can then view each  $u^i$  as generated by first deleting the bits in  $D_i \subseteq [0 : n' - 1]$  from  $x'$  and taking the  $n'$ -bit prefix of what remains. This motivates the definition of the following map  $f_i : [0 : n' - 1] \rightarrow \mathbb{N}$  for each  $i \in [R]$ : For each  $j \in [0 : n' - 1]$ ,  $f_i(j)$  is set to be the unique integer  $k$  such that  $k \notin D_i$  and  $k - |D_i \cap [k - 1]| = j$ . In words,  $f_i(j)$  is simply the original location in  $x'$  of the  $j$ -th bit in the padded version  $u^i$  of  $z^i$ .

We specify some parameters that will be used in the rest of Section 5. Let  $C = \lceil 100/\varepsilon \rceil$  (so  $C$  should be thought of as a large absolute constant) and  $M = 2m + 1$  with  $m = n^{1/3}$ , and recall that by definition  $M$  is the shortest possible length of a desert.

## 5.2 BMA is robust on good sets of traces

The main result of this subsection is Lemma 8, which establishes that BMA is robustly correct in its operation on traces that satisfy a particular “goodness” condition given in Definition 7 below.

Let  $Z = \{z^1, \dots, z^R\}$  be a multiset of traces of  $x'$ . As described above we write  $u^i \in \{0, 1\}^{n'}$  to denote the 0-padded version of  $z^i$ ,  $D_i \subseteq [0 : n' - 1]$  to denote the set of locations that were deleted from  $x'$  to form  $z^i$ , and  $f_i$  to denote the map defined as above for each  $i \in [R]$ . We introduce the following condition for  $Z$  and then prove Lemma 8:

- **Definition 7.** We say  $Z = \{z^1, \dots, z^R\}$  is good if the following two conditions hold:
- (i) For every  $i \in [R]$  and every interval  $[\text{left} : \text{right}] \subset [0 : n' - 1]$  of length  $\text{right} - \text{left} + 1 = L_1 := 2C^2M$ , we have  $|D_i \cap [\text{left} : \text{right}]| \leq C$ .
  - (ii) For every interval  $[\text{left} : \text{right}] \subset [0 : n' - 1]$  of length  $\text{right} - \text{left} + 1 = L_2 := M + C + 1$ , the number of elements  $i \in [R]$  such that  $D_i \cap [\text{left} : \text{right}] \neq \emptyset$  is at most  $R/C^3$ .

Intuitively, (i) says that no interval of moderate length (note that this length  $2C^2M$  is polynomially less than  $1/\delta$ ) has “too many” deletions in it in any trace, whereas (ii) says that for every interval of moderate length (again polynomially less than  $1/\delta$ ), most of the  $R$  traces have no bit deleted within that interval.

Now we are ready to state Lemma 8:

- **Lemma 8.** Let  $Z = \{z^1, \dots, z^R\}$  be a good multiset of  $R$  traces of  $x'$ . Then the string  $w \in \{0, 1\}^{n'}$  that BMA( $n', Z$ ) outputs satisfies  $w_{[0:r'+m]} = x'_{[0:r'+m]}$ . Moreover, during each of the first  $r' + m + 1$  rounds of the execution of BMA, at least  $9R/10$  of the  $R$  bits in the majority vote taken in Step 4 of BMA agree with each other.

We start the proof of Lemma 8 by defining a map  $\text{distance}_i(t)$  for each  $z^i$  in  $Z$ . Recall that  $\text{current}_i(t)$  is the current location of the pointer into the padded trace  $u^i$  at the beginning of round  $t$  in BMA.<sup>6</sup> We let  $\text{position}_i(t) = f_i(\text{current}_i(t))$ , i.e. the original position in  $x'$  of the  $\text{current}_i(t)$ -th bit of  $u^i$ . Then  $\text{distance}_i(t)$  is defined as  $\text{distance}_i(t) = \text{position}_i(t) - t$ , the distance between  $t$  and  $\text{position}_i(t)$ . In Corollary 10 we will show that  $\text{distance}_i(t)$  is always nonnegative, and so it actually measures how many bits  $\text{position}_i(t)$  is ahead at round  $t$ . It may be helpful to visualize  $t$  and  $\text{position}_i(t)$  of a trace by writing down the source string  $x'$  with the deleted bits struck through, and having two arrows pointing to  $x'_t$  and  $x'_{\text{position}_i(t)}$ ; at the beginning of round  $t$ , the BMA algorithm tries to determine  $x'_t$  by looking at  $x'_{\text{position}_i(t)}$ . Intuitively, having  $\text{distance}_i(t) = 0$  means that the  $i$ -th trace was aligned properly at round  $t$ ; at the highest level, we establish Lemma 8 by showing that at least  $9R/10$  of the  $R$  traces have  $\text{distance}_i(t) = 0$ .

We state the following claim about how  $\text{current}_i(t)$ ,  $\text{position}_i(t)$  and  $\text{distance}_i(t)$  compare to their values at the beginning of round  $t-1$ , assuming that the prefix  $w_{[0:t-1]}$  of the output thus far matches  $x'_{[0:t-1]}$ .

▷ **Claim 9.** Let  $t$  be a positive integer such that  $w_{[0:t-1]} = x'_{[0:t-1]}$ . For each  $i \in [R]$ , we have

1. If  $x'_{\text{position}_i(t-1)} \neq x'_{t-1}$ , then  $\text{current}_i(t) = \text{current}_i(t-1)$ ,  $\text{position}_i(t) = \text{position}_i(t-1)$  and  $\text{distance}_i(t) = \text{distance}_i(t-1) - 1$ .
2. If  $x'_{\text{position}_i(t-1)} = x'_{t-1}$ , then  $\text{current}_i(t) = \text{current}_i(t-1) + 1$ ,  $\text{position}_i(t) = \text{position}_i(t-1) + \ell + 1$  and  $\text{distance}_i(t) = \text{distance}_i(t-1) + \ell$ , where  $\ell$  is the nonnegative integer such that  $\text{position}_i(t-1) + 1, \dots, \text{position}_i(t-1) + \ell \in D_i$  and  $\text{position}_i(t-1) + \ell + 1 \notin D_i$  (or equivalently,  $\ell = f_i(\text{current}_i(t)) - f_i(\text{current}_i(t-1)) - 1$ ).

We have the following useful corollary of Claim 9, which tells us that if  $w_{[0:t-1]} = x'_{[0:t-1]}$  then each  $\text{distance}_i(t) \geq 0$  (in other words, no trace can have “gotten behind” where it should be):

► **Corollary 10.** Let  $t$  be a positive integer such that  $w_{[0:t-1]} = x'_{[0:t-1]}$ . Then  $\text{distance}_i(t) \geq 0$  for all  $i \in [R]$ .

We prove three preliminary lemmas before proving Lemma 8. Recall that  $M = 2m + 1$  is the shortest possible length of a desert. Assuming  $w_{[0:t-1]} = x'_{[0:t-1]}$  for some  $t > M$ , the first lemma shows that if  $\text{distance}_i(t - M) = 0$  and no location of  $x'$  is deleted between  $t - M + 1$  and  $t$ , then  $\text{distance}_i(t)$  must stay at 0. (Note that this lemma holds for general  $M$  but we state it using  $M = 2m + 1$  for convenience since this is how it will be used later.) Intuitively, this says that if a length- $M$  subword of  $x'$  experiences no deletions, then a trace that is correctly aligned at the start of the subword will stay correctly aligned throughout the subword and at the end of the subword.

► **Lemma 11.** Suppose that  $w_{[0:t-1]} = x'_{[0:t-1]}$  for some  $t > M$ . Suppose that  $i \in [R]$  is such that  $\text{distance}_i(t - M) = 0$  and

$$D_i \cap [\text{position}_i(t - M) + 1 : \text{position}_i(t - M) + M] = D_i \cap [t - M : t] = \emptyset.$$

Then we have  $\text{distance}_i(t) = 0$ .

<sup>6</sup> Note that whereas  $\text{position}_i(\cdot)$  and  $\text{distance}_i(\cdot)$  refer to quantities defined in terms of the source string  $x$ ,  $\text{current}_i(\cdot)$  refers to a location in a trace string and not the source string.

In the second lemma, we assume  $t$  is such that  $M < t \leq r' + m + 1$  by the choice of  $r$ . We further assume that  $w_{[0:t-1]} = x'_{[0:t-1]}$  and  $0 < \text{distance}_i(t - M) \leq C$  for some  $i \in [R]$ . We show that under these assumptions, if the subword of length  $M$  in  $x'$  starting at  $\text{position}_i(t - M) + 1$  has no deletion, then  $\text{distance}_i(t) < \text{distance}_i(t - M)$ . Intuitively, this says that prior to a desert, if the length- $M$  subword of  $x'$  experiences no deletions and the alignment of a trace is only modestly ahead of where it should be at the start of the subword, then the alignment will improve by the end of the subword.

► **Lemma 12.** *Let  $M < t \leq r' + m + 1$  with  $w_{[0:t-1]} = x'_{[0:t-1]}$ . If  $0 < \text{distance}_i(t - M) \leq C$  for some  $i \in [R]$  and  $D_i \cap [\text{position}_i(t - M) + 1 : \text{position}_i(t - M) + M] = \emptyset$ , then we have  $\text{distance}_i(t) < \text{distance}_i(t - M)$ .*

Finally we use the two previous lemmas to show that if  $t \leq r' + m + 1$  and  $w_{[0:t-1]} = x'_{[0:t-1]}$ , then  $\text{distance}_i(t)$  must lie between 0 and  $C$ . Intuitively, this says that prior to a desert, the alignment of a trace will be at worst modestly ahead of where it should be.

► **Lemma 13.** *Let  $t \leq r' + m + 1$  and suppose that  $w_{[0:t-1]} = x'_{[0:t-1]}$ . Then  $\text{distance}_i(t) \leq C$  for all  $i \in [R]$ .*

**Proof of Lemma 8.** We prove by induction that for every positive integer  $t \leq r' + m + 1$ :

$$w_{[0:t-1]} = x'_{[0:t-1]} \quad \text{and} \quad \sum_{i \in [R]} \text{distance}_i(t) \leq \frac{2R}{C}. \quad (1)$$

It follows that every  $t \leq r' + m + 1$  satisfies  $|\{i \in [R] : \text{distance}_i(t) = 0\}| \geq R - 2R/C \geq 9R/10$  using  $C \geq 20$ . The details are deferred to the full version. ◀

### 5.3 Traces are good with high probability

To conclude the proof of Theorem 6 it remains to prove Lemma 14, which states that with high probability a random multiset of  $O(\log n)$  traces is such that every subset of 9/10 of the traces is good (recall Definition 7).

► **Lemma 14.** *Let  $\tilde{\mathbf{Z}} = \{\tilde{z}^1, \dots, \tilde{z}^N\}$  be a multiset of  $N = O(\log n)$  traces drawn independently from  $\text{Del}_\delta(x')$ . Then with probability at least  $1 - 1/n^2$ , every  $R$ -subset of  $\tilde{\mathbf{Z}}$  is good, where  $R = 9N/10$ .*

## 6 Finding the end of a desert: Proof of Theorem 5

In this section, we describe the algorithm **FindEnd**, which is used to determine the end of a desert in  $x$  using traces from  $\text{Del}_\delta(x)$ , and to align given traces with the end of the desert. (These aligned traces will then be used by **BMA** in the main algorithm.)

Let's recall the setting. Let  $x \in \{0, 1\}^n$  be the unknown string. **FindEnd** is given the first location  $r$  that is deep in some  $s$ -desert subword of  $x$ , for some string  $s \in \{0, 1\}^k$  with  $k \leq C$ . It is also given the prefix  $u = x_{[0:r+m]}$  of  $x$ . We will refer to the  $s$ -desert that contains  $r$  as the *current* desert. (Note that  $s$  can be easily derived from  $u$ .) The goal of **FindEnd** is to figure out the ending location of the current desert which we denote by **end**:

**end** is the smallest integer at least  $r + m$  such that  $x_{\text{end}+1} \neq x_{\text{end}-k+1}$ .

(Note that thanks to the preprocessing step **Preprocess**, we know that **end** exists and satisfies  $r + m \leq \text{end} \leq 3n/4$ .)

In addition to computing `end`, `FindEnd` is also given a multiset of  $N = O(\log n)$  traces  $y^1, \dots, y^N$  and needs to return a location  $\ell_i$  for each  $y^i$  such that most of them are correctly aligned to the end of the desert. Formally, we write  $\text{last}(y)$  for a trace  $y$  to denote the location  $\ell$  in  $y$  such that  $y_\ell$  corresponds to the last bit of  $x_{[0:\text{end}]}$  that survives in  $y$ ; we set  $\text{last}(y) = -1$  by default if all of  $x_{[0:\text{end}]}$  gets deleted. The second goal of `FindEnd` is to output  $\ell_i = \text{last}(y^i)$  for almost all  $y^i$  when they are drawn independently from  $\text{Del}_\delta(x)$ .

We present the algorithm `FindEnd` in Algorithm 3, where

$$\sigma := \lceil \sqrt{\delta n} \cdot \log n \rceil.$$

(Intuitively,  $\sigma$  provides a high-probability upper bound on how far a bit of  $x$  can deviate from its expected position in a trace  $y \sim \text{Del}_\delta(x)$ .) `FindEnd` consists of the following two main procedures:

1. We will refer to the  $8\sigma$ -bit string

$$\text{tail} := x_{\text{end}-k+2} x_{\text{end}-k+3} \cdots x_{\text{end}+8\sigma-k+1}$$

around the end  $x_{\text{end}}$  of the current desert as its *tail* string and denote it by  $\text{tail} \in \{0, 1\}^{8\sigma}$ . (Note that  $\text{end} + 8\sigma - k + 1 < n$  given that  $\text{end} \leq 3n/4$ .) The first procedure, `Coarse-Estimate`, will provide with high probability a *coarse estimate*  $\hat{\beta}$  (see Lemma 15) of the expected location  $(1 - \delta)\text{end}$  of the right end of the current desert in a trace of  $x$ . This procedure is described in Section 6.1.

2. With  $\hat{\beta}$  and  $\text{tail} \in \{0, 1\}^{8\sigma}$  in hand, the second procedure `Align` can help align a given trace with the right end of the current desert. Informally, running on a trace  $y \sim \text{Del}_\delta(x)$ , `Align` returns a position  $\ell$  such that with high probability over the randomness of  $y \sim \text{Del}_\delta(x)$ , it holds that  $\ell = \text{last}(y)$ . The performance guarantee of `Align` is given in Lemma 16. It may sometimes (with a small probability) return `nil`, meaning that it fails to align the given trace. This procedure is described in Section 6.2.

The algorithm `FindEnd` starts by running `Coarse-Estimate` to obtain a coarse estimate  $\hat{\beta}$  of  $(1 - \delta)\text{end}$  and the *tail* string (line 1). It then (line 2) runs `Align` on the given  $N$  traces  $y^i$  to obtain  $\ell_i$  for each  $i \in [N]$ . The second property of `FindEnd` in Theorem 5 about  $\ell_i$ 's follows directly from the performance guarantee of `Align`. To obtain a sharp estimate of `end`, `FindEnd` draws another set of  $\tilde{O}(n^{2/3-\varepsilon})$  traces  $z^i$  (line 3). It runs `Align` on each of them and uses the average of its outputs (discarding traces for which `Align` returns `nil`) to estimate  $(1 - \delta)\text{end}$  (lines 4-6). (It is clear that this average would be accurate to within  $\pm o(1)$  if `Align` always successfully aligned its input trace with the right end of the current desert; the actual performance guarantee of `Align` is weaker than this, but a careful analysis enables us to show that it is good enough for our purposes.)

## 6.1 The Coarse-Estimate procedure

Recall that  $\sigma = \lceil \sqrt{\delta n} \cdot \log n \rceil$ . Given  $r, u$  as specified earlier and sample access to  $\text{Del}_\delta(x)$ , the goal of `Coarse-Estimate` is to obtain an integer  $\hat{\beta}$  such that  $|\hat{\beta} - (1 - \delta)\text{end}| \leq 2\sigma$ . We will refer to such an estimate as a *coarse estimate* of  $(1 - \delta)\text{end}$ . In addition, `Coarse-Estimate` returns a string  $t$  that with high probability is exactly the tail string  $\text{tail} \in \{0, 1\}^{8\sigma}$ . This is done by drawing only  $O(1/\varepsilon)$  many traces.

► **Lemma 15.** *Let  $\delta = n^{-(1/3+\varepsilon)}$  with a fixed constant  $\varepsilon > 0$ . There is an algorithm `Coarse-Estimate` which takes the same two inputs  $r$  and  $u$  as in `FindEnd` and sample access to  $\text{Del}_\delta(x)$  for some unknown string  $x \in \{0, 1\}^n$ , and returns an integer  $\hat{\beta} \in [0 : n - 1]$  and a string  $t \in \{0, 1\}^{8\sigma}$ . It draws  $O(1/\varepsilon)$  traces from  $\text{Del}_\delta(x)$ , runs in time  $O(n)$  and has the following performance guarantee. Suppose that  $r$  and  $u$  satisfy the same conditions as in Theorem 5 with respect to  $x$ . Then with probability at least  $1 - 1/n^3$ , we have that  $t = \text{tail}$  and  $\hat{\beta}$  satisfies  $|\hat{\beta} - (1 - \delta)\text{end}| \leq 2\sigma$ .*

■ **Algorithm 3** Algorithm FindEnd.

---

**Input:**  $r \in [0 : 3n/4]$ ,  $u \in \{0, 1\}^{r+m+1}$ , a multiset  $\{y^1, \dots, y^N\}$  of  $N$  strings from  $\{0, 1\}^{\leq n}$  where  $N = O(\log n)$ , and sample access to  $\text{Del}_\delta(x)$  for some string  $x \in \{0, 1\}^n$ .

**Output:** An integer  $b \geq r + m$  and an integer  $\ell_i$  for each  $i \in [N]$ .

- 1 Run **Coarse-Estimate**( $r, u$ ), which returns an integer  $\hat{\beta}$  and a string  $t \in \{0, 1\}^{8\sigma}$ .
  - 2 For each  $i \in [N]$ , run **Align**( $\hat{\beta}, t, y^i$ ). If **Align** returns nil, set  $\ell_i = -1$ ; otherwise let  $\ell_i$  be the integer **Align** returns.
  - 3 Draw  $\gamma = O(n^{2/3-\varepsilon} \log^3 n)$  traces  $z^1, \dots, z^\gamma$  from  $\text{Del}_\delta(x)$ .
  - 4 For each  $i \in [\gamma]$ , run **Align**( $\hat{\beta}, t, z^i$ ) and let  $h_i$  be its output.
  - 5 Let  $\beta$  be the average of  $h_i$ 's that are not nil, and let  $b$  be the integer nearest to  $\beta/(1 - \delta)$ .
  - 6 Return  $b$ , and  $\ell_i$  for each  $i \in [N]$ .
- 

**Proof.** We start with the coarse estimate  $\hat{\beta}$ . Let  $\hat{r} = \lceil (1 - \delta)r \rceil$  and consider the following collection of overlapping intervals of positions in a trace of  $x$ :

$$\mathcal{I} := \left\{ [\hat{r} + j\sigma : \hat{r} + (j + 4)\sigma] : j \in \mathbb{Z}_{\geq 0} \right\}.$$

Note that each interval  $I$  contains  $4\sigma + 1$  positions. **Coarse-Estimate** draws  $\alpha = O(1/\varepsilon)$  traces  $y^1, \dots, y^\alpha$  from  $\text{Del}_\delta(x)$  and finds the leftmost interval  $I^* \in \mathcal{I}$  such that at least half of  $y^i$ 's satisfy the following property:  $y_{I^*}^i$  contains a  $k$ -bit subword that is not a cyclic shift of  $s$ . The algorithm then sets  $\hat{\beta}$  to be the right endpoint of  $I^*$ .

Finally, **Coarse-Estimate** recovers the tail string as follows. Let  $J'$  be the interval  $[\hat{\beta} - 3\sigma : \hat{\beta} + 3\sigma]$ . It draws another sequence of  $\alpha = O(1/\varepsilon)$  fresh traces  $y^1, \dots, y^\alpha$  from  $\text{Del}_\delta(x)$ . For each  $y^i$  it looks for the leftmost non-cyclic shift of  $s$  in  $y_{J'}^i$ . When such a non-cyclic shift exists, say  $y_\tau^i \cdots y_{\tau+k-1}^i$ ,  $y^i$  votes for the  $8\sigma$ -bit string  $y_\tau^i \cdots y_{\tau+8\sigma-1}^i$  as its candidate for the tail string. It then returns the  $8\sigma$ -bit string with the most votes.

Clearly, the running time of **Coarse-Estimate** is  $O(n)$  as the procedure consists of a linear scan over  $O(1/\varepsilon)$  traces. The proof of correctness is deferred to the full version. ◀

## 6.2 The Align procedure

We start with the performance guarantee of **Align**:

► **Lemma 16.** *Let  $\delta = n^{-(1/3+\varepsilon)}$  for some fixed constant  $\varepsilon > 0$ . There is an algorithm **Align** running in time  $O(n)$  with the following input and output:*

- **Input:** a number  $\hat{\beta} \in [0 : n - 1]$ , and strings  $t \in \{0, 1\}^{8\sigma}$ ,  $y \in \{0, 1\}^{\leq n}$ .
- **Output:** an integer  $\ell \in [0 : n - 1]$ , or nil.

*It has the following performance guarantee. Suppose  $x, u, r$  and end satisfy the hypothesis in Theorem 5,  $\hat{\beta}$  and  $t$  satisfy the conclusion of Lemma 15, and  $y = \mathbf{y} \sim \text{Del}_\delta(x)$  is a random trace. Then*

1. *Whenever **Align** returns an integer  $\ell$ , we have  $|\ell - (1 - \delta)\text{end}| \leq O(\sigma)$ .*
2. *With probability at least  $1 - \tilde{O}(n^{-3\varepsilon/2})$ , **Align** returns exactly  $\text{last}(\mathbf{y})$ ; and*
3. *Conditioned on **Align** not returning nil, the expectation of what **Align** returns is  $(1 - \delta)\text{end} \pm o(1)$ .*

### 6.2.1 Setup for the proof of Lemma 16

For the special case when  $k = |s| = 1$  (so the desert subword is of the form  $0^a$  or  $1^a$  for some  $a \geq M = 2n^{1/3} + 1$ ), the description of **Align** is relatively simple.

- **Description of Align for  $k = 1$ :** Let  $J := [\hat{\beta} - 3\sigma : \hat{\beta} + 3\sigma]$ . **Align** outputs nil if the string  $y_J$  contains no occurrence of  $\bar{b}$ ; if  $y_J$  does contain at least one occurrence of  $\bar{b}$  then **Align** outputs the location in  $J$  of the first occurrence of  $\bar{b}$ .

The proof of correctness is deferred to the full version. Now consider the general case when  $k \geq 2$ . Let  $\text{Cyc}_s$  be the set of all  $k$ -bit strings that can be obtained as cyclic shifts of  $s$ . The key notion behind **Align** is the idea of the “signature.” This is a subword of  $x$  of length at most  $8\sigma$  that starts at the same location  $x_{\text{end}-k+2}$  as **tail** (so it is contained in **tail**; we remind the reader that the first  $k$ -bits of **tail** is a string not in  $\text{Cyc}_s$ ). The signature ends at location  $d$  where  $d$  is the smallest integer  $d \in [\text{end} + k + 1 : \text{end} + 8\sigma - k + 1]$  such that the  $k$ -bit subword that ends at  $d$  is not in  $\text{Cyc}_s$ ; if no such  $d$  exists, the signature is taken to have length  $8\sigma$  and is the same as **tail**. (Alternatively, the signature is the shortest prefix of **tail** that contains a  $k$ -bit subword not in  $\text{Cyc}_s$  that does not use the first  $k$  bits; and it is set to **tail** if every  $k$ -bit subword of **tail** after removing the first  $k$  bits lies in  $\text{Cyc}_s$ .)

We will write **sig** to denote the signature string. We observe that  $2k \leq |\text{sig}| \leq 8\sigma$ , and that given the string **tail** it is algorithmically straightforward to obtain **sig**. Given **sig**, we say that a string  $z$  of length at most  $15\sigma + 1$  is in the *right form* if it can be written as

$$z = w \circ \text{sig} \quad (2)$$

where the leftmost  $k$ -bit subword in  $z$  that is not in  $\text{Cyc}_s$  is the first  $k$  bits of **sig**. The main motivation behind the definition of the signature is the following crucial lemma:

► **Lemma 17.** *Let  $s \in \{0, 1\}^k$  for some  $2 \leq k \leq C$ , and let  $z$  be a string of length at most  $15\sigma + 1$  that is in the right form. For  $\mathbf{y} \sim \text{Del}_\delta(z)$ , the probability that  $|\mathbf{y}| < |z|$  (so at least one deletion occurs) and  $\mathbf{y}$  is the prefix of a string in the right form is at most  $O(\delta)$ .*

The high-level idea is that a deletion is likely to create an additional disjoint  $k$ -bit subword in  $\mathbf{y}$  that is not in  $\text{Cyc}_s$ , unless a deletion occurs in some  $O(k)$  specific places in  $z$  or two deletions are  $O(k)$  close to each other. This additional subword will help us argue that  $\mathbf{y}$  does not have the right form. The detailed proof is deferred to the full version.

### 6.2.2 Proof sketch of Lemma 16 when $k \geq 2$

- **Description of Align for  $k \geq 2$ :** Given a coarse estimate  $\hat{\beta}$  (such that  $|\hat{\beta} - (1 - \delta)\text{end}| \leq 2\sigma$ ),  $\text{sig} \in \{0, 1\}^{\leq 8\sigma}$ , and a trace  $y$ , **Align** checks if the restriction of  $y$  to the interval  $J := [\hat{\beta} - 3\sigma : \hat{\beta} + 12\sigma]$  has a prefix in the right form (see Equation (2)), i.e.,

$$y_J = w \circ \text{sig} \circ v \quad (3)$$

so that the first  $k$  bits of **sig** is the leftmost  $k$ -bit subword of  $y_J$  not in  $\text{Cyc}_s$ . If  $y_J$  is not of this form **Align** returns nil. If  $y_J$  is of this form and **sig** ends at location  $L \in [0 : 15\sigma]$  in  $y_J$ , **Align** returns the index of the  $(k - 1)$ -th bit of **sig** (i.e.,  $\text{sig}_{k-2}$  which intuitively should correspond to  $x_{\text{end}}$ ) in  $y$  with probability

$$p_L := (1 - \delta)^{15\sigma - L}, \quad (4)$$

and with the remaining probability returns nil. Note that

$$(1 - \delta)^{15\sigma - L} = 1 - O(\delta\sigma) = 1 - \tilde{O}(n^{3\varepsilon/2}), \quad \text{for all } L \in [0 : 15\sigma],$$

so **Align** only returns nil with probability  $o(1)$  when  $y_J$  is of the form Equation (3).

**Discussion.** The main subtlety in the definition of **Align** is the “discounting probability” given by Equation (4), which plays an important role in ensuring that the location returned by **Align** (conditioned on **Align** not returning nil) is sufficiently close in expectation to the correct location. The proof of correctness of **Align** is deferred to the full version.

### 6.3 Proof of Theorem 5

**Proof of Theorem 5.** The proof follows from the guarantees in Lemma 15 and Lemma 16, using standard concentration bounds. First, we have from Lemma 15 that the output  $(\hat{\beta}, t)$  of **Coarse-Estimate** satisfies  $|\hat{\beta} - (1 - \delta)\text{end}| \leq 2\sigma$  and  $t = \text{tail}$  with probability  $1 - O(1)/n^3$ . Assume that this holds for the rest of the proof.

By Lemma 16, with probability at least  $1 - \tilde{O}(n^{-3\epsilon/2})$  **Align** returns an integer  $\ell_i$  (and not nil), and  $\ell_i = \text{last}(\mathbf{y}^i)$ , for each  $i \in [N]$ . Now, the Chernoff bound (additive form) implies that  $\ell_i = \text{last}(\mathbf{y}^i)$  for at least 0.9 fraction of  $i \in [N]$  with probability  $1 - \exp(-\Omega(N)) \geq 1 - 1/n^3$ , where we choose the hidden constant in  $N = O(\log n)$  to be sufficiently large.

It remains to show that  $b = \text{end}$  with probability at least  $1 - 1/n^3$ . Recalling step 4 of **FindEnd**, let  $G \subset [\gamma]$  be the set of indices  $i$  for which  $h_i = \text{Align}(\hat{\beta}, t, \mathbf{z}^i) \neq \text{nil}$ . Using the same argument as above, we have that  $|G| \geq 0.9\gamma$  with probability  $1 - \exp(-\Omega(\gamma)) = 1 - \exp(-\tilde{\Omega}(n^{2/3-\epsilon}))$ . The guarantees in Lemma 16 imply that  $|\mathbf{E}[h_i | h_i \neq \text{nil}] - (1 - \delta)\text{end}| \leq o(1)$  and that the random variable  $h_i$  (conditioned on its not being nil) always lies in an interval of width  $O(\sigma)$  for all  $i \in G$ . Moreover,  $\{h_i\}_{i \in G}$  are independent random variables.

Let  $\beta = (1/|G|) \sum_{i \in G} h_i$  be the average of  $h_i$  over  $i \in G$ . By Hoeffding’s inequality and our choice of  $\gamma = O(n^{2/3-\epsilon} \log^3 n) = O(\sigma^2 \log n)$  (with a sufficiently large hidden constant),

$$\Pr[|\beta - \mathbf{E}[h_i | h_i \neq \text{nil}]| \geq 0.1] \leq \exp\left(-\Omega\left(\frac{\gamma}{\sigma^2}\right)\right) \leq \exp(-\Omega(\log n)) \leq 1/n^3.$$

By triangle inequality,  $|\beta - (1 - \delta)\text{end}| \leq 0.1$ , and so  $|\beta/(1 - \delta) - \text{end}| \leq 0.2$ , with probability at least  $1 - 1/n^3$ . Hence, the integer  $b$  closest to  $\beta/(1 - \delta)$  is **end**, which implies **FindEnd** returns **end** with probability at least  $1 - 1/n^2$  (by union bound over all the failure probabilities).

Finally, the runtime of **FindEnd** is dominated by the final procedure to compute  $b$ . Since each run of **Align** on a trace takes  $O(n)$  and **Align** is run on  $\gamma \leq n^{2/3}$  traces, **FindEnd** runs in time  $O(n^{5/3})$ . This concludes the proof of Theorem 5.  $\blacktriangleleft$

## Abstract

We consider a generalization of the fundamental online metrical service systems (MSS) problem where the feasible region can be transformed between requests. In this problem, which we call T-MSS, an algorithm maintains a point in a metric space and has to serve a sequence of requests. Each request is a map (transformation)  $f_t: A_t \rightarrow B_t$  between subsets  $A_t$  and  $B_t$  of the metric space. To serve it, the algorithm has to go to a point  $a_t \in A_t$ , paying the distance from its previous position. Then, the transformation is applied, modifying the algorithm's state to  $f_t(a_t)$ . Such transformations can model, e.g., changes to the environment that are outside of an algorithm's control, and we therefore do not charge any additional cost to the algorithm when the transformation is applied. The transformations also allow to model requests occurring in the  $k$ -taxi problem.

We show that for  $\alpha$ -Lipschitz transformations, the competitive ratio is  $\Theta(\alpha)^{n-2}$  on  $n$ -point metrics. Here, the upper bound is achieved by a deterministic algorithm and the lower bound holds even for randomized algorithms. For the  $k$ -taxi problem, we prove a competitive ratio of  $\tilde{O}((n \log k)^2)$ . For chasing convex bodies, we show that even with contracting transformations no competitive algorithm exists.

The problem T-MSS has a striking connection to the following deep mathematical question: Given a finite metric space  $M$ , what is the required cardinality of an extension  $\tilde{M} \supseteq M$  where each partial isometry on  $M$  extends to an automorphism? We give partial answers for special cases.

## 1 Introduction

*Metrical Service Systems (MSS)* [13] is a fundamental online framework unifying countless problems. It also has a central role in our understanding of online computation and competitive analysis in general. In this problem we are given a metric space  $(M, d)$ . The points of the metric represent possible states/configurations where an algorithm can serve requests; the distance between the states represents the cost of moving from one configuration to

another. Each request consists of a subset of feasible states and the algorithm must serve the request by moving to one of these states. The cost of the algorithm for a sequence of requests is simply the total movement cost.

In the closely related problem of *Metrical Task Systems (MTS)* [8], each request is a cost function  $c_t: M \rightarrow \mathbb{R}_+ \cup \{\infty\}$ . The algorithm can move to any point  $x_t$ , paying the movement cost as well as service cost  $c_t(x_t)$ . Note that MSS is equivalent to the special case of MTS where cost functions only take values 0 and  $\infty$ , which already captures the essential difficulty of MTS.<sup>1</sup> For deterministic algorithms, the competitive ratio on any  $n$ -point metric is  $n - 1$  for MSS [19] and  $2n - 1$  for MTS [8]. For randomized algorithms, it lies between  $O(\log^2 n)$  [9, 15] and  $\Omega(\log n / \log \log n)$  [5, 6], and tight bounds of  $\Theta(\log n)$  are known for some metrics. The MSS/MTS framework captures various central online problems such as paging,  $k$ -server, convex body chasing, layered graph traversal, etc. The competitive ratio of MSS usually serves as a first upper bound for the performance achievable for these special cases.

However, MSS fails to capture more dynamic environments in which configuration changes that are outside of the algorithm's control may occur. For example, new resources or constraints may appear/disappear and modify the configurations. To capture such changes we propose an extension for MSS that allows transformations over the configuration space. For example, we may model the  $k$ -taxi problem<sup>2</sup> by considering the possible configurations of taxis in the metric. A movement of a taxi from the start to the destination of a request simply corresponds to a transformation that maps any configuration that contains a taxi at the start to a configuration with an additional taxi at the destination and one less taxi at the start. As these changes are dictated to any solution, it is reasonable not to account any cost for these changes both for the algorithm and for the offline (benchmark) solution. In this work we initiate the study of *Metrical Service Systems with Transformations (T-MSS)*, a generalization of the standard Metrical Service Systems (MSS) problem. As before, we are given a metric space  $(M, d)$ . In each round  $t$ , we get a function (transformation)  $f_t: A_t \rightarrow B_t$  that maps a subspace  $A_t \subseteq M$  of feasible states to a subspace  $B_t \subseteq M$ . If  $b_{t-1} \in M$  is the state of the algorithm before the request  $f_t$  arrives, it has to choose one of the feasible states  $a_t \in A_t$  and pays movement cost  $d(b_{t-1}, a_t)$ . The new state of the algorithm is then  $b_t := f_t(a_t)$ . The classical MSS problem is thus the special case of T-MSS where  $f_t$  is the identity function on the set of feasible states at time  $t$ . In T-MSS we allow in addition to identity transformations also more complex transformations. The high level question we ask is:

► **Open problem 1.** *What is the competitive ratio of the Metrical Service Systems with Transformations problem for families of metric spaces and allowable transformations?*

## 1.1 Our results and techniques

We give partial answers to the above question, obtaining upper and lower bounds on the competitiveness for several interesting families of metric spaces and transformations. The most general family of transformations we study are  $\alpha$ -Lipschitz transformations. Our main result is the following pair of (almost matching) upper and lower bounds for general metric spaces and  $\alpha$ -Lipschitz transformations.

<sup>1</sup> Our results extend easily to the case where MTS requests are allowed, but we will stick to the MSS view for the sake of simplicity.

<sup>2</sup> In this problem, introduced by [17], there are  $k$  taxis in a metric space. Each request is a pair of two points, representing the start and destination of a travel request by a passenger. Serving a request is done by selecting a taxi that travels first to its start and then its destination. In the hard version of the problem, the cost is defined as the total distance traveled by the taxis *without carrying a passenger*.

► **Theorem 1.** *There exists a deterministic  $2 \max\{2(\alpha + 1), 6\}^{n-2}$ -competitive algorithm for T-MSS with  $\alpha$ -Lipschitz transformations on any  $n$ -point metric space. Any algorithm for T-MSS with  $\alpha$ -Lipschitz transformations has competitive ratio at least  $\min\{\alpha + 1, \alpha^2\}^{n-2}$ , even with randomization.*

Although our results show an exponential lower bound (and an exponential upper bound) for any  $\alpha > 1$ , they do not rule out linear/polynomial or with randomization even polylogarithmic competitive ratios when the transformations are 1-Lipschitz (contractions). Resolving the competitive ratio for this important family of transformations is one of the most interesting remaining open questions. On the other hand, we show that even restricting the transformations to be 1-Lipschitz is not always enough. In particular, when adding contraction transformations to the convex body chasing problem (that can be modeled as a special case of MSS on an infinite metric space) there exists no competitive algorithm even in the easier nested case. By contrast, with isometry transformations the competitive ratios  $O(d)$  for the unrestricted problem and  $O(\sqrt{d \log d})$  for the nested problem due to [20, 2, 10] remain unchanged as  $\mathbb{R}^d$  is ultrahomogeneous (see following discussion for formal definitions).

► **Theorem 2.** *There exists no online algorithm with finite competitive ratio for nested convex body chasing with contractions in the plane, even with randomization.*

As a byproduct of our results we also get a new competitive algorithm for the  $k$ -taxi problem, which can be modeled as a T-MSS with isometry transformations.

► **Theorem 3.** *There is a randomized  $O((n \log k)^2 \log n)$ -competitive algorithm for the  $k$ -taxi problem on  $n$ -point metrics.*

This result is better than the previous best bound of  $O(2^k \log n)$  whenever  $n$  is subexponential in  $k$  [14].

**Extending partial isometries.** As a basic tool to tackle T-MSS with general transformation, we study the problem when the allowable transformations are isometries. A map  $f: A \rightarrow B$  for subsets  $A, B \subseteq M$  is called a *partial isometry of  $M$*  if it is distance-preserving, i.e.,  $d(f(x), f(y)) = d(x, y)$ . A metric space  $M$  is called *ultrahomogeneous* if every partial isometry of  $M$  extends to an automorphism of  $M$ . Notice that on ultrahomogeneous metric spaces, the competitive ratio of T-MSS with isometry transformations is the same as the competitive ratio of MSS: Indeed, when a partial isometry  $f_t: A_t \rightarrow B_t$  arrives, let  $\hat{f}_t$  be its extension to an automorphism of  $M$ . In MSS, this request corresponds to the request  $A_t$  followed by a renaming of the points of the metric space according to  $\hat{f}_t$ . Clearly, isometric renaming of points does not affect the competitive ratio.

If  $M$  is not ultrahomogeneous, one could hope to extend  $M$  to a larger metric space  $\hat{M}$  such that every partial isometry of  $M$  extends to an automorphism of  $\hat{M}$ . In this case, we call  $\hat{M}$  a *weakly ultrahomogeneous extension* of  $M$ . For a family of metric spaces  $\mathcal{M}$  we define the *blow-up* as the supremum over all  $n$ -point metrics  $M \in \mathcal{M}$  – of the minimum cardinality of a weakly ultrahomogeneous extension  $\hat{M}$  of  $M$ . If the blow-up can be bounded as a function of  $n$  it allows us to apply the  $(n - 1)$ -competitive deterministic algorithm or the  $O(\log^2 n)$ -competitive randomized algorithm for MSS on the weakly ultrahomogeneous extension to get competitive algorithms. We study the blow-up also for restricted families of isometries. For example, we study swap isometries (defined on two points that are mapped to one another). We call a metric space *swap-homogeneous* if every swap extends to an automorphism. Swap-homogeneous metric spaces have the intuitive property that the metric space “looks” the same at each point. Similar notions of metric space homogeneity have also been studied in other contexts (see, e.g., [23]). The main question, which we consider to be of independent interest, is thus:

► **Open problem 2.** *What is the blow-up for interesting families of metric spaces and partial isometries?*

Some results on weakly ultrahomogeneous extensions already exist, in particular that every finite metric space has such an extension and it is of finite size [21, 22]. However, no bounds on the size of the extensions as a function of  $n$  are known, and hence these results do not yield any bounds on the blow-up. We refer the reader to Section 5 for further discussion. Some of the algorithms we design for T-MSS are using these new upper bounds that we prove on the blow-up. The following theorem summarizes the upper and lower bounds we obtain.

► **Theorem 4.** *The following bounds on the blow-up are tight.*

Family of metric spaces	Family of isometries	Blow-up
Ultrametrics	General	$2^{n-1}$
Ultrametrics: $k$ distinct non-zero distances	General	$\approx \left(\frac{n+k-1}{k}\right)^k$ <sup>3</sup>
Equally spaced points on a line	General	$2n - 2$
$(\{0, \dots, k\}^D, \text{weighted } \ell_1)$	Translations	$(2k)^D$
General metrics	Swaps	$2^{n-1}$

Using the direct reduction above, we may get directly some interesting results for T-MSS when transformations are isometries. For example, a randomized  $O(n^2)$ -competitive algorithm for ultrametrics and an  $O(\log^2 n)$ -competitive algorithm for equally spaced points on a line.

**The work function algorithm.** The *work function algorithm* (WFA) is a classical algorithm that achieves the optimal deterministic competitive ratio of  $n - 1$  for MSS on any  $n$ -point metric (see [7] for a discussion on its history). The algorithm extends naturally to T-MSS (see Section 2.1), and is a natural candidate algorithm to investigate. We prove that it is in fact optimal for several special cases of the problem. The following result for ultrahomogeneous ultrametrics is also used as part of our main algorithm for general metrics. We also prove that on general metrics, WFA has a superlinear competitive ratio even for isometry transformations (which are 1-Lipschitz). This may indicate that T-MSS has super linear competitive ratio even for isometry transformations.

- **Theorem 5.** *The work function algorithm (WFA) for T-MSS has competitive ratio*
- $n - 1$  on  $n$ -point ultrahomogeneous ultrametrics with 1-Lipschitz transformations.
  - $2n - 3$  on  $n$ -point metric spaces with swap transformations. No deterministic algorithm has competitive ratio better than  $2n - 3$  for this problem.
  - $\omega(n^{1.29})$  on some  $n$ -point metric space with isometry transformations, for each  $n$ .

## 1.2 Organization

In Section 2 we formally define T-MSS, and discuss the work function algorithm (WFA). In Section 3 we design an algorithm for T-MSS on general metrics with competitive ratio depending on the maximal Lipschitz constant of transformations, and prove an almost matching lower bound (Theorem 1). As part of the algorithm we also show that WFA is  $(n-1)$ -competitive for ultrahomogeneous  $n$ -point ultrametrics and 1-Lipschitz transformations, proving the first part of Theorem 5.

<sup>3</sup> The precise blow-up is  $(a+1)^b a^{k-b}$  where  $a = \lfloor \frac{n+k-1}{k} \rfloor$  and  $b = (n-1) \bmod k$ .

In Section 4 we show upper and lower bounds on the competitive ratio for several special cases of T-MSS. In Section 4.1 we show that there exists no online algorithm with finite competitive ratio for nested convex body chasing with contractions in the plane, even with randomization (Theorem 2). In Section 4.2 we design a new randomized algorithm for the  $k$ -taxi problem (Theorem 3). In Section 4.3 we show matching upper and lower bounds for swap transformations, proving the second part of Theorem 5. In Section 4.4 we show a superlinear lower bound on the competitiveness of WFA for isometry transformations, proving the third part of Theorem 5. Finally, in Section 5 we prove upper and lower bounds on the blow-up for several families of metric spaces and transformations (Theorem 4). These results are also used earlier in the proofs of Theorem 1 and Theorem 3.

## 2 Preliminaries

In *Metrical Service Systems with Transformations* (T-MSS), we are given a metric space  $(M, d)$  and an initial state  $b_0 \in M$ . We denote by  $n$  the number of points in the metric space. In each round  $t$ , we get a function (transformation)  $f_t: A_t \rightarrow B_t$  that maps a subset  $A_t \subseteq M$  of feasible states to a subset  $B_t \subseteq M$ . If  $b_{t-1} \in M$  is the state of the algorithm before  $f_t$  arrives, it has to choose one of the feasible states  $a_t \in A_t$  and pays movement cost  $d(b_{t-1}, a_t)$ . The new state of the algorithm is then  $b_t := f_t(a_t)$ . The classical MSS problem is thus a special case of T-MSS where  $f_t$  is the identity function on the set of feasible states at time  $t$ . In T-MSS we always allow the identity transformations (thereby ensuring that T-MSS is a generalization of MSS) and in addition more complex transformations. We study the following important families of transformations  $f: A \rightarrow B$  whose properties are defined below.

Family of transformations	Condition
$\alpha$ -Lipschitz	$\forall x, y \in A: d(f(x), f(y)) \leq \alpha \cdot d(x, y)$
1-Lipschitz (Contractions)	$\forall x, y \in A: d(f(x), f(y)) \leq d(x, y)$
Isometries	$\forall x, y \in A: d(f(x), f(y)) = d(x, y)$
Swaps	$A = \{a, b\}, f(a) = b, f(b) = a$
Translations	$M$ is subset of a vector space. $\forall x \in A: f(x) = x + v$ for a vector $v$

We also study several families of metric spaces. An important family of metric spaces are ultrametrics in which for every three points  $x, y, z \in M$ ,  $d(x, z) \leq \max\{d(x, y), d(y, z)\}$ . Ultrametric spaces may be viewed as the leaves of a rooted tree in which vertices with lowest common ancestor at level  $i$  have distance  $L_i$ , where  $0 < L_1 < L_2 < \dots < L_k$  are the possible distances (where  $k \leq n - 1$ ).

### 2.1 The work function algorithm for T-MSS

The *work function algorithm* (WFA) achieves the optimal deterministic competitive ratio of  $n - 1$  for MSS on any  $n$ -point metric. This algorithm is defined as follows: Denote by  $p_0$  the fixed initial state. For some request sequence and a state  $p \in M$ , let  $w_t(p)$  be the minimal cost to serve the first  $t$  requests and then end up at  $p$ . The function  $w_t$  is called the *work function* at time  $t$ . We denote by  $\mathcal{W}$  the set of all maps  $w: M \rightarrow \mathbb{R}_+$  that are 1-Lipschitz. Notice that every work function is in  $\mathcal{W}$ . The WFA for MSS is the algorithm that, at time  $t$ , goes to a feasible state  $p_t$  minimizing  $w_t(p_t) + d(p_t, p_{t-1})$ .

This algorithm extends naturally to T-MSS: Let  $f_t: A_t \rightarrow B_t$  be the  $t$ th transformation. Let  $w_t$  be defined as above and let  $w_t^-(p)$  be the minimal cost of serving the first  $t-1$  requests, then moving to some state in  $A_t$  and then moving to  $p$ . Let  $b_{t-1}$  be the state of the algorithm before time  $t$ . Upon the arrival of  $f_t$ , the WFA first goes to a state

$$a_t \in \arg \min_{a \in A_t} w_t^-(a) + d(a, b_{t-1})$$

and is then relocated to  $b_t := f_t(a_t)$ .

We say that a work function  $w \in \mathcal{W}$  is *supported* on a set  $S \subseteq M$  if  $w(x) = \min_{s \in S} w(s) + sx$  for each  $x \in M$ . The (unique) minimal such set  $S$  is called the *support* of  $w$ . Notice that  $w_t^-$  is supported on  $A_t$  and  $w_t$  on  $B_t$ .

The following lemma is a variant of a lemma that is ubiquitous in analyses of WFA for other problems [13], adapted here to T-MSS:

► **Lemma 6.** *Let  $M$  be a metric space. Suppose there is a map  $\Phi: \mathcal{W} \rightarrow \mathbb{R}_+$  such that for any  $x \in M$ , time  $t \geq 1$ ,  $w \in \mathcal{W}$ , and any sequence of work functions  $w_0, w_1^-, w_1, w_2^-, w_2, \dots$  arising for (a subclass of) T-MSS on  $M$ ,*

$$w_t^-(x) - w_{t-1}(x) \leq \Phi(w_t^-) - \Phi(w_{t-1}) \quad (1)$$

$$\Phi(w_t^-) \leq \Phi(w_t) \quad (2)$$

$$\Phi(w) \leq \rho_M \cdot \min_{p \in M} w(p) + C_M, \quad (3)$$

where  $\rho_M$  and  $C_M$  are constants depending only on  $M$ . Then WFA is  $(\rho_M - 1)$ -competitive for (this subclass of) T-MSS on  $M$ .

**Proof.** We have

$$\begin{aligned} w_t^-(b_{t-1}) &= \min_{a \in A_t} w_t^-(a) + d(a, b_{t-1}) \\ &= w_t^-(a_t) + d(a_t, b_{t-1}) \\ &= w_t(b_t) + d(a_t, b_{t-1}), \end{aligned} \quad (4)$$

where the first equation is by definition of  $w_t^-$  and the second equation by definition of  $a_t$ . The cost of WFA is

$$\begin{aligned} \text{cost}_{\text{WFA}} &= \sum_{t=1}^T d(b_{t-1}, a_t) \\ &= \sum_{t=1}^T (w_t^-(b_{t-1}) - w_t(b_t)) \\ &= \sum_{t=1}^T (w_t^-(b_{t-1}) - w_{t-1}(b_{t-1}) + w_{t-1}(b_{t-1}) - w_t(b_t)) \\ &\leq \Phi(w_T) - w_T(b_T) \\ &\leq (\rho_M - 1) \cdot \min_{p \in M} w_T(p) + C_M, \end{aligned}$$

where the second equation follows from (4), the first inequality uses (1), (2),  $\Phi(w_0) \geq 0$  and  $w_0(b_0) = 0$ , and the second inequality uses (3). Since  $\min_{p \in M} w_T(p)$  is the optimal offline cost, the lemma follows. ◀

### 3 Competitiveness for Lipschitz Transformations

In this Section we prove Theorem 1.

► **Theorem 1.** *There exists a deterministic  $2 \max\{2(\alpha + 1), 6\}^{n-2}$ -competitive algorithm for T-MSS with  $\alpha$ -Lipschitz transformations on any  $n$ -point metric space. Any algorithm for T-MSS with  $\alpha$ -Lipschitz transformations has competitive ratio at least  $\min\{\alpha + 1, \alpha^2\}^{n-2}$ , even with randomization.*

The proof of the upper bound consists of three main steps: First we give a reduction to the case of 1-Lipschitz transformations in ultrametrics. Then we employ the fact that ultrametrics admit an ultrahomogeneous extension of size  $2^{n-1}$ , which will be proved later in Section 5.2. Finally, we show that the WFA achieves the optimal competitive ratio of  $n - 1$  for this special case of 1-Lipschitz transformations on ultrahomogeneous ultrametrics.

#### 3.1 From $\alpha$ -Lipschitz in general metrics to 1-Lipschitz in ultrametrics

For two metrics  $d$  and  $\hat{d}$  defined on a set  $M$ , we say that  $\hat{d}$  is an  $\alpha$ -distortion of  $d$ , for  $\alpha \geq 1$ , if for any  $x, y \in M$  we have  $d(x, y) \leq \hat{d}(x, y) \leq \alpha \cdot d(x, y)$ .

► **Lemma 7.** *Fix a constant  $\alpha \geq 2$  and an  $n$ -point metric space  $(M, d)$ . There is an ultrametric  $\hat{d}$  on  $M$  that is an  $(\alpha + 1)^{n-2}$ -distortion of  $d$ , and any transformation  $f: A \subseteq M \rightarrow M$  that is  $\alpha$ -Lipschitz with respect to  $d$  is 1-Lipschitz with respect to  $\hat{d}$ .*

**Proof.** The idea is to group the edges (i.e., pairs of distinct elements) in  $M$  into levels according to their distance. In level 1 we start with the minimum distance edges, and repeatedly add all edges which are within a factor  $\alpha$  of the largest level 1 edge until no more are possible. We then continue, constructing level  $k$  by starting with the shortest edge not in a previous level, and then adding all edges within a factor  $\alpha$  of some edge already in level  $k$ . Let  $L_k$  be the longest distance of an edge in level  $k$ . We define  $\hat{d}$  by setting level  $k$  edges to have  $\hat{d}$ -length  $L_k$ .

Note that since  $\alpha \geq 2$ , being connected by edges of level at most  $k$  is an equivalence relation for any  $k$ . Therefore, defining distances to be  $L_k$  in level  $k$  is a valid ultrametric. Since no edge has length in any interval  $(L_k, \alpha L_k]$ , any transformation that is  $\alpha$ -Lipschitz with respect to  $d$  is 1-Lipschitz with respect to  $\hat{d}$ .

It remains to argue that distances were increased by at most a factor  $(\alpha + 1)^{n-2}$  in going from  $d$  to  $\hat{d}$ . We show it for the edges in level  $k$ . Actually we may assume without loss of generality that  $k = 1$ , because if not we may take all edges in levels up to  $k - 1$  and set their distances to the shortest edge distance in level  $k$ . This is still a valid metric and the case of level 1 in this new metric implies the case of level  $k$  in the old metric. For the main argument when  $k = 1$ , consider adding the edges in order starting from an empty graph on the  $n$  points of  $M$ , giving an increasing sequence  $H_0, H_1, \dots$  of graphs. Exactly  $n - 1$  of these edges decrease the number of connected components by 1 at the time they are added. We call these edges critical and denote by  $D_1 \leq \dots \leq D_{n-1}$  their lengths. At any time, the critical edges in  $H_t$  form a spanning forest for  $H_t$ . Therefore the maximum distance of any edge in  $H_t$  is at most the sum of the lengths of the critical edges in  $H_t$ . Therefore the next critical edge to be added has length

$$D_s \leq \alpha \cdot \sum_{r=1}^{s-1} D_r.$$

From this it is easy to see inductively that  $D_s \leq \alpha(\alpha + 1)^{s-2}D_1$  for  $s \geq 2$ . This means the maximum distance of any edge in  $H$  is at most  $\sum_s D_s \leq (\alpha + 1)^{n-2}D_1$  (since there are  $n - 1$  critical edges). We remark that equality is achieved by the set of points  $\{0, 1, \alpha + 1, (\alpha + 1)^2, \dots, (\alpha + 1)^{n-2}\} \subset \mathbb{R}$ . ◀

### 3.2 WFA for 1-Lipschitz transformations on ultrahomogeneous ultrametrics

We now prove that WFA is  $(n - 1)$ -competitive for 1-Lipschitz transformations in ultrahomogeneous ultrametrics, thereby also proving the first statement of Theorem 5. Note that this bound is optimal, since  $n - 1$  is also the exact competitive ratio of ordinary MSS on any  $n$ -point metric space.

► **Lemma 8.** *Let  $(M, d)$  be an ultrahomogeneous ultrametric with  $n$  points. The WFA for T-MSS on  $(M, d)$  with 1-Lipschitz transformation is  $(n - 1)$ -competitive.*

**Proof.** We use the same potential function that also yields  $(n - 1)$ -competitiveness for ordinary MSS on general  $n$ -point metrics and  $(2n - 1)$ -competitiveness for MTS [7]:

$$\Phi(w) := \sum_{p \in M} w(p).$$

The bound (1) follows from the fact that  $w_t^-(p) - w_{t-1}(p) \geq 0$  for all  $p$ . Bound (3) for  $\rho_M = n$  follows from the 1-Lipschitzness of  $w$ , choosing  $C_M$  to be  $n - 1$  times the diameter of  $M$ .

For (2), we need to show that the sum of work function values is non-decreasing when a transformation  $f_t: A_t \rightarrow B_t$  is applied. On a high level, the idea is as follows. The work function  $w_t^-$  before transformation is supported on  $A_t$ , and the work function  $w_t$  afterwards on  $B_t$ . Imagine for simplicity that the work function value of all support points were 0. Then the work function value at other points is simply the distance from the support. Since  $f_t$  is 1-Lipschitz, we can think of  $B_t$  as a contracted version of the set  $A_t$  (and since the metric space is ultrahomogeneous, we can ignore the fact that  $B_t$  might be located in a very different part of the metric space than  $A_t$ ). This shrinking of the support means that most other points of the metric space tend to get further away from the support, and thus their work function values tend to increase.

We now turn to a formal proof of inequality (2). Since  $M$  is an ultrametric, we can view it as the set of leaves of an ultrametric tree.

Denote by  $T_r(p) := \{x \in M: d(p, x) \leq r\}$  the ball of radius  $r$  around  $p$ . Note that this is the set of leaves of the subtree rooted at the highest ancestor of  $p$  whose weight is at most  $r$ . In particular, the sets  $T_r(p)$  form a laminar family. We claim for all  $a, a' \in A_t$  and  $r, r' \geq 0$  that

$$T_r(f_t(a)) \cap T_{r'}(f_t(a')) = \emptyset \implies T_r(a) \cap T_{r'}(a') = \emptyset. \quad (5)$$

To see this, suppose  $x \in T_r(a) \cap T_{r'}(a')$  and say without loss of generality that  $r \leq r'$ . Then, by the ultrametric inequality,  $d(a, a') \leq \max\{d(a, x), d(a', x)\} \leq r'$ . Since  $f_t$  is 1-Lipschitz, this also means that  $d(f_t(a), f_t(a')) \leq r'$ . But then  $f_t(a) \in T_r(f_t(a)) \cap T_{r'}(f_t(a'))$ .

For  $y \geq 0$  and a work function  $w$  supported on a set  $S \in M$ , its  $y$ -sublevel set is given by

$$w^{-1}([0, y]) = \bigcup_{s \in S} T_{y-w(s)}(s).$$

Recall that  $w_t^-$  is supported on  $A_t$ , and note that  $w_t$  is supported on a set  $\tilde{B}_t \subseteq B_t$  such that

$$\forall b \in \tilde{B}_t \exists a_b \in A_t : f_t(a_b) = b \text{ and } w_t(b) = w_t^-(a_b).$$

Since the sets  $T_r(p)$  form a laminar family, we can choose for each  $y \geq 0$  a subset  $\tilde{B}_t^y \subseteq \tilde{B}_t$  such that

$$w_t^{-1}([0, y]) = \dot{\bigcup}_{b \in \tilde{B}_t^y} T_{y-w_t(b)}(b)$$

is a disjoint union. Due to implication (5), this also means that

$$\dot{\bigcup}_{b \in \tilde{B}_t^y} T_{y-w_t^-(a_b)}(a_b)$$

is a disjoint union.

Now, the cardinality of the  $y$ -sublevel set of  $w_t$  is bounded by

$$\begin{aligned} |w_t^{-1}([0, y])| &= \sum_{b \in \tilde{B}_t^y} |T_{y-w_t(b)}(b)| \\ &= \sum_{b \in \tilde{B}_t^y} |T_{y-w_t^-(a_b)}(a_b)| \end{aligned} \tag{6}$$

$$\begin{aligned} &= \left| \dot{\bigcup}_{b \in \tilde{B}_t^y} T_{y-w_t^-(a_b)}(a_b) \right| \\ &\leq \left| \bigcup_{a \in A_t} T_{y-w_t^-(a)}(a) \right| \\ &= |(w_t^-)^{-1}([0, y])|, \end{aligned} \tag{7}$$

where equation (6) uses the fact that since  $M$  is ultrahomogeneous, balls of the same radius have the same cardinality. Thus, for each  $y \geq 0$  there are at least as many points whose  $w_t^-$ -value is at most  $y$  as there are points whose  $w_t$ -value is at most  $y$ . Therefore, if  $p_1, p_2, \dots, p_n$  and  $p_1^-, p_2^-, \dots, p_n^-$  are two enumerations of  $M$  by increasing  $w_t$ - and  $w_t^-$ -values, respectively, then  $w_t^-(p_i^-) \leq w_t(p_i)$ . Hence, inequality (2) follows.  $\blacktriangleleft$

► **Remark.** One may wonder whether the guarantee of Lemma 8 is achieved more generally for ultrahomogeneous *metric* (rather than ultrametric) spaces. The answer is negative: Consider the 8-point metric space  $M = \{0, 2\} \times \{0, 3\} \times \{0, 4\}$  with the  $\ell_1$ -norm. Since  $M$  is isometric to the cube  $\{0, 1\}^3$  with a weighted  $\ell_1$ -norm, and all partial isometries on  $M$  are translations, Theorem 4 (proved in Section 5.3) implies that  $M$  is ultrahomogeneous. Consider the work function  $w$  supported  $\{(0, 0, 0), (2, 3, 0)\}$ , where it takes value 0. We have  $\Phi(w) = 2 + 2 + 4 + 4 + 6 + 6 = 24$ . The updated work function  $w'$  after contracting  $\{(0, 0, 0), (2, 3, 0)\}$  to  $\{(0, 0, 0), (0, 0, 4)\}$  has  $\Phi(w') = 2 \cdot (2 + 3 + 5) = 20 < \Phi(w)$ , meaning that inequality (2) is violated. Crucially, property (5) that disjoint balls remain disjoint when their centers are moved apart is violated on  $M$ . Using this observation, it is not hard to construct a request sequence on  $M$  where (1) is always tight for  $x = b_{t-1}$  and (2) is either tight or violated for each request, and violated for a constant fraction of the requests. For such a request sequence, the analysis in the proof of Lemma 6 yields a *lower* bound strictly larger than  $n - 1$  on the competitive ratio of WFA for T-MSS on  $M$  with 1-Lipschitz transformations.

### 3.3 Putting it together

Given any  $n$ -point metric  $(M, d)$ , we obtain a  $2 \max\{2\alpha + 2, 6\}^{n-2}$ -competitive deterministic algorithm for T-MSS with  $\alpha$ -Lipschitz transformations as follows: Making a multiplicative error of  $\max\{\alpha + 1, 3\}^{n-2}$ , Lemma 7 allows us to assume that  $M$  is an ultrametric and transformations are 1-Lipschitz. By Theorem 4, it further admits a  $2^{n-1}$ -point weakly ultrahomogeneous extension  $(\hat{M}, \hat{d})$ , and the proof of this statement in Theorem 4 actually shows that  $(\hat{M}, \hat{d})$  is still an ultrametric and it is ultrahomogeneous (not just weakly). Therefore, by Lemma 8, the WFA is  $2^{n-1}$ -competitive on  $(\hat{M}, \hat{d})$ . Overall, this gives a competitive ratio of  $\max\{\alpha + 1, 3\}^{n-2} 2^{n-1} = 2 \max\{2\alpha + 2, 6\}^{n-2}$ .

### 3.4 Lower bound for Lipschitz transformations

In this section we prove the lower bound part of Theorem 1 showing that any randomized algorithm for T-MSS with  $\alpha$ -Lipschitz transformations has competitive ratio at least  $\min\{\alpha + 1, \alpha^2\}^{n-2}$ .

Let  $m := \min\{\alpha + 1, \alpha^2\}$ . Assume  $\alpha \geq 1$  since otherwise there is nothing to show. Consider the graph with vertices  $p_1, \dots, p_n$  and edges from  $p_1$  to every vertex and between consecutive vertices of lengths

$$\begin{aligned} d(p_1, p_i) &:= m^{i-2} & i = 2, \dots, n \\ d(p_i, p_{i+1}) &:= \alpha m^{i-2} & i = 2, \dots, n-1. \end{aligned}$$

Note that these edge lengths satisfy the triangle inequality: When adding the vertices to the graph in order, the addition of  $p_i$  only creates the new triangle  $(p_1, p_{i-1}, p_i)$  with edge lengths  $(m^{i-3}, \alpha m^{i-3}, m^{i-2})$ . Since  $1 \leq \alpha \leq m \leq \alpha + 1$ , it satisfies the triangle inequality. Therefore, the shortest path extension of  $d$  defines a valid metric.

Consider a T-MSS instance on this space with  $p_1$  as its initial state. For  $t = 1, 2, \dots, n-2$ , we issue transformations

$$\begin{aligned} f_{2t-1} &: \{p_1, p_{t+1}\} \rightarrow \{p_{t+1}, p_{t+2}\} \\ f_{2t} &: \{p_{t+1}, p_{t+2}\} \rightarrow \{p_1, p_{t+2}\}, \end{aligned}$$

where each transformation maps the first (resp. second) point of the domain to the first (resp. second) point of the codomain. Note that these maps are  $\alpha$ -Lipschitz, using for  $f_{2t}$  that  $m \leq \alpha^2$ . Then, we issue the final transformation

$$f_{2n-3} : \{x\} \rightarrow \{p_1\}$$

with  $x$  chosen uniformly at random from  $\{p_1, p_n\}$ .

With probability  $1/2$ , the online algorithm has to pay  $m^{n-2}$  to move to  $x$  when  $f_{2n-3}$  is issued. An offline algorithm can serve the sequence with expected cost  $1/2$ : Before  $f_1$ , it either stays at  $p_1$  for cost 0 (if  $x = p_1$ ) or moves from  $p_1$  to  $p_2$  for cost 1 (if  $x = p_n$ ), which allows to serve the rest of the request sequence for free. Since the request sequence can be repeated arbitrarily often (with a new random  $x$ ), we conclude a lower bound of  $m^{n-2}$  on the competitive ratio.

## 4 Algorithms and Lower Bounds for Special Cases of T-MSS

In this section we show upper and lower bounds on the competitive ratio for T-MSS for special cases. In Section 4.1 we show that there exists no online algorithm with finite competitive ratio for nested convex body chasing with contractions in the plane, even with randomization.

In Section 4.2 we design a new randomized algorithm for the  $k$ -taxi problem. In Section 4.3 we show upper and lower bounds for swap transformations. Finally, in Section 4.4 we show a superlinear lower bound on the competitiveness of WFA for isometry transformations.

#### 4.1 Contracting convex bodies are unchaseable

Here we show that nested convex body chasing with contractions has no competitive algorithm. In nested convex body chasing, the requests form a nested sequence  $K_0 \supseteq K_1 \supseteq \dots$  of convex sets in  $\mathbb{R}^d$ . The player starts at  $x_0 \in K_0$  and moves online to a point  $x_t \in K_t$ , paying movement cost  $\sum_{t \geq 1} \|x_{t-1} - x_t\|$ . This problem is a special case of the more general convex body chasing problem which allows an arbitrary non-nested sequence  $K_0, K_1, \dots$  of convex sets. This problem has received a lot of recent study without transformations and admits a  $d$ -competitive algorithm – see [3, 1, 11, 10, 2, 20]. Because  $\mathbb{R}^d$  is ultrahomogenous, it follows that the  $d$ -competitive algorithm continues to apply with partial isometry transformations.

Here we show that with contraction transformations  $\mathbb{R}^d \rightarrow \mathbb{R}^d$  there is no competitive algorithm, even in the nested case for  $d = 2$  and with randomization. This gives a non-trivial example in which contractions are provably harder than isometries. In fact all the contractions we use are projections from  $K_t$  to  $K_{t+1}$ . Our proof goes by reduction to a family of 1-dimensional MTS problems known to have arbitrarily large competitive ratio. A related reduction appeared in [12] to show that 2-server convex body chasing is impossible in 2 dimensions.

► **Theorem 2.** *There exists no online algorithm with finite competitive ratio for nested convex body chasing with contractions in the plane, even with randomization.*

**Proof.** Fix a large integer  $n$ , a much larger integer  $M = M(n)$  and a much larger  $N = N(n)$ . We start with  $K_0 = [0, 1] \times [0, N]$  with starting point  $x_0 = (0, 0)$ . The projected convex sets rotate modulo 3: At multiples of 3 we simply have  $K_{3t} = [0, 1] \times [t, N]$ . Now, for a sequence  $(a_1, \dots, a_N)$  of positive integers  $a_i \in \{1, 2, \dots, n\}$  define the points  $p_1^t = (\frac{a_t}{n}, t)$ ,  $p_2^t = (\frac{a_t-1}{n}, t + \frac{1}{Mn})$  and  $p_3^t = (\frac{a_t+1}{n}, t + \frac{1}{Mn})$ . We define  $K_{3t+1}$  by cutting from  $K_{3t}$  along the lines  $p_1^t p_2^t$  and  $p_1^t p_3^t$ . We define  $K_{3t+2}$  by also cutting along the line  $p_2^t p_3^t$ . See Figure 1.

We take  $a_t$  to be an adversarially chosen sequence of such integers, yielding an adversarial nested chasing instance. For  $s$  congruent to 0 or 2 modulo 3, we apply projection maps (which are contractions) from  $K_s$  onto  $K_{s+1}$ . Hence movement cost is incurred only on transitions from  $K_{3t+1} \rightarrow K_{3t+2}$ .

The idea is that the resulting problem is approximately a 1-dimensional MTS, as without loss of generality we may assume  $x_{3t}$  is always on the upper boundary of  $K_{3t}$ . It is easy to see that, crucially, the horizontal movement induced by the projections is  $O(M^{-2})$  per time-step – we will treat this as an additive error term. The vertical movement corresponds to a metrical task system with cost functions given by  $\frac{1}{M}c_{a_t}(x)$  for

$$c_{a_t}(x) = \begin{cases} 0 & \text{if } x \leq \frac{a_t-1}{n} \\ \min\{|x - \frac{a_t-1}{n}|, |x - \frac{a_t+1}{n}|\} & \text{if } x \in [\frac{a_t-1}{n}, \frac{a_t+1}{n}] \\ 0 & \text{if } x \geq \frac{a_t+1}{n}. \end{cases}$$

First, by repeating values of  $a_t$  in blocks of  $M$ , we can obtain an MTS which directly uses cost functions  $c_{a_t}(x)$ , now with an additive error  $O(M^{-1})$  per (block) time step for the horizontal movement. Next we claim any randomized algorithm for this new MTS can be assumed to stay on the finite set of values  $\frac{k}{n}$  for  $k \in \{0, 1, \dots, n\}$ . Indeed, if a randomized algorithm is at position  $\frac{k+\alpha}{n}$  for  $\alpha \in (0, 1)$  we can instead move to  $\frac{k}{n}$  with probability  $1 - \alpha$  and

$\frac{k+1}{n}$  with probability  $\alpha$ . Moreover we can couple these roundings together by first sampling  $u \in [0, 1]$  uniformly and rounding at all times based on whether  $u \leq \alpha$  or not. This turns any algorithm into a randomized algorithm which stays on the values  $\frac{k}{n}$  and has the same expected movement cost. Because the cost functions  $c_{a_t}$  are affine on each interval  $(\frac{k}{n}, \frac{k+1}{n})$  it results in the same expected service cost as well.

If the player is restricted to stay on the  $n + 1$  values  $\frac{k}{n}$ , the movement cost functions  $c_{a_t}$  are 0 at all but one of these values. Hence by repeating requests  $O_n(1)$  times to force movement we may reinterpret this as an  $n$ -server problem on a metric space with  $n + 1$  points, by taking the player's location in the original problem to be the unique spot with no server. It is well-known [5, 6] that the randomized competitive ratio of any  $n$ -server problem in a metric space with at least  $n + 1$  points is  $\Omega(\log n / \log \log n)$ . Finally, it is easy to see that for any MTS on a finite state space with competitive ratio  $C$ , an additive error in cost of  $o(1)$  per time-step affects the competitive ratio by  $o(1)$ . Therefore for any fixed  $n$ , taking  $M \rightarrow \infty$  results eventually in an MTS with competitive ratio  $\Omega(\log n / \log \log n)$  even taking the horizontal effects of the projection maps into account. Finally taking  $N$  sufficiently large to realize this competitive ratio gives the desired lower bound.  $\blacktriangleleft$

**Figure 1** To show that chasing nested convex bodies is impossible with contractions, we construct shrinking sets as shown. Euclidean nearest-point projections are taken onto the sets  $K_{3t+1}, K_{3t+3}$ , so that movement cost is incurred only in moving from  $K_{3t+1}$  to  $K_{3t+2}$ . Up to the negligible horizontal movements from projection, this results in a 1-dimensional metrical task system with unbounded competitive ratio.

## 4.2 A $\text{poly}(n, \log k)$ -competitive $k$ -taxi algorithm

In the  $k$ -taxi problem, there are  $k$  taxis located in a metric space  $(M, d)$ . A sequence of requests arrives, where each request is a pair of points  $(s_t, d_t) \in M \times M$ , representing the start and destination of a passenger request. Each request must be served upon its arrival by sending a taxi to  $s_t$ , from where it is relocated to  $d_t$ . The cost is defined as the distance travelled by taxis *while not carrying a passenger*, i.e., excluding the distances from  $s_t$  to  $d_t$ .

Note that the  $k$ -taxi problem is a special case of T-MSS: As the metric space for T-MSS, we take the set of taxi configurations (i.e.,  $k$ -point multisets of points in  $M$ ), and the distance between two configurations is the minimum cost of moving from one configuration to the other. A taxi request  $(s_t, d_t)$  translates to the transformation that maps configurations containing  $s_t$  to the corresponding configurations with a taxi at  $s_t$  replaced by a taxi at  $d_t$ . Observe that this transformation is an isometry in the configuration space.

In principle, the size of a weakly ultrahomogeneous extension of the configuration space would yield a bound on the competitive ratio of the  $k$ -taxi problem. However, we do not know a bound on this blow-up in general. We overcome this obstacle as follows: First, we apply a well-known embedding of the original  $k$ -taxi metric space into a tree (HST) metric. Then, we consider the configuration space of this tree metric, whose metric is given by a weighted  $\ell_1$ -norm. Moreover, the isometries corresponding to the  $k$ -taxi requests in this tree metric are actually translations, and for this case, Theorem 4 yields a bound on the blow-up (proved later in Section 5.3). The resulting algorithm has competitive ratio  $O((n \log k)^2 \log n)$ , improving upon the previous bound of  $O(2^k \log n)$  [14] whenever  $n$  is sub-exponential in  $k$ .

► **Theorem 3.** *There is a randomized  $O((n \log k)^2 \log n)$ -competitive algorithm for the  $k$ -taxi problem on  $n$ -point metrics.*

**Proof.** By well-known techniques [4, 16], any  $n$ -point metric space can be embedded with distortion  $O(\log n)$  into the set of leaves of a random (weighted) tree. It therefore suffices to describe an  $O((n \log k)^2)$ -competitive algorithm for the  $k$ -taxi problem on the set  $\mathcal{L}$  of leaves of a tree with  $|\mathcal{L}| = n$ . Notice that there is a tree  $\mathcal{T}$  with only  $O(n)$  vertices that induces the metric on  $\mathcal{L}$ .

Let  $V$  be the set of vertices of  $\mathcal{T}$  excluding the root. For  $v \in V$ , let  $w_v$  be the length of the edge from  $v$  to its parent. If we denote by  $x_v$  the number of taxis in the subtree rooted at  $v$ , then a configuration of  $k$  taxis can be denoted by a point in  $M := \{0, \dots, k\}^V$ . Notice that only some points in  $M$  correspond to valid  $k$ -taxi configurations. The cost of moving from configuration  $x$  to configuration  $y$  is given by the metric

$$d(x, y) := \sum_{v \in V} w_v |x_v - y_v|.$$

Thus, the  $k$ -taxi problem on  $\mathcal{T}$  is a special case of T-MSS on  $(M, d)$ . A  $k$ -taxi request  $(s_t, d_t)$  corresponds to a translation by the vector that has 1-entries in coordinates of ancestors of  $d_t$  that are not ancestors of  $s_t$ , -1-entries in coordinates of ancestors  $s_t$  that are not ancestors of  $d_t$ , and 0 in the remaining coordinates. We therefore need to extend  $M$  to a space  $\hat{M}$  where these translations extend to automorphisms. As stated in Theorem 4 and proved later in Section 5.3, such an extension  $\hat{M}$  of size  $(2k)^{|V|}$  exists. Thus, by running an  $O(\log^2 |\hat{M}|)$ -competitive algorithm for MSS on  $\hat{M}$  and treating each automorphism as a renaming of the points of  $\hat{M}$ , we obtain an algorithm for the  $k$ -taxi problem on  $\mathcal{T}$  with competitive ratio  $O(\log^2 |\hat{M}|) = O((n \log k)^2)$ , where we used that  $|V| = O(n)$ . Combined with the  $O(\log n)$  loss due to the tree embedding, the theorem follows. ◀

### 4.3 Competitiveness for swap transformations

In this section, we show tight bounds of  $2n - 3$  on the competitive ratio for T-MSS in general metrics when each transformation is either the identity on its domain (recall that we always allow identity transformations) or a swap, thereby proving the second part of Theorem 5. The upper bound is achieved by the WFA.

**Upper bound.** For brevity, we will denote the distance between two points  $x, y \in M$  by  $xy$  instead of  $d(x, y)$ . For  $X \subseteq M$  and  $x \in M$ , we write  $X - x := X \setminus \{x\}$ . For a work function  $w$  and  $x, y \in M$ , let

$$\begin{aligned}\Psi_{x,y}(w) &:= \text{cl}(M - x - y) + \sum_{p \in M - x - y} \min\{w(x) + yp, w(y) + xp\} \\ \Phi(w) &:= \sum_{p \in M} w(p) + \min_{x,y \in M} \Psi_{x,y}(w)\end{aligned}$$

Here,  $\text{cl}(X) := \sum_{\{x,y\} \subseteq X} xy$  denotes the size of the clique of  $X$ , i.e., the sum of all distances between points in  $X$ . It suffices to show that  $\Phi$  satisfies the properties of Lemma 6 with  $\rho_M = 2n - 2$ .

Inequality (3) is immediate from the fact that  $\Phi(w)$  is a sum of  $2n - 2$  function values of  $w$  and a bounded number of distances of  $M$ , and each function value of  $w$  differs from  $\min_x w(x)$  by at most the diameter of  $M$  due to the 1-Lipschitzness of  $w$ .

Inequality (1) follows from the fact that  $\Phi(w)$  contains the summand  $w(x)$ , the remaining summands of  $\Phi(w)$  are non-decreasing in  $w$ , and  $w_{t-1} \leq w_t^-$  pointwise.

Inequality (2) is trivial if  $f_t$  is the identity on its domain, so it remains to consider the case that  $f_t: \{a, b\} \rightarrow \{a, b\}$  is a swap. Both  $w_t^-$  and  $w_t$  are supported on  $\{a, b\}$ . We first show that if  $w$  is supported on  $\{a, b\}$ , then  $\Psi_{x,y}(w)$  is minimized when  $\{x, y\} = \{a, b\}$ .

Let  $x$  and  $y$  be such that  $\Psi_{x,y}(w)$  is minimized and suppose  $x \notin \{a, b\}$ . Then we can assume without loss of generality (by symmetry) that  $w(x) = w(a) + ax$ . Then  $\min\{w(x) + ya, w(y) + xa\} = w(y) + xa$ . Thus,

$$\begin{aligned}\Psi_{x,y}(w) &= \text{cl}(M - x - y) + w(y) + xa + \sum_{p \in M - x - y - a} \min\{w(a) + ax + yp, w(y) + xp\} \\ &\geq \text{cl}(M - x - y) + w(y) + xa \\ &\quad + \sum_{p \in M - x - y - a} (xp - ap + \min\{w(a) + yp, w(y) + ap\}) \\ &\geq \text{cl}(M - a - y) + \sum_{p \in M - y - a} \min\{w(a) + yp, w(y) + ap\} \\ &= \Psi_{a,y}(w).\end{aligned}$$

Thus,  $\Psi_{x,y}(w)$  is also minimized when  $x = a$ . If  $y \neq b$  and  $w(y) = w(b) + by$ , then the symmetric argument shows that  $\Psi_{x,y}(w)$  is minimized when  $\{x, y\} = \{a, b\}$ . Otherwise, if  $y \neq b$ , then  $w(y) = w(a) + ay$  since  $w$  is supported on  $\{a, b\}$ . Then

$$\begin{aligned}\Psi_{a,y}(w) &= \text{cl}(M - a - y) + \sum_{p \in M - a - y} \min\{w(a) + yp, w(a) + ay + ap\} \\ &= \text{cl}(M - a) + (n - 2)w(a) \\ &\geq \text{cl}(M - a - b) + \sum_{p \in M - a - b} \min\{w(a) + bp, w(b) + ap\} \\ &= \Psi_{a,b}(w).\end{aligned}$$

Thus, it is indeed the case that  $\min_{x,y} \Psi_{x,y}(w) = \Psi_{a,b}(w)$ , for both  $w = w_t^-$  and  $w = w_t$ . Hence,

$$\begin{aligned}\Phi(w_t^-) - \Phi(w_t) &= w_t^-(a) + w_t^-(b) - w_t(a) - w_t(b) \\ &\quad + \sum_{p \in M - a - b} (w_t^-(p) + \min\{w_t^-(a) + bp, w_t^-(b) + ap\}) \\ &\quad - \sum_{p \in M - a - b} (w_t(p) + \min\{w_t(a) + bp, w_t(b) + ap\}).\end{aligned}$$

Since  $w_t(a) = w_t^-(b)$ ,  $w_t(b) = w_t^-(a)$ , and  $w(p) = \min\{w(a) + ap, w(b) + bp\}$  for  $w = w_t^-$  and  $w = w_t$ , everything cancels in the last sum and we obtain (2).

**Lower bound.** Consider the metric with points  $1, 2, \dots, n$  where the distance from 1 to any other point is 1 and the distance between any other two points is 2. The initial location of the server is 1. For  $i = 1, \dots, n-1$ , the  $i$ th request is the identity with domain  $A_i$ , where  $A_1 := \{2, 3, \dots, n\}$  and for  $i \geq 2$ ,  $A_i$  is the subset of  $A_{i-1}$  obtained by removing the location of the online algorithm's server before this request is issued. During these requests, the online algorithm suffers cost  $2n-3$ , but an offline algorithm could immediately go to the one point  $p$  in  $A_{n-1}$  for cost 1. We issue one more request that swaps  $p$  and 1 so as to return to the initial configuration, allowing to repeat the procedure arbitrarily often.

#### 4.4 Superlinear lower bound for WFA with isometries

In this section we show a superlinear lower bound of  $\omega(n^{1.29})$  on the competitiveness of WFA for T-MSS with isometry transformations, proving the third part of Theorem 5.

It suffices to show the statement for values of  $n$  that are a power of 4. Let  $\alpha \in \mathbb{N}$  be some large constant. For  $h \in \mathbb{N}_0$ , we construct a  $4^h$ -point metric space  $T_h$  by induction: The space  $T_0$  is just a single point. For  $h \geq 1$ , space  $T_h$  is a disjoint union of four copies of  $T_{h-1}$ , which we denote  $T_{h-1}^0, T_{h-1}^1, T_{h-1}^2, T_{h-1}^3$ . For points  $x, y$  from two different copies of  $T_{h-1}$  we define their distance as  $\alpha^h$  if one of the copies is  $T_{h-1}^0$  and as  $2\alpha^h$  otherwise.

For a set  $X \subseteq T_{h-1}$  and  $i = 0, 1, 2, 3$ , denote by  $X^i$  the copy of  $X$  in  $T_{h-1}^i$ , and similarly if  $X$  is a point rather than a set. We define a special point  $s_h \in T_h$  as follows:  $s_0$  is the single point in  $T_0$ . For  $h \geq 1$ ,  $s_h := s_{h-1}^0$ .

