### 4.3 Lower Bounds for Randomized Algorithms

The following shows that sensitivity must increase as approximation ratio goes to one.

► **Theorem 20.** *Let  $\epsilon > 0$ . Any (possibly randomized)  $(1 - \epsilon)$ -approximation algorithm for the maximum matching problem has sensitivity  $\Omega(1/\epsilon)$ .*

**Proof.** For simplicity, we assume  $1/10\epsilon$  is an even integer. Let  $A$  be an arbitrary  $(1 - \epsilon)$ -approximation algorithm for the maximum matching problem, and let  $G$  be a graph consisting of a cycle of length  $1/10\epsilon$  and  $n - 1/10\epsilon$  isolated vertices. Clearly  $G$  has two disjoint maximum matchings, say,  $M_1, M_2$ , of size  $1/20\epsilon$ . Let  $p_1$  and  $p_2$  be the probability that  $A$  on  $G$  outputs  $M_1$  and  $M_2$ , respectively. Then as  $A$  has approximation ratio  $1 - \epsilon$ , we have

$$p_1 \cdot \frac{1}{20\epsilon} + p_2 \cdot \frac{1}{20\epsilon} + (1 - p_1 - p_2) \cdot \left( \frac{1}{20\epsilon} - 1 \right) \geq \frac{1 - \epsilon}{20\epsilon}.$$

Hence, we have  $p_1 + p_2 \geq 19/20$ , and it follows that at least one of  $p_1 \geq 19/40$  and  $p_2 \geq 19/40$  hold. Without loss of generality, we assume  $p_1 \geq 19/40$ .

Let  $G'$  be the graph obtained from  $G$  by removing one edge in  $M_1$ . Then,  $G'$  has a unique maximum matching  $M_2$ . Let  $p'_2$  be the probability that  $A$  on  $G'$  outputs  $M_2$ . As  $A$  has approximation ratio  $1 - \epsilon$ , we have

$$p_2 \cdot \frac{1}{20\epsilon} + (1 - p_2) \cdot \left( \frac{1}{20\epsilon} - 1 \right) \geq \frac{1 - \epsilon}{20\epsilon},$$

which implies  $p'_2 \geq 19/20$ . Hence, the sensitivity of  $A$  is at least

$$\max\left(\Pr[A(G) = M_1] - \Pr[A(G') \neq M_2], 0\right) \cdot d_H(M_1, M_2) \geq \left(\frac{19}{40} - \frac{1}{20}\right) \cdot \frac{1}{10\epsilon} = \Omega\left(\frac{1}{\epsilon}\right). \blacktriangleleft$$

## 5 Weighted Sensitivity and Maximum Weighted Matching

In this section, we consider a generalization of sensitivity to weighted graphs, and show an approximation algorithm with low sensitivity for the maximum weighted matching problem.

### 5.1 Weighted Sensitivity

Given a weight function over the edges  $w : E \rightarrow \mathbb{R}$  of a graph  $G = (V, E)$  and two edge sets  $S$  and  $S'$ , let

$$d_H^w(S, S') = \sum_{e \in S \Delta S'} w(e),$$

where  $\triangle$  again denotes the symmetric difference. For random edge sets  $X$  and  $X'$ , we use  $d_{\text{EM}}^w(X, X')$  to denote the weighted earth mover's distance between  $X$  and  $X'$  with respect to  $w$ , so that

$$d_{\text{EM}}^w(X, X') = \min_{\mathcal{D}} \mathbf{E}_{(S, S') \sim \mathcal{D}} d_{\text{H}}^w(S, S'),$$

be the weighted Hamming distance between  $S$  and  $S'$  with respect to  $w$ , where  $\mathcal{D}$  is a distribution such that its marginal distributions on the first and second coordinates are  $X$  and  $X'$ , respectively. For a real-valued function  $\beta$  on graphs, we say that the *weighted sensitivity* of an algorithm  $A$  that outputs a set of edges is at most  $\beta$  if for every graph  $G = (V, E)$ , a weight function  $w : E \rightarrow \mathbb{R}$ , and an edge  $e \in E$ ,

$$d_{\text{EM}}^w(A(G), A(G - e)) \leq \beta(G).$$

A priori, it is not clear whether the weighted sensitivity of an algorithm should correlate with the weight of removed edges. Thus we say that the *normalized weighted sensitivity* is at most  $\beta$  if

$$\frac{d_{\text{EM}}^w(A(G), A(G - e))}{w(e)} \leq \beta(G).$$

## 5.2 Algorithm Description

We use a simple approach of partitioning the input by weight, finding a maximal matching on each partition, and finally forming a weighted matching by greedily adding edges from the maximal matchings, beginning with the matchings in the largest weight classes. The approach is known to give a  $(4 + \epsilon)$ -approximation [1, 5] to the maximum weighted matching. However to bound the weighted sensitivity of our algorithm, we must choose  $\epsilon$  carefully.

Formal description of our algorithm is given in Algorithm 7. It first defines subsets of edges  $E_i$ , where we assume the weight of each edge is polynomially bounded in  $n$ , so that  $1 \leq w(e) \leq n^c$  for some constant  $c$ . For a parameter  $\alpha > 1$ , we define  $E_i$  to be the subset of edges in  $E$  with weight at least  $\alpha^i$ . Algorithm 7 first draws a random permutation  $\pi$  of the edges and greedily forms a maximal matching  $M_i$  on each set  $E_i$  induced by  $\pi$ . It then greedily adds edges to a maximal matching, starting from the matching of the heaviest weight class and moving downward. That is, we initialize  $M$  to be the empty set and greedily add edges of  $M_i$  to  $M$ , starting with  $i = O(\log_\alpha n^c)$  and decrementing  $i$  after each iteration.

► **Theorem 21** ([1, 5]). *Algorithm 7 gives an  $\frac{1}{4\alpha}$ -approximation to the maximum weighted matching and uses runtime  $O(m \log_\alpha n)$  on a graph with  $m$  edges and  $n$  vertices.*

## 5.3 Sensitivity Analysis

We first require the following key structural lemma that we use to prove Theorem 12 in the full version of the paper.

► **Lemma 22.** *In expectation, the deletion of an edge  $e$  alters at most one edge in  $M_i$ , i.e., at most one edge in  $M_i$  is inserted or deleted in expectation.*

The sensitivity analysis follows from the observation that the deletion of an edge  $e$  can only affect the matchings  $E_i$  for which  $\alpha^i \leq w(e)$ . Moreover by Lemma 22, the deletion of edge  $e$  affects at most one edge in  $E_i$ , in expectation. Thus in expectation, the deletion of  $e$  affects at most two edges in  $E_{i-1}$  in expectation and inductively, the deletion of  $e$  affects at most  $2^j$

---

**Algorithm 7** Algorithm for maximum weighted matching.

```

1 Procedure MATCHING( $G, \epsilon, w$ )
2   Let  $C$  be a sufficiently large constant and  $\alpha > 1$  be a trade-off parameter.;
3   Let  $\pi$  be a random ordering of the edges of  $G$ ;
4   For each  $i = 0$  to  $i = C \log n$ , let  $E_i$  be the set of edges with weight at least  $\alpha^i$ ;
5   Let  $M_i$  be the greedy maximal matching of  $E_i$  induced by  $\pi$ ;
6    $M \leftarrow \emptyset$ ;
7   for  $i = C \log n$  to 0 do
8     for  $e \in M_i$  do
9       if  $e$  is not adjacent to  $M$  then
10         $M \leftarrow M \cup \{e\}$ ;
11  return  $M$ .

```

---

edges in  $E_{i-j}$  in expectation. On the other hand, the weight of each edge in  $E_{i-j}$  is at most  $\alpha^{i-j}$  so the weighted sensitivity is  $\sum_j \alpha^{i-j} 2^j$ . Hence for  $\alpha = 2$ , the weighted sensitivity is  $O(2^i \log n)$  and for  $\alpha > 2$ , the weighted sensitivity is  $O(2^i)$ . Similarly for normalized weighted sensitivity, we rescale by  $\frac{1}{2^i}$  so that the normalized weighted sensitivity is  $O(\log n)$  for  $\alpha = 2$  and  $O(1)$  for  $\alpha > 2$ . We now formalize this intuition.

► **Theorem 23.** *Suppose  $1 \leq w(e) \leq W \leq n^c$  for some absolute constants  $W, c > 0$  for all  $e \in E$ . The weighted sensitivity of Algorithm 7 is  $O(W \log n)$  for  $\alpha = 2$  and  $O(W)$  for  $\alpha > 2$ . The normalized weighted sensitivity of Algorithm 7 is  $O(\log n)$  for  $\alpha = 2$  and  $O(1)$  for  $\alpha > 2$ .*

**Proof.** Let  $e$  be an edge of weight  $w(e) \in [2^i, 2^{i+1}]$  for some integer  $i \geq 0$  and suppose  $e$  is removed from  $G$ . For  $j \leq i$ , let  $S_j$  be the set of edges in  $E_j$  affected by the deletion of edge  $e$ , so that by Lemma 22,  $\mathbb{E}[|S_i|] \leq 1$ . Then we have  $\mathbb{E}[|S_i| \cup \{e\}] \leq 2$  so that Lemma 22 implies that  $\mathbb{E}[|S_{i-1}|] \leq 2$ . Now suppose that for a fixed  $j \leq i$ , we have  $\mathbb{E}[|\{e\} \cup \bigcup_{k=j}^i S_k|] \leq 2^{i-j}$ . Then Lemma 22 implies that  $\mathbb{E}[|S_{j-1}|] \leq 2^{i-j}$  so that

$$\mathbb{E} \left[ \left| \{e\} \cup \bigcup_{k=j-1}^i S_k \right| \right] \leq 2^{i-j+1}.$$

Hence by induction, we have  $\mathbb{E}[|S_j|] \leq 2^{i-j}$ .

Since each edge of  $E_i$  has weight at most  $\alpha^i$ , then we have

$$d_{\text{EM}}(A(G), A(G - e)) = \sum_{j=0}^i 2^{i-j} \alpha^j,$$

where  $A(G)$  represents the output of Algorithm 7 on  $G$ . Under the assumption that  $1 \leq w(e) \leq n^c$  for some absolute constant  $c > 0$  for all  $e \in E$ , then  $i = O(\log n)$ . Hence for  $\alpha = 2$ , we have  $\sum_{j=0}^i 2^{i-j} \alpha^j = O(2^i \log n) = O(W \log n)$  and for  $\alpha > 2$ , we have  $\sum_{j=0}^i 2^{i-j} \alpha^j = O(2^i) = O(W)$ . Moreover, we have

$$\overline{d_{\text{EM}}}(A(G), A(G - e)) \leq \frac{1}{2^{i+1}} \sum_{j=0}^i 2^{i-j} \alpha^j,$$

so that  $\overline{d_{\text{EM}}}(A(G), A(G - e)) \leq O(\log n)$  for  $\alpha = 2$  and  $\overline{d_{\text{EM}}}(A(G), A(G - e)) = O(1)$  for  $\alpha > 2$ . ◀

Together, Theorem 21 and Theorem 23 give the full guarantees of Algorithm 7.

► **Theorem 24.** *Let  $G = (V, E)$  be a weighted graph with  $w(e) \leq W \leq n^c$  for some constant  $c > 0$  and all  $e \in E$ . For a trade-off parameter  $\alpha$ , there exists an algorithm that outputs a  $\frac{1}{4\alpha}$ -approximation to the maximum weighted matching in  $O(m \log_\alpha n)$  time. For  $\alpha = 2$ , the algorithm has weighted sensitivity  $O(W \log n)$  and normalized weighted sensitivity  $O(\log n)$ . For  $\alpha > 2$ , the algorithm has weighted sensitivity  $O(W)$  and normalized weighted sensitivity  $O(1)$ .*

We again emphasize that the worst case weighted sensitivity of *any* constant factor approximation algorithm to the maximum weighted matching problem is at least  $\Omega(W)$ . Recall that if an edge of weight  $W = n^c$  is altered in a graph whose remaining edges have weight 1, then any constant factor approximation to the maximum weighted matching must include the heavy edge for sufficiently large  $c > 0$ , which incurs cost  $\Omega(W)$  in the weighted sensitivity. Thus for  $\alpha > 2$ , Algorithm 7 performs well with respect to both weighted sensitivity and normalized weighted sensitivity.

## Abstract

In 1979, Hylland and Zeckhauser [23] gave a simple and general scheme for implementing a one-sided matching market using the power of a pricing mechanism. Their method has nice properties – it is incentive compatible in the large and produces an allocation that is Pareto optimal – and hence it provides an attractive, off-the-shelf method for running an application involving such a market. With matching markets becoming ever more prevalent and impactful, it is imperative to finally settle the computational complexity of this scheme.

We present the following partial resolution:

1. A combinatorial, strongly polynomial time algorithm for the dichotomous case, i.e., 0/1 utilities, and more generally, when each agent’s utilities come from a bi-valued set.
2. An example that has only irrational equilibria, hence proving that this problem is not in PPAD.
3. A proof of membership of the problem in the class FIXP.
4. A proof of membership of the problem of computing an approximate HZ equilibrium in the class PPAD.

We leave open the (difficult) questions of determining if computing an exact HZ equilibrium is FIXP-hard and an approximate HZ equilibrium is PPAD-hard.

In addition, the first author wishes to thank Simons Institute for running a program on matching markets in Fall 2019; this provided valuable exposure to the topic.

## 1 Introduction

In a brilliant and by-now classic paper, Hylland and Zeckhauser [23] gave a simple and general scheme for implementing a one-sided matching market using the power of a pricing mechanism<sup>1</sup>. Their method produces an allocation that is Pareto optimal, envy-free [23]

---

<sup>1</sup> See Remark 5 for a discussion of the advantages of this mechanism.

and is incentive compatible in the large [22]. The Hylland-Zeckhauser (HZ) scheme can be viewed as a marriage between fractional perfect matching and a linear Fisher market, both of which admit not only polynomial time algorithms but also combinatorial ones. These facts have enticed numerous researchers over the years to seek an efficient algorithm for the HZ scheme. The significance of this problem has only grown in recent years, with ever more diverse and impactful matching markets being launched into our economy, e.g., see [17].

Our work on resolving this problem started with an encouraging sign, when we obtained a combinatorial, strongly polynomial time algorithm for the *dichotomous case*, in which all utilities are 0/1, by melding a perfect matching algorithm with the combinatorial algorithm of [13] for the linear Fisher market, see Section 4. This algorithm can be extended to solve a more general problem which we call the *bi-valued utilities case*, in which each agent's utilities can take one of only two values, though the two values can be different for different agents. However, this approach did not extend any further, as described in the next section.

One-sided matching markets can be classified along two dimensions: whether the utility functions are cardinal or ordinal, and whether agents have initial endowments or not. Under this classification, the HZ scheme is (cardinal, no endowments). Section 1.2 gives mechanisms for the remaining three possibilities as well as their game-theoretic properties. Ordinal and cardinal utility functions have their individual pros and cons, and neither dominates the other. Whereas the former are easier to elicit, the latter are far more expressive, enabling an agent to not only report if she prefers one good to another but also by how much, thereby producing higher quality allocations as illustrated in Example 1, which is taken from [20].

► **Example 1.** ([20]) The instance has three types of goods,  $T_1, T_2, T_3$ , and these goods are present in the proportion of (1%, 97%, 2%). Based on their utility functions, the agents are partitioned into two sets  $A_1$  and  $A_2$ , where  $A_1$  constitute 1% of the agents and  $A_2$ , 99%. The utility functions of agents in  $A_1$  and  $A_2$  for the three types of goods are  $(1, \epsilon, 0)$  and  $(1, 1 - \epsilon, 0)$ , respectively, for a small number  $\epsilon > 0$ . The main point is that whereas agents in  $A_2$  marginally prefer  $T_1$  to  $T_2$ , those in  $A_1$  overwhelmingly prefer  $T_1$  to  $T_2$ . Clearly, the ordinal utilities of all agents in  $A_1 \cup A_2$  are the same. Therefore, a mechanism based on such utilities will not be able to make a distinction between the two types of agents. On the other hand, the HZ mechanism, which uses cardinal utilities, will fix the price of goods in  $T_3$  to be zero and those in  $T_1$  and  $T_2$  appropriately so that by-and-large the bundles of  $A_1$  and  $A_2$  consist of goods from  $T_1$  and  $T_2$ , respectively.

While studying the dichotomous case of two-sided markets, Bogomolnaia and Moulin [5] called it an “important special case of the bilateral matching problem.” Using the Gallai-Edmonds decomposition of a bipartite graph, they gave a mechanism that is Pareto optimal and group strategyproof. They also gave a number of applications of their setting, some of which are natural applications of one-sided markets as well, e.g., housemates distributing rooms, having different features, in a house. Furthermore, they say, “Time sharing is the simplest way to deal fairly with indivisibilities of matching markets: think of a set of workers sharing their time among a set of employers.” It turns out that the HZ (fractional) equilibrium allocation is a superior starting point for the problem of designing a randomized time-sharing mechanism; this is discussed in Remark 5 after introducing the HZ model. Roth, Sonmez and Unver [29] extended these results to general graph matching under dichotomous utilities; this setting is applicable to the kidney exchange marketplace.

## 1.1 The gamut of possibilities

The most useful solution for practical applications would of course have been a combinatorial, polynomial time algorithm for the entire scheme. At the outset, this didn't seem unlikely, especially in view of the existence of such an algorithm for the dichotomous case. Next we considered the generalization of the bi-valued utilities case to tri-valued utilities, in particular, to the case of  $\{0, \frac{1}{2}, 1\}$  utilities. However, even this case appears to be intractable.

Underlying the polynomial time solvability of a linear Fisher market is the property of weak gross substitutability<sup>2</sup>. We note that this property is destroyed as soon as one goes to a slightly more general utility function, namely piecewise-linear, concave and separable over goods (SPLC utilities), and this case is PPAD-complete<sup>3</sup> [32]; the class PPAD was introduced in [28]. Since equilibrium allocations for the HZ scheme do not satisfy weak gross substitutability, e.g., see Example 9, we were led us to seek a proof of PPAD-completeness.

A crucial requirement for membership in PPAD is to show that there is always a rational equilibrium if all parameters of the instance are rational numbers. However, even this is not true; we found an example which admits only irrational equilibria, see Section 6. This example consists of four agents and goods, and hence can be viewed as belonging to the four-valued utilities case; see Remark 17 for other intriguing aspects of this example.

The irrationality of solutions suggests that the appropriate class for this problem is the class FIXP, introduced in [16]. The proof in [23], showing the existence of an equilibrium, uses Kakutani's theorem and does not seem to lend itself in any easy way to showing membership in FIXP. For this purpose, we give a new proof of the existence of equilibrium. Our proof defines a suitable Brouwer function which adjusts prices and allocations in case they are not an equilibrium. It uses elementary arithmetic operations that improve their optimality or feasibility of the current prices and allocations. The adjustment scheme is such that the only stable prices and allocations are forced to be equilibria.

Next, we define the notion of an approximate equilibrium. This is still required to be a fractional perfect matching on agents and goods; agents' allocations are allowed to be slightly suboptimal and/or their cost is allowed to slightly exceed the budget of 1 dollar. We show that the problem of computing such an approximate equilibrium is in PPAD. This involves relating approximate equilibria to the approximate fixed points of the Brouwer function we defined for our proof of membership in FIXP. We leave open the questions of determining if the computation (to desired accuracy) of an exact HZ equilibrium is FIXP-hard, and if the computation of an approximate HZ equilibrium is PPAD-hard.

## 1.2 Related work

We first present mechanisms for the remaining three possibilities for the classification of one-sided matching market mechanisms given in the Introduction. The famous Top Trading Cycles mechanism is (ordinal, endowments) [30]; it is efficient, strategyproof and core-stable. Under (ordinal, no endowments) are Random Priority [27], which is strategyproof though not efficient or envy-free, and Probabilistic Serial [4], which is efficient and envy-free but not strategyproof. Under (cardinal, endowments) is  $\epsilon$ -Approximate ADHZ (for Arrow-Debreu Hylland-Zeckhauser) scheme [20], which satisfies Pareto optimality, approximate envy-freeness and incentive compatibility in the large.

<sup>2</sup> Namely, if you increase the price of one good, the demand of another good cannot decrease.

<sup>3</sup> Independently, PPAD-hardness was also established in [10].

We are aware of only the following two computational results on the HZ scheme. Using the algebraic cell decomposition technique of [2], [12] gave a polynomial time algorithm for computing an equilibrium for an Arrow-Debreu market under piecewise-linear, concave (PLC) utilities (not necessarily separable over goods) if the number of goods is fixed. One can see that their algorithm can be adapted to yield a polynomial time algorithm for computing an equilibrium for the HZ scheme if the number of goods is a fixed constant. Extending these methods, [1] gave a polynomial time algorithm for the case that the number of agents is a fixed constant.

There are several results establishing membership and hardness in PPAD and FIXP for equilibria computation problems in different settings. The quintessential complete problem for PPAD is 2-Nash [11, 7] and that for FIXP is multiplayer Nash equilibrium [16]. For the latter problem, computing an approximate equilibrium is PPAD-complete [11].

For the case of market equilibria, in the economics literature, there are two parallel streams of results: one assumes that an excess demand function is given and the other assumes a specific class of utility functions. [16] proved FIXP-completeness of Arrow-Debreu markets whose excess demand functions are algebraic. This result is for the first stream and it does not establish FIXP-completeness of Arrow-Debreu markets under any specific class of utility functions. Results for the second stream include proofs of membership in FIXP for Arrow-Debreu markets under Leontief and piecewise-linear concave (PLC) utility functions in [35] and [18], respectively. This was followed by a proof of FIXP-hardness for Arrow-Debreu markets with Leontief and PLC utilities [19]. For the case of Arrow-Debreu markets with CES (constant elasticity of substitution) utility functions, [9] show membership in FIXP but leave open FIXP-hardness.

For the CES market problem stated above, computing an approximate equilibrium is PPAD-complete, and the same holds more generally for a large class of “non-monotonic” markets [9]. Computing an (exact or approximate) equilibrium under separable, piecewise-linear, concave (SPLC) utilities for Arrow-Debreu and Fisher markets is also known to be PPAD-complete [8, 10, 32].

In recent years, several researchers have proposed Hylland-Zeckhauser-type mechanisms for a number of applications, e.g., see [6, 22, 25, 26]. The basic scheme has also been generalized in several different directions, including two-sided matching markets, adding quantitative constraints, and to the setting in which agents have initial endowments of goods instead of money, see [14, 15].

## 2 The Hylland-Zeckhauser Scheme

Hylland and Zeckhauser [23] gave a general mechanism for a one-sided matching market using the power of a pricing mechanism. Their formulation is as follows: Let  $A = \{1, 2, \dots, n\}$  be a set of  $n$  agents and  $G = \{1, 2, \dots, n\}$  be a set of  $n$  indivisible goods. The mechanism will allocate exactly one good to each agent and will have the following two properties:

- The allocation produced is Pareto optimal.
- The mechanism is incentive compatible in the large.

The Hylland-Zeckhauser scheme is a marriage between linear Fisher market and fractional perfect matching. The agents will reveal to the mechanism their desires for the goods by stating their von Neumann-Morgenstern utilities. Let  $u_{ij}$  represent the utility of agent  $i$  for good  $j$ . We will use language from the study of market equilibria to describe the rest of the formulation. For this purpose, we next define the linear Fisher market model.

A *linear Fisher market* consists of a set  $A = \{1, 2, \dots, n\}$  of  $n$  agents and a set  $G = \{1, 2, \dots, m\}$  of  $m$  infinitely divisible goods. By fixing the units for each good, we may assume without loss of generality that there is a unit of each good in the market. Each agent  $i$  has money  $m_i$  and utility  $u_{ij}$  for a unit of good  $j$ . If  $x_{ij}$ ,  $1 \leq j \leq m$  is the *bundle of goods allocated to  $i$* , then the utility accrued by  $i$  is  $\sum_j u_{ij}x_{ij}$ . Each good  $j$  is assigned a non-negative price,  $p_j$ . Allocations and prices,  $x$  and  $p$ , are said to form an *equilibrium* if each agent obtains a utility maximizing bundle of goods at prices  $p$  and the *market clears*, i.e., each good is fully sold and all money of agents is fully spent.

In order to mold the one-sided market into a linear Fisher market, the HZ scheme renders goods divisible by assuming that there is one unit of probability share of each good. An *allocation* to an agent is a collection of probability shares over the goods. Let  $x_{ij}$  be the probability share that agent  $i$  receives of good  $j$ . Then,  $\sum_j u_{ij}x_{ij}$  is the *expected utility* accrued by agent  $i$ . Each good  $j$  has price  $p_j \geq 0$  in this market and each agent has 1 dollar with which it buys probability shares. The entire allocation must form a *fractional perfect matching in the complete bipartite graph* over vertex sets  $A$  and  $G$  as follows: there is one unit of probability share of each good and the total probability share assigned to each agent also needs to be one unit. Subject to these constraints, each agent should buy a utility maximizing bundle of goods *having the smallest possible cost*. Note that the last condition is not required in the definition of a linear Fisher market equilibrium. It is needed here to guarantee that the allocation obtained is Pareto optimal, see [23] for proof of Pareto optimality. A second departure from the linear Fisher market equilibrium is that in the latter, each agent  $i$  must spend her money  $m_i$  fully; in the HZ scheme,  $i$  need not spend her entire dollar. Since the allocation is required to form a fractional perfect matching, all goods are fully sold. We will define these to be *equilibrium allocation and prices*; we state this formally below after giving some preliminary definitions.

► **Definition 2.** Let  $x$  and  $p$  denote arbitrary (non-negative) allocations and prices of goods. By *size*, *cost* and *value* of agent  $i$ 's bundle we mean

$$\sum_{j \in G} x_{ij}, \quad \sum_{j \in G} p_j x_{ij} \quad \text{and} \quad \sum_{j \in G} u_{ij} x_{ij},$$

respectively. We will denote these by  $\text{size}(i)$ ,  $\text{cost}(i)$  and  $\text{value}(i)$ , respectively.

► **Definition 3** (Hylland and Zeckhauser [23]). *Allocations and prices  $(x, p)$  form an equilibrium for the one-sided matching market stated above if:*

1. *The total probability share of each good  $j$  is 1 unit, i.e.,  $\sum_i x_{ij} = 1$ .*
2. *The size of each agent  $i$ 's allocation is 1, i.e.,  $\text{size}(i) = 1$ .*
3. *The cost of the bundle of each agent is at most 1.*
4. *Subject to constraints 2 and 3, each agent  $i$  maximizes her expected utility at minimum possible cost, i.e., maximize  $\text{value}(i)$ , subject to  $\text{size}(i) = 1$ ,  $\text{cost}(i) \leq 1$ , and lastly,  $\text{cost}(i)$  is smallest among all utility-maximizing bundles of  $i$ .*

Using Kakutani's fixed point theorem, the following is shown:

► **Theorem 4** (Hylland and Zeckhauser [23]). *Every instance of the one-sided market defined above admits an equilibrium; moreover, the corresponding allocation is Pareto optimal.*

Finally, if this “market” is large enough, no individual agent will be able to improve her allocation by misreporting utilities nor will she be able to manipulate prices. For this reason, the HZ scheme is incentive compatible in the large.

As stated above, Hylland and Zeckhauser view each agent's allocation as a lottery over goods. In this viewpoint, agents accrue utility in an *expected sense* from their allocations. Once these lotteries are resolved in a manner faithful to the probabilities, an assignment of indivisible goods will result. The latter can be done using the well-known Theorem of Birkhoff [3] and von Neumann [34] which states that any doubly stochastic matrix can be written as a convex combination of permutation matrices, i.e., perfect matchings; moreover, this decomposition can be obtained efficiently. Next, pick one of these perfect matchings from the discrete distribution given by coefficients in the convex combination. As is well known, since the lottery over goods is Pareto optimal *ex ante*, the integral allocation, viewed stochastically, will also be Pareto optimal *ex post*.

Another viewpoint, forwarded by Bogomolnaia and Moulin [5], considers the fractional perfect matching, or equivalently the doubly-stochastic matrix, as the output of the mechanism, i.e., without resorting to randomized rounding. This viewpoint assumes that the agents are going to “time-share” the goods or resources and the doubly-stochastic matrix, which is derived from a market mechanism, provides a “fair” way of doing so.

► **Remark 5.** In their paper studying the dichotomous case of two-sided matching markets, Bogomolnaia and Moulin [5] state that the preferred way of dealing with indivisibilities inherent in matching markets is to resort to time sharing using randomization. Their method builds on the Gallai-Edmonds decomposition of the underlying bipartite graph; this classifies vertices into three categories: disposable, over-demanded and perfectly matched. This is a much more coarse insight into the demand structure of vertices than that obtained via the HZ equilibrium. The latter is the output of a market mechanism in which equilibrium prices reflect the relative importance of goods in an accurate and precise manner, based on the utilities declared by buyers, and equilibrium allocations are as equitable as possible across buyers. Hence the latter yields a more fair and desirable randomized time-sharing mechanism.

### 3 Properties of Optimal Allocations and Prices

Let  $p$  be given prices which are not necessarily equilibrium prices. An optimal bundle for agent  $i$ ,  $x_i$ , is a solution to the following LP, which has two constraints, one for size and one for cost.

$$\max \sum_j x_{ij} u_{ij} \quad (1)$$

$$\text{s.t.} \quad (2)$$

$$\sum_j x_{ij} = 1 \quad (3)$$

$$\sum_j x_{ij} p_j \leq 1 \quad (4)$$

$$\forall j \quad x_{ij} \geq 0 \quad (5)$$

Taking  $\mu_i$  and  $\alpha_i$  to be the dual variables corresponding to the two constraints, we get the dual LP:

$$\min \quad \alpha_i + \mu_i \quad (6)$$

$$\text{s.t.} \quad (7)$$

$$\forall i, j \quad \alpha_i p_j + \mu_i \geq u_{ij} \quad (8)$$

$$\alpha_i \geq 0 \quad (9)$$

Clearly  $\mu_i$  is unconstrained.  $\mu_i$  will be called the *offset* on  $i$ 's utilities. By complementary slackness, if  $x_{ij}$  is positive then  $\alpha_i p_j = u_{ij} - \mu_i$ . All goods  $j$  satisfying this equality will be called *optimal goods for agent  $i$* . The rest of the goods, called *suboptimal*, will satisfy  $\alpha_i p_j > u_{ij} - \mu_i$ . Obviously an optimal bundle for  $i$  must contain only optimal goods.

The parameter  $\mu_i$  plays a crucial role in ensuring that  $i$ 's optimal bundle satisfies both size and cost constraints. If a single good is an effective way of satisfying both size and cost constraints, then  $\mu_i$  plays no role and can be set to zero. However, if different goods are better from the viewpoint of size and cost, then  $\mu_i$  attains the right value so they both become optimal and  $i$  buys an appropriate combination. We provide an example below to illustrate this.

► **Example 6.** Suppose  $i$  has positive utilities for only two goods,  $j$  and  $k$ , with  $u_{ij} = 10$ ,  $u_{ik} = 2$  and their prices are  $p_j = 2$ ,  $p_k = 0.1$ . Clearly, neither good satisfies both size and cost constraints optimally: good  $j$  is better for the size constraint and  $k$  is better for the cost constraint. If  $i$  buys one unit of good  $j$ , she spends 2 dollars, thus exceeding her budget. On the other hand, she can afford to buy 10 units of  $k$ , giving her utility of 20; however, she has far exceeded the size constraint. It turns out that her optimal bundle consists of 9/19 units of  $j$  and 10/19 units of  $k$ ; the costs of these two goods being 18/19 and 1/19 dollars, respectively. Clearly, her size and cost constraints are both met exactly. Her total utility from this bundle is 110/19. It is easy to see that  $\alpha_i = 80/19$  and  $\mu_i = 30/19$ , and for these settings of the parameters, both goods are optimal.

We next show that equilibrium prices are invariant under the operation of *scaling* the difference of prices from 1.

► **Lemma 7.** *Let  $p$  be an equilibrium price vector and fix any  $r > 0$ . Let  $p'$  be such that  $\forall j \in G, p'_j - 1 = r(p_j - 1)$ . Then  $p'$  is also an equilibrium price vector.*

**Proof.** Consider an agent  $i$ . Clearly,  $\sum_{j \in G} p_j x_{ij} \leq 1$ . Now,

$$\sum_{j \in G} p'_j x_{ij} = \sum_{j \in G} (rp_j - r + 1)x_{ij} \leq 1,$$

where the last inequality follows by using  $\sum_{j \in G} x_{ij} = 1$ . ◀

Using Lemma 7, it is easy to see that if the allocation  $x$  provides optimal bundles to all agents under prices  $p$  then it also does so under  $p'$ . In the rest of this paper we will enforce that the minimum price of a good is zero, thereby fixing the scale. Observe that the main goal of the Hylland-Zeckhauser scheme is to yield the “correct” allocations to agents; the prices are simply a vehicle in the market mechanism to achieve this. Hence arbitrarily fixing the scale does not change the essential nature of the problem. Moreover, setting the minimum price to zero is standard [23] and can lead to simplifying the equilibrium computation problem as shown in Remark 8.

► **Remark 8.** We remark that on the one hand, the offset  $\mu_i$  is a key enabler in construing optimal bundles, on the other, it is also a main source of difficulty in computing equilibria for the HZ scheme. We identify here an interesting case in which  $\mu_i = 0$  and this difficulty is mitigated. In particular, this holds for all agents in the dichotomous case presented in Section 4. Suppose good  $j$  is optimal for agent  $i$ ,  $u_{ij} = 0$  and  $p_j = 0$ , then it is easy to check that  $\mu_i = 0$ . If so, the optimal goods for  $i$  are simply the maximum bang-per-buck goods; the latter notion is replete in market equilibrium papers, e.g., see [13].

Finally, we extend Example 6 to illustrate that optimal allocations for the Hylland-Zeckhauser model do not satisfy the weak gross substitutes condition in general.

► **Example 9.** In Example 6, let us raise the price of  $k$  to 0.2 dollars. Then the optimal allocation for  $i$  changes to  $4/9$  units of  $j$  and  $5/9$  units of  $k$ . Notice that the demand for  $j$  went down from  $9/19$  to  $4/9$ . One way to understand this change is as follows: Let us start with the old allocation of  $10/19$  units of  $k$ . Clearly, the cost of this allocation of  $k$  went up from  $1/19$  to  $2/19$ , leaving only  $17/19$  dollars for  $j$ . Therefore size of  $j$  needs to be reduced to  $17/38$ . However, now the sum of the sizes becomes  $37/38$ , i.e., less than a unit. We wish to increase this to a unit while still keeping cost at a unit. The only way of doing this is to sell some of the more expensive good and use the money to buy the cheaper good. This is the reason for the decrease in demand of  $j$ .

#### 4 Strongly Polynomial Algorithm for Bi-Valued Utilities

In this section, we will study the restriction of the HZ scheme to the bi-valued utilities case, which is defined as follows: for each agent  $i$ , we are given a set  $\{a_i, b_i\}$ , where  $0 \leq a_i < b_i$ , and the utilities  $u_{ij}$ ,  $\forall j \in G$ , are picked from this set. However first, using a perfect matching algorithm and the combinatorial algorithm [13] for linear Fisher markets, we will give a strongly polynomial time algorithm for the dichotomous case, i.e., when all utilities  $u_{ij}$  are 0/1. Next we define the notion of equivalence of utility functions and show that the bi-valued utilities case is equivalent to the dichotomous case, thereby extending the dichotomous case algorithm to this case.

We need to clarify that we will not use the main algorithm from [13], which uses the notion of balanced flows and  $l_2$  norm to achieve polynomial running time. Instead, we will use the “simple algorithm” presented in Section 5 in [13]. Although this algorithm is not proven to be efficient, the simplified version we define below, called Simplified DPSV Algorithm, is efficient; in fact it runs in strongly polynomial time, unlike the balanced-flows-based algorithm of [13]. Remark 8 provides an insight into what makes the dichotomous case computationally easier.

We note that recently, [20] gave a *rational convex program (RCP)* for the dichotomous case of HZ, and more recently, [33] made a small modification to our algorithm to obtain a mechanism that is proven to be strategyproof. An RCP, defined in [31], is a nonlinear convex program all of whose parameters are rational numbers and which always admits a rational solution in which the denominators are polynomially bounded. An RCP can be solved exactly in polynomial time using the ellipsoid algorithm and diophantine approximation [21, 24], and therefore directly implies the existence of a polynomial time algorithm for the underlying problem.

**Notation.** We will denote by  $H = (A, G, E)$  be the bipartite graph on vertex sets  $A$  and  $G$ , and edge set  $E$ , with  $(i, j) \in E$  iff  $u_{ij} = 1$ . For  $A' \subseteq A$  and  $G' \subseteq G$ , we will denote by  $H[A', G']$  the restriction of  $H$  to vertex set  $A' \cup G'$ . If  $\nu$  is a matching in  $H$ ,  $\nu \subseteq E$ , and  $(i, j) \in \nu$  then we will say that  $\nu(i) = j$  and  $\nu(j) = i$ . For any subset  $S \subseteq A$  ( $S \subseteq G$ ),  $N(S)$  will denote the set of neighbors, in  $G$  ( $A$ ), of vertices in  $S$ .

If  $H$  has a perfect matching, the matter is straightforward as stated in Steps 1a and 1b; allocations and prices are clearly in equilibrium. For Step 2, we need the following lemma.

► **Lemma 10.** *The following hold:*

1. For any set  $S \subseteq A_2$ ,  $|N(S)| \geq |S|$ .
2. For any set  $S \subseteq G_1$ ,  $|N(S) \cap A_1| \geq |S|$ .

**Proof.**

1. If  $|N(S)| < |S|$  then  $(G_1 \cup N(S)) \cup (A_2 - S)$  is a smaller vertex cover for  $H$ , leading to a contradiction.
2. If  $|N(S) \cap A_1| < |S|$  then  $(G_1 - S) \cup (A_2 \cup N(S))$  is a smaller vertex cover for  $H$ , leading to a contradiction.  $\blacktriangleleft$

The first part of Lemma 10 together with Hall's Theorem implies that a maximum matching in  $H[A_2, G_2]$  must match all agents. Therefore in Step 2a, each agent  $i \in A_2$  is allocated one unit of a unique good from which it derives utility 1 and having price zero; clearly, this is an optimal bundle of minimum cost for  $i$ . The number of goods that will remain unmatched in  $G_2$  at the end of this step is  $|G_2| - |A_2|$ .

■ **Algorithm 1** Algorithm for the Dichotomous Case.

---

1. If  $H$  has a perfect matching, say  $\nu$ , then do:
    - a.  $\forall i \in A$ : allocate good  $\nu(i)$  to  $i$ .
    - b.  $\forall j \in G$ :  $p_j \leftarrow 0$ . Go to Step 3.
  2. Else do:
    - a. Find a minimum vertex cover in  $H$ , say  $G_1 \cup A_2$ , where  $G_1 \subset G$  and  $A_2 \subset A$ .  
Let  $A_1 = A - A_2$  and  $G_2 = G - G_1$ .
    - b. Find a maximum matching in  $H[A_2, G_2]$ , say  $\nu$ .
    - c.  $\forall i \in A_2$ : allocate good  $\nu(i)$  to  $i$ .
    - d.  $\forall j \in G_2$ :  $p_j \leftarrow 0$ .
    - e. Run the Simplified DPSV Algorithm on agents  $A_1$  and goods  $G_1$ .
    - f.  $\forall i \in A_1$ : Allocate unmatched goods of  $G_2$  to satisfy the size constraint.
  3. Output the allocations and prices computed and Halt.
- 

Allocations are computed for agents in  $A_1$  as follows. First, Step 2e uses the Simplified DPSV Algorithm, which we describe below, to compute equilibrium allocations and prices for the submarket consisting of agents in  $A_1$  and goods in  $G_1$ . At the end of this step, the money of each agent in  $A_1$  is exhausted; however, her allocation may not meet the size constraint. To achieve the latter, Step 2f allocates the unmatched zero-priced goods from  $G_2$  to agents in  $A_1$ . Clearly, the total deficit in size is  $|A_1| - |G_1|$ . Since this equals  $|G_2| - |A_2|$ , the market clears at the end of Step 2f. As shown in Lemma 11, each agent in  $A_1$  also gets an optimal bundle of goods of minimum cost.

Let  $p$  be the prices of goods in  $G_1$  at any point in this algorithm. As a consequence of the second part of Lemma 10, the equilibrium price of each good in  $G_1$  will be at least 1. The Simplified DPSV algorithm will initialize prices of goods in  $G_1$  to 1 and declare all goods active. The algorithm will always raise prices of active goods uniformly<sup>4</sup>.

For  $S \subseteq G_1$  let  $p(S)$  denote the sum of the equilibrium prices of goods in  $S$ . A key notion from [13] is that of a tight set; set  $S \subseteq G_1$  is said to be *tight* if  $p(S) = |N(S)|$ , the latter being the total money of agents in  $A_1$  who are interested in goods in  $S$ . If set  $S$  is tight, then the local market consisting of goods in  $S$  and agents in  $N(S)$  clears. To see this, one needs to use the flow-based procedure given in [13] to show that each agent  $i \in N(S)$  can be allocated 1 dollar worth of those goods in  $S$  from which it accrues unit utility. Thus equilibrium has been reached for goods in  $S$ .

---

<sup>4</sup> In [13], prices of active goods are raised multiplicatively, which amounts to raising prices of active goods uniformly for our simplified setting.

As the algorithm raises prices of all goods in  $G_1$ , at some point a set  $S$  will go tight. The algorithm then *freezes* the prices of its goods and removes them from the active set. It then proceeds to raise the prices of currently active goods until another set goes tight, and so on, until all goods in  $G_1$  are frozen.

We can now explain in what sense we need a “simplified” version of the DPSV algorithm. Assume that at some point,  $S \subset G_1$  is frozen and goods in  $G_1 - S$  are active and their prices are raised. As this happens, agents in  $A_1 - N(S)$  start preferring goods in  $S$  relative to those in  $G_1 - S$ . In the general case, at some point, an agent  $i \in (A_1 - N(S))$  will prefer a good  $j \in S$  as much as her other preferred goods. At this point, edge  $(i, j)$  is added to the active graph. As a result, some set  $S' \subseteq S$ , containing  $j$ , will not be tight anymore and will be unfrozen. However, in our setting, the utilities of agents in  $(A_1 - N(S))$  for goods in  $S$  is zero, and therefore no new edges are introduced and tight sets never become unfrozen. Hence the only events of the Simplified DPSV Algorithm are raising of prices and freezing of sets. Clearly, there will be at most  $n$  freezings. One can check details in [13] to see that the steps executed with each freezing run in strongly polynomial time, hence making the Simplified DPSV Algorithm a strongly polynomial time algorithm<sup>5</sup>.

► **Lemma 11.** *Each agent in  $A_1$  will get an optimal bundle of goods of minimum cost.*

**Proof.** First note that for agents in  $A_1$ , there are no utility 1 goods in  $G_2$  – this follows from the fact that no vertices from  $A_1 \cup G_2$  are in the vertex cover picked. Therefore, for  $i \in A_1$ , an optimum bundle consists of the cheapest way of obtaining one dollar worth of goods from  $N\{i\}$ , which are in  $G_1$ , together with the right amount of zero-priced goods from  $G_2$  to satisfy the size constraint.

Assume that the algorithm freezes  $k$  sets,  $S_1, \dots, S_k$ , in that order; the union of these sets being  $G_1$ . Let  $p_1, p_2, \dots, p_k$  be the prices of goods in these sets, respectively. Clearly, successive freezings will be at higher and higher prices and therefore,  $1 \leq p_1 < p_2 < \dots < p_k$ , and for  $1 \leq j \leq k$ ,  $p_j = |N(S_j)|/|S_j|$ . If  $i \in N(S_j)$ , the algorithm will allocate  $1/p_j$  amount of goods to  $i$  from  $S_j$ , costing 1 dollar.

By definition of neighborhood of sets, if  $i \in N(S_j)$ , then  $i$  cannot have edges to  $S_1, \dots, S_{j-1}$  and can have edges to  $S_{j+1}, \dots, S_k$ . Therefore, the cheapest goods from which it accrues unit utility are in  $S_j$ , the set from which she gets 1 dollar worth of allocation. The rest of the allocation of  $i$ , in order to meet  $i$ 's size constraint, will be from  $G_2$ , which are zero-priced and from which  $i$  gets zero utility. Clearly,  $i$  gets an optimal bundle of minimum cost. ◀

Since all steps of the algorithm, namely finding a maximum matching, a minimum vertex cover and running the Simplified DPSV Algorithm, can be executed in strongly polynomial time, we get:

► **Lemma 12.** *The algorithm given finds equilibrium prices and allocations for the dichotomous case of the Hylland-Zeckhauser scheme. It runs in strongly polynomial time.*

► **Definition 13.** *Let  $I$  be an instance of the HZ scheme and let the utility function of agent  $i$  be  $u_i = \{u_{i1}, u_{i12}, \dots, u_{in}\}$ . Then  $u'_i = \{u'_{i1}, u'_{i12}, \dots, u'_{in}\}$  is equivalent to  $u_i$  if there are two numbers  $s > 0$  and  $h \geq 0$  such that for  $1 \leq j \leq n$ ,  $u'_{ij} = s \cdot u_{ij} + h$ . The numbers  $s$  and  $h$  will be called the scaling factor and shift, respectively.*

<sup>5</sup> In contrast, in the general case, the number of freezings is not known to be bounded by a polynomial in  $n$ , as stated in [13].

► **Lemma 14.** *Let  $I$  be an instance of the HZ scheme and let the utility function of agent  $i$  be  $u_i$ . Let  $u'_i$  be equivalent to  $u_i$  and let  $I'$  be the instance obtained by replacing  $u_i$  by  $u'_i$  in  $I$ . Then  $x$  and  $p$  are equilibrium allocation and prices for  $I$  if and only if they are also for  $I'$ .*

**Proof.** Let  $s$  and  $h$  be the scaling factor and shift that transform  $u_i$  to  $u'_i$ . By the statement of the lemma,  $x_i = \{x_{i1}, \dots, x_{in}\}$  is an optimal bundle for  $i$  at prices  $p$  and hence is a solution to the optimal bundle LP (1). The objective function of this LP is

$$\sum_{j=1}^n u_{ij} x_{ij}.$$

Next observe that the objective function of the corresponding LP for  $i$  under instance  $I'$  is

$$\sum_{j=1}^n u'_{ij} x_{ij} = \sum_{j=1}^n (s \cdot u_{ij} + h) x_{ij} = h + s \cdot \sum_{j=1}^n u_{ij} x_{ij},$$

where the last equality follows from the fact that  $\sum_{j=1}^n x_{ij} = 1$ . Therefore, the objective function of the second LP is obtained from the first by scaling and shifting. Furthermore, since the constraints of the two LPs are identical, the optimal solutions of the two LPs are the same. Finally, for each  $i \in A$ : the bundle under allocation  $x$  is a minimum cost optimal bundle for  $I$  if and only if it is also for  $I'$ . The lemma follows. ◀

Next, let  $u_i$  be bi-valued with the two values being  $0 \leq a < b$ . Obtain  $u'_i$  from  $u_i$  by replacing  $a$  by 0 and  $b$  by 1. Then,  $u'_i$  is equivalent to  $u_i$ , with the shift and scaling being  $a$  and  $b - a$ , respectively. Therefore the bi-valued instance can be transformed to a unit instance, with both having the same equilibria. Now using Lemma 12 we get:

► **Theorem 15.** *There is a strongly polynomial time algorithm for the bi-valued utilities case of the Hylland-Zeckhauser scheme.*

## 5 Characterizing Optimal Bundles

In this section we give a characterization of optimal bundles for an agent at given prices  $p$  which are not necessarily equilibrium prices. This characterization will be used in Section 6.

**Notation.** For each agent  $i$ , let  $G_i^* \subseteq G$  denote the set of goods from which  $i$  derives maximum utility, i.e.,  $G_i^* = \arg \max_{j \in G} \{u_{ij}\}$ . With respect to an allocation  $x$ , let  $B_i = \{j \in G \mid x_{ij} > 0\}$ , i.e., the set of goods in  $i$ 's bundle.

We identify the following four types of optimal bundles.

**Type A bundles:**  $\alpha_i = 0$  and  $\text{cost}(i) < 1$ .

By complementary slackness, optimal goods will satisfy  $u_{ij} = \mu_i$  and suboptimal goods will satisfy  $u_{ij} < \mu_i$ . Hence the set of optimal goods is  $G_i^*$  and  $B_i \subseteq G_i^*$ . Note that the prices of goods in  $B_i$  can be arbitrary, as long as  $\text{cost}(i) < 1$ .

**Type B bundles:**  $\alpha_i = 0$  and  $\text{cost}(i) = 1$ .

The only difference from the previous type is that  $\text{cost}(i)$  is exactly 1.

**Type C bundles:**  $\alpha_i > 0$  and all optimal goods for  $i$  have the same utility.

Recall that good  $j$  is optimal for  $i$  if<sup>6</sup>  $\alpha_i p_j = u_{ij} - \mu_i$ . Suppose goods  $j$  and  $k$  are both optimal. Then  $u_{ij} = u_{ik}$  and  $\alpha_i p_j = u_{ij} - \mu_i = u_{ik} - \mu_i = \alpha_i p_k$ , i.e.,  $p_j = p_k$ . Since  $\alpha_i > 0$ ,

<sup>6</sup> Note that under this case, optimal goods are not necessarily maximum utility goods; the latter may be suboptimal because their prices are too high.

by complementary slackness,  $\text{cost}(i) = 1$ . Further, since  $\text{size}(i) = 1$ , we get that each optimal good has price 1.

**Type D bundles:**  $\alpha_i > 0$  and not all optimal goods for  $i$  have the same utility.

Suppose goods  $j$  and  $k$  are both optimal and  $u_{ij} \neq u_{ik}$ . Then  $\alpha_i p_j = u_{ij} - \mu_i \neq u_{ik} - \mu_i = \alpha_i p_k$ , i.e.,  $p_j \neq p_k$ . Therefore optimal goods have at least two different prices. Since  $\alpha_i > 0$ , by complementary slackness,  $\text{cost}(i) = 1$ . Further, since  $\text{size}(i) = 1$ , there must be an optimal good with price more than 1 and an optimal good with price less than 1. Finally, if good  $z$  is suboptimal for  $i$ , then  $\alpha_i p_z < u_{iz} - \mu_i$ .

## 6 An Example Having Only Irrational Equilibria

Our example has 4 agents  $A_1, \dots, A_4$  and 4 goods  $g_1, \dots, g_4$ <sup>7</sup>. The agents' utilities for the goods are given in Table 1, with rows corresponding to agents and columns to goods.

■ **Table 1** Agents' utilities.

	$g_1$	$g_2$	$g_3$	$g_4$
$A_1$	2	4	0	8
$A_2$	2	3	0	8
$A_3$	2	0	5	0
$A_4$	0	4	5	0

Thus, agents  $A_1$  and  $A_2$  like, to varying degrees, three goods only,  $g_1, g_2, g_4$ , while agents  $A_3$  and  $A_4$  like two goods each,  $\{g_1, g_3\}$  and  $\{g_2, g_3\}$ , respectively. The precise values of the utilities are not that important; the important aspects are: which goods each agent likes, the order between them, and the ratios  $\frac{u_{14}-u_{12}}{u_{12}-u_{11}}$  and  $\frac{u_{24}-u_{22}}{u_{22}-u_{21}}$ . Notice that the latter are unequal.

We show that this example has a unique equilibrium solution with minimum price 0. In this solution, good  $g_1$  has price 0, and all the other goods have positive irrational values. Agents  $A_1, A_3$  and  $A_4$  buy the goods that they like, and  $A_2$  buys  $g_1$  and  $g_4$  only.

Specifically, we show the following:

► **Theorem 16.** *The stated instance has a unique equilibrium. In this equilibrium, the allocations to agents and prices of goods, other than the zero-priced good, are all irrational numbers. The prices are as follows:*

$$p_1 = 0, \quad p_2 = (23 - \sqrt{17})/32, \quad p_3 = (9 + \sqrt{17})/8, \quad p_4 = (69 - 3\sqrt{17})/32.$$

Letting  $r_i = |1 - p_i|$ , the allocations  $x_{ij}$  of each good  $g_j$  to each agent  $A_i$  are as follows:

$$\begin{aligned} A_1 : \quad x_{11} &= 1 - \frac{r_3}{1+r_3} - \frac{r_4}{1+r_4}, & x_{12} &= \frac{r_2}{r_2+r_3}, & x_{13} &= 0, & x_{14} &= \frac{r_4}{1+r_4} \\ A_2 : \quad x_{21} &= \frac{r_4}{1+r_4}, & x_{22} &= 0, & x_{23} &= 0, & x_{24} &= \frac{1}{1+r_4} \\ A_3 : \quad x_{31} &= \frac{r_3}{1+r_3}, & x_{32} &= 0, & x_{33} &= \frac{1}{1+r_3}, & x_{34} &= 0 \\ A_4 : \quad x_{41} &= 0, & x_{42} &= \frac{r_3}{r_2+r_3}, & x_{43} &= \frac{r_2}{r_2+r_3}, & x_{44} &= 0 \end{aligned}$$

<sup>7</sup> It can be shown, by analyzing relations in the bipartite graph on agents and goods with edges corresponding to non-zero allocations, that any instance with 3 agents and 3 goods and rational utilities has a rational equilibrium.

The proof of the theorem is given in the full paper. Even for a small instance like this one, the analysis of the HZ equilibria is not simple. We outline here the main steps. Consider any equilibrium with minimum price 0. We first analyze qualitatively the prices of the goods with respect to 0 and 1: We show that the zero-priced good must be good 1; good 2 must have price strictly between 0 and 1, and goods 3 and 4 must have price strictly greater than 1. Next we characterize qualitatively which goods are bought in non-zero quantity by each agent: We show that every agent buys only goods that she likes. Agents  $A_3$  and  $A_4$  buy both goods that they like, but only one of agents  $A_1, A_2$  buys all three goods that she likes. If  $A_1$  buys  $g_1, g_2, g_4$ , then  $A_2$  buys only  $g_1, g_4$ . If  $A_2$  buys  $g_1, g_2, g_4$ , then  $A_1$  buys only  $g_2, g_4$ . Finally, we analyze quantitatively each of these two cases. In each case, we show that the prices satisfy a system of (nonlinear) equations, and the system has a unique nonnegative solution. Furthermore, the prices determine uniquely the allocation. In the first case where  $A_1$  buys all three goods that she likes, the unique solution and the corresponding allocations are as given in the Theorem. In the second case where agent  $A_2$  buys all three goods, we show that there is no equilibrium: the unique prices that satisfy the equations yield allocations that violate the market clearance conditions (a good is oversold). The analysis uses heavily the primal-dual complementary slackness equations. We refer to the full paper for the details.

► **Remark 17.** Observe that in the equilibrium, the allocations of all four agents are irrational even though each one of them spends their dollar completely and the allocations form a fractional perfect matching, i.e., add up to 1 for each good and each agent.

## 7 Membership of Exact Equilibrium in FIXP

In this section, we will prove that the problem of computing an HZ equilibrium lies in the class FIXP, which was introduced in [16]. This is the class of problems that can be cast, in polynomial time, as the problem of computing a fixed point of an algebraic Brouwer function. Recall that basic complexity classes, such as P, NP, NC and #P, are defined via machine models. For the class FIXP, the role of “machine model” is played by one of the following: a straight line program, an algebraic formula, or a circuit; further it must use the standard arithmetic operations of  $+$ ,  $-$ ,  $*$ ,  $/$ ,  $\min$  and  $\max$ . We will establish membership in FIXP using straight line programs. Such a program should satisfy the following:

1. The program does not have any conditional statements, such as if ... then ... else.
2. It uses the standard arithmetic operations of  $+$ ,  $-$ ,  $*$ ,  $/$ ,  $\min$  and  $\max$ .
3. It never attempts to divide by zero.

A *total problem* is one which always has a solution, e.g., Nash equilibrium and Hylland-Zeckhauser equilibrium. A total problem is in FIXP if there is a polynomial time algorithm which given an instance  $I$  of length  $|I| = n$ , outputs a polynomial sized straight line program which computes a function  $F_I$  on a closed, convex, real-valued domain  $D(n)$  satisfying: each fixed point of  $F_I$  is a solution to instance  $I$ .

Let  $p$  and  $x$  denote the allocation and price variables. We will give a function  $F$  over these variables and a closed, compact, real-valued domain  $D$  for  $F$ . The function will be specified by a polynomial length straight line program using the algebraic operations of  $+$ ,  $-$ ,  $*$ ,  $/$ ,  $\min$  and  $\max$ , hence guaranteeing that it is continuous. We will prove that all fixed points of  $F$  are equilibrium allocations and prices, hence proving that Hylland-Zeckhauser is in FIXP.

**Notation.** We denote the set  $\{1, \dots, n\}$  by  $[n]$ .  $x_i$  denotes agent  $i$ 's bundle. For each agent  $i$ , choose one good from  $G_i^*$  and denote it by  $i^*$ . If  $e$  is an expression, we will use  $(e)_+$  as a shorthand for  $\max\{0, e\}$ .

Domain  $D = D_p \times D_x$ , where  $D_p$  and  $D_x$  are the domains for  $p$  and  $x$ , respectively, with  $D_p = \{p \mid \forall j \in [n], p_j \in [0, n]\}$  and  $D_x = \{x \mid \forall i \in [n], \sum_{j \in G} x_{ij} = 1, \text{ and } \forall i, j \in [n], x_{ij} \geq 0\}$ .

Let  $(p', x') = F(p, x)$ .  $(p, x)$  can be viewed as being composed of  $n + 1$  vectors of variables, namely  $p$  and for each  $i \in [n]$ ,  $x_i$ . Similarly, we will view  $F$  as being composed of  $n + 1$  functions,  $F_p$  and for each  $i \in [n]$ ,  $F_i$ , where  $p' = F_p(p, x)$  and for each  $i \in [n]$ ,  $x'_i = F_i(p, x)$ . The straight line programs for  $F_p$  and  $F_i$  are given in the figures below.

It is easy to see that if  $F_i$  alters a bundle, the new bundle still remains in the domain; in particular,  $\forall i \in [n]$ ,  $\text{size}(i) = 1$ . Similarly, it is easy to see that the output of  $F_p$  is in the domain  $D_p$ .

**Requirements on equilibria.** Observe that  $(p, x)$  will be an equilibrium for the market if, in addition to the conditions imposed by the domain, it satisfies the following:

1.  $\forall j \in [n]$ ,  $\sum_{i \in A} x_{ij} = 1$ .
2.  $\forall i \in [n]$ ,  $\text{cost}(i) \leq 1$ .
3.  $\forall i \in [n]$ ,  $x_i$  is an optimal bundle for  $i$ . Furthermore,  $\text{cost}(i)$  is minimum over all optimal bundles.

Function  $F$  has been constructed in such a way that if any of these conditions is not satisfied by  $(p, x)$ , then  $F(p, x) \neq (p, x)$ , i.e.,  $(p, x)$  is not a fixed point of  $F$ . Equivalently, we show that every fixed point of  $F$  must satisfy all these conditions and is therefore an equilibrium. The converse also holds. That is, we show:

► **Lemma 18.** *Every fixed point  $(x, p)$  of  $F$  is an equilibrium of the matching market. Conversely, every equilibrium  $(p, x)$ , where some good has price 0, is a fixed point of  $F$ .*

■ **Algorithm 2** Straight line program for function  $F_p$ .

- 
1. For all  $j \in [n]$  do:  $p_j \leftarrow \min\{n, \max\{0, p_j + \sum_{i \in A} x_{ij} - 1\}\}$
  2.  $r \leftarrow \min_{j \in [n]} \{p_j\}$
  3. For all  $j \in [n]$  do:  $p_j \leftarrow p_j - r$
- 

The proof of correctness for the function  $F$  is nontrivial, and is given in the full paper. The proof makes essential use of the characterization of the optimal bundles from Section 5. We first show that  $F$  has the following key property: if  $(p, x)$  is a fixed point, then no step of  $F$  will change  $(p, x)$ , i.e., it couldn't be that some step(s) of  $F$  change  $(p, x)$  and some other step(s) change it back, restoring it to  $(p, x)$ . This is easy to check for  $F_p$ . The proof for  $F_i$  is more delicate and uses a potential function argument based on the changes in  $\text{value}(i) = \sum_j u_{ij}x_{ij}$  and  $\text{cost}(i) = \sum_j p_j x_{ij}$  caused by any change in the allocation  $x_i$  in every step of the algorithm for  $F_i$ . Given the key property, we then show that if a pair  $(x, p)$  does not satisfy one of the equilibrium requirements, then some step of  $F$  will change  $(x, p)$ , hence  $(x, p)$  is not a fixed point. We refer to the full paper for the details of the proofs.

Thus, we have:

► **Theorem 19.** *The problem of computing an exact equilibrium for the Hylland-Zeckhauser scheme is in FIXP.*

■ **Algorithm 3** Straight line program for function  $F_i$ .

- 
1.  $r \leftarrow (\sum_j p_j x_{ij} - 1)_+$ .
  2. For all  $j \in [n]$  do:  $x_{ij} \leftarrow \frac{x_{ij} + r \cdot (1 - p_j)_+}{1 + r \cdot \sum_k (1 - p_k)_+}$
  3.  $t \leftarrow (1 - \sum_j p_j x_{ij})_+$
  4. For all  $k \notin G_i^*$  do:
    - a.  $d \leftarrow \min\{x_{ik}, \frac{t}{n^2}\}$
    - b.  $x_{ik} \leftarrow x_{ik} - d$
    - c.  $x_{ii^*} := x_{ii^*} + d$
  5. For all pairs  $j, k$  of goods s.t.  $u_{ij} \leq u_{ik}$  do:
    - a.  $d \leftarrow \min\{x_{ij}, (p_j - p_k)_+\}$
    - b.  $x_{ij} \leftarrow x_{ij} - d/n$
    - c.  $x_{ik} \leftarrow x_{ik} + d/n$
  6. For all triples  $j, k, l$  of goods such that  $u_{ij} < u_{ik} < u_{il}$  do:
    - a.  $d \leftarrow \min\{x_{ik}, ((u_{il} - u_{ik})(p_k - p_j) - (u_{ik} - u_{ij})(p_l - p_k))_+\}$
    - b.  $x_{ik} \leftarrow x_{ik} - d$
    - c.  $x_{ij} \leftarrow x_{ij} + \frac{u_{il} - u_{ik}}{u_{il} - u_{ij}} d$
    - d.  $x_{il} \leftarrow x_{il} + \frac{u_{ik} - u_{ij}}{u_{il} - u_{ij}} d$
  7. For all triples  $j, k, l$  of goods such that  $u_{ij} < u_{ik} < u_{il}$  do:
    - a.  $d := \min(x_{ij}, x_{il}, ((u_{ik} - u_{ij})(p_l - p_k) - (u_{il} - u_{ik})(p_k - p_j))_+)$
    - b.  $x_{ik} := x_{ik} + d$
    - c.  $x_{ij} := x_{ij} - \frac{u_{il} - u_{ik}}{u_{il} - u_{ij}} d$
    - d.  $x_{il} := x_{il} - \frac{u_{ik} - u_{ij}}{u_{il} - u_{ij}} d$
- 

## 8 Membership of Approximate Equilibrium in PPAD

In this section we define approximate equilibria, and show that the problem of computing an approximate equilibrium is in PPAD.

First let us scale the utilities of all the agents so that they lie in  $[0, 1]$ . This can be done clearly without loss of generality without changing the equilibria.

► **Definition 20.** A pair  $(p, x)$  of (non-negative) prices and allocations is an  $\epsilon$ -approximate equilibrium for a given one-sided market if:

1. The total probability share of each good  $j$  is 1 unit, i.e.,  $\sum_i x_{ij} = 1$ .
2. The size of each agent  $i$ 's allocation is 1, i.e.,  $\text{size}(i) = 1$ .
3. The cost of the allocation of each agent is at most  $1 + \epsilon$ .
4. The value of the allocation of each agent  $i$  is at least  $v^*(i) - \epsilon$  where  $v^*(i)$  is the value of the optimal bundle for agent  $i$  under prices  $p$ , i.e. the optimal value of the program: maximize  $\text{value}(i)$ , subject to  $\text{size}(i) = 1$  and  $\text{cost}(i) \leq 1$ . Furthermore, we require that the cost of the allocation  $x_i$  is at most  $c^*(i) - \epsilon$ , where  $c^*(i)$  is the minimum cost of a bundle for agent  $i$  that has the maximum value  $v^*(i)$ .

The corresponding computational problem is: Given a one-sided matching market  $M$  and a rational  $\epsilon > 0$  (in binary as usual), compute an  $\epsilon$ -approximate equilibrium for  $M$ . Polynomial time in this context means time that is polynomial in the encoding size of the

market  $M$  and  $\log(1/\epsilon)$ . We define also a more relaxed version, called a *relaxed  $\epsilon$ -approximate equilibrium* where condition 1 is relaxed to  $|\sum_i x_{ij} - 1| \leq \epsilon$  for all goods  $j$ . It is easy to see that the two versions are polynomially equivalent, i.e., if one can be solved in polynomial time then so can the other.

► **Proposition 21.** *The problems of computing an  $\epsilon$ -approximate equilibrium and a relaxed approximate equilibrium are polynomially equivalent.*

Note however, that in general an  $\epsilon$ -approximate equilibrium may not be close to an actual equilibrium of the matching market. This phenomenon is similar to the case of market equilibria for the standard exchange markets and to the case of Nash equilibria for games.

We will show membership of the approximate equilibrium problem in PPAD by showing that a relaxed approximate equilibrium can be obtained from an approximate fixed point of a variant of the function  $F$  defined in Section 7.

► **Definition 22.** *A weak  $\epsilon$ -approximate fixed point of a function  $F$  (or weak  $\epsilon$ -fixed point for short) is a point  $x$  such that  $\|F(x) - x\|_\infty \leq \epsilon$ .*

Let  $\mathcal{F}$  be a family of functions, where each function  $F_I$  in  $\mathcal{F}$  corresponds to an instance  $I$  of a problem (in our case a one-sided matching market) that is encoded as usual by a string. The function  $F_I$  maps a domain  $D_I$ , to itself. We assume that  $D_I$  is a polytope defined by a set of linear inequalities with rational coefficients which can be computed from  $I$  in polynomial time; this clearly holds for our problem. We use  $|I|$  to denote the length of the encoding of an instance  $I$  (i.e., the length of the string). If  $x$  is a rational vector, we use  $\text{size}(x)$  to denote the number of bits in a binary representation of  $x$ .

► **Definition 23.** *A family  $\mathcal{F}$  of functions is polynomially computable if there is a polynomial  $q$  and an algorithm that, given the string encoding  $I$  of a function  $F_I \in \mathcal{F}$  and a rational point  $x \in D_I$ , computes  $F_I(x)$  in time  $q(|I| + \text{size}(x))$ .*

*A family  $\mathcal{F}$  of functions is polynomially continuous if there is a polynomial  $q$  such that for every  $F_I \in \mathcal{F}$  and every rational  $\epsilon > 0$  there is a rational  $\delta$  such that  $\log(1/\delta) \leq q(|I| + \log(1/\epsilon))$  and such that  $\|x - y\|_\infty \leq \delta$  implies  $\|F_I(x) - F_I(y)\|_\infty \leq \epsilon$  for all  $x, y \in D_I$ .*

It was shown in [16] that, if a family of functions is polynomially computable and polynomially continuous, then the corresponding weak approximate fixed point problem (given  $I$  and rational  $\delta > 0$ , compute a weak  $\delta$ -approximate fixed point of  $F_I$ ) is in PPAD. The family  $\mathcal{F}$  of functions for the online matching market problem defined in Section 7 is obviously polynomially computable. It is easy to check also that it is polynomially continuous.

We will use a variant  $F'$  of the function  $F$  of Section 7, where the functions  $F_i$  for the allocations are modified as follows. Step 5 for all pairs  $j, k$  of goods, and steps 6, and 7 for all triples  $j, k, l$  are applied all independently in parallel to the allocation that results after step 4. In order for the allocation to remain feasible (i.e. have  $x_{ij} \geq 0$  for all  $i, j$ ), we change line 5a in  $F'_i$  to  $d \leftarrow \min\{\frac{x_{ij}}{3}, (p_j - p_k)_+\}$ , change line 6a to  $d \leftarrow \min\{\frac{x_{ik}}{3n^2}, ((u_{il} - u_{ik})(p_k - p_j) - (u_{ik} - u_{ij})(p_l - p_k))_+\}$ , and we change line 7a to  $d \leftarrow \min\{\frac{x_{ij}}{3n^2}, \frac{x_{il}}{3n^2}, ((u_{ik} - u_{ij})(p_l - p_k) - (u_{il} - u_{ik})(p_k - p_j))_+\}$ . In this way, a coordinate  $x_{ij}$  can be decreased by the operations of step 5 for all pairs  $j, k$  at most by  $x_{ij}/3$  in total, and the same is true for the total decrease from the operations of steps 6 and 7 for all triples involving good  $j$ ; therefore, the coordinates  $x_{ij}$  remain nonnegative. The function for the prices remains the same as before. All the properties shown in Section 7 for  $F$  hold also for  $F'$ . The family  $\mathcal{F}'$  of these functions  $F'_I$  is clearly also polynomially computable and polynomially continuous.

Let  $I$  be a given instance of the matching market problem. Every utility  $u_{ij}$  is a rational number, without loss of generality in  $[0, 1]$ , which is given as the ratio of two integers represented in binary. Let  $m$  be the maximum number of bits needed to represent a utility. Note that every nonzero  $u_{ij}$  is at least  $1/2^m$  and the difference between any two unequal utilities is at least  $1/2^{2m}$ . Given a positive rational  $\epsilon$  (wlog in  $[0, 1]$ ), let  $\delta = \epsilon/(n^{10}2^{6m})$ . Note that  $\log(1/\delta)$  is bounded by a polynomial in  $|I|$  and  $\log(1/\epsilon)$ . We show the following:

► **Lemma 24.** *Every weak  $\delta$ -approximate fixed point of  $F_I'$  is a relaxed  $\epsilon$ -approximate equilibrium of the market  $I$ .*

The proof follows and adapts the proof in Section 7 of the analogous statement for the exact fixed points. The proof is rather involved; we refer to the full paper for the details. As a consequence of Lemma 24 and Proposition 21 we have:

► **Theorem 25.** *The problem of computing an  $\epsilon$ -approximate equilibrium of a given matching market is in PPAD.*

## 9 Discussion

As stated in the Introduction, a conclusive proof of intractability of the HZ scheme, via either a proof of FIXP-hardness for exact equilibrium or PPAD-hardness for approximate equilibrium, has eluded us. One of the difficulties is the following: Optimal bundles of agents in an HZ equilibrium may include zero-utility zero-priced goods as “fillers” to satisfy the size constraint, e.g., observe their use in our Algorithm for the case of dichotomous utilities. In this easy setting, we knew which were the “filler” goods. However, when faced with a complex instance of HZ, we don’t a priori know which zero-utility goods will be used as “fillers”. Therefore, even though an agent may have very few positive utility goods, other goods are also in play, thereby giving no “control” on the equilibrium outcome.

We propose exploring the following avenue, in addition to the usual ones, for arriving at evidence of intractability: Relax the notion of polynomial time reducibility suitably and obtain a weaker result than FIXP-hardness or PPAD-hardness.

Other open problems related to our work are: obtain efficient algorithms for computing approximate equilibria, suitably defined, and identify other special cases, besides the bi-valued case, for which equilibrium is easy to compute. Additionally, generalizations and variants of the HZ scheme deserve attention, most importantly to two-sided matching markets [14].

Encouraged by success on the bi-valued utilities case, we considered its generalization to the tri-valued utilities case, in particular,  $\{0, \frac{1}{2}, 1\}$  utilities. We believe even this case has instances with only irrational equilibria. Finding such an example or proving rationality is non-trivial and we leave it as an open problem. Furthermore, it will not be surprising if even this case is intractable; resolving this is a challenging open problem.

---

## Abstract

We design a randomized algorithm that finds a Hamilton cycle in  $\mathcal{O}(n)$  time with high probability in a random graph  $G_{n,p}$  with edge probability  $p \geq C \log n/n$ . This closes a gap left open in a seminal paper by Angluin and Valiant from 1979.

## 1 Introduction

A Hamilton cycle is a cycle in a graph that visits every vertex exactly once. Determining whether a graph has a Hamilton cycle is a notoriously difficult problem that has been tackled in various ways. In general, it is known to be  $\mathcal{NP}$ -hard, putting it in a bag of complexity theory together with colorability or SAT, problems for which one has tried to find polynomial time algorithms for a long time without any success so far.

While the Hamilton cycle problem is a difficult problem in general, it turns out that for most graphs it is actually not. To illustrate this, we take a closer look at the Erdős-Rényi random graph  $G_{n,p}$  which is an  $n$ -vertex graph with each edge being present independently with probability  $p$ . The existence question of the Hamilton cycle problem is very well understood, cf. the comprehensive survey by Frieze [13]. Let  $\mathcal{H}$  be the set of Hamiltonian graphs, then for  $G_{n,p}$  it holds that (Komlós and Szemerédi [19] and Korshunov [20])

$$Pr[G_{n,p(n)} \in \mathcal{H}] = \begin{cases} 0, & p(n) = \frac{\log(n) + \log \log(n) - \omega(1)}{n} \\ e^{-e^{-c}}, & p(n) = \frac{\log(n) + \log \log(n) + c + o(1)}{n} \\ 1, & p(n) = \frac{\log(n) + \log \log(n) + \omega(1)}{n}, \end{cases}$$

which is limitwise the same as the threshold for when  $G_{n,p}$  has minimum degree 2. So really vertices of degree one are the bottleneck for random graphs. In fact, it is known that if we add the edges randomly one by one, the moment we reach minimum degree 2 is the same as

the moment the graph becomes Hamiltonian with high probability [1]. And this threshold is also robust (e.g. [22, 23]). For other random graph models like the random graph with  $m$  edges  $G_{n,m}$ , the random regular graph  $G_{n,r}$  or the  $k$ -out which takes  $k$  random edges from every vertex the corresponding thresholds for Hamiltonicity are also known [7, 9, 11, 26, 29]. Similar to the classical random graph case also in these cases the thresholds coincides with a local obstruction such as minimum degree two or any two vertices have a neighborhood of size at least 3. And this is not a coincidence. Randomness gives us such nice expansion properties that only the small structures can be an obstruction to the Hamilton cycle. This phenomenon has been observed also for other properties such as connectivity, containing a perfect matching or colorability.

The proofs of Komlos and Szemerédi and Korshunov are just existential, i.e. they determine the threshold for the existence of Hamilton cycle, but do not provide an efficient algorithm for finding it. In a seminal paper, Angluin and Valiant [4] show that with the input given as a random adjacency list one can find Hamilton cycles in  $G_{n,p}$  for  $p \geq C \log n/n$  in  $\mathcal{O}(n \log^2 n)$  time with high probability. There are two ways in which this result is possibly non-optimal: the lower bound on  $p$  and the runtime. The first point was considered by Shamir and then Bollobas, Fenner and Frieze, who brought the bound down to the existence threshold of  $G_{n,p}$ . In more recent works the runtime has also been optimized for graphs given in adjacency matrix form, assuming a pair of vertices can be queried in constant time. We summarize these results in the table below. There are various related results that are hard to compare, as their setting is slightly different [2, 12, 14, 15]. Some of the results are assuming the graph is given as an adjacency matrix with black box queries and the runtime  $\mathcal{O}(n/p)$  is optimal in that model.

Authors	Year	Time	$p(n)$	Graph Model
Angluin, Valiant [4]	'79	$\mathcal{O}(n \log^2(n))$	$p \geq \frac{C \log(n)}{n}$	adj. list
Shamir [28]	'83	$\mathcal{O}(n^2)$	$p \geq \frac{\log(n) + (3+\epsilon) \log \log(n)}{n}$	adj. list
Bollobas, Fenner, Frieze [8]	'87	$n^{4+o(1)}$	$p \geq \textit{Existence threshold}$	adj. list
Gurevich, Shelah [16]	'87	$\mathcal{O}(n/p)$	$p \text{ const.}$	adj. matrix
Thomason [30]	'89	$\mathcal{O}(n/p)$	$p \geq Cn^{-1/3}$	adj. matrix
Alon, Krivelevich [3]	'20	$\mathcal{O}(n/p)$	$p \geq 70n^{-1/2}$	adj. matrix

In this paper we consider the second question that was left open in the Angluin-Valiant paper: can the runtime be improved. Note that a graph with  $p \geq C \log n/n$  has  $\Theta(n \log n)$  edges. Thus, improving the runtime below this bound requires a *sublinear* algorithm, i.e. sublinear in the input size. These are algorithms that produce an output without reading the input completely (see e.g. [27] for an overview of the topic). Such algorithms are less restrictive than those designed for online or a (semi-)streaming model as they allow some control over which part of an input is used. However for graphs with  $n$  vertices and  $m \gg n$  edges the algorithm is only allowed to read  $o(m)$  edges, i.e., a negligible fraction of the input – but nevertheless has to compute the desired output correctly.

## 1.1 Our contribution

In this paper we show that given a random graph with edge probability  $p \geq C \log n/n$ , for an appropriately chosen constant  $C$ , we can find a Hamilton cycle in  $\mathcal{O}(n)$  time with high probability. This time is clearly optimal, as the algorithm has to return  $\Omega(n)$  edges. We assume that the graph is given to us with randomly ordered adjacency lists, such that we can query the next neighbor in those lists for any vertex in constant time.

■ **Figure 1** Algorithm uses a random walk like strategy, blue edge is the `newneighbor()`.

► **Theorem 1.** *There exists a randomized algorithm  $\mathcal{R}$  which finds a Hamilton cycle in a random graph  $G_{n,p}$  in  $\mathcal{O}(n)$  time with high probability, provided  $p \geq C \log n/n$  for a sufficiently large constant  $C$ .*

Note that “with high probability” is always meant to mean with probability  $1 - o(1)$  tending to one as  $n$  tends to infinity and takes into account all sources of randomness: i.e., the randomness of the algorithm, the random graph and the randomness of the datastructure used to store the graph (random ordering of the adjacency lists).

Our paper is organized as follows. Section 2 contains the algorithm and the proof of Theorem 1. It is based on three technical lemmas that we prove in Section 3.

## 2 Algorithm

The most commonly used technique for efficient cycle extensions is Posa rotations. This is also the case for the original algorithm of Angluin and Valiant [4], which we outline in Section 2.1 below, cf. also Figure 2. To reduce the runtime to  $\mathcal{O}(n)$  we reduce the total number of Posa rotations that are required and simultaneously also restrict ourselves to certain types of Posa rotations so that we can realize each of them in  $\mathcal{O}(\log n)$  time.

### 2.1 Finding A Hamilton Cycle via Posa Rotations

We sketch here the algorithm of Angluin and Valiant. The main idea of their algorithm is to perform a greedy random walk until all vertices are incorporated in the path/cycle. This means we start from an arbitrary vertex and query a neighbor of that vertex. If the neighbor is already contained in the path we have built so far we consider this a failure and we query a new neighbor. Otherwise we add the neighbor to the path and continue from the new endpoint vertex (see Figure 1).

Once the path is long enough (at least  $n/2$ ) we add possible Posa rotations. Assume we start with a path  $P = (v_1, \dots, v_s)$ , then if we find two edges such that for some index  $i \in [s]$  the edges are of the form  $\{v_{i+1}, v_s\}$  and  $\{v_i, v_j\}$  for some  $j > i + 1$ , we can rearrange the path to form a new path  $P' = (v_1, \dots, v_i, v_j, v_{j+1}, \dots, v_s, v_{i+1}, \dots, v_{j-1})$  and now the new path has the same vertex set but a different endpoint vertex. This we call a Posa rotation. Additionally we will always want *long* Posa rotations meaning  $s - i$  must be at least  $n/2$  to ensure that we can find the second edge needed quickly with high probability.

So during our Algorithm if the neighbor  $(v_{i+1})$  of the endpoint of the path  $(v_s)$  has distance at least  $n/2$  from the endpoint along the path we use that edge to build a cycle and continue from the vertex preceding the neighbor  $(v_i)$  on the path (see Figure 2). This leaves a cycle of size at least  $n/2$  and if we ever find one of the vertices on the cycle to be the neighbor of the current endpoint we reincorporate the large cycle by appending it to the path (again giving a new endpoint).

Many details need to be considered on how random variables interact, etc., but leaving those aside one can easily convince oneself that on average the current vertex changes after a constant number of queries to a new random vertex, and that the number of queries until

■ **Figure 2** Posa rotation, detaching a large cycle.

■ **Figure 3** Reincorporating the large cycle.

the path length increases by one is geometrically distributed and has an expectation of  $n/(n-i)$  where  $i$  is the current length of the path. The total number of Posa rotations is thus bounded by

$$\mathcal{O}\left(\sum_{i=1}^n \frac{n}{i}\right) = \mathcal{O}(n \log n).$$

As each Posa rotation takes time  $\log n$  to realize this gives a total running time of  $\mathcal{O}(n \log^2 n)$ .

## 2.2 Our Algorithm

We give a short overview of the new algorithm we propose. The algorithm comes in two phases. In phase 1 we find two random perfect matchings. The union of these two random perfect matchings forms a two regular graph, i.e., a set of disjoint cycles or double edges covering all vertices. It is not difficult to show that the number of cycles is with high probability bounded by  $2 \log n$ . In phase 2 of the algorithm we stitch these  $2 \log n$  cycles together.

For the analysis of the algorithm it is very helpful to assume that a query for a new neighbor of some vertex  $v$  returns a vertex  $w$  that is *uniformly* distributed over all vertices in  $V - v$  and *independent* from all previous queries. Of course such an assumption a priori does not hold if we simply return the next vertex from the adjacency list of  $v$ . We realize this by directing the edges and resampling. More formally, we will show the following lemma in Section 3; in the remainder of Section 2 we will use the corresponding function `newneighbor()` as a black box.

► **Lemma 8** (`newneighbor`). *It is possible to interact with the graph  $G_{n,p}$ ,  $p \geq \frac{C \log n}{n}$ , with an algorithmic procedure `newneighbor( $v$ )` which has the following properties with high probability:*

- (i) *Calling `newneighbor( $v$ )` returns a neighbor of  $v$  distributed uniformly among  $V - v$  and independent of all calls so far – as long as we make at most  $\mathcal{O}(n)$  calls to `newneighbor()` altogether and every vertex is queried at most  $100 \log n$  times.*
- (ii) *The total run time of all  $\mathcal{O}(n)$  calls is  $\mathcal{O}(n)$ .*

Note that this algorithm uses both internal randomness as well as the randomness of  $G_{n,p}$ . If `newneighbor( $v$ )` ever returns 'there are no more neighbors' we immediately terminate the entire algorithm and return failure. To avoid this, we will prove that we query `newneighbor( $v$ )` from any vertex at most  $100 \log n$  times w.h.p. and choose  $C$  large enough so that with high probability the minimum degree of the random graph is large enough.

### 2.2.1 Phase 1: Perfect Matching

In the first phase of the algorithm we show that we can find a perfect matching in  $\mathcal{O}(n)$  time. We call the algorithmic procedure described in this section **FastPerfectMatching**, see Algorithm 1. In fact, for an easier understanding of the required ideas, we work in this section with a random *bipartite* random graph. This can easily be done by partitioning the vertex set  $V$  into two equal sets  $A$  and  $B$  arbitrarily (if  $n$  is odd we set one vertex aside and include it in phase 2) and only considering the edges between  $A$  and  $B$ . Formally, the function **newABneighbor**( $v$ ) calls **newneighbor**( $v$ ) until we receive a neighbor which is in  $B$  (resp.  $A$ ).

▷ **Claim 2.** If we call **newABneighbor**() for a sequence of  $\mathcal{O}(n)$  vertices, in which every vertex  $v \in A \cup B$  occurs at most  $\log n$  times, then with high probability this results in at most  $\mathcal{O}(n)$  calls to **newneighbor**() with at most  $6 \log n$  calls per vertex.

The claim holds because any call of **newneighbor**() has probability at least  $1/2$  to be in the correct partition and, by our assumptions on **newneighbor**(), the calls are independent. We can thus apply concentration bounds for binomial distributions and union bound for every vertex. Clearly, **newABneighbor**() still has a uniform and independent distribution over all vertices of the opposite partition.

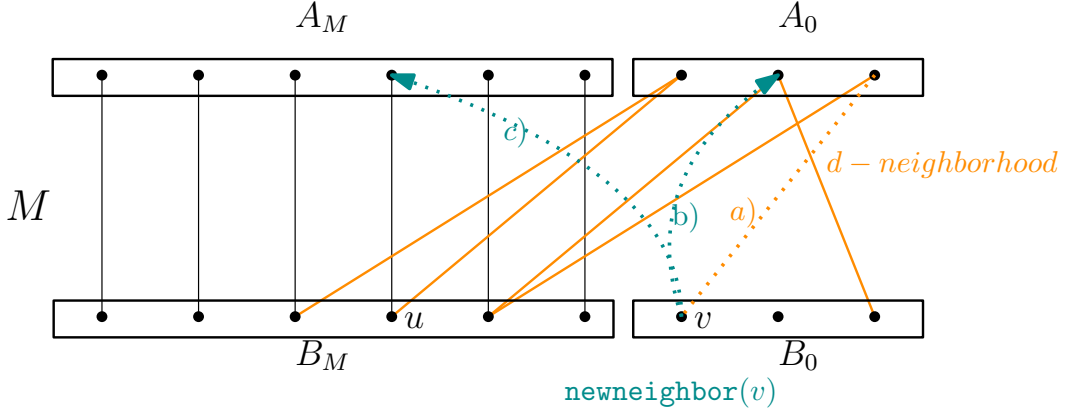

Let  $G$  be the balanced bipartite graph with partitions  $A$  and  $B$ . During the algorithm we will maintain a matching  $M$  which covers some of the vertices and is empty at first. At any point in time, we denote by  $A_M$  the vertices in  $A$  that are covered by the matching and with  $A_0$  the unmatched vertices. Equivalently for  $B_M$  and  $B_0$ .

Additionally we need a set of edges that expand well from the vertices of  $A$ . And we need to be able to keep track of them efficiently and on the fly. So for any vertex  $v$  we define the  $d$ -neighborhood of  $v$ ,  $N_d(v) \subseteq V(G)$ , to be the set of the first  $\lceil d \rceil$  calls to the function **newABneighbor**( $v$ ). In particular this implies that for any  $d' < d$  the  $d'$ -neighborhood is contained in the  $d$ -neighborhood of  $v$ . Similarly, the  $d$ -neighborhood of a set of vertices  $S$ , denoted by  $N_d(S)$ , is defined as the union of the  $d$ -neighborhoods of all vertices in  $S$ . We expose and keep track of the  $d$ -neighborhood of the unmatched vertices  $A_0$ ,  $N_{d(|A_0|)}(A_0)$ , for the function  $d(t) = \min(\sqrt{n/t}, \log n)$ . This gives us a neighborhood large enough for the random walks to be effective, but small enough so that we do not need too much time to update/expose.

To increase the matching we call a subroutine **IncreaseMatching**. **IncreaseMatching** takes as argument the current matching  $M$  and an unmatched vertex  $v \in B_0$ . It proceeds as follows. If  $v$  is in  $N_d(A_0)$  we add the corresponding neighbor in  $A_0$  and  $v$  to the matching. If not we take  $w = \text{newABneighbor}(v)$ . If  $w$  is in  $A_0$  we add the edge  $\{w, v\}$  to  $M$ . If neither of the two is the case, then  $w \in A_M$  and there exists a unique  $u$  such that  $\{w, u\}$  is currently in  $M$ . We swap  $\{w, u\}$  for  $\{w, v\}$ , thereby making  $u$  a new unmatched vertex, and repeat **IncreaseMatching** with  $u$ , cf. Figure 4.

Clearly, during the run of the algorithm we also have to dynamically update the  $d$ -neighborhood of  $A_0$ . In particular this means removing  $N_d(w)$  of a newly matched vertex  $w$  and, if  $d(|A_0|)$  increases, adding vertices from additional calls to **newABneighbor**() for every vertex in  $A_0$ .

To bound the runtime of Algorithm 2, **FastPerfectMatching**, we observe first that we increase the matching exactly  $n$  times, which is inline with our desired bound of  $\mathcal{O}(n)$ . We can thus concentrate on bounding the *recursive* calls to **IncreaseMatching** in line 13 of **IncreaseMatching**.

■ **Figure 4** For `IncreaseMatching` three things can happen. Either a) the vertex is already in the neighborhood of  $A_0$ , in which case we match immediately, b) the vertex `newABneighbor(v)` is in  $A_0$ , which also gets matched, or c) `newABneighbor(v)` is in  $A_M$ . Then we swap the matching and continue from the partner of the `newABneighbor(v)`.

■ **Algorithm 1** `FastPerfectMatching(G)`.

---

```

1:  $B_0 \leftarrow B$ ;  $B_M \leftarrow \{\}$ ;  $A_0 \leftarrow A$ ;  $A_M \leftarrow \{\}$ ;
2:  $d \leftarrow 0$ ;  $M \leftarrow \{\}$ 
3: while  $B_0 \neq \{\}$  do
4:    $v \leftarrow$  arbitrary vertex from  $B_0$  ▷ and remove from  $B_0$ 
5:   IncreasingMatching( $G, M, v$ ); ▷ see Algorithm 2
6:   while  $d < \min\left(\sqrt{\frac{n}{|A_0|}}, \log(n)\right)$  do
7:      $d \leftarrow d + 1$ 
8:     Add newABneighbor(v) to the  $d$ -neighborhood for every vertex in  $v \in A_0$ 
9: return Matching  $M$ 

```

---

► **Lemma 3.** Let  $\mathcal{L}_i$  denote the number of calls `IncreaseMatching` in line 13, while  $|A_0| = i$  for any  $i \in [n]$ . Then the  $\mathcal{L}_i$  are dominated by independent geometric distributions with success probability  $p_i = \frac{i \cdot d(i)}{100n}$ .

**Proof.** Whenever we are at a vertex  $v$  in  $B$  we expose an edge to a random neighbor in the set  $A$ . If that vertex is in  $A_0$  we match  $v$  and  $|A_0|$  decreases by one so we end the count of  $\mathcal{L}_{|A_0|}$ . Otherwise we swap with a matched vertex and get a new starting point in  $B_0$ . As `newABneighbor()` is independent and uniform, and the matching forms a bijection between  $A_M$  and  $B_M$ , the fact that the vertex is not in  $A_0$ , implies that we get a new *random* vertex  $u$  in  $B_M$  for the next call. If this vertex is in the exposed  $d$ -neighborhood of  $A_0$  we stop and match to a vertex in  $A_0$  also ending the count of  $\mathcal{L}_{|A_0|}$ .

To assess the probability of stopping, we use the *expansion properties* of the  $d$ -neighborhood of  $A_0$  that are inherited from the random graph. This means in particular that the exposed neighborhood of  $A_0$ ,  $N_{d(|A_0|)}(A_0)$ , has size at least  $\frac{1}{100}|A_0| \cdot d(|A_0|)$ , cf. Lemma 9 in Section 3 for a proof. The probability of hitting a vertex in  $A_0$  or the  $d$ -neighborhood of  $A_0$  (while looking at the matched vertex of  $w$  in  $B_M$ ) is thus at least  $\frac{|A_0| \cdot d(|A_0|)}{100n}$ . Every new call of `newABneighbor()` is independent by Lemma 8, thus  $\mathcal{L}_i$  is dominated by an independent geometric distribution with success probability as claimed. ◀

---

**Algorithm 2** IncreaseMatching( $G, M, v$ ).
 

---

```

1: if  $v \in N_d(A_0)$  then
2:    $w \leftarrow [\text{neighbor of } v] \in A_0$ 
3:   Add  $\{v, w\}$  to  $M$ 
4:   Remove  $w$  from  $A_0$  and update  $N_d(A_0)$ 
5:   return
6:  $w \leftarrow \text{newABneighbor}(v)$ 
7: if  $w \in A_0$  then
8:   Add  $\{v, w\}$  to  $M$ 
9:   Remove  $w$  from  $A_0$  and update  $N_d(A_0)$ 
10:  return
11:  $u \leftarrow$  unique vertex with  $\{u, w\} \in M$ 
12: Remove  $\{u, w\}$  from  $M$  and replace with  $\{v, w\}$ 
13: IncreaseMatching( $G, M, u$ )
14: return
  
```

---

We are now ready to prove the desired complexity bound:

► **Proposition 4.** *FastPerfectMatching finds a perfect matching in a balanced random bipartite graph in time  $\mathcal{O}(n)$  with high probability.*

**Proof.** There are two main contributions to the running time of the Algorithm. First the subroutine **IncreaseMatching**, which we prove to be fast with the help of Lemma 3, and secondly the updating and revealing of the  $d$ -neighborhood.

Recall that  $\mathcal{L}_i$  is the random variable corresponding to the number of calls of **IncreaseMatching** in line 13, while  $|A_0| = i$  for any  $i \in [n]$ . We set  $\mathcal{L} = \sum_{i=1}^n \mathcal{L}_i$ . Note that we can ignore the calls in line 5 of **FastPerfectMatching**, as these add only at total of  $\mathcal{O}(n)$  to the run time. From Lemma 3 we know that there exists a coupling to a geometrically distributed random variable  $\mathcal{L}'$  such that  $\mathcal{L}'_i \succeq \mathcal{L}_i$  and  $\mathcal{L}'_i$  is geometrically distributed with  $p_i = \frac{i \cdot d(i)}{100n}$ .

From the definition of  $\mathcal{L}'_i$  we know that  $\mathbb{E}[\mathcal{L}'_i] = \frac{100n}{i \cdot d(i)}$  and  $\text{Var}[\mathcal{L}'_i] = \frac{1-p_i}{p_i^2} \leq \frac{1}{p_i^2} \leq (\frac{100n}{i \cdot d(i)})^2$ . Recall that  $d(i) = \sqrt{n/i}$  whenever  $i \geq \frac{n}{(\log n)^2}$ . The total time used for those sets can thus be bounded in expectation by

$$\sum_{i=\frac{n}{(\log n)^2}}^n \mathbb{E}[\mathcal{L}'_i] = \mathcal{O}\left(\sum_{i=1}^n \frac{\sqrt{n}}{\sqrt{i}}\right) = \mathcal{O}(n),$$

as  $\sum_{i=1}^n i^{-1/2} \leq \int_0^n x^{-1/2} dx = 2\sqrt{n}$ . If  $i \leq \frac{n}{(\log n)^2}$ , then  $d(i) = \log n$ , and the total expected time used for these sets is thus bounded by

$$\sum_{i=1}^{\frac{n}{(\log n)^2}} \mathbb{E}[\mathcal{L}'_i] = \mathcal{O}\left(\sum_{i=1}^n \frac{n}{i \cdot \log(n)}\right) = \mathcal{O}(n).$$

We thus have that  $\mathbb{E}[\mathcal{L}'] = \Theta(n)$  as well. To show that the actual run time is concentrated around the expectation we apply Chebyshev's inequality. A similar case distinction as above gives us

$$\text{Var}[\mathcal{L}'] \leq \sum_{i=\frac{n}{(\log n)^2}}^n \frac{10000n}{i} + \sum_{i=1}^{\frac{n}{(\log n)^2}} \frac{10000n^2}{i^2 \cdot (\log n)^2} = \mathcal{O}\left(\frac{n^2}{(\log n)^2}\right).$$

By Chebyshev's inequality we thus get

$$\Pr[\mathcal{L} \geq 2\mathbb{E}[\mathcal{L}']] \leq \Pr[\mathcal{L}' \geq 2\mathbb{E}[\mathcal{L}']] \leq \frac{\text{Var}[\mathcal{L}']}{(\mathbb{E}[\mathcal{L}'])^2} \leq \mathcal{O}\left(\frac{1}{(\log n)^2}\right),$$

which concludes the first part of the proof.

To bound the time needed to expose the  $d$ -neighborhoods, we observe first that we can order the vertices in  $A$  by the order in which they join the matching. As  $N_{d'}(v) \subseteq N_d(v) \forall d' \leq d$ , we thus have to expose for the  $i$ -th vertex in this ordering at most  $d(n-i) + 1$  edges, where  $d(x) = \min\{\sqrt{n/x}, \log n\}$ . Thus, the total number of exposed edges is bounded by

$$\begin{aligned} \sum_{i=1}^n (d(n-i) + 1) &= \sum_{i=1}^{\frac{n}{(\log n)^2}} (d(i) + 1) + \sum_{i=\frac{n}{(\log n)^2}}^n (d(i) + 1) \\ &\leq \sum_{i=1}^{\frac{n}{(\log n)^2}} (\log n + 1) + \sum_{i=\frac{n}{(\log n)^2}}^n \sqrt{\frac{n}{i}} \leq 4n. \end{aligned}$$

Additionally we show the number of calls to the `newABneighbor()` function is at most  $\log n$  for every vertex w.h.p.. For any  $v \in B$  we call `newABneighbor(v)` exactly once for each time it appears as the matched partner of `newABneighbor(v)`. As the distribution on the neighbors is uniform on  $A$  and we only use `IncreaseMatching`  $\mathcal{O}(n)$  many times in total, the probability that  $v \in B$  occurs at least  $\log n$  times is at most

$$\left(\frac{\mathcal{O}(n)}{\log n}\right) \left(\frac{1}{n}\right)^{\log n} = \mathcal{O}(n^{-2}),$$

with room to spare. We can thus apply a union bound over all vertices in  $B$  to see that w.h.p. no vertex in  $B$  has more than  $\log n$  calls to `newABneighbor()`. Clearly the same holds for vertices in  $A$ , as we only expose the  $d$ -neighborhood and  $d(|A_0|) \leq \log n$  always. This concludes the proof of Proposition 4.  $\blacktriangleleft$

### 2.2.2 Phase 2: Incorporating the Cycle Factor

In the previous section we have seen that we can find a perfect matching in  $\mathcal{O}(n)$  time. In this section we show how we can extend this algorithm to find a Hamilton cycle. To do this we first call the perfect matching algorithm *twice*, resetting the  $d$ -neighborhoods after the first run. By our assumption on the independence on the calls to the function `newneighbor()`, we thereby get two *independent* random perfect matchings. Their union forms a union of cycles (or double edges) covering all vertices (if the number of vertices was odd we add the single vertex excluded in phase 1 here back as a cycle with one vertex). Our task in this phase is to join these cycles into a single cycle. We start with a lemma that bounds the number of cycles that we need to join.

► **Lemma 5.** *The union of two random independent perfect matchings in a bipartite graph contains at most  $2 \log n$  cycles with high probability.*

**Proof.** We claim that the two independent perfect matchings can be seen as a random permutation of  $[n/2]$ . Indeed, without loss of generality we may assume that  $M_1$  is just the identity (by renumbering the vertices appropriately).  $M_1$  and  $M_2$  are independent which implies  $M_2$  corresponds to a random assignment of  $B$  to  $A$ . The union of the two matchings thus defines a random permutation of  $A$ .

For random permutations the number of cycles has been well studied and is related to the Stirling numbers of the first kind. Using a double counting argument one can easily see that the expected number of cycles of length  $2k$  will be  $1/k$ . The total expected number of cycles is thus equal to the  $n$ th harmonic number. It is also well-known that this random variable is concentrated, see e.g. [5] or [6, 21]. Thus, with high probability the number of cycles is bounded by  $2 \log n$ , as claimed.  $\blacktriangleleft$

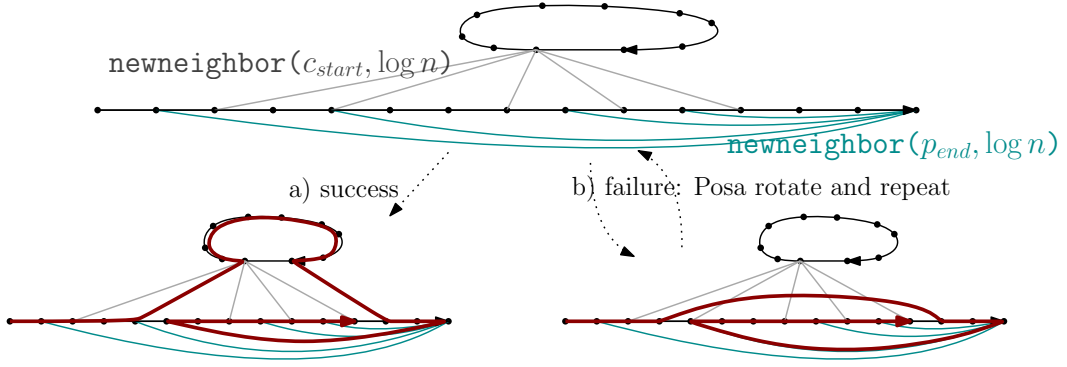

**Description of Algorithm 3 JoinCycles.** To glue the cycles together we proceed in three phases. First we greedily combine cycles into a path, until this path has length at least  $3n/4$ . Then we incorporate the remaining cycles one by one using Algorithm 4 AddSingleCycle. Finally, we close the Hamilton path into a Hamilton cycle (Lemma 7).

The idea behind the first phase is straightforward. We start with an arbitrary cycle and break it apart into a path  $P$ . Consider the endvertex  $p_{end}$  of that path. We use `newneighbor()` to query a new neighbor of  $p_{end}$ . If that neighbor is in a new cycle (which will happen with probability at least  $1/4$ , as long as the path  $P$  contains at most  $3n/4$  vertices), we attach that cycle to  $P$ , thereby also getting a new endpoint  $p_{end}$ . If the latter did not happen, we query a new neighbor. In order to ensure that we do not query too many vertices from a single vertex, we repeat the query for new neighbors at most  $40 \log n$  times. If we have not been successful by then, we give up. It is easy to see that the probability for ever giving up at this stage of the algorithm is bounded by  $o(1)$ . It is also easy to see that the total time spent until the path has length at least  $3n/4$  is bounded by  $\mathcal{O}(n)$ .

Once the path has length at least  $3n/4$ , the probability that a new neighbor is in one of the remaining cycles gets too small (for our purpose) and we thus change strategy. In particular, we add long Posa rotations, so that we can try various endpoints. This is the purpose of the procedure AddSingleCycle (Algorithm 4).

We use a set  $U$  to keep track of *used* vertices. Those are vertices for which we already queried neighbors within the algorithm JoinCycles. We denote the current path by  $P = (p_{start}, \dots, p_{end})$ . We also assume that we have access to a function  $pred_P(v)$  that determines the vertex before  $v$  on the path (null for  $p_{start}$ ), and a function  $half_P(v)$  which is true iff  $v$  is in the first half of  $P$ . We denote the cycle  $C$  that we want to add as  $C = (c_{start}, \dots, c_{end})$ , where  $c_{start}$  is an arbitrary vertex at which we cut  $C$  into a path. We now explore neighborhoods of vertices at once. To do this we denote by `newneighbor`( $v, 40 \log n$ ) the set of vertices that we obtain if we apply `newneighbor`( $v$ )  $40 \log n$  times. Let  $N_{start} = P \cap \text{newneighbor}(c_{start}, 40 \log n)$  and  $N_{end} = P \cap \text{newneighbor}(c_{end}, 40 \log n)$  denote the intersections of these neighborhood vertices with the path  $P$ . Until the cycle  $C$  is part of the path  $P$  we do the following (Figure 5). Let  $N(p_{end}) = \text{newneighbor}(p_{end}, 40 \log n)$  and check for all  $v \in N(p_{end})$  if  $pred_P(v) \in N_{start}$ . If so we also check if  $half_P(v)$  is true.

If we find a vertex  $v$  for which both conditions hold, we join the cycle here. To do this look at  $N_{end}$  and take a vertex  $q \in \text{newneighbor}(c_{end}, 40 \log n)$  such that  $half_P(q)$  is false and  $pred_P(q) \notin U$ . Then we add the cycle to the path by constructing the new path  $P_{new} = (p_{start}, \dots, pred_P(v)) + (c_{start}, \dots, c_{end}) + (q, \dots, p_{end}) + (v, \dots, pred_P(q))$ . Then add  $p_{end}$ ,  $c_{start}$  and  $c_{end}$  to the used vertices  $U$ . (If we cannot find  $q$  we abort the algorithm; it will be easy to show that the probability that this happens is negligible.)

```

1:  $U \leftarrow \{\}$ 
2:  $C_0 \leftarrow$  first cycle of  $M_1 \cup M_2$ ,  $(c_{0,\text{start}}, \dots, c_{0,\text{end}})$ ;
3:  $P \leftarrow (c_{0,\text{start}}, \dots, c_{0,\text{end}})$ ;
4:  $p_{\text{end}} \leftarrow$  last vertex of  $P$ ;
5: while  $|P| \leq \frac{3n}{4}$  do
6:    $N \leftarrow \text{newneighbor}(p_{\text{end}}, 40 \log n)$ ;
7:    $U \leftarrow$  add  $p_{\text{end}}$ ;
8:    $v \leftarrow$  Search  $N$  for  $v$  such that  $v \notin P$ 
9:    $(v, \dots, c_{i,\text{end}}) \leftarrow$  cycle of  $v$ ;
10:   $P \leftarrow P + (v, \dots, c_{i,\text{end}})$ ;
11:   $p_{\text{end}} \leftarrow c_{i,\text{end}}$ ;
12: while  $|P| \neq n$  do
13:    $C_i \leftarrow$  any cycle not in  $P$ 
14:   AddSingleCycle( $G, P, C_i, U$ ) ▷ See Algorithm 4
15: return
16: // If any of the “Search” parts of the algorithm fail, we abort the algorithm and return
    failure.
```

---

If the check fails for all  $v \in N(p_{\text{end}})$  we perform a Posa rotation. To do this we take a  $v \in N(p_{\text{end}})$ ,  $v \neq p_{\text{start}}$ , such that  $\text{half}_P(v)$  is true and such that  $\text{pred}_P(v) \notin U$ , and then take a  $q \in \text{newneighbor}(\text{pred}_P(v), 40 \log n)$  such that both  $\text{half}_P(q)$  is false and  $\text{pred}_P(q)$  is unused. We then use  $v$  and  $q$  to construct a new path with a new endpoint, namely  $P_{\text{new}} = (p_{\text{start}}, \dots, \text{pred}_P(v)) + (q, \dots, p_{\text{end}}) + (v, \dots, \text{pred}_P(q))$ . Now we can repeat the above procedure with  $P_{\text{new}}$  and the new endpoint  $p_{\text{newend}} = \text{pred}_P(q)$ . (If we cannot find  $v$  or  $q$  we abort the algorithm; again it will be easy to show that the probability that this happens is negligible.)

To store the path and cycles we use AVL trees with a linked list. The linked list just stores the vertices in the order as they appear in the path resp. cycle. For the AVL tree we take the ordering in the path/linked list as an ordering of the vertices. With this ordering at hand, the AVL tree is well defined, and it allows for searching resp. answering the query  $\text{half}(v)$  in  $\mathcal{O}(\log n)$  time. In addition, splitting the path resp. concatenating two paths correspond to splitting an AVL tree at a given vertex (into a tree containing all smaller vertices and a

tree containing the remaining vertices) resp. concatenate two AVL trees in which the largest vertex in one tree is smaller than the smallest vertex in the other tree. It is well known that both of these operations can be done for AVL trees in  $\mathcal{O}(\log n)$  time, cf. Lemma 10 in Section 3 for more details.

► **Proposition 6.** *Applying the procedure  $\text{AddSingleCycle}$  at most  $2 \log n$  times will run in time  $\mathcal{O}(n)$  with high probability.*

**Proof.** We want to bound the number of Posa rotations we need to perform while we add at most  $2 \log n$  cycles. Each Posa rotation occurs at the end of a while loop in the pseudocode.

To incorporate a cycle we want to find a vertex  $v$  which, in the order of the path, is right after a vertex in  $N_{\text{start}}$  and is in the first half of  $P$ .  $P$  has size at least  $3n/4$  so the number of vertices in the first half is at least  $n/4$ . A random vertex therefore has a chance of at least  $1/4$  to be in the first half of  $P$ . So every vertex in  $\text{newneighbor}(c_{\text{start}}, 40 \log n)$  has probability at least  $1/4$  independently of being in the first half of  $P$  and different from the other vertices. This implies that the number of vertices in  $N_{\text{start}}$  which are also in the first half of  $P$  dominates a binomial distributed random variable  $F \sim \text{Bin}(40 \log n, 1/4)$ . For  $F$  we know the expectation to be  $10 \log n$  and by a Chernoff bound (11) the probability that  $F$  is less than  $\log n$  is  $\mathcal{O}(n^{-2})$ . We observe that where the Posa rotation happens is independent of  $N_{\text{start}}$ . So we apply a union bound that on fixed  $\mathcal{O}(n)$  many rotations of  $P$  the probability that there are less than  $\log n$  vertices of  $N_{\text{start}}$  in the first half of  $P$  is in  $\mathcal{O}(n^{-1})$ . This implies that any call to  $\text{newneighbor}(p_{\text{end}})$  has a chance of at least  $\log n/n$  to be right after a vertex in  $N_{\text{start}}$  and also in the first half of  $P$ . As each call to  $\text{newneighbor}()$  is independent, the number of tries we must make is geometrically distributed with success probability  $\log n/n$  and we must succeed at most  $2 \log n$  many times. This means the number of Posa rotations

is dominated by a negative binomial distributed random variable  $R \sim NB(2 \log n, \log n/n)$ . So by the concentration of the negative binomial distribution (Lemma 14) the probability that we need to try more than  $4n$  times is at most  $\mathcal{O}(\log^{-1} n)$ . Before every Posa rotation we try `newneighbor`( $p_{end}, 40 \log n$ ) so  $40 \log n$  tries. This proves an upper bound on the number of Posa rotations of  $\mathcal{O}(n/\log n)$  with high probability.

**Posa rotation.** We summarize the operations we need to do per Posa rotation. This assumes that we already failed to find  $v$  which is both after a vertex in  $N_{start}$  and also in the first half of  $P$ . We expose  $40 \log n$  new neighbors of  $p_{end}$  and  $40 \log n$  of the vertex before  $v$  on the path, we need to Posa rotate by splitting the path twice and then joining twice. Checking whether a vertex is in  $U$  and adding vertices to  $U$  is a constant time operation with a lookup table. All of these operations by choice of proper datastructure (Lemma 8 and 10) are done in  $\mathcal{O}(\log n)$ . So over all Posa rotations these sum up to a runtime of at most  $\mathcal{O}(n)$ . Additionally we need to find the vertex  $v$  in the first half of  $P$  with  $pred_P(v) \notin U$ . Since  $U$  is much smaller than  $n/8$  and  $|P| \geq 3n/4$  the number of possible vertices is at least  $n/4$ . This means that if we test a random vertex, the probability that `half_P`() returns true and its predecessor is not in  $U$  is at least  $1/4$ . So the number times we need to call `half_P`() is dominated by a geometric distribution with success probability  $1/4$ . Similarly to find the vertex  $q$  in the second half of  $P$  with  $pred_P(q) \notin U$ , the number of times we need to call `half_P`() is also dominated by a geometric distribution with success probability  $1/4$ . So over all rotations, the number of times we need to call `half_P`() is dominated by a negative binomial distribution  $H \sim NB(2 \cdot \mathcal{O}(n/\log n), 1/4)$ . So by the concentration of the negative binomial distribution (Lemma 14) the probability that we need to call `half_P` more than  $\mathcal{O}(n/\log n)$  times is  $\mathcal{O}(\log n/n)$ . And since we can perform `half_P`() in time  $\mathcal{O}(\log n)$  by Lemma 10 these have a total runtime of  $\mathcal{O}(n)$  with high probability.

**Incorporating cycles.** Very similarly we bound the time we need to incorporate the cycles. To find the vertex  $v$  which in the order of the path is right after a vertex in  $N_{start}$  and is in the first half of  $P$  we need to call `half_P` until we succeed. Note that since  $|N_{start}| \leq 40 \log n$  and as we proved above at least  $\log n$  vertices of them are in the first half of  $P$ , every call to `half_P`() from a random vertex after a vertex in  $N_{start}$  has a chance of succeeding of at least  $1/40$ . This means the number of times we call `half_P` is again dominated by a negative binomial distribution  $NB(2 \log n, 1/40)$  and this runtime is negligible with high probability. As we only incorporate a cycle  $2 \log n$  times, also the join and split operations as well as the exposing of  $N_{end}$  and searching for  $q$  are negligible compared to the  $\mathcal{O}(n)$  runtime.

Note also that we only call `newneighbor`() of vertices we then add to  $U$  and then not again during the entire algorithm so no vertex has `newneighbor`() called more than  $40 \log n$  times. At most  $\mathcal{O}(n/\log n)$  many vertices are added to  $U$ , and  $U$  is small enough so that it is always much smaller than  $n/8$ .

This concludes the proof of Proposition 6. ◀

► **Lemma 7.** *Given a Hamilton path we can transform it to a Hamilton cycle in  $\mathcal{O}(n)$  time.*

**Proof.** Calling the algorithm `AddSingleCycle` with the cycle being  $p_{start}$ , but instead looking for  $v$  such that a vertex after  $v$  is in the neighborhood of  $p_{start}$  instead of a predecessor gives us a cycle  $C = (p_{start}, \dots, v) + (p_{end}, \dots, after_P(v))$ . Analysis of runtime equivalent to the analysis of `AddSingleCycle`. ◀

Propositions 4 and 6 as well as Lemma 7 show that all components of the algorithm run in time  $\mathcal{O}(n)$ . It is also easy to check that both phases together require at most  $50 \log n$  calls to `newneighbor`() from any fixed vertex, so the assumptions of Lemma 8 do hold. So choosing  $C$  large enough, say  $C = 200$ , suffices to guarantee that with high probability the random graph is such that all vertices have more neighbors than we query. This thus concludes the proof of Theorem 1.

### 3 Datastructures

In this section we give the details of the data structures that we used within our algorithm.

#### 3.1 Querying a new vertex

As explained above, we assumed throughout the analysis of our algorithm that we have access to a function `newneighbor(v)`, that returns for a given vertex  $v$  a neighbor  $w$  that is *uniformly* distributed in  $V - v$  and whose result is *independent* from all previous calls.

► **Lemma 8** (`newneighbor`). *It is possible to interact with the graph  $G_{n,p}$ ,  $p \geq \frac{C \log n}{n}$ , with an algorithmic procedure `newneighbor(v)` which has the following properties with high probability:*

- (i) *Calling `newneighbor(v)` returns a neighbor of  $v$  distributed uniformly among  $V - v$  and independent of all calls so far – as long as we make at most  $\mathcal{O}(n)$  calls to `newneighbor()` altogether and every vertex is queried at most  $100 \log n$  times.*
- (ii) *The total run time of all  $\mathcal{O}(n)$  calls is  $\mathcal{O}(n)$ .*

**Proof.** To realize such a function `newneighbor()`, it is important to make the adjacency lists independent of each other. To realize this we transform the graph  $G$  (which is distributed as a random graph  $G_{n,p}$ ) into a directed graph  $G'$  distributed as  $D_{n,p/2}$  (in which each directed edge is present independently with probability  $p/2$ ). It is well known how this can be done. In particular, we can sample  $D_{n,p/2}$  from  $G_{n,p}$  as a subgraph such that every edge in the directed graph is also an undirected edge in the  $G_{n,p}$ . More precisely, we do the following for every edge  $\{i, j\}$  of  $G$ : with probability

$$\begin{aligned} \frac{1}{2} - \frac{p}{4} & \text{ set } (i, j) \in G' \text{ and } (j, i) \notin G' \\ \frac{1}{2} - \frac{p}{4} & \text{ set } (i, j) \notin G' \text{ and } (j, i) \in G' \\ \frac{p}{4} & \text{ set } (i, j) \in G' \text{ and } (j, i) \in G' \\ \frac{p}{4} & \text{ set } (i, j) \notin G' \text{ and } (j, i) \notin G' \end{aligned}$$

In order to be consistent with the transformation from  $G$  to  $G'$  and to not lose too much time we only direct the edges once we see it for the first time. To recall the made decision, we store the random choices of the edges that we have encountered so far into a hashtable. Thus, we can check for each edge that we obtain from querying the adjacency list of a vertex in  $G$ , whether we have seen this edge already and if so, which orientation we have chosen. The hash table has size  $n$  and we use a hashfunction which is 4-wise independent. This way the variance of the number of collisions is equal to a random function, and therefore the time we need for hashing is  $\mathcal{O}(n) + \mathcal{O}(\text{number of collisions}) = \mathcal{O}(n)$ , which can be seen by applying Chebyshev's inequality. A more detailed argument of why linear probing with hash functions works in this context can be found in [24, 31].

Finally, we want the distribution of the next edge to be uniform among the vertices. For this we need to resample from the already seen edges. Assuming we have revealed  $d$  many edges from  $v$  we flip a biased coin. With probability  $d/(n-1)$  we retake an old neighbor and output it, one chosen uniformly at random, and with probability  $1 - d/(n-1)$  we take the next vertex in the adjacency list (which is also in  $D_{n,p}$ ). Otherwise, we return one of the previously seen neighbors uniformly at random. In this way any vertex has probability exactly  $1/(n-1)$  to be returned by `newneighbor(v)`. ◀

### 3.2 Expansion

What we need from the random graph are properties of good expansion. Given the adjacency list of a vertex  $v$  we define the  $d$ -neighborhood  $N_d(v) \subseteq V(G)$  to be the set of the first  $\lceil d \rceil$  calls to the function `newABneighbor(v)`. In the analysis of the algorithm we make use of the following lemma.

► **Lemma 9 (Neighborhood Lemma).** *Let  $G_{n/2, n/2, p}$  be a random bipartite graph with  $p \geq \frac{C \log(n)}{n}$  and partitions  $A$  and  $B$ . Then with high probability we have for all subsets  $A' \subseteq A$  that the  $d$ -neighborhood of  $A'$  is of size at least*

$$|N_{d(A')}(A')| \geq \frac{1}{100} |A'| \cdot d(A'), \quad (1)$$

where  $d(A') = \min(\sqrt{\frac{n}{|A'|}}, \log(n))$ .

**Proof.** The proof follows from a straight forward calculation of probabilities. Let us assume by contradiction there exists a set  $A' \subseteq A$  with  $|N_{d(A')}(A')| < \frac{1}{100} |A'| \cdot d(A')$ . Then there is a set  $B' \subseteq B$  of size  $|B'| = \frac{1}{100} |A'| \cdot d(A')$  containing this  $d$ -neighborhood,  $N_{d(A')}(A') \subseteq B'$ . So this is a probability we want to bound from above. The probability for a single vertex in  $A'$  to have its  $d$ -neighborhood contained in a fixed set  $B'$  is  $\left(\frac{|B'|}{n}\right)^{d(A')}$  since the  $d$ -neighborhood is  $d(A')$  vertices chosen from  $B$  uniformly and independently at random. The probability for two specific sets  $A' \subseteq A$  and  $B' \subseteq B$  to have this property is  $(|B'|/n)^{|A'| \cdot d(A')}$ . Now take the union bound over all possible sets  $A'$  and  $B'$  (with  $|B'| = \frac{1}{100} |A'| \cdot d(A')$ ):

$$Pr[(1) \text{ false}] \leq \sum_{A', B'} Pr[B' \text{ contains } N_{d(A')}(A')] = \sum_{i=1}^n \binom{n}{i} \binom{n}{\frac{1}{100} i d(i)} \left(\frac{\frac{1}{100} i \cdot d(i)}{n}\right)^{i \cdot d(i)}.$$

Then we apply an approximation for the binomial coefficients:  $\binom{n}{k} \leq \left(\frac{en}{k}\right)^k$ . We see that  $\frac{1}{4} \log \frac{100n}{i \cdot d(i)} \geq \log(e \cdot n/i)/d(i)$  so

$$Pr[(1) \text{ false}] \leq \sum_{i=1}^n \exp\left(i \cdot d(i) \cdot \left(-\frac{1}{2} \log\left(\frac{100n}{i \cdot d(i)}\right)\right)\right).$$

Now  $d(i)$  is a known function of  $i$ . So we distinguish between two cases. When  $i \geq n/\log^2(n)$ , then  $d(i) = \sqrt{n/i}$ . And we can calculate ( $i \leq n$ )

$$\sum_{i=1}^n \left(\frac{i^{1/4} \cdot n^{1/4}}{10 \cdot n^{1/2}}\right)^{\sqrt{n \cdot i}} \leq \sum_{i=1}^n \left(\frac{1}{10}\right)^{\sqrt{n \cdot i}} \leq \mathcal{O}(n^{-2}).$$

On the other hand if  $i \leq n/\log^2(n)$ , then  $d(i) = \log(n)$ . And we can calculate

$$\sum_{i=1}^{n/\log^2(n)} \left(\frac{i^{1/2} \cdot \log(n)^{1/2}}{10 \cdot n^{1/2}}\right)^{i \log(n)} \leq \sum_{i=1}^{n/\log^2(n)} \left(\frac{1}{10 \cdot \log(n)^{1/2}}\right)^{i \log(n)} \leq \mathcal{O}(n^{-2}).$$

Together this implies that the lemma holds for random graphs with probability  $\geq 1 - \mathcal{O}(n^{-2})$ . ◀

### 3.3 AVL Trees

► **Lemma 10** (AVL Trees). *We can store a path (or cycle) in an AVL tree joint with a linked list datastructure and can perform the following operations (where we view the cycle as a path split at an arbitrary point):*

- *For any vertex  $v$  find the vertex preceding or succeeding it in the path in constant time  $\mathcal{O}(1)$*
- *For any vertex  $v$  searching the path it is in and determining whether it is in the first or second half of it in time  $\mathcal{O}(\log n)$*
- *Split the path into two paths in time  $\mathcal{O}(\log n)$*
- *Concatenate two paths into one by adding the endpoint of one to the start of the other in time  $\mathcal{O}(\log n)$*

**Proof.** We combine an AVL tree, which is a balanced binary search tree, with a linked list. The AVL tree is built on the order sequence of the path as if numbering the vertices along the path from 1 to  $|P|$ . The linked list ensures that going forward and backward on the path is done in constant time, where the AVL tree can perform search (for the half function) in  $\mathcal{O}(\log n)$ . A split of the path is nothing other than splitting the AVL tree at a leaf node into two trees such that all the nodes smaller go into one tree and all the nodes larger go into the other. The concatenate is the inverse of the split and only requires attaching the smaller tree to the larger one at the appropriate node and rebalancing up to the root. Both operations run in  $\mathcal{O}(\log n)$  time. AVL trees are by now a part of basic datastructure lectures and in particular the split and concatenate operations can be found e.g. in the book by Knuth [18] see page 473, which also cites from [10] or more generally on AVL trees see [25]. ◀

## 4 Concluding remarks

In this paper we presented a simple randomized algorithm based on iterative random walks that construct a Hamilton cycle in time linear in the number of vertices. Our algorithm is based on first building (two) random perfect matchings. The key idea here is to expose more and more edges of the currently unmatched vertices, where the exact number of these exposed neighbors is a function of the currently unmatched vertices. Our analysis requires that the density of the random graph  $G_{n,p}$  is at least  $p \geq \frac{C \log n}{n}$ .  $C$  is chosen such that we have a sufficient minimum degree with high probability.

We leave it as an open question whether our approach can be modified to also find Hamilton cycles in  $G_{n,p}$  for  $p$  at the threshold for existence of Hamilton cycles. This certainly requires additional ideas.

## A

 Concentration Inequalities

We mention here some well-known inequalities used to show concentration on random variables. By the concentration of a random variable  $X$  we usually mean there exist constants  $c$  and  $C$  such that with high probability  $c\mathbb{E}[X] \leq X \leq C\mathbb{E}[X]$ . Often also we ask  $C$  to be 2. Although these are by no means new insights, we present them here for completion and as a help for the reader. The Chernoff and Chebyshev inequality can be found e.g. in the book [17].

► **Theorem 11** (Chernoff Inequality). *If  $X$  is distributed as a binomial random variable  $X \sim \text{Bin}(n, p)$  and  $0 < \varepsilon \leq 3/2$ , then*

$$\Pr[|X - \mathbb{E}[X]| \geq \varepsilon \mathbb{E}[X]] \leq 2e^{-\frac{\varepsilon^2 \mathbb{E}[X]}{3}}.$$

► **Theorem 12** (Chebyshev Inequality). *For any random variable  $X$  for which the variance  $\text{Var}[X]$  exists,*

$$\Pr[|X - \mathbb{E}[X]| \geq t] \leq \frac{\text{Var}[X]}{t^2}.$$

We use the term negative binomial distribution in the analysis and since this is defined slightly differently sometimes we give here the definition we use.

► **Definition 13.** *Let  $X_i$  be independent bernoulli random variables with probability of being one is  $p$  for any  $i \in \mathbb{N}$ . For any  $r \in \mathbb{N}$  let  $Y$  be index of the  $r$ -th  $X_i$  which evaluates to 1. Then  $Y$  has a negative binomial distribution  $NB(r, p)$ .*

We observe that a negative binomial distribution  $Y \sim NB(r, p)$  is equivalent to  $Y$  being distributed as the sum of  $r$  geometric random variables with success probability  $p$ . Further a simple corollary from the Chebyshev inequality:

► **Corollary 14.** *For a negative binomial distributed variable  $Y \sim NB(r, p)$*

$$\Pr\left[Y \geq 2\frac{r}{p}\right] \leq \frac{1}{r}.$$

**Proof.** We calculate  $\mathbb{E}[Y] = r/p$  and  $\text{Var}[Y] = r(1-p)/p^2$  and apply Chebyshev.

$$\Pr\left[Y \geq 2\frac{r}{p}\right] \leq \Pr\left[|Y - \mathbb{E}[Y]| \geq \frac{r}{p}\right] \stackrel{\text{Chebyshev}}{\leq} \frac{1-p}{r} \leq \frac{1}{r} \quad \blacktriangleleft$$

# Communication Memento: Memoryless Communication Complexity

## Abstract

We study the communication complexity of computing functions  $F : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  in the *memoryless communication model*. Here, Alice is given  $x \in \{0, 1\}^n$ , Bob is given  $y \in \{0, 1\}^n$  and their goal is to compute  $F(x, y)$  subject to the following constraint: at every round, Alice receives a message from Bob and her reply to Bob solely depends on the message received and her input  $x$  (in particular, her reply is independent of the information from the previous rounds); the same applies to Bob. The cost of computing  $F$  in this model is the *maximum* number of bits exchanged in any round between Alice and Bob (on the worst case input  $x, y$ ). In this paper, we also consider variants of our memoryless model wherein one party is allowed to have memory, the parties are allowed to communicate quantum bits, only one player is allowed to send messages. We show that some of these different variants of our memoryless communication model capture the garden-hose model of computation by Buhrman et al. (ITCS'13), space-bounded communication complexity by Brody et al. (ITCS'13) and the overlay communication complexity by Papakonstantinou et al. (CCC'14). Thus the memoryless communication complexity model provides a unified framework to study all these space-bounded communication complexity models.

We establish the following main results: (1) We show that the memoryless communication complexity of  $F$  equals the logarithm of the size of the smallest bipartite branching program computing  $F$  (up to a factor 2); (2) We show that memoryless communication complexity equals garden-hose model of computation; (3) We exhibit various exponential separations between these memoryless communication models.

We end with an intriguing open question: can we find an explicit function  $F$  and universal constant  $c > 1$  for which the memoryless communication complexity is at least  $c \log n$ ? Note that  $c \geq 2 + \epsilon$  would imply a  $\Omega(n^{2+\epsilon})$  lower bound for general formula size, improving upon the best lower bound by Nečiporuk [33].

## 1 Introduction

Yao [44] introduced the model of *communication complexity* in 1979 and ever since its introduction, communication complexity has played a pivotal role in understanding various problems in theoretical computer science. In its most general form in this model, the goal is the following: there are two separated parties usually referred to as Alice and Bob, Alice is given an  $n$ -bit string  $x \in \{0, 1\}^n$  and similarly Bob is given  $y \in \{0, 1\}^n$  and together they want to compute  $F(x, y)$  where  $F : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  is a function known to both of them. Here Alice and Bob are given unlimited computational time and memory and the *cost* of any communication protocol between Alice and Bob is the *total number of bits exchanged* between them. Clearly a trivial protocol is Alice sends her input  $x$  to Bob who can then compute  $F(x, y)$ , which takes  $n$  bits of communication. Naturally, the goal in communication complexity is to minimize the number of bits of communication between them before computing  $F(x, y)$ . The *deterministic communication complexity* of a function  $F$  (denoted  $D(F)$ ) is defined as the total number of bits of communication before they can decide  $F(x, y)$  on the worst-case inputs  $x, y$ .

Since its introduction there have been various works that have extended the standard deterministic communication model to the setting where Alice and Bob are allowed to share randomness and need to output  $F(x, y)$  with high probability (probability taken over the randomness in the protocol). Apart from this there have been studies on non-deterministic communication complexity [42], quantum communication complexity [43] (wherein Alice and Bob are allowed to share *quantum bits* and possibly have shared entanglement), *unbounded error communication complexity* [36] and their variants. One-way variants have also been considered where only Alice sends messages to Bob. Study of these different models of communication complexity and their variants have provided many important results in the fields of VLSI [34], circuit lower bounds [22], algorithms [1], data structures [32], property testing [7], streaming algorithms [6], computational complexity [8], extended formulations [18].<sup>1</sup>

### 1.1 Background

**Space-bounded communication complexity.** In the context of our current understanding of computation, the study of space required to solve a problem is a central topic in complexity theory. Several space-bounded models such as width-bounded branching programs [28], limited depth circuits, straight line protocols [29] have been widely studied in this context. In this direction variants of communication complexity have also been analyzed to better understand communication-space trade-offs [23, 26, 28]. In particular, the relation between space-bounded computation and communication complexity was formally initiated by Brody et al. [11] who considered the following question: what happens if we change the standard communication model such that, in each step of communication, Alice and Bob are limited in their ability to store the information from the previous rounds (which includes their private memory and messages exchanged). In this direction, they introduced a new model wherein Alice and Bob each are allowed to store at most  $s(n)$  bits of memory and showed that unlike the standard communication complexity, in this model *super-linear* lower bounds on the amount of communication is possible.<sup>2</sup> Brody et al. mainly studied the one-way communication complexity variant of this limited memory model in which Bob can have two

<sup>1</sup> For more on communication complexity and its applications, we refer the interested reader to the standard textbooks for communication complexity [27, 31].

<sup>2</sup> We remark that the separations obtained by [11] were for non-Boolean functions.

types of memory: an oblivious memory (depends only on Alice's message) and a non-oblivious memory (for computation). With these definitions, they obtained memory hierarchy theorems for such communication models analogous to the space hierarchy theorem in the Turing machine world.

**Overlay communication complexity.** Subsequently, Papakonstantinou, et al. [35] defined a similar space-bounded *one-way* communication model wherein Alice has unlimited memory and Bob has either no memory or constant-sized memory. At each round, messages from Alice to Bob consist of at most  $t(n)$  bits and the complexity of computing  $F$  is the maximum  $t(n)$  required over all inputs to  $F$ . They characterized the complexity in this model by an elegant combinatorial object called the *rectangle overlay* (which is defined in Section 4.2). They also managed to establish connections between their model and the well-known communication complexity polynomial hierarchy, introduced by Babai, Frankl and Simon [3]. Papakonstantinou et al. [35] showed that the message length in their model corresponds to the oblivious memory in a variant of space-bounded model, introduced by Brody et al. [11], where Bob only has access to an oblivious memory.

**Garden-hose model.** Another seemingly unrelated complexity model, the garden-hose complexity was introduced by Buhrman et al. [15] to understand quantum attacks on position-based cryptographic schemes (see Section 5.1 for a formal definition). Polynomial size garden-hose complexity is known to be equivalent to Turing machine log-space computations with pre-processing. In the garden-hose model two distributed players Alice and Bob use several pipes to send water back and forth and compute Boolean functions based on whose side the water spills. Garden-hose model was shown to have many connections to well-established complexity models like formulas, branching programs and circuits. A long-standing open question in this area is, is there an explicit function on  $n$  bits whose garden-hose complexity is super-linear in  $n$ ?

**Branching programs.** Another unrelated computation model is the branching program. Understanding the size of De Morgan formulas that compute Boolean functions has a long history. In particular, there has been tremendous research in understanding lower bounds on size of De Morgan formulas computing a Boolean function. Similar to formulas, branching programs have also been well-studied in complexity theory. For both branching programs and formulas, we have explicit functions which achieve quadratic (in input size) lower bounds on the size of the branching program/formula computing them. A few years ago, Tal [40] considered *bipartite formulas* for  $F : X \times Y \rightarrow \{0, 1\}$  (where each internal node computes an arbitrary function on either  $X$  or  $Y$ , but not both) and showed that the inner product function requires quadratic-sized formulas to compute. In the same spirit as Tal's result, a natural open question is, is there an explicit bipartite function which requires super-linear sized bipartite branching programs to compute?

Given these different models of computation, all exploring the effects on computation under various restrictions, a natural question is, can we view all of them in a unified way:

*Is there a model of communication that captures all the above computational models?*

**In this work** we introduce a very simple and new framework called *the memoryless communication complexity* which captures all the computational models mentioned above.

## 1.2 Memoryless Communication Models

We introduce a *natural* model of communication complexity which we call *the memoryless communication complexity*. Here, like the standard communication complexity, there are two parties Alice and Bob given  $x, y$  respectively and they need to compute  $F(x, y)$ , where  $F : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  is known to both of them. However, we tweak the standard communication model in the following two ways: The first change is that Alice is “*memoryless*”, i.e., at every round Alice computes the next message to send solely based on only her input  $x$  and the message received from Bob in this round. She does not remember the entire transcript of messages that were communicated in the previous rounds and also forgets all the private computation she did in the previous rounds. Similarly Bob computes a message which he sends to Alice, based *only* on his input  $y$  and the message received from Alice in the current round. After Bob sends his message, he also forgets the message received and all his private computations. Alice and Bob repeat this procedure for a certain number of rounds before one of them outputs  $F(x, y)$ .

The second crucial change in the memoryless communication model is that the *cost* of computing  $F$  in this model is the *size of the largest message* communicated between Alice and Bob in any round of the protocol (here size refers to the number of bits in the message). Intuitively, we are interested in knowing what is the size of a re-writable message register (passed back and forth between Alice and Bob) sufficient to compute a function  $F$  on all inputs  $x$  and  $y$ , wherein Alice and Bob do not have any additional memory to remember information between rounds. We denote the *memoryless communication cost of computing*  $F$  as  $\text{NM}(F)$  (where  $\text{NM}$  stands for “no-memory”). We believe this communication model is very natural and as far as we are aware this memoryless communication model wasn’t defined and studied before in the classical literature.

Being more formal, we say  $F : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  can be computed in the memoryless communication model with complexity  $t$ , if the following is true. For every  $x, y \in \{0, 1\}^n$  there exists functions  $\{f_x, g_y : \{0, 1\}^t \rightarrow \{0, 1\}^t\}$  such that, on input  $x, y$ , Alice and Bob use  $f_x$  and  $g_y$  respectively to run the following protocol: the first message in the protocol is  $f_x(0^t)$  from Alice to Bob and thereafter, for every message  $m_B$  Bob receives, he replies with deterministic  $m' = g_y(m_B)$  and similarly for every message  $m_A$  Alice receives she replies with  $m'' = f_x(m_A)$ . The protocol terminates when the transcript is  $(1^{t-1}b)$  at which point they output  $b$  as their guess for  $F(x, y)$ ; and we say the protocol computes  $F$  if for every  $x, y$ , the output  $b$  equals  $F(x, y)$ .  $\text{NM}(F)$  is defined as the smallest  $t$  that suffices to compute  $F$  (using the protocol above) for every  $x, y \in \{0, 1\}^n$ .

It is worth noting that in the memoryless communication protocol, Alice and Bob do not even have access to clocks and hence cannot tell in which round they are in (without looking at the message register). Hence, every memoryless protocol can be viewed as Alice and Bob applying *deterministic* functions (depending on their inputs) which map incoming messages to out-going messages. Also note that unlike the standard communication complexity, where a single bit-message register suffices for computing all functions (since everyone has memory), in the  $\text{NM}$  model because of the memoryless-ness we need more than a single bit register for computing almost all functions.

For better understanding, let us look at a protocol for the standard *equality* function defined as  $\text{EQ}_n : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  where  $\text{EQ}_n(x, y) = 1$  if and only if  $x = y$ . It is well-known that  $\text{D}(\text{EQ}_n) = n$ . In our model, we show that  $\text{NM}(\text{EQ}_n) \leq \log n + 1$ : for  $i = 1, \dots, n$ , at the  $i$ th round, Alice sends the  $(\log n + 1)$ -bit message  $(i, x_i)$  and Bob returns

$(i, [x_i = y_i])$ ,<sup>3</sup> Alice increments  $i$  and repeats this protocol for  $n$  rounds. In case Bob finds an  $i$  for which  $x_i \neq y_i$ , he outputs 0, if not after  $n$  rounds they output 1. Note that this protocol didn't require Alice and Bob to have any memory and the length of the longest message in this protocol was  $\log n + 1$ . We discuss more protocols later in the paper and formally describe the memoryless communication model in Section 3.

**Variants of the memoryless model.** Apart from the memoryless communication complexity, we will also look at the “memory-nomemory communication complexity” wherein Alice is allowed to have memory (i.e., Alice can know which round she is in, can remember the entire transcript and her private computations of each round) whereas Bob doesn't have any memory during the protocol. The goal of the players remains to compute a function  $F$  and the *cost* of these protocols (denoted by  $M(F)$ ) is still defined as the smallest size of a message register required between them on the worst inputs. Apart from this, we will also consider the quantum analogues of these two communication models wherein the only difference is that Alice and Bob are allowed to send *quantum* bits. We formally describe these models of communication in Section 3. In order to aid the reader we first set up some notation which we use to describe our results: for  $F : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$ , let

1.  $NM(F)$  be the memoryless communication complexity of computing  $F$  wherein Alice and Bob both do not have any memory.
2.  $M(F)$  be the memory-nomemory communication complexity of computing  $F$  where Alice has memory and Bob doesn't have memory

Apart from these, we will also allow quantum bits of communication between Alice and Bob and the complexities in these models are denoted by  $QNM(F)$  and  $QM(F)$ . Additionally, we will consider the one-way communication variants wherein only Alice can send messages to Bob and the complexities in these models are denoted by  $NM^\rightarrow(F)$ ,  $M^\rightarrow(F)$ ,  $QNM^\rightarrow(F)$ ,  $QM^\rightarrow(F)$ .

### 1.3 Our Contributions

The main contribution in this paper is to first define the model of the memoryless communication complexity and consider various variants of this model (only some of which were looked at before in the literature). We emphasize that we view our main contribution as a new *simple* communication model that provides a conceptual – rather than technical – contribution to studying space complexity, bipartite branching programs and garden-hose complexity under a single model. Given the vast amount of research in the field of communication complexity, we believe that our memoryless model is a very natural model of computation. We now state of various connections between our memoryless communication model and other computational models.

**1. Characterization in terms of branching programs.** It is well-known that standard models of communication complexity are characterized by the so-called (monochromatic) “rectangles” that partition the communication matrix of the function Alice and Bob are trying to compute. In the study of the memoryless model, Papakonstantinou et al. [35] specifically consider the memory-nomemory model of communication complexity wherein Alice has a memory and Bob doesn't and they are restricted to one-way communication from Alice to Bob. They show a beautiful combinatorial rectangle-overlay characterization (denoted

---

<sup>3</sup> Here  $[\cdot]$  is the indicator of an event in the parenthesis.

$\text{RO}(F)$ ) of the memory-no memory communication model.<sup>4</sup> One natural idea is to improve the  $\text{RO}(F)$  complexity to a more fine-grained rectangle measure that could potentially also characterize  $\text{NM}(F)$ , but this doesn't seem to be true. The fact that both Alice and Bob do not have memory, doesn't allow them to “narrow” down into a rectangle allowing them to compute the function, instead they narrow down into a set of rectangles. This motivates the question, is there a natural characterization of even the memoryless communication model, in which both Alice and Bob do not have memory? Here we answer this in the positive. We provide a characterization of memoryless communication complexity using branching programs. In particular, we show that for every  $F : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$ , the memoryless complexity  $\text{NM}(F)$  is (up to a factor 2) equal to the logarithm of the size of the smallest bipartite branching program computing  $F$ .<sup>5</sup> We give a proof of this statement in Theorem 14.

**2. Characterization in terms of garden-hose complexity.** The garden-hose model of computation was introduced by Buhrman et al. [15] to understand quantum attacks on position-based cryptographic schemes. It is a playful communication model where two players compute a function with set of pipes, hoses and water going back-and-forth through them. Alice and Bob start with  $s$  pipes and based on their private inputs “match” some of the openings of the pipes on their respective sides. Alice also connects a water tap to one of the open pipes. Then based on which side the water spills they decide on the function value. Naturally they want to minimize the number of pipes required over all possible inputs and the garden-hose complexity  $\text{GH}(F)$  is defined to be the minimum *number of pipes* required to compute  $F$  this way. Given its puzzle-like structure, there have been several works to understand this model and various connections between the garden-hose model and other branches of theoretical computer science were established [15, 25, 39, 14, 16, 38, 17].

On the other hand, space-bounded communication complexity was introduced by Brody et al. [11] to study the effects on communication complexity when they players are limited in their ability to store information from previous rounds. Here Alice and Bob each have at most  $s(n)$  bits of memory. Based on their private inputs  $x, y$  they want to compute the function in a manner in which at each round Alice receives a single bit message from Bob and based on her input  $x$ , the incoming message  $m_B$  and her previous  $s(n)$ -bit register content, she computes a new  $s(n)$ -bit register and decides whether to stop and output 0/1 or to continue. Bob does the same. space-bounded communication complexity  $\text{SM}(F)$  of computing a function  $F$  is the minimum register size  $s(n)$  required to compute the function on the hardest input.

It was already shown by [11] that for every function, the logarithm of the garden-hose complexity and the space-bounded communication complexity is factor 2 related. It is also easy to show that our newly defined memoryless communication complexity is also factor 2 related to the space-bounded communication complexity by [11]:  $\text{NM}(F) \leq 2 \cdot \text{SM}(F) + 1$ , and  $\text{SM}(F) \leq \text{NM}(F) + \log \text{NM}(F)$ . We give a proof of this statement in Lemma 20. Thus it immediately follows that the logarithm of the garden-hose complexity and the memoryless communication complexity of any function is also at most factor 3 related. However we improve this relation using an elegant trick of [30] that allows one to make computations reversible; and thereby show that for every function  $F$ ,  $\text{NM}(F)$  and  $\text{GH}(F)$  are equal up to an additive term 4.

$$\log \text{GH}(F) - 4 \leq \text{NM}(F) \leq \log \text{GH}(F).$$

<sup>4</sup> This rectangle-overlay complexity is formally defined in Section 4.2.

<sup>5</sup> We defer the formal definition of such branching programs to Section 2 and Section 4.2.

We give a proof of this in Theorem 21. Hence, the memoryless communication complexity model provides a clean framework for studying all these apparently different looking computational models.

As an immediate application of this new characterization of the garden-hose model, we get a better upper bound for the garden-hose complexity of the indirect storage access function.

► **Definition 1** (Indirect Storage Access). *Let  $n \geq 4$  and  $m \geq 2$  be such that  $n = 2m + \log(m/\log m)$ . The Indirect storage access function  $\text{ISA}_n : \{0,1\}^n \rightarrow \{0,1\}$  is defined on the input string  $(\vec{x}, \vec{y}_1, \dots, \vec{y}_{2^k}, \vec{z})$  where  $k = \log\left(\frac{m}{\log m}\right)$ ,  $\vec{x} \in \{0,1\}^m$ ,  $\vec{y} \in \{0,1\}^{\log m}$ ,  $\vec{z} \in \{0,1\}^k$ . Then  $\text{ISA}_n(\vec{x}, \vec{y}_1, \dots, \vec{y}_{2^k}, \vec{z})$  is evaluated as follows: compute  $a = \text{Int}(z) \in [2^k]$ , then compute  $b = \text{Int}(\vec{y}_a) \in [m]$  and output  $x_b$ .*

*For the communication complexity version Alice gets  $\vec{x}, \vec{z}$  and Bob gets  $\vec{y}_1, \dots, \vec{y}_{2^k}$ , they want to compute  $\text{ISA}_n(\vec{x}, \vec{y}_1, \dots, \vec{y}_{2^k}, \vec{z})$ .*

It was conjectured in [25] that the Indirect Storage Access function has garden-hose complexity  $\Omega(n^2)$ . This function is known to have  $\Omega(n^2)$  lower bound for the branching program [41] and thus is believed to be hard for garden-hose model in general.<sup>6</sup> But it is easy to see that  $\text{NM}(\text{ISA}) \leq \log n$ : Alice sends  $\vec{z}$  to Bob who then replies with  $\vec{y}_{\text{Int}(z)}$ . Finally Alice computes the output. Thus using the memoryless-garden-hose equivalence (in Theorem 21) we immediately get  $\text{GH}(\text{ISA}) \leq 16n$  (thereby refuting the conjecture of [25]).

**3. Separating these models.** We then establish the following inequalities relating the various models of communication complexity.<sup>7</sup>

$$\begin{array}{ccccccc} \text{M}(F) & \leq & \text{NM}(F) & = & \log \text{GH}(F) & \leq & \text{M}^\rightarrow(F) \leq \text{NM}^\rightarrow(F) \\ \vee | & & * \vee | & & || & & \vee | \quad \vee | \\ \text{QM}(F) & & \text{QNM}(F) & & 2 \cdot \text{S}(F) & & \text{QM}^\rightarrow(F) \quad \text{QNM}^\rightarrow(F) \end{array}$$

Furthermore, except the inequality marked by  $(*)$ , we show the existence of various functions  $F : \{0,1\}^n \times \{0,1\}^n \rightarrow \{0,1\}$  for which every inequality is exponentially weak. In order to prove these exponential separations we use various variants of well-known functions such as inner product, disjointness, Boolean hidden matching problem, gap-hamming distance problem. Giving exponential separations between quantum and classical communication complexity<sup>8</sup> is an extensively studied subject [13, 12, 21, 4, 20] and in this paper we show such separations can also be obtained in the memoryless models. We provide the proof in Theorems 17 and 18.

In this paper, we are not been able to give a large separation between QNM and NM, primarily because all lower bound techniques we have for NM seem to apply for QNM as well, e.g., the deterministic one-way communication complexity and the non-deterministic communication complexity<sup>9</sup>. The only “trivial” separation we can give is a factor-2 gap

<sup>6</sup> In a typical garden-hose protocol for computing  $\text{ISA}_n$ , Alice uses  $m$  pipes to describe  $\vec{z}$  to Bob (each pipe for a different value of  $\vec{z}$ ). Bob can then use another set of  $m$  pipes to send  $\vec{y}_{\text{Int}(z)}$  to Alice. But since  $\vec{y}_i$ s need to be unique it appears that Bob needs  $m$  set of such  $m$  pipes in the worst case. This many-to-one mapping seems unavoidable and hard to tackle in the garden-hose model in general. Hence  $\text{ISA}_n$  appears to have an  $\Omega(n^2)$  garden-hose complexity.

<sup>7</sup> Some of the inequalities are straightforward but we explicitly state it for completeness.

<sup>8</sup> These exponential separations are in the standard communication model where the communication complexity is the *total* number of bits or qubits exchanged between Alice and Bob.

<sup>9</sup> We note that [15] defined a quantum version of the garden-hose model which differs from the classical model only by the ability of the players to have pre-shared entanglements. They used it to exhibit an exponential classical-quantum separation. Our definition of the quantum version of the memoryless model is a more natural generalization which involves exchanging quantum registers. Thus their exponential separation does not imply a similar separation in our model.

between QNM and NM using the standard idea of super-dense coding (which in fact applies to *all* classical memoryless protocols). Observe that by our garden-hose characterization earlier, this factor-2 separation translates to a quadratic separation between “quantum-garden-hose” model and the classical garden-hose model.

Since  $\text{NM}(F)$  is at most  $M^\rightarrow(F)$  for any  $F$ , memory-no memory communication complexity can be used to design garden-hose protocols. Using this method we obtain a sub-quadratic garden-hose protocol for computing the function *Disjointness with quadratic universe* which was conjectured to have a quadratic complexity in [25]. We discuss this protocol in Section 5.1.

**4. Towards obtaining better formula bounds.** Finally, it was shown by Klauck and Podder [25] that any formulae of size  $s$  consisting of *arbitrary* fan-in 2 gates (i.e., formulae over the binary basis of fan-in 2 gates) can be simulated by a garden-hose protocol of size  $s^{1+\varepsilon}$  for any arbitrary  $\varepsilon > 0$ . In this work, we show that an arbitrary garden-hose protocol can be simulated by a memoryless protocol without *any* additional loss, i.e., a size  $s$  garden-hose protocol can be turned into a memoryless protocol of size  $\log s$ . In particular, putting together these two connections, it implies that a size  $s$  formula can be turned into a memoryless protocol of size  $(1 + \varepsilon) \log s$ . Thus our result provides a new way of proving formulae size lower bound for arbitrary function  $F$  by analyzing the memoryless protocol of  $F$ .<sup>10</sup> The best known lower bound for formulae size (over the basis of all fan-in 2 gate) is  $\Omega(n^2/\log n)$ , due to Nečiporuk from 1966 [33]. Analogous to the Karchmer-Wigderson games [24] and Goldman and Håstad [22] techniques which uses communication complexity framework to prove circuit lower bounds our new communication complexity framework is a new tool for proving formulae size lower bounds. We note that in the memoryless model, constants really matter, e.g., a lower bound of  $\log n$  is not same as a lower bound of  $2 \log n$  as the former would give an  $n$  lower bound, whereas the latter will yield an  $n^2$  lower bound for the formula size. This is similar, in flavour, to the circuit depth lower bound where it took several decades of research to get from the trivial  $\log n$  lower bound to the sophisticated  $3 \log n$  lower bound by Håstad [22]. In formula size terminology this translates to going from  $n$  to  $n^3$ .

Brody et al. [11] conjectured that the problem of reachability in a graph requires  $\Omega(\log^2 n)$  non-oblivious memory. However as we have mentioned earlier the space-bounded communication complexity and the memoryless communication complexity of any function are equal up to a constant factor. Thus proving this conjecture would imply the same lower bound on the memoryless communication complexity and in turn imply an  $n^{\log n}$  formula-size lower bound for reachability, which would be a break-through in complexity theory. In fact, because of the same general formula to memoryless communication simulation, showing even a  $(2 + \varepsilon) \log n$  lower bound for reachability would be very interesting.

Finally an additional benefit to our characterization is the following: information theory has been used extensively to understand communication complexity [5, 6, 19, 10, 9] (just to cite a few references). As far as we are aware, usage of information theoretic techniques haven’t been explored when understanding the models of computation such as formula size, branching programs and garden-hose model. We believe our characterization using memoryless communication model might be an avenue to use information-theoretic ideas to prove stronger lower bounds in these areas.

<sup>10</sup> Here, the inputs  $x, y$  are distributed among two players and their goal is to compute  $(F \circ g)(x, y)$  where  $g$  is a constant-sized gadget.

**Open questions.** In this work, our main contribution has been to describe a seemingly-simple model of communication complexity and characterize its complexity using branching programs. We believe that our work could open up a new direction of research and results in this direction. Towards this, here we mention the natural open question (referring the reader to the full version for more open questions): Is there a function  $F : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  and a universal constant  $c > 1$  for which we have  $\text{NM}(F) \geq c \log n$ . In particular, there are two consequences of such a result: (a) Using our relation to garden-hose model in Section 5.1, such a function will lead to the first *super-linear*  $n^c$  lower bound for garden-hose complexity, (b) using our characterized to branching programs, this would result in the first super-linear  $n^c$  lower bound for *bipartite* branching programs (analogous to Tal’s first super-linear lower bound on bipartite formula size<sup>11</sup> of inner-product [40]). Also if we could show this for  $c \geq 2 + \epsilon$ , this would imply a  $\Omega(n^{2+\epsilon})$  lower bound for general formula size, improving upon the best lower bound by Nečiporuk [33]. One possible candidate function which we haven’t been to rule out is the distributed 3-clique function: suppose Alice is given  $x \in \{0, 1\}^{\binom{n}{2}}$  and Bob is given  $y \in \{0, 1\}^{\binom{n}{2}}$ . We view their inputs as jointly labelling of the  $\binom{n}{2}$  edges of a graph on  $n$  vertices, then does the graph with edges labelled by  $x \oplus y$  have a triangle? Also, what is the complexity of the  $k$ -clique problem?

## 2 Preliminaries

**Notation.** Let  $[n] = \{1, \dots, n\}$ . For  $x \in \{0, 1\}^n$ , let  $\text{Int}(x) \in \{0, \dots, 2^n - 1\}$  be the integer representation of the  $n$ -bit string  $x$ . We now define a few standard functions which we use often in this paper. The equality function  $\text{EQ}_n : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  is defined as  $\text{EQ}_n(x, y) = 1$  if and only if  $x = y$ . The disjointness function  $\text{DISJ}_n$  defined as  $\text{DISJ}_n(x, y) = 0$  if and only if there exists  $i$  such that  $x_i = y_i = 1$ . The inner product function  $\text{IP}_n$  is defined as  $\text{IP}(x, y) = \sum_i x_i \cdot y_i \pmod{2}$  (where  $\cdot$  is the standard bit-wise product).

We now define formulae, branching programs and refer the interested reader to Wegener’s book [41] for more on the subject.

► **Definition 2 (Branching programs (BP)).** A branching program for computing a Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  is a directed acyclic graph with a source node labelled  $S$  and two sink nodes labelled 0 and 1. Every node except the source and sink nodes are labelled by an input variable  $x_i$ . The out-degree of every node is two and the edges are labelled by 0 and 1. The source node has in-degree 0 and the sink nodes have out-degree 0. The size of a branching program is the number of nodes in it. We say a branching program computes  $f$  if for all  $x \in f^{-1}(1)$  (resp.  $x \in f^{-1}(0)$ ) the algorithm starts from the source, and depending on the value of  $x_i \in \{0, 1\}$  at each node the algorithm either moves left or right and eventually reaches the 1-sink (resp. 0-sink) node. We denote  $\text{BP}(f)$  as the size (i.e., the number of nodes) of the smallest branching program that computes  $f$  for all  $x \in \{0, 1\}^n$ .

<sup>11</sup> Note that no super-linear lower bound is known for bipartite formulas that use all gates with fan-in 2 (in particular XOR gates).

### 3 Memoryless Communication Complexity

In this section we define memoryless communication complexity model and its variants.

#### 3.1 Deterministic Memoryless Communication Model

The crucial difference between the memoryless communication model and standard communication model is that, at any round of the communication protocol Alice and Bob do not have memory to remember previous transcripts and their private computations from the previous rounds. We now make this formal.

► **Definition 3** (Two-way Deterministic memoryless communication complexity). *Let  $F : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$ . Here there are two parties Alice and Bob whose goal is to compute  $F$ . Every  $s$ -bit memoryless protocol is defined by a set of functions  $\{f_x\}_{x \in \{0, 1\}^n}$  and  $\{g_y\}_{y \in \{0, 1\}^n}$  wherein  $f_x, g_y : \{0, 1\}^s \rightarrow \{0, 1\}^s$ . On input  $x, y$  to Alice and Bob respectively a memoryless protocol is defined as follows: at every round Alice obtains a message  $m_B \in \{0, 1\}^s$  from Bob, she computes  $m_A = f_x(m_B) \in \{0, 1\}^s$  and sends  $m_A$  to Bob. On receiving  $m_A$ , Bob computes  $m'_B = g_y(m_A)$  and replies with  $m'_B \in \{0, 1\}^s$  to Alice. They alternately continue doing this for every round until the protocol ends. Without loss of generality we assume the protocol ends once  $m_A, m_B \in \{1^{s-1}0, 1^{s-1}1\}$ , then the function output is given by the last bit. So, once the transcript is  $1^{s-1}b$ , Alice and Bob output  $F(x, y) = b$ .<sup>12</sup>*

*We say a protocol  $P_F$  computes  $F$  correctly if for every  $(x, y)$ , Bob outputs  $F(x, y)$ . We let  $\text{cost}(P_F, x, y)$  be the smallest  $s$  for which  $P_F$  computes  $F$  on input  $(x, y)$ . Additionally, we let*

$$\text{cost}(P_F) = \max_{x, y} \text{cost}(P_F, x, y)$$

*and the memoryless communication complexity of computing  $F$  in this model is defined as*

$$\text{NM}(F) = \min_{P_F} \text{cost}(P_F),$$

*where the minimum is taken over all protocols  $P_F$  that compute  $F$  correctly.*

We crucially remark that in the memoryless model, the players do not even have access to a clock and hence they cannot tell which round of the protocol they are in. At every round they just compute their local functions  $\{f_x\}_x, \{g_y\}_y$  on the message they received and proceed according to the output of these functions.

**One-way Deterministic Memoryless Model.** Similar to the definition above, one can define the *one-way* memoryless communication complexity wherein only Alice is allowed to send messages to Bob and the remaining aspects of this model is the same as Definition 3. We denote the complexity in this model by  $\text{NM}^\rightarrow(F)$ . It is easy to see that since Alice does not have any memory she cannot send multi-round messages to Bob as there is no way for her to remember in which round she is in. Also Bob cannot send messages back to Alice for her to keep a clock. Hence all the information from Alice to Bob has to be conveyed in a single round. Thus one-way memoryless communication complexity is equal to the standard deterministic one-way communication complexity.<sup>13</sup>

► **Fact 4.** *For all function  $F$  we have  $\text{NM}^\rightarrow(F) = D^\rightarrow(F)$ .*

<sup>12</sup> Without loss of generality, we assume that the first message is between Alice and Bob and she sends  $f_x(0^s) \in \{0, 1\}^s$  to Bob.

<sup>13</sup> Without loss of generality, in any one-way standard communication complexity protocol of cost  $c$  Alice can send all the  $c$  bits in a single round.

### 3.2 Deterministic Memory-No Memory Communication Model

We now consider another variant of the memoryless communication model wherein one party is allowed to have a memory but the other party doesn't. In this paper, we always assume that Alice has a memory and call this setup the *memory no-memory model*. In this work, we will *not* consider the other case wherein Bob has a memory and Alice doesn't have a memory. Note that this setting is asymmetric i.e., there exists functions for which the complexity of the function can differ based on whether Alice or Bob has the memory.

**Two-way Memory-No Memory Communication Model.** Here the players are allowed to send messages in both directions. For a function  $F : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$ , we denote the complexity in this model as  $M(F)$ . Observe that  $M(F)$  is trivially upper bounded by  $\log n$  for every  $F$ : for every  $i \in [n]$ , Alice can send  $i$  and Bob replies with  $y_i$ . Since Alice has memory, after  $n$  rounds she has complete knowledge of  $y \in \{0, 1\}^n$  and computes  $F(x, y)$  locally and sends it to Bob.

**One-way Memory-No Memory Communication Model.** Here we allow only Alice to send messages to Bob. Since Alice has a memory she can send multiple messages one after another, but Bob cannot reply to her messages. Hence, after receiving any message Bob computes the function  $g_y(\cdot) \in \{0, 1, \perp\}$  and if he obtains  $\{0, 1\}$ , he outputs 0 or 1, and continues if he obtains  $\perp$ . We denote the communication complexity in this model by  $M^\rightarrow(F)$ . This model was formally studied by Papakonstantinou et al. [35] as *overlay communication complexity* (we discuss their main contributions in Section 4).

Finally, we can also have a model where both players have memory and hence both players can remember the whole transcript of the computation. This is exactly the widely-studied standard communication complexity except that the complexity measure here is the size of the *largest* transcript (so the complexity in our model is just 1 since they could exchange a single bit for  $n$  rounds and compute an arbitrary function on  $2n$  bits) and the latter counts the *total* number of bits exchanged in a protocol.

**Quantum memoryless Models.** Here we introduce the quantum memoryless communication model. There are a few ways one can define the quantum extension of the classical memoryless model. We find the following exposition the simplest to explain. This quantum communication model is defined exactly as the classical memoryless model except that Alice and Bob are allowed to communicate *quantum* states. A  $T$  round quantum protocol consists of the following: Alice and Bob have local  $k$ -qubit memories  $A, B$  respectively,<sup>14</sup> they share a  $m$ -qubit message register  $M$  and for every round they perform a  $q$ -outcome POVM  $\mathcal{P} = \{P_1, \dots, P_q\}$  for  $q = 2^m$  (which could potentially depend on their respective inputs  $x$  and  $y$ ). Let  $\{U_x\}_{x \in \{0, 1\}^n}, \{V_y\}_{y \in \{0, 1\}^n}$  be the set of  $(m + k)$ -dimensional unitaries acting on  $(A, M)$  and  $(B, M)$  respectively (this is analogous to the look-up tables  $\{f_x, g_y : \{0, 1\}^m \rightarrow \{0, 1\}^m\}_{x, y \in \{0, 1\}^n}$  used by Alice and Bob in the classical memoryless protocol). Let  $\psi_0 = (A, M)$  be the all-0 mixed state. Then, the quantum protocol between Alice and Bob can be written as follows: on input  $x, y$  to Alice and Bob respectively, on the  $i$ th round (for  $i \geq 1$ ) Alice sends  $\psi_i$  for odd  $i$  and Bob replies with  $\psi_{i+1}$  defined as follows:

$$\psi_i = \text{Tr}_A(\mathcal{P} \circ U_x \psi_{i-1}) \otimes |0\rangle\langle 0|_B,$$

where  $\mathcal{P} \circ U_x \psi_{i-1}$  is the post-measurement state after performing the POVM  $\mathcal{P}$  on the state  $U_x \psi_{i-1}$  and  $\text{Tr}_A(\cdot)$  refers to taking the partial trace of register  $A$ . Similarly, define

<sup>14</sup> After each round of communication, these registers are set to the all-0 register.

$$\psi_i = |0\rangle\langle 0|_A \otimes \text{Tr}_B(\mathcal{P} \circ U_y \psi_i),$$

where  $\text{Tr}_B(\cdot)$  takes the partial trace of register B. Intuitively, the states  $\psi_i$  (similarly  $\psi_{i+1}$ ) can be thought of as follows: after applying unitaries  $U_x$  to the registers (A, M), Alice applies the  $q$ -outcome POVM  $\mathcal{P}$  which results in a classical outcome and post-measurement state on the registers (A, M) and she discards her private memory register and initializes the register B in the all-0 state. The quantum communication protocol terminates at the  $i$ th round once the  $q$ -outcome POVM  $\mathcal{P}$  results in the classical outcome  $\{(1^{m-1}, b)\}_{b \in \{0,1\}}$ .<sup>15</sup> After they obtain this classical output, Alice and Bob output  $b$ . We say a *protocol computes  $F$*  if for every  $x, y \in \{0,1\}^n$ , with probability at least  $2/3$  (probability taken over the randomness in the protocol), after a certain number of rounds the POVM measurement results in  $(1^{m-1}, F(x, y))$ . The complexity of computing  $F$  in the quantum memoryless model, denoted  $\text{QNM}(F)$  is the smallest  $m$  such that there is a  $m$ -qubit message protocol that computes  $F$ . As defined before, we also let  $\text{QM}^\rightarrow(F)$  (resp.  $\text{QNM}^\rightarrow(F)$ ) to be the model in which Alice has a memory (has no memory) and Bob doesn't have a memory and the communication happens from Alice to Bob.

Note that unlike the classical case, with quantum messages there is no apparent way for the players to know with certainty if they have received a designated terminal state (and whether they should stop and output 0/1) without disturbing the message content. Thus a natural choice is to integrate a partial measurement of the message register at each round into the definition.

**Notation.** For the remaining part of the paper we abuse notation by letting  $\text{NM}(F)$ ,  $\text{QNM}(F)$  denote the memoryless *complexity* of computing  $F$  and we let **NM model** (resp. **QNM model**) be the memoryless communication model (resp. quantum memoryless communication model). Additionally, we omit *explicitly* writing that Alice and Bob exchange the final message  $1^{s-1}f(x, y)$  once either parties have computed  $f(x, y)$  (on input  $x, y$  respectively).

## 4 Understanding and characterization of memoryless models

We now state a few observations and relations regarding the memoryless communication models.

► **Fact 5.** *For every  $F : \{0,1\}^n \times \{0,1\}^n \rightarrow \{0,1\}$ , we have  $\text{M}(F) \leq \text{NM}(F) \leq 2\text{M}^\rightarrow(F) \leq 2\text{NM}^\rightarrow(F)$ .*

We refer the reader to the full version of the paper for the proof. As we mentioned earlier, our main contribution in this paper is the memoryless **NM** model of communication. We saw in Fact 4 that  $\text{NM}^\rightarrow(F)$  is equal to the standard one-way deterministic communication complexity of computing  $F$ . The  $\text{M}^\rightarrow(F)$  model was introduced and studied by Papakonstantinou et al. [35]. Additionally observe that the strongest model of communication complexity  $\text{M}(F)$  is small for every function  $F$ .

► **Fact 6.** *For every  $F : \{0,1\}^n \times \{0,1\}^n \rightarrow \{0,1\}$ , we have  $\text{M}(F) \leq \log n$ .*

<sup>15</sup> We remark that a good quantum communication protocol should be such that for every  $i \in [T]$ , the probability of obtaining  $(1^{m-1}, 1 \oplus F(x, y))$  when measuring  $\psi_i$  using the POVM  $\mathcal{P}$  should be  $\leq 1/3$ .

To see this, observe that in the M model (i.e., two-way memory-no memory model), on the  $i$ th round, Alice sends  $i \in [n]$  and Bob (who doesn't have memory) sends the message  $y_i$  to Alice. Alice stores  $y_i$  and increments  $i$  to  $i + 1$  and repeats. After  $n$  rounds Alice simply has the entire  $y$  and computes  $F(x, y)$  on her own (note that  $F$  is known to both Alice and Bob).

Below we give few protocols in the NM model to give more intuition of this model.

**Algorithms in the memoryless model.** In the introduction we described a  $\log n + 1$  protocol for the equality function. Below we describe a protocol for the inner product function. For the inner product function  $\text{IP}_n$ , a simple protocol is as follows: For  $i = 1, \dots, n$ , on the  $i$ th round, Alice sends  $(i, x_i, \sum_{j=0}^{i-1} x_i \cdot y_j \pmod{2})$  which takes  $\log n + 2$  bits and Bob replies with  $(i, x_i, \sum_{j=0}^{i-1} x_i \cdot y_j + x_i \cdot y_i \pmod{2}) = (i, x_i, \sum_{j=0}^i x_i \cdot y_j \pmod{2})$ .<sup>16</sup> They repeat this protocol for  $n$  rounds and after the  $n$ th round, they have computed  $\text{IP}_n(x, y)$ . Hence  $\text{NM}(\text{IP}_n) \leq \log n + 2$ . Now we describe a protocol for the disjointness function  $\text{DISJ}_n$ . Here a  $\log n$  protocol is as follows: Alice sends the first coordinate  $i \in [n]$  for which  $x_i = 1$  and Bob outputs 0 if  $y_i = 1$ , if not Bob replies with the first  $j$  after  $i$  for which  $y_j = 1$  and they repeat this procedure until  $i$  or  $j$  equals  $n$ . It is not hard to see that  $\text{DISJ}_n(x, y) = 0$  if and only if there exists  $k$  for which  $x_k = y_k = 1$  in which case Alice and Bob will find such (smallest)  $k$  in the protocol above, if not the protocol will run for at most  $n$  rounds and they decide that  $\text{DISJ}_n(x, y) = 1$ . We now mention a non-trivial protocol in the NM model for the majority function defined as  $\text{MAJ}_n(x, y) = [\sum_i x_i \cdot y_i \geq n/2 + 1]$ . A trivial protocol for  $\text{MAJ}_n$  is similar to the  $\text{IP}_n$  protocol, on the  $(i + 1)$ th round, Alice sends  $(i, x_i, \sum_{i=1}^n x_i y_i)$  (without the  $\pmod{2}$ ) and Bob replies with  $(i, x_i, \sum_{i=1}^{n+1} x_i \cdot y_i)$ . Note that this protocol takes  $2 \log n + 1$  bits ( $\log n$  for sending the index  $i \in [n]$  and  $\log n$  to store  $\sum_{i=1}^n x_i \cdot y_i \in [n]$ ). Apriori this seems the best one can do, but interestingly using intricate ideas from number theory there exists a  $n \log^3 n$  [37, 25] garden-hose protocol for computing  $\text{MAJ}_n$ . Plugging this in with Theorem 21 we get a protocol of cost  $\log n + 3 \log \log n$  for computing  $\text{MAJ}_n$  in the NM model.

An interesting question is, are these protocols for  $\text{IP}_n, \text{EQ}_n, \text{DISJ}_n, \text{MAJ}_n$  optimal? Are there more efficient protocols possibly with constant bits of communication in each round? In order to understand this, in the next section we show that the memoryless communication complexity is lower bounded by the standard deterministic one-way communication complexity. Using this connection, we can show the tightness of the first three protocols. Additionally, we show that  $\text{NM}(\text{MAJ}_n) \geq \log n$ , thus the exact status of  $\text{NM}(\text{MAJ}_n) \in \{\log n, \dots, \log n + 3 \log \log n\}$  remains an intriguing open question.

## 4.1 Lower bounds on memoryless communication complexity

In the introduction, we mentioned that it is an interesting open question to find an explicit function  $F$  for which  $\text{NM}(F) \geq 2 \log n$ . Unfortunately we do not even know of an explicit function for which we can prove lower bounds better than  $\log n + \omega(1)$  (we discuss more about this in the open questions). However, it is not hard to show that for a random function  $F$ , the memoryless communication complexity of  $F$  is large.

► **Lemma 7.** *Let  $F : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  be a random function. Then,  $\text{NM}(F) = \Omega(n)$ .*

<sup>16</sup>Technically Bob need not send back the bit  $x_i$ .

The proof is via a simple counting argument. We refer the reader to the full version of the paper for the definition. We remark that similar ideas used in this lemma can be used to show that for all  $s < s'$ , there exists functions that can be computed using  $s'$  bits of communication in each round but not  $s$  bits of communication. This gives rise to a *space hierarchy* theorem for the NM model.

#### 4.1.1 Deterministic one-way communication complexity and memoryless complexity

We now give a very simple lower bound technique for the memoryless communication model in terms of deterministic one-way communication. Although this lower bound is “almost immediate”, as we mentioned in the introduction, it already gives us non-trivial lower bounds on the NM complexity of certain functions.

► **Fact 8.**

$$\text{NM}(F) \geq \log \left( D^{\rightarrow}(F) / \log D^{\rightarrow}(F) \right), \text{ and } \text{QNM}(F) \geq \Omega \left( \log \left( D^{\rightarrow}(F) / \log D^{\rightarrow}(F) \right) \right).$$

Using this lemma, we immediately get the following corollary.

► **Corollary 9.** *Let  $n \geq 2$ . Then  $\text{NM}(\text{EQ}_n), \text{NM}(\text{IP}_n), \text{NM}(\text{DISJ}_n), \text{NM}(\text{MAJ}_n), \text{NM}(\text{Index}), \text{NM}(\text{BHM})$  is  $\Omega(\log n)$ . Similarly, we have QNM complexity of these functions are  $\Omega(\log n)$ .*

This corollary follows immediately from Fact 8 because the deterministic-one way communication complexity of these functions are at least  $n$  (by a simple adversarial argument), thereby showing that the  $(\log n)$ -bit protocols we described in the beginning of this section for the first three of these functions is close-to-optimal. However one drawback of Fact 8 is it cannot be used to prove a lower bound that is better than  $\log n$  since  $D^{\rightarrow}(F) \leq n$  for every function  $F : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$ .

## 4.2 Characterization of memoryless communication

Papakonstantinou et al. [35] consider the memory-nomemory model of communication complexity wherein Alice has a memory and Bob doesn't and they are restricted to one-way communication from Alice to Bob. They show a beautiful combinatorial rectangle-overlay characterization (denoted  $\text{RO}(F)$ ) of the  $M^{\rightarrow}$  model. We refer the reader to the full version of the paper for the definition.

One of the main results of [35] was the following characterization.

► **Theorem 10 ([35]).** *For every  $F$ , we have  $\log \text{RO}(F) \leq M^{\rightarrow}(F) \leq 2 \log \text{RO}(F)$ .*

A natural question following their work is, can we even characterize our new general framework of communication complexity wherein *both* Alice and Bob do not have memory and the communication can be two-way. Generalizing the rectangle-based characterization of [35] to our setting seemed non-trivial because in our communication model the memoryless-ness of the protocol doesn't seem to provide any meaningful way to split the communication matrix into partitions or overlays (as far as we could analyze). Instead we characterize our communication model in terms of *bipartite branching programs*, which we define below.<sup>17</sup>

---

<sup>17</sup> For a definition of general branching program (BP), refer to Section 2.

► **Definition 11** (Bipartite Branching Program (BBP)). *Let  $F : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$ . A bipartite branching program is a BP that computes  $F$  in the following way: for every  $(x, y)$ , each node in the branching program is either labelled by a function  $f_i \in \mathcal{F} = \{f_i : \{0, 1\}^n \rightarrow \{0, 1\}\}_i$  or by  $g_j \in \mathcal{G} = \{g_j : \{0, 1\}^n \rightarrow \{0, 1\}\}_j$ ; the output edge is labelled by 0 or 1 and the output of the function in the node label decides which edge to follow. The size of a BBP is the number of nodes in it. We define  $\text{BBP}(F)$  as the size of the smallest program that computes  $F$  for all  $(x, y) \in \{0, 1\}^{2n}$ .*

Observe that in a BBP every node no longer just queries  $x \in \{0, 1\}^n$  at an arbitrary index  $i$  (like in the standard BP), but instead is allowed to compute an *arbitrary Boolean function* on  $x$  or  $y$ . Of course, another natural generalization of BBP is, why should the nodes of the program just compute Boolean-valued functions? We now define the *generalized BBP* wherein each node can have out-degree  $k$  (instead of out-degree 2 in the case of BBP and BP).

► **Definition 12** (Generalized Bipartite Branching Program (GBBP)). *Let  $k \geq 1$ . A generalized bipartite branching program is a BBP that computes  $F$  in the following way: for every  $(x, y)$ , each node in the branching program can have out-degree  $k$  and labelled by the node  $f_i \in \mathcal{F} = \{f_i : \{0, 1\}^n \rightarrow [k]\}_i$ , or by  $g_j \in \mathcal{G} = \{g_j : \{0, 1\}^n \rightarrow [k]\}_j$ ; the output edges are labelled by  $\{1, \dots, k\}$  and the output of the function in the node label decides which edge to follow. The size of a GBBP is the number of nodes in it. We define  $\text{GBBP}(F)$  as the size of the smallest program that computes  $F$  for all  $(x, y) \in \{0, 1\}^{2n}$ .*

We now show that the generalized bipartite branching programs are not much more powerful than bipartite branching programs, in fact these complexity measures are quadratically related.

► **Fact 13.** *For  $F : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$ , we have  $\text{GBBP}(F) \leq \text{BBP}(F) \leq \text{GBBP}(F)^2$ .*

It is not clear if the quadratic factor loss in the simulation above is necessary and we leave it as an open question. We are now ready to prove our main theorem relating NM communication model and bipartite branching programs.

► **Theorem 14.** *For every  $F$ , we have  $\frac{1}{2} \log \text{BBP}(F) \leq \text{NM}(F) \leq \log \text{BBP}(F)$ .*

We refer the reader to the full version of the paper for the proof. Earlier we saw that GBBP is polynomially related to BBP. We now observe that both these measures can be exponentially smaller than standard branching program size.<sup>18</sup>

► **Fact 15.** *The parity function  $\text{PARITY}_n(x, y) = \sum_i x_i \oplus y_i \pmod{2}$  gives an exponential separation between generalized bipartite branching programs and branching programs.*

**Time Space Trade-off for Memoryless.** Finally, we mention a connection between our communication model and time-space trade-offs. In particular, what are the functions that can be computed if we limit the number of rounds in the memoryless protocol? Earlier we saw that, an arbitrary memoryless protocol of cost  $s$  for computing a function  $F$  could consist of at most  $2^{s+1}$  rounds of message exchanges. If sending one message takes one unit of time, we can ask whether it is possible to simultaneously reduce the message size  $s$  and the time  $t$  required to compute a function. The fact below gives a time-space trade-off in terms of deterministic communication complexity.

<sup>18</sup>The function we use here is the standard function that separates bipartite formula size from formula size.

► **Fact 16.** *For every  $k \geq 1$  and function  $F : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$ , we have  $\text{NM}_k(F) \geq D(F)/k$ , where  $\text{NM}_k(F)$  is the NM communication complexity of computing  $F$  with at most  $k$  rounds of communication, and  $D(F)$  is the standard deterministic communication complexity.*

It is not hard to now see that the number of rounds in an  $\text{NM}(F)$  protocol corresponds to the *depth* of the generalized bipartite branching program computing  $F$ . So an immediate corollary of the fact above is, even for simple functions such as equality, inner product, if we restrict the depth of GBBP to be  $o(n)$ , then we can show *exponential-size* lower bounds on such GBBPs computing these functions. Similarly note that one can separate QNM and NM model of communication if we bound the number of rounds: consider the problem where Alice and Bob get  $x, y \in \{0, 1\}^n$  respectively promised that,  $x = y$  or Hamming distance between  $x, y$  is  $n/2$ . In this case, clearly  $\text{NM}_k(F) \geq n/k$  (from the fact above), which in particular means that constant-round NM protocols need to send  $\Omega(n)$  bits. In contrast, in the QNM model, Alice could simply send  $O(1)$  copies of a fingerprint state  $|\psi_x\rangle = \frac{1}{\sqrt{n}} \sum_i (-1)^{x_i} |i\rangle$  (in a *single round*) and due to the promise, Bob can perform swap test between  $|\psi_x\rangle, |\psi_y\rangle$  and decide if  $x = y$  or the Hamming distance is  $n/2$  with probability 1.

## 5 Relations between memoryless communication models

In this section, we show that there exists exponential separations between the four memoryless communication models defined in Section 3 (and in particular, Fact 5).

► **Theorem 17.** *There exists functions  $F$  for which the following inequalities (as shown in Fact 5) is exponentially weak<sup>19</sup>  $M(F) \leq \text{NM}(F) \leq 2M^\rightarrow(F) \leq 2\text{NM}^\rightarrow(F)$ .*

We refer the reader to the full version of the paper for the definition. We now exhibit exponential separations between the quantum and classical memoryless models of communication complexity.

► **Theorem 18.** *There exist functions  $F : D \rightarrow \{0, 1\}$  where  $D \subseteq \{0, 1\}^n \times \{0, 1\}^n$  for which the following inequalities are exponentially weak: (i)  $\text{QNM}^\rightarrow(F) \leq \text{NM}^\rightarrow(F)$ , (ii)  $\text{QM}^\rightarrow(F) \leq M^\rightarrow(F)$ , (iii)  $\text{QM}(F) \leq M(F)$ .<sup>20</sup>*

We refer the reader to the full version of the paper for the definition. One drawback in the exponential separations above is that we allow a quantum protocol to err with constant probability but require the classical protocols to be correct with probability 1. We remark that except the second inequality, the remaining inequalities also show exponential separations between the randomized memoryless model (wherein Alice and Bob have public randomness and are allowed to err in computing the function) versus the corresponding quantum memoryless model. A natural question is to extend these separations even when the classical model is allowed to err with probability at least  $1/3$ .

### 5.1 Relating the Garden-hose model, Space-bounded communication complexity and Memoryless complexity

In this section, we show that the memoryless communication complexity  $\text{NM}(F)$  of a Boolean function  $F$  is equal to the logarithm of the garden-hose complexity up to an additive constant and is equal to the space-bounded communication complexity up to factor 2. But first we briefly define the garden-hose model and the space-bounded communication complexity model.

<sup>19</sup>We remark that the functions exhibiting these exponential separations are different for the three inequalities.

<sup>20</sup>Again, the functions exhibiting these separations are different for the three inequalities.

**Garden-hose model [15].** In the garden-hose model of computation, Alice and Bob are neighbours (who cannot communicate) and have few pipes going across the boundary of their gardens. Based on their private inputs  $x, y$  and a function  $F : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  known to both, the players connect some of the opening of the pipes on their respective sides with garden-hoses. Additionally, Alice connects a tap to one of the pipes on her side. Naturally, based on the garden-hose connections, water travels back and forth through some of the pipes and finally spills on either Alice's or Bob's side, based on which they decide if a function  $F$  on input  $x, y$  evaluates to 0 or 1. It is easy to show that Alice and Bob can compute every function using this game. The garden-hose complexity  $\text{GH}(F)$  is defined to be the minimum *number of pipes* required to compute  $F$  this way for all possible inputs  $x, y$  to Alice and Bob. For more on garden-hose complexity, we refer the interested reader to [15, 25, 38, 39].

**Space-bounded communication complexity [11].** Alice and Bob each have at most  $s(n)$  bits of memory. Based on their private inputs  $x, y$  they want to compute the function  $F : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  in the following manner: At each round Alice receives a single bit message  $m_B \in \{0, 1\}$  from Bob and based on her input  $x$ , the incoming message  $m_B$  and her previous  $s(n)$ -bit register content, she computes a new  $s(n)$ -bit register and decides whether to stop and output 0/1 or to continue. Bob does the same. At the beginning of the game, the register contents of both players are set to the all-zero strings. The game then starts by Alice sending the first message and continues until one of players outputs 0/1. space-bounded communication complexity  $\text{SM}(F)$  of computing a function  $F$  is the minimum register size  $s(n)$  required to compute  $F$  on the worst possible input  $(x, y)$ . Brody et al. [11] claimed that space-bounded communication complexity is equal to the garden-hose communication complexity upto factor 2.

▷ **Claim 19 ([11]).** For every function  $F$  there exists constants  $c \in (0, 1), d \in \mathbb{N}^+$  such that  $c \cdot 2^{\text{SM}(F)} \leq \text{GH}(F) \leq 2^{2\text{SM}(F)+2} + d$ .

We show the following relation between

► **Lemma 20.** For every function  $F$ ,  $\text{NM}(F) \leq 2\text{SM}(F) + 1$ ,  $\text{SM}(F) \leq \text{NM}(F) + \log \text{NM}(F)$

We refer the reader to the full version of the paper for a proof. Using the Claim 19 and Lemma 20 we can conclude that the logarithm of the garden-hose complexity is equal to the memoryless NM complexity up to factor 2. This seems interesting already given we can connect these two models, but in the NM model, even factor-2s are important since they are related to formula lower bounds. Now we show that it is possible to further tighten the relation in the lemma above. Below we show that NM is actually equivalent to the logarithm of the garden-hose complexity up to an *additive term* of 4. The first observation relating the garden-hose model and memoryless communication complexity is that, the garden-hose model is exactly the NM communication model, except that in addition to the memoryless-ness of Alice and Bob, there is a *bijection* between the incoming and the outgoing messages of both players (i.e., the local functions Alice and Bob apply  $\{f_x : \{0, 1\}^s \rightarrow \{0, 1\}^s\}_x, \{g_y : \{0, 1\}^s \rightarrow \{0, 1\}^s\}_y$  are *bijective functions*). We now state and prove the theorem which shows how GH is related to the standard memoryless communication model.

► **Theorem 21.** For  $F$ , we have  $\log \text{GH}(F) - 4 \leq \text{NM}(F) \leq \log \text{GH}(F)$ .

We refer the reader to the full version of the paper for a proof. Interestingly, Theorem 21 together with Theorem 17 gives us a way to construct a garden-hose protocol using an  $\text{M}^\rightarrow$  protocol and, as we will see below, this could result in potentially stronger upper bound on

the garden-hose model. In an earlier work of Klauck and Podder [25], it was conjectured that the disjointness function with input size  $m = n \cdot 2 \log n$  (i.e., with set size  $n$  and universe size  $n^2$ ) has a quadratic lower bound  $\Omega(m^2)$  in the garden-hose model. Here, we show that GH protocol for this problem has cost  $O(m^2/\log^2 m)$ . Although the improvement is only by a logarithmic-factor, we believe that this complexity can be reduced further which we leave as an open question.

**Disjointness with quadratic universe:** Alice and Bob are given  $n$  numbers each from  $[n^2]$  as a  $m = n \cdot 2 \log n$  long bit strings. Their goal is to check if all of their  $2n$  numbers are unique. Without loss we can assume that the  $n$  numbers on the respective sides of Alice and Bob are unique, if not they can check it locally and output 0 without any communication. Then an  $M^\rightarrow$  protocol for computing this function is as follows: Alice keeps sending all her numbers to Bob one by one (using her local memory to keep track of which numbers she has already sent). This requires  $2 \log n$  size message register on every round. Bob upon receiving any number from Alice, checks if any number of his side matches the number received. If there is a match he outputs 0, else he continues. For the last message Alice sends the number along with a special marker. Bob performs his usual check and output 1 if the check passes and the marker is present. Clearly the cost of this protocol is  $2 \log n$  and thus from Theorem 21 the garden-hose protocol for computing this function has cost  $n^2$ . Since the input size is  $m = n \cdot 2 \log n$ , the cost of the garden-hose protocol is  $O(m^2/\log^2 m)$ .

---

## Abstract

We show that standard extragradient methods (i.e. mirror prox [26] and dual extrapolation [28]) recover optimal accelerated rates for first-order minimization of smooth convex functions. To obtain this result we provide fine-grained characterization of the convergence rates of extragradient methods for solving monotone variational inequalities in terms of a natural condition we call *relative Lipschitzness*. We further generalize this framework to handle local and randomized notions of relative Lipschitzness and thereby recover rates for box-constrained  $\ell_\infty$  regression based on area convexity [34] and complexity bounds achieved by accelerated (randomized) coordinate descent [5, 29] for smooth convex function minimization.

**2012 ACM Subject Classification** Mathematics of computing → Convex optimization

**Keywords and phrases** Variational inequalities, minimax optimization, acceleration,  $\ell_\infty$  regression

**Digital Object Identifier** 10.4230/LIPIcs.ITCS.2021.62

**Related Version** A full version of the paper is available at <https://arxiv.org/abs/2011.06572>.

**Funding** Researchers supported in part by Microsoft Research Faculty Fellowship, NSF CAREER Award CCF-1844855, NSF Grant CCF-1955039, a PayPal research gift, and a Sloan Research Fellowship.

**Acknowledgements** The existence of an extragradient algorithm in the primal-dual formulation of smooth minimization directly achieving accelerated rates is due to discussions with the first author, Michael B. Cohen. The second and third authors are indebted to him, and this work is dedicated in his memory. We also thank our collaborators in concurrent works, Yair Carmon and Yujia Jin, for many helpful and encouraging conversations throughout the duration of this project, Jelena Diakonikolas, Jonathan Kelner, and Jonah Sherman for helpful conversations, and anonymous reviewers for multiple helpful comments on earlier versions of the paper.

## 1 Introduction

We study the classic extragradient algorithms of mirror prox [26] and dual extrapolation [28] for solving variational inequalities (VIs) in monotone operators. This family of problems includes convex optimization and finding the saddle point of a convex-concave game. Due to applications of the latter to adversarial and robust training, extragradient methods have received significant recent attention in the machine learning community, see e.g. [12, 24, 16]. Further, extragradient methods have been the subject of increasing study by the theoretical computer science and optimization communities due to recent extragradient-based runtime improvements for problems including maximum flow [34] and zero-sum games [10, 11].

Given a Lipschitz monotone operator and a bounded strongly-convex regularizer, mirror prox [26] and dual extrapolation [28] achieve  $O(T^{-1})$  regret for solving the associated VI after  $T$  iterations. This rate is worst-case optimal when the Lipschitzness of the operator and strong convexity of the regularizer are with respect to the Euclidean norm [30]. However, in certain structured problems related to VIs, alternative analyses and algorithms can yield improved rates. For instance, when minimizing a smooth convex function (i.e. one with a Lipschitz gradient), it is known that accelerated rates of  $O(T^{-2})$  are attainable, improving upon the standard  $O(T^{-1})$  extragradient rate for the naive associated VI. Further, algorithms inspired by extragradient methods have been developed recovering the  $O(T^{-2})$  rate [13, 37].

Additionally, alternative analyses of extragradient methods, such as optimism [32] and area convexity [34] have shown that under assumptions beyond a Lipschitz operator and a strongly convex regularizer, improved rates can be achieved. These works leveraged modified algorithms which run efficiently under such non-standard assumptions. Further, the area convexity-based methods of [34] have had a number of implications, including faster algorithms for  $\ell_\infty$  regression, maximum flow and multicommodity flow [34] as well as improved parallel algorithms for work-efficient positive linear programming [8] and optimal transport [17].

In this work we seek a better understanding of these structured problems and the somewhat disparate-seeming analyses and algorithms for solving them. We ask, *are the algorithmic changes enabling these results necessary? Can standard mirror prox and dual extrapolation be leveraged to obtain these results? Can we unify analyses for these problems, and further clarify the relationship between acceleration, extragradient methods, and primal-dual methods?*

Towards addressing these questions, we provide a general condition, which we term *relative Lipschitzness* (cf. Definition 1), and analyze the convergence of mirror prox and dual extrapolation for a monotone relatively Lipschitz operator.<sup>1</sup> This condition is derived directly from the standard analysis of the methods and is stated in terms of a straightforward relationship between the operator  $g$  and the regularizer  $r$  which define the algorithm. Our condition is inspired by both area convexity as well as the “relative smoothness” condition in convex optimization [6, 23], and can be thought of as a generalization of the latter to variational inequalities (see Lemma 3). Further, through this analysis we show that standard extragradient methods directly yield accelerated rates for smooth minimization and recover the improved rates of [34] for box-constrained  $\ell_\infty$  regression, making progress on the questions outlined above. We also show our methods recover certain randomized accelerated rates and have additional implications, outlined below.

**Extragradient methods directly yield acceleration.** In Section 4, we show that applying algorithms of [26, 28] to a minimax formulation of  $\min_{x \in \mathbb{R}^d} f(x)$ , when  $f$  is smooth and strongly convex, yields accelerated rates when analyzed via relative Lipschitzness. Specifically, we consider the following problem, termed the *Fenchel game* in [37]:

$$\min_{x \in \mathbb{R}^d} \max_{y \in \mathbb{R}^d} \langle y, x \rangle - f^*(y), \quad (1)$$

<sup>1</sup> A somewhat similarly-named property appeared in [22], which also studied mirror descent algorithms under relaxed conditions; their property  $\|g(x)\|_*^2 \leq \frac{MV_x(y)}{\|y-x\|^2}$  for all  $x, y$ , is different than the one we propose. Further, during the preparation of this work, the relative Lipschitzness condition we propose was also independently stated in [36] (unknownst to the authors of this paper until recently). However, the work [36] does not derive the various consequences of relative Lipschitzness contained in this work (e.g. recovery of acceleration and randomized acceleration, as well as applications of area convexity).

and show that when  $f$  is  $\mu$ -strongly convex and  $L$ -smooth,  $O(\sqrt{L/\mu})$  iterations of either mirror prox [26] or dual extrapolation [28] produces an average iterate which halves the function error of  $f$ . By repeated application, this yields an accelerated linear rate of convergence and the optimal  $O(T^{-2})$  rates for non-strongly convex, smooth function minimization by a reduction [4]. Crucially, to attain this rate we give a sharpened bound on the relative Lipschitzness of the gradient operator of (1) with respect to a primal-dual regularizer.

Our result advances a recent line of research, [1, 2, 13], on applying primal-dual analyses to shed light on the mysterious nature of acceleration. Specifically, [1, 2] show that the classical algorithm of [27] can be rederived via applying primal-dual “optimistic” dynamics, inspired by the framework of [32]. Further, [13] showed that an appropriate discretization of dynamics inspired by extragradient algorithms yields an alternative accelerated algorithm. While these results clarify the primal-dual nature of acceleration, additional tuning is ultimately required to obtain their final algorithms and analysis. We obtain acceleration as a direct application of known frameworks, i.e. standard mirror prox and dual extrapolation, applied to the formulation (1), and hope this helps demystify acceleration.

In the full version of the paper, we further show that analyzing extragradient methods tailored to strongly monotone operators via relative Lipschitzness, and applying this more fine-grained analysis to a variant of the objective (1), also yields an accelerated linear rate of convergence. The resulting proof strategy extends readily to accelerated minimization of smooth and strongly convex functions in general norms, as we discuss at the end of Section 4, and we believe it may be of independent interest.

Finally, we remark that there has been documented difficulty in accelerating the minimization of relatively smooth functions [15]; this was also explored more formally by [14]. It is noted in [15], as well as suggested in others (e.g. in the development of area convexity [34]) that this discrepancy may be due to acceleration fundamentally requiring conditions on relationships between groups of three points, rather than two. Our work, which presents an alternative three-point condition yielding accelerated rates, sheds light on this phenomenon and we believe it is an interesting future direction to explore the relationships between our condition and other alternatives in the literature which are known to yield acceleration.

**Area convexity for bilinear box-simplex games.** In Section 5, we draw a connection between relative Lipschitzness and the notion of an “area convex” regularizer, proposed by [34]. Area convexity is a property which weakens strong convexity, but is suitable for extragradient algorithms with a linear operator. It was introduced in the context of solving a formulation of approximate undirected maximum flow via box-constrained  $\ell_\infty$  regression, or more generally approximating bilinear games between a box variable and a simplex variable. The algorithm of [34] applied to bilinear games was a variant of standard extragradient methods and analyzed via area convexity, which was proven via solving a subharmonic partial differential equation. We show that mirror prox, as analyzed by a local variant of relative Lipschitzness, yields the same rate of convergence as implied by area convexity, for box-simplex games. Our proof of this rate is straightforward and based on a simple Cauchy-Schwarz argument after demonstrating local stability of iterates.

**Randomized extragradient methods via local variance reduction.** In general, the use of stochastic operator estimates in the design of extragradient algorithms for solving general VIs is not as well-understood as their use in the special case of convex function minimization. The best-known known stochastic methods for solving VIs [19] with bounded-variance stochastic estimators obtain  $O(T^{-1/2})$  rates of convergence; this is by necessity, from known

classical lower bounds on the rate of the special case of stochastic convex optimization [25]. Towards advancing the randomized extragradient toolkit, we ask: when can improved  $O(T^{-1})$  rates of convergence be achieved by stochastic algorithms for solving specific VIs and fine-grained bounds on estimator variance (i.e. more local notions of variance)? This direction is inspired by analogous results in convex optimization, where reduced-variance and accelerated rates have been obtained, matching and improving upon their deterministic counterparts [18, 33, 3, 20, 29, 5].

For the special case of bilinear games, this question was recently addressed by the works [31, 10], using proximal reductions to attain improved rates. In this work, we give a framework for direct stochastic extragradient method design bypassing the variance bottleneck limiting prior algorithms to a  $O(T^{-1/2})$  rate of convergence for problems with block-separable structure. We identify a particular criterion of randomized operators used in the context of extragradient algorithms (cf. Proposition 12) which enables  $O(T^{-1})$  rates of convergence. Our approach is a form of “local variance reduction”, where estimators in an iteration of the method share a random seed and we take expectations over the whole iteration in the analysis. Our improved estimator design exploits the separable structure of the problem; it would be interesting to design a more general variance reduction framework for randomized extragradient methods.

Formally, we apply our local variance reduction framework in Section 6 to show that an instance of our new randomized extragradient methods recover acceleration for coordinate-smooth functions, matching the known tight rates of [5, 29]. Along the way, we give a variation of relative Lipschitzness capturing an analogous property between a locally variance-reduced randomized gradient estimator and a regularizer, which we exploit to obtain our runtime. We note that a similar approach was taken in [35] to obtain faster approximate maximum flow algorithms in the bilinear minimax setting; here, we generalize this strategy and give conditions under which our variance reduction technique obtains improved rates for extragradient methods more broadly.

**Additional contributions.** A minor contribution of our framework is that we show, in the full version of the paper, that relative Lipschitzness implies new rates for minimax convex-concave optimization, taking a step towards closing the gap with lower bounds with *fine-grained* dependence on problem parameters. Under operator-norm bounds on blocks of the Hessian of a convex-concave function, as well as blockwise strong convexity assumptions, [38] showed a lower bound on the convergence rate to obtain an  $\epsilon$ -approximate saddle point. When the blockwise operator norms of the Hessian are roughly equal, [21] gave an algorithm matching the lower bound up to a polylogarithmic factor, using an alternating scheme repeatedly calling an accelerated proximal point reduction. Applying our condition with a strongly monotone variant of the mirror prox algorithm of [26] yields a new fine-grained rate for minimax optimization, improving upon the runtime of [21] for a range of parameters. Our algorithm is simple and the analysis follows directly from a tighter relative Lipschitzness bound; we note the same result can also be obtained by considering an operator norm bound of the problem after a rescaling of space, but we include this computation because it is a straightforward implication of our condition.

Finally, in the full version, we also discuss the relation of relative Lipschitzness to another framework for analyzing extragradient methods: namely, we note that our proof of the sufficiency of relative Lipschitzness recovers known bounds for optimistic mirror descent [32].

## 2 Notation

**General notation.** Variables are in  $\mathbb{R}^d$  unless otherwise noted.  $e_i$  is the  $i^{\text{th}}$  standard basis vector.  $\|\cdot\|$  denotes an arbitrary norm; the dual norm is  $\|\cdot\|_*$ , defined as  $\|x\|_* := \max_{\|y\| \leq 1} y^\top x$ . For a variable on two blocks  $z \in \mathcal{X} \times \mathcal{Y}$ , we refer to the blocks by  $z^x$  and  $z^y$ . We denote the domain of  $f : \mathbb{R}^d \rightarrow \mathbb{R}$  by  $\mathcal{X}$ ; when unspecified,  $\mathcal{X} = \mathbb{R}^d$ . When  $f$  is clear from context,  $x^*$  is any minimizing argument. We call any  $x$  with  $f(x) \leq f(x^*) + \epsilon$  an  $\epsilon$ -approximate minimizer.

**Bregman divergences.** The Bregman divergence induced by convex  $r$  is

$$V_x^r(y) := r(y) - r(x) - \langle \nabla r(x), y - x \rangle.$$

The Bregman divergence is always nonnegative, and convex in its argument. We define the following proximal operation with respect to a divergence from point  $z$ .

$$\text{Prox}_x^r(g) := \operatorname{argmin}_y \{ \langle g, y \rangle + V_x^r(y) \}. \quad (2)$$

**Functions.** We say  $f$  is  $L$ -smooth in  $\|\cdot\|$  if  $\|\nabla f(x) - \nabla f(y)\|_* \leq L \|x - y\|$ , or equivalently  $f(y) \leq f(x) + \langle \nabla f(x), y - x \rangle + \frac{L}{2} \|y - x\|^2$  for  $x, y \in \mathcal{X}$ . If  $f$  is twice-differentiable, equivalently  $y^\top \nabla^2 f(x) y \leq L \|y\|^2$ . We say differentiable  $f$  is  $\mu$ -strongly convex if for some  $\mu \geq 0$ ,  $f(y) \geq f(x) + \langle \nabla f(x), y - x \rangle + \frac{\mu}{2} \|y - x\|^2$  for  $x, y \in \mathcal{X}$ . We also say  $f$  is  $\mu$ -strongly convex with respect to a distance-generating function  $r$  if  $V_x^f(y) \geq \mu V_x^r(y)$  for all  $x, y \in \mathcal{X}$ . Further, we use standard results from convex analysis throughout, in particular facts about Fenchel duality, and defer these definitions and proofs to the full version of the paper.

**Saddle points.** We call function  $h(x, y)$  of two variables *convex-concave* if its restrictions to  $x$  and  $y$  are convex and concave respectively. We call  $(x, y)$  an  $\epsilon$ -approximate saddle point if  $\max_{y'} \{h(x, y')\} - \min_{x'} \{h(x', y)\} \leq \epsilon$ . We equip any differentiable convex-concave function with gradient operator  $g(x, y) := (\nabla_x h(x, y), -\nabla_y h(x, y))$ .

**Monotone operators.** We call operator  $g : \mathcal{Z} \rightarrow \mathcal{Z}^*$  monotone if  $\langle g(w) - g(z), w - z \rangle \geq 0$  for all  $w, z \in \mathcal{Z}$ . Examples include the gradient of a convex function and gradient operator of a convex-concave function. We call  $g$   $m$ -strongly monotone with respect to  $r$  if  $\langle g(w) - g(z), w - z \rangle \geq m (V_w^r(z) + V_z^r(w))$ . We call  $z^* \in \mathcal{Z}$  the solution to the variational inequality (VI) in a monotone operator  $g$  if  $\langle g(z^*), z^* - z \rangle \leq 0$  for all  $z \in \mathcal{Z}$ .<sup>2</sup> Examples include the minimizer of a convex function and the saddle point of a convex-concave function.

## 3 Extragradient convergence under relative Lipschitzness

We give a brief presentation of mirror prox [26], and a convergence analysis under relative Lipschitzness. Our results also hold for dual extrapolation [28], which can be seen as a “lazy” version of mirror prox updating a state in dual space (see [9]); we defer details to the full version of the paper.

► **Definition 1** (Relative Lipschitzness). For convex  $r : \mathcal{Z} \rightarrow \mathbb{R}$ , we call operator  $g : \mathcal{Z} \rightarrow \mathcal{Z}^*$   $\lambda$ -relatively Lipschitz with respect to  $r$  if for every three  $z, w, u \in \mathcal{Z}$ ,

$$\langle g(w) - g(z), w - u \rangle \leq \lambda (V_z^r(w) + V_w^r(u))$$

<sup>2</sup> This is also known as a “strong solution”. A “weak solution” is a  $z^*$  with  $\langle g(z), z^* - z \rangle \leq 0$  for all  $z$ .

■ **Algorithm 1** MIRROR-PROX( $z_0, T$ ): Mirror prox [26].

---

**Input:** Distance generating  $r$ ,  $\lambda$ -relatively Lipschitz monotone  $g : \mathcal{Z} \rightarrow \mathcal{Z}^*$ , initial point  $z_0 \in \mathcal{Z}$   
**for**  $0 \leq t < T$  **do**  
     $w_t \leftarrow \text{Prox}_{z_t}^r(\frac{1}{\lambda}g(z_t))$   
     $z_{t+1} \leftarrow \text{Prox}_{z_t}^r(\frac{1}{\lambda}g(w_t))$   
**end for**

---

Definition 1 can be thought of as an alternative to a natural nonlinear analog of the area convexity condition of [34] displayed below:

$$\langle g(w) - g(z), w - u \rangle \leq \lambda \left( r(z) + r(w) - r(u) - 3r\left(\frac{z + w + u}{3}\right) \right).$$

Our proposed alternative is well-suited for the standard analyses of extragradient methods such as mirror prox and dual extrapolation. For the special case of bilinear minimax problems in a matrix  $A$ , the left hand side of Definition 1 measures the area of a triangle in a geometry induced by  $A$ .

Relative Lipschitzness encapsulates the more standard assumptions that  $g$  is Lipschitz and  $r$  is strongly convex (Lemma 2), as well as the more recent assumptions that  $f$  is convex and relatively smooth with respect to  $r$  [6, 23] (Lemma 3).

► **Lemma 2.** *If  $g$  is  $L$ -Lipschitz and  $r$  is  $\mu$ -strongly convex in  $\|\cdot\|$ ,  $g$  is  $L/\mu$ -relatively Lipschitz with respect to  $r$ .*

**Proof.** By Cauchy-Schwarz, Lipschitzness of  $g$ , and strong convexity of  $r$ ,

$$\begin{aligned} \langle g(w) - g(z), w - u \rangle &\leq \|g(w) - g(z)\|_* \|w - u\| \leq L \|w - z\| \|w - u\| \\ &\leq \frac{L}{2} (\|w - z\|^2 + \|w - u\|^2) \leq \frac{L}{\mu} (V_z^r(w) + V_w^r(u)). \end{aligned} \quad \blacktriangleleft$$

► **Lemma 3.** *If  $f$  is  $L$ -relatively smooth with respect to  $r$ , i.e.  $V_x^f(y) \leq LV_x^r(y)$  for all  $x$  and  $y$ , then  $g$ , defined by  $g(x) := \nabla f(x)$  for all  $x$ , is  $L$ -relatively Lipschitz with respect to  $r$ .*

**Proof.** By assumption of relative smoothness of  $f$  and the definition of divergence,

$$\begin{aligned} L(V_z^r(w) + V_w^r(u)) &\geq V_z^f(w) + V_w^f(u) \\ &= f(w) - [f(z) + \nabla f(z)^\top (w - z)] + f(u) - [f(w) + \nabla f(w)^\top (u - w)] \\ &= V_z^f(u) - \nabla f(z)^\top (z - u) - \nabla f(z)^\top (w - z) + \nabla f(w)^\top (w - u) \\ &= V_z^f(u) + \langle g(w) - g(z), u - z \rangle. \end{aligned}$$

The result follows from the fact that  $V_z^f(u) \geq 0$  by convexity of  $f$ . ◀

We now give an analysis of Algorithm 1 showing the average “regret”  $\langle g(w_t), w_t - u \rangle$  of iterates decays at a  $O(T^{-1})$  rate. This strengthens Lemma 3.1 of [26].

► **Proposition 4.** *The iterates  $\{w_t\}$  of Algorithm 1 satisfy for all  $u \in \mathcal{Z}$ ,*

$$\sum_{0 \leq t < T} \langle g(w_t), w_t - u \rangle \leq \lambda V_{z_0}^r(u).$$

**Proof.** First-order optimality conditions of  $w_t, z_{t+1}$  with respect to  $u$  imply

$$\begin{aligned} \frac{1}{\lambda} \langle g(z_t), w_t - z_{t+1} \rangle &\leq V_{z_t}^r(z_{t+1}) - V_{w_t}^r(z_{t+1}) - V_{z_t}^r(w_t), \\ \frac{1}{\lambda} \langle g(w_t), z_{t+1} - u \rangle &\leq V_{z_t}^r(u) - V_{z_{t+1}}^r(u) - V_{z_t}^r(z_{t+1}). \end{aligned} \quad (3)$$

Adding and manipulating gives, via relative Lipschitzness (Definition 1),

$$\begin{aligned} \frac{1}{\lambda} \langle g(w_t), w_t - u \rangle &\leq V_{z_t}^r(u) - V_{z_{t+1}}^r(u) + \frac{1}{\lambda} \langle g(w_t) - g(z_t), w_t - z_{t+1} \rangle - V_{w_t}^r(z_{t+1}) - V_{z_t}^r(w_t) \\ &\leq V_{z_t}^r(u) - V_{z_{t+1}}^r(u). \end{aligned} \quad (4)$$

Finally, summing and telescoping (4) yields the desired conclusion.  $\blacktriangleleft$

We briefly comment on how to use Proposition 4 to approximately solve convex-concave games in a function  $f(x, y)$ . By applying convexity and concavity appropriately to the regret guarantee (and dividing by  $T$ , the iteration count), one can replace the left hand side of the guarantee with the duality gap of an average point  $\bar{w}$  against a point  $u$ , namely  $f(w^x, u^y) - f(u^x, w^y)$ . By maximizing the right hand side over  $u$ , this can be converted into an overall duality gap guarantee. For some of our applications in following sections,  $u$  will be some fixed point (rather than a best response) and the regret statement will be used in a more direct manner to prove guarantees.

## 4 Acceleration via relative Lipschitzness

We show that directly applying Algorithm 1 to the optimization problem (1) recovers an accelerated rate for first-order convex function minimization (for simplicity, we focus on the  $\ell_2$  norm here; our methods extend to general norms, discussed in the full version of the paper). Our main technical result, Lemma 5, shows the gradient operator of (1) is relatively Lipschitz in the natural regularizer induced by  $f$ , which combined with Proposition 4 gives our main result, Theorem 7. Crucially, our method regularizes the dual variable with  $f^*$ , the Fenchel dual of  $f$ , which we show admits efficient implementation, allowing us to obtain our improved bound on the relative Lipschitzness parameter.

► **Lemma 5** (Relative Lipschitzness for the Fenchel game). *Let  $f : \mathbb{R}^d \rightarrow \mathbb{R}$  be  $L$ -smooth and  $\mu$ -strongly convex in the Euclidean norm  $\|\cdot\|_2$ . Let  $g(x, y) = (y, \nabla f^*(y) - x)$  be the gradient operator of the convex-concave problem (1), and define the distance-generating function  $r(x, y) := \frac{\mu}{2} \|x\|_2^2 + f^*(y)$ . Then,  $g$  is  $1 + \sqrt{\frac{L}{\mu}}$ -relatively Lipschitz with respect to  $r$ .*

**Proof.** Consider three points  $z = (z^x, z^y)$ ,  $w = (w^x, w^y)$ ,  $u = (u^x, u^y)$ . By direct calculation,

$$\langle g(w) - g(z), w - u \rangle = \langle w^y - z^y, w^x - u^x \rangle + \langle -w^x + z^x + \nabla f^*(w^y) - \nabla f^*(z^y), w^y - u^y \rangle. \quad (5)$$

By Cauchy-Schwarz and  $L^{-1}$ -strong convexity of  $f^*$  respectively, we have

$$\begin{aligned} \langle w^y - z^y, w^x - u^x \rangle + \langle z^x - w^x, w^y - u^y \rangle &\leq \|w^y - z^y\|_2 \|w^x - u^x\|_2 + \|z^x - w^x\|_2 \|w^y - u^y\|_2 \\ &\leq \sqrt{\frac{L}{\mu}} \left( \frac{\mu}{2} \|w^x - z^x\|_2^2 + \frac{\mu}{2} \|w^x - u^x\|_2^2 + \frac{1}{2L} \|w^y - z^y\|_2^2 + \frac{1}{2L} \|w^y - u^y\|_2^2 \right) \\ &\leq \sqrt{\frac{L}{\mu}} (V_z^r(w) + V_w^r(u)). \end{aligned} \quad (6)$$

The second line used Young's inequality twice. Furthermore, by convexity of  $f^*$  from  $z^y$  to  $u^y$ ,

$$\begin{aligned}
& \langle \nabla f^*(w^y) - \nabla f^*(z^y), w^y - u^y \rangle \\
&= \langle \nabla f^*(z^y), u^y - z^y \rangle - \langle \nabla f^*(w^y), u^y - w^y \rangle - \langle \nabla f^*(z^y), w^y - z^y \rangle \\
&\leq f^*(u^y) - f^*(z^y) - \langle \nabla f^*(w^y), u^y - w^y \rangle - \langle \nabla f^*(z^y), w^y - z^y \rangle \\
&= V_{z^y}^{f^*}(w^y) + V_{w^y}^{f^*}(u^y) \leq V_z^r(w) + V_w^r(u).
\end{aligned} \tag{7}$$

The last inequality used separability of  $r$  and nonnegativity of divergences. Summing the bounds (6) and (7) and recalling (5) yields the conclusion, where we use Definition 1.  $\blacktriangleleft$

We also state a convenient fact about the form our iterates take.

► **Lemma 6.** *In the setting of Lemma 5, let  $z_t = (x_t, y_t)$ ,  $w_t = (x_{t+\frac{1}{2}}, y_{t+\frac{1}{2}})$  be iterates produced by running Algorithm 1 on the pair  $g, r$ . Suppose  $y_0 = \nabla f(v_0)$  for some  $v_0$ . Then,  $y_{t+\frac{1}{2}}$  and  $y_{t+1}$  can be recursively expressed as  $y_{t+\frac{1}{2}} = \nabla f(v_{t+\frac{1}{2}})$ ,  $y_{t+1} = \nabla f(v_{t+1})$ , for*

$$v_{t+\frac{1}{2}} \leftarrow v_t + \frac{1}{\lambda}(x_t - v_t), \quad v_{t+1} \leftarrow v_t + \frac{1}{\lambda}\left(x_{t+\frac{1}{2}} - v_{t+\frac{1}{2}}\right).$$

**Proof.** We prove this inductively; consider some iteration  $t$ . Assuming  $y_t = \nabla f(v_t)$ , by definition

$$\begin{aligned}
y_{t+\frac{1}{2}} &= \operatorname{argmin}_y \left\{ \left\langle \frac{1}{\lambda}(\nabla f^*(y_t) - x_t), y \right\rangle + V_{y_t}^{f^*}(y) \right\} \\
&= \operatorname{argmax}_y \left\{ \left\langle \frac{1}{\lambda}(x_t - v_t) + v_t, y \right\rangle - f^*(y) \right\} = \nabla f\left(v_t + \frac{1}{\lambda}(x_t - v_t)\right).
\end{aligned}$$

Here, we used standard facts about convex conjugates. A similar argument shows that we can compute implicitly  $y_{t+1} = \nabla f(v_t + \frac{1}{\lambda}(x_{t+\frac{1}{2}} - v_{t+\frac{1}{2}}))$ .  $\blacktriangleleft$

We now prove Theorem 7, i.e. that we can halve function error in  $O\left(\sqrt{\frac{L}{\mu}}\right)$  iterations of Algorithm 1. Simply iterating Theorem 7 yields a linear rate of convergence for smooth, strongly convex functions, yielding an  $\epsilon$ -approximate minimizer in  $O\left(\sqrt{\frac{L}{\mu}} \log \frac{f(x_0) - f(x^*)}{\epsilon}\right)$  iterations.

► **Theorem 7.** *In the setting of Lemma 5, run  $T \geq 4\lambda$  iterations of Algorithm 1 initialized at  $z_0 = (x_0, \nabla f(x_0))$  on the pair  $g, r$  with  $\lambda = 1 + \sqrt{\frac{L}{\mu}}$ , and define*

$$\bar{v} = \frac{1}{T} \sum_{0 \leq t < T} v_{t+\frac{1}{2}} \text{ where } w_t = \left(x_{t+\frac{1}{2}}, \nabla f(v_{t+\frac{1}{2}})\right).$$

*Then we have  $f(\bar{v}) - f(x^*) \leq \frac{1}{2}(f(x_0) - f(x^*))$ , where  $x^*$  minimizes  $f$ .*

**Proof.** First, we remark that this form of  $w_t$  follows from Lemma 6, and correctness of  $\lambda$  follows from Lemma 5. By an application of Proposition 4, letting  $u = (x^*, \nabla f(x^*))$ ,

$$\begin{aligned}
\frac{1}{T} \sum_{0 \leq t < T} \langle g(w_t), w_t - u \rangle &\leq \frac{\lambda}{T} \cdot V_{z_0}^r(u) \leq \frac{1}{4} \left( \frac{\mu}{2} \|x_0 - x^*\|_2^2 + V_{\nabla f(x_0)}^{f^*}(\nabla f(x^*)) \right) \\
&= \frac{1}{4} \left( \frac{\mu}{2} \|x_0 - x^*\|_2^2 + f(x_0) - f(x^*) \right) \leq \frac{1}{2} (f(x_0) - f(x^*)).
\end{aligned}$$

The second line used the definition of divergence in  $f^*$  and strong convexity of  $f$ , which implies  $f(x_0) \geq f(x^*) + \frac{\mu}{2} \|x_0 - x^*\|_2^2$ . Moreover, by the definition of  $g$  and  $\nabla f(x^*) = 0$ ,

$$\begin{aligned} \frac{1}{T} \sum_{0 \leq t < T} \langle g(w_t), w_t - u \rangle &= \frac{1}{T} \sum_{0 \leq t < T} \langle \nabla f(v_{t+\frac{1}{2}}), x_{t+\frac{1}{2}} - x^* \rangle + \langle v_{t+\frac{1}{2}} - x_{t+\frac{1}{2}}, \nabla f(v_{t+\frac{1}{2}}) \rangle \\ &\geq \frac{1}{T} \sum_{0 \leq t < T} f(v_{t+\frac{1}{2}}) - f(x^*) \geq f(\bar{v}) - f(x^*). \end{aligned}$$

The last line used convexity twice. Combining these two derivations yields the conclusion. ◀

For convenience, we state the full algorithm of Theorem 7 as Algorithm 2.

■ **Algorithm 2** EG-ACCEL( $x_0, \epsilon$ ): Extragradient accelerated smooth minimization.

**Input:**  $x_0 \in \mathbb{R}^d$ ,  $f$   $L$ -smooth and  $\mu$ -strongly convex in  $\|\cdot\|_2$ , and  $\epsilon_0 \geq f(x_0) - f(x^*)$

**Output:**  $\epsilon$ -approximate minimizer of  $f$

$\lambda \leftarrow 1 + \sqrt{L/\mu}$ ,  $x^{(0)} \leftarrow x_0$ ,  $T \leftarrow 4\lceil\lambda\rceil$ ,  $K \leftarrow \lceil\log_2 \frac{\epsilon_0}{\epsilon}\rceil$

**for**  $0 \leq k < K$  **do**

$x_0 \leftarrow x^{(k)}$ ,  $v_0 \leftarrow x_0$

**for**  $0 \leq t < T$  **do**

$x_{t+\frac{1}{2}} \leftarrow x_t - \frac{1}{\mu\lambda} \nabla f(v_t)$  and  $v_{t+\frac{1}{2}} \leftarrow v_t + \frac{1}{\lambda}(x_t - v_t)$

$x_{t+1} \leftarrow x_t - \frac{1}{\mu\lambda} \nabla f(v_{t+\frac{1}{2}})$  and  $v_{t+1} \leftarrow v_t + \frac{1}{\lambda}(x_{t+\frac{1}{2}} - v_{t+\frac{1}{2}})$

**end for**

$x^{(k+1)} \leftarrow \frac{1}{T} \sum_{0 \leq t < T} v_{t+\frac{1}{2}}$

**end for**

**return**  $x^{(K)}$

In the full version of the paper, we give an alternative proof of acceleration leveraging relative Lipschitzness, as well as a variant of extragradient methods suited for strongly monotone operators, by applying these tools to the saddle point problem (to be contrasted with (1))

$$\min_{x \in \mathbb{R}^d} f(x) = \min_{x \in \mathbb{R}^d} \max_{y \in \mathbb{R}^d} \frac{\mu}{2} \|x\|_2^2 + \langle y, x \rangle - h^*(y), \text{ where } h(x) := f(x) - \frac{\mu}{2} \|x\|_2^2.$$

This alternative proof strategy readily generalizes the accelerated rate of Theorem 7 to general norms. While the rates attained by this alternative method are slightly less sharp (losing a  $\frac{L}{\mu}$  factor in the logarithm) when compared to Theorem 7, the analysis is arguably simpler. This is in the sense that our alternative strategy shows a potential function decreases at a linear rate in every iteration, rather than requiring  $O(\sqrt{L/\mu})$  iterations to halve it.

## 5 Area convexity rates for box-simplex games via relative Lipschitzness

In this section, we show that a local variant of Definition 1 recovers the improved convergence rate achieved by [34] for box-constrained  $\ell_\infty$ -regression, and more generally box-simplex bilinear games. Specifically, we will use the following result, a simple extension to Proposition 4 which states that relative Lipschitzness only must hold with respect to triples of algorithm iterates.

► **Corollary 8.** *Suppose Algorithm 1 is run with a monotone operator  $g$  and a distance generating  $r$  satisfying, for all iterations  $t$ ,*

$$\langle g(w_t) - g(z_t), w_t - z_{t+1} \rangle \leq \lambda (V_{z_t}^r(w_t) + V_{w_t}(z_{t+1})). \quad (8)$$

*Then, the conclusion of Proposition 4 holds.*

**Proof.** Observe that the only applications of relative Lipschitzness in the proof of Proposition 4 are of the form (8) (namely, in (4)). Thus, the same conclusion still holds. ◀

We use Corollary 8 to give an alternative algorithm and analysis recovering the rates implied by the use of area convexity in [34], for box-simplex games, which we now define.

► **Definition 9 (Box-simplex game).** Let  $A \in \mathbb{R}^{m \times n}$  be a matrix and let  $b \in \mathbb{R}^m$ ,  $c \in \mathbb{R}^n$  be vectors. The associated box-simplex game, and its induced monotone operator  $g$ , are

$$\min_{x \in [-1, 1]^n} \max_{y \in \Delta^m} f(x, y) := y^\top Ax - \langle b, y \rangle + \langle c, x \rangle, \quad g(x, y) := (A^\top y + c, b - Ax). \quad (9)$$

Here,  $\Delta^m := \{y \in \mathbb{R}_{\geq 0}^m : \sum_{i \in [m]} y_i = 1\}$  is the nonnegative probability simplex in  $m$  dimensions.

By a simple reduction that at most doubles the size of the input (stacking  $A$ ,  $b$  with negated copies, cf. Section 3.1 of [35]), Definition 9 is a generalization of the box-constrained  $\ell_\infty$ -regression problem

$$\min_{x \in [-1, 1]^m} \|Ax - b\|_\infty.$$

The work of [34] proposed a variant of extragradient algorithms, based on taking primal-dual proximal steps in the following regularizer:<sup>3</sup>

$$r(x, y) := y^\top |A|(x^2) + 10 \|A\|_{\infty \rightarrow \infty} \sum_{i \in [m]} y_i \log y_i. \quad (10)$$

Here,  $|A|$  is the entrywise absolute value of  $A$ . The convergence rate of this algorithm was proven in [34] via an analysis based on “area convexity” of the pair  $(g, r)$ , which required a somewhat sophisticated proof based on solving a partial differential equation over a triangle. We now show that the same rate can be obtained by the extragradient algorithms of [26, 28], and analyzed via local relative Lipschitzness (8).<sup>4</sup> We first make the following simplification without loss of generality.

► **Lemma 10.** For all  $x \in [-1, 1]^n$  the value of  $\max_{y \in \Delta^m} f(x, y)$  in (9) is unchanged if we remove all coordinates of  $b$  with  $b_i \geq \min_{i^* \in [m]} b_{i^*} + 2 \|A\|_{\infty \rightarrow \infty}$ , and the corresponding rows of  $A$ . Therefore, in designing an algorithm to solve (9) to additive error with linear pre-processing it suffices to assume that  $b_i \in [0, 2 \|A\|_{\infty \rightarrow \infty}]$  for all  $i \in [m]$ .

**Proof.** For any  $x \in [-1, 1]^n$ , letting  $i^* \in \operatorname{argmin}_{i \in [m]} b_i$  we have

$$\max_{y \in \Delta^m} y^\top (Ax - b) = \max_{i \in [m]} [Ax - b]_i \geq -\|A\|_{\infty \rightarrow \infty} \|x\|_\infty - \min_{i^* \in [m]} b_i \geq -\|A\|_{\infty \rightarrow \infty} - b_{i^*}.$$

However,  $[Ax - b]_i \leq \|A\|_{\infty \rightarrow \infty} - b_i$  for all  $i \in [m]$ . Consequently, any coordinate  $i \in [m]$  that satisfies  $b_i \geq b_{i^*} + 2 \|A\|_{\infty \rightarrow \infty}$  has  $[Ax - b]_i \leq [Ax - b]_{i^*}$  and the value of  $\max_{y \in \Delta^m} f(x, y)$  is unchanged if this entry of  $b_i$  and the corresponding row of  $A$  is removed. Further, note that  $\langle y, \mathbf{1} \rangle$  is a constant for all  $y \in \Delta^m$ . Consequently, in linear time we can remove all the coordinates  $i$  with  $b_i \geq \min_{i^* \in [m]} b_{i^*} + 2 \|A\|_{\infty \rightarrow \infty}$  and shift all the coordinates by an additive constant so that the minimum coordinate of a remaining  $b_i$  is 0 without affecting additive error of any  $x$ . ◀

<sup>3</sup> We let  $\|A\|_{\infty \rightarrow \infty} := \sup_{\|x\|_\infty=1} \|Ax\|_\infty$ , i.e. the  $\ell_\infty$  operator norm of  $A$  or max  $\ell_1$  norm of any row.

<sup>4</sup> Although our analysis suffices to recover the rate of [34] for  $\ell_\infty$  regression, the analysis of [34] is in some sense more robust (and possibly) more broadly applicable than ours, as it does not need to reason directly about how much the iterates vary in a step. Understanding or closing this gap is an interesting open problem.

We now prove our main result regarding the use of mirror prox to solve box-simplex games, using the regularizer analyzed (with a slightly different algorithm) in [34].

► **Theorem 11.** *Assume the preprocessing of Lemma 10 so that  $b \in [0, 2\|A\|_{\infty \rightarrow \infty}]^m$ . Consider running Algorithm 1 on the operator in (9) with  $\lambda = 3$ , using the regularizer in (10). The resulting iterates satisfy (8), and thus satisfy the conclusion of Proposition 4.*

**Proof.** Fix a particular iteration  $t$ . We first claim that the simplex variables  $w_t^y$  and  $z_{t+1}^y$  obey the following multiplicative stability property: entrywise,

$$w_t^y, z_{t+1}^y \in \left[ \frac{1}{2} z_t^y, 2z_t^y \right]. \quad (11)$$

We will give the proof for  $w_t^y$  as the proof for  $z_{t+1}^y$  follows from the same reasoning. Recall that

$$w_t = \operatorname{argmin}_{w \in \Delta^n \times [-1, 1]^m} \left\{ \left\langle \frac{1}{\lambda} g(z_t), w \right\rangle + V_{z_t}^r(w) \right\},$$

and therefore, defining  $(x)^2$  and  $(z_t^x)^2$  as the entrywise square of these vectors,

$$w_t^y = \operatorname{argmin}_{y \in \Delta^m} \langle \gamma_t^y, y \rangle + 10 \|A\|_{\infty \rightarrow \infty} \sum_{i \in [m]} y_i \log \frac{y_i}{[z_t^y]_i}$$

$$\text{where } \gamma_t^y := \frac{1}{\lambda} (b - Az_t^x) + |A| \left[ (x)^2 - (z_t^x)^2 \right].$$

Consequently, applying log and exp entrywise we have

$$w_t^y \propto \exp \left( \log z_t^y - \frac{1}{10 \|A\|_{\infty \rightarrow \infty}} \gamma_t^y \right).$$

This implies the desired (11), where we use that  $\|\gamma_t^y\|_{\infty} \leq 3\|A\|_{\infty \rightarrow \infty}$ , and  $\exp(0.6) \leq 2$ . Next, we have by a straightforward calculation (Lemma 3.4, [34] or Lemma 6, [17]) that

$$\nabla^2 r(x, y) \succeq \begin{pmatrix} \mathbf{diag}(|A_{:,j}|^\top y) & 0 \\ 0 & \|A\|_{\infty \rightarrow \infty} \mathbf{diag}\left(\frac{1}{y_i}\right) \end{pmatrix}. \quad (12)$$

By expanding the definition of Bregman divergence, we have

$$V_{z_t}^r(w_t) = \int_0^1 \int_0^\alpha \|w_t - z_t\|_{\nabla^2 r(z_t + \beta(w_t - z_t))}^2 d\beta d\alpha.$$

Fix some  $\beta \in [0, 1]$ , and let  $z_\beta := z_t + \beta(w_t - z_t)$ . Since the coordinates of  $z_\beta$  also satisfy the stability property (11), by the lower bound of (12), we have

$$\begin{aligned} \|w_t - z_t\|_{\nabla^2 r(z_\beta)}^2 &\geq \sum_{i \in [m], j \in [n]} |A_{ij}| \left( [z_\beta^y]_i [w_t^x - z_t^x]_j^2 + \frac{1}{[z_\beta^y]_i} [w_t^y - z_t^y]_i^2 \right) \\ &\geq \frac{1}{2} \sum_{i \in [m], j \in [n]} |A_{ij}| \left( [z_t^y]_i [w_t^x - z_t^x]_j^2 + \frac{1}{[z_t^y]_i} [w_t^y - z_t^y]_i^2 \right). \end{aligned}$$

By using a similar calculation to lower bound  $V_{w_t}^r(z_{t+1})$ , we have by Young's inequality the desired

$$\begin{aligned}
V_{z_t}^r(w_t) + V_{w_t}^r(z_{t+1}) &\geq \frac{1}{4} \sum_{i \in [m], j \in [n]} |A_{ij}| \left( [z_t^y]_i [w_t^x - z_t^x]_j^2 + \frac{1}{[z_t^y]_i} [w_t^y - z_t^y]_i^2 \right) \\
&\quad + \frac{1}{4} \sum_{i \in [m], j \in [n]} |A_{ij}| \left( [z_t^y]_i [w_t^x - z_{t+1}^x]_j^2 + \frac{1}{[z_t^y]_i} [w_t^y - z_{t+1}^y]_i^2 \right) \\
&\geq \frac{1}{3} \sum_{i \in [m], j \in [n]} A_{ij} ([w_t^y - z_t^y]_i [w_t^x - z_{t+1}^x]_j - [w_t^y - z_{t+1}^y]_i [w_t^x - z_t^x]_j) \\
&= \frac{1}{\lambda} \langle g(w_t) - g(z_t), w_t - z_{t+1} \rangle. \quad \blacktriangleleft
\end{aligned}$$

The range of the regularizer  $r$  is bounded by  $O(\|A\|_{\infty \rightarrow \infty} \log m)$ , and hence the iteration complexity to find an  $\epsilon$  additively-approximate solution to the box-simplex game is  $O(\frac{\|A\|_{\infty \rightarrow \infty} \log m}{\epsilon})$ . Finally, we comment that the iteration complexity of solving the subproblems required by extragradient methods in the regularizer  $r$  to sufficiently high accuracy is logarithmically bounded in problem parameters via a simple alternating minimization scheme proposed by [34]. Here, we note that the error guarantee e.g. Proposition 4 is robust up to constant factors to solving each subproblem to  $\epsilon$  additive accuracy, and appropriately using approximate optimality conditions (for an example of this straightforward extension, see Corollary 1 of [17]).

## 6 Randomized coordinate acceleration via expected relative Lipschitzness

We show relative Lipschitzness can compose with randomization. Specifically, we adapt Algorithm 2 to coordinate smoothness, recovering the accelerated rate first obtained in [5, 29]. We recall  $f$  is  $L_i$ -coordinate-smooth if its coordinate restriction is smooth, i.e.  $|\nabla_i f(x + ce_i) - \nabla_i f(x)| \leq L_i |c| \forall x \in \mathcal{X}, c \in \mathbb{R}$ ; for twice-differentiable coordinate smooth  $f$ ,  $\nabla_{ii}^2 f(x) \leq L_i$ .

Along the way, we build a framework for randomized extragradient methods via “local variance reduction” in Proposition 12. In particular, we demonstrate how for separable domains our technique can yield  $O(T^{-1})$  rates for stochastic extragradient algorithms, bypassing a variance barrier encountered by prior methods [19]. Throughout, let  $f : \mathbb{R}^d \rightarrow \mathbb{R}$  be  $L_i$ -smooth in coordinate  $i$ , and  $\mu$ -strongly convex in  $\|\cdot\|_2$ , and define the distance generating function  $r(x, y) = \frac{\mu}{2} \|x\|_2^2 + f^*(y)$ .

Our approach modifies that of Section 4 in the following ways. First, our iterates are defined via stochastic estimators which “share randomness” (use the same coordinate in both updates). Concretely, fix some iterate  $z_t = (x_t, \nabla f(v_t))$ . For a distribution  $\{p_i\}_{i \in [d]}$ , sample  $i \sim p_i$  and let

$$\begin{aligned}
g_i(z_t) &:= \left( \frac{1}{p_i} \nabla_i f(v_t), v_t - x_t \right), \quad w_t^{(i)} = \left( x_{t+\frac{1}{2}}^{(i)}, \nabla f(v_{t+\frac{1}{2}}) \right) := \text{Prox}_{z_t}^r \left( \frac{1}{\lambda} g_i(z_t) \right), \\
g_i(w_t^{(i)}) &:= \left( \frac{1}{p_i} \nabla_i f(v_{t+\frac{1}{2}}), v_{t+\frac{1}{2}} - \left( x_t + \frac{1}{p_i} \Delta_t^{(i)} \right) \right) \text{ for } \Delta_t^{(i)} := x_{t+\frac{1}{2}}^{(i)} - x_t, \\
z_{t+1}^{(i)} &= \left( x_{t+1}^{(i)}, \nabla f(v_{t+1}) \right) := \text{Prox}_{z_t}^r \left( \frac{1}{\lambda} g_i(w_t^{(i)}) \right).
\end{aligned} \tag{13}$$

By observation,  $g_i(z_t)$  is unbiased for  $g(z_t)$ ; however, the same cannot be said for  $g_i(w_t^{(i)})$ , as the random coordinate was used in the definition of  $w_t^{(i)}$ . Nonetheless, examining the proof of Proposition 4, we see that the conclusion

$$\langle g(\bar{w}_t), \bar{w}_t - u \rangle \leq V_{z_t}^r(u) - \mathbb{E} \left[ V_{z_{t+1}^{(i)}}^r(u) \right]$$

still holds for some point  $\bar{w}_t$ , as long as

$$\begin{aligned} \mathbb{E} \left[ \langle g_i(w_t^{(i)}), w_t^{(i)} - u \rangle \right] &= \langle g(\bar{w}_t), \bar{w}_t - u \rangle, \\ \mathbb{E} \left[ \langle g_i(w_t^{(i)}) - g_i(z_t), w_t^{(i)} - z_{t+1}^{(i)} \rangle \right] &\leq \lambda \mathbb{E} \left[ V_{z_t}^r(w_t^{(i)}) + V_{w_t^{(i)}}^r(z_{t+1}^{(i)}) \right]. \end{aligned} \quad (14)$$

We make this concrete in the following claim, a generalization of Proposition 4 which handles randomized operator estimates as well as an expected variant of relative Lipschitzness. We remark that as in Corollary 8, the second condition in (14) only requires relative Lipschitzness to hold for the iterates of the algorithm, rather than globally.

► **Proposition 12.** *Suppose in every iteration of Algorithm 1, steps are conducted with respect to randomized gradient operators  $\{g_i(z_t), g_i(w_t^{(i)})\}$  satisfying (14) for some  $\{\bar{w}_t\}$ . Then, for all  $u \in \mathcal{Z}$ ,*

$$\mathbb{E} \left[ \sum_{0 \leq t < T} \langle g(\bar{w}_t), \bar{w}_t - u \rangle \right] \leq \lambda V_{z_0}^r(u).$$

**Proof.** The proof follows identically to that of Proposition 4, where we iterate taking expectations over (4), each time applying the two conditions in (14). ◀

For the rest of this section, we overload  $g_i$  to mean the choices used in (13). This choice is motivated via the following two properties, required by (14).

► **Lemma 13.** *Let  $\bar{w}_t := (x_t + \sum_{i \in [d]} \Delta_t^{(i)}, \nabla f(v_{t+\frac{1}{2}}))$ . Then  $\forall u$ , taking expectations over iteration  $t$ ,*

$$\mathbb{E} \left[ \langle g_i(w_t^{(i)}), w_t^{(i)} - u \rangle \right] = \langle g(\bar{w}_t), \bar{w}_t - u \rangle.$$

**Proof.** Note  $v_{t+\frac{1}{2}}$  is deterministic regardless of the sampled  $i \in [d]$ . Expanding for  $u = (u^x, u^y)$ ,

$$\begin{aligned} \mathbb{E} \left[ \langle g_i(w_t^{(i)}), w_t^{(i)} - u \rangle \right] &= \sum_{i \in [d]} p_i \left( \left\langle \frac{1}{p_i} \nabla_i f(v_{t+\frac{1}{2}}), x_{t+\frac{1}{2}}^{(i)} - u^x \right\rangle \right. \\ &\quad \left. + \left\langle v_{t+\frac{1}{2}} - \left( x_t + \frac{1}{p_i} \Delta_t^{(i)} \right), y_{t+\frac{1}{2}} - u^y \right\rangle \right) \\ &= \langle g(\bar{w}_t), \bar{w}_t - u \rangle. \end{aligned}$$

Here, we used the fact that  $\nabla_i f(v_{t+\frac{1}{2}})$  is 1-sparse. ◀

► **Lemma 14** (Expected relative Lipschitzness). *Let  $\lambda = 1 + S_{1/2}/\sqrt{\mu}$ , where  $S_{1/2} := \sum_{i \in [d]} \sqrt{L_i}$ . Then, for the iterates (13) with  $p_i = \sqrt{L_i}/S_{1/2}$ , taking expectations over iteration  $t$ ,*

$$\mathbb{E} \left[ \langle g_i(w_t^{(i)}) - g_i(z_t), w_t^{(i)} - z_{t+1}^{(i)} \rangle \right] \leq \lambda \mathbb{E} \left[ V_{z_t}^r(w_t^{(i)}) + V_{w_t^{(i)}}^r(z_{t+1}^{(i)}) \right].$$

**Proof.** Equivalently, we wish to show that

$$\mathbb{E} \left[ \left\langle g_i(w_t^{(i)}) - g_i(z_t), w_t^{(i)} - z_{t+1}^{(i)} \right\rangle \right] \leq \left( 1 + \frac{S_{1/2}}{\sqrt{\mu}} \right) \mathbb{E} \left[ V_{z_t}^r(w_t^{(i)}) + V_{w_t^{(i)}}^r(z_{t+1}^{(i)}) \right].$$

The proof is patterned from Lemma 5. By direct calculation, the left hand side is

$$\begin{aligned} & \mathbb{E} \left[ \left\langle g_i(w_t^{(i)}) - g_i(z_t), w_t^{(i)} - z_{t+1}^{(i)} \right\rangle \right] \\ &= \sum_{i \in [d]} p_i \left( \frac{1}{p_i} \left\langle \nabla_i f(v_{t+\frac{1}{2}}) - \nabla_i f(v_t), x_{t+\frac{1}{2}}^{(i)} - x_{t+1}^{(i)} \right\rangle \right. \\ & \quad \left. + \frac{1}{p_i} \left\langle x_t - x_{t+\frac{1}{2}}^{(i)}, \nabla_i f(v_{t+\frac{1}{2}}) - \nabla_i f(v_{t+1}^{(i)}) \right\rangle \right) \\ & \quad + \sum_{i \in [d]} p_i \left\langle v_{t+\frac{1}{2}} - v_t, \nabla f(v_{t+\frac{1}{2}}) - \nabla f(v_{t+1}^{(i)}) \right\rangle. \end{aligned} \tag{15}$$

We first bound the second and third lines of (15):

$$\begin{aligned} & \frac{1}{p_i} \left( \left\langle \nabla_i f(v_{t+\frac{1}{2}}) - \nabla_i f(v_t), x_{t+\frac{1}{2}}^{(i)} - x_{t+1}^{(i)} \right\rangle + \left\langle x_t - x_{t+\frac{1}{2}}^{(i)}, \nabla_i f(v_{t+\frac{1}{2}}) - \nabla_i f(v_{t+1}^{(i)}) \right\rangle \right) \\ & \leq \frac{S_{1/2}}{\sqrt{\mu}} \left( \frac{\mu}{2} \left\| x_{t+\frac{1}{2}}^{(i)} - x_{t+1}^{(i)} \right\|_2^2 + \frac{1}{2L_i} \left\| \nabla_i f(v_{t+\frac{1}{2}}) - \nabla_i f(v_{t+1}^{(i)}) \right\|_2^2 \right. \\ & \quad \left. + \frac{\mu}{2} \left\| x_t - x_{t+\frac{1}{2}}^{(i)} \right\|_2^2 + \frac{1}{2L_i} \left\| \nabla_i f(v_{t+\frac{1}{2}}) - \nabla_i f(v_t) \right\|_2^2 \right) \\ & \leq \frac{S_{1/2}}{\sqrt{\mu}} \left( V_{z_t}^r(w_t^{(i)}) + V_{w_t^{(i)}}^r(z_{t+1}^{(i)}) \right). \end{aligned} \tag{16}$$

The first inequality used the definition  $p_i = \sqrt{L_i/S_{1/2}}$  and Cauchy-Schwarz, and the second used strong convexity and Lemma 13 of the full version of the paper. Next, we bound the fourth line of (15):

$$\begin{aligned} & \left\langle v_{t+\frac{1}{2}} - v_t, \nabla f(v_{t+\frac{1}{2}}) - \mathbb{E} \left[ \nabla f(v_{t+1}^{(i)}) \right] \right\rangle \\ & \leq V_{\nabla f(v_t)}^{f*} \left( \nabla f(v_{t+\frac{1}{2}}) \right) + V_{\nabla f(v_{t+\frac{1}{2}})}^{f*} \left( \mathbb{E} \left[ \nabla f(v_{t+1}^{(i)}) \right] \right) \\ & \leq V_{\nabla f(v_t)}^{f*} \left( \nabla f(v_{t+\frac{1}{2}}) \right) + \mathbb{E} \left[ V_{\nabla f(v_{t+\frac{1}{2}})}^{f*} \left( \nabla f(v_{t+1}^{(i)}) \right) \right] \\ & \leq \mathbb{E} \left[ V_{z_t}^r(w_t^{(i)}) + V_{w_t^{(i)}}^r(z_{t+1}^{(i)}) \right]. \end{aligned}$$

The first inequality is (7), the second is convexity of Bregman divergence, and the third used nonnegativity of  $\frac{\mu}{2} \|\cdot\|_2^2$ . Combining with an expectation over (16) yields the claim.  $\blacktriangleleft$

Crucially, our proof of these results uses the fact that our randomized gradient estimators are 1-sparse in the  $x$  component, and the fact that we “shared randomness” in the definition of the gradient estimators. Moreover, our iterates are efficiently implementable, under the “generalized partial derivative oracle” of prior work [20, 5, 29], which computes  $\nabla_i f(ax + by)$  for  $x, y \in \mathbb{R}^d$  and  $a, b \in \mathbb{R}$ . In many settings of interest, these oracles can be implemented with a dimension-independent runtime; we defer a discussion to previous references.

► **Lemma 15** (Iterate maintenance). *We can implement each iteration of Algorithm 3 using two generalized partial derivative oracle queries and constant additional work.*

We defer a formal statement to the full version of the paper. Combining Lemma 13 and Lemma 14, (14) is satisfied with  $\lambda = 1 + S_{1/2}/\sqrt{\mu}$ . Finally, all of these pieces directly imply the following, via the proof of Theorem 7 and iterating expectations. We give our full method as Algorithm 3.

► **Theorem 16** (Coordinate acceleration). *Algorithm 3 produces an  $\epsilon$ -approximate minimizer of  $f$  in*

$$O\left(\sum_{i \in [d]} \sqrt{\frac{L_i}{\mu}} \log\left(\frac{f(x_0) - f(x^*)}{\epsilon}\right)\right) \text{ iterations in expectation,}$$

with iteration complexity given by Lemma 15.

**Proof.** This follows from the proof of Theorem 7, using Proposition 12 in place of Proposition 4. ◀

■ **Algorithm 3** EG-COORD-ACCEL( $x_0, \epsilon$ ): Extragradient accelerated coordinate minimization.

**Input:**  $x_0 \in \mathbb{R}^d$ ,  $f$   $\{L_i\}_{i \in [d]}$ -coordinate smooth and  $\mu$ -s.c. in  $\|\cdot\|_2$ , and  $\epsilon_0 \geq f(x_0) - f(x^*)$

$$\lambda \leftarrow 1 + \sum_{i \in [d]} \sqrt{L_i/\mu}, T \leftarrow 4\lceil\lambda\rceil, K \leftarrow \lceil\log_2 \frac{\epsilon_0}{\epsilon}\rceil, \mathbf{A} \leftarrow \begin{pmatrix} 1 & \frac{1}{\kappa} - \frac{1}{\kappa^2} \\ 0 & 1 - \frac{1}{\kappa} + \frac{1}{\kappa^2} \end{pmatrix}$$

$p_0 \leftarrow x_0, q_0 \leftarrow x_0, \mathbf{B}_0 \leftarrow \mathbf{I}_{2 \times 2}$

**for**  $0 \leq k < K$  **do**

    Sample  $\tau$  uniformly in  $[0, T - 1]$

**for**  $0 \leq t < \tau$  **do**

        Sample  $i \propto \sqrt{L_i}$

        Compute  $\nabla_i f(v_t), \nabla_i f((1 - \lambda^{-1})v_t + \lambda^{-1}x_t)$  via generalized partial derivative oracle

$$s_t \leftarrow \left( \frac{1}{\mu\lambda p_i} \nabla_i f((1 - \lambda^{-1})v_t + \lambda^{-1}x_t) \quad \frac{1}{\mu\lambda^2 p_i^2} \nabla_i f(v_t) \right)$$

$$\mathbf{B}_{t+1} \leftarrow \mathbf{B}_t \mathbf{A}, (p_{t+1} \quad q_{t+1}) \leftarrow (p_t \quad q_t) - s_t \mathbf{B}_{t+1}^{-1}$$

**end for**

$$\mathbf{B}_0 \leftarrow \begin{pmatrix} [\mathbf{B}_\tau]_{12} & [\mathbf{B}_\tau]_{12} \\ [\mathbf{B}_\tau]_{22} & [\mathbf{B}_\tau]_{22} \end{pmatrix}, p_0 \leftarrow p_\tau, q_0 \leftarrow q_\tau$$

**end for**

**return**  $[\mathbf{B}_\tau]_{12} p_\tau + [\mathbf{B}_\tau]_{22} q_\tau$

## 7 Discussion

We give a general condition for extragradient algorithms to converge at a  $O(T^{-1})$  rate. In turn, we show that this condition (coupled with additional tools such as locality, randomization, or strong monotonicity) yields a recipe for tighter convergence guarantees in structured instances. While our condition applies generally, we find it interesting to broaden the types of instances where it obtains improved runtimes by formulating appropriate VI problems. For example, can we recover acceleration in settings such as finite-sum convex optimization (i.e. for stochastic gradient methods) [3] or composite optimization [7]? Moreover, we are interested in the interplay between (tighter analyses of) extragradient algorithms with other algorithmic frameworks. For example, is there a way to interpolate between our minimax algorithm and the momentum-based framework of [21] to obtain tight runtimes for minimax optimization? Ultimately, our hope is that our methods serve as an important stepping stone towards developing the toolkit for solving e.g. convex-concave games and variational inequalities in general.

## Abstract

The slow convergence rate and pathological curvature issues of first-order gradient methods for training deep neural networks, initiated an ongoing effort for developing faster *second-order* optimization algorithms beyond SGD, without compromising the generalization error. Despite their remarkable convergence rate (*independent* of the training batch size  $n$ ), second-order algorithms incur a daunting slowdown in the *cost per iteration* (inverting the Hessian matrix of the loss function), which renders them impractical. Very recently, this computational overhead was mitigated by the works of [79, 23], yielding an  $O(mn^2)$ -time second-order algorithm for training two-layer overparametrized neural networks of polynomial width  $m$ .

We show how to speed up the algorithm of [23], achieving an  $\tilde{O}(mn)$ -time backpropagation algorithm for training (mildly overparametrized) ReLU networks, which is near-linear in the dimension  $(mn)$  of the full gradient (Jacobian) matrix. The centerpiece of our algorithm is to reformulate the Gauss-Newton iteration as an  $\ell_2$ -regression problem, and then use a Fast-JL type dimension reduction to *precondition* the underlying Gram matrix in time independent of  $M$ , allowing to find a sufficiently good approximate solution via *first-order* conjugate gradient. Our result provides a proof-of-concept that advanced machinery from randomized linear algebra – which led to recent breakthroughs in *convex optimization* (ERM, LPs, Regression) – can be carried over to the realm of deep learning as well.