We consider T-MSS on  $T_h$  when the server starts at  $s_h$ . Let  $w_0 = d(\cdot, s_h)$  be the initial work function. We will construct a request sequence  $\sigma_h$  during which WFA suffers cost  $(6^h - 1)\alpha^h(1 - o(1))$  as  $\alpha \rightarrow \infty$  and at whose end the work function is at most  $\alpha^h + w_0$  pointwise, with WFA returning to  $s_h$  in the end. Since such a request sequence can be repeated, it will imply that the competitive ratio is at least  $6^h - 1 = n^{(\ln 6)/(\ln 4)} - 1 = \omega(n^{1.29})$ .

For  $h = 0$ , we simply choose the empty request sequence. Consider now  $h \geq 1$ . For a partial isometry  $f: A \rightarrow B$  of  $T_{h-1}$  and  $i = 0, 1, 2, 3$ , denote by  $f^i: A^i \cup \bigcup_{j \neq i} T_{h-1}^j \rightarrow B^i \cup \bigcup_{j \neq i} T_{h-1}^j$  the map that acts like  $f$  on  $A^i$  and is the identity on  $T_{h-1}^j$  for  $j \neq i$ . Note that  $f^i$  is a partial isometry of  $T_h$ . Denote by  $\sigma_{h-1}^i$  the sequence obtained by extending each partial isometry in  $\sigma_{h-1}$  (the sequence from the induction hypothesis) in this way.

We construct  $\sigma_h$  as follows: First, we issue  $2\alpha - 2$  copies of  $\sigma_{h-1}^0$ . Since each work function  $w$  during this sequence admits a point  $p \in T_{h-1}^0$  with  $w(p) \leq (2\alpha - 2)\alpha^{h-1}$ , but  $w(x) = \alpha^h$  for all  $x \in \bigcup_{j \neq 0} T_{h-1}^j$ , WFA will stay within  $T_{h-1}^0$  during these requests, suffering cost  $(6^{h-1} - 1)2\alpha^h(1 - o(1))$ . Then we issue the identity request with domain  $\{s_{h-1}^1, s_{h-1}^2, s_{h-1}^3\}$ , forcing the algorithm to move to one of these three points for cost  $\alpha^h$ . By symmetry, we can assume without loss of generality that WFA moves to  $s_{h-1}^1$ . We now issue  $2\alpha - 2$  copies of  $\sigma_{h-1}^1$ , followed by the identity request with domain  $\{s_{h-1}^2, s_{h-1}^3\}$ . Similarly to before, WFA again suffers cost  $(6^{h-1} - 1)2\alpha^h(1 - o(1))$  and then moves to, say,  $s_{h-1}^2$  for cost  $2\alpha^h$ . Finally, we issue  $2\alpha - 2$  copies of  $\sigma_{h-1}^2$  followed by the request  $\{s_{h-1}^3\} \rightarrow \{s_h\}$ ,  $s_{h-1}^3 \mapsto s_h$ , increasing WFA's cost by another  $(6^{h-1} - 1)2\alpha^h(1 - o(1)) + 2\alpha^h$ . Overall, WFA suffers cost

$$(6^{h-1} - 1)(2 + 2 + 2)\alpha^h(1 - o(1)) + (1 + 2 + 2)\alpha^h = (6^h - 1)\alpha^h(1 - o(1)),$$

as claimed. Moreover, the final work function is  $\alpha^h + w_0$  because an offline algorithm could move to  $s_{h-1}^3$  for cost  $\alpha^h$  at the start of the request sequence, suffer no cost during the rest of the sequence, and be mapped back to  $s_h$  (for free) via the final request.

## 5 Bounds on the Metric Extension Blow-up

In this section we prove upper and lower bounds on the blow-up for several families of metric spaces and transformations, proving Theorem 4.

► **Theorem 4.** *The following bounds on the blow-up are tight.*

Family of metric spaces	Family of isometries	Blow-up
Ultrametrics	General	$2^{n-1}$
Ultrametrics: $k$ distinct non-zero distances	General	$\approx \left(\frac{n+k-1}{k}\right)^k$ <sup>4</sup>
Equally spaced points on a line	General	$2n - 2$
$(\{0, \dots, k\}^D, \text{weighted } \ell_1)$	Translations	$(2k)^D$
General metrics	Swaps	$2^{n-1}$

It was shown independently by Solecki [21] and Vershik [22] that every *finite* metric space  $M$  admits a *finite*<sup>5</sup> weakly ultrahomogeneous extension  $\hat{M}$ . An elementary proof of this result was presented very recently in [18]. However, the main part of the construction in [18] consists of  $\lceil R \rceil$  growing steps, where  $R$  is the aspect ratio of  $M$ , and a naive bound on the growth factor in the  $i$ th step alone is already doubly exponential in  $i$ . Thus, this does not yield an upper bound on the cardinality of  $\hat{M}$  in terms of the cardinality of  $M$ , but only one that also involves the aspect ratio. Thus, even though there exists a finite extension for any  $n$ -point metric, it is unclear whether its size can be bounded as a function of  $n$ . If not, this would mean that the blow-up for general metrics and isometries is infinite.

### 5.1 General metrics with swap transformations

Let  $M$  be an  $n$ -point metric. We will show how to extend  $M$  to a  $2^{n-1}$ -point space where every swap extends to an automorphism. The tightness of this upper bound follows from the lower bound for ultrametrics (with  $n - 1$  distinct distances) proved in Section 5.2. There, we will show that even if only maps with 1-point domain need to extend to automorphisms, the extended space may require cardinality  $2^{n-1}$ .

We embed  $M$  into the vector space  $\hat{M} = \mathbb{F}_2^{n-1}$  by enumerating the points  $p_1, \dots, p_n$  of  $M$  in arbitrary order and defining the embedding  $\varphi : p_k \mapsto (1^{k-1}, 0^{n-k})$ . We choose the metric on  $\hat{M}$  to extend that of  $M$  and also be translation invariant, and explain just below why such a choice exists. Now for  $x, y \in \mathbb{F}_2^{n-1}$ , their swap is translation by  $(x + y)$ . Since the metric on  $\hat{M}$  is translation invariant, this translation gives the desired extension to an automorphism on  $\hat{M}$ .

Now we explain why there exists such a translation invariant metric on  $\hat{M}$ . We first extend to a partial metric  $(\hat{M}, \hat{d})$  only by translation invariance, i.e.,  $\hat{d}$  is the partial function on  $\hat{M} \times \hat{M}$  defined by  $\hat{d}(x, y) = d(p_i, p_j)$  if  $x - y = \varphi(p_i) - \varphi(p_j)$ . Viewing  $\hat{d}$  as a weighted graph  $G$ , the shortest path extension of  $\hat{d}$  is also translation invariant. Moreover, it gives a valid metric on  $\hat{M}$  if and only if there is no cycle in  $G$  violating the triangle inequality.

Now, the values  $\varphi(p_i) - \varphi(p_j) \in \hat{M}$  range over vectors with a single continuous block of 1s. A cycle in  $G$  consists of a multiset  $\mathcal{S}$  of such vectors adding to 0. Viewing  $\varphi(p_i) - \varphi(p_j)$  as an edge connecting  $p_i$  and  $p_j$ , we claim that any such multiset  $\mathcal{S}$  must correspond to a

<sup>4</sup> The precise blow-up is  $(a + 1)^b a^{k-b}$  where  $a = \lfloor \frac{n+k-1}{k} \rfloor$  and  $b = (n - 1) \bmod k$ .

<sup>5</sup> The existence of an *infinite* ultrahomogeneous metric space that extends every finite metric space, called the Urysohn universal space, has been known since the 1920s.

multigraph on  $M$  with even degree at each vertex  $p_i$ . Indeed, for  $i \geq 2$ , the parity of the degree at  $p_i$  is the difference between the coordinates  $i-1$  and  $i$  in the summed vector, which is 0 by definition (treat coordinate  $n$  as being identically 0). Since the sum of degrees is even, also  $p_1$  must have even degree. Therefore this multigraph has an Eulerian circuit and in particular a cycle containing each edge. Since the edge weights are now exactly distances in  $M$ , we are done by applying the triangle inequality in  $M$ .

## 5.2 Ultrametrics

We consider ultrametrics with at most  $k$  distinct non-zero distances. Note that any  $n$ -point ultrametric has at most  $n-1$  distinct distances, so the general bounds on ultrametrics follow from the case  $k = n-1$ .

**Upper bound.** Recall that ultrametric spaces may be viewed as the leaves of a rooted tree in which vertices with lowest common ancestor at level  $i$  have distance  $L_i$ , where  $0 < L_1 < L_2 < \dots < L_k$  are the possible distances.

We construct  $\hat{M}$  by augmenting the  $n$ -leaf tree corresponding to  $M$  with additional points to create a symmetric tree  $\hat{M}$  where partial isometries extend to automorphisms. We claim this can be done with at most  $\left(\frac{n+k-1}{k}\right)^k$  total leaves. Indeed, the original tree's non-leaf vertices have  $C_1, \dots, C_j$  children for some numbers satisfying  $\sum_{i=1}^j (C_i - 1) = n - 1$ . Therefore letting  $E_i$  be the maximal number of children for any vertex at level  $i$ , we have  $\sum_i (E_i - 1) \leq n - 1$ . We take  $\hat{M}$  to be the leaves of a fully symmetric tree in which every vertex at level  $i$  has  $E_i$  children. It is clear that any partial isometry of this symmetric tree extends to an automorphism. Moreover  $|\hat{M}| = \prod_i E_i$ . Given the constraint  $\sum_{i=1}^k (E_i - 1) \leq n - 1$ , the bound  $|\hat{M}| \leq \left(\frac{n+k-1}{k}\right)^k$  follows from AM-GM. Since each  $E_i$  is an integer, the precise bound is  $(a+1)^b a^{k-b}$  if  $n-1 = ak + b$  for  $b \in \{0, 1, \dots, k-1\}$ .

**Lower bound.** Let  $M_0, \dots, M_k$  be disjoint sets, where  $M_0 = \{p_0\}$  is a singleton and  $M_1, \dots, M_k$  have cardinalities  $\lfloor \frac{n-1}{k} \rfloor$  or  $\lceil \frac{n-1}{k} \rceil$  such that the union  $M := M_0 \dot{\cup} M_1 \dot{\cup} \dots \dot{\cup} M_k$  has cardinality  $n$ . We define an ultrametric on  $M$  by defining the distance between any two distinct points  $x \in M_i, y \in M_j$  with  $i \leq j$  to be  $2 \cdot 3^{j-1}$ .

Let  $\hat{M} \supseteq M$  be a weakly ultrahomogeneous extension of  $M$ . For a point  $x \in \hat{M}$  and  $j = 0, \dots, k$ , denote by  $B_j(x)$  the set of points in  $\hat{M}$  within distance strictly less than  $3^j$  from  $x$ . We claim that  $|B_j(p_0)| \geq \prod_{i=1}^j (|M_i| + 1)$  for each  $j = 0, \dots, k$ . This implies that  $|\hat{M}| \geq \prod_{i=1}^k (|M_i| + 1) \geq \prod_{i=1}^k \lfloor \frac{n+k-1}{k} \rfloor$ .

To prove the claim, we proceed by induction on  $j$ . Clearly it is true for  $j = 0$ . For  $j \geq 1$ , consider the balls  $B_{j-1}(p)$  for  $p \in M_j \cup \{p_0\}$ . By the triangle inequality, they are disjoint and contained in  $B_j(p_0)$ . Since for each  $p \in M_j$  the map  $p_0 \mapsto p$  extends to an isomorphism, they must also all have the same cardinality, which is at least  $\prod_{i=1}^{j-1} (|M_i| + 1)$  by the induction hypothesis. Thus,  $B_j(p_0)$  has cardinality at least  $\prod_{i=1}^j (|M_i| + 1)$ .

## 5.3 The line and weighted $\ell_1$ -norms with translations

The extension of  $n$  equally spaced points on a line is simple: We extend it to a circle of  $2n-2$  equally spaced points. It is easy to see that the circle is ultrahomogeneous because any (partial) isometry is a combination of a rotation and possibly a reflexion. We will now extend this idea to multiple dimensions.

Consider the space  $M := \{0, 1, \dots, k\}^D$  with the distance given by the weighted  $\ell_1$ -norm  $d(x, y) := \sum_{i=1}^D w_i |x_i - y_i|$ , where  $w_1, \dots, w_D$  are arbitrary positive weights. As partial isometries, we consider the family of translations  $x \rightarrow x + v$  that map a subset of  $M$  to another subset of  $M$ . We will show that the associated blow-up is precisely  $(2k)^D$ . Note that the lower bound for  $D = 1$  also yields a tight lower bound of  $2n - 2$  for the blow-up of equally spaced points on a line,

**Upper bound.** Notice that any translation is a composition of translations of the form  $x \rightarrow x + e_i$  and their inverses, where  $e_i \in \{0, 1\}^D$  is the vector with a 1-entry in only the  $i$ th coordinate. It therefore suffices to extend  $M$  to a metric space  $\hat{M}$  where partial isometries of this restricted type extend to global isometries.

We extend  $M$  to the space  $\hat{M} = \{0, \dots, 2k - 1\}^D$  and define a metric on  $\hat{M}$  by

$$\hat{d}(x, y) := \sum_{i=1}^D w_i \min\{|x_i - y_i|, 2k - |x_i - y_i|\}.$$

This is the metric induced by the weighted  $\ell_1$ -norm when viewing  $\hat{M}$  as a  $D$ -dimensional torus. Clearly,  $\hat{d}$  extends  $d$ . Moreover, any isometry  $x \rightarrow x + e_i$  defined on a subset of  $M$  extends to the automorphism  $x \rightarrow x + e_i \bmod 2k$  on  $\hat{M}$ , where the “mod  $2k$ ” is applied coordinate-wise.

**Lower bound.** Let  $A_0 := \{0, 1, \dots, k\}$  and  $A_1 := \{0, 1\}$ . For a 0-1-string  $i_1 i_2 \dots i_D$ , consider the translation

$$\begin{aligned} f_{i_1 \dots i_D} : A_{i_1} \times \dots \times A_{i_D} &\rightarrow M \\ x &\mapsto x + (k - 1) \cdot (i_1, \dots, i_D). \end{aligned}$$

The choice of domain of  $f_{i_1 \dots i_D}$  is just to ensure that the image is still in  $M$ .

Let  $\hat{M} \supseteq M$  be an extension of  $M$  such that each  $f_{i_1 \dots i_D}$  extends to an automorphism  $\hat{f}_{i_1 \dots i_D}$  of  $\hat{M}$ .

Let  $C_0 := \{0, 1, \dots, k - 1\}$ ,  $C_1 := \{1, 2, \dots, k\}$  and  $S_{i_1 \dots i_D} := \hat{f}_{i_1 \dots i_D}(C_{i_1} \times \dots \times C_{i_D})$ .

Note that each set  $S_{i_1 \dots i_D}$  has cardinality  $k^D$ , and there are  $2^D$  such sets in total, corresponding to the  $2^D$  possible 0-1-strings of length  $D$ . Thus, the lower bound of  $(2k)^D$  on the cardinality of  $\hat{M}$  follows from the following claim.

▷ **Claim 9.** The sets  $S_{i_1 \dots i_D}$  are pairwise disjoint for different 0-1-strings  $i_1 \dots i_D$ .

**Proof.** Let  $y \in S_{i_1 \dots i_D}$  for some 0-1-string  $i_1 \dots i_D$ . We will show that  $i_1 \dots i_D$  is uniquely determined by  $y$ .

We can write  $y = \hat{f}_{i_1 \dots i_D}(x)$  for some  $x \in M$ . It suffices to show that  $i_j = 0$  if and only if  $y$  is closer to  $k \cdot \mathbb{1} - e_j$  than to  $k \cdot \mathbb{1}$ , where  $\mathbb{1}$  denote the all-ones vector. Equivalently, we will show that

$$i_j = 0 \iff d(x, f_{i_1 \dots i_D}^{-1}(k \cdot \mathbb{1} - e_j)) < d(x, f_{i_1 \dots i_D}^{-1}(k \cdot \mathbb{1})).$$

Note that the preimages  $f_{i_1 \dots i_D}^{-1}(k \cdot \mathbb{1})$  and  $f_{i_1 \dots i_D}^{-1}(k \cdot \mathbb{1} - e_j)$  exist in  $M$ , and they differ only in their  $j$ th entry.

If  $i_j = 0$ , then  $x_j \leq k - 1$  (by definition of  $C_{i_j}$ ) and the  $j$ th entries of  $f_{i_1 \dots i_D}^{-1}(k \cdot \mathbb{1} - e_j)$  and  $f_{i_1 \dots i_D}^{-1}(k \cdot \mathbb{1})$  are  $k - 1$  and  $k$ , respectively. Thus,  $x$  is closer to  $f_{i_1 \dots i_D}^{-1}(k \cdot \mathbb{1} - e_j)$  than to  $f_{i_1 \dots i_D}^{-1}(k \cdot \mathbb{1})$ .

If  $i_j = 1$ , then  $x_j \geq 1$  (by definition of  $C_{i_j}$ ) and the  $j$ th entries of  $f_{i_1 \dots i_D}^{-1}(k \cdot \mathbb{1} - e_j)$  and  $f_{i_1 \dots i_D}^{-1}(k \cdot \mathbb{1})$  are 0 and 1, respectively. Thus,  $x$  is further from  $f_{i_1 \dots i_D}^{-1}(k \cdot \mathbb{1} - e_j)$  than from  $f_{i_1 \dots i_D}^{-1}(k \cdot \mathbb{1})$ . ◁

## Abstract

We prove several hardness results for training depth-2 neural networks with the ReLU activation function; these networks are simply weighted sums (that may include negative coefficients) of ReLUs. Our goal is to output a depth-2 neural network that minimizes the square loss with respect to a given training set. We prove that this problem is NP-hard already for a network with a single ReLU. We also prove NP-hardness for outputting a weighted sum of  $k$  ReLUs minimizing the squared error (for  $k > 1$ ) even in the realizable setting (i.e., when the labels are consistent with an unknown depth-2 ReLU network). We are also able to obtain lower bounds on the running time in terms of the desired additive error  $\epsilon$ . To obtain our lower bounds, we use the Gap Exponential Time Hypothesis (Gap-ETH) as well as a new hypothesis regarding the hardness of approximating the well known Densest  $\kappa$ -Subgraph problem in subexponential time (these hypotheses are used separately in proving different lower bounds). For example, we prove that under reasonable hardness assumptions, any *proper* learning algorithm for finding the best fitting ReLU must run in time exponential in  $1/\epsilon^2$ . Together with a previous work regarding improperly learning a ReLU [21], this implies the first separation between proper and improper algorithms for learning a ReLU. We also study the problem of properly learning a depth-2 network of ReLUs with bounded weights giving new (worst-case) upper bounds on the running time needed to learn such networks both in the realizable and agnostic settings. Our upper bounds on the running time essentially matches our lower bounds in terms of the dependency on  $\epsilon$ .

## 1 Introduction

Neural networks have become popular in machine learning tasks arising in multiple applications such as computer vision, natural language processing, game playing and robotics [25]. One attractive feature of neural networks is being universal approximations: a network with a single hidden layer<sup>1</sup> with sufficiently many neurons can approximate arbitrary well any measurable real-valued function [23, 13]. These networks are typically trained on labeled data by setting the weights of the units to minimize the loss function (often the squared loss is used) over the training data. The challenge is to find a computationally efficient way to set the weights to achieve low error. While heuristics such as stochastic gradient descent (SGD) have been successful in practice, our theoretical understanding about the amount of running-time needed to train neural networks is still lacking.

It has been known for decades [8, 31, 24] that finding a set of weights that minimizes the loss of the training set is NP-hard. These hardness results, however, only apply to classification problems and to settings where the neural networks involved use discrete, Boolean activations. Our focus here is on neural networks with real inputs whose neurons have the real-valued ReLU activation function. Specifically, we consider depth-2 networks of ReLUs, namely either a single ReLU or a weighted sum of ReLUs<sup>2</sup>, and the optimization problem of training them given labeled data points, which are defined below.

► **Definition 1.** A rectifier is the real function  $[x]_+ := \max(0, x)$ . A rectified linear unit (ReLU) is a function  $f(\mathbf{x}) : \mathbb{R}^n \rightarrow \mathbb{R}$  of the form  $f(\mathbf{x}) = [\langle \mathbf{w}, \mathbf{x} \rangle]_+$  where  $\mathbf{w} \in \mathbb{R}^n$  is fixed. A depth-2 neural network with  $k$  ReLUs (abbreviated as  $k$ -ReLU) is a function from  $\mathbb{R}^n$  to  $\mathbb{R}$  defined by

$$\text{ReLU}_{\mathbf{w}^1, \dots, \mathbf{w}^k, \mathbf{a}}(\mathbf{z}) = \sum_{j=1}^k a_j [\langle \mathbf{w}^j, \mathbf{z} \rangle]_+.$$

Here  $\mathbf{x} \in \mathbb{R}^n$  is the input,  $\mathbf{a} = (a_1, \dots, a_k) \in \{-1, 1\}^k$  is a vector of “coefficients”,  $\mathbf{w}^j = (w_1^j, \dots, w_n^j) \in \mathbb{R}^n$  is a weight vector associated with the  $j$ -th unit. When  $a_1 = \dots = a_k = 1$ , we refer to  $\text{ReLU}_{\mathbf{w}^1, \dots, \mathbf{w}^k, \mathbf{a}}(\mathbf{z})$  as the sum of  $k$  ReLUs, and we may omit  $\mathbf{a}$  from the subscript.

We note that the assumption that  $a_1, \dots, a_k \in \{+1, -1\}$  is without loss of generality (e.g., [32]): for any non-zero  $a_1, \dots, a_k \in \mathbb{R} \setminus \{0\}$  and  $\mathbf{w}^1, \dots, \mathbf{w}^k$ , we may consider  $\hat{a}_1 = \frac{a_1}{|a_1|}, \dots, \hat{a}_k = \frac{a_k}{|a_k|}$  and  $\hat{\mathbf{w}}^1 = |a_1| \mathbf{w}^1, \dots, \hat{\mathbf{w}}^k = |a_k| \mathbf{w}^k$  instead, which represent the same depth-2 network of  $k$  ReLUs.

When training neural networks composed of ReLUs, a popular method is to find, given training data, a set of coefficients and weights for each gate minimizing the squared loss.

<sup>1</sup> We also refer to such networks as depth-2 networks or shallow networks.

<sup>2</sup> We also assume all the biases of the units are 0.

► **Definition 2.** Given a set of  $m$  samples  $\mathbf{x}_1, \dots, \mathbf{x}_m \in \mathbb{R}^n$  along with  $m$  labels  $y_1, \dots, y_m \in \mathbb{R}$ , our goal is to find  $\mathbf{w}^1, \dots, \mathbf{w}^k, \mathbf{a}$  which minimize the average squared training error of the sample, i.e.,

$$\min_{\mathbf{w}^1, \dots, \mathbf{w}^k, \mathbf{a}} \frac{1}{m} \sum_{i=1}^m (\text{ReLU}_{\mathbf{w}^1, \dots, \mathbf{w}^k, \mathbf{a}}(\mathbf{x}_i) - y_i)^2 \quad (1)$$

We refer to the optimization problem (1) as the  $k$ -ReLU training problem (aka  $k$ -ReLU regression).

When  $\mathbf{w}^j = (w_1^j, \dots, w_n^j)$  are assumed to have Euclidean norm at most 1 and  $y_i$  are assumed to be in  $[-k, k]$ , we refer to the optimization problem above as the bounded  $k$ -ReLU training problem.

Sometimes we assume that the “coefficient” vector  $\mathbf{a}$  is fixed in advance (and known to the optimizer) and not part of the input to the training problem. We mention this explicitly when relevant. Also observe that in the optimization problem above we are looking for a **global minimum** rather than a local minimum. A multiset of samples  $\{(\mathbf{x}_i, y_i)\}_{i \in [m]}$  is said to be *realizable* if there exist  $\mathbf{w}^1, \dots, \mathbf{w}^k, \mathbf{a}$  which result in zero training error.

Our goal is to pin down the computational complexity of the training problem for depth-2 networks of ReLUs, by answering the following question:

► **Question 3.** What is the worst-case running time of training a  $k$ -ReLU?

We focus on depth-2 networks which are rather involved and give rise to nontrivial algorithmic challenges [41, 6]. Understanding shallow networks seems to be a prerequisite for understanding the complexity of training networks of depth greater than 2.

## 1.1 Our results

We first consider arguably the simplest possible network: a single ReLU. We show that, already for such a network, the training problem is NP-hard. In fact, our result even rules out a large factor *multiplicative* approximation of the minimum squared error, as stated below.

► **Theorem 4** (Hardness of Training a single ReLU). *The 1-ReLU training problem is NP-hard. Furthermore, given a sample of  $m$  data points of dimension  $n$  it is NP-hard to approximate the optimal squared error within a multiplicative factor of  $(nm)^{1/\text{poly} \log \log(nm)}$ .*

Given such a strong multiplicative inapproximability result, a natural question is whether one can get a good algorithm for *additive* approximation guarantee. Notice that we cannot hope for additive approximation in general, because scaling the samples and their labels can make the additive approximation gap arbitrarily large. Hence, we must consider the bounded 1-ReLU Training problem. For this, we give a simple  $2^{O(1/\epsilon^2)} \text{poly}(n, m)$  time algorithm with additive approximation  $\epsilon$ . Furthermore, it easily generalizes to the case of the bounded  $k$ -ReLU Training problem for  $k > 1$ , but we have to pay a factor of  $k^5$  in the exponent:

► **Theorem 5** (Training Algorithm). *There is a (randomized) algorithm that can solve the bounded  $k$ -ReLU training problem to within any additive error  $\epsilon > 0$  in time  $2^{O(k^5/\epsilon^2)} \text{poly}(n, m)$ .*

Perhaps more surprisingly, we can prove a tight running time lower bound for the bounded 1-ReLU training problem, which shows that the term  $1/\epsilon^2$  in the exponent is necessary. Our running time lower bound relies on the assumption that there is no subexponential

time algorithm for approximating the *Densest  $\kappa$ -Subgraph* problem within any constant (multiplicative) factor. Recall that, in the Densest  $\kappa$ -Subgraph (D $\kappa$ S) problem, we are given a graph  $G = (V, E)$  and a positive integer  $\kappa$ . The goal is to select a subset  $T \subseteq V$  of  $\kappa$  vertices that induces as many edges as possible. We use  $\text{den}_\kappa(G)$  to denote this optimum<sup>3</sup> and  $N$  to denote the number of vertices,  $|V|$ . Our hypothesis can be stated formally as follows.

► **Hypothesis 6.** *For every constant  $C \geq 1$ , there exist<sup>4</sup>  $\delta = \delta(C) > 0$  and  $d = d(C) \in \mathbb{N}$  such that the following holds. No  $O(2^{\delta N})$ -time algorithm can, given an instance  $(G, \kappa)$  of D $\kappa$ S where each vertex of  $G$  has degree at most  $d$  and an integer  $\ell$ , distinguish between the following two cases:*

- (Completeness)  $\text{den}_\kappa(G) \geq \ell$ .
- (Soundness)  $\text{den}_\kappa(G) < \ell/C$ .

While this hypothesis is new (we are the first to introduce it), it seems fair to say that refuting it will require a breakthrough in current algorithms for the D $\kappa$ S problem. There are also other supporting evidences for the validity of this hypothesis. For example, it is known that  $o(N)$ -level of the Sum-of-Squares Hierarchies do not give constant factor approximation for D $\kappa$ S even for bounded degree graphs [7, 12, 28]. Furthermore, these Sum-of-Squares lower bounds are proved via reductions from a certain family of random CSPs, whose Sum-of-Squares lower bounds are shown in [35, 40]. This means that, if Hypothesis 6 is false, then one can refute this family of sparse random CSPs in subexponential time. This would constitute an arguably surprising development in the area of refuting random CSPs, which has been extensively studied for decades (see [1] and references therein).

As mentioned earlier, assuming Hypothesis 6, we can prove the tight running time lower bound for the bounded 1-ReLU Training problem:

► **Theorem 7** (Tight Running Time Lower Bound for 1-ReLU Training). *Assuming Hypothesis 6, there is no algorithm that, for all given  $\epsilon > 0$ , can solve the bounded 1-ReLU training problem within an additive error  $\epsilon$  in time  $2^{o(1/\epsilon^2)} \text{poly}(n, m)$ .*

We remark that, akin to standard conventions in the area of fine-grained and parameterized complexity, all lower bounds are stated against algorithms that work for *all* values of  $\epsilon$  with the specified running time. Indeed, it is possible to significantly speed up the time bound  $2^{O(1/\epsilon^2)} \text{poly}(n, m)$  for extreme values of  $\epsilon$ ; for instance, enumerating all possible  $\mathbf{w}$  over a  $\Theta(\epsilon)$ -net<sup>5</sup> of  $\mathcal{B}^n$  gives an algorithm that runs in time  $O(1/\epsilon)^{O(n)} \text{poly}(m)$ , which is asymptotically smaller than  $2^{O(1/\epsilon^2)} \text{poly}(n, m)$  when  $\epsilon = o\left(\frac{1}{\sqrt{n \log n}}\right)$ . Nonetheless, our lower bounds can be extended to include a large range of “reasonable”  $\epsilon$ . Further discussion on such an extension is provided before Section 1.3.

An interesting consequence of Theorem 7 is that it gives a separation between proper and improper agnostic learning of 1-ReLU. Specifically, [21] shows that improper agnostic learning of 1-ReLU can be done in  $2^{O(1/\epsilon)} \text{poly}(n)$  time, while Theorem 7 rules out such a possibility for proper agnostic learning.

<sup>3</sup> Equivalently,  $\text{den}_\kappa(G) := \max_{T \subseteq V, |T|=\kappa} |E(T)|$ .

<sup>4</sup> As  $C$  increases,  $\delta$  and  $d$  decreases.

<sup>5</sup> Recall that an  $\delta$ -net (also refer to as an  $\delta$ -cover) of a set  $S \subseteq \mathbb{R}^n$  is a set  $T \subseteq \mathbb{R}^n$  such that, for every  $x \in S$ , there exists  $y \in T$  where  $\|x - y\|_2 \leq \delta$ . It is well-known that, for any  $\delta \in [0, 1]$ , there is a  $\delta$ -net of the unit ball  $\mathcal{B}^n$  of size  $(3/\delta)^n$  and that it can be found in  $(3/\delta)^{O(n)}$  time.

### Training $k$ -ReLU: The Realizable Case

An important special case of the  $k$ -ReLU Training problem is the realizable case, where there is an unknown  $k$ -ReLU that labels every training sample correctly. When  $k = 1$ , it is straightforward to see that the realizable case of 1-ReLU Training can be phrased as a linear program and hence can be solved in polynomial time. On the other hand, we show that, once  $k > 1$ , the problem becomes NP-hard:

► **Theorem 8** (Hardness of Training  $k$ -ReLU in the Realizable Case). *For any constant  $k \geq 2$ , the  $k$ -ReLU training problem is NP-hard even in the realizable case.*

Our result is in fact slightly stronger than stated above: specifically, we show that, when the samples can be realizable by a (non-negative) sum of  $k$  ReLUs (i.e.  $k$ -ReLU when  $\mathbf{a}$  is the all-one vector), it is still NP-hard to find a  $k$ -ReLU that realizes the samples even if negative coefficients in  $\mathbf{a}$  are allowed. Furthermore, while we assume in this theorem that  $k$  is a constant independent of  $n$ , one can also prove an analogous hardness result, when  $k$  grows sufficiently slowly as a function of  $n$ . We refer the full version for more details.

Observe that Theorem 8 implies that efficient *multiplicative* approximation for the  $k$ -ReLU Training problem is impossible (assuming  $P \neq NP$ ) for  $k \geq 2$ . As a result, we once again turn to additive approximation. On this front, we can improve the running time of the algorithm in Theorem 5 when we assume that the samples are realizable, as stated below.

► **Theorem 9** (Training Algorithm in the Realizable Case). *When the given samples are realizable by some  $k$ -ReLU, there is a (randomized) algorithm that can solve the bounded  $k$ -ReLU training problem to within any additive error  $\epsilon > 0$  in time  $2^{O((k^3/\epsilon) \log^3(k/\epsilon))} \text{poly}(n, m)$ .*

Importantly, the dependency of  $\epsilon$  in the exponent is  $\tilde{O}(1/\epsilon)$ , instead of  $1/\epsilon^2$  that appeared in the non-realizable case (i.e. Theorems 5 and 7). We can also show that this dependency is tight (up to log factors), in the realizable case, under the Gap Exponential Time Hypothesis (Gap-ETH) [17, 29], a standard complexity theoretic assumption in parameterized complexity (see e.g. [11]). Gap-ETH states that there exists  $\delta > 0$  such that no  $2^{o(n)}$ -time algorithm can, given a CNF formula with  $n$  Boolean variables, distinguish between (i) the case where the formula is satisfiable, and (ii) the case where any assignment violates at least  $\delta$  fraction of the clauses. Our running time lower bound can be stated more formally as follows.

► **Theorem 10** (Tight Running Time Lower Bound for the Realizable Case). *Assuming Gap-ETH, for any constant  $k \geq 2$ , there is no algorithm that, for all given  $\epsilon > 0$ , can solve the bounded  $k$ -ReLU training problem within an additive error  $\epsilon$  in time  $2^{o(1/\epsilon)} \text{poly}(n, m)$  even when the input samples are realizable by some  $k$ -ReLU.*

### Relation to Learning ReLUs

$k$ -ReLU Training is closely related to the problem of *proper learning* of  $k$ -ReLU. In fact, an algorithm for the latter also solves the former. Hence, our hardness results immediately implies hardness of proper learning of  $k$ -ReLU as well. Furthermore, our algorithm also works for the learning problem. Please refer to the full version for more details.

### Stronger Quantifier in Running Time Lower Bounds

As stated earlier, our running time lower bounds in Theorems 7 and 10 hold only against algorithms that work *for all*  $\epsilon > 0$ . A natural question is whether one can prove lower bounds against algorithms that work only *for some* “reasonable” values of  $\epsilon$ . As explained in more detail below, we can quite easily also get a lower bound with this latter (stronger) quantifier, for any “reasonable” value of  $\epsilon$ .

First, our lower bounds in Theorems 7 and 10 both apply in the regime where the lower bounds themselves are  $2^{\Theta(n)}$ ; in other words,  $\epsilon = \Theta(1/\sqrt{n})$  in Theorem 7 and  $\epsilon = \Theta(1/n)$  in Theorem 10. These are essentially the smallest possible value of  $\epsilon$  for which the lower bounds in Theorems 7 and 10 can hold, because the aforementioned algorithm that enumerates over an  $\epsilon$ -net of  $\mathcal{B}^n$  solves the problem in time  $O(1/\epsilon)^{O(n)} \text{poly}(n)$ . On the other hand, for smaller values of  $\epsilon$ , we can get a running time lower bound easily by “padding” the dimension by “dummy” coordinates that are always zero. For instance, if we start with  $\epsilon = \Theta(1/\sqrt{n})$ , then we may pad the instance to say  $n' = n^2$  dimensions, resulting in the relationship  $\epsilon = \Theta(1/\sqrt{n'})$ . To summarize, this simple padding technique immediately gives the following stronger quantifier version of Theorem 7:

► **Theorem 11.** *For any non-increasing and efficiently computable<sup>6</sup> function  $\epsilon : \mathbb{N} \rightarrow \mathbb{R}^+$  such that  $\omega(\sqrt{\log n}) \leq \frac{1}{\epsilon(n)} \leq o(\sqrt{n})$ , assuming Hypothesis 6, there is no algorithm that can solve the bounded 1-ReLU training problem within an additive error  $\epsilon(n)$  in time  $2^{o(1/\epsilon(n)^2)} \text{poly}(n, m)$ .*

Notice that the constraint  $\omega(\sqrt{\log n}) \leq \frac{1}{\epsilon(n)}$  is also essentially necessary, because for  $\epsilon > \sqrt{\frac{\log \log n}{\log n}}$  our algorithm (Theorem 5) already runs in polynomial time. A strong quantifier version of Theorem 10 similar to above can be shown as well (but with  $\omega(\log n) \leq \frac{1}{\epsilon(n)} \leq o(n)$ ). We omit the full (straightforward) proof via padding of Theorem 11; interested readers may refer to the proof of Lemma 3.4 of [16] which employs the same padding technique.

## 1.2 Independent and concurrent work

There have been several concurrent and independent works to ours that we mention here. We remark that the techniques in these works are markedly different than the ones in this paper. For a single ReLU, [14] proved that the 1-ReLU Training problem is NP-hard. With respect to two ReLUs, [6] showed that finding weights minimizing the squared error of a 2-ReLU is NP-hard, even in the realizable case. The work of [9] considered the problem of training a network with a slightly different architecture, in which there are two ReLUs in the first hidden layer and the final output gate is also a ReLU (instead of a sum gate as in our case); they showed that, for such networks with three ReLUs (two in the hidden layer, one in the output layer), the training problem is NP-hard even for the realizable case. As a result of having an output gate computing a ReLU, our NP-hardness result (regarding training a sum of two ReLUs) does not imply their result and their hardness result does not imply our hardness result for training a sum of 2 ReLUs.

## 1.3 Related work

The computational aspects of training and learning neural networks has been extensively studied. Due to this, we only focus on those directly related to our results.

We are not aware of a previous work showing that the general  $k$ -ReLU training problem is NP-hard for  $k > 2$ , nor are we aware of previous results regarding the hardness of approximating the squared error of a single ReLU. The  $k = 2$  case and the  $k > 2$  case seem to require different ideas and indeed our proof technique for Theorem 10 is different than those of [9, 6]. Moreover, the question of generalizing the NP-hardness result from  $k = 2$  to  $k > 2$  is mentioned explicitly in [9]. Finally, we remark that neither [14] nor [6] provides explicit

---

<sup>6</sup> That is, we assume that computing  $\epsilon(n)$  can be done in time  $\text{poly}(n)$  for any  $n \in \mathbb{N}$ .

running time lower bounds in terms of  $1/\epsilon$  for the problem of training  $k$  ReLUs within an additive error of  $\epsilon$ . To the best of our knowledge, our work is the first to obtain such lower bounds.

[42] has proven that finding weights minimizing the squared error of a  $k$ -ReLU is NP-hard when  $\mathbf{a}$  is the all-one vector (or alternatively, when all the coefficients of the units are restricted to be positive) for every  $k \geq 2$ .

Some sources (e.g. [4, 5]) attribute (either implicitly or explicitly) the NP-hardness of the  $k$ -ReLU Training problem to [8], who consider training a neural network with *threshold units*. However, it is unclear (to us) how to derive the NP-hardness of training ReLUs from the hardness results of [8]. Several NP-hardness results for training neural networks with architectures differing from the fully connected architecture considered here are known. For example, in [10], the training problem is shown to be hard for a depth-2 *convolutional network* with (at least two) *non-overlapping* patches. To the best of our knowledge, these architectural differences render those previous results inapplicable for deriving the hardness results regarding the networks considered in this work.

Several papers have studied a slightly different setting of *improper learning* of neural networks. An example is [26] who show that improper learning of depth-2 networks of  $\omega(1)$  ReLUs is hard, assuming certain average case assumptions. More recently, [21] show that even for a single ReLU, when  $|\langle \mathbf{w}, \mathbf{x} \rangle|$  tends to infinity with  $n$ , learning  $[\langle \mathbf{w}, \mathbf{x} \rangle]_+$  improperly in time  $g(\epsilon) \cdot \text{poly}(n)$  is unlikely as it will result in an efficient algorithm for the problem of learning sparse parities with noise which is believed to be intractable. These hardness results for improper learning do imply hardness for the corresponding training problems. Nonetheless, it should be noted that the fact that these results have to rely on assumptions other than  $P \neq NP$  is not a coincidence: it is known that basing hardness of improper learning on  $P \neq NP$  alone will result in a collapse of the Polynomial Hierarchy [3].

On the algorithmic side, Arora et al. [4] provide a simple and elegant algorithm that exactly solves the ReLU training problem in polynomial time assuming the dimension  $n$  of the data points is an absolute constant; Arora et al.'s algorithm is for the networks we consider, and it has since been also extended to other types of networks [9]. Additionally, there have also been works on (agnostic) learning algorithms for ReLUs. Specifically, Goel et al. [21] consider the bounded norm setting where the inputs to the ReLUs as well as the weight vectors of the units have norms at most 1. For this setting, building on kernel methods and tools from approximation theory, they show how to *improperly* learn a single  $n$ -variable ReLU up to an additive error of  $\epsilon$  in time  $2^{O(1/\epsilon)} \cdot \text{poly}(n)$ . Their result generalizes to depth-2 ReLUs with  $k$  units with running time of  $2^{O(\sqrt{k}/\epsilon)} \cdot \text{poly}(n)$  assuming the coefficient vector  $\mathbf{a}$  has norm at most 1. The algorithm they provide is quite general: it works for arbitrary distribution over input-output pairs, for  $\epsilon$  that can be small as  $1/\log n$  and also for the reliable setting.

A limitation of our hardness results is that they consider “pathological” training data sets that are specifically constructed to encode intractable combinatorial optimization problems. Several works in literature have tried to overcome this issue by considering the training/learning problems on more “benign” data distributions, such as log-concave distributions or those with Gaussian marginals. On this front, both algorithms and lower bounds have been shown for depth-2 networks [38, 6, 22].

Using insights from the study of exponential time algorithms towards understanding the complexity of machine learning problems as is done in this work is receiving attention lately [36, 15, 37].

## 1.4 Organization of the Paper

In the remainder of the main body of this paper, we provide high-level overviews of our proofs (Section 2) and discuss several potential research directions (Section 3). Due to space constraints, all proofs are deferred to the full version.

## 2 Proof Overview

Below we provide the informal overviews of our proofs and intuition behind them.

### NP-Hardness of Training 1-ReLU

Our reduction is from the (NP-hard) Set Cover problem, in which we are given subsets  $T_1, \dots, T_M$  of a universe  $U$ , and the goal is to select as few of these subsets as possible whose union covers the entire universe  $U$ . We reduce this to the problem of 1-ReLU Training, where the dimension  $n$  is equal to  $M$ . We think of each coordinate of  $\mathbf{w}$  as an unknown (i.e. variable); specifically, the desired solution will have  $w_i = -1$  iff  $T_i$  is picked and 0 otherwise. From this perspective, adding a labelled sample  $(\mathbf{x}, y)$  is the same as adding a “constraint”  $[\mathbf{w} \cdot \mathbf{x}]_+ = y$ . There are two types of constraints we will add:

- (Element Constraint) For each  $u \in U$ , we add a constraint of the form  $[1 + \sum_{T_i \ni u} w_i]_+ = 0$ . The point is that such a constraint is satisfied when  $u$  is covered by the selected subsets.
- (Subset Constraint) For each  $i \in [M]$ , we add a constraint of the form  $[\gamma + w_i]_+ = \gamma$  for some small  $\gamma > 0$ . This constraint will be violated for any selected subset.

By balancing the weights (i.e. number of copies) of each constraint carefully, we can ensure that the element constraints are never unsatisfied, and that the goal is ultimately to violate as few subset constraints as possible, which is equivalent to trying to pick as few subsets as possible that can fully cover  $U$ . This completes the high-level overview of our reduction.

We remark that there is a subtle point here because we cannot directly have a constant such that 1 or  $\gamma$  in the constraints themselves. Rather, we need to have “constraint coordinate” and adding the constants through this coordinate. This will also be done in the other reductions presented below, and we will not mention this again.

The outlined proof, together with the  $\Theta(\log |U|)$  inapproximability of Set Cover [27, 20], already gives a hardness of approximation of a multiplicative factor of  $\Theta(\log(nm))$  for the 1-ReLU Training problem. To further improve this inapproximability ratio to  $(nm)^{1/\text{poly} \log \log(nm)}$ , we reduce from the *Minimum Monotone Circuit Satisfiability* (MMCS) problem, which is a generalization of Set Cover. In MMCS, we are given a monotone circuit and the goal is to set as few input wires to true as possible under the condition that the circuit’s output must be true. Strong inapproximability results for MMCS are known (e.g. [18]). Our reduction from MMCS proceeds in a similar manner as that of the Set Cover reduction above. Roughly speaking, the modification is that each unknown is now whether each wire is set/evaluated to true, whereas the constraints are now to ensure that the evaluation at each gate is correct and that the output is true.

### Tight Running Time Hardness of 1-ReLU Training

We now move on to the proof overview of the tight running time lower bound for 1-ReLU Training. Recall that we will be reducing from the Densest  $\kappa$ -Subgraph ( $\text{D}\kappa\text{S}$ ) problem, in which we are given a graph  $G = (V, E)$  and  $\kappa \in \mathbb{N}$ . The goal is to find a set of  $\kappa$  vertices that induces the maximum number of edges.

To motivate our construction, a simple combination of dimensionality reduction and  $\delta$ -net can in fact find a ReLU that point-wise approximates the optimal ReLU to within an additive factor of  $\delta$  in time  $2^{\tilde{O}(1/\delta^2)} \text{poly}(n)$ . That is, if the ReLU that achieves the optimal error has weight vector  $\mathbf{w}^*$ , then we can find a weight vector  $\mathbf{w}$  such that  $|\mathbf{w} \cdot \mathbf{x}|_+ - [\mathbf{w}^* \cdot \mathbf{x}]_+| \leq \delta$  for all input samples  $(\mathbf{x}, y)$  in time<sup>7</sup>  $2^{\tilde{O}(1/\delta^2)} \text{poly}(n)$ .

Indeed, this is an explanation why, in the realizable case, we can get  $\epsilon$  squared error in  $2^{\tilde{O}(1/\delta)} \text{poly}(n)$  time by simply picking  $\delta = \sqrt{\epsilon}$ . Now, since we need our hardness here (for the non-realizable case) to hold with stronger running time lower bound of  $2^{\Theta(1/\epsilon^2)} \text{poly}(n)$ , we have to make sure that whenever  $\delta \gg \epsilon$ , the aforementioned point-wise approximation of  $\delta$  is not sufficient to get an error of  $\epsilon$ . Suppose that, for an input labelled sample  $(\mathbf{x}, y)$ , the optimal ReLU outputs  $y'$  and our approximation outputs  $y''$  (where  $|y'' - y'| \leq \delta$ ). Notice that the difference in the square error between the two for this sample is only at most  $O((y' - y)\delta) + \delta^2$ . Now, if we want this quantity to be at least  $\epsilon$  for any  $\delta \geq \Omega(\epsilon)$ , then it must be that  $|y' - y| = \Omega(1)$ . In other words, we have to make our samples so that even the optimal ReLU is “wrong” by  $\Omega(1)$  additive factor (on average); this indeed means that, if the ReLU we find is “more wrong” by an additive factor of  $\Theta(\epsilon)$ , then the increase in the average squared error would be  $\Omega(\epsilon)$  as desired.

With the observation in the previous paragraph in mind, we will now provide a rough description of our gadget. Given a  $\text{D}\kappa\text{S}$  instance  $(G = (V, E), \kappa)$ , our samples will have  $|V|$  dimensions, one corresponding to each vertex. In the YES case where there is  $T \subseteq V$  of size  $\kappa$  that induces many edges, we aim to have our ReLU weight assigning  $\frac{1}{\sqrt{\kappa}}$  to all coordinates corresponding to vertices in  $T$ , and zero to all other coordinates. To enforce this, we first add a sample for every vertex  $v \in V$  that corresponds to the constraint

$$\left[ \mathbf{w}_v - \frac{1}{2\sqrt{\kappa}} \right]_+ = 1.$$

We refer to these as the *cardinality constraints*. While this may look peculiar at first glance, the effect is that it ensures that roughly speaking  $\mathbf{w}$  has  $\kappa$  coordinates that are “approximately”  $\frac{1}{\sqrt{\kappa}}$  and the remaining coordinates are “small”. To see that this is the case, observe that the average mean squared error here is  $1 - \frac{2}{|V|} \sum_{v \in V} \left[ \mathbf{w}_v - \frac{1}{2\sqrt{\kappa}} \right]_+ + \frac{1}{|V|} \sum_{v \in V} \left[ \mathbf{w}_v - \frac{1}{2\sqrt{\kappa}} \right]_+^2$ . The last term is small and may be neglected. Hence, we essentially have to maximize  $\sum_{v \in V} \left[ \mathbf{w}_v - \frac{1}{2\sqrt{\kappa}} \right]_+$ . This term is indeed maximized when  $\mathbf{w}$  has  $\kappa$  coordinates equal to  $\frac{1}{\sqrt{\kappa}}$ , and zeros in the remaining coordinates. Notice here that this also fits with our intuition from the previous paragraph: even in the optimal ReLU, the value out put by the value (which is either 0 or  $\frac{1}{2\sqrt{\kappa}}$ ) is  $\Omega(1)$  away from the input label of the sample (i.e. 1).

So far, the cardinality constraints have ensured that  $\mathbf{w}$  “represents” a set  $T \subseteq V$  of size roughly  $\kappa$ . However, we have not used the fact that  $T$  contains many edges at all. Thus, for every edge  $e = \{u, v\} \in E$ , we also add the example corresponding to the following constraint to our distribution:

$$\frac{1}{2} \left[ \mathbf{w}_u + \mathbf{w}_v - \frac{1.75}{\sqrt{\kappa}} \right]_+ = 1.$$

We call these the *edge constraints*. The point here is that, if  $e$  is not an induced edge in  $T$ , then the output of the ReLU will be zero. On the other hand, if  $e$  is an edge in  $T$ , then the output of the ReLU will be  $\frac{0.25}{\sqrt{\kappa}}$ . Hence, the more edges  $T$  induces, the smaller the error.

<sup>7</sup> We assume throughout that  $m = \text{poly}(1/\delta)$ , which is w.l.o.g. due to standard generalization bounds.

By carefully selecting weights (i.e. number of copies) of each sample, one can indeed show that the average square error incurred in the completeness and soundness case of Hypothesis 6 differs by  $\epsilon = \Omega\left(\frac{1}{\sqrt{|V|}}\right)$ . Hence, if we can solve the 1-ReLU Training problem to within an additive error of  $\epsilon$  in time  $2^{o(1/\epsilon^2)}\text{poly}(n, m)$ , we can also solve the problem in Hypothesis 6 in time  $2^{o(|V|)}$ , which breaks the hypothesis.

### Hardness of Training $k$ -ReLU in the Realizable Case

We next consider the problems of Training  $k$ -ReLU for  $k \geq 2$  in the realizable case. Both the NP-hardness result (Theorem 8) and the tight running time lower bound (Theorem 10) employ similar reductions. These reductions proceed in two steps. First is to reduce from the NP-hard  $k$ -coloring problem to the problem of training *non-negative sum of  $k$  ReLUs*, in which we fix the coefficient vector  $\mathbf{a}$  to be the all-one vector and only seeks to find  $\mathbf{w}^1, \dots, \mathbf{w}^k$  that minimizes the squared error. Then, in the second step, we reduce this to the original problem of  $k$ -ReLU Training (where the coefficient vector  $\mathbf{a}$  can be negative).

*Step I: From  $k$ -Coloring to Training Sum of  $k$  ReLUs.* The NP-hardness of Sum of  $k$  ReLUs Training in fact follows directly from a reduction of [42]. We will now sketch Vu's reduction, since it will be helpful in our subsequent discussions below. Vu's reduction starts from the  $k$ -coloring problem, in which we are given a hypergraph  $G = (V, E)$  and the goal is to determine whether there is a proper  $k$ -coloring<sup>8</sup> of the hypergraph. Given an instance  $G = (V, E)$  of  $k$ -coloring, the number of dimensions in the training problem will be  $n = |V|$  where we associate each dimension with a vertex. Notice that now we have  $k$  unknowns associated to each vertex  $v$ :  $w_v^1, \dots, w_v^k$ . In the desired solution, these variables will tell us which color  $v$  is assigned to: specifically,  $w_v^i > 0$  iff  $v$  is colored  $i$  and  $w_v^i \leq 0$  otherwise.

Adding a labelled sample  $(\mathbf{x}, y)$  is the same as adding a "constraint"  $[\mathbf{w}^1 \cdot \mathbf{x}]_+ + \dots + [\mathbf{w}^k \cdot \mathbf{x}]_+ = y$ . There are two types of constraints we will add:

- (Vertex Constraint) For every vertex  $v \in V$ , we add a constraint<sup>9</sup>  $[w_v^1]_+ + \dots + [w_v^k]_+ = 1$ . This constraint ensures that, for every  $v \in V$ , we must have  $w_v^{i_v} > 0$  for at least one  $i_v \in [k]$ , meaning that the vertex  $v$  is assigned at least one color.
- (Hyperedge Constraint) For every hyperedge  $e = \{v_1, \dots, v_\ell\} \in E$ , we add a constraint<sup>10</sup>  $[w_{v_1}^1 + \dots + w_{v_\ell}^1]_+ + \dots + [w_{v_1}^k + \dots + w_{v_\ell}^k]_+ = 0$ . This ensures that the hyperedge  $e$  is not monochromatic. Otherwise, we have  $i_{v_1} = \dots = i_{v_\ell}$  meaning that  $w_{v_1}^{i_{v_1}} + \dots + w_{v_\ell}^{i_{v_1}} > 0$ , which violates the hyperedge constraint.

This finishes our summary of Vu's reduction, which gives the NP-hardness of training a (non-negative) sum of  $k$  ReLUs.

*Step II: Handling Negative Coefficients.* The argument above, especially for the hyperedge constraints, relies on the fact that the coefficient vector  $\mathbf{a}$  is the all-one vector. In other words, even if the input hypergraph is not  $k$ -coloring, it is still possible that there is a  $k$ -ReLU (possibly negative weight vector  $\mathbf{a}$ ) that realizes the samples. Hence, the reduction above does not yet work for our original problem of  $k$ -ReLU Training. To handle this issue, we use an additional gadget which is simply a set of labelled samples with the following properties: these samples can be realized by a  $k$ -ReLU only when the weight vectors  $\mathbf{a}$  is the

<sup>8</sup> A proper  $k$ -coloring is a mapping  $\chi : V \rightarrow [k]$  such that no hyperedge is monochromatic, or equivalently  $|\chi(e)| > 1$  for all  $e \in E$ .

<sup>9</sup> This constraint corresponds to  $\mathbf{x}$  being the  $v$ -th vector in the standard basis and  $y = 1$ .

<sup>10</sup> This constraint corresponds to  $\mathbf{x}$  being the indicator vector of  $e$  and  $y = 0$ .

all-one vector. Essentially speaking, by adding these samples also to our sample set, we have forced  $\mathbf{a}$  to be the all-one vector, at which point we restrict ourselves back to the case of (non-negative) sum of  $k$  ReLUs and we can use the hard instance from the above reduction from  $k$ -coloring. These are the main ideas of the proof of Theorem 8.

*Tight Running Time Lower Bound.* As stated earlier, the tight running time lower bound for the bounded  $k$ -ReLU Training problem (Theorem 10) follows from a similar reduction, except that we now have to (1) carefully select the number of copies of each sample and (2) scale the labels  $y_i$ 's down so that the norm of each of  $\mathbf{w}^1, \dots, \mathbf{w}^k$  is at most one. Roughly speaking, this means that the labels for the vertex constraints become  $\Theta(1/\sqrt{|V|})$  instead of 1 as before. In other words, each violated constraint roughly contributes to  $\Theta(1/|V|)$  squared error. Since it is known (assuming Gap-ETH) that distinguishing between a  $k$ -colorable hypergraph and a hypergraph for which every  $k$ -coloring violates a constant fraction of the edges takes  $2^{\Omega(|V|)}$  time (e.g. [33]), we can arrive at the conclusion that solving the bounded  $k$ -ReLU Training problem to within an additive squared error of  $\epsilon = \Theta(1/|V|)$  must take  $2^{\Omega(1/|V|)} = 2^{\Omega(1/\epsilon)}$  time as desired.

We remark here that, interestingly, [42] used the reduction from  $k$ -coloring only for the case of  $k = 2$  units and employed an additional gadget to handle the case  $k > 2$ . To the best of our knowledge, this approach seems to decrease the resulting error  $\epsilon$ , which means that the running time lower bound is not of the form  $2^{\Omega(1/\epsilon)}$ . On the other hand, we argue the hardness directly from  $k$ -coloring for any constant  $k \geq 2$ . This, together with a careful selection of the number of copies of each sample, allows us to achieve the running time lower bound in Theorem 10.

## Training and Learning Algorithms

Our  $k$ -ReLU training algorithm is based on the approach of [4]. The main idea behind the algorithm is to iterate over all possible sign patterns (whether each ReLU is active or not) of the inputs and subsequently solve the so formed convex optimization for each fixed pattern. The best hypothesis over all different sign patterns is chosen as the final hypothesis. It is not hard to see that the run-time for such an algorithm would be  $2^{(m+1)k} \text{poly}(n)$  since there are  $2^{mk}$  different sign patterns.

Using standard generalization bounds, one can show that the number of samples  $m$  needed for the empirical loss to be  $\epsilon$  close to the true loss is at most  $O(k^4/\epsilon^2)$ . Plugging this into the above algorithm gets us the desired running time ( $2^{O(k^5/\epsilon^2)} \text{poly}(n, m)$  as in Theorem 5) for the agnostic setting. For the realizable setting, we use an improved generalization result of [39], which implies that  $m = \tilde{O}(k^2/\epsilon)$  suffices; plugging this into the above algorithm yields us Theorem 9.

## 3 Conclusions and Open Questions

We have studied the computational complexity of training depth-2 networks with the ReLU activation function providing both NP-hardness results and algorithms for training ReLU's. Along the way we have introduced and used a new hypothesis regarding the hardness of approximating the Denset  $\kappa$ -Subgraph problem in subexponential time that may find applications in other settings. Our results provide a separation between proper and improper learning showing that for a single ReLU, proper learning is likely to be harder than improper learning. Our hardness results regarding properly learning shallow networks suggest that improperly learning such networks (for example, learning overparametrized networks whose number of units far exceeds the dimension of the labeled vectors [2, 19]) might be necessary to allow for tractable learning problems.

We stress here that our hardness results apply to minimizing the population loss<sup>11</sup> as well, since one may simply create an instance where the population is just the training data. Furthermore, the standard procedure for training neural networks is to perform ERM which is essentially minimizing the training loss. In fact, a bulk of theoretical work in the field focuses on generalization error assuming training error is small (often 0). Therefore, we believe it is a natural question to study the hardness of minimizing training loss.

Neural networks offer many choices (e.g., number of units, depth, choice of activation function, weight restrictions). Indicating which architectures are NP-hard to train can prove useful in guiding the search for a mathematical model of networks that can be trained efficiently. It should be remembered that our NP-hardness results are worst-case. Therefore they do not preclude efficient algorithms under additional distributional or structural assumptions [34]. Finally, as we focus on networks having significantly fewer units than data-points, the NP-hardness results reported here are not at odds with the ability to train neural networks in the overparameterized regime where there are polynomial time algorithms that can fit the data with zero error [43].

While we restrict our attention to algorithms for training networks with bounded weights, our exponential dependency of the running time on  $k$  (the number of units) makes these algorithms impractical. It remains an interesting question whether the dependency of the running time on  $k$  can be improved, or alternatively whether strong running time lower bounds can be shown in terms of  $k$  (similar to what is done for  $\epsilon$  in this work).

While we have focused on depth-2 networks, algorithms and lower bounds for deeper networks are of interest as well, especially given the multitude of their practical applications. It would be interesting to see whether the algorithms and hardness results extend to the setting of depth greater than 1. An interesting concrete question here is whether training/learning becomes harder as the network becomes deeper. For instance, is it possible to prove running time lower bounds that grow with the depth of the network?

## Abstract

For a polynomial  $f$ , we study the *sum of squares representation (SOS)*, i.e.  $f = \sum_{i \in [s]} c_i f_i^2$ , where  $c_i$  are field elements and the  $f_i$ 's are polynomials. The size of the representation is the number of monomials that appear across the  $f_i$ 's. Its minimum is the *support-sum*  $S(f)$  of  $f$ .

For simplicity of exposition, we consider univariate  $f$ . A trivial lower bound for the support-sum of, a full-support univariate polynomial,  $f$  of degree  $d$  is  $S(f) \geq d^{0.5}$ . We show that the existence of an explicit polynomial  $f$  with support-sum just slightly larger than the trivial bound, that is,  $S(f) \geq d^{0.5+\varepsilon(d)}$ , for a sub-constant function  $\varepsilon(d) > \omega(\sqrt{\log \log d / \log d})$ , implies that  $\text{VP} \neq \text{VNP}$ . The latter is a major open problem in algebraic complexity. A further consequence is that blackbox-PIT is in SUBEXP. Note that a random polynomial fulfills the condition, as there we have  $S(f) = \Theta(d)$ .

We also consider the *sum-of-cubes representation (SOC)* of polynomials. In a similar way, we show that here, an explicit hard polynomial even implies that blackbox-PIT is in P.

## 1 Introduction

The sum-of-squares representation (SOS) is one of the most fundamental in number theory and algebra. Lagrange's four-squares theorem inspired generations of mathematicians [27]. Hilbert's *17th problem* asks whether a multivariate polynomial, that takes only non-negative values over the reals, can be represented as an SOS of rational functions [26]. In engineering, SOS has found many applications in approximation, optimization and control theory, see [28, 18, 19, 4]. In this work, we show a connection to central complexity questions.

Consider the following basic problem on the size of SOS-representations.

► **Open Problem.** *Exhibit an explicit univariate polynomial  $f(x) \in \mathbb{C}[x]$  of degree  $d$  such that any SOS-representation  $f(x) = \sum_i f_i(x)^2$  requires  $\sum_i \text{sparsity}(f_i) > \omega(\sqrt{d})$ .*

Before delving into the meaning of *explicitness*, note that  $\Omega(\sqrt{d})$  is a trivial lower bound, for a polynomial of degree  $d$ , with full support (by counting monomials). Moreover, for most polynomials  $f$ , a larger lower bound of  $\Omega(d)$  holds, by a dimension argument. In other words, we ask for an explicit polynomial  $f(x)$  that has a merely largish  $\sum \wedge^2 \sum \wedge$ -formula. We show that one can bootstrap the seemingly weak hardness condition for SOS to general circuits (see Theorem 6) and to the infamous *determinant vs. permanent* question (see Corollary 14).

## 1.1 Algebraic circuits and univariate polynomials

Valiant defined the algebraic complexity classes VP and VNP based on algebraic circuits (for definitions see Section 2). They are considered as the algebraic analog of boolean classes P and NP. Separating VP from VNP is a long-standing open problem. One of the popular ways has been via depth-reduction results [3, 14, 10, 36]. It seems that showing strong lower bounds require a deeper understanding of the algebraic-combinatorial structure of circuits, which may be easier to unfold for more analytic models that appear in wider mathematics.

It is known that most of the polynomials of degree  $d$  are *hard*, i.e. they require  $\Omega(d)$  size circuits; for a self-contained proof, see [7, Theorem 4.2]<sup>1</sup>. In fact, for  $p_i$  being the  $i$ -th prime,  $\sum_{i=0}^d \sqrt{p_i} x^i$  and  $\sum_{i=0}^d 2^{2^i} x^i$ , both require circuits of size  $\Omega(d/\log d)$ , see [6, Cor.9.4] & [35]. Such polynomials can be converted to an *exponentially hard* multilinear polynomial  $f_n(\mathbf{x})$ . Unfortunately, this *strong* lower bound is insufficient to separate VP and VNP because the polynomial family is *non-explicit*—so  $f_n$  may not be in VNP. For details, see [11, 5].

Thus, the explicitness of the family plays a major role in its usefulness in algebraic complexity.

► **Definition 1 (Explicit functions).** *Let  $(f_d)_d$  be a polynomial family, where  $f_d(x)$  is of degree  $d$ . The family is explicit, if its coefficient-function is computable in time  $\text{poly} \log(d)$  and each coefficient can be at most  $\text{poly}(d)$ -bits long. The coefficient-function gets input  $(j, i, d)$  and outputs the  $j$ -th bit of the coefficient of  $x^i$  in  $f_d$ .*

Alternative versions of explicitness define the coefficient-function to be computable in  $\#P/\text{poly}$  or in the *counting hierarchy* CH, which would be good enough for our purpose (see Theorem 13).

An *explicit* candidate for the hard family is the *Pochhammer-Wilkinson* polynomial,  $f_d(x) := \prod_{i=1}^d (x - i)$ . Other explicit families, but *not* hard, are  $(x + 1)^d$  and the *Chebyshev* polynomial (that writes  $\cos d\theta$  as a function of  $\cos \theta$ ) [22]. These three are quite relevant to this work.

The interplay between proving lower bounds and derandomization is one of the central themes in complexity theory [24]. Blackbox Polynomial Identity Testing (PIT) asks for an algorithm to test the zeroness of a given algebraic circuit via mere query access. It is still an open question to design an efficient deterministic PIT algorithm. A circuit of size  $s$  can have  $\exp(s)$  many monomials. However, since a non-zero polynomial evaluated at a random point is non-zero with high probability (by the *Polynomial Identity Lemma* [25, 8, 41, 33]), one gets a randomized poly-time algorithm for PIT. For PIT refer [31, 32, 34, 23, 39].

<sup>1</sup> The size-bound in the previous such proofs usually counted only the number of nodes in the circuit, achieving square-root in the bound; we use the number of nodes and edges here.

One important direction, from hardness to derandomization, is to design deterministic PIT algorithms for small circuits assuming access to *explicit hard polynomials* [24, 13]. Most of the constructions use the concept of *hitting-set generator* (HSG), see Definition 33. Very recent work discovered that PIT is amenable to the phenomenon of *bootstrapping* (w.r.t. variables) [2, 17]. Finally, Guo et al. [9] showed: ample circuit-hardness of *constant-variate* polynomials (including univariate) implies blackbox-PIT in P.

## 1.2 Sum-of-squares model (SOS)

We want to relate variants of SOS to PIT and circuit lower bounds. Towards that, we show a connection between large SOS representation and hard polynomials; strong enough to imply  $\text{VP} \neq \text{VNP}$  and subsequently  $\text{PIT} \in \text{SUBEXP}$ . This is mainly achieved by an SOS-decomposition result for circuits via Algebraic Branching Programs (ABP) (for definition see Section 2). It expresses any  $d$ -degree polynomial  $f(\mathbf{x})$  of circuit size  $s$  as sum of squares of polynomials with degree at most  $d/2$ . We manage the top-fanin of SOS within a quasi-polynomial blow-up. Finally, we apply a careful *multi-linearization* trick to convert the hardness from the univariate SOS-model to general circuits.

► **Definition 2** (SOS and support-sum size  $S_R(f)$ ). *Let  $R$  be a ring. An  $n$ -variate polynomial  $f(\mathbf{x}) \in R[\mathbf{x}]$  is represented as a (weighted) sum-of-squares (SOS), if*

$$f = \sum_{i=1}^s c_i f_i^2, \quad (1)$$

for some top-fanin  $s$ , where  $f_i(\mathbf{x}) \in R[\mathbf{x}]$  and  $c_i \in R$ .

The size of the representation of  $f$  in (1) is the support-sum, the sum of the support size (or sparsity) of the polynomials  $f_i$ . The support-sum size of  $f$ , denoted by  $S_R(f)$ , is defined as the minimum support-sum of  $f$ .

► **Remark 3.** In real analysis, the SOS representation of a polynomial is defined without the coefficients  $c_i$ , that is, only for non-negative polynomials  $f$ . In these terms, what we define in (1) is a *weighted* SOS. However, we will skip the term “weighted” in the following.

If we consider the expression in (1) as a  $\sum \bigwedge^2 \sum \prod$ -formula, then the support-sum is the number of  $\prod$ -operations directly above the input level.

For any  $N$ -variate polynomial  $f$  of degree  $d$ . Let  $|f|_0$  denote the sparsity of  $f$ . For any field  $R = \mathbb{F}$  of characteristic  $\neq 2$ , we have

$$|f|_0^{1/2} \leq S_{\mathbb{F}}(f) \leq 2|f|_0 + 2. \quad (2)$$

The lower bound can be shown by counting monomials. The upper bound is because

$$f = (f+1)^2/4 - (f-1)^2/4. \quad (3)$$

In particular, the SOS-model is *complete* for any field of characteristic  $\neq 2$ . It can be argued by a geometric-dimension argument that for most  $N$ -variate (constant  $N \geq 1$ ) polynomials  $f$  of degree  $d$ , we have  $S_{\mathbb{F}}(f(\mathbf{x})) = \Theta(d^N)$ , as for random  $f$ ,  $|f|_0 = \Theta(d^N)$ .

We want to explore how  $S_{\mathbb{F}}(f_d)$  behaves w.r.t.  $d$ , for *explicit* families  $(f_d)_d$ , that is, the coefficient-function of the family is computable in time  $\text{poly}(\log d)$ . We call a polynomial family SOS-hard, if its support-sum is just *slightly* larger than the trivial lower bound from (2).

► **Definition 4** (SOS-hardness). *For constant  $N \geq 1$ , an explicit  $N$ -variate polynomial family  $(f_d(\mathbf{x}))_d$  is SOS-hard, if  $S_{\mathbb{F}}(f_d) = \Omega(d^{N(0.5+\varepsilon)})$ , where  $\varepsilon := \varepsilon(d) = \omega\left(\sqrt{\frac{\log \log d}{\log d}}\right)$  is a sub-constant function.*

► **Remark 5.**

1. For our purpose we could relax the explicitness condition such that the  $j$ -th bit of  $\text{coef}_{\mathbf{x}^i}(f_d)$  is computable in  $\text{poly}(2^{1/\varepsilon})$  time. This makes the family *barely explicit* w.r.t.  $d$ . In fact,  $\#P/\text{poly}$  w.r.t.  $2^{1/\varepsilon}$  works too. Eg.  $f_d = \sum_{i \in [d]} 2^{i^2} x^i$  is an easy candidate for  $N = 1$ .
2.  $\Omega(d^{N(0.5+\varepsilon)})$ , instead of  $\Omega(d^N)$ , which is the expected bound for most  $f_d$ , is a much weaker requirement. In fact, the trivial lower bound is  $S(f_d) \geq \Omega(d^{N/2})$ . Thus, we demand just a tiny improvement over the trivial bound, namely, by a factor of  $d^{N\varepsilon} = d^{o(1)}$ . For example,  $(\log d)^{\sqrt{\log d}}$  is such a function that works in  $d^\varepsilon$ .

### 1.3 Our results for SOS

Algebraic circuits are quite well-structured, for eg. , there is a famous depth- $O(\log d)$  reduction result [38, 34, 29]. Its proof methods implicitly establish (see Lemma 28) that an  $n$ -variate, degree  $d$  polynomial  $f(\mathbf{x})$ , computed by a circuit of size  $s$ , can be rewritten as

$$f(\mathbf{x}) = \sum_{i=1}^{O(sd^2)} c_i f_i(\mathbf{x})^2, \quad (4)$$

for  $c_i \in \mathbb{F}$  and  $f_i \in \mathbb{F}[\mathbf{x}]$ , where each  $f_i$  has circuit size at most  $O(sd^2)$  and  $\deg(f_i) \leq 2d/3$ , for all  $i$ . Moreover, with a larger, *quasi*-polynomial blowup in the top-fanin, we bring down the degree really to  $d/2$  (via Algebraic Branching Programs (ABP)); for the details, see Section 3.1.

► **Main Lemma** (SOS Decomposition). *Let  $\mathbb{F}$  be a field of characteristic  $\neq 2$ . Let  $f(\mathbf{x})$  be an  $n$ -variate polynomial over  $\mathbb{F}$  of degree  $d$ , computed by a circuit of size  $s$ . Then there exist  $f_i \in \mathbb{F}[\mathbf{x}]$  and  $c_i \in \mathbb{F}$  such that  $f(\mathbf{x}) = \sum_{i=1}^{s'} c_i f_i(\mathbf{x})^2$ , for  $s' \leq (sd)^{O(\log d)}$  and  $\deg(f_i) \leq \lceil d/2 \rceil$ , for all  $i \in [s']$ .*

The leitmotif of this paper is the interplay between SOS-hardness and derandomization/hardness questions in algebraic complexity. Could a barely explicit and mildly hard polynomial in the SOS-model settle the VP vs. VNP question? We evince a positive answer.

► **Theorem 6** (Circuit hardness). *If there exists an SOS-hard family, then  $\text{VP} \neq \text{VNP}$ .*

► **Remark 7.**

1. Our proof-method from constant- $N$ -variate SOS-hardness to  $\text{VP} \neq \text{VNP}$  is essentially the same as the one for  $N = 1$  (eg. replace  $d$  by  $d^N$ ). So, for simplicity of exposition, from now on we will focus on univariate SOS-hardness.
2. In the *non-commutative* setting, lower bound on sum-of-squares (of multivariates) implies that Permanent is hard [12]. Our theorem can be seen as its natural analog in the commutative setting; where potential cancellations could give smaller representations.
3. Another simple candidate for SOS-hardness is  $f_d = (x+1)^d$  (though, by repeated squaring, it has circuit size  $\Theta(\log d)$ ). However, its coefficients are not  $\text{poly} \log(d)$ -time explicit. Nevertheless, from its CH-explicitness, and GRH, the theorem does hold. Similarly, for the polynomial family,  $f_d(x) = \prod_{i \in [d]} (x-i)$  and  $f_d(x) = \sum_{0 \leq i \leq d} x^i / i!$ , and Chebyshev polynomials.

4. In the theorem and Equation (1), we could restrict the degrees of  $f_i$  to be  $O(d\varepsilon \log d) = d \cdot o(\log d)$  and the top-fanin  $s = d^{o(\varepsilon)} = d^{o(1)}$ . (Also, Corollary 14 works with analogously weaker  $\varepsilon$ .) This might help in constructing polynomials with a weaker SOS-hardness notion. See Section 3.2 for more details.
5. A stronger SOS-hardness notion with *constant*  $\varepsilon$ , gives an *exponential* separation between VP and VNP. This proof has many technical differences; refer to Theorem 32 for the details.

Hardness of general circuits often leads to nontrivial *derandomization* [24, 13, 2, 9]. Our methods in Theorem 6 consequently put blackbox-PIT in SUBEXP [13, Thm. 7.7]. In fact, if  $\varepsilon$  is a constant, then it puts blackbox-PIT  $\in$  QP (*Quasi*-polynomial-time) (Theorem 32).

## 1.4 Sum-of-cubes model (SOC)

We show that a strong lower bound in the sum-of-cubes model leads to a *complete* derandomization of blackbox-PIT. We say that an  $n$ -variate polynomial  $f(\mathbf{x}) \in R[\mathbf{x}]$  over a ring  $R$  is computed as a *sum-of-cubes* (SOC), if

$$f = \sum_{i=1}^s c_i f_i^3, \quad (5)$$

for some top-fanin  $s$ , where  $f_i(\mathbf{x}) \in R[\mathbf{x}]$  and  $c_i \in R$ .

► **Definition 8** (Support-union size  $U_R(f, s)$ ). *The size of the representation of  $f$  in (5) is the size of the support-union, namely the number of distinct monomials in the representation,  $|\bigcup_{i=1}^s \text{supp}(f_i)|$ , where  $\text{supp}(f_i)$  denotes the set of monomials with a nonzero coefficient in the polynomial  $f_i(\mathbf{x})$ . The support-union size of  $f$  with respect to  $s$ , denoted  $U_R(f, s)$ , is defined as the minimum support-union size when  $f$  is written as in (5).*

If we consider the expression in (5) as a  $\sum \wedge^3 \sum \Pi$ -circuit, then the support-union size is the number of  $\Pi$ -operations directly above the input level (unlike  $\sum \wedge^2 \sum \Pi$ -formula in Definition (2)).

The two measures—support-union and support-sum—are largely incomparable, since  $U(\cdot)$  has the extra argument  $s$ . Still one can show:  $S_{\mathbb{F}}(f) \geq \min_s (U_{\mathbb{F}}(f, 4s) - 1)$  (Lemma 26).

For any polynomial  $f$  of sparsity  $|f|_0$ , we have

$$|f|_0^{1/3} \leq U_{\mathbb{F}}(f, s) \leq |f|_0 + 1, \quad (6)$$

where the upper bound is for  $s \geq 3$  and for fields  $R = \mathbb{F}$  of characteristic  $\neq 2, 3$ . The lower bound can be shown by counting monomials. The upper bound is because

$$f = (f+2)^3/24 + (f-2)^3/24 - f^3/12. \quad (7)$$

Hence, the SOC-model is *complete* for any field of characteristic  $\neq 2, 3$ .

For simplicity, fix #variables  $N = 1$ . Here are two more examples (that we know of) for the trade-off between  $s$  and the measure  $U_{\mathbb{F}}(f, s)$ , for any  $f$ .

### ► Example 9.

1. For small  $s = \Theta(d^{1/2})$ , we have  $U_{\mathbb{F}}(f, s) = O(d^{1/2})$  (Corollary 23).
2. For large  $s = \Omega(d^{2/3})$ , we have  $U_{\mathbb{F}}(f, s) = \Theta(d^{1/3})$  (Theorem 24).

However, it is unclear whether, over  $\mathbb{F} = \mathbb{Q}$ , for a very small fanin  $s$ , support-union  $= o(d)$  exists. This trade-off between the measure  $U$  and the top-fanin  $s$  in the above examples, motivated us to define hardness in the SOC-model as follows.

► **Definition 10** (SOC-hardness). A  $\text{poly}(d)$ -time explicit univariate polynomial family  $(f_d)_d$  is SOC-hard, if there exists a positive constant  $\varepsilon' < 1/2$  such that  $U_{\mathbb{F}}(f_d, d^{\varepsilon'}) = \Omega(d)$ .

## 1.5 Our results for SOC

Though technically incomparable, the SOC-hardness feels stronger than SOS-hardness (for  $N = 1$ ); indeed it can be used to prove a connection like Theorem 6. Now, we show an even stronger consequence – a complete derandomization of blackbox-PIT.

► **Theorem 11** (Derandomization). *If there is an SOC-hard family, then blackbox-PIT  $\in \mathsf{P}$ .*

► **Remark 12.**

1. Older results too lead to various conditional derandomizations. E.g. *multi*-variate hard polynomials lead to blackbox-PIT  $\in \mathsf{QP}$  (*quasipoly-time*) [13, 2]. Recently, [9] showed that the *circuit* hardness of a constant-variate polynomial family yields blackbox-PIT  $\in \mathsf{P}$  (Theorem 34). Our hardness assumption is merely in the SOC-model. In fact, SOC is the *first* restricted model where hardness implies *complete* derandomization.
2. For Theorem 11, we could restrict the degrees of  $f_i$ , to be  $O(d)$ . See Section 3.3, Remark 3.3.

## 1.6 Basic arguments

There have been a series of works that connect the hardness in restricted univariate (resp. constant-variate) models to VP vs. VNP and the PIT problem. This work is more about remodeling the major questions in the *simplest* format possible. We show how to transfer the hardness of a (univariate) polynomial family in the SOS, resp. SOC-model, to a hard (multivariate) polynomial family in the circuit-model. To do so, we adapt the existing powerful techniques to our setting. Intuitively, one would expect that the analytic nature of SOS and SOC (over  $\mathbb{R}$  or  $\mathbb{C}$ ) makes it easier to prove hardness in these models than for general circuits. In any case, we show that this would suffice to solve central questions in algebraic complexity.

The gap between the SOS-model and general circuits is mainly bridged by a decomposition lemma (Main Lemma) which emerges via ABPs. Frontiers based depth-reduction [38] implicitly shows that any polynomial  $f(\mathbf{x})$  of degree  $d$ , computed by a homogeneous circuit of size  $s$ , can be decomposed as  $f(\mathbf{x}) = \sum_{i=1}^s f_{i1} \cdot f_{i2}$ , where  $\deg(f_{ij}) \leq 2d/3$  and  $\text{size}(f_{ij}) \leq O(s)$ ; for a proof see Lemma 28. However, such proof strategies can never give intermediate polynomials of degree *exactly*  $d/2$ , simply because degree  $\approx d/2$  polynomial may not even *exist* in the computation tree, and thus, frontiers at appropriate layers do not really help. However, in the case of *homogeneous* ABPs, the intermediate degrees increase gradually, as the labels are *linear* forms. In particular, a layer of vertices computing degree *exactly*  $d/2$  exists. By cutting the ABP, say, of width  $w$ , at the  $d/2$ -th layer, we get  $f = (f_1, \dots, f_w)^T \cdot (f'_1, \dots, f'_w) = \sum_{i=1}^w f_i \cdot f'_i$ . This directly gives an SOS-form of top-fanin at most  $2w$ . The conversion from a homogeneous circuit to a homogeneous ABP is pretty straight-forward in the literature. Use log-depth-reduction [38] and induct on the depth to conclude that  $s^{O(\log d)}$ -size ABP exists. Finally, homogenize the ABP with a polynomial blowup in size. (See [16, Lem.15] or [29].)

**Proof idea of Theorem 6.** The main idea in Theorem 6 is to lift the hardness of  $f = f_d$  in the SOS-model to a multivariate polynomial, which we prove to be super-polynomially hard in the general circuit model (implying  $\notin \mathsf{VP}$ ) and explicit (implying  $\in \mathsf{VNP}$ ). Usually, to convert a univariate polynomial to multivariate, (inverse) Kronecker type substitution is used; here we *do not* use the Kronecker due to a technical barrier and the reason will

be addressed in the next paragraph. Instead, we use a *multilinear* map  $\phi$  that sends  $x^i$  to  $\phi(x^i) := \prod_{j \in [n], \ell \in [0 \dots k-1]} y_{j,\ell}$ , where  $\ell \cdot k^{j-1}$  contributes to the  $\text{base}_k(i)$ -representation in the  $j$ -th position;  $n$  and  $k$  are both functions of  $d$  to be fixed. Consider, by linear extension,  $\phi(f) =: P_{n,k}$ . By construction  $P_{n,k}$  is a  $kn$  variate  $n$  degree multilinear polynomial. With appropriate parameter fixing, we show that  $\text{size}(P_{n,k}) = (kn)^{\omega(1)}$ . The proof goes via contradiction. If the size is smaller, then using Main Lemma, we get  $P_{n,k}$  as sum of  $d^{o(\varepsilon)}$ -many  $Q_i^2$ 's; where the intermediate polynomial  $Q_i$  ( $kn$ -variate) has degree at most  $n/2$ . Thus, a naive upper bound on the support-sum (after proper parameter fixing) is  $d^{o(\varepsilon)} \cdot \binom{kn+n/2}{n/2} < d^{o(\varepsilon)} \cdot d^{1/2+\varepsilon/2} = o(d^{1/2+\varepsilon})$ , a contradiction to the SOS-hardness!

Here we remark that Kronecker type substitution *does not* give the desired result. It basically maps a monomial  $x^e$  to  $\mathbf{x}^e$ , where  $\mathbf{e} := \text{base}_{(n+1)}(e)$  for some  $n$ ; then  $n$  is the individual-degree in the image, and  $(n+1)^k \geq d+1 > n^k$ . However, this map converts  $f$  to be a  $k$ -variate, individual-degree  $n$  polynomial family and the naive binomial upper-bound on the number of terms would be  $\binom{k+kn/2}{k} > (n+1)^k > d$ ; which is useless. (Here we use  $kn/2$  as the degree of  $P_{n,k}$  is  $kn$  while the degree of the intermediate polynomial halves.) Thus, the multi-linearization trick, along with the SOS decomposition lemma via ABPs, are indispensable in our proof.

**Proof idea of Theorem 11.** The proof of Theorem 11 works very differently than that of Theorem 6. As its goal is to devise an amply hard polynomial with a *constant* number of variables only; it limits our tricks quite a bit.<sup>2</sup> It uses (inverse) Kronecker map to construct  $P_{n,k}$  from  $f = f_d$ , a constant- $k$ -variate, individual-degree  $n$  polynomial. We show this polynomial to be  $s = n^{\Omega(1)}$  hard. Recall that an explicit constant-variate *circuit*-hard polynomial can be used as an efficient hitting-set generator; showing blackbox-PIT  $\in \mathsf{P}$  [9]. The hardness result organically comes from a *SOC decomposition lemma* (Lemma 16); using a “constant-boosting” of frontier-based Lemma 28 and a “greedy clustering”. Basically, we show that any homogeneous polynomial  $P(\mathbf{x})$  of degree  $d$ , computed by a homogeneous circuit of size  $s'$ , can be written as  $P(\mathbf{x}) = \sum_{i=1}^{\text{poly}(s')} c_i \cdot Q_i(\mathbf{x})^3$ , where  $\deg(Q_i) \leq 4d/11$ .<sup>3</sup> Applying this to each homogeneous part of  $P_{n,k}$ , and then Kronecker substitution would show (with proper parameter fixing) that  $U_{\mathbb{F}}(f) \leq |\bigcup_{i=1}^{\text{poly}(s,n)} \text{supp}(Q_i)| \leq \binom{k+4kn/11}{k} < c \cdot d$ , for *any* positive constant  $c$ . We use Eqn.(8) to bound the binomial and reach a contradiction. The constant  $4/11$  is nothing special; any constant in  $(1/3, 1/e)$  would work.

Here, we remark that [9] works for constant  $k$ . Thus, any naive upper bound on the support-union size (under the optimal decomposition) would give  $\binom{k+kn/3}{k} = \Theta(d)$ . Hence, the strongest demand of  $\Omega(d)$  is required.

## 2 Preliminaries

**Basic notation.** We work with  $\mathbb{F} = \mathbb{Q}, \mathbb{Q}_p$ , or their fixed extensions. Our results hold also for large characteristic (required for Thm. 11 using [9], and Thm 13 & Lemma 19).

Let  $[n] = \{1, \dots, n\}$ . For  $i \in \mathbb{N}$  and  $b \geq 2$ , we denote by  $\text{base}_b(i)$  the unique  $k$ -tuple  $(i_1, \dots, i_k)$  such that  $i =: \sum_{j=1}^k i_j \cdot b^{j-1}$ .

<sup>2</sup> Eg. the failure analysis above with  $\binom{k+kn/2}{k}$  is also partly the reason why SOS can't give complete PIT.

<sup>3</sup> We cannot use such a decomposition lemma using ABPs, as the *super*-polynomial blowup in the fanin, owing to the larger degree ( $\approx d^{1/k}$ ), would fail to prove the desired circuit-hardness of the resulting polynomial family.

For binomial coefficients, we use an easy bound based on the  $e^k$ -series [40], for  $1 \leq k \leq n$ ,

$$\left(\frac{n}{k}\right)^k \leq \binom{n}{k} \leq \left(\frac{en}{k}\right)^k. \quad (8)$$

**Polynomials.** For  $p \in \mathbb{F}[\mathbf{x}]$ , where  $\mathbf{x} = (x_1, \dots, x_m)$ , for some  $m \geq 1$ , the *support* of  $p$ , denoted by  $\text{supp}(p)$ , is the set of nonzero monomials in  $p$ . *Sparsity* or *support size* of  $p$  is  $|p|_0 := |\text{supp}(p)|$ . By  $\text{coef}(p)$  we denote the *coefficient vector* of  $p$  (in some fixed order).

For an exponent vector  $\mathbf{e} = (e_1, \dots, e_k)$ , we use  $\mathbf{x}^{\mathbf{e}}$  to denote the monomial  $x_1^{e_1} \dots x_k^{e_k}$ .

**Algebraic circuits.** An *algebraic circuit* over a field  $\mathbb{F}$  is a layered directed acyclic graph that uses field operations  $\{+, \times\}$  and computes a polynomial. It can be thought of as an algebraic analog of boolean circuits. The leaf nodes are labeled with the input variables  $x_1, \dots, x_n$  and constants from  $\mathbb{F}$ . Other nodes are labeled as addition and multiplication *gates*. The root node outputs the polynomial computed by the circuit.

Complexity parameters of a circuit are: **1)** the *size*, i.e. number of edges and nodes, **2)** the *depth*, i.e. number of layers, **3)** the *fan-in*, i.e. maximum number of inputs to a node, (resp. the *fan-out*, i.e. maximum number of outputs of a node).

When the graph is in fact a tree, i.e., the fan-out is 1, we call the circuit an *algebraic formula*.

For a polynomial  $f$ , the size of the smallest circuit computing  $f$  is denoted by  $\text{size}(f)$ , it is the *algebraic circuit complexity* of  $f$ . By  $\mathcal{C}(n, D, s)$ , we denote the set of circuits  $C$  that compute  $n$ -variate polynomials of degree  $D$  such that  $\text{size}(C) \leq s$ .

In *complexity classes*, we specify an upper bound on these parameters. Valiant's class **VP** contains the families of  $n$ -variate polynomials of degree  $\text{poly}(n)$  over  $\mathbb{F}$ , computed by circuits of  $\text{poly}(n)$ -size. The class **VNP** can be seen as a non-deterministic analog of the class **VP**. A family of  $n$ -variate polynomials  $(f_n)_n$  over  $\mathbb{F}$  is in **VNP** if there exists a family of polynomials  $(g_n)_n$  in **VP** such that for every  $\mathbf{x} = (x_1, \dots, x_n)$  one can write  $f_n(\mathbf{x}) = \sum_{w \in \{0,1\}^{t(n)}} g_n(\mathbf{x}, w)$ , for some polynomial  $t(n)$  which is called the *witness size*. It is straightforward to see that  $\text{VP} \subseteq \text{VNP}$  and *conjectured* to be different (Valiant's Hypothesis [37]). For more details see [20, 34, 6]. Unless specified particularly, we consider the field  $\mathbb{F} = \mathbb{Q}$  (resp. a finite field with large characteristic).

Valiant [37] showed a *sufficient* condition for a polynomial family  $(f_n(\mathbf{x}))_n$  to be in **VNP**. We use a slightly modified version of the criterion and formulate it only for multi-linear polynomials. For a proof see Appendix D.

► **Theorem 13** (Valiant's VNP criterion, [37]). *Let  $f_n(\mathbf{x}) = \sum_{\mathbf{e} \in \{0,1\}^n} c_n(\mathbf{e}) \mathbf{x}^{\mathbf{e}}$  be a polynomial family such that the coefficients  $c_n(\mathbf{e})$  have length  $\leq 2^n$  in binary. Let  $c_{n,j}(\mathbf{e})$  be the  $j$ -th bit of  $c_n(\mathbf{e})$ . Then*

$$c_{n,j}(\mathbf{e}) \in \#P/\text{poly} \implies f_n \in \text{VNP}.$$

**Algebraic branching programs (ABP).** An *algebraic branching program (ABP)* in variables  $\mathbf{x}$  over a field  $\mathbb{F}$  is a directed acyclic graph with a *starting vertex*  $s$  with in-degree zero, an *end vertex*  $t$  with out-degree zero. The edge between any two vertices is labeled by affine form  $a_1x_1 + \dots + a_nx_n + c \in \mathbb{F}[\mathbf{x}]$ , where  $a_i, c \in \mathbb{F}$ .

The *weight of a path* in an ABP is the product of labels of the edges in the path. The *polynomial computed at a vertex*  $v$  is the sum of weights of all paths from the starting vertex  $s$  to  $v$ . The *polynomial computed by the ABP* is the polynomial computed at the end vertex  $t$ .

The polynomial computed by an ABP can be written as a matrix product  $U^T(\prod_i M_i)V$ , where  $U, V \in \mathbb{F}^{w \times 1}$  and  $M_i \in \mathbb{F}[\mathbf{x}]^{w \times w}$  with entries being affine linear forms. The parameter  $w$  is called the *width* of the ABP. The class **VBP** contains the families of polynomials computed by ABPs of size  $\text{poly}(n)$ . This implies that the degree is  $\text{poly}(n)$  too.

An ABP is a very restricted circuit, but still being able to compute determinants [21].

We say that the ABP is *homogeneous*, if the polynomial computed at every vertex is a homogeneous polynomial. It is known that for an ABP  $S$  of size  $s$  computing a homogeneous polynomial  $f$ , there is an equivalent homogeneous ABP  $A'$  of size  $\text{poly}(s)$ , where each edge-label is a *linear form*  $a_1x_1 + \dots + a_nx_n$ . Moreover, when  $f$  has degree  $D$ , then  $A'$  has  $D + 1$  layers and each vertex in the  $i$ -th layer computes a homogeneous polynomial of degree  $= i$  (see [16, Lem.15] or [29]).

Here, we also remark that each homogeneous part of a degree  $d$  polynomial  $f(\mathbf{x})$ , computed by  $s$ -size circuit, can also be computed by a *homogeneous* circuit of size  $O(sd^2)$ ; see [34, 29].

### 3 Proof of the main results

#### 3.1 SOS decomposition of circuits: Proof of Main Lemma

**Proof of Main Lemma.** Let  $C$  be a circuit of size  $s$  computing  $f(\mathbf{x})$ . W.l.o.g.,  $f(\mathbf{x})$  is a homogeneous polynomial (as later we will apply to every homogeneous component of  $f$ ). Using the log-depth reduction of [38], there is a homogeneous circuit  $C'$  of depth  $\log d$  and size  $\text{poly}(s)$  that computes  $F$ .

Now we convert the circuit  $C'$  to a *layered* ABP  $A$  as follows: first, convert the circuit  $C'$  to a formula  $F$ . By induction on the depth of the circuit one can show that  $F$  has size  $s^{O(\log d)}$ . Secondly, we convert  $F$  to an ABP  $A$ . It is well known that for any formula of size  $t$ , there exists an ABP of size at most  $t + 1$ , computing the same polynomial, for details see [30, Lemma 2.14]. Thus, the ABP  $A$  computing  $f$  has size at most  $s^{O(\log d)}$ .

Further, we *homogenize* the ABP  $A$  as explained at the end of the preliminary section. Let  $A'$  be the homogenized ABP computing  $f$ . Its size is  $s' := \text{poly}(s^{O(\log d)}) = s^{O(\log d)}$ .

Finally, cut ABP  $A'$  in half, at the  $\lceil d/2 \rceil$ -th layer, to get:  $f = (f_1, \dots, f_{s'})^T \cdot (f'_1, \dots, f'_{s'})$  where, degree of each  $f_i, f'_i$  is at most  $\lceil d/2 \rceil$ . This can be easily rewritten as SOS by Equation (3). The top-fanin of SOS is at most  $2s'$ .

For a non-homogeneous polynomial  $f(\mathbf{x})$ , we can apply the above for each homogeneous part of  $f(\mathbf{x})$ . It is well known that each homogeneous part can be computed by a homogeneous circuit of size  $O(sd^2)$ . Thus, for non-homogeneous polynomials,  $s$  can be replaced by  $O(sd^2)$ ; hence the top-fanin of SOS is  $(sd^2)^{O(\log d)} = (sd)^{O(\log d)}$ .  $\blacktriangleleft$

#### 3.2 SOS-hardness to VP $\neq$ VNP: Proof of Theorem 6

**Proof of Theorem 6.** We will construct an explicit (multivariate) polynomial family, using SOS-hard univariate  $f_d$ , which is not in VP, but is in VNP. This would imply that VP  $\neq$  VNP.

**Construction.** We will construct  $(P_{n,k})_k$  from  $f_d$ , where  $P_{n,k}$  is a multilinear degree- $n$  and  $kn$ -variate polynomial, for  $n = n(d)$  and  $k = k(d)$ <sup>4</sup>. We will specify  $k$  and  $n$  in the course of the proof. The basic relation between  $d, n$  and  $k$  is that  $k^n \geq d + 1 > (k - 1)^n$ . Introduce  $kn$  many new variables  $y_{j,\ell}$ , where  $1 \leq j \leq n$  and  $0 \leq \ell \leq k - 1$ . Let  $\phi_{n,k}$  be the map,

$$\phi_{n,k} : x^i \mapsto \prod_{j=1}^n y_{j,i_j}, \text{ where } i =: \sum_{j=1}^n i_j \cdot k^{j-1}, \quad 0 \leq i_j \leq k - 1.$$

<sup>4</sup> In this section think of  $n$  as a *tiny* function of  $k$ . Thus indexing the family over  $k$  suffices.

## 23:10 Largish SOS Implies Circuit Hardness

Note: for  $i \in [0, d]$ ,  $\phi_{n,k}$  maps  $x^i$  uniquely to a multilinear monomial of degree  $n$ . By linear extension, define  $\phi_{n,k}(f_d) =: P_{n,k}$ . By construction,  $P_{n,k}$  is  $n$ -degree,  $kn$ -variate multilinear polynomial. Let  $\psi_{n,k}$  be the homomorphism that maps any  $n$ -degree multilinear monomial, defined on variables  $y_{j,\ell}$ , such that  $y_{j,\ell} \mapsto x^{\ell \cdot k^{j-1}}$ . Observe that,  $\psi_{n,k} \circ \phi_{n,k}(f) = f$ , for any degree  $\leq d$  polynomial  $f \in \mathbb{F}[x]$ .

**SOS-hardness  $\implies$  hardness of  $P_{n,k}$ .** Assume that family  $(f_d)$  is SOS-hard with parameter  $\varepsilon$ . We will show that  $\text{size}(P_{n,k}) \geq d^{\mu(d)} = (kn)^{\omega(1)}$  for some function  $\mu$  depending on  $\varepsilon(d)$ . We have  $\varepsilon > \omega(\sqrt{\log \log d / \log d})$  and w.l.o.g.  $\varepsilon < (\log \log d / \log d)^{1/3}$ , for large  $d$  (Note: Proving for a small  $\varepsilon$  suffices; also  $1/3$  is nothing special, any constant  $< 1/2$  in the exponent works.).

Suppose,  $\text{size}(P_{n,k}) \leq d^\mu$ , for some  $\mu(d)$ . Then, from Main Lemma, we know that  $\exists Q_i$ 's such that  $P_{n,k} = \sum_{i=1}^s c_i \cdot Q_i^2$ , where  $s \leq (d^\mu \cdot n)^{c \log n}$ , for some constant  $c$ , with  $\deg(Q_i) \leq \lceil n/2 \rceil$ . Note:  $f_d = \psi_{n,k} \circ \phi_{n,k}(f_d) = \sum_{i=1}^s c_i \cdot \psi_{n,k}(Q_i)^2$ . As  $\psi_{n,k}$  cannot increase the sparsity,  $|\psi_{n,k}(Q_i)|_0 \leq |Q_i|_0 \leq \binom{kn + \lceil n/2 \rceil}{\lceil n/2 \rceil}$ ,<sup>5</sup> for each  $i \in [s]$ . Thus, by definition  $S_{\mathbb{F}}(f_d) \leq s \cdot \binom{kn + \lceil n/2 \rceil}{\lceil n/2 \rceil}$ . The idea is to fix parameters so that  $S(f_d) < o(d^{1/2+\varepsilon})$ . We will fix  $\mu$  such that

1.  $s \leq d^{\delta_1}$  for some function  $\delta_1$ ,
2.  $\binom{kn + \lceil n/2 \rceil}{\lceil n/2 \rceil} \leq d^{\delta_2}$  for some function  $\delta_2$ ,
3.  $d^{\delta_1 + \delta_2} < o(d^{1/2+\varepsilon})$ ,
4.  $d^\mu > (kn)^{\omega(1)}$ .

Note: from conditions 1-3, if  $\text{size}(P_{n,k}) \leq d^\mu$  then  $S(f_d) < o(d^{1/2+\varepsilon})$ , contradicting the SOS-hardness. Thus, condition 4 would give super-polynomial hardness result.

**Parameter fixing.** Let  $\mu := 1/\sqrt{\log d \cdot \log \log d}$  and  $\delta_1 := c' \cdot \mu \cdot \log n$  for some  $c' > c$ . Let  $\delta_2 := 1/2 + \varepsilon/2$ . Fix  $k := \lceil 6^{1/\varepsilon} + 1 \rceil$ . This fixing of  $k$  together with  $k^n \geq d + 1 > (k-1)^n$  implies that  $n = \Theta(\varepsilon \cdot \log d)$ . We also assume  $n$  to be even for simplicity, to avoid the ceiling function.

**Bound on the binomial.** Note that it is enough to have the following chain of inequalities:

$$\binom{kn + n/2}{n/2} \leq (e + 2ek)^{n/2} \leq (6(k-1))^{n/2} \leq (k-1)^{n\delta_2} \leq d^{\delta_2}.$$

First inequality is by Eqn.(8); the second one is by the fact that  $2e < 6$ , thus for large enough  $k$ , it holds; and the last inequality follows by the assumption that  $d \geq (k-1)^n$ . For the third one, it suffices to ensure that  $(k-1)^{\delta_2 - 1/2} \geq \sqrt{6}$ . This is where we used the fact that  $\delta_2 - 1/2 = \varepsilon/2 > 0$  and thus it is enough to fix  $k-1 = \lceil 6^{1/\varepsilon} \rceil$ .

**Bound on top-fanin  $s$ .** Note that  $s \leq (d^\mu \cdot n)^{c \log n}$  from Main Lemma for some constant  $c$ . We want  $d^{c' \cdot \mu \cdot \log n} = d^{\delta_1} \geq (d^\mu \cdot n)^{c \log n}$ . It suffices to show that  $d^{(c'-c) \cdot \mu} \geq n^c$ . It is fairly straightforward to verify that with our parameters fixing of  $\mu \log d = \sqrt{\log d / \log \log d}$ , and  $\log n \leq O(\log \log d)$ , the above inequality holds for large enough  $d$ .

**Checking  $d^{\delta_1 + \delta_2} = o(d^{1/2+\varepsilon})$ .** Note:  $\log n = O(\log \log d)$  and thus  $\delta_1 = O(\sqrt{\log \log d / \log d}) = o(\varepsilon)$ . Hence,  $\delta_1 + \delta_2 = o(\varepsilon) + 1/2 + \varepsilon/2 < 1/2 + \varepsilon$ ; since  $d^\varepsilon \rightarrow \infty$  as  $d \rightarrow \infty$ , the conclusion follows.

<sup>5</sup> Any  $n$  variate degree  $d$  polynomial can have sparsity at most  $\binom{n+d}{d}$ .

**Checking  $d^\mu = (kn)^{\omega(1)}$ .** Note that  $d^\mu = (kn)^{\omega(1)} \iff \mu = \omega(1) \cdot \log(kn)/\log d \iff \mu \cdot \log d = \omega(\log(kn))$ . It is clear that,  $\log(kn) = \log k + \log n \leq O(1/\varepsilon)$  for large enough  $n$  (or equivalently  $d$ ), as  $\log n = O(\log \log d) = o(1/\varepsilon)$  and  $\log k = \log \lceil 6^{1/\varepsilon} + 1 \rceil = O(1/\varepsilon)$ .

Also, note that  $\mu \cdot \log d = \sqrt{\log d / \log \log d} = \omega(1/\varepsilon) = \omega(\log(kn))$ .

Finally, all the conditions 1-4 are met with the appropriate fixing of parameters as shown above. Thus, we deduce  $\text{size}(P_{n,k}) \geq d^\mu = (kn)^{\omega(1)}$ , i.e.  $P_{n,k}$  requires *super*-polynomial size circuit. Therefore,  $(P_{n,k})_k \notin \text{VP}$ .

**Explicitness.** We will show that  $P_{n,k}$  is explicit, i.e.  $(P_{n,k})_k \in \text{VNP}$ . By construction,  $P_{n,k}$  is a  $kn$  variate, individual degree  $n$  multilinear polynomial, so we can write it as

$$P_{n,k} = \sum_{\mathbf{e} \in \{0,1\}^{kn}} \phi(\mathbf{e}) \cdot \mathbf{y}^{\mathbf{e}}.$$

Here  $\mathbf{y}$  denotes the  $kn$  variables  $y_{j,\ell}$  where  $1 \leq j \leq n$  and  $0 \leq \ell \leq k-1$  and  $\mathbf{e}$  denotes the exponent-vector. As each  $x^{\mathbf{e}}$  in  $\text{supp}(f_d)$  maps to a monomial  $\mathbf{y}^{\mathbf{e}}$  uniquely; given  $\mathbf{e}$ , one can easily compute  $e := \sum_{j=1}^n e_j \cdot k^{j-1}$  and thus  $\phi(\mathbf{e}) = \text{coef}_{x^{\mathbf{e}}}(f_d)$ . By the explicitness hypothesis, any bit of  $\phi(\mathbf{e})$  is computable in  $\text{poly}(\log d) < \text{poly}(2^{1/\varepsilon}) = \text{poly}(kn)$  time. Using Theorem 13, it is clear that  $(P_{n,k})_k \in \text{VNP}$ , by a wide margin.

So,  $(P_{n,k})_k \in \text{VNP}$  and SOS-hardness imply  $(P_{n,k})_k \notin \text{VP}$ . This proves Theorem 6.  $\blacktriangleleft$

► **Corollary 14** (Determinant vs Permanent). *SOS-hardness weakened with  $\varepsilon > \omega(1/\sqrt{\log d})$  (a smaller  $\varepsilon$  than the original) already implies  $\text{VBP} \neq \text{VNP}$ .*

**Proof Sketch.** The log-factor in the exponent is avoidable in the Main Lemma, if the initial polynomial is already an ABP of size  $s$  (instead of a circuit). In the above proof, we could then fix  $\delta_1 := c'\mu$ . This would remove the extra “ $\log n = \log \log d$ ” factors from the calculations.  $\blacktriangleleft$

► **Remark 15.**

1. We showed an explicit super-polynomially hard family  $(P_{n,k})_k$ . The result of [13, Theorem 7.7] then implies  $\text{PIT} \in \text{SUBEXP}$ .
2. If the given  $\varepsilon$  was a constant, say 0.001; then a very different parameters setting ( $k = O(1)$  and  $n = O(\log d)$ ) gives a *sub-exponential* hard polynomial family  $(P_{n,k})_n$  of size  $> 2^{\Omega(\log d / \log \log d)}$ . This happens because of the *super-polynomial* blowup in the size while converting a circuit to an ABP in Main Lemma. However, a repeated boosting of [38] type lemma (Lemma 31) gives a decomposition with intermediate polynomials having degree *close* to  $d/2$ . Finally this gives a truly *exponential* hard family  $(P_{k,n})_n$ ; for details see Theorem 32. Thus, [13] gives  $\text{PIT} \in \text{QP}$ , when  $\varepsilon$  is a constant.

Here, we also remark that “halving” the degree with  $\log d$  exponent in the top-fanin gives *better* result than “close” to halving because finally the contribution of the exponent is *quite small* in our application (and in fact absent in case of Corollary 14). However, for constant  $\varepsilon$ , the scenario changes as mentioned above.

3. As  $\deg(Q_i) \leq n/2$ , we have  $\deg(\psi_{n,k}(Q_i)) \leq n/2 \cdot (k-1) \cdot k^{n-1} < n \cdot k^n = O(nd) = o(d \log d)$ . Here we used that  $k^n/(k-1)^n < (1 + 1/(k-1))^n < e$ , for large  $d$ . Thus, it is enough to consider the restricted-degree SOS representation and prove the conjecture.
4. One can further restrict (proof requirement-wise) the SOS top-fanin to a mere  $d^{\delta_1} = \exp(O(\sqrt{\log d \cdot \log \log d}))$  which is extremely small compared to  $d$  (in fact,  $d^{\delta_1} = d^{o(\varepsilon)}$ ).

### 3.3 SOC-hardness to blackbox-PIT $\in$ P: Proof of Theorem 11

**Proof of Theorem 11.** The idea is to convert the SOC-hard polynomial  $f_d(x)$  to a *constant-k-variate individual-degree-n* polynomial family  $(P_{n,k})_n$  which is “mildly” *hard*. Later, using [9], we will conclude that blackbox-PIT  $\in$  P. The following lemma is the *crucial* ingredient to connect general circuits to an SOC representation.

► **Lemma 16** (SOC decomposition). *Let  $\mathbb{F}$  be a field of characteristic  $\neq 2, 3$ . Let  $f(\mathbf{x}) \in \mathbb{F}[\mathbf{x}]$  be an  $n$ -variate, degree- $d$  polynomial, computed by a circuit of size  $s$ . Then there exist polynomials  $f_i \in \mathbb{F}[x]$  and  $c_i \in \mathbb{F}$  such that  $f(\mathbf{x}) = \sum_{i=1}^{s'} c_i \cdot f_i^3$ , for some top-fanin  $s' \leq \text{poly}(s, d)$ ; achieving  $\deg(f_i) < 4d/11$ , for all  $i \in [s']$ .*

**Proof of Lemma 16.** We will first show this for homogeneous polynomials, and then apply it to each homogeneous part of a general  $f(\mathbf{x})$ . Assume that, circuit of  $f(\mathbf{x})$  is homogeneous. Lemma 28 establishes that  $f(\mathbf{x})$  can be decomposed as  $\sum_{i=1}^s \tilde{f}_{i1} \cdot \tilde{f}_{i2}$ , where  $\tilde{f}_{ij}$  has circuits of size  $O(s)$  and  $\deg(\tilde{f}_{ij}) \leq 2d/3$ , with  $\deg(\tilde{f}_{i1}) + \deg(\tilde{f}_{i2}) = d$ .

Choose a constant  $m$  such that  $(2/3)^m < 4/11 - 1/3 = 1/33$  ( $m := 9$  suffices). Apply Lemma 28  $m$  times, recursively on each successive circuit  $\tilde{f}_{ij}$ . As  $m$  is constant, it is easy to conclude that  $f(\mathbf{x})$  can be written as

$$f(\mathbf{x}) = \sum_{i=1}^{\text{poly}(s)} g_{i,1} \cdot g_{i,2} \cdot \dots \cdot g_{i,2^m},$$

where  $\deg(g_{i,j}) \leq (2/3)^m \cdot d$ , and  $\text{size}(g_{ij}) = O(s)$ . For each product  $g_{i,1} \cdot \dots \cdot g_{i,2^m}$ , pick a  $j_1 \in [2^m]$  such that  $d/3 \leq \sum_{k=1}^{j_1} \deg(g_{i,k}) < 4d/11$ . As each  $\deg(g_{i,k})$  is less than the gap between upper and lower bounds, namely  $4d/11 - d/3$ , such  $j_1$  exists. Note that  $\sum_{k=j_1+1}^{2^m} \deg(g_{i,k}) > d - 4d/11 = 7d/11 > d/3$ . Choose a  $[2^m] \ni j_2 > j_1$  such that  $d/3 \leq \sum_{k=j_1+1}^{j_2} \deg(g_{i,k}) < 4d/11$ ; such  $j_2$  exists by a similar argument.

Define,  $f_{i1} := g_{i,1} \cdot \dots \cdot g_{i,j_1}$ ,  $f_{i2} := g_{i,j_1+1} \cdot \dots \cdot g_{i,j_2}$ , and  $f_{i3} := g_{i,j_2+1} \cdot \dots \cdot g_{i,2^m}$ . By definition,  $\deg(f_{i1}), \deg(f_{i2}) \in [d/3, 4d/11]$ . As,  $\deg(f_{i1}) + \deg(f_{i2}) + \deg(f_{i3}) = \sum_{k \in [2^m]} \deg(g_{i,k}) = d \implies \deg(f_{i3}) \leq d/3 < 4d/11$ . As each  $g_{i,j}$  has a homogeneous circuit of size  $O(s)$ , so does  $f_{ij}$ . Hence,  $f(\mathbf{x}) = \sum_{i=1}^{\text{poly}(s)} f_{i1} \cdot f_{i2} \cdot f_{i3}$ . Use the identity

$$24 \cdot a \cdot b \cdot c = (a + b + c)^3 - (a - b + c)^3 - (a + b - c)^3 + (a - b - c)^3, \quad (9)$$

to write each  $f_{i1} \cdot f_{i2} \cdot f_{i3}$  as sum of four cubes. Relabeling yields  $f(\mathbf{x}) = \sum_{i=1}^{\text{poly}(s)} c_i \cdot f_i^3$ . As each  $f_i$  is a linear combination of  $f_{jk}$ 's, the degree does not change and the size is still  $O(s)$ .

It is well known that each homogeneous part can be computed by a homogeneous circuit of size  $O(sd^2)$ . Thus, for non-homogeneous polynomials,  $s$  can be replaced by  $O(sd^2)$  and the conclusion follows. ◀

Let  $k$  be a constant (to be fixed later) and  $\mathbf{x} := (x_1, \dots, x_k)$ . For all large enough  $n \in \mathbb{N}$ , define  $d := d(n) := (n+1)^k - 1$ . Let  $P_{n,k}$  be a  $k$ -variate polynomial of individual degree at most  $n$  such that after the Kronecker substitution,  $P_{n,k}(x, x^{n+1}, \dots, x^{(n+1)^{k-1}}) := f_d$ . It is easy to construct  $P_{n,k}$  from a given  $d$ ; just convert every  $x^e \in \text{supp}(f_d)$  to  $x_1^{e_1} \cdot \dots \cdot x_k^{e_k}$ , where  $e = \sum_{i=1}^k e_i \cdot (n+1)^{i-1}$  and  $0 \leq e_i \leq n$ .

By the explicitness of  $f_d$ ,  $(P_{n,k})_n$  is a very explicit polynomial family; its coefficient-vector  $\text{coef}(P_{n,k})$  can be computed in  $\text{poly}(d) = \text{poly}(n)$  time.

Next, we will show the hardness of the polynomial family  $(P_{n,k})_n$ . The SOC-hardness implies that there exists a constant  $\delta$  such that  $U(f_d, d^{\varepsilon'}) \geq \delta \cdot d$ , for all large enough  $d$ . Also, let  $c$  be the constant such that  $s' =: (sd)^c$  in Lemma 16. Let  $\mu := 2/(\varepsilon'/c - 1/k)$ , and later we will choose  $k > c/\varepsilon'$ .

▷ **Claim 17 (Hardness of  $P_{n,k}$ ).**  $\text{size}(P_{n,k}) > d^{1/\mu}$ , for all large enough  $n$ .

Assume to the contrary, that there exists an infinite subset  $J \subset \mathbb{N}$  such that  $\text{size}(P_{n,k}) \leq d^{1/\mu}$ , for all  $n \in J$ . We will show that family  $(f_d)$  is not SOC-hard over an infinite subset  $J' := \{d : n \in J\} \subseteq \mathbb{N}$ , which is a contradiction.

Let  $C$  be a circuit of size  $\leq d^{1/\mu}$  that computes  $P_{n,k}$ , for some  $n$ . Then, using Lemma 16, we know that there exist  $Q_i \in \mathbb{F}[x]$ , of degree at most  $4 \cdot \deg(P_{n,k})/11 \leq 4kn/11$ , such that  $P_{n,k} = \sum_{i=1}^{s_0} c_i \cdot Q_i^3$ , where  $s_0 \leq (d^{1/\mu} \cdot kn)^c$ . Apply the Kronecker map  $x_i \mapsto x^{(n+1)^{i-1}}$  on both sides yields  $f_d = \sum_{i=1}^{s_0} c_i \cdot \tilde{Q}_i^3$ , where  $\tilde{Q}_i := Q_i(x, x^{n+1}, \dots, x^{(n+1)^{k-1}})$ . Since Kronecker substitution cannot increase the support size,  $|\bigcup_i \text{supp}(\tilde{Q}_i)| \leq |\bigcup_i \text{supp}(Q_i)| \leq \binom{k+4kn/11}{k} =: s_1$ . Thus,  $U_{\mathbb{F}}(f_d, s_0) \leq s_1$ .

We want to show that  $s_0 < d^{\varepsilon'}$  and  $s_1 < \delta \cdot d$ , for all large enough  $n$ . Then, we have  $U_{\mathbb{F}}(f_d, d^{\varepsilon'}) < \delta \cdot d$ , for all large  $d \in J' \subset \mathbb{N}$ ; which contradicts the SOC-hardness of  $f_d$ .

**Bound on  $s_0$ .** We have for large enough  $n$  (and thus  $d$ ),

$$s_0 \leq (d^{1/\mu} \cdot k \cdot n)^c < d^{c/\mu} \cdot k^c \cdot d^{c/k} = k^c \cdot d^{c/\mu + c/k} < d^{\varepsilon'}.$$

We used that  $d = (n+1)^k - 1 > n^k$  for large  $n$ , and  $\mu > 1/(\varepsilon'/c - 1/k) \iff 1/\mu + 1/k < \varepsilon'/c$ .

**Bound on  $s_1$ .** By Eqn.(8), we have

$$s_1 = \binom{k + 4nk/11}{k} \leq (e(1 + 4n/11))^k < (10.9n/11)^k < (10.9/11)^k \cdot d.$$

As  $4e \approx 10.873$ , we used that  $e(1 + 4n/11) < (10.9/11) \cdot n$  and  $d > n^k$ , for large  $n$ .

Therefore, it suffices to show that  $(10.9/11)^k < \delta$ . Choose  $k > \log_{11/10.9}(1/\delta)$ . It suffices, from the above calculations, to pick  $k > \max(c/\varepsilon', \log_{11/10.9}(1/\delta))$ . This proves Claim 17. ◀

**From hardness to HSG.** We show that from the hardness of  $P_{n,k}$  in Claim 17, we can fulfil the assumption in Theorem 34:  $\text{size}(P_{n,k}) > s^{10k+2} \deg(P_{n,k})^3$ , for some “growing” function  $s = s(n)$ . Recall that  $\deg(P_{n,k}) \leq kn$ . We define,  $s(n) := n^{1/(10k+3)}$ . Then we have

$$s^{10k+2} (kn)^3 = n^{(10k+2)/(10k+3)} (kn)^3 = k^3 n^{4 - (1/(10k+3))} < n^4, \quad (10)$$

for large enough  $n$ . Additionally, assume that  $4 \leq k/\mu$ . Recall the fact:  $n^k < d$  for large  $n$ . So, we can continue Eqn.(10) as

$$n^4 \leq n^{k/\mu} < d^{1/\mu} < \text{size}(P_{n,k}). \quad (11)$$

Equations (10) and (11) give the desired hardness of  $P_{n,k}$ . It remains to ensure the last requirement of  $4 \leq k/\mu$ . We show below that choosing  $k \geq 9c/\varepsilon'$  suffices:

$$\mu = 2/(\varepsilon'/c - 1/k) \leq 2/(9/k - 1/k) = k/4.$$

Hence our final choice for  $k$  is:  $k \geq \max(9c/\varepsilon', \log_{11/10.9}(1/\delta))$ .

Thus, Theorem 34 gives a  $\text{poly}(s)$ -time HSG for  $\mathcal{C}(s, s, s)$ . Hence, blackbox-PIT  $\in \mathcal{P}$ . ◀

▶ **Remark 18.** Recall the proof notation. As the degree of  $Q_i$ 's is  $< 4kn/11$ , the degree of  $\tilde{Q}_i$  is  $\leq (n+1)^{k-1} \cdot 4kn/11 < 4k/11 \cdot (n+1)^k = 4k/11 \cdot (d+1) = O(d)$  ( $\because k$  is a constant). Thus, it suffices to study the representation of  $f_d$  as sum-of-cubes  $\tilde{Q}_i^3$ , where  $\deg(\tilde{Q}_i) \leq O(d)$ .

## 4 Conclusion

This work established that studying the univariate sum-of-squares representation (resp. cubes) is fruitful. Proving a *vanishingly* better lower bound than the trivial one, suffices to both derandomize and prove hardness in algebraic complexity.

Here are some immediate questions which require rigorous investigation.

1. Does existence of a SOS-hard family solve PIT completely? The current proof technique fails to reduce from cubes to squares.
2. Prove existence of a SOS-hard family for the *sum of constantly* many squares.
3. Prove existence of a SOC-hard family for a “generic” polynomial  $f$  with rational coefficients ( $\mathbb{Q}$ ). Does it fail when we move to *complex* coefficients ( $\mathbb{C}$ )?
4. Can we optimize  $\varepsilon$  in the SOS-hardness condition (& Corollary 14)? In particular, does proving an SOS lower-bound of  $\sqrt{d} \cdot \text{poly}(\log d)$ , suffice to deduce a separation between determinant and permanent (similarly VP and VNP)?

## A Sum of powers of small support-union

We give a way to represent any univariate polynomial as sum of  $r$ -th powers of polynomials.

Here we use the notion of sumset. In additive combinatorics, the *sumset*, also called the *Minkowski sum* of two subsets  $A$  and  $B$  of an abelian group  $G$  is defined to be the set of all sums of an element from  $A$  with an element from  $B$ ,

$$A + B = \{a + b \mid a \in A, b \in B\}.$$

The  $n$ -fold iterated sumset of  $A$  is  $nA = A + \dots + A$ , where there are  $n$  summands.

We want a *small support-union* representation of a  $d$ -degree polynomial  $f$  as a sum of  $r$ -th powers, where  $r$  is constant. We consider a *small*  $B$  such that  $rB$  covers  $\{0, 1, \dots, d\}$ . Let  $t$  be the *unique* non-negative integer such that  $(t-1)^r < d+1 \leq t^r$ . Define the set  $B$  as

$$B = \{a_i t^k \mid 0 \leq a_i \leq t-1, 0 \leq k \leq r-1\}.$$

So  $|B| = rt = O(d^{1/r})$ . Let  $k \in \{0, 1, \dots, d\}$ . The base- $t$  representation of  $k$  is a sum of at most  $r$  elements from  $B$ . Hence,  $\{0, 1, \dots, d\} \subseteq rB$ .

The largest element in  $B$  is  $m := (t-1)t^{r-1}$ . Note that for any  $\epsilon > 0$ , we have  $t < (1+\epsilon)(d+1)^{1/r}$ , for all large enough  $d$ . Thus, for *any* constant  $c > 1$  and large enough  $d$ , we have  $m < c(d+1)$ . Therefore, the largest element in  $rB$  is at most  $mr < cr(d+1) = O(d)$ .

► **Lemma 19.** *Let  $\mathbb{F}$  be a field of characteristic 0 or large. For any  $f(x) \in \mathbb{F}[x]$  of degree  $d$ , there exist  $\ell_i \in \mathbb{F}[x]$  with  $\text{supp}(\ell_i) \subseteq B$  and  $c_i \in \mathbb{F}$ , for  $i = 0, 1, \dots, mr$ , such that  $f(x) = \sum_{i=0}^{mr} c_i \ell_i^r$ .*

**Proof.** Consider  $\ell_i(\mathbf{z}_i, x) = \sum_{j \in B} z_{ij} x^j$ , for distinct indeterminates  $z_{ij}$ , for all  $i, j$ . Surely,  $\deg_x(\ell_i) = m$ . There exists  $mr + 1$  many degree- $r$  polynomials  $Q_j$  over  $|B| = rt$  many variables, such that

$$\ell_i(\mathbf{z}_i, x)^r = \sum_{j=0}^{mr} Q_j(\mathbf{z}_i) x^j \quad \forall i \in [mr].$$

Note that from any monomial in  $Q_j$  we could recover  $j$  uniquely. Denote the index set  $S \subseteq [0, mr]$  such that  $Q_j \neq 0$ , for all  $j \in S$ . We could conclude that  $Q_j(\mathbf{z}_i)$  ( $j \in S$ ) are  $\mathbb{F}$ -linearly independent. We would only focus on the  $Q_j$ 's for  $j \in S$ , now onwards. Note:  $[0 \dots d] \subseteq S$ .

Suppose  $f(x) =: \sum_{i=0}^d f_i x^i$ . Define  $\tilde{f} \in \mathbb{F}^{|S|}$  and  $A \in \mathbb{F}[z]^{|S| \times |S|}$  as

$$\tilde{f} := (f_0 \quad f_1 \quad \dots \quad f_d \quad 0 \quad \dots \quad 0), \quad A := \begin{pmatrix} Q_{j_1}(\mathbf{z}_1) & Q_{j_2}(\mathbf{z}_1) & \dots & Q_{j_s}(\mathbf{z}_1) \\ Q_{j_1}(\mathbf{z}_2) & Q_{j_2}(\mathbf{z}_2) & \dots & Q_{j_s}(\mathbf{z}_2) \\ \vdots & \vdots & \dots & \vdots \\ Q_{j_1}(\mathbf{z}_{|S|}) & Q_{j_2}(\mathbf{z}_{|S|}) & \dots & Q_{j_s}(\mathbf{z}_{|S|}) \end{pmatrix}.$$

We want to find  $\mathbf{c} = (c_1 \quad c_2 \quad \dots \quad c_{|S|}) \in \mathbb{F}^{|S|}$  and  $\boldsymbol{\alpha} = (\alpha_{ij})_{i,j}$  such that

$$\sum_{j \in [|S|]} c_j \cdot \ell_j(\boldsymbol{\alpha}, x)^r = \sum_{i=0}^d f_i x^i \iff \mathbf{c} \cdot A|_{\mathbf{z}=\boldsymbol{\alpha}} \cdot \begin{pmatrix} \vdots \\ x^j \\ \vdots \end{pmatrix}_{j \in S} = \tilde{f} \cdot \begin{pmatrix} \vdots \\ x^j \\ \vdots \end{pmatrix}_{j \in S}.$$

The last expression holds  $\iff \mathbf{c} \cdot A|_{\mathbf{z}=\boldsymbol{\alpha}} = \tilde{f}$ . As the  $\mathbf{z}_i$ 's are distinct variables, the first column of  $A$  consists of different variables at each coordinate. Moreover, the first row of  $A$  contains  $\mathbb{F}$ -linearly independent  $Q_j$ 's. Thus, for *random*  $\alpha_{ij} \in \mathbb{F}$ , matrix  $A|_{\mathbf{z}=\boldsymbol{\alpha}}$  has *full rank* over  $\mathbb{F}$ . Fix such an  $\boldsymbol{\alpha}$ . This fixes  $\mathbf{c} = \tilde{f} \cdot (A|_{\mathbf{z}=\boldsymbol{\alpha}})^{-1}$ .

From the above construction, it follows that  $f(x) = \sum_{j \in [|S|]} c_j \cdot \ell_j(\boldsymbol{\alpha}, x)^r$ .  $\blacktriangleleft$

The number of *distinct* monomials across  $\ell_j(\boldsymbol{\alpha}, x)$ 's is  $|B| = O(d^{1/r})$ . While the top-fanin, as seen before, is  $\leq mr + 1 = \Theta(d)$ .

► **Remark 20.**

1. The above calculation does *not* give small support-sum representation of  $f$ , as the top-fanin is already  $\Omega(d)$ .
2. The above representation crucially requires a *field*  $\mathbb{F}$ . E.g. it does not exist for  $f_d$  over the ring  $\mathbb{Z}$ .

## B Further optimizing the top-fanin

In this section, we show a SOS- and SOC-representation for any polynomial  $f(x)$ , wherein both the top-fanin *and* the support-union size are small, namely  $O(\sqrt{d})$ . We assume that characteristic of  $\mathbb{F}$  is  $\neq 2$  in case of SOS, and  $\neq 3$ , in case of SOC. The representations are based on discussions with Agrawal [1].

### B.1 Small SOS

By Lemma 19 for  $r = 2$ , any  $f(x)$  can be written as  $f(x) = \sum_{i=1}^{O(d)} c_i f_i^2$ , with support-sum  $|\bigcup_i \text{supp}(f_i)| = O(\sqrt{d})$ . We show that the top-fanin can be reduced to  $O(\sqrt{d})$ .

► **Theorem 21** (Small SOS-Representation). *Any polynomial  $f \in \mathbb{F}[x]$  of degree  $d$  has a SOS-representation such that the top-fanin and the support-union are bounded by  $O(\sqrt{d})$ .*

The key to prove Theorem 21 is the following lemma. It shows how to decrease the top-fanin in a representation without increasing the support-union.

► **Lemma 22.** *Let  $f \in \mathbb{F}[x]$  be written as  $f = \sum_{i=1}^s c_i f_{i,1} f_{i,2}$ , with support-union  $t = |\bigcup_{i,j} \text{supp}(f_{i,j})|$ . Then there exists a representation  $f = \sum_{i=1}^t c'_i f'_{i,1} f'_{i,2}$  with support-union  $\leq t$ .*

Let us first argue why Lemma 22 implies Theorem 21. We start from the representation given by Lemma 19 mentioned above and apply Lemma 22. It follows that  $f$  can be re-written as  $f(x) = \sum_{i=1}^{O(\sqrt{d})} c'_i f_{i,1} f_{i,2}$ , where  $|\bigcup_{i,j} \text{supp}(f_{i,j})| = O(\sqrt{d})$ . This can be turned into a SOS-representation by  $f_{i,1} f_{i,2} = (f_{i,1} + f_{i,2})^2/4 - (f_{i,1} - f_{i,2})^2/4$ . Note that the last step does not change the support-union, and at most doubles the top-fanin. Thus, Theorem 21 follows.

**Proof of Lemma 22.** For the given representation of  $f$ , we assume w.o.l.g. that  $\deg(f_{i,1}) \geq \deg(f_{i,2})$  and that  $f_{i,1}, f_{i,2}$  are monic, for  $i = 1, 2, \dots, s$ . Let  $S = \bigcup_{i,j} \text{supp}(f_{i,j})$ .

We construct the representation claimed in the lemma by ensuring the following properties:

1. For every  $x^e \in S$  there is exactly one  $i$  such that  $\deg(f'_{i,1}) = e$ .
2.  $\bigcup_{i,j} \text{supp}(f'_{i,j}) \subseteq S$ .

Since we also maintain that  $\deg(f'_{i,1}) \geq \deg(f'_{i,2})$ , it follows that the top-fanin is indeed bounded by  $t = |S|$  as claimed.

We handle the monomials in  $S$  successively according to decreasing degree. Let  $x^e \in S$  be the monomial with the largest  $e$  that occurs more than once as the degree of a  $f_{i,1}$ , say  $\deg(f_{1,1}) = \deg(f_{2,1}) = e$ .

Define  $g_1 = f_{2,1} - f_{1,1}$ . Then we have  $f_{2,1} = f_{1,1} + g_1$  and  $\deg(g_1) < e$ . Moreover, the support of  $g_1$  is contained in the support of  $f_{1,1}$  and  $f_{2,1}$ . If  $\deg(f_{2,2}) = e$ , then we define similarly  $g_2 = f_{2,2} - f_{1,1}$ . Then  $f_{2,2} = f_{1,1} + g_2$  and  $\deg(g_2) < e$ . Now we can write

$$\begin{aligned} c_1 f_{1,1} f_{1,2} + c_2 f_{2,1} f_{2,2} &= c_1 f_{1,1} f_{1,2} + c_2 (f_{1,1} + g_1)(f_{1,1} + g_2) \\ &= f_{1,1} (c_1 f_{1,2} + c_2 f_{1,1} + c_2 g_1 + c_2 g_2) + c_2 g_1 g_2 \end{aligned}$$

The second line is a new sum of two products, where only the first product has terms of degree  $e$ , whereas in the second product,  $g_1, g_2$  have smaller degree. Also, the support-union set has not increased.

In case when  $\deg(f_{2,2}) < e$ , we can just work with  $f_{2,2}$  directly instead of  $f_{1,1} + g_2$ , and the above equations gets even simpler. ◀

## B.2 Small SOC

We show two small SOC-representation with different parameters. First, we show a  $\sqrt{d}$  SOC-representation that follows essentially from Theorem 21.

► **Corollary 23** ( $\sqrt{d}$  SOC-representation). *Any polynomial  $f \in \mathbb{F}[x]$  of degree  $d$  has a SOC-representation such that the top-fanin and the support-union are bounded by  $O(\sqrt{d})$ .*

**Proof.** By Theorem 21 we can write  $f$  as  $f(x) = \sum_{i=1}^{O(\sqrt{d})} c_i f_i^2$ , with support-union  $O(\sqrt{d})$ . Each  $f_i^2$  can in turn be written as  $f_i^2 = \sum_{j=1}^4 c_{i,j} (f_i + \lambda_{i,j})^3$ , for some constants  $c_{i,j}, \lambda_{i,j} \in \mathbb{F}$ , as can be shown by interpolation. This gives the representation claimed in the theorem. ◀

The second way to get a small SOC-representation uses Lemma 19 for  $r = 3$ : Any  $f(x)$  can be written as  $f(x) = \sum_{i=1}^{O(d)} c_i f_i^3$ , with support-sum  $|\bigcup_i \text{supp}(f_i)| = O(d^{1/3})$ . We show that the top-fanin can be reduced to  $O(d^{2/3})$ .

► **Theorem 24** ( $d^{2/3}$  SOC-representation). *Any polynomial  $f \in \mathbb{F}[x]$  of degree  $d$  has a SOC-representation with top-fanin  $O(d^{2/3})$  and support-union  $O(d^{1/3})$ .*

To prove Theorem 24, we show a reduction similar to Lemma 22 for sum of product-of-3.

► **Lemma 25.** *If  $f = \sum_{i=1}^s c_i f_{i,1} f_{i,2} f_{i,3}$  with support-union  $t$ , then  $f$  can be written as  $f = \sum_{i=1}^{t^2} c'_i f'_{i,1} f'_{i,2} f'_{i,3}$  with support-union  $\leq t$ .*

**Proof.** We fix the support-union set  $S$  and the monomial ordering (as seen in Lemma 22). Assume there are  $m > t^2$  many products, like  $f_{i,1} f_{i,2} f_{i,3}$ . W.l.o.g. assume  $\deg(f_{11}) = e_i$ . Rearrange  $\sum_{i \in [m]} c_i f_{i,1} f_{i,2} f_{i,3} =: f_{1,1} \cdot P + R$ , so that  $P$  is a SOS and  $R$  is a SOC without any occurrence of  $x^{e_i}$ . Apply Lemma 22, on  $P$ , to reduce its top-fanin to  $t$ . Repeat this procedure to SOC  $R$ .

Finally, the top-fanin gets upper-bounded by  $t \cdot t = t^2$ , ◀

Theorem 24 now follows by noting that any product-of-3 can be written as a sum of four cubes, by Eqn.(9); and by Lemma 19 we have  $t = O(d^{1/3})$ .

► **Lemma 26.** *For any  $f \in \mathbb{F}[x]$ , we have  $S_{\mathbb{F}}(f) \geq \min_s (U_{\mathbb{F}}(f, 4s) - 1)$ .*

**Proof Sketch.** Suppose  $f = \sum_{i=1}^s c_i f_i^2$ . Write each  $f_i^2$  as  $f_i^2 = \sum_{j=1}^4 c_{ij} (f_i + \lambda_{ij})^3$ , for distinct  $\lambda_{ij} \in \mathbb{F}$ . Thus,  $U_{\mathbb{F}}(f, 4s) \leq (\sum_{i=1}^s |f_i|_0) + 1$ . Taking minimum over  $s$  gives the desired inequality. ◀

► **Corollary 27.** *For  $s = \Omega(d^{2/3})$ , we have  $U_{\mathbb{F}}(f, s) = \Theta(d^{1/3})$ .*

## C Sum of product-of-2 decomposition

The next lemma is can be proved by standard frontier decomposition in [29].

► **Lemma 28** (Sum of product-of-2). *Let  $f(x)$  be an  $n$ -variate, homogeneous, degree  $d$  polynomial computed by a right-heavy homogeneous circuit  $\Phi$  of size  $s$ . Then, there exist polynomials  $f_{ij} \in \mathbb{F}[x]$  s.t.*

$$f(x) = \sum_{i=1}^s f_{i1} \cdot f_{i2}, \quad \text{with the following properties:} \tag{12}$$

1.  $d/3 \leq \deg(f_{i1}), \deg(f_{i2}) \leq 2d/3$ , for all  $i \in [s]$ ,
2.  $\deg(f_{i1}) + \deg(f_{i2}) = d$ , for all  $i \in [s]$ , and
3. each  $f_{ij}$  has a right-heavy homogeneous circuit of size at most  $s_2 := O(s)$ .

► **Remark 29.** For a non-homogeneous polynomial  $f(x)$ , we can apply the above for each homogeneous part of  $f(x)$ . It is well known that each homogeneous part can be computed by a homogeneous circuit of size  $O(sd^2)$ . Thus, for non-homogeneous polynomials,  $s$  can be replaced by  $O(sd^2)$  and the same conclusion follows.

## D

 Valiant's Criterion for VNP: Details for Section 3.2

A useful *sufficient* condition for a polynomial family  $(f_n(\mathbf{x}))_n$  to be in VNP is known, due to Valiant [37].

► **Theorem 30** (VNP criterion, [5]). *Let  $f_n(\mathbf{x}) = \sum_{e \in \{0,1\}^n} c_n(e) \mathbf{x}^e$  be a polynomial family such that the coefficients  $c_n(e)$  have length  $\leq n$  in binary. Then*

$$c_n(e) \in \#P/\text{poly} \implies f_n \in \text{VNP}.$$

One can further relax Theorem 30 such that the coefficients  $c_n(e)$  can actually be  $2^n$  bits long, see Theorem 13 (restated) below. The proof idea is very similar to [15, Lem. 3.2]. We also use the fact that VNP is closed under substitution. That is, for a family of polynomials  $(f(\mathbf{x}, \mathbf{y})) \in \text{VNP}$ , it also holds that  $(f(\mathbf{x}, \mathbf{y}_0)) \in \text{VNP}$ , for any value  $\mathbf{y}_0 \in \mathbb{F}^n$  assigned to the variables in  $\mathbf{y}$ .

► **Theorem 13** (restated). *Let  $f_n(\mathbf{x}) = \sum_{e \in \{0,1\}^n} c_n(e) \mathbf{x}^e$  be a polynomial family such that the coefficients  $c_n(e)$  have length  $\leq 2^n$  in binary. Let  $c_{n,j}(e)$  be the  $j$ -th bit of  $c_n(e)$ . Then*

$$c_{n,j}(e) \in \#P/\text{poly} \implies f_n \in \text{VNP}.$$

**Proof of Theorem 13.** For  $j \in \{0, 1, \dots, 2^n - 1\}$  let  $\text{bin}(j) = (j_1, \dots, j_n)$  denote the  $n$ -bit base-2 representation of  $j$  such that  $j = \sum_{i=1}^n j_i 2^{i-1}$ . Introduce new variables  $\mathbf{y} = (y_1, \dots, y_n)$  and define  $\tilde{c}_n(e, \mathbf{y}) = \sum_{j=0}^{2^n-1} c_{n,j}(e) \mathbf{y}^{\text{bin}(j)}$ . Let  $\mathbf{y}_0 := (2^{2^0}, \dots, 2^{2^{n-1}})$ . Then we have  $\tilde{c}_n(e, \mathbf{y}_0) = c_n(e)$ . Finally, consider the  $2n$ -variate auxiliary polynomial  $h_n(\mathbf{x}, \mathbf{y})$ .

$$h_n(\mathbf{x}, \mathbf{y}) = \sum_{e \in \{0,1\}^n} \tilde{c}_n(e, \mathbf{y}) \mathbf{x}^e = \sum_{e \in \{0,1\}^n} \sum_{j=0}^{2^n-1} c_{n,j}(e) \mathbf{y}^{\text{bin}(j)} \mathbf{x}^e.$$

Then we have  $h_n(\mathbf{x}, \mathbf{y}_0) = f_n(\mathbf{x})$ . Since  $c_{n,j}(e)$  can be computed in  $\#P/\text{poly}$ , we have  $(h_n(\mathbf{x}, \mathbf{y}))_n \in \text{VNP}$ . As VNP is closed under substitution, it follows that  $(f_n(\mathbf{x}))_n \in \text{VNP}$ . ◀

## E

 SOS-hardness with constant  $\varepsilon$  implies truly exponential separation between VP and VNP

We use Lemma 28 repeatedly (constant many times) to bring the degree of the intermediate polynomials “fractional”-close to  $d/2$ , namely  $d \cdot (1/2 + O(1))$ . This would be crucially used to establish the exponential separation between VP and VNP.

► **Lemma 31** (Constant boosting VSBR). *Let  $f(\mathbf{x}) \in \mathbb{F}[\mathbf{x}]$  be a degree- $d$ ,  $n$ -variate polynomial computed by homogeneous circuit of size  $s$ . Then, for any constant  $1 < \gamma < 2$ , there exist polynomials  $f_{ij} \in \mathbb{F}[\mathbf{x}]$  such that*

$$f(\mathbf{x}) = \sum_{i=1}^{\text{poly}(s)} f_{i1} \cdot f_{i2}, \text{ with the following properties} \tag{13}$$

1. each  $f_{ij}$  has a homogeneous circuit of size  $O(s)$ ,
2.  $\deg(f_{ij}) < d/\gamma$ , for all  $i, j$ ,
3.  $\deg(f_{i1}) + \deg(f_{i2}) = d$ , for all  $i$ .

**Proof sketch.** Lemma 28 shows that  $f(\mathbf{x})$  can be decomposed as  $\sum_{i=1}^s \tilde{f}_{i1} \cdot \tilde{f}_{i2}$  where  $\tilde{f}_{ij}$  has circuits of size  $O(s)$  and  $\deg(\tilde{f}_{ij}) \leq 2d/3$ , with  $\deg(\tilde{f}_{i1}) + \deg(\tilde{f}_{i2}) = d$ . Let  $\delta' := 1/\gamma - 1/2$ . Choose a constant  $m := \lceil \log_{3/2}(1/\delta') \rceil$  so that  $(2/3)^m < \delta'$ . Apply the above product-of-2 decomposition  $m$  times repeatedly on each product to conclude that  $f(\mathbf{x})$  can be decomposed as  $f(\mathbf{x}) = \sum_{i=1}^{\text{poly}(s)} g_{i1} \cdot g_{i2} \cdot \dots \cdot g_{i2^m}$ ; where  $\deg(g_{ij}) \leq (2/3)^m \cdot d < d \cdot \delta'$  and  $\text{size}(g_{ij}) = O(s)$ . Cluster each product so that the degree of each is in  $[d/2, d/\gamma]$ ; the choice of  $m$  ensures this. Hence, the conclusion follows.  $\blacktriangleleft$

Using the above fine-grained decomposition, we can prove the exponential separation between VP and VNP; the parameters change due to the different decomposition.

► **Theorem 32** (Constant  $\varepsilon$ ). *If there exists a univariate family  $(f_d(x))_d$  that is SOS-hard with some constant  $\varepsilon$ , then VNP is exponentially harder than VP ( $\mathcal{E}$  blackbox-PIT  $\in$  QP).*

## F

 Hardness to derandomization: Details for Section 3.3

Very recently, Guo et al. in [9] showed utility of the hardness of *constant* variate polynomials to derandomize PIT. To make this discussion formal, we start with the following definition.

► **Definition 33** (Hitting-set generator (HSG)). *A polynomial map  $G : \mathbb{F}^k \rightarrow \mathbb{F}^n$  given by  $G(\mathbf{z}) = (g_1(\mathbf{z}), g_2(\mathbf{z}), \dots, g_n(\mathbf{z}))$  is said to be a hitting-set generator (HSG) for a class  $\mathcal{C} \subseteq \mathbb{F}[x_1, x_2, \dots, x_n]$  of polynomials if for every nonzero  $f \in \mathcal{C}$ , we have that  $f \circ G = f(g_1, g_2, \dots, g_n)$  is nonzero.*

► **Theorem 34** ([9]). *Let  $P \in \mathbb{F}[\mathbf{x}]$  be a  $k$ -variate polynomial of degree  $d$  such that  $\text{coef}(P)$  can be computed in  $\text{poly}(d)$ -time. If  $\text{size}(P) > s^{10k+2} \cdot d^3$ , then there is a  $\text{poly}(s)$ -time HSG for  $\mathcal{C}(s, s, s)$ .*

## Abstract

The best known size lower bounds against unrestricted circuits have remained around  $3n$  for several decades. Moreover, the only known technique for proving lower bounds in this model, gate elimination, is inherently limited to proving lower bounds of less than  $5n$ . In this work, we propose a non-gate-elimination approach for obtaining circuit lower bounds, via certain depth-three lower bounds. We prove that every (unbounded-depth) circuit of size  $s$  can be expressed as an OR of  $2^{s/3.9}$  16-CNFs. For DeMorgan formulas, the best known size lower bounds have been stuck at around  $n^{3-o(1)}$  for decades. Under a plausible hypothesis about probabilistic polynomials, we show that  $n^{4-\epsilon}$ -size DeMorgan formulas have  $2^{n^{1-\Omega(\epsilon)}}$ -size depth-3 circuits which are approximate sums of  $n^{1-\Omega(\epsilon)}$ -degree polynomials over  $\mathbb{F}_2$ . While these structural results do not immediately lead to new lower bounds, they do suggest new avenues of attack on these longstanding lower bound problems.

Our results complement the classical depth-3 reduction results of Valiant, which show that *logarithmic*-depth circuits of linear size can be computed by an OR of  $2^{\epsilon n} n^\delta$ -CNFs, and slightly stronger results for series-parallel circuits. It is known that no purely graph-theoretic reduction could yield interesting depth-3 circuits from circuits of super-logarithmic depth. We overcome this limitation (for small-size circuits) by taking into account both the graph-theoretic and functional properties of circuits and formulas.

We show that improvements of the following pseudorandom constructions imply super-linear circuit lower bounds for log-depth circuits via Valiant's reduction: dispersers for varieties, correlation with constant degree polynomials, matrix rigidity, and hardness for depth-3 circuits with constant bottom fan-in. On the other hand, our depth reductions show that even modest improvements of the known constructions give elementary proofs of improved (but still linear) circuit lower bounds.

## 1 Introduction

The Boolean circuit model is natural for computing Boolean functions. A circuit corresponds to a simple straight line program where every instruction performs a binary operation on two operands, each of which is either an input or the result of a previous instruction. The structure of this program is extremely simple: no loops, no conditional statements. Still, we

know no functions in P (or even NP, or even  $E^{NP}$ ) that requires even  $3.1n$  binary instructions (“size”) to compute on inputs of length  $n$ . This is in sharp contrast with the fact that it is easy to *non-constructively* find such functions: simple counting arguments show a random function on  $n$  variables has circuit size  $\Omega(2^n/n)$  with probability  $1 - o(1)$  [52].

The strongest known circuit size lower bound  $(3 + \frac{1}{86})n - o(n)$  was proved for affine dispersers for sublinear dimension [14]. This proof, as well as all previous proofs for general circuit lower bounds against explicit functions, is based on the method of gate elimination. The main idea is to find a substitution to an input variable that eliminates sufficiently many gates from the given circuit, and then proceed by induction. While this is the most successful method known so far for proving lower bounds for unrestricted circuits, the resulting case analysis becomes increasingly tedious: when eliminating (say) 3 or 4 gates, one must consider all possible cases when two of these gates coincide. It is difficult to imagine a proof of  $5n$  lower bound using these ideas. This intuition was recently made formal in [17], where it was shown that a certain formalization of the gate elimination technique is unable to obtain a stronger than  $5n$  lower bound. Therefore we must find new approaches for proving lower bounds against circuits of unbounded depth. Let us review some of the prior results on various circuit models.

### Linear Circuits

Superlinear lower bounds are not known even for linear circuits, i.e., circuits consisting of only XOR gates (also known as  $\oplus$  gates). Note every linear function with one output has a circuit of size at most  $n - 1$ . For linear circuits, we consider *linear transformations*, multi-output functions of the form  $f(x) = Ax$  where  $A \in \mathbb{F}_2^{m \times n}$ . For a random matrix  $A \in \{0, 1\}^{n \times n}$ , the size of the smallest linear circuit computing  $Ax$  is  $\Theta(n^2/\log n)$  [33] with probability  $1 - o(1)$ , but for explicitly-constructed matrices the strongest known lower bound is  $3n - o(n)$  due to Chashkin [6]. Interestingly, Chashkin’s proof is not based on gate elimination: he first shows that the parity check matrix  $H \in \{0, 1\}^{\log n \times n}$  of the Hamming code has circuit size  $2n - o(n)$  by proving that every circuit for  $H$  has at least  $n - o(n)$  gates of out-degree at least 2.<sup>1</sup> Then he “pads”  $H$  to an  $n \times n$  matrix  $H'$  and shows that  $n - o(n)$  additional gates are needed for  $H'$ . Similarly, the best known lower bound on the complexity of linear circuits with  $\log n \leq m < o(n^2)$  outputs is  $2n + m - o(n)$  (also follows from [6]).

### Log-Depth Circuits

Nothing stronger than a  $(3 + \frac{1}{86})n - o(n)$  size lower bound is known even for circuits of depth  $O(\log n)$ . It is straightforward to show that any function that depends on all of its  $n$  variables requires depth at least  $\log n$ . One can also present an explicit function that cannot be computed by a circuit of depth smaller than  $2 \log n - o(\log n)$  using Nechiporuk’s lower bound of  $n^{2-o(1)}$  on formula size over the full binary basis [35]. Still, proving superlinear size lower bounds for circuits of depth  $O(\log n)$  remains a major open problem [56].

### Constant-Depth Circuits

Another natural and simple model of computation is bounded-depth unbounded fan-in circuits, which correspond to highly parallelizable computation. In this paper, we focus on depth-2 circuits of the form  $\text{AND} \circ \text{OR}$  (i.e., CNFs) and depth-3 circuits of the form

---

<sup>1</sup> All logarithms are base 2 unless noted otherwise.

OR  $\circ$  AND  $\circ$  OR (i.e., ORs of CNFs), where the inputs of the circuit are variables and their negations, and the gates have unbounded fan-in. Such circuits are much more structured, and therefore are easier to analyze and to prove lower bounds. For example, it is easy to show that the minimal number of clauses in a CNF computing the parity of  $n$  bits is equal to  $2^{n-1}$ , which yields an optimal lower bound for depth-2 circuits. However, already for depth 3 there is a large gap between known lower and upper bounds: it is known [10, 50] that the minimum depth-3 circuit size of a random function on  $n$  variables is  $\Theta(2^{n/2})$ , but the best known lower bound for an explicit function is  $2^{\Omega(\sqrt{n})}$  [20, 22, 39, 3, 38, 34].

Much stronger lower bounds are known for depth-3 circuits where the fan-in of the “bottom” gates (those closest to the inputs) is bounded by a parameter  $k$ . Namely, for any  $k \leq O(\sqrt{n})$ , Paturi, Saks, and Zane [39] proved a  $2^{n/k}$  lower bound for computing parity, Wolfowitz [60] proved a lower bound of  $(1 + 1/k)^{n+O(\log n)}$  for  $\text{ETHR}_{\frac{n}{k+1}}$ <sup>2</sup>, and a stronger lower bound of  $2^{\frac{\mu_k n}{k-1}}$  for  $k \geq 3$  and some constants  $\mu_k > 1$  was proven in [38] for a BCH code. For example, [38] gives a lower bound of  $2^{0.612n}$  when the bottom fan-in of the circuit is  $k = 3$ , and a lower bound of  $2^{n/10}$  for the bottom fan-in  $k = 16$ . For the case of bottom fan-in  $k = 2$ , even a  $2^{n-o(n)}$  lower bound is known [40].

A simple counting argument shows that for any constant  $k = O(1)$ , a random function requires depth-3 circuits of size  $2^{n-o(n)}$ . Calabro, Impagliazzo, and Paturi [5] construct a family of  $2^{O(n^2)}$  explicit functions, most of which require depth-3 circuits with  $k = O(1)$  of size  $2^{n-o(n)}$ . Santhanam and Srinivasan [46] improve on this by constructing such a family of functions of size  $2^{f(n)}$  for every  $f(n) = \omega(n \log n)$ .

## DeMorgan Formulas

While explicit super-linear lower bounds for *circuits* are not known, there are super-linear lower bounds for *formulas*. In this paper, we focus on the well-studied DeMorgan formulas, which are circuits where every intermediate computation is used exactly once: all gates have out-degree one, and the operations are fan-in two ANDs and ORs, with inputs being variables and their negations. The two most successful methods for proving lower bounds on DeMorgan formula size are random restrictions [54, 2, 24, 36, 21, 55] as well as Karchmer–Wigderson games and the Karchmer–Raz–Wigderson conjecture [29, 27, 26, 16, 12]. Both approaches have led to a lower bound of  $n^{3-o(1)}$  and are currently stuck at giving stronger lower bounds.

### 1.1 Valiant’s Depth Reduction

Remarkably, a classical result of Valiant from the 70’s relates three of the four models above: linear, log-depth, and constant-depth circuits. Using a depth reduction for DAGs [13], Valiant [56] shows that for any circuit of size  $cn$  and depth  $d$ , and for every integer  $k$ , one can remove at most  $\frac{2ckn}{\log d}$  wires such that the resulting circuit has depth at most  $d/2^k$ . Letting  $k$  be a sufficiently large constant, this wire-removal lemma shows how any circuit of size  $O(n)$  and depth  $O(\log n)$  can be converted into an OR  $\circ$  AND  $\circ$  OR circuit where the OR output gate has fan-in  $2^{O(n/\log \log n)}$  and the lower OR gates have fan-in  $O(n^\varepsilon)$  for any desired  $\varepsilon > 0$ . Hence, by exhibiting a function that has no depth-3 circuit with these restrictions, it follows that this function cannot be computed by circuits of linear size and logarithmic depth. Unfortunately, the best known lower bounds on depth-3 circuits (as mentioned earlier) are still too far from those required for this reduction.

<sup>2</sup>  $\text{ETHR}_{\frac{n}{k+1}}$  outputs 1 if and only if the sum of the  $n$  input bits over the integers equals  $\frac{n}{k+1}$ .

In the same paper, Valiant introduced the notion of matrix rigidity (a similar notion was independently introduced by Grigoriev [19]) and related it to the size of linear circuits of log-depth using ideas similar to those described above. Alas, the known lower bounds on matrix rigidity are also far from being able to give new lower bounds on the size of log-depth linear circuits.

## 1.2 Our Results: New Depth Reductions

The main contributions of this paper are new reductions to depth-3 circuits that work for *unrestricted* circuits and (conditionally) for super-cubic formulas, as well as new results connecting various pseudorandom objects to circuit lower bounds. In particular, we show how to express super-cubic DeMorgan formulas as subexponential-size depth-3 circuits of a certain form, under the hypothesis that DeMorgan formulas have probabilistic polynomials of non-trivial degree. This suggests an approach for improving formula size lower bounds, by proving strong lower bounds on depth-3 circuits.

### 1.2.1 Depth Reductions for Circuits

In Valiant’s depth reduction, one can only have  $d/2^k < \log n$  (and  $< cn$  removed edges) for circuits of depth  $d \leq O(\log n)$ . Thus, Valiant’s depth reduction technique does not yield interesting results for circuits of super-logarithmic depth. Moreover, Schnitger and Klawe [47, 48, 30] construct an explicit family of DAGs showing that the parameters achieved by Valiant are essentially optimal. Their counterexamples convincingly show that a pure graph-theoretic approach to circuit depth reduction cannot give non-trivial results for unrestricted circuits.

In this paper, we overcome this difficulty by presenting a counterpart of Valiant’s depth reduction that works for circuits of unrestricted depth. Our depth reduction takes into account not only the underlying graph of a circuit, but also the *functions* computed by the circuit gates.

Our first result shows that unbounded-depth circuits of size less than  $3.9n$  can be converted into  $2^{\delta n}$  disjunctions of short 16-CNFs, for some  $\delta < 1$ .

► **Theorem 1.** *Every circuit of size  $s$  can be computed as an  $OR_{2^{\lceil \frac{s}{2} \rceil}} \circ AND_s \circ OR_2$  circuit and as an  $OR_{2^{\lceil \frac{s}{3.9} \rceil}} \circ AND_{2^{14 \cdot s}} \circ OR_{16}$  circuit.*

As a consequence, in order to prove a  $3.9n - o(n)$  size lower bound on *unrestricted* circuits, it suffices to provide a function that cannot be computed by an OR of fewer than  $2^{n-o(n)}$  16-CNF’s. To prove Theorem 1, we gradually transform the given circuit into an OR of CNF’s by carefully picking a suitable internal gate and branching on its two possible output values. In contrast to Valiant’s reduction, our transformation works for circuits of arbitrary depth. This is achieved by an argument that takes into account both the graph structure of the circuit *and* the functional properties of the gates involved. Since in this approach we can branch on *internal* gates (inside the circuit), we can avoid a massive case analysis. This also distinguishes our approach from known circuit lower bound proofs based on gate elimination, which must set input gates (or gates very close to the inputs) for the argument to work.

It should be noted that known satisfiability algorithms based on branching, as well as circuit lower bounds based on gate elimination [39, 38, 49, 45, 8] may be viewed as depth-reductions for small circuits: if at most  $k$  variables are set in any branch before the circuit has a “trivial” form, then the circuit can be expressed as an OR of  $2^k$  “trivial” forms. At the same time, the known techniques in this line of work appear stuck at lower bounds of around  $3n$ , and provably cannot go beyond linear-size bounds [17].

On the way to proving Theorem 1, we study structural results about converting small circuits into disjunctions of  $k$ -CNFs, that have curious connections to properties of  $k$ -CNFs found in the Satisfiability Coding Lemma [39, 38] and Sparsification Lemma [25, 5]. In particular, we ask the following question.

► **Open Problem 2.** *Prove or disprove: for any constant  $c$ , any circuit of size  $cn$  can be computed as an*

$$OR_{2^{(1-\delta(c))n}} \circ AND \circ OR_{\gamma(c)}$$

*circuit, for some  $\delta(c) > 0$  and integer  $\gamma(c) \geq 1$ .*

If such depth-3 circuits always existed, this would constitute a new approach to proving superlinear circuit lower bounds. If no depth-3 circuit of this form exists for some linear-size circuits, then we would have a separation between linear-size circuits and (for example) super-linear-size series-parallel circuits (by Valiant’s reduction for such circuits, see Theorem 9). Note that for the gate elimination method such limitations are known [17], and they do not apply to the approach presented in this work.

Our second result is a new “non-rigidity” result for matrices with small linear circuits: if a matrix  $M$  over  $\mathbb{F}_2$  can be computed by a linear circuit of size  $s$ , then it is possible to flip at most 16 bits in every row of  $M$  to drop its rank below  $s/4$ . This opens up an approach to proving linear circuit lower bounds on sizes up to  $4n$ .

► **Theorem 3.** *For every matrix  $M \in \mathbb{F}_2^{m \times n}$  of linear circuit complexity  $s$ ,  $\mathbb{R}_M(\lfloor s/4 \rfloor) \leq 16$ .*

## 1.2.2 Pseudorandom Objects and Circuit Lower Bounds

The classical result by Valiant shows that improvements of known depth-3 circuit lower bounds and rigid matrices imply super-linear log-depth circuit lower bounds. Our depth reductions show that even modest improvements of the known constructions also give modest improvements of unrestricted circuit lower bounds.

In the full version of this paper [18], we show that Valiant’s and our reduction are applicable to two more types of pseudorandom objects: dispersers for varieties, and functions having small correlation with low degree polynomials. These implications are briefly summarized<sup>3</sup> in Table 1.

## 1.2.3 Depth Reduction for Formulas

For DeMorgan formulas we give a conditional depth-reduction (stated informally, see Theorem 14 for a formal statement): if there is an  $\varepsilon > 0$  such that DeMorgan formulas of size  $s$  have probabilistic polynomials of degree  $s^{1-\varepsilon}$  and error  $1/3$  over  $\mathbb{F}_2$ , then for some  $\delta > 0$  every DeMorgan formula of size  $O(n^{3+\delta})$  can be written as an approximate sum of  $2^{n^{1-\gamma}}$  degree- $n^{1-\gamma}$   $\mathbb{F}_2$ -polynomials for a constant  $\gamma > 0$ .<sup>4</sup> Moreover, if there are probabilistic polynomials of degree  $O(\sqrt{s})$  for DeMorgan formulas of size  $s$  (which we conjecture is true), our depth reduction holds for DeMorgan formulas of size  $n^{3.99}$ .

<sup>3</sup> In this table we only present strongest implications from the strongest premises. Our reductions would still give new circuit lower bounds even from weaker objects (see the full version [18] for complete statements of these results). For example, the second line of the table says that a lower bound of  $2^{n-o(n)}$  against depth-3 circuits would give a lower bound of  $3.9n$ . On the other hand, a lower bound of  $2^{0.8n}$  would lead to an elementary proof of a lower bound of  $3.1n$ .

<sup>4</sup> Similar results can be stated for  $\mathbb{F}_p$  where  $p$  is any prime.

■ **Table 1** Comparing the depth reductions of this paper (labeled with \*) with the depth reduction of Valiant [56] (labeled with V). We use the following notation (all formal definitions are given in Section 2 and the full version of the paper [18]):  $s(f)$  is the smallest size of a circuit computing  $f$ ,  $s_{\log}$  refers to circuits of depth  $O(\log n)$ ,  $s_3^k$  refers to circuits that are ORs of  $k$ -CNFs,  $s_{\oplus}$  refers to circuits consisting of  $\oplus$  gates only;  $(d, m, s)$ -disp. stands for a  $(d, m, s)$ -disperser, a function that is not constant on any subset of the Boolean hypercube of size at least  $s$  that is defined as the set of common roots of at most  $m$  polynomials of degree at most  $d$ ;  $\mathbb{R}_M(r)$  is the row-rigidity of  $M$  for the rank  $r$  over  $\mathbb{F}_2$ , i.e., the smallest row-sparsity of a matrix  $A$  such that  $\text{rank}(M \oplus A) \leq r$ .

	improving known lower bound	to lower bound	implies lower bound
V	$s_3^{n^\varepsilon}(f) \geq 2^{n^{1-\varepsilon}}$ [39]	$s_3^{n^\varepsilon}(f) \geq 2^{\omega\left(\frac{n}{\log \log n}\right)}$	$s_{\log}(f) = \omega(n)$
*	$s_3^{16}(f) \geq 2^{\frac{n}{10}}$ [38]	$s_3^{16}(f) \geq 2^{n-o(n)}$	$s(f) \geq 3.9n$
V	$\left(n^\varepsilon, \infty, 2^{n-n^{1/2-\varepsilon}}\right)$ -disp. [44]	$\left(n^\varepsilon, \infty, 2^{n-\omega\left(\frac{n}{\log \log n}\right)}\right)$ -disp.	$s_{\log}(f) = \omega(n)$
*	$(16, \infty, 2^{(1-\varepsilon)n})$ -disp. [58]	$(16, 1.3n, 2^{o(n)})$ -disp.	$s(f) \geq 3.9n$
*	$\left(16, \frac{n}{(\log n)^c}, 2^{o(n)}\right)$ -disp. [9]	$(16, 1.3n, 2^{o(n)})$ -disp.	$s(f) \geq 3.9n$
V	$\mathbb{R}_M\left(\omega\left(\frac{n}{\log \log n}\right)\right) > \log \log n$ [15]	$\mathbb{R}_M\left(\omega\left(\frac{n}{\log \log n}\right)\right) > n^\varepsilon$	$s_{\oplus, \log}(M) = \omega(n)$
*	$\mathbb{R}_M\left(\frac{n}{65}\right) > 16$ [41]	$\mathbb{R}_M(n - o(n)) > 16$	$s_{\oplus}(M) \geq 4n$

Interestingly, the techniques used to express DeMorgan formulas as depth-3 circuits are totally different from those used in Theorem 1 and 3. Namely, we first balance a formula (without increasing its size too much), decompose it into a small top part and several small bottom formulas, approximate the top part by a real-valued low-degree polynomial, then rewrite the bottom parts as probabilistic polynomials (as hypothesized). Finally, we collapse these two polynomials into a depth-3 circuit.

The hypothesis that lower-degree probabilistic polynomials exist for every DeMorgan formula of size  $s$  looks very plausible. We have not found an example of a size- $s$  formula that resists the construction of an  $O(\sqrt{s})$ -degree probabilistic polynomial. Note that such polynomials do exist in the real-approximation sense [43]. For example, every symmetric function (such as MAJORITY) has probabilistic polynomials of  $O(\sqrt{s})$  degree [1], and it is not hard to show that the layered OR-AND tree of depth  $\log_2(s)$  has a probabilistic polynomial of  $O(\sqrt{s})$  degree as well; in fact, *any* layered tree of depth  $\log_2(s)$  with the same gate type at each layer (AND or OR) has such degree.<sup>5</sup> It is possible that there are “nasty” formulas that resist lower-degree probabilistic polynomials, but given the examples we already know, we do not know what they might look like.

► **Open Problem 4.** *Prove or disprove: every DeMorgan formula of size  $s$  has a probabilistic polynomial over  $\mathbb{F}_2$  of degree  $O(\sqrt{s})$  with constant error less than  $1/2$ .*

<sup>5</sup> Briefly: we can always write such formulas as either an OR of ANDs of  $O(\sqrt{s})$  literals, or an AND of ORs of  $O(\sqrt{s})$  literals. From there, we can simply replace the output gate with an  $O(1)$ -degree probabilistic polynomial (as in Razborov [42]), and the other gates with exact polynomials of  $O(\sqrt{s})$  degree.

### 1.3 Motivating Example

Here we provide a simple example of a reduction of unbounded circuits to depth-3 circuits, to give an idea of what is possible.

A *formula* is a circuit where every internal gate (i.e. not the inputs and not the output) has out-degree exactly 1. In our simple example, we will show that a circuit of size, say,  $2.7n$  can be computed by an OR of  $2^{0.9n}$  formulas of small size ( $2.7n$ ). Since we know almost-quadratic lower bounds [35] on formula size, we may hope to find a function which is not computable by an OR of  $\ll 2^n$  linear-size formulas.

► **Lemma 5 (Toy Example).** *Every circuit of size  $s$  can be expressed as an OR of  $2^{\lceil s/3 \rceil}$  formulas, each of size less than  $s$ .*

**Proof.** For a circuit  $C$ , let  $s(C)$  denote its size. For  $s \leq 3$ , we just transform a circuit into a single formula of the same size. For  $s > 3$ , we proceed by induction. If the given circuit  $C$  is a formula, no transformation is needed. Otherwise take the topologically first gate  $G$  of out-degree at least 2. Note  $G$  is computed by a formula (all previous gates have out-degree 1); let  $t = s(G)$  be the size of this formula. Consider two minimum-size circuits  $C_0$  and  $C_1$  that compute the same function as  $C$  on the input sets  $\{x \in \{0,1\}^n : G(x) = 0\}$  and  $\{x \in \{0,1\}^n : G(x) = 1\}$ , respectively. We claim that  $s(C_0), s(C_1) \leq s - t - 2 \leq s - 3$ , since to compute  $C_0$  and  $C_1$  one can remove the subcircuit in  $C$  computing gate  $G$  as well as two successors of  $G$ . The successors can be removed because  $G$  outputs a constant on both parts of the considered partition of the Boolean hypercube, and all gates in the subcircuit of  $G$  are only needed to compute  $G$  ( $G$  is computed by a formula). Now, note that

$$\mathcal{C}(x) \equiv (\neg G(x) \wedge C_0(x)) \vee (G(x) \wedge C_1(x)).$$

Applying the induction hypothesis to  $C_0$  and  $C_1$ , we can rewrite  $\mathcal{C}$  as an OR of at most  $2^{\lceil (s-3)/3 \rceil} \leq 2^{\lceil s/3 \rceil}$  formulas of size  $(s - t - 2) + (t + 1) < s$ . ◀

This result would imply a circuit lower bound of  $3n - o(n)$  for any function that has correlation at most  $2^{-n+o(n)}$  with all formulas of linear size. While we do know functions that have exponentially small correlation  $2^{-\varepsilon n}$  with formulas of linear size [45, 28, 51, 31, 55, 23], none of them gives a bound of  $2^{-n+o(n)}$ . At any rate there is an inherent limitation for this toy approach. By Parseval's identity, every Boolean function has a Fourier coefficient  $\geq 2^{-n/2}$ . This implies that the correlation of this function with the corresponding parity function is at least  $2^{-n/2}$  (and this is essentially tight correlation with small formulas for a random function). Since every parity on a subset of inputs can be computed by a formula of size  $\leq n$ , Lemma 5 would only be able to prove circuit lower bounds of  $1.5n$ .