## 1 Introduction

Understanding the dynamics of gradient-based optimization of deep neural networks has been a central focal point of theoretical machine learning in recent years [49, 81, 80, 48, 31, 4, 5, 3, 13, 58, 9, 67, 27, 39, 22]. This line of work led to a remarkable rigorous understanding of the generalization, robustness and convergence rate of *first-order* (SGD-based) algorithms, which are the standard choice for training DNNs. By contrast, the *computational complexity* of implementing gradient-based training algorithms (e.g., backpropagation) in such non-convex landscape is less understood, and gained traction only recently due to the overwhelming size of training data and complexity of network design [55, 32, 51, 23, 79].

The widespread use first-order methods such as (stochastic) gradient descent in training DNNs is explained, to a large extent, by its computational efficiency – recalculating the gradient of the loss function at each iteration is simple and cheap (linear in the dimension of the full gradient), let alone with the advent of minibatch random sampling [37, 23]. Nevertheless, first-order methods have a slow rate of convergence in non-convex settings (typically  $\Omega(\text{poly}(n) \log(1/\epsilon))$  for overparametrized networks, see e.g., [79]) for reducing the training error below  $\epsilon$ , and it is increasingly clear that SGD-based algorithms are becoming a real bottleneck for many practical purposes. This drawback initiated a substantial effort for developing fast training methods beyond SGD, aiming to improve its convergence rate without compromising the generalization error [16, 53, 55, 32, 44, 59, 23, 79].

Second-order gradient algorithms (which employ information about the Hessian of the loss function), pose an intriguing computational tradeoff in this context: On one hand, they are known to converge extremely fast, at a rate *independent* of the input size (i.e., only  $O(\log 1/\epsilon)$  iterations [79]), and offer a qualitative advantage in overcoming pathological curvature issues that arise in first-order methods, by exploiting the local geometry of the loss function. This feature implies another practical advantage of second order methods, namely, that they do not require tuning the learning rate [23, 79]. On the other hand, second-order methods have a prohibitive *cost per iteration*, as they involve *inverting* a dynamically-changing dense Hessian matrix. This drawback explains the scarcity of second order methods in *large scale non-convex* optimization, in contrast to its popularity in the convex setting.

The recent works of [23, 79] addressed the computational bottleneck of second-order algorithms in optimizing deep neural nets, and presented a training algorithm for overparametrized neural networks with smooth (resp. ReLU) activations, whose running time is  $O(mn^2)$ , where  $m$  is the width of the neural network, and  $n$  is the size of the training data in  $\mathbb{R}^d$ . The two algorithms, which achieve essentially the same running time, are based on the classic Gauss-Newton algorithm (resp. “Natural gradient” algorithm) combined with the recent introduction of *Neural Tangent Kernels* (NTK) [38]. The NTK formulation utilizes a local-linearization of the loss function for overparametrized neural networks, which reduces the optimization problem of DNNs to that of a *kernel regression* problem: The main insight is that when the network is *overparametrized*, i.e., sufficiently wide  $m \gtrsim n^4$  ([67]), the neural network becomes locally convex and smooth, hence the problem is equivalent to a kernel regression problem with respect to the NTK function [38], and therefore solving the latter via (S)GD is guaranteed to converge to a global minimum. The training algorithm of [23] draws upon this equivalence, by designing a second-order variation of the Gauss-Newton algorithm (termed “Gram-Gauss-Newton”), yielding the aforementioned runtime for *smooth activation functions*.

**Single vs. Multilayer Network Training.** Following [23, 79], we focus on two-layer (i.e., single hidden-layer) neural networks. While our algorithm extends to the multilayer case (with a slight compromise on the width dependence), we argue that, as far as training time,

the two-layer case is not only the common case, but in fact the *only* interesting case for constant training error: Indeed, in the multilayer case ( $L \geq 2$ ), we claim that the mere cost of *feed-forward* computation of the network's output is already  $\Omega_\epsilon(m^2 n L)$ . Indeed, the total number of parameters of  $L$ -layer networks is  $M = (L - 1)m^2 + md$ , and as such, feed-forward computation requires, at the very least, computing a single product of  $m \times m$  (dense) matrices  $W$  with a  $m \times 1$  vector for each training data, which already costs  $m^2 n$  time:

$$\hat{y}_i = a^\top \sigma_L \left( \underbrace{W_L}_{m \times m} \sigma_{L-1} \left( \underbrace{W_{L-1}}_{m \times m} \dots \sigma_1 \left( \underbrace{W_1}_{m \times d} x_i \right) \right) \right).$$

Therefore, sublinear-time techniques (as we present) appear futile in the case of multilayer overparametrized networks, where it is possible to achieve linear time (in  $M$ ) using essentially direct (lossless) computation (see next subsection). It may still be possible to use sublinear algorithms to improve the running time to  $O(m^2 n L + \text{poly}(n))$ , though in for overparametrized DNNs this seems a minor saving.

## 1.1 Our Result

Our main result is a quadratic speedup to the algorithm of [23], yielding an *essentially optimal* training algorithm for overparametrized two-layer neural networks. Moreover, in contrast to [23], our algorithm applies to the more complex and realistic case of *ReLU* activation functions. Our main result is shown below (For a more comprehensive comparison, see Table 1 below and references therein).

► **Theorem 1.** *Suppose the width of a two layer ReLU neural network satisfies*

$$m = \Omega(\max\{\lambda^{-4} n^4, \lambda^{-2} n^2 d \log(n/\delta)\}),$$

where  $\lambda > 0$  denotes the minimum eigenvalue of the Gram matrix (see Eq. (5) below),  $n$  is the number of training data,  $d$  is the input dimension. Then with probability  $1 - \delta$  over the random initialization of neural network and the randomness of the training algorithm, our algorithm achieves

$$\|f_{t+1} - y\|_2 \leq \frac{1}{2} \|f_t - y\|_2.$$

The computational cost of each iteration is  $\tilde{O}(mnd + n^3)$ , and the running time for reducing the training loss to  $\epsilon$  is  $\tilde{O}((mnd + n^3) \log(1/\epsilon))$ . Using fast matrix-multiplication, the total running time can be further reduced to  $\tilde{O}((mnd + n^\omega) \log(1/\epsilon))$ .<sup>1</sup>

► **Remark 2.** We stress that that our algorithm runs in (near) linear time even for networks with width  $m \gtrsim n^2$  and in fact, under the common belief that  $\omega = 2$ , this is true so long as  $m \gtrsim n$  (!). This means that the bottleneck for linear-time training of *small-width* DNNs is *not computational*, but rather *analytic*: The overparametrization requirements ( $m \gtrsim n^4$ ) in Theorem 1 stems from current-best analysis of the convergence guarantees of (S)GD-based training of ReLU networks, and any improvement on these bounds would directly yield linear-time training for thinner networks using our algorithm.

<sup>1</sup> Here,  $\omega < 2.373$  denotes the fast matrix-multiplication (FMM) constant for multiplying two  $n \times n$  matrices [73, 46].

■ **Table 1** Summary of state-of-art algorithms for training two-layer neural networks.  $n$  denotes the training batch size (number of input data points in  $\mathbb{R}^d$ ) and  $\epsilon$  denote the desired accuracy of the training loss. For simplicity, here we assume  $d = O(1)$  and omit  $\text{poly}(\log n, 1/\lambda)$  terms. The result of [23] applies only to smooth activation gates and not to ReLU networks. Comparison to SGD algorithms is omitted from this table since they require a much stronger assumption on the width  $m$  for convergence, and have slower convergence rate than GD [48, 4, 5].

Ref.	Method	#Iters	Cost/iter	Width	ReLU?

**Techniques.** The majority of ML optimization literature on overparametrized network training is dedicated to understanding and minimizing the *number of iterations* of the training process [79, 23] as opposed to the *cost per iteration*, which is the focus of our paper. Our work shows that it is possible to harness the toolbox of *randomized linear algebra* – which was heavily used in the past decade to reduce the cost of *convex optimization* tasks – in the nonconvex setting of deep learning as well. A key ingredient in our algorithm is *linear sketching*, where the main idea is to carefully *compress* a linear system underlying an optimization problem, in a way that preserves a good enough solution to the problem yet can be solved much faster in lower dimension. This is the essence of the celebrated *Sketch-and-Solve* (S&S) paradigm [24]. As we explain below, our main *departure* from the classic S&S framework (e.g., [59]) is that we cannot afford to directly solve the underlying compressed regression problem (as this approach turns out to be prohibitively slow for our application). Instead, we use sketching (or sampling) to facilitate *fast preconditioning* of linear systems (in the spirit of [68, 43, 62, 74]), which in turn enables to solve the compressed regression problem to very high accuracy via first-order *conjugate* gradient descent. This approach essentially *decouples* the sketching error from the final precision error of the Gauss-Newton step, enabling a much smaller sketch size. We believe this (somewhat unconventional) approach to non-convex optimization is the most enduring message of our work.

## 1.2 Related Work

**Second-order methods in non-convex optimization.** Despite the prevalence of first order methods in deep learning applications, there is a vast body of ongoing work [18, 17, 55, 35, 36, 23, 79] aiming to design more scalable second-order algorithms that overcome the limitations of (S)GD for optimizing deep models. Grosse and Martens [55, 35] designed the K-FAC method, where the idea is to use Kronecker-factors to approximate the Fisher information matrix, combined with natural gradient descent. This approach has been further explored and extended by [78, 34, 54]. Gupta et al. [36] designed the “Shampoo method”, based on the idea of *structure-aware preconditioning*. Anil et al. [7] further validate the practical performance of Shampoo and incorporated it into hardware. However, despite sporadic empirical evidence of such second-order methods (e.g., K-FAC and Shampoo), these methods generally lack a provable theoretical guarantee on the performance when applied to deep neural networks. Furthermore, in the overparametrized setting, their cost per-iteration in general is at least  $\Omega(mn^2)$ .

We remark that in the *convex* setting, theoretical guarantees for large-scale second-order algorithms have been established (e.g., [1, 59, 56, 21]), but such rigorous analysis in non-convex setting was only recently proposed ([23, 79]). Our algorithm bears some similarities to the *NewtonSketch* algorithm of [59], which also incorporates sketching into second order Newton methods. A key difference, however, is that the algorithm of [59] works only for convex problems, and requires access to  $(\nabla^2 f(x))^{1/2}$  (i.e., the square-root of the Hessian). Most importantly, though, [59] use the standard (black-box) Sketch-and-Solve paradigm to reduce the computational cost, while this approach incurs large computation overhead in our non-convex setting. By contrast, we use sketching as a subroutine for fast preconditioning. As a by-product, in the full version of this paper we show how to apply our techniques to give a substantial improvement over [59] in the *convex* setting.

The aforementioned works of [79] and [23] are most similar in spirit to ours. Zhang et al. [79] analyzed the convergence rate of Natural gradient descent algorithms for two-layer (overparametrized) neural networks, and showed that the number of iterations is *independent* of the training data size  $n$  (essentially  $\log(1/\epsilon)$ ). They also demonstrate similar results for the convergence rate of K-FAC in the overparametrized regime, albeit with larger requirement on the width  $m$ . Another downside of K-FAC is the high cost per iteration ( $\sim mn^2$ ). Cai et al. [23] analyzed the convergence rate of the so-called Gram-Gauss-Newton algorithm for training two-layer (overparametrized) neural network with *smooth* activation gates. They proved a quadratic (i.e., doubly-logarithmic) convergence rate in this setting ( $\log(\log(1/\epsilon))$ ) albeit with  $O(mn^2)$  cost per iteration. It is noteworthy that this quadratic convergence rate analysis does not readily extend to the more complex and realistic setting of ReLU activation gates, which is the focus of our work. [23] also prove bounds on the convergence of “batch GGN”, showing that it is possible to reduce the cost-per-iteration to  $m$ , at the price of  $O(n^2 \log(1/\epsilon))$  iterations, for very heavily overparametrized DNNs (currently  $m = \Omega(n^{18})$ ).

**Sketching.** The celebrated “Sketch and Solve” (S&S) paradigm [24] was originally developed to speed up the cost of solving linear regression and low-rank approximation problems. This dimensionality-reduction technique has since then been widely developed and applied to both convex and non-convex numerical linear algebra problems [20, 61, 76, 6, 14, 12, 72, 28, 65, 64, 15], as well as machine-learning applications [10, 11, 50, 75]. The most direct application of the sketch-and-solve technique is overconstrained regression problems, where the input is a linear system  $[A, b] \in \mathbb{R}^{n \times (d+1)}$  with  $n \gg d$ , and we aim to find an (approximate) solution  $\hat{x} \in \mathbb{R}^d$  so as to minimize the residual error  $\|A\hat{x} - b\|_2$ .

In the classic S&S paradigm, the underlying regression solver is treated as a *black box*, and the computational savings comes from applying it on a smaller *compressed* matrix. Since then, sketching (or sampling) has also been used in a non-black-box fashion for speeding-up optimization tasks, e.g., as a subroutine for preconditioning [74, 62, 68, 43] or fast inverse-maintenance in Linear Programming solvers, semi-definite programming, cutting plane methods, and empirical-risk minimization [25, 42, 40, 41, 47].

**Overparametrization in neural networks.** A long and active line of work in recent deep learning literature has focused on obtaining rigorous bounds on the convergence rate of various local-search algorithms for optimizing DNNs [48, 31, 4, 5, 8, 9, 67, 39]. The breakthrough work of Jacob et al. [38] and subsequent developments<sup>2</sup> introduced the notion of *neural tangent kernels* (NTK), implying that for wide enough networks ( $m \gtrsim n^4$ ), (stochastic) gradient descent provably converges to an optimal solution, with generalization error independent of the number of network parameters.

<sup>2</sup> For a complete list of references, we refer the readers to [8, 9].

## 2 Technical Overview

We now provide a streamlined overview of our main result, Theorem 1. As discussed in the introduction, our algorithm extends to multi-layer ReLU networks, though we focus on the two-layer case (one-hidden layer), which is the most interesting case where one can indeed hope for linear training time.

The main, and most expensive step, of the GGN (or natural gradient descent) algorithms [23, 79] is multiplying, in each iteration  $t$ , the *inverse* of the Gram matrix  $G_t := J_t J_t^\top$  with the Jacobian matrix  $J_t \in \mathbb{R}^{n \times m}$ , whose  $i$ th row contains the gradient of the  $m = md$  network gates w.r.t the  $i$ th datapoint  $x_i$  (in our case, under ReLU activation).

Naively computing  $G_t$  would already take  $mdn^2$  time, however, the *tensor product* structure of the Jacobian  $J$  in fact allows to compute  $G_t$  in  $n \cdot \mathcal{T}_{mat}(m, d, n) \ll mn^2$  time, where  $\mathcal{T}_{mat}(m, d, n)$  is the cost of fast rectangular matrix multiplication [73, 46, 33].<sup>3</sup> Since the Gram-Gauss-Newton (GGN) algorithm requires  $O(\log \log 1/\epsilon)$  iterations to converge to an  $\epsilon$ -global minimum of the  $\ell_2$  loss [23], this observation yields an  $O(n \cdot \mathcal{T}_{mat}(m, d, n) \log \log 1/\epsilon)$  total time algorithm for reducing the training loss below  $\epsilon$ . While already nontrivial, this is still far from linear running time ( $\gg mdn$ ).

We show how to carry out each Gauss-Newton iteration in time  $\tilde{O}(mnd + n^3)$ , at the price of slightly compromising the number of iterations to  $O(\log 1/\epsilon)$ , which is inconsequential for the natural regime of constant dimension  $d$  and constant  $\epsilon$ <sup>4</sup>. Our first key step is to reformulate the Gauss-Newton iteration (multiplying  $G_t^{-1}$  by the error vector) as an  *$\ell_2$ -regression problem*:

$$\min_{g_t} \|J_t J_t^\top g_t - (f_t - y)\|_2 \quad (1)$$

where  $(f_t - y)$  is the training error with respect to the network's output and the training labels  $y$ . Since the Gauss-Newton method is robust to small perturbation errors (essentially [71, 70]), our analysis shows that it is sufficient to find an approximate solution  $g'_t$  such that  $J_t^\top g'_t$  satisfies

$$\|J_t J_t^\top g'_t - y\|_2 \leq \gamma \|y\|_2, \quad \text{for } \gamma \approx 1/n. \quad (2)$$

The benefit of this reformulation is that it allows to use *linear sketching* to first compress the linear system, significantly reducing the dimension of the optimization problem and thereby the cost of finding a solution, at the price of a small error in the found solution (this is the essence of the *sketch-and-solve* paradigm [24]). Indeed, a (variation of) the *Fast-JL* sketch [2, 52] guarantees that we can multiply the matrix  $J_t^\top \in \mathbb{R}^{m \times n}$  by a much smaller  $\tilde{O}(n/\delta^2) \times m$  matrix  $S$ , such that (i) the multiplication takes near-linear time  $\tilde{O}(mn)$  time (using the FFT algorithm), and (ii)  $SJ_t^\top$  is a  $\delta$ -spectral approximation of  $J_t^\top$  (i.e.,  $\|J_t S^\top S J_t^\top x\|_2 = (1 \pm \delta) \|G_t x\|_2$  for every  $x$ ). Since both computing and inverting the matrix  $\tilde{G}_t := J_t S^\top S J_t^\top$  takes  $\tilde{O}(n^3/\delta^2)$  time, the overall cost of finding a  $\delta$ -approximate solution to

<sup>3</sup> To see this, observe that the kronecker-product structure of  $J$  (here  $J \in \mathbb{R}^{n \times md}$  can be constructed from an  $n \times m$  matrix and an  $n \times d$  matrix) allows computing  $Jh$  for any  $h \in \mathbb{R}^{md}$  using fast rectangular matrix multiplication in time  $\mathcal{T}_{mat}(m, d, n)$  which is near linear time in the dimension of  $J$  and  $h$  (that is,  $n \times m + n \times d$  for  $J$  and  $md$  for  $h$ ) so long as  $d \leq n^\alpha = n^{0.31}$  [33], hence computing  $G = JJ^\top$  can be done using  $n$  independent invocations of the aforementioned subroutine, yielding  $n \cdot \mathcal{T}_{mat}(m, d, n)$  as claimed.

<sup>4</sup> We also remark that this slowdown in the convergence rate is also a consequence of a direct extension of the analysis in [23] to ReLU activation functions.

the regression problem becomes at most  $\tilde{O}(mn + n^3/\delta^2)$ . Alas, as noted in Equation (2), the approximation error of the found solution must be *polynomially small*  $\gamma \sim 1/n$  in order to guarantee the desired convergence rate (i.e., constant decrease in training error per iteration). This means that we must set  $\delta \sim \gamma \sim 1/n$ , hence the cost of the naïve “sketch-and-solve” algorithm would be at least  $\tilde{O}(n^3/\delta^2) = \tilde{O}(n^5)$ , which is a prohibitively large overhead in both theory and practice (and in particular, no longer yields linear runtime whenever  $m \ll n^4$  which is the current best overparametrization guarantee [67]). Since the  $O(1/\delta^2)$  dependence of the JL embedding is known to be tight in general [45], this means we need to take a more clever approach to solve the regression (1). This is where our algorithm departs from the naïve sketch-and-solve method, and is the heart of our work.

Our key idea is to use dimension reduction – not to directly invert the compressed matrix – but rather to *precondition* it quickly. More precisely, our approach is to use a (conjugate) gradient-descent solver for the regression problem itself, with a fast preconditioning step, ensuring exponentially faster convergence to very high (polynomially small) accuracy. Indeed, conjugate gradient descent is guaranteed to find a  $\gamma$ -approximate solution to a regression problem  $\min_x \|Ax - b\|_2$  in  $O(\sqrt{\kappa} \log(1/\gamma))$  iterations, where  $\kappa(A)$  is the *condition number* of  $A$  (i.e., the ratio of maximum to minimum eigenvalue). Therefore, if we can ensure that  $\kappa(G_t)$  is small, then we can  $\gamma$ -solve the regression problem in  $\sim mn \log(1/\gamma) = \tilde{O}(mn)$  time, since the per-iteration cost of first-order SGD is linear ( $\sim mn$ ).

The crucial advantage of our approach is that it *decouples* the sketching error from the final precision of the regression problem: Unlike the usual “sketch-and-solve” method, where the sketching error  $\delta$  directly affects the overall precision of the solution to (2), here  $\delta$  only affects the *quality of the preconditioner* (i.e., the ratio of max/min singular values of the sketch  $\tilde{G}_t$ ), hence it suffices to take a *constant* sketching error  $\delta = 0.1$  (say), while letting the SGD deal with the final precision (at it has logarithmic dependence on  $\gamma$ ).

Indeed, by setting the sketching error to  $\delta = 0.1$  (say), the resulting matrix  $\tilde{G}_t = J_t S^\top S J_t^\top$  is small enough ( $n \times \tilde{O}(n)$ ) that we can afford running a standard (QR) algorithm to precondition it, at another  $\tilde{O}(n^3)$  cost per iteration. The output of this step is a matrix  $\tilde{G}'_t := \text{Prec}(\tilde{G}_t)$  with a *constant* condition number  $\kappa(\tilde{G}'_t)$  which preserves  $\tilde{G}'_t x \approx_{\ell_2} \tilde{G}_t x$  up to  $(1 \pm \delta)^2$  relative error. At this point, we can run a (conjugate) gradient descent algorithm, which is guaranteed to find a  $\gamma \approx 1/n$  approximate solution to (1) in time  $\tilde{O}((mn \log((1 + \delta)/\gamma) + n^3))$ , as desired.

We remark that, by definition, the preconditioning step (on the JL sketch) does *not* preserve the eigen-spectrum of  $G_t$ , which is in fact necessary to guarantee the fast convergence of the Gauss-Newton iteration. The point is that this preconditioning step is only preformed as a *local subroutine* so as to solve the regression problem, and does *not* affect the convergence rate of the outer loop.

### 3 Preliminaries

#### 3.1 Model and Problem Setup

We denote by  $n$  the number of data points in the training batch, and by  $d$  the data dimension/feature-space (i.e.,  $x_i \in \mathbb{R}^d$ ). We denote by  $m$  the *width* of neural network, and by  $L$  the number of layers and by  $M$  the number of parameters. We assume the data has been normalized, i.e.,  $\|x\|_2 = 1$ . We begin with the two-layer neural network in the following section, and then extend to multilayer networks. Consider a two-layer ReLU activated neural network with  $m$  neurons in the (single) hidden layer:

$$f(W, x, a) = \frac{1}{\sqrt{m}} \sum_{r=1}^m a_r \phi(w_r^\top x),$$

where  $x \in \mathbb{R}^d$  is the input,  $w_1, \dots, w_m \in \mathbb{R}^d$  are weight vectors in the first layer,  $a_1, \dots, a_m \in \mathbb{R}$  are weights in the second layer. For simplicity, we consider  $a \in \{-1, +1\}^m$  is fixed over all the iterations, this is natural in deep learning theory [48, 31, 4, 3, 67]. Recall the ReLU function  $\phi(x) = \max\{x, 0\}$ . Therefore for  $r \in [m]$ , we have

$$\frac{\partial f(W, x, a)}{\partial w_r} = \frac{1}{\sqrt{m}} a_r x \mathbf{1}_{w_r^\top x \geq 0}. \quad (3)$$

Given  $n$  input data points  $(x_1, y_1), (x_2, y_2), \dots, (x_n, y_n) \in \mathbb{R}^d \times \mathbb{R}$ . We define the objective function  $\mathcal{L}$  as follows

$$\mathcal{L}(W) = \frac{1}{2} \sum_{i=1}^n (y_i - f(W, x_i, a))^2.$$

We can compute the gradient of  $\mathcal{L}$  in terms of  $w_r$

$$\frac{\partial \mathcal{L}(W)}{\partial w_r} = \frac{1}{\sqrt{m}} \sum_{i=1}^n (f(W, x_i, a) - y_i) a_r x_i \mathbf{1}_{w_r^\top x_i \geq 0}. \quad (4)$$

We define the prediction function  $f_t : \mathbb{R}^{d \times n} \rightarrow \mathbb{R}^n$  at time  $t$  as follow

$$f_t = \begin{bmatrix} \frac{1}{\sqrt{m}} \sum_{r=1}^m a_r \cdot \phi(\langle w_r(t), x_1 \rangle) \\ \frac{1}{\sqrt{m}} \sum_{r=1}^m a_r \cdot \phi(\langle w_r(t), x_2 \rangle) \\ \vdots \\ \frac{1}{\sqrt{m}} \sum_{r=1}^m a_r \cdot \phi(\langle w_r(t), x_n \rangle) \end{bmatrix}$$

where  $W_t = [w_1(t)^\top, w_2(t)^\top, \dots, w_m(t)^\top]^\top \in \mathbb{R}^{md}$  and  $X = [x_1, x_2, \dots, x_n] \in \mathbb{R}^{d \times n}$ .

For each time  $t$ , the Jacobian matrix  $J \in \mathbb{R}^{n \times md}$  is defined via the following formulation:

$$J_t = \frac{1}{\sqrt{m}} \begin{bmatrix} a_1 x_1^\top \mathbf{1}_{\langle w_1(t), x_1 \rangle \geq 0} & a_2 x_1^\top \mathbf{1}_{\langle w_2(t), x_1 \rangle \geq 0} & \cdots & a_m x_1^\top \mathbf{1}_{\langle w_m(t), x_1 \rangle \geq 0} \\ a_1 x_2^\top \mathbf{1}_{\langle w_1(t), x_2 \rangle \geq 0} & a_2 x_2^\top \mathbf{1}_{\langle w_2(t), x_2 \rangle \geq 0} & \cdots & a_m x_2^\top \mathbf{1}_{\langle w_m(t), x_2 \rangle \geq 0} \\ \vdots & \vdots & \ddots & \vdots \\ a_1 x_n^\top \mathbf{1}_{\langle w_1(t), x_n \rangle \geq 0} & a_2 x_n^\top \mathbf{1}_{\langle w_2(t), x_n \rangle \geq 0} & \cdots & a_m x_n^\top \mathbf{1}_{\langle w_m(t), x_n \rangle \geq 0} \end{bmatrix}.$$

The Gram matrix  $G_t$  is defined as  $G_t = J_t J_t^\top$ , whose  $(i, j)$ -th entry is  $\left\langle \frac{f(W_t, x_i)}{\partial W}, \frac{f(W_t, x_j)}{\partial W} \right\rangle$ . The crucial observation of [38, 31] is that the asymptotic of the Gram matrix equals a positive semidefinite kernel matrix  $K \in \mathbb{R}^{n \times n}$ , where

$$K(x_i, x_j) = \mathbb{E}_{w \in \mathcal{N}(0, 1)} [x_i^\top x_j \mathbf{1}_{\langle w, x_i \rangle \geq 0, \langle w, x_j \rangle \geq 0}]. \quad (5)$$

► **Assumption 3.** We assume the least eigenvalue  $\lambda$  of the kernel matrix  $K$  defined in Eq. (5) satisfies  $\lambda > 0$ .

### 3.2 Subspace embedding

Subspace embedding was first introduced by Sarlós [63], it has been extensively used in numerical linear algebra field over the last decade [24, 57, 19, 66]. For a more detailed survey, we refer the readers to [74]. The formal definition is:

► **Definition 4** (Approximate subspace embedding, ASE [63]). A  $(1 \pm \epsilon)$   $\ell_2$ -subspace embedding for the column space of an  $N \times k$  matrix  $A$  is a matrix  $S$  for which for all  $x \in \mathbb{R}^k$ ,  $\|SAx\|_2^2 = (1 \pm \epsilon)\|Ax\|_2^2$ . Equivalently,  $\|I - U^\top S^\top S U\|_2 \leq \epsilon$ , where  $U$  is an orthonormal basis for the column space of  $A$ .

Combining Fast-JL sketching matrix [2, 30, 69, 29, 52, 60] with a classical  $\epsilon$ -net argument [74] gives subspace embedding,

► **Lemma 5** (Fast subspace embedding [52, 74]). *Given a matrix  $A \in \mathbb{R}^{N \times k}$  with  $N = \text{poly}(k)$ , then we can compute a  $S \in \mathbb{R}^{k \cdot \text{poly}(\log(k/\delta))/\epsilon^2 \times k}$  that gives a subspace embedding of  $A$  with probability  $1 - \delta$ , i.e., with probability  $1 - \delta$ , we have :*

$$\|SAx\|_2 = (1 \pm \epsilon)\|Ax\|_2$$

holds for any  $x \in \mathbb{R}^n$ ,  $\|x\|_2 = 1$ . Moreover,  $SA$  can be computed in  $O(Nk \cdot \text{poly} \log k)$  time.

## 4 Our Algorithm

Our main algorithm is shown in Algorithm 1. We have the following convergence result of our algorithm.

► **Theorem 6.** *Suppose the width of a ReLU neural network satisfies*

$$m = \Omega(\max\{\lambda^{-4}n^4, \lambda^{-2}n^2d \log(16n/\delta)\}),$$

*then with probability  $1 - \delta$  over the random initialization of neural network and the randomness of the training algorithm, our algorithm (procedure FASTERTWOLAYER in Algorithm 1) achieves*

$$\|f_{t+1} - y\|_2 \leq \frac{1}{2}\|f_t - y\|_2.$$

*The computation cost in each iteration is  $\tilde{O}(mnd + n^3)$ , and the running time for reducing the training loss to  $\epsilon$  is  $\tilde{O}((mnd + n^3) \log(1/\epsilon))$ . Using fast matrix-multiplication, the total running time can be further reduced to  $\tilde{O}((mnd + n^\omega) \log(1/\epsilon))$ .*

The main difference between [23, 79] and our algorithm is that we perform an *approximate Newton update* (see line 6). The crucial observation here is that the Newton method is robust to small loss, thus it suffices to present a fine approximation. This observation is well-known in the convex optimization but unclear to the non-convex (but overparameterized) neural network setting. Another crucial observation is that instead of directly approximating the Gram matrix, it suffices to approximate  $(J_t J_t^\top)^{-1} g_t = G_t^{-1} g_t$ . Intuitively, this follows from

$$J_t^\top g_t \approx J_t (J_t J_t^\top)^{-1} (f_t - y) = (J_t^\top J_t)^\dagger J_t (f_t - y),$$

where  $(J_t^\top J_t)^\dagger$  denotes the pseudo-inverse of  $J_t^\top J_t$  and the last term is exactly the Newton update. This observation allows us to formulate the problem a regression problem (see Eq. (6)), on which we can introduce techniques from *randomize linear algebra* and develop fast algorithm that solves it in near linear time.

8:   end while
9: return  $Rz_t$ 
10: end procedure

```

---

The core component of our algorithm is a fast regression solver (shown in Algorithm 2). The regression solver provides an approximate solution to  $\min_x \|A^\top Ax - y\|$  where  $A \in \mathbb{R}^{N \times k}$  ( $N \gg k$ ). We perform preconditioning on the matrix of  $A^\top A$  (line 3 – 4) and use gradient descent to derive an approximation solution (line 6 – 8).

► **Lemma 7.** *Let  $N = \Omega(k \text{poly}(\log k))$ . Given a matrix  $A \in \mathbb{R}^{N \times k}$ , let  $\kappa$  denote the condition number of  $A$ <sup>5</sup>, consider the following regression problem*

$$\min_{x \in \mathbb{R}^k} \|A^\top Ax - y\|_2. \quad (7)$$

Using procedure FASTREGRESSION (in Algorithm 2), with probability  $1 - \delta$ , we can compute an  $\epsilon$ -approximate solution  $x'$  satisfying

$$\|A^\top Ax' - y\|_2 \leq \epsilon \|y\|_2$$

in  $\tilde{O}(Nk \log(\kappa/\epsilon) + k^3)$  time.

**Speedup in Convex Optimization.** It should come as no surprise that our techniques can help accelerating a broad class of solvers in *convex optimization* problems as well. In the full version of this paper, we elaborate on this application, and in particular show how our technique improves the runtime of the “Newton-Sketch” algorithm of [59].

## 5 Conclusion and Open Problems

Our work provides a computationally-efficient (near-linear time) second-order algorithm for training sufficiently overparametrized two-layer neural network, overcoming the drawbacks of traditional first-order gradient algorithms. Our main technical contribution is developing a *faster regression solver* which uses linear sketching for fast preconditioning (in time

---

<sup>5</sup>  $\kappa = \sigma_{\max}(A)/\sigma_{\min}(A)$

independent of the network width). As such, our work demonstrates that the toolbox of randomized linear algebra can substantially reduce the computational cost of second-order methods in *non-convex optimization*, and not just in the convex setting for which it was originally developed (e.g., [59, 74, 25, 42, 40, 41, 47]).

Finally, we remark that, while the running time of our algorithm is  $\tilde{O}(Mn + n^3)$  (or  $O(Mn + n^\omega)$  using FMM), it is no longer (near) linear for networks with parameters  $M \leq n^2$  (resp.  $M \lesssim n^{\omega-1}$ ). While it is widely believed that  $\omega = 2$  [26], FMM algorithms are impractical at present, and it would therefore be very interesting to improve the extra additive term from  $n^3$  to  $n^{2+o(1)}$  (which seems best possible for dense  $n \times n$  matrices), or even to  $n^{3-\epsilon}$  using a practically viable algorithm. Faster preconditioners seem key to this avenue.

## Abstract

Given a directed acyclic graph (DAG)  $G = (V, E)$ , we say that  $G$  is  $(e, d)$ -depth-robust (resp.  $(e, d)$ -edge-depth-robust) if for any set  $S \subset V$  (resp.  $S \subseteq E$ ) of at most  $|S| \leq e$  nodes (resp. edges) the graph  $G - S$  contains a directed path of length  $d$ . While edge-depth-robust graphs are potentially easier to construct many applications in cryptography require node depth-robust graphs with small indegree. We create a graph reduction that transforms an  $(e, d)$ -edge-depth-robust graph with  $m$  edges into a  $(e/2, d)$ -depth-robust graph with  $O(m)$  nodes and constant indegree. One immediate consequence of this result is the first construction of a provably  $(\frac{n \log \log n}{\log n}, \frac{n}{(\log n)^{1+\log \log n}})$ -depth-robust graph with constant indegree, where previous constructions for  $e = \frac{n \log \log n}{\log n}$  had  $d = O(n^{1-\epsilon})$ . Our reduction crucially relies on ST-Robust graphs, a new graph property we introduce which may be of independent interest. We say that a directed, acyclic graph with  $n$  inputs and  $n$  outputs is  $(k_1, k_2)$ -ST-Robust if we can remove any  $k_1$  nodes and there exists a subgraph containing at least  $k_2$  inputs and  $k_2$  outputs such that each of the  $k_2$  inputs is connected to all of the  $k_2$  outputs. If the graph is  $(k_1, n - k_1)$ -ST-Robust for all  $k_1 \leq n$  we say that the graph is maximally ST-robust. We show how to construct maximally ST-robust graphs with constant indegree and  $O(n)$  nodes. Given a family  $\mathbb{M}$  of ST-robust graphs and an arbitrary  $(e, d)$ -edge-depth-robust graph  $G$  we construct a new constant-indegree graph  $\text{Reduce}(G, \mathbb{M})$  by replacing each node in  $G$  with an ST-robust graph from  $\mathbb{M}$ . We also show that ST-robust graphs can be used to construct (tight) proofs-of-space and (asymptotically) improved wide-block labeling functions.

## 1 Introduction

Given a directed acyclic graph (DAG)  $G = (V, E)$ , we say that  $G$  is  $(e, d)$ -reducible (resp.  $(e, d)$ -edge reducible) if there is a subset  $S \subseteq V$  (resp.  $S \subseteq E$ ) of  $|S| \leq e$  nodes (resp. edges) such that  $G - S$  does not contain a directed path of length  $d$ . If a graph is not  $(e, d)$ -reducible (resp.  $(e, d)$ -edge reducible) we say that the graph is  $(e, d)$ -depth robust (resp.  $(e, d)$ -edge-depth-robust). Depth robust graphs have found many applications in the field of cryptography in the construction of proofs of sequential work [11], proofs of space [7, 12], and in the construction of data independent memory hard functions (iMHFs). For example, highly depth robust graphs are known to be necessary [1] and sufficient [3] to construct

iMHF's with high amortized space time complexity. While edge depth-robust graphs are often easier to construct [14], most applications require node depth-robust graphs with small indegree.

It has been shown [17] that in any DAG with  $m$  edges and  $n$  nodes and any  $i \leq \log_2 n$ , there exists a set  $S_i$  of  $\frac{mi}{\log n}$  edges that will destroy all paths of length  $n/2^i$  forcing  $\text{depth}(G - S_i) \leq \frac{n}{2^i}$ . For DAGs with constant indegree we have  $m = O(n)$  edges so an equivalent condition holds for node depth robustness [1], since a node can be removed by removing all the edges incident to it. In particular, there exists a set  $S_i$  of  $O(\frac{ni}{\log n})$  nodes such that  $\text{depth}(G - S_i) \leq \frac{n}{2^i}$  for all  $i < \log n$ . It is known how to construct an  $(c_1 n / \log n, c_2 n)$ -depth-robust graph, for suitable  $c_1, c_2 > 0$  [3] and an  $(c_3 n, c_4 n^{1-\epsilon})$ -depth-robust graph for small  $\epsilon$  for [14].

An open challenge is to construct constant indegree  $(c_1 ni / \log n, c_2 n / 2^i)$ -depth-robust graphs which match the Valiant bound [17] for intermediate values of  $i = \omega(1)$  and  $i = o(\log n)$ . For example, when  $i = \log \log n$  then the Valiant bound [17] does not rule out the existence of  $(c_1 ni / \log n, c_2 n / \log n)$ -depth-robust graphs with constant indegree. Such a graph would yield asymptotically stronger iMHFs [5]. While there are several constructions that are conjectured to be  $(c_1 ni / \log n, c_2 n / \log n)$ -depth-robust the best provable lower bound for  $(e = cni / \log n, d)$ -depth robustness of a constant indegree graph is  $d = \Omega(n^{1-\epsilon})$ . For edge-depth robustness we have constructions of graphs with  $m = O(n \log n)$  edges which are  $(e_i, d_i)$ -edge depth robust for any  $i$  with  $e_i = mi / \log n$  and  $d_i = n / \log^{i+1} n$  — much closer to matching the Valiant bound [17].

## 1.1 Contributions

Our main contribution is a graph reduction that transforms any  $(e, d)$ -edge-depth-robust graph with  $m$  edges into a  $(e/2, d)$ -depth-robust graph with  $O(m)$  nodes and constant indegree. Our reduction utilizes ST-Robust graphs, a new graph property we introduce and construct. We believe that ST-Robust graphs may be of independent interest.

Intuitively, a  $(k_1, k_2)$ -ST-Robust graph with  $n$  inputs  $I$  and  $n$  outputs  $O$  satisfies the property that, even after deleting  $k_1$  nodes from the graph we can find  $k_2$  inputs  $x_1, \dots, x_{k_2}$  and  $k_2$  outputs  $y_1, \dots, y_{k_2}$  such that *every* input  $x_i$  ( $i \in [k_2]$ ) is still connected to *every* output  $y_j$  ( $j \in [k_2]$ ). If we can guarantee that the each directed path from  $x_i$  to  $y_j$  has length  $d$  then we say that the graph is  $(k_1, k_2, d)$ -ST-Robust. A maximally depth-robust graph should be  $(k_1, n - k_1)$ -depth robust for any  $k_1$ .

► **Definition 1 (ST-Robust).** Let  $G = (V, E)$  be a DAG with  $n$  inputs, denoted by set  $I$  and  $n$  outputs, denoted by set  $O$ . Then  $G$  is  $(k_1, k_2)$ -ST-robust if  $\forall D \subset V(G)$  with  $|D| \leq k_1$ , there exists subgraph  $H$  of  $G - D$  with  $|I \cap V(H)| \geq k_2$  and  $|O \cap V(H)| \geq k_2$  such that  $\forall s \in I \cap V(H)$  and  $\forall t \in O \cap V(H)$  there exists a path from  $s$  to  $t$  in  $H$ . If  $\forall s \in I \cap V(H)$  and  $\forall t \in O \cap V(H)$  there exists a path from  $s$  to  $t$  of length  $\geq d$  then we say that  $G$  is  $(k_1, k_2, d)$ -ST-robust.

► **Definition 2 (Maximally ST-Robust).** Let  $G = (V, E)$  be a constant indegree DAG with  $n$  inputs and  $n$  outputs. Then  $G$  is  $c_1$ -maximally ST-robust (resp.  $c_1$  max ST-robust with depth  $d$ ) if there exists a constant  $0 < c_1 \leq 1$  such that  $G$  is  $(k, n - k)$ -ST-robust (resp.  $(k, n - k, d)$ -ST-robust) for all  $k$  with  $0 \leq k \leq c_1 n$ . If  $c_1 = 1$ , we just say that  $G$  is maximally ST-Robust.

We show how to construct maximally ST-robust graphs with constant indegree and  $O(n)$  nodes and we show how maximally ST-robust graphs can be used to transform any  $(e, d)$ -edge-depth-robust graph  $G$  with  $m$  edges into a  $(e/2, d)$ -depth-robust graph  $G'$  with

$O(m)$  nodes and constant indegree. Intuitively, in our reduction each node  $v \in V(G)$  with degree  $\delta(v)$  is replaced with a maximally ST-robust graph  $M_{\delta(v)}$  with  $\delta(v)$  inputs/outputs. Incoming edges into  $v$  are redirected into the inputs  $I_{\delta(v)}$  of the ST-robust graph. Similarly,  $v$ 's outgoing edges are redirected out of the outputs  $O_{\delta(v)}$  of the ST-robust graph. Because  $M_{\delta(v)}$  is maximally ST-robust, when a node is removed from  $M_{\delta(v)}$  the set of inputs and outputs where each input connects to every output has at most one input and one output node removed. Each input or output node removed from  $M_{\delta(v)}$  corresponds to removing at most one edge from the original graph. Thus, removing  $k$  nodes from  $M_{\delta(v)}$  corresponds to destroying at most  $2k$  edges in the original graph  $G$ .

Our reduction gives us a fundamentally new way to design node-depth-robust graphs: design an edge-depth-robust graph (easier) and then reduce it to a node-depth-robust graph. The reduction can be used with a construction from [14] to construct a  $(\frac{n \log \log n}{\log n}, \frac{n}{(\log n)^{1+\log \log n}})$ -depth-robust graph. We conjecture that several prior DAG constructions (e.g., [4, 8, 14]) are actually  $(n \log \log n, \frac{n}{\log n})$ -edge-depth-robust. If any of these conjectures are true then our reduction would immediately yield the desired  $(\frac{n \log \log n}{\log n}, \frac{n}{\log n})$ -depth-robust graph.

We also present several other applications for maximally ST-robust graphs including (tight) proofs-of-space and wide block-labeling functions.

## 2 Edge to Node Depth-Robustness

In this section, we use the fact that linear sized, constant indegree, maximally ST-robust graphs exist to construct a transformation of an  $(e, d)$ -edge-depth robust graph with  $m$  edges into an  $(e, d)$ -node-depth robust graph with constant indegree and  $O(m)$  nodes. In the next section we will construct a family of ST-robust graphs that satisfies Theorem 3.

► **Theorem 3** (Key Building Block). *There exists a family of graphs  $\mathbb{M} = \{M_n\}_{n=1}^{\infty}$  with the property that for each  $n \geq 1$ ,  $M_n$  has constant indegree,  $O(n)$  nodes, and is maximally ST-Robust.*

### 2.1 Reduction Definition

Let  $G = (V, E)$  be a DAG, and let  $\mathbb{M}$  be as in Theorem 3. Then we define  $\text{Reduce}(G, \mathbb{M})$  in construction 4 as follows:

► **Construction 4** ( $\text{Reduce}(G, \mathbb{M})$ ). *Let  $G = (V, E)$  and let  $\mathbb{M}$  be the family of graphs defined above. For each  $M_n \in \mathbb{M}$ , we say that  $M_n = (V(M_n), E(M_n))$ , with  $V(M_n) = I(M_n) \cup O(M_n) \cup D(M_n)$ , where  $I(M_n)$  are the inputs of  $M_n$ ,  $O(M_n)$  are the outputs, and  $D(M_n)$  are the internal vertices. For  $v \in V$ , let  $\delta(v) = \max\{\text{indegree}(v), \text{outdegree}(v)\}$ . Then we define  $\text{Reduce}(G) = (V_R, E_R)$ , where  $V_R = \{(v, w) \mid v \in V, w \in V(M_{\delta(v)})\}$  and  $E_R = E_{\text{internal}} \cup E_{\text{external}}$ . We let  $E_{\text{internal}} = \{((v, u'), (v, w')) \mid v \in V, (u', w') \in E(M_{\delta(v)})\}$ . Then for each  $v \in V$ , we define an  $\text{In}(v) = \{u : (u, v) \in E\}$  and  $\text{Out}(v) = \{u : (v, u) \in E\}$  and then pick two injective mappings  $\pi_{\text{in}, v} : \text{In}(v) \rightarrow I(V(M_{\delta(v)}))$  and  $\pi_{\text{out}, v} : \text{Out}(v) \rightarrow O(V(M_{\delta(v)}))$ . We let  $E_{\text{external}} = \{((u, \pi_{\text{out}, u}(v)), (v, \pi_{\text{in}, v}(u))) : (u, v) \in E\}$ .*

*Intuitively, to construct  $\text{Reduce}(G, \mathbb{M})$  we replace every node of  $G$  with a constant indegree, maximally ST-robust graph, mapping the edges connecting two nodes from the outputs of one ST-robust graph to the inputs of another. Then for every  $e = (u, w) \in E$ , add an edge from an output of  $M_{\delta(u)}$  to an input of  $M_{\delta(w)}$  such that the outputs of  $M_{\delta(u)}$  have outdegree at most 1, and the inputs of  $M_{\delta(w)}$  have indegree at most 1. If  $v \in V$  is replaced by  $M_{\delta(v)}$ , then we call  $v$  the genesis node and  $M_{\delta(v)}$  its metanode.*

■ **Figure 1** Diagram of the transformation  $\text{Reduce}(G, \mathbb{M})$ .

## 2.2 Proof of Main Theorem

We now state the main result of this section which says that if  $G$  is edge-depth robust then  $\text{Reduce}(G, \mathbb{M})$  is node depth-robust.

► **Theorem 5.** *Let  $G$  be an  $(e, d)$ -edge-depth-robust DAG with  $m$  edges. Let  $\mathbb{M}$  be a family of max ST-Robust graphs with constant indegree. Then  $G' = (V', E') = \text{Reduce}(G, \mathbb{M})$  is  $(e/2, d)$ -depth robust. Furthermore,  $G'$  has maximum indegree  $\max_{v \in V(G)} \{\text{indeg}(M_{\delta(v)})\}$ , and its number of nodes is  $\sum_{v \in V(G)} |V(M_{\delta(v)})|$  where  $\delta(v) = \max\{\text{indeg}(v), \text{outdeg}(v)\}$ .*

A formal proof can be found in Appendix B. We briefly outline the intuition for this proof below.

**Proof (Intuition).** The first thing we note is that each graph  $M_{\delta(v)}$  has constant indegree at most  $c\delta(v)$  nodes for some constant  $c > 0$ . Therefore, the graph  $G'$  has  $\sum_{v \in V(G)} |V(M_{\delta(v)})| \leq c \sum_v \delta(v) \leq 2cm$  nodes and  $G'$  has constant indegree.

Now for any set  $S \subseteq V'$  of nodes we remove from  $G'$  we will map  $S$  to a corresponding set  $S_{irr} \subseteq E$  of at most  $|S_{irr}| \leq 2|S|$  irreparable edges in  $G$ . We then prove that any path  $P$  in  $G - S_{irr}$  corresponds to a longer path  $P'$  in  $G' - S$  that is at least as long. Intuitively, each incoming edge  $(u, v)$  (resp. outgoing edge  $(v, w)$ ) in  $E(G)$  corresponds to an input node (resp. output node) in  $v$ 's corresponding metanode  $M_{\delta(v)}$  which we will label  $x_{u,v}$  (resp.  $y_{v,w}$ ). If  $S \subseteq V'$  removes at most  $k$  nodes from the metanode  $M_{\delta(v)}$  then, by maximal ST-robustness, we still can find  $\delta(v) - k$  inputs and  $\delta(v) - k$  outputs that are *all* pairwise connected. If  $x_{u,v}$  (resp.  $y_{v,w}$ ) is not part of this pairwise connected subgraph then we will add the corresponding edge  $(u, v)$  (resp.  $(v, w)$ ) to the set  $S_{irr}$ . Thus, the set  $S_{irr}$  will have size at most  $2|S|$  (Claim 30 in the appendix).

Intuitively, any path  $P$  in  $G - S_{irr}$  can be mapped to a longer path  $P'$  in  $G' - S$  (Claim 29). If  $P$  contains the edges  $(u, v), (v, w)$  then we know that the input node  $x_{u,v}$  and output node  $y_{v,w}$  node in  $M_{\delta(v)}$  are still connected in  $G' - S$ . ◀

► **Corollary 6** (of Theorem 5). *If there exists some constants  $c_1, c_2$ , such that we have a family  $\mathbb{M} = \{M_n\}_{n=1}^{\infty}$  of linear sized  $|V(M_n)| \leq c_1 n$ , constant indegree  $\text{indeg}(M_n) \leq c_2$ , and maximally ST-Robust graphs, then  $\text{Reduce}(G, \mathbb{M})$  has maximum indegree  $c_2$  and the number of nodes is at most  $2c_1 m$ .*

The next corollary states that if we have a family of maximally ST-Robust graphs with  $\mathbb{M} = \{M_k\}_{k=1}^\infty$  depth  $d_k$  then we can transform any  $(e, d)$ -edge-depth-robust DAG  $G = (V, E)$  with maximum degree  $\delta = \max_{v \in V} \delta(v)$  into  $(e/2, d \cdot d_\delta)$ -depth robust graph. Instead of replacing each node  $v \in G$  with a copy of  $M_{\delta(v)}$ , we instead replace each node with a copy of  $M_{\delta, v} := M_\delta$ , attaching the edges same way as in Construction 4. Thus the transformed graph  $G'$  has  $|V(G)| \times |M_\delta|$  nodes and constant indegree. Intuitively, any path  $P$  of length  $d$  in  $G - S_{irr}$  now maps to a path  $P'$  of length  $d \times d_\delta$  – if  $P$  contains the edges  $(u, v), (v, w)$  then we know that the input node  $x_{u,v}$  and output node  $y_{u,v}$  node in  $M_{\delta, v}$  are connected in  $G' - S$  by a path of length at least  $d_\delta$ .

► **Corollary 7** (of Theorem 5). *Suppose that there exists a family  $\mathbb{M} = \{M_k\}_{k=1}^\infty$  of max ST-Robust graphs with depth  $d_k$  and constant indegree. Given any  $(e, d)$ -edge-depth-robust DAG  $G$  with  $n$  nodes and maximum degree  $\delta$  we can construct a DAG  $G'$  with  $n \times |M_\delta|$  nodes and constant indegree that is  $(e/2, d \cdot d_\delta)$ -depth robust.*

**Proof (sketch).** Instead of replacing each node  $v \in G$  with a copy of  $M_{\delta(v)}$ , we instead replace each node with a copy of  $M_{\delta, v} := M_\delta$ , attaching the edges same way as in Construction 4. Thus the transformed graph  $G'$  has  $|V(G)| \times |M_\delta|$  nodes and constant indegree. Let  $S \subset V(G')$  be a set of nodes that we will remove from  $G'$ . By Claim 29, there exists a path  $P$  in  $G' - S$  that passes through  $d$  metanodes  $M_{\delta, v_1}, \dots, M_{\delta, v_d}$ . Since  $M_\delta$  is maximally ST-robust with depth  $d_\delta$  the sub-path  $P_i = P \cap M_{\delta, v_i}$  through each metanode has length  $|P_i| \geq d_\delta$ . Thus, the total length of the path is at least  $\sum_i |P_i| \geq d \cdot d_\delta$ . ◀

► **Corollary 8** (of Theorem 5). *Let  $\epsilon > 0$  be any fixed constant. Given any family  $\{G_m\}_{m=1}^\infty$  of  $(e_m, d_m)$ -edge-depth-robust DAGs  $G_m$  with  $m$  nodes and maximum indegree  $\delta_m$  then for some constants  $c_1, c_2 > 0$  we can construct a family  $\{H_m\}_{m=1}^\infty$  of DAGs such that each DAG  $H_m$  is  $(e_m/2, d_m \cdot \delta_m^{1-\epsilon})$ -depth robust,  $H_m$  has maximum indegree at most  $c_2$  (constant) and at most  $|V(H_m)| \leq c_1 m \delta_m$  nodes.*

**Proof (sketch).** This follows immediately from Corollary 7 and from our construction of a family  $\mathbb{M}_\epsilon = \{M_{k, \epsilon}\}_{k=1}^\infty$  of max ST-Robust graphs with depth  $d_k > k^{1-\epsilon}$  and constant indegree. ◀

► **Corollary 9** (of Theorem 5). *Let  $\{e_m\}_{m=1}^\infty$  and  $\{d_m\}_{m=1}^\infty$  be any sequence. If there exists a family  $\{G_m\}_{m=1}^\infty$  of  $(e_m, d_m)$ -edge-depth-robust graphs, where each DAG  $G_m$  has  $m$  edges, then there is a corresponding family  $\{H_n\}_{n=1}^\infty$  of constant indegree DAGs such that each  $H_n$  has  $n$  nodes and is  $(\Omega(e_n), \Omega(d_n))$ -depth-robust.*

The original Grate's construction [14],  $G$ , has  $N = 2^n$  nodes and  $m = n2^n$  edges and for any  $s \leq n$ , and is  $(s2^n, \sum_{j=0}^s \frac{N}{\binom{n}{j}})$ -edge-depth-robust. For node depth-robustness we only had matching constructions when  $s = O(1)$  [2, 3] and  $s = \Omega(\log N)$  [14] – no comparable lower bounds were known for intermediate  $s$ .

► **Corollary 10** (of Theorem 5). *There is a family of constant indegree graphs  $\{G_n\}$  such that  $G_n$  has  $O(N = 2^n)$  nodes and  $G_n$  is  $(sN/(2n), \sum_{j=0}^s \frac{N}{\binom{n}{j}})$ -edge-depth-robust for any  $1 \leq s \leq \log n$*

In particular, setting  $s = \log \log n$  and applying the indegree reduction from Theorem 5, we see that the transformed graph  $G'$  has constant indegree,  $N' = O(n2^n)$  nodes, and is  $(\frac{N' \log \log N'}{\log N'}, \frac{N'}{(\log N')^{1+\log \log N'}})$ -depth-robust. Blocki et al. [5] showed that if there exists a node depth robust graph with  $e = \Omega(N \log \log N / \log N)$  and  $d = \Omega(N \log \log N / \log N)$  then

one can obtain another constant indegree graph with pebbling cost  $\Omega(N^2 \log \log N / \log N)$  which is optimal for constant indegree graphs. We conjecture that the graphs in [8] are sufficiently edge depth robust to meet these bounds after being transformed by our reduction.

### 3 ST Robustness

In this section we show how to construct maximally ST-robust graphs with constant indegree and linear size. We first introduce some of the technical building blocks used in our construction including superconcentrators [10, 13, 16] and grates [14]. Using these building blocks we then provide a randomized construction of a  $c_1$ -maximally ST-robust DAG with linear size and constant indegree for some constant  $c_1 > 0$  – sampled graphs are  $c_1$ -maximally ST-robust DAG with high probability. Finally, we use  $c_1$ -maximally ST-robust DAGs to construct a family of maximally ST-robust graphs with linear size and constant indegree.

#### 3.1 Technical Ingredients

We now introduce other graph properties that will be useful for constructing ST-robust graphs.

##### Grates

A DAG  $G = (V, E)$  with  $n$  inputs  $I$  and  $n$  outputs  $O$  is called a  $(c_0, c_1)$ -grate if for any subset  $S \subset V$  of size  $|S| \leq c_0 n$  at least  $c_1 n^2$  input output pairs  $(x, y) \in I \times O$  remain connected by a directed path from  $x$  to  $y$  in  $G - S$ . Schnitger [14] showed how to construct  $(c_0, c_1)$ -grates with  $O(n)$  nodes and constant indegree for suitable constants  $c_0, c_1 > 0$ . The notion of an maximally ST-robust graph is a strictly stronger requirement since there is no requirement on which pairs are connected. However, we show that a slight modification of Schnitger’s [14] construction is a  $(cn, n/2)$ -ST-robust for a suitable constant  $c$ . We then transform this graph into a  $c_1$ -maximally ST-robust graph by sandwiching it in between two superconcentrators. Finally, we show how to use several  $c_1$ -maximally ST-robust graphs to construct a maximally ST-robust graph.

##### Superconcentrators

We say that a directed acyclic graph  $G = (V, E)$  with  $n$  input vertices and  $n$  output vertices is an  **$n$ -superconcentrator** if for any  $r$  inputs and any  $r$  outputs,  $1 \leq r \leq n$ , there are  $r$  vertex-disjoint paths in  $G$  connecting the set of these  $r$  inputs to these  $r$  outputs. We note that there exists linear size, constant indegree superconcentrators [10, 13, 16] and we use this fact throughout the rest of the paper. For example, Pippenger [13] constructed an  $n$ -superconcentrator with at most  $41n$  vertices and indegree at most 16.

##### Connectors

We say that an  $n$ -superconcentrator is an  **$n$ -connector** if it is possible to specify which input is to be connected to which output by vertex disjoint paths in the subsets of  $r$  inputs and  $r$  outputs. Connectors and superconcentrators are potential candidates for ST-robust graphs because of their highly connective properties. In fact, we can prove that any connectors  **$n$ -connector** is maximally ST-robust – the proof of Theorem 11 can be found in the appendix. While we have constructions of  **$n$ -connector** graphs these graphs have  $O(n \log n)$  vertices and indegree of 2, an information theoretic technique of Shannon [15] can be used to

prove that any  $n$ -connector with constant indegree requires *at least*  $\Omega(n \log n)$  vertices – see discussion in the appendix. Thus, we cannot use  $n$ -connectors to build linear sized ST-robust graphs. However, Shannon’s information theoretic argument does not rule out the existence of linear size ST-robust graphs.

► **Theorem 11.** *If  $G$  is an  $n$ -connector, then  $G$  is  $(k, n - k)$ -ST-robust, for all  $1 \leq k \leq n$ .*

### 3.2 Linear Size ST-robust Graphs

ST-robust graphs have similar connective properties to connectors, so a natural question to ask is whether ST-robust graphs with constant indegree require  $\Omega(n \log n)$  vertices. In this section, we show that linear size ST-robust graphs exist by showing that a modified version of the Grates construction [14] becomes  $c$ -maximally ST-robust when sandwiched between two superconcentrators for some constant  $c$ .

In the proof of Theorem A in [14], Schnitger constructs a family of DAGs  $(H_n | n \in N)$  with constant indegree  $\delta_H$ , where  $n$  is the number of nodes and  $H_n$  is  $(cn, n^{2/3})$ -depth-robust, for suitable constant  $c > 0$ . We construct a similar graph  $G_n$  as follows:

► **Construction 12** ( $G_n$ ). *We begin with  $H_n^1, H_n^2$  and  $H_n^3$ , three isomorphic copies of  $H_n$  with disjoint vertex sets  $V_1, V_2$  and  $V_3$ . For each top vertex  $v \in V_3$  sample  $\tau$  vertices  $x_1^v, \dots, x_\tau^v$  independently and uniformly at random from  $V_2$  and for each  $i \leq \tau$  add each directed edge  $(x_i^v, v)$  to  $G_n$  to connect each of these sampled nodes to  $v$ . Similarly, for each node vertex  $u \in V_2$  sample  $\tau$  vertices  $x_1^u, \dots, x_\tau^u$  from  $V_1$  independently and uniformly at random and add each directed edge  $(x_i^u, u)$  to  $G_n$ . Note that  $\text{indeg}(G_n) \leq \text{indeg}(H_n) + \tau$ .*

Schnitger’s construction only utilizes two isomorphic copies of  $H_n$  and the edges connecting  $H_n^1$  and  $H_n^2$  a sampled by picking  $\tau$  random permutations. In our case the analysis is greatly simplified by picking the edges uniformly and we will need three layers to prove ST-robustness. We will use the following lemma from the Grates paper as a building block. A proof of Lemma 13 is included in the appendix for completeness.

► **Lemma 13** ([14]). *For some suitable constant  $c > 0$  any any subset  $S$  of  $cn/2$  vertices of  $G_n$  the graph  $H_n^1 - S$  contains  $k = cn^{1/3}/2$  vertex disjoint paths  $A_1, \dots, A_k$  of length  $n^{2/3}$  and  $H_n^2 - S$  contains  $k$  vertex disjoint paths  $B_1, \dots, B_k$  of the same length.*

We use Lemma 13 to help establish our main technical Lemma 14. We sketch the proof of Lemma 14 below. A formal proof can be found in Appendix B.

► **Lemma 14.** *Let  $G_n$  be defined as in Construction 12. Then for some constants  $c > 0$ , with high probability  $G_n$  has the property that for all  $S \subset V(G_n)$  with  $|S| = cn/2$  there exists  $A \subseteq V(H_n^1)$  and  $B \subseteq V(H_n^3)$  such that for every pair of nodes  $u \in A$  and  $v \in B$  the graph  $G_n - S$  contains a path from  $u$  to  $v$  and  $|A|, |B| \geq 9cn/40$ .*

**Proof (sketch).** Fixing any  $S$  we can apply Lemma 13 to find  $k := cn^{1/3}/2$  vertex disjoint paths  $P_{1,S}^i, \dots, P_{k,S}^i$  in  $H_n^i$  of length  $n^{2/3}$  for each  $i \leq 3$ . Here,  $c$  is the constant from Lemma 13. Let  $U_{j,S}^i$  be the upper half of the  $j$ -th path in  $H_n^i$  and  $L_{j,S}^i$  be the lower half and define the event  $BAD_{i,S}^{upper}$  to be the event that there exists at least  $k/10$  indices  $j \leq k$  s.t.,  $U_{j,S}^i$  is disconnected from  $L_{i,S}^3$ . We construct  $B$  by taking the union of all of upper paths  $U_{i,S}^3$  in  $H_n^3$  for each non-bad (upper) indices  $i$ . Similarly, we define  $BAD_{i,S}^{lower}$  to be the event that there exists at least  $k/10$  indices  $j \leq k$  s.t.  $U_{i,S}^1$  is disconnected from  $L_{j,S}^2$  and we construct  $A$  by taking the union of all of the lower paths  $L_{i,S}^1$  in  $H_n^1$  for each non-bad (lower) indices  $i$ . We can now argue that any pair of nodes  $u \in A$  and  $v \in B$  is connected by invoking

the pigeonhole principle i.e., if  $u \in L_{i,S}^1$  and  $v \in U_{i',S}^3$  for good indices  $i$  and  $i'$  then there exists some path  $P_j^2$  in the middle layer  $H_n^2$  which can be used to connect  $u$  to  $v$ . We still need to argue that  $|A|, |B| \geq cn/3$  for some constant  $c$ . To lower bound  $|B|$  we introduce the event  $BAD_S = |\{i : BAD_{i,S}^{upper}\}| > \frac{k}{10}$  and note that unless  $BAD_S$  occurs we have  $|B| \geq (9k/10)n^{2/3}/2 = 9cn/40$ . Finally, we show that  $\mathbb{P}[BAD_S]$  is very small and then use union bounds to show that, for a suitable constant  $\tau$ , the probability  $\mathbb{P}[\exists SBAD_S]$  becomes negligibly small. A symmetric argument can be used to show that  $|A| \geq 9cn/40$ . ◀

We now use  $G_n$  to construct  $c$ -maximally ST-robust graphs with linear size.

► **Construction 15** ( $M_n$ ). We construct the family of graphs  $M_n$  as follows: Let the graphs  $SC_n^1$  and  $SC_n^2$  be linear sized  $n$ -superconcentrators with constant indegree  $\delta_{SC}$  [13], and let  $H_n^1, H_n^2$  and  $H_n^3$  be defined and connected as in  $G_n$ , where every output of  $SC_n^1$  is connected to a node in  $H_n^1$ , every node of  $H_n^3$  is connected to an input of  $SC_n^2$ .

■ **Figure 2** A diagram of the constant indegree, linear sized, ST-robust graph  $M_n$ .

► **Theorem 16.** *There exists a constant  $c' > 0$  such that for all sets  $S \subset V(M_n)$  with  $|S| \leq c'n/2$ ,  $M_n$  is  $(|S|, n - |S|)$ -ST-robust, with  $n$  inputs and  $n$  outputs and constant indegree.*

**Proof.** Let  $c' = 9c/40$ , where  $c$  is the constant from  $G_n$ . Consider  $M_n - S$ . Then because  $|S \cap (H_n^1 \cup H_n^2)| \leq |S| \leq c'n/2 \leq cn/2$ , by Lemma 14 with a high probability there exists sets  $A$  in  $H_n^1$  and  $B$  in  $H_n^3$  with  $|A|, |B| \geq \frac{9}{10}k\frac{n^{2/3}}{2} = \frac{9}{40}cn = c'n$ , such that every node in  $A$  connects to every node in  $B$ . By the properties of superconcentrators, the size of the set  $BAD_1$  of inputs  $u$  in  $SC_n^1$  that can't reach *any* node in  $A$  in  $M_n - S$ . We claim that  $|BAD_1| \leq |S| \leq c'n$ . Assume for contradiction that  $|BAD_1| > |S|$  then  $SC_n^1$  contains at least  $\min\{|BAD_1|, |A|\} > |S|$  node disjoint paths between  $BAD_1$  and  $A$ . At least one of these node disjoint paths does not intersect  $S$  which contradicts the definition of  $BAD_1$ . Similarly, we can bound the size of  $BAD_2$ , the set of outputs in  $SC_n^2$  which are not reachable from any node in  $B$ . Given any input  $u \notin BAD_1$  of  $SC_n^1$  and any output  $v \notin BAD_2$  of  $SC_n^2$  we can argue that  $u$  is connected to  $v$  in  $M_n - S$  since we can reach some node  $x \in A$  from  $u$  and  $v$  can be reached from some node  $y \in B$  and *any* such pair  $x, y$  is connected by a path in  $M_n - S$ . It follows that  $M_n$  is  $(|S|, n - |S|)$ -ST-robust. ◀

► **Corollary 17** (of Theorem 16). *For all  $\epsilon > 0$ , there exists a family of DAGs  $\mathbb{M} = \{M_n^\epsilon\}_{n=1}^\infty$ , where each  $M_n^\epsilon$  is a  $c$ -maximally ST-robust graphs with  $|V(M_n)| \leq c_\epsilon n$ ,  $\text{indegree}(M_n) \leq c_\epsilon$ , and depth  $d = n^{1-\epsilon}$ .*

**Proof (sketch).** In the proof of Lemma 13, we used  $(cn, n^{2/3})$ -depth robust graphs. When considering the paths  $A_i$  and  $B_j$ , we were considering connecting the upper half of one path to the lower half of another. Thus, after we remove nodes from  $M_n$ , there exists a path of

length at least  $n^{2/3}$  that connects any remaining input to any remaining output. Thus  $M_n$  is  $c$ -maximally ST-robust with depth  $d = n^{2/3}$ . In [14], Schnitger provides a construction that is  $(cn, n^{1-\epsilon})$ -depth robust for all constant  $\epsilon > 0$ . By the same arguments we used in this section, we can construct  $c$ -maximally ST-robust graphs with depth  $d = n^{1-\epsilon}$ , where the constant  $c$  depends on  $\epsilon$ .  $\blacktriangleleft$

### 3.3 Constructing Maximal ST-Robust Graphs

In this section, we construct maximal ST-robust graphs, which are 1-maximally ST-robust, from  $c$ -maximally ST-robust graphs. We give the following construction:

► **Construction 18** ( $\mathbb{O}(M_n)$ ). Let  $M_n$  be a  $c$ -maximally ST-robust graph on  $O(n)$  nodes. Let  $O$  be a set  $o_1, o_2, \dots, o_n$  of  $n$  output nodes and let  $I$  be a set  $i_1, i_2, \dots, i_n$  of  $n$  input nodes. Let  $S_j$  for  $1 \leq j \leq \lceil \frac{1}{c} \rceil$  be a copy of  $M_n$  with outputs  $o_1^j, o_2^j, \dots, o_n^j$  and inputs  $i_1^j, i_2^j, \dots, i_n^j$ . Then for all  $1 \leq j \leq n$  and for all  $1 \leq k \leq n$ , add a directed edge from  $i_k$  to  $i_k^j$  and from  $o_k^j$  to  $o_k$ .

Because we connect  $\lceil \frac{1}{c} \rceil$  copies of  $M_n$  to the output nodes,  $\mathbb{O}(M_n)$  has indegree  $\max\{\delta, \lceil \frac{1}{c} \rceil\}$ , where  $\delta$  is the indegree of  $M_n$ . Also, if  $M_n$  has  $kn$  nodes, then  $\mathbb{O}(M_n)$  has  $(k\lceil \frac{1}{c} \rceil + 2)n$  nodes. We now show that  $\mathbb{O}(M_n)$  is a maximal ST-robust graph.

► **Theorem 19.** Let  $M_n$  be a  $c$ -maximally ST-robust graph. Then  $\mathbb{O}(M_n)$  is a maximal ST-robust graph.

**Proof.** Let  $R \subset V(\mathbb{O}(M_n))$  with  $|R| = k$ . Let  $R = R_I \cup R_M \cup R_O$ , where  $R_I = R \cap I$ ,  $R_O = R \cap O$ , and  $R_M = R \cap \left(\bigcup_{i=1}^{\lceil 1/c \rceil} S_i\right)$ . Consider  $\mathbb{O}(M_n) - R$ . We see that  $|R_M| \leq k$ , so by the Pidgeonhole Principal at least one  $S_j$  has less than  $cn$  nodes removed, say it has  $t$  nodes removed for  $t \leq cn$ . Hence  $t \leq |R_M|$ . Since  $S_j$  is  $c$ -max ST-robust there exists a subgraph  $H$  of  $S_j - R$  containing  $n - t$  inputs and  $n - t$  outputs such that every input is connected to all of the outputs. Let  $H'$  be the subgraph induced by the nodes in  $V(H) \cup I' \cup O'$ , where  $I' = \{(i_a, i_a^b) | i_a^b \in H\}$  and  $O' = \{(o_a^b, o_a) | o_a^b \in H\}$ .

▷ **Claim 20.** The graph  $H'$  contains at least  $n - k$  inputs and  $n - k$  outputs and there is a path between every pair of input and output nodes.

**Proof.** The set  $|I \setminus I'| \leq |I \cap R| + |V(S_j) \cap R| \leq |R| \leq k$ . Similarly,  $|O \setminus O'| \leq |O \cap R| + |V(S_j) \cap R| \leq |R| \leq k$ . Let  $v \in I'$  be some input. By the connectivity of  $H$ ,  $v$  can reach all of the outputs in  $O'$ . Thus there is a path between every pair of input and output nodes.  $\blacktriangleleft$

Thus  $\mathbb{O}(M_n)$  is  $(k, n - k)$ -ST-robust for all  $1 \leq k \leq n$ . Therefore  $\mathbb{O}(M_n)$  is a maximal ST-robust graph.  $\blacktriangleleft$

► **Corollary 21** (of Theorem 19). For all  $\epsilon > 0$ , there exists a family  $\mathbb{M}^\epsilon = \{M_k^\epsilon\}_{k=1}^\infty$  of max ST-robust graphs of depth  $d = n^{1-\epsilon}$  such that  $|V(M_k^\epsilon)| \leq c_\epsilon n$  and  $\text{indegree}(M_k^\epsilon) \leq c_\epsilon$ .

**Proof.** Apply Construction 18 to the family graphs  $\mathbb{M}^\epsilon = \{M_k^\epsilon\}_{k=1}^\infty$  from Corollary 17. Then by Theorem 19, the family of graphs  $\{\mathbb{O}(M_k^\epsilon)\}_{k=1}^\infty$  is the desired family.  $\blacktriangleleft$

## 4 Applications of ST-Robust Graphs

As outlined previously maximally ST-Robust graphs give us a tight connection between edge-depth robustness and node-depth robustness. Because edge-depth-robust graphs are often easier to design than node-depth robust graphs [14] this gives us a fundamentally new approach to construct node-depth-robust graphs. Beyond this exciting connection we can also use ST-robust graphs to construct perfectly tight proofs of space [9, 12] and asymptotically superior wide-block labeling functions [6].

### 4.1 Tight Proofs of Space

In Proof of Space constructions [12] we want to find a DAG  $G = (V, E)$  with small indegree along with a challenge set  $V_C \subseteq V$ . Intuitively, the prover will label the graph  $G$  using a hash function  $H$  (often modeled as a random oracle in security proofs) such that a node  $v$  with parents  $v_1, \dots, v_\delta$  is assigned the label  $L_v = H(L_{v_1}, \dots, L_{v_\delta})$ . The prover commits to storing  $L_v$  for each node  $v$  in the challenge set  $V_C$ . The pair  $(G, V_C)$  is said to be  $(s, t, \epsilon)$ -hard if for any subset  $S \subseteq V$  of size  $|S| \leq s$  at least  $(1 - \epsilon)$  fraction of the nodes in  $V_C$  have depth  $\geq t$  in  $G - S$  – a node  $v$  has depth  $\geq t$  in  $G - S$  if there is a path of length  $\geq t$  ending at node  $v$ . Intuitively, this means that if a cheating prover only stores  $s \leq |V_C|$  labels and is challenged to reproduce a random label  $L_v$  with  $v \in V_C$  that, except with probability  $\epsilon$ , the prover will need at least  $t$  sequential computations to recover  $L_v$  – as long as  $t$  is sufficiently large the verifier the cheating prover will be caught as he will not be able to recover the label  $L_v$  in a timely fashion. Pietrzak argued that  $(s, t, \epsilon)$ -hard graphs translate to secure Proofs of Space in the parallel random oracle model [12].

We want  $G$  to have small indegree  $\delta(G)$  (preferably constant) as the prover will need  $O(N\delta(G))$  steps and we want  $|V_C| = \Omega(N)$  and we want  $\epsilon$  to be small while  $s, t$  should be larger. Pietrzak [12] proposed to let  $G_\epsilon$  be an  $\epsilon$ -extreme depth-robust graph with  $N' = 4N$  nodes and to let  $V_C = [3N + 1, 4N]$  be the last  $N$  nodes in this graph. An  $\epsilon$ -extreme depth-robust graph with  $N'$  nodes is  $(e, d)$ -depth robust for any  $e + d \leq (1 - \epsilon)N'$ . Such a graph is  $(s, N, s/N + 4\epsilon)$ -hard for any  $s \leq N$ . Alwen et al. [4] constructed  $\epsilon$ -extreme depth-robust graphs with indegree  $\delta(G) = O(\log N)$  though the hidden constants seem to be quite large. Thus, it would take time  $O(N \log N)$  for the prover to label the graph  $G$ . We remark that  $\epsilon = s/|V_C|$  is the tightest possible bound one can hope for as the prover can always store  $s$  labels from the set  $V_C$ .

We remark that if we take  $V_C$  to be any subset of output nodes from a maximally ST-robust graph and overlay and  $(e = s, d = t)$ -depth robust graph over the input nodes then the resulting graph will be  $(s, t, \epsilon = s/|V_C|)$ -hard – optimally tight in  $\epsilon$ . In particular, given a DAG  $G = (V = [N], E)$  with  $N$  nodes devise the overlay graph  $H_G$  by starting with a maximally ST-Robust graph with  $|V|$  inputs  $I = \{x_1, \dots, x_{|V|}\}$  and  $|V|$  outputs  $O$  then for every directed edge  $(u, v) \in E(G)$  we add the directed edge  $(x_u, x_v)$  to  $E(H_G)$  and we specify a target set  $V_C \subseteq O$ . Fisch [9] gave a practical construction of  $(G, V_C)$  with indegree  $O(\log N)$  that is  $(s, N, \epsilon = s/N + \epsilon')$ -hard. The constant  $\epsilon'$  can be arbitrarily small though the number of nodes in the graph scales with  $O(N \log 1/\epsilon')$ . Utilizing ST-robust graphs we fix  $\epsilon' = 0$  without increasing the size of the graph<sup>1</sup>.

<sup>1</sup> As a disclaimer we are not claiming that our construction would be more efficient than [9] for practical parameter settings.

► **Theorem 22.** *If  $G$  is  $(e, d)$ -depth robust then the pair  $(H_G, V_C)$  specified above is  $(s, t = d + 1, s/|V_C|)$ -hard for any  $s \leq e$ .*

**Proof.** Let  $S$  be a subset of  $|S| \leq s$  nodes in  $H_G$ . By maximal ST-robustness we can find a set  $A$  of  $N - |S|$  inputs and  $B$  of  $N - |S|$  outputs such that every pair of nodes  $u \in A$  and  $v \in B$  are connected in  $H_G - S$ . We also note since  $A$  contains all but  $s$  nodes from  $G$  that some node  $u \in A$  is the endpoint of a path of length  $t$  by  $(s, t)$ -depth-robustness of  $G$ . Since  $u$  is connected to *every* node in  $B$  this means that every node  $v \in B$  is the endpoint of a path of length *at least*  $t + 1$ . ◀

This result immediately leads to a  $(s, N^{1-\epsilon}, s/N)$ -hard pair for any  $s \leq N$  which the prover can label in  $O(N)$  time as the DAG  $G$  has constant indegree. We expect that in many settings  $t = N^{1-\epsilon}$  would be sufficiently large to ensure that a cheating prover is caught with probability  $s/N$  after each challenge i.e., if the verifier expects a response within 3 seconds, but it would take longer to evaluate the hash function  $H$   $N^{1-\epsilon}$  sequential times.

► **Corollary 23.** *For any constant  $\epsilon > 0$  there is a constant indegree DAG  $G$  with  $O(N)$  nodes along with a target set  $V_C \subseteq V(G)$  of  $N$  nodes such that the pair  $(G, V_C)$  is  $(s, t = N^{1-\epsilon}, s/N)$ -hard for any  $s \leq N$ .*

**Proof (sketch).** Let  $G$  be an  $(N, N^{1-\epsilon})$ -depth robust graph with  $N' = O(N)$  nodes and constant indegree from [14]. We can then take  $V_C$  to be any subset of  $N$  output nodes in the graph  $H_G$  and apply Theorem 22. ◀

If one does not want to relax the requirement that  $t = \Omega(N)$  then we can provide a perfectly tight construction with  $O(N \log N)$  nodes and constant indegree. Since the graph has constant indegree it will take  $O(N \log N)$  work for the prover to label the graph. This is equivalent to [12], but with perfect tightness  $\epsilon = s/N$ .

► **Corollary 24.** *For any constant  $\epsilon > 0$  there is a constant indegree DAG  $G$  with  $N' = O(N \log N)$  nodes along with a target set  $V_C \subseteq V(G)$  of  $N$  nodes such that the pair  $(G, V_C)$  is  $(s, t, s/N)$ -hard for any  $s \leq N$ .*

**Proof (sketch).** Let  $G$  be an  $(N, N \log N)$ -depth robust graph with  $N' = O(N \log N)$  nodes and constant indegree from [2]. We can then take  $V_C$  to be any subset of  $N$  output nodes in the graph  $H_G$  and apply Theorem 22. ◀

Finally, if we want to ensure that the graph only has  $O(N)$  nodes and  $t = \Omega(N)$  we can obtain a perfectly tight construction with indegree  $\delta(G) = O(\log N)$ .

► **Corollary 25.** *For any constant  $\epsilon > 0$  there is a DAG  $G$  with  $O(N)$  nodes and indegree  $\delta(G) = O(\log N)$  along with a target set  $V_C \subseteq V(G)$  of  $N$  nodes such that the pair  $(G, V_C)$  is  $(s, N, s/N)$ -hard for any  $s \leq N$ .*

**Proof (sketch).** Let  $G$  be an  $(N, N)$ -depth robust graph with  $N' = 3N$  nodes from [4]. We can then take  $V_C$  to be any subset of  $N$  output nodes in the graph  $H_G$  and apply Theorem 22. ◀

## 4.2 Wide-Block Labeling Functions

Chen and Tessaro [6] introduced source-to-sink depth robust graphs as a generic way of obtaining a wide-block labeling function  $H_{\delta, W} : \{0, 1\}^{\delta W} \rightarrow \{0, 1\}^W$  from a small-block function  $H_{fix} : \{0, 1\}^{2L} \rightarrow \{0, 1\}^L$  (modeled as an ideal primitive). In their proposed

approach one transforms a graph  $G$  with indegree  $\delta$  and into a new graph  $G'$  by replacing every node with a source-to-sink depth-robust graph. Labeling a graph  $G$  with a wide-block labeling function is now equivalent to labeling  $G'$  with the original labeling function  $H_{fix}$ . The formal definition of Source-to-Sink-Depth-Robustness is presented below:

► **Definition 26** (Source-to-Sink-Depth-Robustness (SSDR) [6]). *A DAG  $G = (V, E)$  is  $(e, d)$ -source-to-sink-depth-robust (SSDR) if and only if for any  $S \subset V$  where  $|S| \leq e$ ,  $G - S$  has a path (with length at least  $d$ ) that starts from a source node of  $G$  and ends up in a sink node of  $G$ .*

If  $G$  is  $(e, d)$ -depth robust and  $G'$  is constructed by replacing every node  $v$  in  $G$  with a  $(e^*, d^*)$ -source-to-sink-depth-robust (SSDR) and orienting incoming (resp. outgoing) edges into the sources (resp. out of the sinks) then the graph  $G'$  is  $(ee^*, dd^*)$ -depth robust [6] and has cumulative pebbling complexity at least  $ed(e^*d^*)$  [3]. The SSDR graphs constructed in [6] are  $(\frac{K}{4}, \frac{\delta K^2}{2})$ -SSDR with  $O(\delta K^2)$  vertices and constant indegree. They fix  $K := W/L$  as the ratio between the length of outputs for  $H_{\delta, W} : \{0, 1\}^{\delta W} \rightarrow \{0, 1\}^W$  and the ideal primitive  $H_{fix}$ . Their graph has  $\delta K$  source nodes for a tunable parameter  $\delta \in \mathbb{N}$ ,  $O(\delta K^2)$  vertices and constant indegree. Ideally, since we are increasing the number of nodes by a factor of  $\delta K^2$  we would like to see the cumulative pebbling complexity increase by a quadratic factor of  $\delta^2 K^4$ . Instead, if we start with an  $(e, d)$ -depth robust graph with cumulative pebbling complexity  $O(ed)$  their final graph  $G'$  has cumulative pebbling complexity  $ed \times \frac{\delta K^3}{8}$ . Chen and Tessaro left the problem of finding improved source-to-sink depth-robust graphs as an open research question.

Our construction of ST-robust graphs can asymptotically<sup>2</sup> improve some of their constructions, specifically their constructions of source-to-sink-depth-robust graphs and wide-block labeling functions.

► **Theorem 27.** *Let  $G$  be a maximal ST-robust graph with depth  $d$  and  $n$  inputs and outputs. Then  $G$  is an  $(n - 1, d)$ -SSDR graph.*

**Proof.** By the maximal ST-robustness property,  $n - 1$  arbitrary nodes can be removed from  $G$  and there will still exist at least one input node that is connected to at least one output node. Since  $G$  has depth  $d$ , the path between the input node and output node must have length at least  $d$ . ◀

By applying Theorem 27 to the construction in Corollary 19, we can construct a family of  $(\delta K, (\delta K)^{1-\epsilon})$ -SSDR graphs with  $O(\delta K)$  nodes and constant indegree and  $\delta K$  sources. In this case the cumulative pebbling complexity of our construction would be already be  $ed \times \delta^2 K^{2-\epsilon}$  which is much closer to the quadratic scaling that we would ideally like to see. We are off by just  $K^\epsilon$  for a constant  $\epsilon > 0$  that can be arbitrarily small. To make the comparison easier we could also applying Theorem 27 to obtain a family of  $(\delta K^2, (\delta K^2)^{1-\epsilon})$ -SSDR graphs with  $O(\delta K^2)$ -nodes and constant indegree. While the size of the SSDR matches [6] our new graph is  $(e\delta K^2, d(\delta K^2)^{1-\epsilon})$ -depth robust and has cumulative pebbling complexity  $ed \times \delta^{2-\epsilon} K^{4-2\epsilon} \gg ed\delta K^3$ .

<sup>2</sup> While we improve the asymptotic performance we do not claim to be more efficient for practical values of  $\delta, K$ .

## A

 Connector Graphs

We say that a directed acyclic graph  $G = (V, E)$  with  $n$  input vertices and  $n$  output vertices is an  **$n$ -connector** if for any *ordered list*  $x_1, \dots, x_r$  of  $r$  inputs and any *ordered list*  $y_1, \dots, y_r$  of  $r$  outputs,  $1 \leq r \leq n$ , there are  $r$  vertex-disjoint paths in  $G$  connecting input node  $x_i$  to output node  $y_i$  for each  $i \leq r$ .

### A.1 Connector Graphs are ST-Robust

We remarked in the paper that any  **$n$ -connector** is maximally ST-robust.

► **Reminder of Theorem 11.** *If  $G$  is an  $n$ -connector, then  $G$  is  $(k, n - k)$ -ST-robust, for all  $1 \leq k \leq n$ .*

**Proof of Theorem 11.** Let  $D \subseteq V(G)$  with  $|D| = k$ . Consider  $G - D$ . Let  $A = \{(s_1, t_1), \dots, (s_m, t_m)\}$ , where the input  $s_i \in S$  is disconnected from the output  $t_i \in T$  in  $G - D$ , or  $s_i \in D$  or  $t_i \in D$ . Let  $B = \emptyset$ .

Perform the following procedure on  $A$  and  $B$ : Pick any pair  $(s_p, t_p) \in A$  and add  $s_p$  and  $t_p$  to  $B$ . Then remove the pair from  $A$  along with any other pair in  $A$  that shares either  $s_p$  or  $t_p$ . Continue until  $A$  is empty.

If we consider the nodes of  $B$  in  $G$ , then there are  $|B|$  vertex-disjoint paths between the pairs in  $B$  by the connector property, and in  $G - D$  at least one vertex is removed from each path. Thus  $|B| \leq k$ , or we have a contradiction.

If  $(s, t) \in G - (D \cup B)$  are an input to output pair, and  $s$  is disconnected from  $t$ , then by the definition of  $A$  and  $B$  we would have a contradiction, since  $(s, t)$  would still be in  $A$ . Thus all of the remaining inputs in  $G - (D \cup B)$  are connected to all the remaining outputs.

Hence, if we let  $H = G - (D \cup B)$ , then  $H$  is a subgraph of  $G$  with at least  $n - k$  inputs and  $n - k$  outputs, and there is a path going from each input of  $H$  to each of its outputs. Therefore,  $G$  is  $(k, n - k)$ -ST-robust for all  $1 \leq k \leq n$ . ◀

### Butterfly Graphs

A well known family of constant indegree  $n$ -connectors, for  $n = 2^k$ , are the  $k$ -dimensional butterfly graphs  $B_k$ , which are formed by connecting two FFT graphs on  $n$  inputs back to back. By Theorem 11, the butterfly graph is also a maximally ST-robust graph. However, the butterfly graph has  $\Omega(n \log n)$  nodes and does not yield a ST-robust graph of linear size. Since  $B_k$  has  $O(n \log n)$  vertices and indegree of 2, a natural question to ask is if there exists  $n$ -connectors with  $O(n)$  vertices and constant indegree.

### A.2 Connector Graphs Have $\Omega(n \log n)$ vertices

An information theoretic argument of Shannon [15] rules out the possibility of linear size  $n$ -connectors.

► **Theorem 28** (Shannon [15]). *An  $n$ -connector with constant indegree requires at least  $\Omega(n \log n)$  vertices.*

Intuitively, given a  $n$ -connector with constant indegree with constant indegree and  $m$  edges Shannon argued that we can use the  $n$ -connector to encode any permutation of  $[n]$  using  $m$  bits. In more detail fixing any permutation  $\pi$  we can find  $n$  node disjoint paths from input  $i$  to output  $\pi(i)$ . Because the paths are node disjoint we can encode  $\pi$  simply

■ **Figure 3** The butterfly graph  $B_3$  is both an 8-superconcentrator and an 8-connector. All edges are directed from left to right.

by specifying the subset  $S_\pi$  of directed edges which appear in one of these node disjoint paths. We require at most  $m$  bits to encode  $S_\pi$  and from  $S_\pi$  we can reconstruct the set of node-disjoint paths and recover  $\pi$ . Thus, we must have  $m = \Theta(n \log n)$  since we require  $\log n! = \Theta(n \log n)$  bits to encode a permutation.

We stress that this information theoretic argument breaks down if the graph  $G$  is only ST-robust. We are guaranteed that  $G$  contains a path from input  $i$  to output  $\pi(i)$ , but we are not guaranteed that all of the paths are node disjoint. Thus,  $S_\pi$  is insufficient to reconstruct  $\pi$ .

## B Missing Proofs

► **Reminder of Theorem 5.** *Let  $G$  be an  $(e, d)$ -edge-depth-robust DAG with  $m$  edges. Let  $\mathbb{M}$  be a family of max ST-Robust graphs with constant indegree. Then  $G' = (V', E') = \text{Reduce}(G, \mathbb{M})$  is  $(e/2, d)$ -depth robust. Furthermore,  $G'$  has maximum indegree  $\max_{v \in V(G)} \{\text{indeg}(M_{\delta(v)})\}$ , and its number of nodes is  $\sum_{v \in V(G)} |V(M_{\delta(v)})|$  where  $\delta(v) = \max\{\text{indeg}(v), \text{outdeg}(v)\}$ .*

**Proof of Theorem 5.** We know that each graph in  $\mathbb{M}$  has constant indegree, and that each node  $v$  in  $G$  will be replaced with a graph in  $\mathbb{M}$  with indegree  $\text{indeg}(M_{\delta(v)})$ . Thus  $G'$  has maximum indegree  $\max_{v \in V(G)} \{\text{indeg}(M_{\delta(v)})\}$ . Furthermore, the metanode corresponding to the node  $v$  has size  $|M_{\delta(v)}|$ . Thus  $G'$  has  $\sum_{v \in V(G)} |M_{\delta(v)}|$  nodes.

Let  $S \subset V(G')$  be a set of nodes that we will remove from  $G'$ . For a specific node  $v \in V(G)$  we let  $S_v = S \cap (\{v\} \times V_{\delta(v)})$  denote the subset of nodes deleted from the corresponding metanode. We say that the node  $v \in V(G)$  is *irreparable* with respect to  $S$  if  $|S_v| \geq \delta(v)$ ; otherwise we say that  $v$  is *reparable*. If a node  $v$  is reparable, then because the metanodes are maximally ST-Robust we can find subsets  $I_{v,S}$  and  $O_{v,S}$  (with  $|I_{v,S}|, |O_{v,S}| \geq \delta(v) - |S_v|$ ) such that each input node  $s \in I_{v,S}$  is connected to every output node in  $O_{v,S}$ .

We say that an edge  $(u, v) \in E(G)$  is *irreparable* with respect if  $u$  or  $v$  is irreparable, or if the corresponding edge  $e' = (u', v') \in E(G')$  has  $u' \notin O_{u,S}$  or  $v' \notin I_{v,S}$ . We let  $S_{irr} \subset E(G)$  be the set of irreparable edges after we remove  $S$  from  $G$ . We begin the proof by first proving two claims.

▷ **Claim 29.** Let  $P$  be a path of length  $d$  in  $G - S_{irr}$ . Then there exists a path of length at least  $d$  in  $G' - S$ .

*Proof.* In  $G - S_{irr}$  we have removed all of the irreparable edges, so any path in the graph contains only repairable edges. By definition, if  $(u, v)$  is a repairable edge, both  $u$  and  $v$  will be repairable, and  $(u, \pi_{out,u}(v)) \in O_{u,S}$  and  $(v, \pi_{in,v}(u)) \in I_{v,S}$ . Thus the edge corresponding to  $(u, v)$  in  $G' - S$  will connect the metanodes of  $u$  and  $v$ , and  $(u, \pi_{out,u}(v))$  connects to every node in  $I_{u,S}$  and  $(v, \pi_{in,v}(u))$  connects to every node in  $O_{v,S}$ . Thus the edges in  $G' - S$  corresponding to the edges in  $P$  form a path of length at least  $d$ . ◁

▷ **Claim 30.** Let  $S_{irr} \subset E(G)$  be the set of irreparable edges with respect to the removed set  $S$ . Then

$$|S_{irr}| \leq 2|S|.$$

*Proof.* If a node  $v$  is repairable with respect to  $S$  then let  $S_{irr,v}^{in} \subseteq E(G)$  (resp.  $S_{irr,v}^{out}$ ) denote the subset of edges  $(u, v) \in E(G)$  (resp.  $(v, u) \in E(G)$ ) that are irreparable because of  $S_v$  i.e., the corresponding edge  $e' = (u', v') \in E(G')$  has  $v' \notin I_{v,S}$  (resp. the corresponding edge  $(v', u') \in E(G')$  has  $v' \notin O_{v,S}$ ). Let  $S_{irr,v} = S_{irr,v}^{in} \cup S_{irr,v}^{out}$ . Similarly, if  $v$  is irreparable we let  $S_{irr,v} = \{(u, v) : (u, v) \in E(G)\} \cup \{(v, u) : (v, u) \in E(G)\}$  denote the set of all of  $v$ 's incoming and outgoing edges. We note that  $|S_{irr}| \leq \sum_v |S_{irr,v}|$  since  $S_{irr} = \bigcup_v S_{irr,v}$  any irreparable edge must be in one of the sets  $S_{irr,v}$ . Now we claim that  $|S_{irr,v}| \leq |S_v|$  where  $S_v = S \cap (\{v\} \times V_{\delta(v)})$  denote the subset of nodes deleted from the corresponding metanode. We now observe that

$$\begin{aligned} |S_{irr,v}| &\leq |S_{irr,v}^{in}| + |S_{irr,v}^{out}| \\ &\leq (\delta(v) - |I_{v,S}|) + (\delta(v) - |O_{v,S}|) \leq 2|S_v|. \end{aligned}$$

The last inequality invokes maximal ST-robustness to show that  $\delta(v) - |O_{v,S}| \leq |S_v|$  and  $\delta(v) - |I_{v,S}| \leq |S_v|$ . If a node  $v$  is irreparable then the subsets  $I_{v,S}$  and  $O_{v,S}$  might be empty since  $\delta(v) - |S_v| \leq 0$ , but it still holds that  $\delta(v) - |O_{v,S}| \leq |S_v|$  and  $\delta(v) - |I_{v,S}| \leq |S_v|$ . Thus, we have

Thus

$$|S_{irr}| \leq \sum_v |S_{irr,v}| \leq \sum_v 2|S_v| \leq 2|S|. \quad \triangleleft$$

► **Reminder of Corollary 7.** (of Theorem 5) Suppose that there exists a family  $\mathbb{M} = \{M_k\}_{k=1}^{\infty}$  of max ST-Robust graphs with depth  $d_k$  and constant indegree. Given any  $(e, d)$ -edge-depth-robust DAG  $G$  with  $n$  nodes and maximum degree  $\delta$  we can construct a DAG  $G'$  with  $n \times |M_\delta|$  nodes and constant indegree that is  $(e/2, d \cdot d_\delta)$ -depth robust.

**Proof of Corollary 7 (sketch).** We slightly modify our reduction. Instead of replacing each node  $v \in G$  with a copy of  $M_{\delta(v)}$ , we instead replace each node with a copy of  $M_{\delta,v} := M_\delta$ , attaching the edges same way as in Construction 4. Thus the transformed graph  $G'$  has

$|V(G)| \times |M_\delta|$  nodes and constant indegree. Let  $S \subset V(G')$  be a set of nodes that we will remove from  $G'$ . By Claim 29, there exists a path  $P$  in  $G' - S$  that passes through  $d$  metanodes  $M_{\delta,v_1}, \dots, M_{\delta,v_d}$ . The only difference is that each  $M_{\delta,v_i}$  is maximally ST-robust *with depth*  $d_\delta$  meaning we can assume that the sub-path  $P_i = P \cap M_{\delta,v_i}$  through each metanode has length  $|P_i| \geq d_\delta$ . Thus, the total length of the path is at least  $\sum_i |P_i| \geq d \cdot d_\delta$ . ◀

► **Reminder of Lemma 13 [14].** *For some suitable constant  $c > 0$  any any subset  $S$  of  $cn/2$  vertices of  $G_n$  the graph  $H_n^1 - S$  contains  $k = cn^{1/3}/2$  vertex disjoint paths  $A_1, \dots, A_k$  of length  $n^{2/3}$  and  $H_n^2 - S$  contains  $k$  vertex disjoint paths  $B_1, \dots, B_k$  of the same length.*

**Proof of Lemma 13 [14].** Consider  $H_n^1 - S$ . Since  $H_n^1$  is  $(cn, n^{2/3})$ -depth-robust and  $|S| = cn/2$ , there must exist a path  $A_1 = (v_1, \dots, v_{n^{2/3}})$  in  $H_n^1 - S$ . Remove all vertices of  $A_1$  and repeat to find  $A_2, \dots$ . Then we finish with  $cn/(2n^{2/3}) = cn^{1/3}/2$  vertex disjoint paths of length  $n^{2/3}$ . We perform the same process on  $H_n^2$  to find the  $B_i$ . ◀

► **Reminder of Lemma 14.** *Let  $G_n$  be defined as in Construction 12. Then for some constants  $c > 0$ , with high probability  $G_n$  has the property that for all  $S \subset V(G_n)$  with  $|S| = cn/2$  there exists  $A \subseteq V(H_n^1)$  and  $B \subseteq V(H_n^3)$  such that for every pair of nodes  $u \in A$  and  $v \in B$  the graph  $G_n - S$  contains a path from  $u$  to  $v$  and  $|A|, |B| \geq 9cn/40$ .*

**Proof of Lemma 14.** By Lemma 13, we know that in  $G_n - S$  there exists  $k := c'n^{1/3}/2$  vertex disjoint paths  $A_1, \dots, A_k$  in  $H_n^1$  of length  $n^{2/3}$  and  $k$  vertex disjoint paths  $B_1, \dots, B_k$  in  $H_n^2$  of length  $n^{2/3}$ . Here,  $c'$  is the constant from Lemma 13. Let  $U_{j,S}^i$  be the upper half of the  $j$ -th path in  $H_n^i$  and  $L_{j,S}^i$  be the lower half, both of which are relative to the removed set  $S$ .

Now for each  $i \leq k$  define the event  $BAD_{i,S}$  to be the event that there exists  $j \leq k$  s.t.,  $U_{j,S}^1$  is disconnected from  $L_{j,S}^2$ . We now set  $GOOD_S = [k] \setminus \{i : BAD_{i,S}\}$  and define

$$B_S := \bigcup_{i \in GOOD_S}^k U_{i,S}^2, \quad \text{and} \quad A_S := \bigcup_{i=1}^k L_{i,S}^1.$$

Now we claim that for every node  $u \in A_S$  and  $v \in B_S$  the graph  $G_n - S$  contains a path from  $u$  to  $v$ . Since  $u \in A_S$  we have  $u \in L_{i,S}^1$  for some  $i \leq k$ . Thus, all nodes in  $U_{i,S}^1$  are reachable from  $u$ . Since,  $v \in B_S$  we have  $v \in U_{j,S}^2$  for some good  $j \in GOOD$ . We know that  $v$  is reachable from any node in  $L_{j,S}^2$ . By definition of  $GOOD_S$  there must be an edge  $(x, y)$  from some node  $x \in U_{i,S}^1$  to some node  $y \in L_{j,S}^2$  since we already know that there is a directed path from  $u$  to  $x$  and from  $y$  to  $v$  there is a directed path from  $u$  to  $v$ . Thus, every pair of nodes in  $A_S$  and  $B_S$  are connected.

We have  $|A_S| \geq kn^{2/3} = c'n/2$ . It remains to argue that for any set  $S$  the resulting set  $|B_S| = |GOOD_S|n^{2/3}$  is sufficiently large. Now we define the event

$$BAD_S := |\{i : BAD_{i,S}\}| > \frac{k}{10}.$$

Intuitively,  $BAD_S$  occurs when more than a small fraction of the events  $BAD_{i,S}$  occur. Assuming that  $BAD_S$  never occurs then for any set  $S$  we have

$$|B_S| \geq |GOOD_S|n^{2/3} \geq (9/10)kn^{2/3} = 9c'n/20.$$

Consider, for the sake of finding the probabilities, that  $S$  is fixed before all of the random edges are added to  $G_n$ . We will then union bound over all choices of sets  $S$ . First we consider the probability that a single upper path, say  $U_{1,S}^1$  is disconnected from a particular lower

path, say  $L_{1,S}^2$ . There are  $n^{1/3}$  possible lower parts to connect to, and there are  $n^{2/3}/2$  nodes in the upper part that can connect to the lower part, and there are  $\tau$  random edges added from each node in the upper part, so we have that

$$\mathbb{P}[U_{1,S}^1 \text{ disconnected from } L_{1,S}^2] \leq \left(1 - \frac{1}{2n^{1/3}}\right)^{\tau n^{2/3}/2} \leq \left(\frac{1}{e}\right)^{\tau n^{1/3}/4}.$$

Union bounding over all indices  $j$  we have

$$\mathbb{P}[BAD_{i,S}] \leq k \left(\frac{1}{e}\right)^{\tau n^{1/3}/4} = \left(\frac{1}{e}\right)^{\tau n^{1/3}/4 - \ln k}.$$

We remark that for  $i \neq j$  the event  $BAD_{i,S}$  is independent of  $BAD_{j,S}$  since the  $\tau$  random incoming edges connected to  $L_i^2$  are sampled independently of the edges for  $L_j^2$ .

We will show that the probability of the event  $BAD_S$  is very small and then take a union bound over all possible  $S$  to show our desired result.

$$\begin{aligned} \mathbb{P}[BAD_S] &\leq \binom{k}{k/10} \mathbb{P}[BAD_{1,S} \wedge \dots \wedge BAD_{k/10,S}] \\ &= \binom{k}{k/10} \mathbb{P}[BAD_{1,S}^{upper}]^{k/10} \\ &\leq \binom{k}{k/10} \left[ \left(\frac{1}{e}\right)^{\tau n^{1/3}/4 - \ln k} \right]^{k/10} \\ &= \binom{k}{k/10} \left(\frac{1}{e}\right)^{(k\tau n^{1/3} - 4k \ln k)/40}. \end{aligned}$$

Finally, we take the union bound over every possible  $S$  of size  $cn/2$  nodes. Since  $G_n$  has  $2n$  nodes there are at most  $2^{2n} = e^{2n \ln 2}$  such sets. Thus,

$$\mathbb{P}[\exists S \text{ s.t. } BAD_S] \leq e^{2n \ln 2} \mathbb{P}[BAD_S^{upper}] \leq \left(\frac{1}{e}\right)^{(k\tau n^{1/3} - 4k \ln k)/40 - 2n \ln 2}.$$

By selecting a sufficiently large constant like  $\tau = 800/c'$  we can ensure that  $(k\tau n^{1/3} - 4k \ln k)/40 - 2n \ln 2 = 20n - 2n \ln 2 - (k \ln k)/10 \geq n$  so that

$$\mathbb{P}[\exists S \text{ s.t. } BAD_S] \leq 2^{-n}.$$

Thus, except with negligible probability for any  $S$  of size  $cn/2$  the event  $BAD_S$  does not occur for any set  $S$  selected *after*  $G_n$  is sampled.  $\blacktriangleleft$

## Abstract

We introduce the *hemicubic codes*, a family of quantum codes obtained by associating qubits with the  $p$ -faces of the  $n$ -cube (for  $n > p$ ) and stabilizer constraints with faces of dimension  $(p \pm 1)$ . The quantum code obtained by identifying antipodal faces of the resulting complex encodes one logical qubit into  $N = 2^{n-p-1} \binom{n}{p}$  physical qubits and displays local testability with a soundness of  $\Omega(1/\log(N))$  beating the current state-of-the-art of  $1/\log^2(N)$  due to Hastings. We exploit this local testability to devise an efficient decoding algorithm that corrects arbitrary errors of size less than the minimum distance, up to polylog factors.

We then extend this code family by considering the quotient of the  $n$ -cube by arbitrary linear classical codes of length  $n$ . We establish the parameters of these *generalized hemicubic codes*. Interestingly, if the soundness of the hemicubic code could be shown to be constant, similarly to the ordinary  $n$ -cube, then the generalized hemicubic codes could yield quantum locally testable codes of length not exceeding an exponential or even polynomial function of the code dimension.

## 1 Quantum LDPC codes, local testability and robustness of entanglement

Entanglement is arguably the central concept of quantum theory and despite decades of study, many questions about it remain unsolved today. One particular mystery is the robustness of phases of highly entangled states, such as the ones involved in quantum computation. Given such a state, does it remain entangled in the presence of noise? A closely related question concerns low-energy states of local Hamiltonians: while ground states, *i.e.*, states of minimal energy, are often highly entangled, is it also the case of higher energy states? These questions are related through the concept of quantum error correction: logical information is often encoded in a quantum error correcting code (QECC) in order to be processed during a quantum computation, and the ground space of a local Hamiltonian is nothing but a special case of a QECC called quantum low-density parity-check (LDPC) code.

Leibniz International Proceedings in Informatics

LIPICs Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Physically it indeed makes sense to implement quantum error correction by relying on local interaction, for example by encoding the quantum state in the degenerate ground space of a local Hamiltonian, that is an  $N$ -qubit operator  $H \propto \sum_i \Pi_i$ , where each  $\Pi_i$  is a projector acting nontrivially on a small number  $q$  of qubits (we talk of  $q$ -local terms). By “small”, one usually means constant or sometimes logarithmic in  $N$ . A quantum stabilizer code is a subspace of the space  $(\mathbb{C}^2)^{\otimes N}$  of  $N$  qubits defined as the common  $+1$  eigenspace of a set  $\{S_1, \dots, S_m\}$  of commuting Pauli operators, that is, the space

$$\text{span}\{|\psi\rangle \in (\mathbb{C}^2)^{\otimes N} : S_i|\psi\rangle = |\psi\rangle, \forall i \in [m]\}.$$

Such a code is said to be *LDPC* if all the generators  $S_i$  act nontrivially on at most  $q$  qubits for small  $q$ . With this language, a quantum LDPC stabilizer code corresponds to the ground space of the local Hamiltonian  $H = \frac{1}{m} \sum_{i=1}^m \Pi_i$ , with  $\Pi_i = \frac{1}{2}(I - S_i)$ .

Entanglement can be quantified in many ways, but a relevant definition is to say that a quantum state is highly entangled (or displays *long-range entanglement*) if it cannot be obtained by processing an initial product state via a quantum circuit of constant depth. By contrast, a quantum state that can be obtained that way, and which is therefore of the form  $U_{\text{circ}}(\otimes_{i=1}^n |\phi_i\rangle)$  for some  $|\phi_i\rangle \in \mathbb{C}^2$ , is said to be *trivial*. An important property of trivial states is that they admit an efficient classical description and that one can efficiently compute the value of local observables such as  $\Pi_i$  for such states: this is because the operator  $U_{\text{circ}}^\dagger \Pi_i U_{\text{circ}}$  remains local (since the circuit has constant depth) and its expectation can therefore be computed efficiently for a product state. In particular, such a classical description can serve as a witness that a local Hamiltonian admits a trivial state of low energy. It is well known how to construct  $N$ -qubit Hamiltonians with highly entangled ground states, for instance by considering a Hamiltonian associated with a quantum LDPC code with non-constant minimum distance [9], but the question of the existence of local Hamiltonians such that low-energy states are non-trivial remains poorly understood.

The no low-energy trivial state (NLTS) conjecture asks whether there exists a local Hamiltonian such that all states of small enough (normalized) energy are nontrivial [20]. More precisely, is there some  $H = \frac{1}{m} \sum_{i=1}^m \Pi_i$  as above, such that there exists a constant  $\alpha > 0$  such that all states  $\rho$  satisfying  $\text{tr}(\rho H) \leq \alpha$  are nontrivial? What is interesting with the NLTS conjecture is that it is a consequence of the quantum PCP conjecture [1], and therefore corresponds to a possible milestone on the route towards establishing the quantum PCP conjecture. We note that there are several versions of the quantum PCP conjecture in the literature, corresponding to the quantum generalizations of equivalent versions of the classical PCP theorem, but not known to be equivalent in the quantum case, and that the multiprover version was recently established [28]. Here, however, we are concerned with the Hamiltonian version of the quantum PCP conjecture which still remains wide open. This conjecture is concerned with the complexity of the *Local Hamiltonian* problem: given a local Hamiltonian as before, two numbers  $a < b$  and the promise that the minimum eigenvalue of the Hamiltonian is either less than  $a$ , or greater than  $b$ , decide which is the case. The quantum PCP conjecture asserts that this problem is QMA-hard when the gap  $b - a$  is constant. This generalizes the PCP theorem that says that the satisfiability problem is NP-hard when the relative gap is constant [11]. Here, QMA is the class of languages generalizing NP (more precisely generalizing MA), where the witness can be a quantum state and the verifier is allowed to use a quantum computer. Assuming that  $\text{NP} \not\subseteq \text{QMA}$ , we see that Hamiltonians with trivial states of low energy cannot be used to prove the quantum PCP conjecture since the classical description of such states would be a witness that could be checked efficiently by a classical verifier. In other words, if the quantum PCP conjecture is true, it implies that NLTS holds. The converse statement is unknown.

Eldar and Harrow made progress towards the NLTS conjecture by establishing a simpler variant, called NLETS [15], by giving an explicit local Hamiltonian where states close to ground states are shown to be nontrivial. (See also Ref. [29] for an alternate proof exploiting approximate low-weight check codes.) The subtlety here is that closeness is not defined as “low energy” as in NLTS, but by the existence of a low weight operator mapping the state to a ground state. Viewing the ground space as a quantum LDPC code, [15] shows that states which are  $\delta N$ -close to the code (for some sufficiently small  $\delta > 0$ ) are nontrivial. The NLTS conjecture asks for something stronger: that all states with energy less than a small, constant, fraction of the operator norm of the Hamiltonian are nontrivial. Of course, states close to the codespace have a low (normalized) energy or syndrome weight, but the converse does not hold in general, and this is what makes the NLTS conjecture difficult to tackle.

One case where the distance to the code is tightly related to the syndrome weight is for *locally testable codes* (LTC): classical locally testable codes are codes for which one can efficiently decide, with high probability, whether a given word belongs to the code or is far from it, where efficiency is quantified in the number of queries to the coordinates of the word. To see the link between the two notions, the idea is to distinguish between codewords and words far from the code by computing a few elements of the syndrome and deciding that the word belongs to the code if all these elements are zero. An LTC is such that any word at constant relative distance from the code will have a constant fraction of unsatisfied checknodes, that is a syndrome of weight linear in the blocklength. The Hadamard code which maps a  $k$ -bit word  $x$  to a string of length  $2^k$  corresponding to the evaluations at  $x$  of all linear functions provides such an example with the syndrome corresponding to all possible linearity tests between the bits of the word: indeed, any word that satisfies most linearity tests can be shown to be close to the codespace [6].

While LTCs have been extensively studied in the classical literature [19] and provide a crucial ingredient for the proof of the classical PCP theorem, their quantum generalization is relatively new and much less understood. The concept was only recently introduced in a paper by Aharonov and Eldar [2] which showed that the classical approaches to local testability seem to fail in the quantum world: for instance, defining a code on a (hyper)graph with too much expansion seems to be a bad idea. In any case, if quantum LTCs with constant minimum distance existed, they would provide a proof of the NLTS conjecture [15], and this motivates trying to understand whether such codes can exist. Let us, however, mention that while classical LTCs are useful for performing alphabet reduction in the context of the PCP theorem, the same doesn’t seem to apply in the quantum regime since it is known that directly quantizing Dinur’s combinatorial proof of the PCP theorem [11] is bound to fail [8, 1].

An additional difficulty in the quantum case is that good quantum LDPC codes are not even known to exist. While taking a random LDPC code yields a code with linear minimum distance with high probability in the classical case, the same statement is not known to hold in the quantum setting. Even restricting our attention to codes only encoding a constant number of logical qubits, it is hard to find families of codes with minimum distance much larger than  $\sqrt{N}$ : a construction due to Freedman, Meyer and Luo gives a minimum distance  $\Theta(N^{1/2} \log^{1/4} N)$  [18] while recent constructions based on high-dimensional expanders yield a polylogarithmic improvement [23, 16, 24] and hold the current record for quantum LDPC codes. (Note that considering subsystem codes [30] or approximate codes [10, 5] is helpful to get a large minimum distance [4, 29, 7].) For these reasons, while a lot of work on classical LTCs focusses on codes with linear minimum distance and aims at minimizing the length of the code, the current goals in the quantum case are much more modest at this point.

A possible formal definition of a quantum LTC was suggested by [15], which we detail now. Recall that the objective is to relate two notions: the distance of a state to the code, and the energy of the state. A quantum code, or equivalently, its associated Hamiltonian, will be locally testable if any word at distance  $t$  from the code (or the ground space) has energy  $\Omega(t)$  and if this energy can be estimated by accessing only a small number of qubits (this is why we insist on having local terms in the Hamiltonian). First, one defines a quantum version of the Hamming distance as follows. Consider the code space  $\mathcal{C} \subset (\mathbb{C}^2)^{\otimes N}$  and define its  $t$ -fattening  $\mathcal{C}_t$  as the span of states at distance at most  $t$  from  $\mathcal{C}$ :

$$\mathcal{C}_t := \text{Span}\{(A_1 \otimes \cdots \otimes A_n)|\psi\rangle : |\psi\rangle \in \mathcal{C}, |\{i : A_i \neq I\}| \leq t\},$$

where the  $A_i$  are single-qubit Pauli matrices. States at distance  $t$  belong to  $\mathcal{C}_t$ , but not to  $\mathcal{C}_{t-1}$ , which we formalize by considering the projector  $\Pi_{\mathcal{C}_t}$  onto  $\mathcal{C}_t$  and forming the *distance operator*

$$D_{\mathcal{C}} := \sum_t t(\Pi_{\mathcal{C}_t} - \Pi_{\mathcal{C}_{t-1}}).$$

Informally, the eigenspace of  $D_{\mathcal{C}}$  with eigenvalue  $t$  corresponds to states which are at distance  $t$  from the code. We now define the averaged normalized Hamiltonian  $H_{\mathcal{C}}$  associated with the quantum code  $\mathcal{C}$  with  $q$ -local projections  $(\Pi_1, \dots, \Pi_m)$ :

$$H_{\mathcal{C}} = \frac{1}{m} \sum_{i=1}^m \Pi_i.$$

The normalization by  $m$  ensures that  $\|H_{\mathcal{C}}\| \leq 1$ . With these notations, we say that a  $q$ -local quantum code  $\mathcal{C} \subseteq (\mathbb{C}^2)^{\otimes n}$  is an  $(s, q)$ -quantum LTC with soundness  $s \in [0, 1]$  if<sup>1</sup>

$$H_{\mathcal{C}} \succeq \frac{s}{N} D_{\mathcal{C}}, \tag{1}$$

where  $A \succeq B$  means that the operator  $A - B$  is positive semidefinite. In words, condition (1) means that any low-energy state is close to the codespace in terms of the quantum Hamming distance, and that simple energy tests allow one to distinguish codewords from states far from the code. More precisely, one can distinguish between a codeword (with energy 0) and a state at distance  $\delta N$  from the code (therefore with energy  $\geq s\delta$ ) by measuring approximately  $1/(s\delta)$  terms of the Hamiltonian. Ideally, one would want the soundness  $s$  and the locality  $q$  to be constant, so that accessing a constant number of qubits would suffice to distinguish codewords from states at distance greater than  $\delta N$  from the code, for constant  $\delta > 0$ .

Known constructions of quantum LTCs are rare. For instance, quantum expander codes yield one example of  $(s, q)$ -quantum LTCs with both  $s = O(1)$ ,  $q = O(1)$ , but with the *major caveat* that Eq. (1) doesn't hold in general, but only on the restriction of the Hilbert space consisting of states  $O(\sqrt{N})$ -close to the codespace [27]. In fact, there exist states at distance  $\Omega(\sqrt{N})$  violating only a single projection  $\Pi_i$ . This means that such codes cannot be used to establish the NLTS conjecture. By allowing the locality to be logarithmic in the number of qubits instead of constant, that is  $q = O(\log N)$ , a recent construction of Hastings [21] yields a quantum LTC with soundness  $s = O\left(\frac{1}{\log^2 N}\right)$ , without any restriction on the validity of Eq. (1). The construction is a generalization of the toric code where instead of taking the product of two 1-cycles of length  $p$ , one rather considers the product of two  $d$ -cycles of area  $p^d$  for the appropriate values of  $p = \omega(1)$  and  $d = \omega(1)$ .

<sup>1</sup> In a previous version of this manuscript, <https://arxiv.org/abs/1911.03069v1>, we were additionally normalizing the Hamiltonian by  $q$ , leading to a soundness value of  $s/q$ . We remove this extra factor here, in accordance with the literature in classical and quantum locally testable codes.

## Our results

In this work, we present a different construction of a quantum LTC which shares with Hastings' the property that it is set in a high-dimensional space with  $d = \Theta(\log N)$  and therefore a similar locality<sup>2</sup>  $q = \Theta(\log N)$ . Our code, however, achieves a slightly better soundness  $r = \Omega\left(\frac{1}{\log N}\right)$ , and in fact, we were not able to rule out that the soundness is not constant, which would be optimal. While this hemicube code only encodes a single logical qubit, we can introduce a generalized family of codes with polynomial rate. These codes are obtained starting with the chain complex associated to the  $n$ -dimensional Hamming cube, where we identify faces corresponding to the same coset of a classical code of length  $n$ . A CSS quantum code is obtained by placing qubits on the  $p$ -faces and stabilizers either on  $(p-1)$ -faces or  $(p+1)$ -faces, with constraints given by the incidence relations between the faces in the cube. While this construction is arguably quite natural, computing the parameters (dimension and minimum distance) of this code family turned out to be rather subtle, relying in nontrivial arguments from algebraic topology. The parameters of the CSS code resulting from the quotient of the cube by a linear code of parameters  $[n, k, d]$  are

$$\left\lfloor 2^{n-p-k} \binom{n}{p}, \binom{p+k-1}{p}, \min \left\{ \binom{d}{p}, 2^{n-p-k} \right\} \right\rfloor$$

when qubits are placed on  $p$ -faces for  $p \leq d-2$ . Whether these codes are also locally testable is left as an open question. In that case, these would provide the first examples of quantum LTCs of exponential or even polynomial length in the code dimension. Remember indeed that both the hemicubic and Hastings' codes have constant dimension.

## 2 Construction of the hemicubic code

We start with the simplest member of our quantum code family, corresponding to the quotient of the  $n$ -cube by the repetition code. It has been known since Kitaev [25] that one can associate a quantum CSS code with any chain complex of binary vector spaces of the form:  $C_2 \xrightarrow{\partial_2} C_1 \xrightarrow{\partial_1} C_0$ , where the boundary operators  $\partial_2$  and  $\partial_1$  satisfy  $\partial_1 \partial_2 = 0$ . One first defines two classical codes  $C_X = \ker \partial_1$  and  $C_Z = (\text{Im } \partial_2)^\perp = \ker \partial_2^T$ . These codes satisfy  $C_Z^\perp \subseteq C_X$  since  $\partial_1 \partial_2 = 0$  and the resulting quantum CSS code is the linear span of  $\left\{ \sum_{z \in C_Z^\perp} |x+z\rangle : x \in C_X \right\}$ , where  $\{|x\rangle : x \in \mathbb{F}_2^N\}$  is the canonical basis of  $(\mathbb{C}^2)^{\otimes N}$  and  $N$  is the dimension of the central space  $C_1$  of the chain complex. One obtains in this way a quantum code of length  $N$  and dimension  $\dim(C_X/C_Z^\perp) = \dim(C_X) + \dim(C_Z) - N$ . Its minimum distance is given by  $d_{\min} = \min(d_X, d_Z)$  with  $d_X = \min\{|w| : w \in C_X \setminus C_Z^\perp\}$  and  $d_Z = \min\{|w| : w \in C_Z \setminus C_X^\perp\}$ . Here,  $|w|$  stands for the Hamming weight of the word  $w$ .

Our construction relies on the  $n$ -dimensional hemicube, where a  $p$ -face is formed by a pair of antipodal  $p$ -dimensional faces of the Hamming cube  $\{0, 1\}^n$ . A  $p$ -face of the Hamming cube is a string of  $n$ -elements from  $\{0, 1, *\}$  where symbol  $*$  appears exactly  $p$  times. Let us denote by  $C_p^n$  the  $\mathbb{F}_2^n$ -vector space spanned by  $p$ -faces of the hemicube. Boundary  $\partial_p$  and coboundary  $\delta_p$  operators are obtained by extending the natural operators for the Hamming cube to the hemicube

$$\begin{aligned} \partial_p x_1 \dots x_n &:= \bigoplus_{i \text{ s.t. } x_i = *} x_1 \dots x_{i-1} 0 x_{i+1} \dots x_n \oplus x_1 \dots x_{i-1} 1 x_{i+1} \dots x_n \\ \delta_p x_1 \dots x_n &:= \bigoplus_{i \text{ s.t. } x_i \neq *} x_1 \dots x_{i-1} * x_{i+1} \dots x_n \end{aligned}$$

<sup>2</sup> We note that in both our construction and Hastings', each qubit is only involved in a logarithmic number of constraints.

and are further extended to  $p$ -chains by linearity. We reserve the notation  $+$  for the standard addition in  $\mathbb{F}_2$  and use  $\oplus$  for summing chains. The hemicubic code is then defined as the CSS code obtained from the chain complex

$$C_{p+1}^n \xrightarrow{\partial_{p+1}} C_p^n \xrightarrow{\partial_p} C_{p-1}^n.$$

Choosing  $p = \alpha n$  for  $0 < \alpha < 1$ , the resulting code will be LDPC with generators of logarithmic weight since the boundary and coboundary operators act nontrivially on  $O(n) = O(\log N)$  coordinates. The dimension of the hemicubic code corresponds to that of the homology groups  $H_p^n = \ker \partial_p / \text{Im } \partial_{p+1}$ . Since the hemicube, viewed as a cellular complex, has the same topology as the real projective plane, its homology groups all have the same dimension equal to 1. We note that the quantum code obtained here can be described with a completely different approach exploiting Khovanov homology [3]. Obtaining the minimum distance of the code requires more care since one needs to find lower bounds on the weight of minimal nontrivial cycles and cocycles in the hemicube. Summarizing, we establish the following result.

► **Theorem 1.** *The hemicubic code is a CSS code with parameters*

$$\left[ \left[ N = 2^{n-p-1} \binom{n}{p}, 1, d_{\min} = \min \left\{ \binom{n}{p}, 2^{n-p-1} \right\} \right] \right].$$

Let  $\alpha^* \approx 0.227$  be the unique nonzero solution of  $h(\alpha^*) = 1 - \alpha^*$  where  $h$  is the binary entropy function. Then choosing  $p = \lfloor \alpha^* n \rfloor$  yields a quantum code family with  $d_{\min} \geq \frac{\sqrt{N}}{1.62}$  [3].

### 3 Local testability of the hemicubic code

We now turn our attention to the local testability of the hemicubic code. This property results from isoperimetric bounds on the hemicube.

► **Theorem 2.** *The hemicubic code is locally testable with soundness  $s = \Omega\left(\frac{1}{\log N}\right)$ .*

This improves over Hastings' construction [22] obtained by taking the product of two  $n$ -spheres and which displays soundness  $s = \Theta(\log^{-2}(N))$ . It would be interesting to understand whether the bounds of Theorem 2 are tight or not. At the moment, we believe it might be possible to get rid of the logarithmic factor and obtain a constant soundness for the hemicubic code. This would then match the soundness of the standard Hamming cube, which does not encode any logical qubit since its associated complex has zero homology.

We say that a  $p$ -chain  $X$  is a *filling* of  $Y$  if  $\partial X = Y$  and that a  $p$ -cochain  $X$  is a *cofilling* of  $Y$  if  $\delta X = Y$ . The main tools to establish the soundness of the hemicubic code are upper bounds on the size of fillings (resp. cofillings) for boundaries (resp. coboundaries) in the cube. Denoting the Hamming weight of chains and cochains by  $\| \cdot \|$ , we have:

► **Lemma 3.** *Let  $E$  be a  $p$ -chain of  $C_p^n$ . Then there exists a  $p$ -chain  $F$  which is a filling of  $\partial E$ , satisfying  $\partial F = \partial E$  such that*

$$\|F\| \leq \frac{n-p}{2} \|\partial E\|.$$

*Let  $E$  be a  $p$ -cochain of  $C_p^n$ . Then there exists a  $p$ -cochain  $F$  which is a cofilling of  $\delta E$ , satisfying  $\delta F = \delta E$  such that*

$$\|F\| \leq (p+1) \|\delta E\|.$$

It is straightforward to translate these results in the language of quantum codes. Let us represent an arbitrary Pauli error of the form  $\bigotimes_{i \in E_X, j \in E_Z} X^i Z^j$  by a couple  $E = (E_X, E_Z)$  where  $E_X$  is the support of the  $X$ -type errors and  $E_Z$  is the support of the  $Z$ -type error. Interpreting  $E_X$  as a  $p$ -chain and  $E_Z$  as a  $p$ -cochain, we see that the syndrome of  $E$  is given by the pair  $(\partial E_X, \delta E_Z)$ . In order to compute the soundness of the quantum code, one needs to lower bound the ratio:

$$\min_{(E_X, E_Z)} \frac{\|\partial E_X\| + \|\delta E_Z\|}{\|[E_X]\| + \|[E_Z]\|} \geq \min \left\{ \min_{E_X} \frac{\|\partial E_X\|}{\|[E_X]\|}, \min_{E_Z} \frac{\|\delta E_Z\|}{\|[E_Z]\|} \right\},$$

where the minimum is computed over all errors with a nonzero syndrome, i.e., for  $p$ -chains  $E_X$  which are not a  $p$ -cycle and  $p$ -cochains  $E_Z$  which are not a  $p$ -cocycle. In these expressions, we denote by  $[E]$  the representative of the equivalence class of error  $E$ , with the smallest weight. Indeed, recall that two errors differing by an element of the stabilizer group are equivalent. The fact that one considers  $[E]$  instead of  $E$  makes the analysis significantly subtler in the quantum case than in the classical case. A solution is to work backward (as was also done by Dotterer in the case of the Hamming cube [13]): start with a syndrome and find a small weight error giving rise to this syndrome. This is essentially how we establish Lemma 3:

$$\min_{E_X, \partial E_X \neq 0} \frac{\|\partial E_X\|}{\|[E_X]\|} \geq \frac{2}{n-p}, \quad \min_{E_Z, \delta E_Z \neq 0} \frac{\|\delta E_Z\|}{\|[E_Z]\|} \geq \frac{1}{p+1}.$$

This implies the soundness in Theorem 2 since  $n-p, p+1 = \Theta(\log N)$ .

While Dotterer established tight bounds for the size of (co)fillings in the Hamming cube, we do not know whether the bounds of Lemma 3 are tight. Right now, we lose a logarithmic factor in the case of the hemicube, but it is not clear that this should be the case. In fact, it is not even excluded that the hemicube could display a *better* soundness than the standard cube. We expand on these ideas in the full version of the paper [26].

## 4 An efficient decoding algorithm for the hemicubic code

The existence of the small fillings and cofillings promised by the soundness of the code is particularly interesting in the context of decoding since it guarantees the existence of a low-weight error associated to any low-weight syndrome. To turn this into an efficient decoding algorithm, the main idea is to notice that one can efficiently find the required fillings and cofillings and therefore find Pauli errors giving the observed syndrome. While finding the smallest possible fillings or cofillings does not appear to be easy, finding ones satisfying the bounds of Lemma 3 can be done efficiently.

We note, however, that the decoding algorithm does not seem to perform so well against random errors of linear weight. In particular, arguments from percolation theory that would imply that errors tend to only form small clusters and that therefore it is sufficient to correct these errors (similarly to [17] for instance) will likely fail here because of the logarithmic weight of the generators. Indeed, the factor graph of the code has logarithmic degree and there does not exist a constant threshold for the error probability such that below this threshold, errors appear in clusters of size  $o(N)$ . In addition, and more importantly, our decoding algorithm is not local in the sense that it explores only the neighborhood of some violated constraints to take a local decision, and for this reason, it is not entirely clear whether the algorithm processes disconnected clusters of errors independently.

► **Theorem 4.** *The hemicubic code comes with an efficient decoding algorithm that corrects adversarial errors of weight  $O(d_{\min}/\log^2 N)$  with complexity  $O(n^4 N)$ .*

The decoding complexity is quasilinear in the error size and the algorithm can be parallelized to run in logarithmic depth. Finding a filling (or cofilling) can be done recursively by fixing one of the  $n$  coordinates and finding fillings in the projective cube of dimension  $n - 1$ . While the choice of the special coordinate is not immediately obvious if one wants to find the smallest filling, it is nevertheless possible to make a reasonably good choice efficiently by computing upper bounds on the final filling size for each possible choice of coordinate. We establish Theorem 4 in the full version of the paper [26].

## 5 Generalized hemicubic codes: quotients by arbitrary linear codes

A key remark is that identifying antipodal  $p$ -faces of the  $n$ -cube is equivalent to considering the cosets of the repetition code  $\{0^n, 1^n\}$  in the cube complex. It is therefore tempting to generalize this approach by identifying the elements of the cosets of arbitrary linear codes  $\mathcal{C}$  with parameters  $[n, k, d]$ . We form in this way a new complex where two  $p$ -faces  $x$  and  $y$  are identified if there exists a codeword  $c \in \mathcal{C}$  such that  $x = y + c$ . Recall that addition is coordinate-wise here and that  $*$  is an absorbing element.

Deriving the parameters of the quantum CSS code associated to these new complexes has been surprisingly challenging. In particular it does not seem particularly obvious that the quantum parameters, especially the minimum distance, should depend only on the parameters  $[n, k, d]$  of the classical code  $\mathcal{C}$  and not otherwise on its particular structure: it turns out indeed to be the case however. We managed to derive the quantum parameters by exhibiting explicit representatives of the  $\mathbb{F}_2$ -homology and cohomology classes, through a double induction on  $p$  and the classical code dimension  $k$ . We obtain a lower bound on the minimum homologically non-trivial cycle weight by exhibiting a set of representatives of a cohomology class all of which must be orthogonal to the cycle, and in particular intersect it. Since a non-trivial cycle meets this bound it is exact. A similar method is used to derive the minimum non-trivial cocycle weight and we obtain the following theorem.

► **Theorem 5.** *The quantum code obtained as the quotient of the  $n$ -cube by a linear code  $[n, k, d]$  admits parameters*

$$\left\lfloor 2^{n-p-k} \binom{n}{p}, \binom{p+k-1}{p}, \min \left\{ \binom{d}{p}, 2^{n-p-k} \right\} \right\rfloor$$

when qubits are placed on  $p$ -faces for  $p \leq d - 2$ .

An interesting case is  $k = 2$ , which yields a quantum code of exponential length (that is, dimension logarithmic in the code length):

$$\left\lfloor 2^{n-p-2} \binom{n}{p}, p + 1, \min \left\{ \binom{d}{p}, 2^{n-p-2} \right\} \right\rfloor.$$

We are only able to prove a lower bound on the soundness of the code (for  $X$ -errors) of  $\Omega(1/p!)$ . However, a much improved soundness would follow from the conjectured filling and cofilling constants of the original hemicubic complex: generalized hemicubic codes are therefore candidates for quantum locally testable codes of growing dimension, of which no examples are presently known.

## 6 Discussion and open questions

In this paper, we have introduced a family of quantum code constructions that live on the quotient of the  $n$ -dimensional Hamming cube by classical linear codes. Despite the apparent simplicity of the construction, it does not seem to have appeared before in the literature.

Deriving the parameters of these codes turned out to be significantly subtler than expected, and quite surprisingly, the parameters of the quantum code only depend on the parameters of the classical code and not on any additional structure. The simplest member of our quantum code family, the hemicubic code, basically inherits its local testability from the soundness of the Hamming cube, which was established by Dotterer. In our view, the fact that our code construction relies so much on the Hamming cube may be expected to yield additional advantages, through the import of other interesting properties from the cube, as well as tools from Boolean analysis.

The most pressing question is to understand whether the generalized hemicubic codes also display local testability. At the moment, we can only establish it for the simplest member of the family, which only encodes a single logical qubit. If we could show that the codes corresponding to the quotient of the Hamming cube by arbitrary linear codes of dimension  $k$  remain locally testable, then this would provide the first examples of quantum locally testable codes of exponential (if  $k > 1$ ) or polynomial (if  $k = \Omega(n)$ ) length. As we discuss in the full version of the paper [26], improving our bound on the soundness of the one-qubit hemicubic code from  $\frac{1}{\log N}$  to constant would already prove that the generalized code with  $k = 2$  remains locally testable. An indication that such an improvement might be possible comes from the 0-qubit code defined on the standard hypercube (without identifying antipodal faces) which indeed displays constant soundness [12]. More generally, the question of what parameters are achievable for quantum locally testable codes is essentially completely open at the moment.

Another intriguing question is whether the hemicubic code might help towards establishing the NLTS conjecture (albeit with a quasilocal Hamiltonian with terms of logarithmic weight) or more generally whether it is relevant for many-body physics. As mentioned earlier, any quantum LTC with linear minimum distance would yield such a proof [15]. The hemicubic code, however, is restricted by a  $O(\sqrt{N})$  minimum distance, and the argument of [15] does not directly apply anymore. This is in particular a line of research followed by Eldar which relies on the hemicubic code and which provides positive partial results [14]. We note that in the physics context of the Local Hamiltonian, it is crucial that every individual quantum system (say, qubit) is acted upon by a small number of terms. In this sense, the problem is somewhat more constrained than in the local testability case where one is typically fine if the number of qubits is much larger than the number of constraints. Our quantum codes satisfy this requirement since each qubit is only involved in a logarithmic number of local constraints.

Finally, while classical LTCs have found a number of applications in recent years, notably for constructing PCPs, it is fair to say that not much is presently known about possible applications of quantum LTCs. At the same time, local testability is a notion that makes perfect sense in the quantum regime and it seems reasonable to think that quantum LTCs might also find applications. Finding explicit families encoding a non-constant number of qubits is a natural first step.

## Abstract

We exhibit several computational problems that are *complete* for multi-pseudodeterministic computations in the following sense: (1) these problems admit 2-pseudodeterministic algorithms (2) if there exists a pseudodeterministic algorithm for any of these problems, then any multi-valued function that admits a  $k$ -pseudodeterministic algorithm for a constant  $k$ , also admits a pseudodeterministic algorithm. We also show that these computational problems are complete for *Search-BPP*: a pseudodeterministic algorithm for any of these problems implies a pseudodeterministic algorithm for all problems in Search-BPP.

**2012 ACM Subject Classification** Theory of computation → Probabilistic computation; Theory of computation → Problems, reductions and completeness

## 1 Introduction

Consider the search problem of producing a witness that two multi-variate polynomials  $f$  and  $g$  over a field are different. A simple probabilistic polynomial-time algorithm for this problem randomly picks an element  $t$  from the domain and outputs it if  $f(t) \neq g(t)$ . Even though this algorithm is simple and efficient and the error probability can be made arbitrarily small, Gat and Goldwasser [3] pointed out a deficiency: two different runs of the algorithm can produce two different witnesses with very high probability. Well-known probabilistic algorithms for several search problems, such as finding a large prime number or computing generators of cyclic groups, also exhibit this deficiency. This raises the question of whether we can design a probabilistic algorithm for search problems that will output the same witness on multiple executions, with high probability. Motivated by the above question, Gat and Goldwasser [3] introduced the notion of *pseudodeterministic algorithms*<sup>1</sup>. Informally, a probabilistic algorithm  $M$  is pseudodeterministic if for every  $x$ , there exists a

---

<sup>1</sup> Originally termed Bellagio algorithms

unique value  $v$  such that  $\Pr[M(x) = v]$  is high. Pseudodeterministic algorithms are appealing in several contexts, such as distributed computing and cryptography, where it is desirable that different invocations of an algorithm by different parties should produce the same output. In complexity theory, the notion of pseudodeterminism clarifies the relationship between search and decision problems in the context of randomized computation. It is not known whether derandomizing BPP to P implies derandomization of probabilistic search algorithms. However,  $\text{BPP} = \text{P}$  implies that pseudodeterministic search algorithms can be made deterministic [5].

## Prior Work

Since its introduction, pseudodeterminism and its generalizations have received considerable attention. In particular, designing pseudodeterministic algorithms for problems that admit polynomial-time randomized algorithms but without known deterministic algorithms continues to be a key line of research with some success. Gat and Goldwasser showed that there exist polynomial-time pseudodeterministic algorithms for algebraic problems such as finding quadratic non-residues and finding certificates that two multivariate polynomials are different [3]. Goldwasser and Grossman exhibited a pseudodeterministic NC algorithm for computing matchings in bipartite graphs [8]. Grossman designed a pseudodeterministic algorithm for computing primitive roots whose runtime matches the best known Las Vegas algorithm [11]. Oliveira and Santhanam [13] showed that there is a sub-exponential time pseudodeterministic algorithm for generating primes that works at infinitely many input lengths.

Subsequent works extended pseudodeterminism to several other scenarios. Works of Goemans, Goldwasser, Grossman, and Holden investigated pseudodeterminism in the context of interactive proofs [9, 4]. Goldwasser, Grossman, Mohanty and Woodruff [10] investigated pseudodeterminism in the data stream model. They showed that certain streaming problems admit faster pseudodeterministic algorithms in comparison to their deterministic counterparts. They also obtain space lower bounds for sketch based pseudodeterministic estimation of  $\ell_2$  norm. Goldreich, Goldwasser, and Ron [5] investigated pseudodeterminism in the context of sublinear-time algorithms. Dixon, Pavan, and Vinodchandran [2] studied pseudodeterminism in the context of approximation algorithms and showed that making Stockmeyer's [16] well-known approximate counting algorithm pseudodeterministic will yield new circuit lower bounds. Oliveira and Santhanam studied pseudodeterminism in the context of learning algorithms and showed that some randomized learning algorithms can be made pseudodeterministic under certain complexity theoretic assumptions [14]. Since then a few generalizations of pseudodeterminism such as *reproducible algorithms*, *influential bit algorithms* and *multi-pseudodeterministic algorithms* have been introduced [12, 7].

## Multi-Pseudodeterminism

Our main focus is on the notion of *multi-pseudodeterminism* recently introduced by Goldreich [7]. Consider the problem of estimating the average value of a function that is defined over a large but finite universe. It is well known that there is an efficient additive error, probabilistic approximation for this problem. So far, we do not know how to make this algorithm pseudodeterministic. Suppose that we relax the restriction of pseudodeterminism - instead of requiring that the algorithm outputs an unique approximation, the algorithm must output *one of two approximate values* with high probability. Then it is very easy to obtain such probabilistic algorithms [7]. Motivated by this, Goldreich

introduced the notion of *multi-pseudodeterminism*. For a positive integer  $k$ , a probabilistic algorithm  $A$  is  $k$ -pseudodeterministic if, for every input  $x$ , there exists a set  $S_x$  of size at most  $k$  such that  $A(x)$  belongs to  $S_x$  with probability at least  $\frac{k+1}{k+2}$ . Thus a pseudodeterministic algorithm is 1-pseudodeterministic. Goldreich's work established several key properties of multi-pseudodeterministic algorithms. This work showed that, as with the case of probabilistic and pseudodeterministic algorithms, error reduction is possible for multi-pseudodeterministic algorithms. Goldreich's work also established an equivalence between multi-pseudodeterminism and reproducible algorithms introduced by Grossman and Liu [12] and presented a composition result for multi-pseudodeterministic algorithms.

## Our Contributions

Our main focus is on the notion of *multi-pseudodeterminism*. The notion of multi-pseudodeterminism is especially interesting because there are computational problems that admit 2-pseudodeterministic algorithms for which we do not know of any pseudodeterministic algorithms. As mentioned earlier, it can be shown that randomized approximation algorithms can be made 2-pseudodeterministic (see Section 2). Thus it is significant to investigate the possibility of designing pseudodeterministic algorithms for problems that admit  $k$ -pseudodeterministic algorithms for small values of  $k$ .

Our main contribution is to show the existence of complete problems for multi-pseudodeterministic computations in the following sense: (1) these computational problems admit 2-pseudodeterministic algorithms, and (2) if there exists a pseudodeterministic algorithm for any of these problems, then all multi-valued functions that admit  $k$ -pseudodeterministic algorithms for a constant  $k$ , also admit pseudodeterministic algorithms.

The computational problems we consider are the following. We note that all of these problems admit 2-pseudodeterministic algorithms.

### ► Definition 1 (Computational Problems).

- COLLISION PROBABILITY ESTIMATION PROBLEM. *Given a Boolean circuit  $C : \{0, 1\}^n \rightarrow \{0, 1\}$ , give a  $(\varepsilon, \delta)$ -additive approximation of the collision probability of  $C$ .*
- ACCEPTANCE PROBABILITY ESTIMATION PROBLEM: *Given a Boolean circuit  $C : \{0, 1\}^n \rightarrow \{0, 1\}$ , give a  $(\varepsilon, \delta)$ -additive approximation for  $\Pr_{x \in U_n}[C(x) = 1]$ .*
- ENTROPY ESTIMATION PROBLEM: *Given a Boolean circuit  $C : \{0, 1\}^n \rightarrow \{0, 1\}$ , give an  $(\varepsilon, \delta)$ -additive approximation of the entropy of the distribution  $C(U_n)$ .*

We first show that if any of the above problems have a pseudodeterministic algorithm, then all 2-pseudodeterministic algorithms can be made pseudodeterministic and thus any  $(\varepsilon, \delta)$ -approximation algorithm for a function  $f$  can be made pseudodeterministic.

**Result 1:** *If any of the problems from Definition 1 admits a pseudodeterministic algorithm, every function that has a  $(\varepsilon, \delta)$ -approximation algorithm has a pseudodeterministic  $(\varepsilon, \delta)$ -approximation algorithm.*

Next we extend this result to  $k$ -pseudodeterminism.

**Result 2:** *If any of the problems from Definition 1 admits a pseudodeterministic algorithm, then any multivalued function that admits a  $k$ -pseudodeterministic algorithm also admits a pseudodeterministic algorithm.*

Note that the above result holds for any multivalued function computation. *Search problems* are multivalued functions whose outputs have an efficient verification procedure. Much of the work on pseudodeterminism focuses on problem in the class *Search-BPP*: search problems that have randomized algorithms whose outputs can be verified in BPP [6]. We extend the above result to problems in Search-BPP.

**Result 3:** *If any of the problems from Definition 1 admits a pseudodeterministic algorithm, then any problem in Search-BPP has a pseudodeterministic algorithm.*

Extending this result on Search-BPP to other classes of multivalued functions is an interesting question. Note that there are natural multivalued functions that admit efficient probabilistic algorithms but are not known to be in Search-BPP (because of the lack of an efficient verification procedure). For example the problem of outputting a Boolean function with high circuit complexity has a simple probabilistic algorithm but not known to be in Search-BPP.

## 2 Pseudodeterminism in Approximation Algorithms

In this section, we establish that COLLISION PROBABILITY ESTIMATION PROBLEM is complete. We first define the notions of pseudodeterminism and multi-pseudodeterminism for approximation algorithms formally. In general, an approximation algorithm can output different good approximations on different random choices. For an approximation algorithm  $A$  to be  $k$ -pseudodeterministic,  $A$  has to output with high probability at most  $k$  good approximations for any input.

► **Definition 2** (Multiplicative Approximation). *Let  $f$  be a function whose range is the integers. We say that a probabilistic algorithm  $A$  is an  $(\varepsilon, \delta)$ -multiplicative approximation algorithm for  $f$  if for every  $x$ , the random variable  $A(x)$  has the following property:  $\Pr \left[ \frac{f(x)}{(1+\varepsilon)} \leq A(x) \leq (1+\varepsilon)f(x) \right] \geq (1-\delta)$ . We say that  $A$  is an  $(\varepsilon, \delta)$   $k$ -pseudodeterministic multiplicative approximation algorithm for  $f$  if for every  $x$  there exists a set of integers  $V_x$  such that  $|V_x| \leq k$  and for every  $v \in V_x$*

$$\frac{f(x)}{(1+\varepsilon)} \leq v \leq (1+\varepsilon)f(x) \text{ and } \Pr[A(x) \in V_x] \geq 1 - \delta.$$

When  $k = 1$ , we call the algorithm pseudodeterministic.

► **Definition 3** (Additive Approximation). *Let  $f$  be a function whose range is  $[0, 1]$ . We say that a probabilistic polynomial-time algorithm  $A$  is an  $(\varepsilon, \delta)$ -additive approximation algorithm for  $f$  if for every  $x$ , the random variable  $A(x)$  has the following property:  $\Pr[(f(x) - \varepsilon) \leq A(x) \leq f(x) + \varepsilon] \geq (1 - \delta)$ . We say that  $A$  is an  $(\varepsilon, \delta)$   $k$ -pseudodeterministic additive approximation algorithm for  $f$  if for every  $x$  there exists a set  $V_x \subseteq [0, 1]$  such that for all  $v \in V_x$*

$$f(x) - \varepsilon \leq v \leq f(x) + \varepsilon \text{ and } \Pr[A(x) \in V_x] \geq 1 - \delta.$$

When  $k = 1$ , we call the algorithm pseudodeterministic.

► **Remark.** In general, for  $(\varepsilon, \delta)$  approximation algorithms (additive or multiplicative), error reduction is possible when  $\delta < 1/2$  and is bounded away from  $1/2$ . This is done by repeating the algorithm multiple times and taking the median value. Thus without loss of generality, we may assume that for every  $(\varepsilon, \delta)$  approximation algorithm,  $\delta \leq 1/2^n$ . Similarly, the error probability of  $(\varepsilon, \delta)$  pseudodeterministic approximation algorithms can be reduced to less than  $1/2^n$ .

Goldreich [7] observed that every additive error approximation algorithm can be made 2-pseudodeterministic; this extends to multiplicative approximation algorithms as well.

► **Proposition 4.** *Every optimization problem that admits an  $(\varepsilon, \delta)$  multiplicative approximation algorithm admits a  $(2\varepsilon + \varepsilon^2, \delta)$  2-pseudodeterministic multiplicative approximation algorithm. Similarly, every optimization problem that admits an  $(\varepsilon, \delta)$  additive approximation algorithm admits a  $(2\varepsilon, \delta)$  2-pseudodeterministic additive approximation algorithm.*

**Proof.** We give a proof for the multiplicative case. A similar argument holds for additive approximation algorithms. Let  $f$  be a function and let  $A$  be an  $(\varepsilon, \delta)$ -multiplicative approximation algorithm for  $f$ . The proposed 2-pseudodeterministic algorithm  $B$  will first run  $A(x)$  to get an approximation  $v$ .  $B$  outputs  $v_i$  from a set of points  $P$  (defined next) by choosing the smallest  $v_i \in P$  that is larger than  $v$ .  $P$  is defined as the set of points  $\{v_i \mid i \in \mathbb{N}\}$  where  $v_i = \lceil (1 + \varepsilon)^i \rceil$ .

Observe that  $v_{i+1} = (1 + \varepsilon)v_i$  for all  $i$ . For any input  $x$ ,  $A(x)$  outputs a value in the range  $\left[\frac{f(x)}{(1+\varepsilon)}, (1+\varepsilon)f(x)\right]$  and this range will contain at most 2 values from  $P$ . Hence  $B$  is 2-pseudodeterministic. Rounding up to the nearest value in  $P$  makes the approximation factor at most  $(1 + \varepsilon)^2 = 1 + 2\varepsilon + \varepsilon^2$ . ◀

## 2.1 Completeness of Collision Probability Estimation

In this section, we prove that COLLISION PROBABILITY ESTIMATION PROBLEM is complete for approximation algorithms in the context of pseudodeterminism. We start with the following observation.

► **Proposition 5.** COLLISION PROBABILITY ESTIMATION PROBLEM admits  $(\varepsilon, \delta)$  2-pseudodeterministic additive approximation algorithms for every  $\varepsilon < 1$  and  $\delta < 1$ .

**Proof.** We can estimate collision probability of  $C$  by generating  $O(1/\varepsilon^2 \log 1/\delta)$  independent pairs of strings  $\langle x_i, y_i \rangle$  and counting the number of times  $C(x_i) = C(y_i)$ . Simple application of Chernoff bound implies that this is a  $(\varepsilon, \delta)$  additive approximation algorithm. By the previous proposition, we can convert this algorithm into a 2-pseudodeterministic algorithm. ◀

We now prove the main theorem of the section.

► **Theorem 6.** *There exists  $\varepsilon' > 0$  such that if COLLISION PROBABILITY ESTIMATION PROBLEM has an  $(\varepsilon', \delta)$ -pseudodeterministic additive approximation algorithm, then every function  $f$  that admits a  $(\varepsilon, \delta)$  multiplicative approximation algorithm (resp. additive), has a  $(2\varepsilon + \varepsilon^2, \delta)$ -pseudodeterministic multiplicative approximation algorithm (resp. additive).*

**Proof.** We first provide intuition behind the proof. By Proposition 4, we can assume that  $f$  has a  $(\varepsilon', \delta)$  2-pseudodeterministic algorithm  $A$ , where  $\varepsilon' = 2\varepsilon + \varepsilon^2$ . The idea is to combine two strategies. For an input  $x$ , let  $a$  and  $b$  be the two good outputs of  $A(x)$ . Consider the case when one of the good outputs, say  $a$ , has a noticeably higher probability of occurrence than  $b$ . In that case we can run  $A$  several times and output the most frequent output. With high probability  $A(x)$  will output  $a$ . Another case is when both  $a$  and  $b$  appear with roughly equal probability. In this case, we can run  $A$  several times and output the smallest value. Since  $a$  and  $b$  appear with equal probability, the probability that in several runs of  $A$  we will see both  $a$  and  $b$  is very high and hence, this strategy will output  $\min\{a, b\}$ . The challenge is to decide which of these cases holds (note that these cases are not disjoint). However, if we have a pseudodeterministic algorithm for COLLISION PROBABILITY ESTIMATION PROBLEM, then we show that we can pseudodeterministically choose a good strategy. Now we provide details.

## 66:6 Complete Problems for Multi-Pseudodeterministic Computations

Let  $B$  be a pseudodeterministic algorithm that estimates collision probabilities of Boolean circuits. In particular, assume that  $B$  can pseudodeterministically estimate the collision probability of a circuit,  $\text{CP}(C)$ , with additive error  $1/49$  with probability  $\geq \frac{11}{12}$ . Without loss of generality we assume that the success probability of  $A$  is  $\geq 48/49$ . Assume that  $A$  uses  $m$  random bits on input  $x$ . Consider the following algorithm  $A'$ .

**Algorithm  $A'$ :** On input  $x$ ,  $A'(x)$  constructs a Boolean circuit  $C_x : \{0, 1\}^m \rightarrow \{0, 1\}$  that on input  $r$ , simulates  $A(x, r)$ , where  $A'(x)$  runs  $B$  on  $C_x$  to obtain an estimate of  $\text{CP}(C_x)$ . If  $B(C_x) \geq \frac{51}{98}$ ,  $A'$  runs  $A(x)$  *three* times and outputs the most frequent result. Otherwise, if  $B(C_x) < \frac{51}{98}$ ,  $A'$  runs  $A(x)$  16 times and outputs the smallest value.  $\lrcorner$

Now we will show that  $A'$  is a pseudodeterministic algorithm for  $f$ . Since  $A$  is 2-pseudodeterministic, there exists a set  $S_x$  of size at most 2 such that  $\Pr[A(x) \in S_x] \geq 48/49$  and every element in  $S_x$  is a  $(1 + \varepsilon')$  multiplicative approximation of  $f(x)$ . We first consider the case where the size of  $S_x$  is 1, say  $S_x = \{a\}$ . Note that in this case  $\text{CP}(C_x)$  is at least  $(48/49)^2 > 0.9$ . Thus  $A'(x)$  runs  $A$  three times and outputs the most frequent result, which is  $a$  with probability at least  $(48/49)^3 \geq 0.9$ . Thus  $A'(x)$  is pseudodeterministic. Thus, in the rest of the proof, assume that  $S_x = \{a, b\}$ . Let  $p = \Pr[A(x) = a]$  and  $q = \Pr[A(x) = b]$ . Assume without loss of generality that  $p \geq q$ . We first establish a relationship among  $p$ ,  $q$  and  $\text{CP}(C_x)$ .

▷ **Claim 7.** If  $\text{CP}(C_x) > \frac{25}{49}$ , then  $p > q + 1/7$

*Proof.* We prove the contrapositive: if  $p \leq q + 1/7$ , then  $\text{CP}(C_x) \leq \frac{25}{49}$ . Notice that  $\text{CP}(C_x)$  is maximized when  $p = q + \frac{1}{7}$  and  $\delta = 0$ , where  $\delta$  is the error probability of  $A$ . Since  $p + q + \delta = 1$ , it follows that  $p = 4/7$  and  $q = 3/7$ . Thus,  $\text{CP}(C_x) \leq (4/7)^2 + (3/7)^2 = 25/49$ .  $\triangleleft$

▷ **Claim 8.** If  $\text{CP}(C_x) < \frac{26}{49}$ , then  $q > \frac{1}{7}$

*Proof.* We prove the contrapositive: if  $q \leq \frac{1}{7}$ , then  $\Pr[\text{CP}(C_x)] \geq \frac{26}{49}$ . Note that  $\text{CP}(C_x)$  is minimized when  $p$  is as close to  $q$  as possible, and all other outputs are different from  $a$  and  $b$ . Then  $q = \frac{1}{7}$  and  $p = 1 - \frac{1}{7} - \frac{1}{49} = \frac{41}{49} \geq \frac{5}{7}$ . Thus  $\text{CP}(C_x) \geq (\frac{1}{7})^2 + (\frac{5}{7})^2 = \frac{26}{49}$ .  $\triangleleft$

▷ **Claim 9.** If  $p > q + 1/7$ , then the probability that in 3 independent runs  $A(x)$  outputs  $a$  at least twice is  $\geq 57/100$ .

*Proof.* The worst case is when  $p = q + 1/7$  and  $\delta = 1/49$ . In this case,  $p = \frac{55}{98}$  and  $q = \frac{41}{98}$ . The probability that  $A(x)$  outputs  $a$  at least twice in three runs is  $\geq \left(\frac{55}{98}\right)^3 + 3 \left(\frac{55}{98}\right)^2 \frac{44}{98} \geq \frac{57}{100}$ .  $\triangleleft$

▷ **Claim 10.** Let  $E$  be following event: “Among 16 independent runs of  $A(x)$ , every run outputs either  $a$  or  $b$  and at least one run outputs  $a$  and at least one run outputs  $b$ ”. If  $q \geq \frac{1}{7}$ , then  $\Pr[E] \geq 3/5$ .

*Proof.* Note that the probability of  $\overline{E}$  is at most the sum of the probabilities of i)  $A(x) \notin \{a, b\}$ , ii) Every run of  $A(x)$  outputs only  $a$ , and iii) Every run of  $A(x)$  outputs only  $b$ . This sum is maximized when  $q = 1/7$ ,  $\delta = 1/49$ ,  $p = 1 - 1/7 - 1/49$ . In this case,  $\Pr[\overline{E}] \leq 1 - (1 - \delta)^{16} p^{16} + q^{16} \leq \left(\frac{6}{7}\right)^{16} + \left(\frac{1}{7}\right)^{16} + 1 - \left(\frac{48}{49}\right)^{16} < \frac{2}{5}$ .  $\triangleleft$

▷ **Claim 11.**  $A'$  is pseudodeterministic.

Let  $y$  be the pseudodeterministic output of the probability estimator  $B$  on input  $C_x$ . If  $y > \frac{51}{98}$ , then  $\text{CP}(C_x) \geq \frac{25}{49}$ . By Claim 7,  $p > q + 1/7$ . By Claim 9, the probability that  $A(x)$  outputs  $a$  more often than  $b$  among three runs is at least  $\frac{57}{100}$ . Since  $y > \frac{51}{98}$ ,  $A'$  will run  $A$  3 times and output the most frequent result; this will output  $a$  with probability  $\geq \frac{57}{100}$ .

On the other hand, if  $y \leq \frac{51}{98}$ , then  $\text{CP}(C_x) \leq \frac{53}{98}$ . By Claim 8,  $q \geq 1/7$ . Since  $y \leq \frac{51}{98}$ ,  $A'$  will run  $A$  16 times and output the lexicographically smallest result. By Claim 10,  $\Pr[A \text{ outputs only } a \text{ and } b, \text{ and outputs } a \text{ and } b \text{ at least once}] \geq \frac{3}{5}$ , so  $\Pr[A' \text{ outputs } \min(a, b)] \geq \frac{3}{5}$ .

So, given that  $B$  outputs  $y$ ,  $A'$  will output one particular value  $x$  with probability  $\geq \frac{57}{100}$ .  $\Pr[A' \text{ outputs } x] \geq \Pr[B \text{ outputs } y] \Pr[A' \text{ outputs } x | B \text{ outputs } y] \geq \frac{11}{12} \frac{57}{100} \geq \frac{52}{100}$ . This can be increased to  $1 - \frac{1}{n}$  using standard amplification techniques. ◀

### 3 Pseudodeterminism for Multi-valued Functions

In this section, we generalize the results from the previous section to  $k$ -pseudodeterminism. Goldreich [7] defined the notion of  $k$ -pseudodeterminism for search problems and this definition can be extended to multivalued functions. A function  $f$  is multivalued if  $f(x)$  is a subset of the range (possibly empty set). Note that search problems can be cast as multivalued functions: Let  $R$  be a binary relation associated with a search problem, and define  $f(x)$  as the set of all  $y$  such that  $\langle x, y \rangle \in R$ .

► **Definition 12.** Let  $f$  be a multivalued function, i.e.,  $f(x)$  is a set. We say that  $f$  admits pseudodeterministic algorithms if there is a probabilistic polynomial-time algorithm  $A$  such that for every  $x$ , there exists a  $v \in f(x)$  such that  $A(x) = v$  with probability at least  $2/3$ . The function  $f$  admits  $k$ -pseudodeterministic algorithms if there is a probabilistic polynomial-time algorithm  $A$  such that for every  $x$ , there exists a set  $S_x \subseteq f(x)$  of size at most  $k$  and the probability that  $A(x) \in S(x)$  is at least  $\frac{k+1}{k+2}$ .

Goldreich [7] showed that if we threshold success probability to at least  $\frac{k+1}{k+2}$ , the success probability for  $k$ -pseudodeterministic algorithms can be amplified to  $1 - 1/2^{p(n)}$  for any polynomial  $p(\cdot)$ .

We show that if COLLISION PROBABILITY ESTIMATION PROBLEM can be made pseudodeterministic, then any  $k$ -pseudodeterministic algorithm for a multi-valued function problem can be made pseudodeterministic for a constant  $k$ . We first show how to reduce the size of the output set from  $k$  to  $k - 1$ .

► **Theorem 13.** If COLLISION PROBABILITY ESTIMATION PROBLEM has a  $(\varepsilon, \delta)$ -pseudodeterministic additive approximation algorithm with  $\varepsilon = 1/100$ , then for every multi-valued function  $f$  that admits a  $k$ -pseudodeterministic algorithm,  $f$  has a  $(k - 1)$ -pseudodeterministic algorithm.

**Proof.** Let  $B$  be a pseudodeterministic algorithm for COLLISION PROBABILITY ESTIMATION PROBLEM. In particular, assume that  $B$ , given a circuit  $C$ , estimates  $\text{CP}(C)$  to within  $\frac{1}{100}$  additive error with probability  $1 - \delta$ , where  $n$  is the length of the input to  $C$ .

Let  $A$  be a  $k$ -pseudodeterministic algorithm for a multi-valued function  $f$  with error probability  $\delta \leq \frac{1}{72k}$ . That is,  $A$ , on input  $x$ , outputs from a set  $S_x \subseteq f(x)$  of size  $\leq k$ , with probability  $\geq 1 - \frac{1}{72k}$ . We call the elements of  $S_x$  *good outputs* of  $A$ . Let  $m$  be the number of random bits used by  $A$ . We will design a  $(k - 1)$ -pseudodeterministic algorithm  $A'$  as follows:

**Algorithm  $A'$ :** On input  $x$ , first construct a circuit  $C_x$  that gets as input  $r$  and outputs  $A(x, r)$ . Then compute  $B(C_x)$ .

If  $B(C_x) < \frac{65}{100}$ , run  $A$   $n$  times on independent random bits. Output the *lexicographically smallest* element that appears at least  $\frac{n}{12k}$  times.

If  $B(C_x) \geq \frac{65}{100}$ , run  $A$   $n$  times using independent random bits. Output the most frequent value.  $\lrcorner$

As in the proof of Theorem 6, it is easy to see that if the size of  $S_x$  is 1,  $A'(x)$  is pseudodeterministic. Thus in the rest of the proof, we assume that the size of  $S_x$  is at least 2. For the proof of correctness, we first establish certain claims relating the collision probability of  $C_x$  and the behavior of  $A$ .

▷ **Claim 14.** If  $\text{CP}(C_x) \leq \frac{2}{3}$ , then there exist two *good* outputs  $a$  and  $b$  of  $A$  so that  $\Pr[A(x) = a] \geq \frac{1}{6k}$  and  $\Pr[A(x) = b] \geq \frac{1}{6k}$ .

*Proof.* Suppose only one good output  $a$  of  $A$  has probability  $\geq \frac{1}{6k}$ . Then that output has probability  $\geq \frac{5}{6} - \delta$ . This is because if the other  $(k-1)$  good outputs have probability  $< \frac{1}{6k}$ , the total probability of outputs other than  $a$  is  $< 1/6 + \delta$ . Thus  $\Pr[A(x) = a] \geq \frac{5}{6} - \delta$ .

$$\begin{aligned} \text{CP}(C_x) &\geq \Pr[A \text{ outputs } a \text{ on both runs}] \\ &\geq \left(\frac{5}{6} - \delta\right)^2 \\ &\geq \frac{25}{36} - 2\delta \geq \frac{2}{3} \end{aligned}$$

The last inequality holds since  $\delta \leq \frac{1}{72k}$  and  $k \geq 2$ .  $\triangleleft$

▷ **Claim 15.** Let  $a, b$  be the most and least likely good outputs of  $A$  with probabilities  $p$  and  $q$  respectively. If  $\text{CP}(C_x) > \frac{64}{100}$ , then  $p > q + \frac{1}{8k}$ .

*Proof.* If  $p \leq q + \frac{1}{8k}$ , then  $p \leq \frac{9}{8k} - \frac{\delta}{k} \leq \frac{9}{8k}$ . Then  $\text{CP}(C_x) \leq k \cdot \frac{81}{64k^2} + \delta^2 = \frac{81}{64k} + \delta^2$ . For  $k \geq 2$ , and  $\delta \leq \frac{1}{72k}$ , this quantity is  $\leq \frac{64}{100}$ .  $\triangleleft$

Now we will prove correctness of  $A'$ . On input  $x$ , let  $y$  be the pseudodeterministic output of  $B(C_x)$ . We will consider two cases:  $y \leq \frac{65}{100}$  and  $y > \frac{65}{100}$ .

**Case:  $y \leq \frac{65}{100}$**

▷ **Claim 16.** If  $y \leq \frac{65}{100}$ , then there exists a set  $S'_x(x) \subset S_x$  of size at most  $k-1$  such that

$$\Pr[A'(x) \in S'_x] \geq 1 - 2e^{-\frac{n}{72k^2}} - \delta$$

*Proof.* Note that  $B(C_x)$  outputs  $y$  with probability at least  $1 - \delta$ . Thus, if  $y \leq \frac{65}{100}$ , then with probability  $\geq 1 - \delta$ ,  $A'$  will run  $A$   $n$  times and output the lexicographically smallest result that appears at least  $\frac{n}{12k}$  times. Since  $y \leq \frac{65}{100}$ ,  $\text{CP}(C_x) \leq \frac{66}{100} < \frac{2}{3}$ . Therefore by Claim 14, there are at least 2 elements  $a$  and  $b$  from  $S_x$  that  $A$  outputs with probability  $\geq \frac{1}{6k}$ . Let  $b$  be the lexicographically larger of the two. We set  $S'_x = S_x \setminus \{b\}$ . Clearly  $S'_x$  contains at most  $k-1$  elements. Thus the probability that  $A'(x)$  outputs an element outside of  $S'_x$  is at most the sum of the probabilities of the following events: i)  $A'$  outputs  $b$  ii)  $A'$  outputs an element that is not in  $S_x$ , iii)  $B(C_x)$  does not output  $y$ .

We first bound the probability that  $A'$  outputs  $b$ . For  $A'$  to output  $b$ , it must be the case that in the  $n$  runs of  $A$  the value  $b$  is output at least  $n/12k$  times and the value  $a$  is output at most  $n/12k$  times. Thus

$$\Pr[A'(x) = b] \leq \Pr[A(x) \text{ outputs } a \text{ less than } n/12k \text{ times among } n \text{ runs}]$$

Since the probability that  $A(x)$  outputs  $a$  is least  $n/6k$ , the expected number of times  $A(x)$  outputs  $a$  in  $n$  runs is  $\geq \frac{n}{6k}$ . Thus by Chernoff bound, this is at most  $e^{-n/72k^2}$ . We now bound the probability of the second event. The probability that  $A(x)$  does not belong to  $S_x$  is at most  $1/72k$ . For  $A'(x)$  to output an element  $c$  that is not in  $S_x$ , it must be the case that  $c$  is output  $\geq n/12k$  times among  $n$  runs of  $A$ . Again by Chernoff bound, this is at most  $e^{-n/18k^2}$ . Finally, the probability that  $B(C_x)$  does not output  $y$  is at most  $\delta$ . Thus  $A'(x) \in S'_x$  with probability at least  $1 - 2e^{-n/72k^2} - \delta$ .  $\triangleleft$

**Case:**  $y > \frac{65}{100}$

$\triangleright$  **Claim 17.** If  $y > \frac{65}{100}$ , there exists a sets  $S'_x \subseteq S_x$  of size at most  $k - 1$  such that

$$\Pr[A'(x) \in S'_x] \geq 1 - 2e^{-\frac{n}{8k}} - \delta$$

*Proof.* If  $y > \frac{65}{100}$ , then with probability  $\geq 1 - \delta$ ,  $A'$  will run  $A$   $n$  times and output the most frequent result. Also,  $\text{CP}(C_x) > \frac{64}{100}$ . By Claim 15,  $p > q + \frac{1}{8k}$  where  $p$  is the probability of the most likely element  $a$  from  $S_x$  and  $q$  is the probability of least likely element  $b$  from  $S_x$ . We define  $S'_x$  as  $S_x - \{b\}$ . As before, the probability that the output of  $A'$  does not belong to  $S'_x$  is at most the sum of the probabilities of: i)  $A'(x)$  outputs  $b$  ii) the output of  $A'(x)$  does not belong to  $S_x$  iii)  $B(C_x)$  does not output  $y$ .

We will first analyze the probability of the event that  $A'$  outputs  $b$ . For this, consider the event  $E = 'A \text{ outputs } b \text{ more often than } a \text{ in } n \text{ trials}'$ . Clearly, the probability that  $A'(x)$  outputs  $b$  is at most  $\Pr[E]$ . Define random variables  $X_i$  that take value 0 if  $A(x)$  outputs  $a$  in  $i^{\text{th}}$  run, 1 if  $A(x)$  outputs  $b$  in the  $i^{\text{th}}$  run, and  $1/2$  otherwise. Note that  $E[X_i] = \frac{1}{2} - \frac{p-q}{2}$ , which is at most  $\frac{1}{2} - \frac{1}{16k}$ . Let  $X = \sum_{i=1}^n X_i$ . Now,  $\Pr[E]$  is  $\Pr[X > n/2]$ .

$$\begin{aligned} \Pr[X > n/2] &= \Pr\left[\frac{\sum X_i}{n} > 1/2\right] \\ &\leq \Pr\left[\left|\frac{\sum X_i}{n} - E[X_i]\right| \geq \frac{1}{16k}\right] \\ &\leq e^{-n/256k^2} \text{ by Chernoff bound} \end{aligned}$$

To bound the probability of the second event, consider the probability that  $A(x)$  outputs an element not in  $S_x$  more frequently than  $a$  in  $n$  runs. Since the probability that  $A(x)$  outputs an element that is not in  $S_x$  is at most  $1/72k$ , by the same argument the probability of this event is at most  $e^{-n/256k^2}$ . Finally the probability that  $B(C_x)$  does not output  $y$  is at most  $\delta$ . The claim follows.  $\triangleleft$

Combining Claims 16 and 17, we have that  $A'$  outputs a value from  $S'_x$  with probability at least  $1 - 2e^{-n/72k^2} - \delta \geq \frac{k}{k+1}$  for large enough  $n$ , since  $\delta$  can be made exponentially small.  $\blacktriangleleft$

We now state the main result of this section.

► **Theorem 18.** *If COLLISION PROBABILITY ESTIMATION PROBLEM has a  $(\varepsilon, \delta)$ -pseudodeterministic additive approximation algorithm with  $\varepsilon = 1/100$ , every multi-valued function  $f$  that admits a  $k$ -pseudodeterministic algorithm, has a pseudodeterministic algorithm.*

**Proof.** Let  $B$  be the pseudodeterministic algorithm for COLLISION PROBABILITY ESTIMATION PROBLEM, where  $B$  runs in time  $n^c$  with error probability  $\leq \delta$ . To convert a  $k$ -pseudodeterministic algorithm to a pseudodeterministic algorithm, we repeatedly apply Theorem 13. We start with a  $k$ -pseudodeterministic algorithm  $A_k$  whose runtime is bounded by  $n^t$ . On input  $x$ ,  $A_{k-1}$  constructs  $C_{A_k, x}$  with size  $\leq 4n^{2t}$ .  $A_{k-1}$  computes  $B(C)$ , which takes  $\leq 4^c n^{2tc}$  time, then runs  $A_k(x)$   $n$  times. In total,  $A_{k-1}(x)$  takes  $\leq n^{t+1} + 4^c n^{2tc} \leq n^{4tc}$ . Applying this conversion  $(k-1)$  times, we obtain  $A_1$ , a pseudodeterministic algorithm with runtime of  $O(n^{t(4c)^k})$ . Since  $k$  is a constant the runtime is polynomial. Note that in each iteration, the error probability remains the same. Thus  $A_1$  is pseudodeterministic. ◀

### 3.1 Circuit Probability Acceptance

In this subsection we observe the equivalence of COLLISION PROBABILITY ESTIMATION PROBLEM and ACCEPTANCE PROBABILITY ESTIMATION PROBLEM in the context of pseudodeterminism.

► **Proposition 19.** *There exist  $\varepsilon, \varepsilon' > 0$  such that COLLISION PROBABILITY ESTIMATION PROBLEM has an  $(\varepsilon, \delta)$ -pseudodeterministic additive approximation algorithm if and only if ACCEPTANCE PROBABILITY ESTIMATION PROBLEM has an  $(\varepsilon', \delta)$ -pseudodeterministic additive approximation algorithm.*

**Proof.** It is easy to see that ACCEPTANCE PROBABILITY ESTIMATION PROBLEM admits an  $(\varepsilon, \delta)$  additive approximation algorithm. Thus by Proposition 4, it has a 2-pseudodeterministic  $(\varepsilon, \delta)$  approximation algorithm. By Theorem 6, if COLLISION PROBABILITY ESTIMATION PROBLEM admits a pseudodeterministic algorithm, then ACCEPTANCE PROBABILITY ESTIMATION PROBLEM admits a pseudodeterministic algorithm.

Let  $B$  be a pseudodeterministic algorithm for ACCEPTANCE PROBABILITY ESTIMATION PROBLEM. Consider the following algorithm to estimate the collision probability of a circuit  $C$ : If  $B(C)$  outputs  $v$ , output  $v^2 + (1-v)^2$ . Let  $p = \Pr[C(U_n) = 1]$ . If  $v \in (p - \varepsilon, p + \varepsilon)$ , then the output of  $B$  belongs to  $(\text{CP}(C) - 8\varepsilon, \text{CP}(C) + 8\varepsilon)$ . Clearly  $B$  is pseudodeterministic. ◀

The following result is a corollary of the above proposition and Theorem 18.

► **Theorem 20.** *There exists  $\varepsilon' > 0$  such that if ACCEPTANCE PROBABILITY ESTIMATION PROBLEM admits an  $(\varepsilon', \delta)$  pseudodeterministic additive approximation algorithm, then every function  $f$  that admits an  $(\varepsilon, \delta)$  multiplicative approximation algorithm has a  $(3\varepsilon, \delta)$ -pseudodeterministic multiplicative approximation algorithm.*

### 3.2 Entropy Estimation

In this subsection we show that ENTROPY ESTIMATION PROBLEM and ACCEPTANCE PROBABILITY ESTIMATION PROBLEM are equivalent in the context of pseudodeterminism. We first observe that ENTROPY ESTIMATION PROBLEM admits an  $(\varepsilon, \delta)$ , 2-pseudodeterministic additive approximation algorithm.

► **Proposition 21.** *There is an  $(\varepsilon, \delta)$  2-pseudodeterministic approximation algorithm for the ENTROPY ESTIMATION PROBLEM.*

**Proof.** Given a circuit  $C$ , let  $p = \Pr[C(U_n) = 1]$ . As in Proposition 5, compute an approximate value  $q$  of  $p$  and output  $H(q)$ . It follows that  $H(q)$  is an approximation of  $H(p)$  due to the known result that entropy can be approximated by the empirical distribution obtained from sampling, for example see [15, 1]. By Proposition 4, we obtain a 2-pseudodeterministic algorithm.  $\blacktriangleleft$

Note that the above proof yields the following.

► **Proposition 22.** *There exist  $\varepsilon$  and  $\varepsilon'$  such that if ACCEPTANCE PROBABILITY ESTIMATION PROBLEM has an  $(\varepsilon, \delta)$  pseudodeterministic additive error approximation algorithm, then ENTROPY ESTIMATION PROBLEM has  $(\varepsilon', \delta)$  pseudodeterministic, additive error approximation algorithm.*

Next we reduce ACCEPTANCE PROBABILITY ESTIMATION PROBLEM to ENTROPY ESTIMATION PROBLEM. Thus a pseudodeterministic algorithm for ENTROPY ESTIMATION PROBLEM implies a pseudodeterministic algorithm for ACCEPTANCE PROBABILITY ESTIMATION PROBLEM.

The main technical result that we show is that an approximation of the entropy of  $C(U_n)$  can be used to approximate the probability that  $C(U_n) = 1$ . It is possible that this technical result is known or is a folklore; we could not find a reference. Thus, for completeness a proof is provided in the appendix.

► **Theorem 23.** *Suppose that there is a  $(\varepsilon, \delta)$  pseudodeterministic approximation algorithm for ENTROPY ESTIMATION PROBLEM for a sufficiently small  $\varepsilon$ . Then there is a  $(1/100, \delta + e^{-O(n)})$  pseudodeterministic approximation algorithm for ACCEPTANCE PROBABILITY ESTIMATION PROBLEM.*

Using Proposition 19 and Theorem 23, we obtain that both ACCEPTANCE PROBABILITY ESTIMATION PROBLEM and ENTROPY ESTIMATION PROBLEM are complete for  $k$ -pseudodeterministic computations.

► **Theorem 24.** *There exist  $\varepsilon > 0$ , such that if either of ACCEPTANCE PROBABILITY ESTIMATION PROBLEM or ENTROPY ESTIMATION PROBLEM admit  $(\varepsilon, \delta)$ -pseudodeterministic, additive approximation algorithm, then every multivalued function that has a  $k$ -pseudodeterministic algorithm has a pseudodeterministic algorithm.*

## 4 Pseudodeterminism for Search Problems

In this section we show that if any of the 3 computational problems we consider has pseudodeterministic approximation schemes then every problem in Search-BPP has pseudodeterministic algorithms. The class Search-BPP was formally introduced by Goldreich [6]

► **Definition 25** (Search BPP [6]). *A search problem is a relation  $R \subseteq \{0, 1\}^* \times \{0, 1\}^*$ . For every  $x$ , the witness set  $W_x$  of  $x$  with respect to  $R$  is  $\{y \mid (x, y) \in R\}$ . A search problem  $R$  is in search-BPP (1) if there exists a probabilistic polynomial-time algorithm  $A$  such that for every  $x$  for which  $W_x \neq \emptyset$ ,  $A(x) \in W_x$  with probability  $\geq 2/3$ , (2) and there exists a probabilistic polynomial time algorithm  $B$  such that if  $(x, y) \in R$ , then  $B(x, y)$  accepts with probability  $> 2/3$ , and if  $(x, y) \notin R$  then  $B(x, y)$  accepts with probability  $< 1/3$ .*

We will first show that if ACCEPTANCE PROBABILITY ESTIMATION PROBLEM has a pseudodeterministic, additive, approximation scheme, then Search-BPP problems can be made pseudodeterministic. Then we will use Theorem 20 to prove that if ACCEPTANCE

## 66:12 Complete Problems for Multi-Pseudodeterministic Computations

PROBABILITY ESTIMATION PROBLEM has a  $(\epsilon, \delta)$  pseudodeterministic approximation algorithm, then Search-BPP problems admit pseudodeterministic algorithms. We first recall the definition of approximation scheme.

► **Definition 26.** A function  $f : \Sigma^* \rightarrow \mathbb{Q}$  has an additive, approximation scheme if there is a probabilistic polynomial time algorithm  $A$  that gets  $x, \epsilon$ , and  $\delta$  as input and

$$\Pr[f(x) - \epsilon \leq A(x, \epsilon, \delta) \leq f(x) + \epsilon] \geq 1 - \delta$$

► **Theorem 27.** If ACCEPTANCE PROBABILITY ESTIMATION PROBLEM has a pseudodeterministic, additive, approximation algorithm scheme, then every problem in Search-BPP has a pseudodeterministic algorithm.

**Proof.** Let  $R$  be a problem in Search-BPP and let  $A$  and  $B$  be probabilistic algorithms that witness  $R$  in search-BPP according to the definition.

The idea is to use the method of conditional probabilities to construct a good random choice  $z_A$  for  $A$  on input  $x$  first, and then output  $A(x, z_A)$ . The search for  $z_A$  will be aided by the pseudodeterministic approximation algorithm for ACCEPTANCE PROBABILITY ESTIMATION PROBLEM.

Consider the following probabilistic algorithm  $B'$  that, on input  $x$  of length  $n$ , first simulates  $A$  to get an output  $y$  and then runs  $B(x, y)$  and accepts if  $B$  accepts. Then  $\Pr[B'(x) \text{ accepts}] \geq 2/5$ . Let  $m = p(n)$  be the polynomial bounding the length of the random string of  $B'$ . We will view the random string  $r$  that  $B'$  uses as  $r_A r_B$  where  $r_A$  is the random string that  $B'$  uses to simulate  $A$  and  $r_B$  is to simulate  $B$ . Let  $A_{\text{ape}}$  be a pseudodeterministic approximation algorithm for ACCEPTANCE PROBABILITY ESTIMATION PROBLEM. We will use  $A_{\text{ape}}$  with error  $\epsilon \leq \frac{1}{n \cdot p(n)}$  and confidence  $1 - \delta \geq 1 - \frac{1}{n \cdot p(n)}$ .

For an input  $x$  let  $C(r_A r_B)$  be the Boolean circuit that simulates  $B'$  on  $x$  using random string  $r = r_A r_B$  and outputs 1 if and only if  $B'$  accepts  $x$  on  $r$ . Thus for any  $x$  where  $W_x \neq \emptyset$ ,  $\Pr[C = 1] \geq 2/5$ . For a binary string  $z \in \{0, 1\}^l$ , let  $C_z : \{0, 1\}^{m-l} \rightarrow \{0, 1\}$  be the circuit obtained by fixing the first  $l$  bits of  $C$ 's input to  $z$ . We now describe the algorithm  $A_R$  for the search problem that pseudodeterministically outputs a  $y \in W_x$ .

**Algorithm PseudoA<sub>R</sub>:** On input  $x$ , construct the circuit  $C$  that gets  $r = r_A r_B$  as input and outputs 1 if  $B'$  accepts  $(x, r)$  on random string  $r = r_A r_B$ . Initialize  $z = \lambda$ , the empty string. Iterate from  $i = 1$  to  $m = p(n)$ . At the  $i^{\text{th}}$  iteration, simulate  $A_{\text{ape}}(C_z 0)$  (pseudodeterministically) to approximate  $\Pr[C_{z0}(r) = 1]$  up to an additive error  $\epsilon$  and confidence  $(1 - \delta)$  to get a value  $v$ . If  $v \geq 2/5 - (2i + 1)\epsilon$  then  $z \leftarrow z0$  otherwise  $z \leftarrow z1$ . Continue to the next iteration. After the  $m^{\text{th}}$  iteration let  $z = z_A z_B$  be the binary string of length  $m$  constructed. Output  $A(x, z_A)$ .  $\lrcorner$

**Correctness:** Since error probability of  $A_{\text{ape}}$  is  $\leq \frac{1}{n \cdot m}$ , and we are making  $m$  calls to  $A_{\text{ape}}$ , by the union bound, the probability that any one of the calls makes an error is  $\leq 1/n$ . For the rest of the argument we assume all the calls to  $A_{\text{ape}}$  pseudodeterministically output an approximation to acceptance probability within an additive error of  $\epsilon$ .

► **Claim 28.** For every  $i$ , for the string  $z$  constructed at the end of the  $i^{\text{th}}$  iteration,  $\Pr[C_z = 1] \geq \frac{2}{5} - 2i\epsilon$ .

**Proof.** We prove this by induction on  $i$ . For  $i = 0$ , the hypothesis holds since  $\Pr[C = 1] \geq 2/5$ . Assume the hypothesis holds for  $i$ . Consider the  $(i + 1)^{\text{th}}$  iteration. Using conditional probabilities, after the  $i^{\text{th}}$  iteration,  $\Pr[C_{z0} = 1] \geq \frac{2}{5} - 2i\epsilon$  or  $\Pr[C_{z1} = 1] \geq \frac{2}{5} - 2i\epsilon$ . Suppose at the  $(i + 1)^{\text{th}}$  iteration the value  $v$  returned by  $A_{\text{ape}}(C_{z0})$  is  $\geq 2/5 - (2i + 1)\epsilon$ . Then  $z$

is updated to  $z_0$  by the algorithm and from the approximation guarantee of  $A_{ape}$  we have that  $\Pr[C_{z_0} = 1] \geq 2/5 - (2i + 1)\epsilon - \epsilon = 2/5 - 2(i + 1)\epsilon$ . On the other hand suppose  $v < 2/5 - (2i + 1)\epsilon$ . Then  $z$  is updated to  $z_1$ . Also  $\Pr[C_{z_0} = 1] < v + \epsilon = 2/5 - 2i\epsilon$  and hence  $\Pr[C_{z_1} = 1] \geq 2/5 - 2i\epsilon \geq 2/5 - 2(i + 1)\epsilon$   $\triangleleft$

Thus for any  $1 \leq i \leq m$   $\Pr[C_z = 1] \geq 2/3 - 1/n$  and hence the algorithm outputs a  $z$  so that  $B'(x, z)$  accepts. Hence the output of the algorithm  $A(x, z_A) \in W_x$ .

The algorithm  $\text{Pseudo}A_R$  can be seen as a deterministic algorithm making subroutine calls to the pseudodeterministic algorithm  $A_{ape}$ . Hence the overall algorithm is pseudodeterministic. The probability of error is bounded by any one of the calls to  $A_{ape}$  making an error which is  $\leq 1/n$ .  $\blacktriangleleft$

Next we will show that if ACCEPTANCE PROBABILITY ESTIMATION admits  $(\epsilon, \delta)$  pseudodeterministic additive approximation, then admits pseudodeterministic additive approximation scheme.

► **Proposition 29.** *There exists  $\epsilon > 0$  such that if ACCEPTANCE PROBABILITY ESTIMATION admits an  $(\epsilon, \delta)$  pseudodeterministic additive approximation, then it admits a pseudodeterministic approximation scheme.*

**Proof.** We first note that ACCEPTANCE PROBABILITY ESTIMATION PROBLEM admits an additive, approximation scheme. By Theorem 20, there is an  $\epsilon' > 0$  such that if ACCEPTANCE PROBABILITY ESTIMATION PROBLEM has an  $(\epsilon', \delta)$  pseudodeterministic approximation algorithm, then every  $(\epsilon, \delta)$ -additive approximation algorithm for a function  $f$  can be made into a  $(3\epsilon, \delta)$  pseudodeterministic, additive approximation algorithm. The same proof shows that if  $f$  admits an approximation scheme, then it can be made into a pseudodeterministic approximation scheme.  $\blacktriangleleft$

The main result of this section is a corollary of the above proposition and Theorem 27.

► **Theorem 30.** *There exists  $\epsilon > 0$  such that if ACCEPTANCE PROBABILITY ESTIMATION PROBLEM has a  $(\epsilon, \delta)$  pseudodeterministic approximation algorithm, then every problem in Search-BPP has a pseudodeterministic algorithm.*

## A Proof of Theorem 23

We first start with the following lemma. Here  $H$  is the binary entropy function  $H(p) = -p \log p - (1-p) \log(1-p)$ .

▷ **Claim 31.** Let  $0 \leq a + b \leq 1$ .  $H(a + b) \geq H(a) + b \log \frac{1-a-b}{a+b}$

Proof.

$$\begin{aligned}
 H(a + b) &= -(a + b) \log(a + b) - (1 - a - b) \log(1 - a - b) \\
 &= -a \log(a + b) - (1 - a) \log(1 - a - b) - b \log(a + b) - (-b) \log(1 - a - b) \\
 &\geq -a \log(a) - (1 - a) \log(1 - a) + b(\log(1 - a - b) - \log(a + b)) \\
 &= H(a) + b \log \frac{1 - a - b}{a + b}
 \end{aligned}$$

where the third line follows by Gibbs' inequality. ◁

We now provide a proof of Theorem 23.

**Proof of Theorem 23.** Suppose  $A$  is a pseudodeterministic algorithm that, given a Boolean circuit  $C$ , outputs  $(\varepsilon, \delta)$  approximation of  $H(C(U_n))$ . Let  $r = \Pr[C(U_n) = 1]$ . Our goal is to design a pseudodeterministic algorithm to estimate  $r$ . Let  $q$  be the smaller of  $1 - r$  and  $r$ . We will first design a pseudodeterministic algorithm  $B$  that outputs a value  $p$  such that  $p$  is within  $1/100$  of  $q$ .

$B(C)$  runs  $A(C)$  to obtain  $y$ . If  $y \geq H(\frac{1}{2} - \frac{1}{100}) + \varepsilon$ , then output  $\frac{1}{2}$ . Otherwise, do a binary search for  $p$  in the range  $(0, 1/2)$  such that  $-p \log p - (1-p) \log(1-p)$  lies within  $[y, y + 1/2^n)$ . We consider two cases.

**Case 1:**  $y \geq H(\frac{1}{2} - \frac{1}{100}) + \varepsilon$ . In this case, then clearly  $\frac{1}{2} - \frac{1}{100} \leq r \leq \frac{1}{2} + \frac{1}{100}$ .  $B(C)$  will output  $\frac{1}{2}$ , which is within  $\frac{1}{100}$  of  $r = \Pr[C = 1]$ , with probability  $\geq 1 - \delta$ .

**Case 2:**  $y < H(\frac{1}{2} - \frac{1}{100}) + \varepsilon$ . Since  $|H(p) - y| \leq 1/2^n$  and  $|H(q) - y| \leq \varepsilon$ , we have that  $|H(p) - H(q)| \leq \varepsilon + 1/2^n = \varepsilon'$ . Now we bound how far  $p$  is from  $q$ . For this we need the following two technical claims.

▷ **Claim 32.** Let  $a \leq \frac{1}{2}$ . If  $H(a) \leq H(\frac{1}{2} - \frac{1}{100}) + \varepsilon'$ , then  $a \leq \frac{1}{2} - \frac{1}{100} + \frac{1}{c}$ , for any  $c$  that satisfies  $\varepsilon' \leq \frac{1}{2c} \log(\frac{102c-200}{98c+200})$ .

Proof.

$$\begin{aligned} H(a) &\leq H\left(\frac{1}{2} - \frac{1}{100}\right) + 2\varepsilon \\ &\leq H\left(\frac{1}{2} - \frac{1}{100}\right) + \frac{1}{c} \log\left(\frac{102c-200}{98c+200}\right) \\ &= H\left(\frac{1}{2} - \frac{1}{100}\right) + \frac{1}{c} \log\left(\frac{\frac{1}{2} + \frac{1}{100} - \frac{1}{c}}{\frac{1}{2} - \frac{1}{100} + \frac{1}{c}}\right) \\ &\leq H\left(\frac{1}{2} - \frac{1}{100} + \frac{1}{c}\right) \text{ by Claim 31} \end{aligned}$$

Thus  $a \leq \frac{1}{2} - \frac{1}{100} + \frac{1}{c}$ . ◁

▷ **Claim 33.** Let  $a = b + \ell$  where  $a \leq \frac{1}{2}$ ,  $a, b, \ell \geq 0$ . If  $H(a) - H(b) \leq \varepsilon'$  and  $a \leq \frac{1}{2} - \frac{1}{100} + \frac{1}{c} \leq \frac{1}{2}$ , then  $\ell \leq \frac{\varepsilon'}{\log \frac{102c-200}{98c+200}}$ .

Proof.

$$\begin{aligned} \varepsilon' &\geq H(a) - H(b) \\ &= H(b + \ell) - H(b) \\ &\geq H(b) + \ell \log\left(\frac{1-b-\ell}{b+\ell}\right) - H(b) \text{ (By Claim 31)} \\ &= \ell \log\left(\frac{1-a}{a}\right) \end{aligned}$$

Since  $a \leq \frac{1}{2}$ , the minimum value for this is when  $a$  is as close to  $\frac{1}{2}$  as possible.

$$\begin{aligned} &\geq \ell \log \frac{1 - (\frac{1}{2} - \frac{1}{100} + \frac{1}{c})}{(\frac{1}{2} - \frac{1}{100} + \frac{1}{c})} \\ &= \ell \log \frac{102c-200}{98c+200} \\ \Rightarrow \ell &\leq \frac{\varepsilon'}{\log \frac{102c-200}{98c+200}} \end{aligned} \quad \text{◁}$$

▷ **Claim 34.** If  $\varepsilon'$  is sufficiently small, then there is a constant  $c$  satisfying

$$\frac{\varepsilon'}{\log \frac{102c-200}{98c+200}} \leq \frac{1}{100} \text{ and } \varepsilon' \leq \frac{1}{2c} \log\left(\frac{102c-200}{98c+200}\right)$$

## 66:16 Complete Problems for Multi-Pseudodeterministic Computations

Proof. It can be verified that when  $\varepsilon' = 1/42000$  and  $c = 1100$ , the above inequalities are satisfied.  $\triangleleft$

Now we are ready to prove that  $|p - q| \leq \frac{1}{100}$

▷ Claim 35.  $|p - q| \leq \frac{1}{100}$

Proof. First, suppose  $p > q$ . Then  $p = q + \ell$ . Since,  $y < H(\frac{1}{2} - \frac{1}{100}) + \varepsilon$  and  $|y - H(p)| \leq \frac{1}{2^n}$ , so  $H(p) \leq H(\frac{1}{2} - \frac{1}{100}) + \varepsilon + \frac{1}{2^n} = H(\frac{1}{2} - \frac{1}{100}) + \varepsilon'$ . By Claim 34, we have that  $c = 1/1100$ . By claim 32,  $p \leq \frac{1}{2} - \frac{1}{100} + \frac{1}{c}$ . By claim 33, we obtain that  $\ell \leq \frac{\varepsilon'}{\log \frac{102c-200}{98c+200}} \leq 1/100$ , thus  $p \leq q + 1/100$ . A similar argument shows that if  $p < q$ , then  $p \geq q - 1/100$ .  $\triangleleft$

We found a value  $p$  that is  $1/100$ -close to  $q$ , and the goal is to estimate  $r = \Pr[C(U_n) = 1]$ , where  $q = \min\{r, 1 - r\}$ . Thus  $p$  is either close to  $r$  or to  $1 - r$ . Now we run  $C(U_n)$ ,  $n$  times; if there are more 1s than 0s output  $1 - p$ ; else output  $p$ . Using Chernoff bounds, it follows that the output is  $1/100$ -close to  $q$  with probability  $\leq 1 - e^{-2n/(110^2)}$ .

Finally, recall that we needed  $\varepsilon' = \varepsilon + 1/2^n \leq 1/42000$ . Thus we can take  $\varepsilon \leq 1/43000$  (for large enough  $n$ ). So, if it's possible to pseudodeterministically estimate  $H(\Pr[C = 1])$  within  $\frac{1}{43000}$  with probability  $1 - \delta$ , it's possible to pseudodeterministically estimate  $\Pr[C = 1]$  within  $\frac{1}{100}$  with probability  $1 - \delta - e^{-2n/(110^2)}$ .  $\blacktriangleleft$

## Abstract

This paper considers a variant of the online *paging* problem, where the online algorithm has access to multiple *predictors*, each producing a sequence of predictions for the page arrival times. The predictors may have occasional prediction errors and it is assumed that at least one of them makes a sublinear number of prediction errors in total. Our main result states that this assumption suffices for the design of a randomized online algorithm whose time-average *regret* with respect to the optimal offline algorithm tends to zero as the time tends to infinity. This holds (with different regret bounds) for both the *full information* access model, where in each round, the online algorithm gets the predictions of all predictors, and the *bandit* access model, where in each round, the online algorithm queries a single predictor.

While online algorithms that exploit inaccurate predictions have been a topic of growing interest in the last few years, to the best of our knowledge, this is the first paper that studies this topic in the context of multiple predictors for an online problem with unbounded request sequences. Moreover, to the best of our knowledge, this is also the first paper that aims for (and achieves) online algorithms with a vanishing regret for a classic online problem under reasonable assumptions.

## 1 Introduction

A critical bottleneck in the performance of digital computers, known as the “memory wall”, is that the main memory (a.k.a. DRAM) is several orders of magnitude slower than the multiprocessor [26, 16, 4]. Modern computer architectures bridge this performance gap by utilizing a cache, namely, a memory structure positioned next to the multiprocessor that

LIPICs Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

responds much faster than the main memory. However, the cache is inherently smaller than the main memory which means that some of the memory items requested by the running program may be missing from the cache. When such a *cache miss* occurs, the multiprocessor is required to fetch the requested item from the main memory into the cache; if the cache is already full, then some previously stored item must be evicted to make room for the new one. Minimizing the number of cache misses is known to be a primary criterion for improving the computer's performance [26, 17].

The aforementioned challenge is formalized by means of a classic *online* problem called *paging* [21] (a.k.a. unweighted *caching*), defined over a main memory that consists of  $n \in \mathbb{Z}_{>0}$  *pages* and a cache that holds  $k \in \mathbb{Z}_{>0}$  pages at any given time,  $k < n$ . The execution of a paging algorithm **Alg** progresses in  $T \in \mathbb{Z}_{>0}$  discrete *rounds*, where round  $t \in T$  occupies the time interval  $[t, t-1)$ . An instance of the paging problem is given by a sequence  $\sigma = \{\sigma_t\}_{t \in [T]}$  of page *requests* so that request  $\sigma_t \in [n]$  is revealed at time  $t \in [T]$ . Denoting the *cache configuration* of **Alg** at time  $t$  by  $C_t \subset [n]$ ,  $|C_t| = k$ , if  $\sigma_t \in C_t$ , then **Alg** does nothing in round  $t$ ; otherwise ( $\sigma_t \notin C_t$ ), a *cache miss* occurs and **Alg** should bring the requested page into the cache so that  $\sigma_t \in C_{t+1}$ . Since  $|C_{t+1}| = |C_t| = k$ , it follows that upon a cache miss, **Alg** must evict some page  $i \in C_t$  and its policy is reduced to the selection of this page  $i$ . The *cost* incurred by **Alg** on  $\sigma$  is defined to be the number of cache misses it suffers throughout the execution, denoted by

$$\text{cost}_\sigma(\text{Alg}) = |\{t \in [T] : \sigma_t \notin C_t\}| ,$$

taking the expectation if **Alg** is a randomized algorithm. When  $\sigma$  is clear from the context, we may omit the subscript, writing  $\text{cost}(\text{Alg}) = \text{cost}_\sigma(\text{Alg})$ .

**NAT and the FitF Algorithm.** To avoid cumbersome notation, we assume hereafter that the request sequence  $\sigma$  is augmented with a suffix of  $n$  virtual requests so that  $\sigma_{T+i} = i$  for every  $i \in [n]$ . This facilitates the definition of the *next arrival time (NAT)* of page  $i \in [n]$  with respect to time  $t \in [T]$  as the first time after  $t$  at which page  $i$  is requested, denoted by

$$A_t(i) = \min\{t' > t \mid \sigma_{t'} = i\} .$$

Based on that, we can define the **FitF** (stands for furthest in the future) paging algorithm that on a cache miss at time  $t \in [T]$ , evicts the page  $i \in C_t$  that maximizes  $A_t(i)$ . A classic result of Belady [5] states that **FitF** is optimal in terms of the cost it incurs for the given request sequence  $\sigma$ ; we subsequently denote  $\text{OPT}_\sigma = \text{cost}_\sigma(\text{FitF})$  and omit the subscript, writing  $\text{OPT} = \text{OPT}_\sigma$ , when  $\sigma$  is clear from the context. It is important to point out that **FitF** is an *offline* algorithm as online algorithms are oblivious to the NATs.

**Regret.** We define the *regret* of an online paging algorithm **Alg** on  $\sigma$  as

$$\text{regret}_\sigma(\text{Alg}) = \text{cost}_\sigma(\text{Alg}) - \text{OPT}_\sigma$$

and omit the subscript, writing  $\text{regret}(\text{Alg}) = \text{regret}_\sigma(\text{Alg})$  when  $\sigma$  is clear from the context. Our goal in this paper is to develop an online algorithm that admits a *vanishing regret*, namely, an online algorithm **Alg** for which it is guaranteed that

$$\lim_{T \rightarrow \infty} \frac{\sup \{\text{regret}_\sigma(\text{Alg}) \mid \sigma \in [n]^T\}}{T} = 0 .$$

The following theorem states that this goal is hopeless unless the online algorithm has access to some additional information; its proof should be a folklore, we add it in the full version [11] of this paper for completeness.

► **Theorem 1.** Fix  $n = k + 1$  and let  $\sigma$  be a request sequence generated by picking  $\sigma_t$  uniformly at random (and independently) from  $[n]$  for  $t = 1, \dots, T$ . Then,  $\mathbb{E}(\text{cost}(\text{Alg})) \geq \Omega\left(\frac{T}{k}\right)$  for any (possibly randomized) online paging algorithm  $\text{Alg}$ , whereas  $\mathbb{E}(\text{OPT}) \leq O\left(\frac{T}{k \log k}\right)$ .

## 1.1 Machine Learned Predictions

Developments in *machine learning (ML)* technology suggest a new direction for reducing the number of cache misses by means of predicting the request sequence. Indeed, recent studies have shown that neural networks can be employed to predict the memory pages accessed by a program with high accuracy [16, 9, 22, 19, 23]. When provided with an accurate prediction of the request sequence  $\sigma$ , one can simply simulate **FitF**, thus ensuring an optimal performance.

Unfortunately, the predictions generated by ML techniques are usually not 100% accurate as a result of a distribution drift between the training and test examples or due to adversarial examples [24, 18]. This gives rise to a growing interest in developing algorithmic techniques that can overcome inaccurate predictions, aiming for the design of online algorithms with performance guarantee that improves as the predictions become more accurate [18, 20, 1, 25]. The existing literature in this line of research studies a setting where the online algorithm  $\text{Alg}$  is provided with a sequence of predictions for  $\sigma$  and focuses on bounding  $\text{Alg}$ 's *competitive ratio* as a function of the proximity of this sequence to  $\sigma$  (more on that in Section 2).

The current paper tackles the challenge of overcoming inaccurate predictions from a different angle: Motivated by the abundance of forecasting algorithms that may be trained on different data sets or using different models (e.g., models that are robust to adversarial examples [15]), we consider a decision maker with access to *multiple* predicting sequences for  $\sigma$ . Our main goal is to design an online algorithm  $\text{Alg}$  that admits a vanishing regret assuming that at least one of the predicting sequences is sufficiently accurate, even though the decision maker does not know in advance which predicting sequence it is.

**Explicit Predictors.** Formally, we consider  $M \in \mathbb{Z}_{>0}$  predictors whose role is to predict the request sequence  $\sigma$ . In the most basic form, referred to hereafter as the *explicit predictors* setting, each predictor  $j \in [M]$  produces a page sequence  $\pi^j = \{\pi_t^j\}_{t \in [T]} \in [n]^T$ , where  $\pi_t^j$  aims to predict  $\sigma_t$  for every  $t \in [T]$ , and the sequences  $\pi^1, \dots, \pi^M$  are revealed to the online algorithm  $\text{Alg}$  at the beginning of the execution. Under the explicit predictors setting, predictor  $j \in [M]$  is said to have a *prediction error* in round  $t \in [T]$  if  $\pi_t^j \neq \sigma_t$ . We measure the accuracy of predictor  $j$  by means of her *cumulative prediction error*

$$\eta_e^j = \eta_e(\pi^j) = \left| \left\{ t \in [T] : \pi_t^j \neq \sigma_t \right\} \right|$$

and define  $\eta_e^{\min} = \min\{\eta_e^j \mid j \in [M]\}$ .

The fundamental assumption that guides the current paper, referred to hereafter as the *good predictor* assumption, is that there exists at least one predictor whose cumulative prediction error is sublinear in  $T$ , namely,  $\eta_e^{\min} = o(T)$ . We emphasize that  $\text{Alg}$  has no a priori knowledge of  $\eta_e^1, \dots, \eta_e^M$  nor does it know the predictor that realizes  $\eta_e^{\min}$ . Our main research question can now be stated as follows:

Does the good predictor assumption provide a sufficient condition for the existence of an online algorithm that admits a vanishing regret?

**NAT Predictors.** For the paging problem, it is arguably more natural to consider the setting of *NAT predictors*, where predictor  $j \in [M]$  produces in each round  $t \in [T]$ , a prediction  $a_t^j \in (t, T + n]$  for the NAT  $A_t(\sigma_t)$  of the page that has just been requested. Under this

setting, predictor  $j \in [M]$  is said to have a *prediction error* in round  $t \in [T]$  if  $a_t^j \neq A_t(\sigma_t)$ . As in the explicit predictors setting, we measure the accuracy of (NAT) predictor  $j$  by means of her *cumulative prediction error*, now defined as

$$\eta_N^j = \left| \left\{ t \in [T] : a_t^j \neq A_t(\sigma_t) \right\} \right| \quad (1)$$

(this measure is termed *classification loss* in [18]), and define  $\eta_N^{\min} = \min\{\eta_N^j \mid j \in [M]\}$ .<sup>1</sup> The NAT predictors version of the good predictor assumption states that  $\eta_N^{\min} = o(T)$ .

Given a page sequence  $\pi = \{\pi_t\}_{t \in [T]} \in [n]^T$  augmented with a suffix of  $n$  pages such that  $\pi_{T+i} = i$  for every  $i \in [n]$ , we say that (NAT) predictor  $j \in [M]$  is *consistent* with  $\pi$  if  $a_t^j = \min\{t' > t \mid \pi_{t'} = \sigma_t\}$  for every  $t \in [T]$ ; if the page sequence  $\pi$  is not important or clear from the context, then we may say that predictor  $j$  is *consistent* without mentioning  $\pi$ . The key observation here is that if predictor  $j$  is consistent with a page sequence  $\pi$ , then  $\eta_N^j$  provides a good approximation for  $\eta_e(\pi)$ , specifically,

$$\eta_e(\pi) - n \leq \eta_N^j \leq 2 \cdot \eta_e(\pi) \quad (2)$$

(the proof is deferred to the full version [11]). This means that the setting of NAT predictors is stronger than that of explicit predictors in the sense that NAT predictor  $j \in [M]$  can be simulated (consistently) from explicit predictor  $j$  by deriving the NAT prediction  $a_t^j$  in round  $t \in [T]$  from the (explicit) predictions  $\pi_{t+1}^j, \pi_{t+2}^j, \dots, \pi_T^j$ , while ensuring that  $\eta_N^j$  is a good approximation for  $\eta_e^j$ . Therefore, unless stated otherwise, we subsequently restrict our attention to NAT predictors and in particular omit the subscript from the cumulative prediction error notation, writing  $\eta^j = \eta_N^j$  and  $\eta^{\min} = \eta_N^{\min}$ . It is important to point out though that the results established in the current paper hold regardless of whether the (NAT) predictors are consistent or not.

**Access Models.** Recall that the (NAT) predictors  $j \in [M]$  produce their predictions in an online fashion so that the NAT prediction  $a_t^j$  is produced in round  $t$ . This calls for a distinction between two *access models* that determine the exact manner in which  $a_t^j$  is revealed to the online paging algorithm **Alg**. First, we consider the *full information* access model, where in each round  $t \in [T]$ , **Alg** receives  $a_t^j$  for all  $j \in [M]$ . Motivated by systems in which accessing the ML predictions is costly in both time and space (thus preventing **Alg** from querying multiple predictors in the same round and/or predictions belonging to past rounds), we also consider the *bandit* access model, where in each round  $t \in [T]$ , **Alg** receives  $a_t^j$  for a single predictor  $j \in [M]$  selected by **Alg** in that round. To make things precise, we assume, under both access models, that if **Alg** has to evict a page in round  $t$ , then the decision on the evicted page is made prior to receiving the prediction(s) in that round. Notice though that the information that **Alg** receives from the predictor(s) is not related to the evicted page and as such, should not be viewed as a feedback that **Alg** receives in response to the action it takes in the current round.

## 1.2 Our Contribution

Consider a (single) predictor that in each round  $t \in [T]$ , produces a prediction  $a_t$  for the NAT  $A_t(\sigma_t)$  of the page that has just been requested and let  $\eta$  be her cumulative prediction error. Our first technical contribution comes in the form of a thorough analysis of the performance

<sup>1</sup> In Section 2, we provide a refined definition for the cumulative prediction error of a NAT predictor that is more robust against adversarial interference such as shifting each  $a_t^j$  by a constant. For simplicity of the exposition, the definition presented in Eq. (1) is used throughout the current section; we emphasize though that all our results hold for the stronger notion of prediction error as defined in Section 2.

of a simple online paging algorithm called **Sim** that simulates **FitF**, replacing the actual NATs with the ones derived from the prediction sequence  $\{a_t\}_{t \in [T]}$ . Using some careful combinatorial arguments, we establish the following bound.

► **Theorem 2.** *The regret of **Sim** satisfies  $\text{regret}(\text{Sim}) \leq O(\eta + k)$ .*

Relying on online learning techniques, Blum and Burch [6] develop an online algorithm “multiplexer” that given multiple online algorithms as subroutines, produces a randomized online algorithm that performs almost as good as the best subroutine in hindsight. Applying Theorem 2 to the  $M$  predictors so that each predictor  $j \in [M]$  yields its own online paging algorithm  $\text{Sim}^j$  and plugging algorithms  $\text{Sim}^1, \dots, \text{Sim}^M$  into the multiplexer of [6], we establish the following theorem, thus concluding that the good predictor assumption implies an online paging algorithm with a vanishing regret under the full information access model.

► **Theorem 3.** *There exists a randomized online paging algorithm that given full information access to  $M$  NAT predictors with minimum cumulative prediction error  $\eta^{\min}$ , has regret at most  $O(\eta^{\min} + k + (Tk \log M)^{1/2})$ .*

Combined with (2), we obtain the same asymptotic regret bound for explicit predictors.

► **Corollary 4.** *There exists a randomized online paging algorithm that given access to  $M$  explicit predictors with minimum cumulative prediction error  $\eta_e^{\min}$ , has regret at most  $O(\eta_e^{\min} + k + (Tk \log M)^{1/2})$ .*

The explicit predictors setting is general enough to make it applicable to virtually any online problem. This raises the question of whether other online problems admit online algorithms with a vanishing regret given access to explicit predictors whose minimum cumulative prediction error is sublinear in  $T$ . We view the investigation of this question as an interesting research thread that will hopefully arise from the current paper.

Going back to the setting of NAT predictors, one wonders if a vanishing regret can be achieved also under the bandit access model since the technique of [6] unfortunately does not apply to this more restricted access model. An inherent difficulty in the bandit access model is that we cannot keep track of the cache configuration of  $\text{Sim}^j$  unless predictor  $j$  is queried in each round (which means that no other predictor can be queried). To overcome this obstacle, we exploit certain combinatorial properties of the **Sim** algorithm to show that  $\text{Sim}^j$  can be “chased” without knowing its current cache configuration, while bounding the accumulated cost difference. By a careful application of online learning techniques, this allows us to establish the following theorem, thus concluding that the good predictor assumption implies an online paging algorithm with a vanishing regret under the bandit access model as well.

► **Theorem 5.** *There exists a randomized online paging algorithm that given bandit access to  $M$  NAT predictors with minimum cumulative prediction error  $\eta^{\min}$ , has regret at most  $O(\eta^{\min} + T^{2/3}kM^{1/2})$ .*

### 1.3 Related Work and Discussion

We say that an online algorithm **Alg** for a minimization problem  $\mathcal{P}$  has *competitive ratio*  $\alpha$  if for any instance  $\sigma$  of  $\mathcal{P}$ , the cost incurred by **Alg** on  $\sigma$  is at most  $\alpha \cdot \text{OPT}_\sigma + \beta$ , where  $\text{OPT}_\sigma$  is the cost incurred by an optimal offline algorithm on  $\sigma$  and  $\beta$  is a constant that may depend on  $\mathcal{P}$ , but not on  $\sigma$  [21, 7]. In comparison, the notion of regret as defined in the current paper uses the optimal offline algorithm as an absolute (additive), rather than

relative (multiplicative), benchmark. Notice that the vanishing regret condition cannot be expressed in the scope of the competitive ratio definition. In particular,  $\alpha = 1$  is a stronger requirement than vanishing regret as the latter can accommodate an additive parameter  $\beta$  that does depend on  $\sigma$  as long as it is sublinear in  $T = |\sigma|$ . On the other hand,  $\alpha > 1$  implies a non-vanishing regret when  $\text{OPT}_\sigma$  scales linearly with  $T$ .

As mentioned in Section 1.1, most of the existing literature on augmenting online algorithms with ML predictions is restricted to the case of a single predictor [18, 20, 1, 25]. The goal of these papers is to develop online algorithms with two guarantees: (i) their competitive ratio tends to  $O(1)$  (though not necessarily to 1) as the predictor's accuracy improves; and (ii) they are robust in the sense that regardless of the predictor's accuracy, their competitive ratio is not much worse than that of the best online algorithm that has no access to predictions.

In contrast, the current paper addresses the setting of multiple predictors, working under the assumption that at least one of them is sufficiently accurate, and seeking to develop online algorithms with a vanishing regret. To the best of our knowledge, this is the first paper that aims at this direction.

Most closely related to the current paper are the papers of [18, 20, 25] on online paging with predictions. The authors of these papers stick to the setting of a (single) NAT predictor and quantify the predictor's accuracy by means of the  $L_1$ -norm. Specifically, taking  $\{a_t\}_{t \in [T]}$  to be the sequence of NAT predictions, they define the predictor's cumulative prediction error to be  $\sharp L_1 = \sum_t |a_t - A_t(\sigma_t)|$ . It is easy to see that for any NAT predictor, the cumulative prediction error as defined in (1) is never larger than its  $\sharp L_1$ , while the former can be  $\Omega(T)$ -times smaller.

In particular, Lykouris and Vassilvitskii [18] design a randomized online paging algorithm whose competitive ratio is at most  $O\left(\min\left\{1 + \sqrt{\sharp L_1 / \text{OPT}}, \log k\right\}\right)$ . Rohatgi [20] presents an improved randomized online algorithm with competitive ratio upper bounded by  $O\left(\min\left\{1 + \frac{\log k}{k} \frac{\sharp L_1}{\text{OPT}}, \log k\right\}\right)$  and accompany this with a lower bound of  $\Omega\left(\min\left\{1 + \frac{1}{k \log k} \frac{\sharp L_1}{\text{OPT}}, \log k\right\}\right)$ . Notice that the online algorithms presented in [18, 20] belong to the *marking family* of paging algorithms [13] and it can be shown that the competitive ratio of any such algorithm is bounded away from 1 even when provided with a fully accurate predictor (consider for example the paging instance defined by setting  $n = 4$ ,  $k = 2$ , and  $\sigma_t = (t \bmod 4) + 1$  for every  $t \in [T]$ ).

Recently, Wei [25] advanced the state of the art of this problem further, presenting a randomized  $O\left(\min\left\{1 + \frac{1}{k} \frac{\sharp L_1}{\text{OPT}}, \log k\right\}\right)$ -competitive online paging algorithm. To do so, Wei analyzes an algorithm called *BlindOracle*, that can be viewed as a variant of our *Sim* algorithm (see Section 1.2), and proves that its competitive ratio is at most  $\min\left\{1 + O\left(\frac{\sharp L_1}{\text{OPT}}\right), O\left(1 + \frac{1}{k} \frac{\sharp L_1}{\text{OPT}}\right)\right\}$ . He then plugs this algorithm into the multiplexer of [6] together with an  $O(\log k)$ -competitive off-the-shelf randomized online paging algorithm to obtain the promised competitive ratio. Notice that the bound that Wei establishes on the competitive ratio of *BlindOracle* immediately implies an  $O(\sharp L_1)$  bound on the regret of this algorithm. As such, Theorem 2 can be viewed as a refinement of Wei's result, bounding the regret as a function of  $\eta$  rather than the weaker measure of  $\sharp L_1$ .

Antoniadis et al. [1] studies online algorithms with ML predictions in the context of the *metrical task system (MTS)* problem [8]. They consider a different type of predictor that in each round  $t \in [T]$ , provides a prediction  $\hat{s}_t$  for the state  $s_t$  of an optimal offline algorithm, measuring the prediction error by means of  $\sharp \text{Distances} = \sum_{t \in [T]} \text{dist}(s_t, \hat{s}_t)$ , where  $\text{dist}(\cdot, \cdot)$  is the distance function of the underlying metric space. It is well known that any paging

instance  $\mathcal{I}$  can be transformed into an MTS instance  $\mathcal{I}_{\text{MTS}}$ . Antoniadis et al. prove that the prediction sequence  $\{a_t\}_{t \in [T]}$  of a NAT predictor for  $\mathcal{I}$  can also be transformed into a prediction sequence  $\{\hat{s}_t\}_{t \in [T]}$  for  $\mathcal{I}_{\text{MTS}}$ . However, the resulting prediction error  $\# \text{Distances}$  of the latter sequence is incomparable to the prediction error  $\# \text{L}_1$  of the former; this remains true also for the stronger notion of cumulative prediction error as defined in (1).

Online algorithms with access to multiple predictors have been studied by Gollapudi and Panigrahi for the *ski rental* problem [14]. Among other results, they prove that a competitive ratio of  $\alpha = \frac{4}{3}$  (resp.,  $\alpha = \frac{\sqrt{5}+1}{2}$ ) can be achieved by a randomized (resp., deterministic) online algorithm that has access to two predictors assuming that at least one of them provides an accurate prediction for the number of skiing days. Notice that the length of the request sequence in the ski rental problem is inherently bounded by the cost of buying the ski gear; this is in contrast to the paging problem considered in the current paper, where much of the challenge comes from the unbounded request sequence.

The reader may have noticed that some of the terminology used in the current paper is borrowed from the *online learning* domain [10]. The main reason for this choice is that the research objectives of the current paper are, to a large extent, more in line with the objectives common to the online learning literature than they are in line with the objectives of the literature on online computation. In particular, as discussed already, we measure the quality of our online algorithms by means of their regret (rather than competitiveness), indicating that the online algorithm can be viewed as a decision maker that tries to learn the best offline algorithm.

## 1.4 Paper's Organization

The remainder of this paper is organized as follows. In Section 2, we refine the notion of cumulative prediction error as defined in (1) and compare the refined notion with the number of inversions used in some of the related literature [20, 25]. The analysis of the **Sim** algorithm (using a single predictor), leading to the proof of Theorem 2, is carried out in Section 3. Section 4 is then dedicated to the setting of multiple (NAT) predictors under the bandit access model and establishes Theorem 5. As discussed in Section 1.3, Theorem 3, dealing with the full information access model, follows from Theorem 2 combined with a technique of [6]; this is explained in more detail in the full version [11].

## 2 Measurements of Prediction Errors

The measurement of the prediction errors plays an important role in the study on online paging algorithms augmented by predictions. This part makes a comparison between different measurements for the scenario where there is a single NAT predictor. To avoid ambiguity, in this part we use  $\# \text{ErrorRounds}$  to represent the measurement defined in Eq. (1) for the single predictor  $j$ . In the following, the superscript  $j$  for the predictor is omitted for convenience.

In the analysis of [25], the prediction errors are measured with the number of *inverted pairs*. For a pair of two rounds  $\{t, t'\}$ , we say it is an inverted pair if  $A_t(\sigma_t) < A_{t'}(\sigma_{t'})$  and  $a_t \geq a_{t'}$ . Let  $\text{INV}$  be the set of all the inverted pairs, and define  $\# \text{InvertedPairs} = |\text{INV}|$ . To compare the measurement  $\# \text{InvertedPairs}$  with  $\# \text{ErrorRounds}$ , we also define the following notations.

$$\begin{aligned} \# \text{InvertedRounds} &\doteq \left| \{t \mid \exists t' \text{ s.t. } \{t, t'\} \in \text{INV}\} \right| \\ \# \text{ErrorRoundsInInversion} &\doteq \left| \{t \mid A_t(\sigma_t) \neq a_t \wedge \exists t' \text{ s.t. } \{t, t'\} \in \text{INV}\} \right| \end{aligned}$$

First, it trivially holds that  $\# \text{InvertedRounds} \leq 2 \cdot \# \text{InvertedPairs}$ , and  $\# \text{InvertedPairs}$  can be  $\Omega(T)$  times larger than  $\# \text{InvertedRounds}$ . To see the second claim, consider the following sequence  $\sigma$  of requested pages and a prediction sequence  $\pi$ .

$$\sigma_t = \begin{cases} 1 & \text{if } t \leq \frac{T}{2} \\ 2 & \text{if } t > \frac{T}{2} \end{cases}, \quad \text{and} \quad \pi_t = \begin{cases} 2 & \text{if } t \leq \frac{T}{2} \\ 1 & \text{if } t > \frac{T}{2} \end{cases}.$$

It can be verified that for a sequence of predictions in the form of NATs that are consistent with the settings above,  $\# \text{InvertedPairs}$  is in the order of  $T^2$  while  $\# \text{InvertedRounds}$  is in the order of  $T$ .

Second, we claim that  $\# \text{InvertedRounds}$  and  $\# \text{ErrorRounds}$  are incomparable, which means that there exists an example where  $\# \text{InvertedRounds}$  is  $\Omega(T)$  times larger than  $\# \text{ErrorRounds}$ , and vice versa. Still, we demonstrate these examples with the sequence  $\sigma$  of requests and the prediction sequence  $\pi$ , and the claims above can be verified after converting the predictions in the form of requests to consistent predictions in the form of NATs. The configuration of the first example is given as follows.

$$\sigma_t = \begin{cases} (t \bmod (k-1)) + 1 & \text{if } 1 < t < T \\ k & \text{otherwise} \end{cases}, \quad \text{and} \quad \pi = \begin{cases} (t \bmod (k-1)) + 1 & \text{if } t > 2 \\ k & \text{otherwise} \end{cases}.$$

The second example is configured as follows.

$$\sigma_t = (t \bmod (k-1)) + 1, \quad \text{and} \quad \pi = \begin{cases} ((t-1) \bmod (k-1)) + 1 & \text{if } t > 1 \\ k & \text{otherwise} \end{cases}.$$

Third, it is obvious that

$$\# \text{ErrorRoundsInInversion} \leq \min \{ \# \text{ErrorRounds}, \# \text{InvertedRounds} \}.$$

Although in Section 1.1 we define  $\eta^j$  for every predictor  $j$  in the form of  $\# \text{ErrorRounds}$  for simplicity, our technique indeed works for the better measurement  $\# \text{ErrorRoundsInInversion}$ . Therefore, in the technical parts of the current paper, including Section 3 and Section 4, we use the following refined definition of  $\eta^j$  by abuse of notation:

$$\eta^j \doteq \left| \{t \mid A_t(\sigma_t) \neq a_t^j \wedge \exists t' \text{ s.t. } \{t, t'\} \in \text{INV}^j\} \right|,$$

where  $\text{INV}^j = \{(t, t') \mid A_t(\sigma_t) < A_{t'}(\sigma_{t'}) \wedge a_t^j \geq a_{t'}^j\}$ .

### 3 Single NAT Predictor

We start with the NAT predictor setting with  $M = 1$ . In such a case, there is no difference between the full information access model and the bandit access model. Throughout this section, we still omit the superscript  $j$  for the index of the predictor.

The algorithm **Sim** that we consider for this setting simulates **FitF** with maintaining a value  $\hat{a}_t(i)$ , which we call the *remedy prediction*, for each round  $t \in [T]$  and each page  $i \in [n]$ . In particular, for each page  $i \in [n]$ , **Sim** sets

$$\begin{aligned} \hat{a}_1(i) &= \begin{cases} a_1 & \text{if } i = \sigma_1 \\ Z+1 & \text{otherwise} \end{cases}, \quad \text{and} \\ \forall t \in [2, T] \quad \hat{a}_t(i) &= \begin{cases} a_t & \text{if } i = \sigma_t \\ Z & \text{if } \hat{a}_{t-1}(i) \leq t \wedge i \neq \sigma_t \wedge \hat{a}_{t-1}(i) \leq \hat{a}_{t-1}(\sigma_t) < Z, \\ \hat{a}_{t-1}(i) & \text{otherwise} \end{cases} \end{aligned} \quad (3)$$

where  $Z > T + n$  is a sufficiently large integer. For each round  $t$  when a cache miss happens, the algorithm evicts the page  $\hat{e}_t = i$  that maximizes  $\hat{a}_t(i)$ , and ties are broken in an arbitrary way. The following statements can be directly inferred from Eq. (3).

- **Lemma 6.** *The following properties are satisfied for every round  $t \in [T]$ :*
- *If  $a_t > A_t(\sigma_t)$ , then for each round  $t' \in [t, \min\{T, A_t(\sigma_t) - 1\}]$ , we have  $\hat{a}_{t'}(\sigma_t) > A_{t'}(\sigma_t)$ .*
  - *If  $a_t < A_t(\sigma_t)$ , then for each round  $t' \in [t, \min\{T, A_t(\sigma_t) - 1\}]$ , either  $\hat{a}_{t'}(\sigma_t) < A_{t'}(\sigma_t)$  or  $\hat{a}_{t'}(\sigma_t) = Z > A_{t'}(\sigma_t)$ . Particularly, if  $t' \leq a_t - 1$ , then  $\hat{a}_{t'}(\sigma_t) < A_{t'}(\sigma_t)$ .*
  - *If  $a_t = A_t(\sigma_t)$ , then for each round  $t' \in [t, \min\{T, A_t(\sigma_t) - 1\}]$ , we have  $\hat{a}_{t'}(\sigma_t) = A_{t'}(\sigma_t)$ .*

Next, we will analyze the cost incurred by **Sim** and show that it has a vanishing regret.

### 3.1 Definitions and Notations for Analysis

For each round  $t$ , we use  $e_t$  and  $\hat{e}_t$  to represent the pages that are evicted by **FitF** and **Sim**, respectively. We say  $e_t = \perp$  (resp.  $\hat{e}_t = \perp$ ) if **FitF** (resp. **Sim**) does not evict any page.

For each page  $i \in [n]$  and each round  $t \in [T]$ , define  $R_t(i)$  to be the last round before  $t$  when  $i$  is requested. Formally,

$$R_t(i) \doteq \begin{cases} \max\{t' < t \mid \sigma_{t'} = i\} & \text{if } \exists t' \in [1, t) \text{ s.t. } \sigma_{t'} = i \\ -1 & \text{otherwise} \end{cases}. \quad (4)$$

The following results can be inferred from Eq. (4) and Lemma 6.

For any round  $t \in [T]$ , let  $C_t$  and  $\hat{C}_t$  be the *cache profiles* incurred by **FitF** and **Sim**, respectively. More specifically,  $C_1$  and  $\hat{C}_1$  represent the cache items given at the beginning. To provide tools for the more complicated scenario where there are multiple predictors, the analysis in this section is carried out without assuming that  $C_1 = \hat{C}_1$ . For each  $t \in [T-1]$ , the cache profile  $C_t$  (resp.  $\hat{C}_t$ ) is updated to  $C_{t+1}$  (resp.  $\hat{C}_{t+1}$ ) immediately after **FitF** (resp. **Sim**) has processed the request  $\sigma_t$ . The cache profiles of **FitF** and **Sim** after serving  $\sigma_T$  are denoted by  $C_{T+1}$  and  $\hat{C}_{T+1}$ , respectively.

Denote the intersection between the cache profiles at each round  $t \in [T]$  by  $I_t = C_t \cap \hat{C}_t$ . Define the *distance* between the cache profiles to be  $d_t = k - |I_t|$ . We use  $\delta_t$  to represent the difference in the costs between **FitF** and **Sim** for serving  $\sigma_t$ . Formally,  $\delta_t \doteq 1_{\sigma_t \notin \hat{C}_t} - 1_{\sigma_t \notin C_t}$ .

Define  $\mathcal{H}_x^y$  for  $x \in \mathbb{Z}$ ,  $y \in \mathbb{Z}$  to be the set of rounds  $t \in [T]$  where the  $d_{t+1} - d_t = x$  and  $\delta_t = y$ . Let  $\mathcal{H}_x = \bigcup_y \mathcal{H}_x^y$  and  $\mathcal{H}^y = \bigcup_x \mathcal{H}_x^y$ .

For a round  $t \in [T]$ , we say that  $t$  is a *troublemaker* if and only if  $t$  satisfies

$$(\hat{e}_t \neq \perp) \wedge (\hat{e}_t \in I_t) \wedge A_t(\hat{e}_t) \in [T] \wedge (\hat{e}_t \in C_{A_t(\hat{e}_t)}) \wedge (e_t = \perp \vee e_t \notin I_t). \quad (5)$$

The set of troublemaker rounds is denoted by  $\Gamma$ . For any troublemaker  $\gamma \in \Gamma$  and any round  $t \in (\gamma, T]$ , we say  $\gamma$  is *active* at  $t$  if  $t < A_\gamma(\hat{e}_\gamma)$ . The set of troublemakers that are active at  $t$  is denoted by  $\Gamma_t \subseteq \Gamma \cap [t-1]$ . The *active period*  $[\gamma+1, A_\gamma(\hat{e}_\gamma)-1]$  of  $\gamma$  is denoted by  $\theta_\gamma$ .

**Preliminary results.** The following results are directly inferred from the definitions above.

- **Lemma 7.** *For any round  $t$  and any page  $i$ , the following properties are satisfied.*

- *If  $R_t(i) = -1$  and  $i \neq \sigma_t$ , then  $\hat{a}_t(i) = Z + 1$ , and vice versa.*
- *The equality  $\hat{a}_t(i) = A_t(i)$  holds if  $a_r = A_r(\sigma_r)$ , where  $r = R_t(i)$ .*

**Proof.** The first statement can be proved inductively with using Eq. (3). The first statement implies that if  $\hat{a}_t(i) = A_t(i)$ , then  $R_t(i) \neq -1$ . Therefore, the second statement can be inferred from Lemma 6. ◀

► **Lemma 8.**  $|\{t \mid \hat{e}_t \neq \perp \wedge R_t(\hat{e}_t) = -1\}| \leq k$ .

**Proof.** For each round  $t$  and each page  $i \in \hat{C}_t$ , the equality  $R_t(i) = -1$  holds only if  $i \in \hat{C}_1$ . The initial cache profile  $\hat{C}_1$  contains  $k$  different pages, and for each page  $i \in \hat{C}_1$ , if there exist two rounds  $t, t'$  with  $t < t'$  and  $\hat{e}_t = \hat{e}_{t'} = i$ , then  $R_{t'}(i) \geq t \neq -1$ . This implies that there are at most  $k$  rounds  $t$  with  $R_t(\hat{e}_t) = -1$ . ◀

► **Lemma 9.**  $|\{t \mid R_t(\sigma_t) = -1 \wedge t \in \mathcal{H}_0^1\}| \leq k$

**Proof.** For a round  $t \in \mathcal{H}_0^1$ , we have  $\sigma_t \in C_t$ . Since  $R_t(\sigma_t) = -1$ , we have  $\sigma_t \in C_1$ . Then this lemma can be proved in a similar way with Lemma 8. ◀

► **Lemma 10.** For every round  $t$  and any troublemaker  $\gamma \in \Gamma_t$ , we have (1)  $\hat{e}_\gamma \in C_t \setminus \hat{C}_t$ , and (2)  $\hat{e}_\gamma \neq \hat{e}_{\gamma'}$  for any troublemaker  $\gamma' \in \Gamma_t$  with  $\gamma \neq \gamma'$ .

**Proof.** The first statement is directly inferred from the definition of active troublemakers. Now consider the second statement. Without loss of generality, we assume that  $\gamma < \gamma'$ . Then the first statement shows that  $\hat{e}_\gamma \notin \hat{C}_{\gamma'}$ , which means that **Sim** cannot evict  $\hat{e}_\gamma$  at  $\gamma'$ . ◀

### 3.2 Reducing Cost Analysis to Troublemaker Counting

► **Lemma 11.** For each round  $t \in [T]$ , we have  $d_{t+1} - d_t \in \{-1, 0, 1\}$  and  $\delta_t \in \{-1, 0, 1\}$ .

The proof of Lemma 11 is deferred to the full version [11]. This lemma implies that for the sets  $\mathcal{H}_x^y$ , we only need to consider the parameters  $x, y \in \{-1, 0, 1\}$ . The following result on  $\mathcal{H}_x^y$  can be inferred from the proof of Lemma 11.

► **Lemma 12.** It holds that  $\mathcal{H}_1 = \mathcal{H}_1^0 = \{t \mid e_t \neq \perp \wedge \hat{e}_t \neq \perp \wedge e_t \neq \hat{e}_t \wedge \hat{e}_t \in I_t \wedge e_t \in I_t\}$ .

Lemma 12 implies that  $\mathcal{H}_1^1 = \emptyset$ , therefore,  $\text{cost}(\text{Sim}) - \text{OPT}$  can be bounded by  $|\mathcal{H}^1| - |\mathcal{H}^{-1}| = |\mathcal{H}_0^1| + |\mathcal{H}_{-1}^1| - |\mathcal{H}^{-1}|$ .

► **Lemma 13.**  $|\mathcal{H}_{-1}| \leq |\mathcal{H}_1| + k$ .

**Proof.** By definition,  $\mathcal{H}_{-1}$  is the set of rounds  $t$  with  $d_{t+1} - d_t < 0$ , and  $\mathcal{H}_1$  is the set of rounds  $t$  with  $d_{t+1} - d_t > 0$ . Since  $d_1 \leq k$  and  $d_t \geq 0$  for every  $t \in [T + 1]$ , this proposition holds. ◀

Lemma 13 allows us to bound  $|\mathcal{H}_{-1}^1|$  with  $|\mathcal{H}_1|$ . The following result follows from the mechanisms of **FitF** and **Sim** in choosing the page for eviction when cache miss happens.

► **Lemma 14.** For each round  $t \in \mathcal{H}_1$ , we have  $A_t(\hat{e}_t) < A_t(e_t)$  and  $\hat{a}_t(e_t) \leq \hat{a}_t(\hat{e}_t)$ .

For each round  $t \in \mathcal{H}_1$ , we say that  $t$  *blames* another round  $t'$  specified as follows. Let  $r = R_t(\hat{e}_t)$  and  $r' = R_t(e_t)$ , then the round blamed by  $t$  is

$$t' = \begin{cases} r & \text{if } (r \neq -1) \wedge (a_r \neq A_r(\sigma_r)) \\ r' & \text{if } (r = -1 \vee a_r = A_r(\sigma_r)) \wedge (r' \neq -1 \wedge a_{r'} \neq A_{r'}(\sigma_{r'})) \\ -1 & \text{otherwise} \end{cases}.$$

► **Lemma 15.** For each  $t \in \mathcal{H}_1$ , let  $t'$  be the round blamed by  $t$ . If  $t' = -1$ , then  $R_t(\hat{e}_t) = -1$ . If  $R_t(\hat{e}_t) \neq -1$ , then there exists a round  $t''$  such that  $\{t', t''\} \in \text{INV}$ .

**Proof.** For the first claim, suppose on the contrary  $r = R_t(\hat{e}_t) \neq -1$ . Now consider two cases,  $r' \neq -1$  and  $r' = -1$ , where  $r' = R_t(e_t)$ .

- $r' \neq -1$ : Since  $t' = -1$ , in such a case we have  $a_r = A_r(\sigma_r)$  and  $a_{r'} = A_{r'}(\sigma_{r'})$ . By Lemma 7, it holds that  $\hat{a}_t(\hat{e}_t) = a_r = A_r(\sigma_r) = A_t(\hat{e}_t)$ . Similarly, we have  $\hat{a}_t(e_t) = A_t(e_t)$ . This conflicts with Lemma 14.
- $r' = -1$ : By Lemma 7, in such a case we have  $\hat{a}_t(e_t) = Z + 1$ , because  $e_t \neq \sigma_t$ . As it still holds that  $\hat{a}_t(\hat{e}_t) = A_t(\hat{e}_t) < Z$ , we have  $\hat{a}_t(\hat{e}_t) < \hat{a}_t(e_t)$ , which conflicts with Lemma 14.

For the second claim, since  $R_t(\hat{e}_t) \neq -1$ , Lemma 7 indicates that  $\hat{a}_t(\hat{e}_t) \leq Z$ . Now consider the following two cases.

- $\hat{a}_t(\hat{e}_t) < Z$ : By Lemma 14, in such a case we also have  $\hat{a}_t(e_t) < Z$ . It can be inferred from Eq. (3) that  $\hat{a}_t(\hat{e}_t) = a_r$  and  $\hat{a}_t(e_t) = a_{r'}$ . Notice that the second equality holds because  $\hat{a}_t(e_t) < Z$  means that  $r' \neq -1$ . Then by Lemma 14, we have  $a_{r'} = \hat{a}_t(e_t) \leq \hat{a}_t(\hat{e}_t) = a_r$  and  $A_r(\sigma_r) = A_t(\hat{e}_t) < A_t(e_t) = A_{r'}(\sigma_{r'})$ . This means that the pair  $\{r, r'\}$  is an inversion. Since  $R_t(\hat{e}_t) = -1$ , we have either  $t' = r$  or  $t' = r'$ . By taking

$$t'' = \begin{cases} r' & \text{if } t' = r \\ r & \text{if } t' = r' \end{cases},$$

this claim is proved.

- $\hat{a}_t(\hat{e}_t) = Z$ : Let  $t_1$  be the first round in  $(r, t]$  so that  $\hat{a}_{t_1}(\hat{e}_t) = Z$ . Then Eq. (3) indicates that  $\hat{a}_{t_1-1}(\sigma_{t_1}) < Z$ . By Lemma 7, we have  $r_1 = R_{t_1}(\sigma_{t_1}) \neq -1$ . Then,  $A_{r_1}(\sigma_{r_1}) = t_1 < A_t(\hat{e}_t) = A_r(\sigma_r)$ . Moreover,  $\hat{a}_{t_1-1}(\sigma_r) \leq \hat{a}_{t_1-1}(\sigma_{t_1}) < Z$  means that  $a_r = \hat{a}_{t_1-1}(\sigma_r)$  and  $a_{r_1} = \hat{a}_{t_1-1}(\sigma_{t_1})$ . Therefore, the pair  $\{r_1, r\}$  is an inversion. Then this claim is established if  $t' = r$ . This equation holds because (1)  $r = R_t(\hat{e}_t) \neq -1$ , and (2) Lemma 7 implies that  $A_r(\sigma_r) \neq a_r$ , because otherwise  $\hat{a}_t(\hat{e}_t) = A_t(\hat{e}_t) < Z$ .

This completes the proof.  $\blacktriangleleft$

► **Lemma 16.** *For each round  $t' \neq -1$ , it can be blamed by at most two rounds in  $\mathcal{H}_1$ .*

**Proof.** Suppose that  $t'$  is blamed by  $t \in \mathcal{H}_1$  such that  $t' = R_t(e_t)$ . Then for any round  $t'' \in \mathcal{H}_1$  with  $t' < t'' < t$ , it cannot blame  $t'$  by taking  $t' = R_{t''}(e_{t''})$ . This is because if there exists such a round  $t''$ , then by definition we have  $e_t = e_{t''}$ . In such a case, there must exist a round  $\tilde{t} \in (t'', t)$  with  $\sigma_{\tilde{t}} = e_t$ , otherwise  $e_t \notin C_t$ . This conflicts with the definition that  $R_t(e_t)$  is the last round before  $t$  when  $e_t$  is requested. For any  $t'' \in \mathcal{H}_1$  with  $t'' > t$ , it cannot blame  $t'$  by taking  $t' = R_{t''}(e_{t''})$ , either. Still, if  $e_t = e_{t''}$ , there must exist a round  $\tilde{t} \in (t, t'')$  with  $\sigma_{\tilde{t}} = e_t$ . In such a case,  $R_{t''}(e_{t''}) \geq \tilde{t} > t > t'$ . The case  $t' = R_t(\hat{e}_t)$  is symmetric with the case above.  $\blacktriangleleft$

► **Lemma 17.** *It holds that  $|\mathcal{H}_1| \leq 2 \cdot \eta + k$  and  $|\mathcal{H}_{-1}^1| \leq 2 \cdot \eta + 2k$ .*

**Proof.** The statement  $|\mathcal{H}_1| \leq 2 \cdot \eta + k$  follows from Lemma 8, Lemma 15 and Lemma 16. The statement  $|\mathcal{H}_{-1}^1| \leq 2 \cdot \eta + 2k$  then follows from Lemma 13.  $\blacktriangleleft$

Next, we analyze  $|\mathcal{H}_0^1|$  with the notion of troublemakers defined in Section 3.1. In particular, for two rounds  $t, t'$  with  $t' < t$ , we say  $t'$  is the *parent* of  $t$  and  $t$  is the *child* of  $t'$  if  $t \in \mathcal{H}_0^1$  and  $t' = \max\{t'' < t \mid \sigma_t \in \hat{C}_{t''}\}$ .

► **Lemma 18.** *Every round  $t \in \mathcal{H}_0^1 \setminus \{\tilde{t} \mid R_{\tilde{t}}(\sigma_{\tilde{t}}) = -1\}$  has one parent  $t' \in \Gamma \cup \mathcal{H}_1$ , and any round  $t'$  has at most one child.*

**Proof.** Since  $t \notin \{\tilde{t} \mid R_{\tilde{t}}(\sigma_{\tilde{t}}) = -1\}$ , the page  $\sigma_t$  is requested at round  $r = R_t(i) \in [1, t)$ , which gives that  $\sigma_t \in \hat{C}_{r+1}$ . As  $t \in \mathcal{H}_0^1$ , we know that  $\sigma_t \notin \hat{C}_t$ . Therefore, there must exist a round  $t'' \in [r+1, t)$  with  $\sigma_t = \hat{e}_{t''} \in \hat{C}_{t''}$ . Since  $\{t'' \mid t'' < t \wedge \sigma_t \in \hat{C}_{t''}\} \neq \emptyset$ , the existence of the parent round of  $t$  is ensured.

For the parent  $t'$  of round  $t$ , we know that  $\hat{e}_{t'} = \sigma_t$ , because  $\sigma_t \in \hat{C}_{t'} \setminus \hat{C}_{t'+1}$ . Then we have  $\hat{e}_{t'} \neq \perp$  and  $\hat{e}_{t'} \in I_{t'}$ , where the second equality holds because  $\sigma_t \in C_t$  and  $\sigma_{t''} \neq \sigma_t$  for every  $t'' \in [t', t-1]$ . Then by the definitions of the parent round and  $\mathcal{H}_0^1$ , we have  $A_{t'}(\hat{e}_{t'}) = t \in [T]$  and  $\hat{e}_{t'} \in C_t$ , which means that  $\hat{e}_{t'} \in C_{A_{t'}(\hat{e}_{t'})}$ . Therefore,  $t' \in \Gamma$  if  $e_{t'} = \perp$  or  $e_{t'} \notin I_{t'}$ . If  $e_{t'} \neq \perp$  and  $e_{t'} \in I_{t'}$ , then we have  $e_{t'} \neq \hat{e}_{t'}$ , because otherwise  $\hat{e}_{t'} \notin C_t$ . By Lemma 12, in such a case we have  $t' \in \mathcal{H}_1$ .

It remains to prove that any round  $t'$  has at most one child. Suppose that  $t'$  has two children  $t_1, t_2$  with  $t_1 < t_2$ . In such a case,  $\sigma_{t_2} = \hat{e}_{t'} = \sigma_{t_1} \in \hat{C}_{t_1+1}$ , which conflicts with the definition of the parent round.  $\blacktriangleleft$

Putting Lemma 9, Lemma 17, and Lemma 18 together gives the following result.

► **Theorem 19.**  $\text{cost}(\text{Sim}) - \text{OPT} \leq 4\eta + 4k + |\Gamma| - |\mathcal{H}^{-1}|$ .

We defer the proof of Theorem 19 to the full version [11]. The upper bound on  $|\Gamma| - |\mathcal{H}^{-1}|$  is studied in the next subsection.

### 3.3 Labeling for Troublemakers

From the high level, the analysis in this part on  $|\Gamma| - |\mathcal{H}^{-1}|$  is done by showing that each troublemaker  $\gamma$  either can be mapped a distinct round in  $\mathcal{H}^{-1}$ , or can be mapped to a round  $t < \gamma$  that has a prediction error. We specify the mappings with a procedure called **Labeling**, which is designed to avoid mapping too many troublemakers to a single prediction error. Notice that **Labeling** is only used in the analysis, while the paging algorithm is unaware of the output generated by **Labeling**.

Procedure **Labeling** takes  $\langle \{A_t(i)\}_{t \in [T], i \in [n]}, \{a_t\}_{t \in [T]} \rangle$  as the input, which implicitly encodes the operations of **FitF** and **Sim**, and for each troublemaker  $\gamma \in \Gamma$ , **Labeling** outputs a labeling function  $\lambda_\gamma : \theta_\gamma \mapsto ([n] \cup \perp)$ , which maps each round in the active period  $\theta_\gamma$  of  $\gamma$  to either a page  $i$  or an empty value. For each  $\gamma \in \Gamma$  and each round  $t$  in the active period  $\theta_\gamma$  with  $\lambda_\gamma(t) \neq \perp$ , we say that page  $i = \lambda_\gamma(t)$  is labelled by  $\gamma$ . Procedure **Labeling** is presented in Algorithm 1 with notions defined as follows.

$$\forall t \in [T] : \quad \mathcal{L}_t \doteq \bigcup_{\gamma \in \Gamma_t} \lambda_\gamma(t), \quad \text{and} \quad \Phi_t \doteq \hat{C}_t \setminus (C_t \cup \mathcal{L}_t),$$

$$\forall t \in [2, T] : \quad \Psi_t \doteq \hat{C}_t \setminus (C_t \cup \mathcal{L}_{t-1}).$$

Briefly speaking, for every  $\gamma \in \Gamma$ , **Labeling** picks an arbitrary page  $i = \hat{\delta}_\gamma$  from  $\Phi_\gamma$  and labels  $i$  with  $\gamma$  for the first round in the active period of  $\gamma$ , which means setting  $\lambda_\gamma(\gamma+1) = i$ . For convenience, the NAT of  $i$  after  $\gamma$  is denoted by  $\tau_\gamma$ . Then we consider the following cases.

- $\tau_\gamma > A_\gamma(\hat{e}_\gamma)$ : Then the label on  $\hat{\delta}_\gamma$  is kept throughout the active period  $\theta_\gamma$  of  $\gamma$ .
- $\tau_\gamma < A_\gamma(\hat{e}_\gamma)$  and  $\hat{\delta}_\gamma \in \hat{C}_{\tau_\gamma}$ : This means that  $\hat{\delta}_\gamma$  is not evicted by **Sim** before its NAT after  $\gamma$ . In such a case, the label on  $\hat{\delta}_\gamma$  is kept until the last round before its NAT.
- $\tau_\gamma < A_\gamma(\hat{e}_\gamma)$  and  $\hat{\delta}_\gamma \notin \hat{C}_{\tau_\gamma}$ : In such a case, a labelled page is evicted by **Sim** before its NAT after  $\gamma$ . For each round  $t$  with such an eviction, we label a new page at round  $t+1$  in  $\Psi_{t+1}$  with  $\gamma$ . We stop labelling new pages either when the labelled page is requested, or the NAT of the previous labelled page after the previous round is less than the NAT of the current labelled page.

---

**Algorithm 1** Procedure Labeling.
 

---

**Input:**  $\{A_t(i)\}_{t \in [T], i \in [n]}, \{a_t\}_{t \in [T]}$   
**Output:**  $\{\lambda_\gamma\}_{\gamma \in \Gamma}$