In order to prove stronger circuit lower bounds, we need to improve both parameters: the constant 3 in the exponent, and the class of formulas we reduce circuits to. Our Theorem 1 achieves this: it reduces a circuit to an OR of  $2^{\lceil \frac{s}{3.5} \rceil}$  formulas, each of which is a 16-CNF. Therefore strong enough correlation bounds against 16-CNFs would yield new circuit lower bounds.

## 2 Definitions and Preliminaries

### 2.1 Unrestricted Circuits

Let  $B_{n,m}$  be the set of all Boolean functions  $f: \{0,1\}^n \rightarrow \{0,1\}^m$  and let  $B_2 = B_{2,1}$ . A *circuit* is a directed acyclic graph that has  $n$  nodes of in-degree 0 labeled with  $x_1, \dots, x_n$  that are called *input gates*. All other nodes are called *internal gates*, have in-degree 2, and are labeled

with operations from  $B_2$ . Some  $m$  gates are also marked as output gates. Such a circuit computes a function from  $B_{n,m}$  in a natural way. The *size*  $s(\mathcal{C})$  of a circuit  $\mathcal{C}$  is its number of *internal* gates. This definition extends naturally to functions:  $s(f)$  is the smallest size of a circuit computing the function  $f$ .

The *depth* of a gate  $G$  is the maximum number of edges (also called *wires*) on a path from an input gate to  $G$ . The depth of a circuit is the maximum depth of its gates. By  $s_{\log n}(f)$  we denote the smallest size of a circuit of depth  $O(\log n)$  computing  $f$ .

A circuit is called *linear* if it consists of  $\oplus$  gates only. The corresponding circuit size measure is denoted by  $s_{\oplus}$ .

Our unrestricted circuits are usually drawn with input gates at the top, so by a top gate of a circuit we mean a gate that is fed by two variables.

## 2.2 Series-Parallel Circuits

A *labeling* of a directed acyclic graph  $G = (V, E)$  is a function  $\ell: V \rightarrow \mathbb{N}$  such that for every edge  $(u, v) \in E$  one has  $\ell(u) < \ell(v)$ . A graph/circuit  $G$  is called *series-parallel* if there exists a labeling  $\ell$  such that for no two edges  $(u, v), (u', v') \in E$ ,  $\ell(u) < \ell(u') < \ell(v) < \ell(v')$ . The corresponding circuit complexity measure is  $s_{\text{sp}}$ .

## 2.3 Depth-3 Circuits

Unlike unrestricted circuits, depth-3 circuits are usually drawn the other way around, i.e., with the output gate at the top. In this paper, we focus on  $\text{OR} \circ \text{AND} \circ \text{OR}$  circuits, i.e., ORs of CNFs. We will use subscripts to indicate the fact that the fan-in of a particular layer is bounded. Namely, an  $\text{OR}_p \circ \text{AND}_q \circ \text{OR}_r$  circuit is an OR of at most  $p$  CNFs each of which contains at most  $q$  clauses and at most  $r$  literals in every clause. Since the gates of a depth 3 circuit are allowed to have an unbounded fan-in, it is natural to define the size of such a circuit as its number of wires. It is not difficult to see that for  $k = O(1)$  the size of an  $\text{OR} \circ \text{AND} \circ \text{OR}_k$  circuit is equal to the fan-in of its output gate up to a polynomial factor in  $n$ . By  $s_3^k(f)$  we denote the smallest size of an  $\text{OR} \circ \text{AND} \circ \text{OR}_k$  circuit computing  $f$ .

## 2.4 Rigidity

We say that a matrix  $M \in \mathbb{F}_2^{m \times n}$  is *s-sparse* if each *row* of  $M$  contains at most  $s$  non-zero elements. The *rigidity* of a matrix  $M \in \mathbb{F}_2^{m \times n}$  for the rank parameter  $r$  is the minimum sparsity of a matrix  $A \in \{0, 1\}^{m \times n}$  such that  $\text{rank}_{\mathbb{F}_2}(M \oplus A) \leq r$ :

$$\mathbb{R}_M(r) = \min\{s: \text{rank}_{\mathbb{F}_2}(M \oplus A) \leq r, A \text{ is } s\text{-sparse}\}.$$

## 2.5 Probabilistic, Approximate, and Robust Polynomials

Since even functions of small circuit and formula complexity may only have large-degree polynomial representations, it often proves convenient to use randomized polynomials or polynomials which approximate (rather than exactly compute) a given function.

► **Definition 6** (Probabilistic polynomials). *Let  $f: \{0, 1\}^n \rightarrow \{0, 1\}$  be a Boolean function. A distribution  $\mathcal{D}$  of  $n$ -variate degree- $d$  polynomials over  $\mathbb{F}_2$  is a probabilistic polynomial for  $f$  with degree  $d$  and error  $\varepsilon$  if for every  $x \in \{0, 1\}^n$ ,*

$$\Pr_{p \sim \mathcal{D}}[f(x) = p(x)] \geq 1 - \varepsilon.$$

► **Definition 7** (Approximate Polynomials). Let  $f: \{0, 1\}^n \rightarrow \{0, 1\}$  be a Boolean function. An  $n$ -variate multilinear degree- $d$  polynomial  $p$  over  $\mathbb{R}$  is an approximate polynomial for  $f$  with degree  $d$  and error  $\varepsilon$  if for every  $x \in \{0, 1\}^n$ ,

$$|p(x) - f(x)| \leq \varepsilon.$$

► **Definition 8** (Robust Polynomials). Let  $f: \{0, 1\}^n \rightarrow [0, 1]$  be a polynomial over  $\mathbb{R}$ . Then a polynomial  $p: \mathbb{R}^n \rightarrow \mathbb{R}$  is  $\delta$ -robust for  $f$  if for every  $x \in \{0, 1\}^n$  and for every  $\varepsilon \in [-1/3, 1/3]^n$ ,

$$|f(x) - p(x + \varepsilon)| \leq \delta.$$

## 2.6 Valiant's Depth Reductions

Here we formally recall the classical depth reduction results by Valiant [56].

► **Theorem 9** ([56, 4, 57]). For every  $c \geq 1$  and  $\varepsilon > 0$  there exists a  $\delta > 0$  such that every circuit  $\mathcal{C}$  of size  $cn$  and depth  $c \log n$  can be computed as

1. an  $OR_{\frac{\delta n}{2^{\log \log n}}} \circ AND \circ OR_{n^\varepsilon}$  circuit
2. and as an  $OR_{2^{\varepsilon n}} \circ AND \circ OR_{2^{(\log n)^{1-\delta}}}$  circuit.

Furthermore, for every  $c \geq 1$  and  $\varepsilon > 0$  there is a  $k \geq 1$  such that every series-parallel circuit of size  $cn$  and unbounded depth can be computed as an  $OR_{2^{\varepsilon n}} \circ AND \circ OR_k$  circuit.

Theorem 9 applied to linear circuits yields the following.

► **Theorem 10** ([56, 4, 57]). Let  $M \in \mathbb{F}^{m \times n}$  be a matrix. For every  $c \geq 1$  and  $\varepsilon > 0$  there exists  $\delta > 0$  such that, if a linear circuit  $\mathcal{C}$  of size  $cn$  and depth  $c \log n$  computes  $Mx$  for every  $x \in \mathbb{F}^n$ , then

1.  $\mathbb{R}_M \left( \frac{\delta n}{\log \log n} \right) \leq n^\varepsilon$ ;
2. and  $\mathbb{R}_M(\varepsilon n) \leq 2^{(\log n)^{1-\delta}}$ .

Furthermore, for every  $c \geq 1$  and  $\varepsilon > 0$  there is a  $k \geq 1$  such that if  $\mathcal{C}$  is a series-parallel linear circuit of size  $cn$  and unbounded depth, then  $\mathbb{R}_M(\varepsilon n) \leq k$ .

## 3 Formula Depth Reduction

In this section, we give a (conditional) depth reduction for DeMorgan formulas. We start by balancing a given formula. For this we use the following result due to Tal [55].

► **Lemma 11** (Claim VI.2 in [55]). Let  $F$  be a DeMorgan formula of size  $s$  over the set of variables  $X = \{x_1, \dots, x_n\}$ , and  $t$  be some parameter; then, there exist  $k \leq 36s/t$  formulas over  $X$ , denoted by  $T_1, \dots, T_k$ , each of size at most  $t$ , and there exists a read-once formula  $F'$  of size  $k$  such that  $F'(T_1(x), \dots, T_k(x)) = F(x)$  for all  $x \in \{0, 1\}^n$ .

Below we will also make use of the following results by Reichardt [43] and Sherstov [53].

► **Theorem 12** ([43]). If  $f: \{0, 1\}^n \rightarrow \{0, 1\}$  can be computed by a DeMorgan formula of size  $s$ , then  $f$  has an approximate polynomial of degree  $O(\sqrt{s})$  with error  $\varepsilon = 1/10$ .

► **Theorem 13** ([53]). If  $f: \{0, 1\}^n \rightarrow [0, 1]$  is a polynomial of degree  $d$  over  $\mathbb{R}$ , then there is a  $\delta$ -robust polynomial  $p$  for  $f$  of degree  $O(d + \log(1/\delta))$ .

## 24:10 Circuit Depth Reductions

Now we are ready to present the main result of this section: Assuming DeMorgan formulas of size  $s$  have probabilistic polynomials of degree  $O(s^{1-\delta})$  for some  $\delta > 0$ , we will obtain subexponential-size depth-3 circuits computing formulas of super-cubic size.

In the following, a **SUM** gate will compute an *approximate sum*: a (real-weighted) sum of the inputs such that, over all Boolean inputs, the sum is within  $\pm 1/3$  of the 0-1 value of a desired Boolean function.

► **Theorem 14.** *Suppose for some  $\delta > 0$ , DeMorgan formulas of size  $\ell$  have probabilistic polynomials of degree  $\ell^{1-\delta}$  with error  $1/3$ . Then for every  $\alpha < \delta/(1-\delta)$  there is a  $\gamma > 0$ , so that for every formula  $F$  of size  $s = O(n^{3+\alpha})$ , there is a  $2^{n^{1-\gamma}}$ -size approximate sum of degree- $n^{1-\gamma}$   $\mathbb{F}_2$ -polynomials computing  $F$ . That is,  $F$  can be computed by a*

$$\text{SUM}_{2^{n^{1-\gamma}}} \circ \text{MOD2}_{2^{n^{1-\gamma}}} \circ \text{AND}_{n^{1-\gamma}}.$$

**Proof.** First, we apply Lemma 11 to  $F$  for some parameter  $t$  to be defined later. We obtain a read-once formula  $F'$  of size  $k = O(s/t)$ , and  $k$  formulas  $T_1, \dots, T_k$  each of size  $\leq t$ .

Let  $p$  be an approximate polynomial (over the reals) for  $F'$  of degree  $d = O(\sqrt{k})$  with error  $1/10$ , guaranteed by Theorem 12. Applying Theorem 13, we get a  $1/10$ -robust polynomial  $p'$  for  $p$  of degree  $d' = O(\sqrt{k})$ .

By the hypothesis of the theorem, we know that each  $T_i$  has a probabilistic polynomial of degree  $O(t^{1-\delta})$  with error  $\varepsilon = 1/3$ . For each  $T_i$ , draw  $O(\log s)$  independent copies of this probabilistic polynomial, and take their majority vote with an  $O(\log s)$ -degree polynomial. For an appropriate leading constant in the big-O, we can obtain a probabilistic polynomial for  $T_i$  of degree  $O(t^{1-\delta} \cdot \log s)$  with error  $1/(10s)$ .

Let  $\mathcal{D}_1, \dots, \mathcal{D}_k$  be probabilistic polynomials of degree  $D = O(t^{1-\delta} \cdot \log s)$  with error  $\varepsilon = 1/(10s)$  for the formulas  $T_1, \dots, T_k$ . The error bound  $\varepsilon = 1/(10s)$  guarantees that for every  $x \in \{0, 1\}^n$ , all  $k$  polynomials compute the correct value with probability at least  $9/10$ .

Now for every  $T_i$ , we compute the average  $A_i$  (over the reals) of  $O(n)$  independent samples from  $\mathcal{D}_i$ . By a Chernoff bound and union bound, each  $A_i$  is within  $\pm 1/10$  of the correct 0-1 value for  $T_i$ , over all  $2^n$  inputs  $x$ , with probability of error  $1/\exp(n)$ . By the properties of robust polynomials,  $p'$  fed the sums  $A_i$  will still output the correct value (within  $\pm 1/10$ ) for all inputs  $x \in \{0, 1\}^n$ , for some choice of samples.

Therefore  $F$  can be computed by a

$$\text{SUM}_{n^{d'}} \circ \text{PRODUCT}_{d'} \circ \text{SUM}_{O(n)} \circ \text{MOD2} \circ \text{AND}_D.$$

Applying distributivity to the PRODUCT of SUMs, we get

$$\text{SUM}_{n^{d'}} \circ \text{SUM}_{n^{O(d')}} \circ \text{PRODUCT}_{d'} \circ \text{MOD2} \circ \text{AND}_D.$$

Noting the PRODUCTs now take 0/1 inputs, we can replace them with ANDs:

$$\text{SUM}_{n^{d'}} \circ \text{SUM}_{n^{O(d')}} \circ \text{AND}_{d'} \circ \text{MOD2} \circ \text{AND}_D.$$

Taking the Fourier expansion of the AND function, we can replace each AND gate with a SUM of  $2^{d'}$  MOD2s of fan-in  $\leq d'$ :

$$\text{SUM}_{n^{d'}} \circ \text{SUM}_{n^{O(d')}} \circ \text{SUM}_{2^{d'}} \circ \text{MOD2} \circ \text{AND}_D.$$

Merging the SUMs, our final expression has the form:

$$\text{SUM}_{n^{O(d')}} \circ \text{MOD2} \circ \text{AND}_D.$$

Finally, we want to choose a value of  $t$  so that the fan-in of the SUM is subexponential, and the fan-ins of the AND's are sublinear (which will also imply that the fan-in of the MOD2's are sub-exponential). Let  $t = n^{1+\beta}$ , where  $\beta$  is an arbitrary number between  $\alpha < \beta < \delta/(1-\delta)$ . Note that

$$d' = O(\sqrt{k}) = O(\sqrt{s/t}) = O(n^{1-\frac{\beta-\alpha}{2}}) = O(n^{1-\gamma})$$

for every  $0 < \gamma < \frac{\beta-\alpha}{2}$ . Also, observe that

$$D = O(t^{1-\delta} \cdot \log s) = O(n^{1-(1-\delta)(\delta/(1-\delta)-\beta)} \log n) = O(n^{1-\gamma})$$

for every  $0 < \gamma < (1-\delta)(\delta/(1-\delta)-\beta)$ .

From the upper bounds on  $d'$  and  $D$ , we have that  $F$  can be computed by

$$\text{SUM}_{2^{n^{1-\gamma}}} \circ \text{MOD2}_{2^{n^{1-\gamma}}} \circ \text{AND}_{n^{1-\gamma}}$$

for some  $\gamma > 0$ . ◀

The above formula depth reduction shows that, if there are more efficient probabilistic polynomials for DeMorgan formulas (and we have no reason to doubt this), then super-cubic formulas have interesting representations as approximate sums of sub-exponentially many sub-linear degree  $\mathbb{F}_2$ -polynomials. Recent work [59, 7] can already be applied to prove interesting lower bounds against approximate sums of  $2^{n^\alpha}$   $\mathbb{F}_2$ -polynomials of degree  $n^\beta$ , where  $\alpha + \beta < 1$ . The remaining challenge will be to prove lower bounds when  $\max\{\alpha, \beta\} < 1$ .

## 4 Circuit Depth Reductions

In this section, we present new depth reductions for circuits with unrestricted depth.

### 4.1 Linear Circuits

We start by considering *linear* circuits, i.e., circuits consisting of  $\oplus$  gates only. For technical reasons, we assume that there are  $n+1$  input gates in a linear circuit:  $x_1, \dots, x_n$  as well as the constant 0. For a matrix  $M \in \{0,1\}^{m \times n}$ , we say that a linear circuit  $\mathcal{C}$  with  $m$  outputs computes the linear transformation  $M$  if the  $i$ -th output of  $\mathcal{C}(x)$  equals the  $i$ -th row of  $Mx$  for all  $x \in \{0,1\}^n$ , treating  $\mathcal{C}(x)$  as the vector of output values. We say that a linear circuit  $\mathcal{C}$  computing  $M$  is *optimal* if no circuit of smaller size computes  $M$ .

The main result of this subsection asserts that matrices computable by small linear circuits are not too rigid. The contrapositive says: to get an improved lower bound on the size of linear circuits, it suffices to construct a matrix with good rigidity parameters. Below, we restate the corresponding theorem formally and then prove it.

► **Theorem 3.** *For every matrix  $M \in \mathbb{F}_2^{m \times n}$  of linear circuit complexity  $s$ ,  $\mathbb{R}_M(\lfloor s/4 \rfloor) \leq 16$ .*

**Proof.** Let  $\mathcal{C}$  be an optimal circuit of size  $s$  computing  $M$ . If  $s < 16$  or the depth of  $\mathcal{C}$  is at most 4, then each output depends on at most 16 variables. Hence  $M$  is 16-sparse and the theorem statement holds. Consider this as the base case of an induction on  $s$ .

For the induction step, we “normalize”  $\mathcal{C}$ . Namely, we show how to express  $M$  as the (modulo 2) sum of two  $\mathbb{F}_2$ -matrices  $A$  and  $B$ , where  $A$  is 16-sparse (each row has  $\leq 16$  ones) and  $B$  has rank at most  $\lfloor s/4 \rfloor$ . Note that if  $\mathcal{C}$  has an output gate  $H$  of depth at most 4, then  $H$  depends on at most  $2^4 = 16$  inputs. Thus the corresponding row  $r_H$  of  $M$  has at most 16 ones. Consider the  $(m-1) \times n$  matrix  $M_{-H}$  obtained by removing  $r_H$  from  $M$ . We claim

that  $\mathbb{R}_{M-H}(\lfloor s/4 \rfloor) \leq 16$  implies  $\mathbb{R}_M(\lfloor s/4 \rfloor) \leq 16$ . Indeed, suppose  $M_{-H} = A_{-H} \oplus B_{-H}$  where  $A_{-H}$  is 16-sparse and  $\text{rank}(B_{-H}) \leq \lfloor s/4 \rfloor$ . To get matrices  $A$  and  $B$  for  $M$ , we simply add the row  $r_H$  to  $A_{-H}$  and a corresponding all-zero row to  $B_{-H}$ . Clearly, the resulting matrix  $A$  is 16-sparse and the rank of the resulting matrix  $B$  does not change. Thus, in the following, we assume WLOG that  $\mathcal{C}$  has no output gates of depth at most 4. Our crucial step is the following claim.

▷ **Claim 15.** Let  $\mathcal{C}$  be an optimal linear circuit computing  $M \in \{0,1\}^{m \times n}$  such that  $s(\mathcal{C}) \geq 16$ , and no output gate of  $\mathcal{C}$  has depth smaller than 5. Then there is a gate  $G$  in  $\mathcal{C}$  and a linear circuit  $\mathcal{C}'$  computing a matrix  $M' \in \{0,1\}^{m \times n}$  with the properties:

1.  $s(\mathcal{C}') \leq s(\mathcal{C}) - 4$ , and
2. for every  $x \in \{0,1\}^n$ , if  $G(x) = 0$  then  $\mathcal{C}(x) = \mathcal{C}'(x)$ .

For now, suppose the claim is proved. Consider the circuit  $\mathcal{C}'$ , gate  $G$  in  $\mathcal{C}$ , and matrix  $M'$  provided by Claim 15. Let  $g \in \{0,1\}^{1 \times n}$  be the characteristic vector of the linear function computed by  $G$ , so that  $G(x) = gx$ . By the claim,  $gx = 0$  implies  $(M \oplus M')x = 0$ . Hence  $(M \oplus M')$  is either the zero matrix, or it defines the same linear subspace as  $g$ :  $M \oplus M' = tg$  for a vector  $t \in \{0,1\}^{m \times 1}$ .

By the induction hypothesis,  $M' = A' \oplus B'$  where  $A'$  is 16-sparse, and  $\text{rank}(B') \leq \lfloor \frac{s-4}{4} \rfloor = \lfloor \frac{s}{4} \rfloor - 1$ . Thus,  $M = A' \oplus B$ , where the matrix  $B = B' \oplus tg$  has rank at most  $\lfloor s/4 \rfloor$  by subadditivity of the rank function. ◀

We now turn to proving the remaining claim.

Proof of Claim 15.

**Case 1: There is a gate  $G$  in  $\mathcal{C}$  of depth at least 2 and at most 4, and has out-degree at least 2.** Let the predecessors of  $G$  be  $B$  and  $C$ , and call two of its successors  $D$  and  $E$ , see Figure 1 (in this and the following figures, we write the out-degrees of some of the gates near them). The circuit  $\mathcal{C}'$  is obtained from  $\mathcal{C}$  by “assigning” the output of  $G$  to be 0. Note that  $B(x) = C(x)$  for all  $x \in \{0,1\}^n$  where  $G(x) = 0$ . At least one of  $B$  and  $C$  must be an internal gate (otherwise  $G$  would have depth 1), let it be  $C$ . Since  $C$  computes the same function as  $B$ , it may be removed from  $\mathcal{C}'$ : we remove it, and replace every wire of the form  $C \rightarrow H$  by a new wire  $B \rightarrow H$ . Note that neither  $G$  nor  $C$  is an output gate. Now, we show that both  $D$  and  $E$  can also be removed. Let us focus on the gate  $D$  (for  $E$  it is shown similarly) and call its other predecessor  $F$ . Since  $G = 0$ , the gate  $D$  computes the same function as  $F$ . This means that one may remove  $D$ : we remove it and replace every wire  $D \rightarrow H$  by a wire  $F \rightarrow H$ . If  $D$  happens to be an output gate, we move the corresponding output label from  $D$  to  $F$ .

**Case 2: All gates of depth at least 2 and at most 4 have out-degree exactly 1 in  $\mathcal{C}$ .** Take a gate  $G$  of depth 4 and trace back its longest path to an input:  $x_i \rightarrow D \rightarrow C \rightarrow B \rightarrow G$ . Let also  $E$  be the successor of  $G$  (which exists because  $\mathcal{C}$  has depth at least 5). By assumption, gates  $B$  and  $C$  have out-degree 1. This means that in  $\mathcal{C}$  they are only used for computing the gate  $G$ . This, in turn, means that assuming  $G = 0$ , we can remove  $G$ ,  $B$ , and  $C$  (note none of them is an output). Finally, the gate  $E$  can be replaced by the other input  $F$  of  $E$  (note  $F \notin \{B, C, G\}$ , since  $\mathcal{C}$  is optimal).

This completes the proof. ◀

► **Remark 16.** Extending the same ideas, one can show that any linear circuit  $\mathcal{C}$  of size  $s$  can be computed by an  $\text{OR}_{2^{\lceil \frac{s}{4} \rceil}} \circ \text{AND}_{s \cdot 2^{14}} \circ \text{OR}_{16}$  circuit. For this, one considers two optimal circuits  $\mathcal{C}_0$  and  $\mathcal{C}_1$  resulting from  $\mathcal{C}$  by assuming  $G = 0$  and  $G = 1$ , respectively. As shown in the proof, both  $\mathcal{C}_0$  and  $\mathcal{C}_1$  have size at most  $s - 4$ . One then proceeds by induction. We illustrate this approach in full detail in the next subsection.

Case 1: assuming  $G = 0$ , the gate  $G$  is removed,  $B$  is replaced by  $C$ , and  $D$  and  $E$  are replaced by their other predecessors.

Case 2: assuming  $G = 0$ , the gates  $B$ ,  $C$ , and  $G$  are removed whereas  $E$  is replaced by  $F$ .

■ **Figure 1** Cases in the proof of Claim 15.

► **Remark 17.** The proof of Theorem 3 gives a decomposition  $M = A \oplus B = A \oplus (C \cdot D)$ , where  $A \in \mathbb{F}^{m \times n}$  is 16-sparse,  $C \in \mathbb{F}^{m \times s/4}$  is composed of vectors  $t$ , and  $D \in \mathbb{F}^{s/4 \times n}$  is composed of vectors  $g$ . Since the chosen gate  $G$  always has depth at most four, the vector  $g$  is 16-sparse. Thus, we in fact have a decomposition  $M = A \oplus (C \cdot D)$ , where both  $A$  and  $D$  are 16-sparse. In particular, the row-space of  $M$  is spanned by the union of row-spaces of  $A$  and  $D$ . This implies that the row-space of  $M$  can be spanned by at most  $(m + \frac{s}{4})$  16-sparse vectors. The corresponding matrix property is called *outer dimension*, and it is studied in [37, 32]. While the current lower bounds on the outer dimension of explicit matrices do not lead to new circuit lower bounds, it would be interesting to study their applications in this context.

## 4.2 General Boolean Circuits

In this section, we study the following natural question: given a Boolean circuit<sup>6</sup> and given an integer  $k \geq 2$ , what is the smallest  $\text{OR} \circ \text{AND} \circ \text{OR}_k$  circuit computing the same function? To this end, we introduce the following notation. For an integer  $k \geq 2$ , we define  $\alpha(k)$  as the infimum of all values  $\alpha$  such that any circuit of size  $s$  can be rewritten as a  $\text{OR}_{2^{\alpha s}} \circ \text{AND} \circ \text{OR}_k$  circuit.

For proving upper bounds on  $\alpha(k)$  it will be convenient to consider the following class of circuits. Let  $\text{OR}_p \circ \text{AND}_q \circ C(r)$  be a class of circuits with an output OR that is fed by at most  $p$  AND's of at most  $q$  circuits of size at most  $r$ .

► **Theorem 18.** *Every circuit of size  $s$  can be computed as:*

1. an  $\text{OR}_{2^{\lceil \frac{s}{2} \rceil}} \circ \text{AND}_{\lceil \frac{s}{2} \rceil} \circ C(1)$  circuit;
2. an  $\text{OR}_{2^{\lceil \frac{s}{3.9} \rceil}} \circ \text{AND}_{\lceil \frac{s}{3} \rceil} \circ C(15)$  circuit.

<sup>6</sup> In this section we consider functions with one output, but these results can be trivially generalized to the multi-output case.

## 24:14 Circuit Depth Reductions

Note that any circuit of size  $r$  depends on at most  $r + 1$  variables, and hence can be written as an  $(r + 1)$ -CNF with at most  $2^r$  clauses. Therefore every  $\text{OR}_p \circ \text{AND}_q \circ C(r)$  circuit can be easily converted into a  $\text{OR}_p \circ \text{AND}_{q2^r} \circ \text{OR}_{r+1}$  circuit. Theorem 1, which we restate below, is then an immediate corollary of Theorem 18. In turn, it implies that  $\alpha(2) \leq \frac{1}{2}$  and  $\alpha(16) \leq \frac{1}{3.9}$ .

► **Theorem 1.** *Every circuit of size  $s$  can be computed as an  $\text{OR}_{2^{\lceil \frac{s}{2} \rceil}} \circ \text{AND}_s \circ \text{OR}_2$  circuit and as an  $\text{OR}_{2^{\lceil \frac{s}{3.9} \rceil}} \circ \text{AND}_{2^{14} \cdot s} \circ \text{OR}_{16}$  circuit.*

**Proof of Theorem 18.** Both parts are proven in a similar fashion. We proceed by induction on  $s$ . The base case is when  $s$  is small. We then just have an  $\text{OR}_1 \circ \text{AND}_1 \circ C(s)$  circuit.

For the induction step we take a gate  $G$  of  $\mathcal{C}$  and consider two circuits  $\mathcal{C}_0$  and  $\mathcal{C}_1$  where  $\mathcal{C}_i$  computes the same as  $\mathcal{C}$  on all inputs  $\{x \in \{0, 1\}^n : G(x) = i\}$ . We may assume both  $\mathcal{C}_i$ 's are minimal size among all such circuits. Since  $\mathcal{C}_i$  can be obtained from  $\mathcal{C}$  by removing the gate  $G$  (as it computes the constant  $i$  on the corresponding subset of the Boolean hypercube), we conclude that  $s(\mathcal{C}_i) < s$ . This allows us to proceed by induction. Assume that by the induction hypothesis  $\mathcal{C}_i$  is guaranteed to be expressible as an  $\text{OR}_{p_i} \circ \text{AND}_{q_i} \circ C(r_i)$  circuit. We use the following identity to convert  $\mathcal{C}$  into the required circuit:

$$\mathcal{C}(x) \equiv ([G(x) = 0] \wedge \mathcal{C}_0(x)) \vee ([G(x) = 1] \wedge \mathcal{C}_1(x)). \quad (1)$$

Assume that the subcircuit of  $\mathcal{C}$  computing the gate  $G$  has at most  $t$  gates. We claim that  $[G(x) = i] \wedge \mathcal{C}_i$  can be written as an  $\text{OR}_{p_i} \circ \text{AND}_{q_i+1} \circ C(\max\{r_i, t\})$  circuit. For this, we just feed a new circuit computing  $G$  to every AND gate. Plugging this into (1), gives an

$$\text{OR}_{p_0+p_1} \circ \text{AND}_{\max\{q_0, q_1\}+1} \circ C(\max\{t, r_0, r_1\}) \quad (2)$$

circuit for computing  $\mathcal{C}$ .

Below, we provide details specific to each of the two items from the theorem statement. In particular, we estimate the parameters  $p_i$ 's,  $q_i$ 's,  $r_i$ 's, and  $t$  and plug them into (2).

1. The base case is  $s = 1$ . Then  $\mathcal{C}$  consists of a single gate and can be expressed as an  $\text{OR}_1 \circ \text{AND}_1 \circ C(1)$  circuit. For the induction step, assume that  $s \geq 2$  and take a gate  $A$  that depends on two variables. Let  $G = A$ , hence  $t = 1$ . The gate  $A$  must have at least one successor (otherwise  $\mathcal{C}$  can be replaced by a circuit with smaller than  $s$  gates). Clearly,  $A$  and its successors are not needed in  $\mathcal{C}_i$ 's. Hence, by the induction hypothesis  $p_i \leq 2^{\frac{s-2}{2}+1}$ ,  $q_i \leq \frac{s-2}{2} + 1$ ,  $r_i \leq 1$ . Plugging this into (2) gives the desired result.
2. Take a gate  $A$  that is fed by two variables  $x$  and  $z$  and has the maximum distance to an output. If its distance to output is at most 4, then  $s(\mathcal{C}) \leq 15$  and we just rewrite it as an  $\text{OR}_1 \circ \text{AND}_1 \circ C(15)$  circuit. This is the base case. Assume now that the distance from  $A$  to the output gate is at least 5. In the analysis below, we always “follow” the longest path from  $A$  to the output. This allows us to conclude that any such path is long enough and hence each gate considered has positive out-degree (i.e., is not an output). Moreover, each gate on this path cannot depend on too many variables. Let  $B$  be a successor of  $A$  on the longest path to the output.

In the five cases below, we show that we can always find a gate  $G$  that  $s(G) \leq 15$  and both  $s(\mathcal{C}_0)$  and  $s(\mathcal{C}_1)$  are small enough. In particular,  $s(\mathcal{C}_0), s(\mathcal{C}_1) \leq s - 4$  works for us:  $p_0 + p_1 \leq 2 \cdot 2^{\lceil \frac{s-4}{3.9} \rceil} < 2^{\lceil \frac{s}{3.9} \rceil}$ ,  $\max\{q_0, q_1\} + 1 \leq \lceil \frac{s-4}{3} \rceil + 1 < \lceil \frac{s}{3} \rceil$ .

See Figure 2 for an illustration of the five cases. For a gate  $G$ , by  $\text{out}(G)$  we denote the out-degree of  $G$ .

Case 1.1: when  $E$  is constant, one removes  $B$ ,  $C$ ,  $E$ , and successors of  $E$ . Case 1.2: when  $C$  is constant, one removes  $B$ ,  $C$ , and successors of  $C$ . Case 2.1: when  $B$  is constant, one removes  $B$  and its successors, replace  $A$  by  $D \oplus c$ . Case 2.2.1: when  $B$  is constant, one removes  $B$  and its successors, and  $A$ . Case 2.2.2: when  $B$  is constant, one removes  $B$  and its successors; moreover,  $B = 1$  it forces  $A$  to be a constant and removes  $A$  and its successors.

■ **Figure 2** Cases in the proof of the second part of Theorem 18.

**Case 1:**  $\text{out}(B) = 1$ . Let  $C$  be the successor of  $B$ .

**Case 1.1:**  $\text{out}(C) = 1$ . Let  $E$  be the successor of  $C$ . Let  $G = E$ . In  $\mathcal{C}_i$ 's, one removes  $B$ ,  $C$  (as they were only needed to compute  $E$  that is now a constant),  $E$ , and the successors of  $E$ .

**Case 1.2:**  $\text{out}(C) \geq 2$ . Let  $G = C$ . In  $\mathcal{C}_i$ 's, one removes  $B$ ,  $C$ , and the successors of  $C$ .

**Case 2:**  $\text{out}(B) \geq 2$ . Let  $D$  be the other input of  $B$ . It may be a gate or an input variable. If  $B$  computes a constant Boolean binary operation or an operation that depends on  $A$  or  $D$  only, then  $C$  is not optimal. Otherwise,  $B$  computes one of the following two types of functions (either linear or quadratic polynomial over  $\mathbb{F}_2$ ):

**Case 2.1:**  $B(A, D) = A \oplus D \oplus c$  where  $c \in \{0, 1\}$ . Let  $G = B$ . In  $\mathcal{C}_i$ 's, one immediately removes  $B$  and its successors. Also, in  $\mathcal{C}_i$ ,  $D \oplus A = i \oplus c$ . Hence,  $A$  may be replaced by  $D \oplus i \oplus c$ .

**Case 2.2:**  $B(A, D) = (A \oplus a) \cdot (D \oplus d) \oplus c$  where  $a, d, c \in \{0, 1\}$ .

**Case 2.2.1:**  $\text{out}(A) = 1$ . Let  $G = C$ . In  $\mathcal{C}_i$ 's, one removes  $B$ , its successors, and  $A$ .

**Case 2.2.2:**  $\text{out}(A) \geq 2$ . Let  $D$  be the other successor of  $B$ . Let  $G = B$ . In  $\mathcal{C}_i$ 's, one removes  $B$  and its successors. Also,  $B = c \oplus 1$  forces  $A = a \oplus 1$  and  $D = d \oplus 1$ . Hence, in  $\mathcal{C}_{c \oplus 1}$  two additional gates are removed:  $A$  and its successors (if a successor of  $B$  happens to be a successor of  $A$  also, then it is a function on  $A$  and  $D$  and the circuit can be simplified, which contradicts its optimality). Hence,  $p_0 + p_1 \leq 2^{\lceil \frac{s-3}{3.9} \rceil} + 2^{\lceil \frac{s-5}{3.9} \rceil}$ . This is smaller than  $2^{\lceil \frac{s}{3.9} \rceil}$  since  $2^{-\frac{3}{3.9}} + 2^{-\frac{5}{3.9}} < 1$ .

This completes the proof. ◀

► **Remark 19.** It is not difficult to see that the output OR gate is a “disjoint OR”, and can be replaced by a SUM gate over the integers. In other words, for every  $x \in \{0, 1\}^n$ , at most one subcircuit feeding into the OR gate may evaluate to 1. This holds because we always consider two mutually exclusive cases:  $G = 0$  or  $G = 1$ .

### 4.3 Properties of $\alpha(k)$

We start by observing a lower bound on  $\alpha(k)$ .

► **Lemma 20.** *For any integer  $k \geq 2$ ,  $\alpha(k) \geq 1/k$ .*

**Proof.** Let  $\oplus_n$  denote the parity function of  $n$  inputs. It has  $2^{n-1}$  inputs where it is equal to 1 and all these inputs are isolated, that is, the Hamming distance between any pair of them is at least 2. As proven by Paturi, Pudlák, and Zane [39], every  $k$ -CNF has at most  $2^{n(1-1/k)}$  isolated satisfying assignments. This implies that  $\oplus_n$  cannot be computed by an OR of fewer than  $2^{n/k-1}$   $k$ -CNFs. Since  $s(\oplus_n) = n - 1$ , this implies that

$$\alpha(k) \geq \frac{\frac{n}{k} - 1}{n - 1}.$$

Since this must hold for arbitrary large  $n$ ,  $\alpha(k) \geq 1/k$ . ◀

Thus, we know the exact value of  $\alpha(2) = \frac{1}{2}$ . This immediately implies a circuit lower bound of  $2n - o(n)$  for BCH codes. Indeed, it was shown in [40] that when the bottom fan-in is restricted to  $k = 2$ , then BCH codes require depth-3 circuits of size  $2^{n-o(n)}$ . And, since  $\alpha(2) = \frac{1}{2}$ , they must have circuit complexity at least  $2n - o(n)$ .

One can use techniques from Theorem 18 to prove an upper bound of  $\alpha(3) \leq \frac{\log_2 3}{4}$ . Thus, we know that

$$\frac{1}{3} \leq \alpha(3) \leq \frac{\log_2 3}{4} < 0.3963.$$

We conjecture that the upper bound on  $\alpha_3$  is tight. One way to prove this would be to find the  $s_3^3$  complexity of the inner product function:  $\text{IP}(x_1, \dots, x_n) = x_1x_2 \oplus x_3x_4 \oplus \dots \oplus x_{n-1}x_n$ . In particular, if the upper bound shown in the next lemma is tight, then  $\alpha(3) = \frac{\log_2 3}{4}$ .

► **Lemma 21.**

1.  $2^{\frac{n}{4}} \leq s_3^2(\text{IP}) \leq 2^{\frac{n}{2}-o(n)}$ .
2.  $2^{\frac{n}{6}} \leq s_3^3(\text{IP}) \leq 3^{\frac{n}{4}}$ .

**Proof.** Note that by substituting every other input of IP by 1, one gets the parity function  $\oplus_{\frac{n}{2}}$  on the remaining  $n/2$  inputs. Now both lower bounds follow from the corresponding lower bounds for the parity function:  $s_3^2(\oplus_k) \geq 2^{\frac{k}{2}}$  and  $s_3^3(\oplus_k) \geq 2^{\frac{k}{3}}$ .

1. The first upper bound follows from the fact that  $\text{IP}(x_1, \dots, x_n) = 1$  iff there is an odd number of ones among

$$p_1 = x_1x_2, p_2 = x_3x_4, \dots, p_{\frac{n}{2}} = x_{n-1}x_n.$$

Hence,

$$\text{IP}(x_1, \dots, x_n) \equiv \bigvee_{S \subseteq [\frac{n}{2}]: |S| \bmod 2 = 1} \left( \bigwedge_{i \in S} [p_i = 1] \wedge \bigwedge_{i \notin S} [p_i = 0] \right).$$

It remains to note that each  $[p_i = c]$  can be expressed as a 2-CNF because  $p_i$  depends on two variables.

2. For the second upper bound, note that  $\text{IP}(x_1, \dots, x_n) = 1$  iff there is an odd number of 1's among

$$p_1 = x_1x_2 \oplus x_3x_4, p_2 = x_5x_6 \oplus x_7x_8, \dots, p_{\frac{n}{4}} = x_{n-3}x_{n-2} \oplus x_{n-1}x_n.$$

To compute IP by a depth 3 circuit, we go through all possible  $2^{\frac{n}{4}-1}$  values of  $p_1, \dots, p_{\frac{n}{4}}$  such that an odd number of them is equal to 1:

$$\text{IP}(x_1, \dots, x_n) \equiv \bigvee_{S \subseteq [\frac{n}{4}]: |S| \bmod 2 = 1} \left( \bigwedge_{i \in S} [p_i = 1] \wedge \bigwedge_{i \notin S} [p_i = 0] \right) \quad (3)$$

Now, we show that  $[p_i = 0]$  can be written as a single 3-CNF, whereas  $[p_i = 1]$  can be expressed as an OR of two 3-CNFs. W.l.o.g. assume that  $i = 1$ . The clauses of a 3-CNF expressing  $[p_i = 0]$  should reject all assignments to  $x_1, x_2, x_3, x_4 \in \{0, 1\}$  where  $\text{IP}(x_1, x_2, x_3, x_4) = 1$ . In all such assignments, one of the two monomials ( $x_1 x_2$  and  $x_3 x_4$ ) is equal to 0 whereas the other one is equal to 1. Hence, one needs to write down a set of clauses rejecting the following four partial assignments:  $\{x_1 = 0, x_3 = x_4 = 1\}$ ,  $\{x_2 = 0, x_3 = x_4 = 1\}$ ,  $\{x_1 = x_2 = 1, x_3 = 0\}$ ,  $\{x_1 = x_2 = 1, x_4 = 0\}$ . Thus,

$$[p_1(x_1, x_2, x_3, x_4) = 0] \equiv (x_1 \vee \neg x_3 \vee \neg x_4) \wedge (x_2 \vee \neg x_3 \vee \neg x_4) \wedge (\neg x_1 \vee \neg x_2 \vee x_3) \wedge (\neg x_1 \vee \neg x_2 \vee x_4).$$

In turn, to express  $[p_1 = 1]$  as an OR of two 3-CNFs we consider both assignments to  $x_1$ :

$$[p_1(x_1, x_2, x_3, x_4) = 1] \equiv ((x_1) \wedge [x_2 \oplus x_3 x_4 = 0]) \vee ((\neg x_1) \wedge [x_3 x_4 = 1]).$$

It remains to note that each of  $[x_2 \oplus x_3 x_4 = 0]$  and  $[x_3 x_4 = 1]$  can be written as a 3-CNF. Let  $[p_i = 0] \equiv P_i$  and  $[p_i = 1] \equiv ((x_i) \wedge Q_i) \vee ((\neg x_i) \wedge R_i)$  where  $P_i$ ,  $Q_i$ , and  $R_i$  are 3-CNFs. One may then expand (3) as follows:

$$\bigvee_{S \subseteq [\frac{n}{4}]: |S| \bmod 2 = 1} \left( \bigvee_{T \subseteq S} \left( \bigwedge_{i \in T} ((x_i) \wedge Q_i) \wedge \bigwedge_{i \in S \setminus T} ((\neg x_i) \wedge R_i) \wedge \bigwedge_{i \notin S} P_i \right) \right)$$

The fan-in of the resulting OR-gate is

$$\sum_{S \subseteq [\frac{n}{4}]: |S| \bmod 2 = 1} 2^{|S|} \leq \sum_{i=0}^{\frac{n}{4}} \binom{n/4}{i} 2^i = 3^{\frac{n}{4}}. \quad \blacktriangleleft$$

► **Open Problem 22.** Determine  $s_3^3(\text{IP})$ .

Besides finding the exact values of  $\alpha(k)$ , it would be interesting to find out whether every circuit of *linear size* can be computed by a non-trivial depth 3 circuit with constant bottom fan-in. We restate this open problem below.

► **Open Problem 2.** Prove or disprove: for any constant  $c$ , any circuit of size  $cn$  can be computed as an

$$\text{OR}_{2^{(1-\delta(c))n}} \circ \text{AND} \circ \text{OR}_{\gamma(c)}$$

circuit, for some  $\delta(c) > 0$  and integer  $\gamma(c) \geq 1$ .

This paper supports the conjecture by showing that it holds for small values of  $c$ . As another example, we can consider a class of functions where we know linear *upper bounds* on circuit complexity. For any *symmetric* function  $f$  (i.e., a function whose value depends only on the sum over integers of the input bits) we know that  $s(f) \leq 4.5n + o(n)$  [11]. It is also known [40, 60] that symmetric functions can be computed by relatively small depth-3 circuits:  $s_3^k(f) \leq \text{poly}(n) \cdot (1 + 1/k)^n$  (and this bound is tight [60]).

Since in our depth reduction results, we always get  $k$ -CNFs with small linear number of clauses, it is interesting to study the expressiveness of OR of exponential number of such  $k$ -CNFs. Let us define  $\alpha(k, c)$  as the infimum of all values  $\alpha$  such that any circuit of size at most  $cn$  can be computed as an  $\text{OR}_{2^{\alpha n}} \circ \text{AND}_{cn} \circ \text{OR}_k$ . We can upper bound the rate of convergence of  $\alpha(k, c)$  using the following width reduction result for CNF-formulas [49, 5].

► **Theorem 23** ([49, 5]). *For any constant  $0 < \varepsilon \leq 1$  and a function  $C: \mathbb{N} \rightarrow \mathbb{N}$ , any CNF formula  $f$  with  $n$  variables and  $n \cdot C(n)$  clauses can be expressed as  $f = \text{OR}_{i=1}^t f_i$ , where  $t \leq 2^{\varepsilon n}$  and each  $f_i$  is a  $k$ -CNF formula with at most  $n \cdot C(n)$  clauses, where  $k = O\left(\frac{1}{\varepsilon} \cdot \log\left(\frac{C(n)}{\varepsilon}\right)\right)$ .*

For our applications, we are interested in  $\alpha(k, c)$  for small fixed  $c$ . Since for every  $c$ ,  $\alpha(k, c)$  is a non-increasing bounded sequence, we let  $\alpha(\infty, c) = \lim_{k \rightarrow \infty} \alpha(k, c)$ . Then Theorem 23 implies that  $\alpha(k, c) \geq \alpha(\infty, c) \geq \alpha(k, c) - O\left(\frac{\log(c/k)}{k}\right)$ .

## Abstract

Probabilistic graphical models, such as Markov random fields (MRFs), are useful for describing high-dimensional distributions in terms of local dependence structures. The probabilistic inference is a fundamental problem related to graphical models, and sampling is a main approach for the problem. In this paper, we study probabilistic inference problems when the graphical model itself is changing dynamically with time. Such dynamic inference problems arise naturally in today's application, e.g. multivariate time-series data analysis and practical learning procedures.

We give a dynamic algorithm for sampling-based probabilistic inferences in MRFs, where each dynamic update can change the underlying graph and all parameters of the MRF simultaneously, as long as the total amount of changes is bounded. More precisely, suppose that the MRF has  $n$  variables and polylogarithmic-bounded maximum degree, and  $N(n)$  independent samples are sufficient for the inference for a polynomial function  $N(\cdot)$ . Our algorithm dynamically maintains an answer to the inference problem using  $\tilde{O}(nN(n))$  space cost, and  $\tilde{O}(N(n) + n)$  incremental time cost upon each update to the MRF, as long as the Dobrushin-Shlosman condition is satisfied by the MRFs. This well-known condition has long been used for guaranteeing the efficiency of Markov chain Monte Carlo (MCMC) sampling in the traditional static setting. Compared to the static case, which requires  $\Omega(nN(n))$  time cost for redrawing all  $N(n)$  samples whenever the MRF changes, our dynamic algorithm gives a  $\tilde{\Omega}(\min\{n, N(n)\})$ -factor speedup. Our approach relies on a novel dynamic sampling technique, which transforms local Markov chains (a.k.a. single-site dynamics) to dynamic sampling algorithms, and an “algorithmic Lipschitz” condition that we establish for sampling from graphical models, namely, when the MRF changes by a small difference, samples can be modified to reflect the new distribution, with cost proportional to the difference on MRF.

## 1 Introduction

The probabilistic graphical models provide a rich language for describing high-dimensional distributions in terms of the dependence structures between random variables. The *Markov random field* (MRF) is a basic graphical model that encodes pairwise interactions of complex systems. Given a graph  $G = (V, E)$ , each vertex  $v \in V$  is associated with a function  $\phi_v : Q \rightarrow \mathbb{R}$ , called the *vertex potential*, on a finite domain  $Q = [q]$  of  $q$  *spin states*, and each edge  $e \in E$  is associated with a symmetric function  $\phi_e : Q^2 \rightarrow \mathbb{R}$ , called the *edge potential*, which describes a pairwise interaction. Together, these induce a probability distribution  $\mu$  over all configurations  $\sigma \in Q^V$ :

$$\mu(\sigma) \propto \exp(H(\sigma)) = \exp\left(\sum_{v \in V} \phi_v(\sigma_v) + \sum_{e=\{u,v\} \in E} \phi_e(\sigma_u, \sigma_v)\right).$$

This distribution  $\mu$  is known as the Gibbs distribution and  $H(\sigma)$  is the *Hamiltonian*. It arises naturally from various physical models, statistics or learning problems, and combinatorial problems in computer science [29, 25].

The *probabilistic inference* is one of the most fundamental computational problems in graphical model. Some basic inference problems ask to calculate the marginal distribution, conditional distribution, or maximum-a-posteriori probabilities of one or several random variables [37]. Sampling is perhaps the most widely used approach for probabilistic inference. Given a graphical model, independent samples are drawn from the Gibbs distribution and certain statistics are computed using the samples to give estimates for the inferred quantity. For most typical inference problems, such statistics are easy to compute once the samples are given, for instance, for estimating the marginal distribution on a variable subset  $S$ , the statistics is the frequency of each configuration in  $Q^S$  among the samples, thus the cost for inference is dominated by the cost for generating random samples [24, 35].

The classic probabilistic inference assumes a static setting, where the input graphical model is fixed. In today's application, dynamically changing graphical models naturally arise in many scenarios. In various practical algorithms for learning graphical models, e.g. the contrastive divergence algorithm for learning the restricted Boltzmann machine [22] and the iterative proportional fitting algorithm for maximum likelihood estimation of graphical models [37], the optimal model  $\mathcal{I}^*$  is obtained by updating the parameters of the graphical model iteratively (usually by gradient descent), which generates a sequence of graphical models  $\mathcal{I}_1, \mathcal{I}_2, \dots, \mathcal{I}_M$ , with the goal that  $\mathcal{I}_M$  is a good approximation of  $\mathcal{I}^*$ . Also in the study of the multivariate time-series data, the dynamic Gaussian graphical models [5], multiregression dynamic model [32], dynamic graphical model [14], and dynamic chain graph models [2], are all dynamically changing graphical models and have been used in a variety of applications. Meanwhile, with the advent of Big Data, scalable machine learning systems need to deal with continuously evolving graphical models (see e.g. [33] and [34]).

The theoretical studies of probabilistic inference in dynamically changing graphical models are lacking. In the aforementioned scenarios in practice, it is common that a sequence of graphical models is presented with time, where any two consecutive graphical models can differ from each other in all potentials but by a small total amount. Recomputing the

inference problem from scratch at every time when the graphical model is changed, can give the correct solution, but is very wasteful. A fundamental question is whether probabilistic inference can be solved dynamically and efficiently.

In this paper, we study the problem of probabilistic inference in an MRF when the MRF itself is changing dynamically with time. At each time, the whole graphical model, including all vertices and edges as well as their potentials, are subject to changes. Such *non-local* updates are very general and cover all applications mentioned above. The problem of *dynamic inference* then asks to maintain a correct answer to the inference in a dynamically changing MRF with low incremental cost proportional to the amount of changes made to the graphical model at each time.

## 1.1 Our results

We give a dynamic algorithm for sampling-based probabilistic inferences. Given an MRF instance with  $n$  vertices, suppose that  $N(n)$  independent samples are sufficient to give an approximate solution to the inference problem, where  $N : \mathbb{N}^+ \rightarrow \mathbb{N}^+$  is a polynomial function. We give dynamic algorithms for general inference problems on dynamically changing MRF.

Suppose that the current MRF has  $n$  vertices and polylogarithmic-bounded maximum degree, and each update to the MRF may change the underlying graph and/or all vertex/edge potentials, as long as the total amount of changes is bounded. Our algorithm maintains an approximate solution to the inference with  $\tilde{O}(nN(n))$  space cost, and with  $\tilde{O}(N(n) + n)$  incremental time cost upon each update, assuming that the MRFs satisfy the Dobrushin-Shlosman condition [8, 9, 7]. The condition has been widely used to imply the efficiency of Markov chain Monte Carlo (MCMC) sampling (e.g. see [19, 12]). Compared to the static algorithm, which requires  $\Omega(nN(n))$  time for redrawing all  $N(n)$  samples each time, our dynamic algorithm significantly improves the time cost with an  $\tilde{\Omega}(\min\{n, N(n)\})$ -factor speedup.

On specific models, the Dobrushin-Shlosman condition has been established in the literature, which directly gives us following efficient dynamic inference algorithms, with  $\tilde{O}(nN(n))$  space cost and  $\tilde{O}(N(n) + n)$  time cost per update, on graphs with  $n$  vertices and maximum degree  $\Delta = O(1)$ :

- for Ising model with temperature  $\beta$  satisfying  $e^{-2|\beta|} > 1 - \frac{2}{\Delta+1}$ , which is close to the uniqueness threshold  $e^{-2|\beta_c|} = 1 - \frac{2}{\Delta}$ , beyond which the static versions of sampling or marginal inference problem for anti-ferromagnetic Ising model is intractable [17, 16];
- for hardcore model with fugacity  $\lambda < \frac{2}{\Delta-2}$ , which matches the best bound known for sampling algorithm with near-linear running time on general graphs with bounded maximum degree [36, 28, 13];
- for proper  $q$ -coloring with  $q > 2\Delta$ , which matches the best bound known for sampling algorithm with near-linear running time on general graphs with bounded maximum degree [23].

Our dynamic inference algorithm is based on a dynamic sampling algorithm, which efficiently maintains  $N(n)$  independent samples for the current MRF while the MRF is subject to changes. More specifically, we give a dynamic version of the *Gibbs sampling* algorithm, a local Markov chain for sampling from the Gibbs distribution that has been studied extensively. Our techniques are based on: (1) couplings for dynamic instances of graphical models; and (2) dynamic data structures for representing single-site Markov chains so that the couplings can be realized algorithmically in sub-linear time. Both these techniques are of independent interest, and can be naturally extended to more general settings with multi-body interactions.

Our results show that on dynamically changing graphical models, sampling-based probabilistic inferences can be solved significantly faster than rerunning the static algorithm at each time. This has practical significance in speeding up the iterative procedures for learning graphical models.

## 1.2 Related work

The problem of dynamic sampling from graphical models was introduced very recently in [14]. There, a dynamic sampling algorithm was given for graphical models with soft constraints, and can only deal with local updates that change a single vertex or edge at each time. The regimes for such dynamic sampling algorithm to be efficient are much more restrictive than the conditions for the rapid mixing of Markov chains. Our algorithm greatly improves the regimes for efficient dynamic sampling for the Ising and hardcore models in [14], and for the first time, can handle non-local updates that change all vertex/edge potentials simultaneously. Besides, the dynamic/online sampling from log-concave distributions was also studied in [31, 26].

Another related topic is the dynamic graph problems, which ask to maintain a solution (e.g. spanners [15, 30, 38] or shortest paths [3, 21, 20]) while the input graph is dynamically changing. More recently, important progress has been made on dynamically maintaining structures that are related to graph random walks, such as spectral sparsifier [11, 1] or effective resistances [10, 18]. Instead of one particular solution, dynamic inference problems ask to maintain an estimate of a statistics, such statistics comes from an exponential-sized probability space described by a dynamically changing graphical model.

## 1.3 Organization of the paper

In Section 2, we formally introduce the dynamic inference problem. In Section 3, we formally state the main results. Preliminaries are given in Section 4. In Section 5, we outline our dynamic inference algorithm. In Section 6, we present the algorithms for dynamic Gibbs sampling. The conclusion is given in Section 7. The analyses of the dynamic sampling algorithms and the proof of the main theorem on dynamic inference are provided in the full version of the paper.

## 2 Dynamic inference problem

### 2.1 Markov random fields

An instance of (*pairwise*) *Markov random field (MRF)* is specified by a tuple  $\mathcal{I} = (V, E, Q, \Phi)$ , where  $G = (V, E)$  is an undirected simple graph;  $Q$  is a domain of  $q = |Q|$  *spin states*, for some finite  $q > 1$ ; and  $\Phi = (\phi_a)_{a \in V \cup E}$  associates each  $v \in V$  a *vertex potential*  $\phi_v : Q \rightarrow \mathbb{R}$  and each  $e \in E$  an *edge potential*  $\phi_e : Q^2 \rightarrow \mathbb{R}$ , where  $\phi_e$  is symmetric.

A *configuration*  $\sigma \in Q^V$  maps each vertex  $v \in V$  to a spin state in  $Q$ , so that each vertex can be interpreted as a variable. And the *Hamiltonian* of a configuration  $\sigma \in Q^V$  is defined as:

$$H(\sigma) \triangleq \sum_{v \in V} \phi_v(\sigma_v) + \sum_{e=\{u,v\} \in E} \phi_e(\sigma_u, \sigma_v).$$

This defines the *Gibbs distribution*  $\mu_{\mathcal{I}}$ , which is a probability distribution over  $Q^V$  such that

$$\forall \sigma \in Q^V, \quad \mu_{\mathcal{I}}(\sigma) = \frac{1}{Z} \exp(H(\sigma)),$$

where the normalizing factor  $Z \triangleq \sum_{\sigma \in Q^V} \exp(H(\sigma))$  is called the *partition function*.

The Gibbs measure  $\mu(\sigma)$  can be 0 as the functions  $\phi_v, \phi_e$  can take the value  $-\infty$ . A configuration  $\sigma$  is called *feasible* if  $\mu(\sigma) > 0$ . To trivialize the problem of constructing a feasible configuration, we further assume the following natural condition for the MRF instances considered in this paper:<sup>1</sup>

$$\forall v \in V, \forall \sigma \in Q^{\Gamma_G(v)} : \sum_{c \in Q} \exp \left( \phi_v(c) + \sum_{u \in \Gamma_v} \phi_{uv}(\sigma_u, c) \right) > 0. \quad (1)$$

where  $\Gamma_G(v) \triangleq \{u \in V \mid \{u, v\} \in E\}$  denotes the neighborhood of  $v$  in graph  $G = (V, E)$ .

Some well studied typical MRFs include:

- *Ising model*: The domain of each spin is  $Q = \{-1, +1\}$ . Each edge  $e \in E$  is associated with a *temperature*  $\beta_e \in \mathbb{R}$ ; and each vertex  $v \in V$  is associated with a *local field*  $h_v \in \mathbb{R}$ . For each configuration  $\sigma \in \{-1, +1\}^V$ ,  $\mu_{\mathcal{I}}(\sigma) \propto \exp \left( \sum_{\{u, v\} \in E} \beta_e \sigma_u \sigma_v + \sum_{v \in V} h_v \sigma_v \right)$ .
- *Hardcore model*: The domain is  $Q = \{0, 1\}$ . Each configuration  $\sigma \in Q^V$  indicates an independent set in  $G = (V, E)$ , and  $\mu_{\mathcal{I}}(\sigma) \propto \lambda^{|\sigma|}$ , where  $\lambda > 0$  is the *fugacity* parameter.
- *proper  $q$ -coloring*: uniform distribution over all proper  $q$ -colorings of  $G = (V, E)$ .

## 2.2 Probabilistic inference and sampling

In graphical models, the task of probabilistic inference is to derive the probabilities regarding one or more random variables of the model. Abstractly, this is described by a function  $\theta : \mathfrak{M} \rightarrow \mathbb{R}^K$  that maps each graphical model  $\mathcal{I} \in \mathfrak{M}$  to a target  $K$ -dimensional probability vector, where  $\mathfrak{M}$  is the class of graphical models containing the random variables we are interested in and the  $K$ -dimensional vector describes the probabilities we want to derive. Given  $\theta(\cdot)$  and an MRF instance  $\mathcal{I} \in \mathfrak{M}$ , the inference problem asks to estimate the probability vector  $\theta(\mathcal{I})$ .

Here are some fundamental inference problems [37] for MRF instances. Let  $\mathcal{I} = (V, E, Q, \Phi)$  be an MRF instance and  $A, B \subseteq V$  two disjoint sets where  $A \uplus B \subseteq V$ .

- *Marginal inference*: estimate the marginal distribution  $\mu_{A, \mathcal{I}}(\cdot)$  of the variables in  $A$ , where

$$\forall \sigma_A \in Q^A, \quad \mu_{A, \mathcal{I}}(\sigma_A) \triangleq \sum_{\tau \in Q^{V \setminus A}} \mu_{\mathcal{I}}(\sigma_A, \tau).$$

- *Posterior inference*: given any  $\tau_B \in Q^B$ , estimate the posterior distribution  $\mu_{A, \mathcal{I}}(\cdot \mid \tau_B)$  for the variables in  $A$ , where

$$\forall \sigma_A \in Q^A, \quad \mu_{A, \mathcal{I}}(\sigma_A \mid \tau_B) \triangleq \frac{\mu_{A \cup B, \mathcal{I}}(\sigma_A, \tau_B)}{\mu_{B, \mathcal{I}}(\tau_B)}.$$

- *Maximum-a-posteriori (MAP) inference*: find the maximum-a-posteriori (MAP) probabilities  $P_{A, \mathcal{I}}^*(\cdot)$  for the configurations over  $A$ , where

$$\forall \sigma_A \in Q^A, \quad P_{A, \mathcal{I}}^*(\sigma_A) \triangleq \max_{\tau_B \in Q^B} \mu_{A \cup B, \mathcal{I}}(\sigma_A, \tau_B).$$

<sup>1</sup> This condition guarantees that the marginal probabilities are always well-defined, and the problem of constructing a feasible configuration  $\sigma$ , where  $\mu_{\mathcal{I}}(\sigma) > 0$ , is trivial. The condition holds for all MRFs with soft constraints, or with hard constraints where there is a permissive spin, e.g. the hardcore model. For MRFs with truly repulsive hard constraints such as proper  $q$ -coloring, the condition may translate to the condition  $q \geq \Delta + 1$  where  $\Delta$  is the maximum degree of graph  $G$ , which is necessary for the irreducibility of local Markov chains for  $q$ -colorings.

All these fundamental inference problems can be described abstractly by a function  $\theta : \mathfrak{M} \rightarrow \mathbb{R}^K$ . For instances, for marginal inference,  $\mathfrak{M}$  contains all MRF instances where  $A$  is a subset of the vertices,  $K = |Q|^{|A|}$ , and  $\theta(\mathcal{I}) = (\mu_{A,\mathcal{I}}(\sigma_A))_{\sigma_A \in Q^A}$ ; and for posterior or MAP inference,  $\mathfrak{M}$  contains all MRF instances where  $A \uplus B$  is a subset of the vertices,  $K = |Q|^{|A|}$  and  $\theta(\mathcal{I}) = (\mu_{A,\mathcal{I}}(\sigma_A \mid \tau_B))_{\sigma_A \in Q^A}$  (for posterior inference) or  $\theta(\mathcal{I}) = (P_{A,\mathcal{I}}^*(\sigma_A))_{\sigma_A \in Q^A}$  (for MAP inference).

One canonical approach for probabilistic inference is by sampling: sufficiently many independent samples are drawn (approximately) from the Gibbs distribution of the MRF instance and an estimate of the target probabilities is calculated from these samples. Given a probabilistic inference problem  $\theta(\cdot)$ , we use  $\mathcal{E}_\theta(\cdot)$  to denote an estimating function that approximates  $\theta(\mathcal{I})$  using independent samples drawn approximately from  $\mu_{\mathcal{I}}$ . For the aforementioned problems of marginal, posterior and MAP inferences, such estimating function  $\mathcal{E}_\theta(\cdot)$  simply counts the frequency of the samples that satisfy certain properties.

The sampling cost of an estimator is captured in two aspects: the number of samples it uses and the accuracy of each individual sample it requires.

► **Definition 1** ( $(N, \epsilon)$ -estimator for  $\theta$ ). *Let  $\theta : \mathfrak{M} \rightarrow \mathbb{R}^K$  be a probabilistic inference problem and  $\mathcal{E}_\theta(\cdot)$  an estimating function for  $\theta(\cdot)$  that for each instance  $\mathcal{I} = (V, E, Q, \Phi) \in \mathfrak{M}$ , maps samples in  $Q^V$  to an estimate of  $\theta(\mathcal{I})$ . Let  $N : \mathbb{N}^+ \rightarrow \mathbb{N}^+$  and  $\epsilon : \mathbb{N}^+ \rightarrow (0, 1)$ . For any instance  $\mathcal{I} = (V, E, Q, \Phi) \in \mathfrak{M}$  where  $n = |V|$ , the random variable  $\mathcal{E}_\theta(\mathbf{X}^{(1)}, \dots, \mathbf{X}^{(N(n))})$  is said to be an  $(N, \epsilon)$ -estimator for  $\theta(\mathcal{I})$  if  $\mathbf{X}^{(1)}, \dots, \mathbf{X}^{(N(n))} \in Q^V$  are  $N(n)$  independent samples drawn approximately from  $\mu_{\mathcal{I}}$  such that  $d_{\text{TV}}(\mathbf{X}^{(j)}, \mu_{\mathcal{I}}) \leq \epsilon(n)$  for all  $1 \leq j \leq N(n)$ .*

In Definition 1, an estimator is viewed as a black-box algorithm specified by two functions  $N$  and  $\epsilon$ . Usually, the estimator is more accurate if more independent samples are drawn and each sample provides a higher level of accuracy. Thus, one can choose some large  $N$  and small  $\epsilon$  to achieve a desired quality of estimate.

## 2.3 Dynamic inference problem

We consider the inference problem where the input graphical model is changed dynamically: at each step, the current MRF instance  $\mathcal{I} = (V, E, Q, \Phi)$  is updated to a new instance  $\mathcal{I}' = (V', E', Q, \Phi')$ . We consider general update operations for MRFs that can change both the **underlying graph** and **all edge/vertex potentials** simultaneously, where the update request is made by a *non-adaptive adversary* independently of the randomness used by the inference algorithm. Such updates are general enough and cover many applications, e.g. analyses of time series network data [5, 32, 14, 2], and learning algorithms for graphical models [22, 37].

The difference between the original and the updated instances is measured as follows.

► **Definition 2** (difference between MRF instances). *The difference between two MRF instances  $\mathcal{I} = (V, E, Q, \Phi)$  and  $\mathcal{I}' = (V', E', Q, \Phi')$ , where  $\Phi = (\phi_a)_{a \in V \cup E}$  and  $\Phi' = (\phi'_a)_{a \in V' \cup E'}$ , is defined as*

$$d(\mathcal{I}, \mathcal{I}') \triangleq \sum_{v \in V \cap V'} \|\phi_v - \phi'_v\|_1 + \sum_{e \in E \cap E'} \|\phi_e - \phi'_e\|_1 + |V \oplus V'| + |E \oplus E'|, \quad (2)$$

where  $A \oplus B = (A \setminus B) \cup (B \setminus A)$  stands for the symmetric difference between two sets  $A$  and  $B$ ,  $\|\phi_v - \phi'_v\|_1 \triangleq \sum_{c \in Q} |\phi_v(c) - \phi'_v(c)|$ , and  $\|\phi_e - \phi'_e\|_1 \triangleq \sum_{c, c' \in Q} |\phi_e(c, c') - \phi'_e(c, c')|$ .

Given a probability vector specified by the function  $\theta : \mathfrak{M} \rightarrow \mathbb{R}^K$ , the *dynamic inference problem* asks to maintain an estimator  $\hat{\theta}(\mathcal{I})$  of  $\theta(\mathcal{I})$  for the current MRF instance  $\mathcal{I} = (V, E, Q, \Phi) \in \mathfrak{M}$ , with a data structure, such that when  $\mathcal{I}$  is updated to  $\mathcal{I}' = (V', E', Q, \Phi') \in \mathfrak{M}$ , the algorithm updates  $\hat{\theta}(\mathcal{I})$  to an estimator  $\hat{\theta}(\mathcal{I}')$  of the new vector  $\theta(\mathcal{I}')$ , or equivalently, outputs the difference between the estimators  $\hat{\theta}(\mathcal{I})$  and  $\hat{\theta}(\mathcal{I}')$ .

It is desirable to have the dynamic inference algorithm which maintains an  $(N, \epsilon)$ -estimator for  $\theta(\mathcal{I})$  for the current instance  $\mathcal{I}$ . However, the dynamic algorithm cannot be efficient if  $N(n)$  and  $\epsilon(n)$  change drastically with  $n$  (so that significantly more samples or substantially more accurate samples may be needed when a new vertex is added), or if recalculating the estimating function  $\mathcal{E}_\theta(\cdot)$  itself is expensive. We introduce a notion of *dynamical efficiency* for the estimators that are suitable for dynamic inference.

► **Definition 3** (dynamical efficiency). *Let  $N : \mathbb{N}^+ \rightarrow \mathbb{N}^+$  and  $\epsilon : \mathbb{N}^+ \rightarrow (0, 1)$ . Let  $\mathcal{E}(\cdot)$  be an estimating function for some  $K$ -dimensional probability vector of MRF instances. A tuple  $(N, \epsilon, \mathcal{E})$  is said to be dynamically efficient if it satisfies:*

■ **(bounded difference)** *there exist constants  $C_1, C_2 > 0$  such that for any  $n \in \mathbb{N}^+$ ,*

$$|N(n+1) - N(n)| \leq \frac{C_1 \cdot N(n)}{n} \quad \text{and} \quad |\epsilon(n+1) - \epsilon(n)| \leq \frac{C_2 \cdot \epsilon(n)}{n};$$

■ **(small incremental cost)** *there is a deterministic algorithm that maintains  $\mathcal{E}(\mathbf{X}^{(1)}, \dots, \mathbf{X}^{(m)})$  using  $(mn + K) \cdot \text{polylog}(mn)$  bits where  $\mathbf{X}^{(1)}, \dots, \mathbf{X}^{(m)} \in Q^V$  and  $n = |V|$ , such that when  $\mathbf{X}^{(1)}, \dots, \mathbf{X}^{(m)} \in Q^V$  are updated to  $\mathbf{Y}^{(1)}, \dots, \mathbf{Y}^{(m')} \in Q^{V'}$ , where  $n' = |V'|$ , the algorithm updates  $\mathcal{E}(\mathbf{X}^{(1)}, \dots, \mathbf{X}^{(m)})$  to  $\mathcal{E}(\mathbf{Y}^{(1)}, \dots, \mathbf{Y}^{(m')})$  within time cost  $\mathcal{D} \cdot \text{polylog}(mm'nn') + O(m + m')$ , where  $\mathcal{D}$  is the size of the difference between two sample sequences defined as:*

$$\mathcal{D} \triangleq \sum_{i \leq \max\{m, m'\}} \sum_{v \in V \cup V'} \mathbf{1}[\mathbf{X}^{(i)}(v) \neq \mathbf{Y}^{(i)}(v)], \quad (3)$$

where an unassigned  $\mathbf{X}^{(i)}(v)$  or  $\mathbf{Y}^{(i)}(v)$  is not equal to any assigned spin.

The dynamic efficiency basically asks  $N(\cdot), \epsilon(\cdot)$ , and  $\mathcal{E}(\cdot)$  to have some sort of “Lipschitz” properties. To satisfy the bounded difference condition,  $N(n)$  and  $1/\epsilon(n)$  are necessarily polynomially bounded, and they can be any constant, polylogarithmic, or polynomial functions, or multiplications of such functions. The condition with small incremental cost also holds very commonly. In particular, it is satisfied by the estimating functions for all the aforementioned problems for the marginal, posterior and MAP inferences as long as the sets of variables have sizes  $|A|, |B| = O(\log n)$ . We remark that the  $O(\log n)$  upper bound is somehow necessary for the efficiency of inference, because otherwise the dimension of  $\theta(\mathcal{I})$  itself (which is at least  $q^{|A|}$ ) becomes super-polynomial in  $n$ .

### 3 Main results

Let  $\mathcal{I} = (V, E, Q, \Phi)$  be an MRF instance, where  $G = (V, E)$ . Let  $\Gamma_G(v)$  denote the neighborhood of  $v$  in  $G$ . For any vertex  $v \in V$  and any configuration  $\sigma \in Q^{\Gamma_G(v)}$ , we use  $\mu_{v, \mathcal{I}}^\sigma(\cdot) = \mu_{v, \mathcal{I}}(\cdot \mid \sigma)$  to denote the marginal distribution on  $v$  conditional on  $\sigma$ :

$$\forall c \in Q : \quad \mu_{v, \mathcal{I}}^\sigma(c) = \mu_{v, \mathcal{I}}(c \mid \sigma) \triangleq \frac{\exp\left(\phi_v(c) + \sum_{u \in \Gamma_G(v)} \phi_{uv}(\sigma_u, c)\right)}{\sum_{a \in Q} \exp\left(\phi_v(a) + \sum_{u \in \Gamma_G(v)} \phi_{uv}(\sigma_u, a)\right)}.$$

Due to the assumption in (1), the marginal distribution is always well-defined. The following condition is the *Dobrushin-Shlosman condition* [8, 9, 7, 19, 12].

► **Condition 4** (Dobrushin-Shlosman condition). Let  $\mathcal{I} = (V, E, Q, \Phi)$  be an MRF instance with Gibbs distribution  $\mu = \mu_{\mathcal{I}}$ . Let  $A_{\mathcal{I}} \in \mathbb{R}_{\geq 0}^{V \times V}$  be the influence matrix which is defined as

$$A_{\mathcal{I}}(u, v) \triangleq \begin{cases} \max_{(\sigma, \tau) \in B_{u,v}} d_{\text{TV}}(\mu_v^{\sigma}, \mu_v^{\tau}), & \{u, v\} \in E, \\ 0 & \{u, v\} \notin E, \end{cases}$$

where the maximum is taken over the set  $B_{u,v}$  of all  $(\sigma, \tau) \in Q^{\Gamma_G(v)} \times Q^{\Gamma_G(v)}$  that differ only at  $u$ , and  $d_{\text{TV}}(\mu_v^{\sigma}, \mu_v^{\tau}) \triangleq \frac{1}{2} \sum_{c \in Q} |\mu_v^{\sigma}(c) - \mu_v^{\tau}(c)|$  is the total variation distance between  $\mu_v^{\sigma}$  and  $\mu_v^{\tau}$ . An MRF instance  $\mathcal{I}$  is said to satisfy the Dobrushin-Shlosman condition if there is a constant  $\delta > 0$  such that

$$\max_{u \in V} \sum_{v \in V} A_{\mathcal{I}}(u, v) \leq 1 - \delta.$$

Our main theorem assumes the following setup: Let  $\theta : \mathfrak{M} \rightarrow \mathbb{R}^K$  be a probabilistic inference problem that maps each MRF instance in  $\mathfrak{M}$  to a  $K$ -dimensional probability vector, and let  $\mathcal{E}_{\theta}$  be its estimating function. Let  $N : \mathbb{N}^+ \rightarrow \mathbb{N}^+$  and  $\epsilon : \mathbb{N}^+ \rightarrow (0, 1)$ . We use  $\mathcal{I} = (V, E, Q, \Phi) \in \mathfrak{M}$ , where  $n = |V|$ , to denote the current instance and  $\mathcal{I}' = (V', E', Q, \Phi') \in \mathfrak{M}$ , where  $n' = |V'|$ , to denote the updated instance.

► **Theorem 5** (dynamic inference algorithm). Assume that  $(N, \epsilon, \mathcal{E}_{\theta})$  is dynamically efficient, both  $\mathcal{I}$  and  $\mathcal{I}'$  satisfy the Dobrushin-Shlosman condition, and  $d(\mathcal{I}, \mathcal{I}') \leq L = o(n)$ .

There is an algorithm that maintains an  $(N, \epsilon)$ -estimator  $\hat{\theta}(\mathcal{I})$  of the probability vector  $\theta(\mathcal{I})$  for the current MRF instance  $\mathcal{I}$ , using  $\tilde{O}(nN(n) + K)$  bits, such that when  $\mathcal{I}$  is updated to  $\mathcal{I}'$ , the algorithm updates  $\hat{\theta}(\mathcal{I})$  to an  $(N, \epsilon)$ -estimator  $\hat{\theta}(\mathcal{I}')$  of  $\theta(\mathcal{I}')$  for the new instance  $\mathcal{I}'$ , within expected time cost

$$\tilde{O}(\Delta^2 LN(n) + \Delta n),$$

where  $\tilde{O}(\cdot)$  hides a  $\text{polylog}(n)$  factor,  $\Delta = \max\{\Delta_G, \Delta_{G'}\}$ , where  $\Delta_G$  and  $\Delta_{G'}$  denote the maximum degree of  $G = (V, E)$  and  $G' = (V', E')$  respectively.

Note that the extra  $O(\Delta n)$  cost is necessary for editing the current MRF instance  $\mathcal{I}$  to  $\mathcal{I}'$ .

Typically, the difference between two MRF instances  $\mathcal{I}, \mathcal{I}'$  is small<sup>2</sup>, and the underlying graphs are sparse [6], that is,  $L, \Delta \leq \text{polylog}(n)$ . In such cases, our algorithm updates the estimator within time cost  $\tilde{O}(N(n) + n)$ , which significantly outperforms static sampling-based inference algorithms that require time cost  $\Omega(n'N(n')) = \Omega(nN(n))$  for redrawing all  $N(n')$  independent samples.

**Dynamic sampling.** The core of our dynamic inference algorithm is a dynamic sampling algorithm: Assuming the Dobrushin-Shlosman condition, the algorithm can maintain a sequence of  $N(n)$  independent samples  $\mathbf{X}^{(1)}, \dots, \mathbf{X}^{(N(n))} \in Q^V$  that are  $\epsilon(n)$ -close to  $\mu_{\mathcal{I}}$  in total variation distance, and when  $\mathcal{I}$  is updated to  $\mathcal{I}'$  with difference  $d(\mathcal{I}, \mathcal{I}') \leq L = o(n)$ , the algorithm can update the maintained samples to  $N(n')$  independent samples  $\mathbf{Y}^{(1)}, \dots, \mathbf{Y}^{(N(n'))} \in Q^{V'}$  that are  $\epsilon(n')$ -close to  $\mu_{\mathcal{I}'}$  in total variation distance, using a time cost  $\tilde{O}(\Delta^2 LN(n) + \Delta n)$  in expectation. This shows an “algorithmic Lipschitz” condition

<sup>2</sup> In multivariate time-series data analysis, the MRF instances of two sequential times are similar. In the iterative algorithms for learning graphical models, the difference between two sequential MRF instances generated by gradient descent are bounded to prevent oscillations. Specifically, the difference is very small when the iterative algorithm approaches to the convergence state [22, 37].

holds for sampling from Gibbs distributions: when the MRF changes insignificantly, a population of samples can be modified to reflect the new distribution, with cost proportional to the difference on MRF. We show that such property is guaranteed by the Dobrushin-Shlosman condition. This dynamic sampling algorithm is formally described in Theorem 9 and is of independent interest [14].

**Applications on specific models.** On specific models, we have the following results, where  $\delta > 0$  is an arbitrary constant.

■ **Table 1** Dynamic inference for specific models.

model	regime	space cost	time cost for each update
Ising	$e^{-2 \beta } \geq 1 - \frac{2-\delta}{\Delta+1}$	$\tilde{O}(nN(n) + K)$	$\tilde{O}(\Delta^2 LN(n) + \Delta n)$
hardcore	$\lambda \leq \frac{2-\delta}{\Delta-2}$	$\tilde{O}(nN(n) + K)$	$\tilde{O}(\Delta^3 LN(n) + \Delta n)$
$q$ -coloring	$q \geq (2 + \delta)\Delta$	$\tilde{O}(nN(n) + K)$	$\tilde{O}(\Delta^2 LN(n) + \Delta n)$

The results for Ising model and  $q$ -coloring are corollaries of Theorem 5. The regime for hardcore model is better than the Dobrushin-Shlosman condition (which is  $\lambda \leq \frac{1-\delta}{\Delta-1}$ ), because we use the coupling introduced by Vigoda [36] to analyze the algorithm.

## 4 Preliminaries

**Total variation distance and coupling.** Let  $\mu$  and  $\nu$  be two distributions over  $\Omega$ . The *total variation distance* between  $\mu$  and  $\nu$  is defined as

$$d_{\text{TV}}(\mu, \nu) \triangleq \frac{1}{2} \sum_{x \in \Omega} |\mu(x) - \nu(x)|.$$

A *coupling* of  $\mu$  and  $\nu$  is a joint distribution  $(X, Y) \in \Omega \times \Omega$  such that marginal distribution of  $X$  is  $\mu$  and the marginal distribution of  $Y$  is  $\nu$ . The following coupling lemma is well-known.

► **Proposition 6** (coupling lemma). *For any coupling  $(X, Y)$  of  $\mu$  and  $\nu$ , it holds that*

$$\Pr[X \neq Y] \geq d_{\text{TV}}(\mu, \nu).$$

*Furthermore, there is an optimal coupling that achieves equality.*

**Local neighborhood.** Let  $G = (V, E)$  be a graph. For any vertex  $v \in V$ , let  $\Gamma_G(v) \triangleq \{u \in V \mid \{u, v\} \in E\}$  denote the neighborhood of  $v$ , and  $\Gamma_G^+(v) \triangleq \Gamma_G(v) \cup \{v\}$  the inclusive neighborhood of  $v$ . We simply write  $\Gamma_v = \Gamma(v) = \Gamma_G(v)$  and  $\Gamma_v^+ = \Gamma^+(v) = \Gamma_G^+(v)$  for short when  $G$  is clear in the context. We use  $\Delta = \Delta_G \triangleq \max_{v \in V} |\Gamma_v|$  to denote the maximum degree of graph  $G$ .

A notion of **local neighborhood for MRF** is frequently used. Let  $\mathcal{I} = (V, E, Q, \Phi)$  be an MRF instance. For  $v \in V$ , we denote by  $\mathcal{I}_v \triangleq \mathcal{I}[\Gamma_v^+]$  the restriction of  $\mathcal{I}$  on the inclusive neighborhood  $\Gamma_v^+$  of  $v$ , i.e.  $\mathcal{I}_v = (\Gamma_v^+, E_v, Q, \Phi_v)$ , where  $E_v = \{\{u, v\} \in E\}$  and  $\Phi_v = (\phi_a)_{a \in \Gamma_v^+ \cup E_v}$ .