```

1 for each  $\gamma \in \Gamma$  do
2   Pick an arbitrary element  $i \in \Phi_\gamma$  and set  $\hat{\delta}_\gamma = i$ ;
3   Set  $\lambda_\gamma(\gamma + 1) = \hat{\delta}_\gamma$  and  $\tau_\gamma = A_\gamma(\hat{\delta}_\gamma)$ ;
4   if  $\tau_\gamma > A_\gamma(\hat{e}_\gamma)$  then
5     Set  $\lambda_\gamma(t) = \hat{\delta}_\gamma$  for all the remaining rounds  $t$  in  $\theta_\gamma$ ;
6   else
7     Set  $t = \gamma + 2$ ;
8     while  $t < A_\gamma(\hat{e}_\gamma)$  do
9       if  $\lambda_\gamma(t - 1) = \sigma_{t-1}$  then
10        break;
11       if  $\lambda_\gamma(t - 1) \neq \hat{e}_{t-1}$  then
12        Set  $\lambda_\gamma(t) = \lambda_\gamma(t - 1)$ ;
13       else
14        Pick an arbitrary element  $i$  from  $\Psi_t$  and set  $\lambda_\gamma(t) = i$ ;
15        if  $A_{t-1}(\lambda_\gamma(t)) > A_{t-1}(\lambda_\gamma(t - 1))$  then
16          Set  $\lambda_\gamma(t') = i$  for every round  $t' \in [t + 1, \min\{A_\gamma(\hat{e}_\gamma), A_t(i)\}]$ ;
17          Set  $t = \min\{A_\gamma(\hat{e}_\gamma), A_t(i)\} - 1$ ;
18          break;
19        Set  $t = t + 1$ ;
20    Set  $\lambda_\gamma(t') = \perp$  for every  $t' \in [t, A_\gamma(\hat{e}_\gamma)]$ ;
  
```

---

Before describing how Procedure **Labeling** is applied to map each troublemaker to a round with a prediction error or a round in  $\mathcal{H}^{-1}$ , we first prove that this procedure is consistent by showing that  $\Phi_t$  (resp.  $\Psi_t$ ) is not empty whenever we need to find a new page to label from  $\Phi_t$  (resp.  $\Psi_t$ ). For every troublemaker round  $t \in \Gamma$ , define

$$\zeta_t = \begin{cases} \sigma_t & \text{if } e_t = \perp \\ e_t & \text{otherwise} \end{cases}.$$

Then we have the following results.

► **Lemma 20.** *For each troublemaker round  $t \in \Gamma$ , we have (1)  $\zeta_t \neq \perp$ , (2)  $\zeta_t \in C_t \setminus \hat{C}_t$ , and (3) for any  $\gamma \in \Gamma_t$ , we have  $\zeta_t \neq \hat{e}_\gamma$ .*

**Proof.** Claim (1) and (2) are obvious. Now consider claim (3). Since  $\gamma < t < A_\gamma(\hat{e}_\gamma)$ ,  $\sigma_t \neq \hat{e}_\gamma$ , because otherwise  $t = A_\gamma(\hat{e}_\gamma)$ . By the definition of troublemakers,  $\hat{e}_\gamma \in C_{A_\gamma(\hat{e}_\gamma)}$ , so for any  $t \in [\gamma + 1, A_\gamma(\hat{e}_\gamma) - 1]$ , it holds that  $e_t \neq \hat{e}_\gamma$ . ◀

► **Lemma 21.** *For each troublemaker round  $t \in \Gamma$ , it holds that  $|\Phi_t| \geq 1$ .*

**Proof.** By Lemma 10 and Lemma 20, we have  $C_t \setminus \hat{C}_t \supseteq \{\hat{e}_\gamma\}_{\gamma \in \Gamma_t} \cup \{\zeta_t\}$ . Still by Lemma 20, it follows that  $\zeta_t \neq \hat{e}_\gamma$  for every  $\gamma \in \Gamma_t$ , then  $|C_t \setminus \hat{C}_t| \geq |\{\hat{e}_\gamma\}_{\gamma \in \Gamma_t}| + 1 = |\Gamma_t| + 1$ . Because  $|C_t| = |\hat{C}_t|$ , we have  $|\hat{C}_t \setminus C_t| \geq |\Gamma_t| + 1$ . Since for every  $\gamma$  with  $t \in \theta_\gamma$ , we have  $\gamma \in \Gamma_t$ , then it always holds that  $|\mathcal{L}_t| \leq |\Gamma_t|$ . This finishes the proof. ◀

► **Lemma 22.** *For each round  $t \in [T]$ , we have  $C_t \cap \mathcal{L}_t = \emptyset$ .*

**Proof.** This proposition is true because for any round  $t$  when we find a new page  $i$  to label,  $i \notin C_t$ , and the label on any page  $i$  is cancelled before  $i$  is requested.  $\blacktriangleleft$

► **Lemma 23.** *For every  $\gamma \in \Gamma$  and every  $t \in [\gamma + 2, A_\gamma(\hat{e}_\gamma) - 1]$ , if  $\hat{e}_{t-1} = \lambda_\gamma(t - 1)$ , then  $\Psi_t \neq \emptyset$ .*

**Proof.** First, consider the case where  $\Phi_{t-1} \neq \emptyset$ . For each page  $i \in \Phi_{t-1}$ , we know  $i \neq \hat{e}_{t-1}$  because  $i \notin \mathcal{L}_{t-1}$  while  $\hat{e}_{t-1} = \lambda_\gamma(t - 1) \in \mathcal{L}_{t-1}$ . This gives  $i \in \hat{C}_t$ . Moreover, we have  $i \neq \sigma_{t-1}$  because  $\hat{e}_{t-1} \neq \perp$ . This gives  $i \notin C_t$ . Therefore,  $i \in \hat{C}_t \setminus (C_t \cup \mathcal{L}_{t-1}) = \Psi_t$ .

Now consider  $\Phi_{t-1}$  is empty. In such a case,  $|\hat{C}_{t-1} \setminus C_{t-1}| = |\mathcal{L}_{t-1}|$ . Lemma 10 indicates that for every  $\gamma' \in \Gamma_{t'}$  with  $t' \in \theta_{\gamma'}$ , we have  $\hat{e}_{\gamma'} \in C_{t'} - \hat{C}_{t'}$ . Then  $|\hat{C}_{t-1} \setminus C_{t-1}| = |\mathcal{L}_{t-1}|$  implies that  $C_{t-1} \setminus \hat{C}_{t-1} = \{\hat{e}_{\gamma'}\}_{\gamma' \in \Gamma_{t-1}}$ . By the definition of active troublemakers,  $\sigma_{t-1} \notin C_{t-1} - \hat{C}_{t-1}$ . Also, we have  $\sigma_{t-1} \notin I_{t-1} = C_{t-1} \cap \hat{C}_{t-1}$ , because  $\hat{e}_{t-1} \neq \perp$ . Therefore,  $\sigma_{t-1} \notin C_{t-1}$ , which means that  $e_{t-1} \neq \perp$ . Still by the definition of the troublemakers, we have  $e_{t-1} \notin \{\hat{e}_{\gamma'}\}_{\gamma' \in \Gamma_{t-1}} = C_{t-1} \setminus \hat{C}_{t-1}$ . Thus,  $e_{t-1} \in I_{t-1} \subseteq \hat{C}_{t-1}$ . By Lemma 22, we have  $e_{t-1} \notin \mathcal{L}_{t-1}$  and  $e_{t-1} \neq \hat{e}_{t-1}$ . Putting  $e_{t-1} \neq \hat{e}_{t-1}$  and  $e_{t-1} \in \hat{C}_{t-1}$  together, we get  $e_{t-1} \in \hat{C}_t - C_t$ . Therefore,  $e_{t-1} \in \Psi_t$ .  $\blacktriangleleft$

Lemma 21 and Lemma 23 ensure the consistency of Procedure **Labeling**.

► **Lemma 24.** *For every round  $t$  and any page  $i \in [n]$ , there exists at most one troublemaker  $\gamma \in \Gamma_t$  so that  $\lambda_\gamma = i$ .*

The proof of Lemma 24 is deferred to the full version [11]. It also gives the following byproduct.

► **Lemma 25.** *For each round  $t \in [2, T]$ , we have  $|\mathcal{L}_t \setminus \mathcal{L}_{t-1}| \leq 1$ .*

Let  $t$  be an arbitrary round with  $\hat{e}_t \neq \perp$ . Suppose that there exists a page  $i \in \hat{C}_t$  satisfying  $A_t(i) > A_t(\hat{e}_t)$ ,  $i \notin \mathcal{L}_t$ , and  $i \in \mathcal{L}_{t'}$  for every  $t' \in [t + 1, \min\{A_t(\hat{e}_t), t^\circ\}]$ , where

$$t^\circ = \begin{cases} \min\{t'' \mid t'' > t \wedge \hat{e}_{t''} = i\} & \text{if } \exists t'' \in (t + 1, T] \text{ s.t. } \hat{e}_{t''} = i \\ \infty & \text{otherwise} \end{cases}. \quad (6)$$

Lemma 25 implies that such a page  $i$  is unique if it exists. In such a case, we say that the page  $i$  is the *competitor* of  $\hat{e}_t$ , and the round  $t$  has an *abettor* round  $t^*$  specified as follows. Let  $r = R_t(\hat{e}_t)$  and  $r' = R_t(i)$ , then the abettor of  $t$  is

$$t^* = \begin{cases} r & \text{if } r \neq -1 \wedge A_r(\sigma_r) \neq a_r \\ r' & \text{if } (r = -1 \vee A_r(\sigma_r) = a_r) \wedge (r' \neq -1 \wedge A_{r'}(\sigma_{r'}) \neq a_{r'}) \\ -1 & \text{otherwise} \end{cases}. \quad (7)$$

► **Lemma 26.** *For any round  $t^* \in [T]$ , the number of rounds in  $\{t \mid \hat{e}_t \neq \perp \wedge R_t(\hat{e}_t) \neq -1 \wedge t^* \text{ is the abettor of } t\}$  is at most two.*

**Proof.** It can be proved in a similar way with Lemma 16 that  $\{t \mid \hat{e}_t \neq \perp \wedge R_t(\hat{e}_t) \neq -1 \wedge t^* \text{ is the abettor of } t \wedge t^* = R_t(\hat{e}_t)\}$  contains at most one round. It remains to prove that  $\{t \mid \hat{e}_t \neq \perp \wedge R_t(\hat{e}_t) \neq -1 \wedge t^* \text{ is the abettor of } t \wedge t^* = R_t(i)\}$  contains at most a single round, where  $i$  is the competitor of  $\hat{e}_t$  as defined in Eq. (6). Notice that different from the case considered in the proof of Lemma 16, the page  $i$  may not be evicted by **FitF**. Therefore, we need to utilize the properties of procedure **Labeling** to prove the uniqueness of the round  $t$  which satisfies  $t^* = R_t(i)$ .

▷ **Claim 27.** If a round  $t$  has an abettor  $t^* = R_t(i)$  with  $i$  being the competitor of  $\hat{e}_t$  and  $r = R_t(\hat{e}_t) \neq -1$ , then it holds that  $\hat{a}_t(i) < Z$  and  $\hat{a}_{t'}(i) = Z$  for any round  $t' \in [A_t(\hat{e}_t), A_t(i))$ .

*Proof.* Since  $t^* = R_t(i)$  and  $r \neq -1$ , we have  $A_r(\sigma_r) = a_r$ , which by Lemma 7 gives  $A_t(\hat{e}_t) = \hat{a}_t(\hat{e}_t) < Z$ . Following Lemma 14, we have  $\hat{a}_t(i) \leq A_t(\hat{e}_t)$  and  $\hat{a}_t(i) < Z$ . If there exists a round  $t'' \in (t, A_t(\hat{e}_t))$  so that  $\hat{a}_{t''}(i) = Z$ , then it follows from Eq. (3) that for any round  $t' \in [A_t(\hat{e}_t), A_t(i))$ , it holds that  $\hat{a}_{t'}(i) = Z$ , which means that this proposition holds. We proceed to prove that  $\hat{a}_{A_t(\hat{e}_t)}(i) = Z$  if  $\hat{a}_{t''}(i) \neq Z$  holds for every round  $t'' \in (t, A_t(\hat{e}_t))$ . In such a case, it can be inferred from Eq. (3) that  $\hat{a}_{t''}(i) = \hat{a}_t(i)$ . Since  $A_r(\sigma_r) = a_r$ , Lemma 7 indicates that  $\hat{a}_{t''}(\hat{e}_t) = A_{t''}(\hat{e}_t) = A_t(\hat{e}_t) = \hat{a}_t(\hat{e}_t)$  and  $\hat{a}_{t''}(\hat{e}_t) < Z$  hold for any round  $t'' \in (t, A_t(\hat{e}_t))$ . Combining  $\hat{a}_{t''}(\hat{e}_t) = \hat{a}_t(\hat{e}_t)$  with  $\hat{a}_{t''}(i) = \hat{a}_t(i)$  gives  $\hat{a}_{t''}(\hat{e}_t) \geq \hat{a}_{t''}(i)$ . Therefore,  $\hat{a}_{A_t(\hat{e}_t)-1}(i) \leq \hat{a}_{A_t(\hat{e}_t)-1}(\hat{e}_t) < Z$ . Moreover, we have  $\hat{a}_{A_t(\hat{e}_t)-1}(i) < A_t(\hat{e}_t)$  because  $A_t(\hat{e}_t) \geq \hat{a}_t(i) = \hat{a}_{t''}(i)$  holds for every  $t'' \in (t, A_t(\hat{e}_t))$ . By Eq. (3), the conditions for  $\hat{a}_{A_t(\hat{e}_t)}(i) = Z$  are all satisfied. Thus, the equality  $\hat{a}_{t'}(i) = Z$  holds for any round  $t' \in [A_t(\hat{e}_t), A_t(i))$ . ◀

For any round  $t' \in (t^*, t)$ , the round  $t^*$  cannot be the abettor of  $t'$  with taking  $t^* = R_{t'}(i)$ , because otherwise,

- if  $A_{t'}(\hat{e}_{t'}) \geq t$ , then by the definition of abettors, we have  $i \in \mathcal{L}_t$ , which conflicts with the requirement in the definition of abettors; else
- if  $A_{t'}(\hat{e}_{t'}) < t$ , then we get  $\hat{a}_t(i) = Z$  with using the second statement in Claim 27, which conflicts with the first statement in Claim 27.

Therefore, this proposition holds. ◀

The following result can be proved by following the same line of arguments with the proof of Lemma 15.

▶ **Lemma 28.** Let  $t$  be an arbitrary round that has an abettor  $t^*$ . If  $t^* = -1$ , then  $R_t(\hat{e}_t) = -1$ . If  $R_t(\hat{e}_t) \neq -1$ , then there exists a round  $t'$  such that  $\{t^*, t'\} \in \text{INV}$ .

▶ **Remark 29.** Notice that the statement of Lemma 28 is consistent because for any round  $t$  having an abettor, by definition we have  $\hat{e}_t \neq \perp$ .

For an arbitrary round  $t$ , if there exists a page  $i$  in  $\hat{C}_t$  satisfies (1)  $A_t(i) \leq T$ , (2)  $i \notin \mathcal{L}_t$  and (3)  $i \in \mathcal{L}_{t'}$  for every  $t' \in [t+1, A_t(i)]$ , we say that  $t^\Delta = A_t(i)$  is the *savior* of  $t$ .

▶ **Lemma 30.** If a round  $t$  has a savior  $t^\Delta$ , then (1)  $t^\Delta \in \mathcal{H}^{-1}$ , and (2) for any  $t^\Delta \in \mathcal{H}^{-1}$ , it is the savior of at most one step  $t$ .

**Proof.** The first claim follows from the definition of  $\mathcal{H}^{-1}$ . For any round  $t' \in [t+1, t^\Delta]$ ,  $t^\Delta$  is not the savior of  $t'$ , because  $\sigma_{t^\Delta} \in \mathcal{L}_{t'}$ . Therefore, the second claim holds. ◀

▶ **Theorem 31.**  $|\Gamma| - |\mathcal{H}^{-1}| \leq 2 \cdot \eta + k$ .

**Proof.** The main idea of this proof is to show that each troublemaker can be mapped to a distinct *broker* round, and each broker either has an abettor or has a savior. In particular, we classify the troublemakers  $\gamma \in \Gamma$  into the following three categories.

1.  $\{\gamma \in \Gamma \mid \tau_\gamma > A_\gamma(\hat{e}_\gamma)\}$ : Here, the troublemaker  $\gamma$  as a round has an abettor  $t^*$ , because  $\hat{\delta}_\gamma \in \mathcal{L}_t$  for every step  $t \in [\gamma+1, \min\{A_\gamma(\hat{e}_\gamma), t^\circ\}]$  where  $t^\circ$  is defined in the same way with Eq. (6). In such a case, we say  $\gamma$  is the broker of itself.
2.  $\{\gamma \in \Gamma \mid \tau_\gamma < A_\gamma(\hat{e}_\gamma) \wedge \hat{\delta}_\gamma \in \hat{C}_{\tau_\gamma}\}$ : Now the troublemaker  $\gamma$  as a round has a savior  $\tau_\gamma$ , because by the definition of the troublemaker,  $A_\gamma(\hat{e}_\gamma) \leq T$ , which gives  $\tau_\gamma \leq T$ . Moreover, it holds for every round  $t \in [\gamma+1, A_\gamma(\hat{\delta}_\gamma)]$  that  $\hat{\delta}_\gamma \in \mathcal{L}_t$ . The broker for such a troublemaker  $\gamma$  is also itself.

3.  $\{\gamma \in \Gamma \mid \tau_\gamma < A_\gamma(\hat{e}_\gamma) \wedge \hat{\delta}_\gamma \notin \hat{C}_{\tau_\gamma}\}$ : In such a case, let  $i$  be the last page labelled by  $\gamma$  and  $t$  be the first round with  $\lambda_\gamma(t) = i$ . Since  $\hat{\delta}_\gamma \notin \hat{C}_{\tau_\gamma}$ , we have  $t-1 \in \theta_\gamma$ . Let  $i' = \lambda_\gamma(t-1)$ , then we have  $i' \in \hat{C}_{t-1}$  because  $\hat{e}_{t-1} = i'$ . Also, we have  $i \in \hat{C}_{t-1}$ , because  $i$  is chosen from  $\Psi_t \subseteq \hat{C}_t \setminus C_t$  and  $i \neq \hat{e}_{t-1}$ . Now consider two subcases.
- $A_{t-1}(i') < A_{t-1}(i)$ : In such a case, the round  $t-1$  has an abettor  $t^*$ , because we have  $i \in \mathcal{L}_{t^*}$  for every  $t^* \in [t, \min\{A_{t-1}(i), \tau_\gamma, t^\circ\}]$ , which satisfies the requirement in the definition of abettors because  $\tau_\gamma > A_{t-1}(i')$ .
  - $A_{t-1}(i') > A_{t-1}(i)$ : It can be proved inductively that  $A_{t-1}(i) < \tau_\gamma$ , which implies that  $A_{t-1}(i) \leq T$ . By definition, it follows that  $t-1$  has a savior  $t^\Delta = A_{t-1}(i)$ .
- The round  $t-1$  is said to be the *broker* of the troublemaker  $\gamma$ . Lemma 24 ensures that the round  $t-1$  cannot be the broker of two different troublemakers, because  $\hat{e}_{t-1} = \lambda_\gamma(t-1)$ . Moreover, by Lemma 25, the broker  $t-1$  is not a troublemaker.

To sum up, each troublemaker  $\gamma$  can be mapped to a distinct broker  $t$ , and each broker  $t$  either has an abettor or has a savior. Then by Lemma 26, Lemma 28 and Lemma 30, this theorem holds.  $\blacktriangleleft$

The following result is obtained by combining Theorem 19 and Theorem 31.

► **Theorem 32.** *It follows that  $\text{cost}(\text{Sim}) - \text{OPT} \leq 6\eta + 5k$ .*

Because the cumulative prediction error is assumed to satisfy  $\eta \in o(T)$ , we have  $\text{cost}(\text{Sim}) - \text{OPT} \in o(T)$ . Therefore, **Sim** has the vanishing regret when there is a single predictor.

## 4 Multiple NAT Predictors

This section extends the result obtained in Section 3 to the general case where there are  $M > 1$  predictors making NAT predictions under the bandit access model. Our results on the full information access model are deferred to the full version [11].

For the bandit access model, in this part, we design an algorithm called *Sightless Chasing and Switching* (**S-C&S**) and prove that it has the vanishing regret.

The procedure of **S-C&S** is described in Algorithm 2. It is assumed that **S-C&S** is provided with blackbox accesses to the online algorithm *Implicitly Normalized Forecaster* (**INF**) [2] for the *Multiarmed Bandit Problem* (**MBP**) [3]. The MBP problem is an online problem defined over  $\Upsilon \in \mathbb{Z}_{>0}$  rounds and a set  $X$  of arms. An oblivious adversary specifies a cost function  $F_v : X \mapsto [0, 1]$  for each round  $v \in [\Upsilon]$  that maps each arm  $x \in X$  to a cost in  $[0, 1]$ . An algorithm for MBP needs to choose an arm  $x_v$  at the beginning of each round  $v \in [\Upsilon]$ , and then the cost  $F_v(x_v)$  incurred by the chosen arm  $x_v$  is revealed to the algorithm. The objective of MBP is to minimize the cumulative cost incurred by the chosen arms  $\{x_v\}_{v \in [\Upsilon]}$ .

► **Theorem 33** ([2]). *The algorithm **INF** ensures that the chosen arms  $\{x_v\}_{v \in [\Upsilon]}$  satisfy*

$$\sum_{v \in [\Upsilon]} F_v(x_v) - \min_{x^* \in X} \sum_{v \in [\Upsilon]} F_v(x^*) \in O(\sqrt{|X| \cdot \Upsilon}).$$

Our algorithm **S-C&S** partitions the rounds into consecutive epochs of length  $\tau \in \mathbb{Z}_{>0}$  and initializes **INF** by setting  $\Upsilon = \lceil \frac{T}{\tau} \rceil$  and  $X = [M]$ , which means that each epoch in the online paging problem is mapped to a round in MBP, and each predictor is taken as an arm. The choice of the value for  $\tau$  is discussed later. At the beginning of the first round  $t_1^v = (v-1)\tau + 1$  in each epoch  $v \in [\Upsilon]$ , **S-C&S** accesses **INF** to pick one predictor  $j_{t_1^v}$ . Then,

---

**Algorithm 2** Algorithm S-C&S.

---

**Input:**  $\{\sigma_t\}_{t \in [T]}$ , MBP algorithm INF, initial cache profile  $\hat{C}_1$   
**Output:**  $\{\hat{e}_t\}_{t \in [T]}$

- 1 Initialize the MBP algorithm INF with the number of rounds  $\Upsilon = \lceil T/\tau \rceil$  and the set of arms  $X = [M]$ ;
- 2 **for** each round  $t \in [T]$  **do**
- 3   **if**  $t \bmod \tau = 1$  **then**
- 4     Invoke INF to choose a predictor  $j_t \in [M]$ ;
- 5     Set  $j = j_t$ ;
- 6   **else**
- 7     Set  $j = j_{t'}$  with  $t' = \lfloor t/\tau \rfloor \cdot \tau + 1$ ;
- 8   Query the predictor  $j$  to obtain the prediction  $a_t^j$ ;
- 9   **for** each page  $i \in [n]$  **do**
- 10     **if**  $i = \sigma_t$  **then**
- 11       Set  $\hat{a}_t(i) = a_t^j$ ;
- 12     **else if**  $t \bmod \tau = 1$  **then**
- 13       Set  $\hat{a}_t(i) = Z + 1$ ;
- 14     **else if**  $\hat{a}_{t-1}(i) = t \wedge i \neq \sigma_t \wedge \hat{a}_{t-1}(i) \leq \hat{a}_{t-1}(\sigma_t) < Z$  **then**
- 15       Set  $\hat{a}_t(i) = Z$ ;
- 16     **else**
- 17       Set  $\hat{a}_t(i) = \hat{a}_{t-1}(i)$ ;
- 18   **if**  $\sigma_t \notin \hat{C}_t$  **then**
- 19     Set  $\hat{e}_t$  be the page  $i \in C_t$  that maximizes  $\hat{a}_t(i)$  with breaking ties arbitrarily;
- 20     Update  $\hat{C}_{t+1} = (\hat{C}_t \setminus \{\hat{e}_t\}) \cup \{\sigma_t\}$ ;
- 21   **else**
- 22     Set  $\hat{e}_t = \perp$ , and set  $\hat{C}_{t+1} = \hat{C}_t$ ;
- 23   **if**  $t \bmod \tau = 0$  **then**
- 24     Set  $f = 0$ ;
- 25     **for** each round  $t' \in [t - \tau + 1, t]$  **do**
- 26       **if**  $(t' = t - \tau + 1) \vee (\hat{e}_{t'} \neq \perp) \vee ((\hat{e}_{t'} = \perp) \wedge (t' > t - \tau + 1) \wedge (\hat{a}_{t'-1}(\sigma_{t'}) = Z + 1))$  **then**
- 27         Set  $f = f + 1$ ;
- 28     Send  $\frac{f}{\tau}$  to INF as the cost incurred by  $j_{t-\tau+1}$  in the epoch  $\frac{t}{\tau}$ ;

---

S-C&S simulates the algorithm **Sim**, which is proposed in Section 3, throughout the epoch  $v$  with taking  $t_1^v$  as its initial round,  $\hat{C}_{t_1^v}$  as its initial cache profile, and  $j_{t_1^v}$  as the single predictor. At the end of the last round  $t_\tau^v = v \cdot \tau$  in epoch  $v$ , S-C&S sends

$$F_v(j_{t_1^v}) = \frac{1}{n} \left| \left\{ t' \in [t_1^v, t_\tau^v] \mid (t' = t_1^v) \vee (\hat{e}_{t'} \neq \perp) \vee ((\hat{e}_{t'} = \perp) \wedge (t' > t_1^v) \wedge (\hat{a}_{t'-1}(\sigma_{t'}) = Z + 1)) \right\} \right| \quad (8)$$

to INF as the cost  $F_v(j_{t_1^v})$  of choosing  $j_{t_1^v}$  for  $v$ .

Notice that in MBP, the cost functions are generated by an oblivious adversary. We take this setting as a requirement that the cost function  $F_v$  for each round  $v$  in MBP should not depend on the arms chosen in the previous rounds  $x_1, x_2, \dots, x_{v-1}$ . The following result shows that by feeding INF a cost that can be larger than the normalized cost that is actually incurred by S-C&S in the epoch, this requirement is satisfied.

► **Lemma 34.** Let  $F_v(j_{t_1^v} | j_{t_1^1}, \dots, j_{t_1^{v-1}})$  be the cost sent by  $\mathcal{S}\text{-}\mathcal{C}\&\mathcal{S}$  to  $\text{INF}$  at the end of an arbitrary epoch  $v$  conditioned on the predictors chosen for the previous epochs  $j_{t_1^1}, \dots, j_{t_1^{v-1}}$ . Then for any different sequence of predictors  $\tilde{j}_{t_1^1}, \dots, \tilde{j}_{t_1^{v-1}}$ , we have  $F_v(j_{t_1^v} | j_{t_1^1}, \dots, j_{t_1^{v-1}}) = F_v(j_{t_1^v} | \tilde{j}_{t_1^1}, \dots, \tilde{j}_{t_1^{v-1}})$ .

**Proof.** For the epoch  $v$ , a round  $t$  is said to be *fresh* if for any earlier round  $t' < t$  in  $v$ , it holds that  $\sigma_t \neq \sigma_{t'}$ . We first consider the case where there are at least  $k$  fresh rounds in the epoch, which means that at least  $k$  different pages are requested. Let  $t$  be the first round after the first  $k$  fresh rounds. We first consider the interval  $[t_1^v, t - 1]$ . For each page  $i \in [n]$  and each round  $t' \in [t_1^v, t - 1]$ , we say  $i$  is *marked* at  $t'$  if there exists a round  $t'' \in [t_1^v, t']$  with  $\sigma_{t''} = i$ , otherwise  $i$  is said to be *unmarked* at  $t'$ . Then it can be inferred from Lemma 7 that  $\hat{a}_{t'}(i) = Z + 1$  if  $i$  is unmarked at  $t'$ , and  $\hat{a}_{t'}(i) \leq Z$  if  $i$  is marked at  $t'$ . Thus, there is no marked page getting evicted before  $t$ , and any round  $t' \in [t_1^v, t - 1]$  that satisfies  $\hat{e}_{t'} \neq \perp$  must be a fresh round.

► **Claim 35.** For each round  $t' \in [t_1^v, t - 1]$ , it is counted by Eq. (8) if and only if  $t'$  is fresh.

**Proof.** By definition, the round  $t_1^v$  is a fresh round. Now consider a round  $t' \in [t_1^v + 1, t - 1]$ . As mentioned above, if  $\hat{e}_{t'} \neq \perp$ , then  $t'$  is fresh. Also, if  $t'$  is fresh, then it can be inferred from Lemma 7 that  $\hat{a}_{t'-1}(\sigma_{t'}) = Z + 1$ . If  $t'$  is not fresh, which means that  $\sigma_{t'}$  is marked, then it holds that  $\hat{e}_{t'} = \perp$  and  $\hat{a}_{t'-1}(\sigma_{t'}) \leq Z$ . Therefore, this claim holds. ◀

Therefore, the contribution of the rounds in  $[t_1^v, t - 1]$  to  $F_v(j_{t_1^v})$  is always  $\frac{k}{n}$ , which is independent of  $j_{t_1^1}, \dots, j_{t_1^{v-1}}$ . A similar result can also be obtained when there are less than  $k$  fresh rounds in the epoch  $v$ .

At the beginning of round  $t$ ,  $\hat{C}_t$  contains exactly the first  $k$  different pages required in the epoch  $v$ , and for each page  $i \in \hat{C}_t$ , the remedy prediction  $\hat{a}_t(i)$  is computed only based on  $\{a_{t'}^{j_{t_1^v}}\}_{t' \in [t_1^v, t]}$  and  $\{\sigma_{t'}\}_{t' \in [t_1^v, t]}$ . Therefore, for any  $t' \geq t$ , the decision on  $\hat{e}_{t'}$  is independent of the choices over  $j_{t_1^1}, \dots, j_{t_1^{v-1}}$ .

Furthermore, since at round  $t - 1$ , every page  $i \in \hat{C}_{t-1}$  is marked, then for any round  $t' \geq t$  with  $\hat{e}_t = \perp$ , the page  $\sigma_{t'}$  has been requested at least once in the interval  $[t_1^v, t' - 1]$ , which means that  $\hat{a}_{t'-1}(\sigma_{t'}) \leq Z$ . This observation is formally stated in the following claim.

► **Claim 36.** For any round  $t' \geq t$ , it is counted by Eq. (8) if and only if  $\hat{e}_{t'} \neq \perp$ .

Thus, the contribution of the rounds in  $[t, v \cdot \tau]$  to  $F_v(j_{t_1^v})$  does not depend on the previous epochs  $\{j_{t_1^1}, \dots, j_{t_1^{v-1}}\}$ , either. ◀

For an epoch  $v \in \Upsilon$  and a predictor  $j \in [M]$  chosen for  $v$ , let  $\sharp\text{Evictions}_v(j) = |\{t \in [t_1^v, t_\tau^v] \mid \hat{e}_t \neq \perp\}|$ . The following result is also obtained by combining Claim 35 with Claim 36.

► **Lemma 37.** For each epoch  $v$ ,  $\sharp\text{Evictions}_v(j) \leq \tau \cdot F_v(j) \leq \sharp\text{Evictions}_v(j) + k$ .

The following result is obtained by putting Theorem 32, Theorem 33, Lemma 34, and Lemma 37 together.

► **Theorem 38.** By taking  $\tau = \lfloor T^{\frac{1}{3}} \rfloor$ , the regret of  $\mathcal{S}\text{-}\mathcal{C}\&\mathcal{S}$  is bounded by  $O(kT^{\frac{2}{3}}\sqrt{M} + \eta^{\min})$ .

The proof of this theorem is deferred to the full version [11]. By assumption, we have  $\eta^{\min} \in o(T)$ . Therefore, Theorem 38 implies that  $\mathcal{S}\text{-}\mathcal{C}\&\mathcal{S}$  has a vanishing regret.

Note that the result in this section cannot be obtained by using the results in [12] directly, because the algorithms proposed in [12] requires to know the cache profile of the algorithm  $\text{Sim}$  that follows each predictor, which is unavailable under the bandit access model.

## Abstract

Oblivious RAM (ORAM) is a machinery that protects any RAM from leaking information about its secret input by observing only the access pattern. It is known that every ORAM must incur a logarithmic overhead compared to the non-oblivious RAM. In fact, even the seemingly weaker notion of differential obliviousness, which intuitively “protects” a single access by guaranteeing that the observed access pattern for every two “neighboring” logical access sequences satisfy  $(\epsilon, \delta)$ -differential privacy, is subject to a logarithmic lower bound.

In this work, we show that any *Turing machine* computation can be generically compiled into a differentially oblivious one with only *doubly* logarithmic overhead. More precisely, given a Turing machine that makes  $N$  transitions, the compiled Turing machine makes  $O(N \cdot \log \log N)$  transitions in total and the physical head movements sequence satisfies  $(\epsilon, \delta)$ -differential privacy (for a constant  $\epsilon$  and a negligible  $\delta$ ). We additionally show that  $\Omega(\log \log N)$  overhead is necessary in a natural range of parameters (and in the balls and bins model).

As a corollary, we show that there exist natural data structures such as stack and queues (supporting online operations) on  $N$  elements for which there is a differentially oblivious implementation on a Turing machine incurring amortized  $O(\log \log N)$  overhead per operation, while it is known that any oblivious implementation must consume  $\Omega(\log N)$  operations unconditionally even on a RAM. Therefore, we obtain the first *unconditional* separation between obliviousness and differential obliviousness in the most natural setting of parameters where  $\epsilon$  is a constant and  $\delta$  is negligible. Before this work, such a separation was only known in the balls and bins model. Note that the lower bound applies in the RAM model while our upper bound is in the Turing machine model, making our separation stronger.

**2012 ACM Subject Classification** Theory of computation  $\rightarrow$  Turing machines

**Keywords and phrases** Differential privacy, Turing machines, obliviousness

## 1 Introduction

An oblivious RAM (ORAM), introduced in the seminal work of Goldreich and Ostrovsky [17, 30, 18], is a tool for “encrypting” the access pattern of any RAM so that it looks “unrelated” to the underlying data. It is known that any ORAM scheme must incur at least  $\Omega(\log N)$  overhead, where  $N$  is the size of the memory. This was first shown by Goldreich and Ostrovsky [18] in the balls and bins model<sup>2</sup> and assuming that no cryptographic assumptions are used. More recently, Larsen and Nielsen [25] proved the same lower bound without the two aforementioned restrictions but requiring the ORAM to support operations arriving in an online manner. In fact, a follow-up work by Jacob et al. [23] showed that  $\Omega(\log N)$  overhead is necessary even for obliviously implementing very specific data structures (as defined in [43]) such as stacks, queues, and more.

Apparently, logarithmic overhead is necessary even for implementing a RAM with a (seemingly) much weaker security guarantee than full obliviousness. Persiano and Yeo [34] considered the notion of differentially oblivious RAM,<sup>3</sup> a relaxation of ORAM that only protects individual operations by guaranteeing  $(\epsilon, \delta)$ -differential privacy for the observed access pattern of the RAM (see Section 2.3 for a formal definition).<sup>4</sup> Differential obliviousness was also studied in the context of *specific* functionalities by Chan et al. [7] and Beimel et al. [4]. It is shown that there are tasks for which obtaining differential obliviousness might be easier than full obliviousness. For instance, Chan et al. [7] show that there is a differentially oblivious algorithm for sorting  $N$  records according to a 1-bit key while maintaining the relative ordering of records with identical keys in time  $O(N \cdot \log \log N)$ ,<sup>5</sup> while [26] showed a conditional  $\Omega(N \cdot \log N)$  lower bound for full fledged obliviousness *in the balls and bins model*. This leaves the following natural question open.

*Is there an unconditional separation between obliviousness and differential obliviousness?*

Let us remark that in the above question we are interested in the most standard models and range of parameters. For RAMs, we consider the standard word-RAM where each memory word is large enough to store its own logical address, where word-level addition and Boolean operations can be done in unit cost, and where the CPU has constant number of private registers. For  $(\epsilon, \delta)$ -differential obliviousness, we want schemes that are secure for  $\epsilon$  being a fixed constant and  $\delta$  being a negligible function. For Turing machines, we allow an arbitrary number (which is fixed as part of the machine’s description) of one-dimensional bi-directional infinite work tapes, where in every step the head can moved left, right, or stay in place.

<sup>2</sup> This model assumes that each memory word is “indivisible” and restricts the ORAM to only move blocks around and not apply any non-trivial encoding of the underlying secret data; see Boyle and Naor [6].

<sup>3</sup> Persiano and Yeo [34] called this notion differentially private RAM, but we prefer to use differentially oblivious RAM to (1) relate to the notion of oblivious RAM and stress that the goal is to preserve the physical access pattern’s privacy and (2) be aligned with previous work on the topic (Chan et al. [7]).

<sup>4</sup> Usually, differential privacy concerns the observed output of some algorithm. In our context, the output of an algorithm consists of the transcript of the computation: the physical memory accesses performed during the computation.

<sup>5</sup> Maintaining the relative ordering of records is called *stability*. Without stability, sorting records according to 1-bit keys is known to be doable (deterministically and obliviously) in linear time [2, 3].

## 1.1 Our Results

We present a large class of functionalities that can be made differentially oblivious with only  $O(\log \log N)$  overhead. The class includes many natural and useful algorithms and data structures such as stacks and queues and therefore implies an *unconditional* separation between obliviousness and differential obliviousness.

► **Theorem 1** (A separation; informal). *There exists a data structure (e.g., a stack or a queue) supporting  $N$  operations for which:*

1. *Any oblivious implementation (even on a RAM) requires  $\Omega(N \cdot \log N)$  operations;*
2. *There is an  $(\epsilon, \delta)$ -differentially oblivious two-tape Turing machine (defined below) that requires*

$$O(N \cdot (\log(1/\epsilon) + \log \log N + \log \log(1/\delta)))$$

*operations.*

*In particular, letting  $\epsilon > 0$  be a constant and  $\delta = 2^{-\log^2 N}$  (which is negligible), the number of operations incurred by the differentially oblivious machine is  $O(N \cdot \log \log N)$ .*

The above theorem follows from a much more general result about differentially oblivious Turing machines. Oblivious Turing machines were first introduced in 1979 by Pippenger and Fischer [35]. In this model, “memory accesses” correspond to the head’s movements throughout the execution of the algorithm (i.e., Left, Right, or Stay). Pippenger and Fischer showed how any multi-tape Turing machine can be *obliviously* simulated by a two-tape Turing machine with a *logarithmic* slowdown in running time. More precisely, any Turing machine that makes  $N$  steps can be simulated obliviously while consuming  $O(N \cdot \log N)$  steps. The simulation is deterministic and perfectly oblivious: the same sequence of head movements is observed for any two inputs.

Adapting the notion of differential obliviousness to the Turing machine model, we show that any Turing machine that makes  $N$  steps can be simulated by a differentially oblivious machine while making only  $O(N \cdot \log \log N)$  steps. Here, neighboring sequences of head movements are ones where only one transition is different. For instance, the logical sequences of transitions {Left, Right, Left, Right} and {Left, Right, Right, Right} are neighboring.

► **Theorem 2** (A differentially oblivious Turing machine; see Theorem 11). *For any  $\epsilon, \delta > 0$ , any  $k$ -tape Turing machine that makes at most  $N$  steps can be simulated by an  $(\epsilon, \delta)$ -differentially oblivious machine with  $\max\{2, k\}$  tapes making  $O(N \cdot (\log(1/\epsilon) + \log \log N + \log \log(1/\delta)))$  steps.*

As above, letting  $\epsilon > 0$  be a constant and  $\delta = \delta(N)$  be a particular negligible function, the number of steps incurred by the differentially oblivious machine is  $O(N \cdot \log \log N)$ . We note that the constant hidden in the  $O$  notation depends only on the description size of the given Turing machine (i.e., its alphabet size, number of tapes, etc). Let us remark that the number of tapes we use is essentially optimal since even without any security requirements simulating a  $k$ -tape Turing machine for  $k \geq 3$  on a  $(k - 1)$ -tape one is not known to be possible with better than logarithmic overhead in steps (Hennie and Stearns [22]). Also, simulating a 2-tape machine on a single tape machine has *polynomial* overhead (Hartmanis and Stearns [20] for the upper bound and Hennie [21] for a lower bound).

Theorem 1 follows from Theorem 2 as follows. Consider (for instance) the stack data structure on  $N$  elements, supporting (“online”) PUSH and Pop operations. By Theorem 2 and using the fact that a stack can be implemented in linear time on a Turing machine,

there is an  $(\epsilon, \delta)$ -differentially oblivious Turing machine implementing it whose overhead is  $O(\log \log N)$  for a constant  $\epsilon$  and negligible  $\delta$ , as above. As mentioned, the logarithmic lower bound follows from Jacob et al. [23].

Lastly, we observe that a lower bound of Chan et al. [7] can be tweaked to show that our construction is essentially optimal by showing that  $\Omega(\log \log N)$  overhead is necessary for differential obliviousness in a natural range of parameters and in the balls and bins model.

► **Theorem 3** (A lower bound; see Theorem 13). *There exists an algorithmic task for which there is a Turing machine that on input of size  $N$  completes it in  $O(N)$  steps. On the other hand, for any  $0 < s \leq \sqrt{N}$ ,  $\epsilon > 0$ ,  $0 < \beta < 1$ , and  $0 \leq \delta \leq \beta \cdot (\epsilon/s) \cdot e^{-2\epsilon \cdot s}$ , any  $(\epsilon, \delta)$ -differentially oblivious implementation in the balls and bins model (even on a RAM) for this task must consume  $\Omega(N \cdot \log s)$  steps with probability  $1 - \beta$ .*

In particular, for a constant  $\epsilon > 0$  and  $s \geq \log^2 N$ , we can set  $\delta = 2^{-\Omega(\log^2 N)}$  (which is negligible) and get that  $\Omega(\log s) = \Omega(\log \log N)$  overhead is necessary. Note that if we want  $\delta = 2^{-N^{0.1}}$ , then the lower bound above says that the best we can hope for is  $\Omega(\log N)$  overhead. As mentioned, with logarithmic overhead we can actually get perfect obliviousness for any Turing machine [35].

## 1.2 Related Work

Goldreich and Ostrovsky [17, 18] showed that any RAM that uses a memory of size  $N$  and makes  $T$  accesses, can be made oblivious using only  $O(T \cdot \text{poly} \log N)$  accesses. The resulting RAM is probabilistic and obliviousness holds against polynomial-time distinguishers assuming the existence of one-way functions. The concept of oblivious RAM has inspired an immense amount of research. One line of work, focuses on applications of such compilers to cryptography and security, including applications in cloud computing, secure processor design, multi-party computation, and more (for example, [31, 38, 39, 5, 14, 36, 29, 15, 42, 16, 27, 45, 28, 44]). Another line of work, focuses on improving the overhead of the compiler [37, 24, 19, 8, 40, 41]. Only recently, a couple of works [32, 2] have resolved the problem by presenting a compiler whose overhead is  $O(\log N)$  (while still relying on one-way functions).

Patel et al. [33] considered the natural question of what kind of security can one hope for while limiting the overhead of a RAM simulation to constant. They show a construction of an  $(\epsilon, 0)$ -differentially oblivious RAM with  $O(1)$  overhead for  $\epsilon = O(\log N)$  and also assuming that the client can store  $\omega(\log N)$  records. They also proved a lower bound which quantitatively improves upon the one of [34] in the dependence on  $\epsilon$  but is qualitatively worse since it is in the balls and bins model. Throughout this work, we focus on the setting where  $\epsilon$  is a fixed constant and also that the client's storage is a constant number of blocks.

The work of Pippenger and Fischer [35] came in a long line of works trying to pin down the exact relation between various different computational models. One notable work is that of Hennie and Stearns [22] who showed that any multi-tape Turing machine can be simulated by a two-tape machine with *logarithmic* overhead. Pippenger and Fischer's result can be viewed as a similar compiler except that their resulting machine is also oblivious. Note that the result of [22] is the reason why one should not hope to improve the number of tapes in the resulting machine in Theorem 2 to two (as this task, even without privacy, is not known to be possible with less than logarithmic overhead). Simulating a 2-tape Turing machine on a single tape machine requires polynomial overhead due to Hartmanis and Stearns [20] and Hennie [21].

Some of our ideas in the differentially oblivious Turing machine construction are reminiscent of the aforementioned differentially oblivious algorithm (in the RAM model) for *stable* tight compaction due to Chan et al. [7]. Technically, their algorithm uses similar tools from the differential privacy literature (namely, differentially private prefix sums due to Chan et al. and Dwork et al. [9, 10, 12]) but the way they use it differ in nature from our approach. Partly, this is because our target machine is a Turing machine rather than a RAM, and therefore, standard building blocks such as oblivious sorting (which they use) are inapplicable. Second, even if we allow compiling a Turing machine to a differentially oblivious RAM (rather than insisting on Turing machine as the target machine), we still cannot directly use their techniques for constructing stable tight compaction because their techniques which rely on oblivious sorting are *offline* in nature; and thus not compatible with the *online* nature of our differentially oblivious simulation.

### 1.3 Technical Roadmap

In this overview we will focus on simulating a Turing machine with a single tape for  $N$  steps. There are many complications and technical difficulties that arise in the multi-tape case, but we refer to the technical sections for details.

Given a Turing machine our goal is to hide the location of the head during the execution of the machine, in a differentially private manner. To this end, we first develop an efficiently *differentially private* algorithm for estimating the location of the head at pre-defined points in time. Naively, we could add a fresh Laplacian noise every time we need an estimate, but this will incur at least  $\sqrt{N}$  loss in the privacy budget (by standard composition theorems).

To get around this, inspired by the work of Chan et al. [7], we use a differentially private prefix sum algorithm [9, 10, 12] to account for the location of the head. Recall that in the prefix sum algorithm, a stream of number arrives in an online manner and the algorithm outputs the sum of all number seen so far, after seeing every number. We set up the numbers to correspond to head movements (“Left” for -1 and “Right” for 1) and show that this approach incurs only  $\text{poly log } N$  loss in privacy budget, which is good enough in terms of privacy. One challenge that we run into is that we need to implement the differentially private prefix sum algorithm on a Turing machine. It turns out that every time we need to get an estimate of the head’s location (i.e., get a prefix sum), we need to pay some non-trivial factor in running time and so we need to minimize the number of such estimations. Therefore, we design our algorithm to work with only one estimate of the head’s location every  $\text{poly log } N$  steps and amortize the cost of this estimation while processing the next  $\text{poly log } N$  steps of the Turing machine.

Once we have a good-enough estimate of the head’s location every  $\text{poly log } N$  steps, all that is left is to copy the nearby positions to a smaller *oblivious* Turing machine which we use to simulate the next  $\text{poly log } N$  steps. We set up the parameters in such a way that we copy enough positions around the estimated head’s location to actually include the *real* head position along with the relevant tape around it to perform the next  $\text{poly log } N$  steps so the above is well defined. The oblivious Turing machine that we need must provide an “initialization” procedure that allow us to start an oblivious Turing machine from an existing memory, and a “destruction” procedure which allows us to extract the memory to its original structure in the end of the execution. Pippenger and Fischer’s [35] construction does not provide such procedures so we describe a variant that does. As an independent contribution, our new oblivious Turing Machine is described in a language that more closely resembles the hierarchical oblivious RAM construction of Goldreich and Ostrovsky [17, 18] so it might be easier to understand for those who are familiar with the latter.

Lastly, let us remark that the above description was very high level and glossed over many technical details. For example, one technicality arises because we have to use the tapes sparingly in the compiled Turing machine to get a theorem that is tight in the number of tapes. To achieve this, we develop algorithmic tricks that allow us to reuse the same tape for multiple purposes without incurring any overhead in asymptotic running time. Another technical challenge arises because unlike earlier explorations on differentially obliviousness [7, 4], our target machine is a Turing machine rather than a RAM. This imposes additional constraints for our algorithm design, since we cannot use common building blocks such as oblivious sorting. Moreover, the *online* nature of our differentially oblivious simulation also renders some previous building blocks inadequate (which we discuss more in the Related Work section). We refer to the technical sections for details.

## 2 Preliminaries

For an integer  $n \in \mathbb{N}$  we denote by  $[n]$  the set  $\{1, \dots, n\}$ . A function  $\text{negl}: \mathbb{N} \rightarrow \mathbb{R}^+$  is *negligible* if for every constant  $c > 0$  there exists an integer  $N_c$  such that  $\text{negl}(\lambda) < \lambda^{-c}$  for all  $\lambda > N_c$ .

### 2.1 Turing Machines

We follow the presentation of Arora and Barak [1] for the definition of a  $k$ -tape Turing machine. A tape is an infinite bi-directional line of cells, each of which can hold a symbol from a finite set called the alphabet. Each tape is associated to a tape head that can potentially read or write symbols to the tape one cell at a time. The machine's computation is divided into discrete time steps, and the head can either stay in place or move left or right one cell in each step. More formally, a Turing machine  $M$  is described by a tuple  $(\Gamma, Q, \delta)$ , where  $\Gamma$  is a set of symbols that  $M$ 's tapes can contain,  $Q$  is the set of  $M$ 's possible states, and  $\delta: Q \times \Gamma^k \rightarrow Q \times \Gamma^k \times \{L, S, R\}^k$  is  $M$ 's transition function.

If the machine is in state  $q \in Q$  and  $(\sigma_1, \sigma_2, \dots, \sigma_k)$  are the symbols currently being read in the  $k$  tapes, and  $\delta(q, (\sigma_1, \dots, \sigma_k)) = (q', (\sigma'_1, \dots, \sigma'_k), z)$ , where  $z \in \{L, S, R\}^k$ , then at the next step the  $\sigma$  symbols in the  $k$  tapes will be replaced by the  $\sigma'$  symbols, the machine will be in state  $q'$ , and the  $k$  heads will move Left, Right, Stay in place, as given by  $z$ . There are additionally a read-only tape for the input and a write-only tape for the output, and perhaps a randomness tape if needed, but we ignore those when counting the number of tapes and only account for the work tapes.

The definition above is quite robust to the choices one makes regarding the alphabet size, the number of tapes, etc, since they are all equivalent in terms of complexity up to small factors. We recall the known facts which can be found, for example, in Arora and Barak [1].

► **Fact 4.** *It holds that:*

1. *Every function  $f$  that is computable in time  $T$  using alphabet  $\Gamma$ , can be computed in time  $O(\log |\Gamma| \cdot T)$  using an alphabet of size  $O(1)$ .*
2. *Every function  $f$  that is computable in time  $T$  using  $k$  tapes, can be computed in time  $O(k \cdot T^2)$  on a single tape machine and in time  $O(k \cdot T \cdot \log T)$  on a two-tape machine.*
3. *Every function  $f$  that is computable in time  $T$  using  $k$  bi-directional tapes, can be computed in time  $O(T)$  using  $k$  standard (uni-directional) tapes.*
4. *Every function  $f$  that is computable in time  $T$  using  $k$  tapes, can be computed in time  $k \cdot T$  using  $k$  tapes such that in each step only one of the tapes moves.*

We mention the dependence on  $k$  in the above terms for explicitness even though it is a constant.

In this work, we care about logarithmic factors so, by default, our Turing machine model is that of a two-tape machine. By the above, it does not matter if we consider uni-directional or bi-directional tapes. Constant factors in the alphabet size do not matter as well. All of the above only affect the constants which are hidden inside the  $O$  notation.

## 2.2 Differential Privacy

Differential privacy, introduced by Dwork et al. [11], is a property of algorithms that, very roughly, guarantees “security” for a single record in the input. Namely, if the algorithm acts on the information of a set of individuals, from the output it is hard to decide whether a particular individual’s information was used in the computation. This is formalized as follows. Let  $A$  be a probabilistic algorithm that takes as input a dataset. Let  $\text{Im}(A)$  be the set of all possible outputs of  $A$ . The algorithm  $A$  is said to be  $(\epsilon, \delta)$ -differentially private if for all datasets  $D_0$  and  $D_1$ , that differ only on one entry, and all possible subsets  $S \subseteq \text{Im}(A)$ , it holds that

$$\Pr[A(D_0) \in S] \leq e^\epsilon \cdot \Pr[A(D_1) \in S] + \delta,$$

where  $e$  is the base of the natural logarithm.

We refer to Dwork and Roth [13] for more information on differential privacy.

## 2.3 (Differentially) Oblivious Turing Machines

**Obliviousness.** Obliviousness is nowadays usually defined for RAMs and it guarantees that the access pattern of the RAM is “independent” of the underlying input. More specifically, given a RAM  $M$  and an input  $\mathbf{I}$ , we consider a random variable  $\text{Accesses}(M, \mathbf{I})$  that corresponds to the ordered sequence of memory locations  $M$  accesses during an execution on input  $\mathbf{I}$ . We then require that the distribution of  $\text{Accesses}(M, \mathbf{I}_1)$  is indistinguishable from  $\text{Accesses}(M, \mathbf{I}_2)$  for any  $\mathbf{I}_1$  and  $\mathbf{I}_2$  of the same length. The precise notion of indistinguishability can be either computational, statistical, or perfect, depending on the context.

A Turing machine can be thought of as a restricted version of RAM where random accesses are not allowed but any two consecutive accessed addresses must be to adjacent locations (i.e., the head can move at most one cell at a time). Adapting the notion of obliviousness to the Turing machine model requires that the tape’s head movements during the execution of the algorithm to not leak information about the inputs. Again one can define various notions of obliviousness, including computation, statistical, or perfect. We consider the strong notion of *deterministic* perfect obliviousness.

► **Definition 5** (Oblivious Turing machine). *A Turing machine  $M$  is said to be oblivious if for every input  $x \in \{0, 1\}^*$  and  $i \in [N]$ , the location of each of  $M$ ’s heads at the  $i$ th step of execution on input  $x$  is only a function of  $|x|$  and  $i$ .*

**Differential obliviousness.** Differential obliviousness was introduced by Chan et al. [7] as a relaxation of obliviousness for RAMs. At a high level, this security notion only protects individual operations, rather than the whole sequence of operations. This is formalized by requiring  $(\epsilon, \delta)$ -differential privacy for the observed access pattern of the RAM. In this case, two sequences of accesses  $\mathbf{I}_0$  and  $\mathbf{I}_1$  are neighboring if they are of the same length and differ in exactly one location accessed.

When we adapt the notion to the Turing machine model, one needs to distinguish between the input of the computation and the induced sequence of head movements that this input causes. While in some cases the two are analogous (which is the case in some of our results), in other cases there might be a gap. Namely, there are cases where the inputs are very close (in say, Hamming distance) and yet the resulting head movements are far from each other. Nevertheless, defining neighboring inputs w.r.t the observed sequence of head movements, as we do next, still implies a privacy guarantee for the inputs using standard group privacy theorems [11].

► **Definition 6** (Neighboring inputs). *Let  $M$  be a  $k$ -tape Turing machine. For  $\mathbf{J} \in \{0, 1\}^*$ , let  $\text{Movements}(M, \mathbf{J}) \in (\{L, R, S\}^k)^*$  be the sequence of head movements that  $M$  does on input  $\mathbf{J}$ . Two inputs  $\mathbf{J}_0, \mathbf{J}_1 \in \{0, 1\}^*$  are called neighboring if*

1.  $|\text{Movements}(M, \mathbf{J}_0)| = |\text{Movements}(M, \mathbf{J}_1)|$  and
  2.  $\text{Movements}(M, \mathbf{J}_0)$  and  $\text{Movements}(M, \mathbf{J}_1)$  differ in exactly one location.
- That is, letting  $(\ell_1^{b,1}, \dots, \ell_k^{b,1}), \dots, (\ell_1^{b,N}, \dots, \ell_k^{b,N}) = \text{Movements}(M, \mathbf{J}_b)$  for  $b \in \{0, 1\}$ , there is exactly one pair  $(i^*, j^*) \in [N] \times [k]$  such that  $\ell_{j^*}^{0,i^*} \neq \ell_{j^*}^{1,i^*}$  while for all other  $(i, j) \in [N] \times [k] \setminus \{(i^*, j^*)\}$ , it holds that  $\ell_j^{0,i} = \ell_j^{1,i}$ .*

Given this notion of neighboring inputs, we give the definition of differential obliviousness.

► **Definition 7** ( $(\epsilon, \delta)$ -differentially oblivious Turing machine). *A Turing machine  $M$  satisfies  $(\epsilon, \delta)$ -differential privacy iff for any neighboring inputs  $\mathbf{J}_0$  and  $\mathbf{J}_1$  and any set  $S \in (\{L, R, S\}^k)^*$  of possible sequence of head movements, it holds that*

$$\Pr[\text{Movements}(M, \mathbf{J}_0) \in S] \leq e^\epsilon \cdot \Pr[\text{Movements}(M, \mathbf{J}_1) \in S] + \delta.$$

### 3 Estimating Heads' Locations

In this section, we present an algorithm running on a Turing machine that outputs estimates to the location of the heads in a Turing machine computation. More precisely, the input to the algorithm is a sequence of movements of the heads of the machine (i.e., Left, Right or Stay for each tape), and it outputs an estimate to the location of the head in a-priori fixed intervals of time in an online fashion. The algorithm (1) outputs an estimate which is not too far from the true position of the head, (2) the estimates is differentially private, (3) the algorithm's head movements themselves are oblivious (i.e., data-independent), and (4) the algorithm is very efficient. The intervals at which we output an estimate on the location of the heads are denoted  $p$ .

► **Theorem 8.** *There exists an algorithm  $\text{EstimateHead}_{\epsilon, \delta}$  such that for any  $\epsilon, \delta > 0$ , the following holds. Fix any stream  $\mathbf{a} = a_1, a_2, \dots, a_N \in \{L, S, R\}^k$  that corresponds to the movements of the heads of a  $k$ -tape Turing machine. Let  $\sigma_i = \sum_{j=1}^{i \cdot p} a_j$  for  $i \in [N/p]$  (i.e., the true position of the heads every  $p$  steps). Let  $\{\tilde{\sigma}_i\}_{i \in [N/p]}$  denote a possible output of the algorithm  $\text{EstimateHead}_{\epsilon, \delta}$  when fed  $\mathbf{a}$  as an input in an online fashion. It holds that:*

1. **Utility:** *With probability 1 over the randomness of  $\text{EstimateHead}_{\epsilon, \delta}$ , it holds that*

$$\max_{i \in [N/p]} |\tilde{\sigma}_i - \sigma_i| \in O\left((1/\epsilon) \cdot \log^{1.5} N \cdot \log(1/\delta)\right).$$

2. **Differential privacy:**  $\text{EstimateHead}_{\epsilon, \delta}$  is  $(\epsilon, \delta)$ -differentially private. Here, neighboring sequences are defined in the natural way by allowing only one of the  $k$  indices in one of the  $N$   $a_i$ 's to differ between the two sequences.
3. **Obliviousness:** *The algorithm itself is perfectly oblivious.*
4. **Efficiency:** *The algorithm runs in time  $O(k \cdot N + k \cdot (N/p) \cdot (\log N))$ .*

**Proof.** The algorithm builds on the differentially private prefix-sum algorithm of Chan et al. [9, 10] and Dwork et al. [12]. Their algorithms address the problem of continuously estimating the prefix sums of elements in a given stream of numbers while maintaining differential privacy. We follow the presentation of these algorithm from Dwork and Roth [13, §12.3]. The algorithm is given a stream of numbers  $\mathbf{b} = b_1, b_2, \dots, b_N \in \{-1, 0, 1\}$  that the algorithm sees in an online fashion. The algorithm outputs, after seeing  $b_1, \dots, b_j$  an approximation of  $\sum_{i=1}^j b_i$ . This task is almost what we need to prove our theorem for  $k = 1$  (i.e., the machine has one tape). Indeed, a movement left (resp. right) can be interpreted as -1 (resp. 1) and staying in place corresponds to seeing 0. The location of the head is exactly the sum of those numbers. Additionally, it is not hard to observe that their algorithm is in fact oblivious (see below). Nevertheless, the running time of their algorithm on a Turing machine is  $O(N \cdot \log N)$  (see below). So, we need to (1) extend the algorithm to handle any  $k \geq 1$  tapes and (2) show how to implement it in the specified running time on a Turing machine. Since both goals are somewhat non-trivial to achieve, let us first briefly recall their algorithm and state its guarantees, and then describe our modifications.

Assume that  $N$  is a power of 2 (for simplicity and without loss of generality). We associate the  $N$  numbers to leaves of a full binary tree and then label each node in the tree with an “interval”. The  $i$ th leaf (for  $i \in [N]$ ) is labeled with  $[i, i]$ . An internal node is labeled with the interval that is the union of the intervals associated with its children. Now, with each node, labeled  $[s, t]$  in this tree, we associate a noisy count that approximates the sum of the values seen in positions  $s, s+1, \dots, t$  by adding noise from the appropriate distribution. In [9, 10, 12] the added noise was sampled from  $\text{Lap}((1 + \log_2 N)/\epsilon)$ , where  $\text{Lap}(s)$  denotes the (continuous) Laplace distribution with mean 0 and variance  $2s^2$ . To output  $\tilde{\sigma}_i$  (i.e., the approximation of  $\sum_{j=1}^i a_j$ ), we write  $i$  in binary to find at most  $\log_2 N$  intervals whose union is  $[1, i]$ , and compute the sum of the corresponding noisy counts. These intervals are associated to the nodes which are called *the frontier*. This algorithm satisfies  $(\epsilon, 0)$ -differential privacy and satisfies the following utility property: With probability  $1 - \delta$  over the randomness of the algorithm,

$$\max_{i \in [N/p]} |\tilde{\sigma}_i - \sigma_i| \leq O\left((1/\epsilon) \cdot \log^{1.5} N \cdot \log(1/\delta)\right).$$

It is easy to turn the utility property to be satisfied with probability 1 by outputting the exact prefix sum in the clear whenever the error in the output is too large. This causes the algorithm to be  $(\epsilon, \delta/2)$ -differentially private, as needed.

**Handling multiple tapes.** We extend the algorithm to handle  $k$  tapes by maintaining  $k$  prefix sums computed in parallel. This clearly does not hurt utility or obliviousness and only incurs a  $k$  factor in running time. However, naively, it incurs a  $k$  factor in differential privacy. Nevertheless, we observe that considering any two neighboring sequences of inputs,  $k - 1$  of the tapes will have the exact same access pattern while only one will differ in one position, and so this extension, in fact, does not incur a  $k$  factor in differential privacy.

**Running time.** The main challenge is to maintain an updated version of the noisy counts associated to the nodes in the frontier. Recall that the frontier is of size  $\log_2 N + 1$ . Naively, with the above algorithm, computing the frontier at time  $i + 1$  from the frontier at time  $i$  may cost up to  $O(\log N)$  work which is too expensive for us. However, recall that we do not need a prefix sum after every  $a_i$ , but rather we want to output one after every  $p$  inputs. So, instead of having a full binary tree where the leaves correspond to each input, we consider a full binary tree where each leaf corresponds to a sequence of  $p$  inputs and it is labeled by

their sum. The depth of this tree is  $\log_2(N/p)$  and the point is that we need to compute the “next” frontier (which costs about  $\log_2 N$ ) only once every  $p$  operations, so the total cost is  $O(k \cdot (N/p) \cdot \log N)$  plus the time it takes to aggregate the sum itself which is  $O(k \cdot N)$ , as needed.  $\blacktriangleleft$

► **Remark 9 (Sampling from Lap).** We emphasize that the above algorithm assumes that a Turing machine is capable of sampling from  $\text{Lap}(\cdot)$  in  $O(1)$  time. This is assumed for simplicity of presentation. However, it is possible to efficiently compute an estimate of this distribution on a standard Turing machine. The cost of this approximation is small good enough to obtain (asymptotically) the same final result in Theorem 11. Therefore, the assumption being made in this section is without loss of generality in the context of our main result. See details in Appendix A.

## 4 Oblivious Turing Machines

A classical result by Pippenger and Fischer [35] shows that any Turing machine computation can be made perfectly oblivious (i.e., Definition 5) on a two-tape machine with amortized logarithmic overhead. More precisely, any Turing machine that makes at most  $N$  steps can be made perfectly oblivious while making  $O(N \cdot \log N)$  steps.

In our application we need an oblivious Turing machine which support two additional properties. The first, called “initialization”, is that one can initialize an oblivious Turing machine with a given memory (as opposed to starting off with an empty memory). The second, called “destruction”, returns the state of the memory in a linear fashion.

Our construction is similar in spirit to the one of Pippenger and Fischer [35]. However, we present it in a language that more closely resembles the hierarchical oblivious RAM construction of Goldreich and Ostrovsky [17, 18] so it might be easier to understand for those who are familiar with the latter.

► **Theorem 10 (Oblivious Turing machine, revisited).** *Any  $k$ -tape Turing machine that makes at most  $N$  steps can be executed obliviously on a two-tape Turing machine with  $O(N)$  space and with  $O(k \cdot N \cdot \log N)$  steps. Additionally, the machine supports initialization and destruction.*

**Proof.** We will present the main idea in the special case where the given Turing machine has only a single tape and the resulting machine will have  $\ell = \lceil \log N \rceil$  tapes. Later, we will explain how to handle multiple tape machines in the input and simulate them obliviously with just two tapes (at the same cost).

We have  $\ell$  tapes and sometimes we will refer to these tapes as “levels” (analogously to levels in [18]’s hierarchical ORAM construction). For each  $i \geq 1$ , level  $T_i$  is a tape that contains at most  $\ell_i \triangleq 2^i - 1$  elements and it is thought of as a cyclic buffer. That is, the element on the right of the  $(2^i - 1)$ th element in level  $T_i$  is the 1st one. Our construction will maintain the following invariant. Let  $p$  be the pointer to the current head location of the original Turing machine. At the end of every  $2^i$  steps,  $T_i$  stores the content of the tape at positions  $[p - 2^{i-1} : p + 2^{i-1}]$ .

According to this, level  $T_1$  will always store the content of the cell pointed to by the head, level  $T_2$  stores the content of cells  $p - 1, p, p + 1$ , and so on. Notice that the same cell may be part of several levels and not all of the values will be consistent with each other. The freshest copy of a cell is always in the  $T_i$  with the smallest  $i$  that contains the cell. Reading the value of the cell pointed to by the head or writing to that cell is done by reading or writing (respectively) directly to  $T_1$ .

For every  $i \geq 0$ , at the end of every  $2^i$  steps, the following reorganization steps are performed:

1.  $T_{i+1}$  writes its updated contents to  $T_{i+2}$ . This is done by making a pass over  $T_{i+2}$  and scanning over  $T_{i+1}$  as a cycle buffer, making a real write whenever needed and making a dummy write otherwise.
2.  $T_{i+1}$  copies the corresponding segment it ought to store from  $T_{i+2}$ . This is done, as above, by making a pass over  $T_{i+2}$  and scanning over  $T_{i+1}$  as a cycle buffer, making a real write whenever needed and making a dummy write otherwise.

Correctness follows immediately by description. Perfect obliviousness follows from the fact that the head's movements are deterministic and a-priori fixed. For efficiency, consider any sequence of  $N$  steps. A read or a write are done at a single operations cost by just accessing  $T_1$ . It remains to account for the cost of the reorganization steps. Note that the  $N$  operations are confined to levels  $T_i$  for  $i \leq \log N + 2$ . By description and recalling that the size of level  $T_i$  is  $2^i - 1$ , the total amount of steps performed by the oblivious Turing machine is bounded by

$$\sum_{i=1}^{\log N + 2} \left\lceil \frac{N}{2^{i-1}} \right\rceil \cdot O(|T_{i+2}|) \in O(N \cdot \log N).$$

We now explain how to remove the simplifying assumptions we had, the first being that the input machine has only one tape and the second being that the resulting oblivious machine uses  $\log N$  many tapes. Let us first handle the former, letting  $k$  be the number of tapes used by the input machine. We use an encoding trick. We encode the  $k$  tapes into a single tape by first placing all the first cells from each tape, then the second cell, and so on. Each “track” will have its own head marker. By the construction of the oblivious Turing machine, all the tracks can be processed simultaneously (recall that our head movement sequence is deterministic), incurring a  $k$  multiplicative factor.

Now, we explain how to modify our Turing machine to use only two tapes. As a first step, let us place the different levels one after the other on the single tape. Naively, this incurs a blowup in running time due to the reorganization steps. Indeed, in the reorganization steps, we need to scan two levels “in parallel” as cyclic buffers. The only way to do this with a single tape is by moving back and forth in the tape which is too expensive. This is where we will use the second tape. When such a “parallel” scan is needed, we will copy one of the levels to the second tape, do the “parallel” scan by scanning both tapes in parallel, and then copy it back. This only incurs a constant overhead.

**Initialization and destruction.** In our application, we will need to an oblivious Turing machine with two additional features so we explain how to implement them next. The first is that we need to support initialization with a given memory which might not necessarily be empty. We implement this by starting with an empty memory, as described above, and modifying the memory one element at a time. If the number of steps that we eventually perform on the Turing machine is about the size of the initial memory, the cost of this step will be amortized away.

The second feature is a destruction procedure which outputs the memory at the end of the computation in a linear fashion. This is not so immediate since our construction does not store the memory in a linear fashion. Recall that our construction satisfies that at the end of every  $2^i$  steps, the cells corresponding to the level  $T_i$  store the content of the tape at positions  $[p - 2^{i-1} : p + 2^{i-1}]$ . This means that if “destruct” is invoked after a power-of-2

many steps, the memory is stored exactly in the cells corresponding to some level and one can make one linear scan to extract those elements and put them one next to the other. If `destruct` is invoked after some other number of steps, we need to modify this procedure slightly by collecting the most updated memory values of each cell from the appropriate level (now, the most updated values are spread amongst different cells). This again can be done by a single scan. ◀

## 5 A Differentially Oblivious Turing Machine

In this section, we describe our transformation from any Turing machine into a differentially oblivious one.

► **Theorem 11.** *For any  $\epsilon, \delta > 0$ , any  $k$ -tape Turing machine that makes at most  $N$  steps and consumes  $S$  space can be transformed into an  $(\epsilon, \delta)$ -differentially oblivious  $\max\{2, k\}$ -tape Turing machine that makes  $O(N \cdot (\log(1/\epsilon) + \log \log N + \log \log(1/\delta)))$  steps and consumes  $O(S + (1/\epsilon) \cdot \log^2 N \cdot \log(1/\delta))$  space.*

The construction of the differentially oblivious Turing machine uses the oblivious Turing machine construction from Section 4 and the head's location estimation algorithm from Theorem 3. We will present the construction in steps. We first assume that the input machine uses only one tape and the resulting machine will use many tapes. Then, we will explain how to get rid of both simplifying assumptions and therefore obtain Theorem 11.

### 5.1 From One Tape to Four Tapes

Assume first that the given machine,  $M$ , uses only a single tape. We first present a construction that compiles  $M$  into a differentially oblivious Turing machine  $\text{dp}M$  with 4 tapes. Fix  $\epsilon, \delta > 0$  for the rest of this section.

**Tape allocation.** The resulting Turing machine,  $\text{dp}M$ , will consist of four tapes, numbered 1, 2, 3, and 4, in the following order:

1. One tape to simulate the input Turing machine computation (recall that we assumed that the input machine has only one tape).
2. Two tapes for running an oblivious Turing machine (according to Section 4).
3. One tape to compute differentially private head's location estimation algorithm (according to Section 3).

**The algorithm.** As mentioned, we use the oblivious Turing machine implementation from Section 4 but since its overhead is logarithmic (in the running time of the non-oblivious machine), we do not want to apply it directly on our machine. Instead, we are going to break down the computation of the original machine into epochs and invoke the oblivious machine only within epochs. Concretely, we split the computation of  $M$  into epochs of size

$$p \triangleq (1/\epsilon) \cdot \log^2 N \cdot \log(1/\delta).$$

Each such epoch will be executed in its own “fresh” oblivious Turing machine and so the overhead will only be a doubly logarithmic factor in  $N$ . Next, we explain how  $\text{dp}M$  works.

---

**Algorithm**  $\text{dp}M_{\epsilon,\delta}$ .

---

1. Set  $h_{\approx}^0 = 0$  be the initial approximate position of the head (it is equal to the real position).
  2. Break the  $T$ -step computation into epochs of  $p$  steps of computation. For epoch  $i = 1, \dots, N/p$ , do:
    - a. Copy an area of size  $4p + 1$  around  $h_{\approx}^{i-1}$ , namely  $[h_{\approx}^{i-1} - 2p, h_{\approx}^{i-1} + 2p]$  to the oblivious Turing machine (Theorem 10). Perform the next  $p$  steps of computation there. At the end of the epoch, copy the state of these  $4p + 1$  cells back to the main tape.
    - b. In parallel, keep track of the movements of the head and count the offset of the head compared to the previous location,  $h_{\approx}^{i-1}$ . At the end of the epoch, invoke the differentially private head's location estimation algorithm (Theorem 8) with privacy parameters  $\epsilon$  and  $\delta$  to update the location of the head  $h_{\approx}^i$ .
- 

► **Theorem 12.** *For any  $\epsilon, \delta > 0$  and given any single-tape Turing machine  $M$  that makes at most  $N$  steps and consumes  $S$  space, the 4-tape machine  $\text{dp}M_{\epsilon,\delta}$  is  $(\epsilon, \delta)$ -differentially oblivious, makes at most  $O(N \cdot (\log(1/\epsilon) + \log \log N + \log \log(1/\delta)))$  steps and consumes  $O(S + (1/\epsilon) \cdot \log^2 N \cdot \log(1/\delta))$  space.*

**Proof.** We first prove correctness, ignoring obliviousness. Consider any sequence of operations. At any point in time, the oblivious Turing machine contains  $2p + 1$  memory cells and performs all necessary operations within. For correctness, by description, it is enough to show that the  $p$  operations are indeed contained within those  $2p + 1$  cells. Indeed, for this to hold it is enough to argue that  $h_{\approx}^i$  is close enough to the real location of the head:  $h_{\approx}^i - 2p \leq h^i - p$  and  $h_{\approx}^i + 2p \geq h^i + p$ , where  $h^i$  is the true location of the head. In other words, we need to show that

$$|h_{\approx}^i - h^i| \leq p.$$

By the utility property of the head's location estimation algorithm (Theorem 8), we know that  $|h_{\approx}^i - h^i| \leq (1/\epsilon) \cdot \log^{1.5} N \cdot \log(1/\delta)$  (this is the upper bound on the additive error of each head's location estimation for every  $i$ ). Now, the above inequality follows by recalling that  $p = (1/\epsilon) \cdot \log^2 N \cdot \log(1/\delta)$ .

To prove  $(\epsilon, \delta)$ -differential obliviousness, consider any two sequences of operations  $\mathbf{I}_0$  and  $\mathbf{I}_1$  that differ at one operation. Consider the random variable  $\tilde{I}_b$  corresponding to the physical tape heads locations on input  $\mathbf{I}_b$  for  $b \in \{0, 1\}$ . Say the two sequences  $\mathbf{I}_0$  and  $\mathbf{I}_1$  differ in the  $i$ th operation and are otherwise identical. Then, the first  $i - 1$  operations result with identical distributions of head locations in both executions (as all the underlying building blocks are perfectly oblivious). The only difference is in the  $i$ th operation. There, the head's locations might differ due to a different distribution of the head's location estimation algorithm (Theorem 8). However, we are guaranteed that this algorithm is  $(\epsilon, \delta)$ -differentially private. The rest of the heads' movements are perfectly oblivious: the oblivious Turing machine is perfectly oblivious, the head's location estimation algorithm itself is perfectly oblivious, and the other operations that we do in the implementation of  $\text{dp}M$  are trivially oblivious.

Lastly, we analyze efficiency by counting the total amount of work and space required to handle any sequence  $N$  operations that consume  $S$  space. Step 2a costs  $O(p \cdot \log p)$  operations and space due to Theorem 10 (the rest of the operations can be implemented in  $O(p)$  time and space). Computing the differentially private head's location estimation in Step 2b takes overall  $O(N + (N/p) \cdot (\log N + \log(1/\delta))) < O(N)$  time due to Theorem 8 (i.e., constant

amortized work per access). Otherwise, simulating the original computation and accounting for the location of the head, requires  $O(N)$  work and space. Overall, over  $N$  operations, the total space is  $O(N + p \cdot \log p)$  and the work is bounded by  $O(N \cdot \log p)$ . Plugging in  $p = (1/\epsilon) \cdot \log^2 N \cdot \log(1/\delta)$  completes the proof.  $\blacktriangleleft$

## 5.2 From One Tape to Two Tapes

In this section we show how to obtain the same result as in the previous section (i.e., Theorem 12), except that our resulting Turing machine will only use two tapes (instead of four). One tape will be used for the simulation of the original Turing machine plus one of the tapes of the oblivious Turing machine and the other tape will be used to perform the head's location estimation algorithm and the other tape of the oblivious Turing machine.

Recall that the tapes used for the oblivious Turing machine, both consume about  $p$  space, but one interacts with the main tape (call it tape  $o\text{TM}_1$ ) and the other acts as a scratch pad and the values that are written there are never accessed outside of the oblivious Turing machine implementation (call it tape  $o\text{TM}_2$ ). We will merge tape  $o\text{TM}_2$  into the tape that simulates the original computation, and tape  $o\text{TM}_1$  to the tape that computes the prefix sums.

**Tape 1 (Main Tape).** This tape will consist of the main computation tape as well as a blank area which is used for tape  $o\text{TM}_2$  of the oblivious Turing machine. We use the fact that the required space for the oblivious Turing machine is  $O(p)$  cells and so we will maintain such a “space of blanks” which will not be too far from the real position of the head and will be used whenever a new oblivious Turing machine is instantiated. Let us denote by  $S_{o\text{TM}} = O(p)$  the space consumption of the oblivious Turing machine. Our first tape, the one that simulates the computation of the original Turing machine, will maintain the invariant that in distance  $S_{o\text{TM}}$  from the location of the approximate head  $h_{\approx}$  to the right, there are  $S_{o\text{TM}}$  blank cells (the last blank cell has distance  $2S_{o\text{TM}}$  from  $h_{\approx}$ ). If this invariant holds, then whenever an epoch begins, we can move to the blank area and use it as the oblivious Turing machine tape. At the end of the epoch, we can go back to where we were. Since we perform  $p$  operations inside the oblivious Turing machine, the amortized cost of moving back and forth is  $O(1)$  per operation which is what we need.

We thus need to explain how to maintain the above invariant. The idea is to move the blank area together with the location of the head once every epoch. Namely, once we update the approximate position of the head  $h_{\approx}$ , we will also move the blank area appropriately so that its distance from the new  $h_{\approx}$  is as we require. Moving the blank area, as above, can be done simply in time  $O(p)$  using a designated size  $O(p)$  space in the other tape (tape 2) – this is done by moving the area that needs to go to the blank area to tape 2 (and replacing it with blanks), and then copying by moving both heads “in parallel”.

**Tape 2 (Secondary Tape).** This tape will consist of three areas, each of size  $O(p)$ . One of these areas will be used for moving the blank area in tape 1, as we explained above. Another area is for the computation of the head's location estimation – this algorithm has state of size  $O(\log N) < O(p)$  (which contains a frontier of a tree of noisy sums per interval). The third part is for tape  $o\text{TM}_1$  of the oblivious Turing machine (which also uses  $O(p)$  space).

The first and second parts in this tape are accessed at the end of every epoch and some computation of length  $O(p)$  is performed on each of them (either updating the prefix sum or moving data around). Since each epoch handles  $O(p)$  operations, the amortized cost of this part is  $O(1)$  per operation of the original machine. The third part, in contrast, is accessed throughout the epoch, and there we get  $O(\log p)$  overhead per operation.

### 5.3 From $k$ Tapes to $k$ Tapes (for $k \geq 2$ )

This extension is done by making two changes. First we use  $k$  tapes to simulate the computation of the original  $k$ -tape machine (instead of just a single tape). Second, we use the algorithm for estimating the head's position which works for  $k$  tape machines (Theorem 8) – this incurs an overhead of  $k$  operations per step. Recall that this algorithm just runs the algorithm for estimating the head's position of a single tape  $k$  times (independently). It remains to explain where we execute this algorithm and also where we execute the oblivious Turing machine since now we do not have an extra work tape.

The idea is to first modify each tape to have *two* “blank areas”, each as above. Say that one blank area will be on the left of the head's position and the other one on the right. The one on the left will act as the “Main Tape” in the above construction and the one on the right as the “Secondary Tape” for another tape. Concretely, tape  $(i + 1) \bmod k$  acts as the “Secondary Tape” of tape  $i$  (for all  $i \in [k]$ ).

That is, the blank area on the left of the head of tape  $i$ , is used to simulate the computation of tape  $i$  in the original machine and also to execute tape  $\text{oTM}_2$  of the oblivious Turing machine when simulating tape  $i$  (this is exactly the same usage of the blank area as above). The blank area on the right of the head of tape  $i$  consists of three areas: (1) an area used to maintain the blank areas in tape  $(i + 1) \bmod k$ , (2) an area used for the computation of the head's location estimation of tape  $(i + 1) \bmod k$ , and (3) tape  $\text{oTM}_1$  of the oblivious Turing machine when simulating tape  $(i + 1) \bmod k$ . Overall, these changes incur an extra  $O(k)$  factor in the overhead of the simulation.

## 6 Lower Bound

In this section we prove that our differentially oblivious Turing machine is optimal in terms of overhead in a natural range of parameters. Specifically, we prove the following theorem.

► **Theorem 13.** *There exists an algorithmic task for which there is a Turing machine that on input of size  $N$  completes it in  $O(N)$  steps. On the other hand, for any  $0 < s \leq \sqrt{N}$ ,  $\epsilon > 0$ ,  $0 < \beta < 1$ , and  $0 \leq \delta \leq \beta \cdot (\epsilon/s) \cdot e^{-2\epsilon \cdot s}$ , any  $(\epsilon, \delta)$ -differentially oblivious implementation (even on a RAM and in the balls and bins model) for this task must consume  $\Omega(N \cdot \log s)$  steps with probability  $1 - \beta$ .*

**Proof.** In the work of Chan et al. [7] the following theorem concerning the required overhead to stably sort a set of balls according to associated 1-bit keys while maintaining differential obliviousness. Here, we assume that the balls are opaque and so no non-trivial encoding on them can be done [6].

► **Theorem 14** (Theorem 4.7 in [7]). *Let  $0 < s \leq \sqrt{N}$ . Suppose  $\epsilon > 0$ ,  $0 < \beta < 1$ , and  $0 \leq \delta \leq \beta \cdot (\epsilon/s) \cdot e^{-2\epsilon \cdot s}$ . Then, any (even randomized) stable sorting algorithm for balls according to associated 1-bit keys in the RAM model that is  $(\epsilon, \delta)$ -differentially oblivious must have some input, on which it incurs at least  $\Omega(N \cdot \log s)$  memory accesses with probability at least  $1 - \beta$ .*

The task of stably sorting  $N$  balls according to associated 1-bit keys can be implemented using a Turing machine in  $O(N)$  steps. Consider an input of the form  $(k_1, v_1), \dots, (k_N, v_N)$ , where  $k_i \in \{0, 1\}$  is a 1-bit key and  $v_i$  is the  $i$ th ball. The idea is to scan the input from the beginning and whenever we see an element  $(k_i, v_i)$  we do one of the following. If  $k_i = 0$ , we write  $(k_i, v_i)$  to the next position in the output tape. If  $k_i = 1$ , we write it to the next position in the work tape. After we finish scanning the input, we scan the output again and write all elements from first to last into the output tape. It is immediate that this algorithm is correct and has  $O(N)$  running time. ◀

## A Sampling Noise on a Turing machine

One of the operations our differentially oblivious Turing machine needs to do is to sample from the (continuous) Laplacian distribution  $\text{Lap}(x)$ ; this is used in the algorithm for estimating the head’s location; see Section 3. There, we need to generate a sample from  $\text{Lap}((1 + \log_2 N)/\epsilon)$  and we need to do this about  $N$  times. Recall that a Laplacian distribution is unbounded and samples need infinite precision. We show that with small tolerable loss in precision (which does not affect our final result), one can sample an approximation from this distribution on a standard Turing machine.

We assume that  $\ln(1/\epsilon)$  is an integer so that we do not have rounding issues. Also, recall that  $\delta$  is a negligible function of the form  $\exp(-\log^2 N)$ . First, we switch to a bounded version of the distribution, chopping off the tail which contains elements that occur with negligible probability. We can assume that we sample from the range  $\pm(\log(N)/\epsilon) \cdot \text{poly} \log(1/\delta)$ . Let us call  $\delta_0$  the probability mass that we chopped off. Sampling from the bounded version turns our  $(\epsilon, \delta')$ -differentially private prefix sum algorithm into an  $(\epsilon, \delta)$ -differentially private one, where  $\delta = \delta' + N \cdot (\epsilon^\epsilon \cdot \delta_0 + \delta_0)$ . To see this, observe that we have essentially  $N$  instances of the  $\text{Lap}$  noise and so by a simple union bound, the statistical distance between each event w.r.t the bounded distribution happens with probability at most  $N \cdot \delta_0$  larger than in the unbounded version. Namely, for any set  $S$ ,  $\Pr[X_{\text{bounded}} \in S] \leq \Pr[X \in S] + N \cdot \delta_0$ , where  $X_{\text{bounded}}$  is the output of the mechanism when using bounded noise and  $X$  is the original mechanism. Then, by differential privacy,  $\Pr[X \in S] + N \cdot \delta_0 \leq e^\epsilon \Pr[Y \in S] + \delta' + N\delta_0$ , where  $Y$  is another arbitrary event sampled from the unbounded noise version. Then again by bounding the noise used in  $Y$ , we get

$$\Pr[X_{\text{bounded}} \in S] \leq e^\epsilon (\Pr[Y_{\text{bounded}} \in S] + N\delta_0) + \delta' + N\delta_0.$$

Since we think of  $\delta_0$  as being negligible in  $N$  and  $\epsilon$  being a constant,  $\delta$  is also negligible.<sup>6</sup>

<sup>6</sup> The above analysis was very loose. In particular, one can do a tighter analysis and not lose the linear-in- $N$  factor in  $\delta$  but for our purposes it does not matter since  $\delta$  is negligible in  $N$  anyway.

The next step is to represent each element in the bounded range with finite precision. We want to lose at most  $\delta$  factor in precision (which will add another additive  $\delta$  factor to our additive error), and so if we use  $\ell$  bits of precision, we have the inequality:

$$2^{-\ell} \cdot ((\log N)/\epsilon) \cdot \text{poly log}(1/\delta) \leq \delta.$$

This means that it is enough to use  $\ell \in O(\log((\log N \cdot \log \log(1/\delta))/(\epsilon\delta)))$  bits of precision which can be bounded by  $O(\log^2(1/\delta))$  bits since  $\delta$  is negligible in  $N$  and  $\epsilon$  is a constant. Therefore, all operations can be executed efficiently enough (in time  $O(\text{poly log } N)$ ), which by slightly changing parameters (e.g., the value of  $p$ ), does not affect our asymptotic upper bound on the running time of our differentially private Turing machine.

## Abstract

Most correlation inequalities for high-dimensional functions in the literature, such as the Fortuin-Kasteleyn-Ginibre inequality and the celebrated Gaussian Correlation Inequality of Royen, are *qualitative* statements which establish that any two functions of a certain type have non-negative correlation. We give a general approach that can be used to bootstrap many *qualitative* correlation inequalities for functions over product spaces into *quantitative* statements. The approach combines a new extremal result about power series, proved using complex analysis, with harmonic analysis of functions over product spaces. We instantiate this general approach in several different concrete settings to obtain a range of new and near-optimal quantitative correlation inequalities, including:

- A quantitative version of Royen’s celebrated Gaussian Correlation Inequality [23]. In [23] Royen confirmed a conjecture, open for 40 years, stating that any two symmetric convex sets must be non-negatively correlated under any centered Gaussian distribution. We give a lower bound on the correlation in terms of the vector of degree-2 Hermite coefficients of the two convex sets, conceptually similar to Talagrand’s quantitative correlation bound for monotone Boolean functions over  $\{0, 1\}^n$  [26]. We show that our quantitative version of Royen’s theorem is within a logarithmic factor of being optimal.
- A quantitative version of the well-known FKG inequality for monotone functions over any finite product probability space. This is a broad generalization of Talagrand’s quantitative correlation bound for functions from  $\{0, 1\}^n$  to  $\{0, 1\}$  under the uniform distribution [26]; the only prior generalization of which we are aware is due to Keller [17, 15, 16], which extended [26] to product distributions over  $\{0, 1\}^n$ . In the special case of  $p$ -biased distributions over  $\{0, 1\}^n$  that was considered by Keller, our new bound essentially saves a factor of  $p \log(1/p)$  over the quantitative bounds given in [17, 15, 16]. We also give a quantitative version of the FKG inequality for monotone functions over the continuous domain  $[0, 1]^n$ , answering a question of Keller [16].

## 1 Introduction

*Correlation inequalities* are theorems stating that for certain classes of functions and certain probability distributions  $\mathcal{D}$ , any two functions  $f, g$  in the class must be non-negatively correlated with each other under  $\mathcal{D}$ , i.e. it must be the case that  $\mathbf{E}_{\mathcal{D}}[fg] - \mathbf{E}_{\mathcal{D}}[f] \mathbf{E}_{\mathcal{D}}[g] \geq 0$ . Inequalities of this type have a long history, going back at least to a well-known result of Chebyshev, “Chebyshev’s order inequality,” which states that for any two nondecreasing sequences  $a_1 \leq \dots \leq a_n$ ,  $b_1 \leq \dots \leq b_n$  and any probability distribution  $p$  over  $[n] = \{1, \dots, n\}$ , it holds that

$$\sum_{i=1}^n a_i b_i p_i \geq \left( \sum_{i=1}^n a_i p_i \right) \left( \sum_{i=1}^n b_i p_i \right).$$

Modern correlation inequalities typically deal with high dimensional rather than one dimensional functions. Results of this sort have proved to be of fundamental interest in many fields such as combinatorics, analysis of Boolean functions, statistical physics, and beyond.

Perhaps the simplest high-dimensional correlation inequality is the well known Harris-Kleitman theorem [10, 19], which states that if  $f, g : \{0, 1\}^n \rightarrow \{0, 1\}$  are monotone functions (meaning that  $f(x) \leq f(y)$  whenever  $x_i \leq y_i$  for all  $i$ ) then  $\mathbf{E}[fg] - \mathbf{E}[f] \mathbf{E}[g] \geq 0$ , where expectations are with respect to the uniform distribution over  $\{0, 1\}^n$ . The Harris-Kleitman theorem has a one-paragraph proof by induction on  $n$ ; on the other end of the spectrum is the Gaussian Correlation Inequality (GCI), which states that if  $K, L \subseteq \mathbb{R}^n$  are any two symmetric convex sets and  $\mathcal{D}$  is any centered Gaussian distribution over  $\mathbb{R}^n$ , then  $\mathbf{E}_{\mathcal{D}}[KL] - \mathbf{E}_{\mathcal{D}}[K] \mathbf{E}_{\mathcal{D}}[L] \geq 0$  (where we identify sets with their 0/1-valued indicator functions). This was a famous conjecture for four decades before it was proved by Thomas Royen in 2014 [23]. Other well-known correlation inequalities include the Fortuin-Kasteleyn-Ginibre (FKG) inequality [7], which is an important tool in statistical mechanics and probabilistic combinatorics; the Griffiths-Kelly-Sherman (GKS) inequality [9, 18], which is a correlation inequality for ferromagnetic spin systems; and various generalizations of the GKS inequality to quantum spin systems [8, 25].

### 1.1 Quantitative Correlation Inequalities

Here, we attempt to obtain *quantitative* correlation inequalities. Consider the following representative example: For two monotone Boolean functions  $f, g : \{0, 1\}^n \rightarrow \{0, 1\}$ , as discussed above, the Harris-Kleitman theorem states that  $\mathbf{E}[fg] - \mathbf{E}[f] \mathbf{E}[g] \geq 0$ . It is easy to check that the Harris-Kleitman inequality is tight if and only if  $f$  and  $g$  depend on disjoint sets of variables. One might therefore hope to get an improved bound by measuring how much  $f$  and  $g$  depend simultaneously on the same coordinates. Such a bound was obtained by Talagrand [26] in an influential paper (appropriately titled “How much are increasing sets correlated?”).

To explain Talagrand’s main result, we recall the standard notion of *influence* from the analysis of Boolean functions [21]. For a Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ , the *influence* of coordinate  $i$  on  $f$  is defined to be  $\mathbf{Inf}_i[f] := \Pr_{\mathbf{x} \sim U_n}[f(\mathbf{x}) \neq f(\mathbf{x}^{\oplus i})]$ , where  $U_n$  is the uniform distribution on  $\{0, 1\}^n$  and  $\mathbf{x}^{\oplus i}$  is obtained by flipping the  $i^{\text{th}}$  bit of  $\mathbf{x}$ . Talagrand proved the following *quantitative* version of the Harris-Kleitman inequality:

$$\mathbf{E}[fg] - \mathbf{E}[f] \mathbf{E}[g] \geq \frac{1}{C} \cdot \Psi \left( \sum_{i=1}^n \mathbf{Inf}_i[f] \mathbf{Inf}_i[g] \right) \quad (1)$$

■ **Table 1** Qualitative and quantitative correlation inequalities. Here  $\gamma$  denotes the standard Gaussian distribution  $\mathcal{N}(0, 1)^n$ ;  $\{0, 1\}_p^n$  denotes the  $p$ -biased hypercube (with no subscript corresponding to  $p = 1/2$ , i.e. the uniform distribution);  $\pi$  denotes any distribution over  $\{0, \dots, m-1\}$ ; and  $[0, 1]^n$  is endowed with the Lebesgue measure.

	Qualitative Bounds	Quantitative Bounds
Monotone $f, g \in L^2(\mathbb{R}^n, \gamma)$	[7]	[14]
Symmetric, convex $K, L \subseteq \mathbb{R}_\gamma^n$	[23]	Theorem 21
Convex $f, g \in L^2(\mathbb{R}^n, \gamma)$	[11]	Deferred to full version.
Monotone $f, g : \{0, 1\}^n \rightarrow \{0, 1\}$	[10, 19, 7]	[26]
Monotone $f, g : \{0, 1\}_p^n \rightarrow \mathbb{R}$	[7]	[15], Theorem 29
Monotone $f, g : \{0, \dots, m-1\}_\pi^n \rightarrow \mathbb{R}$	[7]	Theorem 29
Monotone $f, g \in L^2([0, 1]^n)$	[22]	Deferred to full version.

where  $\Psi(x) := x/\log(e/x)$ ,  $C > 0$  is an absolute constant, and the expectations are with respect to the uniform measure. A simple corollary of this result is that  $\mathbf{E}[fg] = \mathbf{E}[f]\mathbf{E}[g]$  if and only if the sets of influential variables for  $f$  and  $g$  are disjoint. In [26] itself, Talagrand gives an example for which Equation (1) is tight up to constant factors.

Talagrand’s result has proven to be influential in the theory of Boolean functions, and several works [15, 16, 17, 12] have obtained extensions and variants of this inequality for product distributions over  $\{0, 1\}^n$ . An analogue of Talagrand’s inequality in the setting of monotone functions over Gaussian space was obtained by Keller, Mossel and Sen [14] using a new notion of “geometric influences.” Beyond these results, we are not aware of *quantitative* correlation inequalities in other settings, even though (as discussed above) a wide range of *qualitative* correlation inequalities are known. In particular, even for very simple and concrete settings such as the solid cube  $[0, 1]^n$  endowed with the uniform measure or the  $m$ -ary cube  $\{0, 1, \dots, m-1\}^n$  with a product measure, no quantitative versions of the FKG inequality were known (see the discussion immediately following Theorem 4 of Keller [13]). As a final example, no quantitative version of the Gaussian Correlation Inequality was previously known.

## 1.2 Our Contributions

We establish a general framework to transfer qualitative correlation inequalities into quantitative correlation inequalities. We apply this general framework to obtain a range of new quantitative correlation inequalities, which include the following:

1. Quantitative versions of Royen’s Gaussian Correlation Inequality and Hu’s correlation inequality [11] for symmetric convex functions over Gaussian space;
2. A quantitative FKG inequality for a broad class of product distributions, including arbitrary product distributions over finite domains and the uniform distribution over  $[0, 1]^n$ .

All these results are obtained in a unified fashion via simple proofs that are substantially different from previous works [26, 15, 16, 17, 12]. We also give several lower bound examples, including one which shows that our quantitative version of the Gaussian Correlation Inequality is within a logarithmic factor of the best possible bound.

We note that the special case of item 2 above with the uniform distribution on  $\{0, 1\}^n$  essentially recovers Talagrand’s correlation inequality [26]. In more detail, our bound is weaker than that obtained in [26] by a logarithmic factor, but our proof is significantly simpler and easily generalizes to other domains. For  $p$ -biased distributions over  $\{0, 1\}^n$ , our bound avoids any dependence on  $p$  compared to the results of Keller [15, 16, 17] which have a  $p \log(1/p)$  dependence (though, similar to the situation vis-a-vis [26], we lose a logarithmic factor in other dependencies). Finally, for the uniform distribution over  $[0, 1]^n$ , our result gives an answer to a question posed by Keller [16], who wrote “It seems tempting to find a generalization of Talagrand’s result to the continuous setting, but it is not clear what is the correct notion of influences in the continuous case that should be used in such generalization.”

### 1.3 The Approach

We start with a high level meta-observation before explaining our framework and techniques in detail. While the statements of the Harris-Kleitman inequality, the FKG inequality, and the Gaussian Correlation Inequality have a common flavor, the proofs of these results are extremely different from each other. (As noted earlier, the Harris-Kleitman inequality admits a simple inductive proof which is only a few lines long; in contrast the Gaussian Correlation Inequality was an open problem for nearly four decades, and no inductive proof for it is known.) Thus, at first glance, it is not clear how one might come up with a common framework to obtain quantitative versions of these varied qualitative inequalities.

Our approach circumvents this difficulty by using the qualitative inequalities essentially as “black boxes.” This allows us to extend the qualitative inequalities into quantitative ones while essentially sidestepping the difficulties of proving the initial qualitative statements themselves.

#### 1.3.1 Our General Framework

In this subsection we give an overview of our general framework and the high-level ideas underlying it, with our quantitative version of the Gaussian Correlation Inequality serving as a running example throughout for concreteness.

We begin by defining a function  $\Phi : [0, 1] \rightarrow [0, 1]$  which will play an important role in our results:

$$\Phi(x) := \min \left\{ x, \frac{x}{\log^2(1/x)} \right\}. \quad (2)$$

(Note the similarity between  $\Phi$  and the function  $\Psi$  mentioned earlier that arose in Talagrand’s quantitative correlation inequality [26]; the difference is that  $\Phi$  is smaller by essentially a logarithmic factor in the small- $x$  regime.)

Let  $\mathcal{F}$  be a family of real-valued functions on some domain (endowed with measure  $\mu$ ) with  $\mathbf{E}_\mu[f^2] \leq 1$  for all  $f \in \mathcal{F}$ . For example, the Gaussian Correlation Inequality is a correlation inequality for the family  $\mathcal{F}_{\text{csc}}$  of centrally symmetric, convex sets (identified with their 0/1-indicator functions), and  $\mu$  is the standard Gaussian measure  $\mathcal{N}(0, 1)^n$ , usually

denoted  $\gamma$ .<sup>1</sup> A *quantitative* correlation inequality for  $f, g \in \mathcal{F}$  gives a (non-negative) lower bound on the quantity  $\mathbf{E}_{\mathbf{x} \sim \mu}[f(\mathbf{x})g(\mathbf{x})] - \mathbf{E}_{\mathbf{x} \sim \mu}[f(\mathbf{x})] \mathbf{E}_{\mathbf{y} \sim \mu}[g(\mathbf{y})]$ , typically in terms of some measure of “how much  $f$  and  $g$  simultaneously depend on the same coordinates.” Our general approach establishes such a quantitative inequality in two main steps:

**Step 1:** For this step, we require an appropriate family of “noise operators”  $(T_\rho)_{\rho \in [0,1]}$  with respect to the measure  $\mu$ . Very briefly, each of these operators  $T_\rho$  will be a (re-indexed version of a) symmetric Markov semigroup whose stationary distribution is  $\mu$ ; this is defined more precisely in Section 4. (Looking ahead, we will see, for example, that in the case of the GCI, the appropriate noise operator is the Ornstein-Uhlenbeck noise operator, defined in Definition 18.) The crucial property we require of the family  $(T_\rho)_{\rho \in [0,1]}$  with respect to  $\mathcal{F}$  is what we refer to as *monotone compatibility*:

► **Definition 1** (Monotone compatibility). *A class of functions  $\mathcal{F}$  and background measure  $\mu$  is said to be monotone compatible with respect to a family of noise operators  $(T_\rho)_{\rho \in [0,1]}$  if (i) for all  $f, g \in \mathcal{F}$ , the function*

$$q(\rho) := \mathbf{E}_{\mathbf{x} \sim \mu}[f(\mathbf{x})T_\rho g(\mathbf{x})]$$

*is a non-decreasing function of  $\rho$ , and (ii) for  $\rho = 1$  we have  $T_1 = \text{Id}$  (the identity operator).*

The notion of monotone compatibility should be seen as a mild extension of qualitative correlation inequalities. As an example, in the case of the Gaussian Correlation Inequality, Royen’s proof [23] in fact shows that the family  $\mathcal{F}_{\text{csc}}$  is monotone compatible with Ornstein-Uhlenbeck operators.

**Step 2:** We express the operator  $T_\rho$  in terms of its eigenfunctions. In all the cases we consider in this paper, the eigenvalues of the operator  $T_\rho$  are  $\{\rho^j\}_{j \geq 0}$ . Let  $\{\mathcal{W}_j\}_{j \geq 0}$  be the corresponding eigenspaces. Consequently, we can express  $q(\rho) - q(0)$  as

$$q(\rho) - q(0) = \mathbf{E}_{\mathbf{x} \sim \mu}[f(\mathbf{x})T_\rho g(\mathbf{x})] - \mathbf{E}_{\mathbf{x} \sim \mu}[f(\mathbf{x})] \cdot \mathbf{E}_{\mathbf{y} \sim \mu}[g(\mathbf{y})] = \sum_{j > 0} \rho^j \mathbf{E}[f_j(\mathbf{x})g_j(\mathbf{x})], \quad (3)$$

where  $f_j$  (respectively  $g_j$ ) is the projection of  $f$  (respectively  $g$ ) on the space  $\mathcal{W}_j$ . To go back to our running example, for the Gaussian Correlation Inequality,  $\mathcal{W}_j$  is the subspace spanned by degree- $j$  Hermite polynomials on  $\mathbb{R}^n$ .

Define  $a_j := \mathbf{E}[f_j(\mathbf{x})g_j(\mathbf{x})]$ , so  $q(\rho) = \sum_{j \geq 0} a_j \rho^j$ . Now, corresponding to any family  $\mathcal{F}$  and noise operators  $(T_\rho)_{\rho \in [0,1]}$ , there will be a unique  $j^* \in \mathbb{N}$  such that the following properties hold:

1. If  $a_{j^*} = 0$ , then  $\mathbf{E}_{\mathbf{x} \sim \mu}[f(\mathbf{x})g(\mathbf{x})] = \mathbf{E}_{\mathbf{x} \sim \mu}[f(\mathbf{x})] \cdot \mathbf{E}_{\mathbf{y} \sim \mu}[g(\mathbf{y})]$ . In other words,  $a_{j^*}$  *qualitatively* captures the “slack” in the correlation inequality (in fact, as we will soon see,  $a_{j^*}$  also gives a quantitative lower bound on this slack). For example, for the Gaussian Correlation Inequality, it turns out that  $j^* = 2$  (for most of the other applications of our general framework in this paper, it turns out that  $j^* = 1$ ).
2. For any  $i$  such that  $j^*$  does not divide  $i$ ,  $a_i = 0$ .

<sup>1</sup> Since convexity is preserved under linear transformation, no loss of generality is incurred in assuming that the background measure is the standard normal distribution  $\mathcal{N}(0, 1)^n$  rather than an arbitrary centered Gaussian.

Now, from the fact that the spaces  $\{\mathcal{W}_j\}$  are orthonormal and the fact that every  $f \in \mathcal{F}$  has  $\mathbf{E}_\mu[f^2] \leq 1$ , it follows that  $\sum_{j>0} |a_j| \leq 1$ . Our main technical lemma, Lemma 12, implies (see the proof of Theorem 14) that for any such power series  $q(\cdot)$ , there exists some  $\rho^* \in [0, 1]$  such that

$$q(\rho^*) - q(0) \geq \frac{1}{C} \cdot \Phi(a_{j^*}).$$

The proof crucially uses tools from complex analysis. As the class  $\mathcal{F}$  is monotone compatible with the operators  $(T_\rho)_{\rho \in [0,1]}$ , recalling Equation (3), it follows that

$$q(1) - q(0) = \mathbf{E}_{\mathbf{x} \sim \mu} [f(\mathbf{x})g(\mathbf{x})] - \mathbf{E}_{\mathbf{x} \sim \mu} [f(\mathbf{x})] \cdot \mathbf{E}_{\mathbf{y} \sim \mu} [g(\mathbf{y})] \geq \frac{1}{C} \cdot \Phi(a_{j^*}), \quad (4)$$

which is the desired quantitative correlation inequality for  $\mathcal{F}$ .

► **Remark 2.** We emphasize the generality of our framework; the argument sketched above can be carried out in a range of different concrete settings. For example, by using the Harris-Kleitman qualitative correlation inequality for monotone Boolean functions in place of the GCI, and the Bonami-Beckner noise operator over  $\{0, 1\}^n$  in place of the Ornstein-Uhlenbeck noise operator, the above arguments give a simple proof of the following (slightly weaker) version of Talagrand’s correlation inequality (Equation (1)):

$$\mathbf{E}[fg] - \mathbf{E}[f] \mathbf{E}[g] \geq \frac{1}{C} \cdot \Phi \left( \sum_{i=1}^n \mathbf{Inf}_i[f] \mathbf{Inf}_i[g] \right), \quad (5)$$

for an absolute constant  $C > 0$ . While our bound is weaker than that of [26] by a log factor (recall the difference between  $\Psi$  and  $\Phi$ ), our methods are applicable to a much wider range of settings (such as the GCI and the other applications given in this paper). Finally, we emphasize that our proof strategy is really quite different from that of [26]; for example, [26]’s proof relies crucially on bounding the degree-2 Fourier weight of monotone Boolean functions by the degree-1 Fourier weight, whereas our strategy does not analyze the degree-2 spectrum of monotone Boolean functions at all.

► **Remark 3.** Coupled with the first property described above, Equation (4) shows that  $a_{j^*}$  not only qualitatively captures the “correlation gap”

$$\mathbf{E}_{\mathbf{x} \sim \mu} [f(\mathbf{x})g(\mathbf{x})] - \mathbf{E}_{\mathbf{x} \sim \mu} [f(\mathbf{x})] \cdot \mathbf{E}_{\mathbf{y} \sim \mu} [g(\mathbf{y})],$$

but also provides a quantitative lower bound on this gap.

## 2 Preliminaries

In this section we give preliminaries setting notation, recalling useful background on noise operators and orthogonal decomposition of functions over product spaces, and recalling a well-known result that we will require from complex analysis.

### 2.1 Noise Operators and Orthogonal Decompositions

Let  $(\Omega, \pi)$  be a probability space; we do not require  $\Omega$  to be finite, and we assume without loss of generality that  $\pi$  has full support.

The background we require for noise operators on functions in  $L^2(\Omega, \pi)$  is most naturally given using the language of “Markov semigroups.” Our exposition below will be self-contained; for a general and extensive resource on Markov semigroups, we refer the interested reader to [1].

► **Definition 4** (Markov semigroup). *A collection of linear operators  $(P_t)_{t \geq 0}$  on  $L^2(\Omega, \pi)$  is said to be a Markov semigroup if*

1.  $P_0 = \text{Id}$ ;
2. *for all  $s, t \in [0, \infty)$ , we have  $P_s \circ P_t = P_{s+t}$ ; and*
3. *for all  $t \in [0, \infty)$  and all  $f, g \in L^2(\Omega, \pi)$ , the following hold:*
  - a. Identity:  $P_t 1 = 1$  where 1 is the identically-1 function.
  - b. Positivity:  $P_t f \geq 0$  almost everywhere if  $f \geq 0$  almost everywhere.<sup>2</sup>

It is well known that a Markov semigroup can be constructed from a Markov process and vice versa [1]. We call a Markov semigroup *symmetric* if the underlying Markov process is time-reversible; the following definition is an alternative elementary characterization of symmetric Markov semigroups. (Recall that for  $f, g \in L^2(\Omega, \pi)$  the inner product  $\langle f, g \rangle$  is defined as  $\mathbf{E}_{\mathbf{x} \sim \pi}[f(\mathbf{x})g(\mathbf{x})]$ .)

► **Definition 5** (Symmetric Markov semigroup). *A Markov semigroup  $(P_t)_{t \geq 0}$  on  $L^2(\Omega, \pi)$  is symmetric if for all  $t \in [0, \infty)$ , the operator  $P_t$  is self-adjoint; equivalently, for all  $t \in [0, \infty)$  and all  $f, g \in L^2(\Omega, \pi)$ , we have  $\langle f, P_t g \rangle = \langle P_t f, g \rangle$ .*

We note that the families of noise operators  $(U_\rho)_{\rho \in [0,1]}$  and  $(T_\rho)_{\rho \in [0,1]}$  that we consider in Section 5 and Section 6 respectively will be parametrized by  $\rho \in [0, 1]$  where  $\rho = e^{-t}$  for  $t \in [0, \infty)$ , as is standard in theoretical computer science. (For example, the Bonami-Beckner noise operator  $T_\rho$  mentioned in the Introduction, which is a special case of the  $T_\rho$  operator defined in Section 6, corresponds to  $P_t$  for  $(P_t)_{t \geq 0}$  a suitable Markov semigroup and  $\rho = e^{-t}$ .)

Given a Markov semigroup  $(P_t)_{t \geq 0}$  on the probability space  $(\Omega, \pi)$ , we can naturally define the Markov semigroup  $(\otimes_{i=1}^n P_{t_i})_{t_i \geq 0}$  on  $L^2(\Omega^n, \pi^{\otimes n})$ . We write  $P_{\vec{t}}$  to denote this semigroup, and write  $P_t$  to denote the Markov semigroup  $(\otimes_{i=1}^n P_t)_{t \geq 0}$ . We next define a decomposition of  $L^2(\Omega^n, \pi^{\otimes n})$  that is particularly well-suited to the action of a Markov semigroup  $(P_t)_{t \geq 0}$ .

► **Definition 6** (Chaos decomposition). *Consider a Markov semigroup  $(P_t)_{t \geq 0}$  on  $L^2(\Omega^n, \pi^{\otimes n})$ . We call an orthogonal decomposition of*

$$L^2(\Omega^n, \pi^{\otimes n}) = \bigoplus_{i=0}^{\infty} \mathcal{W}_i$$

*a chaos decomposition with respect to the Markov semigroup  $(P_t)_{t \geq 0}$  if*

1.  $\mathcal{W}_0 = \text{span}(1)$  where 1 is the identically-1 function (i.e.  $\mathcal{W}_0 = \mathbb{R}$ ).
2. For all  $t \geq 0$ , there exists  $\lambda_t \in [0, 1]$  such that if  $f \in \mathcal{W}_i$ , then  $P_t f = \lambda_t^i f$ .
3. If  $t_1 > t_2$ , then  $\lambda_{t_1} < \lambda_{t_2}$ .

► **Remark 7.** The term “chaos decomposition” is used in the literature to describe the spectral decomposition of  $L^2(\mathbb{R}^n, \gamma)$  with respect to the Laplacian of the Ornstein–Uhlenbeck semigroup (see Proposition 19); its usage in the broader sense defined above is not standard (to our knowledge).

► **Remark 8.** Given an orthogonal decomposition  $L^2(\Omega^n, \pi^{\otimes n}) = \bigoplus_i \mathcal{W}_i$ , for  $f \in L^2(\Omega^n, \pi^{\otimes n})$  we will write  $f = \bigoplus_i f_i$  where  $f_i$  is the projection of  $f$  onto  $\mathcal{W}_i$ .

<sup>2</sup> Note that this implies the following *order* property: if  $f \geq g$  almost everywhere, then  $P_t f \geq P_t g$  almost everywhere.

We note that  $\lambda_0 = 1$ , and as  $1 \in \mathcal{W}_0$ , it follows that  $f_0 = \langle f, 1 \rangle$ . We revisit the definition of monotone compatibility given in the introduction in the language of Markov semigroups:

► **Definition 9** (Monotone compatibility). *Let  $(P_t)_{t \geq 0}$  be a Markov semigroup on  $L^2(\Omega^n, \pi^{\otimes n})$ . We say that  $(P_t)_{t \geq 0}$  is monotone compatible with a family of functions  $\mathcal{F} \subseteq L^2(\Omega^n, \pi^{\otimes n})$  if for all  $f, g \in \mathcal{F}$ , we have*

$$\frac{\partial}{\partial t} \langle P_t f, g \rangle \leq 0.$$

Recalling that our noise operators such as  $(T_\rho)_{\rho \in [0,1]}$  are reparameterized versions of the Markov semigroup operators  $(P_t)_{t \geq 0}$  under the reparameterization  $T_\rho = P_t$  with  $\rho = e^{-t}$ , and recalling item 1 in Definition 4, we see that Definition 9 coincides with Definition 1.

► **Example 10.** To provide intuition for Definition 9, a useful concrete example to consider is

- $\Omega = \{0, 1\}$  and  $\pi$  = the uniform distribution on  $\Omega$ , so  $L^2(\Omega^n, \pi^{\otimes n})$  is the space of all real-valued functions on the Boolean cube  $\{0, 1\}^n$  under the uniform distribution;
- $\mathcal{F}_{\text{mon}}$  = the class of all monotone Boolean functions, i.e. all  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  such that if  $x_i \leq y_i$  for all  $i$  then  $f(x) \leq f(y)$ ;
- $(P_t)_{t \geq 0}$  is defined by  $P_t = T_{e^{-t}}$ , where  $T_\rho$  is the Bonami-Beckner operator. We remind the reader that for any  $f : \{0, 1\}^n \rightarrow \mathbb{R}$  and any  $0 \leq \rho \leq 1$ , the function  $T_\rho f(x)$  is defined to be  $\mathbf{E}_{\mathbf{y} \sim N_\rho(x)}[f(\mathbf{y})]$ , where “ $\mathbf{y} \sim N_\rho(x)$ ” means that  $\mathbf{y} \in \{0, 1\}^n$  is randomly chosen by independently setting each  $\mathbf{y}_i$  to be  $x_i$  with probability  $\rho$  and to be uniform random with probability  $1 - \rho$ .

In this setting, as will be shown later, we have that for any two monotone functions  $f, g \in \mathcal{F}$ , the function  $\mathbf{E}_{\mathbf{x} \sim \{\pm 1\}^n}[T_\rho f(\mathbf{x})g(\mathbf{x})]$  is a non-decreasing function of  $\rho$ ; hence  $\frac{\partial}{\partial t} \mathbf{E}_{\mathbf{x} \sim \{\pm 1\}^n}[P_t f(\mathbf{x})g(\mathbf{x})]$  is always at most 0 (note that as  $t$  increases  $\rho = e^{-t}$  decreases), so  $(P_t)_{t \geq 0}$  is monotone compatible with  $\mathcal{F}_{\text{mon}}$ .

## 2.2 Complex Analysis

Let  $U \subseteq \mathbb{C}$  be a connected, open set. Recall that a function  $f : U \rightarrow \mathbb{C}$  is said to be *holomorphic* if at every point in  $U$  it is complex differentiable in a neighborhood of the point. For  $U$  a connected closed set,  $f$  is said to be holomorphic if it is holomorphic in an open set containing  $U$ . Our main technical lemma appeals to the following classical result, a proof of which can be found in [24].

► **Theorem 11** (Hadamard Three Circles Theorem). *Suppose  $f$  is holomorphic on the annulus  $\{z \in \mathbb{C} \mid r_1 \leq |z| \leq r_2\}$ . For  $r \in [r_1, r_2]$ , let  $M(r) := \max_{|z|=r} |f(z)|$ . Then*

$$\log \left( \frac{r_2}{r_1} \right) \log M(r) \leq \log \left( \frac{r_2}{r} \right) \log M(r_1) + \log \left( \frac{r}{r_1} \right) \log M(r_2).$$

## 3 A New Extremal Bound for Power Series with Bounded Length

Given a complex power series  $p(t) = \sum_{i=1}^{\infty} c_i t^i$  where  $c_i \in \mathbb{C}$ , its *length* is defined to be the sum of the absolute values of its coefficients, i.e.  $\sum_{i=1}^{\infty} |c_i|$ . Our main technical lemma is a lower bound on the sup-norm of complex power series with no constant term and bounded length:<sup>3</sup>

<sup>3</sup> The “3/2” in the lemma below could be replaced by any constant bounded above 1; we use 3/2 because it is convenient in our later application of Lemma 12.

► **Lemma 12** (Main technical lemma). *Let  $p(t) = \sum_{i=1}^{\infty} c_i t^i$  with  $c_1 = 1$  and  $\sum_{i=1}^{\infty} |c_i| \leq M$  where  $M \geq 3/2$ . Then:*

$$\sup_{t \in [0,1]} |p(t)| \geq \frac{\Theta(1)}{\log^2 M}.$$

The proof given below is inspired by arguments with a similar flavor in [3, 4], where the Hadamard Three Circles Theorem is used to prove various extremal bounds on polynomials.

**Proof.** Consider the meromorphic map (easily seen to have a single pole at  $z = 0$ ) given by

$$h(z) = A \left( z + \frac{1}{z} \right) + B,$$

which maps origin-centered circles to ellipses centered at  $B$ . Let  $0 < \delta < c$  be a parameter that we will fix later, where  $0 < c < 1$  is an absolute constant that will be specified later. We impose the following constraints on  $A$  and  $B$ :

$$-2A + B = \delta \quad \frac{17}{4}A + B = 1,$$

and note that these constraints imply that  $A = \frac{4(1-\delta)}{25}$  and  $B = \frac{8+17\delta}{25}$ .

We define three circles in the complex plane that we will use for the Hadamard Three Circles Theorem:

1. Let  $C_1$  be the circle centered at 0 with radius 1. Note that for all  $z \in C_1$ , the value  $h(z)$  is a real number in the interval  $[\delta, \frac{16+9\delta}{25}] \subseteq [\delta, 1]$ .
2. Let  $r > 1$  be such that  $h(-r) = 0$ , so  $r + \frac{1}{r} = \frac{8+17\delta}{4-4\delta} = 2 + \Theta(\delta)$  and hence  $r = 1 + \Theta(\sqrt{\delta})$ , which is less than 4. Define  $C_2$  to be the circle centered at 0 with radius  $r$ .
3. Let  $C_3$  be the circle centered at 0 with radius 4. Note that  $|h(z)| \leq 1$  for  $z \in C_3$ .

Define  $q(t) := \frac{p(t)}{t}$ . Note that  $q(0) = c_1 = 1$  and that for all  $z \in \mathbb{C}$  such that  $|z| \leq 1$ , we have  $|q(z)| \leq M$ . Define  $\psi(z) := q(h(z))$ . Note that  $\psi$  is holomorphic on  $\mathbb{C} \setminus \{0\}$ ; in particular, it is holomorphic on the annulus defined by  $C_1$  and  $C_3$ . Consequently, by Theorem 11, we have:

$$\log \left( \frac{4}{1} \right) \log \alpha(r) \leq \log \left( \frac{4}{r} \right) \log \alpha(1) + \log \left( \frac{r}{1} \right) \log \alpha(4)$$

with  $\alpha(r) := \sup_{|z|=r} |\psi(z)|$ . As  $h(-r) = 0$ , we have  $\psi(-r) = 1$  and so  $\log \alpha(r) \geq 0$ . Consequently, the left hand side of the above inequality is non-negative, which implies:

$$1 \leq \alpha(1)^{\log \left( \frac{4}{r} \right)} \cdot \alpha(4)^{\log r}.$$

As  $\log \left( \frac{4}{r} \right) = \Theta(1)$ ,  $\log r = \log \left( 1 + \Theta(\sqrt{\delta}) \right) = \Theta(\sqrt{\delta})$ , and  $\alpha(4) \leq M$ , we get:

$$1 \leq \alpha(1)^{\Theta(1)} \cdot M^{\Theta(\sqrt{\delta})}, \quad \text{and hence} \quad M^{-\Theta(\sqrt{\delta})} \leq \alpha(1).$$

By (i) and the definition of  $\alpha$ , we have:

$$\sup_{t \in [\delta, 1]} q(t) \geq M^{-\Theta(\sqrt{\delta})} \quad \text{and hence} \quad \sup_{t \in [0, 1]} p(t) \geq \sup_{\delta \in [0, 1]} \delta M^{-\Theta(\sqrt{\delta})}.$$

Setting  $\delta = \frac{\Theta(1)}{\log^2 M}$ , we get that

$$\sup_{t \in [0, 1]} |p(t)| \geq \frac{\Theta(1)}{\log^2 M},$$

and the lemma is proved. ◀

It is natural to wonder whether Lemma 12 is quantitatively tight. The polynomial  $p(t) = t(1-t)^{\log M}$  is easily seen to have length  $M$  and  $\sup_{t \in [0,1]} p(t) = \Theta(1/\log M)$ , and it is tempting to wonder whether this might be the smallest achievable value. However, it turns out that the  $1/\log^2 M$  dependence of Lemma 12 is in fact the best possible result; a proof of the following result can be found in the appendix to the full version of this paper.

▷ **Claim 13.** For sufficiently large  $M$ , there exists a real polynomial  $p(t) = \sum_{i=1}^d c_i t^i$  with  $c_1 = 1$  and  $\sum_{i=1}^d |c_i| \leq M$  such that

$$\sup_{t \in [0,1]} p(t) \leq O\left(\left(\frac{1}{\log M}\right)^2\right).$$

#### 4 A General Approach to Quantitative Correlation Inequalities

This section presents our general approach to obtaining *quantitative* correlation inequalities from *qualitative* correlation inequalities. While our main result, Theorem 14, is stated in an abstract setting, subsequent sections will instantiate this result in concrete settings that provided the initial impetus for this work. Section 5 deals with the setting of centrally symmetric, convex sets over Gaussian space, and Section 6 deals with finite product domains.

► **Theorem 14 (Main Theorem).** *Consider a symmetric Markov semigroup  $(P_t)_{t \geq 0}$  on  $L^2(\Omega^n, \Pi^{\otimes n})$  with a chaos decomposition*

$$L^2(\Omega^n, \Pi^{\otimes n}) = \bigoplus_{\ell} \mathcal{W}_{\ell}.$$

*Let  $(P_t)_{t \geq 0}$  be monotone compatible with  $\mathcal{F} \subseteq L^2(\Omega^n, \Pi^{\otimes n})$ , where  $\|f\| \leq 1$  for all  $f \in \mathcal{F}$ . Furthermore, suppose that there exists  $j^* \in \mathbb{N}_{>0}$  such that every  $f \in \mathcal{F}$  has a decomposition as*

$$f = \bigoplus_{\ell=0}^{\infty} f_{\ell \cdot j^*},$$

*i.e.  $f_{\ell} = 0$  for  $j^* \nmid \ell$ . Then for all  $f, g \in \mathcal{F}$ , we have*

$$\langle f, g \rangle - f_0 g_0 \geq \frac{1}{C} \cdot \Phi(\langle f_{j^*}, g_{j^*} \rangle), \quad (6)$$

*where recall from Equation (2) that  $\Phi : [0, 1] \rightarrow [0, 1]$  is  $\Phi(x) = \min\left\{x, \frac{x}{\log^2(1/x)}\right\}$  and  $C > 0$  is a universal constant.*

The proof of the above theorem uses an interpolating argument along the Markov semigroup, and appeals to Lemma 12 to obtain the lower bound.

**Proof of Theorem 14.** Fix  $f, g \in \mathcal{F}$  and let us write  $a_{\ell} := \langle f_{\ell}, g_{\ell} \rangle$ . It follows from Definition 6 that  $f_{\ell}, g_{\ell}$  are eigenfunctions of  $P_t$  with eigenvalue  $\lambda_t^{\ell}$ . This, together with the assumption that  $f = \bigoplus_{j^* \mid \ell} f_{\ell}$  and  $g = \bigoplus_{j^* \mid \ell} g_{\ell}$ , implies that for  $t > 0$  we have

$$\langle P_t f, g \rangle = \sum_{j^* \mid \ell} \lambda_t^{\ell} \langle f_{\ell}, g_{\ell} \rangle = \sum_{j^* \mid \ell} a_{\ell} \lambda_t^{\ell}. \quad (7)$$

Here we remark that the argument to  $\Phi(\cdot)$  in the right hand side of Equation (6) is non-negative, i.e.  $a_{j^*} \geq 0$ . To see this, observe that

$$a_{j^*} = \frac{\partial}{\partial \lambda_t^{j^*}} \langle P_t f, g \rangle = \frac{\partial}{\partial t} \langle P_t f, g \rangle \cdot \frac{\partial t}{\partial \lambda_t^{j^*}} \geq 0$$

where we used the monotone compatibility of  $\mathcal{F}$  with  $(P_t)_{t \geq 0}$  and Property 3 of Definition 6.

Returning to Equation (7), rearranging terms gives that