**Gibbs sampling.** The *Gibbs sampling* (a.k.a. *heat-bath*, *Glauber dynamics*), is a classic Markov chain for sampling from Gibbs distributions. Let  $\mathcal{I} = (V, E, Q, \Phi)$  be an MRF instance and  $\mu = \mu_{\mathcal{I}}$  its Gibbs distribution. The chain of Gibbs sampling (Algorithm 1) is on the space  $\Omega \triangleq Q^V$ , and has the stationary distribution  $\mu_{\mathcal{I}}$  [27, Chapter 3].

■ **Algorithm 1** Gibbs sampling.

---

**Initialization:** an initial state  $\mathbf{X}_0 \in \Omega$  (not necessarily feasible);

- 1 **for**  $t = 1, 2, \dots, T$  **do**
- 2     pick  $v_t \in V$  uniformly at random;
- 3     draw a random value  $c \in Q$  from the marginal distribution  $\mu_{v_t}(\cdot \mid X_{t-1}(\Gamma_{v_t}))$ ;
- 4      $X_t(v_t) \leftarrow c$  and  $X_t(u) \leftarrow X_{t-1}(u)$  for all  $u \in V \setminus \{v_t\}$ ;

---

**Marginal distributions.** Here  $\mu_v(\cdot \mid \sigma(\Gamma_v)) = \mu_{v, \mathcal{I}}(\cdot \mid \sigma(\Gamma_v))$  denotes the marginal distribution at  $v \in V$  conditioning on  $\sigma(\Gamma_v) \in Q^{\Gamma_v}$ , which is computed as:

$$\forall c \in Q : \quad \mu_v(c \mid \sigma(\Gamma_v)) = \frac{\phi_v(c) \prod_{u \in \Gamma_v} \phi_{uv}(\sigma_u, c)}{\sum_{c' \in Q} \phi_v(c') \prod_{u \in \Gamma_v} \phi_{uv}(\sigma_u, c')}. \quad (4)$$

Due to the assumption (1), this marginal distribution is always well defined, and its computation uses only the information of  $\mathcal{I}_v$ .

**Coupling for mixing time.** Consider a chain  $(\mathbf{X}_t)_{t=0}^{\infty}$  on space  $\Omega$  with stationary distribution  $\mu_{\mathcal{I}}$  for MRF instance  $\mathcal{I}$ . The *mixing rate* is defined as: for  $\epsilon > 0$ ,

$$\tau_{\text{mix}}(\mathcal{I}, \epsilon) \triangleq \max_{\mathbf{X}_0} \min \{t \mid d_{\text{TV}}(\mathbf{X}_t, \mu_{\mathcal{I}}) \leq \epsilon\},$$

where  $d_{\text{TV}}(\mathbf{X}_t, \mu_{\mathcal{I}})$  denotes the *total variation distance* between  $\mu_{\mathcal{I}}$  and the distribution of  $\mathbf{X}_t$ .

A coupling of a Markov chain is a joint process  $(\mathbf{X}_t, \mathbf{Y}_t)_{t \geq 0}$  such that  $(\mathbf{X}_t)_{t \geq 0}$  and  $(\mathbf{Y}_t)_{t \geq 0}$  marginally follow the same transition rule as the original chain. Consider the following type of couplings.

► **Definition 7** (one-step optimal coupling for Gibbs sampling). A coupling  $(\mathbf{X}_t, \mathbf{Y}_t)_{t \geq 0}$  of Gibbs sampling on an MRF instance  $\mathcal{I} = (V, E, Q, \Phi)$  is a one-step optimal coupling if it is constructed as follows: For  $t = 1, 2, \dots$ ,

1. pick the same random  $v_t \in V$ , and let  $(X_t(u), Y_t(u)) \leftarrow (X_{t-1}(u), Y_{t-1}(u))$  for all  $u \neq v_t$ ;
2. sample  $(X_t(v_t), Y_t(v_t))$  from an optimal coupling  $D_{\text{opt}, \mathcal{I}_{v_t}}^{\sigma, \tau}(\cdot, \cdot)$  of the marginal distributions  $\mu_{v_t}(\cdot \mid \sigma)$  and  $\mu_{v_t}(\cdot \mid \tau)$  where  $\sigma = X_{t-1}(\Gamma_{v_t})$  and  $\tau = Y_{t-1}(\Gamma_{v_t})$ .

The coupling  $D_{\text{opt}, \mathcal{I}_{v_t}}^{\sigma, \tau}(\cdot, \cdot)$  is an *optimal coupling* of  $\mu_{v_t}(\cdot \mid \sigma)$  and  $\mu_{v_t}(\cdot \mid \tau)$  that attains the maximum  $\Pr[\mathbf{x} = \mathbf{y}]$  for all couplings  $(\mathbf{x}, \mathbf{y})$  of  $\mathbf{x} \sim \mu_{v_t}(\cdot \mid \sigma)$  and  $\mathbf{y} \sim \mu_{v_t}(\cdot \mid \tau)$ . The coupling  $D_{\text{opt}, \mathcal{I}_{v_t}}^{\sigma, \tau}(\cdot, \cdot)$  is determined by the local information  $\mathcal{I}_v$  and  $\sigma, \tau \in Q^{\deg(v)}$ .

With such a coupling, we can establish the following relation between the Dobrushin-Shlosman condition and the rapid mixing of the Gibbs sampling [8, 9, 7, 4, 19, 12].

► **Proposition 8** ([4, 19]). Let  $\mathcal{I} = (V, E, Q, \Phi)$  be an MRF instance with  $n = |V|$ , and  $\Omega = Q^V$  the state space. Let  $H(\sigma, \tau) \triangleq |\{v \in V \mid \sigma_v \neq \tau_v\}|$  denote the Hamming distance between  $\sigma \in \Omega$  and  $\tau \in \Omega$ . If  $\mathcal{I}$  satisfies the Dobrushin-Shlosman condition (Condition 4) with constant  $\delta > 0$ , then the one-step optimal coupling  $(\mathbf{X}_t, \mathbf{Y}_t)_{t \geq 0}$  for Gibbs sampling (Definition 7) satisfies

$$\forall \sigma, \tau \in \Omega : \quad \mathbb{E}[H(\mathbf{X}_t, \mathbf{Y}_t) \mid \mathbf{X}_{t-1} = \sigma \wedge \mathbf{Y}_{t-1} = \tau] \leq \left(1 - \frac{\delta}{n}\right) \cdot H(\sigma, \tau),$$

and hence the mixing rate of Gibbs sampling on  $\mathcal{I}$  is bounded as  $\tau_{\text{mix}}(\mathcal{I}, \epsilon) \leq \lceil \frac{n}{\delta} \log \frac{n}{\epsilon} \rceil$ .

## 5 Outlines of algorithm

Let  $\theta : \mathfrak{M} \rightarrow \mathbb{R}^K$  be a probabilistic inference problem that maps each MRF instance in  $\mathfrak{M}$  to a  $K$ -dimensional probability vector, and let  $\mathcal{E}_\theta$  be its estimating function. Let  $\mathcal{I} = (V, E, Q, \Phi) \in \mathfrak{M}$  be the current instance, where  $n = |V|$ . Our dynamic inference algorithm maintains a sequence of  $N(n)$  independent samples  $\mathbf{X}^{(1)}, \dots, \mathbf{X}^{(N(n))} \in Q^V$  which are  $\epsilon(n)$ -close to the Gibbs distribution  $\mu_{\mathcal{I}}$  in total variation distance and an  $(N, \epsilon)$ -estimator  $\hat{\theta}(\mathcal{I})$  of  $\theta(\mathcal{I})$  such that

$$\hat{\theta}(\mathcal{I}) = \mathcal{E}_\theta(\mathbf{X}^{(1)}, \mathbf{X}^{(2)}, \dots, \mathbf{X}^{(N(n))}).$$

Upon an update request that modifies  $\mathcal{I}$  to a new instance  $\mathcal{I}' = (V', E', Q, \Phi') \in \mathfrak{M}$ , where  $n' = |V'|$ , our algorithm does the followings:

- *Update the sample sequence.* Update  $\mathbf{X}^{(1)}, \dots, \mathbf{X}^{(N(n))}$  to a new sequence of  $N(n')$  independent samples  $\mathbf{Y}^{(1)}, \dots, \mathbf{Y}^{(N(n'))} \in Q^{V'}$  that are  $\epsilon(n')$ -close to  $\mu_{\mathcal{I}'}$  in total variation distance, and output the difference between two sample sequences.
- *Update the estimator.* Given the difference between the two sample sequences, update  $\hat{\theta}(\mathcal{I})$  to  $\hat{\theta}(\mathcal{I}') = \mathcal{E}_\theta(\mathbf{Y}^{(1)}, \dots, \mathbf{Y}^{(N(n'))})$  by accessing the oracle in Definition 3.

Obviously, the updated estimator  $\hat{\theta}(\mathcal{I}')$  is an  $(N, \epsilon)$ -estimator for  $\theta(\mathcal{I}')$ .

Our main technical contribution is to give an algorithm that dynamically maintains a sequence of  $N(n)$  independent samples for  $\mu_{\mathcal{I}}$ , while  $\mathcal{I}$  itself is dynamically changing. The dynamic sampling problem was recently introduced in [14]. The dynamical sampling algorithm given there only handles update of a single vertex or edge and works only for graphical models with soft constraints.

In contrast, our dynamic sampling algorithm maintains a sequence of  $N(n)$  independent samples for  $\mu_{\mathcal{I}}$  within total variation distance  $\epsilon(n)$ , while the entire specification of the graphical model  $\mathcal{I}$  is subject to dynamic update (to a new  $\mathcal{I}'$  with difference  $d(\mathcal{I}, \mathcal{I}') \leq L = o(n)$ ). Specifically, the algorithm updates the sample sequence within expected time  $O(\Delta^2 N(n) L \log^3 n + \Delta n)$ . Note that the extra  $O(\Delta n)$  cost is necessary for just editing the current MRF instance  $\mathcal{I}$  to  $\mathcal{I}'$  because a single update may change all the vertex and edge potentials simultaneously. This incremental time cost dominates the time cost of the dynamic inference algorithm, and is efficient for maintaining  $N(n)$  independent samples, especially when  $N(n)$  is sufficiently large, e.g.  $N(n) = \Omega(n/L)$ , in which case the average incremental cost for updating each sample is  $O(\Delta^2 L \log^3 n + \Delta n/N(n)) = O(\Delta^2 L \log^3 n)$ .

We illustrate the main idea by explaining how to maintain one sample. The idea is to represent the trace of the Markov chain for generating the sample by a dynamic data structure, and when the MRF instance is changed, this trace is modified to that of the new chain for generating the sample for the updated instance. This is achieved by both a set of efficient dynamic data structures and the coupling between the two Markov chains.

Specifically, let  $(\mathbf{X}_t)_{t=0}^T$  be the Gibbs sampler chain for distribution  $\mu_{\mathcal{I}}$ . When the chain is rapidly mixing, starting from an arbitrary initial configuration  $\mathbf{X}_0 \in Q^V$ , after suitably many steps  $\mathbf{X} = \mathbf{X}_T$  is an accurate enough sample for  $\mu_{\mathcal{I}}$ . At each step,  $\mathbf{X}_{t-1}$  and  $\mathbf{X}_t$  may differ only at a vertex  $v_t$  which is picked from  $V$  uniformly and independently at random. The evolution of the chain is fully captured by the initial state  $\mathbf{X}_0$  and the sequence of pairs  $\langle v_t, X_t(v_t) \rangle$ , from  $t = 1$  to  $t = T$ , which is called the *execution log* of the chain in the paper.

Now suppose that the current instance  $\mathcal{I}$  is updated to  $\mathcal{I}'$ . We construct such a coupling between the original chain  $(\mathbf{X}_t)_{t=0}^T$  and the new chain  $(\mathbf{Y}_t)_{t=0}^T$ , such that  $(\mathbf{Y}_t)_{t=0}^T$  is a faithful Gibbs sampling chain for the updated instance  $\mathcal{I}'$  given that  $(\mathbf{X}_t)_{t=0}^T$  is a faithful chain for  $\mathcal{I}$ , and the difference between the two chains is small, in the sense that they have almost the same execution logs except for about  $O(TL/n)$  steps, where  $L$  is the difference between  $\mathcal{I}$  and  $\mathcal{I}'$ .

To simplify the exposition of such coupling, for now we restrict ourselves to the cases where the update to the instance  $\mathcal{I}$  does not change the set of variables. Without loss of generality, we only consider the following two basic update operations that modifies  $\mathcal{I}$  to  $\mathcal{I}'$ .

- *Graph update.* The update only adds or deletes some edges, while all vertex potentials and the potentials of unaffected edges are not changed.
- *Hamiltonian update.* The update changes (possibly all) potentials of vertices and edges, while the underlying graph remains unchanged.

The general update of graphical model can be obtained by combining these two basic operations.

Then the new chain  $(\mathbf{Y}_t)_{t=0}^T$  can be coupled with  $(\mathbf{X}_t)_{t=0}^T$  by using the same initial configuration  $\mathbf{Y}_0 = \mathbf{X}_0$  and the same sequence  $v_1, v_2, \dots, v_T \in V$  of randomly picked vertices. And for  $t = 1, 2, \dots, T$ , the transition  $\langle v_t, Y_t(v_t) \rangle$  of the new chain can be generated using the same vertex  $v_t$  as in the original  $(\mathbf{X}_t)_{t=0}^T$  chain, and a random  $Y_t(v_t)$  generated according to a coupling of the marginal distributions of  $X_t(v_t)$  and  $Y_t(v_t)$ , conditioning respectively on the current states of the neighborhood of  $v_t$  in  $(\mathbf{X}_t)_{t=0}^T$  and  $(\mathbf{Y}_t)_{t=0}^T$ . Note that these two marginal distributions must be identical unless (I)  $\mathbf{X}_{t-1}$  and  $\mathbf{Y}_{t-1}$  differ from each other over the neighborhood of  $v_t$  or (II) the  $v_t$  itself is incident to where the models  $\mathcal{I}$  and  $\mathcal{I}'$  differ. The event (II) occurs rarely due to the following reasons.

- For graph update, the event (II) occurs only if  $v_t$  is incident to an updated edge. Since only  $L$  edges are updated, the event occurs in at most  $O(TL/n)$  steps in expectation.
- For Hamiltonian update, all the potentials of vertices and edges can be changed, thus  $\mathcal{I}, \mathcal{I}'$  may differ everywhere. The key observation is that, as the total difference between the current and updated potentials is bounded by  $L$ , we can apply a filter to first select all candidate steps where the coupling may actually fail due to the difference between  $\mathcal{I}$  and  $\mathcal{I}'$ , which can be as small as  $O(TL/n)$ , and the actual coupling between  $(\mathbf{X}_t)_{t=0}^\infty$  and  $(\mathbf{Y}_t)_{t=0}^\infty$  is constructed with such prior.

Finally, when  $\mathcal{I}$  and  $\mathcal{I}'$  both satisfy the Dobrushin-Shlosman condition, the percolation of disagreements between  $(\mathbf{X}_t)_{t=0}^T$  and  $(\mathbf{Y}_t)_{t=0}^T$  is bounded, and we show that the two chains are almost always identically coupled as  $\langle v_t, X_t(v_t) \rangle = \langle v_t, Y_t(v_t) \rangle$ , with exceptions at only  $O(TL/n)$  steps. The original chain  $(\mathbf{X}_t)_{t=0}^T$  can then be updated to the new chain  $(\mathbf{Y}_t)_{t=0}^T$  by only editing these  $O(TL/n)$  local transitions  $\langle v_t, Y_t(v_t) \rangle$  which are different from  $\langle v_t, X_t(v_t) \rangle$ . This is aided by the dynamic data structure for the execution log of the chain, which is of independent interest.

## 6 Dynamic Gibbs sampling

In this section, we give the dynamic sampling algorithm that updates the sample sequences.

In the following theorem, we use  $\mathcal{I} = (V, E, Q, \Phi)$ , where  $n = |V|$ , to denote the current MRF instance and  $\mathcal{I}' = (V', E', Q, \Phi')$ , where  $n' = |V'|$ , to denote the updated MRF instance. And define

$$\begin{aligned} d_{\text{graph}}(\mathcal{I}, \mathcal{I}') &\triangleq |V \oplus V'| + |E \oplus E'| \\ d_{\text{Hamil}}(\mathcal{I}, \mathcal{I}') &\triangleq \sum_{v \in V \cap V'} \|\phi_v - \phi'_v\|_1 + \sum_{e \in E \cap E'} \|\phi_e - \phi'_e\|_1. \end{aligned}$$

Note that  $d(\mathcal{I}, \mathcal{I}') = d_{\text{graph}}(\mathcal{I}, \mathcal{I}') + d_{\text{Hamil}}(\mathcal{I}, \mathcal{I}')$ , where  $d(\mathcal{I}, \mathcal{I}')$  is defined in (2).

► **Theorem 9** (dynamic sampling algorithm). *Let  $N : \mathbb{N}^+ \rightarrow \mathbb{N}^+$  and  $\epsilon : \mathbb{N}^+ \rightarrow (0, 1)$  be two functions satisfying the bounded difference condition in Definition 3. Assume that  $\mathcal{I}$  and  $\mathcal{I}'$  both satisfy Dobrushin-Shlosman condition,  $d_{\text{graph}}(\mathcal{I}, \mathcal{I}') \leq L_{\text{graph}} = o(n)$  and  $d_{\text{Hamil}}(\mathcal{I}, \mathcal{I}') \leq L_{\text{Hamil}}$ .*

*There is an algorithm that maintains a sequence of  $N(n)$  independent samples  $\mathbf{X}^{(1)}, \dots, \mathbf{X}^{(N(n))} \in Q^V$  where  $d_{\text{TV}}(\mu_{\mathcal{I}}, \mathbf{X}^{(i)}) \leq \epsilon(n)$  for all  $1 \leq i \leq N(n)$ , using  $O(nN(n) \log n)$  memory words, each of  $O(\log n)$  bits, such that when  $\mathcal{I}$  is updated to  $\mathcal{I}'$ , the algorithm updates the sequence to  $N(n')$  independent samples  $\mathbf{Y}^{(1)}, \dots, \mathbf{Y}^{(N(n'))} \in Q^{V'}$  where  $d_{\text{TV}}(\mu_{\mathcal{I}'}, \mathbf{Y}^{(i)}) \leq \epsilon(n')$  for all  $1 \leq i \leq N(n')$ , within expected time cost*

$$O(\Delta^2(L_{\text{graph}} + L_{\text{Hamil}})N(n) \log^3 n + \Delta n), \quad (5)$$

where  $\Delta = \max\{\Delta_G, \Delta_{G'}\}$ , and  $\Delta_G, \Delta_{G'}$  denote the maximum degree of  $G = (V, E)$  and  $G' = (V', E')$ .

Our algorithm is based on the Gibbs sampling algorithm. Let  $N : \mathbb{N}^+ \rightarrow \mathbb{N}^+$  and  $\epsilon : \mathbb{N}^+ \rightarrow (0, 1)$  be two functions in Theorem 9. We first give the *single-sample dynamic Gibbs sampling algorithm* (Algorithm 2) that maintains a single sample  $\mathbf{X} \in Q^V$  for the current MRF instance  $\mathcal{I} = (V, E, Q, \Phi)$  where  $n = |V|$  such that  $d_{\text{TV}}(\mathbf{X}, \mu_{\mathcal{I}}) \leq \epsilon(n)$ . We then use this algorithm to obtain the *multi-sample dynamic Gibbs sampling algorithm* that maintains  $N(n)$  independent samples for the current instance.

Given the error function  $\epsilon : \mathbb{N}^+ \rightarrow (0, 1)$ , suppose that  $T(\mathcal{I})$  is an easy-to-compute integer-valued function that upper bounds the mixing time on instance  $\mathcal{I}$ , such that

$$T(\mathcal{I}) \geq \tau_{\text{mix}}(\mathcal{I}, \epsilon(n)), \quad (6)$$

where  $\tau_{\text{mix}}(\mathcal{I}, \epsilon(n))$  denotes the mixing rate for the Gibbs sampling chain  $(\mathbf{X}_t)_{t \geq 0}$  on instance  $\mathcal{I}$ . By Proposition 8, if the Dobrushin-Shlosman condition is satisfied, we can set

$$T(\mathcal{I}) = \left\lceil \frac{n}{\delta} \log \frac{n}{\epsilon(n)} \right\rceil. \quad (7)$$

Our algorithm for single-sample dynamic Gibbs sampling maintains a random process  $(\mathbf{X}_t)_{t=0}^T$ , which is a Gibbs sampling chain on instance  $\mathcal{I}$  of length  $T = T(\mathcal{I})$ , where  $T(\mathcal{I})$  satisfies (6). Clearly  $\mathbf{X}_T$  is a sample for  $\mu_{\mathcal{I}}$  with  $d_{\text{TV}}(\mathbf{X}_T, \mu_{\mathcal{I}}) \leq \epsilon(n)$ .

When the current instance  $\mathcal{I}$  is updated to a new instance  $\mathcal{I}' = (V', E', Q, \Phi')$  where  $n' = |V'|$ , the original process  $(\mathbf{X}_t)_{t=0}^T$  is transformed to a new process  $(\mathbf{Y}_t)_{t=0}^{T'}$  such that the following holds as an invariant:  $(\mathbf{Y}_t)_{t=0}^{T'}$  is a Gibbs sampling chain on  $\mathcal{I}'$  with  $T' = T(\mathcal{I}')$ . Hence  $\mathbf{Y}_T$  is a sample for the new instance  $\mathcal{I}'$  with  $d_{\text{TV}}(\mathbf{Y}_T, \mu_{\mathcal{I}'}) \leq \epsilon(n')$ . This is achieved through the following two steps:

1. We construct couplings between  $(\mathbf{X}_t)_{t=0}^T$  and  $(\mathbf{Y}_t)_{t=0}^{T'}$ , so that the new process  $(\mathbf{Y}_t)_{t=0}^{T'}$  for  $\mathcal{I}'$  can be obtained by making small changes to the original process  $(\mathbf{X}_t)_{t=0}^T$  for  $\mathcal{I}$ .
2. We give a data structure which represents  $(\mathbf{X}_t)_{t=0}^T$  incrementally and supports various updates and queries to  $(\mathbf{X}_t)_{t=0}^T$  so that the above coupling can be generated efficiently.

The data structure is provided in the full version. In the following, we give the couplings.

## 6.1 Coupling for dynamic instances

The Gibbs sampling chain  $(\mathbf{X}_t)_{t=0}^T$  can be uniquely and fully recovered from: the initial state  $\mathbf{X}_0 \in Q^V$ , and the pairs  $\langle v_t, X_t(v_t) \rangle_{t=1}^T$  that record the transitions. We call  $\langle v_t, X_t(v_t) \rangle_{t=1}^T$  the *execution-log* for the chain  $(\mathbf{X}_t)_{t=0}^T$ , and denote it with

$$\text{Exe-Log}(\mathcal{I}, T) \triangleq \langle v_t, X_t(v_t) \rangle_{t=1}^T.$$

The following invariants are assumed for the random execution-log with an initial state.

► **Condition 10** (invariants for Exe-Log). *Fixed an initial state  $\mathbf{X}_0 \in Q^V$ , the followings hold for the random execution-log  $\text{Exe-Log}(\mathcal{I}, T) = \langle v_t, X_t(v_t) \rangle_{t=1}^T$  for the Gibbs sampling chain  $(\mathbf{X}_t)_{t=0}^T$  on instance  $\mathcal{I} = (V, E, Q, \Phi)$ :*

- $T = T(\mathcal{I})$  where  $T(\mathcal{I})$  satisfies (6);
- the random process  $(\mathbf{X}_t)_{t=0}^T$  uniquely recovered from the transitions  $\langle v_t, X_t(v_t) \rangle_{t=1}^T$  and the initial state  $\mathbf{X}_0$ , is identically distributed as the Gibbs sampling (Algorithm 1) on instance  $\mathcal{I}$  starting from initial state  $\mathbf{X}_0$  with  $v_t$  as the vertex picked at the  $t$ -th step.

Such invariants guarantee that  $\mathbf{X}_T$  provides a sample for  $\mu_{\mathcal{I}}$  with  $d_{TV}(\mathbf{X}_T, \mu_{\mathcal{I}}) \leq \epsilon(|V|)$ .

Suppose the current instance  $\mathcal{I}$  is updated to a new instance  $\mathcal{I}'$ . We construct couplings between the execution-log  $\text{Exe-Log}(\mathcal{I}, T) = \langle v_t, X_t(v_t) \rangle_{t=1}^T$  with initial state  $\mathbf{X}_0 \in Q^V$  for  $\mathcal{I}$  and the execution-log  $\text{Exe-Log}(\mathcal{I}', T') = \langle v'_t, Y_t(v'_t) \rangle_{t=1}^{T'}$  with initial state  $\mathbf{Y}_0 \in Q^{V'}$  for  $\mathcal{I}'$ . Our goal is as follows: assuming Condition 10 for  $\mathbf{X}_0$  and  $\text{Exe-Log}(\mathcal{I}, T)$ , the same condition should hold invariantly for  $\mathbf{Y}_0$  and  $\text{Exe-Log}(\mathcal{I}', T')$ .

Unlike traditional coupling of Markov chains for the analysis of mixing time, where the two chains start from arbitrarily distinct initial states but proceed by the same transition rule, here the two chains  $(\mathbf{X}_t)_{t=0}^T$  and  $(\mathbf{Y}_t)_{t=0}^{T'}$  start from similar states but have to obey different transition rules due to differences between instances  $\mathcal{I}$  and  $\mathcal{I}'$ .

Due to the technical reason, we divide the update from  $\mathcal{I} = (V, E, Q, \Phi)$  to  $\mathcal{I}' = (V', E', Q, \Phi')$  into two steps: we first update  $\mathcal{I} = (V, E, Q, \Phi)$  to

$$\mathcal{I}_{\text{mid}} = (V, E, Q, \Phi^{\text{mid}}), \quad (8)$$

where the potentials  $\Phi^{\text{mid}} = (\phi_a^{\text{mid}})_{a \in V \cup E}$  in the middle instance  $\mathcal{I}_{\text{mid}}$  are defined as

$$\forall a \in V \cup E, \quad \phi_a^{\text{mid}} \triangleq \begin{cases} \phi'_a & \text{if } a \in V' \cup E' \\ \phi_a & \text{if } a \notin V' \cup E'; \end{cases}$$

then we update  $\mathcal{I}_{\text{mid}} = (V, E, Q, \Phi^{\text{mid}})$  to  $\mathcal{I}' = (V', E', Q, \Phi')$ . In other words, the update from  $\mathcal{I}$  to  $\mathcal{I}_{\text{mid}}$  is only caused by updating the potentials of vertices and edges, while the underlying graph remains unchanged; and the update from  $\mathcal{I}_{\text{mid}}$  to  $\mathcal{I}'$  is only caused by updating the underlying graph, i.e. adding vertices, deleting vertices, adding edges and deleting edges.

The dynamic Gibbs sampling algorithm can be outlined as follows.

- **UpdateHamiltonian**: update  $\mathbf{X}_0$  and  $\langle v_t, X_t(v_t) \rangle_{t=1}^T$  to a new initial state  $\mathbf{Z}_0$  and a new execution log  $\text{Exe-Log}(\mathcal{I}_{\text{mid}}, T) = \langle u_t, Z_t(u_t) \rangle_{t=1}^T$  such that the random process  $(\mathbf{Z}_t)_{t=0}^T$  is the Gibbs sampling on instance  $\mathcal{I}_{\text{mid}}$ .
- **UpdateGraph**: update  $\mathbf{Z}_0$  and  $\langle u_t, Z_t(u_t) \rangle_{t=1}^T$  to a new initial state  $\mathbf{Y}_0$  and a new execution log  $\text{Exe-Log}(\mathcal{I}', T) = \langle v'_t, Y_t(v'_t) \rangle_{t=1}^{T'}$  such that the random process  $(\mathbf{Y}_t)_{t=0}^{T'}$  is the Gibbs sampling on instance  $\mathcal{I}'$ .
- **LengthFix**: change the length of the execution log  $\langle v'_t, Y_t(v'_t) \rangle_{t=1}^{T'}$  from  $T$  to  $T'$ , where  $T' = T(\mathcal{I}')$  and  $T(\mathcal{I}')$  satisfies (6).

The dynamic Gibbs sampling algorithm is given in Algorithm 2.

The subroutine **LengthFix** is given in Algorithm 3. The subroutine **UpdateGraph** is provided in the full version of the paper. In the following, we give the subroutines **UpdateHamiltonian**.

We consider the update of changing potentials of vertices and edges. The update do not change the underlying graph. Let  $\mathcal{I} = (V, E, Q, \Phi)$  be the current MRF instance. Let  $\mathbf{X}_0$  and  $\langle v_t, X_t(v_t) \rangle_{t=1}^T$  be the current initial state and execution log such that the random process  $(\mathbf{X}_t)_{t=0}^T$  is the Gibbs sampling on instance  $\mathcal{I}$ . Upon such an update, the new instance becomes

■ **Algorithm 2** Dynamic Gibbs sampling.

---

**Data** :  $\mathbf{X}_0 \in Q^V$  and  $\text{Exe-Log}(\mathcal{I}, T) = \langle v_t, X_t(v_t) \rangle_{t=1}^T$  for current  $\mathcal{I} = (V, E, Q, \Phi)$ .  
**Update**: an update that modifies  $\mathcal{I}$  to  $\mathcal{I}' = (V', E', Q, \Phi')$ .  
1 compute  $T' = T(\mathcal{I}')$  satisfying (6) and construct  $\mathcal{I}_{\text{mid}} = (V', E', Q, \Phi^{\text{mid}})$  as in (8);  
2  $(\mathbf{Z}_0, \langle u_t, Z_t(u_t) \rangle_{t=1}^T) \leftarrow \text{UpdateHamiltonian}(\mathcal{I}, \mathcal{I}_{\text{mid}}, \mathbf{X}_0, \langle v_t, X_t(v_t) \rangle_{t=1}^T)$ ;  
// update the potentials:  $\mathcal{I} \rightarrow \mathcal{I}_{\text{mid}}$   
3  $(\mathbf{Y}_0, \langle v'_t, Y_t(v'_t) \rangle_{t=1}^T) \leftarrow \text{UpdateGraph}(\mathcal{I}_{\text{mid}}, \mathcal{I}', \mathbf{Z}_0, \langle u_t, Z_t(u_t) \rangle_{t=1}^T)$ ;  
// update the underlying graph:  $\mathcal{I}_{\text{mid}} \rightarrow \mathcal{I}'$   
4  $(\mathbf{Y}_0, \langle v'_t, Y_t(v'_t) \rangle_{t=1}^{T'}) \leftarrow \text{LengthFix}(\mathcal{I}', \mathbf{Y}_0, \langle v'_t, Y_t(v'_t) \rangle_{t=1}^T, T')$ , where  $T' = T(\mathcal{I}')$ ;  
// change the length of the execution log from  $T$  to  $T' = T(\mathcal{I}')$   
5 update the data to  $\mathbf{Y}_0$  and  $\text{Exe-Log}(\mathcal{I}', T') = \langle v'_t, Y_t(v'_t) \rangle_{t=1}^{T'}$ ;

---

■ **Algorithm 3** LengthFix  $(\mathcal{I}, \mathbf{X}_0, \langle v_t, X_t(v_t) \rangle_{t=1}^T, T')$ .

---

**Data** :  $\mathbf{X}_0 \in Q^V$  and  $\text{Exe-Log}(\mathcal{I}, T) = \langle v_t, X_t(v_t) \rangle_{t=1}^T$  for current  $\mathcal{I} = (V, E, Q, \Phi)$ .  
**Input** : the new length  $T' > 0$ .  
1 **if**  $T' < T$  **then**  
2   truncate  $\langle v_t, X_t(v_t) \rangle_{t=1}^T$  to  $\langle v_t, X_t(v_t) \rangle_{t=1}^{T'}$ ;  
3 **else**  
4   extend  $\langle v_t, X_t(v_t) \rangle_{t=1}^T$  to  $\langle v_t, X_t(v_t) \rangle_{t=1}^{T'}$  by simulating the Gibbs sampling chain  
   on  $\mathcal{I}$  for  $T - T'$  more steps;  
5 update the data to  $\mathbf{X}_0$  and  $\text{Exe-Log}(\mathcal{I}, T') = \langle v_t, X_t(v_t) \rangle_{t=1}^{T'}$

---

$\mathcal{I}' = (V, E, Q, \Phi')$ . The algorithm  $\text{UpdateHamiltonian}(\mathcal{I}, \mathcal{I}', \mathbf{X}_0, \langle v_t, X_t(v_t) \rangle_{t=1}^T)$  updates the data to  $\mathbf{Y}_0$  and  $\langle v'_t, Y_t(v'_t) \rangle_{t=1}^T$  such that the random process  $(\mathbf{Y}_t)_{t=0}^T$  is the Gibbs sampling on instance  $\mathcal{I}'$ .

We transform the pair of  $\mathbf{X}_0 \in Q^V$  and  $\langle v_t, X_t(v_t) \rangle_{t=1}^T$  to a new pair of  $\mathbf{Y}_0 \in Q^V$  and  $\langle v_t, Y_t(v_t) \rangle_{t=1}^T$  for  $\mathcal{I}'$ . This is achieved as follows: the vertex sequence  $(v_t)_{t=1}^T$  is identically coupled and the chain  $(\mathbf{X}_t)_{t=0}^T$  is transformed to  $(\mathbf{Y}_t)_{t=0}^T$  by the following one-step local coupling between  $\mathbf{X}$  and  $\mathbf{Y}$ .

► **Definition 11** (one-step local coupling for Hamiltonian update). *The two chains  $(\mathbf{X}_t)_{t=0}^\infty$  on instance  $\mathcal{I} = (V, E, Q, \Phi)$  and  $(\mathbf{Y}_t)_{t=0}^\infty$  on instance  $\mathcal{I}' = (V, E, Q, \Phi')$  are coupled as:*

- Initially  $\mathbf{X}_0 = \mathbf{Y}_0 \in Q^V$ ;
- for  $t = 1, 2, \dots$ , the two chains  $\mathbf{X}$  and  $\mathbf{Y}$  jointly do:
  1. pick the same  $v_t \in V$ , and let  $(X_t(u), Y_t(u)) \leftarrow (X_{t-1}(u), Y_{t-1}(u))$  for all  $u \in V \setminus \{v_t\}$ ;
  2. sample  $(X_t(v_t), Y_t(v_t))$  from a coupling  $D_{\mathcal{I}_v, \mathcal{I}'_v}^{\sigma, \tau}(\cdot, \cdot)$  of the marginal distributions  $\mu_{v_t, \mathcal{I}}(\cdot \mid \sigma)$  and  $\mu_{v_t, \mathcal{I}'}(\cdot \mid \tau)$  with  $\sigma = X_{t-1}(\Gamma_G(v_t))$  and  $\tau = Y_{t-1}(\Gamma_G(v_t))$ , where  $G = (V, E)$ .

The local coupling  $D_{\mathcal{I}_v, \mathcal{I}'_v}^{\sigma, \tau}(\cdot, \cdot)$  for Hamiltonian update is specified as follows.

► **Definition 12** (local coupling  $D_{\mathcal{I}_v, \mathcal{I}'_v}^{\sigma, \tau}(\cdot, \cdot)$  for Hamiltonian update). *Let  $v \in V$  be vertex and  $\sigma, \tau \in Q^{\Gamma_G(v)}$  two configurations, where  $G = (V, E)$ . We say a random pair  $(c, c') \in Q^2$  is drawn from the coupling  $D_{\mathcal{I}_v, \mathcal{I}'_v}^{\sigma, \tau}(\cdot, \cdot)$  if  $(c, c')$  is generated by the following two steps:*

- **sampling step:** sample  $(c, c') \in Q^2$  jointly from an optimal coupling  $D_{\text{opt}, \mathcal{I}_v}^{\sigma, \tau}$  of the marginal distributions  $\mu_{v, \mathcal{I}}(\cdot | \sigma)$  and  $\mu_{v, \mathcal{I}}(\cdot | \tau)$ , such that  $c \sim \mu_{v, \mathcal{I}}(\cdot | \sigma)$  and  $c' \sim \mu_{v, \mathcal{I}}(\cdot | \tau)$ ;
- **resampling step:** flip a coin independently with the probability of HEADS being

$$p_{\mathcal{I}_v, \mathcal{I}'_v}^{\tau}(c') \triangleq \begin{cases} 0 & \text{if } \mu_{v, \mathcal{I}}(c' | \tau) \leq \mu_{v, \mathcal{I}'}(c' | \tau), \\ \frac{\mu_{v, \mathcal{I}}(c' | \tau) - \mu_{v, \mathcal{I}'}(c' | \tau)}{\mu_{v, \mathcal{I}}(c' | \tau)} & \text{otherwise;} \end{cases} \quad (9)$$

if the outcome of coin flipping is HEADS, resample  $c'$  from the distribution  $\nu_{\mathcal{I}_v, \mathcal{I}'_v}^{\tau}$  independently, where the distribution  $\nu_{\mathcal{I}_v, \mathcal{I}'_v}^{\tau}$  is defined as

$$\forall b \in Q: \quad \nu_{\mathcal{I}_v, \mathcal{I}'_v}^{\tau}(b) \triangleq \frac{\max\{0, \mu_{v, \mathcal{I}'}(b | \tau) - \mu_{v, \mathcal{I}}(b | \tau)\}}{\sum_{x \in Q} \max\{0, \mu_{v, \mathcal{I}}(x | \tau) - \mu_{v, \mathcal{I}'}(x | \tau)\}}. \quad (10)$$

► **Lemma 13.**  $D_{\mathcal{I}_v, \mathcal{I}'_v}^{\sigma, \tau}(\cdot, \cdot)$  in Definition 12 is a valid coupling between  $\mu_{v, \mathcal{I}}(\cdot | \sigma)$  and  $\mu_{v, \mathcal{I}'}(\cdot | \tau)$ .

By Lemma 13, the resulting  $(\mathbf{Y}_t)_{t=0}^T$  is a faithful copy of the Gibbs sampling on instance  $\mathcal{I}'$ , assuming that  $(\mathbf{X}_t)_{t=0}^T$  is such a chain on instance  $\mathcal{I}$ .

Next we give an upper bound for the probability  $p_{\mathcal{I}_v, \mathcal{I}'_v}^{\tau}(\cdot)$  defined in (9).

► **Lemma 14.** For any two instances  $\mathcal{I} = (V, E, Q, \Phi)$  and  $\mathcal{I}' = (V, E, Q, \Phi')$  of MRF model, and any  $v \in V, c \in Q$  and  $\sigma \in Q^{\Gamma_G(v)}$ , it holds that

$$p_{\mathcal{I}_v, \mathcal{I}'_v}^{\tau}(c) \leq 2 \left( \|\phi_v - \phi'_v\|_1 + \sum_{e=\{u, v\} \in E} \|\phi_e - \phi'_e\|_1 \right), \quad (11)$$

where  $\|\phi_v - \phi'_v\|_1 = \sum_{c \in Q} |\phi_v(c) - \phi'_v(c)|$  and  $\|\phi_e - \phi'_e\|_1 = \sum_{c, c' \in Q} |\phi_e(c, c') - \phi'_e(c, c')|$ .

By Lemma 14, for each vertex  $v \in V$ , we define an upper bound of the probability  $p_{\mathcal{I}_v, \mathcal{I}'_v}^{\tau}(\cdot)$  as

$$p_v^{\text{up}} \triangleq \min \left\{ 2 \left( \|\phi_v - \phi'_v\|_1 + \sum_{e=\{u, v\} \in E} \|\phi_e - \phi'_e\|_1 \right), 1 \right\}. \quad (12)$$

With  $p_v^{\text{up}}$ , we can implement the one-step local coupling in Definition 11 as follows. We first sample each  $v_i \in V$  for  $1 \leq i \leq T$  uniformly and independently. For each vertex  $v \in V$ , let  $T_v \triangleq \{1 \leq t \leq T \mid v_t = v\}$  be the set of all the steps that pick the vertex  $v$ . We select each  $t \in T_v$  independently with probability  $p_v^{\text{up}}$  to construct a random subset  $\mathcal{P}_v \subseteq T_v$ , and let  $\mathcal{P} \triangleq \bigcup_{v \in V} \mathcal{P}_v$ . We then couple the two chains  $(\mathbf{X}_t)_{t=0}^T$  and  $(\mathbf{Y}_t)_{t=0}^T$ . First set  $\mathbf{X}_0 = \mathbf{Y}_0$ . For each  $1 \leq t \leq T$ , we set  $(X_t(u), Y_t(u)) \leftarrow (X_{t-1}(u), Y_{t-1}(u))$  for all  $u \in V \setminus \{v_t\}$ ; then generate the random pair  $(X_t(v_t), Y_t(v_t))$  by the following procedure.

- **sampling step:** Let  $\sigma = X_{t-1}(\Gamma_G(v_t))$  and  $\tau = Y_{t-1}(\Gamma_G(v_t))$ . We draw a random pair  $(c, c') \in Q^2$  from the optimal coupling  $D_{\text{opt}, \mathcal{I}_v}^{\sigma, \tau}$  of the marginal distributions  $\mu_{v, \mathcal{I}}(\cdot | \sigma)$  and  $\mu_{v, \mathcal{I}}(\cdot | \tau)$  such that  $c \sim \mu_{v, \mathcal{I}}(\cdot | \sigma)$  and  $c' \sim \mu_{v, \mathcal{I}}(\cdot | \tau)$ ;
- **resampling step:** If  $t \notin \mathcal{P}$ , set  $X_t(v_t) = c$  and  $Y_t(v_t) = c'$ . Otherwise, set  $X_t(v_t) = c$  and

$$Y_t(v_t) = \begin{cases} b \sim \nu_{\mathcal{I}_{v_t}, \mathcal{I}'_{v_t}}^{\tau} & \text{with probability } p_{\mathcal{I}_{v_t}, \mathcal{I}'_{v_t}}^{\tau}(c')/p_{v_t}^{\text{up}} \\ c' & \text{with probability } 1 - p_{\mathcal{I}_{v_t}, \mathcal{I}'_{v_t}}^{\tau}(c')/p_{v_t}^{\text{up}}. \end{cases} \quad (13)$$

Note that  $p_{v_t}^{\text{up}} > 0$  if  $t \in \mathcal{P}$ . By Lemma 14, it must hold that  $p_{\mathcal{I}_{v_t}, \mathcal{I}'_{v_t}}^{\tau}(c') \leq p_{v_t}^{\text{up}}$ . Hence, the probability  $p_{\mathcal{I}_{v_t}, \mathcal{I}'_{v_t}}^{\tau}(c')/p_{v_t}^{\text{up}}$  is valid. Note that the probability that  $Y_t(v_t)$  is set as  $b$  is

$$\Pr[Y_t(v_t) \text{ is set as } b] = \Pr[t \in \mathcal{P}] \cdot \frac{p_{\mathcal{I}_{v_t}, \mathcal{I}'_{v_t}}^{\tau}(c')}{p_{v_t}^{\text{up}}} = p_{v_t}^{\text{up}} \cdot \frac{p_{\mathcal{I}_{v_t}, \mathcal{I}'_{v_t}}^{\tau}(c')}{p_{v_t}^{\text{up}}} = p_{\mathcal{I}_{v_t}, \mathcal{I}'_{v_t}}^{\tau}(c').$$

Hence, our implementation perfectly simulates the coupling in Definition 11.

Let  $\mathcal{D}_t$  denote the *set of disagreements* between  $\mathbf{X}_t$  and  $\mathbf{Y}_t$ . Formally,

$$\mathcal{D}_t \triangleq \{v \in V \mid X_t(v) \neq Y_t(v)\}.$$

Note that if  $v_t \notin \Gamma_G(\mathcal{D}_{t-1})$ , the random pair  $(c, c')$  drawn from the coupling  $D_{\text{opt}, \mathcal{I}_v}^{\sigma, \tau}$  must satisfy  $c = c'$ . Thus it is easy to make the following observation for the  $(\mathbf{X}_t)_{t=0}^T$  and  $(\mathbf{Y}_t)_{t=0}^T$  coupled as above.

► **Observation 15.** *For any integer  $t \in [1, T]$ , if  $v_t \notin \Gamma_G^+(\mathcal{D}_{t-1})$  and  $t \notin \mathcal{P}$ , then  $X_t(v_t) = Y_t(v_t)$  and  $\mathcal{D}_t = \mathcal{D}_{t-1}$ .*

With this observation, the new  $\mathbf{Y}_0$  and  $\text{Exe-Log}(\mathcal{I}', T) = \langle v_t, Y_t(v_t) \rangle_{t=1}^T$  can be generated from  $\mathbf{X}_0$  and  $\text{Exe-Log}(\mathcal{I}, T) = \langle v_t, X_t(v_t) \rangle_{t=1}^T$  as Algorithm 4.

Observation 15 says that the nontrivial coupling between  $X_t(v_t)$  and  $Y_t(v_t)$  is only needed when  $v_t \in \Gamma_G^+(\mathcal{D}_{t-1})$  or  $t \in \mathcal{P}$ , which occurs rarely as long as  $\mathcal{D}_{t-1}$  and  $\mathcal{P}$  are small. This is a key to ensure the small incremental time cost of Algorithm 4. The following lemma bounds the expected cost for UpdateHamiltonian.

► **Lemma 16** (cost of the coupling for UpdateHamiltonian). *Let  $\mathcal{I} = (V, E, Q, \Phi)$  be the current MRF instance and  $\mathcal{I}' = (V, E, Q, \Phi')$  the updated instance. Assume that  $\mathcal{I}$  satisfies Dobrushin-Shlosman condition (Condition 4) with constant  $\delta > 0$ , and  $d_{\text{Hamil}}(\mathcal{I}, \mathcal{I}') = \sum_{v \in V} \|\phi_v - \phi'_v\|_1 + \sum_{e \in E} \|\phi_e - \phi'_e\|_1 \leq L$ . It holds that  $\mathbb{E} \left[ \sum_{t=1}^T \mathbf{1}[t \in \mathcal{P} \vee v_t \in \Gamma_G^+(\mathcal{D}_{t-1})] \right] = O\left(\frac{\Delta T L}{n\delta}\right)$ , where  $n = |V|$ ,  $\Delta$  is the maximum degree of graph  $G = (V, E)$ .*

## 6.2 Dynamic Gibbs sampling algorithm

The couplings constructed in Section 6.1 can be implemented as the algorithm for dynamic Gibbs sampling. Recall  $d_{\text{graph}}(\cdot, \cdot)$  and  $d_{\text{Hamil}}(\cdot, \cdot)$  are defined in (2).

► **Lemma 17** (single-sample dynamic Gibbs sampling algorithm). *Let  $\epsilon : \mathbb{N}^+ \rightarrow (0, 1)$  be an error function. Let  $\mathcal{I} = (V, E, Q, \Phi)$  be an MRF instance with  $n = |V|$  and  $\mathcal{I}' = (V', E', Q, \Phi')$  the updated instance with  $n' = |V'|$ . Denote  $T = T(\mathcal{I})$ ,  $T' = T(\mathcal{I}')$  and  $T_{\max} = \max\{T, T'\}$ . Assume  $d_{\text{graph}}(\mathcal{I}, \mathcal{I}') \leq L_{\text{graph}} = o(n)$ ,  $d_{\text{Hamil}}(\mathcal{I}, \mathcal{I}') \leq L_{\text{Hamil}}$ , and  $T, T' \in \Omega(n \log n)$ . The single-sample dynamic Gibbs sampling algorithm (Algorithm 2) does the followings:*

- **(space cost)** *The algorithm maintains an explicit copy of a sample  $\mathbf{X} \in Q^V$  for the current instance  $\mathcal{I}$ , and also a data structure using  $O(T)$  memory words, each of  $O(\log T)$  bits, for representing an initial state  $\mathbf{X}_0 \in Q^V$  and an execution-log  $\text{Exe-Log}(\mathcal{I}, T) = \langle v_t, X_t(v_t) \rangle_{t=1}^T$  for the Gibbs sampling  $(\mathbf{X}_t)_{t=0}^T$  on  $\mathcal{I}$  generating sample  $\mathbf{X} = \mathbf{X}_T$ .*
- **(correctness)** *Assuming that Condition 10 holds for  $\mathbf{X}_0$  and  $\text{Exe-Log}(\mathcal{I}, T)$  for the Gibbs sampling on  $\mathcal{I}$ , upon each update that modifies  $\mathcal{I}$  to  $\mathcal{I}'$ , the algorithm updates  $\mathbf{X}$  to an explicit copy of a sample  $\mathbf{Y} \in Q^{V'}$  for the new instance  $\mathcal{I}'$ , and correspondingly updates the  $\mathbf{X}_0$  and  $\text{Exe-Log}(\mathcal{I}, T)$  represented by the data structure to a  $\mathbf{Y}_0 \in Q^{V'}$  and  $\text{Exe-Log}(\mathcal{I}', T') = \langle v'_t, Y_t(v'_t) \rangle_{t=1}^{T'}$  for the Gibbs sampling  $(\mathbf{Y}_t)_{t=0}^{T'}$  on  $\mathcal{I}'$  generating the new sample  $\mathbf{Y} = \mathbf{Y}_{T'}$ , where  $\mathbf{Y}_0$  and  $\text{Exe-Log}(\mathcal{I}', T')$  satisfy Condition 10 for the Gibbs sampling on  $\mathcal{I}'$ , therefore,*

$$d_{\text{TV}}(\mathbf{Y}, \mu_{\mathcal{I}'}^*) \leq \epsilon(n').$$

■ **Algorithm 4** UpdateHamiltonian  $(\mathcal{I}, \mathcal{I}', \mathbf{X}_0, \langle v_t, X_t(v_t) \rangle_{t=1}^T)$ .

---

**Data** :  $\mathbf{X}_0 \in Q^V$  and  $\text{Exe-Log}(\mathcal{I}, T) = \langle v_t, X_t(v_t) \rangle_{t=1}^T$  for  $\mathcal{I} = (V, E, Q, \Phi)$ .  
**Update**: an update that modifies  $\mathcal{I}$  to  $\mathcal{I}' = (V, E, Q, \Phi')$ .

- 1  $t_0 \leftarrow 0$ ,  $\mathcal{D} \leftarrow \emptyset$ , and construct a  $\mathbf{Y}_0 \leftarrow \mathbf{X}_0$ ;
- 2 for each  $v \in V$ , construct a random subset  $\mathcal{P}_v \subseteq T_v \triangleq \{1 \leq t \leq T \mid v_t = v\}$  such that each element in  $T_v$  is selected independently with probability  $p_v^{\text{up}}$  defined in (12);
- 3 construct the set  $\mathcal{P} \leftarrow \bigcup_{v \in V} \mathcal{P}_v$ ;
- 4 **while**  $\exists t_0 < t \leq T$  such that  $v_t \in \Gamma_G^+(\mathcal{D})$  or  $t \in \mathcal{P}$  **do**
- 5     find the smallest  $t > t_0$  such that  $v_t \in \Gamma_G^+(\mathcal{D})$  or  $t \in \mathcal{P}$ ;
- 6     for all  $t_0 < i < t$ , let  $Y_i(v_i) = X_i(v_i)$ ;
- 7     sample  $Y_t(v_t) \in Q$  conditioning on  $X_t(v_t)$  according to the optimal coupling between  $\mu_{v_t, \mathcal{I}}(\cdot \mid X_{t-1}(\Gamma_G(v_t)))$  and  $\mu_{v_t, \mathcal{I}'}(\cdot \mid Y_{t-1}(\Gamma_G(v_t)))$ ;
- 8     **if**  $t \in \mathcal{P}$  **then**
- 9         **with probability**  $p_{\mathcal{I}_{v_t}, \mathcal{I}'_{v_t}}^\tau(Y_t(v_t))/p_{v_t}^{\text{up}}$  where  $\tau = Y_{t-1}(\Gamma_G(v_t))$  **do**
- 10             resample  $Y_t(v_t) \sim \nu_{\mathcal{I}_{v_t}, \mathcal{I}'_{v_t}}^\tau$ , where  $\nu_{\mathcal{I}_{v_t}, \mathcal{I}'_{v_t}}^\tau$  is defined in (10) ;
- 11     **if**  $X_t(v_t) \neq Y_t(v_t)$  **then**  $\mathcal{D} \leftarrow \mathcal{D} \cup \{v_t\}$  **else**  $\mathcal{D} \leftarrow \mathcal{D} \setminus \{v_t\}$ ;
- 12      $t_0 \leftarrow t$ ;
- 13 for all remaining  $t_0 < i \leq T$ : let  $Y_i(v_i) = X_i(v_i)$ ;
- 14 update the data to  $\mathbf{Y}_0$  and  $\text{Exe-Log}(\mathcal{I}', T) = \langle v_t, Y_t(v_t) \rangle_{t=1}^T$ ;

---

■ **(time cost)** Assuming Condition 10 for  $\mathbf{X}_0$  and  $\text{Exe-Log}(\mathcal{I}, T)$  for the Gibbs sampling on  $\mathcal{I}$ , the expected time complexity for resolving an update is

$$O\left(\Delta n + \Delta\left(|T - T'| + \left(\Delta \log n + \frac{T_{\max}}{n}\right)(L_{\text{Hamil}} + L_{\text{graph}})\right) \log^2 T_{\max}\right),$$

where  $\Delta = \max\{\Delta_G, \Delta_{G'}\}$ ,  $\Delta_G, \Delta_{G'}$  denote the maximum degrees of  $G = (V, E)$  and  $G' = (V', E')$ .

We remark that the  $O(\Delta n)$  in time cost is necessary because the update from  $\mathcal{I}$  to  $\mathcal{I}'$  may change all the potentials of vertices and edges. One can reduce the  $O(\Delta n)$  from the time cost if we further restrict that one update can only change constant number of vertices, edges, and potentials.

One can extend Algorithm 2 to an *Multi-sample dynamic Gibbs sampling algorithm* that maintains multiple independent random samples for the current MRF instance. By Lemma 17, it is easy to prove that the Multi-sample algorithm is correct and efficient. Thus Theorem 9 follows immediately. The detail of the Multi-sample dynamic Gibbs sampling algorithm and the proof of Theorem 9 are provided in the full version of the paper.

## 7 Conclusion

In this paper we study probabilistic inference problem in a graphical model when the model itself is changing dynamically with time. We study the non-local updates so that two consecutive graphical models may differ everywhere as long as the total amount of their difference is bounded. This general setting covers many typical applications. We give a sampling-based dynamic inference algorithm that maintains an inference solution efficiently against the dynamic inputs. The algorithm significantly improves the time cost compared to the static sampling-based inference algorithm.

Our algorithm generically reduces the dynamic inference to dynamic sampling problem. Our main technical contribution is a dynamic Gibbs sampling algorithm that maintains random samples for graphical models dynamically changed by non-local updates. Such technique is extendable to all single-site dynamics. This gives us a systematic approach for transforming classic MCMC samplers on static inputs to the sampling and inference algorithms in a dynamic setting. Our dynamic algorithms are efficient as long as the one-step optimal coupling exhibits a step-wise decay, a key property that has been widely used in supporting efficient MCMC sampling in the classic static setting and captured by the Dobrushin-Shlosman condition.

Our result is the first one that shows the possibility of efficient probabilistic inference in dynamically changing graphical models (especially when the graphical models are changed by non-local updates). Our dynamic inference algorithm has potentials in speeding up the iterative algorithms for learning graphical models, which deserves more theoretical and experimental research. In this paper, we focus on discrete graphical models and sampling-based inference algorithms. Important future directions include considering more general distributions and the dynamic algorithms based on other inference techniques.

## Abstract

We give alternate proofs for three related results in analysis of Boolean functions, namely the KKL Theorem, Friedgut's Junta Theorem, and Talagrand's strengthening of the KKL Theorem. We follow a new approach: looking at the first Fourier level of the function after a suitable random restriction and applying the Log-Sobolev inequality appropriately. In particular, we avoid using the hypercontractive inequality that is common to the original proofs. Our proofs might serve as an alternate, uniform exposition to these theorems and the techniques might benefit further research.

## 1 Introduction

Let us consider the Boolean cube  $\{0,1\}^n$  equipped with the uniform measure and let  $f: \{0,1\}^n \rightarrow \{0,1\}$  be a function. The influence of a coordinate  $i \in [n]$ , denoted by  $I_i[f]$ , is defined to be  $\Pr_x[f(x) \neq f(x \oplus e_i)]$ , where  $x \in \{0,1\}^n$  is sampled uniformly and  $x \oplus e_i$  denotes the input  $x$  with the  $i^{\text{th}}$  bit flipped. The total influence of  $f$  is  $I[f] = \sum_{i=1}^n I_i[f]$ . One of the most basic inequalities, known as Poincare's inequality, states that  $I[f] \geq \text{var}(f)$ , where  $\text{var}(f)$  is the variance of the random variable  $f(x)$  when  $x \in \{0,1\}^n$  is sampled uniformly. In general, Poincare's inequality may be tight, which raises the following question: can it

be the case that not only  $I[f] \approx \text{var}(f)$ , but actually  $I_i[f] \approx \frac{\text{var}(f)}{n}$  for all  $i \in [n]$ ? In other words, can all influences of  $f$  be as small as possible simultaneously? The landmark result of Kahn, Kalai, and Linial [13] gives a negative answer to this question:

► **Theorem 1.** *There exists an absolute constant  $c > 0$ , such that for any  $f: \{0, 1\}^n \rightarrow \{0, 1\}$ , there is a coordinate  $i \in [n]$  with  $I_i[f] \geq c \cdot \frac{\log n}{n} \text{var}(f)$ .*

The KKL Theorem and its strengthenings by Friedgut [9] and Talagrand [19] are foundational results in analysis of Boolean functions. These have found several applications, e.g. to the threshold phenomena, computational learning theory, extremal combinatorics, communication complexity, hardness of approximation, non-embeddability results in metric geometry, and coding theory [10, 18, 5, 11, 3, 6, 14, 15, 4, 16]. Before we discuss the theorems of Friedgut and Talagrand, let us state a dimension-free variant of the KKL Theorem (that is morally equivalent to Theorem 1 and is easily implied by the techniques in [13]).

► **Theorem 2.** *There exists an absolute constant  $K > 0$ , such that for any  $f: \{0, 1\}^n \rightarrow \{0, 1\}$ , there is a coordinate  $i \in [n]$  with  $I_i[f] \geq 2^{-K \frac{I[f]}{\text{var}(f)}}$ .*

We note that Theorem 2 implies Theorem 1: if  $I[f] \geq \frac{\log n}{2^K} \text{var}(f)$ , then clearly there is a coordinate  $i \in [n]$  such that  $I_i[f] \geq \frac{I[f]}{n} \geq \frac{1}{2^K} \frac{\log n}{n} \text{var}(f)$ . Otherwise, by Theorem 2, there is a coordinate  $i \in [n]$  such that  $I_i[f] \geq 2^{-K \frac{I[f]}{\text{var}(f)}} \geq \frac{1}{\sqrt{n}}$  and we are done either way. Friedgut's Junta Theorem can now be stated as below.

► **Theorem 3.** *There exists an absolute constant  $K > 0$ , such that for any  $f: \{0, 1\}^n \rightarrow \{0, 1\}$  and  $\varepsilon > 0$ , the function  $f$  is  $\varepsilon$ -close to a function  $g: \{0, 1\}^n \rightarrow \{0, 1\}$  (in Hamming distance) that depends on at most  $2^{K \frac{I[f]}{\varepsilon}}$  coordinates.*

Morally speaking, Theorem 3 states that not only that there is a coordinate with significant influence as in Theorem 2, but actually all coordinates that have smaller influence, combined, barely affect the output of the function  $f$  (and this is how its proof proceeds). Talagrand's strengthening of the KKL Theorem is stated below.

► **Theorem 4.** *There exists an absolute constant  $c > 0$ , such that for any  $f: \{0, 1\}^n \rightarrow \{0, 1\}$ ,*

$$\sum_{i=1}^n \frac{I_i[f]}{\log(1/I_i[f])} \geq c \cdot \text{var}(f).$$

We note that Theorem 4 implies Theorem 2 as follows: suppose on the contrary that all influences  $I_i[f]$  are at most  $2^{-K \frac{I[f]}{\text{var}(f)}}$ . Then the “Talagrand sum” as above is at most  $\frac{\text{var}(f)}{K I[f]} \sum_{i=1}^n I_i[f] = \frac{\text{var}(f)}{K}$ , a contradiction for a large enough constant  $K$ .

A key technique used in the original proofs of all the theorems above is the hypercontractive inequality (stated in Section 2.3). The use of this inequality is, by now, nearly ubiquitous in analysis of Boolean functions. Still, using this inequality might impose limitations of its own, limiting the discovery of new results, both qualitatively and quantitatively. As far as we know, researchers in this area have wondered whether there is “life” beyond the hypercontractive inequality, and certainly there have been efforts to prove the KKL Theorem (and its strengthenings) without using it. In particular, proofs using “only” the Log-Sobolev inequality (stated in Section 2.3) for the KKL Theorem and Friedgut's Junta Theorem are known [8] (their argument though does not seem to extend to Talagrand's Theorem). There is also a recent proof of the KKL Theorem (as well as Talagrand's result and some strengthenings) using stochastic calculus [7].

In this paper, we prove Theorems 1, 2, 3, 4 using “only” the Log-Sobolev inequality. Since the hypercontractive inequality and the Log-Sobolev inequality are equivalent to each other and both have separate not-so-difficult proofs as well, whether one uses one or the other is, admittedly, splitting hairs. Still, another interesting aspect of this paper is that our proof approach is very different from all earlier proofs. We look at the first Fourier level of the function after a suitable random restriction and apply the Log-Sobolev inequality appropriately. The approach is, in our subjective opinion, more direct, natural, and less mysterious, though the overall proofs are not necessarily “easier”. The additional structural information implicit in these proofs might benefit further research. In Section 3, we describe the basic skeleton that is common to all our proofs and the main technical lemma, Lemma 20. The paper might have some benefit from expository perspective as all our proofs are uniformly built around the same skeleton.

Before proceeding to formal proofs, we illustrate here the underlying intuition and how it morally explains the KKL Theorem (translating the intuition into a formal proof takes some effort). We assume here that the reader is somewhat familiar with the area and the standard terminology. Let  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  be a balanced function and suppose all its influences are at most (say)  $\frac{1}{\sqrt{n}}$ . We hope to conclude that the total influence is then  $\Omega(\log n)$ . Suppose  $f$  has degree  $d$  (we are referring to the so-called average degree, but never mind). Consider a  $\frac{1}{d}$ -random restriction  $f_{\bar{J} \rightarrow z}$  of the function where each coordinate stays alive with probability  $\frac{1}{d}$  independently and denoting the set of alive coordinates as  $J$ , the coordinates in  $\bar{J} = [n] \setminus J$  are set to a uniformly random setting  $z$ . Since  $f$  has degree  $d$ , we expect that the restricted function  $f_{\bar{J} \rightarrow z}$  has constant Fourier weight at the first level and ideally, is even a dictatorship function (indeed, if the Fourier weight at the first level exceeds a certain threshold, a Boolean function is necessarily a dictatorship). Suppose, for the sake of illustration, that the restricted function  $f_{\bar{J} \rightarrow z}$  is always a dictatorship function. However, it could be the dictatorship of a different coordinate for different settings of  $z$ . Let  $A_j \subseteq \{0, 1\}^{\bar{J}}$  consist of those settings of  $z$  for which  $f_{\bar{J} \rightarrow z}$  is the dictatorship of coordinate  $j \in J$ . We note that the fractional size of  $A_j$ , denoted  $\mu(A_j)$ , is at most the influence of the coordinate  $j$  (why?) and hence  $\mu(A_j) \leq \frac{1}{\sqrt{n}}$  for all  $j \in J$ . Now we simply note that since the sets  $A_1, \dots, A_{|J|}$  are all polynomially small in size and form a partition of  $\{0, 1\}^{\bar{J}}$ , at least  $\frac{\log n}{n}$  fraction of the edges in the hypercube  $\{0, 1\}^{\bar{J}}$  are across some  $A_j$  and  $A_{j'}$  with  $j \neq j'$ . These edges, along with the fact that  $A_j$  and  $A_{j'}$  are restrictions leading to dictatorships of  $j$  and  $j'$  respectively, contribute  $\Omega(\log n)$  to the total influence of the function  $f$  as desired (why?)! We use here the standard isoperimetric result on the hypercube that for a small set  $A \subseteq \{0, 1\}^n$ , at least  $\frac{\log(1/\mu(A))}{n}$  fraction of hypercube edges incident on it, go outside of  $A$  (this is also a special case of the Log-Sobolev inequality, see Lemma 11).

## 2 Preliminaries

We denote  $[n] = \{1, 2, \dots, n\}$ . We write  $X \gtrsim Y$  to say that there exists an absolute constant  $c > 0$  such that  $X \geq c \cdot Y$ .

### 2.1 Standard Fourier Analysis

We consider the space of real-valued functions  $f : \{0, 1\}^n \rightarrow \mathbb{R}$ , equipped with the inner product  $\langle f, g \rangle = \mathbb{E}_{x \in_R \{0, 1\}^n} [f(x)g(x)]$ . Here and throughout the paper, we consider the uniform distribution over  $\{0, 1\}^n$ . It is well-known that the collection of functions  $\chi_S : \{0, 1\}^n \rightarrow \{-1, 1\}$ , one for each subset  $S \subseteq [n]$ , defined as  $\chi_S(x) = (-1)^{\oplus_{i \in S} x_i}$ , is an orthonormal basis w.r.t. the said inner product. Thus each function  $f : \{0, 1\}^n \rightarrow \mathbb{R}$  can be written uniquely as

$$f(x) = \sum_{S \subseteq [n]} \hat{f}(S) \chi_S(x), \quad \text{where } \hat{f}(S) = \langle f, \chi_S \rangle.$$

Since the basis  $\{\chi_S\}_{S \subseteq [n]}$  is orthonormal, one has the Plancherel/Parseval equality:

► **Fact 5.** For any  $f, g: \{0, 1\}^n \rightarrow \mathbb{R}$ , we have  $\langle f, g \rangle = \sum_{S \subseteq [n]} \hat{f}(S) \hat{g}(S)$ . Also

$$\langle f, f \rangle = \mathbb{E}_x [f(x)^2] = \|f\|_2^2 = \sum_{S \subseteq [n]} \hat{f}(S)^2.$$

We will also consider other  $L_p$  norms of functions for  $p \geq 1$  (mostly  $L_1$ -norm), similarly defined as  $\|f\|_p = (\mathbb{E}_x [|f(x)|^p])^{1/p}$ . It will be useful to consider the “Fourier weight” of a function on a given “level”.

► **Definition 6.** For integer  $d \geq 1$ , the level  $d$  Fourier weight of a function  $f: \{0, 1\}^n \rightarrow \mathbb{R}$  is  $W_{=d}[f] = \sum_{|S|=d} \hat{f}(S)^2$ . Also, its Fourier weight on the “chunk”  $d$  is  $W_{\approx d}[f] = \sum_{d \leq |S| < 2d} W_{=|S|}[f]$ .

For a noise parameter  $\varepsilon \in (0, 1)$ , the noise operator  $T_{1-\varepsilon}$  is defined as follows. For a function  $f: \{0, 1\}^n \rightarrow \mathbb{R}$ , the function  $T_{1-\varepsilon}f$  is

$$T_{1-\varepsilon}f(x) = \mathbb{E}_{y \sim_\varepsilon x} [f(y)],$$

where the input  $y$  is obtained from input  $x$  by resampling each coordinate of  $x$  with probability  $\varepsilon$  independently. It is well-known that the Fourier representation of  $T_{1-\varepsilon}f$  is

$$T_{1-\varepsilon}f = \sum_{S \subseteq [n]} (1-\varepsilon)^{|S|} \hat{f}(S) \chi_S.$$

## 2.2 Discrete Derivatives and Influences

For a coordinate  $i \in [n]$ , the discrete derivatives of  $f$  along the  $i^{\text{th}}$  direction is a function  $\partial_i f: \{0, 1\}^{n-1} \rightarrow \mathbb{R}$  defined as

$$\partial_i f(y) = f(x_{-i} = y, x_i = 1) - f(x_{-i} = y, x_i = 0).$$

► **Definition 7.** The  $L_p$ -influence of a coordinate  $i \in [n]$  is defined as  $I_i^p[f] = \|\partial_i f\|_p^p$ . The  $L_p$  total-influence is  $I^p[f] = \sum_{i=1}^n I_i^p[f]$ . We stress here that in the notation  $I_i^p[f]$  and  $I^p[f]$  herein, the “ $p$ ” is a super-script and not an exponent.

We will be concerned with only  $L_2$  and  $L_1$  influences. In the literature, the notion usually refers to  $L_2$ -influences, so in this case the superscript  $p$  is omitted, writing  $I_i[f] = I_i^2[f]$  and  $I[f] = I^2[f]$  for the individual and total influence respectively. We note that for Boolean functions, all the  $L_p$ -influences are equal. We will be concerned with the more general case of bounded functions, i.e. functions taking values in the interval  $[-1, 1]$ , and state our variants of Theorems 1, 2, 3, and 4 using  $L_1$ -influences instead. We remark that for bounded functions, one has  $I_i^p[f] \leq I_i^q[f]$  for  $p \geq q \geq 1$ . In particular and via Cauchy-Schwartz,  $I_i[f] \leq I_i^1[f] \leq \sqrt{I_i[f]}$ . Using the Fourier expansion of the discrete derivatives and Parseval equality gives the following standard formula for the total  $L_2$ -influence.

► **Fact 8.** For any  $f: \{0, 1\}^n \rightarrow \mathbb{R}$ , we have  $I[f] = 4 \sum_{S \subseteq [n]} |S| \hat{f}(S)^2$ . In particular, by an averaging argument, for any  $\varepsilon > 0$ ,  $\sum_{|S| \geq I[f]/\varepsilon} \hat{f}(S)^2 \leq \varepsilon$ .

### 2.3 Hypercontractive Inequality and Log-Sobolev Inequality

The hypercontractive inequality states that for each  $\varepsilon > 0$ , there is  $p > 2$  such that  $T_{1-\varepsilon}$  is a contraction from  $L_2$  to  $L_p$ , i.e. that  $\|T_{1-\varepsilon}f\|_p \leq \|f\|_2$  for any  $f: \{0,1\}^n \rightarrow \mathbb{R}$ . The inequality has an equivalent form (which is often times used) that does not involve the noise operator  $T_{1-\varepsilon}$ , and is instead concerned with bounded degree functions.

The degree of a function  $f$ , denoted  $\deg(f)$ , is the maximum of  $|S|$  over all  $S$  such that  $\hat{f}(S) \neq 0$ . The Bonami-Beckner hypercontractive inequality [2, 1] asserts that the  $L_p$ -norm and the  $L_2$ -norm of a low-degree function are comparable. More precisely, for any  $f: \{0,1\}^n \rightarrow \mathbb{R}$  and any  $p > 2$ ,

► **Theorem 9.**  $\|f\|_p \leq (p-1)^{\deg(f)/2} \|f\|_2$ .

To motivate the Log-Sobolev inequality and its relationship to the hypercontractive inequality, let us rewrite the above as

$$\deg(f) \geq \frac{2}{\log(p-1)} \log \left( \frac{\|f\|_p}{\|f\|_2} \right). \quad (1)$$

Instead of looking at the maximal degree of a non-zero monomial that appears in  $f$ , one may consider the average degree of  $f$ , defined as  $\sum_S |S| \hat{f}(S)^2$ , where the weight given to a characters  $S$  equals the squared Fourier coefficient  $\hat{f}(S)^2$ . When  $f$  is  $\{-1,1\}$ -valued, the squared Fourier coefficients sum up to 1, giving a probability distribution over them, explaining the term “average degree”. As noted, the average degree is same as the total influence  $I[f]$  (up to the factor 4). The Log-Sobolev inequality, established by Gross [12], can be seen as the limiting case of the above inequality as  $p \rightarrow 2$  and replacing the degree by average degree (see [12], [17, Chapter 10.1] and [17, Pages 319-320] for the equivalence between the two inequalities and also separate inductive proofs). Towards stating this inequality, one needs the notion of entropy of a non-negative function  $h: \{0,1\}^n \rightarrow [0, \infty)$ :

$$\text{Ent}(h) := \mathbb{E}_x [h(x)] \log \left( \frac{1}{\mathbb{E}_x [h(x)]} \right) - \mathbb{E}_x \left[ h(x) \log \left( \frac{1}{h(x)} \right) \right],$$

with the convention that  $0 \log(1/0) = 0$ . The Log-Sobolev inequality is (note that the entropy is of the non-negative function  $f^2$ ):

► **Theorem 10.** For any  $f: \{0,1\}^n \rightarrow \mathbb{R}$ , we have  $I[f] \geq \frac{1}{2} \text{Ent}(f^2)$ .

A simple corollary of this inequality, when  $f: \{0,1\}^n \rightarrow \{0,1\}$  is Boolean, is below. This is also known as the standard isoperimetric inequality for the Boolean hypercube.

► **Lemma 11.** For any  $f: \{0,1\}^n \rightarrow \{0,1\}$ ,  $\beta = \mathbb{E}[f] \leq \frac{1}{2}$ , we have  $I[f] \geq \frac{1}{2} \beta \log(1/\beta)$ .

It will be more convenient for us to use the following easy consequence of the Log-Sobolev inequality.

► **Lemma 12.** There exists an absolute constant  $K > 0$ , such that for any  $f: \{0,1\}^n \rightarrow [-1,1]$ , we have

$$I[f] \gtrsim \|f\|_2^2 \log \left( \frac{1}{\|f\|_2^2} \right) - K \cdot \|f\|_1^{\frac{1}{2}} \|f\|_2.$$

**Proof.** By Theorem 10,  $I[f] \gtrsim \text{Ent}(f^2)$ , so it is enough to show that the entropy of  $f^2$  is at least the right hand side. Indeed, the first term in the definition of the entropy is precisely  $\|f\|_2^2 \log(1/\|f\|_2^2)$ . The second term is (using Cauchy-Schwarz and that  $t^2 \log^2(1/t^2) \lesssim |t|$  for  $t \in [-1,1]$ )

$$\begin{aligned} \mathbb{E}_x \left[ f(x)^2 \log \left( \frac{1}{f(x)^2} \right) \right] &\leq \sqrt{\mathbb{E}_x \left[ f(x)^2 \log^2 \left( \frac{1}{f(x)^2} \right) \right] \mathbb{E}_x [f(x)^2]} \lesssim \sqrt{\mathbb{E}_x [|f(x)|] \mathbb{E}_x [f(x)^2]} \\ &= \|f\|_1^{\frac{1}{2}} \|f\|_2. \end{aligned}$$

◀

## 2.4 Random Restrictions

Let  $J \subseteq [n]$  be a subset of coordinates thought of as “alive” and coordinates in  $\bar{J} = [n] \setminus J$  thought of as “restricted”. Given a function  $f: \{0, 1\}^n \rightarrow \mathbb{R}$  and a setting  $z \in \{0, 1\}^{\bar{J}}$ , we denote by  $f_{\bar{J} \rightarrow z}$ , the restriction of  $f$  to the domain  $z \times \{0, 1\}^J$ . More precisely,  $f_{\bar{J} \rightarrow z}: \{0, 1\}^J \rightarrow \mathbb{R}$  is defined as  $f_{\bar{J} \rightarrow z}(y) = f(x_{\bar{J}} = z, x_J = y)$ . The following standard fact gives the Fourier coefficients of the restricted function:

► **Fact 13.** For any  $T \subseteq J$ , we have  $\hat{f}_{\bar{J} \rightarrow z}(T) = \sum_{S \subseteq \bar{J}} \hat{f}(S \cup T) \chi_S(z)$ .

For a parameter  $\delta > 0$ , a  $\delta$ -random restriction is the function  $f_{\bar{J} \rightarrow z}$  after choosing  $J$  to be a random subset of  $[n]$  in which each  $j \in [n]$  is included with probability  $\delta$  independently and choosing  $z \in \{0, 1\}^{\bar{J}}$  uniformly. Using Fact 13 and Parseval, one can easily compute the expected squared Fourier coefficient of a random restriction and then the expected level  $d$  Fourier weight.

► **Fact 14.** Let  $f: \{0, 1\}^n \rightarrow \mathbb{R}$  and  $T \subseteq J$ . Then  $\mathbb{E}_z [|\hat{f}_{\bar{J} \rightarrow z}(T)|^2] = \sum_{S \subseteq \bar{J}} \hat{f}(S \cup T)^2$ .

► **Fact 15.** Let  $f: \{0, 1\}^n \rightarrow \mathbb{R}$ ,  $d \geq 1$  be an integer, and  $\delta \in [0, 1]$ . Let  $f_{\bar{J} \rightarrow z}$  denote the  $\delta$ -random restriction. Then

$$\mathbb{E}_{J, z} [W_{=d}[f_{\bar{J} \rightarrow z}]] = \sum_S \hat{f}(S)^2 \cdot \Pr_J[|J \cap S| = d].$$

## 3 A Basic Argument towards the KKL Theorem

In this section, we prove the lemma below. It proves the KKL Theorem in the special case when the function  $f: \{0, 1\}^n \rightarrow [0, 1]$  has a constant fraction of its Fourier weight on some “chunk”. Alternately, it proves the KKL Theorem at a loss of  $\log \log n$  factor. More importantly, the proof illustrates the basic approach underlying all the subsequent proofs.

► **Lemma 16.** Let  $f: \{0, 1\}^n \rightarrow [0, 1]$  be a function and  $d \geq 1$  be an integer. Then there exists a coordinate  $i \in [n]$  such that  $I_i^1[f] \gtrsim \frac{\log n}{n} W_{\approx d}[f]$ .

We make some remarks before proceeding to the proof. Firstly, we note that the lemma holds for bounded functions and with respect to the  $L_1$ -influences. Secondly, we note that if a constant fraction of the Fourier weight is on some chunk, i.e. if for some  $d$ ,  $W_{\approx d}[f] \gtrsim \text{var}(f)$ , then there is a coordinate  $i \in [n]$  with  $I_i^1[f] \gtrsim \frac{\log n}{n} \text{var}(f)$ , proving the KKL Theorem. Thirdly, we note that it proves the KKL Theorem at a loss of factor  $\log \log n$  as follows. We may assume that  $I[f] \leq \frac{1}{2} \log n \text{var}(f)$ . Since  $\text{var}(f) = \sum_{1 \leq |S|} \hat{f}(S)^2$  and  $I[f] = 4 \sum_S |S| \hat{f}(S)^2$ , by Markov’s inequality, we have

$$\sum_{1 \leq |S| \leq \log n} \hat{f}(S)^2 \geq \frac{1}{2} \text{var}(f).$$

Thus, by partitioning the interval  $[1, \log n]$  into  $\log \log n$  dyadic intervals  $\bigcup_{k=0}^{\log \log n} [2^k, 2^{k+1})$ , it follows that there is some  $1 \leq d \leq \log n$  such that  $W_{\approx d} \gtrsim \frac{\text{var}(f)}{\log \log n}$ . Hence by the lemma, there is a coordinate  $i \in [n]$  such that  $I_i^1[f] \gtrsim \frac{\log n}{n} W_{\approx d}[f] \gtrsim \frac{\log n}{n} \frac{\text{var}(f)}{\log \log n}$ .

### 3.1 Proof of Lemma 16

We now prove Lemma 16. The proof formalizes the intuition described at the end of the introductory section. One begins by considering a  $\frac{1}{d}$ -random restriction of the function, notes that the expected Fourier weight at the first level of the restricted function is at least  $W_{\approx d}[f]$ , and then one examines the coefficients at the first level and applies Log-Sobolev appropriately.

#### Weight on the First Level after Random Restriction

Let  $f_{\bar{J} \rightarrow z}$  be a  $\frac{1}{d}$ -random restriction,  $J$  being the set of coordinates left alive. We have by Fact 15 that

$$\mathbb{E}_{J,z} [W_{=1}[f_{\bar{J} \rightarrow z}]] \geq \sum_{d \leq |S| < 2d} \hat{f}(S)^2 \cdot \Pr_J[|S \cap J| = 1] \gtrsim W_{\approx d}[f], \quad (2)$$

where we used the simple fact that for any set  $S$  with  $d \leq |S| < 2d$ , the probability it intersects  $J$  in a single element is constant. For the rest of the argument, we fix some  $J \subseteq [n]$  such that (it exists due to Equation (2))

$$\mathbb{E}_z [W_{=1}[f_{\bar{J} \rightarrow z}]] \gtrsim W_{\approx d}[f]. \quad (3)$$

#### Relating First Level Coefficients after Restriction and Influences of $f$

We now consider the first level coefficients of the restricted function  $f_{\bar{J} \rightarrow z}$  and somehow relate them to the influences of the original function  $f$ . We note that  $J$  is the set of alive coordinates. For each  $j \in J$ , define a function  $g_j: \{0, 1\}^{\bar{J}} \rightarrow \mathbb{R}$  by  $g_j(z) = \hat{f}_{\bar{J} \rightarrow z}(\{j\})$ . That is,  $g_j(z)$  is the  $j^{\text{th}}$  coefficient of the first level (= linear part) of the restricted function. By definition,  $W_{=1}[f_{\bar{J} \rightarrow z}] = \sum_{j \in J} g_j(z)^2$ . Let  $p_j = \|g_j\|_2^2 = \mathbb{E}_z [g_j(z)^2]$ . For the sake of future reference, let  $q_j = \|g_j\|_1$ . Thus (3) can be re-stated as

$$\mathbb{E}_z [W_{=1}[f_{\bar{J} \rightarrow z}]] = \sum_{j \in J} p_j \gtrsim W_{\approx d}[f]. \quad (4)$$

Since  $f$  is bounded, so is its restriction, and hence  $|g_j(z)| \leq 1$  for every  $z, j$ .

► **Lemma 17.**  $p_j = \|g_j\|_2^2$  and  $q_j = \|g_j\|_1$  satisfy

- $q_j = \|g_j\|_1 \leq \frac{1}{2} \cdot I_j^1[f]$ .
- $p_j = \|g_j\|_2^2 \leq \frac{1}{4} \cdot I_j[f]$ .
- $p_j \leq q_j \leq \sqrt{p_j}$ .

**Proof.** The third item is because of the boundedness  $|g_j(z)| \leq 1$  and Cauchy-Schwartz. Towards the first two items, we note that

$$g_j(z) = \hat{f}_{\bar{J} \rightarrow z}(\{j\}) = \mathbb{E}_y [f(z, y) \chi_{\{j\}}(y_j)] = \mathbb{E}_{y-j} \left[ \frac{f(z, y_{-j}, y_j = 0) - f(z, y_{-j}, y_j = 1)}{2} \right].$$

Taking expectation over  $z$  gives (and using Cauchy-Schwartz in the second case)

$$\begin{aligned}\|g_j\|_1 &= \mathbb{E}_z [|g_j(z)|] \leq \mathbb{E}_{z, y-j} \left[ \left| \frac{f(z, y-j, y_j=0) - f(z, y-j, y_j=1)}{2} \right| \right] = \frac{1}{2} \cdot I_j^1[f]. \\ \|g_j\|_2^2 &= \mathbb{E}_z [|g_j(z)|^2] \leq \mathbb{E}_{z, y-j} \left[ \left| \frac{f(z, y-j, y_j=0) - f(z, y-j, y_j=1)}{2} \right|^2 \right] = \frac{1}{4} \cdot I_j[f]. \quad \blacktriangleleft\end{aligned}$$

Summing the previous inequality over all  $j \in J$ , we conclude that:

► **Lemma 18.**  $\sum_{j \in J} q_j = \sum_{j \in J} \|g_j\|_1 \leq \frac{1}{2} \cdot I^1[f]$ .

The following lower bound on  $I[f]$  is a key observation.

► **Lemma 19.**  $\sum_{j \in J} I[g_j] \leq I[f]$ .

**Proof.** We lower bound  $I[f]$  by  $\sum_{i \in \bar{J}} I_i[f]$ . Fix some  $i \in \bar{J}$  for now. As before,  $z$  and  $y$  denote the inputs on the parts  $\bar{J}$  and  $J$  respectively.

$$I_i[f] = \mathbb{E}_{z, y} [|f(z, y) - f(z \oplus e_i, y)|^2] = \mathbb{E}_z [\|f_{\bar{J} \rightarrow z} - f_{\bar{J} \rightarrow z \oplus e_i}\|_2^2].$$

By Parseval, we express the squared norm in terms of Fourier coefficients and then lower bound by considering only coefficients of size one.

$$I_i[f] = \mathbb{E}_z \left[ \sum_{T \subseteq J} |\hat{f}_{\bar{J} \rightarrow z}(T) - \hat{f}_{\bar{J} \rightarrow z \oplus e_i}(T)|^2 \right] \geq \mathbb{E}_z \left[ \sum_{j \in J} |\hat{f}_{\bar{J} \rightarrow z}(\{j\}) - \hat{f}_{\bar{J} \rightarrow z \oplus e_i}(\{j\})|^2 \right].$$

The latter are simply  $g_j(z)$  and  $g_j(z \oplus e_i)$  by definition and hence

$$I_i[f] \geq \sum_{j \in J} \mathbb{E}_z [|g_j(z) - g_j(z \oplus e_i)|^2] = \sum_{j \in J} I_i[g_j].$$

Summing over  $i \in \bar{J}$  gives

$$I[f] \geq \sum_{i \in \bar{J}} I_i[f] \geq \sum_{i \in \bar{J}} \sum_{j \in J} I_i[g_j] = \sum_{j \in J} \sum_{i \in \bar{J}} I_i[g_j] = \sum_{j \in J} I[g_j]. \quad \blacktriangleleft$$

## The Main Argument

Our main argument tries to obtain a lower bound on  $I[f]$  as follows. Using Lemma 19 and the Log-Sobolev Lemma 12,

$$I[f] \geq \sum_{j \in J} I[g_j] \geq \sum_{j \in J} (p_j \log(1/p_j) - K\sqrt{q_j} \cdot \sqrt{p_j}).$$

Using Cauchy-Schwartz, we get

$$I[f] \geq \sum_{j \in J} p_j \log(1/p_j) - K \sqrt{\sum_{j \in J} q_j} \cdot \sqrt{\sum_{j \in J} p_j}.$$

By Lemma 18,  $\sum_{j \in J} q_j \leq I^1[f]$ , so we get our main technical inequality

$$I[f] \geq \sum_{j \in J} p_j \log(1/p_j) - K \sqrt{I^1[f]} \cdot \sqrt{\sum_{j \in J} p_j}. \quad (5)$$

We recall that  $p_j \leq \frac{1}{2} I_j^1[f]$  by Lemma 17. Letting  $W := \sum_{j \in J} p_j = \mathbb{E}_z[W_{=1}[f_{\bar{J} \rightarrow z}]]$ , we rewrite this inequality, for future reference, as below. We note that in application,  $J$  is the subset of alive coordinates after a random restriction. In our proof of KKL and Friedgut Theorems, the set  $J$  is fixed so as to maximize the expected first level Fourier weight. In the proof of Talagrand Theorem, we average over the choice of  $J$  as well.

► **Lemma 20.** *Let  $f: \{0, 1\}^n \rightarrow [0, 1]$  be a function and  $J \subseteq [n]$ . Then*

$$I[f] \geq \log \left( \frac{1}{\max_{j \in J} I_j^1[f]} \right) \cdot W - K \sqrt{I^1[f]} \cdot \sqrt{W},$$

$$W = \mathbb{E}_z[W_{=1}[f_{\bar{J} \rightarrow z}]] = \sum_{S \subseteq [n], |S \cap J|=1} \hat{f}(S)^2.$$

The proof of Lemma 16 is now completed immediately. We may assume that for all coordinates  $i \in [n]$ ,  $I_i^1[f] \leq \frac{\log n}{n}$ ,  $W_{\approx d}[f] \leq \frac{1}{\sqrt{n}}$  as otherwise we are done already. This implies that the total  $L_1$ -influence  $I^1[f] \leq \log n W_{\approx d}[f]$ . Lemma 20 (= Equation (5)) then gives (the log-factor therein is at least  $\frac{1}{2} \log n$  since all  $L_1$ -influences are at most  $\frac{1}{\sqrt{n}}$ )

$$I[f] \geq \frac{1}{2} \log n \cdot W - K \sqrt{\log n \cdot W_{\approx d}[f]} \cdot \sqrt{W}, \quad W \gtrsim W_{\approx d}[f].$$

Clearly, the first term above dominates the second, giving  $I[f] \geq \frac{1}{4} \log n \cdot W \gtrsim \log n \cdot W_{\approx d}[f]$ , implying now that there is a coordinate with in fact  $L_2$ -influence  $\gtrsim \frac{\log n}{n} W_{\approx d}[f]$ .

## 4 The KKL Theorem

We now prove the KKL Theorem, stated below for a bounded function, with respect to  $L_1$ -influences, and in a slightly different form.

► **Theorem 21.** *There exists an absolute constant  $c > 0$  such that the following holds. Let  $f: \{0, 1\}^n \rightarrow [0, 1]$  be a function. Then either  $I^1[f] \geq c \cdot \log n \cdot \text{var}(f)$ , or there is a coordinate  $i \in [n]$  such that  $I_i^1[f] \geq \frac{1}{\sqrt{n}}$ .*

It will be more convenient for us to prove a dimension-independent version of the KKL Theorem below. It is easily seen to imply the statement above.

► **Theorem 22.** *There exists an absolute constant  $C > 0$  such that the following holds. Let  $f: \{0, 1\}^n \rightarrow [0, 1]$  be a function. Then there is a coordinate  $i \in [n]$  such that  $I_i^1[f] \geq 2^{-C \cdot \frac{I^1[f]}{\text{var}(f)}}$ .*

In the proof of Lemma 16, we only “utilized” Fourier weight from a single chunk of Fourier coefficients, i.e. those of size in the range  $[d, 2d)$ , and this led to a loss of factor  $\log \log n$  if used towards the KKL Theorem. In this section, we show how to utilize and combine the Fourier weight from multiple chunks, avoiding this loss. The idea is to “partition”  $f$  into chunks as  $f = \hat{f}(\emptyset) + \sum_{d=2^k, k \geq 0} h_d^*$ , apply the main technical inequality (5) to each chunk  $h_d^*$ , and then “sum up”. A natural way to partition is to let  $h_d^* = \sum_{d \leq |S| < 2d} \hat{f}(S) \chi_S$ . The problem with this approach however is that the chunk functions  $h_d^*$  as here are not necessarily bounded functions and the earlier arguments cannot be applied directly. To get around this, we instead consider a soft notion of chunks,  $f \approx \hat{f}(\emptyset) + \sum_{d=2^k, k \geq 0} h_d$ , that behaves similarly, that is

$$\sum_d \text{var}(h_d) = \Theta(\text{var}(f)), \quad \sum_d I_i[h_d] = \Theta(I_i[f]), \quad \sum_d I[h_d] = \Theta(I[f]),$$

and in addition, preserves boundedness and the  $L_1$ -influences of each soft chunk  $h_d$  are bounded by those of the original function!

### 4.1 Soft Chunks

► **Definition 23.** Let  $f: \{0, 1\}^n \rightarrow [0, 1]$  be a function and let  $d \geq 1$  be integer (thought of as a power of 2). The soft chunk of  $f$  of degree  $d$  is given by the function  $h_d: \{0, 1\}^n \rightarrow [0, 1]$  defined by  $h_d = (T_{1-\frac{1}{2d}} - T_{1-\frac{1}{d}})f$ .

The following lemma summarizes the useful properties of soft chunks (the proof appears in Appendix A.1). We point out, in particular, that the  $L_1$ -influences of the soft chunk are upper bounded by those of the original function (up to a factor 2).

► **Lemma 24.** Let  $f: \{0, 1\}^n \rightarrow [0, 1]$  and for integer  $d = 2^k, k \geq 0$ , let  $h_d = (T_{1-\frac{1}{2d}} - T_{1-\frac{1}{d}})f$  denote the soft chunk of  $f$  of degree  $d$ . Then (the sums are over  $d = 2^k, k \geq 0$  and  $i \in [n]$  is arbitrary)

- $h_d$  is bounded in  $[-1, 1]$ ,  $\hat{h}(\emptyset) = 0$ .
- $I_i^1[h_d] \leq 2I_i^1[f]$ .
- For any  $S \subseteq [n]$ ,  $d \leq |S| < 2d$ , we have  $|\hat{f}(S)| \lesssim |\hat{h}_d(S)| \leq |\hat{f}(S)|$ . In particular, we have lower bounds

$$\|h_d\|_2^2 \geq W_{\approx d}[h_d] \gtrsim W_{\approx d}[f], \quad \sum_d I_i[h_d] \gtrsim I_i[f], \quad \sum_d I[h_d] \gtrsim I[f].$$

- And the upper bounds,

$$\sum_d \|h_d\|_2^2 \leq \text{var}(f), \quad \sum_d I[h_d] \leq I[f].$$

For technical reasons, we will be able to “utilize” only those chunks that have a significant amount of Fourier weight, referred to as the good chunks. It will turn out that the good chunks still capture a constant fraction of the variance of  $f$ , so this will not be a problem. Towards this end, we have (proof appears in Appendix A.2)

► **Lemma 25.** Let

$$D_{\text{good}} := \left\{ d = 2^k, k \geq 0 \mid W_{\approx d}[f] \geq \frac{\text{var}(f)^2}{16 \cdot I^1[f]} \right\}.$$

Then

$$\sum_{d \in D_{\text{good}}} W_{\approx d}[f] \gtrsim \text{var}(f).$$

### 4.2 Proof of Theorem 22

Assume, for the sake of contradiction, that for all coordinates  $i \in [n]$ ,  $I_i^1[f] \leq 2^{-C \cdot \frac{I^1[f]}{\text{var}(f)}}$  where  $C$  is a large enough constant chosen later. Let  $h_d, d \in D_{\text{good}}$  be any good soft chunk. We recall that

- $h_d$  is a bounded function.
- Its  $L_1$ -influences are upper bounded by those of  $f$  up to a factor 2 (and hence also the total  $L_1$ -influence).
- $W_{\approx d}[h_d] \gtrsim W_{\approx d}[f] \geq \frac{\text{var}(f)^2}{16 \cdot I^1[f]}$ .

We apply Lemma 20 to the function  $h_d$ , considering  $\frac{1}{d}$ -random restriction, and letting  $J$  to be the subset of alive coordinates (fixed so as to maximize expected weight at first Fourier level). This yields the inequality

$$I[h_d] \geq \log \left( \frac{1}{\max_{j \in J} I_j^1[h_d]} \right) \cdot W - K \sqrt{I^1[h_d]} \cdot \sqrt{W}, \quad W \gtrsim W_{\approx d}[h_d] \gtrsim W_{\approx d}[f] \geq \frac{\text{var}(f)^2}{16 \cdot I^1[f]}.$$

Since the  $L_1$ -influences of  $h_d$  are bounded by those of  $f$ , in particular all of them at most  $2^{-C \cdot \frac{I^1[f]}{\text{var}(f)}}$ , we get

$$I[h_d] \geq C \cdot \frac{I^1[f]}{\text{var}(f)} \cdot W - K \sqrt{I^1[f]} \cdot \sqrt{W}, \quad W \gtrsim W_{\approx d}[f] \geq \frac{\text{var}(f)^2}{16 \cdot I^1[f]}.$$

It is easily seen that for a large enough constant  $C$ , the first term dominates the second term (this is why we considered only the good chunks) and thus

$$I[h_d] \gtrsim C \cdot \frac{I^1[f]}{\text{var}(f)} \cdot W_{\approx d}[f].$$

Now summing over all good  $d$  gives a contradiction:

$$I^1[f] \geq I[f] \geq \sum_{d \in D_{\text{good}}} I[h_d] \gtrsim C \cdot \frac{I^1[f]}{\text{var}(f)} \sum_{d \in D_{\text{good}}} W_{\approx d}[f] \gtrsim C \cdot \frac{I^1[f]}{\text{var}(f)} \cdot \text{var}(f) = C \cdot I^1[f].$$

We used Lemma 24 in the second step and Lemma 25 in the second-last step. Taking the constant  $C$  large enough gives a contradiction.

## 5 The Friedgut's Junta Theorem

Friedgut's Junta Theorem (restated below) is proved by a careful adjustment to the argument in the previous section.

► **Theorem 26.** *There is an absolute constant  $C > 0$  such that the following holds. For every function  $f: \{0, 1\}^n \rightarrow [0, 1]$  and for every  $\varepsilon > 0$ , there exists a function  $g: \{0, 1\}^n \rightarrow [0, 1]$  depending on at most  $2^{C \cdot I^1[f]/\varepsilon}$  variables such that  $\|f - g\|_2^2 \lesssim \varepsilon$ .*

We provide a proof sketch. While in the proof of the KKL Theorem, we may assume that all influences are small, this is not the case with Friedgut's Theorem. Here we “separate out” the set  $L$  of coordinates with “non-negligible” influence and apply the previous argument to the remaining set  $\bar{L} = [n] \setminus L$ . Towards this end, let

$$L = \left\{ i \mid I_i^1[f] \geq \tau := 2^{-C \cdot I^1[f]/\varepsilon} \right\}.$$

Clearly,  $|L| \leq \frac{I^1[f]}{\tau} \leq 2^{2C \cdot I^1[f]/\varepsilon}$ . Let  $g = \sum_{S \subseteq \bar{L}} \hat{f}(S) \chi_S$ . It is easily observed that

- $g$  depends only on the coordinates of  $\bar{L}$ .
- $g$  is also bounded in  $[0, 1]$  since  $g$  is simply the average of  $f$  over coordinates in  $\bar{L}$  and
- for the same reason,  $L_1$ -influences of  $g$  are bounded by those of  $f$ .

Let  $\varphi = f - g$ . We will show that  $\|\varphi\|_2^2 \lesssim \varepsilon$ . Clearly,  $\varphi$  is bounded in  $[-1, 1]$  and its  $L_1$  influences are also bounded by those of  $f$  up to a factor 2. We intend to apply the same argument used to prove the KKL Theorem to  $\varphi$ , except that all “action” happens only on the set of coordinates  $\bar{L}$ . More specifically:

- The “size” of any Fourier term is counted as  $|S \cap \bar{L}|$  instead of as  $|S|$ .
- For an integer  $d \geq 1$  (thought of as power of 2), the Fourier weight on the corresponding chunk is defined as

$$W_{\approx d}^{\bar{L}}[\varphi] := \sum_{d \leq |S \cap \bar{L}| < 2d} \hat{f}(S)^2.$$

## 26:12 Analytical Theorems via Random Restrictions and Log-Sobolev Inequality

- Towards defining the soft chunk  $h_d$  of  $\varphi$ , the noise operator is applied only to coordinates in  $\bar{L}$ . We denote this as

$$h_d = \left( T_{1-\frac{1}{2d}}^{\bar{L}} - T_{1-\frac{1}{d}}^{\bar{L}} \right) \varphi.$$

- In a random restriction, only coordinates in  $\bar{L}$  may stay alive. That is, a  $\frac{1}{d}$ -random restriction amounts to letting  $J$  to be a random subset of  $\bar{L}$  where every coordinate in  $\bar{L}$  is included with probability  $\frac{1}{d}$  and then the coordinates outside  $J$  (including those in  $L$ ) are set uniformly at random.
- Since  $J \subseteq \bar{L}$ , we have  $I_j^1[\varphi] \leq 2^{-C \cdot I^1[f]/\varepsilon}$  for all  $j \in J$ .

Modulo these considerations, we repeat the proof in Section 4.2. We apply Lemma 20 to the function  $h_d$ , considering  $\frac{1}{d}$ -random restriction, and letting  $J$  be the subset of alive coordinates (fixed so as to maximize expected weight at first Fourier level). This yields the inequality

$$I[h_d] \geq \log \left( \frac{1}{\max_{j \in J} I_j^1[h_d]} \right) \cdot W - K \sqrt{I^1[h_d]} \cdot \sqrt{W}, \quad W \gtrsim W_{\approx d}^{\bar{L}}[h_d] \gtrsim W_{\approx d}^{\bar{L}}[\varphi].$$

Since the  $L_1$ -influences of  $h_d$  are bounded by those of  $\varphi$  which are in turn bounded by those of  $f$  and those for coordinates in  $J \subseteq \bar{L}$  are at most  $2^{-C \cdot \frac{I^1[f]}{\varepsilon}}$ , we get

$$I[h_d] \geq C \cdot \frac{I^1[f]}{\varepsilon} \cdot W - K \sqrt{I^1[f]} \cdot \sqrt{W}, \quad W \gtrsim W_{\approx d}^{\bar{L}}[\varphi].$$

Let  $D_{\text{good}}$  be the subset of  $d = 2^k$  such that  $W_{\approx d}^{\bar{L}}[\varphi] \geq \frac{\varepsilon^2}{16I^1[f]}$  so that for such good  $d$  and for large enough constant  $C$ , the first term above dominates the second and we get

$$I[h_d] \gtrsim C \cdot \frac{I^1[f]}{\varepsilon} W_{\approx d}^{\bar{L}}[\varphi].$$

Now summing over all good  $d \in D_{\text{good}}$  gives:

$$I^1[f] \geq I^1[\varphi] \geq I[\varphi] \geq \sum_{d \in D_{\text{good}}} I[h_d] \gtrsim C \cdot \frac{I^1[f]}{\varepsilon} \cdot \sum_{d \in D_{\text{good}}} W_{\approx d}^{\bar{L}}[\varphi].$$

By Lemma 25 (applied to  $\varphi$ ), the last sum is at least  $\gtrsim \text{var}(\varphi)$  and we get  $\text{var}(\varphi) \lesssim \varepsilon$  as desired. An astute reader might object that the definition of the good soft chunks here seems different than that in Lemma 25, i.e. the threshold is set at  $\frac{\varepsilon^2}{16I^1[f]}$  instead of  $\frac{\text{var}(\varphi)^2}{16I^1[\varphi]}$  therein. However since  $I^1[\varphi] \leq I^1[f]$  and we could assume a priori that  $\text{var}(\varphi) \geq \varepsilon$  (otherwise we would already be done), this slight difference only works in our favor.

## 6 The Talagrand's Theorem

In this section, we prove Talagrand's Theorem, restated as Theorem 28 later. For now we prove the following weaker theorem to illustrate the main idea.

► **Theorem 27.** *Let any  $f: \{0, 1\}^n \rightarrow [0, 1]$  be a function and  $d \geq 1$  an integer (thought of as power of 2). Then one of these two conclusions holds:*

- (Case 1):  $\sum_{j \in [n]} \frac{I_j[f]}{\log(1/I_j^1[f])} \gtrsim \frac{d(W_{\approx d}[f])^2}{I[f]}.$
- (Case 2):  $\sum_{j \in [n]} \frac{I_j^1[f]}{\log(1/I_j^1[f])} \gtrsim dW_{\approx d}[f].$

We make a few remarks. On the left hand side of the inequalities, what appear in the numerators are the  $L_2$ -influences in Case 1 and  $L_1$ -influences in Case 2. This distinction will be important later. In both cases, in the denominator, it does not matter whether we write  $L_1$  or  $L_2$  influences since their logarithms are the same up to a factor 2 (since  $I_j[f] \leq I_j^1[f] \leq \sqrt{I_j[f]}$ ). If one pretends that all non-zero Fourier coefficients of  $f$  have size between  $d$  and  $2d$ , we have  $W_{\approx d}[f] = \text{var}(f)$  and  $I[f] = \Theta(d \cdot \text{var}(f))$  and we get  $\text{var}(f)$  on the right hand side in Case 1 and (even better)  $d \cdot \text{var}(f)$  in Case 2, giving Talagrand's Theorem.

We now prove Theorem 27. Consider a  $\frac{1}{d}$ -random restriction as in Section 3 letting  $J$  to be the set of coordinates alive. As therein, let  $g_j(z) = \hat{f}_{\bar{J} \rightarrow z}(\{j\})$ ,  $p_j = \|g_j\|_2^2$ ,  $q_j = \|g_j\|_1$ . Unlike therein however, we will not fix the set  $J$  and instead take expectation over its choice. Exactly as in Equation (5), we get

$$I[f] \geq \sum_{j \in J} p_j \log(1/p_j) - K \sum_{j \in J} \sqrt{q_j} \sqrt{p_j}.$$

We now divide into two cases depending on whether or not, on the right hand side, the first term dominates the second. It will be more convenient to do this after considering expectation over choice of  $J$ .

**Case 1:**  $\mathbb{E}_J \left[ \sum_{j \in J} p_j \log(1/p_j) \right] \geq 2 \cdot \mathbb{E}_J \left[ K \sum_{j \in J} \sqrt{q_j} \sqrt{p_j} \right]$ .

In this case, we get

$$I[f] \gtrsim \mathbb{E}_J \left[ \sum_{j \in J} p_j \log(1/p_j) \right].$$

Cauchy-Schwartz gives,

$$\mathbb{E}_J \left[ \sum_{j \in J} \frac{p_j}{\log(1/p_j)} \right] \cdot \mathbb{E}_J \left[ \sum_{j \in J} p_j \log(1/p_j) \right] \geq \left( \mathbb{E}_J \left[ \sum_{j \in J} p_j \right] \right)^2.$$

The second term is bounded by  $I[f]$  (as above) and on the right hand side we have,  $\mathbb{E}_J \left[ \sum_{j \in J} p_j \right] \gtrsim W_{\approx d}[f]$ . This gives

$$\mathbb{E}_J \left[ \sum_{j \in J} \frac{p_j}{\log(1/p_j)} \right] \gtrsim \frac{(W_{\approx d}[f])^2}{I[f]}.$$

Replacing  $p_j$  by its upper bound  $I_j[f]$  in the numerator and its upper bound  $I_j^1[f]$  in the denominator, and noting that each coordinate appears in  $J$  with probability  $\frac{1}{d}$ , gives the desired inequality

$$\sum_{j \in [n]} \frac{I_j[f]}{\log(1/I_j^1[f])} \gtrsim \frac{d(W_{\approx d}[f])^2}{I[f]}.$$

**Case 2:**  $\mathbb{E}_J \left[ \sum_{j \in J} \sqrt{q_j} \sqrt{p_j} \right] \gtrsim \mathbb{E}_J \left[ \sum_{j \in J} p_j \log(1/p_j) \right].$

In this case, Cauchy-Schwartz gives

$$\begin{aligned} \mathbb{E}_J \left[ \sum_{j \in J} \frac{q_j}{\log(1/p_j)} \right] \cdot \mathbb{E}_J \left[ \sum_{j \in J} p_j \log(1/p_j) \right] &\geq \left( \mathbb{E}_J \left[ \sum_{j \in J} \sqrt{q_j} \sqrt{p_j} \right] \right)^2 \\ &\gtrsim \left( \mathbb{E}_J \left[ \sum_{j \in J} p_j \log(1/p_j) \right] \right)^2. \end{aligned}$$

Canceling  $\mathbb{E}_J \left[ \sum_{j \in J} p_j \log(1/p_j) \right]$  from both sides gives

$$\mathbb{E}_J \left[ \sum_{j \in J} \frac{q_j}{\log(1/p_j)} \right] \gtrsim \mathbb{E}_J \left[ \sum_{j \in J} p_j \log(1/p_j) \right] \geq \mathbb{E}_J \left[ \sum_{j \in J} p_j \right].$$

As before, the right hand side is  $\gtrsim W_{\approx d}[f]$ , and  $q_j, p_j$  are upper bounded by  $I_j^1[f]$ , and each coordinate appears in  $J$  with probability  $\frac{1}{d}$ . This gives the desired inequality

$$\sum_{j \in [n]} \frac{I_j^1[f]}{\log(1/I_j^1[f])} \gtrsim d W_{\approx d}[f].$$

## 6.1 Talagrand's Theorem by Combining Chunks: First Attempt

We (re-)state Talagrand's Theorem below.

► **Theorem 28.** *For any  $f: \{0, 1\}^n \rightarrow [0, 1]$ , we have  $\sum_{j \in [n]} \frac{I_j^1[f]}{\log(1/I_j^1[f])} \gtrsim \text{var}(f)$ .*

We attempt to prove this result by splitting

$$f = \hat{f}(\emptyset) + \sum_{d=2^k, k \geq 0} h_d,$$

where  $h_d = \sum_{d \leq |S| < 2d} \hat{f}(S) \chi_S$  are the chunks of  $f$ . The strategy is to apply Theorem 27 to each chunk  $h_d$  separately and “sum up” or “combine” the outcomes. A crucial observation is that the  $L_2$ -influences indeed sum up, that is

$$I_i[f] = \sum_d I_i[h_d].$$

This strategy (almost) works with a careful consideration of whether the Case 1 or the Case 2 applies for different chunks. The catch, as before, is that the chunks  $h_d$  are not necessarily bounded functions and their  $L_1$ -influences might not be under control. To get around this issue, we instead work with the soft chunks as before and the full proof is completed in the next sub-section. For now, we pretend that the chunks  $h_d$  are bounded functions and see how the proof proceeds. We also pretend that the  $L_1$ -influences of  $h_d$  are upper bounded by those of  $f$  (both these conditions do hold when soft chunks are considered!).

We apply Theorem 27 to  $h_d$ . Noting that  $W_{\approx d}[h_d] \geq W_{\approx d}[f]$ ,  $I[h_d] = \Theta(d \cdot W_{\approx d}[f])$ , and that  $L_1$ -influences of  $h_d$  are upper bounded by those of  $f$ , we conclude that for every  $d = 2^k, k \geq 0$ , one of these conclusions holds (perhaps both conclusions hold and if so, we pick one arbitrarily):

- (Case 1):  $\sum_{j \in [n]} \frac{I_j[h_d]}{\log(1/I_j^1[f])} \gtrsim W_{\approx d}[f]$ . Let  $D'$  be the set of such  $d$ .
- (Case 2):  $\sum_{j \in [n]} \frac{I_j^1[f]}{\log(1/I_j^1[f])} \gtrsim d W_{\approx d}[f]$ . Let  $D''$  be the set of such  $d$ .

Now we complete the proof as follows. Since  $\text{var}(f) = \sum_{d \in D'} W_{\approx d}[f] + \sum_{d \in D''} W_{\approx d}[f]$ , either of the two sums is at least  $\frac{1}{2} \text{var}(f)$ . If the first sum is, then (crucially using the fact that  $L_2$ -influences sum up)

$$\sum_{j \in [n]} \frac{I_j[f]}{\log(1/I_j^1[f])} \geq \sum_{j \in [n]} \sum_{d \in D'} \frac{I_j[h_d]}{\log(1/I_j^1[f])} = \sum_{d \in D'} \sum_{j \in [n]} \frac{I_j[h_d]}{\log(1/I_j^1[f])} \gtrsim \sum_{d \in D'} W_{\approx d} \gtrsim \text{var}(f),$$

as desired. Otherwise, we may assume  $\sum_{d \in D''} W_{\approx d}[f] \geq \frac{1}{2} \text{var}(f)$ . Since  $d$  ranges only over powers of 2, it follows that there is some  $d \in D''$  such that  $d W_{\approx d}[f] \gtrsim \text{var}(f)$  (why!). Using this particular choice of  $d$  in the Case 2 above, we get as desired

$$\sum_{j \in [n]} \frac{I_j^1[f]}{\log(1/I_j^1[f])} \gtrsim \text{var}(f).$$

## 6.2 Talagrand's Theorem by Combining Soft Chunks

We now complete the proof of Talagrand's Theorem 28. We carry out the same proof as in the previous sub-section, except that we use the soft chunks  $h_d = (T_{1-\frac{1}{2d}} - T_{1-\frac{1}{d}})f$ . It holds that  $W_{\approx d}[h_d] = \Theta(W_{\approx d}[f])$ . However one place we need to be careful about is that we required that  $I[h_d] = \Theta(d W_{\approx d}[f])$ . This need not be true in general. Hence we restrict ourselves to only those  $d \in D_{\text{good}}$  for which this condition holds. The lemma below shows that there is still a constant fraction of variance on these good chunks and this is enough to complete the proof (the sets  $D'$  and  $D''$  above are subsets of  $D_{\text{good}}$  now).

► **Lemma 29.** *Let*

$$D_{\text{good}} = \left\{ d = 2^k, k \geq 0 \mid d W_{\approx d}[f] \geq \frac{1}{40} I[h_d] \right\}.$$

*Then*

$$\sum_{d \in D_{\text{good}}} W_{\approx d}[f] \geq \frac{1}{2} \text{var}(f).$$

**Proof.** As we will see, it suffices to show that  $\sum_d \frac{I[h_d]}{d} \leq 20 \text{var}(f)$ . To see that, as  $\text{var}(f) = \sum_{S \neq \emptyset} \hat{f}(S)^2$ , it is enough to show that for each  $S \neq \emptyset$ , the term  $\hat{f}(S)^2$  appears in the sum  $\sum_d \frac{I[h_d]}{d}$  with a multiplicative factor of at most 20. Note that this factor is

$$|S| \sum_d \frac{1}{d} \left( \left(1 - \frac{1}{2d}\right)^{|S|} - \left(1 - \frac{1}{d}\right)^{|S|} \right)^2.$$

We analyze the contribution from  $d \leq |S|$  and  $d > |S|$  separately, showing that each one of them contributes at most  $\frac{10}{|S|}$ . Let  $k$  be such that  $2^k \leq |S| < 2^{k+1}$ . The first part is bounded as

$$\sum_{d \leq |S|} \frac{1}{d} \left(1 - \frac{1}{2d}\right)^{2|S|} \leq \sum_{d \leq |S|} \frac{1}{d} e^{-|S|/d} \leq \sum_{j=0}^k \frac{1}{2^j} e^{-2^{k-j}} \leq 2^{-k} \sum_{\ell=0}^{\infty} 2^{\ell} e^{-2^{\ell}} \leq 5 \cdot 2^{-k} \leq \frac{10}{|S|}.$$

The second part is bounded as (we approximate  $1 - r\alpha \leq (1 - \alpha)^r$  in this range).

$$\sum_{d > |S|} \frac{1}{d} \left( 1 - \left( 1 - \frac{1}{d} \right)^{|S|} \right)^2 \leq \sum_{d > |S|} \frac{1}{d} \leq \sum_{r=k+1} \frac{1}{2^r} = \frac{2}{2^{k+1}} \leq \frac{2}{|S|}.$$

This shows that  $\sum_d \frac{I[h_d]}{d} \leq 20 \operatorname{var}(f)$ . Now we complete the proof of the lemma as:

$$\begin{aligned} \sum_{d \in D_{\text{good}}} W_{\approx d}[f] &= \sum_d W_{\approx d}[f] - \sum_{d \notin D_{\text{good}}} W_{\approx d}[f] \\ &\geq \operatorname{var}(f) - \frac{1}{40} \sum_{d \notin D_{\text{good}}} \frac{I[h_d]}{d} \\ &\geq \operatorname{var}(f) - \frac{1}{40} \cdot 20 \cdot \operatorname{var}(f) \geq \frac{\operatorname{var}(f)}{2}. \end{aligned}$$

## A Missing Proofs

### A.1 Proof of Lemma 24

Towards the first property, we note that both functions  $T_{1-1/2d}f$  and  $T_{1-1/d}f$ , being averages of  $f$ , are bounded in the interval  $[0, 1]$ . Towards the second property, we note that  $I_i^1[h_d] \leq I_i^1[T_{1-1/2d}f] + I_i^1[T_{1-1/d}f]$  and that the latter are at most  $I_i^1[f]$ , again because  $T_{1-1/2d}f$  and  $T_{1-1/d}f$  are averages of  $f$ . Towards the third property, we note that by definition

$$\hat{h}_d(S) = \left( \left(1 - \frac{1}{2d}\right)^{|S|} - \left(1 - \frac{1}{d}\right)^{|S|} \right) \hat{f}(S).$$

The multiplicative factor in front of  $\hat{f}(S)$ , when  $d \leq |S| \leq 2d$ , is easily seen to be a constant. Towards the last property, we note that for each set  $S \neq \emptyset$ , its contribution to  $\text{var}(f)$  is  $\hat{f}(S)^2$  and to  $I[f]$  is  $|S|\hat{f}(S)^2$ , whereas the corresponding contributions to  $\sum_d \|h_d\|_2^2$  and  $\sum_d I[h_d]$  are similar up to the multiplicative factor

$$\sum_d \left( \left(1 - \frac{1}{2d}\right)^{|S|} - \left(1 - \frac{1}{d}\right)^{|S|} \right)^2.$$

It is enough to show that this sum is at most 1. Indeed, since each summand is square of a number in the range  $[0, 1]$ , we can ignore the squares and then it is just a telescoping sum upper bounded by 1.

### A.2 Proof of Lemma 25

In the following, sums run over all  $d$  that are powers of 2 unless the sum is restricted explicitly to a subset. Clearly,  $\sum_d W_{\approx d}[f] = \text{var}(f)$ , so it is enough to show that this sum over only those  $d \notin D_{\text{good}}$  is at most  $\frac{1}{2}\text{var}(f)$ . We consider two cases: those  $d$  that are “large”, that is  $d \geq T = \frac{4I^1[f]}{\text{var}(f)}$ , and those  $d$  that are “not large” but not in  $D_{\text{good}}$ . In the first case, we use Markov and in the second case, we note that there are only a few summands. Indeed, in the first case (using  $I[f] \leq I^1[f]$ ),

$$I[f] \geq T \cdot \sum_{d \geq T} W_{\approx d}[f], \quad \text{implying that} \quad \sum_{d \geq T} W_{\approx d}[f] \leq \frac{I[f]}{T} = \frac{I[f] \text{var}(f)}{4I^1[f]} \leq \frac{1}{4}\text{var}(f).$$

In the second case,  $d \leq T$ , so there are at most  $\log T$  chunks and when  $d \notin D_{\text{good}}$ , we have  $W_{\approx d}[f] \leq \frac{\text{var}(f)^2}{16 \cdot I^1[f]} = \frac{\text{var}(f)}{4T}$ . Hence

$$\sum_{d \leq T, d \notin D_{\text{good}}} W_{\approx d}[f] \leq \log T \cdot \frac{1}{4T} \cdot \text{var}(f) \leq \frac{1}{4}\text{var}(f).$$

## Abstract

We propose a variant of the 2-to-1 Games Conjecture that we call the Rich 2-to-1 Games Conjecture and show that it is equivalent to the Unique Games Conjecture. We are motivated by two considerations. Firstly, in light of the recent proof of the 2-to-1 Games Conjecture [16, 6, 5, 17], we hope to understand how one might make further progress towards a proof of the Unique Games Conjecture. Secondly, the new variant along with perfect completeness in addition, might imply hardness of approximation results that necessarily require perfect completeness and (hence) are not implied by the Unique Games Conjecture.

## 1 Introduction

The Unique Games Conjecture [11] is considered a central question in theoretical computer science. It has many applications to hardness of approximation (e.g. tight results for Max-Cut and Vertex Cover problems [14, 18]) and connections to algorithms, computational complexity, analysis, and geometry (e.g. see the surveys [22, 12, 13]). Recently, a related conjecture called the 2-to-1 Games Conjecture has been proved [16, 6, 5, 17]. This conjecture has many applications of its own, implies the Unique Games Conjecture “half-way” (in the technical sense, with “completeness”  $\frac{1}{2}$  instead of  $1 - o(1)$ ), and provides strong evidence in favor of the Unique Games Conjecture.

In light of this development, it is natural to ask whether the proof of the 2-to-1 Games Conjecture can somehow be extended to that of the Unique Games Conjecture. A straightforward extension does not look likely, so we raise the following possibility: perhaps the 2-to-1 Games Conjecture holds with additional structure on its instances, and hardness on such instances is then enough to prove the Unique Games Conjecture? In this paper, we investigate this possibility and make a concrete proposal in this regard. The proposal, that

we call the Rich 2-to-1 Games Conjecture, is described next along with the overall context. Our main result is that this variant of the 2-to-1 Games Conjecture turns out to be equivalent to the Unique Games Conjecture.

## 1.1 The Unique Games Conjecture

The Unique Games and 2-to-1 Games are specialized cases of the more general 2-Prover-1-Round Games.

► **Definition 1.** A 2P1R Games instance  $\Psi = (L \cup R, E, \Sigma_L, \Sigma_R, \Phi)$  consists of a regular, bipartite graph  $(L \cup R, E)$ , the alphabet  $\Sigma_L$  for the vertex set  $L$ , the alphabet  $\Sigma_R$  for the vertex set  $R$ , and a set of constraints  $\Phi = \{\phi_e\}_{e \in E}$ , one for each edge. Each vertex is supposed to receive a label from the respective alphabet. The constraint  $\phi_e$  for an edge  $e = (u, v) \in E, u \in L, v \in R$  is defined by a relation  $\phi_e \subseteq \Sigma_L \times \Sigma_R$ , thought of as the set of label-pairs to the vertices  $u$  and  $v$  that satisfy the constraint.

For  $1 \geq c > s > 0$ , and integers  $k, n$ , let  $\text{Gap-2P1R}_{k,n}[c, s]$  denote the promise problem where given a 2P1R Games instance  $\Psi$  as above with  $|\Sigma_L| = k, |\Sigma_R| = n$ , the problem is to distinguish whether there is a labeling to its vertices that satisfies  $c$  fraction of the constraints or whether every labeling satisfies at most  $s$  fraction of the constraints (we will often drop the subscripts  $k, n$  when clear from context).

2P1R Games are central to the theory of hardness of approximation and Probabilistically Checkable Proofs. These serve as canonical starting point for hardness reductions. The parameters of interest (from the viewpoint of making such reductions “work”) are: the alphabet size  $\max\{m, k\}$ , the “gap”  $(c, s)$ , and the nature of the relations  $\phi_e$ . Throughout this paper, the parameters  $k, n, c, s$  are thought of as constants and the size of the bipartite graph  $(L \cup R, E)$  as the instance size.

The 2P1R Games studied in applications are almost exclusively “Projection Games”, i.e. instances in which  $|\Sigma_L| \geq |\Sigma_R|$  and the constraint on each edge  $e = (u, v)$  is defined by a mapping  $\pi_e: \Sigma_L \rightarrow \Sigma_R$ ; the relation  $\phi_e$  is then  $\phi_e = \{(\sigma, \pi_e(\sigma)) \mid \sigma \in \Sigma_L\}$ , so that for every label to vertex  $u$ , there is a unique label to the vertex  $v$  that satisfies the constraint. We will restriction to Projection Games henceforth and denote the corresponding gap problem as **Gap-Projection**.

In the language of 2P1R Games, the celebrated PCP Theorem [8, 2, 1] states that  $\text{Gap-Projection}_{7,2}[1, s]$  is NP-hard for some absolute constant  $s < 1$ . Combining the PCP Theorem and Raz’s Parallel Repetition Theorem [20] gives the very important theorem that  $\text{Gap-Projection}_{k,n}[1, s]$  is NP-hard for every constant  $s > 0$  and with the alphabet size at most polynomial in  $\frac{1}{s}$ .

For an integer  $d$  (thought of as a small constant, say  $d = 2$ ), a  $d$ -to-1 Games instance is a Projection Games instance in which  $|\Sigma_L| = d \cdot |\Sigma_R|$  and the projection map  $\pi_e: \Sigma_L \rightarrow \Sigma_R$  defining the constraint is a  $d$ -to-1 map. The 1-to-1 Games are more commonly called the Unique Games and were studied by Feige and Lovasz [9] (in a different context). The corresponding gap versions are denoted as **Gap- $d$ -to-1** and **Gap-Unique** and the alphabet sizes are identified by one parameter  $n$  such that  $|\Sigma_L| = d \cdot n$  and  $|\Sigma_R| = n$ . The conjectures made in [11] are stated below (we take liberty to modify statements slightly regarding the issue of perfect versus imperfect completeness):

► **Conjecture 2 (Unique Games Conjecture).** For every constant  $\varepsilon > 0$ , there is a sufficiently large integer  $n$  such that  $\text{Gap-Unique}_n[1 - \varepsilon, \varepsilon]$  is NP-hard.

► **Conjecture 3** (*d*-to-1 Games Conjecture). *For every constant  $\varepsilon > 0$ , there is a sufficiently large integer  $n$  such that  $\text{Gap-d-to-1}_n[1 - \varepsilon, \varepsilon]$  is NP-hard.*

► **Conjecture 4** (*d*-to-1 Games Conjecture with Perfect Completeness). *For every constant  $\varepsilon > 0$ , there is a sufficiently large integer  $n$  such that  $\text{Gap-d-to-1}_n[1, \varepsilon]$  is NP-hard.*

In a recent development, the 2-to-1 Games Conjecture is proved in a sequence of papers [16, 6, 5, 17] (with additional contributions from [3, 15]), also proving as a simple corollary that  $\text{Gap-Unique}[\frac{1}{2}, \varepsilon]$  is NP-hard (for every  $\varepsilon > 0$  and for sufficiently large alphabet size). This gives a strong evidence towards correctness of the Unique Games Conjecture (which prior to this development was viewed skeptically by most researchers).

## 1.2 The Rich 2-to-1 Games

One naturally asks whether the proof of the 2-to-1 Games Conjecture extends, without substantial effort, to that of the Unique Games Conjecture. We do not believe this to be the case and instead make the following proposal and conjecture. We conjecture that the 2-to-1 Games Conjecture holds with additional structure on its instances (referred to as “richness”) and is then enough to prove the Unique Games Conjecture (in fact is equivalent to it). The new conjecture and the notion of richness are well-motivated as explained later on.

Let  $\Psi = (L \cup R, E, \Sigma_L, \Sigma_R, \Phi)$  be a 2-to-1-Game, with  $|\Sigma_L| = 2n$  and  $|\Sigma_R| = n$ . Fix a vertex  $u \in L$ . Let  $e = (u, v) \in E$  be an edge incident on  $u$  and let  $\pi_e$  be the 2-to-1 projection defining that constraint. The map defines a partition of  $\Sigma_L$  as  $\Sigma_L = \bigcup_{\rho \in \Sigma_R} \pi_e^{-1}(\rho)$  into disjoint sets of size 2. Let us denote by  $\mathcal{P}(u)$  the distribution over partitions of  $\Sigma_L$  into sets of size 2, given by first sampling a uniformly random edge  $e = (u, v)$  incident on  $u$  and then outputting the partition of  $\Sigma_L$  as above.

► **Definition 5.** *An instance of Rich 2-to-1 Games is an instance of 2-to-1 Games with the additional property that for every vertex  $u \in L$ , the distribution  $\mathcal{P}(u)$  is uniform over all partitions of  $\Sigma_L$  into sets of size 2.*

We now state the new conjecture (and also throw in a stronger version with perfect completeness). Our main result is that it is equivalent to the Unique Games Conjecture.

► **Conjecture 6** (Rich 2-to-1 Games Conjecture). *For every constant  $\varepsilon > 0$ , there is a sufficiently large integer  $n$  such that  $\text{Gap-Rich-2-to-1}_n[1 - \varepsilon, \varepsilon]$  is NP-hard.*

► **Conjecture 7** (Rich 2-to-1 Games Conjecture with Perfect Completeness). *For every constant  $\varepsilon > 0$ , there is a sufficiently large integer  $n$  such that  $\text{Gap-Rich-2-to-1}_n[1, \varepsilon]$  is NP-hard.*

► **Theorem 8** (Main Result). *The Unique Games Conjecture 2 and the Rich 2-to-1 Games Conjecture 6 are equivalent.*

The reduction from Unique Games to Rich 2-to-1 Games is straightforward, and is given in the full version of the paper. The reverse reduction requires new analytic results to analyze it. These results are stated in Section 3 and proved in Section 4. The reduction itself is presented in Section 5.

## 1.3 Motivation to Study the Rich 2-to-1 Games

We now explain how the notion of richness arises from natural (but admittedly technical) considerations. In short, the notion of richness is tailor-made so as to ensure the “sub-code covering” property; this property was identified and used in [19] and was crucial in the

proof of the 2-to-2 Games Conjecture [16, 6] (however there are differences that are outlined below). We then comment on how the notion of richness might be useful towards proving the Unique Games Conjecture and towards proving hardness of approximation results with perfect completeness. These comments are speculative in nature.

### Sub-code Covering Property

We describe, at a very high level, a typical PCP reduction starting with an instance of a Projection Game.<sup>1</sup> We admit that the description might not be friendly to a reader who is not already somewhat familiar with the area.

Let  $\Psi = (L \cup R, E, \Sigma_L, \Sigma_R, \Phi)$  be an instance of Projection Game. In the reduction (or equivalently the PCP proof), each vertex  $u \in L$  is replaced by a string  $\text{Enc}^*(u) \in [m]^{k_L}$  which is intended to be the encoding of the supposed label of  $u$  via an encoding scheme  $\text{Enc} : \Sigma_L \rightarrow [m]^{k_L}$ . The encoding scheme is chosen a priori. Here  $[m]$  is the proof alphabet (e.g.  $\{0, 1\}$ ) and  $k_L$  is the encoding length. Similarly, each vertex  $v \in R$  is replaced by a string  $\text{Enc}^*(v) \in [m]^{k_R}$  which is intended to be the encoding of the supposed label of  $v$  via the encoding scheme  $\text{Enc} : \Sigma_R \rightarrow [m]^{k_R}$ . For convenience, we use the same notation, namely  $\text{Enc}(\cdot)$ , to denote both encodings. Also, similar notation, namely  $\text{Enc}^*(\cdot)$  and  $\text{Enc}(\cdot)$ , is used to emphasize their relationship: the latter is a true encoding whereas the former is a purported encoding.

The task of the PCP verifier is to check, given a purported proof and an edge  $e = (u, v) \in E$ ,

- that the strings  $\text{Enc}^*(u)$  and  $\text{Enc}^*(v)$  in the purported proof are indeed codewords, i.e. that they are same as  $\text{Enc}(\sigma)$  for some label  $\sigma \in \Sigma_L$  and  $\text{Enc}(\rho)$  for some label  $\rho \in \Sigma_R$  respectively.
- that  $\pi_e(\sigma) = \rho$  where  $\pi_e : \Sigma_L \rightarrow \Sigma_R$  is the projection map defining the constraint.

These two tasks are referred to as the codeword test and the consistency test respectively and are often somehow incorporated into a single combined test (as seen below). Further, a combination of necessity and convenience dictates that:

- One needs to work with a relaxed conclusion that  $\text{Enc}^*(u)$  and  $\text{Enc}^*(v)$  are close to some codewords  $\text{Enc}(\sigma)$  and  $\text{Enc}(\rho)$  respectively so that  $\pi_e(\sigma) = \rho$ . This amounts to decoding or (more often) list-decoding the given strings  $\text{Enc}^*(u)$  and  $\text{Enc}^*(v)$ .
- One needs that the codeword  $\text{Enc}(\rho)$  is a “sub-code” of the codeword  $\text{Enc}(\sigma)$  whenever  $\pi_e(\sigma) = \rho$ . Specifically, for every location  $x \in [k_R]$  on the  $v$ -side, there is a location  $\pi_e^{-1}(x) \in [k_L]$  on the  $u$ -side such that  $\text{Enc}(\sigma)[\pi_e^{-1}(x)] = \text{Enc}(\rho)[x]$  whenever  $\pi_e(\sigma) = \rho$ .

Now we are ready to describe a typical PCP test. It picks  $v \in R$  randomly and generates query locations  $x_1, \dots, x_k$  for the codeword tester of the purported codeword  $\text{Enc}^*(v)$  along with a predicate  $P(\text{Enc}^*(v)[x_1], \dots, \text{Enc}^*(v)[x_k])$  that would determine whether the test accepts or rejects. However this test and the query locations are only virtual. To define the actual test and the query locations, one uses the property that the encoding  $\text{Enc}(\rho)$  of the supposed label  $\rho$  of  $v \in R$  is a sub-code of the encoding  $\text{Enc}(\sigma_i)$  of the supposed label  $\sigma_i$  of a neighbor  $u_i \in L$  of  $v$ ,  $e_i = (u_i, v)$ . Thus, one may read-off the symbol  $\text{Enc}^*(v)[x_i]$  from the corresponding symbol  $\text{Enc}^*(u_i)[y_i]$  for appropriate location  $y_i = \pi_{e_i}^{-1}(x_i)$  therein. More specifically, the test picks random, independent neighbors  $u_1, \dots, u_k \in L$  of  $v$ , and tests the predicate  $P(\text{Enc}^*(u_1)[y_1], \dots, \text{Enc}^*(u_k)[y_k])$ . This completes the description of a typical

<sup>1</sup> This paradigm is referred to as the “Inner/Outer PCP” in literature, but we avoid the usage of this terminology.

PCP test. To make this approach “work” however, more is needed. To see the difficulty involved, let’s assume that the (virtual) codeword test succeeds perfectly for every  $v \in R$ , i.e. that  $\text{Enc}^*(v) = \text{Enc}(\rho(v))$  for some label  $\rho(v)$  (that depends on  $v$ ). Looking at things from the perspective of some fixed  $u \in L$ , this amounts to saying that the purported encoding  $\text{Enc}^*(u)$  has, as its sub-strings, correct sub-codewords  $\text{Enc}(\rho(v_j))$  for all neighbors  $v_j \in R$  of  $u$ . Can we conclude now that  $\text{Enc}^*(u)$  is also a correct codeword or at least resembles a correct codeword? Not necessarily and that’s the trouble.

It is possible that the sub-codewords  $\text{Enc}(\rho(v_j))$  (or rather the set of their locations) constitute only a negligible portion of the purported codeword  $\text{Enc}^*(u)$  “on the larger side” (or rather the set of its locations). If so, the consistency of  $\text{Enc}^*(u)$  with all its correct sub-codewords would not say anything about correctness of  $\text{Enc}^*(u)$  itself. Clearly, the disparity in the encoding lengths  $k_L$  and  $k_R$  on the two sides and the number of neighbors  $v$  for a fixed  $u \in L$ , both have bearing on this issue. In [19], the authors defined the “sub-code covering property” that is informally stated as follows.

► **Definition 9 (Informal).** *The encoding scheme  $\text{Enc}(\cdot)$  along with the Projection Game structure is said to achieve sub-code covering property if for every fixed  $u \in L$ , the “pull-back distribution” on the (query) location  $y \in [k_L]$  as described next is statistically close to the uniform distribution over  $[k_L]$ . The pull-back distribution is defined by picking a random neighbor  $v \in R$  of  $u$ ,  $e = (u, v)$ , then picking a uniformly random location  $x \in [k_R]$  and letting  $y = \pi_e^{-1}(x)$ .*

In [19], the authors managed to achieve the sub-code covering property using Hadamard encoding (which sufficed for the application therein). This technique was subsequently used in the proof of the 2-to-1 Games Conjecture [16, 6] using Grassmann encoding (which again sufficed for the application therein). The Hadamard and Grassmann codes have length polynomial in the alphabet size  $|\Sigma_L|$  and  $|\Sigma_R|$  and while there is still a big disparity between the encoding lengths on the two sides, it is possible to arrange for a vertex  $u \in L$  to have sufficiently many neighbors  $v \in R$  and achieve the sub-code covering property (we omit the details). A serious restriction however is that using Hadamard and Grassmann encodings requires the projections  $\pi_e$  as well as the PCP test to be linear (limiting the efficacy of this approach).

## Long Code and Richness

In this paper, we attempt to work with the so-called Long encoding (defined below; this is extremely important in Unique Games based reductions). As is well-said, the Long code is too long. Its length is exponential in the alphabet size, making the disparity in encoding lengths on the two sides insurmountable (as far as we foresee). Still, we attempt to identify a scenario where the sub-code property is achievable using Long codes, possibly in a more relaxed sense. Indeed, we are able to do so when  $|\Sigma_L| = 2|\Sigma_R|$ , the projections  $\pi_e$  are 2-to-1, and the game is “rich” (meaning, for a fixed  $u \in L$ , for its random neighbor  $v \in R$ ,  $e = (u, v)$ , the partition of  $\Sigma_L$  into sets of size 2 induced by the projection  $\pi_e$  is uniform among all possible such partitions). We informally state this observation below.

► **Lemma 10 (Informal).** *The Long code along with the Rich 2-to-1 Game structure achieves a relaxed sub-code covering property in the following sense. For every fixed  $u \in L$ , the “pull-back distribution” on the (query) location  $y \in [k_L]$  as described in Definition 9 has the property that for most locations  $y \in [k_L]$ , their probability under the pull-back distribution is not much larger than their probability under uniform distribution on  $[k_L]$ .*

Formally, let  $\Sigma_L = [2n] = \{1, \dots, 2n\}$  and  $\Sigma_R = [n] = \{1, \dots, n\}$ . Fix a vertex  $u \in L$  in a Rich 2-to-1 Game and consider its randomly chosen neighbor  $v \in R$ . Then, by definition of richness,  $\pi = \pi_{(u,v)} : [2n] \rightarrow [n]$  is a uniformly random 2-to-1 map.

The  $m$ -ary Long code for the label of  $u$  corresponds to a function  $F : [m]^{2n} \rightarrow [m]$  and the codeword for the label  $i_0 \in [2n]$  corresponds to the  $i_0^{th}$  dictatorship function

$$\text{Dict}_{i_0}(z) = \text{Dict}_{i_0}(z_1, \dots, z_{2n}) = z_{i_0}.$$

Similarly, the Long code for the label of  $v$  corresponds to a function  $G : [m]^n \rightarrow [m]$  and the codeword for the label  $j_0 \in [n]$  corresponds to the  $j_0^{th}$  dictatorship function

$$\text{Dict}_{j_0}(x) = \text{Dict}_{j_0}(x_1, \dots, x_n) = x_{j_0}.$$

We observe that if one defines for  $x \in [m]^n$ ,  $\pi^{-1}(x) \in [m]^{2n}$  by letting  $\pi^{-1}(x)_i = x_{\pi(i)}$  for all  $i \in [2n]$ , it indeed holds that

$$\text{Dict}_{i_0}(\pi^{-1}(x)) = \text{Dict}_{j_0}(x) \quad \text{whenever } \pi(i_0) = j_0.$$

In this sense, the encoding corresponding to  $v$  is a sub-code of the encoding corresponding to  $u$ . A location  $z$  from the pull-back distribution on  $[m]^{2n}$  is sampled by first picking a uniformly random 2-to-1 map  $\pi : [2n] \rightarrow [n]$ , picking  $x \in [m]^n$  uniformly, and letting  $z = \pi^{-1}(x)$ . Clearly, this distribution is supported only on  $z \in [m]^{2n}$  for which each  $s \in [m]$  appears an even number of times as its co-ordinate, and hence is statistically far from the uniform distribution on  $[m]^{2n}$ . On the other hand, we show that for “typical”  $z \in [m]^{2n}$  (those for which all  $s \in [m]$  occur roughly equal number of times as its coordinate), its probability under the pull-back distribution is at most a constant times its probability under the uniform distribution. We refer the reader to Lemma 27 for a formal statement.

We have explained how the notion of richness is tailor-made to achieve the sub-code covering property for the Long code (albeit in a more relaxed sense). We now describe two motivations to study Rich 2-to-1 Games. Our comments are speculative, but we hope that these lead to fruitful research directions.

## Hardness Results with Perfect Completeness?

From the discussion so far, it is evident that Rich 2-to-1 Games could be an excellent problem to reduce from. In particular, we show that it can be reduced to the Unique Games problem, and is equivalent to the latter. In light of this equivalence, why not just stick to the Unique Games Conjecture then? The additional advantage of using the Rich 2-to-1 Games Conjecture could be that this conjecture could hold even with perfect completeness. This could be useful towards proving hardness of approximation results where perfect completeness is essential. We cite couple of plausible candidates where hardness results could follow from the Rich 2-to-1 Games Conjecture with perfect completeness:

- Hardness of coloring 3-colorable graphs with a constant number of colors.
- Hardness of CSPs (constraint satisfaction problems) on satisfiable instances. A concrete example is the query-efficient dictatorship test with perfect completeness that is proposed and analyzed in [21, 4]. Therein, one does not know how to translate the dictatorship test to a hardness result, lacking a suitable, conjectured hard problem to reduce from.

We remark that such results could follow by developing the appropriate analytic machinery on specialized domains (minor adjustments to the reduction are needed). A concrete example (related to the problem of proving hardness of coloring 3-colorable graphs with a

constant number of colors) is the multi-slice with an appropriate noise operator. Namely,  $V = \left\{ x \in \{0, 1, 2\}^{6n} \mid \text{the number of 0's, 1's and 2's in } x \text{ is } 2n \right\}$ , with the noise operator  $T$  that acts on  $V$  in the following way: given  $x$ , randomly change half of the 0-valued coordinates in  $x$  to 1's, and the rest into 2's, and similarly for the 1-valued and 2-valued coordinates. This operator can naturally be viewed as an averaging operator over functions, and one would need a “Majority is Stablest” type bound: if all of the low-degree influences of  $f: V \rightarrow \{0, 1\}$  are small, then  $\langle f, Tf \rangle$  is bounded away from 0.

More ambitiously, one could hope that by developing the necessary analytical tools on such non-classical domains, any dictatorship test with perfect completeness could be used to prove an NP-hardness result for the corresponding predicate, assuming Conjecture 7. We leave further investigation along this direction to future works.

## Making Games Richer?

One might argue that since 2-to-1 Games are now known to be hard, we should now work towards showing that “rich” 2-to-1 Games are hard as well, showing in turn that the Unique Games are hard. It might be possible to consider “degree of richness” and design a sequence of reductions that successively achieve higher degree of richness, finally achieving full richness as in the definition of Rich 2-to-1 Games.

Formally, let  $\mathcal{F}$  be a family of partitions of  $[2n]$  into sets of size 2 each. A 2-to-1 Game is called  $\mathcal{F}$ -rich if for every fixed vertex  $u \in L$ , for its random neighbor  $v \in R$ , the partition of  $[2n]$  induced by the projection  $\pi = \pi_{(u,v)}$  is uniform over the family  $\mathcal{F}$ . We defined the game to be rich if it is  $\mathcal{F}_{\text{all}}$ -rich, where  $\mathcal{F}_{\text{all}}$  is the family of all such partitions possible.

As is the case in the proof of the 2-to-1 Games Conjecture [16, 6], the 2-to-1 Games shown to be hard therein are  $\mathcal{F}_{\text{lin}}$ -rich. Here  $[2n]$  is identified with the additive group  $GF(2)^k$  and  $\mathcal{F}_{\text{lin}}$  consists of one partition for every  $b \in GF(2)^k, b \neq 0$  that induces the “linear pairing”  $(x, x + b)$  for all  $x \in GF(2)^k$ . We float the idea to define a sequence of families

$$\mathcal{F}_0 = \mathcal{F}_{\text{lin}} \subseteq \mathcal{F}_1 \dots \subseteq \mathcal{F}_T = \mathcal{F}_{\text{all}},$$

and design a sequence of reductions achieving  $\mathcal{F}_j$ -richness successively from  $j = 0$  (which we now know) to  $j = T$  (proving the Rich 2-to-1 Games Conjecture and hence the Unique Games Conjecture).

## 2 Preliminaries

**Notation:** We denote by  $[n]$  the set  $\{1, \dots, n\}$  and by  $[n]_d$  the set of ordered  $d$ -tuples of elements of  $[n]$  consisting of distinct elements. The set of all permutations on  $[n]$  is denoted by  $S_n$  and the set of all 2-to-1 mappings  $\pi: [2n] \rightarrow [n]$  is denoted by  $S_{2n,n}$ .

We consider functions  $f: [m]^n \rightarrow \mathbb{R}$ . The distribution on  $[m]^n$  is, by default, uniform (but we will have occasions to consider non-uniform distributions and if so, it will be clear from the context). A sample  $x \in [m]^n$  will, by default, denote a uniform sample. For  $p \geq 1$ , the  $p$ -norm is defined in the standard manner,  $\|f\|_p = \mathbb{E}_x [|f(x)|^p]^{1/p}$ . The inner product of two functions is  $\langle f, g \rangle = \mathbb{E}_x [f(x)g(x)]$ .

Throughout the paper,  $C(m), C(K, m), C(d, K, m)$  etc will denote a constant that depends on the respective parameters and this constant could change from time to time.

## 2.1 Basic Analytic Notions

We recall the standard way to express  $f: [m]^n \rightarrow \mathbb{R}$  in the Fourier basis. Here, it is more convenient to define  $[m] = \mathbb{Z}_m = \{0, 1, \dots, m-1\}$  with the additive group structure. Let  $\{Y_s : [m] \rightarrow \mathbb{R} \mid s \in [m]\}$  be an orthonormal set of random variables with  $Y_0 \equiv 1$ . One can then express a function  $f: [m]^n \rightarrow \mathbb{R}$  uniquely as a “multi-linear” polynomial in random variables  $\{X_{i,s} \mid 1 \leq i \leq n, s \in [m]\}$  where for each  $1 \leq i \leq n$ , the  $\{X_{i,s}\}$  are copies of  $\{Y_s\}$ , and are independent for different  $i$ . A degree- $d$  “monomial” looks like  $\prod_{j=1}^d X_{i_j, s_j}$  with  $s_j \neq 0$  and  $i_j$  distinct for  $1 \leq j \leq d$ . The degree of a polynomial is the maximum degree of its non-zero monomials.

► **Theorem 11 (Hypercontractivity).** *Let  $f: [m]^n \rightarrow \mathbb{R}$  be a function of degree at most  $d$ . Then for all  $p \geq 2$ ,  $\|f\|_p \leq \sqrt{m(p-1)}^d \|f\|_2$ .*

► **Definition 12.** *The noise operator  $T_{1-\varepsilon}$  acts on functions  $f: [m]^n \rightarrow \mathbb{R}$  by defining  $T_{1-\varepsilon}f(x) = \mathbb{E}_{z \sim_{1-\varepsilon} x} [f(z)]$ . Here  $z \sim_{1-\varepsilon} x$  denotes a random input  $z$  that is  $(1-\varepsilon)$ -correlated with  $x$ , i.e. independently for each coordinate  $1 \leq i \leq n$ , the  $i^{\text{th}}$  coordinate of  $z$  equals the  $i^{\text{th}}$  coordinate of  $x$  with probability  $1-\varepsilon$  and is sampled uniformly from  $[m]$  with probability  $\varepsilon$ .*

► **Definition 13.** *The influence of a coordinate  $i \in [n]$  on a function  $f: [m]^n \rightarrow \mathbb{R}$  is defined by  $I_i[f] = \mathbb{E}_x [(f(x) - \mathbb{E}_{s \in [m]} [f(x + se_i)])^2]$ .*

► **Lemma 14.** *Let  $f: [m]^n \rightarrow \mathbb{R}$  be a function and  $i \in [n]$ .*

$$\frac{1}{4} \mathbb{E}_{x, s \in [m]} [(f(x) - f(x + se_i))^2] \leq I_i[f] \leq \mathbb{E}_{x, s \in [m]} [(f(x) - f(x + se_i))^2].$$

**Proof.** Deferred to the full version. ◀

► **Definition 15.** *Let  $f^{\leq d}$  and  $f^{> d}$  denote the parts of  $f$  with degree at most  $d$  and larger than  $d$  respectively. The degree- $d$  influence of a variable  $i \in [n]$  on  $f$  is defined as  $I_i^{\leq d}[f] = I_i[f^{\leq d}]$ .*

We need the following noise-stability result of [7]. It upper-bounds the noise-stability of functions all of whose influences are low.

► **Theorem 16.** *For every integer  $m \geq 2$  and constants  $\varepsilon, \theta > 0$ , there is a sufficiently small constant  $\delta > 0$ , such that the following holds. Let  $f: [m]^n \rightarrow [0, 1]$  with  $\mathbb{E}[f] \leq \theta$  and assume that for all  $i \in [n]$ ,  $I_i[f] \leq \delta$ . Then  $\langle f, T_{1-\varepsilon}f \rangle \leq 2\Gamma_{1-\varepsilon}(\theta)$ .*

The function  $\Gamma_{1-\varepsilon}(\theta)$  is defined in [14] and the only property we need is that for a fixed  $\varepsilon > 0$ ,  $\frac{\Gamma_{1-\varepsilon}(\theta)}{\theta} \rightarrow 0$  as  $\theta \rightarrow 0$ . A known upper bound is  $\Gamma_{1-\varepsilon}(\theta) \leq C(\varepsilon) \theta^{2/(2-\varepsilon)}$ .

**Functions with range  $[m]$ :** We also consider functions  $F: [m]^n \rightarrow [m]$ , which are more convenient to view as  $F: [m]^n \rightarrow \Delta_m$  where  $\Delta_m$  is the standard  $m$ -dimensional simplex,  $\Delta_m = \{(t_0, \dots, t_{m-1}) \mid \forall i, t_i \geq 0, \sum_{i=0}^{m-1} t_i = 1\}$ . The value  $s \in [m]$  is then identified with the vertex  $e_s \in \Delta_m$  of the simplex. Usually, we consider the function  $F: [m]^n \rightarrow \Delta_m$  as a vector of  $[0, 1]$ -valued functions  $(F_0, F_1, \dots, F_{m-1})$ .

---

<sup>2</sup>  $e_i$  denotes an input that is 1 in the  $i^{\text{th}}$  coordinate and zero otherwise.

## 2.2 Hypercontractivity on the Symmetric Group and the 2-to-1 Mappings Domain

In this section, we give the basic background towards analyzing functions on the symmetric group and state the hypercontractive result we need. We consider functions  $F: S_n \rightarrow \mathbb{R}$ . For  $S, T \in [n]_k$ ,  $S = (i_1, \dots, i_k)$ ,  $T = (j_1, \dots, j_k)$ , we write  $\pi(S) = T$  if  $\pi(i_1) = j_1, \dots, \pi(i_k) = j_k$ . Let  $1_{\pi(S)=T}$  be the indicator function on  $S_n$  indicating that  $\pi(S) = T$ .

► **Definition 17.** For  $d = 0, \dots, n$ , let  $V_d(S_n)$  be the linear subspace spanned by all functions  $\{1_{\pi(S)=T} \mid S, T \in [n]_k, 0 \leq k \leq d\}$ . We say the “degree” of  $F$  is (at most)  $d$  if  $F \in V_d(S_n)$ .

► **Definition 18.** A degree- $d$  function  $F: S_n \rightarrow \mathbb{R}$  is called  $\varepsilon$ -pseudo-random if for any  $S, T \in [n]_d$ ,  $\mathbb{E}_{\pi: \pi(S)=T} [F[\pi]^2] \leq \varepsilon$ .

We need the following hypercontractive inequality from [10]. We will use it to show certain concentration properties of functions on the symmetric group (or more precisely on the 2-to-1 mappings domain defined next).

► **Theorem 19.** Let  $F: S_n \rightarrow \mathbb{R}$  be a degree- $d$ ,  $\varepsilon$ -pseudo-random function. Then  $(C(d) = 2^{40d^2} \text{ suffices}) \mathbb{E}_{\pi} [F[\pi]^4] \leq C(d)\varepsilon^2$ .

What we really need to analyze are functions on the 2-to-1 mappings domain  $S_{2n,n}$ , i.e. the set of 2-to-1 mappings  $\pi: [2n] \rightarrow [n]$ . We define the notion of degree of a function  $F: S_{2n,n} \rightarrow \mathbb{R}$  in a similar manner. For  $S \in [2n]_{2k}$ ,  $T \in [n]_k$ ,  $S = (i_1, i'_1, \dots, i_k, i'_k)$ ,  $T = (j_1, \dots, j_k)$ , we write  $\pi(S) = T$  if  $\pi(i_1) = \pi(i'_1) = j_1, \dots, \pi(i_k) = \pi(i'_k) = j_k$ . Let  $1_{\pi(S)=T}$  be the indicator function on  $S_{2n,n}$  indicating that  $\pi(S) = T$ .

► **Definition 20.** For  $d = 0, \dots, n$ , let  $V_d(S_n)$  be the linear subspace spanned by all functions  $\{1_{\pi(S)=T} \mid S \in [2n]_{2k}, T \in [n]_k, 0 \leq k \leq d\}$ . We say the “degree” of  $F$  is (at most)  $d$  if  $F \in V_d(S_n)$ .

► **Definition 21.** A degree- $d$  function  $F: S_{2n,n} \rightarrow \mathbb{R}$  is called  $\varepsilon$ -pseudo-random if for any  $S \in [2n]_{4d}$  and  $T \in [n]_{2d}$  we have  $\mathbb{E}_{\pi: \pi(S)=T} [F[\pi]^2] \leq \varepsilon$ .

► **Theorem 22.** Let  $F: S_{2n,n} \rightarrow \mathbb{R}$  be a degree- $d$ ,  $\varepsilon$ -pseudo-random function. Then  $(C(d) = 2^{160d^2} \text{ suffices}) \mathbb{E}_{\pi} [F[\pi]^4] \leq C(d)\varepsilon^2$ .

**Proof.** The proof proceeds by embedding  $S_{2n}$  into  $S_{2n,n}$ , and is deferred to the full version. ◀

## 3 Main Analytic Lemma

We now state our main analytic lemma. Let  $\pi \in S_{2n,n}$  be a 2-to-1 map. We recall that for  $x \in [m]^n$ , its “pull-back”  $\pi^{-1}(x) \in [m]^{2n}$  is defined as  $\pi^{-1}(x)_i = x_{\pi(i)}$  for  $i \in [2n]$ . For a function  $f: [m]^{2n} \rightarrow \mathbb{R}$ , the “restriction”  $f|_{\pi}: [m]^n \rightarrow \mathbb{R}$  is defined as <sup>3</sup>  $f|_{\pi}(x) = f(\pi^{-1}(x))$ . Our main lemma states, loosely speaking, that if  $f$  is a low-degree, bounded function and if  $\pi \in S_{2n,n}$  is a random 2-to-1 map, then the influential co-ordinates of  $f$  and those of the restricted function  $f|_{\pi}$  are related. More specifically, it is unlikely to happen that  $f|_{\pi}$  has some influential co-ordinate  $j$  without either of  $i, i' \in \pi^{-1}(j)$  being influential for  $f$ .

<sup>3</sup> This is indeed restriction of  $f$  to the pull-back domain  $\pi^{-1}([m]^n)$ .

► **Lemma 23.** Fix the alphabet size  $m \geq 2$ . For every constants  $\delta, \zeta > 0$  and integer  $d \geq 1$ , there are sufficiently small constants  $\gamma = \gamma(m, \delta, \zeta), \tau = \tau(d, m, \delta, \zeta) > 0$  such that the following holds. Suppose  $f: [m]^{2n} \rightarrow [0, 1]$  is a function such that  $\|f^{>d}\|_2^2 \leq \gamma$ . Then

$$\Pr_{\pi} \left[ \exists j \in [n] : I_j[f|_{\pi}] \geq \delta \quad \wedge \quad \max_{i \in \pi^{-1}(j)} I_i^{\leq d}[f] \leq \tau \right] \leq \zeta.$$

For convenience, we prove a very similar lemma stated below, which considers the special case when  $f$  itself has no degree- $d$  influential variables at all. Its proof contains all the main ingredients and the above Lemma 23 then follows with minor modifications. Due to space constraints, we defer this derivation to the full version of the paper.

► **Lemma 24.** Fix the alphabet size  $m \geq 2$ . For every constants  $\delta, \zeta > 0$  and integer  $d \geq 1$ , there are sufficiently small constants  $\gamma = \gamma(m, \delta, \zeta), \tau = \tau(d, m, \delta, \zeta) > 0$  such that the following holds. Suppose  $f: [m]^{2n} \rightarrow [0, 1]$  is a function such that  $\|f^{>d}\|_2^2 \leq \gamma$  and moreover that for all  $i \in [2n]$ ,  $I_i^{\leq d}[f] \leq \tau$ . Then,  $\Pr_{\pi} [\exists j \in [n] : I_j[f|_{\pi}] \geq \delta] \leq \zeta$ .

► **Remark 25.** It is important that in the statements of the lemmas above,  $\gamma$  does not depend on  $d$ . When we apply these lemmas,  $f$  itself will be a smoothed version  $T_{1-\varepsilon}h$  for some  $[0, 1]$ -valued function  $h$ . Thus  $\|f^{>d}\|_2^2 \leq \gamma = 2^{-\Omega(d/\varepsilon)}$  and in fact  $d$  will be chosen sufficiently large so as to make  $\gamma$  sufficiently small (so the dependence “in practice” is really the other way round).

## 4 Proof of the Main Analytic Lemma

In this section, we prove Lemma 24 (and the proof of Lemma 23 follows by minor modifications). We will work, for the large part, with function  $g$  that is, roughly speaking,  $f^{\leq d}$ . However, for technical reasons, we will zero-out its values on a small set of “atypical” inputs that are outside a certain set  $E \subseteq [m]^{2n}$ . Formally,  $g = f^{\leq d} 1_E$  where  $1_E$  is the indicator of set  $E$ . Towards the end of the proof, we will relate influences of  $f$  and  $g$ . Motivation and overview of successive steps in the proof is presented as we go along.

### 4.1 The Pull-back Distribution

While trying to relate influences of a function  $g: [m]^{2n} \rightarrow \mathbb{R}$  to those of its restrictions  $g|_{\pi}$ , a technical hurdle is that the “pull-back distribution” on  $[m]^{2n}$  that we define next differs from the uniform distribution on  $[m]^{2n}$ . The pull-back distribution arises while considering the average of influences of  $g|_{\pi}$  over the choice of  $\pi$  whereas the influences of  $g$  itself are defined with respect to the uniform distribution. We are able to show that the pull-back distribution resembles the uniform distribution on  $[m]^{2n}$  in a loose, but controlled manner.

► **Definition 26.** The pull-back distribution  $\nu_{2n,m}$  over  $[m]^{2n}$  is defined by the following process: sample  $\pi \in S_{2n,n}$ ,  $x \in [m]^n$  and output  $z = \pi^{-1}(x)$ .

Clearly, this distribution is supported only on  $z \in [m]^{2n}$  for which each  $s \in [m]$  appears an even number of times as its coordinate, and hence is statistically far from the uniform distribution on  $[m]^{2n}$ . On the other hand, we show that for “typical”  $z \in [m]^{2n}$ , its probability under the distribution  $\nu_{2n,m}$  is at most a constant times its probability under the uniform distribution (this and an additional related fact is all we need).

► **Lemma 27.** A point  $z \in [m]^{2n}$  is called  $K$ -roughly balanced if every value  $s \in [m]$  appears in  $\frac{2n}{m} \pm \sqrt{K \log m \frac{n}{m}}$  of the coordinates of  $z$ . For a  $K$ -roughly balanced point  $z$ ,

$$\nu_{2n,m}(z) \leq C(K, m) m^{-2n}.$$

**Proof.** Let  $A_s$  be the set of coordinates of  $z$  that are equal to  $s \in [m]$ , let  $a_s = |A_s|$ , and let  $a_s = \frac{2n+v_s}{m}$ . We may assume that all sets  $A_s$  are even-sized, since otherwise  $\nu_{n,m}(z) = 0$ . In this case,  $\nu_{n,m}(z)$  is equal to  $m^{-n}$  times the probability that for a random  $\pi \in S_{2n,n}$ ,  $z$  happens to be in the range of  $\pi^{-1}$ , or equivalently that  $\pi$  matches off each set  $A_s$  within itself. By Lemma 40, this probability is  $\frac{\binom{n}{a_0/2, \dots, a_{m-1}/2}}{\binom{2n}{a_0, \dots, a_{m-1}}}$ . Since  $z$  is  $K$ -roughly balanced, we have that  $|v_s| \leq \sqrt{(K \log m) m n}$ . Using Lemma 39, the ratio between the two multinomial coefficients is at most  $C(m) 2^{K \log m \cdot m} m^{-n} = C(K, m) m^{-n}$ . ◀

► **Remark 28.** We will often use the lemma above with additional conditioning on the choice of  $\pi$ , say for example that  $\pi$  is sampled uniformly with the condition  $\pi(2n-1) = \pi(2n) = n$ . The lemma continues to hold. The distribution  $\tilde{\nu}_{2n,m}$  on inputs  $z \in [m]^{2n}$  is now supported on  $z$  where every  $s \in [m]$  occurs an even number of times as its coordinate and moreover that  $z_{2n-1} = z_{2n}$ . Writing  $z = (\tilde{z}, z_{2n-1}, z_{2n})$ , if  $z$  is  $K$ -roughly balanced, then  $\tilde{z} \in [m]^{2n-2}$  is  $(K+1)$ -roughly balanced and the probability that  $\tilde{z}$  is output is  $C(K, m)$  times its probability under uniform distribution.

The lemma above immediately implies the following. It is then used to relate influences of  $g : [m]^{2n} \rightarrow \mathbb{R}$  to those of  $g|_\pi$  (the latter in expectation).

► **Lemma 29.** *Let  $h : [m]^{2n} \rightarrow [0, \infty)$  be a function supported only on  $K$ -roughly balanced inputs. Then  $\mathbb{E}_{z \sim \nu_{2n,m}} [h(z)] \leq C(K, m) \mathbb{E}_{z \in_R [m]^{2n}} [h(z)]$ .*

We now show how this is useful. Let  $g : [m]^{2n} \rightarrow \mathbb{R}$  and consider a random choice of  $\pi \in S_{2n,n}$  such that  $\pi(2n-1) = \pi(2n) = n$ . Such  $\pi$  can be chosen at random by first choosing  $\pi' \in S_{2(n-1), (n-1)}$  at random, letting  $\pi = \pi'$  on  $[2(n-1)]$ , and then extending by letting  $\pi(2n-1) = \pi(2n) = n$ . We wish to consider the expected influence of the  $n^{\text{th}}$  coordinate on the restriction  $g|_\pi$ .

► **Remark 30.** Here we specifically consider the  $n^{\text{th}}$  coordinate of  $g|_\pi$  under the requirement  $\pi(2n-1) = \pi(2n) = n$ . This is for notational convenience only and is without loss of generality. The same results hold for any given  $j^{\text{th}}$  coordinate of  $g|_\pi$  under the requirement that  $\pi(i) = \pi(i') = j$  for any given  $i \neq i' \in [2n]$ .

► **Lemma 31.** *Let  $g : [m]^{2n} \rightarrow \mathbb{R}$  be a function supported only on  $K$ -roughly balanced inputs. Then  $\mathbb{E}_\pi [I_n[g|_\pi]] \leq C(K, m) (I_{2n-1}[g] + I_{2n}[g])$ .*

**Proof.** Let  $e_{2n}$  be the input with the  $(2n)^{\text{th}}$  coordinate 1 and all other coordinates zero. Let  $e_{2n-1}$  be similarly defined and let  $e = e_{2n-1} + e_{2n}$ . By Lemma 14,

$$\mathbb{E}_\pi [I_n[g|_\pi]] \leq \mathbb{E}_{\substack{\pi, x \in [m]^n \\ s \in [m]}} \left[ \left( g(\pi^{-1}(x)) - g(\pi^{-1}(x) + s e) \right)^2 \right].$$

Let  $z = \pi^{-1}(x)$  so that  $z$  is distributed according to the distribution  $\tilde{\nu}_{2n,m}$  (see Remark 28). Since  $g$  is supported only on  $K$ -roughly balanced inputs, the term above is non-zero only if  $z$  is  $(K+1)$ -roughly balanced. Hence by Lemma 29, the above expectation is at most

$$C(K, m) \cdot \mathbb{E}_{z \in_R [m]^{2n}, s} \left[ \left( g(z) - g(z + s e) \right)^2 \right].$$

Note that we think of  $z \in_R [m]^{2n}$  as uniformly distributed now onwards. Using  $(a-b)^2 \leq 2(a-c)^2 + 2(c-b)^2$ , the last expectation is at most twice

$$\mathbb{E}_{z,s} \left[ \left( g(z) - g(z + s e_{2n-1}) \right)^2 \right] + \mathbb{E}_{z,s} \left[ \left( g(z + s e_{2n-1}) - g(z + s e_{2n-1} + s e_{2n}) \right)^2 \right].$$

Since the distribution of  $z \in [m]^{2n}$  is uniform, so is the distribution of  $z + s e_{2n-1}$  and hence these expectations are equal (up to a factor 4) to  $I_{2n-1}[g]$  and  $I_{2n}[g]$  respectively. ◀

## 4.2 The Function $G$ on $S_{2n,n}$ and its Pseudo-randomness

We seek to show that under appropriate conditions, if a function  $g : [m]^{2n} \rightarrow \mathbb{R}$  has all influences low, then with high probability over the choice of  $\pi$ , the same is true for the restriction  $g|_\pi$ . We begin by a (somewhat imprecise) proof-sketch.

Suppose that  $g$  has all influences low, say at most  $\tau$ . By above Lemma 31, the expected value of the influence  $I_n[g|_\pi]$ , over the choice of  $\pi$ , is at most  $O(\tau)$ . We would like to show that in fact  $I_n[g|_\pi]$  is at most  $O(\tau)$  with high probability over the choice of  $\pi$ . We would then argue that the same holds for the influence  $I_j[g|_\pi]$  for every  $1 \leq j \leq n$  (since consideration of the  $n^{\text{th}}$  coordinate was just for notational convenience), then take a union bound over all  $1 \leq j \leq n$ , and conclude that the restriction  $g|_\pi$  has all influences low.

However, such an argument requires strong probabilistic guarantees. It is natural to seek an upper bound on the higher moments of the random variable  $G[\pi] = I_n[g|_\pi]$ . We are able to do this, but only in a rather convoluted manner. We show that  $G[\pi]$  is pseudo-random as a function on  $S_{2n,n}$  (or strictly speaking, on  $S_{2(n-1),n-1}$  since  $\pi(2n-1) = \pi(2n) = n$  is pre-defined) in the sense of Definition 21. Concretely, we show that for small  $d$  and any sets  $|A| = 2(d-1)$ ,  $|B| = d-1$ , the conditional second moment  $\mathbb{E}_{\pi(A)=B} [G[\pi]^2]$  remains bounded by  $O(1)$  times (the unconditional second moment)  $\mathbb{E} [G[\pi]^2]$ . For notational convenience (only), one can think of

$$A = \{2(n-(d-1))-1, 2(n-(d-1)), \dots, 2(n-1)-1, 2(n-1)\}, \quad B = \{n-(d-1), \dots, n-1\},$$

and the event  $\pi(A) = B$  denotes the event that  $\pi(2(n-j)-1) = \pi(2(n-j)) = n-j$  for  $1 \leq j \leq d-1$  (and in addition,  $\pi(2n-1) = \pi(2n) = n$  is pre-defined, corresponding to  $j=0$ ).