$$\langle P_t f, g \rangle - f_0 g_0 = \sum_{\substack{\ell \geq 0 \\ j^* | \ell}} a_\ell \lambda_t^\ell = a_{j^*} p(\lambda_t^{j^*}), \quad \text{where} \quad p(\lambda_t^{j^*}) := \lambda_t^{j^*} + \frac{1}{a_{j^*}} \sum_{\substack{\ell \geq j^* \\ j^* | \ell}} a_\ell \lambda_t^\ell. \quad (8)$$

As  $\lambda_t \in [0, 1]$ , we re-parametrize  $u := \lambda_t^{j^*}$  and write  $b_\ell := \frac{a_{\ell j^*}}{a_{j^*}}$  for ease of notation; this gives us

$$p(u) = u + \sum_{\ell \geq 2} b_\ell u^\ell.$$

By the Cauchy–Schwarz inequality, we have

$$a_\ell^2 = \langle f_\ell, g_\ell \rangle^2 \leq \langle f_\ell, f_\ell \rangle \langle g_\ell, g_\ell \rangle = \|f_\ell\|^2 \|g_\ell\|^2, \quad \text{and hence} \quad |a_\ell| \leq \|f_\ell\| \|g_\ell\|.$$

Once again using the Cauchy–Schwarz inequality, we get

$$\sum_\ell |a_\ell| \leq \sum_{\ell=0} \|f_\ell\| \cdot \|g_\ell\| \leq \sqrt{\left( \sum_\ell \|f_\ell\|^2 \right) \cdot \left( \sum_\ell \|g_\ell\|^2 \right)} \leq 1$$

where the last inequality follows from the assumption that  $\|f\| \leq 1$  for all  $f \in \mathcal{F}$ . This implies that

$$\sum_\ell |b_\ell| = \frac{1}{|a_{j^*}|} \sum_\ell |a_{\ell j^*}| \leq \frac{1}{|a_{j^*}|} = \frac{1}{a_{j^*}}.$$

where the last equality holds because of  $a_{j^*} \geq 0$  as shown earlier. If  $a_{j^*} > 2/3$  then  $\sum_{\ell \geq 2} |b_\ell| \leq 1/2$  while  $b_1 = 1$ , from which it easily follows that  $\sup_{u \in [0,1]} p(u) \geq 1/2$ . If  $a_{j^*} < 2/3$  then the power series  $p(u)$  satisfies the assumptions of Lemma 12 with  $M = \frac{1}{a_{j^*}}$ . This gives us

$$\sup_{u \in [0,1]} p(u) \geq \min \left\{ \frac{1}{2}, \Theta \left( \frac{1}{\log^2(a_{j^*}^{-1})} \right) \right\}.$$

It follows from Definition 6 that as  $t$  ranges over  $(0, \infty)$ ,  $\lambda_t$  and consequently  $u$  ranges over the interval  $(0, 1]$ . Together with Equation (8), this implies that

$$\sup_{t \in (0, \infty)} \langle P_t f, g \rangle - f_0 g_0 = \sup_{t \in (0, \infty)} a_{j^*} \cdot p(\lambda_t) = a_{j^*} \cdot \sup_{u \in (0, 1]} p(u) \geq \Theta \left( \min \left\{ a_{j^*}, \frac{a_{j^*}}{\log^2(a_{j^*}^{-1})} \right\} \right).$$

However, because of monotone compatibility, we have that  $\langle P_t f, g \rangle$  is decreasing in  $t$ . As  $P_0 = \text{Id}$ , we can conclude that

$$\langle f, g \rangle - f_0 g_0 \geq \Theta \left( \min \left\{ a_{j^*}, \frac{a_{j^*}}{\log^2(a_{j^*}^{-1})} \right\} \right),$$

which completes the proof. ◀

## 5 A Quantitative Extension of the Gaussian Correlation Inequality

In this section, we prove a quantitative versions of Royen’s Gaussian Correlation Inequality (GCI) [23] for symmetric convex sets. We start by recalling some elementary facts about harmonic analysis over Gaussian space in Section 5.1, after which we derive our “robust” form of the Gaussian Correlation Inequality in Section 5.2 as a consequence of Theorem 14. In Section 5.3 we discuss how our robust GCI can be viewed as a Gaussian-space analogue of Talagrand’s celebrated correlation inequality for monotone Boolean functions over the Boolean hypercube [26]. We analyze the tightness of our robust GCI in Section 5.4.

### 5.1 Harmonic (Hermite) Analysis over Gaussian space

Our notation and terminology presented in this subsection follows Chapter 11 of [21]. We say that an  $n$ -dimensional *multi-index* is a tuple  $\alpha \in \mathbb{N}^n$ , and we define

$$\text{supp}(\alpha) := \{i : \alpha_i \neq 0\}, \quad \#\alpha := |\text{supp}(\alpha)|, \quad |\alpha| := \sum_{i=1}^n \alpha_i. \quad (9)$$

We write  $\mathcal{N}(0,1)^n$  to denote the  $n$ -dimensional standard Gaussian distribution. For  $n \in \mathbb{N}_{>0}$ , we write  $L^2(\mathbb{R}^n, \gamma)$  to denote the space of functions  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  that have finite 2<sup>nd</sup> moment  $\|f\|_2^2$  under the standard Gaussian measure  $\gamma$ , that is:

$$\|f\|_2^2 = \mathbf{E}_{\mathbf{z} \sim \mathcal{N}(0,1)^n} [f(\mathbf{z})^2]^{1/2} < \infty.$$

We view  $L^2(\mathbb{R}^n, \gamma)$  as an inner product space with  $\langle f, g \rangle := \mathbf{E}_{\mathbf{z} \sim \mathcal{N}(0,1)^n} [f(\mathbf{z})g(\mathbf{z})]$  for  $f, g \in L^2(\mathbb{R}^n, \gamma)$ . We recall the “Hermite basis” for  $L^2(\mathbb{R}, \gamma)$ :

► **Definition 15** (Hermite basis). *The Hermite polynomials  $(h_j)_{j \in \mathbb{N}}$  are the univariate polynomials defined as*

$$h_j(x) = \frac{(-1)^j}{\sqrt{j!}} \exp\left(\frac{x^2}{2}\right) \cdot \frac{d^j}{dx^j} \exp\left(-\frac{x^2}{2}\right).$$

► **Proposition 16** (Proposition 11.33, [21]). *The Hermite polynomials  $(h_j)_{j \in \mathbb{N}}$  form a complete, orthonormal basis for  $L^2(\mathbb{R}, \gamma)$ . For  $n > 1$  the collection of  $n$ -variate polynomials given by  $(h_\alpha)_{\alpha \in \mathbb{N}^n}$  where*

$$h_\alpha(x) := \prod_{i=1}^n h_{\alpha_i}(x)$$

*forms a complete, orthonormal basis for  $L^2(\mathbb{R}^n, \gamma)$ .*

Given a function  $f \in L^2(\mathbb{R}^n, \gamma)$  and  $\alpha \in \mathbb{N}^n$ , we define its *Hermite coefficient on  $\alpha$*  as  $\tilde{f}(\alpha) = \langle f, h_\alpha \rangle$ . It follows that  $f$  is uniquely expressible as  $f = \sum_{\alpha \in \mathbb{N}^n} \tilde{f}(\alpha) h_\alpha$  with the equality holding in  $L^2(\mathbb{R}^n, \gamma)$ ; we will refer to this expansion as the *Hermite expansion* of  $f$ . One can check that Parseval’s and Plancharel’s identities hold in this setting.

► **Proposition 17** (Plancharel’s identity). *For  $f, g \in L^2(\mathbb{R}^n, \gamma)$ , we have:*

$$\langle f, g \rangle = \mathbf{E}_{\mathbf{z} \sim \mathcal{N}(0,1)^n} [f(\mathbf{z})g(\mathbf{z})] = \sum_{\alpha \in \mathbb{N}^n} \tilde{f}(\alpha) \tilde{g}(\alpha),$$

*and as a special case we have Parseval’s identity,*

$$\langle f, f \rangle = \mathbf{E}_{\mathbf{z} \sim \mathcal{N}(0,1)^n} [f(\mathbf{z})^2] = \sum_{\alpha \in \mathbb{N}^n} \tilde{f}(\alpha)^2.$$

Next we recall the standard Gaussian noise operator (parameterized so that the noise rate  $\rho$  ranges over  $[0, 1]$ ):

► **Definition 18** (Ornstein-Uhlenbeck semigroup). *We define the Ornstein-Uhlenbeck semigroup as the family of operators  $(U_\rho)_{\rho \in [0,1]}$  on the space of functions  $f \in L^1(\mathbb{R}^n, \gamma)$  given by*

$$U_\rho f(x) := \mathbf{E}_{\mathbf{g} \sim \mathcal{N}(0,1)^n} \left[ f\left(\rho \cdot x + \sqrt{1-\rho} \cdot \mathbf{g}\right) \right].$$

The Ornstein-Uhlenbeck semigroup is sometimes referred to as the family of *Gaussian noise operators* or *Mehler transforms*. The Ornstein-Uhlenbeck semigroup acts on the Hermite expansion as follows:

► **Proposition 19** (Proposition 11.33, [21]). *For  $f \in L^2(\mathbb{R}^n, \gamma)$ , the function  $U_\rho f$  has Hermite expansion*

$$U_\rho f = \sum_{\alpha \in \mathbb{N}^n} \rho^{|\alpha|} \tilde{f}(\alpha) h_\alpha.$$

## 5.2 A Robust Extension of the Gaussian Correlation Inequality

We start by making a crucial observation regarding Royen's proof of the Gaussian correlation inequality (GCI) [23]. Recall that the GCI states that if  $K$  and  $L$  are the indicator functions of two centrally symmetric (i.e.  $K(x) = 1$  implies  $K(-x) = 1$ ), convex sets, then they are non-negatively correlated under the Gaussian measure; that is,

$$\mathbf{E}_{\mathbf{x} \sim \mathcal{N}(0,1)^n} [K(\mathbf{x})L(\mathbf{x})] - \mathbf{E}_{\mathbf{x} \sim \mathcal{N}(0,1)^n} [K(\mathbf{x})] \mathbf{E}_{\mathbf{y} \sim \mathcal{N}(0,1)^n} [K(\mathbf{y})] \geq 0.$$

In order to prove this, Royen interpolates between  $\mathbf{E}[K] \mathbf{E}[L]$  and  $\mathbf{E}[KL]$  via the Ornstein-Uhlenbeck semigroup, and shows that this interpolation is monotone nondecreasing; indeed, note that

$$\langle U_1 K, L \rangle = \mathbf{E}_{\mathbf{x} \sim \mathcal{N}(0,1)^n} [K(\mathbf{x})L(\mathbf{x})], \quad \text{and that} \quad \langle U_0 K, L \rangle = \mathbf{E}_{\mathbf{x} \sim \mathcal{N}(0,1)^n} [K(\mathbf{x})] \mathbf{E}_{\mathbf{y} \sim \mathcal{N}(0,1)^n} [K(\mathbf{y})].$$

Thus, Royen's main result can be interpreted as follows (we refer the interested reader to a simplified exposition of Royen's proof by Latała and Matlak [20] for further details):

► **Proposition 20** (Royen's Theorem, [23]). *Let  $\mathcal{F}_{\text{csc}} \subseteq L^2(\mathbb{R}^n, \gamma)$  be the family of indicators of centrally symmetric, convex sets, and let  $(U_\rho)_{\rho \in [0,1]}$  be the Ornstein-Uhlenbeck semigroup. Then for  $K, L \in \mathcal{F}_{\text{csc}}$ , we have*

$$\frac{\partial}{\partial \rho} \langle U_\rho K, L \rangle \geq 0 \quad \text{for all } 0 < \rho < 1.$$

In particular,  $\mathcal{F}_{\text{csc}}$  is monotone compatible with  $(U_\rho)_{\rho \in [0,1]}$ .

Recall that we are parametrizing the Ornstein-Uhlenbeck semigroup by  $\rho \in [0, 1]$  where  $\rho = e^{-t}$  for  $t \in [0, \infty)$ ; see the discussion following Definition 4. We can now state our main result:

► **Theorem 21** (Quantitative GCI). *Let  $\mathcal{F}_{\text{csc}} \subseteq L^2(\mathbb{R}^n, \gamma)$  be the family of indicators of centrally symmetric, convex sets. Then for  $K, L \in \mathcal{F}_{\text{csc}}$ , we have*

$$\mathbf{E}[KL] - \mathbf{E}[K] \mathbf{E}[L] \geq \frac{1}{C} \cdot \Phi \left( \sum_{|\alpha|=2} \tilde{K}(\alpha) \tilde{L}(\alpha) \right)$$

where recall from Equation (2) that  $\Phi : [0, 1] \rightarrow [0, 1]$  is  $\Phi(x) = \min \left\{ x, \frac{x}{\log^2(1/x)} \right\}$  and  $C > 0$  is a universal constant.

**Proof.** Consider the orthogonal decomposition

$$L^2(\mathbb{R}^n, \gamma) = \bigoplus_{i=0}^{\infty} \mathcal{W}_i$$

where  $\mathcal{W}_i = \text{span}\{h_\alpha : |\alpha| = i\}$ ; the orthogonality of this decomposition follows from Proposition 16. From Proposition 19, it follows that this decomposition is in fact a chaos decomposition (recall Definition 6) with respect to the Ornstein-Uhlenbeck semigroup  $(U_\rho)_{\rho \in [0,1]}$ .

If  $K \in \mathcal{F}_{\text{csc}}$ , then  $K(x) = K(-x)$  as  $K$  is the indicator of a centrally symmetric set; in other words,  $K$  is an even function. Consequently, its Hermite expansion is given by

$$K = \bigoplus_{\substack{i=0 \\ |\alpha|=2i}}^{\infty} h_\alpha.$$

Furthermore, from Proposition 17, we have that

$$\|K\|^2 = \sum_{\alpha \in \mathbb{N}^n} \tilde{K}(\alpha)^2 = \mathbf{E}[K^2] \leq 1.$$

It follows that the hypotheses of Theorem 14 hold for  $\mathcal{F}_{\text{csc}}$  with  $j^* = 2$ ; consequently, for  $K, L \in \mathcal{F}_{\text{csc}}$  we have

$$\langle U_1 K, L \rangle - \langle U_0 K, L \rangle = \mathbf{E}[KL] - \mathbf{E}[K] \mathbf{E}[L] \geq \frac{1}{C} \cdot \Phi \left( \sum_{|\alpha|=2} \tilde{K}(\alpha) \tilde{L}(\alpha) \right),$$

which completes the proof of the theorem.  $\blacktriangleleft$

It is natural to ask whether Theorem 21 can be extended to a broader class of functions than 0/1-valued indicator functions of centrally symmetric, convex sets  $\mathcal{F}_{\text{csc}}$ . Indeed, the GCI implies the monotone compatibility of centrally symmetric, *quasiconcave*<sup>4</sup>, non-negative functions (which is a larger family of functions than  $\mathcal{F}_{\text{csc}}$ ) with the Ornstein-Uhlenbeck semigroup. This allows us to once again use Theorem 14 to obtain a quantitative correlation inequality for this family of functions; we defer this to the full version of this paper.

### 5.3 Interpreting Theorem 21

Recall Talagrand's correlation inequality [26]: If  $f, g : \{0, 1\}^n \rightarrow \{0, 1\}$  are monotone Boolean functions, then

$$\mathbf{E}[fg] - \mathbf{E}[f] \mathbf{E}[g] \geq \frac{1}{C} \cdot \Psi \left( \sum_{i=1}^n \hat{f}(i) \hat{g}(i) \right)$$

where  $\Psi(x) = \frac{x}{\log(e/x)}$ . However (see Chapter 2 of [21]), for monotone  $f : \{+1, -1\}^n \rightarrow \{+1, -1\}$ , we have  $\hat{f}(i) = \mathbf{Inf}_i[f]$  where

$$\mathbf{Inf}_i[f] := \mathbf{Pr}_{\mathbf{x} \sim \{+1, -1\}^n} [f(\mathbf{x}) \neq f(\mathbf{x}^{\oplus i})].$$

<sup>4</sup> A function  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  is *quasiconcave* if for all  $\lambda \in [0, 1]$  we have  $f(\lambda x + (1 - \lambda)y) \geq \min\{f(x), f(y)\}$ .

In other words, the degree-1 Fourier coefficient  $\widehat{f}(i)$  captures the “dependence” of  $f$  on its  $i^{\text{th}}$  coordinate, and the quantity  $\sum_{i=1}^n \widehat{f}(i)\widehat{g}(i)$  captures the extent to which “both  $f$  and  $g$  simultaneously depend on the same coordinates”. This intuitively explains why it is plausible for such a quantity to appear in Talagrand’s inequality.

Inspired by the resemblance between our quantitative Gaussian correlation inequality and Talagrand’s correlation inequality, we believe that the (negated) degree-2 Hermite coefficients of centrally symmetric, convex sets over Gaussian space are natural analogues of the degree-1 Fourier coefficients (i.e. the coordinate influences) of monotone Boolean functions. However, while functions on the Boolean hypercube have influences only along  $n$  “directions”, there are infinitely many directions over Gaussian space. We make the following definition:

► **Definition 22** (Influences for  $\mathcal{F}_{\text{csc}}$ ). *Let  $K \subseteq \mathbb{R}^n$  be a centrally symmetric, convex set. Given a unit vector  $v \in S^{n-1}$ , we define the influence of  $K$  along direction  $v$  as*

$$\mathbf{Inf}_v[K] := -\widetilde{K}(2v) = \mathbf{E}_{\mathbf{x} \sim \mathcal{N}(0,1)^n} [-K(\mathbf{x})h_2(v \cdot \mathbf{x})]$$

where  $h_2(x) = \frac{x^2-1}{\sqrt{2}}$  is the degree-2 univariate Hermite polynomial (see Section 11.2 of [21]).

It follows from the proof of Theorem 14 that the quantity  $\sum_{|\alpha|=2} \widetilde{K}(\alpha)\widetilde{L}(\alpha)$  for  $K, L \in \mathcal{F}_{\text{csc}}$  is non-negative. In fact more is true: if  $K$  is a centrally symmetric, convex set, then each  $\mathbf{Inf}_{e_i}[K]$  is itself non-negative. The proof of the following proposition can be found in the appendix to the full version of this paper.

► **Proposition 23** (Influences are non-negative). *If  $K$  is a centrally symmetric, convex set, then  $\mathbf{Inf}_v[K] \geq 0$  for all  $v \in S^{n-1}$ , with equality holding if and only if  $K(x) = K(y)$  whenever  $x_{v^\perp} = y_{v^\perp}$  (the projection of  $x$  orthogonal to  $v$  coincides with that of  $y$ ), except possibly on a set of measure zero.*

It is natural to define the “total influence of  $K$ ” to be  $\mathbf{Inf}[K] := \sum_{i=1}^n \mathbf{Inf}_{e_i}[K]$ ; we observe that this quantity is given by

$$\mathbf{Inf}[K] = -\sum_{i=1}^n \widetilde{K}(2e_i) = \frac{\mathbf{E}_{\mathbf{x} \sim \mathcal{N}(0,1)^n} [-f(\mathbf{x}) \cdot (\|\mathbf{x}\|^2 - n)]}{\sqrt{2}},$$

and hence it is invariant under orthogonal transformations (i.e. any orthonormal basis  $v_1, \dots, v_n$  could have been used in place of  $e_1, \dots, e_n$  in defining  $\mathbf{Inf}[K]$ ).

The above discussion suggests that the notion of “influences” for centrally symmetric, convex sets in Gaussian space proposed in Definition 22 is indeed “influence-like”. A forthcoming paper [5] will further explore this notion.

## 5.4 On the Tightness of Theorem 21

In [26], Talagrand gave the following family of example functions for which Equation (1) is tight up to constant factors: let  $f, g : \{0, 1\}^n \rightarrow \{0, 1\}$  be given by

$$f(x) = \begin{cases} 1 & \sum_i x_i \geq n - k \\ 0 & \text{otherwise} \end{cases}, \quad \text{and} \quad g(x) = \begin{cases} 1 & \sum_i x_i > k \\ 0 & \text{otherwise} \end{cases}$$

where  $k \leq n/2$ . Writing  $\epsilon$  to denote  $\mathbf{E}[f]$ , we have  $\epsilon^2 = \epsilon - \epsilon(1 - \epsilon) = \mathbf{E}[fg] - \mathbf{E}[f]\mathbf{E}[g]$ , and it can be shown that  $\Psi\left(\sum_{i=1}^n \widehat{f}(i)\widehat{g}(i)\right) = \Theta(\epsilon^2)$ , so Equation (1) is tight up to constant factors. We note that in this example  $f$  and  $g$  are the indicator functions of Hamming balls, and that  $f \subseteq g$  (i.e.  $f(x) = 1$  implies that  $g(x) = 1$ ).

Motivated by this example, we consider an analogous pair of functions in the setting of centrally symmetric, convex sets over Gaussian space, where we use origin-centered balls of different radii in place of Hamming balls. In particular, let  $K, L \in \mathcal{F}_{\text{csc}}$  be  $n$ -dimensional origin-centered balls of radii  $r_1$  and  $r_2$  respectively such that  $r_1 < r_2$  with

$$\mathbf{E}[K] = \epsilon \quad \text{and} \quad \mathbf{E}[L] = 1 - \epsilon$$

where the expectations are taken with respect to the  $n$ -dimensional Gaussian measure. As  $K \subseteq L$ , we have  $\mathbf{E}[KL] - \mathbf{E}[K]\mathbf{E}[L] = \epsilon - \epsilon(1 - \epsilon) = \epsilon^2$ . Since  $K(x_1, \dots, x_n) = K(x_1, \dots, x_{i-1}, -x_i, x_{i+1}, \dots, x_n)$  for all  $x \in \mathbb{R}^n$  and all  $i \in [n]$ , it easily follows that  $\tilde{K}(e_i + e_j) = \mathbf{E}[K(\mathbf{x})\mathbf{x}_i\mathbf{x}_j] = 0$  for all  $i \neq j$ , and the same is true for  $L$ . Furthermore, as  $K, L$  are rotationally invariant, we have  $\tilde{K}(2e_i) = \tilde{K}(2e_j)$  and  $\tilde{L}(2e_i) = \tilde{L}(2e_j)$  for all  $i, j \in [n]$ . It follows that

$$-\sum_{|\alpha|=2} \tilde{K}(\alpha) = -\sum_{i=1}^n \tilde{K}(2e_i) = \frac{1}{\sqrt{2}} \mathbf{E}_{\mathbf{x} \sim \mathcal{N}(0,1)^n} [K(\mathbf{x}) (n - \|\mathbf{x}\|^2)].$$

An application of the Berry-Esseen Central Limit Theorem (see [2, 6] or, for example, Section 11.5 of [21]) together with standard anti-concentration bounds on Gaussian tails (we omit the details here; a complete calculation can be found in the full version of this paper) gives that

$$\mathbf{E}_{\mathbf{x} \sim \mathcal{N}(0,1)^n} [K(\mathbf{x}) (n - \|\mathbf{x}\|^2)] = \Omega\left(\epsilon \sqrt{n \ln\left(\frac{2}{\epsilon}\right)}\right).$$

A similar calculation for  $L$  gives that  $-\tilde{L}(2e_i) = \Omega\left(\epsilon \sqrt{\frac{1}{n} \ln\left(\frac{2}{\epsilon}\right)}\right)$ , from which it follows that  $\sum_{i=1}^n \tilde{K}(2e_i) \tilde{L}(2e_i) = \Omega(\epsilon^2 \ln(\frac{2}{\epsilon}))$ . Recalling Equation (2), we get that for small enough  $\epsilon$ , the quantity

$$\Phi\left(\sum_{|\alpha|=2} \tilde{K}(\alpha) \tilde{L}(\alpha)\right) = \Omega\left(\frac{\epsilon^2}{\log(2/\epsilon)}\right),$$

which lets us conclude that Theorem 21 is tight to within a logarithmic factor.

## 6 Generalizing Talagrand's Inequality to Arbitrary Finite Product Domains

The main result of this section, Theorem 29, is an extension of Talagrand's correlation inequality [26] to real-valued functions on general, finite, product spaces. (Recall that Talagrand's inequality applies only to Boolean-valued functions on the domain  $\{0, 1\}^n$  under the uniform distribution.)

### 6.1 Harmonic Analysis over Finite Product Spaces

Our notation and terminology presented in this subsection follows Chapter 8 of [21]. We use multi-index notation for  $\alpha \in \mathbb{N}^n$  as defined in Equation (9).

Let  $(\Omega, \pi)$  be a finite probability space with  $|\Omega| = m \geq 2$ , where we always assume that the distribution  $\pi$  over  $\Omega$  has full support (i.e.  $\pi(\omega) > 0$  for every  $\omega \in \Omega$ ). We write  $L^2(\Omega^n, \pi^{\otimes n})$  for the real inner product space of functions  $f : \Omega^n \rightarrow \mathbb{R}$ , with inner product  $\langle f, g \rangle := \mathbf{E}_{\mathbf{x} \sim \pi^{\otimes n}} [f(\mathbf{x})g(\mathbf{x})]$ .

It is easy to see that there exists an orthonormal basis for the inner product space  $L^2(\Omega, \pi)$ , i.e. a set of functions  $\phi_0, \dots, \phi_{m-1} : \Omega \rightarrow \mathbb{R}$ , with  $\phi_0 = 1$ , that are orthonormal with respect to  $\pi$ . Moreover, such a basis extends to an orthonormal basis for  $L^2(\Omega^n, \pi^{\otimes n})$  by a straightforward  $n$ -fold product construction: given a multi-index  $\alpha \in \mathbb{N}_{<m}^n$ , if we define  $\phi_\alpha \in L^2(\Omega^n, \pi^{\otimes n})$  as

$$\phi_\alpha(x) := \prod_{i=1}^n \phi_{\alpha_i}(x_i),$$

then the collection  $(\phi_\alpha)_{\alpha \in \mathbb{N}_{<m}^n}$  is an orthonormal basis for  $L^2(\Omega^n, \pi^{\otimes n})$  (see Proposition 8.13 of [21]). So every function  $f : \Omega^n \rightarrow \mathbb{R}$  has a decomposition

$$f = \sum_{\alpha \in \mathbb{N}_{<m}^n} \hat{f}(\alpha) \phi_\alpha. \quad (10)$$

This can be thought of as a “Fourier decomposition” for  $f$ , in that it satisfies both Parseval’s and Plancherel’s identities (see Proposition 8.16 of [21]). We now proceed to define a noise operator for finite product spaces.

► **Definition 24** (Noise operator for finite product spaces). *Fix a finite product probability space  $L^2(\Omega^n, \pi^{\otimes n})$ . For  $\rho \in [0, 1]$  we define the noise operator for  $L^2(\Omega^n, \pi^{\otimes n})$  as the linear operator*

$$T_\rho f(x) := \mathbf{E}_{\mathbf{y} \sim N_\rho(x)}[f(\mathbf{y})],$$

where “ $\mathbf{y} \sim N_\rho(x)$ ” means that  $\mathbf{y} \in \Omega^n$  is randomly chosen as follows: for each  $i \in [n]$ , with probability  $\rho$  set  $\mathbf{y}_i$  to be  $x_i$  and with the remaining  $1 - \rho$  probability set  $\mathbf{y}_i$  by independently making a draw from  $\pi$ .

► **Proposition 25** (Proposition 8.28 of [21]). *We have  $T_\rho f = \sum_{\alpha} \rho^{\#\alpha} \hat{f}(\alpha) \phi_\alpha$ .*

## 6.2 A Quantitative Correlation Inequality for Finite Product Domains

Throughout this subsection, let  $\Omega = \{0, 1, \dots, m-1\}$  endowed with the natural ordering (though any  $m$ -element totally ordered set would do). We will consider monotone functions on  $(\Omega^n, \pi^{\otimes})$ ; while our results hold in the more general setting of functions on  $(\Omega^n, \otimes_{i=1}^n \pi_i)$ , we stick to the setting of  $L^2(\Omega^n, \pi^{\otimes n})$  for ease of exposition.

In order to appeal to Theorem 14, we must first show that the family of monotone (nondecreasing) functions on  $\Omega^n$  is monotone compatible with the Bonami–Beckner noise operator (see Definition 24). To this end, we define noise operators that act on each coordinate of the input:

► **Definition 26** (coordinate-wise noise operators). *Let  $T_\rho^i$  be the operator on functions  $f : \Omega^n \rightarrow \mathbb{R}$  defined by*

$$T_\rho^i f(x) = \mathbf{E}_{\mathbf{y} \sim N_\rho(x_i)}[f(x_1, \dots, \mathbf{y}, \dots, x_n)],$$

and define  $T_{\rho_1, \dots, \rho_n} f := T_{\rho_1}^1 \circ T_{\rho_2}^2 \circ \dots \circ T_{\rho_n}^n f$ .

This is well-defined as the operators  $T_{\rho_i}^i$  and  $T_{\rho_j}^j$  commute.

► **Lemma 27.** *Let  $\Omega = \{0, 1, \dots, m-1\}$  and let  $f : \Omega^n \rightarrow \mathbb{R}$  be a monotone function. Then  $T_\rho^i f : \Omega^n \rightarrow \mathbb{R}$  is a monotone function.*

**Proof.** Suppose  $x, y \in \Omega^n$  are such that  $x_i \leq y_i$  for all  $i \in [n]$ . We wish to show that  $T_\rho^i f(x) \leq T_\rho^i f(y)$ , which is equivalent to showing

$$\mathbf{E}_{z \sim N_\rho(x_i)} [f(x^{i \rightarrow z})] \leq \mathbf{E}_{z \sim N_\rho(y_i)} [f(y^{i \rightarrow z})].$$

Indeed, because of the monotonicity of  $f$ , via the natural coupling we have

$$\begin{aligned} \mathbf{E}_{z \sim N_\rho(x_i)} [f(x^{i \rightarrow z})] &= \delta f(x) + (1 - \delta) \mathbf{E}_{z \sim \Omega^n} [f(x^{i \rightarrow z})] \\ &\leq \delta f(y) + (1 - \delta) \mathbf{E}_{z \sim \Omega^n} [f(y^{i \rightarrow z})] = \mathbf{E}_{z \sim N_\rho(y_i)} [f(y^{i \rightarrow z})]. \quad \blacktriangleleft \end{aligned}$$

► **Lemma 28.** Let  $\Omega = \{0, 1, \dots, m-1\}$  and let  $f, g : \Omega^n \rightarrow \mathbb{R}$  be monotone functions. Then  $\langle T_\rho f, g \rangle$  is nondecreasing in  $\rho \in [0, 1]$ .

**Proof.** We have

$$\langle T_{\rho_1, \dots, \rho_n} f, g \rangle = \langle T_{\rho_1, \dots, 1} f, T_{1, \rho_2, \dots, \rho_n} g \rangle = \langle T_{\rho_1}^1 f, h \rangle$$

where  $h := T_{1, \rho_2, \dots, \rho_n} g$ . It follows from a repeated application of Lemma 27 that  $h$  is monotone. Now, note that

$$\langle T_{\rho_1}^1 f, h \rangle = \hat{f}(\bar{0}) \cdot \hat{h}(\bar{0}) + \sum_{\alpha_1 > 0} \rho_1 \hat{f}(\alpha) \hat{h}(\alpha) + \sum_{\substack{\bar{0} \neq \alpha \\ \alpha_1 = 0}} \hat{f}(\alpha) \hat{h}(\alpha)$$

where  $\bar{0} = (0, \dots, 0)$ . By Cheybshev's order inequality, we know that  $\langle T_1^1 f, h \rangle \geq \langle T_0^1 f, h \rangle = \hat{f}(\bar{0}) \cdot \hat{h}(\bar{0}) + \sum_{\bar{0} \neq \alpha, \alpha_1 = 0} \hat{f}(\alpha) \hat{h}(\alpha)$ . From the above expression, we have:

$$\frac{\partial}{\partial \rho_1} \langle T_{\rho_1}^1 f, h \rangle = \sum_{\alpha_1 > 0} \hat{f}(\alpha) \hat{h}(\alpha)$$

which must be nonnegative since  $\langle T_1^1 f, h \rangle \geq \langle T_0^1 f, h \rangle$ , and so we can conclude that  $\langle T_{\rho_1}^1 f, h \rangle$  is nondecreasing in  $\rho_1$ . The result then follows by repeating this for each coordinate. ◀

Let  $\mathcal{F}_{\text{mon}} \subseteq L^2(\Omega^n, \pi^{\otimes n})$  be the family of monotone functions  $f : \Omega^n \rightarrow \mathbb{R}$ . Then Lemma 28 shows that  $\mathcal{F}_{\text{mon}}$  is monotone compatible with the Bonami–Beckner noise operator. We can now prove our Talagrand-analogue for monotone functions over  $\Omega^n$ :

► **Theorem 29.** Let  $\Omega = \{0, 1, \dots, m-1\}^n$  and let  $\mathcal{F}_{\text{mon}} \subseteq L^2(\Omega^n, \pi^{\otimes n})$  denote the family of monotone functions on  $\Omega^n$  such that  $\|f\| \leq 1$  for all  $f \in \mathcal{F}_{\text{mon}}$ . Then for  $f, g \in \mathcal{F}_{\text{mon}}$ , we have

$$\mathbf{E}[fg] - \mathbf{E}[f] \mathbf{E}[g] \geq \frac{1}{C} \cdot \Phi \left( \sum_{\# \alpha = 1} \hat{f}(\alpha) \hat{g}(\alpha) \right)$$

where recall from Equation (2) that  $\Phi : [0, 1] \rightarrow [0, 1]$  is  $\Phi(x) = \min \left\{ x, \frac{x}{\log^2(1/x)} \right\}$  and  $C > 0$  is a universal constant.

**Proof.** Consider the orthogonal decomposition

$$L^2(\Omega^n, \pi^{\otimes n}) = \bigoplus_{i=0}^n \mathcal{W}_i$$

where  $\mathcal{W}_i = \text{span} \{ \phi_\alpha : \# \alpha = i \}$ ; the orthogonality of this decomposition follows from the orthonormality of  $(\phi_\alpha)_{\alpha \in \mathbb{N}_{< m}^n}$ . Furthermore, this decomposition is a chaos decomposition with respect to the Bonami–Beckner operator  $(T_\rho)_{\rho \in [0, 1]}$ . It follows that the hypotheses of Theorem 14 hold for  $\mathcal{F}_{\text{mon}}$  with  $j^* = 1$ , from which the result follows. ◀

Theorem 29 can be interpreted in terms of the *Efron–Stein decomposition* of a function (see Chapter 8 of [21]); a complete discussion of this can be found in the full version of this paper.

### 6.3 Comparison with Keller’s Inequality for the $p$ -biased Hypercube

In this subsection, we restrict our attention to the  $p$ -biased hypercube, i.e.  $\{+1, -1\}_p^n := (\{+1, -1\}^n, \pi_p^{\otimes n})$  where  $\pi_p(-1) = p$  and  $\pi_p(+1) = 1 - p$ . In this setting our Theorem 29 generalizes Talagrand’s inequality in two ways: it holds for real-valued monotone functions on  $\{+1, -1\}^n$  that have 2-norm at most 1 (rather than just monotone Boolean functions), and it holds for any  $p$  (as opposed to just  $p = 1/2$ ). Keller [15, 16] has earlier given a generalization of Talagrand’s inequality that holds for general  $p$  and for real-valued monotone functions with  $\infty$ -norm at most 1:

► **Theorem 30** (Theorem 7 of [15]; see also [17] for a slightly weaker version). *Let  $f, g \in L^2(\{0, 1\}^n, \pi_p^{\otimes n})$  be monotone functions such that for all  $x \in \{+1, -1\}^n$ , we have  $|f(x)|, |g(x)| \leq 1$ . Then*

$$\mathbf{E}[fg] - \mathbf{E}[f] \mathbf{E}[g] \geq \frac{1}{C} \cdot H(p) \cdot \Psi \left( \sum_{i=1}^n \hat{f}_p(i) \hat{g}_p(i) \right)$$

where  $\hat{f}_p(i)$  is the  $p$ -biased degree-1 Fourier coefficient on coordinate  $i$ ,  $\Psi : [0, 1] \rightarrow [0, 1]$  is given by  $\Psi(x) = \frac{x}{\log(e/x)}$  as in Section 1.1,  $C > 0$  is a universal constant, and  $H : [0, 1] \rightarrow [0, 1]$  is the binary entropy function  $H(x) = -x \log x - (1 - x) \log(1 - x)$ .

Comparing Theorem 29 to Theorem 30, we see that the latter has an extra factor of  $H(p)$ , whereas the former shows that in fact no dependence on  $p$  is necessary (but the former has an extra factor of  $1/\log \left( 1 / \sum_i \hat{f}_p(i) \hat{g}_p(i) \right)$ ). Theorem 29 can be significantly stronger than Theorem 30 in a range of natural settings because of these differences. We show that for every  $\omega(1)/n \leq p \leq 1/2$ , there is a pair of  $\{+1, -1\}$ -valued functions  $f, g$  (depending on  $p$ ) such that under the  $p$ -biased distribution (i) the quantity  $\mathbf{E}[fg] - \mathbf{E}[f] \mathbf{E}[g]$  is at least an absolute constant independent of  $n$  and  $p$ ; (ii) the RHS of Theorem 29 is at least an absolute constant independent of  $n$  and  $p$ ; but (iii) the RHS of Theorem 30 is  $\Theta(p \log(1/p))$ . A proof can be found in the appendix to the full version of this paper.

## Abstract

We establish nearly tight bounds on the expected shrinkage of decision lists and DNF formulas under the  $p$ -random restriction  $\mathbf{R}_p$  for all values of  $p \in [0, 1]$ . For a function  $f$  with domain  $\{0, 1\}^n$ , let  $\text{DL}(f)$  denote the minimum size of a decision list that computes  $f$ . We show that

$$\mathbb{E}[\text{DL}(f|_{\mathbf{R}_p})] \leq \text{DL}(f)^{\log_{2/(1-p)}(\frac{1+p}{1-p})}.$$

For example, this bound is  $\sqrt{\text{DL}(f)}$  when  $p = \sqrt{5} - 2 \approx 0.24$ . For Boolean functions  $f$ , we obtain the same shrinkage bound with respect to DNF formula size plus 1 (i.e., replacing  $\text{DL}(\cdot)$  with  $\text{DNF}(\cdot) + 1$  on both sides of the inequality).

## 1 Introduction

Random restrictions are a powerful tool in circuit complexity and the analysis of Boolean functions. A *restriction* is a partial assignment to the input bits of a function  $f$  on the hypercube  $\{0, 1\}^n$ . For a parameter  $p \in [0, 1]$ , the  $p$ -random restriction  $\mathbf{R}_p$  independently leaves each input bit free with probability  $p$  and otherwise assigns it to 0 or 1 with equal probability. We denote by  $f|_{\mathbf{R}_p}$  the function obtained from  $f$  by restricting its inputs to the subcube of  $\{0, 1\}^n$  that correspond to  $\mathbf{R}_p$ .

Random restrictions are known to reduce the complexity of functions in simple models of computations, such as decision trees (DT), decision lists (DL), DNF formulas (DNF), and DeMorgan formulas ( $\mathcal{L}$ ); the symbols in parentheses are notation for the corresponding size measures (see Section 2 for definitions). With respect to DeMorgan formula leaf-size  $\mathcal{L}$ , it is easy to see that  $\mathcal{L}(f|_{\mathbf{R}_p})$  has expectation at most  $p \cdot \mathcal{L}(f)$ . (This follows by linearity of expectation from the observation that each input literal in a minimal formula for  $f$  is eliminated by  $\mathbf{R}_p$  with probability  $p$ .) Subbotovskaya [25] was the first to show that the expected shrinkage factor is in fact significantly smaller than  $p$  (she showed an upper bound  $O(p^{3/2})$  for  $p \geq 1/\mathcal{L}(f)^{2/3}$ ). A subsequent line of results [1, 14, 19, 11, 26], culminating in an  $p^{2-o(1)}$  bound of Håstad [11] and a low-order improvement by Tal [26], eventually established an asymptotically tight bound:

► **Theorem 1** (Shrinkage of DeMorgan formulas [26]). *For all Boolean functions  $f$ ,*

$$\mathbb{E}[\mathcal{L}(f|_{\mathbf{R}_p})] = O(p^2 \mathcal{L}(f) + p\sqrt{\mathcal{L}(f)}).$$

The constant 2 in the exponent  $p$  in Theorem 1 is known as the “shrinkage exponent” of DeMorgan formulas. Shrinkage under  $\mathbf{R}_p$  has also been studied for restricted types of formulas, namely read-once, monotone, and bounded-depth ( $\text{AC}^0$ ). It was shown in [5, 13] that read-once formulas have shrinkage exponent  $\log_{\sqrt{5}-1}(2) \approx 3.27$ . The shrinkage exponent of monotone formulas is between 2 and  $\log_{\sqrt{5}-1}(2)$  and conjectured to equal the latter; determining the exact constant is a longstanding question (Open Problem 4). In the  $\text{AC}^0$  setting (bounded-depth formulas with unbounded AND and OR gates), it is known that depth- $d$  formulas with fan-in  $m$  shrink to expected size  $O(1)$  under  $\mathbf{R}_p$  when  $p$  is  $O(1/\log m)^{d-1}$  [22]. However, it is open to determine the shrinkage rate for larger  $p$ , particularly in the “mild random restriction” regime where  $p$  is  $\Omega(1)$  or  $1 - o(1)$  (Open Question 2).

The results of this paper give nearly tight bounds on the shrinkage under  $\mathbf{R}_p$  of depth-2 formulas (also known as DNF and CNF formulas), as well as the more general computational model of *decision lists*. Before stating our main result, it is instructive to first consider shrinkage in the simpler model of *decision trees*. For a function  $f$  on the hypercube (with domain  $\{0, 1\}^n$  and arbitrary range), we denote by  $\text{DT}(f)$  the minimum number of leaves (i.e., output nodes) in a decision tree that computes  $f$ . The following bound is shown by straightforward induction on  $\text{DT}(f)$ . (I believe this bound is probably folklore, but could not find a reference so have included the short proof in Section 3.1.)

► **Theorem 2** (Shrinkage of decision trees). *For all functions  $f$  on the hypercube,*

$$\mathbb{E}[\text{DT}(f|_{\mathbf{R}_p})] \leq \text{DT}(f)^{\log_2(1+p)}.$$

*This bound holds with equality when  $f$  is a parity function.*

Decision lists are a natural computational model that has been studied in many contexts [3, 4, 16, 9, 21]. A *decision list of size  $m$*  is a sequence  $L = ((C_1, b_1), \dots, (C_m, b_m))$  where  $b_1, \dots, b_m$  are arbitrary output values and  $C_1, \dots, C_m$  are conjunctive clauses (ANDs of literals) such that  $C_1 \vee \dots \vee C_m$  is a tautology.<sup>1</sup>  $L$  computes a function on the hypercube as follows: on input  $x \in \{0, 1\}^n$ , the output is  $b_i$  for the first index  $i \in [m]$  such that  $C_i(x)$  is satisfied. We denote by  $\text{DL}(f)$  the minimum size of a decision list that computes  $f$ .

Decision lists are a generalization decision trees: every decision tree is equivalent to a decision list of the same size, and thus  $\text{DL}(f) \leq \text{DT}(f)$  for all functions  $f$  on the hypercube.<sup>2</sup> Boolean decision lists, in which  $b_1, \dots, b_m \in \{0, 1\}$ , are moreover a generalization of both DNF and CNF formulas. In particular, *DNF formulas* are the special case where  $b_1 = \dots = b_{m-1} = 1$  and  $b_m = 0$ . Following custom, we count the *size* of a DNF formula as  $m - 1$  instead of  $m$ , and thus  $\text{DL}(f) \leq \text{DNF}(f) + 1$  for all Boolean functions  $f$ .

Despite decision lists and DNF/CNF formulas being more complex computational models than decision trees, our main result shows that they shrink at a similar rate under  $\mathbf{R}_p$ .

<sup>1</sup> In other words, every input  $x \in \{0, 1\}^n$  satisfies at least one of  $C_1, \dots, C_m$ . Without loss of generality,  $C_m$  may be chosen as the empty (always true) conjunctive clause  $\top$ . We allow  $C_1 \vee \dots \vee C_m$  to be an arbitrary tautology in order to more naturally define the class of *orthogonal* decision lists later on in Section 3.3.

<sup>2</sup> The name “decision list” elsewhere commonly refers to (what we call) width-1 decision trees, in which each clause is a single literal (i.e., an input variable  $x_i$  or its negation  $\bar{x}_i$ ). Whereas unbounded-width decision lists are a generalization decision trees, width-1 decision lists are instead a special case.

► **Theorem 3** (Shrinkage of decision lists and DNF formulas). *For all functions  $f$  on the hypercube,*

$$\mathbb{E}[\text{DL}(f|_{\mathbf{R}_p})] \leq \text{DL}(f)^{\gamma(p)} \quad \text{where} \quad \gamma(p) := \log_{\frac{2}{1-p}}\left(\frac{1+p}{1-p}\right).$$

*If  $f$  is Boolean, then also  $\mathbb{E}[\text{DNF}(f|_{\mathbf{R}_p}) + 1] \leq (\text{DNF}(f) + 1)^{\gamma(p)}$  (and similarly for  $\text{CNF}(\cdot) + 1$ ).*

■ **Figure 1** Plots of  $\gamma(p) := \log_{\frac{2}{1-p}}\left(\frac{1+p}{1-p}\right)$  (blue) and  $\log_2(1+p)$  (red).

Note that  $\gamma : [0, 1] \rightarrow [0, 1]$  is an increasing function with  $\gamma(0) = 0$  and  $\gamma(1) = 1$  (see Figure 1). The bound of Theorem 3 is thus nontrivial for all values of  $p \in (0, 1)$ . This bound is moreover close to optimal:  $\log_2(1+p)$  is a lower bound on the best possible function  $\gamma(p)$  (Section 3.4). As corollaries, we obtain additional bounds  $\text{ODL}(f)^{\gamma(p)}$  and  $\text{wODL}(f)^{\gamma(p)}$  on the shrinkage of orthogonal and weakly orthogonal decision lists (Corollary 14), as well as  $(\mathcal{L}_2(f) + 1)^{\gamma(2p)}$  for depth-2 formula leaf-size (Corollary 18).

Theorem 3 yields the following bounds for particular settings of  $p$  in terms of  $m = \text{DL}(f)$ :

$$\mathbb{E}[\text{DL}(f|_{\mathbf{R}_p})] \leq \begin{cases} 2 & \text{for } p = O\left(\frac{1}{\log m}\right), \\ \sqrt{m} & \text{for } p = \sqrt{5} - 2 \approx 0.24, \\ m/2 & \text{for } p = 1 - O\left(\frac{\log \log m}{\log m}\right), \\ m - 1 & \text{for } p = 1 - O\left(\frac{\log m}{m}\right). \end{cases}$$

For small  $p = O(1/\log m)$ , a variant of Håstad’s Switching Lemma (discussed below) actually implies a stronger inequality  $\mathbb{E}[\text{DT}(f|_{\mathbf{R}_p})] \leq 2$  with DT in place of DL (Corollary 6). Theorem 3 is mainly interesting for larger values of  $p$ . In particular, the “mild random restriction” regime when  $p$  is  $\Omega(1)$  or  $1 - o(1)$  has important applications in pseudorandomness [8, 20], DNF sparsification [7, 17] and hypercontractivity [18].

## 1.1 Switching lemmas and size measures vs. width/depth measures

We have so far discussed the shrinkage of various complexity measures under the  $p$ -random restriction  $\mathbf{R}_p$ . The switching lemmas stated below can be viewed as apples-to-oranges shrinkage results that bound one complexity measure on  $f|_{\mathbf{R}_p}$  in terms of another complexity measure on  $f$ . Here there is a useful distinction between “size measures” DT, DL, DNF and their corresponding “width/depth measures”, denoted by  $\text{DT}_{\text{depth}}$ ,  $\text{DL}_{\text{width}}$ ,  $\text{DNF}_{\text{width}}$ . Width/depth measures are typically related to the logarithm of size measures: functions

with size complexity  $m$  are approximable by (or in some cases equivalent to) functions with width/depth complexity  $O(\log m)$ . Håstad's Switching Lemma [10] gives a tail bound on the decision tree size of  $f|_{\mathbf{R}_p}$  in terms of the decision list width of  $f$ .<sup>3</sup>

► **Theorem 4** (Switching Lemma [10]). *For all functions  $f$  on the hypercube and  $t \in \mathbb{N}$ ,*

$$\mathbb{P}[\text{DT}_{\text{depth}}(f|_{\mathbf{R}_p}) \geq t] \leq O(p \cdot \text{DL}_{\text{width}}(f))^t.$$

A variant of the Switching Lemma with  $\log \text{DL}(f)$  in place of  $\text{DL}_{\text{width}}(f)$  was proved in [22].

► **Theorem 5** (Switching Lemma in terms of decision list size [22]). *For every function  $f$  on the hypercube and  $t \in \mathbb{N}$ ,*

$$\mathbb{P}[\text{DT}_{\text{depth}}(f|_{\mathbf{R}_p}) \geq t] \leq O(p \cdot \log \text{DL}(f))^t.$$

We remark that Theorem 5 follows directly from Theorem 4 for  $t \leq O(\log \text{DL}(f))$  (by the standard width reduction argument), but not for larger  $t$ . Obtaining a tail bound for all  $t \in \mathbb{N}$  is essentially to the following:

► **Corollary 6** (Decision tree size of decision lists). *For all functions  $f$  on  $\{0,1\}^n$ ,*

$$\mathbb{E}[\text{DT}(f|_{\mathbf{R}_p})] \leq 2 \quad \text{and} \quad \text{DT}(f) \leq O(2^{(1-p)^n}) \quad \text{where} \quad p = O(1/\log \text{DL}(f)).$$

As previously mentioned, Corollary 6 strengthens the bound  $\mathbb{E}[\text{DL}(f|_{\mathbf{R}_p})] \leq 2$  for  $p = O(1/\log \text{DL}(f))$  that follows from Theorem 3 (albeit for  $p$  that is a constant factor smaller). However, note that Corollary 6 is trivial for  $p$  above  $\Omega(1/\log \text{DL}(f))$ . A different switching lemma for large  $p$  (even  $1 - o(1)$ ) in terms of  $\text{DNF}_{\text{width}}(f)$  was introduced by Segerlind, Buss and Impagliazzo [24] and quantitatively improved by Razborov [20]. It is unclear if these switching lemmas for “mild random restriction” have analogues in terms of  $\log \text{DL}(f)$ ; if so, that might entail a shrinkage bound for  $\text{DL}$  that is nontrivial for all  $p \in (0, 1)$ , although potentially weaker than Theorem 3.

Our proof of Theorem 3 involves an application of Jensen's inequality with respect to a certain carefully defined probability distribution on the set of clauses in a decision list  $L$ . This distribution is related to (but not identical to) the distribution of the first satisfied clause of  $L$  under a uniform random input. A similar convexity argument appears in the proof of Theorem 5 in [22]. A second key idea, the notion of “useful indices” of  $L$  under a restriction  $\rho$ , comes from a recent paper of Lovett, Wu and Zhang [17] who proved the following result as the main lemma in establishing tight bound on the sparsification of bounded-width decision lists.

► **Theorem 7** (Decision list shrinkage in terms of width [17]). *For every function  $f$  on the hypercube,*

$$\mathbb{E}[\text{DL}(f|_{\mathbf{R}_p})] \leq \left( \frac{4}{1-p} \right)^{\text{DL}_{\text{width}}(f)}.$$

Note that our main result, Theorem 3, stands in relation to Theorem 7 just as Theorem 5 does to Theorem 4: in both cases we are essentially replacing  $\text{DL}_{\text{width}}(f)$  with  $\log \text{DL}(f)$ .

<sup>3</sup> In its application to  $\text{AC}^0$  circuit lower bounds, Theorem 4 is usually stated (more narrowly) in the form

$$\mathbb{P}[\text{CNF}_{\text{width}}(f|_{\mathbf{R}_p}) \geq t] \leq O(p \cdot \text{DNF}_{\text{width}}(f))^t$$

for Boolean functions  $f$ . The name “Switching Lemma” refers to the conversion of a DNF formula to a CNF formula. The more general bound stated in Theorem 4 is implicit in proofs of [10].

## 1.2 Other related work

There are different ways to quantify the effect of random restrictions on complexity measures. Instead of bounding expectation, one may show that shrinkage occurs with high probability. For DeMorgan formulas, high probability shrinkage results were shown in [23, 15]. Shrinkage results and switching lemmas have also been studied for random restrictions other than  $\mathbf{R}_p$  (see [2]). Very interesting recent work of Filmus, Meir and Tal [6] extends the technique of Håstad [11] to obtain  $p^{2-o(1)}$  factor shrinkage bounds for DeMorgan formulas under a family of pseudorandom projections that generalize  $\mathbf{R}_p$ .

## 2 Preliminaries

Throughout this paper,  $p$  is an arbitrary parameter in  $[0, 1]$ . All inequalities involving  $p$  hold for all values in  $[0, 1]$ . We often use the special case of Jensen's inequality  $\mathbb{E}[X^c] \leq \mathbb{E}[X]^c$  where  $X$  is a nonnegative random variable and  $c \in [0, 1]$  (in particular, when  $c$  is  $\log_2(1+p)$  or  $\gamma(p)$ ). We write  $\mathbb{N}$  for the natural numbers  $\{0, 1, 2, \dots\}$ , and for  $m \in \mathbb{N}$ , we write  $[m]$  for  $\{1, \dots, m\}$ .

### 2.1 Functions and restrictions on the hypercube

*Function on the hypercube* refers to any function with domain  $\{0, 1\}^n$  where  $n$  is a positive integer. A *Boolean function* is a function on the hypercube with codomain  $\{0, 1\}$ . (The parameter  $n$  plays no role in most results in this paper, so we suppress its mention whenever possible.)

A *restriction* is a partial assignment of Boolean variables  $x_1, \dots, x_n$  to values 0 and 1; this is formally defined as a function  $\varrho : \{1, \dots, n\} \rightarrow \{0, 1, *\}$  where  $\varrho(i) = *$  signifies that  $x_i$  is left free by  $\varrho$ . We denote by  $\text{Stars}(\varrho) \subseteq [n]$  the set of free variables under  $\varrho$ . For a function  $f$  on the hypercube  $\{0, 1\}^n$  and a restriction  $\varrho$ , we denote by  $f|_{\varrho}$  the restricted function on the subcube  $\{0, 1\}^{\text{Stars}(\varrho)}$  defined in the obvious way:  $(f|_{\varrho})(y) = f(x)$  where  $x \in \{0, 1\}^n$  is the input with  $x_i = y_i$  if  $i \in \text{Stars}(\varrho)$  and  $x_i = \varrho(i)$  otherwise.

For  $p \in [0, 1]$ , the  $p$ -*random restriction*  $\mathbf{R}_p$  is the random restriction that independently leaves each variable  $x_i$  free with probability  $p$  and otherwise sets  $x_i$  to 0 or 1 with equal probability. Thus, for any particular restriction  $\varrho$ , we have  $\mathbb{P}[\mathbf{R}_p = \varrho] = p^{|\text{Stars}(\varrho)|}((1-p)/2)^{n-|\text{Stars}(\varrho)|}$ .

### 2.2 Complexity measures DL, DT, DNF, CNF and their width/depth versions

► **Definition 8** (DNF formulas). We first define literals, conjunctive clauses, and DNF formulas over  $n$  variables.

- A *literal* is a Boolean variable  $x_i$  or negated Boolean variable  $\overline{x_i}$  where  $i \in \{1, \dots, n\}$ .
- A *conjunctive clause* (a.k.a. *term*) is an expression  $C$  of the form  $\ell_1 \wedge \dots \wedge \ell_w$  where  $\ell_1, \dots, \ell_w$  are literals on disjoint variables. The parameter  $w$  is the *width* of  $C$ ; this may be any nonnegative integer. The conjunctive clause of width zero is denoted by  $\top$ .
- A *DNF formula* is an expression  $F$  of the form  $C_1 \vee \dots \vee C_m$  where  $C_1, \dots, C_m$  are conjunctive clauses. The parameter  $m$  is the *size* of  $F$ ; this may be any nonnegative integer. The DNF formula of size 0 is denoted by  $\perp$ . The *width* of  $F$  is defined as the maximum width of any  $C_i$ .
- *CNF formulas* are defined dually (with the roles of  $\vee$  and  $\wedge$  exchanged).

## 70:6 Shrinkage of Decision Lists and DNF Formulas

Every literal, conjunctive clause, and DNF formula computes a Boolean function  $\{0, 1\}^n \rightarrow \{0, 1\}$  in the usual way.

- A DNF formula  $F$  is a *tautology* if it computes the identically 1 function. Note that any DNF formula that includes the empty conjunctive clause  $\top$  is a tautology.

► **Definition 9** (Decision lists).

- A *decision list* is an expression  $L$  of the form  $((C_1, b_1), \dots, (C_m, b_m))$  where  $b_1, \dots, b_m$  are arbitrary output values (not necessarily Boolean) and  $C_1, \dots, C_m$  are conjunctive clauses such that  $C_1 \vee \dots \vee C_m$  is a tautology. The parameter  $m$  is the *size* of  $L$ ; this may be any positive integer. The *width* of  $C$  is defined as the maximum width of any  $C_i$ .

A decision list  $L$  computes a function  $\{0, 1\}^n \rightarrow \{b_1, \dots, b_m\}$  as follows: on input  $x$ , the output is  $b_\ell$  where  $\ell \in [m]$  is the minimum index such that  $C_\ell(x) = 1$ . (Note that the final clause  $C_m$  may be replaced by  $\top$  without changing the function computed by  $L$ .)

► **Definition 10** (Decision trees).

- A *decision tree* is a rooted binary tree  $T$  in which each leaf is labeled by an output value (not necessarily Boolean) and each non-leaf node is labeled by a variable  $x_i$ , with the edges to its two children labeled “ $x_i = 0$ ” and “ $x_i = 1$ ”. The *size* of  $T$  is the number of leaves; this may be any positive integer. The *depth* of  $T$  is the maximum number of non-leaf nodes on any root-to-leaf branch; this may be any nonnegative integer.

► **Definition 11** (Associated complexity measures). For a function  $f$  with domain  $\{0, 1\}^n$  (and arbitrary codomain), let

$\text{DT}(f) :=$  minimum size of a decision tree that computes  $f$ ,

$\text{DL}(f) :=$  minimum size of a decision list that computes  $f$ ,

When  $f$  is Boolean, we additionally define

$\text{DNF}(f) :=$  minimum size of a DNF formula that computes  $f$ ,

$\text{CNF}(f) :=$  minimum size of a CNF formula that computes  $f$ .

For constant functions  $\underline{0}$  and  $\underline{1}$ , note that  $\text{DNF}(\underline{0}) = 0$  and  $\text{DNF}(\underline{1}) = 1$  according to our definition, since  $\underline{0}$  is computed by the empty DNF formula, while  $\underline{1}$  is computed by the DNF formula with a single empty clause. Also note that  $\text{CNF}(f) = \text{DNF}(\neg f)$ .

Each of the above size measures has a corresponding width/depth measure. These are denoted by

$$\text{DT}_{\text{depth}}(f), \quad \text{DL}_{\text{width}}(f), \quad \text{DNF}_{\text{width}}(f), \quad \text{CNF}_{\text{width}}(f).$$

► **Proposition 12** (see [3, 16]). *These size measures satisfy the following inequalities for all Boolean functions:*

$$1 \leq \text{DL} \leq \left\{ \begin{array}{c} \text{DNF} + 1 \\ \text{CNF} + 1 \end{array} \right\} \leq \text{DNF} + \text{CNF} \leq \text{DT}.$$

*The corresponding width/depth measures satisfy:*

$$0 \leq \text{DL}_{\text{width}} \leq \left\{ \begin{array}{c} \text{DNF}_{\text{width}} \\ \text{CNF}_{\text{width}} \\ \lceil \log_2(\text{DT}) \rceil \end{array} \right\} \leq \text{DT}_{\text{depth}} \leq \text{DNF}_{\text{width}} \cdot \text{CNF}_{\text{width}}.$$

*The above inequalities that involve decision trees and decision lists also apply to non-Boolean functions on the hypercube.*

We introduce additional computational models later on: (weakly) orthogonal decision lists in Section 3.3 and  $AC^0$  formulas in Section 4.

### 3 Shrinkage of decision trees and decision lists

We prove Theorems 2 and 3 in Sections 3.1 and 3. We then discuss extensions of our shrinkage bound to (weakly) orthogonal decision lists in Section 3.3 and tightness of the bounds Section 3.4.

#### 3.1 Shrinkage of decision trees

**Proof of Theorem 2.** Let  $T$  be a decision tree (with arbitrary output values). We must show that

$$\mathbb{E}[\text{size}(T \upharpoonright \mathbf{R}_p)] \leq \text{size}(T)^{\log_2(1+p)}.$$

We argue by induction of the size of  $T$ . The inequality is trivial in the base case that  $T$  has size 1.

Assume  $T$  has size  $m \geq 2$ . Then  $T$  has the form “If  $x_i = 0$  then  $T_0$  else  $T_1$ ” where  $T_0, T_1$  are decision trees of size  $m_0, m_1 \geq 1$  with  $m_0 + m_1 = m$ . Without loss of generality,  $T_0$  and  $T_1$  never query  $x_i$ . We have

$$\begin{aligned} \mathbb{E}[\text{size}(T \upharpoonright \mathbf{R}_p)] &= p \mathbb{E}[\text{size}(T \upharpoonright \mathbf{R}_p) \mid \mathbf{R}_p(x_i) = *] \\ &\quad + \frac{1-p}{2} \left( \mathbb{E}[\text{size}(T_0 \upharpoonright \mathbf{R}_p) \mid \mathbf{R}_p(x_i) = 0] + \mathbb{E}[\text{size}(T_1 \upharpoonright \mathbf{R}_p) \mid \mathbf{R}_p(x_i) = 1] \right) \\ &= \frac{1+p}{2} \left( \mathbb{E}[\text{size}(T_0 \upharpoonright \mathbf{R}_p)] + \mathbb{E}[\text{size}(T_1 \upharpoonright \mathbf{R}_p)] \right) \\ &\leq \frac{1+p}{2} \left( (m_0)^{\log_2(1+p)} + (m_1)^{\log_2(1+p)} \right) \quad (\text{induction hypothesis}) \\ &\leq (1+p) \left( \frac{m}{2} \right)^{\log_2(1+p)} \quad (\text{Jensen's inequality}) \\ &= m^{\log_2(1+p)}. \end{aligned}$$

As for tightness of the bound: If  $f$  is a parity function  $f(x_1, \dots, x_k) = x_1 \oplus \dots \oplus x_k$ , then we have  $\text{DT}(f) = 2^k$  and

$$\begin{aligned} \mathbb{E}[\text{DT}(f \upharpoonright \mathbf{R}_p)] &= \mathbb{E}[2^{\text{Bin}(k,p)}] = \sum_{i=0}^k 2^i \mathbb{P}[\text{Bin}(k,p) = i] \\ &= \sum_{i=0}^k \binom{k}{i} (2p)^i (1-p)^{k-i} = (1+p)^k = \text{DT}(f)^{\log_2(1+p)}. \blacktriangleleft \end{aligned}$$

#### 3.2 Shrinkage of decision lists

We now prove our main result on the shrinkage of decision lists and DNF formulas.

**Proof of Theorem 3.** Let  $f$  be any function on the hypercube and let  $p \in [0, 1]$ . (Note: Neither the hypercube dimension  $n$  nor the nature of output values of  $f$  play no role in our analysis.)

## 70:8 Shrinkage of Decision Lists and DNF Formulas

Let  $L = ((C_1, b_1), \dots, (C_m, b_m))$  be a decision list of minimum size that computes  $f$ , that is, with  $m = \text{DL}(f)$ . For  $\ell \in [m]$ , let  $|C_\ell|$  denote the width of the clause  $C_\ell$  (i.e., the number of literals in  $C_\ell$ ). Without loss of generality, we have  $|C_1|, \dots, |C_{m-1}| \geq 1$  and  $|C_m| = 0$  (i.e.,  $C_m$  is the empty clause  $\top$ ).

Following Lovett, Wu and Zhang [17], for a restriction  $\varrho$ , we define the set  $U(\varrho) \subseteq [m]$  of *useful indices of  $L$  under  $\varrho$*  by

$$U(\varrho) := \{\ell \in [m] : \exists x \text{ consistent with } \varrho \text{ s.t. } C_\ell(x) = 1 \text{ and } C_1(x) = \dots = C_{\ell-1}(x) = 0\}.$$

If  $U(\varrho) = \{\ell_1, \dots, \ell_t\}$  where  $1 \leq \ell_1 < \dots < \ell_t \leq m$ , then the restricted function  $f|_\varrho$  is computed by the decision list  $L|_\varrho$  defined by

$$L|_\varrho := ((C_{\ell_1}|_\varrho, b_{\ell_1}), \dots, (C_{\ell_t}|_\varrho, b_{\ell_t}))$$

where  $C_{\ell_i}|_\varrho$  is the sub-clause of  $C_{\ell_i}$  on the variables left unrestricted by  $\varrho$ . (Note that  $C_{\ell_1} \vee \dots \vee C_{\ell_t}$  is a tautology, so  $L|_\varrho$  is indeed a decision list.) Thus, we have

$$\text{DL}(f|_\varrho) \leq |U(\varrho)|. \tag{1}$$

For example, suppose  $m = 4$  and

$$C_1 = x_1 \wedge x_3, \quad C_2 = \overline{x_1} \wedge x_4, \quad C_3 = x_2 \wedge \overline{x_3}, \quad C_4 = \top.$$

For  $\varrho_1 := \{x_1 \mapsto 1\}$  (the restriction fixing  $x_1$  to 1 and leaving other variables free), we have

$$U(\varrho_1) = \{1, 3, 4\}, \quad L|_{\varrho_1} = ((x_3, b_1), (x_2 \wedge \overline{x_3}, b_3), (\top, b_4)).$$

For  $\varrho_2 := \{x_1 \mapsto 1, x_2 \mapsto 1\}$ , we have

$$U(\varrho_2) = \{1, 3\}, \quad L|_{\varrho_2} = ((x_3, b_1), (\overline{x_3}, b_3)).$$

In particular, the final clause  $C_4$  is not useful under  $\varrho_2$  (since any input consistent with  $\varrho_2$  satisfies  $C_1$  or  $C_3$ ).

Now comes a key definition: let  $\mu = (\mu_1, \dots, \mu_m)$  be the probability density vector (defining a probability distribution on  $[m]$ )

$$\mu_\ell := \mathbb{P}_{\varrho \sim \mathbf{R}_p} [\max(U(\varrho)) = \ell \text{ and } C_\ell|_\varrho \equiv 1] \quad \text{for } \ell \in [m-1],$$

$$\mu_m := \mathbb{P}_{\varrho \sim \mathbf{R}_p} [\max(U(\varrho)) = m \text{ or } C_{\max(U(\varrho))}|_\varrho \not\equiv 1].$$

Since events  $\max(U(\varrho)) = \ell$  are mutually exclusive, clearly we have  $\mu_1 + \dots + \mu_m = 1$ .

Note that  $\max(U(\varrho)) = \ell$  does not imply  $C_\ell|_\varrho \equiv 1$ , that is,  $\mu_\ell$  does not necessarily equal  $\mathbb{P}_{\varrho \sim \mathbf{R}_p} [\max(U(\varrho)) = \ell]$ . This is illustrated by the restriction  $\varrho_2$  in the above example, for which we have  $\max(U(\varrho_2)) = 3$ , yet  $C_3|_{\varrho_2} = \overline{x_3} \not\equiv 1$ . Restrictions  $\varrho_1$  and  $\varrho_2$  both contribute to probability mass  $\mu_4$ : in the case of  $\varrho_1$ , this is because  $\max(U(\varrho_1)) = 4$ , and in the case of  $\varrho_2$ , this is because  $C_{\max(U(\varrho_2))}|_{\varrho_2} \not\equiv 1$ .

For each  $\ell \in [m]$ , we have  $\mu_\ell \leq \mathbb{P}[C_\ell|_\varrho \equiv 1] = ((1-p)/2)^{|C_\ell|}$  and therefore

$$|C_\ell| \leq \log_{2/(1-p)}(1/\mu_\ell). \tag{2}$$

We require one more definition. For a restriction  $\varrho$  and a useful index  $\ell \in U(\varrho)$ , let  $\varrho^{(\ell)}$  be the restriction obtained by augmenting  $\varrho$  by the unique satisfying assignment for the clause  $C_\ell$ . That is,  $\varrho^{(\ell)}$  fixes a variable  $x_i$  to  $a \in \{0, 1\}$  if, and only if,  $\varrho$  fixes  $x_i$  to  $a$  or  $x_i = a$  in the satisfying assignment to  $C_\ell$ .

As in proofs of the Switching Lemma, we will use the fact that

$$\frac{\mathbb{P}[\mathbf{R}_p = \varrho]}{\mathbb{P}[\mathbf{R}_p = \varrho^{(\ell)}]} = \left( \frac{2p}{1-p} \right)^{|\text{Stars}(\varrho) \cap \text{Vars}(C_\ell)|} \quad (3)$$

since  $\varrho^{(\ell)}$  has exactly  $|\text{Stars}(\varrho) \cap \text{Vars}(C_\ell)|$  fewer unrestricted variables (“stars”) than  $\varrho$ .

As observed in [17], for every  $\ell \in U(\varrho)$ , we have  $U(\varrho^{(\ell)}) = U(\varrho) \cap [\ell]$  and therefore

$$\max(U(\varrho^{(\ell)})) = \ell \quad \text{and} \quad C_\ell \upharpoonright \varrho^{(\ell)} \equiv 1. \quad (4)$$

Thus,  $\varrho^{(\ell)}$  contributes to the probability mass  $\mu_\ell$ .

As a consequence of (3) and (4), we claim that for all  $\ell \in [m]$ ,

$$\mathbb{P}_{\varrho \sim \mathbf{R}_p} [\ell \in U(\varrho)] \leq \mu_\ell \left( \frac{1+p}{1-p} \right)^{|C_\ell|}. \quad (5)$$

In the case  $\ell = m$ , this follows from  $m \in U(\varrho) \Rightarrow \max(U(\varrho)) = m$ . For  $\ell \in [m-1]$ , this is shown as follows:

$$\begin{aligned} & \mathbb{P}_{\varrho \sim \mathbf{R}_p} [\ell \in U(\varrho)] \\ &= \sum_{S \subseteq \text{Vars}(C_\ell)} \mathbb{P}_{\varrho \sim \mathbf{R}_p} [\ell \in U(\varrho) \text{ and } \text{Stars}(\varrho) \cap \text{Vars}(C_\ell) = S] \\ &\stackrel{(4)}{\leq} \sum_{S \subseteq \text{Vars}(C_\ell)} \mathbb{P}_{\varrho \sim \mathbf{R}_p} [\ell = \max(U(\varrho^{(\ell)})) \text{ and } C_\ell \upharpoonright \varrho^{(\ell)} \equiv 1 \text{ and } \text{Stars}(\varrho) \cap \text{Vars}(C_\ell) = S] \\ &= \sum_{S \subseteq \text{Vars}(C_\ell)} \sum_{\varrho : \ell = \max(U(\varrho^{(\ell)})) \text{ and } C_\ell \upharpoonright \varrho^{(\ell)} \equiv 1 \text{ and } \text{Stars}(\varrho) \cap \text{Vars}(C_\ell) = S} \mathbb{P}[\mathbf{R}_p = \varrho] \\ &= \sum_{S \subseteq \text{Vars}(C_\ell)} \sum_{\sigma : \ell = \max(U(\sigma)) \text{ and } C_\ell \upharpoonright \sigma \equiv 1} \sum_{\varrho : \varrho^{(\ell)} = \sigma \text{ and } \text{Stars}(\varrho) \cap \text{Vars}(C_\ell) = S} \mathbb{P}[\mathbf{R}_p = \varrho] \\ &\stackrel{(3)}{=} \sum_{S \subseteq \text{Vars}(C_\ell)} \sum_{\sigma : \ell = \max(U(\sigma)) \text{ and } C_\ell \upharpoonright \sigma \equiv 1} \sum_{\varrho : \varrho^{(\ell)} = \sigma, \text{Stars}(\varrho) \cap \text{Vars}(C_\ell) = S} \left( \frac{2p}{1-p} \right)^{|S|} \mathbb{P}[\mathbf{R}_p = \sigma] \\ &= \sum_{S \subseteq \text{Vars}(C_\ell)} \left( \frac{2p}{1-p} \right)^{|S|} \sum_{\sigma : \ell = \max(U(\sigma)), C_\ell \upharpoonright \sigma \equiv 1} \mathbb{P}[\mathbf{R}_p = \sigma] \quad (\varrho \text{ is determined by } \sigma \text{ and } S) \\ &= \mu_\ell \sum_{S \subseteq \text{Vars}(C_\ell)} \left( \frac{2p}{1-p} \right)^{|S|} \quad (\text{definition of } \mu_\ell) \\ &= \mu_\ell \left( \frac{1+p}{1-p} \right)^{|C_\ell|} \quad (\text{binomial expansion of } (1 + \frac{2p}{1-p})^{|C_\ell|}). \end{aligned}$$

Finally, we obtain the shrinkage bound of Theorem 3 by the following calculation, which uses Jensen’s inequality in addition to the above observations:

## 70:10 Shrinkage of Decision Lists and DNF Formulas

$$\begin{aligned}
\mathbb{E}_{\varrho \sim \mathbf{R}_p} [\text{DL}(f|_{\varrho})] &\stackrel{(1)}{\leq} \mathbb{E}_{\varrho \sim \mathbf{R}_p} [|U(\varrho)|] = \sum_{\ell \in [m]} \mathbb{P}_{\varrho \sim \mathbf{R}_p} [\ell \in U(\varrho)] \\
&\stackrel{(5)}{=} \sum_{\ell \in [m]} \mu_{\ell} \left( \frac{1+p}{1-p} \right)^{|C_{\ell}|} \\
&\stackrel{(2)}{\leq} \sum_{\ell \in [m]} \mu_{\ell} \left( \frac{1+p}{1-p} \right)^{\log_2/(1-p)(1/\mu_{\ell})} \\
&= \mathbb{E}_{\ell \sim \mu} \left[ \left( \frac{1}{\mu_{\ell}} \right)^{\gamma(p)} \right] \quad (\text{def. of } \gamma(p) = \log_{\frac{2}{1-p}} \left( \frac{1+p}{1-p} \right)) \\
&\leq \left( \mathbb{E}_{\ell \sim \mu} \left[ \frac{1}{\mu_{\ell}} \right] \right)^{\gamma(p)} \quad (\text{Jensen's inequality}) \\
&= m^{\gamma(p)}.
\end{aligned}$$

Since  $m = \text{DL}(f)$ , this complete the proof of our bound on decision list shrinkage.

We shall now assume that  $f$  is Boolean and  $C_1 \vee \dots \vee C_m$  is a minimum size DNF formula computing  $f$ . Let  $L$  be the equivalent decision list  $((C_1, 1), \dots, (C_m, 1), (\top, 0))$  of size  $m + 1$ . The shrinkage bound

$$\mathbb{E}[\text{DNF}(f|_{\mathbf{R}_p}) + 1] \leq (\text{DNF}(f) + 1)^{\gamma(p)}$$

now follows from the above analysis, noting that  $\text{DNF}(f|_{\varrho}) + 1 \leq \text{size}(L|_{\varrho})$  for all restrictions  $\varrho$ .  $\blacktriangleleft$

### 3.3 Shrinkage of (weakly) orthogonal decision lists

► **Definition 13.** Let  $L = ((C_1, b_1), \dots, (C_m, b_m))$  be a decision list. We say that  $L$  is

- *orthogonal* if each input  $x$  satisfies exactly one of the conjunctive clauses  $C_1, \dots, C_m$ ,
- *weakly orthogonal* if each input  $x$  satisfies at most one of  $C_1, \dots, C_{m-1}$ .

(Note that if  $L$  is weakly orthogonal, then it remains so after replacing  $C_m$  with  $\top$ . In contrast, an orthogonal decision list has  $C_m = \top$  if and only if  $m = 1$ .)

For a function  $f$  on the hypercube, we denote by  $\text{wODL}(f)$  the minimum size of a (weakly) orthogonal decision list that computes  $f$ . These complexity measures lies in-between DL and DT:

$$\text{DL} \leq \text{wODL} \leq \text{ODL} \leq \text{DT}.$$

Our proof of Theorem 3 implies a shrinkage bound for ODL and wODL in the same way as for DNF + 1.

► **Corollary 14.** For every function  $f$  on the hypercube,

$$\mathbb{E}[\text{ODL}(f|_{\mathbf{R}_p})] \leq \text{ODL}(f)^{\gamma(p)} \quad \text{and} \quad \mathbb{E}[\text{wODL}(f|_{\mathbf{R}_p})] \leq \text{wODL}(f)^{\gamma(p)}.$$

This follows from the observation that if  $L$  is orthogonal, then so is  $L|_{\varrho}$  for any restriction  $\varrho$ , and if  $L$  is semi-orthogonal, then  $L|_{\varrho}$  is semi-orthogonal after replacing the final conjunctive clause with  $\top$ .

### 3.4 Lower bound on the optimal $\gamma(p)$

What is the optimal function  $\gamma(p)$  that may be chosen in the bound on decision list shrinkage of Theorem 3? We observe that  $\gamma(p)$  cannot be improved beyond  $\log_2(1+p)$ . The lower bound is given by a (non-Boolean) function  $f$  computed by a read-once decision tree of depth  $k$  and size  $2^k$ , in which each internal node queries a distinct variable and each leaf returns a distinct output value. For this  $f$ , we have  $\text{DL}(f) = 2^k$  and  $\mathbb{E}[\text{DL}(f \upharpoonright \mathbf{R}_p)] = (1+p)^k = \text{DL}(f)^{\log_2(1+p)}$ . The same function also shows that  $\gamma(p)$  in Corollary 14 cannot be improved beyond  $\log_2(1+p)$ . Since this function is not Boolean, it does not imply a lower bound on DNF shrinkage; however, a similar bound can be shown asymptotically by considering parity functions.

## 4 Shrinkage of $\text{AC}^0$ formulas

Our bound the shrinkage DNF and CNF formulas implies an (only slightly weaker) bound on the shrinkage of depth-2 formula leaf-size. We also discuss the relationship between leaf-size and a related size measure on  $\text{AC}^0$  formulas, the number of depth-1 gates.

► **Definition 15.** An  $\text{AC}^0$  formula is a formula composed unbounded fan-in AND and OR gates with inputs labeled by literals. We measure *depth* by the maximum number of gates on an input-to-output path; the expression “depth- $d$  formula” refers to an  $\text{AC}^0$  formula of depth at most  $d$ . As with DeMorgan formulas, the *leaf-size* of an  $\text{AC}^0$  formula is the number of leaves labeled by literals. An alternative size measure is the number of depth-1 gates (that have only literals as inputs). This number is at least half the total number of gates in any formula with no (useless) gates of fan-in 1.

For a Boolean function  $f$  and  $d \geq 2$ , we denote by  $\mathcal{L}_d(f)$  the minimum leaf-size of depth- $d$  formula that computes  $f$ , and we denote by  $\mathcal{F}_d(f)$  the minimum number of depth-1 gates in a depth- $d$  formula that computes  $f$ . Note that  $\mathcal{L}_d(f) = 1$  iff  $f$  is a literal, and  $\mathcal{F}_d(f) = 1$  iff  $f$  is a nonempty conjunctive or disjunctive clause, and  $\mathcal{L}_d(f) = \mathcal{F}_d(f) = 0$  iff  $f$  is constant (hence computed by a single AND or OR gate with fan-in zero, which as a formula has no inputs and no depth-1 gates).

Finally, we denote by  $\mathcal{F}(f)$  the minimum number of depth-1 gates in an (unbounded depth, unbounded fan-in) formula that computes  $f$ .

Note that  $\mathcal{F}_2 = \min\{\text{DNF}, \text{CNF}\}$ . Theorem 3 therefore implies:

► **Corollary 16.** For all Boolean functions  $f$ ,

$$\mathbb{E}[\mathcal{F}_2(f \upharpoonright \mathbf{R}_p) + 1] \leq (\mathcal{F}_2(f) + 1)^{\gamma(p)}.$$

Over  $n$ -variable Boolean functions, clearly  $\mathcal{F}_d \leq \mathcal{L}_d \leq n \cdot \mathcal{F}_d$  and  $\mathcal{F} \leq \mathcal{L} \leq n \cdot \mathcal{F}$ . The next lemma shows that, under a  $1/2$ -random restriction,  $\mathcal{F}_d$  shrinks below  $\mathcal{L}_d$  and  $\mathcal{F}$  shrinks below  $\mathcal{L}$  (independent of  $n$ ).

► **Lemma 17.** For all Boolean functions  $f$  and  $d \geq 2$ ,

$$\mathbb{E}[\mathcal{L}_d(f \upharpoonright \mathbf{R}_{1/2})] \leq \mathcal{F}_d(f) \quad \text{and} \quad \mathbb{E}[\mathcal{L}(f \upharpoonright \mathbf{R}_{1/2})] \leq \mathcal{F}(f).$$

**Proof.** Let  $F$  be a [depth- $d$ ]  $\text{AC}^0$  formula that computes  $f$  using the minimum number of depth-1 gates. By linearity of expectation, it suffices to show that each depth-1 subformula of  $F$  (i.e., conjunctive or disjunctive clause) has expected leaf-size at most 1 under  $\mathbf{R}_{1/2}$ . Indeed, for any  $k \geq 1$  and  $p \in [0, 1]$ ,

## 70:12 Shrinkage of Decision Lists and DNF Formulas

$$\mathbb{E}[\mathcal{L}(\text{AND}_k \upharpoonright \mathbf{R}_p)] = \mathbb{E}[\mathcal{L}(\text{OR}_k \upharpoonright \mathbf{R}_p)] = \sum_{j=0}^k j \binom{k}{j} p^j \left(\frac{1-p}{2}\right)^{k-j} = kp \left(\frac{1-p}{2}\right)^{k-1}.$$

When  $p = \frac{1}{2}$ , we have  $\frac{k}{2} \left(\frac{3}{4}\right)^{k-1} < 1$  for all  $k \geq 1$ . ◀

Using Lemma 17, we obtain the following bound on the shrinkage of depth-2 formula leaf-size  $\mathcal{L}_2$ , which has a slightly worse exponent  $\gamma(2p)$  compared to  $\gamma(p)$  for  $\mathcal{F}_2$  in Corollary 16.

► **Corollary 18** (Shrinkage of depth-2 formula leaf-size). *For all Boolean functions  $f$ ,*

$$\mathbb{E}[\mathcal{L}_2(f \upharpoonright \mathbf{R}_p) + 1] \leq (\mathcal{L}_2(f) + 1)^{\gamma(2p)}.$$

**Proof.** Viewing  $\mathbf{R}_p$  as a composition of  $\mathbf{R}_{1/2}$  (first) and  $\mathbf{R}_{2p}$  (second), we have

$$\begin{aligned} \mathbb{E}[\mathcal{L}_2(f \upharpoonright \mathbf{R}_p) + 1] &= \mathbb{E}_{\varrho \sim \mathbf{R}_{2p}} \left[ \mathbb{E}_{\sigma \sim \mathbf{R}_{1/2}} [\mathcal{L}_2((f \upharpoonright \varrho) \upharpoonright \sigma) + 1] \right] \\ &\leq \mathbb{E}_{\varrho \sim \mathbf{R}_{2p}} [\mathcal{F}_2(f \upharpoonright \varrho) + 1] && \text{(Lemma 17)} \\ &= (\mathcal{F}_2(f) + 1)^{\gamma(2p)} && \text{(Corollary 16)} \\ &\leq (\mathcal{L}_2(f) + 1)^{\gamma(2p)} && (\mathcal{F}_2 \leq \mathcal{L}_2). \end{aligned} \quad \blacktriangleleft$$

As an additional consequence of Lemma 17, we observe that  $\mathcal{F}$  has the same expected shrinkage factor (up to a constant factor) as DeMorgan leaf-size  $\mathcal{L}$ .

► **Corollary 19** (Shrinkage of unbounded fan-in, unbounded depth formulas). *For all Boolean functions  $f$ ,*

$$\mathbb{E}[\mathcal{F}(f \upharpoonright \mathbf{R}_p)] = O(p^2 \mathcal{F}(f) + p\sqrt{\mathcal{F}(f)}).$$

**Proof.** Assume  $p \leq 1/2$ , since the bound is trivial otherwise. Viewing  $\mathbf{R}_p$  as a composition of  $\mathbf{R}_{2p}$  (first) and  $\mathbf{R}_{1/2}$  (second), we have

$$\begin{aligned} \mathbb{E}[\mathcal{F}(f \upharpoonright \mathbf{R}_p)] &= \mathbb{E}_{\sigma \sim \mathbf{R}_{1/2}} \left[ \mathbb{E}_{\varrho \sim \mathbf{R}_{2p}} [\mathcal{F}((f \upharpoonright \sigma) \upharpoonright \varrho)] \right] \\ &\leq \mathbb{E}_{\sigma \sim \mathbf{R}_{1/2}} \left[ \mathbb{E}_{\varrho \sim \mathbf{R}_{2p}} [\mathcal{L}((f \upharpoonright \sigma) \upharpoonright \varrho)] \right] && (\mathcal{F} \leq \mathcal{L}) \\ &= \mathbb{E}_{\sigma \sim \mathbf{R}_{1/2}} \left[ O(4p^2 \mathcal{L}(f \upharpoonright \sigma) + 2p\sqrt{\mathcal{L}(f \upharpoonright \sigma)}) \right] && \text{(Theorem 1)} \\ &= O\left(p^2 \mathbb{E}_{\sigma \sim \mathbf{R}_{1/2}} [\mathcal{L}(f \upharpoonright \sigma)] + p\sqrt{\mathbb{E}_{\sigma \sim \mathbf{R}_{1/2}} [\mathcal{L}(f \upharpoonright \sigma)]}\right) && \text{(Jensen's inequality)} \\ &= O(p^2 \mathcal{F}(f) + p\sqrt{\mathcal{F}(f)}) && \text{(Lemma 17)}. \end{aligned} \quad \blacktriangleleft$$

## 5 Open problems

We conclude by mentioning some questions raised by this work.

► **Open Problem 1.** *Determine the optimal function  $\gamma_{\text{DL}}(p)$  in Theorem 3. We have shown that*

$$\log_2(1+p) = \gamma_{\text{DT}}(p) \leq \gamma_{\text{DL}}(p) \leq \log_{\frac{2}{1-p}}\left(\frac{1+p}{1-p}\right).$$

*A simpler problem is to determine the least constant  $C_{\text{DL}}$  such that  $\mathbb{E}[\text{DL}(f \upharpoonright \mathbf{R}_p)] \leq O(\text{DL}(f)^{C_{\text{DL}} \cdot p})$ . It follows from our bounds that  $\frac{1}{\ln 2} = C_{\text{DT}} \leq C_{\text{DL}} \leq \frac{2}{\ln 2}$ . The same questions may be asked with respect to complexity measures ODL, wODL and DNF.*

► **Open Problem 2.** *Determine the shrinkage rate of depth- $d$   $\text{AC}^0$  formulas for  $d \geq 3$ . We expect that*

$$\mathbb{E}[\mathcal{L}_d(f \upharpoonright \mathbf{R}_p)] \leq \mathcal{L}_d(f)^{O(p^{1/(d-1)})}. \quad (6)$$

*Ideally the constant in this big- $O$  should not depend on  $d$ .*

We remark that inequality (6) is known to hold for small  $p = O(1/\log \mathcal{L}_d(f))^{d-1}$ , when the bound is  $O(1)$ . This can be shown using the (Multi-)Switching Lemma of Håstad [12]. It is also a direct consequence of the following result of the author [22], which generalizes Corollary 6 (on the decision tree size of decision lists) to  $\text{AC}^0$  formulas of any depth.

► **Theorem 20** (Decision tree size of  $\text{AC}^0$  formulas [22]). *For all functions  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  computable by depth- $d$   $\text{AC}^0$  formulas with fan-in  $m$  (and leaf-size at most  $nm^{d-1}$ ),*

$$\mathbb{E}[\text{DT}(f \upharpoonright \mathbf{R}_p)] \leq 2 \quad \text{and} \quad \text{DT}(f) \leq O(2^{(1-p)^n}) \quad \text{where} \quad p = O(1/\log m)^{d-1}.$$

A related question:

► **Open Problem 3.** *Prove a stronger version of Theorem 20 for depth- $d$   $\text{AC}^0$  formulas with  $m = \mathcal{F}_d(f)^{1/(d-1)}$  (instead of fan-in, which is larger for unbalanced formulas). Such a result could be helpful in proving the shrinkage bound (6).*

Finally, we repeat the longstanding question concerning shrinkage of monotone formulas:

► **Open Problem 4.** *Determine the shrinkage exponent of monotone formulas. That is, find the maximum constant  $\Gamma_m$  such that*

$$\mathbb{E}[\mathcal{L}_m(f \upharpoonright \mathbf{R}_p)] \leq O(p^{\Gamma_m - o(1)} \mathcal{L}_m(f) + 1)$$

*for all monotone Boolean functions  $f$ , where  $\mathcal{L}_m$  is monotone formula leaf-size. It is known that  $2 = \Gamma_{\text{DeMorgan}} \leq \Gamma_m \leq \Gamma_{\text{read-once}} = \log_{\sqrt{5}-1}(2) \approx 3.27$ , and the second inequality is believed to be tight [5, 13].*

## Abstract

We prove that a sufficiently strong parallel repetition theorem for a special case of multiplayer (multiprover) games implies super-linear lower bounds for multi-tape Turing machines with advice. To the best of our knowledge, this is the first connection between parallel repetition and lower bounds for time complexity and the first major potential implication of a parallel repetition theorem with more than two players.

Along the way to proving this result, we define and initiate a study of *block rigidity*, a weakening of Valiant’s notion of *rigidity* [36]. While rigidity was originally defined for matrices, or, equivalently, for (multi-output) linear functions, we extend and study both rigidity and block rigidity for general (multi-output) functions. Using techniques of Paul, Pippenger, Szemerédi and Trotter [28], we show that a block-rigid function cannot be computed by multi-tape Turing machines that run in linear (or slightly super-linear) time, even in the non-uniform setting, where the machine gets an arbitrary advice tape.

We then describe a class of multiplayer games, such that, a sufficiently strong parallel repetition theorem for that class of games implies an explicit block-rigid function. The games in that class have the following property that may be of independent interest: for every random string for the verifier (which, in particular, determines the vector of queries to the players), there is a unique correct answer for each of the players, and the verifier accepts if and only if all answers are correct. We refer to such games as *independent games*. The theorem that we need is that parallel repetition reduces the value of games in this class from  $v$  to  $v^{\Omega(n)}$ , where  $n$  is the number of repetitions.

As another application of block rigidity, we show conditional size-depth tradeoffs for boolean circuits, where the gates compute arbitrary functions over large sets.

## 1 Introduction

We study relations between three seemingly unrelated topics: parallel repetition of multiplayer games, a variant of Valiant’s notion of rigidity, that we refer to as block rigidity, and proving super-linear lower bounds for Turing machines with advice.

## 1.1 Super-Linear Lower Bounds for Turing Machines

Deterministic multi-tape Turing machines are the standard model of computation for defining time-complexity classes. Lower bounds for the running time of such machines are known by the time-hierarchy theorem [18], using a diagonalization argument. Moreover, the seminal work of Paul, Pippenger, Szemerédi and Trotter gives a separation of non-deterministic linear time from deterministic linear time, for multi-tape Turing machines [28] (using ideas from [20] and [27]). That is, it shows that  $\text{DTIME}(n) \subsetneq \text{NTIME}(n)$ . This result has been slightly improved to give  $\text{DTIME}(n\sqrt{\log^* n}) \subsetneq \text{NTIME}(n\sqrt{\log^* n})$  [33].

However, the above mentioned lower bounds do not hold in the non-uniform setting, where the machines are allowed to use arbitrary advice depending on the length of the input. In the non-uniform setting, no super-linear lower bound is known for the running time of deterministic multi-tape Turing machines. Moreover, such bounds are not known even for a multi-output function.

## 1.2 Block Rigidity

The concept of matrix rigidity was introduced by Valiant as a means to prove super-linear lower bounds against circuits of logarithmic depth [36]. Since then, it has also found applications in communication complexity [32] (see also [39, 25]). We extend Valiant's notion of rigid matrices to the concept of *rigid functions*, and further to *block-rigid functions*. We believe that these notions are of independent interest. We note that block-rigidity is a weaker condition than rigidity and hence it may be easier to find explicit block-rigid functions. Further, our result gives a new application of rigidity.

Over a field  $\mathbb{F}$ , a matrix  $A \in \mathbb{F}^{n \times n}$  is said to be an  $(r, s)$ -rigid matrix if it is not possible to reduce the rank of  $A$  to at most  $r$ , by changing at most  $s$  entries in each row of  $A$ . Valiant showed that if  $A \in \mathbb{F}^{n \times n}$  is  $(\epsilon n, n^\epsilon)$ -rigid for some constant  $\epsilon > 0$ , then  $A$  is not computable by a linear-circuit of logarithmic depth and linear size. As in many problems in complexity, the challenge is to find explicit rigid matrices. By explicit, we mean that a polynomial time deterministic Turing machine should be able to output a rigid matrix  $A \in \mathbb{F}^{n \times n}$  on input  $1^n$ . The best known bounds on explicit rigid matrices are far from what is needed to get super-linear circuit lower bounds (see [15, 35, 34, 24, 26, 23, 2, 17, 1, 4]).

We extend the above definition to functions  $f : \{0, 1\}^n \rightarrow \{0, 1\}^n$ , by saying that  $f$  is *not* an  $(r, s)$ -rigid function if there exists a subset  $X \subseteq \{0, 1\}^n$  of size at least  $2^{n-r}$ , such that over  $X$ , each output bit of  $f$  can be written as a function of some  $s$  input bits (see Definition 7). By a simple counting argument (see Proposition 8), it follows that random functions are rigid with good probability.

We further extend this definition to what we call block-rigid functions (see Definition 11). For this, we'll consider vectors  $x \in \{0, 1\}^{nk}$ , which are thought of as composed of  $k$  blocks, each of size  $n$ . We say that a function  $f : \{0, 1\}^{nk} \rightarrow \{0, 1\}^{nk}$  is *not* an  $(r, s)$ -block-rigid function, if there exists a subset  $X \subseteq \{0, 1\}^{nk}$  of size at least  $2^{nk-r}$ , such that over  $X$ , each *output block* of  $f$  can be written as a function of some  $s$  *input blocks*.

We conjecture that it is possible to obtain large block-rigid functions, using smaller rigid functions. For a function  $f : \{0, 1\}^k \rightarrow \{0, 1\}^k$ , we define the function  $f^{\otimes n} : \{0, 1\}^{nk} \rightarrow \{0, 1\}^{nk}$  as follows. For each  $x = (x_{ij})_{i \in [n], j \in [k]} \in \{0, 1\}^{nk}$ , we define  $f^{\otimes n}(x)$  to be the vector obtained by applying  $f$  to  $(x_{i1}, \dots, x_{ik})$ , in place for each  $i \in [n]$  (see Definition 13).

► **Conjecture 1.** *There exists a universal constant  $c > 0$  such that the following is true. Let  $f : \{0, 1\}^k \rightarrow \{0, 1\}^k$  be an  $(r, s)$ -rigid function, and  $n \in \mathbb{N}$ . Then,  $f^{\otimes n} : \{0, 1\}^{nk} \rightarrow \{0, 1\}^{nk}$  is a  $(cnr, cs)$ -block-rigid function.*

We prove the following theorem. It is restated and proved as Theorem 28 in Section 5.

- **Theorem 2.** *Let  $t : \mathbb{N} \rightarrow \mathbb{N}$  be any function such that  $t(n) = \omega(n)$ . Assuming Conjecture 1, there exists an (explicitly given) function  $f : \{0, 1\}^* \rightarrow \{0, 1\}^*$  such that*
1. *On inputs  $x$  of length  $n$  bits, the output  $f(x)$  is of length at most  $n$  bits.*
  2. *The function  $f$  is computable by a multi-tape deterministic Turing machine that runs in time  $O(t(n))$  on inputs of length  $n$ .*
  3. *The function  $f$  is not computable by any multi-tape deterministic Turing machine that takes advice and runs in time  $O(n)$  on inputs of length  $n$ .*

More generally, we show that families of block-rigid functions cannot be computed by non-uniform Turing machines running in linear-time. This makes it interesting to find such families that are computable in polynomial time. The following theorem is restated as Theorem 29.

- **Theorem 3.** *Let  $k : \mathbb{N} \rightarrow \mathbb{N}$  be a function such that  $k(n) = \omega(1)$  and  $k(n) = 2^{o(n)}$ , and  $f_n : \{0, 1\}^{nk(n)} \rightarrow \{0, 1\}^{nk(n)}$  be a family of  $(\epsilon nk(n), \epsilon k(n))$ -block-rigid functions, for some constant  $\epsilon > 0$ . Let  $M$  be any multi-tape deterministic linear-time Turing machine that takes advice. Then, there exists  $n \in \mathbb{N}$ , and  $x \in \{0, 1\}^{nk(n)}$ , such that  $M(x) \neq f_n(x)$ .*

As another application, based on Conjecture 1, we show size-depth tradeoffs for boolean circuits, where the gates compute arbitrary functions over large (with respect to the input size) sets (see Section 6).

### 1.3 Parallel Repetition

In a  $k$ -player game  $\mathcal{G}$ , questions  $(x_1, \dots, x_k)$  are chosen from some joint distribution  $\mu$ . For each  $j \in [k]$ , player  $j$  is given  $x_j$  and gives an answer  $a_j$  that depends only on  $x_j$ . The players are said to win if their answers satisfy a fixed predicate  $V(x_1, \dots, x_k, a_1, \dots, a_k)$ . We note that  $V$  might be randomized, that is, it might depend on some random string that is sampled independently of  $(x_1, \dots, x_k)$ . The value of the game  $\text{val}(\mathcal{G})$  is defined to be the maximum winning probability over the possible strategies of the players.

It is natural to consider the parallel repetition  $\mathcal{G}^{\otimes n}$  of such a game  $\mathcal{G}$ . Now, the questions  $(x_1^{(i)}, \dots, x_k^{(i)})$  are chosen from  $\mu$ , independently for each  $i \in [n]$ . For each  $j \in [k]$ , player  $j$  is given  $(x_j^{(1)}, \dots, x_j^{(n)})$  and gives answers  $(a_j^{(1)}, \dots, a_j^{(n)})$ . The players are said to win if the answers satisfy  $V(x_1^{(i)}, \dots, x_k^{(i)}, a_1^{(i)}, \dots, a_k^{(i)})$  for every  $i \in [n]$ . The value of the game  $\text{val}(\mathcal{G}^{\otimes n})$  is defined to be the maximum winning probability over the possible strategies of the players. Note that the players are allowed to correlate their answers to different repetitions of the game.

Parallel repetition of games was first studied in [13], owing to its relation with multiprover interactive proofs [3]. It was hoped that the value  $\text{val}(\mathcal{G}^{\otimes n})$  of the repeated game goes down as  $\text{val}(\mathcal{G})^n$ . However, this is not the case, as shown in [14, 10, 11, 31].

A lot is known about parallel repetition of 2-player games. The, so called, parallel repetition theorem, first proved by Raz [30] and further simplified and improved by Holenstein [19], shows that if  $\text{val}(\mathcal{G}) < 1$ , then  $\text{val}(\mathcal{G}^{\otimes n}) \leq 2^{-\Omega(n/s)}$ , where  $s$  is the length of the answers given by the players. The bounds in this theorem were later made tight even for the case when the initial game has small value (see [8] and [5]).

Much less is known for  $k$ -player games with  $k \geq 3$ . Verbitsky [38] showed that if  $\text{val}(\mathcal{G}) < 1$ , then the value of the repeated game goes down to zero as  $n$  grows larger. The result shows a very weak rate of decay, approximately equal to  $\frac{1}{\alpha(n)}$ , where  $\alpha$  is the

inverse-Ackermann function, owing to the use of the density Hales-Jewett theorem (see [16] and [29]). A recent result by Dinur, Harsha, Venkat and Yuen [7] shows exponential decay, but only in the special case of what they call *expanding games*. This approach fails when the input to the players have strong correlations.

In this paper (see Section 4), we show that a sufficiently strong parallel repetition theorem for multiplayer games implies Conjecture 1. The following theorem is proved formally as Theorem 19 in Section 4.

► **Theorem 4.** *There exists a family  $\{\mathcal{G}_{\mathcal{S},k}\}$  of  $k$ -player games (where  $\mathcal{S}$  is some parameter), such that a strong parallel repetition theorem for all games in  $\{\mathcal{G}_{\mathcal{S},k}\}$  implies Conjecture 1.*

Although the games in this family do not fit into the framework of [7], they satisfy some very special properties. Every  $k$ -player game in the family satisfies the following:

1. The questions to the  $k$ -players are chosen as follows: First,  $k$  bits,  $x_1, \dots, x_k \in \{0, 1\}$ , are drawn uniformly and independently. Each of the  $k$ -players sees some subset of these  $k$ -bits.
2. The predicate  $V$  satisfies the condition that on fixing the bits  $x_1, \dots, x_k$ , there is a unique accepting answer for each player (independently of all other answers) and the verifier accepts if every player answers with the accepting answer. We refer to games that satisfy this property as *independent games*.

We believe that these properties may allow us to prove strong upper bounds on the value of parallel repetition of such games, despite our lack of understanding of multiplayer parallel repetition. The bounds that we need are that parallel repetition reduces the value of such games from  $v$  to  $v^{\Omega(n)}$ , where  $n$  is the number of repetitions (as is proved in [8] and [5] for 2-player games).

## 1.4 Open Problems

1. The main open problem is to make progress towards proving Conjecture 1, possibly using the framework of parallel repetition. The remarks after Theorem 28 mention some weaker statements that suffice for our applications. The examples of matrix-transpose and matrix-product in Section 8 also serve as interesting problems.
2. Our techniques, which are based on [28], heavily exploit the fact that the Turing machines have one-dimensional tapes. Time-space lower bounds for satisfiability in the case of multi-tape Turing machines with random access [12], and Turing machines with one  $d$ -dimensional tape [37], are known. Extending such results to the non-uniform setting is an interesting open problem.
3. The question of whether a rigid-matrix  $A \in \mathbb{F}_2^{n \times n}$  is rigid when seen as a function  $A : \{0, 1\}^n \rightarrow \{0, 1\}^n$  is very interesting (see Section 7). This question is closely related to a Conjecture of Jukna and Schnitger [21] on the linearization of depth-2 circuits. This is also related to the question of whether data structures for linear problems can be optimally linearized (see [9]). We note that there are known examples of linear problems for which the best known data-structures are non-linear, without any known linear data-structure achieving the same bounds (see [22]).

## 2 Preliminaries

Let  $\mathbb{N} = \{1, 2, 3, \dots\}$  be the set of all natural numbers. For any  $k \in \mathbb{N}$ , we use  $[k]$  to denote the set  $\{1, 2, \dots, k\}$ .

We use  $\mathbb{F}$  to denote an arbitrary finite field, and  $\mathbb{F}_2$  to denote the finite field on two elements.

Let  $x \in \{0, 1\}^k$ . For  $i \in [k]$ , we use  $x_i$  to denote the  $i^{\text{th}}$  coordinate of  $x$ . For  $S \subseteq [k]$ , we denote by  $x|_S$  the vector  $(x_i)_{i \in S}$ , which is the restriction of  $x$  to coordinates in  $S$ .

We also consider vectors  $x \in \{0, 1\}^{nk}$ , for some  $n \in \mathbb{N}$ . We think of these as composed of  $k$  blocks, each consisting of a vector in  $\{0, 1\}^n$ . That is,  $x = (x_{ij})_{i \in [n], j \in [k]}$ . By abuse of notation, for  $S \subseteq [k]$ , we denote by  $x|_S$  the vector  $(x_{ij})_{i \in [n], j \in S}$ , which is the restriction of  $x$  to the blocks indexed by  $S$ .

Let  $A \in \mathbb{F}^{nk \times nk}$  be an  $nk \times nk$  matrix. We think of  $A$  as a block-matrix consisting of  $k^2$  blocks, each block being an  $n \times n$  matrix. That is,  $A = (A_{ij})_{i, j \in [k]}$ , where for all  $i, j \in [k]$ ,  $A_{ij} \in \mathbb{F}^{n \times n}$ . For each  $i \in [k]$ , we call  $(A_{ij})_{j \in [k]}$  the  $i^{\text{th}}$  block-row of  $A$ .

For every  $n \in \mathbb{N}$ , we define  $\log^* n = \min\{\ell \in \mathbb{N} \cup \{0\} : \underbrace{\log_2 \log_2 \dots \log_2}_{\ell \text{ times}} n \leq 1\}$ .

### 3 Rigidity and Block Rigidity

#### 3.1 Rigidity

The concept of matrix rigidity was introduced by Valiant [36]. It is defined as follows.

► **Definition 5.** A matrix  $A \in \mathbb{F}^{n \times n}$  is said to be an  $(r, s)$ -rigid matrix if it cannot be written as  $A = B + C$ , where  $B$  has rank at most  $r$ , and  $C$  has at most  $s$  non-zero entries in each row.

Valiant [36] showed the existence of rigid matrices by a simple counting argument. For the sake of completeness, we include this proof.

► **Proposition 6.** For any constant  $0 < \epsilon \leq \frac{1}{8}$ , and any  $n \in \mathbb{N}$ , there exists a matrix  $A \in \mathbb{F}^{n \times n}$  that is an  $(\epsilon n, \epsilon n)$ -rigid matrix.

**Proof.** Fix any  $0 < \epsilon \leq \frac{1}{8}$ . We bound the number of  $n \times n$  matrices that are not  $(\epsilon n, \epsilon n)$ -rigid matrices.

1. Any  $n \times n$  matrix with rank at most  $r$  can be written as the product of an  $n \times r$  and an  $r \times n$  matrix. Hence, the number of matrices of rank at most  $\epsilon n$  is at most  $|\mathbb{F}|^{2\epsilon n^2} \leq |\mathbb{F}|^{\frac{n^2}{4}}$ .
2. The number of matrices that have at most  $\epsilon n$  non-zero entries in each row is at most

$$\left( \binom{n}{\epsilon n} |\mathbb{F}|^{\epsilon n} \right)^n \leq \left( \frac{e}{\epsilon} \right)^{\epsilon n^2} |\mathbb{F}|^{\epsilon n^2} = |\mathbb{F}|^{\epsilon n^2 (1 + \log_{|\mathbb{F}|} \frac{e}{\epsilon})} < |\mathbb{F}|^{\frac{3n^2}{4}}.$$

We used the binomial estimate  $\binom{n}{r} \leq \left(\frac{en}{r}\right)^r$ .

Since each matrix that is not an  $(r, s)$ -rigid matrix can be written as the sum of a matrix with rank at most  $r$ , and a matrix with at most  $s$  non-zero entries in each row, the number of matrices that are not  $(\epsilon n, \epsilon n)$ -rigid matrices is strictly less than  $|\mathbb{F}|^{\frac{n^2}{4}} \cdot |\mathbb{F}|^{\frac{3n^2}{4}} = |\mathbb{F}|^{n^2}$ , which is the total number of  $n \times n$  matrices. ◀

Observe that a matrix  $A \in \mathbb{F}_2^{n \times n}$  is not an  $(r, s)$ -rigid matrix if and only if there is a subspace  $X \subseteq \mathbb{F}_2^n$  of dimension at least  $n - r$ , and a matrix  $C$  with at most  $s$  non-zero entries in each row, such that  $Ax = Cx$  for all  $x \in X$ .

We use this formulation to extend the concept of rigidity to general functions.

► **Definition 7.** A function  $f : \{0, 1\}^n \rightarrow \{0, 1\}^n$  is said to be an  $(r, s)$ -rigid function if for every subset  $X \subseteq \{0, 1\}^n$  of size at least  $2^{n-r}$ , and subsets  $S_1, \dots, S_n \subseteq [n]$  of size  $s$ , and functions  $g_1, \dots, g_n : \{0, 1\}^s \rightarrow \{0, 1\}$ , there exists  $x \in X$  such that  $f(x) \neq (g_1(x|_{S_1}), g_2(x|_{S_2}), \dots, g_n(x|_{S_n}))$ .

Using a similar counting argument as in Proposition 6, we show the existence of rigid functions.

► **Proposition 8.** *For any constant  $0 < \epsilon \leq \frac{1}{8}$ , and any (large enough) integer  $n$ , there exists a function  $f : \{0, 1\}^n \rightarrow \{0, 1\}^n$  that is an  $(\epsilon n, \epsilon n)$ -rigid function.*

**Proof.** Fix any constant  $0 < \epsilon \leq \frac{1}{8}$ , and any integer  $n \geq \frac{2}{\epsilon}$ . We count the number of functions  $f : \{0, 1\}^n \rightarrow \{0, 1\}^n$  that are not  $(\epsilon n, \epsilon n)$ -rigid functions.

1. Note that in Definition 7, it is without loss of generality to assume that  $|X| = 2^{n-\epsilon n}$ . The number subsets  $X \subseteq \{0, 1\}^n$  of size  $2^{n-\epsilon n}$  is  $\binom{2^n}{2^{n-\epsilon n}} \leq (e2^{\epsilon n})^{2^{n-\epsilon n}} < 2^{2\epsilon n 2^{n-\epsilon n}} \leq 2^{\frac{n}{4} 2^{n-\epsilon n}}$ .
  2. The number of subsets  $S_1, \dots, S_n \subseteq [n]$  of size  $\epsilon n$  is at most  $\binom{n}{\epsilon n}^n < n^{\epsilon n^2} < 2^{\frac{n}{4} 2^{n-\epsilon n}}$ .
  3. The number of functions  $g_1, \dots, g_n : \{0, 1\}^{\epsilon n} \rightarrow \{0, 1\}$  is at most  $2^{n 2^{\epsilon n}} < 2^{\frac{n}{4} 2^{n-\epsilon n}}$ .
  4. The number of choices for values of  $f$  on  $\{0, 1\}^n \setminus X$  is at most  $2^{n(2^n - |X|)} \leq 2^{n(2^n - 2^{n-\epsilon n})}$ .
- Hence, the total number of functions  $f : \{0, 1\}^n \rightarrow \{0, 1\}^n$  that are not  $(\epsilon n, \epsilon n)$ -rigid functions is strictly less than  $\left(2^{\frac{n}{4} 2^{n-\epsilon n}}\right)^3 2^{n 2^n - n 2^{n-\epsilon n}} < 2^{n 2^n}$ . ◀

### 3.2 Block Rigidity

In this section, we introduce the notion of block rigidity.

► **Definition 9.** *A matrix  $A \in \mathbb{F}^{nk \times nk}$  is said to be an  $(r, s)$ -block-rigid matrix if it cannot be written as  $A = B + C$ , where  $B$  has rank at most  $r$ , and  $C$  has at most  $s$  non-zero matrices in each block-row.*

Observe that if  $A \in \mathbb{F}^{nk \times nk}$  is an  $(r, ns)$ -rigid matrix, then it is also  $(r, s)$ -block-rigid matrix. Combining this with Proposition 6, we get the following.

► **Observation 10.** *For any constant  $0 < \epsilon \leq \frac{1}{8}$ , and positive integers  $n, k$ , there exists an  $(\epsilon nk, \epsilon k)$ -block-rigid matrix  $A \in \mathbb{F}^{nk \times nk}$ .*

Following the definition of rigid-functions in Section 3.1, we define block-rigid functions as follows.

► **Definition 11.** *A function  $f : \{0, 1\}^{nk} \rightarrow \{0, 1\}^{nk}$  is said to be an  $(r, s)$ -block-rigid function if for every subset  $X \subseteq \{0, 1\}^{nk}$  of size at least  $2^{nk-r}$ , and subsets  $S_1, \dots, S_k \subseteq [k]$  of size  $s$ , and functions  $g_1, \dots, g_k : \{0, 1\}^{ns} \rightarrow \{0, 1\}^n$ , there exists  $x \in X$  such that  $f(x) \neq (g_1(x|_{S_1}), g_2(x|_{S_2}), \dots, g_k(x|_{S_k}))$ .*

Observe that if  $f : \{0, 1\}^{nk} \rightarrow \{0, 1\}^{nk}$  is an  $(r, ns)$ -rigid function, then it is also  $(r, s)$ -block-rigid function. Combining this with Proposition 8, we get the following.

► **Observation 12.** *For any constant  $0 < \epsilon \leq \frac{1}{8}$ , and (large enough) integers  $n, k$ , there exists an  $(\epsilon nk, \epsilon k)$ -block-rigid function  $f : \{0, 1\}^{nk} \rightarrow \{0, 1\}^{nk}$ .*

Note that  $n = 1$  in the definition of block-rigid matrices (functions) gives the usual definition of rigid matrices (functions). For our applications, we will mostly be interested in the case when  $n$  is much larger than  $k$ .

### 3.3 Rigidity Amplification

A natural question is whether there is a way to amplify rigidity. That is, given a rigid matrix (function), is there a way to obtain a larger matrix (function) which is rigid, or even block-rigid.

► **Definition 13.** Let  $f : \{0, 1\}^k \rightarrow \{0, 1\}^k$  be any function. Define  $f^{\otimes n} : \{0, 1\}^{nk} \rightarrow \{0, 1\}^{nk}$  as following. Let  $x = (x_{ij})_{i \in [n], j \in [k]} \in \{0, 1\}^{nk}$  and  $i \in [n], j \in [k]$ . The  $(i, j)^{\text{th}}$  coordinate of  $f^{\otimes n}(x)$  is defined to be the  $j^{\text{th}}$  coordinate of  $f(x_{i1}, x_{i2}, \dots, x_{ik})$ .

Basically, applying  $f^{\otimes n}$  on  $x \in \{0, 1\}^{nk}$  is the same as applying  $f$  on  $(x_{i1}, x_{i2}, \dots, x_{ik})$ , in place for each  $i \in [n]$ . For a linear function given by matrix  $A \in \mathbb{F}_2^{k \times k}$ , this operation corresponds to  $A \otimes I_n$ , where  $I_n$  is the  $n \times n$  identity matrix, and  $\otimes$  denotes the Kronecker product of matrices.

It is easy to see that if  $f$  is not rigid, then  $f^{\otimes n}$  is not block-rigid.

► **Observation 14.** Suppose  $f : \{0, 1\}^k \rightarrow \{0, 1\}^k$  is not an  $(r, s)$ -rigid function. Then  $f^{\otimes n}$  is not an  $(nr, s)$ -block-rigid function.

The converse of Observation 14 is more interesting. We believe that it is true, and restate Conjecture 1 below.

► **Conjecture 15.** There exists a universal constant  $c > 0$  such that the following is true. Let  $f : \{0, 1\}^k \rightarrow \{0, 1\}^k$  be an  $(r, s)$ -rigid function, and  $n \in \mathbb{N}$ . Then,  $f^{\otimes n} : \{0, 1\}^{nk} \rightarrow \{0, 1\}^{nk}$  is a  $(cnr, cs)$ -block-rigid function.

## 4 Parallel Repetition

In this section, we show an approach to prove Conjecture 15 regarding rigidity amplification. This is based on proving a strong parallel repetition theorem for a  $k$ -player game.

Fix some  $k \in \mathbb{N}$ , a function  $f : \{0, 1\}^k \rightarrow \{0, 1\}^k$ , an integer  $1 \leq s < k$ , and  $\mathcal{S} = (S_1, \dots, S_k)$ , where each  $S_i \subseteq [k]$  is of size  $s$ . We define a  $k$ -player game  $\mathcal{G}_{\mathcal{S}}$  as follows:

The  $k$ -players choose functions  $g_1, \dots, g_k : \{0, 1\}^s \rightarrow \{0, 1\}$ , which we call a strategy. A verifier chooses  $x_1, \dots, x_k \in \{0, 1\}^s$  uniformly and independently. Let  $x = (x_1, \dots, x_k) \in \{0, 1\}^{ks}$ . For each  $j \in [k]$ , Player  $j$  is given the input  $x|_{S_j}$ , and they answer  $a_j = g_j(x|_{S_j}) \in \{0, 1\}$ . The verifier accepts if and only if  $f(x) = (a_1, \dots, a_k)$ . The goal of the players is to maximize the winning probability. Formally, the value of the game is defined as

$$\text{val}(\mathcal{G}_{\mathcal{S}}) := \max_{g_1, \dots, g_k} \Pr_{x_1, \dots, x_k \in \{0, 1\}^s} [f(x) = (g_1(x|_{S_1}), \dots, g_k(x|_{S_k}))].$$

The  $n$ -fold repetition of  $\mathcal{G}_{\mathcal{S}}$ , denoted by  $\mathcal{G}_{\mathcal{S}}^{\otimes n}$  is defined as follows. The players choose a strategy  $g_1, \dots, g_k : \{0, 1\}^s \rightarrow \{0, 1\}$ . The verifier chooses  $x_1, \dots, x_k \in \{0, 1\}^s$  uniformly and independently. Let  $x = (x_1, \dots, x_k) \in \{0, 1\}^{ks}$ . Player  $j$  is given the input  $x|_{S_j}$ , and they answer  $a_j = g_j(x|_{S_j}) \in \{0, 1\}$ . The verifier accepts if and only if  $f^{\otimes n}(x) = (a_1, \dots, a_k)$ . That is, for each  $i \in [n]$ ,  $j \in [k]$ , the  $j^{\text{th}}$  bit of  $f(x_{i1}, \dots, x_{ik})$  equals the  $i^{\text{th}}$  bit of  $a_j$ . The value of this repeated game is

$$\text{val}(\mathcal{G}_{\mathcal{S}}^{\otimes n}) := \max_{g_1, \dots, g_k} \Pr_{x_1, \dots, x_k \in \{0, 1\}^s} [f^{\otimes n}(x) = (g_1(x|_{S_1}), \dots, g_k(x|_{S_k}))].$$

From Definition 11, we get the following:

► **Observation 16.** Let  $f : \{0, 1\}^k \rightarrow \{0, 1\}^k$  be a function, and  $n \in \mathbb{N}$ . Then,  $f^{\otimes n}$  is an  $(r, s)$ -block-rigid function if and only if for every  $\mathcal{S} = (S_1, \dots, S_k)$  with set sizes as  $s$ ,  $\text{val}(\mathcal{G}_{\mathcal{S}}^{\otimes n}) < 2^{-r}$ .

**Proof.** Let  $f^{\otimes n}$  be an  $(r, s)$ -block-rigid function. Suppose, for the sake of contradiction, that  $\mathcal{S} = (S_1, \dots, S_k)$  is such that  $\text{val}(\mathcal{G}_{\mathcal{S}}^{\otimes n}) \geq 2^{-r}$ . Let the functions  $g_1, \dots, g_k : \{0, 1\}^s \rightarrow \{0, 1\}$  be an optimal strategy for the players. Define  $X :=$

$\left\{x \in \{0,1\}^{nk} : f^{\otimes n}(x) = (g_1(x|_{S_1}), \dots, g_k(x|_{S_k}))\right\}$ . Then,  $|X| = \text{val}(\mathcal{G}_S) \cdot 2^{nk} \geq 2^{nk-r}$ , which contradicts the block rigidity of  $f^{\otimes n}$ .

Conversely, suppose that  $f^{\otimes n}$  is not  $(r, s)$ -block-rigid. Then, there exists  $X \subseteq \{0,1\}^{nk}$  with  $|X| \geq 2^{nk-r}$ , subsets  $S_1, \dots, S_k \subseteq [k]$  of size  $s$ , and functions  $g_1, \dots, g_k : \{0,1\}^{ns} \rightarrow \{0,1\}^n$ , such that for all  $x \in X$ ,  $f^{\otimes n}(x) = (g_1(x|_{S_1}), \dots, g_k(x|_{S_k}))$ . Let  $\mathcal{S} = (S_1, \dots, S_k)$ , and suppose the players use strategy  $g_1, \dots, g_k$ . Then,  $\text{val}(\mathcal{G}_S^{\otimes n}) \geq |X| \cdot 2^{-nk} \geq 2^{-r}$ .  $\blacktriangleleft$

In particular, for  $n = 1$ , Observation 16 gives the following:

► **Observation 17.** *A function  $f : \{0,1\}^k \rightarrow \{0,1\}^k$  is an  $(r, s)$ -rigid-function if and only if for every  $\mathcal{S} = (S_1, \dots, S_k)$  with set sizes as  $s$ ,  $\text{val}(\mathcal{G}_S) < 2^{-r}$ .*

We conjecture the following strong parallel repetition theorem.

► **Conjecture 18.** *There exists a constant  $c > 0$  such that the following is true. Let  $f : \{0,1\}^k \rightarrow \{0,1\}^k$  be any function, and  $\mathcal{S} = (S_1, \dots, S_k)$  be such that for each  $i \in [k]$ ,  $S_i \subseteq [k]$  is of size  $s$ . Then, for all  $n \in \mathbb{N}$ ,  $\text{val}(\mathcal{G}_S^{\otimes n}) \leq (\text{val}(\mathcal{G}_S))^{cn}$ .*

Combining Observation 16 and 17, we get the following:

► **Theorem 19.** *Conjecture 18  $\implies$  Conjecture 15.*

► **Remarks.**

- (i) *By looking only at some particular player, it can be shown that if  $\text{val}(\mathcal{G}_S) < 1$ , then  $\text{val}(\mathcal{G}_S^{\otimes n}) \leq 2^{-\Omega(n)}$ . In fact, such a result holds for all independent games. The harder part seems to be showing strong parallel repetition when the initial game has small value.*
- (ii) *Observe that the game  $\mathcal{G}_S$  has a randomized predicate in the case  $\cup_{j=1}^k S_j \neq [k]$ . This condition can be removed (even for general independent games) by introducing a new player. This player is given the random string used by the verifier, and is always required to answer a single bit equal to zero. This maintains the independent game property, and ensures that the predicate used by the verifier is a deterministic function of the vector of input queries to the players.*

## 5 Turing Machine Lower Bounds

In this section, we show a conditional super-linear lower bound for multi-tape deterministic Turing machines that can take advice.

Without loss of generality, we only consider machines that have a separate read-only input tape. We assume that the advice string, which is a function of the input length, is written on a separate advice tape at the beginning of computation. We are interested in machines that compute multi-output functions. For this, we assume that at the end of computation, the machine writes the entire output on a separate write-only output tape, and then halts.

We consider the following problem.

- **Definition 20.** *Let  $k : \mathbb{N} \rightarrow \mathbb{N}$  be a function. We define the problem  $\text{Tensor}_k$  as follows:*
- *Input:  $(f, x)$ , where  $f : \{0,1\}^k \rightarrow \{0,1\}^k$  is a function, and  $x \in \{0,1\}^{nk}$ , for some  $n \in \mathbb{N}$  and  $k = k(n)$ .*
  - *Output:  $f^{\otimes n}(x) \in \{0,1\}^{nk}$ .*

*The function  $f$  is given as input in the form of its entire truth table. The input  $x = (x_{ij})_{i \in [n], j \in [k]}$  is given in the order  $(x_{11}, \dots, x_{n1}, x_{12}, \dots, x_{n2}, \dots, x_{1k}, \dots, x_{nk})$ . The total length of the input is  $m(n) := 2^k k + nk$ .*

We observe that if the function  $k : \mathbb{N} \rightarrow \mathbb{N}$  grows very slowly with  $n$ , the problem  $\text{Tensor}_k$  can be solved by a deterministic Turing machine in slightly super-linear time.

► **Observation 21.** *Let  $k : \mathbb{N} \rightarrow \mathbb{N}$  be a function. There exists a deterministic Turing machine that solves the problem  $\text{Tensor}_k$  in time  $O(nk2^k)$ , on input  $(f, x)$  of length  $nk + 2^k k$ , where  $k = k(n)$ .*

**Proof.** We note that applying  $f^{\otimes n}$  on  $x = (x_{ij})_{i \in [n], j \in [k]}$  is the same as applying  $f$  on  $(x_{i1}, x_{i2}, \dots, x_{ik})$ , in place for each  $i \in [n]$ . A Turing machine can do the following:

1. Find  $n$  and  $k$ , using the fact that the description of  $f$  is of length  $2^k k$ , and that of  $x$  is of length  $nk$ .
2. Rearrange the input so that for each  $i \in [n]$ , the part  $(x_{i1}, x_{i2}, \dots, x_{ik})$  is written consecutively on the tape.
3. Using the truth table of  $f$ , compute the output for each such part.
4. Rearrange the entire output back to the desired form.

The total time taken is  $O(nk + nk^2 + nk2^k + nk^2) = O(nk2^k)$ . ◀

We now state and prove the main technical theorem of this section.

► **Theorem 22.** *Let  $k : \mathbb{N} \rightarrow \mathbb{N}$  be a function such that  $k(n) = \omega(1)$  and  $k(n) = o(\log_2 n)$ . Let  $m = m(n) := 2^k k + nk$ , where  $k = k(n)$ .*

*Suppose  $M$  is a deterministic multi-tape Turing machine that takes advice, and runs in linear time in the length of its input. Assuming Conjecture 15, the machine  $M$  does not solve the problem  $\text{Tensor}_k$  correctly for all inputs. That is, there exists  $n \in \mathbb{N}$ , and  $y = (f, x) \in \{0, 1\}^m$  such that  $M(y) \neq f^{\otimes n}(x)$ .*

There are two main technical ideas that will be useful to us. The first is the notion of block-respecting Turing machines, defined by Hopcroft, Paul and Valiant [20]. The second is a graph theoretic result, which was proven by Paul, Pippenger, Szemerédi and Trotter [28], and was used to show a separation between deterministic and non-deterministic linear time.

► **Definition 23.** *Let  $M$  be a Turing machine, and let  $b : \mathbb{N} \rightarrow \mathbb{N}$  be a function. Partition the computation of  $M$ , on any input  $y$  of length  $m$ , into time segments of length  $b(m)$ , with the last segment having length at most  $b(m)$ . Also, partition each of the tapes of  $M$  into blocks, each consisting of  $b(m)$  contiguous cells.*

*We say that  $M$  is block-respecting with respect to block size  $b$ , if on inputs of length  $m$ , the tape heads of  $M$  cross blocks only at times that are integer multiples of  $b(m)$ .*

► **Lemma 24.** [20] *Let  $t : \mathbb{N} \rightarrow \mathbb{N}$  be a function, and  $M$  be a multi-tape deterministic Turing machine running in time  $t(m)$  on inputs of length  $m$ . Let  $b : \mathbb{N} \rightarrow \mathbb{N}$  be a function such that  $b(m)$  is computable from  $1^m$  by a multi-tape deterministic Turing machine running in time  $O(t(m))$ . Then, the language recognized by  $M$  is also recognized by a multi-tape deterministic Turing Machine  $M'$ , which runs in time  $O(t(m))$ , and is block-respecting with respect to  $b$ .*

The rest of this section is devoted to the proof of Theorem 22. Let  $k : \mathbb{N} \rightarrow \mathbb{N}$  be a function such that  $k(n) = \omega(1)$  and  $k(n) = o(\log_2 n)$ . Let  $m = m(n) := 2^k k + nk$ , where  $k = k(n)$ .

Suppose that  $M$  is a deterministic multi-tape Turing Machine, which on input  $y = (f, x) \in \{0, 1\}^m$ , takes advice, runs in time  $O(m)$ , and outputs  $f^{\otimes n}(x)$ .

Let  $b : \mathbb{N} \rightarrow \mathbb{N}$  be a function such that  $b(m) = n$ . By our assumption that  $k(n) = o(\log_2 n)$ , we can assume that the input  $y = (f, x) \in \{0, 1\}^m$  consists of  $k + 1$  blocks, where the first block contains  $f$  (possibly padded by blank symbols to the left), and the remaining  $k$  blocks

contain  $x$ . By Lemma 24, we can further assume that  $M$  is block-respecting with respect to  $b$ . Note that we can assume  $n$  to be a part of the advice, and hence we don't need to care about the computability of  $b$ .

For an input  $y = (f, x) \in \{0, 1\}^m$ , the number of time segments for which  $M$  runs on  $x$  is at most  $\frac{O(m)}{b(m)} = \frac{O(nk)}{n} = O(k) := a(n)$ .

We define the computation graph  $G_M(y)$ , for input  $y \in \{0, 1\}^m$ , as follows.

► **Definition 25.** *The vertex set of  $G_M(y)$  is defined to be  $V_M(y) = \{1, \dots, a(n)\}$ . For each  $1 \leq i < j \leq a(n)$ , the edge set  $E_M(y)$  has the edge  $(i, j)$ , if either*

- (i)  $j = i + 1$ , or
- (ii) *there is some tape, such that, during the computation on  $y$ ,  $M$  visits the same block on that tape in both time-segments  $i$  and  $j$ , and never visits that block during any time-segment strictly between  $i$  and  $j$ .*

In a directed acyclic graph  $G$ , we say that a vertex  $u$  is a predecessor of a vertex  $v$ , if there exists a directed path from  $u$  to  $v$ .

► **Lemma 26** ([28]). *For every  $y$ , the graph  $G_M(y)$  satisfies the following:*

1. *Each vertex in  $G_M(y)$  has degree  $O(1)$ .*
2. *There exists a set of vertices  $J \subset V_M(y)$  in  $G_M(y)$ , of size  $O\left(\frac{a(n)}{\log^* a(n)}\right)$  such that every vertex of  $G_M(y)$  has at most  $O\left(\frac{a(n)}{\log^* a(n)}\right)$  many predecessors in the induced subgraph on the vertex set  $V_M(y) \setminus J$ .*

*We note that the constants here might depend on the number of tapes of  $M$ .*

► **Lemma 27.** *Let  $\epsilon > 0$  be any constant and  $\mathcal{Y} \subseteq \{0, 1\}^m$  be any subset of the inputs. For all (large enough)  $n$ , there exists a subset  $Y \subseteq \mathcal{Y}$  of size  $|Y| \geq |\mathcal{Y}| \cdot 2^{-\epsilon nk}$ , and subsets  $S_1, \dots, S_k \subseteq [k]$  of size  $\epsilon k$ , such that for each  $y = (f, x) \in Y$ , and each  $i \in [k]$ , the  $i^{\text{th}}$  block (of length  $n$ ) of  $f^{\otimes n}(x)$  can be written as a function of  $x|_{S_i}$  and the truth-table of  $f$ .*

**Proof.** For input  $y = (f, x) \in \{0, 1\}^m$ , let  $J(y) \subset V_M(y)$  be a set as in Lemma 26.

Let  $C(y)$  denote the following information about the computation of  $M$ :

- (i) The internal state of  $M$  at the end of each time-segment.
- (ii) The position of all tape heads at the end of each time-segment.
- (iii) For each time segment in  $J(y)$ , and for each tape of  $M$ , the final transcription (of length  $n$ ) of the block that was visited on this tape during this segment.

Let  $g : \mathcal{Y} \rightarrow \{0, 1\}^*$  be the function given by  $g(y) = (G_M(y), J(y), C(y))$ . Observe that the output of  $g$  can be described using  $O\left(k \log_2 k + \frac{nk}{\log^* k}\right)$  bits. By our assumption that  $k(n) = \omega(1)$  and  $k(n) = o(\log_2 n)$ , we have that for large  $n$ , this is at most  $\epsilon nk$  bits. Hence, there exists a set  $Y \subseteq \mathcal{Y}$  of size  $|Y| \geq |\mathcal{Y}| \cdot 2^{-\epsilon nk}$ , such that for each  $y \in Y$ ,  $g(y)$  takes on some fixed value  $(G = (V, E), J, C)$ .

Now, consider any  $y = (f, x) \in Y$ . The machine writes the  $k$  blocks of the output  $f^{\otimes n}(x)$  on the output tape in the last  $k$  time segments before halting. For each of these time segments, the corresponding vertex in  $G$  has at most  $O\left(\frac{k}{\log^* k}\right) \leq \epsilon k$  predecessors in the induced subgraph on  $V \setminus J$ . These further correspond to at most  $\epsilon k$  distinct blocks of  $y$  that are visited (on the input tape) during these predecessor time segments. Since the relevant block transcriptions at the end of time segments for vertices in  $J$  are fixed in  $C$ , each output block can be written as a function of at most  $\epsilon k$  blocks of  $y$ . For the  $i^{\text{th}}$  block of output, without loss of generality, this includes the first block of  $y$ , which contains the truth table of  $f$ , and blocks of  $x$  which indexed by some subset  $S_i \subseteq [k]$  of size  $\epsilon k$ . ◀

**Proof of Theorem 22.** Let  $\delta = \frac{1}{8}$ . Fix some sufficiently large  $n$ , and a  $(\delta k, \delta k)$ -rigid function  $f_0 : \{0, 1\}^k \rightarrow \{0, 1\}^k$ . The existence of such a function is guaranteed by Proposition 8. By Conjecture 15, the function  $f_0^{\otimes n}$  is an  $(\epsilon n k, \epsilon k)$ -block-rigid function for some constant  $\epsilon > 0$ . On the other hand, Lemma 27, with  $\mathcal{Y} = \{(f_0, x) : x \in \{0, 1\}^{nk}\}$ , shows that  $f_0^{\otimes n}$  is not an  $(\epsilon n k, \epsilon k)$ -block-rigid function for any constant  $\epsilon > 0$ . ◀

We now restate and prove Theorem 2.

▶ **Theorem 28.** *Let  $t : \mathbb{N} \rightarrow \mathbb{N}$  be any function such that  $t(n) = \omega(n)$ . Assuming Conjecture 15, there exists a function  $f : \{0, 1\}^* \rightarrow \{0, 1\}^*$  such that*

1. *On inputs  $x$  of length  $n$  bits, the output  $f(x)$  is of length at most  $n$  bits.*
2. *The function  $f$  is computable by a multi-tape deterministic Turing machine that runs in time  $O(t(n))$  on inputs of length  $n$ .*
3. *The function  $f$  is not computable by any multi-tape deterministic Turing machine that takes advice and runs in time  $O(n)$  on inputs of length  $n$ .*

**Proof.** Let  $k : \mathbb{N} \rightarrow \mathbb{N}$  be a function such that  $k(n) = \omega(1)$ ,  $k(n) = o(\log_2 n)$ , and  $nk2^k \leq t(2^k k + nk)$ . The theorem then follows from Observation 21 and Theorem 22. ◀

▶ **Remarks.**

- (i) *We note that for the proof of Theorem 22, it suffices to find, for infinitely many  $n$ , a single function  $f : \{0, 1\}^{k(n)} \rightarrow \{0, 1\}^{k(n)}$  such that  $f^{\otimes n}$  is an  $(\epsilon n k, \epsilon k)$ -block-rigid function, where  $\epsilon > 0$  is a constant. This would show that  $M$  cannot give the correct answer to  $\text{Tensor}_k$  for inputs of the form  $(f, x)$ , where  $x \in \{0, 1\}^{nk}$ .*
- (ii) *For the proof of Theorem 22, it can be shown that it suffices for the following condition to hold for infinitely many  $n$ , and some constant  $\epsilon > 0$ . Let  $S_1, \dots, S_k \subseteq [k]$  be fixed sets of size  $\epsilon k$ , and  $f : \{0, 1\}^k \rightarrow \{0, 1\}^k$  be a function chosen uniformly at random. Then, with probability at least  $1 - 2^{-\omega(k \log_2 k)}$ , the function  $f^{\otimes n}$  is an  $(\epsilon n k, \epsilon k)$ -block-rigid function against the fixed sets  $S_1, \dots, S_k$ . We note that the probability here is not good enough to be able to union bound over  $S_1, \dots, S_k$  and get a single function as mentioned in the previous remark.*

Essentially the same argument as that of Theorem 22 also proves Theorem 3, which we restate below.

▶ **Theorem 29.** *Let  $k : \mathbb{N} \rightarrow \mathbb{N}$  be a function such that  $k(n) = \omega(1)$  and  $k(n) = 2^{o(n)}$ , and  $f_n : \{0, 1\}^{nk(n)} \rightarrow \{0, 1\}^{nk(n)}$  be a family of  $(\epsilon n k(n), \epsilon k(n))$ -block-rigid functions, for some constant  $\epsilon > 0$ . Let  $M$  be any multi-tape deterministic linear-time Turing machine that takes advice. Then, there exists  $n \in \mathbb{N}$ , and  $x \in \{0, 1\}^{nk(n)}$ , such that  $M(x) \neq f_n(x)$ .*

The above theorem makes it interesting to find families of block-rigid functions that are computable in polynomial time.

## 6 Size-Depth Tradeoffs

In this section, we will consider boolean circuits over a set  $F$ . These are directed acyclic graphs with each node  $v$  labelled either as an input node or by an arbitrary function  $g_v : F \times F \rightarrow F$ . The input nodes have in-degree 0 and all other nodes have in-degree 2. Some nodes are further labelled as output nodes, and they compute the outputs (in the usual manner), when the inputs are from the set  $F$ . The size of the circuit is defined to be the number of edges in the graph. The depth of the circuit is defined to be the length of a longest directed path from an input node to an output node.

Valiant [36] showed that if  $A \in \mathbb{F}^{n \times n}$  is an  $(\epsilon n, n^\epsilon)$ -rigid matrix for some constant  $\epsilon > 0$ , then the corresponding function cannot be computed by an  $O(n)$ -size and  $O(\log_2 n)$ -depth linear circuit over  $\mathbb{F}$ . By a linear circuit, we mean that each gate computes a linear function (over  $\mathbb{F}$ ) of its inputs. A similar argument can be used to prove the following.

► **Lemma 30** ([36]). *Suppose  $f : \{0, 1\}^{nk} \rightarrow \{0, 1\}^{nk}$  is an  $(\epsilon nk, k^\epsilon)$ -block-rigid function, for some constant  $\epsilon > 0$ . Then, the function  $g : (\{0, 1\}^n)^k \rightarrow (\{0, 1\}^n)^k$  corresponding to  $f$  cannot be computed by an  $O(k)$ -size and  $O(\log_2 k)$ -depth circuit over the set  $F = \{0, 1\}^n$ .*

► **Theorem 31.** *Let  $k : \mathbb{N} \rightarrow \mathbb{N}$  be a function such that  $k(n) = \omega(1)$  and  $k(n) = o(\log_2 n)$ . Let  $m = m(n) := 2^k k + nk$ , where  $k = k(n)$ .*

*Assuming Conjecture 15, the problem  $\text{Tensor}_k$  is not solvable by  $O(k)$ -size and  $O(\log_2 k)$ -depth circuits over the set  $F = \{0, 1\}^n$ . Here, the input  $(f, x)$  to the circuit is given in the form of  $k + 1$  elements in  $\{0, 1\}^n$ , the first one being the truth table of  $f$ , and the remaining  $k$  being the blocks of  $x$ .*

**Proof.** Let  $\delta = \frac{1}{8}$ . Fix some large  $n$ , and a  $(\delta k, \delta k)$ -rigid function  $f_0 : \{0, 1\}^k \rightarrow \{0, 1\}^k$ , where  $k = k(n)$ . The existence of such a function is guaranteed by Proposition 8. Assuming Conjecture 15, the function  $f_0^{\otimes n}$  is an  $(\epsilon nk, \epsilon k)$ -block-rigid function, for some universal constant  $\epsilon > 0$ . By Lemma 30, the corresponding function on  $(\{0, 1\}^n)^k$  cannot be computed by an  $O(k)$ -size and  $O(\log_2 k)$ -depth circuit over  $F = \{0, 1\}^n$ . Since  $f_0$  can be hard-wired in any circuit solving  $\text{Tensor}_k$ , we have the desired result. ◀

## 7 Rigid Matrices and Rigid Functions

A natural question to ask is whether the functions corresponding to rigid matrices are rigid functions or not.

► **Conjecture 32.** *There exists a universal constant  $c > 0$  such that whenever  $A \in \mathbb{F}_2^{n \times n}$  is an  $(r, s)$ -rigid matrix, the corresponding function  $A : \mathbb{F}_2^n \rightarrow \mathbb{F}_2^n$  is a  $(cr, cs)$ -rigid function.*

We show that a positive answer to the above resolves a closely related conjecture by Jukna and Schnitger [21].

► **Definition 33.** *Consider a depth-2 circuit, with  $x = (x_1, \dots, x_n)$  as the input variables,  $w$  gates in the middle layer, computing boolean functions  $h_1, \dots, h_w$  and  $m$  output gates, computing boolean functions  $g_1, \dots, g_m$ . The circuit computes a function  $f = (f_1, \dots, f_m) : \mathbb{F}_2^n \rightarrow \mathbb{F}_2^m$  satisfying  $f_i(x_1, \dots, x_n) = g_i(x, h_1(x), \dots, h_w(x))$ , for each  $i \in [m]$ . The width of the circuit is defined to be  $w$ . The degree of the circuit is defined to be the maximum over all gates  $g_i$ , of the number of wires going directly from the inputs  $x_1, \dots, x_n$  to  $g_i$ .*

We remark that Lemma 27 essentially shows that any function computable by a deterministic linear-time Turing Machine has a depth-2 circuit of small width and small “block-degree”.

► **Conjecture 34** ([21]). *Suppose  $f : \mathbb{F}_2^n \rightarrow \mathbb{F}_2^n$  is a linear function computable by a depth-2 circuit with width  $w$  and degree  $d$ . Then,  $f$  is computable by a depth-2 circuit, with width  $O(w)$ , and degree  $O(d)$ , each of whose gates compute a linear function.*

► **Observation 35.** *Conjecture 32  $\implies$  Conjecture 34.*

**Proof.** Suppose  $f : \mathbb{F}_2^n \rightarrow \mathbb{F}_2^n$  is a linear function computable by a depth-2 circuit with width  $w$  and degree  $d$ . Then, there exists a set  $X \subseteq \mathbb{F}_2^n$  of size at least  $2^{n-w}$ , such that for each  $x \in X$ , the value of the functions computed by the gates in the middle layer is the same.

Hence, for each  $x \in X$ , each element of  $f(x)$  can be written as a function of at most  $d$  elements of  $x$ . This shows that  $f$  is not an  $(w, d)$ -rigid function. Assuming Conjecture 32, the matrix  $A \in \mathbb{F}_2^{n \times n}$  for the function  $f$  is not a  $(cw, cd)$ -rigid matrix, for some constant  $c > 0$ . Then,  $A = B + C$ , where the rank of  $B$  is at most  $cw$ , and  $C$  has at most  $cd$  non-zero entries in each row. Now, there exist matrices  $B_1 \in \mathbb{F}_2^{n \times cw}$  and  $B_2 \in \mathbb{F}_2^{cw \times n}$ , such that  $B = B_1 B_2$ . Then,  $f$  is computable by a linear depth-2 circuit with width  $cw$  and degree  $cd$ , where the middle layer computes output of the function corresponding to  $B_2$ . ◀

## 8 Future Directions

In this section, we state some well known problems related to matrices. It seems interesting to study the block-rigidity of these functions.

### 8.1 Matrix Transpose

The matrix-transpose problem is described as follows:

- *Input:* A matrix  $X \in \mathbb{F}_2^{n \times n}$  as a vector of length  $n^2$  bits, in row-major order, for some  $n \in \mathbb{N}$ .
- *Output:* The matrix  $X$  column-major order (or equivalently, the transpose of  $X$  in row-major order).

It is well known (see [6] for a short proof) that the above problem can be solved on a 2-tape Turing machine in time  $O(N \log N)$ , on inputs of length  $N = n^2$ . We believe that this cannot be solved by Turing machines in linear-time, and that the notion of block-rigidity might be a viable approach to prove this. Next, we observe some structural details about the problem.

The matrix-transpose problem computes a linear function, whose  $N \times N$  matrix  $A$  on inputs of length  $N = n^2$  is described as follows. For each  $i, j \in [n]$ , let  $e_{ij} \in \mathbb{F}_2^{n \times n}$  denote the matrix whose  $(i, j)$ <sup>th</sup> entry is 1 and rest of the entries are zero. The matrix  $A$  is an  $N \times N$  matrix made up of  $n^2$  blocks, with the  $(i, j)$ <sup>th</sup> block equal to  $e_{ji}$ .

Using a similar argument as in Observation 16, one can show that the value of the following game captures the block-rigidity of the matrix-transpose function. Fix integers  $n \in \mathbb{N}$ ,  $1 \leq s < n$ , and a collection  $\mathcal{S} = (S_1, \dots, S_n)$ , where each  $S_i \subseteq [n]$  is of size  $s$ . We define an  $n$ -player game  $\mathcal{G}_{\mathcal{S}}$  as follows: A verifier chooses a matrix  $X \in \mathbb{F}_2^{n \times n}$ , with each entry being chosen uniformly and independently. For each  $j \in [n]$ , player  $j$  is given the rows of the matrix indexed by  $S_j$ , and they answer  $y_j \in \mathbb{F}_2^n$ . The verifier accepts if and only if for each  $j \in [n]$ ,  $y_j$  equals the  $j$ <sup>th</sup> column of  $X$ .

► **Conjecture 36.** *There exists a constant  $c > 0$  such that the function given by the matrix  $A$  is a  $(cn^2, cn)$ -block-rigid function. Equivalently, for each collection  $\mathcal{S}$  with set sizes as  $cn$ , the value of the game  $\mathcal{G}_{\mathcal{S}}$  is at most  $2^{-cn^2}$ .*

We note that the above game is of independent interest from a combinatorial point of view as well. Basically, it asks whether there exists a large family of  $n \times n$  matrices, in which each column can be represented as some function of a small fraction of the rows. The problem of whether the matrix  $A$  is a block-rigid matrix is also interesting. This corresponds to the players in the above game using strategies which are linear functions.

## 8.2 Matrix Product

The matrix-product problem is described as follows:

- *Input:* Matrices  $X, Y \in \mathbb{F}_2^{n \times n}$  as vectors of length  $n^2$  bits, in row-major order, for some  $n \in \mathbb{N}$ .
- *Output:* The matrix  $Z = XY$  in row-major order.

The block-rigidity of the matrix-product function is captured by the following game: Fix integers  $n \in \mathbb{N}$ ,  $1 \leq s < n$ , and collections  $\mathcal{S} = (S_1, \dots, S_n)$ ,  $\mathcal{T} = (T_1, \dots, T_n)$  where each  $S_i, T_i \subseteq [n]$  is of size  $s$ . We define a  $n$ -player game  $\mathcal{G}_{\mathcal{S}, \mathcal{T}}$  as follows: A verifier chooses matrices  $X, Y \in \mathbb{F}_2^{n \times n}$ , with each entry being chosen uniformly and independently. For each  $j \in [n]$ , player  $j$  is given the rows of the matrices  $X$  and  $Y$  indexed by  $S_j$  and  $T_j$  respectively, and they answer  $y_j \in \mathbb{F}_2^n$ . The verifier accepts if and only if for each  $j \in [n]$ ,  $y_j$  equals the  $j^{\text{th}}$  row of  $XY$ .

► **Conjecture 37.** *There exists a constant  $c > 0$  such that for each  $\mathcal{S}, \mathcal{T}$  with set sizes as  $cn$ , the value of the game  $\mathcal{G}_{\mathcal{S}, \mathcal{T}}$  is at most  $2^{-cn^2}$ .*

One may change the row-major order for some (or all) of the matrices to column-major order. It is easy to modify the above game in such a case.

## Abstract

Blockchain is a disruptive new technology introduced around a decade ago. It can be viewed as a method for recording timestamped transactions in a public database. Most of blockchain protocols do not scale well, i.e., they cannot process quickly large amounts of transactions. A natural idea to deal with this problem is to use the blockchain only as a timestamping service, i.e., to hash several transactions  $tx_1, \dots, tx_m$  into one short string, and just put this string on the blockchain, while at the same time posting the hashed transactions  $tx_1, \dots, tx_m$  to some public place on the Internet (“off-chain”). In this way the transactions  $tx_i$  remain timestamped, but the amount of data put on the blockchain is greatly reduced. This idea was introduced in 2017 under the name *Plasma* by Poon and Buterin. Shortly after this proposal, several variants of Plasma have been proposed. They are typically built on top of the Ethereum blockchain, as they strongly rely on so-called *smart contracts* (in order to resolve disputes between the users if some of them start cheating). Plasmas are an example of so-called *off-chain protocols*.

In this work we initiate the study of the inherent limitations of Plasma protocols. More concretely, we show that in every Plasma system the adversary can either (a) force the honest parties to communicate a lot with the blockchain, even though they did not intend to (this is traditionally called *mass exit*); or (b) an honest party that wants to leave the system needs to quickly communicate large amounts of data to the blockchain. What makes these attacks particularly hard to handle in real life is that these attacks do not have so-called *uniquely attributable faults*, i.e. the smart contract cannot determine which party is malicious, and hence cannot force it to pay the fees for the blockchain interaction. An important implication of our result is that the benefits of two of the most prominent Plasma types, called *Plasma Cash* and *Fungible Plasma*, cannot be achieved simultaneously.

Besides of the direct implications on real-life cryptocurrency research, we believe that this work may open up a new line of theoretical research, as, up to our knowledge, this is the first work that provides an impossibility result in the area of off-chain protocols.

## 1 Introduction

What does it mean to *timestamp* a digital document? Haber and Stornetta in their seminal paper [17] define timestamping as a method to certify when a given document was created. In many settings the timestamped document  $T$  remains secret after it was timestamped, until its creator decides to make it public. This is often because of efficiency reasons – for example in the scheme of [17] what is really timestamped is the cryptographic hash<sup>1</sup>  $H(T)$  (not  $T$ ), which leads to savings in communication between  $T$ 's creator and the timestamping service. Sometimes the secrecy of  $T$  is actually a desired feature. According to [29] several researchers in the past (including Galileo Galilei and Isaac Newton) have used ad-hoc methods to timestamp their research ideas before publishing them, in order to later claim priority.

Recently, in the context of blockchain, timestamping has been used in a slightly different way. Namely, in the paper that introduced this technology [25], the “timestamping” mechanism is such that  $T$ 's creator does not only get a proof that  $T$  has been created at a given time, but also that it has been *made public* at this time. Let us call this kind of scheme *public timestamping*, and let us refer to the former type of timestamping as *secret timestamping*. The public timestamping feature of blockchain has been one of the main reasons why this technology attracted so much attention. In fact one of the first projects that use blockchain for purposes other than purely financial was *Namecoin* that used the timestamping to create a decentralized domain name system (see, e.g., [19] for more on this project).

In many cases timestamping is expensive, and its costs grow linearly with the length of the timestamped document. This is especially true for blockchain-based solutions, where all parties in the network need to reach *consensus* about what document was published and when. For example, Bitcoin (the blockchain system introduced in [25]) can process at most around 1MB of data per 10 minutes. In Ethereum, which is another very popular blockchain system [31] “timestamping” a word of 32 bytes cost currently around USD 0.80. A similar problem appears in several other blockchain protocols. We give a short introduction to blockchain in Sec. 1.1. For a moment let us just say that typical blockchains come with their own virtual currencies (also called *cryptocurrencies*). In the most standard case the “timestamped” messages define financial transfers between the network participants, and are hence called *transactions*. We will refer to timestamping a transaction as *posting it on the blockchain*.

To summarize, from the efficiency point of view the secret timestamping is better than the public one (as only hashes need to be timestamped). From the security perspective these two types of timestamping are incomparable as the fact that the timestamped document  $T$  needs to be published can be considered to be both an advantage and a disadvantage, depending on the particular application. For example, one could argue that considering timestamped hashes of academic papers as being sufficient evidence for claiming priority would slow down scientific progress, as it would disincentive making the papers public (until, say, the author writes down all followup papers that build upon the timestamped paper).

---

<sup>1</sup> In this paper we assume reader's familiarity with basic cryptographic notions such as hash functions, negligible functions, etc. For an introduction to this topic see, e.g., [20].

A natural question therefore is as follows. Suppose we have access to a timestamping service that is expensive to use (so we would rather timestamp only very short messages there). Can we use it to “emulate” public timestamping that would be cheap for long documents  $T$ ? Of course this “emulation” cannot work in general, since some scenarios may simply require a proof that the whole  $T$  was available publicly at a given time. So the best we can hope for is to find *some* applications which permit such emulation. An idea for such emulation emerged recently within the cryptocurrency community under the names *Plasma* or *commit chains*<sup>2</sup> [26, 21, 16, 28, 24]. Very informally speaking, Plasma allows to “compress” a number of blockchain transactions  $tx_1, \dots, tx_m$  into one very short string  $h = H(T)$ , where  $T := (tx_1, \dots, tx_m)$ . The transactions can come from different parties called *users*. The only document that gets posted on the blockchain is  $h$ . The compression and posting  $h$  is done by one designated party called the *operator* (denoted  $Op$ ). Besides of posting  $h$ , the operator publishes all the transactions  $T$  on some public network (say: on her web-page). Since this publication is *not* done on the blockchain we also say that it is performed *off-chain*.

Publishing  $T$  off-chain is important since only then each user can verify that her transaction was indeed included into the hashed value. Moreover, typical Plasma designs use as  $H$  the so-called *Merkle-tree hashing* with  $tx_1, \dots, tx_m$  being the labels of the leaves (see the full version of this paper [11] for more on this technique). Thanks to this, every user can prove that his transaction was included in  $H(T)$  with a proof of length  $O(\log n)$ . If the operator does not include some  $tx_i$  in  $T$  then the user  $U$  that produced  $tx_i$  can always post  $tx_i$  directly to the blockchain. In this case using Plasma does not bring any benefits to  $U$  compared to just using the blockchain directly from the beginning. However, in reality it is expected that this is not going to happen often, especially since the operators are envisioned to be commercial entities that will charge some fee for their services.

What is much more problematic is the case when the malicious operator does *not* publish  $T$  off-chain. This situation is typically referred to as *data unavailability*. Note that data unavailability is subjective, i.e., the parties can have different views on whether it happened or not. This is because, unlike the situation on the blockchain, there may be no consensus on what was published off-chain. Moreover, there is no way to produce a proof that data unavailability happens: even if some parties complain on the blockchain that they did not receive  $T$  there is no way to determine (just by looking at the blockchain) whether they are right, or if they are just falsely accusing the operator. The situation when a disagreement between parties happens but there is no “blockchain-only” way to verify which party is corrupt, is commonly referred to as a *non-uniquely attributable fault*. Finally, some Plasma protocols require all the honest parties to immediately act on blockchain after a data unavailability attack happened. This is called “mass exit”, although (for the reasons explained in Sec. 1.1 in this paper we call it “large forced on-chain action”)

Plasma comes in many variants and has been discussed in countless articles (see Sec. 1.1). One of the most fundamental distinction is between the two types of Plasma systems: *Plasma Cash* and *Fungible Plasma*. As we explain in more detail in Sec. 1.1 they both serve for the “emulation” that we outlined above, but have different incomparable features. From one point of view Fungible Plasma is better than Plasma Cash since it is “fungible”, which means that the money can be arbitrarily divided and merged. On the other hand: Fungible Plasma suffers from some problems that Plasma Cash does not have, namely the adversary can cause a “non-uniquely attributable large forced mass actions” (we explain these notions Sec. 1.1). The cryptocurrency community has been unsuccessfully looking for a Plasma solution that

<sup>2</sup> In this paper we mostly use the name “Plasma” due to its brevity.

would have the benefits of both Plasma Cash and Fungible Plasma. The main result of this paper is that such Plasma cannot be achieved simultaneously. In other words, we show inherent limitations of the compression technique, at least for compressing blockchain financial transactions. Our paper can also be viewed as initiating the theoretical analysis of lower bounds for the smart contract protocols. We write more about our contribution in Sec. 1.2. First, however, let us provide some more introduction to blockchain and to Plasmas.

## 1.1 Introduction to Plasma

Let us start with providing some more background on blockchain and smart contracts. Blockchain can be viewed as a public *ledger* containing timestamped transactions that have to satisfy some correctness constraints. Moreover, several blockchains permit to execute the so-called *smart contracts* [27] (or simply: “contracts”), which informally speaking, are “self-executable” agreements described in form of computer programs. Examples of such blockchain platforms include *Ethereum*, *Hyperledger Fabric*, or *Cardano*. Typically, it is assumed that contracts are deterministic and have a public state. Moreover, they can own some coins. Executing a contract is done by posting transactions on the blockchain and it costs fees that depend on the computational complexity of the given operation, and on the amount of data that needs to be transmitted to the contract.

Let us now explain the basic idea of Plasma, and introduce some standard terminology. Since it is an informal presentation, we mix the definition of the protocol with its construction. In the formal sections of the paper these two parts are separated (the definition appears in Sec. 2, and the constructions in the full version of this paper [11]). As highlighted above Plasma address the scalability problem of blockchain by keeping the massive bulk of transactions outside of the blockchain (“off-chain”). The parties that are involved in the protocol rely on a smart contract that is deployed on the ledger of the underlying cryptocurrency, but they try to minimize interacting with it. Typically, this interaction happens only when the parties join and leave the protocol, or when they disagree. Since all parties know that in case of disagreement, disputes can always be settled on the ledger, there is no incentive for the users to disagree, and honest behavior is enforced.

In the optimistic case, when the parties involved in the protocol play honestly, and the off-chain transactions never hit the ledger, these protocols significantly reduce transaction fees and allow for instantaneous executions. Off-chain protocols also resemble an idea explored in cryptography around two decades ago under the name “optimistic protocols” [7, 1]. In this model the parties are given access to a trusted server that is “expensive to use”, and hence they do not want to contact it, unless it is absolutely necessary.

Plasma’s operator *Op* provides a “simulated ledger”, in which other parties can deposit their coins, and then perform operations between each other. The key requirement is that its users do not need to trust the operator, and in particular if they discover that she is cheating, then they can safely withdraw their funds. The latter is called an *exit* from the simulated ledger, and requires communication with the underlying ledger.

Plasma protocols come in different variants (see Sec. 1.1), however, they are all based on a single framework proposed in [26]. The parties that execute Plasma are: the *users*  $U_1, \dots, U_n$ , and the *operator* *Op*. Moreover, the parties have access to a contract on the blockchain. In our formal modeling this contract will be represented as a trusted interactive machine  $\Gamma$  with public state, owning some amount of coins. Each user  $U_i$  has some number of coins initially deposited in his Plasma account which is maintained by  $\Gamma$ . This number is called a *balance* and is denoted with  $b_i \in \mathbb{Z}_{\geq 0}$ . Users’ balances are changing dynamically during the execution of the protocol. The total number of coins owned by the contract  $\Gamma$  is

equal to the sum of all balances of its users. A vector  $\vec{b} := (b_1, \dots, b_n)$  is called a *Plasma chain*. When referring to the underlying blockchain (i.e. the one on which  $\Gamma$  is deployed) we use the term *main chain*. Note that the operator  $Op$  has no account and only facilitates transfers of the users. In some variants of Plasma (see Sec. 1.1) the operator blocks some amount of coins (called operator's *collateral*) that can be used to compensate the users their losses in case she misbehaves.

Let us briefly describe the different operations that parties of the Plasma protocol can execution during the lifetime of the system. We divide time into *epochs* (e.g. 1 epoch takes 1 hour). In the  $i$ th epoch the operator sends some information  $C_i$  to  $\Gamma$ . We can think of  $C_i$  as “compressed” information about the vector  $(b_1, \dots, b_n)$  containing the users' balances. By “compressed” we mean that  $|C_i|$  is much shorter than the description of  $(b_1, \dots, b_n)$ , and usually its length is constant in every epoch. We will refer to  $C_i$  as a “commitment” to  $(b_1, \dots, b_n)$ . The length of  $C_i$  is called the *commit size*.

In each epoch every user  $U_i$  can request to *exit*, by which we mean that all  $b_i$  coins from her Plasma account get converted to the “real” coins on the main chain, and she is no longer a part of this Plasma chain (which, in our formal modeling will be indicated by setting  $b_i := \perp$ ). Plasma's security properties guarantee that every user can exit with all the coins that she currently has in the given Plasma chain. It is often required that exiting can be done cheaply, and in particular that the total length of the messages sent by the exiting user to  $\Gamma$  is small. The amount of data that a user needs to send to  $\Gamma$  in order to exit the Plasma chain is called the *exit size*.

Finally, any two users of the same Plasma chain can make *transfers* between each other. Suppose  $U_k$  wants to transfer  $v$  coins from her account to  $U_j$ . This transfer operation involves only communicating with  $U_j$ , and with the operator  $Op$ , while no interaction with the contract  $\Gamma$  is needed. Under normal circumstances (i.e. when the operator is honest) the next Plasma block that is committed to the main chain will simply have  $v$  coins deduced from  $U_k$ 's account and  $v$  coins added to  $U_j$ 's account.<sup>3</sup>

### 1.1.1 Challenges in designing Plasma systems

The main challenge when designing a Plasma system is to guarantee that every user can exit with her money. This is usually achieved as follows: each  $C_i$  is a commitment to  $(b_1, \dots, b_n)$ , computed using a Merkle tree. An honest operator  $Op$  is obliged to obey the following rule:

**Explaining commitments** – each time  $Op$  sends  $C_i$  to  $\Gamma$ , she sends the corresponding  $\vec{b} := (b_1, \dots, b_n)$  to all the users.

Technically, sending  $\vec{b}$  to the users can be realized, e.g., by publishing it on the operator's web-page (i.e.: “off-chain”). Every user  $U_j$  can now check if she has the correct amount on her account and if  $C_i$  was computed correctly. Moreover, thanks to the properties of Merkle trees,  $U_j$  has a short proof of size  $O(\log(n))$  that  $b_j$  has been “committed” into  $C_i$ .

The above description assume that the operator is honest. If she is corrupt things get more complicated. Note that  $C_i$  sent by the operator to  $\Gamma$  is publicly known (due to the properties of the underlying blockchain). Hence, we can assume that all the users agree on whether  $C_i$  was published and what is its exact value. The situation is different when it comes to the vector  $\vec{b}$  that should be published off-chain. In particular, if  $\vec{b}$  has *not* been published, then the users have no way to prove this to  $\Gamma$ . This is because whether some data

<sup>3</sup> To keep things simple, in this paper we do not discuss things like “transfer receipts”, i.e., confirmations for the sender that the coins have been transferred.

has been published off-chain or not does not have a digital evidence that can be interpreted by  $\Gamma$ . This leads us to the following attack that can be carried out by a malicious operator, and is intensively studied by the cryptocurrency community (see, e.g., [3]).

**Data unavailability attack** – in this attack the corrupt operator publishes  $C_i$  but does not publish  $\vec{b}$ .

Note that this attack has no extra cost for the operator because from the point of view of the smart contract  $\Gamma$ , the operator behaves honestly, and hence the users cannot complain to  $\Gamma$  and request, e.g., that  $Op$  sends  $\vec{b}$  to  $\Gamma$ . Furthermore determining if this attack happened is “subjective”, i.e., every user  $U_j$  has to detect it herself. Moreover, in case of data unavailability it is impossible for  $\Gamma$  to determine whether  $U_j$  or  $Op$  is dishonest, since a sheer declaration of  $U_j$  that  $Op$  did not send him the data obviously cannot serve as a proof that it indeed happened. This leads to the following definition.

**Non-uniquely attributable faults** – this refers to the situation when the contract has to intervene in the execution of the protocol (because the protocol is under attack), but it unable to determine which party misbehaved (see, e.g., [2]).

Non-uniquely attributable faults appear typically in situations when a party claims that it has not received a message from another party. In contrast if a contract *is* able to determine which party is corrupt then we have a *uniquely*-attributable fault. A typical example of such a fault is when a party signs two contradictory messages. Unfortunately, non-uniquely attributable faults are hard to handle in real life, since it is not clear which party should pay the fees for executing the smart contract, or which party should be punished for misbehaving. In particular, what is unavoidable in such a case is that a malicious party  $P$  can force another participant  $P'$  to lose money on fees (potentially also loosing money herself). This phenomenon is known as *griefing* [2].

When a user realizes that the operator is dishonest, then she often needs to start quickly interacting with  $\Gamma$  in order to protect her coins. This action has to be done quickly, and has to be performed by each honest user. This leads to the following definition.

**Forced on-chain action of size  $\alpha$**  – this term refers to the situation that honest parties who did not intend to perform an exit are forced by the adversary to quickly interact with  $\Gamma$ , and the total length of the messages sent by them to  $\Gamma$  is  $\alpha$ . Informally, when  $\alpha$  is large (e.g.  $\alpha = \Omega(n)$ ) we say this is a *mass* forced on-chain action.

Note that this definition talks about all honest “parties”, and hence it includes also the case when the operator is honest, but it is forced to act because of the behavior of the corrupt users. Typically  $\alpha = \Omega(n)$  and by “quickly” we mean “1 epoch”. In most Plasma proposals [23, 26, 4] “interacting with the smart contract” means simply exiting the Plasma chain with all the coins. Hence, a more common term for this situation is “mass exit”. Since in our work we are dealing with the lower bounds, we need to be ready to cover also other, non-standard, ways of protecting honest users’ coins. For example, it could be the case that a user  $U_j$  does *not* exit immediately, but, instead, keeps her coins in a special account “within  $\Gamma$ ” and withdraws them much later. Of course, this requires interacting with  $\Gamma$  immediately, but, technically speaking does not require “exiting”. To capture such situations, we use the term “forced on-chain *action*”, instead of “mass *exit*”.

After a party announces an exit, we need to ensure that she is exiting with the right amount of coins. The main problem comes from the fact that we cannot require that users exit from the last  $C_i$  by sending the explanation for her balance  $b_i$  to  $\Gamma$ . This is because it could be the case that a given user does not know the explanation  $\vec{b}$  of  $C_i$  (due to the data unavailability attack). For a description of how this can be done in practice see [26, 4], or the full version of this paper [11].

Mass exits (or large forced on-chain actions) caused by data unavailability are considered a major problem for Plasma constructions. They are mentioned multiple times in the original Plasma paper [26] (together with some ad-hoc mechanism for mitigating them). They are also routinely discussed on “Ethereum’s Research Forum”<sup>4</sup>, with even conferences organized on this topic<sup>5</sup>. One of the main reasons why the mass exits are so problematic is that they may result in blockchain congestion (i.e., situations when too many users want to send transactions to the underlying blockchain). Moreover, the adversary can choose to attack Plasma precisely in the moments when the blockchain is already close to being congested (see, e.g., [30] for a description of real-life incident of the Ethereum blockchain congestion). She can also attack different Plasma chains (established over the same main chain) so their users simultaneously send large amounts of data to the blockchain. In order to be prepared for such events in real-life Plasma proposals it is sometimes suggested that the time  $T$  for reacting to data unavailability should be very large (e.g.  $T = 2$  weeks). This, unfortunately, has an important downside, namely that also an honest coin withdrawal requires time  $T$ .

Consider a non-fungible Plasma that supports coin identifiers from some set  $\mathcal{C}$ . In a non-fungible Plasma the Plasma chain is of a different form than before: instead of a vector of balances  $\vec{b}$ , it is a function  $f : \mathcal{C} \rightarrow \{U_1, \dots, U_n, \perp\}$  that assigns to every coin  $c \in \mathcal{C}$  its current owner  $f(c)$  (or  $\perp$  if the coin has been withdrawn). Similar to before the commitment to the value of  $f$  will be done using Merkle trees. Whenever a coin is withdrawn its identifier  $c$  is sent to the smart contract  $\Gamma$ , and hence it becomes public. This is important for the mechanism that prevents parties from stealing coins. To this end, each user  $U$  monitors  $\Gamma$ , and sends a complaint whenever some (corrupt) user  $U'$  tries to withdraw one of  $U$ ’s coins. For the contract  $\Gamma$  to decide if  $c$  belongs to  $U$  or  $U'$  can require some additional interaction, but the system is designed in such a way that the honest user is guaranteed that finally she will win such dispute. Hence, every malicious attempt to withdraw someone else’s coin will be stopped.

The main difference between Plasma Cash and Fungible Plasma is that in Plasma Cash every user has to “protect” only her own coins. Thanks to this, even in case of the data unavailability attack, each honest user  $U$  does *not* need to immediately take any action. Instead, she can just monitor  $\Gamma$ , and has to act only if someone tries to withdraw one of  $U$ ’s coins. Of course, the corrupt user can still force all the honest ones to quickly act on the blockchain. However, this requires much more effort from them than in Fungible Plasma, namely: they need to withdraw many coins of the honest users at once, hence forcing the honest users to react. This is “fairer” both honest and malicious users have to make similar effort. Most importantly, however, this attack has *uniquely-attributable faults*.

This advantage of Plasma Cash comes at a price, namely the “exit size” is not constant anymore, as it depends on the number of coins that a user has (since each coin has to be withdrawn “independently”). The Ethereum research community has been making some efforts to deal with this problem. One promising approach is to “compress” the information about withdrawn coins. For example one could assume that the identifiers in  $\mathcal{C}$  are natural numbers. Then a user  $U$  who owns coins from some interval  $[a, \dots, b]$  (with  $a, b \in \mathbb{N}$ ) could simply withdraw them by posting a message “User  $U$  withdraws all coins from the interval  $[a, \dots, b]$  (instead of withdrawing each  $i \in [a, \dots, b]$  independently). This, of course, works only if the coins that users own can be divided into such intervals. Some authors (in particular V. Buterin) have been suggesting “defragmentation” techniques for achieving

<sup>4</sup> Available at: [ethresear.ch](https://ethresear.ch).

<sup>5</sup> See: [ethresear.ch/t/data-unavailability-unconference-devcon4](https://ethresear.ch/t/data-unavailability-unconference-devcon4).

such a distribution of coins. This is based on the assumption that the parties periodically *cooperate* to “clean up” the system. Hence, it does not work in a fully malicious settings<sup>6</sup> (if the goal of the adversary is to prevent the cleaning procedure).

### 1.1.2 The landscape of Plasmas

Soon after the original groundbreaking work on Plasma [26], some concrete variants have been proposed. Some of them we already described in Sec. 1.1. Since this paper focuses on the *impossibility* results, we do not provide a complete overview of the many different variants that exist and what features they achieve. Plasma projects that are frequently mentioned in the media are Loom, Bankex, NOCUST and OmiseGO [28, 24]. This area is mostly developed by a very vibrant on-line community that typically communicates results in form of so-called “white-papers”, blog articles, or post on discussion forums (such as the “Ethereum Research Forum”, see footnote 4 on page 7). See also the diagram called “Plasma World Map” illustrating the different flavors of Plasma in the full version of this paper [11]. A notable exception are NOCUST and NOCUST-ZKP described in [21]. This work, up to our knowledge, is the first academic paper on this topic. It provides a formal protocol description (with several interesting innovations such as “Merkle interval trees”) and a security argument. Moreover, the authors of [21] describe a version of NOCUST that puts a collateral on the operator (this is done in order to achieve instant transaction confirmation). The authors of [21] (see also [16]) introduce the term “commit chains”. Yet, unfortunately, they do not define a full formal security model that we could re-use in our work.

Let us also mention some of the so-called “distributed exchanges” that look very similar to Plasma. One example is StarkDEX (informally described in [15]), which is also based on the idea of a central operator batching transactions using Merkle trees, and a procedure for the users to “escape” from the system if something goes wrong. This protocol uses non-interactive zero-knowledge protocols to ensure correctness of the operator’s actions (similar approach has been informally sketched in the original Plasma paper [26], and has been also used in NOCUST-ZKP [21]). While zero knowledge can be used to demonstrate that some data was computed correctly, it *cannot* be used to prove that the off-chain data *was published at all*. Consequently, the authors of this system also encountered the challenge of handling the data unavailability attack. Currently, in StarkDEX this problem is solved by introducing an external committee that certifies if data is available.<sup>7</sup> StarkDEX plans to eventually replace the committee-based solution with an approach that is only based on trusting the underlying blockchain. Our result however shows that in general this will be impossible, as long as fungibility and short exits are required (unless the operator puts a huge collateral).

## 1.2 Our contribution and organization of the paper

We initiate the study of lower bounds (or: “impossibility results”) in the area of off-chain protocols. Our results can also be viewed as a part of a general research program of “bringing order to Plasma”. We believe that the scientific cryptographic community can provide significant help in the efforts to systematize this area, and to determine the formal security guarantees of the protocols (in a way that is similar to the work on “Bitcoin backbone” [14], or more recently on “Mimblewimble” [13], state channels [9], or the Lightning Network [22]).

<sup>6</sup> See [ethresear.ch/t/plasma-cash-defragmentation](https://ethresear.ch/t/plasma-cash-defragmentation) and subsequent posts by Buterin on the Ethereum Research Forum.

<sup>7</sup> See their FAQs at <https://www.starkdex.io>.

Investigating the limits of what Plasma can achieve is part of this process. We focus on proving lower bounds that concern the necessity of mass forced on-chain actions, especially caused by the attack that have no uniquely attributable faults (as a result of data unavailability). This is motivated by the fact that such attacks are particularly important for the off-chain protocols: since the main goal of such protocols is to move the transactions *off*-chain, the necessity of quickly acting *on*-chain can be viewed as a big disadvantage.

We start with a formal definition of Plasma (this is done in Sec. 2). Since in this work we are interested only in the impossibility results, our definition is very restrictive for practical systems. By “restrictive” we mean that we make several assumptions about how the protocol operates. For example we have very strict synchronicity rules, and in particular we only allow the users to start the Plasma operations in certain moments (see “payment orders” and “exit orders” phases in Sec. 2.1). Obviously, such restrictions make our lower bounds only stronger, since they also apply to a more realistic model (without such restrictions). We believe that fully formalizing real-life Plasma (e.g. in the style of [12, 10, 22]) is an important future research project, but it is beyond the scope of this work.

Our main result is presented in Thm. 1, stated formally in Sec. 3. It states that in certain cases the adversary can force mass on-chain actions of the honest users of *any* Plasma system. One subtle point that we want to emphasize is that whenever we talk about “forcing actions” on the honest users, we mean a situation when the users that did *not* want to exit (in a given epoch) are forced to act on-chain. This is important, as otherwise our theorem would hold trivially (one can always imagine a scenario when lots of users decide to exit Plasma because of some other, external, reasons). The notion of “wanting to exit” is formalized by an *environment machine*  $\mathcal{Z}$  (borrowed from the *Universal Composability* framework [8]) that “orders” the parties to behave in certain way.

More formally, Thm. 1 states that in Plasma either there exists an attack that provokes a mass action, or there is an attack that requires a party that exits to post long messages on the blockchain (i.e. this Plasma has large exits). Moreover, both attacks have *no* uniquely attributable faults. Note that, strictly speaking, this theorem also covers Plasma systems where the commit size is large (even  $\Omega(n)$ )<sup>8</sup>, but in this case it holds trivially since the honest operator needs to send the large commitments to  $\Gamma$  even if everybody is honest (hence: there is an “unprovoked” mass action in every epoch).

The most interesting practical implication of this theorem is that it confirms the need for “two different” Plasma flavors, as long as the operator is not required to put aside a collateral of size comparable to the total amount of coins in the system<sup>9</sup>. One way to look at it is: either we want to have a Plasma system that does not have large exits, in which case we need to have (non-uniquely attributable) mass actions (this is Fungible Plasma/Plasma MVP); or alternatively we insist on having Plasma without such mass actions, but then we have to live with large exits (as in Plasma Cash). Our theorem implies that there is no Plasma that would combine the benefits of both Fungible Plasma and Plasma Cash, and hence can serve as a justification why both approaches are complementary. Before our result one could hope that the opposite is true and that, e.g., the only reason why Plasma Cash is popular is its relative simplicity (compared to Fungible Plasma). Besides of this reason, and the general scientific interest, we believe that our lower bound has some other important practical applications. In particular, lower bounds often serve as a guideline for constructing new systems or tweaking

<sup>8</sup> In practice, Plasma systems with unbounded commit size are not interesting since they do not bring any advantages to the users. Moreover, they can be trivially constructed just by putting every transaction on the main chain.

<sup>9</sup> This is clearly impractical for most of the applications. Actually most of Plasma constructions assume no such collateral at all.

the definitions. We hope it will contribute to consolidate the countless research efforts in constructing new Plasma systems<sup>10</sup> and simplify identifying proposals that are not sound (e.g., because they claim to achieve the best of both worlds).

Let us also stress that our Thm. 1 does *not* rely on any assumptions of complexity-theoretic type and does *not* use a concept of “black-box separations” [18]. This means that the lower bound that we prove cannot be circumvented by introducing any kind of strong cryptographic assumptions. Hence, of course, it also holds for Plasmas that use non-interactive zero-knowledge (like NOCUST-ZKP [21] or StarkDEX [15]). Moreover, we manage to generalize our lower bound. Thm. 1 even holds for Plasma systems where the operator deposits a certain amount of coins for compensating parties for malicious behavior (e.g., it could be used when a malicious operator does not explain commitments).

For completeness, we also describe (in the full version of this paper [11]) “positive” results, i.e., two protocols that satisfy our security definition (Plasma Cash and Fungible Plasma). We stress that we do not consider it to be a part of our main contribution, and we do not claim novelty with these constructions, as they strongly rely on ideas published earlier (in particular [26, 5, 23, 4, 21, 15]).

**Notation.** For a formal definition of an *interactive (Turing) machine* and a *protocol*, see, e.g., [8]. In our modeling the communication between the parties is synchronous and happens in *rounds* (see Section 2). During the execution of the protocol a party  $P$  may send messages to a party  $P'$ . A *transcript* of the messages sent from  $P$  to  $P'$  is a sequence  $\{(m_i, t_i)\}_{i=1}^\ell$ , where each  $m_i$  was sent by  $P$  to  $P'$  in the  $t_i$ -th round. A transcript of messages sent from some set of parties to a different set of parties is a sequence  $\{(W_i, W'_i, m_i, t_i)\}_{i=1}^\ell$ , where each  $m_i$  was sent by  $W_i$  to  $W'_i$  in the  $t_i$ -th round. By the *length of a transcript* we mean its bit-length (in some fixed encoding). We sometimes refer to it also as *communication size* (between the parties).

## 2 Plasma Payment Systems

A *Plasma payment system* (or “Plasma” for short) is a protocol  $\Pi$  consisting of a randomized non-interactive machine  $\Psi$  representing the *setup* of the system; deterministic<sup>11</sup> interactive poly-time machines  $U_1, \dots, U_n, Op$  representing the *users* and the *operator* of the Plasma system (respectively); and a deterministic interactive poly-time machine  $\Gamma$ , which represents the *Plasma contract*. We use the notation  $\mathcal{U} = \{U_1, \dots, U_n\}$  to refer to the set of users of the system. The contract machine  $\Gamma$  has no secret state, and moreover its entire execution history is known to all the parties. We can think of it as a Turing machine that keeps the entire log of its execution history, and moreover all the other parties in the system have a (read-only) access to this log. The Plasma system comes with a parameter  $\gamma \in \mathbb{R}_{\geq 0}$  called *operator’s collateral fraction*. Informally, this parameter describes the amount of coins that are held by the operator as a “collateral” (as a fraction of user’s coins). These coins can be used to cover users’ losses if the operator misbehaves. This is formally captured in Section 2.2 (see “limited responsibility of the operator”). If  $\gamma = 0$  then we say that the operator is *not collateralized*. We introduce the notion of collateral in order to make our results stronger and to cover also cases of real-life systems that have such a collateral (e.g., NOCUST, see Section 1.1).

<sup>10</sup> see <https://ethresear.ch/c/plasma/>.

<sup>11</sup> We assume that these machines are deterministic, since all their internal randomness will be passed to them by  $\Psi$ .

The protocol is attacked by a randomized poly-time adversary  $\mathcal{A}$ . We assume that  $\mathcal{A}$  can corrupt any number of users and the operator except the contract  $\Gamma$  (hence  $\Gamma$  can be seen as a trusted third party). Once  $\mathcal{A}$  corrupts a party  $P$ , she learns all its secrets, and takes full control over it (i.e. she can send messages on behalf of  $P$ ). A party that has not been corrupted is called *honest*. An execution of a Plasma payment system  $\Pi$  is parametrized by the *security parameter*  $1^\lambda$ .

To model the fact that users perform actions, we use the concept of an environment  $\mathcal{Z}$  (which is also a poly-time machine) that is responsible for “orchestrating” the execution of the protocol. The environment can send and receive messages from all the parties (it also has full access to the state of  $\Gamma$ ). It also knows which parties are corrupt and which are honest. For an adversary  $\mathcal{A}$  and an environment  $\mathcal{Z}$ , a pair  $(\mathcal{A}, \mathcal{Z})$  will be called an *attack* (on a given Plasma system  $\Pi$ ). The contract machine  $\Gamma$  can output special messages (*attribute-fault*,  $P$ ) (where  $P \in \mathcal{U} \cup \{Op\}$ ). In this case we say that  $\Gamma$  *attributed a fault to*  $P$ . We require that the probability that  $\Gamma$  attributes a fault to an honest party is negligible in  $\lambda$ . An attack  $(\mathcal{A}, \mathcal{Z})$  *has no attributable faults* if the probability that  $\Gamma$  attributes a fault to some party is negligible.

## 2.1 Protocol operation

Let us now describe the general scheme in which a Plasma payment protocol operates. In this section, we focus only on describing what messages are sent between the parties. The “semantics” of these messages, and the security properties of the protocol are described in Section 2.2. We assume that all the parties are connected by authenticated and secret communication channels, and a message sent by a party  $P$  in the  $i$ th round, arrives to  $P'$  at the beginning of the  $(i + 1)$ th round. The communication is synchronous and happens in *rounds*. It consists of three stages, namely: “setup”, “initialization”, and “payments”. The execution starts with the *setup stage*. In this stage parameter  $1^\lambda$  is passed to all the machines in  $\Pi$ . Upon receiving this parameter, machine  $\Psi$  samples a tuple  $(\psi_{U_1}, \dots, \psi_{U_n}, \psi_{Op}, \psi_\Gamma)$  (where each  $\psi_P \in \{0, 1\}^*$ ). Then for each  $P \in \{U_1, \dots, U_n, Op, \Gamma\}$  the string  $\psi_P$  is passed to  $P$ . Afterwards, the parties proceed to the *initialization stage*. In this stage the environment generates a sequence  $(a_1^{\text{init}}, \dots, a_n^{\text{init}})$  of non-negative integers and passes it to the contract  $\Gamma$  (recall that the state of  $\Gamma$  is public, and hence, as a consequence, all the parties in the system also learn the  $a_i^{\text{init}}$ ). Then the protocol proceeds to the *payment stage*. This stage consists of an unbounded number of *epochs*. Each  $i$ th epoch (for  $i = 1, 2, \dots$ ) is divided into two *phases*.

**Payment phase.** In this phase the environment sends a number of *payment orders* to the users (for simplicity we assume that this happens simultaneously in a single round). Each order has a form of a message “(send,  $v, U_i$ )”, where  $v \in \mathbb{Z}_{\geq 0}$ , and  $U_i \in \mathcal{U}$ . It can happen that some users receive no payment orders in a given epoch. It is also ok if a user receives more than one order in an epoch. Informally, the meaning of these messages is as follows: if a user  $U_j$  receives a “(send,  $v, U_i$ )” message, then she is ordered to transfer  $v$  coins to user  $U_i$ . We require that this message can only be sent if none of  $b_i$  and  $b_j$  are equal to  $\perp$  (i.e.: if none of  $U_i$  and  $U_j$  “exited”, see below). The parties execute a multiparty sub-protocol. During this executions some of the users send a message “(received,  $v, U_i$ )” to the environment  $\mathcal{Z}$ . This sub-protocol ends when  $\Gamma$  outputs a message *payments-processed*.

**Exit phase.** In this phase the environment sends *exit orders* to some of the users (again: this happens in a single round). Each such order is simply a message “exit”. Informally, sending this message to some  $U_i$  means that  $U_i$  is ordered to exit the system with all

her coins. The environment can send an exit message to  $U_i$  only if  $b_i \neq \perp$  (i.e.  $U_i$  has not already “exited”, see below). The parties again execute a multiparty protocol. The protocol ends when  $\Gamma$  outputs a sequence

$$\{(\text{exited}, U_{i_j}, v_{i_j})\}_{j=1}^m, \quad (1)$$

where  $m$  is some non-negative integer, and each  $U_{i_j} \in \mathcal{U}$  and  $v_{i_j} \in \mathbb{Z}_{\geq 0}$ . For each  $U_{i_j}$  in Eq. (1) we say that  $U_{i_j}$  *exited (with  $v_{i_j}$  coins)*, and we let  $b_{i_j} := \perp$ . We require that no party can exit more than once. In other words: it cannot happen that two messages  $(\text{exited}, U_i, v)$  and  $(\text{exited}, U_i, v')$  are issued by  $\Gamma$ .

We make some assumptions on the communication between the parties. Informally we require that if  $U$  and  $U'$  are some honest users, then the procedure of transferring coins from  $U$  to  $U'$  is done by a “sub-protocol” involving only parties in the set  $U$  and  $U'$ . Since we do not have a concept of “sub-protocol” this is formalized as follows:

**Communication locality.** Two honest users  $U$  and  $U'$  exchange messages only in epochs in which they do transactions between each other (i.e. a message  $(\text{send}, U, v)$  is sent by  $\mathcal{Z}$  to  $U'$ , for some  $v$ ).

This requirement is very natural since Plasma is supposed to work even when an arbitrary set of users is corrupt. Hence, relying on the other users’ help in financial transfers would be impractical. Up to our knowledge all “pure” Plasma proposals in the literature satisfy this requirement. On the other hand: it may *not* hold if we incorporate some techniques that assume some type of cooperation between larger sets of parties (e.g. consensus mechanisms). Examples include: Buterin’s Plasma Chash defragmentation (where a large set of users has to regularly cooperate in order to “clean-up” the system), and StarkDEX’s “data availability committee” (see Section 1.1), if we treat the committee members as “users”. One way to view our result is that it implies that such techniques are inherent for every fungible Plasma.

## 2.2 Security properties

During the interaction with the protocol, the environment keeps track of balances of *honest* users (we do not define balances of dishonest users). Formally, for each honest user  $U_i$  it maintains a variable  $b_i \in \mathbb{Z}_{\geq 0} \cup \{\perp\}$  (a *balance* of  $U_i$ ), where the symbol “ $\perp$ ” means that a party exited. It also maintains a variable  $t \in \mathbb{Z}_{\geq 0}$  (initially set to 0) that is used to keep track on the amount of coins that have been withdrawn. The rules for maintaining these variables are as follows. Initially, for each  $i := 1, \dots, n$  the environment  $\mathcal{Z}$  lets  $b_i := a_i^{\text{init}}$ . Whenever  $\Gamma$  outputs  $(\text{exited}, U_i, v)$  (for some  $U_i$  and  $v$ ) we let  $b_i := \perp$  and increment  $t$  by  $v$ . Each time  $\mathcal{Z}$  receives a message  $(\text{received}, v, U_i)$  from some *honest*  $U_j$ , it adds  $v$  to  $b_j$  (recipient balance) and, if  $U_i$  (sender) is honest too, subtracts  $v$  from  $b_i$ . We require that the environment never issues an order if  $U_i$  or  $U_j$  exited (i.e. if  $b_i = \perp$  or  $b_j = \perp$ ). The environment also never sends an order exit to the same user more than once, and it never sends exit order to a user  $U_i$  that already exited (i.e. such that  $b_i = \perp$ ). We have the following security properties.

**Responsiveness to “send” orders.** Suppose  $Op, U_i$ , and  $U_j$  are honest, and the environment issued an order  $(\text{send}, v, U_i)$  to  $U_j$  then in the same epoch party  $U_i$  sends a message  $(\text{received}, v, U_j)$  to the environment.

**Correctness of “received” messages.** Suppose  $U_i$  and  $U_j$  are honest and  $U_i$  outputs a message  $(\text{received}, v, U_j)$ , then environment has issued an order  $(\text{send}, v, U_i)$  to  $U_j$  in the same epoch.

**Responsiveness to “exit” orders.** Suppose  $U_i$  is honest and the environment issued an order exit to  $U_i$  then in the same epoch  $\Gamma$  outputs a message  $(\text{exited}, U_i, v)$  (for some  $v$ ).

**No forced exits if operator honest.** Suppose  $Op$  and  $U_i$  are honest and  $\Gamma$  outputs message  $(\text{exited}, U_i, v)$  at epoch  $r$ , then environment has sent the order exit to  $U_i$  in the same epoch.

**Fairness for the users.** If  $\Gamma$  outputs a message  $(\text{exited}, U_i, v)$  (for some honest  $U_i$ ) then  $v \geq b_i$  (where  $b_i$  is the current balance of  $U_i$ ).

**Limited responsibility of the operator.** If the operator is honest, then the total amount of coins that are withdrawn from the system is at most  $a_1^{\text{init}} + \dots + a_n^{\text{init}}$ . Otherwise (if she is dishonest) the total amount of coins that are withdrawn from the system is at most  $\lceil (1 + \gamma)(a_1^{\text{init}} + \dots + a_n^{\text{init}}) \rceil$ . This definition captures the notion of operator’s collateral, and the fact that it is used (to cover users’ losses) if the operator is caught cheating.

If an attack  $(\mathcal{A}, \mathcal{Z})$  succeeds to violate any of the requirements from this section, then we say that  $(\mathcal{A}, \mathcal{Z})$  broke a given Plasma payment system. We say that  $\Pi$  is secure if for every environment  $(\mathcal{A}, \mathcal{Z})$  the probability that  $\mathcal{A}$  breaks  $\Pi$  is negligible in  $1^\lambda$ .

As explained in the introduction, certain attacks on Plasma are of particular importance, due to the fact that they are hard to handle in real life. We say that  $(\mathcal{A}, \mathcal{Z})$  force an on-chain action of size  $M$  (in some epoch  $i$ ) if the following happened. Let  $T$  be the set of honest parties that did not receive any order from  $\mathcal{Z}$  in epoch  $i$ . Then the total length of messages sent by parties from  $T$  to  $\Gamma$  is at least  $M$ . As explained in the introduction, the term that is more standard than “forced on-chain action” is “mass exit”. See 1.1 for a discussion why “forced on-chain action” is a better term when impossibility results are considered.

### 3 Our main result

We now present Thm. 1, which is the main result of this paper. The main implication of this theorem is that for every non-collateralized Plasma system there exists an attack that provokes a mass forced on-chain action, i.e., it forces the honest users to make large communication with the contract even if they did not receive any exit order from the environment (see point 1 in the statement of the theorem), unless a given Plasma system has large exits (point 2). Moreover, this can be done by an attack that has no uniquely attributable faults. This fact cannot be circumvented by putting a collateral on the operator, unless this collateral is very large.

► **Theorem 1** (Mass forced on-chain actions or large exits without uniquely attributable faults are necessary). *Let  $\Pi$  be a secure Plasma payment system with  $n$  users and let  $\gamma \geq 0$  be the operator’s collateral fraction. Then either*

1. *there exists an attack on  $\Pi$  that causes a forced on-chain action of size greater than  $(n - \lceil \gamma n \rceil \cdot \log_2 n - 5)/4$  with probability at least  $1/16 + \text{negl}(\lambda)$ , or*
2. *there exists an attack on  $\Pi$  such that one honest user, when ordered to exit by the environment, makes communication to  $\Gamma$  of size at least  $(n - \lceil \gamma n \rceil \cdot \log_2 n - 5)/4$  with probability at least  $1/16 + \text{negl}(\lambda)$ .*

*Moreover, both attacks have no uniquely attributable faults.*

One way to look at this theorem is as follows. First, consider a non-collateralized Plasma, i.e., assume that  $\gamma = 0$ . Let  $\mathcal{P}^1$  be a class of non-collateralized Plasma that with overwhelming probability do not have uniquely attributable forced on-chain actions (of any size larger than 0). In this case point 1 cannot hold, and hence, every Plasma  $\Pi \in \mathcal{P}^1$  needs to satisfy point 2. This means that there exists an attack on every  $\Pi \in \mathcal{P}^1$  such that one honest user, when

ordered to exit by the environment, makes communication to  $\Gamma$  of size at least  $(n - 5)/4$  with probability around  $1/16$ . Or, in other words: every Plasma from class  $\mathcal{P}^1$  must have a large exist size with noticeable probability. We know Plasma with such properties: it is essentially Plasma Cash (see the full version of this paper [11])

On the other hand, let  $\mathcal{P}^2$  be a class of non-collateralized Plasmas that with high probability have no large exits, in the sense of point 2 of Thm. 1. This means that point 1 has to hold, which implies that every  $\Pi \in \mathcal{P}^2$  needs to have large (at least around  $(n - 5)/4$ ) non-uniquely attributable mass forced on-chain actions. Plasma with such properties is called Fungible Plasma (see the full version of this paper [11]) Hence, informally speaking, Thm. 1 states that we cannot have the “best of two types of Plasma” simultaneously.

If we consider non-zero collaterals, i.e., we let  $\gamma > 0$  then the situation does not improve much, unless the collateral fraction is large, i.e., the total collateral blocked by the operator is at least around  $n \cdot \gamma = n/\log_2 n$ <sup>12</sup>. This essentially means that we cannot get around the bounds from Thm. 1 by introducing collateral, unless the amount of coins blocked in operator’s collateral is of roughly the same order as the total amount of coins stored by the users.

Note that even trivial versions of Plasma “fit” into Thm. 1. For example, consider Plasma in which the operator always puts all the transactions on-chain. Of course, the details would need to be worked out, but clearly such a Plasma can be made secure. The existence of such a trivial Plasma does not contradict our Thm. 1, since it clearly satisfies point 1: a large number of transfers in one epoch will cause a forced mass on-chain action (by the operator). The same also holds if every user needs to put each transaction on-chain.

## 4 Proof of Theorem 1

Before we present the proof let us introduce some auxiliary machinery. This is done in the next section.

### 4.1 Isolation scenario

Let  $\Pi$  be a Plasma payment system, let  $\mathcal{Z}$  be an environment, and let  $\mathcal{W}$  be some subset of the users of  $\Pi$ . We now introduce a procedure that we call *isolation of  $\mathcal{W}$* . In this scenario  $\Pi$  is executed as in the normal execution, except that we “isolate” the users  $\mathcal{W} \subseteq \mathcal{U}$  from the operator. More precisely: all the messages sent between any  $U \in \mathcal{W}$  and the operator  $Op$  are dropped, i.e., they never arrive to the destination. This scenario can be viewed as an “attack” although it does not fit into the framework from Section 2.1, since it violates the assumption that messages sent by an honest party to another honest party always arrive to the destination.

Although the isolation scenario cannot be performed within our model, it can be “emulated” by corrupting either the operator  $Op$ , or the users from  $\mathcal{W}$ . In the first case we corrupt the operator and instruct him to behave as if she was honest, except that she does not send messages to the users in  $\mathcal{W}$  and ignores all messages sent by these users. This will be called the *data unavailability (DU) attack against  $\mathcal{W}$  by the operator*. In the second, symmetric case (the *pretended data unavailability (PDU) attack by  $\mathcal{W}$  on the operator*) we corrupt the users in  $\mathcal{W}$ . Then, every user  $U \in \mathcal{W}$  behaves as if she was honest, except that she does not send messages to  $Op$ , and ignores all messages from  $Op$ .

<sup>12</sup> This is because we need to have  $\gamma \approx 1/\log_2 n$  to make the expression “ $(n - \lceil \gamma n \rceil \cdot \log_2 n - 5)/4$ ” equal to 0.

If this is the only type of malicious behavior, then “from the point of view” of all the other parties, and, most importantly, from the point of view of the contract machine  $\Gamma$ , it is impossible to say who is corrupt (the users in  $\mathcal{W}$  or the operator  $Op$ ). More precisely, we have the following.

► **Observation 1.** *Let  $\Pi$  be a Plasma payment system and consider the attack that isolates users in some set  $\mathcal{W}$  from the operator. Let  $\mathcal{Z}$  be an arbitrary environment and let  $\mathcal{T}_{\text{isolate}}^{\mathcal{W}, \mathcal{Z}}$  be the random variable denoting the transcript of messages received by  $\Gamma$ . Moreover, let  $\mathcal{T}_{\text{PDU}}^{\mathcal{W}, \mathcal{Z}}$  and  $\mathcal{T}_{\text{DU}}^{\mathcal{W}, \mathcal{Z}}$  be the random variable denoting the transcripts of messages received by  $\Gamma$  in the PDU attack and in the DU attack (respectively), both with environment  $\mathcal{Z}$ . Then  $\mathcal{T}_{\text{DU}}^{\mathcal{W}, \mathcal{Z}} \stackrel{d}{=} \mathcal{T}_{\text{isolate}}^{\mathcal{W}, \mathcal{Z}} \stackrel{d}{=} \mathcal{T}_{\text{PDU}}^{\mathcal{W}, \mathcal{Z}}$ .*

This fact is useful in the proof of the following simple lemma.

► **Lemma 1.** *Fix an arbitrary Plasma  $\Pi$ . Let  $\mathcal{W}$  be some set of users. Suppose  $\mathcal{A}$  performs a DU attack against  $\mathcal{W}$  or a PDU attack by  $\mathcal{W}$  (either by corrupting the operator or by corrupting the users), and let  $\mathcal{Z}$  be arbitrary. Then the attack  $(\mathcal{A}, \mathcal{Z})$  has no uniquely attributable faults.*

**Proof.** From the security of  $\Pi$  we get that if the users are corrupt then the probability that  $\Gamma$  attributes a fault to them is negligible. Symmetrically, if the operator is corrupt then the probability that  $\Gamma$  attributes a fault to her is negligible. By Observation 1 the transcripts of messages received by  $\Gamma$  in both attacks are distributed identically, so the probability that  $\Gamma$  attributes *any* fault has to be negligible. ◀

## 4.2 Proof overview

Fix some secure Plasma payment system  $\Pi$  that works for  $n$  users. We construct either an attack such that

$$\Pr \left[ \begin{array}{l} \text{the set of all honest users makes communication to } \Gamma \text{ of size} \\ \text{at least } (n - \lceil \gamma n \rceil \cdot \log_2 n - 5)/4 \\ \text{(without receiving an exit order from the environment)} \end{array} \right] \geq 1/16 + \text{negl}(\lambda), \quad (2)$$

or an attack such that

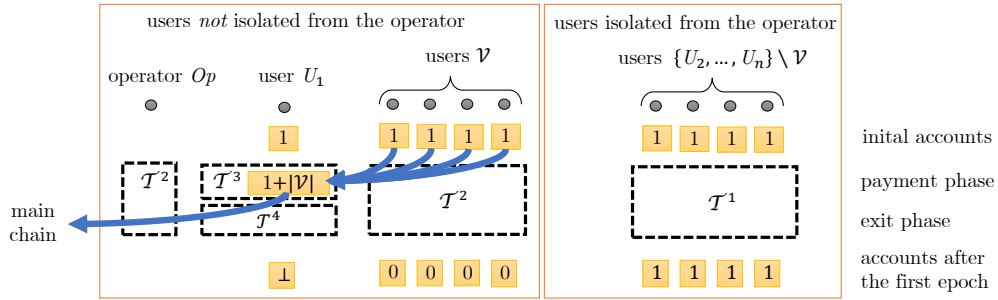

$$\Pr \left[ \begin{array}{l} \text{user } U_1, \text{ when ordered to exit by the environment, makes} \\ \text{communication to } \Gamma \text{ of size at least} \\ (n - \lceil \gamma n \rceil \cdot \log_2 n - 5)/4 \end{array} \right] \geq 1/16 + \text{negl}(\lambda). \quad (3)$$

In both of these attacks the amount of coins given to the users is  $n$ , but our proof can be generalized to cover cases when it is required that the amount of coins is larger than  $n$  (we comment more on this at the end of Section 4). On the other hand, the proof does not go through in the (unrealistic) case when this amount is very small (sublinear in  $n$ ).

The attacks that we construct in both cases ((2) and (3)) have no uniquely attributable faults. Note that for  $n \leq 5$  Eq. (3) holds trivially, and therefore we can assume that  $n > 5$ . Let  $\Upsilon$  denote the family of all *non-empty proper* subsets of  $\{U_2, \dots, U_n\}$ , i.e. sets  $\mathcal{V}$  such that  $\emptyset \subsetneq \mathcal{V} \subsetneq \{U_2, \dots, U_n\}$  (note that  $U_1 \notin \mathcal{V}$ ). Since we assumed that  $n > 5$  we have that  $\log |\Upsilon| = \log_2(2^{n-1} - 2) \geq n - 2$ , and, in particular,  $\Upsilon$  is non-empty. In the proof we construct an experiment (denoted by  $\text{Exp}(\mathcal{V})$  and presented in details in the full version of this paper [11]) and analyze its performance, assuming that  $\mathcal{V}$  is sampled uniformly at random from  $\Upsilon$ . Depending on this analysis, the experiment  $\text{Exp}(\mathcal{V})$  can be “transformed” into an attack that satisfies Eq. (2) or Eq. (3).

Experiment  $\text{Exp}(\mathcal{V})$  “simulates” an execution of two epochs of Plasma II. In the first epoch the adversary isolates the users in  $\{U_2, \dots, U_n\} \setminus \mathcal{V}$  from the operator (in the attacks that we construct later this will be done either by corrupting these users, or the operator). The environment gives 1 coin to each user  $U \in \mathcal{U}$ . Then, in the “payment” phase of the first epoch all the users from  $\mathcal{V}$  transfer their coins to  $U_1$ . In the “exit” phase of the first epoch user  $U_1$  receives an exit order from the environment and consequently exits with all her coins. Note that in the first epoch every party behaved honestly (except of the isolation attack against the users in  $\{U_2, \dots, U_n\} \setminus \mathcal{V}$ ), and hence  $U_1$  is guaranteed to successfully exit with her coins (she has 1 such coin from the “initialization” phase, and  $|\mathcal{V}|$  coins that were transferred to her by the users in  $\mathcal{V}$ ).

Of course the honest parties from  $\{U_2, \dots, U_n\} \setminus \mathcal{V}$  will usually realize that they are isolated from the operator. As a reaction to this they may send some messages to  $\Gamma$ . This, in turn can provoke the other parties to react by sending their messages to  $\Gamma$ . Hence, in general there can be a longer interaction between all the parties and  $\Gamma$  in this phase. Let  $\mathcal{T}^1$  be the transcript of the messages sent by the users in  $\{U_2, \dots, U_n\} \setminus \mathcal{V}$  to  $\Gamma$  in both phases, let  $\mathcal{T}^2$  be the messages sent by the users in  $\mathcal{V}$  and the operator to  $\Gamma$  in both phases, let  $\mathcal{T}^3$  be the messages sent by  $U_1$  to  $\Gamma$  in the “payment” phase, and finally let  $\mathcal{T}^4$  be the messages sent by  $U_1$  to  $\Gamma$  in the “exit” phase. The first epoch of the experiment  $\text{Exp}(\mathcal{V})$  and the transcripts are depicted on Fig. 1.

■ **Figure 1** The first epoch of the experiment  $\text{Exp}(\mathcal{V})$ . Gray circles denote the parties, and the  $\mathcal{T}^i$ 's denote the transcripts of the communication with  $\Gamma$  (see, e.g., Section 4.2 for their definitions).

Before discussing the second epoch of the experiment, let us note that in the first epoch the only way in which we deviate from the totally honest execution is the “isolation” of  $\{U_2, \dots, U_n\} \setminus \mathcal{V}$ . This will later allow us to be “flexible” and corrupt different sets of parties ( $\{Op\}$  or  $\{U_2, \dots, U_n\} \setminus \mathcal{V}$ ) depending on the results of our analysis of  $\text{Exp}(\mathcal{V})$ . This will be different in the second epoch, where we always assume that parties from  $\mathcal{V}$  are corrupt. This is ok because while constructing the attacks that satisfy (2) or (3) we will only use the first epoch of  $\text{Exp}(\mathcal{V})$ . The only reason to have the second epoch of  $\text{Exp}(\mathcal{V})$  is to make sure that the users have to send large amounts of data to  $\Gamma$  during the first epoch, as otherwise corrupt  $\mathcal{V}$  can steal the money (in the second epoch).

Let us now present some more details of the second epoch. Initially we corrupt all the users from  $\mathcal{V}$  and “rewind” them to the state that they had at the beginning of the first epoch. This is done in order to let them “pretend” that they still have their coins. We then let all of them try to (“illegally”) exit with these coins. Technically, “rewinding a user  $U$ ” is done via a procedure denoted  $\text{Reconstruct}_U$ . This procedure outputs the state that  $U$  would have at the end of the “payment” phase if she did not transfer her coins to  $U_1$ . To make it look consistent with the state of  $\Gamma$ , this procedure takes as input the transcripts defined

above. Then, each user  $U \in \mathcal{V}$  tries to exit (in the “exit” phase) from her state computed by  $\text{Reconstruct}_U$ . Also the honest users try to exit (they receive an “exit” order from the environment). Let  $\mathcal{Q}$  be the set of users that managed to exit with at least 1 coin. From the security of Plasma we get that  $\mathcal{Q}$  is equal to the set of honest users ( $\{U_2, \dots, U_n\} \setminus \mathcal{V}$ ) plus a small (of size at most  $\lceil \gamma n \rceil$ ) subset  $\mathcal{D}$  of dishonest users.

The key observation is now that all that is needed to “simulate” the second epoch of  $\text{Exp}(\mathcal{V})$  are the transcripts  $\mathcal{T}^1, \mathcal{T}^2, \mathcal{T}^3$ , and  $\mathcal{T}^4$ . On the other hand  $\mathcal{V}$  can be approximately computed from  $\mathcal{Q}$  (i.e., we can compute  $\mathcal{V}$  with elements  $\mathcal{D}$  missing, where  $|\mathcal{D}| = \lceil \gamma n \rceil$ ). Hence the variable  $(\mathcal{T}^1, \mathcal{T}^2, \mathcal{T}^3, \mathcal{T}^4)$  carries enough information to “approximately” describe  $\mathcal{V}$ . Thanks to this we can construct a “compression” algorithm that “compresses” a random  $\mathcal{V} \leftarrow \mathfrak{S} \Upsilon$  by simulating the first epoch of  $\text{Exp}(\mathcal{V})$  and obtaining  $(\mathcal{T}^1, \mathcal{T}^2, \mathcal{T}^3, \mathcal{T}^4)$  and then “decompresses” it by simulating the second epoch, and computing the output as  $\mathcal{V} := \{U_2, \dots, U_n\} \setminus \mathcal{Q}$  (the additional  $\lceil \gamma n \rceil$  elements can be simply listed as an additional output of  $\mathsf{C}$  and passed to  $\mathsf{D}$  as input that has to be added to the output of  $\mathsf{D}$ ).

On the other hand, clearly (for completeness we show this fact in the full version of this paper [11]), a random  $\mathcal{V} \leftarrow \mathfrak{S} \Upsilon$  with high probability cannot be compressed to a string that is significantly shorter than  $\log |\Upsilon| \geq n - 2$ . This implies that with a noticeable probability  $|(\mathcal{T}^1, \mathcal{T}^2, \mathcal{T}^3, \mathcal{T}^4)| \approx n - \lceil \gamma n \rceil \log_2 n$ , where  $\lceil \gamma n \rceil \log_2 n$  is the number of bits needed to describe set  $\mathcal{D}$ .

Obviously, the above fact implies that for at least one  $i \in \{1, \dots, 4\}$  we have that  $\mathcal{T}^i \geq (n - \lceil \gamma n \rceil \log_2 n)/4$  with noticeable probability for concrete parameters). The rest of the proof of Thm. 1 is based on the case analysis of the implications of “ $\mathcal{T}^i \geq n/4$ ” for different  $i$ ’s. More concretely, we show that in the first three cases ( $i = 1, 2$ , and  $3$ ) we can construct attacks that satisfy Eq. (2), and in case  $i = 4$  – an attack that satisfies Eq. (3). All these attacks are based on the experiment  $\text{Exp}(\mathcal{V})$ , but are only using its first epoch. In the proof we exploit the fact that the only malicious behavior that happens in this epoch is the “isolation” (i.e., not sending messages). Hence, we can use Observation 1 and “switch” between scenarios when different groups of parties are corrupt (while still getting the same transcripts  $\mathcal{T}^i$ ). Moreover these attacks do not have uniquely attributable faults.

The detailed proof of Thm. 1 can be found in the full version of this paper [11].

► **Remark 1.** Our proof would also go through even if the total balance of the users  $a$  is arbitrarily large. The only difference would be that instead of giving 1 coin to every user, the environment would give to each user  $U_i$  (for  $i > 1$ )  $\lfloor a/n \rfloor$  coins, and to user  $U_1$  the environment would give the remaining coins (say). The rest of the proof would be essentially identical to the proof of Thm. 1.

► **Remark 2.** Although the attack presented requires two epochs, the second epoch only captures the scenario where the underlying protocol is insecure and hence it can be seen as a “thought experiment”. In other words, if the honest parties do not make large communication with the contact  $\Gamma$  in the first epoch, they risk losing their coins in the second epoch. Therefore, under the assumption that the plasma system is indeed secure and consequently parties make large communication with  $\Gamma$  in the first epoch, the adversary cannot steal any coins in the second epoch and hence the second epoch would become obsolete.

## Conclusion

The main contribution of this work is that we have shown that the distinction between Plasma Cash and Fungible Plasma is inherent, i.e., we ruled out the possibility of constructing Plasma that combines benefits of both Plasmas. We believe that, besides of the general

scientific interest, our work (especially ruling out existence of some Plasma constructions) can help the practical blockchain community in developing Plasma protocols, and in general can bring more understanding in what is possible and what is impossible in the area of off-chain protocols, and under what assumptions. It can also serve as a formal justification why “hybrid” approaches (such as “rollups”) [6] may be needed in real life. We also hope that this work may expand the scope of theory by identifying a new area where theoretical lower bounds can have direct impact on the real life problems.

## Abstract

The theory of majorizing measures, extensively developed by Fernique, Talagrand and many others, provides one of the most general frameworks for controlling the behavior of stochastic processes. In particular, it can be applied to derive quantitative bounds on the expected suprema and the degree of continuity of sample paths for many processes.

One of the crowning achievements of the theory is Talagrand's tight alternative characterization of the suprema of Gaussian processes in terms of majorizing measures. The proof of this theorem was difficult, and thus considerable effort was put into the task of developing both shorter and easier to understand proofs. A major reason for this difficulty was considered to be theory of majorizing measures itself, which had the reputation of being opaque and mysterious. As a consequence, most recent treatments of the theory (including by Talagrand himself) have eschewed the use of majorizing measures in favor of a purely combinatorial approach (the *generic chaining*) where objects based on sequences of partitions provide roughly matching upper and lower bounds on the desired expected supremum.

In this paper, we return to majorizing measures as a primary object of study, and give a viewpoint that we think is natural and clarifying from an optimization perspective. As our main contribution, we give an algorithmic proof of the majorizing measures theorem based on two parts:

- We make the simple (but apparently new) observation that finding the best majorizing measure can be cast as a convex program. This also allows for efficiently computing the measure using off-the-shelf methods from convex optimization.
- We obtain tree-based upper and lower bound certificates by *rounding*, in a series of steps, the primal and dual solutions to this convex program.

While duality has conceptually been part of the theory since its beginnings, as far as we are aware no explicit link to convex optimization has been previously made.

## 1 Introduction

Let  $(Z_x)_{x \in X}$  denote a family of centered (mean zero) jointly Gaussian random variables, indexed by points of a set  $X$ . A fundamental statistic of such a process is the expected supremum  $\mathbb{E}[\sup_{x \in X} Z_x]$ , which provides an important measure of the size of the process. This statistic has applications in a wide variety of areas. We list some relevant examples. In convex geometry, one can associate a process to any symmetric convex body  $K$ , whose supremum gives lower bounds on the size of the largest nearly spherical sections of  $K$  [13]. In the context of dimensionality reduction, one can associate a Gaussian process to any point set  $S$  in  $\mathbb{R}^d$  whose squared expected supremum upper bounds the projection dimension needed to approximately preserve distances between points in  $S$  [7, 14]. In the study of Markov Chains, the square of the expected supremum of the Gaussian free field of a graph  $G$  was shown to characterize the cover time of the simple random walk on  $G$  [3].

The above list of applications, which is by no means exhaustive, help motivate the interest in many areas of Mathematics for obtaining a fine grained understanding of such suprema. We now retrace some of the key developments in the theory of Gaussian processes leading up to Talagrand's celebrated majorizing measure theorem [17], which gives an alternate characterization of Gaussian suprema in terms of an optimization problem over measures on  $X$ . The goal of this paper is to give a novel optimization based perspective on this theory, as well as a new *constructive* proof of Talagrand's theorem. For this purpose, some of the earlier concepts, in particular, majorizing measures, will be central to the exposition. We will also cover some generalizations of the theory to the non-Gaussian setting, as our results will be applicable there as well. Throughout our exposition, we rely on the terminology introduced by van Handel [22] for the various combinatorial objects within the theory (i.e., labelled nets, admissible nets and packing trees).

### 1.1 Bounding the Supremum of Stochastic Processes

In what follows we use the notation  $A \lesssim B$  ( $A \gtrsim B$ ) if there exists an absolute constant  $c > 0$  such that  $A \leq cB$  ( $cA \geq B$ ). We use  $A \asymp B$  to denote  $A \lesssim B$  and  $A \gtrsim B$ .

A first basic question one may ask is what information about the Gaussian process  $(Z_x)_{x \in X}$  is sufficient to exactly characterize the expected supremum? An answer to this problem was given by Sudakov [16], strengthening a result of Slepian [15]. Sudakov showed that it is uniquely identified by the natural (pseudo) distance metric

$$d(u, v) := \mathbb{E}[(Z_u - Z_v)^2]^{1/2}, \quad \forall u, v \in X. \quad (1.1)$$

In fact, Sudakov proved the following stronger comparison theorem: if  $(Y_x)_{x \in X}$  and  $(Z_x)_{x \in X}$  are Gaussian processes on the same index set  $X$  and for every  $u, v \in X$ , it holds that  $\mathbb{E}[(Y_u - Y_v)^2] \leq \mathbb{E}[(Z_u - Z_v)^2]$ , then  $\mathbb{E}[\sup_x Y_x] \leq \mathbb{E}[\sup_x Z_x]$ .

Given the above, it is natural to wonder what properties of the metric space  $X$  allow us to obtain upper and lower bounds on  $\mathbb{E}[\sup_{x \in X} Z_x]$ ? A first intuitively relevant quantity is the diameter of  $X$  defined by  $\mathbf{D}(X) := \sup_{u, v \in X} d(u, v)$ . For any  $u, v \in X$ , we have the following simple lower bound:

$$\begin{aligned} \mathbb{E}[\sup_x Z_x] &\geq \mathbb{E}[\max\{Z_u, Z_v\}] = \mathbb{E}[\max\{Z_u - Z_v, 0\}] + \mathbb{E}[Z_v] \\ &= \frac{1}{2} \mathbb{E}[|Z_u - Z_v|] = \frac{d(u, v)}{\sqrt{2\pi}}. \end{aligned} \quad (1.2)$$

Here, we use that  $\mathbb{E}[Z_v] = 0$ , and that  $Z_u - Z_v$  is Gaussian with variance  $d(u, v)^2$ . Thus  $\mathbb{E}[\sup_x Z_x] \geq \mathbf{D}(X)/\sqrt{2\pi}$ .

Instead of looking at two maximally separated points, one might expect to get stronger lower bounds using a large set of well-separated points in  $X$ . Such an inequality was given by Sudakov [16], who showed that

$$\max_{r>0} r \sqrt{\log N_X(r)} \lesssim \mathbb{E}[\sup_x Z_x],$$

where  $N_X(r) := \min\{|S| \mid S \subseteq X, \forall x \in X, \min_{s \in S} d(x, s) \leq r\}$  is the minimum size of an  $r$ -net of  $X$ . This is in fact a direct consequence of Sudakov's comparison theorem. Precisely, the restriction of the process  $\{Z_x\}_{x \in X}$  to a suitable  $r$ -net  $S$ , chosen greedily so that every two points in  $S$  are at distance at least  $r$ , majorizes the maximum of  $|S| \geq N_X(r)$  independent Gaussians with standard deviation  $r/\sqrt{2}$ , where a standard computation then yields the left-hand side.

On the upper bound side, Dudley [4] proved that the covering numbers can in fact be *chained* together to upper bound the supremum:

$$\mathbb{E}[\sup_x Z_x] \lesssim \int_0^\infty \sqrt{\log N_X(r)} dr. \quad (1.3)$$

Note that the integral can be restricted to the range  $r \in (0, \mathbf{D}(X)]$ , since  $\log N_X(\mathbf{D}(X)) = \log 1 = 0$ . Dudley's proof of this inequality was extremely influential and showed the power of combining simple tail bounds on pairs of variables  $Z_u - Z_v$  to get a global bound on the supremum. In particular, the main inequality used in Dudley's proof is the standard Gaussian tail bound: for  $u, v \in X$ , and for any  $s > 0$

$$\mathbb{P}[|Z_u - Z_v| \geq d(u, v) \cdot s] \leq 2e^{-s^2/2}. \quad (1.4)$$

The strategy of combining the above inequalities to control the maximum of a process is what is now called *chaining*.

**Basics of Chaining.** The concept of chaining is central to this paper, so we explain the basic mechanics here. As it will be more convenient for the exposition, we will more directly work with symmetric version of the supremum

$$\sup_{x_1, x_2 \in X} Z_{x_1} - Z_{x_2}$$

which is always non-negative. Note that since  $(Z_x)_{x \in X}$  and  $(-Z_x)_{x \in X}$  are identically distributed,

$$\mathbb{E} \left[ \sup_{x_1, x_2 \in X} Z_{x_1} - Z_{x_2} \right] = \mathbb{E} \left[ \sup_{x \in X} Z_x \right] + \mathbb{E} \left[ \sup_{x \in X} -Z_x \right] = 2\mathbb{E} \left[ \sup_{x \in X} Z_x \right],$$

and thus the expected supremum is the same after dividing by 2.

From here, instead of bounding the expectation, we focus on upper bounding the median of  $\sup_{x_1, x_2 \in X} Z_{x_1} - Z_{x_2}$ , which is known to be within a constant factor of the expectation. Precisely, we seek to compute a number  $M > 0$  such that  $\mathbb{P}[\sup_{x_1, x_2 \in X} Z_{x_1} - Z_{x_2} \geq M] \leq 1/2$ . To arrive at such bounds, we define the notion of a *chaining tree*.

► **Definition 1.1** (Chaining Tree). *A (Gaussian) chaining tree  $\mathcal{C}$  for a finite metric space  $(X, d)$  is a rooted spanning tree on  $X$ , with root node  $w \in X$ , together with probability labels  $p_e \in (0, 1/2)$ , for each edge  $e \in E[\mathcal{C}]$ . The edge probabilities are required to satisfy*

### 73:4 Majorizing Measures for the Optimizer

$\sum_{e \in E[\mathcal{C}]} p_e \leq 1/2$ . For each edge  $\{u, v\} = e \in E[\mathcal{C}]$ , we define the induced edge length  $l_e := l_e(p_e, e)$  to satisfy

$$\mathbb{P}_{Z \in \mathcal{N}(0, d(u, v)^2)}[|Z| \geq l_e] = p_e. \quad (1.5)$$

For each  $x \in X$ , let  $\mathcal{P}_x$  denote the unique path from  $x$  to the root  $w$  in  $\mathcal{C}$ . We define the value of  $\mathcal{C}$  to be

$$\text{val}(\mathcal{C}) = \max_{x \in X} \sum_{e \in \mathcal{P}_x} l_e. \quad (1.6)$$

For a Gaussian process  $(Z_x)_{x \in X}$ , where  $d$  is the induced metric as in (1.1), for any chaining tree  $\mathcal{C}$  on  $X$ , we now show that

$$\mathbb{P} \left[ \sup_{x_1, x_2} Z_{x_1} - Z_{x_2} \geq 2 \cdot \text{val}(\mathcal{C}) \right] \leq 1/2. \quad (1.7)$$

By construction, for any edge  $\{u, v\} \in E[\mathcal{C}]$  we first note that

$$\mathbb{P}[|Z_u - Z_v| \geq l_e] = p_e,$$

recalling that  $Z_u - Z_v$  is distributed as  $\mathcal{N}(0, d(u, v)^2)$ . Since  $\sum_{e \in \mathcal{C}} p_e \leq 1/2$ , by the union bound the event  $\mathcal{E}$  defined as “ $|Z_u - Z_v| \leq l_{u, v}$ ,  $\forall \{u, v\} \in E[\mathcal{C}]$ ”, holds with probability at least  $1/2$ . For  $x \in X$ , let us now define  $\mathcal{P}_x$  to be the unique path from the root  $w$  to  $x$  in  $\mathcal{C}$ .

Conditioning on the event  $\mathcal{E}$ , by the triangle inequality

$$|Z_x - Z_w| \leq \sum_{\{u, v\} \in \mathcal{P}_x} |Z_u - Z_v| \leq \sum_{e \in \mathcal{P}_x} l_e. \quad (1.8)$$

Applying the triangle inequality again, we have that

$$\sup_{x_1, x_2} Z_{x_1} - Z_{x_2} \leq 2 \sup_{x \in X} |Z_x - Z_w| \leq 2 \cdot \text{val}(\mathcal{C}).$$

The bound (1.7) now follows since the above occurs with probability at least  $1/2$ .

To work with such chaining trees, it is important to have easy approximations of the edge lengths used above. For  $e = \{u, v\} \in E[\mathcal{C}]$  and  $p_e \in (0, 1/2]$ , it is well known that

$$l_e \asymp d(u, v) \sqrt{\log(1/p_e)}. \quad (1.9)$$

Note that by the standard Gaussian tail bounds (1.4), for any  $p \in (0, 1)$ , we have the upper bound,  $l_e \leq d(u, v) \sqrt{2 \log(2/p_e)}$ .

To relate to earlier lower bounds, it is instructive to see that  $\text{val}(\mathcal{C}) \gtrsim \mathbf{D}(X)$ , for any chaining tree. Firstly, since each  $p_{u, v} \in (0, 1/2]$ , by (1.9), it follows that  $l_{u, v} \gtrsim d(u, v)$ . From here, for any pair of points  $u, v \in X$ , by the triangle inequality  $2 \cdot \text{val}(\mathcal{C})$  pays for the cost of going from  $u$  to the root  $w$  and from  $w$  to  $v$ , yielding the desired upper bound on the diameter.

**Chaining beyond Gaussians.** Importantly, in the above framework, the only element specific to Gaussian processes is the edge length function (1.5). As our results will apply to this more general setting, we explain how chaining can straightforwardly be adapted to work with processes satisfying appropriate tail bounds.

Let us examine a jointly distributed sequence of random variables  $(Z_x)_{x \in X}$  indexed by a metric space  $(X, d)$ . To constrain the process we will make the following assumptions on the tails. Let  $f : \mathbb{R}_+ \rightarrow \mathbb{R}_+$  be a continuous and non-increasing probability density function on the non-negative reals and let  $F(s) = \int_s^\infty f(t) dt$  denote the complementary cumulative distribution function. Then, for all  $x_1, x_2 \in X$  and  $s \geq 0$ , we assume that

$$\mathbb{P}[|Z_{x_1} - Z_{x_2}| \geq d(x_1, x_2) \cdot s] \leq F(s). \quad (1.10)$$

► **Definition 1.2** (Chaining Functional). *We define the chaining functional induced by  $f$  to be  $h(p) := h_f(p) = F^{-1}(p)$ , for  $p \in (0, 1]$ , which is well-defined since  $f$  is non-increasing. Note that  $h(1) = 0$  and that  $h(p)$  is strictly decreasing on  $(0, 1]$ . We say that  $h$  is of log-concave type if the density  $f$  is log-concave.*

A property that we make crucial use of is that  $h(p)$  is, in fact, a convex function of  $p \in (0, 1]$ . To see this, for  $p \in (0, 1)$ , a direct computation yields that  $h'(p) = 1/F'(h(p)) = -1/f(h(p))$ , where the derivative is well-defined since  $f$  is continuous and non-decreasing. Since  $f(s)$  is non-increasing and  $h(p)$  is strictly decreasing,  $h'(p)$  is non-decreasing and hence,  $h$  is convex. Throughout the rest of the paper, we will mainly be interested in chaining functionals of log-concave type.

To apply the chaining framework to the process  $(Z_x)_{x \in X}$ , we use a chaining tree  $\mathcal{C}$  exactly as in Definition 1.1 except that we now compute the edge lengths according to the chaining functional  $h$ . Specifically, for  $e = \{u, v\} \in E[\mathcal{C}]$  and probability  $p_e \in (0, 1)$ , we define

$$l_e := l_e(e, p_e) := d(u, v) \cdot h(p_e). \quad (1.11)$$

We now define  $\text{val}_h(\mathcal{C})$  exactly as in (1.6), using  $h$  to compute the edge lengths.

With this setup, with an identical proof to the previous section, we have the inequality

$$\mathbb{P} \left[ \sup_{x_1, x_2 \in X} Z_{x_1} - Z_{x_2} \geq 2 \cdot \text{val}_h(\mathcal{C}) \right] \leq \frac{1}{2}.$$

As in the Gaussian setup, it is useful to keep in mind what the “trivial” diameter lower bound on  $\text{val}_h(\mathcal{C})$  should be. Since the edge probability  $p_e \in (0, 1/2]$ , for  $e = \{u, v\} \in E[\mathcal{C}]$ , we have that  $l_e \geq d(u, v) \cdot h(1/2)$ . Therefore, for any  $u, v \in X$ , by the triangle inequality, the cost of the paths from  $u$  or  $v$  to the root  $w$  is at least  $d(u, v) \cdot h(1/2)$  for any chaining tree  $\mathcal{T}$ . In particular, for any chaining tree  $\mathcal{C}$ , we derive the lower bound

$$2 \cdot \text{val}_h(\mathcal{C}) \geq \mathbf{D}(X) \cdot h(1/2). \quad (1.12)$$

It is important to note that the Gaussian chaining setup is indeed a special case of the above. Precisely, in that setup the edge lengths are  $l_{u,v} := d(u, v) \cdot h_f(p_{u,v})$ , where  $f(s) = \sqrt{\frac{2}{\pi}} e^{-s^2/2}$  is the density of the absolute value of the standard Gaussian.

**Dudley’s Construction.** To gain intuition about how to apply the chaining framework, we now explain how to build and analyze the chaining tree used in Dudley’s inequality. For simplicity of notation, let us assume that the diameter  $\mathbf{D}(X) = 1$ . For each  $k \geq 0$ , let  $\mathcal{N}_k$  denote a  $2^{-k}$ -net of  $X$  of minimum size, i.e., satisfying  $|\mathcal{N}_k| = N_X(2^{-k})$ . By our diameter assumption,  $\mathcal{N}_0 = \{w\}$  is clearly a single point, which gives the root of the tree  $\mathcal{C}$ . From here, we construct the tree by induction on  $k \geq 1$ . At iteration  $k \geq 1$ , we attach each element of  $\mathcal{N}_k$  not already in  $\mathcal{C}$  to a closest point in  $\mathcal{C}$ . From here, we set the edge probability  $p_{u,v} = p_k := 2^{-(k+1)}/|\mathcal{N}_k|$  and let  $l_{u,v} > 0$  be minimal subject to  $\mathbb{P}[|Z_u - Z_v| \geq l_{u,v}] \leq p_k$ . This completes the construction.

To analyze the tree  $\mathcal{C}$ , we make the following observations. Firstly, the number of edges we add to the tree at iteration  $k$  is at most  $|\mathcal{N}_k|$ . Therefore, the total probability sum is at most  $\sum_{k=1}^{\infty} |\mathcal{N}_k| \cdot p_k = 1/2$ , and hence  $\mathcal{C}$  is a valid chaining tree. Second, any edge  $\{u, v\}$  added during iteration  $k$  satisfies  $d(u, v) \leq 2^{-k+1}$ . Consequently, by the Gaussian tail bound (1.4),

$$l_{u,v} \lesssim d(u, v) \sqrt{\log(1/p_k)} \lesssim 2^{-k+1} \left( \sqrt{\log N_X(2^{-k})} + \sqrt{k+1} \right).$$

In particular, the value of  $\mathcal{C}$  satisfies

$$\text{val}(\mathcal{C}) \lesssim \sum_{k=1}^{\infty} 2^{-k+1} \left( \sqrt{\log N_X(2^{-k})} + \sqrt{k+1} \right) \lesssim 1 + \sum_{k=1}^{\infty} 2^{-k+1} \sqrt{\log(N_X(2^{-k}))}.$$

One can now easily show that the above expression is upper bounded by (1.3) by discretizing the range of the integral along powers of 2 (recalling that  $\mathbf{D}(X) = 1$ ).

**The Method of Majorizing Measures.** Given the above, it is natural to wonder how one might construct an *optimal* chaining tree for a given process  $(Z_x)_{x \in X}$ . A principal goal of this paper will be to give efficient constructions for such trees. At first sight, this may seem like a daunting task, as one must somehow simultaneously optimize over all spanning trees and edge probabilities. Nevertheless, a major step towards this goal was achieved for Gaussian processes by Fernique [5], who proved the following remarkable theorem:

$$\mathbb{E} \left[ \sup_{x \in X} Z_x \right] \lesssim \gamma_2(X) := \inf_{\mu} \sup_{x \in X} \int_0^{\infty} g(\mu(B(x, r))) dr. \quad (1.13)$$

Some definitions are in order. Firstly, the infimum over  $\mu$  is taken over all probability measures on  $X$ . Secondly,  $g(p) := \sqrt{\log(1/p)}$ , for  $p \in [0, 1]$  corresponds to (an approximation of) the Gaussian edge length function in (1.5). Lastly,  $B(x, r) = \{y \in X : d(x, y) \leq r\}$  is the metric ball of radius  $r$  around  $x$ , where  $d$  is the canonical metric induced by the Gaussian process.

Importantly, the natural analogue of  $\gamma_2$  for the general setup in (1.10) also yields upper bounds on the expected supremum, provided the tails of  $f$  decay sufficiently quickly. In particular, for  $(Z_x)_{x \in X}$  satisfying (1.10), for any “nice enough”  $f$ , we have that

$$\mathbb{E} \left[ \sup_{x_1, x_2 \in X} Z_{x_1} - Z_{x_2} \right] \lesssim \gamma_h(X) := \inf_{\mu} \sup_{x \in X} \int_0^{\infty} h(\mu(B(x, r))) dr, \quad (1.14)$$

where  $h$  is as in (1.11). Note that since  $h(1) = 0$ , one can truncate the range of the integral to  $r \in [0, \mathbf{D}(X)]$ . Very general results of the above type can be found in [18, 1]. We note that the requirements of the process in these works are parametrized in a somewhat different way in terms of Orlicz norms. In this work, we will focus on the setting where the chaining functional  $h$  is of log-concave type (where the tail density  $f$  is log-concave), where these different parametrizations are equivalent. Prototypical examples in this class are the tail densities of *exponential type*, which are proportional to  $e^{-x^q}$ ,  $x \geq 0$ , for  $q \geq 1$ , and where  $h(p) \asymp \ln^{1/q}(1/p)$  for  $p \in (0, 1/2)$ .

Given that any probability measure  $\mu$  can be used to upper bound the expected supremum, Fernique dubbed the above technique the method of *majorizing measures*. It is worthwhile to note that Fernique did not prove inequality (1.13) via chaining. He relied instead on a more general technique, which first proves a generic concentration inequality for real valued functions on the metric space, and recovers the desired inequality by averaging over the ensemble of functions induced by the process. The fact that one can recover the same bound via chaining for Gaussian processes would only be proved later, at first implicitly in Talagrand [17], and explicitly in [21], where the latter work also covered processes of exponential type mentioned above.

As noted above, the quantity  $\gamma_2(X)$  and more generally  $\gamma_h(X)$  (for  $h$  of log-concave type), rather miraculously models the value of the best chaining tree as a continuous optimization problem. As majorizing measures may seem like rather opaque objects at first sight, we

believe it is instructive to note that from a chaining tree  $\mathcal{C}$ , one can construct a measure  $\mu$  whose value in (1.13) is at most  $3 \cdot \text{val}_h(\mathcal{C})$ . The construction is simple: set  $\mu_w = 1/2$  on the root  $w$ , and for each  $e = \{u, v\} \in E[\mathcal{C}]$  (with  $v$  closer to the root than  $u$ ), set  $\mu_u = p_e$ . The details of the comparison can be found in the appendix of the full version of the paper.

From the above discussion, we see that the majorizing measures are indeed powerful tools for upper bounding suprema. Given this, together with the many tools for *lower bounding* Gaussian suprema (which are not available in general), Fernique [5] conjectured that majorizing measures should fully characterize the expected supremum of Gaussian processes. This conjecture was verified in the ground-breaking work of Talagrand [17], which is now called the majorizing measures theorem:

► **Theorem 1.3** (Fernique-Talagrand [5, 17]). *For any centered Gaussian process  $(Z_x)_{x \in X}$  over the metric space  $X = (X, d)$ , where  $d$  is the canonical metric induced by the process, we have*

$$\mathbb{E} \left[ \sup_{x \in X} Z_x \right] \asymp \gamma_2(X).$$

The original proof of the majorizing measure theorem [17] was considered notoriously difficult. Due to its importance in the theory of stochastic processes, many simpler as well as different proofs were found [19, 20, 21, 12, 2, 22], often by Talagrand himself.

As stated at the beginning of the introduction, the goal of this paper is to give an alternative constructive proof of this theorem using a convex optimization approach. In particular, our starting point is the simple observation that  $\gamma_h(X)$  is in fact a convex program, which follows directly from the convexity of  $h^1$ . While simple (and most certainly known to experts), we have not seen this observation leveraged in earlier proofs. In our context, convexity will allow for near-optimal solutions to  $\gamma_h(X)$  to be efficiently computed using off-the-shelf methods. Furthermore, convex duality will allow us to inspect the structure of solutions to natural dual program(s) for  $\gamma_h(X)$ , enabling us to reason about lower bounds. Our proof will operate entirely at the level of the metric space, and will produce a natural combinatorial variant of an optimal primal-dual solution pair for  $\gamma_h(X)$ , namely a chaining tree and packing tree (defined shortly). These solutions will in fact be obtained by “rounding” solutions to the corresponding continuous programs. Specializing to the Gaussian case, we recover the majorizing measure theorem by an easy comparison between the value of the Gaussian supremum and the value of the combinatorial solutions (which are tailor made for this purpose). This strategy has the benefit of clearly separating the role of the metric space and the role of the Gaussian process, which are often intertwined in difficult to disentangle ways in many proofs.

We now review some of the key ideas in known proofs, which will be important for our approach as well. In particular, we will require appropriate dual analogue to chaining trees.

**Primal Proof Strategies.** Given what we have seen so far, a main missing ingredient is a stronger form of lower bound for the value of the Gaussian supremum (noting that chaining already provides the upper bound). For this purpose, we examine the natural functional induced by the process on subsets of  $X$ , defining

$$G(S) := \mathbb{E} \left[ \sup_{x \in S} Z_x \right], \quad \forall S \subseteq X. \quad (1.15)$$

<sup>1</sup> The formulation  $\gamma_2(X)$  is “essentially convex”. This is because  $g(p)$  is only convex on the interval  $[0, 1/\sqrt{e}]$ , which is easily remedied. We note this non-convexity is principally due to  $g(p)$  being a poor approximation of (1.5) for  $p \in [1/\sqrt{e}, 1]$ .

The following functional inequality, named the “super-Sudakov” inequality in [22], was proven in [19]: there exists  $\gamma \in (0, 1)$ , such that given an  $r$ -separated (non-empty) subsets  $A_1, \dots, A_N \subseteq S$ , i.e., satisfying  $d(A_i, A_j) \geq r$ ,  $\forall i \neq j$ , and  $\mathbf{D}(A_i) \leq \gamma r$ ,  $\forall i \in [N]$ , then

$$G(S) \geq \gamma \cdot r \cdot g(1/N) + \min_{i \in [N]} G(A_i), \quad (1.16)$$

where  $g(x) = \sqrt{\log 1/x}$  for  $x \in [0, 1]$ , as before.

In [19], Talagrand gave a construction which takes a functional  $G$  on  $X$  satisfying (1.16), and produces (a variant of) a chaining tree  $\mathcal{C}$  satisfying  $\text{val}(\mathcal{C}) \lesssim G(X)$ . Talagrand’s construction is based on a recursive partitioning scheme, where the partitions roughly correspond to subtrees, which greedily chooses metric balls of large  $G$  value to construct the partition. We note that this construction comes in different flavors, each yielding more structured versions of chaining trees (i.e., labelled nets [19] and admissible nets [20]). By instantiating  $G$  to be the functional given by (1.15) immediately yields Theorem 1.3. While Talagrand’s construction was certainly algorithmic, the Gaussian functional  $G$  is not easy to compute (at least deterministically). As mentioned previously, in [21], Talagrand also gave another procedure that directly converts measures to chaining trees. Note that this yields a good chaining tree from a good measure, but by itself does not yield Theorem 1.3.

**Dual Proof Strategies.** One reason the “difficult” Gaussian functional  $G$  was required to prove Theorem 1.3 is that there was no simple dual object to compare to that certifies a lower bound. From the convex optimization perspective, this should morally correspond to a solution to the dual of  $\gamma_2(X)$  (or  $\gamma_h(X)$ ). Such an object, called a *packing tree* in the terminology of [22], was in fact developed in Talagrand’s original proof [17] for the Gaussian case, and extended to general chaining functionals in [10].

► **Definition 1.4 (Packing Tree).** Let  $\alpha \in (0, \frac{1}{10}]$ . An  $\alpha$ -packing tree  $\mathcal{T}$  on a finite metric space  $(X, d)$  is a rooted tree on subsets of  $X$ , with root node  $W \subseteq X$ , together with a labelling  $\chi : \mathcal{T} \rightarrow \mathbb{Z}_{\geq 0}$ . We enforce that every leaf node  $V \in \mathcal{T}$  is a singleton, i.e.,  $V = \{x\}$  for some  $x \in X$ . We denote  $\text{leaf}(\mathcal{T}) \subseteq X$  to be the union of all leaf nodes of  $\mathcal{T}$ . Every node  $V \in \mathcal{T}$  has a (possibly empty) set of children  $C_1, \dots, C_k \subseteq V$  which are pairwise disjoint. We let  $\deg_+(V) := k$  denote the number of children of  $V$ . We enforce the follow metric properties on  $\mathcal{T}$ :

1. For any child  $C$  of  $V \in \mathcal{T}$ , we have that  $\mathbf{D}(C) \leq \alpha^{\chi(V)+1} \cdot \mathbf{D}(X)$ .
2. For  $V \in \mathcal{T}$  and distinct children  $C_1, C_2$  of  $V$ , we have  $d(C_1, C_2) \geq \frac{1}{10} \alpha^{\chi(V)} \cdot \mathbf{D}(X)$ .

The value of an  $\alpha$ -packing tree  $\mathcal{T}$  with respect to a chaining functional  $h$  is defined as

$$\text{val}_h(\mathcal{T}) := \inf_{x \in \text{leaf}(\mathcal{T})} \sum_{V \in \mathcal{P}_x \setminus \{x\}} \alpha^{\chi(V)} \cdot \mathbf{D}(X) \cdot h(1/\deg_+(V)), \quad (1.17)$$

where  $\mathcal{P}_x$  is the unique path from the root  $W$  to the leaf  $\{x\}$ . We use the shorthand  $\text{val}_2(\mathcal{T})$  to denote the value with respect to the Gaussian functional  $g$ .

We remark that we do not count the edge going to the parent in  $\deg_+(V)$  mostly for notational convenience – in this case, nodes with a sole child do not contribute to the value of the packing tree. Also, there is quite a bit of flexibility in the parameters of the packing tree, which are chosen above for convenience. Packing trees are objects that allow us to chain lower bounds together in analogy to upper bounds via chaining trees. The combinatorial structure of a packing tree is more constrained than that of a chaining tree however, and their construction (at least more from the perspective of the analysis) is more delicate.

In the Gaussian setting, an  $\alpha$ -packing tree  $\mathcal{T}$  is perfectly tailored for combining the “super-Sudakov” inequalities given by (1.16). In particular, for  $\alpha = 1/(2\gamma)$ , a direct proof by induction starting from the leaves of the tree certifies that  $G(X) \gtrsim \text{val}_2(\mathcal{T})$  (see Theorem 6.36 in [22]). This was in fact first established in [17] using Slepian’s lemma instead of (1.16). Independently of any process however, they also directly serve as combinatorial lower bounds for  $\gamma_h(X)$ .

► **Lemma 1.5.** *Let  $\alpha \in (0, \frac{1}{10}]$ . For a finite metric space  $(X, d)$ , an  $\alpha$ -packing tree  $\mathcal{T}$  on  $X$ , and any chaining functional  $h$ , we have*

$$\gamma_h(X) \geq \frac{1}{2}(1 - \alpha) \cdot \text{val}_h(\mathcal{T}).$$

While known to experts, it is not so easy to find combinatorial proofs of the above inequality, i.e. not related to a process, in the literature (see for example Exercise 6.12 in [22] or Lemma 3.7 in [3]). We include a proof in the appendix of the full version of the paper.

Talagrand’s original proof of the majorizing measures theorem worked almost entirely on the dual side. As generalized in [10], the main work in the proof was in fact to construct an  $\alpha$ -packing tree  $\mathcal{T}$  satisfying  $\text{val}_h(\mathcal{T}) \gtrsim \gamma_h(\mathcal{T})$  (for  $h$  of log-concave type). As for the primal side, the construction is based on similar greedy ball (sub-)partitioning using an appropriate functional  $H$  on  $X$  satisfying a so-called “super-chaining” inequality in the terminology of [22]. Specifically, for any set  $S \subseteq X$ , and a partition  $S = \sqcup_{i=1}^N P_i$ ,  $H$  satisfies

$$H(S) \leq \max_{i \in [N]} \beta \cdot \mathbf{D}(S)h(1/(i+1)) + H(P_i), \quad (1.18)$$

for some absolute constant  $\beta > 0$ . Interestingly, the functional  $H$  used in [17, 10] was a variant of  $\gamma_h(X)$ , which is deterministically computable, and not the Gaussian functional in the case  $h = g$  (though this works as well [22]). This construction was in fact leveraged in [3] to give a deterministic polynomial time dynamic programming algorithm for computing a nearly optimal packing tree.

## 1.2 Our Results

### 1.2.1 A Constructive Min-Max Theorem

The main result of this paper is the following constructive variant of the combinatorial core of the majorizing measure theorem.

► **Theorem 1.6.** *Let  $(X, d)$  be an  $n$  point metric space,  $h$  be a chaining functional of log-concave type. Then there is a deterministic algorithm which computes a chaining tree  $\mathcal{C}^*$  and an  $1/10$ -packing tree  $\mathcal{T}^*$  satisfying*

$$\text{val}_h(\mathcal{C}^*) \asymp \text{val}_h(\mathcal{T}^*),$$

*using  $\tilde{O}(n^{\omega+1})$  arithmetic operations and evaluations of  $h$  and  $h'$ , where  $\omega \leq 2.373$  is the matrix multiplication constant.*

We note that the packing tree parameter  $1/10$  can be made smaller at the cost increasing the hidden constant in the  $\asymp$  notation. Recall that for any pair of trees  $\mathcal{C}$  and  $\mathcal{T}$  as above, we have already seen that

$$\text{val}_h(\mathcal{C}) \gtrsim \gamma_h(X) \gtrsim \text{val}_h(\mathcal{T}), \quad (1.19)$$

so the pair in Theorem 1.6 form a nearly-optimal primal-dual pair. Furthermore, in the Gaussian setting where  $h = g$ , replacing  $\gamma_2(X)$  above by  $\mathbb{E}[\sup_x Z_x]$  corresponds to the “easy direction” of the majorizing measures theorem. Plugging in the solutions from Theorem 1.6 immediately yield the hard direction of the theorem. This allows us to view the metric space part of the majorizing measure theorem as an instance of a combinatorial min-max theorem. We remark that such a combinatorial min-max characterization of the Majorizing Measures theorem was already observed by Guédon and Zvavitch [8]. They showed that the value of the optimal packing tree defines a functional that satisfies the super-Sudakov inequality; when combined with Talagrand’s framework, this implies the combinatorial min-max theorem described above. This does not directly yield deterministic constructions of nearly-optimal chaining or packing trees, however.

Ding, Lee and Peres [3] essentially used this observation of [8] along with a suitable dynamic program to give an efficient deterministic algorithm to compute nearly optimal packing trees, as mentioned previously. For nearly optimal chaining trees, we make the simple observation (which seems to have gone unnoticed) that these can be extracted from Talagrand’s [21] “rounding” algorithm applied to a nearly optimal solution for the efficiently solvable convex program  $\gamma_h(X)$ . By themselves however, these algorithms do not directly say much about how the values of these different trees relate to each other.

In Theorem 1.6, we build further on the convex programming approach. At a high level, we build the primal and dual solutions at the same time and rely on convex programming duality to ensure they have (nearly) the same value. In essence, we replace the “magic functionals” satisfying super-Sudakov or super-chaining inequalities that appear in Talagrand’s constructions with convex duality. As we will see in the next section, the dual objects will also correspond to probability measures. In contrast to the primal however, where the rounding to a suitable chaining tree can be done in one shot, the dual measures will require multiple levels of rounding.

The primal and dual solutions we require correspond to nearly optimal primal and dual measures associated with a saddle-point formulation of  $\gamma_h(X)$  (see (1.20) in the next subsection). There are in fact many existing solvers that are able to compute nearly optimal solutions to such saddle point problems, where we will rely on a recent fast solver of [9]. This computation in fact forms the bulk of the running time of the algorithm in Theorem 1.6. The details of this part of the algorithm can be found in the full version of this paper. An interesting open problem is whether one can reduce the running time of Theorem 1.6 to  $\tilde{O}(n^2)$ , which would be nearly-linear in the input size (recall that an  $n$  point metric consists of  $n^2$  distances). The main bottleneck is the use of an all purpose blackbox solver [9] to approximately solve (1.20), and it seems likely that an appropriately tailored first-order method could bring the running time down to  $\tilde{O}(n^2)$ .

While our main contribution is conceptual, we expect and hope that novel and interesting applications of an “algorithmic” theory of chaining will be found. As a contribution on this front, we give an application of Theorem 1.6 in the context of derandomization: we give a deterministic algorithm for computing Johnson-Lindenstrauss projections achieving the guarantees of Gordon’s theorem [7], where we rely on the chaining based proof from [14]. As far as we are aware, no prior deterministic construction was known.

### 1.2.2 Simplifying the Dual of $\gamma_h(X)$

For simplicity of notation, throughout this section (and most of the paper), we will assume that  $(X, d)$  is a fixed  $n$ -point metric space and that  $h$  is a chaining functional of log-concave type satisfying  $|h'(1)| = 1$  (interpreted as the left directional derivative). Under this normalization

on  $h$ , the trivial diameter lower bound on  $\gamma_h(X)$  will be at least  $\mathbf{D}(X)/4$ , which we will use to convert additive errors to multiplicative ones. This normalization is without loss of generality, and can be achieved by appropriately scaling the  $h$  and the metric  $d$  so that  $\gamma_h(X)$  remains unchanged (see Section 2.1 for a full explanation).

We now describe the dual formulation of  $\gamma_h(X)$  and describe the process of simplifying it. For this purpose, we start with the basic saddle-point formulation of  $\gamma_h(X)$ :

$$\gamma_h(X) = \min_{\mu} \max_{x \in X} \int_0^\infty h(\mu(B(x, r))) dr = \min_{\mu} \max_{\nu} \int_X \int_0^\infty h(\mu(B(x, r))) dr d\nu(x) \quad (1.20)$$

where  $\nu$  also ranges over all probability measures on  $X$  (the optimal  $\nu$  above puts mass 1 on any maximizer of  $\int_0^\infty h(\mu(B(x, r))) dr$ ).

To obtain the dual program to  $\gamma_h(X)$ , we interchange  $\mu$  and  $\nu$ :

$$\gamma_h(X) \geq \max_{\nu} \min_{\mu} \int_X \int_0^\infty h(\mu(B(x, r))) dr d\nu(x) := \gamma_h^*(X). \quad (1.21)$$

In particular, for any fixed dual measure  $\nu$ , we have

$$\gamma_h(X) \geq \min_{\mu} \int_X \int_0^\infty h(\mu(B(x, r))) dr d\nu(x). \quad (1.22)$$

Since the objective  $\int_X \int_0^\infty h(\mu(B(x, r))) dr d\nu(x)$  is convex in  $\mu$  and linear in  $\nu$ , and the probability simplex is compact and convex, by Sion's theorem the value of both convex programs is equal. That is,  $\gamma_h(X) = \gamma_h^*(X)$ . The measures required within the construction in Theorem 1.6 will be nearly optimal primal and dual measures  $\mu^*$  and  $\nu^*$  to  $\gamma_h(X)$  and  $\gamma_h^*(X)$  respectively.

Unfortunately, it is not clear at this point that the dual is terribly useful. In particular, even evaluating the objective in (1.22) for a given dual measure  $\nu$  requires solving a non-trivial convex optimization problem (note that the corresponding objective of  $\gamma_h(X)$  can be computed by simply evaluating  $n$  integrals). Rather surprisingly, it turns out that for  $h$  of log-concave type, one can in fact “guess” a near-optimal  $\mu$  in (1.22), namely, we can set  $\mu = \nu$ .

► **Lemma 1.7.** *For any probability measure  $\nu$  on  $X$ , we have that*

$$\int_X \int_0^\infty h(\nu(B(x, r))) dr d\nu(x) \leq 2 \min_{\mu} \int_X \int_0^\infty h(\mu(B(x, r))) dr d\nu(x) + \mathbf{D}(X)/e,$$

where the minimum is taken over all probability measures  $\mu$ .

The proof of the above proceeds on a “per scale” basis. More precisely, for a given  $r > 0$ , we show that  $\int_X h(\nu(B(x, 2r))) d\nu(x) \leq \int_X h(\mu(B(x, r))) d\nu(x) + 1/e$ . This statement is easily restated in graph-theoretic terms, by defining a graph  $G = (X_1 \cup X_2, E)$ , with  $X_1, X_2$  both being copies of  $X$  and where  $x_1 \in X_1$  is adjacent to  $x_2 \in X_2$  if  $d(x_1, x_2) \leq r$ . Then  $\mu(B(x, r))$  corresponds to the mass under  $\mu$  within the neighborhood of  $x$ , and  $\nu(B(x, 2r))$  to the mass under  $\nu$  within the two-hop neighborhood of  $x$ . In this setting, we use a tool from combinatorial optimization, namely, a generalization of Hall's theorem. We note the two properties needed from  $h$  above are that  $h$  be decreasing and  $\max_{a \in (0, 1]} |ah'(a)| \leq 1$ . The latter property in fact follows from  $h$  being of log-concave type and the normalization  $|h'(1)| = 1$ .

Motivated by the above, we consider the following simplification of  $\gamma_h^*(X)$ , which we call the *entropic dual*:

$$\delta_h^{\text{Ent}}(X) := \max_{\nu} \int_X \int_0^\infty h(\nu(B(x, r))) dr d\nu(x). \quad (1.23)$$

This corresponds to the value  $\nu$  using the nearly optimal guess for  $\mu$  in (1.22), which is now readily computable. The following direct corollary relates the value of the entropic dual to the actual dual.

► **Corollary 1.8.**

$$\gamma_h^*(X) \leq \delta_h^{\text{Ent}}(X) \leq 2\gamma_h^*(X) + \mathbf{D}(X)/e.$$

In terms of the additive error above, as mentioned at the beginning of the section,  $\mathbf{D}(X)/4$  will be the trivial lower bound on  $\gamma_h^*(X) = \gamma_h(X)$ . Therefore, the right hand in Theorem 1.8 is at most  $(2 + 4/e)\gamma_h^*(X)$  in the worst-case. In most interesting cases however, one would expect  $\gamma_h(X)$  to be far from the trivial lower bound, in which case one can think of the right hand side as  $(2 + o(1))\gamma_h^*(X)$ .

We are now ready to give the final simplified form of the dual whose value will most directly relate to the value of packing trees: we define the *simplified dual* by

$$\delta_h(X) := \max_{\nu} \min_{x \in X, \nu(x) > 0} \int_0^\infty h(\nu(B(x, r))) dr. \quad (1.24)$$

Note that we restrict to the minimum of the points supported by  $\nu$ . These will correspond to the potential leaf nodes in the packing tree. Furthermore, the minimum in (1.24) is in direct analogy to the minimum cost of a path down a packing tree.

Trivially, since we replaced the average by a minimum, we have that  $\delta_h^{\text{Ent}}(X) \geq \delta_h(X)$ . We show that the reverse direction also holds up to additive error. For a probability measure  $\nu$  on  $X$  and for any subset  $S \subseteq X$ , satisfying  $\nu(S) > 0$ , define  $\nu_S$  by

$$\nu_S(A) := \nu_S(A \cap S)/\nu(S), \forall A \subseteq X, \quad (1.25)$$

i.e.,  $\nu_S$  is the conditional probability measure induced by  $\nu$  on  $S$ . The following lemma shows that one can easily convert a measure  $\nu$  with large  $\delta_h^{\text{Ent}}$  value to one with large  $\delta_h$  value via conditioning.

► **Lemma 1.9.** *For any probability measure  $\nu$  on  $X$ , there exists  $S \subseteq \{x \in X : \nu(x) > 0\}$  such that*

$$\int_X \int_0^\infty h(\nu(B(x, r))) dr \leq \min_{x \in S} \int_0^\infty h(\nu_S(B(x, r))) dr + \mathbf{D}(X).$$

Furthermore,  $S$  can be computed using at most  $O(n^3)$  arithmetic operations and evaluations of  $h$ .

The algorithm achieving the above is in fact very simple: we start with  $S = \{x \in X : \nu(x) > 0\}$ , and iteratively kick out the element  $x \in S$  with lowest value as long as the above inequality is not met.

Combining Corollary 1.8 and Lemma 1.9, we obtain the following relations between the dual program  $\gamma_h^*(X)$  and the simplified dual  $\delta_h(X)$ .

► **Theorem 1.10.**

$$\gamma_h^*(X) - \mathbf{D}(X) \leq \delta_h(X) \leq 2\gamma_h^*(X) + \mathbf{D}(X)/e.$$

Furthermore, given any probability measure  $\nu$  on  $X$ , one can compute  $S \subseteq \{x \in X : \nu(x) > 0\}$  satisfying

$$\int_X \int_0^\infty h(\nu(B(x, r))) dr d\nu(x) \leq \min_{x \in S} \int_0^\infty h(\nu_S(B(x, r))) dr + \mathbf{D}(X),$$

using at most  $O(n^3)$  arithmetic operations and evaluations of  $g$ .

We are in fact not the first to examine the  $\delta_h^{\text{Ent}}(X)$  and  $\delta_h(X)$  programs. The analysis of solutions to  $\delta_2^{\text{Ent}}(X)$  (i.e.,  $h = g$ ) in fact already goes back all the way to Fernique [5]. Starting from a Gaussian process  $(Z_x)_{x \in X}$ , Fernique examined the measure  $\nu$  on  $X$  satisfying  $\nu(u) = \mathbb{P}[Z_u = \max_{x \in X} Z_x]$ ,  $\forall u \in X$ , where we assume  $X$  is finite and that the maximum is uniquely attained with probability 1. For this “argmax” measure  $\nu$ , it was shown that

$$\mathbb{E} \left[ \sup_{x \in X} Z_x \right] \asymp \int_X \int_0^\infty g(\nu(B(x, r))) dr d\nu(x),$$

where the inequalities  $\lesssim$  and  $\gtrsim$  were proven by Fernique [5] and Talagrand [17] respectively.

The relationship between  $\gamma_h(X)$  and  $\delta_h(X)$  was also already studied by Naor and Mendel [11] as well as Bednorz [2]. In particular, for any continuous  $h$  satisfying  $\lim_{x \rightarrow 0^+} h(x) = \infty$  (i.e., not necessarily of log-concave type), [11, 2] showed that  $\gamma_h(X) \leq \delta_h(X)$ . This was proved using Brouwer’s fixed-point theorem, which was used to find a measure  $\mu$  where the quantities  $\int_0^\infty h(\mu(B(x, r))) dr$  are equal for all  $x \in X$ . Recalling that  $\gamma_h(X) = \gamma_h^*(X)$ , this bound is stronger than  $\gamma_h^*(X) - \mathbf{D}(X) \leq \delta_h(X)$  in Theorem 1.10. However, we do not require  $\lim_{x \rightarrow 0^+} h(x) = \infty$  (e.g.,  $h(x) = 1 - x$  is valid for us), which is crucially used to prove the existence of the above Brouwer measure. Mendel and Naor [11] further prove that  $\delta_h(X) \lesssim \gamma_h(X)$ , for any decreasing  $h$  satisfying  $h(x^2) \lesssim h(x)$ . This is achieved by rounding any dual measure  $\nu$  to what they call an *ultrametric skeleton*, which one can interpret as a very sophisticated analogue of a packing tree which is agnostic to  $h$ . These skeletons are also used to derive optimal bounds for the largest subset of a metric space embeddable into  $\ell_2$  with small distortion (known as a non-linear Dvoretzky theorem). [11] asked whether one can improve their bound to  $\delta_h(X) \leq (2 + o(1))\gamma_h(X)$ , where the factor of 2 is tight up to  $o(1)$  factors for an  $n$ -point star-metric with  $h = g$ . Up to the additive constant (which is often  $o(1)$  compared to  $\gamma_h(X)$ ) and the restriction that  $h$  be of log-concave type, Theorem 1.10 resolves their question in the affirmative.