This pseudo-randomness property then implies that the fourth moment  $\mathbb{E} [G[\pi]^4]$  is upper bounded by  $O(1)$  times (the square of the second moment)  $\mathbb{E} [G[\pi]^2]^2$ . This gives sufficiently strong guarantees to make the “with high probability” and union bound arguments to go through. Towards implementing the details of this proof, we need the following ad hoc sounding lemma. We then show how to use it and prove the desired pseudo-randomness property.

- **Lemma 32.** *Let a pair of inputs  $z_1, z_2 \in [m]^{2n}$  be chosen by two different methods:*
- *Choose a random  $\pi \in S_{2n,n}$ , then choose  $x_1, x_2 \in [m]^n$  at random, and then define  $z_i = \pi^{-1}(x_i)$ . Let  $\mu(z_1, z_2)$  denote the probability that the pair  $(z_1, z_2)$  is output.*
  - *Let  $A = \{2(n-(d-1))-1, 2(n-(d-1)), \dots, 2n-1, 2n\}$ ,  $B = \{n-(d-1), \dots, n\}$ , and the event  $\pi(A) = B$  denotes the event that  $\pi(2(n-j)-1) = \pi(2(n-j)) = n-j$  for  $0 \leq j \leq d-1$ . Let  $\mu_{\text{cond}}(z_1, z_2)$  denote the probability that the pair  $(z_1, z_2)$  is output by the method above, but conditional on the event  $\pi(A) = B$ .*

*Then if the pair  $(z_1, z_2)$  is “typical”, we have  $\mu_{\text{cond}}(z_1, z_2) \leq C(d, m) \mu(z_1, z_2)$ , where the pair  $(z_1, z_2)$  is “typical” if among the multi-set  $\{(z_1(i), z_2(i)) | 1 \leq i \leq 2n\}$  of their coordinates, each of the  $m^2$  patterns in  $[m] \times [m]$  appears at least  $\frac{2n}{20m^2}$  times.*

**Proof.** Among the multi-set  $\{(z_1(i), z_2(i)) | 1 \leq i \leq 2n\}$ , let the number of occurrences of the  $m^2$  possible patterns be  $v_1, \dots, v_{m^2}$ . We may assume that these numbers are all even since otherwise the pair  $(z_1, z_2)$  will never be output. The probability  $\mu(z_1, z_2)$  is equal to (using Lemma 40)  $\frac{\binom{\frac{v_1}{2}, \dots, \frac{v_{m^2}}{2}}{2n}}{\binom{v_1, \dots, v_{m^2}}{2n}}$ . Denote by  $u_1, \dots, u_{m^2}$  the number of occurrences of these patterns that appear in the  $2d$  coordinates of  $A$  so that  $2d = u_1 + \dots + u_{m^2}$ . The probability  $\mu_{\text{cond}}(z_1, z_2)$  is equal to (using Lemma 40 again)  $\frac{\binom{\frac{v_1-u_1}{2}, \dots, \frac{v_{m^2}-u_{m^2}}{2}}{2n-2d}}{\binom{v_1-u_1, \dots, v_{m^2}-u_{m^2}}{2n-2d}}$ . Applying Lemma 38,

we see that the numerator of the second fraction is at most  $C(d, m)$  times the numerator of the first fraction, and its denominator is at least  $c(d, m)$  times the denominator of the first fraction for some  $c(d, m) > 0$ , and hence we conclude that  $\mu_{\text{cond}}(z_1, z_2) \leq C(d, m)\mu(z_1, z_2)$  for a typical pair  $(z_1, z_2)$ .  $\blacktriangleleft$

► **Lemma 33.** *Let  $g : [m]^{2n} \rightarrow \mathbb{R}$  be a function supported on  $K$ -roughly balanced inputs. Let  $A = \{2(n - (d - 1)) - 1, 2(n - (d - 1)), \dots, 2(n - 1) - 1, 2(n - 1)\}$ ,  $B = \{n - (d - 1), \dots, n - 1\}$ . Then the random variable  $G[\pi] = I_n[g|\pi]$  satisfies  $(\pi(2n - 1) = \pi(2n) = n)$  is pre-defined)*

$$\mathbb{E}_{\pi(A)=B} [G[\pi]^2] \leq C(d, m) \mathbb{E} [G[\pi]^2] + 2^{-\Omega(\frac{n}{m^2})} \cdot C(d, K, m) \cdot \|g\|_4^4.$$

**Proof.** Denote  $h(z) = (g(z) - \mathbb{E}_{s \in [m]} [g(z + s e)])^2$  where the last two coordinates of  $e$  equal 1 and the rest are zero. By definition,  $\mathbb{E}_{\pi(A)=B} [G[\pi]^2]$  equals

$$\mathbb{E}_{\pi(A)=B} [I_n[g|\pi]^2] = \mathbb{E}_{\pi(A)=B} \left[ \mathbb{E}_{x_1, x_2} [h(\pi^{-1}(x_1))h(\pi^{-1}(x_2))] \right] = \mathbb{E}_{(z_1, z_2) \sim \mu_{\text{cond}}} [h(z_1)h(z_2)]. \quad (1)$$

We wish to upper bound this expression in terms of  $\mathbb{E} [G[\pi]^2]$  which may be written similarly as  $\mathbb{E} [G[\pi]^2] = \mathbb{E}_{(z_1, z_2) \sim \mu} [h(z_1)h(z_2)]$ , the two expectations being similar, but under different distributions  $\mu_{\text{cond}}$  and  $\mu$  respectively. The proof proceeds by splitting the expectation in (1) into two parts, over the pairs  $(z_1, z_2)$  that are typical versus that are atypical. For the first part, we upper bound using the above Lemma 32 and hence are able to “switch” to the distribution  $\mu$ . We now show how to upper bound the second part; this is by using Cauchy-Schwartz carefully and noting that only a negligible number of pairs are atypical. Let  $1_{\text{Bad}}$  denote the indicator of the event that the pair  $(z_1, z_2)$  is atypical. We note that the probability of this event is at most  $2^{-\Omega(\frac{n}{m^2})}$ . We wish to upper bound

$$\mathbb{E}_{(z_1, z_2) \sim \mu_{\text{cond}}} [h(z_1)h(z_2)1_{\text{Bad}}(z_1, z_2)] = \mathbb{E}_{(z_1, z_2) \sim \mu_{\text{cond}}} [h(z_1)1_{\text{Bad}}(z_1, z_2) \cdot h(z_2)1_{\text{Bad}}(z_1, z_2)].$$

By Cauchy-Schwartz, this is upper bounded by

$$\mathbb{E}_{(z_1, z_2) \sim \mu_{\text{cond}}} [h(z_1)^2 1_{\text{Bad}}(z_1, z_2)]. \quad (2)$$

Since  $g(z_1)$  is non-zero only on  $K$ -roughly balanced inputs  $z_1$ , the same holds for  $h(z_1)$  (possibly replacing  $K$  by  $K + 1$ ; we ignore this minor point). We may thus assume that  $z_1$  is  $K$ -roughly balanced. Provided that  $z_1$  is  $K$ -roughly balanced, the probability that  $(z_1, z_2)$  is atypical remains  $2^{-\Omega(\frac{n}{m^2})}$ . We note in addition that  $h(z_1)^2 \leq C(m) \cdot \mathbb{E}_{s \in [m]} [g(z_1 + s e)^4]$ , and that since  $z_1$  is  $K$ -roughly balanced, its probability under  $\mu_{\text{cond}}$  is at most  $C(d, K, m)$  times that under the uniform distribution on  $[m]^{2n}$  (by Lemma 27; the conditioning  $\pi(A) = B$  may give additional factor of  $m^d$ ). Putting these observations together, we upper bound (2), as desired, by  $2^{-\Omega(\frac{n}{m^2})} \cdot C(d, K, m) \cdot \mathbb{E}_{z \in [m]^{2n}} [g(z)^4]$ .  $\blacktriangleleft$

### 4.3 Using Hypercontractivity on $S_{2n, n}$

We now present the key hypercontractive argument, almost completing the proof as far as the function  $g = f^{\leq d} 1_E$  is concerned. In subsequent sections, we carry out the final steps relating influences of  $f$  and  $g$ .

► **Lemma 34.** *Let  $f : [m]^{2n} \rightarrow [0, 1]$  be a bounded function and  $E \subseteq [m]^{2n}$  be the set of  $K$ -roughly balanced inputs. Define  $g = f^{\leq d} \cdot 1_E$ , i.e.  $g$  is the low-degree part of  $f$ , but in addition zeroed out on the imbalanced inputs. Then*

$$\Pr_{\pi} [I_n[g|\pi] \geq \delta] \leq \frac{C(d, K, m)}{\delta^4} (I_{2n-1}[g]^4 + I_{2n}[g]^4).$$

**Proof.** We use Lemma 33 to conclude that

$$\mathbb{E}_{\pi(A)=B} [G[\pi]^2] \leq C(d, m) \mathbb{E} [G[\pi]^2] + 2^{-\Omega(\frac{n}{m^2})} \cdot C(d, K, m) \cdot \|g\|_4^4.$$

Towards bounding the second term, we observe

$$\|g\|_4^4 = \|f^{\leq d} 1_E\|_4^4 \leq \|f^{\leq d}\|_4^4 \leq (3m)^{2d} \|f^{\leq d}\|_2^4 \leq (3m)^{2d} \|f\|_2^4 \leq (3m)^{2d}.$$

Here we used the fact that  $f$  is a bounded function and Theorem 11. The  $2^{-\Omega(\frac{n}{m^2})}$  factor in the second term makes the term negligible. This term does not really affect subsequent arguments, so for the clarity of presentation, we take the liberty to ignore it henceforth. Thus we have  $\mathbb{E}_{\pi(A)=B} [G[\pi]^2] \leq C(d, m) \mathbb{E} [G[\pi]^2]$ . Since this holds for any  $|A| = 2d - 2, |B| = d - 1$ , the function  $G[\pi]$ , as a function on  $S_{2(n-1), n-1}$ , is pseudo-random in the sense of Definition 21 (we stress again that  $\pi(2n - 1) = \pi(2n) = n$  is pre-defined). Moreover, the degree of  $G[\pi]$  is (at most)  $2d$ . The subtle explanation is as follows.<sup>4</sup> By definition,  $G[\pi]$  is the average of

$$(g(\pi^{-1}(x)) - g(\pi^{-1}(x + s e)))^2 = g(\pi^{-1}(x))^2 + g(\pi^{-1}(x + s e))^2 - 2g(\pi^{-1}(x))g(\pi^{-1}(x + s e)) \quad (3)$$

over some distribution over  $x, s$ , so it is enough to argue about the degree for each fixed  $x, s$ . If either of the inputs  $\pi^{-1}(x)$  or  $\pi^{-1}(x + s e)$  falls outside of the set  $E$ , their  $g$ -value is zero and can be dropped from consideration. Otherwise their  $g$ -values are given by the degree- $d$  function  $f^{\leq d} : [m]^{2n} \rightarrow \mathbb{R}$ . Thus (3) can be written as a linear combination of monomials of degree at most  $2d$  and any monomial, say on coordinates  $i_1, \dots, i_{2d}$ , is determined by  $\pi(i_1), \dots, \pi(i_{2d})$  when regarded as a function on  $S_{2(n-1), n-1}$ .

Thus  $G[\pi]$  is a degree- $2d$  pseudo-random function and we can apply Lemma 22 to upper bound its fourth moment as  $\mathbb{E}_{\pi} [G[\pi]^4] \leq C(d, m) \mathbb{E}_{\pi} [G[\pi]^2]^2$ . Finally, by  $(\frac{3}{2}, 3)$ -Holder's inequality,  $\mathbb{E}_{\pi} [G[\pi]^2] = \mathbb{E}_{\pi} [G[\pi]^{\frac{2}{3}} \cdot G[\pi]^{\frac{4}{3}}] \leq (\mathbb{E}_{\pi} [G[\pi]])^{\frac{2}{3}} (\mathbb{E}_{\pi} [G[\pi]^4])^{\frac{1}{3}}$ , which yields, using the bound on the fourth moment,  $\mathbb{E}_{\pi} [G[\pi]^2] \leq C(d, m) \mathbb{E}_{\pi} [G[\pi]]^2$ , and then  $\mathbb{E}_{\pi} [G[\pi]^4] \leq C(d, m) \mathbb{E}_{\pi} [G[\pi]]^4$ . Using Markov and Lemma 31, we conclude as desired, that

$$\Pr_{\pi} [G[\pi] \geq \delta] \leq \frac{\mathbb{E}_{\pi} [G[\pi]^4]}{\delta^4} \leq \frac{C(d, m)}{\delta^4} \mathbb{E}_{\pi} [G[\pi]]^4 \leq \frac{C(d, K, m)}{\delta^4} (I_{2n-1}[g]^4 + I_{2n}[g]^4). \blacktriangleleft$$

► **Lemma 35.** *Let  $f : [m]^{2n} \rightarrow [0, 1]$  be a bounded function and  $E \subseteq [m]^{2n}$  be the set of  $K$ -roughly balanced inputs. Define  $g = f^{\leq d} \cdot 1_E$  as in the statement of Lemma 34. Then*

$$\Pr_{\pi} [\exists j : I_j[g|\pi] \geq \delta] \leq \frac{C(d, K, m)}{\delta^4} \cdot \sum_{i=1}^{2n} I_i[g]^4.$$

**Proof.** We use Lemma 34, but note that the consideration of the  $n^{th}$  coordinate and the requirement that  $\pi(2n - 1) = \pi(2n) = n$  is only for notational convenience. What we have actually proved is that for any  $1 \leq j \leq n$  and any  $1 \leq i \neq i' \leq 2n$ ,

$$\Pr_{\pi: \pi(i) = \pi(i') = j} [I_j[g|\pi] \geq \delta] \leq \frac{C(d, K, m)}{\delta^4} (I_i[g]^4 + I_{i'}[g]^4).$$

<sup>4</sup> To be in strict accordance with Definition 21, one actually argues here that  $G[\pi]$  has degree  $d^* = 2d$  and the pseudo-randomness condition holds for all  $|A| = 4d^*, |B| = d^*$ . We have avoided this minor point for ease of presentation.

Fixing  $j$  and taking average over all  $1 \leq i \neq i' \leq 2n$  gives

$$\Pr_{\pi} [I_j[g|\pi] \geq \delta] \leq \frac{C(d, K, m)}{\delta^4} \mathbb{E}_{\pi} \left[ \sum_{i \in \pi^{-1}(j)} I_i[g]^4 \right].$$

Now taking a union bound over all  $1 \leq j \leq n$  gives the result.  $\blacktriangleleft$

The above Lemma 35 shows, morally speaking, that with high probability over the choice of  $\pi$ , all influences of  $g|_{\pi}$  are low provided that all influences of  $g$  are low. We could upper bound  $\sum_{i=1}^{2n} I_i[g]^4$  by  $\tau(g)^3 I[g]$  where  $\tau(g)$  is the maximum influence  $I_i[g]$  and  $I[g] = \sum_{i=1}^{2n} I_i[g]$  is the total influence. The total influence, since  $g$  is morally speaking same as  $f^{\leq d}$ , should be  $O(d)$ . However, the fact that  $g = f^{\leq d} 1_E$  is a truncation of  $f^{\leq d}$  complicates matters and we have to go through a somewhat tedious argument.

#### 4.4 Relating Influences of $f$ and $g$

► **Lemma 36.** *Let  $f : [m]^{2n} \rightarrow [0, 1]$  be a bounded function and  $E \subseteq [m]^{2n}$  be the set of  $K$ -roughly balanced inputs. Define  $g = f^{\leq d} \cdot 1_E$ . Then for any coordinate  $1 \leq i \leq 2n$ ,  $I_i[g] \leq C(m) I_i^{\leq d}[f] + C(d, m) n^{-\frac{3}{8}}$ .*

**Proof.** By definition,  $g = f^{\leq d} \cdot 1_E$  and  $I_i[g]$  equals (possibly up to a factor  $m$ )

$$\mathbb{E}_{z \in_R [m]^{2n}} [|f^{\leq d}(z) \cdot 1_E(z) - f^{\leq d}(z + e_i) \cdot 1_E(z + e_i)|^2].$$

Now if both  $z$  and  $z + e_i$  are in  $E$ , the term inside is same as  $|f^{\leq d}(z) - f^{\leq d}(z + e_i)|^2$  and it contributes to the influence  $I_i^{\leq d}[f]$ . So only additional contribution to  $I_i[g]$  on top of  $I_i^{\leq d}[f]$  is due to inputs  $z$  such that  $z \in E$ , but  $z + e_i \notin E$  (or vice versa). Let  $\partial E$  denote the set of such  $z$  so that it constitutes at most  $\frac{C(m)}{\sqrt{n}}$  fraction of inputs in  $[m]^{2n}$ . The additional contribution to  $I_i[g]$  is now upper bounded as (using  $(4, \frac{4}{3})$ -Holder)

$$\mathbb{E} [f^{\leq d}(z)^2 1_{\partial E}] \leq \mathbb{E} [f^{\leq d}(z)^8]^{\frac{1}{4}} \mathbb{E} [1_{\partial E}^{\frac{4}{3}}]^{\frac{3}{4}} \leq C(d, m) \left( \frac{C(m)}{\sqrt{n}} \right)^{\frac{3}{4}}.$$

We used  $\mathbb{E} [f^{\leq d}(z)^8] \leq C(d, m) \mathbb{E} [f^{\leq d}(z)^2]^4 \leq C(d, m)$  that follows from Theorem 11. This completes the proof.  $\blacktriangleleft$

► **Lemma 37.** *Let  $f : [m]^{2n} \rightarrow [0, 1]$  be a bounded function and  $E \subseteq [m]^{2n}$  be the set of  $K$ -roughly balanced inputs. Define  $g = f^{\leq d} \cdot 1_E$ . Then except with probability  $\zeta$  over the choice of  $\pi$ , we have*

$$\max_{1 \leq j \leq n} I_j[f|\pi] \leq 3 \cdot \max_{1 \leq j \leq n} I_j[g|\pi] + \delta.$$

This holds as long as  $K = O(\log \frac{1}{\delta \zeta})$  is sufficiently large and  $\|f^{>d}\|_2^2 \leq \gamma = \gamma(m, \delta, \zeta)$  is sufficiently small. We emphasize that  $\gamma$  does not depend on  $d$ .

**Proof.** We write  $f = g + h + q$  where  $g = f^{\leq d} \cdot 1_E$ ,  $h = f^{>d} \cdot 1_E$ , and  $q = f \cdot 1_{\bar{E}}$ . Clearly, for any coordinate  $1 \leq j \leq n$  (using  $(a + b + c)^2 \leq 3(a^2 + b^2 + c^2)$ ),

$$I_j[f|\pi] \leq 3 \cdot (I_j[g|\pi] + I_j[h|\pi] + I_j[q|\pi]).$$

We will show that except with “small” probability over the choice of  $\pi$ , both  $\|h|_{\pi}\|_2^2$  and  $\|q|_{\pi}\|_2^2$  are “small”. Since these are upper bounds on  $I_j[h|\pi]$  and  $I_j[q|\pi]$  respectively, the lemma follows. We will just show that  $\mathbb{E}_{\pi} [\|h|_{\pi}\|_2^2]$  and  $\mathbb{E}_{\pi} [\|q|_{\pi}\|_2^2]$  are “small” (i.e.  $\ll \delta \zeta$ ) and this determines the quantitative constraints on  $K$  and  $\gamma$  and then use Markov. Indeed,

## 27:16 On Rich 2-to-1 Games

- Towards upper-bounding  $\mathbb{E}_\pi [\|q|_\pi\|_2^2]$ , we note that  $f$  is bounded in  $[0, 1]$  and

$$\mathbb{E}_\pi [\|q|_\pi\|_2^2] = \mathbb{E}_{\pi, x \in [m]^n} [f(\pi^{-1}(x)) \cdot 1_{\overline{E}}(\pi^{-1}(x))] \leq \mathbb{E}_{\pi, x \in [m]^n} [1_{\overline{E}}(\pi^{-1}(x))],$$

and the probability that  $\pi^{-1}(x)$  is imbalanced is at most  $2^{-\Omega(K)}$ .

- Towards upper-bounding  $\mathbb{E}_\pi [\|h|_\pi\|_2^2]$ , we argue that ( $z = \pi^{-1}(x)$ )

$$\mathbb{E}_\pi [\|h|_\pi\|_2^2] = \mathbb{E}_{\pi, x \in [m]^n} [f^{>d}(z)^2 1_E(z)] \leq C(K, m) \|f^{>d}\|_2^2 \leq C(K, m) \gamma.$$

In the second step, since one is concerned only with  $K$ -roughly balanced inputs, one can “switch” to uniform distribution over input thanks to Lemma 27. ◀

### Proof of Lemma 24

We now complete the proof of Lemma 24. Let  $f : [m]^{2n} \rightarrow [0, 1]$  be a function as therein with  $\|f^{>d}\|_2^2 \leq \gamma$  and for all  $i \in [2n]$ ,  $I_i^{\leq d}[f] \leq \tau$ . Let  $g = f^{\leq d} 1_E$  where  $E$  is the set of  $K$ -roughly balanced inputs. The parameters  $K, \gamma, \tau$  are chosen as needed by the proof.

By Lemma 36, we get an upper bound as below. We note that the total influence of  $f^{\leq d}$  is  $O(d)$  and its maximum influence is at most  $\tau$  by hypothesis.

$$\sum_{i=1}^{2n} I_i[g]^4 \leq C(d, m) \left( \sum_{i=1}^{2n} I_i^{\leq d}[f]^4 + \frac{1}{\sqrt{n}} \right) \leq C(d, m) \tau^3.$$

This gives, by Lemma 35, that  $\Pr_\pi [\exists j : I_j[g|_\pi] \geq \delta] \leq \frac{C(d, K, m)}{\delta^4} \tau^3$ . Finally, by Lemma 37, except with probability  $\zeta$  over the choice of  $\pi$ , it holds that  $\max_{1 \leq j \leq n} I_j[f|_\pi] \leq 3 \cdot \max_{1 \leq j \leq n} I_j[g|_\pi] + \delta$ . Putting the two conclusions together, we conclude that

$$\Pr_\pi [\exists j : I_j[f|_\pi] \geq 4\delta] \leq \zeta + \frac{C(d, K, m)}{\delta^4} \tau^3 \leq 2\zeta,$$

completing the proof of Lemma 24. In terms of quantitative constraints on the parameters,  $K = K(\delta, \zeta)$ ,  $\gamma = \gamma(m, \delta, \zeta)$  are determined by Lemma 35 and  $\tau = \tau(d, m, \delta, \zeta)$  needs to obey the very last inequality above.

## 5 The Reduction

We now prove Theorem 8 that the Rich 2-to-1 Games Conjecture is equivalent to the Unique Games Conjecture. The reduction from Unique Games to Rich 2-to-1 Games as well as its analysis are standard and appear in the full version. The reduction from Rich 2-to-1 Games to Unique Games is also standard and is presented in this section. Its analysis however needs new analytic tools, specifically Lemma 23.

We are given a Rich 2-to-1 Games instance  $\Psi = (L \cup R, E, \Sigma_L, \Sigma_R, \Phi)$  with  $\Sigma_L = [2n]$ ,  $\Sigma_R = [n]$ , completeness (at least)  $1 - \eta$ , and soundness (at most)  $\eta$ . The reduction outputs an instance of Unique Games with alphabet  $[m]$ , completeness (at least)  $1 - 5\varepsilon$ , and soundness (at most)  $\varepsilon$ . For given  $\varepsilon$ , first  $m$  needs to be taken sufficiently large, then  $\eta$  sufficiently small, and in turn  $n$  sufficiently large. The instance of Unique Games produced is linear, i.e. its alphabet  $[m]$  is identified with  $\mathbb{Z}_m$ , the additive group of integers modulo  $m$ , and the constraints are linear equations.

As is standard, we replace a vertex  $u \in L$  with the (supposed)  $m$ -ary long code of the (supposed) label of  $u$ . The positions in the long code correspond to the variables of the Unique Games instance. An assignment to these variables corresponds to a function  $F_u : [m]^{2n} \rightarrow [m]$ . The intention is that if  $i \in [2n]$  is the label of  $u$  (in the 2-to-1 Games instance), then  $F_u(x) = F_u(x_1, \dots, x_{2n}) = x_i$  is the corresponding dictatorship function. In our reduction, the long codes for labels of vertices  $v \in R$  do not appear explicitly, but it will be convenient to imagine them “virtually”.

The PCP test is straightforward: one performs a two-query “noise-test” on the virtual long code of a vertex  $v \in R$ , but actually reads off the queries from the long codes of neighbors  $u, w$  of the vertex  $v$  respectively (the virtual long code for  $v$  is “contained” in that of  $u$  as well as  $w$ ). Each test is viewed as a Unique Games constraint and this defines the Unique Games instance produced by the reduction. Formally, a test/equation is produced as follows:

- Sample  $v \in R$  uniformly,  $a \in [m]^n$  at random, and  $b \in [m]^n$  to be  $1 - \varepsilon$  correlated with  $a$ .
- Sample two neighbours  $u, w$  of  $v$  independently at random.
- Set  $A = \pi_{(u,v)}^{-1}(a)$ ,  $B = \pi_{(w,v)}^{-1}(b) \in [m]^{2n}$ .
- Finally, sample  $x \in [m]^{2n}$  that is  $1 - \varepsilon$  correlated with  $A$ , and  $y \in [m]^{2n}$  that is  $1 - \varepsilon$  correlated with  $B$ . Output the equation  $F_u(x) = F_w(y)$ .

## Folding

As is standard, we can assume that the functions  $F_u : [m]^{2n} \rightarrow [m]$  that appear in the PCP proof are folded, meaning  $F_u(x + se) = F_u(x) + s$  where  $e \in [m]^{2n}$  is the all 1 vector. In particular,  $F_u$  is then balanced, i.e. takes all values in  $[m]$  equally often. Technically, folding is enforced by keeping only one of the inputs in the set  $\{x + se \mid s \in [m]\}$  as a representative and inferring values at other inputs from the representative. The effect of folding is that the equations produced are of the type  $p = q + s$  instead of just  $p = q$  where  $p, q$  are the Unique Games variables in the output instance and  $s \in [m]$ .

## 5.1 Completeness

If the 2-to-1 Games instance  $\Psi$  has a labeling  $\sigma : L \rightarrow [2n]$ ,  $\rho : R \rightarrow [n]$  that satisfies at least  $1 - \eta$  fraction of the constraints, we show that the Unique Games instance is (at least)  $1 - 2\eta - 3\varepsilon \geq 1 - 5\varepsilon$  satisfiable for  $\eta$  sufficiently small.

Indeed, define for any  $u \in L$ , the long-code assignment  $F_u(x) = x_{\sigma(u)}$ . Since the edges  $(u, v), (w, v)$  are distributed uniformly, with probability at least  $1 - 2\eta$ , both edges are satisfied by the labeling, i.e.  $\pi_{(u,v)}(\sigma(u)) = \rho(v) = \pi_{(w,v)}(\sigma(w))$ . Whenever this happens, the test accepts with probability at least  $1 - 3\varepsilon$  since the failure to accept can be attributed to one of three events: strings  $a$  and  $b$  differing on the co-ordinate  $\rho(v)$ , strings  $x$  and  $A$  differing on the co-ordinate  $\sigma(u)$ , or strings  $y$  and  $B$  differing on the co-ordinate  $\sigma(w)$ .

## 5.2 Soundness

We will show that if the 2-to-1 Games instance has soundness at most  $\eta$  (to be chosen sufficiently small later), then the probability that the test accepts is upper bounded by  $\varepsilon$ .

Let  $F_u : [m]^{2n} \rightarrow [m]$  be the folded functions given as assignment to the Unique Games instance. In a standard manner, we view the functions as  $F_u : [m]^{2n} \rightarrow \Delta_m$  where  $\Delta_m = \{(t_0, \dots, t_{m-1}) \mid t_i \geq 0, \sum_{i=0}^{m-1} t_i = 1\}$  is the standard  $m$ -dimensional simplex. Each function  $F_u$  is then thought of as a vector  $(F_{u,0}, \dots, F_{u,m-1})$  where each  $F_{u,r}$  is a  $\{0, 1\}$ -valued function and  $\mathbb{E}[F_{u,r}] = \frac{1}{m}$  since  $F_u$  is folded and balanced. Moreover, the acceptance criterion

of the test, i.e.  $F_u(x) = F_w(y)$ , can be written arithmetically as  $\sum_{r=0}^{m-1} F_{u,r}(x) \cdot F_{w,r}(y)$ . Hence the probability that the test accepts can be written as (the expectation is over all the choices made)

$$\mathbb{E}_{v,u,w,a,b,A,B,x,y} \left[ \sum_{r=0}^{m-1} F_{u,r}(x) \cdot F_{w,r}(y) \right] = \sum_{r=0}^{m-1} \mathbb{E}_{v,u,w,a,b,A,B,x,y} [F_{u,r}(x) \cdot F_{w,r}(y)]. \quad (4)$$

Henceforth we will fix the index  $0 \leq r \leq m-1$  and then show an upper bound on the expectation on the right (with the overall upper bound being  $m$  times that). For notational convenience, we drop the subscript  $r$  and define  $\{0,1\}$ -valued functions  $f_u = F_{u,r}$ . Thus the goal is to upper bound (note that  $a, b \in [m]^n$  and  $A, B, x, y \in [m]^{2n}$ )

$$\begin{aligned} \mathbb{E}_{\substack{v,u,w \\ a \sim_{1-\varepsilon} b}} \left[ \mathbb{E}_{x \sim_{1-\varepsilon} A, y \sim_{1-\varepsilon} B} [f_u(x) \cdot f_w(y)] \right] &= \mathbb{E}_{\substack{v,u,w \\ a \sim_{1-\varepsilon} b}} [T_{1-\varepsilon} f_u(A) \cdot T_{1-\varepsilon} f_w(B)] \\ &= \mathbb{E}_{\substack{v,u,w \\ a \sim_{1-\varepsilon} b}} [g_u(A) \cdot g_w(B)], \end{aligned}$$

where  $g_u = T_{1-\varepsilon} f_u$ . We note that  $g_u$  is  $[0,1]$ -valued and  $\mathbb{E}[g_u] = \mathbb{E}[f_u] = \frac{1}{m}$ . We further define  $g_{u,v} = g_u|_{\pi(u,v)}$  and we still have  $\mathbb{E}[g_{u,v}] = \frac{1}{m}$ . The expectation can be rewritten as

$$\mathbb{E}_{\substack{v,u,w \\ a \sim_{1-\varepsilon} b}} [g_{u,v}(a) \cdot g_{w,v}(b)] = \mathbb{E}_{v,u,w} [\langle g_{u,v}, T_{1-\varepsilon} g_{w,v} \rangle] = \mathbb{E}_v [\langle h_v, T_{1-\varepsilon} h_v \rangle], \quad (5)$$

where in the last step we used the fact that the choices of  $u, w$  are independent (for a fixed  $v$ ) and defined  $h_v = \mathbb{E}_u [g_{u,v}]$ . We note that  $\mathbb{E}[h_v] = \frac{1}{m}$  as well. We now show, by way of contradiction, that if the expectation in (5) is at least  $\beta = \frac{\varepsilon}{m}$ , then one can define a labeling to the 2-to-1 Games instance that satisfies more than  $\eta$  fraction of its constraints. It then follows that (5) is bounded by  $\beta$  and hence (4) (i.e. the acceptance probability of PCP test) by  $m\beta = \varepsilon$  as desired.

Assume therefore that the expectation in (5) is at least  $\beta$ . By an averaging argument, for at least  $\frac{\beta}{2}$  fraction of vertices  $v \in R$ , the inner product  $\langle h_v, T_{1-\varepsilon} h_v \rangle$  is at least  $\frac{\beta}{2}$ . Let  $R_{\text{Good}} \subseteq R$  be the subset of such vertices. That is, for  $v \in R_{\text{Good}}$ ,  $\langle h_v, T_{1-\varepsilon} h_v \rangle \geq \frac{\beta}{2}$ . Using Theorem 16, the function  $h_v$  then must have an influential co-ordinate, and moreover since  $h_v = \mathbb{E}_u [g_{u,v}]$ , so does the function  $g_{u,v}$  for a good fraction of the neighbors  $u \in L$ . In light of this observation, we hope to come up with a labeling to vertices  $v \in R$  and  $u \in L$  by choosing an influential co-ordinate of the function  $h_v$  and the function  $g_u$  respectively (we need to use the fact that  $g_u$  is smooth or low-degree). This strategy works thanks to our main technical Lemma 23.

Indeed, for  $v \in R_{\text{Good}}$ , define its label  $\rho(v)$  to be an arbitrary co-ordinate  $j \in [n]$  such that  $I_j[h_v] \geq \delta$ . Such a coordinate exists since  $\langle h_v, T_{1-\varepsilon} h_v \rangle \geq \frac{\beta}{2}$  and using Theorem 16. One needs to take  $m$  sufficiently large so that  $\mathbb{E}[h_v] = \frac{1}{m} = \theta$  is sufficiently small to bring the bound  $2\Gamma_{1-\varepsilon}(\theta)$  in Theorem 16 below  $\frac{\beta}{2} = \frac{\varepsilon}{2} \frac{1}{m} = \frac{\varepsilon}{2} \theta$ . One then needs to take the influence parameter  $\delta$  therein sufficiently small.

Since  $h_v = \mathbb{E}_u [g_{u,v}]$  and  $\rho(v)$  has influence at least  $\delta$  on  $h_v$ , it follows that for at least  $\frac{\delta}{2}$  fraction of neighbors  $u \in L$  of  $v$  we have  $I_{\rho(v)}[g_{u,v}] \geq \frac{\delta}{2}$ . Let  $N_{\text{Good}}(v)$  denote the subset of such neighbors. We emphasize that for a random choice of edge  $(u, v)$ , we have  $v \in R_{\text{Good}}$  and  $u \in N_{\text{Good}}(v)$  with probability at least  $\frac{\beta}{2} \frac{\delta}{2}$ .

Now, by the main Lemma 23, except with probability  $\zeta \ll \frac{\beta\delta}{8}$  over the choice of the edge  $(u, v)$ , it is the case that whenever  $I_j[g_{u,v}] \geq \frac{\delta}{2}$  for some  $j \in [n]$ , one has  $I_i[g_u] \geq \tau$  for some  $i \in \pi^{-1}(j), \pi = \pi_{(u,v)}$ . We note that since  $g_u = T_{1-\varepsilon}f_u$ , its Fourier mass beyond degree  $d$  is at most  $\gamma = 2^{-\Omega(d/\varepsilon)}$ , which can be made sufficiently small by taking  $d$  sufficiently large. Finally,  $\tau$  is taken to be sufficiently small so that the lemma applies. It follows that with probability  $\frac{\beta\delta}{8}$ , all these events happen simultaneously:

$$v \in R_{\text{Good}}, \quad u \in N_{\text{Good}}(v), \quad I_{\rho(v)}[g_{u,v}] \geq \frac{\delta}{2}, \quad I_i^{\leq d}[g_u] \geq \tau \quad \text{for some } i \in \pi^{-1}(\rho(v)).$$

Thus if we defined a label for  $u \in L$  by making a list of all co-ordinates with degree- $d$  influence at least  $\tau$  on  $g_u$  and then picked one label at random from this list, it would agree with  $\rho(v)$  (via  $\pi = \pi_{(u,v)}$ ) with probability at least  $\Omega(\frac{\tau}{d})$  (the list size is  $O(\frac{d}{\tau})$  since the total degree- $d$  influence is at most  $d$ ). This gives a labeling to the 2-to-1 Games instance that satisfies overall  $\Omega(\frac{\beta\delta\tau}{d})$  fraction of its constraints. Choosing the soundness  $\eta$  of the 2-to-1 Games instance to be even lower a priori completes the proof.

## A Standard Facts and Calculations

In this section we collect several standard statements; the proofs can be found in the full version of the paper.

► **Lemma 38.** *For any positive integers  $r, t$ , there are constants  $0 < c(r, t) < C(r, t)$  such that the following holds for large enough  $n$ . Let  $v_1, \dots, v_r \geq \frac{n}{10r}$  be integers that sum up to  $n$ , let  $u_1, \dots, u_r$  be non-negative integers that are each at most  $t$ , and denote  $u = u_1 + \dots + u_r$ . Then  $c(r, t) \binom{n}{v_1, \dots, v_r} \leq \binom{n-u}{v_1-u_1, \dots, v_r-u_r} \leq C(r, t) \binom{n}{v_1, \dots, v_r}$ .*

► **Lemma 39.** *For any positive integer  $r$ , there is a constant  $C(r) > 0$  such that the following holds for large enough  $n$ . Let  $v_1, \dots, v_r$  be integers of absolute value at most  $\sqrt{K \cdot r \cdot n}$  that sum to zero, and such that for every  $1 \leq i \leq r$ , the integer  $n + v_i$  is divisible by  $r$ . Then*

$$\frac{\binom{(n+v_1)/r, \dots, (n+v_r)/r}{2n}}{\binom{2(n+v_1)/r, \dots, 2(n+v_r)/r}} \leq C(r) 2^{Kr} r^{-n}.$$

Let  $A_1, \dots, A_r$  be a partition of  $[2n]$  into  $r$  even-sized sets. We say a mapping  $\pi \in S_{2n,n}$  is consistent with  $A_1, \dots, A_r$  if matching given by  $\pi$  matches off each set  $A_i$  within itself (or equivalently that  $\pi^{-1}(\pi(A_i)) = A_i$ ).

► **Lemma 40.** *Let  $A_1, \dots, A_r$  be a partition of  $[2n]$  into even-sized sets, and denote their sizes by  $a_1, \dots, a_r$ . Then  $\Pr_{\pi \in S_{2n,n}} [\pi \text{ is consistent with } A_1, \dots, A_r] = \frac{\binom{a_1}{2}, \dots, \binom{a_r}{2}}{\binom{2n}{2}}.$*

## Abstract

This paper tackles the issue of *checking* that all copies of a large data set replicated at several nodes of a network are identical. The fact that the replicas may be located at distant nodes prevents the system from verifying their equality locally, i.e., by having each node consult only nodes in its vicinity. On the other hand, it remains possible to assign *certificates* to the nodes, so that verifying the consistency of the replicas can be achieved locally. However, we show that, as the replicated data is large, classical certification mechanisms, including distributed Merlin-Arthur protocols, cannot guarantee good completeness and soundness simultaneously, unless they use very large certificates. The main result of this paper is a distributed *quantum* Merlin-Arthur protocol enabling the nodes to collectively check the consistency of the replicas, based on small certificates, and in a single round of message exchange between neighbors, with short messages. In particular, the certificate-size is logarithmic in the size of the data set, which gives an exponential advantage over classical certification mechanisms. We propose yet another usage of a fundamental quantum primitive, called the SWAP test, in order to show our main result.

## 1 Introduction

In the context of distributed systems, the presence of faults potentially corrupting the individual states of the nodes creates a need to regularly check whether the system is in a global state that is legal with respect to its specification. A basic example is a system storing data, and using replicas in order to support crash failures. In this case, the application managing the data is in charge of regularly checking that the several replicas of the same

data, stored at different nodes scattered in the network, are all identical. Another example is an application maintaining a tree spanning the nodes of a network, e.g., for multicast communication. In this case, every node stores a pointer to its parent in the tree, and the application must regularly check that the collection of pointers forms a spanning tree. This paper addresses the issue of checking the correctness of a distributed system configuration at low cost.

Several mechanisms have been designed for certifying the correctness of the global state of a system in a distributed manner. One popular mechanism is called *locally checkable proofs* [24], and it extends the seminal concept of *proof-labeling schemes* [35]. In these frameworks, the distributed application does not only construct or maintain some distributed data structure (e.g., a spanning tree), but also constructs a distributed *proof* that the data structure is correct. This proof has the form of a *certificate* assigned to each node (the certificates assigned to different nodes do not need to be the same). For collectively checking the legality of the current global system state, the nodes exchange their certificates with their neighbors in the network. Then, based on its own individual state, its certificate, and the certificates of its neighbors, every node accepts or rejects, according to the following specification. If the global state is legal, and if the certificates are assigned properly by the application, then all nodes accept. Conversely, if the global state is illegal, then at least one node rejects, *no matter which certificates are assigned to the nodes*. Such a rejecting node can raise an alarm, or launch a recovery procedure. The main aim of locally checkable proofs is to be *compact*, that is, to use certificates as small as possible, for two reasons: first, to limit the space complexity at each node, and, second, to limit the message complexity of the verification procedure involving communications between neighbors.

For instance, in the case of the Spanning Tree predicate, the application does not only construct a spanning tree  $T$  of the network, but also a distributed proof that  $T$  is indeed a spanning tree, i.e., that the collection  $T$  of pointers forms a cycle-free connected spanning subgraph. It has been known for long [2, 6, 26] that, by assigning to every node a certificate of logarithmic size, the nodes can collectively check whether  $T$  is indeed a spanning tree, in a single round of communication between neighboring nodes. The certificate assigned to a node is the identity of the root of the tree, and its distance to this root (both are of logarithmic size as long as the IDs are in a range polynomial in the number of nodes). Every node just checks that it is provided with the same root-ID as all its neighbors in the network, and that the distance given to its parent in its certificate is one less than its own given distance – a node with distance 0 checks that its ID is indeed the root-ID provided in its certificate. Obviously, if the collection  $T$  of pointers forms a spanning tree, and if the certificates are assigned properly by the application, then all nodes pass these tests, and accept. On the other hand, it is easy to check that if  $T$  is not a spanning tree (it is not connected, or it contains a cycle), then at least one node detects a discrepancy and rejects, no matter which certificates are assigned to the nodes.

Unfortunately, not all boolean predicates on labeled graphs can be distributedly certified using certificates as small as for spanning tree. This is typically the case of the aforementioned scenario of a distributed data storage using replicas, for which one must certify equality. Let us for instance consider the case of two nodes Alice and Bob at the two extremities of a path, that is, the two players are separated by intermediate nodes. Alice and Bob respectively store two  $n$ -bit strings  $x$  and  $y$ , and the objective is to certify that  $x = y$ . That is, one wants to certify equality (EQ) between *distant* players. A direct reduction from the non-deterministic communication complexity of EQ shows that certifying EQ cannot be achieved with certificates smaller than  $\Omega(n)$  bits.

Randomization may help circumventing the difficulty of certifying some boolean predicates on labeled graphs using small certificates. Hence, a weaker form of protocols has been considered, namely *distributed Merlin-Arthur* protocols (dMA), a.k.a. *randomized proof-labeling schemes* [22]. In this latter context, Merlin provides the nodes with a proof, just like in locally checkable proofs, and Arthur performs a *randomized* local verification at each node. Unfortunately, some predicates remain hard in this framework too. In particular, as we show in the paper, there are no classical dMA protocols for (distant) EQ using compact certificates. Recently, several extensions of dMA protocols were proposed, e.g., by allowing more interaction between the prover and the verifier [15, 21, 39]. In this work, we add the quantum aspect, while considering only a single interaction, and only in the prescribed order: Merlin sends a proof to Arthur, and then there is no more interaction between them.

## 1.1 Our Results

We carry on the recent trend of research consisting of investigating the power of quantum resources in the context of distributed network computing (cf., e.g., [17, 37, 27, 38, 28, 23]), by designing a distributed Quantum Merlin-Arthur (dQMA) protocol for distant EQ, using compact certificates and small messages. While we use the dQMA terminology in order to be consistent with prior work, we emphasize that the structure of the discussed protocols is rather simple: each node is given a quantum state as a certificate, the nodes exchange these states, perform a local computation, and finally accept or reject.

Our main result is the following. A collection of  $n$ -bit strings  $x_1, \dots, x_t$  are stored at  $t$  terminal nodes  $u_1, \dots, u_t$  in a network  $G = (V, E)$ , where node  $u_i$  stores  $x_i$ . We denote  $\text{EQ}_n^t$  the problem of checking the equality  $x_1 = \dots = x_t$  between the  $t$  strings. Let us define the *radius* of a given instance of  $\text{EQ}_n^t$  as  $r = \min_i \max_j \text{dist}_G(u_i, u_j)$ , where  $\text{dist}_G$  denotes the distance in the (unweighted) graph  $G$ . Our main result is the design of a dQMA protocol for  $\text{EQ}_n^t$ , using small certificate. This can be summarized by the following informal statement (the formal statement is in Section 5):

► **Main Result.** *There is a distributed Quantum Merlin-Arthur (dQMA) protocol for certifying equality between  $t$  binary strings ( $\text{EQ}_n^t$ ) of length  $n$ , and located at a radius- $r$  set of  $t$  terminals, in a single round of communication between neighboring nodes using certificates of size  $O(tr^2 \log n)$  qubits, and messages of size  $O(tr^2 \log(n + r))$  qubits.*

It is worth mentioning that, although the dependence in  $r$  and  $t$  is polynomial, the dependence in the actual size  $n$  of the instance remains logarithmic, which is our main concern. Indeed, for applications such as the aforementioned distributed data storage motivating the distant  $\text{EQ}_n^t$  problem, it is expected that both the number  $t$  of replicas, and the maximum distance between the nodes storing these replicas are of several orders of magnitude smaller than the size  $n$  of the stored replicated data.

It is also important to note that our protocol satisfies the basic requirement of *reusability*, as one aims for protocols enabling regular and frequent verifications that the data are not corrupted. Specifically, the quantum operations performed on the certificates during the local verification phase operated between neighboring nodes preserve the quantum nature of these certificates. That is, if  $\text{EQ}_n^t$  is satisfied, i.e., if all the replicas  $x_i$ 's are equal, then, up to an elementary local relocation of the quantum certificates, these certificates are available for a next test. If  $\text{EQ}_n^t$  is not satisfied, i.e., if there exists a pair of replicas  $x_i \neq x_j$ , then the certificates do not need to be preserved as this scenario corresponds to the case where the correctness of the data structure is violated, requiring the activation of recovery procedures for fixing the bug, and reassigning certificates to the nodes.

Our quantum protocol is based on the SWAP test [12], which is a basic tool in the theory of quantum computation and quantum information. This test allows to check if a quantum state is symmetric, and has several applications, such as estimating the inner product of two states (e.g., [12, 9, 47]), checking whether a given state (or a reduced state of it) is pure or entangled with the environment system (e.g., [1, 33, 25, 32]), and more. In this paper, we use the SWAP test in yet another way: *for checking if two of the reduced states of a given state are close*. A similar use was done by Rosgen [44] in a different context – transforming quantum circuits to shallow ones in a hardness reduction proof.

Finally, observe that our logarithmic upper bound for dQMA protocols is in contrast to the linear lower bound that can be shown for classical dMA protocols even for  $t = 2$  on a path of 4 nodes and even for the case where communication between the neighboring nodes is extended to multiple rounds (see precise statement and proof in Section 6). Our results thus show that quantum certification mechanism can provide an exponential advantage over classical certification mechanisms.

## 1.2 Related Work

The concept of distributed proofs is a part of the framework of distributed network computing since the early works on fault-tolerance (see, e.g., [2, 6, 26]). Proof-labeling schemes were introduced in [35], and variants have been studied in [24, 20]. Randomized proof-labeling schemes have been studied in [22]. Extensions of distributed proofs to a hierarchy of decision mechanisms have been studied in [18] and [7]. Frameworks like cloud computing recently enabled envisioning systems in which the nodes of the network could interact with a third party, leading to the concept of *distributed interactive proofs* [34]. There, each node can interact with an *oracle* who has a complete view of the system, is computationally unbounded, but is not trustable. For instance, in Arthur-Merlin (dAM) protocols, the nodes start by querying the oracle Merlin, which provides them with answers in their certificates. There is a simple classical compact dAM protocol for distant EQ, where the two players stand at the extremities of a path (see Section 3). We refer to [15, 21, 39] for recent developments in the framework of distributed interactive proofs. While distributed Arthur-Merlin protocols and their extensions provide an appealing theoretical framework for studying the power of interactive proofs in the distributed setting, the practical implementation of such protocols remains questionable, since they all require the existence of a know-all oracle, Merlin, and it is unclear if a Cloud could play this role. On the other hand, in dMA and dQMA protocols, interaction with an external party is not required, but only a one-time assignment of certificates is needed, which are then reusable for regular verification. As in the classical proof-labeling schemes setting, these certificates can actually be *created* by the nodes themselves during a pre-processing phase, making the reliance on a know-all oracle unnecessary.

After a few early works [8, 17, 23, 45] that shed light on the potential and limitations of quantum distributed computing (see also [5, 11, 16] for general discussions), evidence of the advantage of quantum distributed computing over classical distributed computing have been obtained recently for three fundamental models of (synchronous fault-free) distributed network computing: the CONGEST model [28, 37], the CONGEST-CLIQUE model [27] and the LOCAL model [38]. The present paper adds to this list another important task for which quantum distributed computing significantly outperforms classical distributed computing, namely, distributed certification.

Note that while this paper is the first to study quantum Merlin-Arthur protocols in a distributed computing framework, there are a number of prior works studying them in communication complexity [43, 30, 31, 10]. In particular, quantum Merlin-Arthur protocols

are shown to improve some computational measure (say, the total length of the messages from the prover to Alice, and of the messages between Alice and Bob) exponentially compared to Merlin-Arthur protocols where the messages from the prover are classical [43, 31].

The question of computing functions on inputs that are given to graph nodes was also studied in the context of communication complexity. The equality function was studied for the case where all nodes have inputs [4]. Other works considered a setting similar to ours, i.e., where only some nodes have inputs [13, 14], but did not study the equality problem.

## 2 Model and Definitions

**Distributed verification on graphs.** Let  $t \geq 2$ , and let  $f: (\{0, 1\}^n)^t \rightarrow \{0, 1\}$  be a function. The aim of the nodes is to collectively decide whether  $f(x_1, \dots, x_t) = 1$  or not, where  $x_1, \dots, x_t$  are assigned to  $t$  nodes of a graph. Specifically, an instance of the problem  $f$  is a  $t$ -tuple  $(x_1, \dots, x_t) \in \{0, 1\}^n \times \dots \times \{0, 1\}^n$ , a connected graph  $G = (V, E)$ , and an ordered sequence  $v_1, \dots, v_t$  of distinct nodes of  $G$ . The node  $v_i$  is given  $x_i$  as input, for  $i = 1, \dots, t$ . All the other nodes receive no inputs. We consider distributed Merlin-Arthur (dMA) protocols for deciding whether  $f(x_1, \dots, x_t) = 1$ , in which a non-trustable *prover* (Merlin) assigns (or “sends”) *certificates* to the nodes, and then the nodes (Arthur) perform a 1-round randomized verification algorithm. The verification algorithm consists of each node simultaneously sending messages to all its immediate neighbors, receiving messages from them, then performing a local computation, and finally accepting or rejecting locally.<sup>1</sup> We say that a dMA protocol has *completeness*  $a$  and *soundness*  $b$  for a function  $f$  if the following holds for every  $(x_1, \dots, x_t) \in \{0, 1\}^n \times \dots \times \{0, 1\}^n$ , every connected graph  $G$ , and every ordered sequence  $v_1, \dots, v_t$  of distinct nodes in  $G$ :

- (**completeness**) if  $f(x_1, \dots, x_t) = 1$ , then the prover can assign certificates to the nodes such that  $\Pr[\text{all nodes accept}] \geq a$ ;
- (**soundness**) if  $f(x_1, \dots, x_t) = 0$ , then, for every certificate assignment by the prover,  $\Pr[\text{all nodes accept}] \leq b$ .

The completeness condition guarantees that, when the system is in a “legal” state (specified by  $f(x_1, \dots, x_t) = 1$ ), with probability at least  $a$  all nodes accept. The soundness condition guarantees that, when the system is in an “illegal” state (specified by  $f(x_1, \dots, x_t) = 0$ ), with probability at least  $1 - b$  at least one node rejects. The value  $b$  represents the error probability of the protocol on an illegal instance, and thus we sometimes refer to it as the *soundness error*. A node detecting illegality of the state can raise an alarm, or launch a recovery procedure. Protocols with completeness 1 are called 1-sided protocols, or protocols with perfect completeness. Similarly to prior works on distributed verification, the certificate size of the protocol is measured as the maximum size (over all the nodes of the network) of the certificate sent by the prover to one of the nodes, and the message size of the protocol is measured as the maximum size (over all pairs of adjacent nodes) of the message exchanged between two adjacent nodes. Specifically, we will consider the multi-party version of the equality function,  $\text{EQ}_n^t$ , which is the boolean-valued function from  $(\{0, 1\}^n)^t$  such that  $\text{EQ}_n^t(x_1, \dots, x_t) = 1 \iff x_1 = \dots = x_t$ .

<sup>1</sup> We can naturally extend this definition to define dMA protocols with  $\mu$  rounds of communication among neighbors, for any integer  $\mu \geq 1$ . In this paper, however, we focus on the case  $\mu = 1$  since all the protocols we design use only 1-round verification algorithms. The only exception is Section 6, where we show classical lower bounds that hold even for  $\mu > 1$ .

In this work, we extend the framework of dMA protocols, to consider also cases where the certificates given to the nodes can contain qubits (although they may also contain classical bits) and the nodes can exchange messages consisting of qubits. These will be called *distributed Quantum Merlin-Arthur* (dQMA) protocols. More precisely, in a dQMA protocol for a function  $f$ , a non-trustable prover first sends a certificate to each node, which consists of a quantum state and classical bits; the quantum states may be entangled, even though all our quantum protocols do not require any prior entanglement, nor any shared classical random bits. Then the nodes perform a 1-round quantum verification algorithm, where each node simultaneously sends a quantum message to all its immediate neighbors, receives quantum messages from them, then performs a local computation, and finally accepts or rejects locally. Note that, as opposed to the classical setting, we cannot assume that a node simply broadcasts its certificate to all its neighbors, as quantum states cannot be duplicated. However, a node can still send copies of the classical parts of the certificate. We define completeness and soundness of dQMA protocols as for dMA protocols.

► **Remark.** A special case of interest is when the graph  $G$  is a path  $v_0, \dots, v_r$ ,  $r \geq 1$ , where the left-end node  $v_0$  has an  $n$ -bit string  $x$  as input, the right-end node  $v_r$  has an  $n$ -bit string  $y$  as input, and the intermediate nodes  $v_1, \dots, v_{r-1}$  have no inputs. That is,  $t = 2$ . Given a function  $f: \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$ , the aim of the nodes is to collectively decide whether  $f(x, y) = 1$  or not. This setting is very much related to communication complexity.

**Classical two-party communication complexity.** We refer to [36] for the basic concepts of two-party communication complexity. In this paper we will only consider two-party one-way communication complexity. In this model two parties, denoted Alice and Bob, each receives an input  $x \in \{0, 1\}^n$  and  $y \in \{0, 1\}^n$ , respectively. The goal is for Bob to output the value  $f(x, y)$  for some known Boolean function  $f: \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$ . Only Alice can send a message to Bob. The one-way two-sided-error communication complexity of  $f$  is the minimum number of bits that have to be sent on the worst input in a protocol that outputs the correct answer with probability at least  $2/3$ . The one-way one-sided-error communication complexity of  $f$  is the minimum number of bits that have to be sent on the worst input in a protocol that outputs the correct answer with probability 1 on any 1-input, and outputs the correct answer with probability at least  $2/3$  on any 0-input.

We shall especially consider the following two functions. The equality function  $\text{EQ}_n$  is defined as  $\text{EQ}_n(x, y) = 1$  when  $x = y$  and  $\text{EQ}_n(x, y) = 0$  otherwise, for any  $x, y \in \{0, 1\}^n$ . Its one-way one-sided-error communication complexity is  $O(\log n)$  – see, e.g., [36]. For any integer  $d \geq 0$ , the Hamming distance function  $\text{HAM}_n^d$  is defined as follows: for any  $x, y \in \{0, 1\}^n$ ,  $\text{HAM}_n^d(x, y) = 1$  if the Hamming distance between  $x$  and  $y$  is at most  $d$ , and  $\text{HAM}_n^d(x, y) = 0$  otherwise. It is known [47] that, for  $d$  constant, the one-way two-sided-error communication complexity of  $\text{HAM}_n^d$  is  $O(\log n)$ .

For any Boolean function  $f: \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$ , a set  $S \subseteq \{0, 1\}^n \times \{0, 1\}^n$  is a *1-fooling set* for  $f$  if, on the one hand, for every  $(x, y) \in S$ ,  $f(x, y) = 1$ , and, on the other hand, for every two pairs  $(x_1, y_1) \neq (x_2, y_2)$  in  $S \times S$ ,  $f(x_1, y_2) = 0$  or  $f(x_2, y_1) = 0$ .

**Quantum two-party communication complexity.** We assume the reader is familiar with the basics of quantum computation, in particular the notion of qubits, Dirac notation such as  $|\psi\rangle$  and  $\langle\psi| := (|\psi\rangle)^\dagger$ , and the quantum circuit model (see Sections 2 and 4 in Ref. [40], for instance). In the full version of this paper, we present more advanced concepts such as mixed states that will be used in some of our proofs.

Quantum two-party communication complexity, first introduced by Yao [46], is defined

similarly to the classical version. The only difference is that the players are allowed to exchange qubits instead of bits (the cost of a quantum protocol is the number of qubits sent by the protocol). Note that since quantum protocols can trivially simulate classical protocols, the quantum communication complexity of a function is never larger than its classical communication complexity. More precisely, an  $m$ -qubit one-way quantum protocol  $\pi$  for the function  $f$  can be described in its most general form as follows. Alice prepares an  $m$ -qubit (pure) quantum state  $|h_x\rangle$  and sends it to Bob.<sup>2</sup> Bob then makes a measurement on the state  $|h_x\rangle$ , which gives an outcome  $b \in \{0, 1\}$ . Finally, Bob outputs  $b$ . Since Bob's measurement in the above description depends only on his input  $y$ , it can be mathematically described, for each  $y \in \{0, 1\}^n$ , by two positive semi-definite matrices  $M_{y,0}$  and  $M_{y,1}$  such that  $M_{y,0} + M_{y,1} = I$ . This pair  $\{M_{y,0}, M_{y,1}\}$  is called a POVM measurement (POVM measurements are the most general form of measurements allowed by quantum mechanics). If  $|h_x\rangle$  is measured by the POVM  $\{M_{y,0}, M_{y,1}\}$ , the probability that  $b = 0$  is  $\text{tr}(M_{y,0}(|h_x\rangle\langle h_x|))$ , while the probability that  $b = 1$  is  $\text{tr}(M_{y,1}(|h_x\rangle\langle h_x|))$ .

### 3 General Overview of our Techniques

Let us provide an intuition of our protocol in the case of  $\text{EQ}_n^2$  over a path  $v_0, \dots, v_r$  of length  $r \geq 1$  in which the terminals are the two nodes  $v_0$  and  $v_r$  (that we rename Alice and Bob, for convenience). Let us call  $x$  and  $y$  the  $n$ -bit strings owned by Alice and Bob, respectively. There is a simple classical protocol for distant equality in a somewhat similar setting, where the verifier (Arthur, consisting of all the graph nodes) can send random bits to the prover (Merlin) before receiving the certificates; this is called a **dAM** protocol. In this protocol, Alice picks a hash function  $h$  at random in an appropriate family of hash functions (i.e., a family such that both  $h$  and  $h(x)$  can be encoded using  $O(\log n)$  bits and such that the probability that  $h(x) \neq h(y)$  is high when  $x \neq y$ ). Merlin provides every node with the certificate  $(h, h(x))$ , each node checks it received the same certificates as its neighbors, and Bob additionally checks whether  $h(x) = h(y)$ . Obviously, one cannot switch the order of Arthur and Merlin, as letting Merlin choose the hash function would enable him to fool Arthur on illegal instances by picking  $h$  that hashes identically the distinct input strings  $x$  and  $y$ . The main idea of our **dQMA** protocol is to ask Merlin to provide the nodes with a quantum certificate consisting of the *quantum superposition* of all the possible hashes.

Entering slightly more into the details, for any  $x \in \{0, 1\}^n$  we consider the *quantum fingerprint*  $|h_x\rangle = \frac{1}{\sqrt{K}} \sum_h |h\rangle |h(x)\rangle$ , where the sum is over all the hash functions, and  $\frac{1}{\sqrt{K}}$  is the normalization factor of the quantum state. By using the same family of hash functions as in the aforementioned **dAM** protocol, these fingerprints can be constructed in such a way that their length is  $O(\log n)$  qubits, and  $|h_x\rangle$  and  $|h_y\rangle$  are very far (more precisely, almost orthogonal) when  $x \neq y$ . Checking whether the two quantum fingerprints  $|h_x\rangle$  and  $|h_y\rangle$  are either equal or far apart can be achieved by a quantum test called the **SWAP** test [12]. Formally, the probability that the **SWAP** test accepts is  $1/2 + |\langle h_x | h_y \rangle|^2 / 2$ , where  $\langle h_x | h_y \rangle$  denotes the inner product between the two quantum states  $|h_x\rangle$  and  $|h_y\rangle$ .

Let us now describe the outline of our **dQMA** protocol. In the protocol each intermediate node  $v_1, \dots, v_{r-1}$  expects to receive the quantum fingerprint  $|h_x\rangle$ . Alice, who does not receive any certificate, creates by herself the fingerprint  $|h_x\rangle$ , which depends only on  $x$ . Similarly, Bob creates by himself the fingerprint  $|h_y\rangle$ . The checking procedure simply checks whether

<sup>2</sup> Without loss of generality, we assume that Alice does not use any mixed state (i.e., a probability distribution on pure states) in her message, as she can simulate it using a pure state called the *purification* [40] whose length is at most twice the one of the mixed state.

all these  $(r + 1)$  fingerprints are equal. This is done by applying the SWAP test to check whether the fingerprints owned by adjacent nodes are equal or not. There are however a few subtleties. In particular, since our analysis crucially requires that the SWAP tests do not overlap, for each node we need to decide whether it will perform the SWAP test with its right neighbor or its left neighbor. We do it in a randomized way and deal carefully with the conflicting choices that appear. For the case  $x = y$  all the SWAP tests then succeed with probability 1 and thus all the nodes accept.

For the case  $x \neq y$ , let us provide some intuition about why a prover cannot fool the nodes for convincing them to all accept. To simplify the description we assume below that  $|h_x\rangle$  and  $|h_y\rangle$  are orthogonal (instead of only almost orthogonal). If the prover was forced to send certificates restricted to *product states* of the form  $|g_1\rangle \otimes |g_2\rangle \otimes \cdots |g_{r-1}\rangle$  where  $|g_j\rangle$  is the state to the  $j$ th node, then a fairly straightforward argument would guarantee that, with large probability, at least one node rejects. Indeed, under the product states restriction, intuitively the best strategy for the prover to cheat is to send states “intermediate” between  $|h_x\rangle$  and  $|h_y\rangle$ , namely, to send the state  $|g_j\rangle = \cos(\pi j/2r)|h_x\rangle + \sin(\pi j/2r)|h_y\rangle$  to node  $v_j$  for each  $j \in \{1, \dots, r-1\}$ . Then, the probability that all nodes accept when performing the SWAP tests would be roughly  $\prod_{j=1}^{r-1} (1/2 + |\langle g_j | g_{j+1} \rangle|^2/2) = 1 - \Omega(1/r)$ . The cheating prover could then be caught with probability  $\Omega(1/r)$ , and this probability can be amplified to  $\Omega(1)$  by asking the prover to send several copies of the certificates (amplification is possible since our protocol has perfect completeness).

The formal analysis of the protocol however faces several difficulties, which are mostly due to the nature of quantum computation, and are especially challenging to handle in the framework of distributed computation. For instance, quantum states cannot be duplicated (the “no-cloning Theorem”), which implies that a same quantum state cannot be used for parallel tests. Additionally, even sequential tests face the difficulty that the first test may collapse the quantum state, making the second test impossible to perform (or at least significantly complicating the analysis of the second test). Thus node  $v_i$  cannot perform the SWAP test with its two neighbors  $v_{i-1}$  and  $v_{i+1}$  simultaneously and (as already mentioned) we have to design carefully the protocol so that the SWAP tests do not overlap. A second, and much more problematic issue is that the non-trustable Merlin can send arbitrary certificates to the nodes for fooling them. In particular it is not restricted to send certificates that are product states. A priori, it may seem that the SWAP test is not strong enough to handle fooling strategies beyond product states. In this work we show that the SWAP test can actually detect such fooling strategies.

Specifically, our approach consists in considering the so-called *reduced states*, and to establish the following property of the SWAP test (cf. Lemma 5 in Section 4). If the SWAP test accepts with high probability when applied on the part of any two adjacent nodes in a (possibly non-product) global quantum state resulting from the certificates, then the two reduced states of that part (which is a bipartite state) must be close. As the two states  $|h_x\rangle$  and  $|h_y\rangle$  are very far apart when  $x \neq y$ , we can thus use this result to show that there is a good probability that the SWAP test rejects at some node. Moreover, using reduced states allows us to overcome other technical difficulties in the analysis of the (non-overlapping) SWAP tests we consider. Indeed, some form of average-case success probability of all the SWAP tests can be considered, instead of having to argue about the probability that all the SWAP tests individually accept.

## 4 Quantum Distributed Proofs on Paths

In this section we restrict ourselves to the case of a path  $v_0, \dots, v_r$  of length  $r \geq 1$ , in which only the two extremities  $v_0$  and  $v_r$  are given inputs. This framework allows us to elaborate our main technique, that will be extended to arbitrary graphs in Section 5. Let  $x \in \{0, 1\}^n$  be the input to  $v_0$ , and  $y \in \{0, 1\}^n$  be the input to  $v_r$ . Our goal is to design a dQMA protocol to decide whether  $f(x, y) = 1$  or not, for some given Boolean function on  $\{0, 1\}^n \times \{0, 1\}^n$ .

We show the following general theorem that converts a one-way quantum communication complexity protocol into a quantum Merlin-Arthur protocol for the corresponding long-distance problem on the path. This theorem applies not only to one-sided-error protocols, but also to the two-sided-error case (with a logarithmic additional factor in the complexity).

► **Theorem 1.** *Let  $f: \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  be a Boolean function.*

- *If  $f$  has a quantum one-way one-sided-error communication protocol transmitting at most  $q$  qubits, then there exists a 1-sided distributed quantum Merlin-Arthur protocol for  $f$  on the path of length  $r$ , with soundness  $1/3$ , using certificates of size  $O(r^2 q)$  qubits, and exchanging messages of length  $O(r^2(q + \log r))$  qubits.*
- *If  $f$  has a quantum one-way two-sided-error communication protocol transmitting at most  $q$  qubits, then, for any constant  $c$ , there exists a distributed quantum Merlin-Arthur protocol for  $f$  on the path of length  $r$  with completeness  $1 - 1/n^c$ , soundness  $1/3$ , using certificates of size  $O(r^2 q \log(n + r))$  qubits, and exchanging messages of length  $O(r^2 q \log(n + r))$  qubits.*

Using known results (cf. Section 2) about one-way communication complexities of  $\text{EQ}_n$  and  $\text{HAM}_n^d$ , the following two results are direct applications of Theorem 1.

► **Corollary 2.** *There exists a one-sided quantum Merlin-Arthur protocol for  $\text{EQ}_n$  in the path of length  $r$  with soundness  $1/3$ , using certificates of size  $O(r^2 \log n)$  qubits, and exchanging messages of length  $O(r^2 \log(n + r))$  qubits.<sup>3</sup>*

► **Corollary 3.** *For any  $c > 0$  and  $d > 0$ , there exists a quantum Merlin-Arthur protocol for  $\text{HAM}_n^d$  in the path of length  $r$  with completeness  $1 - 1/n^c$ , soundness  $1/3$ , using certificates of length  $O(r^2(\log n) \log(n + r))$  qubits, and exchanging messages of length  $O(r^2(\log n) \log(n + r))$  qubits.*

The rest of this section is dedicated to proving Theorem 1. Let us first give an overview of the proof. In our dQMA protocol in the path, the verification algorithm performed by the nodes on the line is merely a simulation of a two-party one-way quantum communication complexity protocol  $\pi$  between Alice and Bob for the function  $f(x, y)$ , with the help of certificates provided by the prover. Specifically, every intermediate node  $v_1, \dots, v_{r-1}$  expects to receive the quantum state sent by Alice to Bob in  $\pi$ , as certificate. Let us denote by  $|h_x\rangle$  this state, which depends on  $x$ . The right-end node  $v_r$  simulates the two-party protocol  $\pi$  using  $|h_x\rangle$  received from the left neighbor  $v_{r-1}$ , and applying Bob's measurement (i.e., the POVM measurement). If  $f(x, y) = 1$ , the prover honestly sends the desired state, and  $v_r$  accepts as it does receive  $|h_x\rangle$ . However, if  $f(x, y) = 0$ , then the malicious prover does not necessarily send a desired state. To catch the potentially malicious behavior of the prover on “illegal” instances (i.e., those for which  $f(x, y) = 0$ ), each intermediate node checks whether its local proof is “close to” the one of its right neighbor. This is performed by an application of the SWAP test.

<sup>3</sup> Here we are using the fact that  $\log n + \log r$  is of the same order as  $\log(n + r)$  for conciseness.

Section 4.1 below describes in more detail how to construct the distributed quantum Merlin-Arthur protocol, denoted  $\mathcal{P}_\pi$ , from an arbitrary one-way quantum communication protocol  $\pi$  for the function  $f$ . Section 4.2 analyzes the completeness and the soundness of the protocol  $\mathcal{P}_\pi$ . Finally, Section 4.3 shows how to reduce the soundness error using “parallel repetitions” and how to apply this analysis to prove Theorem 1.

#### 4.1 A dQMA Protocol for the Path

Let  $\varepsilon \geq 0$  be a constant, which will be fixed small enough later in the proof. Let  $\pi$  be a quantum one-way communication protocol for  $f$  transmitting at most  $q$  qubits, such that, for every input pair  $(x, y)$ , if  $f(x, y) = 1$  then  $\pi$  outputs 1 with probability at least  $1 - \varepsilon$ , and if  $f(x, y) = 0$  then  $\pi$  outputs 0 with probability at least  $2/3$ . Let  $|h_x\rangle$  be the  $q$ -qubit (pure) state sent from Alice to Bob, and let  $\{M_{y,1}, M_{y,0}\}$  be the POVM measurement performed by Bob on  $|h_x\rangle$ , where  $M_{y,1}$  corresponds to the measurement result 1 (accept) and  $M_{y,0}$  to the measurement result 0 (reject). Our quantum Merlin-Arthur protocol  $\mathcal{P}_\pi$  is as follows.

**Protocol  $\mathcal{P}_\pi$  for function  $f$  on input pair  $(x, y)$  in path  $v_0, \dots, v_r$ :**

1. If  $f(x, y) = 1$  then the prover sends the quantum register  $R_j$  that has the state  $|h_x\rangle$  (or  $|h_x\rangle\langle h_x|$  as the mixed state representation) as certificate to each of the intermediate nodes  $v_j$ ,  $j \in \{1, \dots, r-1\}$ .
2. The left-end node  $v_0$  prepares the state  $\rho_0 = |h_x\rangle\langle h_x|$  in quantum register  $R_0$ .
3. For every  $j = 0, \dots, r-1$ , the node  $v_j$  chooses a bit  $b_j$  uniformly at random, and sends its quantum register  $R_j$  to the right neighbor  $v_{j+1}$  whenever  $b_j = 0$ .
4. For every  $j = 1, \dots, r-1$ , if  $v_j$  receives a quantum register from its left neighbor  $v_{j-1}$ , and if  $b_j = 1$ , then  $v_j$  performs the SWAP test on the registers  $(R_{j-1}, R_j)$ , and accepts or rejects accordingly; Otherwise,  $v_j$  accepts.
5. If the right-end node  $v_r$  receives a quantum register  $R_{r-1}$  from its left neighbor, then  $v_r$  performs the POVM measurement  $\{M_{y,1}, M_{y,0}\}$  corresponding to  $\pi$  applied to the state in  $R_{r-1}$ , and accepts or rejects accordingly; Otherwise,  $v_r$  accepts.

In the above protocol  $\mathcal{P}_\pi$ , the size of the quantum certificate that each node receives from the prover is at most  $q$ , and the length of the quantum message that each node sends to the neighbor is also at most  $q$ . In the next subsection, we prove that the above protocol has completeness  $1 - \varepsilon/2$  and soundness  $1 - 1/42r^2$ .

#### 4.2 Analysis of Protocol $\mathcal{P}_\pi$

For the analysis, we recall the SWAP test. The test is a protocol with a given input state on  $\mathcal{H} = \mathcal{H}_1 \otimes \mathcal{H}_2$ , where  $\mathcal{H}_1$  and  $\mathcal{H}_2$  are complex Euclidian spaces. Here, we consider  $\mathcal{H}_1$  and  $\mathcal{H}_2$  as quantum registers  $R_1$  and  $R_2$ .

**SWAP test** on a pure state  $|\psi\rangle$  on  $\mathcal{H}$ , which is given in registers  $(R_1, R_2)$ .

1. Prepare the single-qubit state  $|+\rangle = \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)$  in register  $R_0$ .
2. If the content of  $R_0$  is 1, then apply the swap operator  $S$  on the state  $|\psi\rangle$  in registers  $(R_1, R_2)$ , where  $S$  is defined by  $S(|j_1\rangle|j_2\rangle) = |j_2\rangle|j_1\rangle$  (namely,  $S$  swaps register  $R_1$  and register  $R_2$ ).
3. Apply the Hadamard operator  $H = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$  on the state in register  $R_0$ , and measure the content in the standard basis. Accept if the content is 0, and reject otherwise.

**Completeness.** The following lemma is a direct consequence of the definition of the SWAP test. Here,  $\mathcal{H}_S$  is the symmetric subspace in  $\mathcal{H}$  (namely, the subspace spanned by the states invariant by the swap operator  $S$ , or equivalently, the eigenstates of  $S$  with eigenvalue 1), and  $\mathcal{H}_A$  is the anti-symmetric subspace in  $\mathcal{H}$  (namely, the subspace spanned by the eigenstates of  $S$  with eigenvalue  $-1$ ). Note that any state in  $\mathcal{H}$  is represented as the superposition of a state in  $\mathcal{H}_S$  (symmetric state) and a state in  $\mathcal{H}_A$  (anti-symmetric state) as the swap operator  $S$  is a Hermitian matrix that only has  $+1$  and  $-1$  eigenvalues.

► **Lemma 4.** *Assume that  $|\psi\rangle = \alpha|\psi_S\rangle + \beta|\psi_A\rangle$  where  $|\psi_S\rangle \in \mathcal{H}_S$  and  $|\psi_A\rangle \in \mathcal{H}_A$ . Then, the SWAP test on input  $|\psi\rangle$  accepts with probability  $|\alpha|^2$ .*

For the completeness, assume  $f(x, y) = 1$ . The prover then sends  $|h_x\rangle$  to all the intermediate nodes. Then, all the nodes except the right-end node have  $|h_x\rangle$ . By Lemma 4, all the SWAP tests done in Step 4 are accepted with probability 1 (note that  $|h_x\rangle \otimes |h_x\rangle$  is a symmetric state). Furthermore, the right-end node accepts with probability at least  $(1 - \varepsilon)/2 + 1/2 = 1 - \varepsilon/2$  as  $v_r$  can receive  $|h_x\rangle$  and simulate  $\pi$  with probability  $1/2$  and accepts otherwise in Step 5.

**Soundness.** The following lemma presents a crucial property of the SWAP test: its applicability for checking whether the two *reduced* states are close. It is a trace-distance version of a lemma by Rosgen [44, Lemma 5.1]. Here, a reduced state intuitively represents the local information on its own quantum system, by disregarding the outside systems. Note that the trace distance between two quantum states  $\rho$  and  $\sigma$  is characterized as  $\text{dist}(\rho, \sigma) = \max_M \text{tr}(M(\rho - \sigma))$ , where the maximization is taken over all positive semi-definite matrices  $M$  such that  $M \leq I$ .

► **Lemma 5.** *Let  $z \geq 1$ , and assume that the SWAP test on input  $\rho$  in the input register  $(R_1, R_2)$  accepts with probability  $1 - 1/z$ . Then,  $\text{dist}(\rho_1, \rho_2) \leq 2/\sqrt{z} + 1/z$ , where  $\rho_j$  is the reduced state on  $R_j$  of  $\rho$ . Moreover, if the SWAP test on input  $\rho$  accepts with probability 1, then  $\rho_1 = \rho_2$  (and hence  $\text{dist}(\rho_1, \rho_2) = 0$ ).*

For the soundness, let  $(x, y)$  be any pair such that  $f(x, y) = 0$ .

► **Lemma 6.** *For every  $j \in \{1, \dots, r\}$ , let  $F_j$  be the event that  $v_j$  performs the local test (SWAP or POVM) in Protocol  $\mathcal{P}_\pi$ , and let  $E_j$  be the event that this local test rejects. Then we have  $\sum_{j=1}^r \Pr[E_j | F_j] \geq \frac{1}{2^{1/r}}$ .*

**Proof.** Let  $\alpha_j = \Pr[E_j | F_j]$ . Then, for every  $j \in \{1, \dots, r\}$ ,  $\Pr[\overline{E_j} | F_j] = 1 - \alpha_j$ , where we note that the complementary event  $\overline{E_j}$  for  $j = 1, \dots, r-1$  is the event where the SWAP test on the two  $q$ -qubit states  $\rho_{j-1}$  and  $\rho_j$  accepts, and  $\overline{E_r}$  represents the event that the result of the POVM measurement is 1 (accept), which corresponds to the POVM element  $M_{y,1}$ . By Lemma 5, the trace distance  $\text{dist}$  between the reduced  $q$ -qubit states  $\rho_{j-1}$  on  $v_{j-1}$  and  $\rho_j$  on  $v_j$  is

$$\text{dist}(\rho_{j-1}, \rho_j) \leq \begin{cases} \frac{2}{\sqrt{1/\alpha_j}} + \frac{1}{1/\alpha_j} & \text{if } \alpha_j \neq 0 \\ 0 & \text{otherwise} \end{cases}$$

and thus  $\text{dist}(\rho_{j-1}, \rho_j) \leq 3\sqrt{\alpha_j}$ . Then, by the triangle inequality,

$$\text{dist}(\rho_0, \rho_{r-1}) \leq \sum_{j=1}^{r-1} \text{dist}(\rho_{j-1}, \rho_j) \leq 3 \sum_{j=1}^{r-1} \sqrt{\alpha_j}.$$

## 28:12 Distributed Quantum Proofs for Replicated Data

For  $\Pr[E_r|F_r]$ , the soundness of  $\pi$  promises that the probability that the test  $\{M_{y,1}, M_{y,0}\}$  rejects  $\rho_0 = |h_x\rangle\langle h_x|$  is at least  $2/3$ , i.e.,  $\text{tr}(M_{y,0}\rho_0) \geq 2/3$ . Hence,

$$\alpha_r = \Pr[E_r|F_r] = \text{tr}(M_{y,0}\rho_{r-1}) \geq \frac{2}{3} - \text{dist}(\rho_0, \rho_{r-1}) \geq \frac{2}{3} - 3 \sum_{j=1}^{r-1} \sqrt{\alpha_j},$$

where the first inequality comes from the characterization of  $\text{dist}$  on indistinguishability of two states, that is,  $|\text{tr}(M_{y,0}\rho_0) - \text{tr}(M_{y,0}\rho_{r-1})| \leq \text{dist}(\rho_0, \rho_{r-1})$ . Thus, we have

$$3 \sum_{j=1}^r \sqrt{\alpha_j} \geq \alpha_r + 3 \sum_{j=1}^{r-1} \sqrt{\alpha_j} \geq \frac{2}{3}.$$

By the Cauchy-Schwarz inequality,

$$\sqrt{r} \sqrt{\sum_{j=1}^r \alpha_j} \geq \sum_{j=1}^r \sqrt{\alpha_j},$$

and thus we have

$$\sum_{j=1}^r \alpha_j \geq \left( \frac{2}{9\sqrt{r}} \right)^2 \geq \frac{1}{21r}. \quad \blacktriangleleft$$

In Steps 4 and 5, node  $v_j$ ,  $1 \leq j \leq r$ , performs the local test (SWAP or POVM) with probability at least  $1/4$  (more precisely,  $v_j$ ,  $1 \leq j \leq r-1$ , performs the SWAP test with probability  $1/4$  and  $v_r$  performs the POVM with probability  $1/2$ ). It follows that, for every  $j \in \{1, \dots, r\}$ , the event  $F_j$  occurs in at least  $(1/4) \times 2^r$  outcomes of all the  $2^r$  possible outcomes  $b_0 \cdots b_{r-1}$  that can be obtained in Step 3. Here, we consider any fixed outcomes  $b_0 \cdots b_{r-1}$  that induce  $k$  events  $F_{j_1}, F_{j_2}, \dots, F_{j_k}$  with  $k \neq 0$  where we note that  $0 \leq k \leq \lfloor r/2 \rfloor$  in general. The probability that some node rejects in Steps 4 or 5 *under this outcome* is

$$\Pr[\vee_{t=1}^k E_{j_t} | \wedge_{i'=1}^k F_{j_{i'}}] \geq \frac{1}{\lfloor r/2 \rfloor} \sum_{i=1}^k \Pr[E_{j_i} | \wedge_{i'=1}^k F_{j_{i'}}] = \frac{1}{\lfloor r/2 \rfloor} \sum_{i=1}^k \Pr[E_{j_i} | F_{j_i}],$$

where the inequality follows from  $k \Pr[\vee_{t=1}^k E_{j_t}] = \sum_{i=1}^k \Pr[\vee_{t=1}^k E_{j_t}] \geq \sum_{i=1}^k \Pr[E_{j_i}]$  and  $k \leq \lfloor r/2 \rfloor$ , and the equality comes from the fact that each  $F_{j_i}$  and  $E_{j_i}$  are independent from all the other event  $F_{j_{i'}}$  with  $i' \neq i$  (note that  $|j_{i'} - j_i| \geq 2$  since  $F_{j-1}$  and  $F_j$  never occur at the same time). As each outcome occurs with probability  $1/2^r$ , the probability that some node rejects in Steps 4 or 5 is at least

$$\frac{1}{2^r} \cdot [(1/4) \cdot 2^r] \cdot \frac{1}{\lfloor r/2 \rfloor} \sum_{j=1}^r \Pr[E_j | F_j] \geq \frac{1}{2^r} \sum_{j=1}^r \Pr[E_j | F_j] \geq \frac{1}{2^r} \cdot \frac{1}{21r} = \frac{1}{42r^2},$$

where the second last inequality comes from Lemma 6.

### 4.3 Proof of Theorem 1

So far, we have shown that the protocol  $\mathcal{P}_\pi$  has a completeness parameter very close to 1, but high soundness error. To establish Theorem 1, we need to reduce the soundness error without degrading the completeness too much. This is achieved via a form of parallel repetition of  $\mathcal{P}_\pi$ , by taking the logical conjunction of the outputs obtained by repetitions. The protocol resulting from  $k$  repetitions of  $\mathcal{P}_\pi$  is denoted by  $\mathcal{P}_\pi[k]$ , and works as follows.

**Protocol  $\mathcal{P}_\pi[k]$ : Soundness reduction of Protocol  $\mathcal{P}_\pi$** 

1. If  $f(x, y) = 1$  then the prover sends the  $k$  quantum registers  $R_{j,i}$  ( $i = 1, \dots, k$ ), each of which has a state  $|h_x\rangle$  as certificate, to each of the intermediate nodes  $v_j$ ,  $j \in \{1, \dots, r-1\}$ .
2. The left-end node  $v_0$  prepares the  $k$  quantum registers  $R_{0,i}$ , each of which has  $|h_x\rangle$ .
3. For every  $j = 0, \dots, r-1$ , the node  $v_j$  chooses a  $k$ -bit string  $b_{j,1} \dots b_{j,k}$  uniformly at random, and sends  $R_{j,i}$ , together with the index  $i$ , to its right neighbor  $v_{j+1}$  whenever  $b_{j,i} = 0$ .
4. For every  $j = 1, \dots, r-1$  and for every  $i = 1, \dots, k$ , if the node  $v_j$  receives an index  $i$ , and if  $b_{j,i} = 1$ , then  $v_j$  performs the SWAP test on  $(R_{j-1,i}, R_{j,i})$ . Node  $v_j$  rejects whenever at least one of the performed SWAP tests rejects, and it accepts otherwise.
5. If the right-end node  $v_r$  receives an index  $i \in \{1, \dots, k\}$ , then it performs the POVM measurement  $\{M_{y,1}, M_{y,0}\}$  corresponding to  $\pi$  applied to the state in  $R_{r-1,i}$ . Node  $v_r$  rejects if at least one of the performed POVM measurements rejects, and it accepts otherwise.

Protocol  $\mathcal{P}_\pi[k]$  has completeness  $(1 - \varepsilon/2)^k$ , that is, the completeness has not reduced much whenever  $\varepsilon$  is small. By a similar analysis of standard error reduction techniques for quantum Merlin-Arthur games as the analysis in [3, 29], one can show that  $\mathcal{P}_\pi[k]$  has soundness  $(1 - 1/42r^2)^k$ . By choosing  $k = 84r^2$ , the resulting protocol  $\mathcal{P}_\pi[k]$  has completeness  $1 - 42r^2\varepsilon$  and soundness error  $(1/e)^2 < 1/3$ , while the size of the certificates is  $O(r^2q)$  qubits, and the length of the message exchanged between neighbors is  $O(r^2(q + \log r))$  (where the additional term  $\log r$  comes from the index to the right neighbor in Step 3 of  $\mathcal{P}_\pi[k]$ ).

Theorem 1 can now be easily derived from the above analysis. For the first part of the theorem, where  $f$  is having a one-sided-error one-way protocol  $\pi$ , simply use the protocol  $\mathcal{P}_\pi$  from Section 4.1 with  $\varepsilon = 0$ . The result then follows from the analysis of Section 4.2 and from the above discussion about soundness reduction.

For the case of second part of the theorem, where  $f$  is having a two-sided-error one-way protocol, we repeat the protocol  $\pi$  for  $O(\log(n + r))$  times and using *majority voting* to get a protocol that correctly computes the value of the function with probability at least  $1 - 1/42n^c r^2$ . The protocol  $\pi$  of Section 4.1 can thus be chosen with  $\varepsilon = 1/42n^c r^2$ , with message size  $O(q \log(n + r))$ . The result then follows similarly. ◀

## 5 Certifying Equality in General Graphs

We now extend our protocol for checking equality between  $n$ -bit strings  $x_1, \dots, x_t$  stored at  $t \geq 2$  distinct nodes  $u_1, \dots, u_t$  of a connected simple graph  $G$ . We first show how to reduce the problem to trees of a specific structure, and then present a protocol for trees.

### 5.1 Reduction to Trees

Let  $G = (V, E)$  be a connected simple graph, and let  $u_1, \dots, u_t$  be  $t \geq 2$  distinct nodes of  $G$ . Assume, without loss of generality, that  $u_1$  is the most central node among them, i.e., it satisfies  $\max_{i=1, \dots, t} \text{dist}_G(u_1, u_i) = \min_{j=1, \dots, t} \max_{i=1, \dots, t} \text{dist}_G(u_j, u_i)$ . Let  $r = \max_{i=1, \dots, t} \text{dist}_G(u_1, u_i)$  be the *radius* of the  $t$  terminals  $u_1, \dots, u_t$ . We construct a tree  $T$  rooted at  $u_1$ , that has all terminals as leaves, maximum degree  $t$  and depth at most  $r + 1$  (see Figure 1). To this end, start with a BFS tree  $T'$  in  $G$ , rooted at  $u_1$ . Truncate the tree at each terminal  $u_i$  that does not have any terminal as successors, thus limiting

■ **Figure 1** The construction of a spanning tree: a graph  $G$  (left) and its corresponding spanning tree  $T$  (right). Terminals are marked by squares, and  $c$  is the root. Node  $b$  (resp.  $c$ ), which was a terminal, is replaced by a non-terminal node  $b'$  (resp.  $c'$ ), while the other terminals are leaves in the tree so they remain unmodified.

the depth to  $r$  and the degree to  $t$ . For every terminal  $u_i$  that is not a leaf, including  $u_1$ , replace  $u_i$  with a node  $u'_i$ , and connect  $u_i$  to  $u'_i$  as a leaf, where the input  $x_i$  stays at  $u_i$  – this guarantees that all inputs are now on leaves, the same degree bound holds, and the depth is increased by at most 1.

While  $T$  is not a sub-tree of  $G$ , we can easily emulate an algorithm or a labeling scheme designed for  $T$ , in  $G$  (specifically, in  $T'$ ). To this end, every internal terminal  $u_i$  in  $T'$  simulates the behavior of  $u_i$  itself, and also of  $u'_i$ . The following lemma is using classical assumptions of network computing (see, e.g., [42]) and can be proved using standard techniques (see, e.g., [35]). We refer to the tree  $T$  in the construction described above.

► **Lemma 7.** *For any graph  $G = (V, E)$  with nodes IDs taken in a range polynomial in  $|V|$ , there is a deterministic distributed Merlin-Arthur protocol for the tree  $T$  using certificates on  $O(\log |V|)$  bits.*

The term *deterministic* in the above lemma means that the verification process is deterministic, which implies perfect completeness and perfect soundness (i.e., soundness error 0). Roughly speaking, in this protocol each non-tree node will have a (non-quantum) label indicating its distance from the tree, and each tree node will have as label its depth in the tree, the ID of its parent, and the ID of the root.

## 5.2 Certifying Equality in Trees

Based on our tree construction from a graph and Lemma 7, we can restrict our attention to the case in which the  $t$  terminals  $u_1, \dots, u_t$ , who hold the  $n$ -bit strings  $x_1, \dots, x_t$ , belong to a tree  $T$  rooted at  $u_1$ , of depth equal to  $r + 1$ , where  $r$  is the radius of the terminals, with maximum degree  $t$ , and with leaves  $u_2, \dots, u_t$ . Moreover, we assume that the root  $u_1$  itself is of degree 1 due to our tree construction. We present a distributed quantum Merlin-Arthur protocol for the equality function  $\text{EQ}_n^t$  in this setting, and hence prove our main result.

► **Theorem 8.** *There is a distributed quantum Merlin-Arthur protocol on  $T$  for  $\text{EQ}_n^t$  between  $t$  terminals of radius  $r$ , with perfect completeness, soundness  $1/3$ , certificate size  $O(t r^2 \log n)$  qubits, and message length  $O(t r^2 \log(n + r))$  qubits.*

**Proof.** Let  $\pi$  be a one-way communication protocol for  $\text{EQ}_n$  transmitting  $m = O(\log n)$  qubits such that, for every input pair  $(x, y)$ , if  $x = y$  then  $\pi$  outputs 1 with probability 1 and if  $x \neq y$  then  $\pi$  outputs 0 with probability at least  $2/3$  (such a protocol exists, as mentioned in Section 2). For input  $(x, y)$ , let  $|h_x\rangle$  be the quantum message from Alice to Bob in  $\pi$ , and let

$\{M_{y,1}, M_{y,0}\}$  be the POVM measurement done by Bob on  $|h_x\rangle$  in  $\pi$ , where  $M_{y,1}$  corresponds to the measurement result 1 (accept), and  $M_{y,0}$  corresponds to the measurement result 0 (reject), respectively. Our quantum Merlin-Arthur protocol is as follows.

**Protocol  $\mathcal{P}(\text{EQ}_n^t)$  for equality in trees**

1. If  $\text{EQ}_n^t(x_1, \dots, x_t) = 1$  then the prover sends an  $m$ -qubit state equal to  $|h_{x_1}\rangle$  to each of the nodes  $v$  that have no input.
2. For every  $i \in \{1, \dots, t\}$ , node  $u_i$  prepares the  $m$ -qubit state  $|h_{x_i}\rangle$ .
3. Every non-root node  $v$  of the tree chooses a bit  $b_v$  uniformly at random. If  $b_v = 0$ , then  $v$  sends its  $m$ -qubit state to its parent in  $T$ .
4. For every non-terminal node  $v$ , if  $v$  receives a state from the children, and if  $b_v = 1$ , then  $v$  performs the SWAP test on the  $2m$ -qubit state that consists of the  $m$ -qubit state received from the prover and an  $m$ -qubit state received from the children, which is chosen uniformly at random if he/she receives multiple  $m$ -qubit states from the children, and accepts or rejects accordingly. Otherwise,  $v$  accepts.
5. If the root node  $u_1$  receives a state from its children, then  $u_1$  performs the POVM measurement  $\{M_{x_1,1}, M_{x_1,0}\}$  on an  $m$ -qubit state received from the children, which is chosen uniformly at random if he/she receives multiple  $m$ -qubit states from the children, and accepts or rejects accordingly. Otherwise,  $u_1$  accepts.

The perfect completeness trivially holds since every local test yields acceptance with certainty. For the soundness, if  $\text{EQ}_n^t(x_1, \dots, x_t) = 0$  then there is a leaf  $u_i$ ,  $i > 1$ , with  $x_i \neq x_1$ . Then, we can perform almost the same analysis as in Section 4, but for the path connecting  $u_1$  and  $u_i$  in  $T$ . The only difference is the probability that each local test occurs; it is at least  $1/4$  in the analysis of  $\mathcal{P}_\pi$  done in Section 4, while it is at least  $(1/4) \cdot (1/t)$  in the protocol  $\mathcal{P}(\text{EQ}_n^t)$  we are now considering, as every non-terminal node  $v_j$  or  $u_1$  on the path chooses the  $m$ -qubit state from the child on the path uniformly at random from the multiple  $m$ -qubit states (possibly) sent from all the children. Hence,  $\mathcal{P}(\text{EQ}_n^t)$  has soundness error  $1 - O(1/tr^2)$ . The proof is completed by performing  $O(tr^2)$  parallel repetitions of  $\mathcal{P}(\text{EQ}_n^t)$  for error reduction, similarly to the  $O(r^2)$  parallel repetitions of  $\mathcal{P}_\pi$  in Section 4. ◀

► **Remark.** Using Lemma 7, we get that, up to adding  $O(\log |V|)$  classical bits in the certificates of the nodes, Theorem 8 can be extended to the case where the terminals are in a connected graph  $G = (V, E)$ .

## 6 Classical Lower Bounds

In this section, we show that non-quantum distributed Merlin-Arthur (dMA) protocols for distant EQ require certificates of linear size. In fact, we establish a more general lower bound which applies to all functions  $f$  with large fooling set, even using shared randomness. In addition, the bound holds for settings which allow the graph nodes to have multiple communication rounds among them, after receiving the certificates and before deciding if they finally accept (see, e.g., [19, 41]).

For the lower bound, it is sufficient to consider the path  $v_0, \dots, v_r$  in which  $v_0$  and  $v_r$  are provided with inputs  $x$  and  $y$ , respectively.

► **Theorem 9.** *Let  $r \geq 2\mu + 1$ , and let  $f(x, y)$  be any Boolean function with a 1-fooling set of size at least  $k$ . Let  $\mathcal{P}$  be a classical Merlin-Arthur protocol for  $f$  in a path of  $r$  edges, with  $\mu$  rounds of communication among the nodes, shared randomness, certificates of size  $\lfloor \frac{1}{2\mu} \log(k-1) \rfloor$  bits, and completeness  $1 - p$ . Then  $\mathcal{P}$  has soundness error at least  $1 - 2p$ .*

**Proof.** Consider the path  $v_0, \dots, v_r$  with a fixed identifier assignment, and inputs  $x$  and  $y$  given to  $v_0$  and  $v_r$ , respectively. Since  $f$  has large 1-fooling set but small certificates, there exist two distinct pairs of “fooling” inputs that have the same certificate assignments on the  $2\mu$  node  $v_1, \dots, v_{2\mu}$ . That is, we can fix two input pairs  $(x, y)$  and  $(x', y')$ , with  $f(x, y) = f(x', y') = 1$ , and, w.l.o.g.,  $f(x, y') = 0$ , with corresponding certificate assignments  $w$  and  $w'$ , such that

$$w(v_i) = w'(v_i) \text{ for every } i \in \{1, \dots, 2\mu\},$$

where  $w(v_i)$  and  $w'(v_i)$  are the certificate assigned to the node  $v_i$  in the assignments  $w$  and  $w'$ , respectively.

We interpret the outputs as Boolean values, where accept = 1 and reject = 0, and denote by  $\text{out}_i(x, y, w)$  the output of  $v_i$  when the inputs are  $x$  and  $y$  and the certificate assignment is  $w$ . Since  $\mathcal{P}$  has completeness  $1 - p$ , we have

$$\Pr_s \left[ \bigwedge_{i \leq \mu} \text{out}_i(x, y, w) = 1 \wedge \bigwedge_{i \geq \mu+1} \text{out}_i(x, y, w) = 1 \right] \geq 1 - p,$$

and the same holds for  $(x', y', w')$ . Hence,

$$\Pr_s \left[ \bigwedge_{i \leq \mu} \text{out}_i(x, y, w) = 1 \right] \geq 1 - p, \text{ and } \Pr_s \left[ \bigwedge_{i \geq \mu+1} \text{out}_i(x', y', w') = 1 \right] \geq 1 - p.$$

The output  $\text{out}_i$  of every node  $v_i$  is a function of its own identifier and certificate, the certificates of the nodes in its distance- $\mu$  neighborhood, and the public random string  $s$ . In addition, the outputs of  $v_0, v_1, \dots, v_\mu$  may also depend on the input  $x$  to  $v_0$ , and the outputs of  $v_{r-\mu}, \dots, v_r$  may also depend on the input  $y$  to  $v_r$ . Formally speaking, the outputs can also depend on the identifiers of the neighbors, but these are fixed given the node’s identifier, so we ignore them henceforth.

Let  $w''$  be the certificate assignment defined by

$$\begin{aligned} w''(v_0) &= w(v_0); \\ w''(v_i) &= w(v_i) = w'(v_i) \quad \text{for } i \in \{1, \dots, 2\mu\}; \\ w''(v_i) &= w'(v_i) \quad \text{for } i \in \{2\mu+1, \dots, r\}. \end{aligned}$$

Consider the input assignment  $(x, y')$  combined with the certificate assignment  $w''$ . The definition of  $w''$  implies that nodes  $v_0, \dots, v_{2\mu}$  receive the same certificates as in  $w$ , and thus nodes  $v_0, \dots, v_\mu$  cannot distinguish this from the input assignment  $(x, y)$  with certificates assignment  $w$ . On the other hand, nodes  $v_1, \dots, v_r$  receive the same certificates as in  $w'$ , so the nodes  $v_{\mu+1}, \dots, v_r$  cannot distinguish this from the input assignment  $(x', y')$  with certificates assignment  $w'$ .

A union bound finishes the proof:

$$\begin{aligned} & \Pr_s \left[ \bigwedge_{i \leq \mu} \text{out}_i(x, y', w'') = 1 \wedge \bigwedge_{i \geq \mu+1} \text{out}_i(x, y', w'') = 1 \right] \\ &= \Pr_s \left[ \bigwedge_{i \leq \mu} \text{out}_i(x, y, w) = 1 \wedge \bigwedge_{i \geq \mu+1} \text{out}_i(x', y', w') = 1 \right] \\ &\geq 1 - \Pr_s \left[ \neg \bigwedge_{i \leq \mu} \text{out}_i(x, y, w) = 1 \right] - \Pr_s \left[ \neg \bigwedge_{i \geq \mu+1} \text{out}_i(x', y', w') = 1 \right] \\ &\geq 1 - 2p. \end{aligned}$$

That is, we found a certificate assignment  $w''$  for the input  $(x, y')$  which makes all node accept with probability at least  $1 - 2p$ , even though  $f(x, y') = 0$ . Hence, the soundness error is at least  $1 - 2p$ , as claimed.  $\blacktriangleleft$

Since  $\text{EQ}_n$  has a 1-fooling set of size  $2^n$ , the corollary below follows directly from Theorem 9. The case  $r = 3$  and  $\mu = 1$  gives a linear lower bound for dMA protocols on a 4-node path.

► **Corollary 10.** *For every  $r \geq 2\mu + 1$ , every distributed (classical) Merlin-Arthur protocol for  $\text{EQ}_n^2$  with  $\mu$  rounds of communication among the nodes in the path of  $r$  edges with certificates of size at most  $\lfloor (n-1)/2\mu \rfloor$  bits, and completeness  $1-p$  has soundness error at least  $1-2p$ .*

The requirements for a good protocol is to have a high completeness (i.e., small value for  $p$ , ideally  $p = 0$ ) and a reasonably small soundness error. Corollary 10 precisely shows that for the equality function such protocols cannot exist in the classical setting unless the certificate size is linear in  $n$ .

► **Remark.** The completeness-soundness gap of Theorem 9 is optimal in general, in the sense that it cannot be improved for  $\text{EQ}_1^2$ , i.e., distant equality between two input bits. Consider the following protocol  $\mathcal{P}$  for  $\text{EQ}_1^2$ , on input  $(x, y) \in \{0, 1\} \times \{0, 1\}$ . It uses a shared random variable  $X \in \{-1, 0, 1\}$  with  $\Pr[X = 0] = \Pr[X = 1] = p$ , and  $\Pr[X = -1] = 1 - 2p$ . In the case  $X = -1$ , all the nodes accept. In the case  $X \in \{0, 1\}$ ,  $v_0$  accepts whenever  $X = x$ ,  $v_r$  accepts whenever  $X = y$ , and all the other nodes accept. If  $x = y$ , the probability that all the nodes accept is  $1 - 2p + (1/2) \cdot (2p) = 1 - p$ . If  $x \neq y$ , then either  $v_0$  or  $v_r$  systematically rejects for  $X \neq -1$ , and thus the probability that all the nodes accept is  $1 - 2p$ .

## 7 Conclusion

In this paper, we extended the notion of randomized proof-labeling scheme to the quantum setting. We showed the efficiency of distributed quantum certification mechanisms by designing a distributed quantum Merlin-Arthur protocol for  $\text{EQ}_n^t$  between  $t$  parties spread out in a graph, using certificates and messages whose size depend logarithmically on  $n$ , the size of the data. This is in contrast to classical distributed Merlin-Arthur protocols, which require certificates of size linear in  $n$ , even when messages of unbounded size can be used. Our result was obtained by using an interesting property of the SWAP test: it can be applied for checking proximity properties between reduced states.

Which other Boolean predicates on labeled graphs, beyond equality, could take benefit from quantum resources for the design of compact distributed certification schemes is an intriguing question. Theorem 1 gives a partial answer on the path. A complete answer to this question would significantly help improving our comprehension of the power of quantum computing in the distributed setting.

## Abstract

Constructing one-way functions based on NP-hardness is a central challenge in theoretical computer science. Unfortunately, Akavia et al. [2] presented strong evidence that a nonadaptive black-box (BB) reduction is insufficient to solve this challenge. However, should we give up such a central proof technique even for an intermediate step?

In this paper, we turn our eyes from standard cryptographic primitives to weaker cryptographic primitives allowed to take auxiliary-input and continue to explore the capability of nonadaptive BB reductions to base auxiliary-input primitives on NP-hardness. Specifically, we prove the followings:

- if we base an auxiliary-input pseudorandom generator (AIPRG) on NP-hardness via a nonadaptive BB reduction, then the polynomial hierarchy collapses;
- if we base an auxiliary-input one-way function (AIOWF) or auxiliary-input hitting set generator (AIHSG) on NP-hardness via a nonadaptive BB reduction, then an (i.o.-)one-way function also exists based on NP-hardness (via an adaptive BB reduction).

These theorems extend our knowledge on nonadaptive BB reductions out of the current worst-to-average framework. The first result provides new evidence that nonadaptive BB reductions are insufficient to base AIPRG on NP-hardness. The second result also yields a weaker but still surprising consequence of nonadaptive BB reductions, i.e., a one-way function based on NP-hardness. In fact, the second result is interpreted in the following two opposite ways. Pessimistically, it shows that basing AIOWF or AIHSG on NP-hardness via nonadaptive BB reductions is harder than constructing a one-way function based on NP-hardness, which can be regarded as a negative result. Note that AIHSG is a weak primitive implied even by the hardness of learning; thus, this pessimistic view provides conceptually stronger limitations than the currently known limitations on nonadaptive BB reductions. Optimistically, it offers a new hope: breakthrough construction of auxiliary-input primitives might also provide construction standard cryptographic primitives. This optimistic view enhances the significance of further investigation on constructing auxiliary-input or other intermediate cryptographic primitives instead of standard cryptographic primitives.

## 1 Introduction

How can we translate computational hardness into cryptography? This is a central question in theoretical computer science. Specifically, one of the most significant and long-standing challenges on this question is constructing fundamental cryptographic primitives such as a one-way function based on NP-hardness. At the moment, several breakthroughs seem to be required for solving this challenge, as surveyed by Impagliazzo [20].

A central ingredient for solving the above challenge is a *reduction*; in other words, the way to translate recognizing a language into breaking a cryptographic primitive. A reduction is a powerful proof technique even if it is restricted to a quite simple form, and in fact, a nonadaptive black-box (BB) reduction is sufficient to show many brilliant results and has played a crucial role in theoretical computer science. Therefore, it is a natural attempt to apply such a familiar proof technique even for constructing secure cryptographic primitives.

However, Akavia et al. [10] presented strong evidence that such a simple reduction is insufficient for cryptography based on NP-hardness. Generally, breaking cryptographic primitives is formulated as an NP problem on an efficiently samplable distribution that is fixed in advance. They showed that there is no nonadaptive BB reduction from an NP-hard problem to such a distributional NP problem unless the polynomial hierarchy collapses. As a corollary, their work excluded the attempt to apply nonadaptive BB reductions for cryptography based on NP-hardness under the reasonable assumption that the polynomial hierarchy does not collapse. Further, subsequent work provided stronger consequences in more specific cases of several cryptographic primitives [2, 12, 5, 13, 9, 8, 27, 17].

Then should we also give up all nonadaptive BB strategies even for an intermediate step towards cryptography? This question originally motivated our work. In this spirit, we focus on the capability of nonadaptive BB reduction for a weaker cryptographic notion, i.e., an *auxiliary-input* cryptographic primitive introduced first by Ostrovsky and Wigderson [30]. Informally speaking, an auxiliary-input cryptographic primitive is defined as a family of primitives indexed by the auxiliary-input and has a relaxed security requirement: at least one primitive in the family must be secure depending on each adversary (instead of one specific primitive secure against all adversaries). In other words, adversaries for auxiliary-input primitives must break all primitives in the worst-case sense on auxiliary-input. This task is not directly formulated as a distributional NP-problem because the distribution is not uniquely determined in advance due to auxiliary-input. Thus, the previous work on distributional NP problem cannot be directly applied to auxiliary-input cryptography.

Herein, we present the current status of nonadaptive BB reductions to auxiliary-input cryptography. Applebaum et al. [5] observed that nonadaptive fixed-auxiliary-input BB reductions are insufficient even for auxiliary-input cryptography unless the polynomial hierarchy collapses. Their reduction is a restricted case of nonadaptive BB reduction where only one auxiliary-input is accessible. However, this restricted access to auxiliary-input seems too strict and implicitly yields a reduction from an NP-hard language to some fixed cryptographic primitive (depending on the instance). In fact, this result was shown in almost the same way to the previous result for standard cryptographic primitives in [2]. The same work and later Xiao [34] observed that generalizing their result to nonadaptive BB reductions seems hard by giving the explicit technical issue. To the best of our knowledge, we had no negative result on general nonadaptive BB reductions to base auxiliary-input cryptography on NP-hardness before this work. For more detailed reason why the previous work such as [10, 2] is not applicable for auxiliary-input primitives, refer to Section 4.

The recent progress on the minimum circuit size problem revealed that an auxiliary-input one-way function indeed implies a hard-on-average distributional NP problem [3, 16]. However, such an implication requires adaptive techniques at present (e.g., [15]). Thus, the property of nonadaptive black-box is lost in translating reductions for the auxiliary-input primitive into reductions for the distributional NP problem.

In this paper, based on the above status, we continue to investigate the capability of nonadaptive BB reductions for auxiliary-input cryptographic primitives based on NP-hardness. The importance of our work is to extend our current knowledge on such a central proof technique out of the previous worst-to-average framework in [10] and to identify the inherent difficulty on constructing cryptographic primitives on NP-hardness more finely.

## 1.1 Our Contribution

Our main contribution is to provide new knowledge about nonadaptive BB reductions from an NP-hard problem to an auxiliary-input cryptographic primitive. In particular, we handle the auxiliary-input analogs of the following three fundamental primitives: a one-way function, a pseudorandom generator, and a hitting set generator. A definition of each primitive will be presented in Section 2 with a formal description of our main results. First, we informally state the main theorem as follows.

► **Theorem (informal).** *If there is a nonadaptive BB reduction from an NP-hard language  $L$  to breaking an auxiliary-input cryptographic primitive  $P$ , then the following statements hold according to the type of  $P$ :*

- *if  $P$  is an auxiliary-input pseudorandom generator, then the polynomial hierarchy collapses;*
- *if  $P$  is an auxiliary-input one-way function or an auxiliary-input hitting set generator, then there is also an adaptive reduction from  $L$  to inverting some (i.o.-)one-way function.*

The first result provides reasonable evidence that auxiliary-input pseudorandom generators (AIPRG) cannot be based on NP-hardness via nonadaptive BB reductions as standard cryptography. The second result shows that a nonadaptive BB reduction for basing the other auxiliary-input primitives yields another strong consequence: an “infinitely often” analog of one-way function based on NP-hardness. Note that an auxiliary-input hitting set generator (AIHSG) is much weaker primitive than standard cryptographic primitives: for example, the existence is even weaker than the hardness of PAC learning [28]. What is surprising is that even a nonadaptive BB reduction to such a weak primitive yields a solution close to the long-standing challenge, i.e., characterization of one-way functions based on NP-hardness.

The second result is not sufficient to exclude nonadaptive BB reductions which base auxiliary-input primitives on NP-hardness, and it has two opposite interpretations. However, let us stress that both interpretations are quite nontrivial and yield new knowledge about nonadaptive BB reductions. One interpretation is a pessimistic (or realistic) one. As mentioned in the introduction, no one has not come up with the construction of a one-way function based on NP-hardness for several decades despite its importance. Thus, this result is still strong evidence of difficulty finding such a simple reduction. The other interpretation is an optimistic one as a new approach to constructing a one-way function. We will further discuss this optimistic perspective and its novelty in Section 3.

A reader who is familiar with cryptography may wonder why the consequences are different between an auxiliary-input one-way function (AIOWF) and AIPRG. In fact, AIPRG is constructed from any AIOWF by applying the known BB construction of a pseudorandom generator from a one-way function. However, if such construction requires an adaptive security proof, then the property of nonadaptive is lost in translating reductions for AIOWF

into reductions for AIPRG via the adaptive security reduction. To the best of our knowledge, all currently known constructions of pseudorandom generators (e.g., [15, 19, 14]) use adaptive techniques in the security proof; for instance, construction of false entropy generators and the uniform hardcore lemma [18]. This technical issue prevents us from applying the first result for AIPRG to AIOWF. For a similar reason, our second result on AIOWF is incomparable with the previous work [5] on hardness of learning because we need to construct AIPRG first to show the hardness of learning from the existence of AIOWF.

## 2 Formal Descriptions

In this section, we present formal descriptions of auxiliary-input primitives and our results. Let us introduce a few notations. For any  $n \in \mathbb{N}$ , let  $U_n$  denote a random variable selected according to a uniform distribution over  $\{0, 1\}^n$ . For any function  $f : \mathcal{X} \rightarrow \mathcal{Y}$  and subsets  $X \subseteq \mathcal{X}$ ,  $Y \subseteq \mathcal{Y}$ , let  $f(X) = \{f(x) : x \in X\}$  and  $f^{-1}(Y) = \{x \in X : f(x) \in Y\}$ . For a language  $L$ , let  $(L, U)$  denote a distributional problem of recognizing  $L(x)$  on an instance  $x$  selected uniformly at random. An auxiliary-input cryptographic primitive is defined as an auxiliary-input function with some additional security conditions.

► **Definition 1** (Auxiliary-input function). *A (polynomial-time computable) auxiliary-input function is a family  $f = \{f_z : \{0, 1\}^{n(|z|)} \rightarrow \{0, 1\}^{\ell(|z|)}\}_{z \in \{0, 1\}^*}$ , where  $n(|z|)$  and  $\ell(|z|)$  are polynomially-related<sup>1</sup> to  $|z|$ , which satisfies that there exists a polynomial-time evaluation algorithm  $F$  such that for any  $z \in \{0, 1\}^*$  and  $x \in \{0, 1\}^{n(|z|)}$ ,  $F(z, x)$  outputs  $f_z(x)$ .*

In this paper, we use the term “an auxiliary-input function (AIF)” to refer to polynomial-time computable one as in the above definition unless otherwise stated. For the sake of simplicity, we assume that  $n(\cdot)$  and  $\ell(\cdot)$  are increasing functions. Note that the length of auxiliary-input is possibly longer than the length of input and output, i.e.,  $|z| > n(|z|)$  and  $|z| > \ell(|z|)$ . We may write  $n(|z|)$  (resp.  $\ell(|z|)$ ) as  $n$  (resp.  $\ell$ ) when the dependence of  $|z|$  is obvious.

### 2.1 Auxiliary-Input Pseudorandom Generator

A pseudorandom generator is a primitive stretching a short random seed to a long binary string random-looking from all efficiently computable adversaries. The auxiliary-input analog is formally defined as follows:

► **Definition 2** (Auxiliary-input pseudorandom generator). *Let  $G = \{G_z : \{0, 1\}^n \rightarrow \{0, 1\}^{\ell(n)}\}_{z \in \{0, 1\}^*}$  be an auxiliary-input function. For a function  $\gamma : \mathbb{N} \rightarrow (0, 1)$ , we say that a randomized algorithm  $A$   $\gamma$ -distinguishes  $G$  if for all auxiliary-inputs  $z \in \{0, 1\}^*$ ,*

$$\left| \Pr_{A, U_n} [A(z, G_z(U_n)) = 1] - \Pr_{A, U_{\ell(n)}} [A(z, U_{\ell(n)}) = 1] \right| \geq \gamma(n).$$

*We say that  $G$  is an auxiliary-input pseudorandom generator (AIPRG) if  $\ell(n) > n$  and for all polynomials  $p$ , there exists no polynomial-time randomized algorithm  $(1/p)$ -distinguishing  $G$ .*

A BB reduction for AIPRG is defined as follows. It is easily verified that the following BB reduction from a language  $L$  to distinguishing an AIF  $G$  shows that  $G$  is an AIPRG if  $L \notin \text{BPP}$ .

<sup>1</sup> In the case of  $n(|z|)$ , it means that there exist  $c, c' \in \mathbb{N}$  such that  $|z| \leq c \cdot n(|z|)^c$  and  $n(|z|) \leq c' \cdot |z|^{c'}$ .

► **Definition 3** (Black-box reduction to distinguishing AIF). *Let  $L$  be a language and  $G := \{G_z : \{0,1\}^n \rightarrow \{0,1\}^{\ell(n)}\}_{z \in \{0,1\}^*}$  be an auxiliary-input function with  $\ell(n) > n$ . We say that there exists a black-box (BB) reduction from  $L$  to distinguishing  $G$  if for all polynomials  $p$ , there exists a randomized polynomial-time oracle machine  $R^?$  such that for all oracles  $\mathcal{O}$  that  $(1/p)$ -distinguish  $G$  and  $x \in \{0,1\}^*$ ,  $R$  satisfies that*

$$\Pr_R[R^{\mathcal{O}}(x) = L(x)] \geq 2/3.$$

Moreover, we say that there exists a nonadaptive BB reduction from  $L$  to distinguishing  $G$  if all  $R$  make their queries independently of any answer by oracle for previous queries.

The first main result on AIPRG is stated as follows.

► **Theorem 4.** *For any auxiliary-input function  $G = \{G_z : \{0,1\}^n \rightarrow \{0,1\}^{\ell(n)}\}_{z \in \{0,1\}^*}$  with  $\ell(n) > n$ , there exists no nonadaptive BB reduction from an NP-hard language  $L$  to distinguishing  $G$  unless the polynomial hierarchy collapses.*

## 2.2 Auxiliary-Input One-Way Function

A one-way function is a function which is easy to compute but hard to invert, and it is a fundamental primitive in the sense that most cryptographic tools do not exist without a one-way function [23, 32]. The formal definition is the following:

► **Definition 5** (One-way function). *Let  $s, \ell$  be polynomials. We say that a family of function  $f = \{f_n\}_{n \in \mathbb{N}}$  where  $f_n : \{0,1\}^{s(n)} \rightarrow \{0,1\}^{\ell(n)}$  is an (i.o.-)one-way function (OWF)<sup>2</sup> if  $f$  is polynomial-time computable, and there exists a polynomial  $p$  such that for all polynomial-time randomized algorithms  $A$ , there exist infinitely many  $n \in \mathbb{N}$  such that*

$$\Pr_{A, U_{s(n)}} [A(1^n, f_n(U_{s(n)})) \notin f_n^{-1}(f_n(U_{s(n)}))] \geq 1/p(n).$$

For the sake of simplicity, we may omit to write the input  $1^n$  to  $A$ .

The auxiliary-input analog of OWF, first introduced by Ostrovsky and Wigderson [30], is defined as follows.

► **Definition 6** (Auxiliary-input one-way function). *Let  $f = \{f_z : \{0,1\}^n \rightarrow \{0,1\}^{\ell}\}_{z \in \{0,1\}^*}$  be an auxiliary-input function and  $\gamma : \mathbb{N} \rightarrow (0,1)$  be a function. We say that a randomized algorithm  $A$   $\gamma$ -inverts  $f$  if for all  $z \in \{0,1\}^*$ ,*

$$\Pr_{A, U_n} [A(z, f_z(U_n)) \in f_z^{-1}(f_z(U_n))] \geq \gamma(n).$$

We say that  $f$  is an auxiliary-input one-way function (AIOWF) if there exists a polynomial  $p$  such that no polynomial-time randomized algorithm  $(1 - 1/p)$ -inverts  $f$ .

In fact, the existence of AIOWF and AIPRG is equivalent [15]. However, we cannot directly apply Theorem 4 to AIOWF due to the adaptive security reduction, as we mentioned in Section 1.1.

A BB reduction for AIOWF is defined as follows. It is easily verified that for any polynomial  $p$ , the following BB reduction from a language  $L$  to  $(1 - 1/p)$ -inverting an AIF  $f$  shows that  $f$  is an AIOWF if  $L \notin \text{BPP}$ .

<sup>2</sup> Strictly speaking, a one-way function defined in Definition 5 is usually called a “weak” one-way function, which implies the standard (strong) one-way function.

► **Definition 7** (Black-box reduction to inverting AIF). *Let  $L$  be a language,  $p$  be a polynomial, and  $f := \{f_z : \{0,1\}^n \rightarrow \{0,1\}^\ell\}_{z \in \{0,1\}^*}$  be an auxiliary-input function. We say that a randomized polynomial-time oracle machine  $R^?$  is a black-box (BB) reduction from  $L$  to  $(1 - 1/p)$ -inverting  $f$  if for all oracles  $\mathcal{O}$  that  $(1 - 1/p)$ -invert  $f$  and  $x \in \{0,1\}^*$ ,  $R$  satisfies that*

$$\Pr_R[R^{\mathcal{O}}(x) = L(x)] \geq 2/3.$$

Moreover, we say that  $R$  is nonadaptive if all  $R$ 's queries are made independently of any answer by oracle for previous queries.

The second main result on AIOWF is stated as follows.

► **Theorem 8.** *For any auxiliary-input function  $f = \{f_z : \{0,1\}^n \rightarrow \{0,1\}^\ell\}_{z \in \{0,1\}^*}$  and polynomial  $p$ , if there exists a nonadaptive BB reduction from an NP-hard language  $L$  to  $(1 - 1/p)$ -inverting  $f$ , then  $\text{NP} \not\subseteq \text{BPP}$  also implies that a one-way function exists (via an adaptive BB reduction).*

## 2.3 Auxiliary-Input Hitting Set Generator

A hitting set generator is a weak variant of a pseudorandom generator, introduced in the context of derandomization by Andreev et al. [4]. For the original purpose, they considered (possibly) exponential-time computable generators. In this paper, we focus on polynomial-time computable generators as in cryptography. We define the auxiliary-input analog as follows.

► **Definition 9** (Auxiliary-input hitting set generator). *Let  $G = \{G_z : \{0,1\}^n \rightarrow \{0,1\}^{\ell(n)}\}_{z \in \{0,1\}^*}$  be an auxiliary-input function. For a function  $\gamma : \mathbb{N} \rightarrow (0,1)$ , we say that a randomized adversary  $A$   $\gamma$ -avoids  $G$  if for all (public) auxiliary-inputs  $z \in \{0,1\}^*$  and (private) inputs  $x \in \{0,1\}^{n(|z|)}$ ,*

$$\Pr_A[A(z, G_z(x)) = 0] \geq 2/3 \quad \text{and} \quad \Pr_{y \sim \{0,1\}^{\ell(n(|z|))}} \left[ \Pr_A[A(z, y) = 1] \geq 2/3 \right] \geq \min(\gamma(n), \tau_z),$$

where  $\tau_z$  be a trivial limitation<sup>3</sup> defined as  $\tau_z = 1 - \frac{|G_z(\{0,1\}^n)|}{2^{\ell(n)}}$ .

We say that  $G$  is a  $\gamma$ -secure auxiliary-input hitting set generator (AIHSG) if  $\ell(n) > n$  and there exists no polynomial-time randomized algorithm  $(1 - \gamma)$ -avoiding  $G$ .

Although it is easily verified that AIPRG is also AIHSG (for any security  $\gamma(n) = 1/\text{poly}(n)$ ), the opposite direction is open at present. In fact, the hardness of learning implies the existence of AIHSG [28]; on the other hand, we must overcome the barrier by oracle separation to show the existence of AIPRG (equivalently, AIOWF) from the hardness of learning [35]. Thus, AIHSG seems to be a much weaker notion than AIOWF and AIPRG under current knowledge.

A BB reduction for AIHSG is defined as follows. It is easily verified that the following BB reduction from a language  $L$  to  $(1 - \gamma)$ -avoiding an AIF  $G$  shows that  $G$  is a  $\gamma$ -secure AIHSG if  $L \notin \text{BPP}$ .

<sup>3</sup> In this paper, we consider general settings of  $\gamma$  and  $\ell$ . Thus, we adopted the trivial limitation in the definition to avoid arguing about invalid settings where  $\gamma$ -avoiding the generator is impossible by definition.

► **Definition 10** (Black-box reduction to avoiding AIF). *Let  $L$  be a language,  $\gamma$  be a function, and  $G := \{G_z : \{0,1\}^n \rightarrow \{0,1\}^\ell\}_{z \in \{0,1\}^*}$  be an auxiliary-input function. We say that a randomized polynomial-time oracle machine  $R^?$  is a black-box (BB) reduction from  $L$  to  $(1 - \gamma)$ -avoiding  $G$  if for all oracles  $\mathcal{O}$  that  $(1 - \gamma)$ -avoid  $G$  and  $x \in \{0,1\}^*$ ,  $R$  satisfies that*

$$\Pr_R[R^{\mathcal{O}}(x) = L(x)] \geq 2/3.$$

*Moreover, we say that  $R$  is nonadaptive if all  $R$ 's queries are made independently of any answer by oracle for previous queries.*

The third main result on AIHSG is stated as follows.

► **Theorem 11.** *Let  $p$  be a polynomial and  $G := \{G_z : \{0,1\}^n \rightarrow \{0,1\}^{\ell(n)}\}_{z \in \{0,1\}^*}$  be an auxiliary-input function where  $\ell(n) > (1 + \epsilon) \cdot n$  for some constant  $\epsilon > 0$ . If there exists a nonadaptive BB reduction from an NP-hard language  $L$  to  $(1 - 1/p)$ -avoiding  $G$ , then  $\text{NP} \not\subseteq \text{BPP}$  also implies that a one-way function exists (via an adaptive BB reduction).*

### 3 Discussion and Future Directions

As discussed in Section 1.1, Theorems 8 and 11 are also regarded as approaches to construct one-way functions based on NP-hardness. In this section, we discuss the novelty of this optimistic perspective and suggest future directions, including the investigation of the validity.

Our results are rephrased as follows: Assume that we could connect NP-hardness to some auxiliary-input primitives (i.e., AIOWF or AIHSG) via a novel nonadaptive BB reduction, then we can automatically extend the connection to standard cryptographic primitives, that is, OWF. At present, the latter task of removing auxiliary-input from primitives seems quite non-trivial, as mentioned in [5, 33]. In this paper, we also provide a simple oracle separation between AIOWF and OWF as follows. This indicates that we cannot expect any relativized technique to remove auxiliary-input from cryptographic primitives.

► **Theorem 12.** *There exists an oracle  $\mathcal{O}$  such that relative to  $\mathcal{O}$  an auxiliary-input one-way function exists, but a one-way function does not exist.*

Additionally, there are several barriers by other oracle separations at the intermediate levels to base OWF on NP-hardness (e.g., [35, 21]). Although such barriers on relativization are common throughout theoretical computer science (e.g., the P vs. NP problem [6]), there are only a few success stories of overcoming such barriers at present. Unfortunately, Theorems 8 and 11 do not provide any solution to break these barriers, and a new non-relativized technique is still required. Specifically, if a nonadaptive BB reduction to AIOWF or AIHSG is also relativized<sup>4</sup>, then our proof also yields relativized reductions that contradict Theorem 12 or the oracle separation presented in [21].

However, our result offers one hope. Although there seems to be several barriers towards cryptography based on NP-hardness as discussed above, the essential barrier we must overcome might be few. Theorems 8 to 12 certainly show that if we could find a non-relativized breakthrough at an intermediate level toward cryptography (that is, auxiliary-input primitives), then it will be lifted and break the other barriers at the higher level. From this perspective, we conjecture that the difficulty in basing OWF on NP-hardness could rely on

<sup>4</sup> Note that oracle separations do not necessarily rule out BB reductions from particular languages, not as fully BB reductions defined in [31].

a much smaller part of tasks at an intermediate level. This conjecture seems somewhat controversial but enhances the significance of further investigation on auxiliary-input or other intermediate cryptographic primitives instead of standard ones.

The above discussion leads to the following two possible directions. The first direction is to find other scenarios where a breakthrough at an intermediate level also brings benefits at the higher level. This direction might reduce constructing standard cryptographic primitives to the task at the low level and give new insights into complexity-based cryptography. The second direction is to refute such an attempt on intermediate primitives with convincing evidence if it gives the wrong direction. Particularly, in our case, there is a possibility that nonadaptive BB reductions for AIOWF and AIHSG indeed yield the collapse of the polynomial-hierarchy as in the case of AIPRG.

For the second direction, we list two concrete ways: (1) finding a new construction of AIPRG from AIOWF with nonadaptive security proof; (2) generalizing the previous results for OWF [2] or HSG [17] to each auxiliary-input analog for the stronger consequence. At least the latter approach seems to require some new technique to simulate nonadaptive BB reductions by constant-round interactive proof systems, as observed in [5] and [34].

#### 4 A First Attempt: Applying [10] and [2]

Before presenting our proof strategies, we roughly explain why the previous technique developed by Bogdanov and Trevisan [10] for the worst-to-average framework is not applicable in the case of auxiliary-input cryptography. For the sake of simplicity, we assume that there exists a nonadaptive BB reduction  $R$  from an NP-hard language  $L$  to a distributional NP-problem  $(L', U)$ , and  $R$  makes queries of the same length  $n$  determined by the size of input to  $R$ . Note that if we can answer these queries by an oracle which correctly recognizes  $L'$  on average, then  $R$  must recognize  $L$ . Bogdanov and Trevisan construct an AM/poly protocol for recognizing  $L$  by leaving this role of the oracle to a prover, which implies that  $\text{coNP} \subseteq \text{AM/poly}$  and the collapse of the polynomial hierarchy.

Roughly speaking, their central idea is to divide each  $R$ 's query  $x \in \{0, 1\}^n$  into “light” and “heavy” queries according to the probability  $p_x$  that the query  $x$  is generated by  $R$ . Specifically, they determine a threshold  $p(n) = \text{poly}(n)$  depending on the permissible error probability for solving  $(L', U)$  on average and define a light (resp. heavy) query  $x$  as a query satisfying the condition  $p_x \leq p(n)2^{-n}$  (resp.  $p_x > p(n)2^{-n}$ ). Then, they make the prover answer (ideally) all light queries correctly, i.e., simulate the following oracle.

$$\mathcal{O}_{\mathcal{L}} = \{x \in \{0, 1\}^* : x \in L' \text{ and } x \text{ is a light query}\}$$

Because the number of heavy queries is at most  $2^n/p(n)$ , the above oracle  $\mathcal{O}_{\mathcal{L}}$  solves  $(L', U)$  with error probability at most  $p(n)$ . Therefore, it is enough to make a prover simulate  $\mathcal{O}_{\mathcal{L}}$  for constructing an AM/poly protocol which recognizes  $L$  based on  $R$ . For the soundness, the verifier must accomplish the following two tasks without being deceived by malicious provers: (1) distinguishing between light and heavy queries and (2) identifying the correct answer for each light query. Bogdanov and Trevisan developed such a verifier by introducing sophisticated protocols called the heavy sampling protocol and the hiding protocol.

Herein, we consider the case of auxiliary-input primitives, where each  $R$ 's query takes the form of  $(z, x)$  where  $z$  denotes auxiliary-input. For the sake of simplicity, we assume that the task of breaking an auxiliary-input primitive is further reduced to an average-case deterministic problem on uniform distribution with auxiliary-input by applying the techniques

in [22, 7] as in the previous work [10] and the length of instances of the average-case problem is the same as the length of auxiliary-input. We also assume that a reduction  $R$  makes queries of the form  $(z, x)$  where  $|z| = |x| = n$  and  $n$  is determined by the size of input to  $R$ .

There are two possible ways to extend the above idea to the case of auxiliary-input primitives: considering auxiliary-input in queries (a) together or (b) separately. For the first approach (a), we must determine a light query as a query satisfying the condition  $p_x \leq \text{poly}(n)2^{-2n}$  for applying the hiding protocol. This is problematic because the number of heavy queries is possibly  $2^{2n}/\text{poly}(n)$ , and many of them can be concentrated on one auxiliary-input. In other words, the above oracle  $\mathcal{O}_{\mathcal{L}}$  does not always solve the average-case problem in the worst-case sense on auxiliary-input. On the other hand, for the second approach (b), their verifier needs information on some statistics as advice for each auxiliary-input. Because there are exponentially many possibilities on auxiliary-input, the total length of such advice is exponentially large, which is unfeasible as an  $\text{AM}/\text{poly}$  protocol.

The subsequent work [2] provided the method to remove the above advice in the case of standard cryptographic primitives by applying an additional property of breaking cryptographic primitives (therefore, they constructed an  $\text{AM}$  protocol for  $\neg L$  instead of an  $\text{AM}/\text{poly}$  protocol). Unfortunately, even this method cannot be applied directly in the case of auxiliary-input cryptography. To obtain the statistics corresponding to the above advice, their protocol needs to generate query set by executing  $R$ . In our case, remember that we consider each auxiliary-input separately, so we need to simulate a conditional distribution on queries for fixed auxiliary-input. However, such distributions are not efficiently samplable in general: for example, consider the query distribution on  $(h(y), y)$  where  $h$  is a collision-free hashing function. Then, a polynomial-time verifier which simulates a conditional distribution for a fixed auxiliary-input (i.e., hash value) can easily find the collision of  $h$ .

## 5 Proof Sketches

In this section, we present proof ideas of Theorems 4, 8, 11, and 12. Note that Theorem 11 heavily relies on Theorem 8, and Theorem 8 heavily relies on Theorem 4. Therefore, although each proof idea may look pretty simple and intuitive, our construction of OWF for Theorem 11 becomes complicated and quite non-trivial as a whole. For the formal proofs, refer to the full version [29].

### 5.1 The Case of AIPRG: Proof Idea of Theorem 4

First, we formally introduce a hitting set generator, which takes a crucial role in our proof.

► **Definition 13** (Hitting set generator). *Let  $\gamma(n)$  be a function. A function  $G : \{0, 1\}^n \rightarrow \{0, 1\}^{\ell(n)}$  with  $\ell(n) > n$  is a (polynomial-time computable)  $\gamma$ -secure hitting set generator (HSG) if  $G$  is polynomially computable and there is no polynomial-time randomized adversary  $A$   $\gamma$ -avoiding  $G$ , i.e., satisfying the condition that for all sufficiently large  $n \in \mathbb{N}$ ,*

$$\forall x \in \{0, 1\}^n \Pr_A[A(G(x)) = 0] \geq 2/3 \text{ and } \Pr_{y \sim \{0, 1\}^{\ell(n)}} \left[ \Pr_A[A(y) = 1] \geq 2/3 \right] \geq \min(\gamma(n), \tau_n),$$

where  $\tau_n$  be a trivial limitation defined as  $\tau_n := 1 - \frac{|G(\{0, 1\}^n)|}{2^{\ell(n)}}$ .

Theorem 4 essentially follows from a nonadaptive BB security reduction from distinguishing AIPRG to avoiding HSG. Note that HSG based on AIPRG with a nonadaptive BB security reduction has been implicitly given in the study on MCSP [3, 16]. To see this explicitly, we will provide a much simpler construction of HSG based on AIPRG and a

self-contained proof. Although the reader may think that our construction is too fundamental and looks somewhat trivial, to the best of our knowledge, no one has mentioned such a direct relationship between AIPRG and HSG.

First, we assume that there is a nonadaptive BB security reduction from distinguishing AIPRG to avoiding HSG. Avoiding HSG is directly formulated as the following distributional NP problem (with zero-error): for uniformly chosen  $y$ , determine whether  $y$  is contained in the image of HSG. Therefore, the reduction also yields a nonadaptive BB reduction from distinguishing AIPRG to the distributional NP problem. Thus, any nonadaptive BB reduction from an NP-hard problem to distinguishing AIPRG indeed yields a nonadaptive BB reduction from the same NP-hard problem to the distributional NP problem. By the previous result by Bogdanov and Trevisan [10], such a reduction implies the collapse of the polynomial-hierarchy.

Our construction of HSG from AIPRG is the following: just considering the both of auxiliary-input and input to AIPRG as usual input to HSG. More specifically, let  $G = \{G_z : \{0, 1\}^n \rightarrow \{0, 1\}^{\ell(n)}\}_{z \in \{0, 1\}^*}$  be an AIPRG. Then the construction of HSG  $G'$  is given as  $G'(z \circ x) = G_z(x)$ . Note that, when  $z + n(|z|) \geq \ell(n(|z|))$  holds,  $G'$  does not satisfy the syntax on stretching input. In the formal proof, therefore, we first stretch the output of  $G$  by the standard technique in cryptography. It can be easily verified that the security reduction for this stretching (shown by the famous hybrid argument) is nonadaptive.

Let  $\gamma(n)$  be a reciprocal of polynomial. The security reduction from  $\gamma$ -avoiding  $G'$  to distinguishing  $G$  is also simple: just employing an adversary  $A$  for  $G'$  as an adversary for  $G$ . Obviously, this reduction is nonadaptive. To show the correctness, assume that  $A$   $\gamma$ -avoids  $G'$ . For the sake of simplicity, we also assume that  $A$  is deterministic and  $\gamma(n) < \tau_n$ . Whenever the input  $y$  is pseudorandom string contained in the image of  $G'$ ,  $A(y)$  does not output 1. On the other hand, if  $y$  is a truly random string, then  $A(y)$  outputs 1 with probability at least  $\gamma(n)$ . Thus,  $A$  can distinguish the uniform distribution from all distributions on the image of  $G'$  with an advantage at least  $\gamma(n)$ . For any auxiliary-input  $z$ ,  $G_z(U_{n(|z|)})$  is distributed on the image of  $G'$ . Thus,  $A$  also  $\gamma$ -distinguishes  $G$ .

## 5.2 The Case of AIOWF: Proof Idea of Theorem 8

In this section, we omit all arguments about the success probabilities of adversaries to focus on the proof idea. First, we introduce several reductions as elements of a standard OWF. Let  $R_{L \rightarrow f}$  denote the nonadaptive BB reduction from  $L$  to inverting  $f$  in the assumption. By the construction of PRG from OWF (e.g., [15]), there exist an auxiliary-input generator  $G$  and an adaptive BB reduction  $R_{f \rightarrow G}$  from inverting  $f$  to distinguishing  $G$ . By the result in Section 5.1, there exist an NP-language  $L'$  and a nonadaptive BB reduction  $R_{G \rightarrow L'}$  from distinguishing  $G$  to a distributional NP problem  $(L', U)$  (with zero-error). Since  $L' \in \text{NP}$  and  $L$  is NP-hard, there exists a Karp reduction  $R_{L' \rightarrow L}$  from  $L'$  to  $L$ .

Now we consider the following procedure:

1. select an instance  $x'$  of  $L'$  at random;
  2. translate  $x'$  into an instance  $x$  of  $L$  as  $x = R_{L' \rightarrow L}(x')$ ;
  3. plug  $x$  into  $R_{L \rightarrow f}$  with a random tape  $r$ ;
- At this stage,  $R_{L \rightarrow f}$  makes polynomially many queries  $(z_1, y_1), \dots, (z_q, y_q)$ .
4. answer the queries by some inverting oracle  $\mathcal{O}$ ;
  5. if  $R_{L \rightarrow f}$  outputs  $b \in \{0, 1\}$ , then output the same decision  $b$ .

Note that if the oracle  $\mathcal{O}$  correctly inverts  $f$ , then the resulting decision  $b$  is  $L(x)$  with high probability by the property of  $R_{L \rightarrow f}$ , and  $L(x)$  is equal to  $L'(x')$  by the property of  $R_{L' \rightarrow L}$ .

The crucial observation is that there is no worst-case sense at all in the above procedure because both  $x'$  and  $r$  are selected at random. Therefore, all queries at the stage 3 are indeed efficiently samplable, and the inverting oracle no longer needs to invert  $f$  for every auxiliary-input at the stage 4. This observation leads to the following construction of a standard OWF  $g$ .

The function  $g$  takes three inputs  $x', r$ , and  $x^f$ , which intuitively represents a random instance of  $L'$ , randomness for  $R_{L \rightarrow f}$ , and input for  $f$ , respectively. Then  $g(x', r, x^f)$  imitates the above procedure as follows: (2') translate  $x'$  into an instance  $x$  of  $L$  as  $x = R_{L' \rightarrow L}(x')$ , (3') plug  $x$  into  $R_{L \rightarrow f}$  with randomness  $r$ , then randomly pick one of auxiliary-input  $z$  in queries by  $R_{L \rightarrow f}$  and output  $f_z(x^f)$ .

We will show that the above  $g$  is one-way if  $\text{NP} \not\subseteq \text{BPP}$ . For contradiction, we assume that there exists an adversary  $A$  that inverts  $g$ . Remember that  $g$  simulates a distribution on queries produced by  $R_{L \rightarrow f}$  in the above procedure. Thus, intuitively, we can replace the inverting oracle  $\mathcal{O}$  with the adversary  $A$  at the stage 4 with high probability. This is a little technical part, and we present further details in the full version [29]. Then the above procedure no longer needs any oracle and yields a randomized algorithm solving  $(L', U)$  on average. By applying reductions  $R_{G \rightarrow L'}$ ,  $R_{f \rightarrow G}$ , and  $R_{L \rightarrow f}$  in this order, this also yields a randomized polynomial-time algorithm for  $L$ . Since  $L$  is NP-hard, we conclude that  $\text{NP} \subseteq \text{BPP}$ .

Remark that  $R_{G \rightarrow L'}$  is a nonadaptive BB reduction thanks to our simple construction in Section 5.1. Therefore, if we also have a construction of AIPRG  $G$  from AIOWF  $f$  with a nonadaptive BB reduction from inverting  $f$  to distinguishing  $G$ , then the above proof leads to a nonadaptive BB reduction from  $L$  to  $(L', U)$ , which implies the collapse of the polynomial hierarchy as in Theorem 4. Thus, finding such a simple construction of AIPRG is one direction for excluding a nonadaptive BB reduction to base AIOWF on NP-hardness, as mentioned in Section 3.

### 5.3 The Case of AIHSG: Proof Idea of Theorem 11

Our goal is to simulate an avoiding oracle for a nonadaptive BB reduction by another protocol in some restricted complexity class, in our case, BPP. The key idea for this is to classify each query generated by the nonadaptive BB reduction into “light” and “heavy” queries as in [10]. A similar technique was also applied in the previous work for HSG [12, 17]. Thus, we first review the previous case of HSG and then explain the difference to our case of AIHSG.

#### The Case of Hitting Set Generator (Previous work)

Let  $G : \{0, 1\}^n \rightarrow \{0, 1\}^{\ell(n)}$  denote a generator with  $\ell(n) \geq (1 + \Omega(1)) \cdot n$  and  $R^?$  denote a nonadaptive BB reduction from an NP-language  $L$  to avoiding  $G$ . W.l.o.g., we can assume that marginal distributions on each query by  $R$  are identical regardless of each query position by applying a random permutation on query positions before asking them to oracle. Thus, for each input  $x \in \{0, 1\}^n$  to  $R$ , one marginal distribution  $Q_x$  on  $R$ 's queries is determined. We choose a threshold (roughly)  $\tau = 1/\tilde{\Theta}(2^n)$  and define a light (resp. heavy) query  $y \in \{0, 1\}^{\ell(n)}$  as a query generated according to  $Q_x$  with probability less (resp. greater) than the threshold  $\tau$ .

We simulate the avoiding oracle for  $G$  by using the classification of queries as follows. First, assume that we could (somehow) distinguish the heavy case and the light case for a given query. Then we can also simulate one of avoiding oracles simply as follows: for each query  $y$  generated by  $R(x)$ , (1) determine whether  $y$  is heavy or light; (2) answer 0 (resp. 1)

if  $y$  is heavy (resp. light) query. Let  $\mathcal{O}'$  denote the induced oracle by the above simulating procedure. Note that the probability that  $\mathcal{O}'(y)$  outputs 0 is exponentially small because the fraction of light queries is  $\tilde{\Theta}(2^n)/2^{\ell(n)} \leq 2^{-\Omega(n)}$ . Thus,  $\mathcal{O}'$  satisfies the condition on the probability of outputting 1. However,  $\mathcal{O}'$  is not avoiding oracle for  $G$ , because there is possibly a query  $y$  such that  $y$  is heavy but contained in  $\text{Im}G$ . In this case,  $\mathcal{O}'(y)$  outputs 1 even for  $y \in \text{Im}G$  and fails to avoid  $G$ .

The key observation to overcome this issue is the following:

- ( $\star$ ) For each length  $\ell(n)$  of query (i.e., the input size is  $n$ ), the size of  $\text{Im}G$  is at most  $2^n$ ; thus the probability that  $R$  asks some light query contained in  $\text{Im}G$  (we refer to it as a “bad” query) is bounded above by  $2^n/\tilde{\Theta}(2^n) \leq 1/\text{poly}(n)$ .

Therefore,  $\mathcal{O}'$  is consistent with some avoiding oracle, and  $R^{\mathcal{O}'}(x)$  correctly recognizes  $x$  with high probability over the execution of  $R$ .

By the above argument, we can reduce avoiding a generator to distinguishing heavy and light queries. For the latter task, Gutfreund and Vadhan [12] presented a  $\text{BPP}^{\text{NP}}$  algorithm by approximation of counting in [26], and Hirahara and Watanabe [17] presented an  $\text{AM} \cap \text{coAM}$  algorithm by generalizing the protocol in [11].

### The Case of Auxiliary-input Hitting Set Generator (Our work)

We move on to our case of AIHSG. Let  $G = \{G_z : \{0, 1\}^{n(|z|)} \rightarrow \{0, 1\}^{\ell(n(|z|))}\}_{z \in \{0, 1\}^*}$  denote an auxiliary-input generator with  $\ell(n) \geq (1 + \Omega(1)) \cdot n$  and  $R^?$  denote a nonadaptive BB reduction from an NP-language  $L$  to avoiding  $G$ . We can also assume that all marginal query distributions of  $R^?(x)$  are identical to  $Q_x$  regardless of query position.

To extend the above argument to our case of AIHSG, the problematic part is the key observation ( $\star$ ). Remember that an adversary for AIHSG must avoid  $G_z$  for all  $z \in \{0, 1\}^*$ , and auxiliary-input is possibly longer than output. Therefore, we cannot bound the size of the image of the generator in general because the image may span the whole range (for example, consider the following generator  $G_z(x) = z \oplus (x \circ 0^{|z|-|x|})$  for  $|z| > n(|z|)$ ).

To overcome this, we need to consider each case of auxiliary-input  $z$  separately. Therefore, we change the definitions of “light” and “heavy” queries depending on auxiliary-input. Let  $p_x(z)$  denote a probability that  $Q_x$  generates a query of auxiliary-input  $z$ . If we can bound the probability that  $R$  makes light query  $(z, y)$  with  $y \in \text{Im}G_z$  by  $1/(\text{poly}(n) \cdot p_x(z))$  for any  $z$ , then  $R$  makes such a “bad” query  $(z, y)$  with probability at most  $\sum_z p_x(z) \cdot 1/(\text{poly}(n) \cdot p_x(z)) = 1/\text{poly}(n)$ . Then we can use the same argument in the case of HSG and reduce avoiding  $G$  to distinguishing heavy and light cases. This idea naturally leads to the following new definition of “light” and “heavy”: separating each query  $(z, y)$  by the conditional probability  $p_x(y|z)$  that  $y$  is asked conditioned on the event that the auxiliary-input in the query is  $z$ . In fact, this modification will work well even for AIHSG (for the formal argument, refer to the full version [29]).

However, one issue remains: how can we distinguish heavy and light queries? To this end, we must verify the largeness of the conditional probability of the given query. This part essentially prevents us from applying the previous results. Since we consider a polynomial-time computable generator, the simulation with NP oracle does not yield any nontrivial result, not as the work in [12]<sup>5</sup>. Even for the simulation in  $\text{AM} \cap \text{coAM}$  in [17], there are

<sup>5</sup> Their work concerned the original aim of HSG, i.e., derandomization (e.g., [25]). For this purpose, they considered (possibly) exponential-time computable HSG  $G$ , where avoiding  $G$  in  $\text{BPP}^{\text{NP}}$  is quite nontrivial. However, in our case where  $G$  is polynomial-time computable, avoiding  $G$  is in NP trivially.

several technical issues. We cannot trivially verify the size of conditional probability by such protocols due to the restricted use of the upper bound protocol developed in [1]. Moreover, we cannot possibly even sample the conditional distribution efficiently for fixed auxiliary-input, as discussed in Section 4.

Our idea is to adopt universal extrapolation in [22]. Intuitively speaking, the universal extrapolation is a tool to reduce approximating the probability  $p_y = \Pr_{U_n}[y = f(U_n)]$  to inverting  $f$  for a polynomial-time computable  $f$  and a given  $y = f(x)$  where  $x \in \{0, 1\}^n$  is selected at random. In fact, the universal extrapolation holds even for an auxiliary-input function, and a similar technique was also used in [30]. By using the universal extrapolation for each circuit which generates query and auxiliary-input, we have a good approximation of  $p_x(y|z)$  for query  $(z, y)$  generated by  $R^2(x)$ . Thus, the universal extrapolation enables us to classify the given  $(z, y)$  correctly. Note that the auxiliary-input in the universal extrapolation essentially corresponds to the input  $x$  for each circuit sampling query and auxiliary-input.

To show Theorem 11, we need further observations. Since  $R$  makes its queries non-adaptively, we can also invoke the universal extrapolation nonadaptively. Moreover, the universal extrapolation algorithm indeed uses an inverting adversary for a certain AIOWF as black-box and nonadaptively (we also see this formally in the full version [29]). As a result, a nonadaptive BB reduction from an NP-hard language  $L$  to avoiding AIHSG yields a nonadaptive BB reduction from  $L$  to inverting AIOWF. Thus, by Theorem 8,  $R$  also yields a one-way function under the assumption that  $\text{NP} \not\subseteq \text{BPP}$ .

## 5.4 Oracle Separation between OWF and AIOWF: Proof Idea of Theorem 12

To show Theorem 12, we employ a random function  $\mathcal{F} = \{\mathcal{F}_n : \{0, 1\}^n \rightarrow \{0, 1\}^n\}_{n \in \mathbb{N}}$ , where each  $\mathcal{F}_n$  is selected uniformly from length-preserving functions of input size  $n$ . As shown in [24], any polynomial-time oracle machine cannot invert  $\mathcal{F}$  with non-negligible probability (with probability 1 over the choice of  $\mathcal{F}$ ). In other words, if a primitive given access to  $\mathcal{F}$  directly outputs the value of  $\mathcal{F}$ , such a primitive must be one-way. Therefore, all we have to do is to let a random function  $\mathcal{F}$  available for auxiliary-input primitives but unavailable for standard primitives.

To this end, we simply add  $n$ -bit auxiliary-input to a random function of the input size  $n$ . Then we choose one auxiliary-input  $z_n$  from  $2^n$  possibilities of  $\{0, 1\}^n$  as a target auxiliary-input and embed the random function to the position indexed by  $z_n$ . Let  $\mathcal{F} = \{F_z : \{0, 1\}^{|z|} \rightarrow \{0, 1\}^{|z|}\}_{z \in \{0, 1\}^*}$  be such an embedded random function. Note that the similar random embedding technique was also used in the previous work for other oracle separations (e.g., [35]). If an auxiliary-input primitive  $f$  given access to  $\mathcal{F}$  identifies the auxiliary-input of  $F$  with own auxiliary-input, then  $f$  must be AIOWF because an adversary for  $f$  must invert  $f_z$  for all auxiliary-inputs  $z$ , including the random function. On the other hand, any polynomial-time computable primitive (without auxiliary-input) cannot find the target auxiliary-input of  $\mathcal{F}$  with non-negligible probability because they were selected at random. Thus, any (standard) primitive does not take nontrivial advantage of  $\mathcal{F}$ .

For the oracle separation, we combine the above embedded random function  $\mathcal{F}$  with the PSPACE oracle (w.l.o.g., the oracle TQBF determining satisfiability of quantified Boolean formulae). Let  $\mathcal{O}_{\mathcal{F}}$  denote this oracle. Since the random function in  $\mathcal{F}$  is selected independently of TQBF, the additional access to TQBF does not help to invert the random function at all. Thus, AIOWF still exists relative to  $\mathcal{O}_{\mathcal{F}}$ .

On the other hand, we consider a function  $f$  which is polynomial-time computable with access to  $\mathcal{O}_{\mathcal{F}}$  arbitrarily. Since the target auxiliary-input is selected independently of TQBF, the additional access to TQBF does not help to find the target auxiliary-input at all. Thus,  $f$

cannot still take nontrivial advantage of  $\mathcal{F}$  and is regarded as a function given only access to TQBF. We can easily verify that any polynomial-time computable function with access to TQBF is efficiently invertible by TQBF. Since the above argument holds for any  $f$ , OWF does not exist relative to  $\mathcal{O}_{\mathcal{F}}$ . Thus, we have the oracle separation between AIOWF and OWF.

---

## Abstract

The *linear cross-entropy benchmark* (Linear XEB) has been used as a test for procedures simulating quantum circuits. Given a quantum circuit  $C$  with  $n$  inputs and outputs and purported simulator whose output is distributed according to a distribution  $p$  over  $\{0, 1\}^n$ , the linear XEB fidelity of the simulator is  $\mathcal{F}_C(p) = 2^n \mathbb{E}_{x \sim p} q_C(x) - 1$ , where  $q_C(x)$  is the probability that  $x$  is output from the distribution  $C|0^n\rangle$ . A trivial simulator (e.g., the uniform distribution) satisfies  $\mathcal{F}_C(p) = 0$ , while Google's noisy quantum simulation of a 53-qubit circuit  $C$  achieved a fidelity value of  $(2.24 \pm 0.21) \times 10^{-3}$  (Arute et. al., Nature'19).

In this work we give a classical randomized algorithm that for a given circuit  $C$  of depth  $d$  with Haar random 2-qubit gates achieves in expectation a fidelity value of  $\Omega(\frac{n}{L} \cdot 15^{-d})$  in running time  $\text{poly}(n, 2^L)$ . Here  $L$  is the size of the *light cone* of  $C$ : the maximum number of input bits that each output bit depends on. In particular, we obtain a polynomial-time algorithm that achieves large fidelity of  $\omega(1)$  for depth  $O(\sqrt{\log n})$  two-dimensional circuits. This is the first such result for two dimensional circuits of super-constant depth. Our results can be considered as an evidence that fooling the linear XEB test might be easier than achieving a full simulation of the quantum circuit.

**2012 ACM Subject Classification** Theory of computation  $\rightarrow$  Quantum complexity theory

**Keywords and phrases** Quantum supremacy, Linear cross-entropy benchmark

## 1 Introduction

*Quantum computational supremacy* refers to experimental violations of the extended Church Turing Hypothesis using quantum computers. The most famous (and arguably at this point the only) example of such an experiment was carried out by Google [2]. The Google team

constructed a device  $D$  that provides a “noisy simulation” of a quantum circuit  $C$  with  $n$  inputs and  $n$  outputs. The device can be thought as a “black box” that samples from a distribution  $p_D$  over  $\{0, 1\}^n$  that (loosely) approximates the distribution  $q_C$  that corresponds to measuring  $C$  applied to the all-zeroes string  $0^n$ . The quality of the device was measured using a certain benchmark known as the *Linear Cross-Entropy* benchmark (*a.k.a.* Linear XEB). The computational hardness assumption underlying the experiment is that no efficient classical algorithm can achieve a similar score. In this paper we investigate this assumption, giving a new classical algorithm for “spoofing” this benchmark in certain regimes. While our algorithm falls short of spoofing the benchmark in the parameter regime corresponding to the Google experiment, we do manage to achieve non-trivial results for deeper circuits than were known before. To our knowledge, this is the first algorithm that directly targets the linear XEB benchmark, without going through a full simulation of the underlying quantum circuit. Thus our work can be viewed as evidence that obtaining non-trivial performance for this benchmark is *not* equivalent to simulating quantum circuits.

The linear XEB benchmark is defined as follows. Let  $C$  be an  $n$ -qubit quantum circuit and  $q_C : \{0, 1\}^n \rightarrow [0, 1]$  be the pdf of the distribution obtained by measuring  $C|0^n\rangle$ . For each  $x \in \{0, 1\}^n$ , the instance linear XEB of  $x$  is defined as  $\mathcal{F}_C(x) := 2^n q_C(x) - 1$ . For every probability distribution  $p$ , the linear XEB fidelity of  $p$  with respect to circuit  $C$  is defined as

$$\mathcal{F}_C(p) := \mathbb{E}_{x \sim p} [\mathcal{F}_C(x)] = 2^n \sum_{x \in \{0, 1\}^n} q_C(x) p(x) - 1.$$

If  $C$  is a fully random circuit, then in expectation a perfect simulation  $p = q_C$  achieves  $\mathcal{F}_C(p) = 2$ .<sup>1</sup> Google’s “quantum computational supremacy” experiment demonstrated a noisy simulator sampling from a distribution  $p$  with  $\mathcal{F}_C(p) \approx (2.24 \pm 0.21) \times 10^{-3}$  for two dimensional 53-qubit circuits of depth 20. A trivial simulation (e.g. a distribution  $p$  which is the uniform distribution or another distribution independent of  $C$ ) will achieve  $\mathcal{F}_C(p) = 0$ . Motivated by the above, we say that  $p$  achieves *non-trivial fidelity* with respect to the circuit  $C$  if  $\mathcal{F}_C(p) = 1/\text{poly}(n)$ .<sup>2</sup>

The computational assumption underlying quantum computational supremacy with respect to some distribution  $\mathcal{D}$  over quantum circuits can be defined as follows. For every efficient randomized classical algorithm  $A$ , with high probability over  $C \sim \mathcal{D}$ , if we let  $A_C$  be the distribution of  $A$ ’s output on input  $C$ , then  $\mathcal{F}_C(A_C) = n^{-\omega(1)}$ . That is, the distribution output by  $A(C)$  has trivial fidelity with respect to  $C$ . Aaronson and Gunn [1] showed that this assumption follows from a (very strong) assumption they called “Linear Cross-Entropy Quantum Threshold Assumption” or XQUATH.<sup>3</sup>

In this work, we present an efficient classical algorithm  $A$  that satisfies  $\mathcal{F}_C(A_C) = \Omega(1)$  for quantum circuit  $C$  sampled from a distribution with Haar random 2-qubit gates with small *light cones* (see Definition 4).<sup>4</sup> Specifically, we prove the following theorem:

<sup>1</sup> This follows since  $q_C$  is the *Porter Thomas distribution*. However,  $q_C$  is *not* the maximizer of  $\mathcal{F}_C(p)$ : a distribution  $p$  that has all its mass on the mode  $x$  of the distribution  $q_C$  will achieve  $\mathcal{F}_C(p) \geq \Omega(n)$  for fully random circuits, and even higher values for shallower circuits as we’ll see below.

<sup>2</sup> As mentioned above, for an ideal simulation in random circuits the fidelity will be a constant. For noisy quantum circuits such as Google’s, the fidelity is roughly  $\exp(-\epsilon s)$  where  $\epsilon$  is the level of noise per gate and  $s = \Theta(d \cdot n)$  is the number of gates in the circuit.

<sup>3</sup> While [1] state their result for  $\Omega(1)$  fidelity, their proof shows that the XQUATH assumption implies that classical algorithms can not achieve  $1/\text{poly}(n)$  empirical fidelity with  $\text{poly}(n)$  samples.

<sup>4</sup> If  $C$  is a quantum circuit and  $i$  is an output bit of  $C$ , then the *light cone* of  $i$  is the set of all input bits  $j$  that are connected to  $i$  via a path in the circuit. For general circuits the light cone size can be exponential in the depth, but for one or two dimensional circuits, of the type used in quantum supremacy experiment, the light cone size is polynomial in the depth.

► **Theorem 1** (Linear XEB for circuits with small light cones). *Let  $n, d, L \in \mathbb{N}$  and let  $\mathcal{D}$  be a distribution over  $n$ -qubit quantum circuits with (i) light cone size at most  $L$ , (ii) depth at most  $d$ , and (iii) Haar random 2-qubit gates. Then, there exists a classical randomized algorithm  $A$  running in  $\text{poly}(n, 2^L)$  time such that*

$$\mathbb{E}_{C \sim \mathcal{D}} [\mathcal{F}_C(A_C)] \geq (1 + 15^{-d})^{\lfloor \frac{n}{L} \rfloor} - 1.$$

For constant dimensional circuits (such as the 2D quantum architecture used by Google), Theorem 1 yields the following corollary:

► **Corollary 2** (Constant dimensional circuits). *Let  $n \in \mathbb{N}$  and  $d = O(\log n)$ . Let  $c \in \mathbb{N}$  be a constant and  $\mathcal{D}$  be the distribution of  $n$ -qubit  $c$ -dimensional circuits of depth  $d$  with Haar random 2-qubit gates. There is a randomized algorithm  $A$  running in time  $2^{O(d^c)}$  such that*

$$\mathbb{E}_{C \sim \mathcal{D}} \mathcal{F}_C(A_C) = 1/\text{poly}(n).$$

**Proof.** A  $c$ -dimensional of depth  $d$  circuit has light-cone of size  $L = O(d^c) = n^{o(1)}$  for  $d = O(\log n)$ . Let  $d = \alpha \log n$ . By plugging in the parameters of Theorem 1, we see that (using  $\log_2 15 < 4$  and  $n/L \geq n^{1-o(1)}$ ) the expected value of the fidelity is at least

$$(1 + 2^{-4d})^{n^{1-o(1)}} - 1 \geq \Omega\left(\frac{n^{1-o(1)}}{n^{4\alpha}}\right).$$

The right hand side is at least  $1/\text{poly}(n)$  for every constant  $\alpha$  and in fact is at least  $\omega(1)$  for  $\alpha < 1/4$ . ◀

The bounds of Corollary 2 do *not* correspond to the Google experiment where the depth is roughly comparable to  $\sqrt{n}$ , rather than logarithmic. However, prior works in the literature were only able to achieve good linear XEB performance for circuits of *constant* depth (see Section 1.2). More importantly (in our view) is that our bounds show that it may be possible to achieve good linear XEB performance without achieving a full simulation.

## 1.1 From expectation to concentration

In actual experiments, one measures the *empirical* linear XEB, obtained by sampling  $x_1, \dots, x_T$  independently from the distribution  $p$  and computing  $\frac{1}{T} \sum_{i=1}^T 2^n q_C(x_i) - 1$ . Thus in our classical simulation we want to go beyond achieving large *expected* linear XEB benchmark, to show that our algorithm  $A$  actually achieves non-trivial empirical linear XEB with probability at least inverse polynomial over the choice of the circuit and with a number of samples  $T$  that is at most polynomial in  $n$ . These probability bounds are more challenging to prove, and at the moment our results are weaker than the optimal bounds one can hope for.

### Probability over circuits

For bounding the probability over *circuits* we show in Section 5.1, that in the setting of Theorem 1, for logarithmic depth circuits, we can obtain  $1/\text{poly}(n)$  fidelity with probability at least  $1/\text{poly}(n)$ . We also obtain more general tradeoffs between the fidelity, probability, and depth, see Corollary 12. We conjecture that random circuits from the distributions we consider exhibit much better concentration, and fact that the fidelity sharply concentrates around its expectation.

### Sample complexity, or probability over the algorithms' randomness

Bounding the *sample complexity* of our algorithm is a more difficult task than the expectation analysis because it requires higher moment information on  $\mathcal{F}_C(A_C)$ . We obtain only partial bounds in this setting, which we believe to be far from optimal. In Section 6 we show that an upper bound for the *collision probability* of  $q_C$  is sufficient to give an upper bound for the sample complexity of our algorithm. Specifically, letting  $CP(q) = \sum_{x \in \{0,1\}^n} q(x)^2$ , we show that if  $CP(q) = M \cdot 2^{-n}$  then the number of samples needed for the empirical linear XEB to achieve a value of at least  $\epsilon$  is  $M \cdot \exp(O(\epsilon \cdot 15^d))$ . In particular, for logarithmic depth circuits we can get inverse-polynomial empirical fidelity using  $O(M)$  samples. For *random* quantum circuits, where  $q_C$  is the Porter-Thomas distribution (with  $q_C(x)$  drawn independently as the square of a mean zero variance  $2^{-n}$  normal variable), it is known that  $CP(q_C) = O(2^{-n})$ , i.e.,  $M = O(1)$ . For shallow circuits, of the type we study, we show in Lemma 16 that  $CP(q_C) = O(2^{-n})$  for random *one dimensional* circuits of depth at least  $c \log n$  for some constant  $c > 0$ , which shows that we can achieve for such circuits inverse polynomial empirical fidelity using a polynomial number of samples. While this is significantly more technically challenging to prove, we conjecture that the same collision probability bound holds for *two dimensional* circuits of depth  $\Omega(\sqrt{\log n})$ . This conjecture, if true, will imply that for such circuits we can achieve  $1/\text{poly}(n)$  empirical fidelity using a polynomial number of samples, and constant fidelity using a sub-exponential (e.g.  $\exp\{\exp\{O(\sqrt{\log n})\}\}$ ) number of samples.<sup>5</sup>

## 1.2 Prior works

Prior classical algorithms mostly focused on the task of obtaining a full simulation (sampling from  $C|0^n\rangle$  or from a distribution close to it in statistical distance). We are not aware of any prior work that directly targeted the linear XEB measure and gave explicit bounds for the performance in this measure that are not implied by approximating the full distribution.

Napp et al [8] gave an algorithm to simulate random two-dimensional circuits of some small constant depth. They gave strong theoretical evidence that up to a certain constant depth, such circuits can be approximated by 1D circuits of small entanglement (i.e., “area law” as opposed to “volume law”), which can be effectively simulated using Matrix Product States [10]. However, [8] also gave evidence that the system undergoes a *phase transition* when the depth is more than some constant size (around 4), at which case the entanglement grows according to a “volume law” and hence their methods cannot be used to simulate circuits of super-constant depth.

Another direction of approximating large quantum circuits has considered the effect of *noise*. Some restricted classes of noisy quantum circuits were shown to be simulated by polynomial time classical algorithms in [4, 11] (in contrast to their noiseless variant [3]). This was also extended to more general random circuits by [6]. Very recent work has given numerical results suggesting that states generated by noisy quantum circuits could be approximated by Matrix Product States or Operators under the state fidelity measure [12, 9].<sup>6</sup> Low degree Fourier expansions yield other candidates for approximating such quantum states [6, 4].

<sup>5</sup> Very recently we have learned that Dalzell, Hunter-Jones, and Brandao (personal communication) refuted Conjecture 10 though we have not yet had a chance to verify their proof. The refutation of Conjecture 10 would only rule out a specific approach to upper bound the sample complexity. It is still possible that our algorithm achieves  $1/\text{poly}(n)$  empirical fidelity using a polynomial number of samples for *two dimensional* circuits of depth  $\Omega(\sqrt{\log n})$ .

<sup>6</sup> [12] briefly discusses the linear XEB measure as well, see Figure 7 there.

## 2 Preliminaries

In this section we introduce some of the notions we use for quantum circuits, and in particular distributions of random quantum circuits of fixed architecture, as well as tensor networks for analyzing quantum circuits. We include this here since some of this notation, and in particular tensor networks, might be unfamiliar to theoretical computer science audience. However, the reader can choose to skip this section and refer back to it as needed.

For  $n \in \mathbb{N}$ , an  $n$ -qubit quantum state  $|\psi\rangle = \sum_{x \in \{0,1\}^n} \alpha_x |x\rangle$  is a unit vector in  $\mathbb{C}^{2^n}$ . We let  $I, X, Y, Z$  denote the Pauli matrices where