### 1.2.3 Rounding Measures to Trees

Towards proving our main theorem (Theorem 1.6), we show how to round a measure  $\rho$  to chaining and packing trees with values approximately  $\gamma_h(\rho, X)$  and  $\delta_h(\rho, X)$  respectively. As remarked before, the primal rounding strategy was already introduced by Talagrand [21] himself. While the algorithm is simple, it is based on a not terribly intuitive variant of ball partitioning, which is perhaps due to the structure of the object he converts to (an admissible sequence). In the present work, we show that Talagrand’s basic greedy ball partitioning scheme with the functional replaced by a measure, very transparently yields a construction of good chaining trees. The greedy ball partition algorithm iteratively selects centers that maximize the measure of balls of a smaller radius and removes a ball of a larger radius centered at the previously chosen points. One does this until the removed pieces form a partition and then proceeds recursively on those pieces. Here we show that this can be implemented in near linear time in the input size which is  $O(n^2)$  for an  $n$ -point metric space.

► **Theorem 1.11.** *There exists a deterministic algorithm that runs in  $O(n^2 \log n)$  time and given a probability measure  $\rho$  on an  $n$ -point metric space  $X$ , finds a chaining tree  $\mathcal{C}$  such that  $\text{val}_h(\mathcal{C}) \lesssim \gamma_h(\rho, X)$ .*

On the dual side, as far as we are aware there were no rounding strategies to compute packing trees starting from a measure  $\rho$ . The previous approaches for rounding [17, 10, 3] were based on defining a functional that satisfies the previously mentioned “super-chaining” inequality and used a greedy partitioning procedure based on the value of this functional.

This analysis was rather delicate and somewhat mysterious. Moreover, the corresponding functionals in these instances were themselves solutions to optimization problem on the metric space, so implementing this strategy deterministically was rather slow. In fact, Ding, Lee and Peres [3] showed that using a carefully constructed dynamic program, one can implement the above strategy and compute a packing tree in polynomial time in the input size when the metric space is given as the input. Although, they don't specify a precise bound on the running time, one can directly infer a  $O(n^4)$  deterministic running time for building a packing tree; with an additional observation, this can in fact be improved to a  $O(n^3 \log n)$  bound.<sup>2</sup>

In this work, we revisit the above approach and show that in fact, one can round a probability measure  $\rho$  on the metric space to a packing tree with approximately the same value as  $\delta_h(\rho, X)$ . This has certain advantages over a rounding strategy using functionals as it can be implemented in near linear time in the input size. Moreover, this rounding algorithm is quite similar to the primal rounding algorithm and in our opinion clarifies why such a construction works. In particular, the basic strategy of choosing centers that maximize the measure of a smaller ball remains exactly the same – one just selects smaller balls to add as children and recurses on them instead, followed by some post-processing.

► **Theorem 1.12.** *There exists a deterministic algorithm that runs in  $O(n^2 \log n)$  time and given a probability measure  $\rho$  on an  $n$ -point metric space  $X$ , finds a  $(1/10)$ -packing tree  $\mathcal{T}$  such that  $\delta_h(\rho, X) \lesssim \text{val}_h(\mathcal{T})$ .*

### 1.2.4 Proof of the Combinatorial Min-Max Theorem (Theorem 1.6)

Of course, without a way to compute measures which have almost optimal values for  $\gamma_h(\rho, X)$  and  $\delta_h(\rho, X)$ , the above rounding algorithms would not have been very useful. Fortunately, we can obtain almost optimal primal and dual measures  $\mu$  and  $\nu$  by solving the saddle point formulation (1.20) of  $\gamma_h(X)$ . Plugging the measure  $\mu$  in Theorem 1.11 gives us a chaining tree  $\mathcal{C}^*$  such that  $\text{val}_h(\mathcal{C}^*) \lesssim \gamma(\mu, X) \asymp \gamma_h(X)$ .

On the dual side, the measure  $\nu$  is not enough as it might not be a good solution to the approximate dual  $\delta_h(X)$ . However, using Theorem 1.10, one can find a set  $S \subset X$  such that the probability measure  $\nu_S$  obtained by conditioning  $\nu$  on the set  $S$  satisfies  $\delta_h(\nu_S, X) \asymp \gamma_h(X)$ . Plugging the measure  $\nu_S$  in Theorem 1.12, gives us a packing tree  $\mathcal{T}^*$  satisfying  $\delta_h(\nu_S, X) \lesssim \text{val}_h(\mathcal{T}^*)$ . Combining the two yields that

$$\text{val}_h(\mathcal{C}^*) \lesssim \gamma_h(X) \asymp \delta_h(\nu_S, X) \lesssim \text{val}_h(\mathcal{T}^*). \quad (1.26)$$

Recall that the weak duality relation (1.19) between chaining and packing trees implies the reverse inequality for  $\text{val}_h(\mathcal{T}) \lesssim \text{val}_h(\mathcal{C})$  for any chaining tree  $\mathcal{C}$  and any packing tree  $\mathcal{T}$ . Thus, (1.26) gives us the combinatorial min-max statement given by Theorem 1.6. Moreover, this can be made algorithmic by solving the saddle point formulation and using the algorithm to find the set  $S$  given by Theorem 1.10. The details for solving the saddle point formulation are given in the appendix of the full version of this paper and the algorithm to find the set  $S$  is presented in the proof of Theorem 1.10.

<sup>2</sup> Their running time is  $O(n^2)$  times the number of “distance scales” in the metric, meaning the number of dyadic intervals  $[2^k, 2^{k+1})$  containing at least one distance  $d(u, v)$  in the metric. To bound the number of distance scales by  $O(n \log n)$ , compute a minimum spanning tree  $T$  in the complete graph describing the metric. Consider any edge  $e = \{v, w\}$  not in the tree, and let  $m(v, w)$  denote an edge on the path between  $v$  and  $w$  in  $T$  of maximum length. Then  $e$  has length at least the length of  $m(v, w)$  since  $T$  is an MST, but not more than  $n$  times larger. That is, the distance scale of  $e$  is in a range of size  $O(\log n)$  of the distance scale of  $m(v, w)$ . Now consider assigning each non-tree edge  $\{v, w\}$  to  $m(v, w)$ ; there are  $O(\log n)$  distance scales assigned to each tree edge, so  $O(n \log n)$  in total.

### 1.3 Organization

In Section 2, we list some basic notation as well as the main useful properties of chaining functionals of log-concave type. In Section 3, we simplify the dual program  $\gamma_h^*(X)$ , proving the main inequalities relating it to the entropic and simplified duals  $\delta_h^{\text{Ent}}(X)$  and  $\delta_h(X)$  respectively. Other details including near-linear time rounding algorithms from measures to chaining trees and packing trees, deterministic construction of Johnson-Lindenstrauss projections achieving Gordon's bound, using a black-box solver to compute nearly-optimal primal and dual measures for the saddle-point formulation of  $\gamma_h(X)$ , and proofs of other technical statements can be found in the full version of this paper.

## 2 Preliminaries

**Notation.** Throughout this paper,  $\log$  denotes the natural logarithm unless the base is explicitly mentioned. We use  $[k]$  to denote the set  $\{1, 2, \dots, k\}$ . For a vector  $z \in \mathbb{R}^n$ , we will use  $z_i$  or  $z(i)$  interchangeably to denote the  $i$ -th coordinate of  $z$ . Given a probability measure  $\mu$  over a set  $X$ , we use  $\mathbb{E}_{x \sim \mu}[f(x)]$  to denote the expectation of  $f(x)$  where  $x$  is sampled from  $\mu$ .

### 2.1 Properties of Chaining Functionals

Recall that we work with a chaining functional  $h : (0, 1] \rightarrow \mathbb{R}_+$  defined by  $h(p) = F^{-1}(p)$ , where  $F(s) = \int_s^\infty f(x)dx$  and where  $f$  is non-decreasing and continuous probability density on  $\mathbb{R}_+$ . We assume throughout the rest of the paper that  $h$  is of log-concave type, i.e., that  $f$  is log-concave.

The fundamental property of such functionals, that we make extensive use of, is the following:

► **Proposition 2.1.** *For a chaining functional  $h$  of log-concave type,*

$$h(ab) \leq h(a) + h(b) \text{ for } a, b \in (0, 1].$$

Before giving a proof, we note that the above property appears in [10] as the base assumption for the chaining functionals they consider. The above shows that this condition is very natural and applies to a wide variety of functionals.

**Proof.** Let us define  $\varphi : [0, \infty) \rightarrow [0, \infty)$  as  $\varphi(t) := h(e^{-t})$ . We will show that  $\varphi$  is concave on its domain, which implies that  $h$  is sub-additive as

$$h(ab) = \varphi\left(\log \frac{1}{ab}\right) \leq \frac{1}{2}\varphi\left(2\log \frac{1}{a}\right) + \frac{1}{2}\varphi\left(2\log \frac{1}{b}\right) \leq \varphi\left(\log \frac{1}{a}\right) + \varphi\left(\log \frac{1}{b}\right) = h(a) + h(b),$$

where both inequalities follow from concavity and  $\varphi(0) = 0$ .

To see that  $\varphi$  is concave, we show that  $\varphi'(t) = -e^{-t}h'(e^{-t}) = \frac{e^{-t}}{f(F^{-1}(e^{-t}))}$  is a decreasing function of  $t$ . Substituting  $x = F^{-1}(e^{-t})$ , and noting that  $f$  is decreasing, it suffices to show that  $\frac{F(x)}{f(x)}$  is decreasing for  $x$  on the positive real line. Taking arbitrary  $0 \leq x_1 \leq x_2$ , we have that

$$\frac{F(x_1)}{f(x_1)} = \int_0^\infty \frac{f(x_1+t)}{f(x_1)} dt \geq \int_0^\infty \frac{f(x_2+t)}{f(x_2)} dt = \frac{F(x_2)}{f(x_2)},$$

where the inequality follows from the following elementary property of non-negative log-concave functions: for any four points  $a \leq b \leq c \leq d$ , we have that  $f(b)f(c) \geq f(a)f(d)$  which in the above scenario implies that  $\frac{f(x_1+t)}{f(x_1)} \geq \frac{f(x_2+t)}{f(x_2)}$ . This completes the proof of the proposition. ◀

When working on a metric space  $(X, d)$  with a chaining functional  $h$ , we observe the following rescaling symmetry: for any constant  $\beta > 0$ , if we replace  $h$  by  $\beta h$  (equivalently, the density function  $f$  is replaced by  $z \rightarrow \beta f(\beta z)$ ) and  $d(u, v)$  by  $d(u, v)/\beta$  for all  $u, v \in X$ , the values of the various quantities we consider remain unaffected. In particular, if we have an underlying process  $(Z_x)_{x \in X}$  amenable to  $X$  and  $f$  as in (1.10), the condition  $\mathbb{P}[|Z_{x_1} - Z_{x_2}| \geq d(x_1, x_2)s] \leq F(s)$  is identical for both scalings, and the values of the various programs and trees we consider remain unchanged.

So from now on, we make the convenient choice that  $f(0) = 1$ . This implies that the (left) derivative  $h'(1) = -1/f(0) = -1$ . We maintain this normalization for the remainder of the paper.

Given this normalization, the following useful bound is easy to show.

► **Proposition 2.2.** *For every  $a \in (0, 1]$ , we have that*

$$-1 \leq ah'(a) \leq 0 \text{ and } h(a) \leq \log(1/a).$$

**Proof.** As  $h$  is decreasing,  $h'(a) \leq 0$  for  $a \in (0, 1]$ . Therefore, for any  $a$ ,

$$\begin{aligned} ah'(a) &= \lim_{\epsilon \rightarrow 0^+} \frac{a(h(a) - h(a(1 - \epsilon)))}{a - a(1 - \epsilon)} \geq \lim_{\epsilon \rightarrow 0^+} \frac{h(a) - h(a) - h(1 - \epsilon)}{1 - (1 - \epsilon)} \\ &= \lim_{\epsilon \rightarrow 0^+} \frac{h(1) - h(1 - \epsilon)}{1 - (1 - \epsilon)} = h'(1) = -1, \end{aligned} \quad (2.1)$$

where the first inequality follows from sub-multiplicativity and the last equality holds since  $h(1) = 0$ . The first statement in the proposition follows.

To see the second statement, one can observe that as  $h$  is decreasing, (2.1) implies the following differential inequality:  $h'(a) \geq -\frac{1}{a}$  for every  $a \in (0, 1]$ . Together with the boundary condition that  $h(1) = 0$ , this implies that  $h(a) \leq \log(1/a)$ . ◀

### 3 Dual simplifications

In this section, we provide the main arguments that allow for rounding a solution to  $\gamma_h^*(X)$  to a solution to the simplified dual, via the entropic dual, as described in Section 1.2.2.

**Proof of Lemma 1.7.** Our goal is to prove that taking  $\mu = \nu$  in (1.22) does not cause too much error. We will prove this on a “per scale” basis:

► **Lemma 3.1.** *For any probability measures  $\mu$  and  $\nu$  on  $X$ , and any  $r > 0$ , we have*

$$\int_X h(\nu(B(x, 2r))d\nu(x) \leq \int_X h(\mu(B(x, r)))d\nu(x) + 1/e.$$

Lemma 1.7 follows easily from this:

$$\begin{aligned} \int_X \int_0^\infty h(\nu(B(x, r)))drd\nu(x) &\leq \min_\mu \int_X \int_0^{\mathbf{D}(X)} (h(\mu(B(x, r/2))) + 1/e)drd\nu(x) \\ &\leq 2 \min_\mu \int_X \int_0^\infty h(\mu(B(x, r)))drd\nu(x) + \mathbf{D}(X)/e. \end{aligned}$$

**Proof of Lemma 3.1.** We first recast the statement in graph theoretic terms. Let us define a bipartite graph on the vertex set  $X_1 \cup X_2$  where each  $X_i$  for  $i \in [2]$  is a copy of the index set  $X$ . We add an edge between two vertices  $x_1 \in X_1, x_2 \in X_2$  if  $d(x_1, x_2) \leq r$  – note that

every vertex has an edge incident to it. Define the weight of a vertex  $x \in X_i$  as  $\mu(x)$  and the weight of a vertex  $x \in X_2$  as  $\nu(x)$ . Let  $E$  denote the set of edges in the graph, let  $N(S)$  be the neighbors of a subset of the vertices  $S \subset X_1 \cup X_2$  and let  $N^2(S) = N(N(S))$ . For brevity, we will write  $N(x)$  instead of  $N(\{x\})$  for singleton sets.

With this setup, the statement we want to prove is

$$\sum_{x \in X_2} \nu(x) h(\nu(N^2(x))) \leq \sum_{x \in X_2} \nu(x) h(\mu(N(x))) + 1/e. \quad (3.1)$$

To prove the above, we will use the following structural result which is a consequence of the theory of principal sequences of matroids [6], applied to transversal matroids; we include a self-contained proof in the full version of the paper.

► **Proposition 3.2.** *There exist sequences  $\emptyset = S_0 \subset S_1 \subset \dots \subset S_k = X_1$  and  $0 < \beta_1 < \beta_2 < \dots < \beta_k$ , such that*

1.  $\beta_i \mu(S_i \setminus S_{i-1}) = \nu(N(S_i) \setminus N(S_{i-1}))$  for all  $i \in [k]$ .
2. For all  $i \in [k]$  and  $A \subseteq X_1 \setminus S_{i-1}$ , we have that  $\beta_i \mu(A) \leq \nu(N(A) \setminus N(S_{i-1}))$ .

The proposition above can be viewed as a kind of strengthening of Hall's theorem. For instance, if there is a fractional perfect matching between  $\mu$  and  $\nu$ , i.e., a way of transporting mass distributed according to  $\mu$  on  $X_1$  along edges of the graph to yield precisely the distribution  $\nu$  on  $X_2$ , then the claim will be satisfied with  $k = 1$ ,  $S_1 = X_1$  and  $\beta_1 = 1$ , for in this case,  $\mu(A) \leq \nu(N(A))$  for any  $A \subseteq X_1$  (essentially the easy direction of Hall's theorem). If there is no fractional perfect matching, Hall's theorem implies the existence of a set  $S \subset X_1$  with  $\nu(N(S)) < \mu(S)$ . In the proposition,  $S_1$  is the “least matchable” set: only a  $\beta_1$  fraction of the mass in  $S_1$  can be transported to  $N(S_1)$ . The full sequence is then obtained by removing  $S_1$  and  $N(S_1)$  and repeating on the remainder.

Taking the sequences guaranteed by the proposition, define  $\tilde{\beta}_i := \min\{\beta_i, 1\}$ .

We split the left hand side of (3.1) as follows:

$$\sum_{x \in X_2} \nu(x) h(\nu(N^2(x))) = \sum_{i=1}^k \sum_{x \in N(S_i) \setminus N(S_{i-1})} \nu(x) h(\nu(N^2(x))).$$

Note that for any  $i \in [k]$ , if  $x \in X_2 \setminus N(S_{i-1})$ , then  $N(x) \subseteq X_1 \setminus S_{i-1}$ , and hence, Proposition 3.2 implies that  $\tilde{\beta}_i \mu(N(x)) \leq \nu(N^2(x))$ . Furthermore, using sub-multiplicativity of  $h$  and Proposition 2.2, we find that for any  $i \in [k]$  and  $x \in N(S_i) \setminus N(S_{i-1})$ ,

$$\begin{aligned} h(\nu(N^2(x))) &= h\left(\mu(N(x)) \cdot \frac{\nu(N^2(x))}{\mu(N(x))}\right) \leq h(\mu(N(x))) + h\left(\min\left\{1, \frac{\nu(N^2(x))}{\mu(N(x))}\right\}\right) \\ &\leq h(\mu(N(x))) + h(\tilde{\beta}_i) \leq h(\mu(N(x))) + \log\left(\frac{1}{\tilde{\beta}_i}\right). \end{aligned}$$

For the first inequality above, sub-multiplicativity is used when  $\frac{\nu(N^2(x))}{\mu(N(x))} > 1$ ; otherwise, the inequality follows because  $h$  is decreasing and  $h(1) = 0$ . (The first inequality does still hold if  $\mu(N(x)) = 0$ , taking the minimum in the second term to have value 1 in this case, again because  $h$  is decreasing.)

The second inequality again uses that  $h$  is decreasing, as well as that  $\tilde{\beta}_i \leq 1$  for every  $i \in [k]$ ; and the final inequality uses Proposition 2.2.

### 73:18 Majorizing Measures for the Optimizer

Let  $\ell$  be maximal such that  $\tilde{\beta}_\ell < 1$ ; so  $\beta_i = \tilde{\beta}_i$  for  $i \leq \ell$ . Summing the last inequality over all  $i \in [k]$  and  $x \in N(S_i) \setminus N(S_{i-1})$ , we obtain

$$\begin{aligned} \sum_{x \in X_2} \nu(x) h(\nu(N^2(x))) &\leq \sum_{x \in X_2} \nu(x) h(\mu(N(x))) + \sum_{i=1}^k \nu(N(S_i) \setminus N(S_{i-1})) \cdot \log \left( \frac{1}{\tilde{\beta}_i} \right) \\ &= \sum_{x \in X_2} \nu(x) h(\mu(N(x))) + \sum_{i=1}^{\ell} \tilde{\beta}_i \mu(S_i \setminus S_{i-1}) \cdot \log \left( \frac{1}{\tilde{\beta}_i} \right) \\ &\leq \sum_{x \in X_2} \nu(x) h(\mu(N(x))) + \left( \max_{\beta \in (0,1]} \beta \log \left( \frac{1}{\beta} \right) \right) \sum_{i=1}^{\ell} \mu(S_i \setminus S_{i-1}), \end{aligned}$$

where the second line follows from Proposition 3.2. From this (3.1) readily follows as  $\sum_{i=1}^{\ell} \mu(S_i \setminus S_{i-1}) \leq \sum_{i=1}^k \mu(S_i \setminus S_{i-1}) = \mu(X_1) = 1$  and  $\max_{\beta \in (0,1]} \beta \log \left( \frac{1}{\beta} \right) = 1/e$ .  $\blacktriangleleft$

**Proof of Lemma 1.9.** For convenience, define

$$H(\mu, t) := \int_0^\infty h(\mu(B(t, r))) dr \quad \text{and} \quad H(\mu, \nu) := \int_X H(\mu, t) d\nu(t).$$

Start by setting  $S = \{x \in X : \nu(x) > 0\}$ . Consider the following greedy algorithm:

As long as  $H(\nu_S, \nu_S) > \min_{x \in S} H(\nu_S, x) + \mathbf{D}(X)$ , choose  $s \in S$  so that  $H(\nu_S, s)$  is minimized, and remove  $s$  from  $S$ .

Note that  $H(\nu_S, \nu_S) \leq \min_{x \in S} H(\nu_S, x) + \mathbf{D}(X)$  when this terminates, since it is vacuous for  $S = \emptyset$ .

We will now show that  $H(\nu_S, \nu_S)$  can only increase during the progression of the algorithm. This suffices to prove the lemma, since then upon termination

$$H(\nu, \nu) \leq H(\nu_S, \nu_S) \leq \min_{x \in S} H(\nu_S, x) + \mathbf{D}(X).$$

So, consider a moment in the algorithm where  $s \in S$  is about to be removed from  $S$ , yielding  $S' := S \setminus \{s\}$ . From our choice of  $s$ ,

$$H(\nu_S, \nu_S) > H(\nu_S, s) + \mathbf{D}(X). \quad (3.2)$$

Let  $\alpha = 1/(1 - \nu_S(s))$ ; so  $\nu_{S'}(t) = \alpha \nu_S(t)$  for  $t \neq s$ , and  $\nu_{S'}(s) = 0$ . Thus

$\triangleright$  **Claim 3.3.** For every  $t \in X$ ,

$$H(\nu_{S'}, t) \geq H(\nu_S, t) - \mathbf{D}(X) \cdot (\alpha - 1).$$

**Proof.** Recall that  $h$  is convex and satisfies  $-1 \leq ah'(a) \leq 0$  for any  $a \in (0, 1]$  by Proposition 2.2. Thus for any  $z \in (0, 1]$ ,

$$\begin{aligned} h(z) &\geq h(z/\alpha) + z(1 - 1/\alpha)h'(z/\alpha) \\ &= h(z/\alpha) - (\alpha - 1) \left| (z/\alpha)h'(z/\alpha) \right| \geq h(z/\alpha) - (\alpha - 1). \end{aligned} \quad (3.3)$$

Now notice that for any  $T \subseteq S$ , we have that  $\nu_S(T) \geq \nu_{S'}(T)/\alpha$ . Therefore, since  $h$  is decreasing,

$$\begin{aligned} H(\nu_S, t) &= \int_0^{\mathbf{D}(X)} h(\nu_S(B(t, r))) dr \\ &\leq \int_0^{\mathbf{D}(X)} h(\nu_{S'}(B(t, r))/\alpha) dr \\ &\leq \int_0^{\mathbf{D}(X)} h(\nu_{S'}(B(t, r))) dr + \mathbf{D}(X) \cdot (\alpha - 1) = H(\nu_{S'}, t) + \mathbf{D}(X) \cdot (\alpha - 1), \end{aligned}$$

where the last inequality follows from (3.3).  $\triangleleft$

We can now compare  $H(\nu_{S'}, \nu_{S'})$  with  $H(\nu_S, \nu_S)$ :

$$\begin{aligned} H(\nu_{S'}, \nu_{S'}) &\geq H(\nu_S, \nu_{S'}) - \mathbf{D}(X) \cdot (\alpha - 1) && \text{(by Claim 3.3)} \\ &= \frac{1}{1-\nu_S(s)} (H(\nu_S, \nu_S) - \nu_S(s)H(\nu_S, s)) - \frac{\nu_S(s)}{1-\nu_S(s)} \cdot \mathbf{D}(X) \\ &\geq \frac{1}{1-\nu_S(s)} (H(\nu_S, \nu_S) - \nu_S(s)(H(\nu_S, \nu_S) - \mathbf{D}(X))) - \frac{\nu_S(s)}{1-\nu_S(s)} \cdot \mathbf{D}(X) && \text{(by (3.2))} \\ &= H(\nu_S, \nu_S), \end{aligned}$$

which finishes the proof of Lemma 1.9.

**Runtime Analysis.** It is easily seen that the algorithm can be implemented in  $O(n^3)$  time. First, by pre-processing the input, we may assume that the pairs of points are sorted by their pairwise distances – this only adds an additional overhead of  $O(n^2 \log n)$ . Then, as in each iteration we remove one element, there are  $O(n)$  iterations to compute the final set  $S'$ . Furthermore, in each of these iterations, we are required to compute a minimizer  $s$  of  $H(\nu_S, x)$ . This takes  $O(n^2)$  time since for each  $x \in S$ , one can compute the measure of all possible balls  $B(x, r)$  in  $O(n)$  time using a straightforward dynamic program.

## Abstract

We study the outcome in a matching market where both sides have limited ability to consider options. For example, in the national residency matching program, doctors are limited to apply to a small set of hospitals, and hospitals are limited by the time required to interview candidates.

Our main findings are the following: (1) In markets where jobs can only consider a limited number of candidates for interview, it increases the size of the resulting matching if the system has a limit on the number of applications a candidate can send. (2) The fair system of all applicants being allowed to apply to the exact same number of positions maximizes the expected size of the matching. More particularly, starting from an integer  $k$  as the number of applications, the matching size decreases as a few applicants are allowed to apply to one additional position (and then increases again as they are all allowed to apply to  $k + 1$ ). Although it seems natural to expect that the size of the matching would be a monotone increasing and concave function in the number of applications, our results show that neither is true. These results hold even in a market where a-priori all jobs and all candidates are equally likely to be good, and the judgments of different employers and candidates are independent.

Our main technical contribution is computing the expected size of the matching found via the deferred acceptance algorithm as a function of the number of interviews and applications in a market where preferences are uniform and independent. Through simulations we confirm that these findings extend to markets where rankings become correlated after the interviews.

## 1 Introduction

Matching is a fundamental paradigm in a variety of real-world situations and arises in various domains, e.g., students applying to attend schools, or colleges, applicants get matched with jobs at various job markets, and medical residents get matched with hospitals, just to name a few. In some of these domains, matchings are found through a centralized algorithm such as the deferred acceptance algorithm by Gale and Shapley [5]. Prominent examples include: national residency matching program (NRMP) for assigning medical students to hospital residency programs; schools assignments in some cities the US; and college admissions in

some countries [10]. Although the deferred acceptance algorithm is designed for centralized markets, it can also be thought of as a rough model of how uncoordinated matching markets as applicants collect offers and as they turn down offers, new offers may be made.

An important aspect that is not modeled under the classical deferred acceptance algorithm is the fact that both sides of the market can only consider a limited set of options. This is the issue we will focus on in the current paper. The deferred acceptance algorithm is typically studied assuming that participants express their full list of ordered preferences. However, typically both sides of the match are limited in the number of options they can consider. In some markets, such as the national residency matching program, there are application limits imposed by the system. But even without such explicit limits, preparing applications and interviewing applicants is costly and time consuming; and hence typically extremely limited. Applications, e.g. for college admission, often require writing specialized essays. Residency programs, as well as some of the colleges, and almost all jobs, interview their applicants, which requires significant time and effort. In large matching markets it is not feasible for either side to consider a large set. For instance, in NRMP, there are nearly 5000 residency programs and applicants have to limit their choices. Similarly, interviewing consumes significant time of the hospitals, and so hospitals can only grant interviews to a limited set of doctors. An alternative view of the limitations of the employer side is a limit on the offers they can make for one position: based on their interviews with all or a subset of the applicants, they may consider only a limited number of their favorite applicants. Such selective offer making is observed in the academic job markets, e.g., when some high ranked departments prefer to wait till next year, rather than make offers to applicants they liked less.

The goal of this paper is to study the effect of the number of applications and the number of interviews on the resulting matching. We think of our procedure as a simplified version of the matching process of the national residency matching program. In this program, the matching mechanism has two stages. In the first stage, doctors express their interest to a set of hospitals, and hospitals choose to interview a subset of the applicants. In the second stage, both doctors and hospitals submit their ordered preference list over the set they interviewed with. The centralized matching market uses these preference lists to perform the deferred acceptance algorithm and outputs the final matching.

We will primarily consider a *symmetric* market, where doctors and hospitals are similar in terms of popularity, and as a primary metric of the social welfare of the system, we will mainly consider the size of the matching found. In asymmetric markets, where some applicants and some jobs are a-priori better and preferred by most applicants, the limit on the number of choices gives rise to strategic issues resulting in top candidates getting too many offers, and a number of jobs remaining unfilled – see the discussion in related literature section. In this paper we isolate the effect of limitation from strategicness. We focus on large symmetric markets, where it will be equilibrium for both sides to report their true preferences. We find a number of surprising effects of this limited choice, resulting in two policy recommendations.

- With limited ability granting interviews, social welfare may be maximized by also severely limiting the number of applications one applicant can send.
- The best social welfare is achieved by a fair system, where all applicants can send the same number of applications. Allowing a small subset to send even just one additional application decreases the overall welfare of the system.

## 1.1 Main Results

The main contribution of the paper is studying the effect of limitation on the number of applications and interviews in matching markets. In contrast to the majority of the previous work that focused on correlated preferences, we completely abstract away the role of correlation, consider a purely random model, and study the role of randomness extensively. The main results of the paper are as following.

- We compute the expected size of matching resulted from the deferred acceptance algorithm as a function of the limit on the number of applications and interviews. See Proposition 6, Theorem 10, and Proposition 20.
- We find the optimal way for distributing the applications among applicants, when the total number of allowed applications is fixed. The maximum size of matching is achieved when all doctors apply to the same number of positions or two consecutive integers. See Proposition 11.
- With a fixed number of interviews per position, the size of the matching as a function of the number of applications is a scallop-shape figure (see Figures 2 to 5), where the function between consecutive integers is U-shaped.

### Contribution to Balls in Bins Literature

Numerous findings in the matching literature utilize the results and techniques from *balls in bins* problems. Although this paper is written in the matching language, it has analogues in balls in bins language and contributes to that literature as well. For example consider the following problem: There is a set of  $n$  balls and  $n$  bins. Each ball  $d$  has  $k_d$  copies. Each bin has capacity one. All copies of the balls are thrown independently and uniformly at random to the bins. Each bin only accepts one ball at random among those that have been thrown to it. We are interested in  $S$  which is the expected number of unique balls (counting only a single copy from each ball) that land in bins. Various questions can be asked in this scenario. For example, what is the optimal value of  $S$ ? What distribution for  $k_d$  achieves this value? Section 3, which is a warm-up for our main result, completely analyses this problem and surprisingly shows the optimal value of  $S$  is  $\approx 0.68$  for large enough  $n$  and it is achieved when there are 3 copies from each ball,  $k_d = 3$ .

## 1.2 Related Work

Papers studying matching with short lists have different viewpoints on how the short lists are selected. For example, Immorlica and Mahdian [6], Kojima and Pathak [8], and Arnosti [1] study matchings when preference lists are inherently short, i.e. the participants prefer to stay unmatched rather than being matched outside their preference lists. In contrast, Avery and Levin [2], Kadam [7], Drummond et al. [4], and Beyhaghi et al. [3] study how applicants make the strategic choice to select a limited number of positions for their short preference lists. In this paper, because of the uniform preference of participants we do not focus on their strategic behavior.

Arnosti [1], Lee and Schwarz [9], and Kadam [7] study efficiency of matching either as matching size or social welfare in presence of short lists. Arnosti evaluates social welfare under different preference models. However, unlike our paper, in [1] the preference lists are limited only for one side of the market. Similar to us, Lee and Schwarz study matching size in a setting with an interview stage, where the ex-ante preferences are i.i.d. However, they solve the problem of some doctors not receiving any offer while others receive many, by coordinating the set of doctors that each hospital interviews. In contrast, in this paper, we

assume that the interviews are selected in a decentralized way without imposing coordination; and our solution is to limit the number of applications and let the applicants have the same number of applications. Similar to our work, Kadam studies a model with limit on both sides of the market and shows that limiting the length of lists can have positive effects of the size of matching. However, in [7] these effects are due to almost common preferences: When some doctors are more preferred, with a stricter limit on the interviews for doctors, the more preferred doctors do not accept interviews with less preferred hospitals. In this paper, we show that limiting the length can be helpful in the exactly opposite case where all participants are identical in terms of popularity.

## Roadmap

The rest of the paper is organized as follows. Section 2 discusses the model and preliminaries. In Section 3, as a warm-up we analytically compute the size of the matching when the number of interviews is limited to one. In Section 4, we compute the size of the matching for arbitrary number of interviews. Section 5 discusses two extensions to the main result in Section 4. In Section 5.1, we show that the same phenomena remain true in unbalanced markets (when the two sides are of different size). In Section 5.2, we study a model where the hospitals and doctors preferences are a-priori uniform, but become correlated after interviewing.

## 2 Preliminaries

We explain our model in Section 2.1, and discuss the unlimited interview case in Section 2.2.

### 2.1 Model

There is a finite set of doctors  $\mathcal{D}$  and a finite set of hospitals  $\mathcal{H}$ , with  $|\mathcal{D}| = n$  and  $|\mathcal{H}| = rn$ . We are interested in one-to-one matchings between doctors and hospitals.

#### Description of the Game

We consider a two-stage matching mechanism. In the first stage, each doctor applies to a set of hospitals and requests interviews. Hospitals then choose a subset from their applications to conduct interviews. In the interview process, doctors and hospitals refine their preferences. In the second stage, at the end of interviews, both doctors and hospitals order the list that they interviewed with, based on their preferences. They submit their ordered preferences to the system which performs a doctor-proposing deferred acceptance algorithm to determine the final assignment of doctors to hospitals. The algorithm starts with all doctors unmatched. In each step, the algorithm simulates all unmatched doctors, who have not yet exhausted their options, propose to their most preferred hospital among those to which he/she has not yet proposed. Now the algorithm simulates that each hospital tentatively accepts their most preferred doctor from the doctors now proposing and the one who has been tentatively assigned to this hospital, and rejects all other doctors. The procedure is repeated until all unmatched doctors have been rejected from every hospital in their lists.

We use the following terminology throughout the whole paper.

**Application:** The procedure in the first stage where the doctors submit an application and ask for interview.

**Grant interview or reject for interview:** The procedure in the first stage where the hospitals grant interviews to a number of doctors that have applied for the position and reject the rest.

**Valid application:** Any application that is granted an interview is a valid application. Other applications are *invalid*.

**Proposal:** The procedure in the second stage that simulates doctors proposing to hospitals as steps of the deferred acceptance algorithm.

**Offer:** In the special case where the hospitals limit their number of interviews to one, conducting interviews is of no use because the hospital offers the position to the selected doctor in any case. Therefore, we use offer instead of interview in this case.

### Limits on Applications and Interviews

Each doctor  $d$  is allowed to apply to  $k_d$  positions. In the simpler case, there is a universal limit on the number of applications,  $k_d = k$ , inspired by NRMP granting all doctors 10 initial applications. There is a universal limit  $k'$  on the number of interviews each hospital can conduct.

### Random Preferences

For the most of the paper, we assume that everybody's preference comes independently from uniform distribution over the other side. Both doctors and hospitals refine their preference order for the list they interviewed. However, the overall distribution of doctors preferences and hospitals preferences stays uniform and independent. For analytic purposes we can assume that preferences stay unchanged after the interviews.

► **Observation 1.** *Suppose prior to interviews preferences are drawn independently from uniform distributions, and after interviews, the overall distribution of preferences are uniform and independent. In this case, assuming that the preferences remained unchanged leads to the same analytic results including the same matching size.*

► **Observation 2.** *Being truthful is a Bayes Nash equilibrium.<sup>1</sup> We assume both doctors and hospitals follow this strategy and are truthful during the matching procedure: In the first stage, doctors apply to their favorite hospitals; and hospitals grant interviews to their favorite applicants. In the second stage, both doctors and hospitals submit the list that they interviewed, ordered from the most preferred to the least preferred.*

### Efficiency Measure

We focus on the size of the matching as our notion of efficiency. We define social welfare as the ratio of size of the matching outcome to the size of the maximum matching. Since we assume all doctors/hospitals prefer to be matched to any hospital/doctor rather than being unmatched, in a maximum-size matching everybody on the less populated side of the market is matched.

► **Definition 3 (Social Welfare).** *We define social welfare of the matching outcome as the ratio of the size of the matching outcome compared to the size of the maximum-size matching. In a two sided market, maximum-size matching will be the size of the smaller side of the market.*

---

<sup>1</sup> For more discussion, see the appendix.

## Large Markets

The results consider outcome in “large markets” as introduced in [1]. Formally, a sequence of markets indexed by  $n$  are considered. In this sequence, the number of applications  $k$ , the number of interviews  $k'$ , and the ratio of number of hospitals to doctors  $r$  are held constant. The  $n^{\text{th}}$  market is characterized by a set of doctors  $\mathcal{D}^n$  and a set of hospitals  $\mathcal{H}^n$ . Consider  $n = |\mathcal{D}^n| = |\mathcal{H}^n|/r$ . The results in this paper study the properties of the matching for  $n \rightarrow \infty$ .

## 2.2 No Limit for Granting Interviews

In this section, we recall an analysis from [3] with  $n$  doctors and  $n$  hospitals in the market. In this case there is no limit on the number of interviews by hospitals and doctors are allowed to list only up to  $k$  hospitals, for  $k \ll n$ . When doctors apply to  $k$  hospitals, Proposition 4 finds the probability  $p$  of a single random proposal resulting to a permanent match as  $n$  grows to infinity. The main idea is that in the limit as  $n$  goes to infinity, the probability of a proposal resulting in a match is independent of the previous proposals of the applicant being rejected.

► **Proposition 4** ([1]). *When each doctor applies to  $k$  hospitals, the probability  $p$  of a single random proposal resulting in a permanent match in the deferred acceptance procedure, satisfies the following equation.*

$$(1 - p)^k = e^{-(1-(1-p)^k)/p} \quad (1)$$

**Proof sketch.** Since the outcome of the deferred acceptance algorithm does not depend on the order in which doctors propose, we may hold out a single doctor  $d$  and run the deferred acceptance algorithm on the remainder of the market. Now consider doctor  $d$  proposing to her favorite position. Her first few proposals may get rejected. Once a hospital accepts her proposal, it may reject a different doctor, who may propose for her next position, etc. We call the resulting sequence of rejections a *rejection chain*. The probability that a proposal of doctor  $d$  causes a rejection chain that gets doctor  $d$  rejected from the hospital that first accepted her vanishes as the market grows, therefore we may assume that  $d$ 's first tentatively accepted proposal will lead to a permanent match. Also, in a large market, the rejection of  $d$ 's first  $m$  proposals does not affect the probability of acceptance of other proposals. Thus, from  $d$ 's perspective, each hospital that she applied to in the first stage, should be available to her with some probability  $p$ , and their availability should be independent. With this argument, the probability that  $d$  matches is  $1 - (1 - p)^k$ , and the expected number of hospitals  $d$  proposes to is

$$1 + (1 - p) + (1 - p)^2 + \dots + (1 - p)^{k-1} = \frac{1}{p}(1 - (1 - p)^k).$$

From the point of view of each hospital, each of these proposals is sent to them roughly with probability  $1/n$ ; thus the probability that a hospital receives at least one proposal is

$$1 - (1 - 1/n)^{\frac{1}{p}(1-(1-p)^k)};$$

which approaches  $1 - e^{-(1-(1-p)^k)/p}$  when  $n \rightarrow \infty$ . Since doctors match with probability  $1 - (1 - p)^k$ , and the number of doctors and hospitals that match must be equal, we have that  $(1 - p)^k = e^{-(1-(1-p)^k)/p}$ . ◀

► **Proposition 5.** *Suppose that either all the doctors apply to the same number of hospitals or a fraction of them apply to  $k$  while others apply to  $k + 1$  hospitals. In a setting where there is no limit on the number of interviews by hospitals and the preferences are uniformly random, the social welfare of the matching is increasing in the expected number of applications.*

**Proof.** See the appendix. ◀

### 3 Warm-Up: Single Offer

In this section, we find the efficiency of matching as a function of the expected number of applications by doctors, when hospitals only select one applicant in the first stage of the mechanism. We begin with the case where all doctors apply to the same number of hospitals,  $k_d = k$ , and then we move to the case where doctors send different number of applications. We find allocating the number of applications equally results in the most efficient matching and allowing a small subset to apply to an extra position or restricting a small set to apply to one less position, results in a smaller matching.

In this part we assume that hospitals only select one of their applicants in the first stage of the matching. As discussed in Observation 2, they choose their favorite applicant. Since interviews are conducted to compare the selected doctors, in this case that only one doctor is selected, interviews are of no use from the hospitals' point of view. Therefore the hospital immediately offers the position to the selected doctor. Consequently, the outcome of the deferred acceptance algorithm can be easily found in this case; each doctor will be matched to his/her favorite hospital among those who gave an offer. Therefore without going through the complication of the deferred acceptance algorithm, each doctor accepts the most preferred offer. This discussion implies that the size of matching in this case, is the number of doctors who receive an offer.

#### 3.1 Same Number of Applications

First, we study the social welfare of the matching with respect to the number of applications by doctors, where all doctors apply to the same number of hospitals,  $k$ .

► **Proposition 6.** *Suppose for all  $d$ ,  $k_d = k$  and  $k' = 1$ . The social welfare equals  $1 - (1 - \frac{(1-e^{-k})}{k})^k$ .*

To illustrate some of the main points in the proof of the proposition we start with a simple example in which doctors are allowed to send one application.

► **Example 7.** When  $k = k' = 1$ , the social welfare of the matching approaches  $(1 - 1/e) \approx 0.63$  in a large market. In a matching between hospitals and doctors the size of matching equals the number of matched hospitals. Each hospital that receives an application is matched. The reason is when a hospital accepts a doctor, that doctor does not have any other offers and accepts the match. The probability of a hospital receiving at least one application is  $1 - (1 - 1/n)^n$  which tends to  $1 - 1/e$  with  $n$  approaching  $\infty$ .

Now, we consider the general case of arbitrary  $k$ . The following definition is central to our proof.

► **Definition 8** (covered hospital). *A hospital is covered if it receives at least one application. The number of covered hospitals equals the number of offers.*

**Proof of Proposition 6.** First, we find the expected number of covered hospitals. By Observation 2, doctors apply to their favorite positions. Since doctors preferences are independent, the set of hospitals that a doctor applies to is independent from other doctors. Although a doctor applies to  $k$  different hospitals and these applications are not technically independent, as  $n$  grows large, the dependence between different applications of a doctor becomes negligible tends to 0. In other words, the probability that a fresh random choice of a doctor is identical to a previous choice approaches to 0. Therefore, we assume that different applications of a doctor are independent. The independence among applications of the same doctor and the set of applications of different doctors, implies the  $nk$  hospitals chosen by applications are selected uniformly and independently at random. The probability of a hospital receiving any application is  $\approx 1 - (1 - 1/n)^{nk}$ , which tends to  $(1 - e^{-k})$  in the limit.

Now, we formulate the probability of a doctor being matched. A doctor is matched if one of its applications turns to an offer. The probability of application  $(d, h)$  turning into an offer depends on the number of applications that hospital  $h$  has received. (Each hospital gives offer to one of its applications.) However, doctors have no knowledge about the number applications a hospital receives and to them all hospitals look identical in terms of the number of applications they have. Thus, from a doctor's perspective, each of their applications has the same probability of turning into an offer. Let  $p$  be the probability of an application turning to an offer. The probability of a doctor being matched equals  $1 - (1 - p)^k$ .

So far, we found the probability of a hospital being covered and the probability of a doctor being matched as a function of  $p$ . Now, we can relate these two terms. The main observation here is that the probability of an application turning to an offer,  $p$ , equals the ratio between the number of offers and all applications. Therefore,  $p = \frac{1-e^{-k}}{k}$ .

The expected social welfare of matching is equal to the probability of a doctor being matched, which is  $(1 - (1 - \frac{1-e^{-k}}{k})^k)$ . ◀

Figure 1 shows the size of matching with respect to the number of applications.

■ **Figure 1** Size of matching with respect to the number of applications, when hospitals make only one offer.

### Positive and negative effects of having more applications

As shown in Figure 1, having more applications can have both positive and negative effects: As a positive effect, with more applications the number of hospitals who receive an application increases. This can potentially increase the size of matching. On the other hand, as the number of applications increases, the hospitals become more congested. Since the total number

of offers is limited by the number of hospitals (each hospital makes at most one offer), this causes an increase in the probability of rejection of an application. This may increase the number of doctors with no offer, leading to a negative effect on the size of matching. As seen in the picture, The biggest jump in the size of matching occurs when moving from one application to two applications. When increasing the number of applications from one to two, the fraction of covered hospitals changes from  $1 - 1/e \approx 0.63$  to  $1 - 1/e^2 \approx 0.86$ , which is the highest increase when adding more applications. This causes the highest increase in the matching size. The increase stops with only three number of applications, with which the fraction of covered hospitals is  $1 - 1/e^3 \approx 0.95$ . From this point forward the negative effect takes over and because of the random allocation of hospitals some doctors receive multiple offers while others receive none.

The following example considers the extreme case where doctors apply to all hospitals. Interestingly, the size of the matching in this case equals to the case where doctors were allowed to apply to a single hospital.

► **Example 9** (One application equals  $n$  applications.). With  $n$  applications for each doctor and hospitals accepting one interview, the social welfare of the matching approaches  $(1 - 1/e) \approx 0.63$  in a large market.

**Proof.** Since hospital preferences are uniformly random, each hospital selects an applicant to make an offer to, uniformly at random. Because doctors have  $n$  applications, the set of doctors applying to each hospital is the set of all doctors. Therefore the number of doctors who receive an offer is:

$$\lim_{n \rightarrow \infty} 1 - (1 - \frac{1}{n})^n = 1 - \frac{1}{e}$$

◀

### 3.2 Fractional Expected Number of Applications: A Scallop-Shape Function

Unlike Section 3.1, where there was a universal limit on the number of applications by doctors, in this subsection we study the social welfare when doctors are allowed to send different number of applications. First we show that for any expected number of applications  $x$ , the optimal social welfare occurs when doctors send either  $\lceil x \rceil$  or  $\lfloor x \rfloor$  applications. Then we study the social welfare as a function of the expected number of applications. We observe that granting extra applications to a small set of doctors and also retracting an application from a small set both hurt the market; suggesting that unfair treatment is not efficient in terms of social welfare.

► **Theorem 10.** *The social welfare of the matching with expected number of applications  $k < x < k + 1$ , when applicants either apply to  $k$  or  $k + 1$  positions is:*

$$(\lceil x \rceil - x)(1 - (1 - \frac{(1 - e^{-x})}{x})^k) + (x - \lfloor x \rfloor)(1 - (1 - \frac{(1 - e^{-x})}{x})^{k+1});$$

*this function is illustrated in Figure 2.*

The following proposition shows that for any expected number of applications  $x$ , the optimal social welfare occurs when doctors send either  $\lceil x \rceil$  or  $\lfloor x \rfloor$  applications.

► **Proposition 11.** *With any expected number of applications,  $x$ , the distribution of number of applications that achieves the highest social welfare, is one that allocates  $\lfloor x \rfloor$  applications to some doctors and  $\lceil x \rceil$  to the others, such that the expected number of applications equals  $x$ .*

**Proof.** Suppose the applications are distributed in a different way. Therefore, there are two doctors with  $l$  and  $k$  applications such that  $k - l \geq 2$ . We show that the size of matching is improved if we allocate  $f = \lfloor (k + l)/2 \rfloor$  and  $c = \lceil (k + l)/2 \rceil$  applications to those doctors. This alteration does not change the probability of receiving offers by other doctors as the applications are independent from doctors' perspective. So the only difference is the probability of receiving offers by these two doctors. Let  $p$  be the probability of a random application to lead to an offer. We claim

$$1 - (1 - p)^k + 1 - (1 - p)^l \leq 1 - (1 - p)^c + 1 - (1 - p)^f.$$

Since  $(1 - p)^c$  and  $(1 - p)^f$  have the same product as  $(1 - p)^k$  and  $(1 - p)^l$ , their sum is larger when the two factors are far apart, therefore:

$$(1 - p)^c + (1 - p)^f \leq (1 - p)^k + (1 - p)^l$$

which implies the conclusion. ◀

► **Remark.** This argument shows that in order to find the optimal social welfare for different expected number of applications, we only need to study the case where doctors apply to the same number of hospitals –as studied in Section 3.1– or two consecutive numbers.

**Proof of Theorem 10.** This proof is similar to that of Proposition 6. From a doctor's perspective, the probability of a random application, leading to an offer is  $c/\mathcal{A}$ , where  $c$  is the number of covered hospitals, and  $\mathcal{A}$  is the number of applications. With  $nx$  applications, the fraction of covered hospitals equals  $(1 - e^{-x})$ . Thus, the probability of an application turning to an offer equals  $(1 - e^{-x})/x$ . Therefore, the expected social welfare of the matching which is the same as the probability of a random doctor receiving an offer is:

$$(\lceil x \rceil - x)(1 - (1 - \frac{(1 - e^{-x})}{x})^k) + (x - \lfloor x \rfloor)(1 - (1 - \frac{(1 - e^{-x})}{x})^{k+1}).$$
◀

■ **Figure 2** Size of matching with respect to expected number of applications, when hospitals make only one offer.

The scallop-shape Figure 2 illustrates the size of matching as a function of expected number of applications. The unusual behavior of the function at integer points shows that allowing a small group to apply to one more position, or limiting the number of applications of a small group to one less application, has a negative effect on size of matching.

► **Observation 12** (3 applications per doctor is the most efficient). *Theorem 10, depicted in Figure 6, and Proposition 11 imply that for any expected number of applications per doctor, and any independent distribution of those applications to doctors, the efficiency of the matching never exceeds  $\approx 0.68$ . This efficiency is achieved when all doctors apply to 3 hospitals. This is in sharp contrast with unlimited number of interviews (Proposition 5).*

#### 4 Granting multiple interviews

In this section we describe our approach for the general case. The key simplifying feature of the single-offer case was that each hospital immediately made an offer to their top applicant and each doctor was matched to their most preferred hospital that they received an offer from. However, with multiple interviews, finding the final matching requires actually running the usual procedure of the deferred acceptance algorithm.

The main result of this section is the following.

► **Theorem 13.** *Suppose each doctor has  $k$  applications and each hospital grants interviews to at most  $k'$  doctors. The social welfare of the matching in this case is  $1 - (1 - p)^k$  where  $0 < p < 1$  is the solution to*

$$1 - (1 - p)^k = \sum_{i=1}^{k'-1} [g(i, k, p)f(i; k)] + g(k', k, p)(1 - F(k' - 1; k));$$

where  $g(i, k, p) = 1 - (1 - \frac{1-(1-p)^k}{pk})^i$ ,  $f(i; k) = \frac{k^i e^{-k}}{i!}$  is the pmf of Poisson distribution with mean  $k$ , and  $F(\cdot; k)$  is the CDF of that distribution. Also when the expected number of applications is  $x$  such that  $x - \lfloor x \rfloor = z$ , the social welfare is upperbounded by  $(1 - z)(1 - (1 - p)^{\lfloor x \rfloor}) + z(1 - (1 - p)^{\lceil x \rceil})$ , where  $0 < p < 1$  is the solution to

$$(1 - z)(1 - (1 - p)^k) + z(1 - (1 - p)^{k+1}) = \sum_{i=1}^{k'-1} [h(i, x, p)f(i; x)] + h(k', x, p)(1 - F(k' - 1; x));$$

and  $h(i, x, p) = (1 - (1 - \frac{(1-(x-\lfloor x \rfloor))(1-(1-p)^{\lfloor x \rfloor}) + (x-\lfloor x \rfloor)(1-(1-p)^{\lceil x \rceil})}{px})^i)$ . The upperbound is tight when all doctors apply to either  $k$  or  $k + 1$  positions.

Before proceeding with the proof we give a high-level overview of the main steps. In a market of two equal sides the probability of a doctor being matched is equal to the probability of a hospital being matched. We use this equation to find the size of matching. The formula for probability of a doctor being matched is similar to the previous section; however, formulating the probability of a hospital being matched is more complicated. The main technical portion of this section is devoted to formulating this probability. First, we define a modified implementation of the matching procedure which results in the same outcome as the original implementation, but is easier to deal with for analytic purposes. The new implementation introduces a concept called “semi-proposal”. Later, we find the relationship between the number of applications, valid applications, proposals, and semi-proposals. The probability of a hospital being matched can be formulated in terms of the number of proposals. Finally, by finding the three other quantities, we find the number of proposals, and formulate the probability of a hospital being matched.

**Modified Implementation of Matching Procedure.** For the sake of analysis, it is useful to define a *modified implementation* of the matching procedure. Similar to the original implementation, in the first stage doctors apply to hospitals using all their applications and

hospitals conduct interviews with a subset of their applicants. The difference between the two implementations arises in the second stage. In the modified implementation, doctors submit their ordered preferences including *both* the hospitals they interviewed and the hospitals that rejected them for interview. Therefore, when the system simulates doctor-proposing deferred acceptance algorithm, doctors are allowed to propose using any of their applications; both valid and invalid ones. Since the invalid applications do not exist in hospitals' lists they get rejected immediately and the outcomes of both implementations are the same. In contrast to the modified implementation, we refer to the main procedure previously defined as the *original* implementation.

**Semi-proposal.** The procedure in the second stage of the modified implementation that simulates doctors proposing to hospitals as steps of the deferred acceptance algorithm. Note that this includes both the proposals that do not really count (because the hospital didn't extend an interview) and those that led to an interview.

► **Lemma 14.** *The expected number of semi-proposals made by a doctor is  $\frac{1-(1-p)^k}{p}$ , where  $p$  is the probability of a random application turning to a permanent match.*

**Proof.** By Proposition 4 from a doctor's perspective each hospital they propose to is available to them with equal probability, and their availabilities are independent<sup>2</sup>. Consider the modified implementation defined above. In the second stage of the game doctors send semi-proposals to hospitals. Let  $p$  be the probability of a random semi-proposal becoming a permanent match. By independence the probability that a doctor becomes matched is  $1 - (1 - p)^k$ . Also the expected number of semi-proposals made by a doctor is  $1 + (1 - p) + \dots + (1 - p)^{k-1} = \frac{1-(1-p)^k}{p}$ . ◀

► **Lemma 15.** *For any application  $\mathcal{A} = (d, h)$ , consider  $\mathcal{E}_{\text{semi}}(\mathcal{A})$  as the event that  $\mathcal{A}$  turns to a semi-proposal, i.e.,  $d$  sends a semi-proposal to  $h$ , and  $\mathcal{E}_{\text{valid}}(\mathcal{A})$  as the event where  $\mathcal{A}$  is valid.  $\mathcal{E}_{\text{semi}}(\mathcal{A})$  and  $\mathcal{E}_{\text{valid}}(\mathcal{A})$  are independent.*

**Proof.** Application  $\mathcal{A} = (d, h)$  is turned into a semi-proposal if the previous semi-proposals of  $d$  are rejected. Similarly, a valid application  $\mathcal{V}$  is turned into a proposal if the previous semi-proposals are rejected. Since preferences are distributed uniformly at random for both doctors and hospitals, the fact that  $\mathcal{A}$  is valid or invalid is independent of the rank of  $h$  in the preference list of  $d$ . Therefore, the probability of  $\mathcal{A}$  turning into a semi-proposal conditioned on it being valid is equal to the unconditional probability. ◀

► **Corollary 16.** *The probability of a random valid application turning into a proposal,  $p_{V \rightarrow P}$ , equals the probability of a random application into a semi-proposal,  $p_{A \rightarrow S}$ . This probability is  $\frac{\mathcal{P}}{\mathcal{A}} = \frac{\mathcal{S}}{\mathcal{V}}$ , where  $\mathcal{P}$ ,  $\mathcal{A}$ ,  $\mathcal{S}$ , and  $\mathcal{V}$  represent the number of proposals, applications, semi-proposals and valid applications, respectively.*

**Proof.** Lemma 15 implies  $p_{V \rightarrow P} = p_{A \rightarrow S}$ . The first probability equals the ratio of total number of proposals to valid applications, and the second equals the total number of semi-proposals to applications. ◀

A key observation for finding the number of valid applications is the following.

<sup>2</sup> Note that considering proposals *with replacement* is accurate up to lower order terms; with constant proposals, a doctor will make a repeat only with vanishingly small probability.

► **Observation 17.** *The number of applications that a hospital receives in the first stage forms a binomial distribution which converges to a Poisson distribution with mean  $k$  in the limit. This is due to the independent and uniform preferences of doctors.*

► **Lemma 18.** *The expected number of proposals that a hospital receives is*

$$\frac{1 - (1 - p)^k}{p} \cdot \frac{\sum_{i=1}^{k'-1} \left[ i \cdot \frac{k^i e^{-k}}{i!} \right] + k'(1 - e^{-k} \sum_{i=0}^{k'-1} \frac{k^i}{i!})}{k}.$$

**Proof.** By Corollary 16,  $\frac{\mathcal{P}}{\mathcal{A}} = \frac{\mathcal{S}}{\mathcal{V}}$ . In order to find  $\mathcal{P}$ , we need  $\mathcal{A}$ ,  $\mathcal{S}$ , and  $\mathcal{V}$ . By definition,  $\mathcal{A} = k$  and by Lemma 14,  $\mathcal{S} = \frac{1 - (1 - p)^k}{p}$ . Therefore, we only need to find  $\mathcal{V}$ . Recall that an application  $(d, h)$  is valid if hospital  $h$  does not reject it in the first stage. A hospital rejects an application only if it receives more than  $k'$ . Therefore, by Observation 17, the expected number of valid applications per hospital is,

$$\mathcal{V} = \sum_{i=1}^{k'-1} i \cdot \frac{k^i e^{-k}}{i!} + k'(1 - e^{-k} \sum_{j=0}^{k'-1} \frac{k^j}{j!}).$$

Substituting  $\mathcal{A}$ ,  $\mathcal{S}$ , and  $\mathcal{P}$  in Corollary 16, the expected number of proposals a hospital receives is

$$\frac{1 - (1 - p)^k}{p} \cdot \frac{\sum_{i=1}^{k'-1} i \cdot \frac{k^i e^{-k}}{i!} + k'(1 - e^{-k} \sum_{i=0}^{k'-1} \frac{k^i}{i!})}{k}. \quad \blacktriangleleft$$

Now we find the probability that a random hospital is matched.

► **Lemma 19.** *The probability of a random hospital being matched is*

$$\sum_{i=1}^{k'-1} [g(i, k, p) f(i; k)] + g(k', k, p)(1 - F(k' - 1; k));$$

where  $g(i, k, p) = 1 - (1 - \frac{1 - (1 - p)^k}{pk})^i$ ,  $f(i; k) = \frac{k^i e^{-k}}{i!}$  is the pmf of Poisson distribution with mean  $k$ ,  $F(\cdot; k)$  is the CDF of that distribution, and  $p$  is the probability of a random application turning to a permanent match.

**Proof.** From the hospitals' point of view, each of their valid applications has the same probability of becoming a proposal. Let  $q$  be the probability of a random valid application turning into a proposal. In a doctors-proposing deferred-acceptance algorithm, if a hospital is once tentatively matched it will remain matched forever. A hospital becomes tentatively matched if it receives a proposal, in other words if at least one of its valid applications becomes a proposal. The probability that a random hospital with  $j$  valid applications receives a proposal is  $1 - (1 - q)^j$ . Therefore, the probability that a random hospital is matched equals,

$$\sum_{i=1}^{k'-1} \left[ (1 - (1 - q)^i) \frac{k^i e^{-k}}{i!} \right] + (1 - (1 - q)^{k'}) (1 - e^{-k} \sum_{i=0}^{k'-1} \frac{k^i}{i!}).$$

The probability of a random valid application turning into a proposal,  $q$ , is equal to the ratio of the total number of proposals to the total number of valid applications. By Lemma 15, this ratio is equal to the ratio of the total number of semi-proposals to the total number of applications. Therefore,  $q = \frac{1 - (1 - p)^k}{pk}$ . ◀

**Proof of Theorem 13.** Lemma 14, Lemma 19 and the fact that in a matching of two equal sides, the probability of a random doctor being matched is equal to a hospital being matched implies:

$$1 - (1 - p)^k = \sum_{i=1}^{k'-1} [g(i, k, p)f(i; k)] + g(k', k, p)(1 - F(k' - 1; k)).$$

Similar reasoning holds when the expected number of applications is an arbitrary real number  $x$  such that each doctor has either  $\lfloor x \rfloor$  or  $\lceil x \rceil$  applications, deriving the formula for general  $x$ . By Proposition 11, the size of the matching with expected  $k \leq x < k + 1$  applications is maximized when all doctors apply to either  $k$  or  $k + 1$  positions. This concludes the proof. ◀

**Figure 3** Size of matching with respect to expected number of application. The curves represents the settings where hospitals allow one to five interviews. The lowest curve belongs to one interview and the highest curve to five interviews.

## 5 Extensions

In this section we discuss two extensions to our main results in Section 4. Section 5.1 discusses the extension to unbalanced markets where the number of doctors and positions is different. Section 5.2 discusses the extension to correlated preferences.

### 5.1 Beyond Balanced Markets

In this part, we show that the phenomenon of the positive effect of setting the same limit for all doctors is not limited to a balanced market – where the number of applicants and positions are the same – but extends to unbalanced markets with different number of applicants and

positions. Although the same phenomenon exists more generally, the exact function is not preserved and the optimum number of applications depends on the ratio between the sizes of the two sides.

We study the case where hospitals make one offer (similar to Section 3) and the ratio of the number of hospitals to the number of doctors is  $r$ . The results from Section 4 with multiple interviews also generalize to this setting. However, for simplicity and similarity of the outcomes, we just present the results for the model with one offer. Similar to the previous section, we can compute the size of the matching as a function of the expected number of applications, when doctors send  $k$  or  $k + 1$  applications.

► **Proposition 20.** *The expected fraction of matched doctors with expected number of applications  $k < x < k + 1$ , when applicants either apply to  $k$  or  $k + 1$  positions and when the ratio of number of hospitals to number of doctors is  $r$  is:*

$$(\lceil x \rceil - x)(1 - (1 - \frac{r(1 - e^{-x/r})}{x})^k) + (x - \lfloor x \rfloor)(1 - (1 - \frac{r(1 - e^{-x/r})}{x})^{k+1}).$$

**Proof.** As shown in the proof of Proposition 6, from the doctors perspective, the probability of a random application, leading to an offer is  $\frac{\mathcal{C}}{\mathcal{A}}$ , where  $\mathcal{C}$  is the number of covered hospitals and  $\mathcal{A}$  is the number of application. From the hospitals perspective, each application is equally likely to be sent to each hospital. Therefore the number of applications received is distributed as a Poisson distribution with  $\lambda = \frac{x}{r}$ . So the number of expected covered hospitals is  $rn(1 - e^{-x/r})$  and the probability of a random application, leading to an offer is  $\frac{r(1 - e^{-x/r})}{x}$ . Therefore the expected fraction of doctors who are matched which is the same as the probability of a random doctor receiving an offer is:

$$(\lceil x \rceil - x)(1 - (1 - \frac{r(1 - e^{-x/r})}{x})^k) + (x - \lfloor x \rfloor)(1 - (1 - \frac{r(1 - e^{-x/r})}{x})^{k+1}). \quad \blacktriangleleft$$

Based on Definition 3, the social welfare of a matching is the ratio of the size of the matching to the size of maximum matching; and in unbalanced markets, the maximum size is the size of the smaller side of the matching. For  $r \geq 1$ , the doctors make the smaller side therefore the social welfare is equal to expected fraction of doctors who are matched as computed in Proposition 20. If  $r < 1$ , the social welfare is the expected fraction of doctors who are matched as computed in Proposition 20 divided by  $r$ .

Section 5.1 shows the social welfare of the matching as a function of expected number of applications for  $r = \frac{1}{2}, 1, 2$ . In the figure, the red function refers to  $r = 2$ , the blue function to  $r = 1/2$  and the green function to  $r = 1$ .

As seen in the figure a similar structure holds for unbalanced networks, but the optimal number of applications depends on the factor of balancedness  $r$ . When the number of hospitals is half of the number of doctors, the market achieves its maximum size when each doctor applies to just one position. With more applications, hospitals become more congested; and the number of covered hospitals and therefore the number of total offers does not increase significantly. Therefore, the rejection probability of applications increases and with higher probability a doctor remains unmatched. In contrast, when the number of hospitals is more than the number of doctors, allowing more applications has a positive effect. With more applications –while the number of applications is still small– more hospitals receive at least one application; therefore, the number of offers increases considerably.

Also, note that in the figure, the social welfare of the balanced market is generally lower than the social welfare of markets with  $r = 1/2, 2$ . This is not surprising since by definition the social welfare is the fraction of matched individuals on the smaller side of the market:

■ **Figure 4** Social welfare of the matching with respect to the expected number of applications. The red curve refers to  $r = 2$ , blue curve to  $r = 1/2$  and the green curve to  $r = 1$ , where  $r$  is the ratio of the number of hospitals to doctors.

doctors for  $r \leq 1$ , and hospitals for  $r > 1$ . For  $r = 2$ , with the same number of applications per doctor, more hospitals are covered that leads to more offers and a higher fraction of matched doctors. For  $r = 1/2$ , with the same number of applications, a higher fraction of hospitals is covered which leads to a higher fraction of matched hospitals.

## 5.2 Beyond Uniform Preferences

In this part, we go beyond the uniform and independent assumptions and use simulations to show that the properties of limited interviews exist more generally. The model studied in the previous sections assumes that doctors and hospitals preferences remain uniform and independent after the interview stage. We relax this assumption. We study a model where the two sides have no information prior to the matching procedure. However, after the interview stage, all participants refine their lists with information learned in the interviews. Therefore, preference lists may become correlated.

Without prior knowledge about the other side, the behaviors in the first stage is similar to what stated previously: there is a Bayes Nash Equilibrium such that doctors and hospitals pick the top of their lists. In the second stage, doctors and hospitals are not anymore identical in terms of popularity. We will be assuming that preferences among the interviews are independent samples from a distribution that reflects popularity. Immorlica and Mahdian [6] show that in a large market short preference lists sampled from a distribution, all participants are likely to prefer to be truthful. While this is not exactly the same as our model, analogous to this case, we will make the assumption in our simulation that participants do act truthfully.

To show how generally the properties hold, for simulations we study the other extreme in preferences: completely aligned preferences after interviews. We use a market of 10,000 doctors and hospitals. Similar to previous sections we start with uniform and independent preference in the first stage. For the second stage we simulate running the deferred acceptance algorithm when hospitals agree on a random preference over doctors. Figure 5 shows the size of matching as a function of number of applications when the number of interviews for hospitals is limited to two and four interviews.

■ **Figure 5** Size of matching with respect to expected number of application. In the first stage the preferences are uniform and independent. In the second stage hospitals preferences are aligned. The bottom curve belongs to two interviews and the top one to four interviews.

As observed in Figure 5, the properties of limited interviews are not restricted to uniform preferences. They hold even in the other extreme case where the preferences are completely correlated after interviews.

## A Missing Proofs

**Discussion of Observation 2.** The truthful equilibrium is due to the independence and symmetry and the private information model (the doctors and hospitals are unaware of the number of applications and preference lists of others). At all times, no hospital or doctor is more popular than the rest. Therefore from a doctor's point of view the probability of acceptance in all hospitals is the same and there is no benefit in not applying to a favorite hospital or be non-truthful about the preference order. The same holds for hospitals. ◀

**Proof of Proposition 5.** We show that if one of the doctors who previously had  $k$  applications, now has  $k + 1$  applications and the number of applications of other doctors remain the same, the size of the matching can only increase. By Observation 2, both doctors and hospitals are truthful, therefore we are comparing the size of matching as the result of deferred acceptance algorithm when doctor  $d$  has an extra application and all other doctors have the same number of applications. Since the deferred acceptance algorithm is oblivious to the order in which doctors proposes, we may hold out the last application of doctor  $d$  and find the outcome when the doctor  $d$  does not have this application in his/her list. The result of the deferred acceptance algorithm, without this application is the same as the case where doctor  $d$  had  $k$  applications. We show that this last application can only increase the number of matching. If doctor  $d$  is matched with one of his/her first  $k$  proposals, the last application does not change. If doctor  $d$  proposes to  $k + 1_{st}$  hospital, it can only increase the number of hospitals who have received any proposal. ◀

## Abstract

A conjecture of Hopkins (2018) posits that for certain high-dimensional hypothesis testing problems, no polynomial-time algorithm can outperform so-called “simple statistics”, which are low-degree polynomials in the data. This conjecture formalizes the beliefs surrounding a line of recent work that seeks to understand statistical-versus-computational tradeoffs via the *low-degree likelihood ratio*. In this work, we refute the conjecture of Hopkins. However, our counterexample crucially exploits the specifics of the noise operator used in the conjecture, and we point out a simple way to modify the conjecture to rule out our counterexample. We also give an example illustrating that (even after the above modification), the symmetry assumption in the conjecture is necessary. These results do not undermine the low-degree framework for computational lower bounds, but rather aim to better understand what class of problems it is applicable to.

## 1 Introduction

A primary goal of computer science is to understand which problems can be solved by efficient algorithms. Given the formidable difficulty of proving unconditional computational hardness, state-of-the-art results typically rely on unproven conjectures. While many such results rely only upon the widely-believed conjecture  $P \neq NP$ , other results have only been proven under stronger assumptions such as the unique games conjecture [19, 20], the exponential time hypothesis [16], the learning with errors assumption [25], or the planted clique hypothesis [17, 4].

It has also been fruitful to conjecture that a specific *algorithm* (or limited class of algorithms) is optimal for a suitable class of problems. This viewpoint has been particularly prominent in the study of average-case noisy statistical inference problems, where it appears that optimal performance over a large class of problems can be achieved by methods such as the sum-of-squares hierarchy (see [24]), statistical query algorithms [18, 5], the approximate message passing framework [9, 22], and low-degree polynomials [15, 14, 13]. It is helpful to have such a conjectured-optimal meta-algorithm because this often admits a *systematic* analysis of hardness. However, the exact class of problems for which we believe these methods

are optimal has typically not been precisely formulated. In this work, we explore this issue for the class of low-degree polynomial algorithms, which admits a systematic analysis via the low-degree likelihood ratio.

The *low-degree likelihood ratio* [15, 14, 13] has recently emerged as a framework for studying computational hardness in high-dimensional statistical inference problems. It has been shown that for many “natural statistical problems,” all known polynomial-time algorithms only succeed in the parameter regime where certain “simple” (low-degree) statistics succeed. The power of low-degree statistics can often be understood via a relatively simple explicit calculation, yielding a tractable way to precisely predict the statistical-versus-computational tradeoffs in a given problem. These “predictions” can rigorously imply lower bounds against a broad class of spectral methods [21, Theorem 4.4] and are intimately connected to the *sum-of-squares hierarchy* (see [14, 13, 24]). Recent work has (either explicitly or implicitly) carried out this type of low-degree analysis for a variety of statistical tasks [3, 15, 14, 13, 2, 1, 21, 8, 6, 23, 7]. For more on these methods, we refer the reader to the PhD thesis of Hopkins [13] or the survey article [21].

Underlying the above ideas is the belief that for certain “natural” problems, low-degree statistics are as powerful as all polynomial-time algorithms – we refer broadly to this belief as the “low-degree conjecture”. However, formalizing the notion of “natural” problems is not a straightforward task. Perhaps the easiest way to illustrate the meaning of “natural” is by example: prototypical examples (studied in the previously mentioned works) include planted clique, sparse PCA, random constraint satisfaction problems, community detection in the stochastic block model, spiked matrix models, tensor PCA, and various problems of a similar flavor. All of these can be stated as simple hypothesis testing problems between a “null” distribution (consisting of random noise) and a “planted” distribution (which contains a “signal” hidden in noise). They are all high-dimensional problems but with sufficient symmetry that they can be specified by a small number of parameters (such as a “signal-to-noise ratio”). For all of the above problems, the best known polynomial-time algorithms succeed precisely in the parameter regime where simple statistics succeed, i.e., where there exists a  $O(\log n)$ -degree polynomial of the data whose value behaves noticeably different under the null and planted distributions (in a precise sense). Thus, barring the discovery of a drastically new algorithmic approach, the low-degree conjecture seems to hold for all the above problems. In fact, a more general version of the conjecture seems to hold for runtimes that are not necessarily polynomial: degree- $D$  statistics are as powerful as all  $n^{\tilde{\Theta}(D)}$ -time algorithms, where  $\tilde{\Theta}$  hides factors of  $\log n$  [13, Hypothesis 2.1.5] (see also [21, 8]).

A precise version of the low-degree conjecture was formulated in the PhD thesis of Hopkins [13]. This includes precise conditions on the null distribution  $\nu$  and planted distribution  $\mu$  which capture most of the problems mentioned above. The key conditions are that there should be sufficient symmetry, and that  $\mu$  should be injected with at least a small amount of noise. Most of the problems above satisfy this symmetry condition (a notable exception being the spiked Wishart model<sup>1</sup>, which satisfies a mild generalization of it), but it remained unclear whether this assumption was needed in the conjecture. On the other hand, the noise assumption is certainly necessary, as illustrated by the example of solving a system of linear equations over a finite field: if the equations have an exact solution then it can be obtained via Gaussian elimination even though low-degree statistics suggest that the

---

<sup>1</sup> Here we mean the formulation of the spiked Wishart model used in [1], where we directly observe Gaussian samples instead of only their covariance matrix.

problem should be hard; however, if a small amount of noise is added (so that only a  $1 - \varepsilon$  fraction of the equations can be satisfied) then Gaussian elimination is no longer helpful, and the low-degree conjecture seems to hold.

In this work we investigate more precisely what kinds of noise and symmetry conditions are needed in the conjecture of Hopkins [13]. Our first result (Theorem 4) actually refutes the conjecture in the case where the underlying random variables are real-valued. Our counterexample exploits the specifics of the noise operator used in the conjecture, along with the fact that a single real number can be used to encode a large (but polynomially bounded) amount of data. In other words, we show that a *stronger* noise assumption than the one in [13] is needed; Remark 6 explains a modification of the conjecture that we do not know how to refute. Our second result (Theorem 7) shows that the symmetry assumption in [13] cannot be dropped, i.e., we give a counterexample for a weaker conjecture that does not require symmetry. Both of our counterexamples are based on efficiently decodable error-correcting codes.

## Notation

Asymptotic notation such as  $o(1)$  and  $\Omega(1)$  pertains to the limit  $n \rightarrow \infty$ . We say that an event occurs with *high probability* if it occurs with probability  $1 - o(1)$ , and we use the abbreviation w.h.p. (“with high probability”). We use  $[n]$  to denote the set  $\{1, 2, \dots, n\}$ . The *Hamming distance* between vectors  $x, y \in F^n$  (for some field  $F$ ) is  $\Delta(x, y) = |\{i \in [n] : x_i \neq y_i\}|$  and the *Hamming weight* of  $x$  is  $\Delta(x, 0)$ .

## 2 The Low-Degree Conjecture

We now state the formal variant of the low-degree conjecture proposed in the PhD thesis of Hopkins [13, Conjecture 2.2.4]. The terminology used in the statement will be explained below.

► **Conjecture 1.** *Let  $\mathcal{X}$  be a finite set or  $\mathbb{R}$ , and let  $k \geq 1$  be a fixed integer. Let  $N = \binom{n}{k}$ . Let  $\nu$  be a product distribution on  $\mathcal{X}^N$ . Let  $\mu$  be another distribution on  $\mathcal{X}^N$ . Suppose that  $\mu$  is  $S_n$ -invariant and  $(\log n)^{1+\Omega(1)}$ -wise almost independent with respect to  $\nu$ . Then no polynomial-time computable test distinguishes  $T_\delta \mu$  and  $\nu$  with probability  $1 - o(1)$ , for any  $\delta > 0$ . Formally, for all  $\delta > 0$  and every polynomial-time computable  $t : \mathcal{X}^N \rightarrow \{0, 1\}$  there exists  $\delta' > 0$  such that for every large enough  $n$ ,*

$$\frac{1}{2} \mathbb{P}_{x \sim \nu}(t(x) = 0) + \frac{1}{2} \mathbb{P}_{x \sim T_\delta \mu}(t(x) = 1) \leq 1 - \delta'.$$

We now explain some of the terminology used in the conjecture, referring the reader to [13] for the full details. We will be concerned with the case  $k = 1$ , in which case  $S_n$ -invariance of  $\mu$  means that for any  $x \in \mathcal{X}^n$  and any  $\pi \in S_n$  (the symmetric group) we have  $\mathbb{P}_\mu(x) = \mathbb{P}_\mu(\pi \cdot x)$  where  $\pi$  acts by permuting coordinates. The notion of *D-wise almost independence* captures how well degree- $D$  polynomials can distinguish  $\mu$  and  $\nu$ . For our purposes, we do not need the full definition of *D-wise almost independence* (see [13]), but only the fact that it is implied by *exact D-wise independence*, defined as follows.

► **Definition 2.** *A distribution  $\mu$  on  $\mathcal{X}^N$  is  $D$ -wise independent with respect to  $\nu$  if for any  $S \subseteq [N]$  with  $|S| \leq D$  we have equality of the marginal distributions  $\mu|_S = \nu|_S$ .*

Finally, the *noise operator*  $T_\delta$  is defined as follows.

► **Definition 3.** Let  $\nu$  be a product distribution on  $\mathcal{X}^N$  and let  $\mu$  be another distribution on  $\mathcal{X}^N$ . For  $\delta \in [0, 1]$ , let  $T_\delta\mu$  be the distribution on  $\mathcal{X}^N$  generated as follows. To sample  $z \sim T_\delta\mu$ , first sample  $x \sim \mu$  and  $y \sim \nu$  independently, and then, independently for each  $i$ , let

$$z_i = \begin{cases} x_i & \text{with probability } 1 - \delta, \\ y_i & \text{with probability } \delta. \end{cases}$$

(Note that  $T_\delta$  depends on  $\nu$  but the notation suppresses this dependence;  $\nu$  will always be clear from context.)

### 3 Main Results

We first give a counterexample that refutes Conjecture 1 in the case  $\mathcal{X} = \mathbb{R}$ .

► **Theorem 4.** *The following holds for infinitely many  $n$ . Let  $\mathcal{X} = \mathbb{R}$ , and  $\nu = \text{Unif}([0, 1]^n)$ . There exists a distribution  $\mu$  on  $\mathcal{X}^n$  such that  $\mu$  is  $S_n$ -invariant (with  $k = 1$ ) and  $\Omega(n)$ -wise independent with respect to  $\nu$ , and for some constant  $\delta > 0$  there exists a polynomial-time computable test distinguishing  $T_\delta\mu$  and  $\nu$  with probability  $1 - o(1)$ .*

The proof is given in Section 5.1.

► **Remark 5.** We assume a standard model of finite-precision arithmetic over  $\mathbb{R}$ , i.e., the algorithm  $t$  can access polynomially-many bits in the binary expansion of its input.

Note that we refute an even weaker statement than Conjecture 1 because our counterexample has *exact*  $\Omega(n)$ -wise independence instead of only  $(\log n)^{1+\Omega(1)}$ -wise *almost* independence.

► **Remark 6.** Essentially, our counterexample exploits the fact that a single real number can be used to encode a large block of data, and that the noise operator  $T_\delta$  will leave many of these blocks untouched (effectively allowing us to use a super-constant alphabet size). We therefore propose modifying Conjecture 1 in the case  $\mathcal{X} = \mathbb{R}$  by using a different noise operator that applies a small amount of noise to *every* coordinate instead of resampling a small number of coordinates. If  $\nu$  is i.i.d.  $\mathcal{N}(0, 1)$  then the standard Ornstein-Uhlenbeck noise operator is a natural choice (and in fact, this is mentioned by [13]). Formally, this is the noise operator  $T_\delta$  that samples  $T_\delta\mu$  as follows: draw  $x \sim \mu$  and  $y \sim \nu$  and output  $\sqrt{1 - \delta}x + \sqrt{\delta}y$ .

Our second result illustrates that in the case where  $\mathcal{X}$  is a finite set, the  $S_n$ -invariance assumption cannot be dropped from Conjecture 1. (In stating the original conjecture, Hopkins [13] remarked that he was not aware of any counterexample when the  $S_n$ -invariance assumption is dropped).

► **Theorem 7.** *The following holds for infinitely many  $n$ . Let  $\mathcal{X} = \{0, 1\}$  and  $\nu = \text{Unif}(\{0, 1\}^n)$ . There exists a distribution  $\mu$  on  $\mathcal{X}^n$  such that  $\mu$  is  $\Omega(n)$ -wise independent with respect to  $\nu$ , and for some constant  $\delta > 0$  there exists a polynomial-time computable test distinguishing  $T_\delta\mu$  and  $\nu$  with probability  $1 - o(1)$ .*

The proof is given in Section 5.2.

Both of our counterexamples are in fact still valid in the presence of a stronger noise operator  $T_\delta$  that *adversarially* changes any  $\delta$ -fraction of the coordinates.

The rest of the paper is organized as follows. Our counterexamples are based on error-correcting codes, so in Section 4 we review the basic notions from coding theory that we will need. In Section 5 we construct our counterexamples and prove our main results.

## 4 Coding Theory Preliminaries

Let  $F = \mathbb{F}_q$  be a finite field. A *linear code*  $C$  (over  $F$ ) is a linear subspace of  $F^n$ . Here  $n$  is called the (*block*) *length*, and the elements of  $C$  are called *codewords*. The *distance* of  $C$  is the minimum Hamming distance between two codewords, or equivalently, the minimum Hamming weight of a nonzero codeword.

► **Definition 8.** Let  $C$  be a linear code. The *dual distance* of  $C$  is the minimum Hamming weight of a vector in  $F^n$  that is orthogonal to all codewords. Equivalently, the dual distance is the distance of the dual code  $C^\perp = \{x \in F^n : \langle x, c \rangle = 0 \ \forall c \in C\}$ .

The following standard fact will be essential to our arguments.

► **Proposition 9.** If  $C$  is a linear code with dual distance  $d$ , then the uniform distribution over codewords is  $(d - 1)$ -wise independent with respect to the uniform distribution on  $F^n$ .

**Proof.** This is a standard fact in coding theory, but we give a proof here for completeness. Fix  $S \subseteq [n]$  with  $|S| \leq d - 1$ . For some  $k$ , we can write  $C = \{x^\top G : x \in F^k\}$  for some  $k \times n$  generator matrix  $G$  whose rows form a basis for  $C$ . Let  $G_S$  be the  $k \times |S|$  matrix obtained from  $G$  by keeping only the columns in  $S$ . It is sufficient to show that if  $x$  is drawn uniformly from  $F^k$  then  $x^\top G_S$  is uniform over  $F^{|S|}$ . The columns of  $G_S$  must be linearly independent, because otherwise there is a vector  $y \in F^n$  of Hamming weight  $\leq d - 1$  such that  $Gy = 0$ , implying  $y \in C^\perp$ , which contradicts the dual distance. Thus there exists a set  $T \subseteq [k]$  of  $|S|$  linearly independent rows of  $G_S$  (which form a basis for  $F^{|S|}$ ). For any fixed choice of  $x_{[k] \setminus T}$  (i.e., the coordinates of  $x$  outside  $T$ ), if the coordinates  $x_T$  are chosen uniformly at random then  $x^\top G_S$  is uniform over  $F^{|S|}$ . This completes the proof. ◀

► **Definition 10.** A code  $C$  admits *efficient decoding* from  $r$  errors and  $s$  erasures if there is a deterministic polynomial-time algorithm  $\mathcal{D} : (F \cup \{\perp\})^n \rightarrow F^n \cup \{\text{fail}\}$  with the following properties.

- For any codeword  $c \in C$ , let  $c' \in F^n$  be any vector obtained from  $c$  by changing the values of at most  $r$  coordinates (to arbitrary elements of  $F$ ), and replacing at most  $s$  coordinates with the erasure symbol  $\perp$ . Then  $\mathcal{D}(c') = c$ .
- For any arbitrary  $c' \in F^n$  (not obtained from some codeword as above),  $\mathcal{D}(c')$  can output any codeword or fail (but must never output a vector that is not a codeword<sup>2</sup>).

Note that the decoding algorithm knows where the erasures have occurred but does not know where the errors have occurred.

Our first counterexample (Theorem 4) is based on the classical *Reed-Solomon codes*  $\text{RS}_q(n, k)$ , which consist of univariate polynomials of degree at most  $k$  evaluated at  $n$  canonical elements of the field  $\mathbb{F}_q$ , and are known to have the following properties.

► **Proposition 11 (Reed-Solomon Codes).** For any integers  $0 \leq k < n$  and for any prime power  $q \geq n$ , there is a length- $n$  linear code  $C$  over  $\mathbb{F}_q$  with the following properties:

- the dual distance is  $k + 2$ ,
- $C$  admits efficient decoding from  $r$  errors and  $s$  erasures whenever  $2r + s < n - k$ .

**Proof.** See e.g., [11] for the construction and basic facts regarding Reed-Solomon codes  $\text{RS}_q(n, k)$ . The distance of  $\text{RS}_q(n, k)$  is  $n - k$ . It is well known that the dual code of  $\text{RS}_q(n, k)$  is  $\text{RS}_q(n, n - k - 2)$ , which proves the claim about dual distance. Efficient decoding is discussed e.g., in Section 3.2 of [11]. ◀

<sup>2</sup> The codes we deal with in this paper can be efficiently constructed, and so it is easy to test whether a given vector is a codeword. Thus, this assumption is without loss of generality.

Our second counterexample (Theorem 7) is based on the following construction of efficiently correctable binary codes with large dual distance. A proof (by Guruswami) can be found in [26, Theorem 4]. Similar results were proved earlier [27, 10, 12].

► **Proposition 12.** *There exists a universal constant  $\zeta \geq 1/30$  such that for every integer  $i \geq 1$  there is a linear code  $C$  over  $\mathbb{F}_2 = \{0, 1\}$  of block length  $n = 42 \cdot 8^{i+1}$ , with the following properties:*

- *the dual distance is at least  $\zeta n$ , and*
- *$C$  admits efficient decoding from  $\zeta n/2$  errors (with no erasures).*

## 5 Proofs

Before proving the main results, we state some prerequisite notation and lemmas.

► **Definition 13.** *Let  $F$  be a finite field. For  $S \subseteq [n]$  (representing erased positions), the  $S$ -restricted Hamming distance  $\Delta_S(x, y)$  is the number of coordinates in  $[n] \setminus S$  where  $x$  and  $y$  differ:*

$$\Delta_S(x, y) = |\{i \in [n] \setminus S : x_i \neq y_i\}|.$$

*We allow  $x, y$  to belong to either  $F^n$  or  $F^{[n] \setminus S}$ , or even to  $(F \cup \{\perp\})^n$  so long as the “erasures”  $\perp$  occur only in  $S$ .*

The following lemma shows that a random string is sufficiently far from any codeword.

► **Lemma 14.** *Let  $C$  be a length- $n$  linear code over a finite field  $F$ . Suppose  $C$  admits efficient decoding from  $2r$  errors and  $s$  erasures, for some  $r, s$  satisfying  $r \leq (n - s)/(8e)$ . For any fixed choice of at most  $s$  erasure positions  $S \subseteq [n]$ , if  $x$  is a uniformly random element of  $F^{[n] \setminus S}$  then*

$$\mathbb{P}_x(\exists c \in C : \Delta_S(c, x) \leq r) \leq (r + 1)2^{-r}.$$

**Proof.** Let  $B_r(c) = \{x \in F^{[n] \setminus S} : \Delta_S(c, x) \leq r\} \subseteq F^{[n] \setminus S}$  denote the Hamming ball (with erasures  $S$ ) of radius  $r$  and center  $c$ , and let  $|B_r|$  denote its cardinality (which does not depend on  $c$ ). We have the following basic bounds on  $|B_r|$ :

$$\binom{n - |S|}{r} (|F| - 1)^r \leq |B_r| \leq (r + 1) \binom{n - |S|}{r} (|F| - 1)^r.$$

Since decoding from  $2r$  errors and  $s$  erasures is possible, the Hamming balls  $\{B_{2r}(c)\}_{c \in C}$  are disjoint, and so

$$\begin{aligned} \mathbb{P}_x(\exists c \in C : \Delta_S(c, x) \leq r) &\leq |B_r| / |B_{2r}| \\ &\leq (r + 1) \binom{n - |S|}{r} \binom{n - |S|}{2r}^{-1} (|F| - 1)^{-r} \\ &\leq (r + 1) \binom{n - |S|}{r} \binom{n - |S|}{2r}^{-1}. \end{aligned}$$

Using the standard bounds  $\left(\frac{n}{k}\right)^k \leq \binom{n}{k} \leq \left(\frac{ne}{k}\right)^k$ , this becomes

$$\begin{aligned} &\leq (r + 1) \left( \frac{4er}{n - |S|} \right)^r \\ &\leq (r + 1) \left( \frac{4er}{n - s} \right)^r \end{aligned}$$

which is at most  $(r + 1)2^{-r}$  provided  $r \leq (n - s)/(8e)$ . ◀

► **Lemma 15.** *Let  $j_1, \dots, j_n$  be uniformly and independently chosen from  $[n]$ . For any constant  $\alpha < 1/e$ , the number of indices  $i \in [n]$  that occur exactly once among  $j_1, \dots, j_n$  is at least  $\alpha n$  with high probability.*

**Proof.** Let  $X_i \in \{0, 1\}$  be the indicator that  $i$  occurs exactly once among  $j_1, \dots, j_n$ , and let  $X = \sum_{i=1}^n X_i$ . We have (as  $n \rightarrow \infty$ )

$$\mathbb{E}[X_i] = n(1/n)(1 - 1/n)^{n-1} \rightarrow e^{-1},$$

$$\mathbb{E}[X_i^2] = \mathbb{E}[X_i], \text{ and for } i \neq i',$$

$$\mathbb{E}[X_i X_{i'}] = n(n-1)(1/n)^2(1 - 2/n)^{n-2} \rightarrow e^{-2}.$$

This means  $\mathbb{E}[X] = (1 + o(1))n/e$  and

$$\begin{aligned} \text{Var}(X) &= \sum_i (\mathbb{E}[X_i^2] - \mathbb{E}[X_i]^2) + \sum_{i \neq i'} (\mathbb{E}[X_i X_{i'}] - \mathbb{E}[X_i] \mathbb{E}[X_{i'}]) \\ &\leq n(1 + o(1))(e^{-1} - e^{-2}) + n(n-1) \cdot o(1) \\ &= o(n^2). \end{aligned}$$

The result now follows by Chebyshev's inequality. ◀

## 5.1 Proof of Theorem 4

The idea of the proof is as follows. First imagine the setting where  $\mu$  is not required to be  $S_n$ -invariant. By using each real number to encode an element of  $F = \mathbb{F}_q$ , we can take  $\nu$  to be the uniform distribution on  $F^n$  and take  $\mu$  to be a random Reed-Solomon codeword in  $F^n$ . Under  $T_\delta \mu$ , the noise operator will corrupt a few symbols (“errors”), but the decoding algorithm can correct these and thus distinguish  $T_\delta \mu$  from  $\nu$ .

In order to have  $S_n$ -invariance, we need to modify the construction. Instead of observing an ordered list  $y = (y_1, \dots, y_n)$  of symbols, we will observe pairs of the form  $(i, y_i)$  (with each pair encoded by a single real number) where  $i$  is a random index. If the same  $i$  value appears in two different pairs, this gives conflicting information; we deal with this by simply throwing it out and treating  $y_i$  as an “erasure” that the code needs to correct. If some  $i$  value does not appear in any pairs, we also treat this as an erasure. The full details are given below.

**Proof of Theorem 4.** Let  $C$  be the length- $n$  code from Proposition 11 with  $k = \lceil \alpha n \rceil$  for some constant  $\alpha \in (0, 1)$  to be chosen later. Fix a scheme by which a real number encodes a tuple  $(j, y)$  with  $j \in [n]$  and  $y \in F = \mathbb{F}_q$ , in such a way that a uniformly random real number in  $[0, 1]$  encodes a uniformly random tuple  $(j, y)$ . More concretely, we can take  $n = q = 2^m$  for some integer  $m \geq 1$ , in which case  $(j, y)$  can be directly encoded using the first  $2m$  bits of the binary expansion of a real number. Under  $x \sim \nu$ , each coordinate  $x_i$  encodes an independent uniformly random tuple  $(j_i, y_i)$ . Under  $\mu$ , let each coordinate  $x_i$  be a uniformly random encoding of  $(j_i, y_i)$ , drawn as follows. Let  $\tilde{c}$  be a uniformly random codeword from  $C$ . Draw  $j_1, \dots, j_n \in [n]$  independently and uniformly. For each  $i$ , if  $j_i$  is a unique index (in the sense that  $j_i \neq j_{i'}$  for all  $i' \neq i$ ) then set  $y_i = \tilde{c}_{j_i}$ ; otherwise choose  $y_i$  uniformly from  $F$ .

Note that  $\mu$  is  $S_n$ -invariant. Since the dual distance of  $C$  is  $k + 2 = \Omega(n)$ , it follows (using Proposition 9) that  $\mu$  is  $\Omega(n)$ -wise independent with respect to  $\nu$ . By choosing  $\delta > 0$  and  $\alpha > 0$  sufficiently small, we can ensure that  $16\delta n + (2n/3 + 4\delta n) < n - k$  and so  $C$  admits efficient decoding from  $8\delta n$  errors and  $2n/3 + 4\delta n$  erasures (see Proposition 11). The algorithm to distinguish  $T_\delta \mu$  and  $\nu$  is as follows. Given a list of  $(j_i, y_i)$  pairs, produce  $c' \in F^n$

by setting  $c'_{j_i} = y_i$  wherever  $j_i$  is a unique index (in the above sense), and setting all other positions of  $c'$  to  $\perp$  (an “erasure”). Let  $S \subseteq [n]$  be the indices  $i$  for which  $c'_i = \perp$ . Run the decoding algorithm on  $c'$ ; if it succeeds and outputs a codeword  $c$  such that  $\Delta_S(c, c') \leq 4\delta n$  then output “ $T_\delta \mu$ ”, and otherwise output “ $\nu$ ”.

We can prove correctness as follows. If the true distribution is  $\nu$  then Lemma 15 guarantees  $|S| \leq 2n/3$  (w.h.p.). Since the non-erased values in  $c'$  are uniformly random, Lemma 14 ensures there is no codeword  $c$  with  $\Delta_S(c, c') \leq 4\delta n$  (w.h.p.), provided we choose  $\delta \leq 1/(96e)$ , and so our algorithm outputs “ $\nu$ ” (w.h.p.).

Now suppose the true distribution is  $T_\delta \mu$ . In addition to the  $\leq 2n/3$  erasures caused by non-unique  $j_i$ ’s sampled from  $\mu$ , each coordinate resampled by  $T_\delta$  can create up to 2 additional erasures and can also create up to 2 errors (i.e., coordinates  $i$  for which  $c'_i \neq \perp$  but  $c'_i \neq \tilde{c}_i$ ). Since at most  $2\delta n$  coordinates get resampled (w.h.p.), this means we have a total of (up to)  $4\delta n$  errors and  $2n/3 + 4\delta n$  erasures. This means decoding succeeds and outputs  $\tilde{c}$  (i.e., the true codeword used to sample  $\mu$ ), and furthermore,  $\Delta_S(\tilde{c}, c') \leq 4\delta n$ . ◀

## 5.2 Proof of Theorem 7

The idea of the proof is similar to the previous proof, and somewhat simpler (since we do not need  $S_n$ -invariance). We take  $\nu$  to be the uniform distribution on binary strings and take  $\mu$  to be the uniform distribution on codewords, using the binary code from Proposition 12. The decoding algorithm is able to correct the errors caused by  $T_\delta$ .

**Proof of Theorem 7.** Let  $C$  be the code from Proposition 12. Each codeword  $c \in C$  is an element of  $\mathbb{F}_2^n$ , which can be identified with  $\{0, 1\}^n = \mathcal{X}^n$ . Let  $\mu$  be the uniform distribution over codewords. Since the dual distance of  $C$  is at least  $\zeta n$ , we have from Proposition 9 that  $\mu$  is  $\Omega(n)$ -wise independent with respect to the uniform distribution  $\nu$ . We also know that  $C$  admits efficient decoding from  $\zeta n/2$  errors.

Let  $\delta = \min\{1/(16e), \zeta/8\}$ . The algorithm to distinguish  $T_\delta \mu$  and  $\nu$ , given a sample  $c'$ , is to run the decoding algorithm on  $c'$ ; if decoding succeeds and outputs a codeword  $c$  such that  $\Delta(c, c') \leq 2\delta n$  then output “ $T_\delta \mu$ ”, and otherwise output “ $\nu$ ”.

We can prove correctness as follows. If  $c'$  is drawn from  $T_\delta \mu$  then  $c'$  is separated from some codeword  $c$  by at most  $2\delta n \leq \zeta n/4$  errors (w.h.p.), and so decoding will find  $c$ . If instead  $c'$  is drawn from  $\nu$  then (since  $\delta \leq 1/(16e)$ ) by Lemma 14, there is no codeword within Hamming distance  $2\delta n$  of  $c'$  (w.h.p.). ◀

## Abstract

*Locally decodable codes* (LDCs) allow any single encoded message symbol to be retrieved from a codeword with good probability by reading only a tiny number of codeword symbols, even if the codeword is partially corrupted. LDCs have surprisingly many applications in computer science and mathematics (we refer to [13, 10] for extensive surveys). But despite their ubiquity, they are poorly understood. Of particular interest is the tradeoff between the codeword length  $N$  as a function of message length  $k$  when the *query complexity*—the number of probed codeword symbols—and alphabet size are constant. The Hadamard code is a 2-query LDC of length  $N = 2^{O(k)}$  and this length is optimal in the 2-query regime [11]. For  $q \geq 3$ , near-exponential gaps persist between the best-known upper and lower bounds. The family of Reed-Muller codes, which generalize the Hadamard code, were for a long time the best-known examples, giving  $q$ -query LDCs of length  $\exp(O(k^{1/(q-1)}))$ , until breakthrough constructions of *matching vector* LDCs of Yekhanin and Efremenko [12, 6].

In contrast with other combinatorial objects such as expander graphs, the probabilistic method has so far not been successfully used to beat the best explicit LDC constructions. In [3], a probabilistic framework was given that could in principle yield best-possible LDCs, albeit non-constructively. A special instance of this framework connects LDCs with a probabilistic version of Szemerédi’s theorem. The setup for this is as follows: For a finite abelian group  $G$  of size  $N = |G|$ , let  $D \subseteq G$  be a random subset where each element is present with probability  $\rho$  independently of all others. For  $k \geq 3$  and  $\varepsilon \in (0, 1)$ , let  $E$  be the event that every subset  $A \subseteq G$  of size  $|A| \geq \varepsilon|G|$  contains a proper  $k$ -term arithmetic progression with common difference in  $D$ . For fixed  $\varepsilon > 0$  and sufficiently large  $N$ , it is an open problem to determine the smallest value of  $\rho$ —denoted  $\rho_k$ —such that  $\Pr[E] \geq \frac{1}{2}$ . In [3] it is shown that there exist  $k$ -query LDCs of message length  $\Omega(\rho_k N)$  and codeword length  $O(N)$ . As such, Szemerédi’s theorem with random differences, in particular lower bounds on  $\rho_k$ , can be used to show the existence of LDCs. Conversely, this connection indirectly implies the best-known upper bounds on  $\rho_k$  for all  $k \geq 3$  [8, 4]. However, a conjecture from [9] states that over  $\mathbb{Z}_N$  we have  $\rho_k \leq O_k(N^{-1} \log N)$  for all  $k$ , which would be best-possible. Truth of this conjecture would imply that over this group, Szemerédi’s theorem with random differences cannot give LDCs better than the Hadamard code. For finite fields, Altman [1] showed that this is false. In particular, over  $\mathbb{F}_p^n$  for  $p$  odd, he proved that  $\rho_3 \geq \Omega(p^{-n} n^2)$ ; generally,  $\rho_k \geq \Omega(p^{-n} n^{k-1})$  holds when  $p \geq k + 1$  [2]. In turn, these bounds are conjectured to be optimal for the finite-field setting, which would imply that over finite fields, Szemerédi’s theorem with random differences cannot give LDCs better than Reed-Muller codes.

The finite-field conjecture is motivated mainly by the possibility that so-called *dual functions* can be approximated well by *polynomial phases*, functions of the form  $e^{2\pi i P(x)/p}$  where  $P$  is a multivariate polynomial over  $\mathbb{F}_p$ . We show that this is false. Using Yekhanin’s matching-vector-code construction, we give dual functions of order  $k$  over  $\mathbb{F}_p^n$  that cannot be approximated in  $L_\infty$ -distance by polynomial phases of degree  $k - 1$ . This answers in the negative a natural finite-field analog of a problem of Frantzikinakis over  $\mathbb{N}$  [7, Problem 1].

## Abstract

We consider a model where an agent has a repeated decision to make and wishes to maximize their total payoff. Payoffs are influenced by an action taken by the agent, but also an unknown state of the world that evolves over time. Before choosing an action each round, the agent can purchase noisy samples about the state of the world. The agent has a budget to spend on these samples, and has flexibility in deciding how to spread that budget across rounds. We investigate the problem of choosing a sampling algorithm that optimizes total expected payoff. For example: is it better to buy samples steadily over time, or to buy samples in batches? We solve for the optimal policy, and show that it is a natural instantiation of the latter. Under a more general model that includes per-round fixed costs, we prove that a variation on this batching policy is a 2-approximation.

## 1 Introduction

The growing demand for machine learning practitioners is a testament to the way data-driven decision making is shaping our economy. Data has proven so important and valuable because so much about the current state of the world is *a priori* unknown. We can better understand the world by investing in data collection, but this investment can be costly; deciding how much data to acquire can be a non-trivial undertaking, especially in the face of budget constraints. Furthermore, the value of data is typically not linear. Machine learning algorithms often see diminishing returns to performance as their training dataset grows [22, 10]. This non-linearity is further complicated by the fact that a data-driven decision approach is typically intended to replace some existing method, so its value is relative to the prior method's performance.

As a motivating example for these issues, consider a politician who wishes to accurately represent the opinion of her constituents. These constituents have a position on a policy, say the allocation of funding to public parks. The politician must choose her own position on the policy or abstain from the discussion. If she states a position, she experiences a disutility that is increasing in the distance of her position from that of her constituents. If she abstains, she incurs a fixed cost for failing to take a stance. To help her make an optimal decision she can hire a polling firm that collects data on the participants' positions.

Leibniz International Proceedings in Informatics

Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

We focus on the dynamic element of this story. In many decision problems, the state of the world evolves over time. In the example above, the opinions of the constituents might change as time passes, impacting the optimal position of the politician. As a result, data about the state of the world becomes stale. Furthermore, many decisions are not made a single time; instead, decisions are made repeatedly. In our example, the politician can update funding levels each fiscal quarter.

When faced with budget constraints on data collection and the issue of data staleness, decisions need to be made about when to collect data and when to save budget for the future, and whether to make decisions based on stale data or apply a default, non-data-driven policy. Our main contribution is a framework that models the impact of such budget constraints on data collection strategies. In our example, the politician has a budget for data collection. A polling firm charges a fixed cost to initiate a poll (e.g., create the survey) plus a fee per surveyed participant. The politician may not have enough budget to hire the firm to survey every constituent every quarter. Should she then survey fewer constituents every quarter? Or survey a larger number of constituents every other quarter, counting on the fact that opinions do not drift too rapidly?

We initiate the study with arguably the simplest model that exhibits this tension. The state of the world (constituents' opinions) is hidden but drawn from a known prior distribution, then evolves stochastically. Each round, the decision-maker (politician) can collect one or more noisy samples that are correlated with the hidden state at a cost affine in the number of samples (conduct a poll). Then she chooses an action and incurs a loss. Should the decision-maker not exhaust her budget in a given round, she can bank it for future rounds. A sampling algorithm describes an online policy for scheduling the collection of samples given the budget and past observations.

We instantiate this general framework by assuming Gaussian prior, perturbations and sample noise.<sup>1</sup> We capture the decisions that need to be made as the problem of estimating the current state value, using the classic squared loss to capture the cost of making a decision using imprecise information. Alternatively, there is always the option to not make a decision based on the data and instead accept a default constant loss. We assume a budget on the number of samples collected per unit time, and importantly this budget can be banked for future rounds if desired.

## 1.1 A Simple Example

To illustrate our technical model, suppose the hidden state (constituents' average opinion) is initially drawn from a mean-zero Gaussian of variance 1. In each round, the state is subject to mean-zero Gaussian noise of variance 1 (the constituents update their opinions), which is added to the previous round's state. Also, any samples we choose to take are also subject to mean-zero Gaussian noise of variance 1 (polls are imperfect). Our budget for samples is 1 per period, and one can either guess at the hidden state (incurring a penalty equal to the squared loss) or pass and take a default loss of  $3/4$ . What is the expected average loss of the policy that takes a single sample each round, and then takes the optimal action? As it turns out, the expected loss is precisely  $\phi - 1 \approx 0.618$ , where  $\phi$  is the golden ratio  $\frac{1+\sqrt{5}}{2}$  (see Section 3.5 for the analysis). However, this is not optimal: saving up the allotted budget and taking

---

<sup>1</sup> A Gaussian prior is justified in our running example if we assume a large population limit of constituents' opinions. That the prior estimate of drift is also Gaussian is likewise motivated as the number of periods grows large. We discuss alternative distributional assumptions on the prior, perturbations and noise in Section 6.

two samples every other round leads to an expected loss of  $\frac{0.75+\sqrt{2}-1}{2} \approx 0.582$ . The intuition behind the improvement is that taking a single sample every round beats the outside option, but not by much; it is better to beat the outside option significantly on even-numbered rounds (by taking 2 samples), then simply use the outside option on odd-numbered rounds. It turns out that one cannot improve on this by saving up for 3 or more rounds to take even more samples all at once. However, one can do better by alternating between taking no samples for two periods and then two samples each for two periods, which results in a long-run average loss of  $\approx 0.576$ .

## 1.2 Our Results

As we can see from the example above, the space of policies to consider is quite large. One simple observation is that since samples become stale over time it is never optimal to collect samples and then take the outside option (i.e., default fixed-cost action) in the same round; it would be better to defer data collection to later rounds where decisions will be made based on data. As a result, a natural class of policies to consider is those which alternate between collecting samples and saving budget. Such “on-off” policies can be thought of as engaging in “data drives” while neglecting data collection the rest of the time.

Our main result is that these on-off policies are asymptotically optimal, with respect to all dynamic policies. Moreover, it suffices to collect samples at a constant rate during the sampling part of the policy’s period. Our argument is constructive, and we show how to compute an asymptotically optimal policy. This policy divides time into exponentially-growing chunks and collects data in the latter end of each chunk.

The solution above assumes that costs are linear in the number of samples collected. We next consider a more general model with a fixed up-front cost for the first sample collected in each round. This captures the costs associated with setting up the infrastructure to collect samples on a given round, such as hiring a polling firm which uses a two-part tariff. Under such per-round costs, it can be suboptimal to sample in sequential periods (as in an on-off policy), as this requires paying the fixed cost twice. For this generalized cost model, we consider simple and approximately optimal policies. When evaluating performance, we compare against a null “baseline” policy that eschews data collection and simply takes the outside option every period. We define the value of a policy to be its improvement over this baseline, so that the null policy has a value of 0 and every policy has non-negative value. While this is equivalent to simply comparing the expected costs of policies this alternative measure is intended to capture how well a policy leverages the extra value obtainable from data; we feel that this more accurately reflects the relative performance of different policies.

We focus on a class of *lazy policies* that collect samples only at times when the variance of the current estimate is worse than the outside option. This class captures a heuristic based on a threshold rule: the decision-maker chooses to collect data when they do not have enough information to gain over the outside option. We show the optimal lazy policy is a  $1/2$ -approximation to the optimal policy. The result is constructive, and we show how to compute an asymptotically optimal lazy policy. Moreover, this approximation factor is tight for lazy policies.

To derive these results, we begin with the well-known fact that the expected loss under the squared loss cost function is the variance of the posterior. We use an analysis based on Kalman filters [23], which are used to solve localization problems in domains such as astronautics [27], robotics [34], and traffic monitoring [36], to characterize the evolution of variance given a sampling policy. We show how to maximize value using geometric arguments and local manipulations to transform an optimal policy into either an on-off policy or a lazy policy, respectively.

We conclude with two extensions. We described our results for a discrete-time model, but one might instead consider a continuous-time variant in which samples, actions, and state evolution occur continuously. We show how to extend all of our results to such a continuous setting. Second, we describe a non-Gaussian instance of our framework, where the state of the world is binary and switches with some small probability each round. We solve for the optimal policy, and show that (like the Gaussian model) it is characterized by non-uniform, bursty sampling.

### 1.3 Other Motivating Examples

We motivated our framework with a toy example of a politician polling his or her constituents. But we note that the model is general and applies to other scenarios as well. For example, suppose a phone uses its GPS to collect samples, each of which provides a noisy estimate of location (reasonably approximated by Gaussian noise). The “cost” of collecting samples is energy consumption, and the budget constraint is that the GPS can only reasonably use a limited portion of the phone’s battery capacity. The worse the location estimate is, the less useful this information is to apps; sufficiently poor estimates might even have negative value. However, as an alternative, apps always have the outside option of providing location-unaware functionality. Our analysis shows that it is approximately optimal to extrapolate from existing data to estimate the user’s location most of the time, and only use the GPS in “bursts” once the noise of the estimate exceeds a certain threshold. Note that in this scenario the app never observes the “ground truth” of the phone’s location. Similarly, our model might capture the problem faced by a firm that runs user studies when deciding which features to include in a product, given that such user studies are expensive to run and preferences may shift within the population of customers over time.

### 1.4 Future Directions

Our results provide insight into the trade-offs involved in designing data collection policies in dynamic settings. We construct policies that navigate the trade-off between cost of data collection and freshness of data, and show how to optimize data collection schedules in a setting with Gaussian noise. But perhaps our biggest contribution is conceptual, in providing a framework in which these questions can be formalized and studied. We view this work as a first step toward a broader study of the dynamic value of data. An important direction for future work is to consider other models of state evolution and/or sampling within our framework, aimed at capturing other applications. For example, if the state evolves in a heavy-tailed manner, as in the non-Gaussian instance explored in Section 6, then we show it is beneficial to take samples regularly in order to detect large, infrequent jumps in state value, and then adaptively take many samples when such a jump is evident. We solve this extension only for a simple two-state Markov chain. Can we quantify the dynamic value of data and find an (approximately) optimal and simple data collection policy in a general Markov chain?

### 1.5 Related work

While we are not aware of other work addressing the value of data in a dynamic setting, there has been considerable attention paid to the value of data in static settings. Arietta-Ibarra et al. [4] argue that the data produced by internet users is so valuable that they should be compensated for their labor. Similarly, there is growing appreciation for the value of the

data produced on crowdsourcing platforms like Amazon Mechanical Turk [6, 20]. Other work has emphasized that not all crowdsourced data is created equal and studied the way tasks and incentives can be designed to improve the quality of information gathered [17, 30]. Similarly, data can have non-linear value if individual pieces are substitutes or complements [8]. Prediction markets can be used to gather information over time, with participants controlling the order in which information is revealed [11].

There is a growing line of work attempting to determine the marginal value of training data for deep learning methods. Examples include training data for classifying medical images [9] and chemical processes [5], as well as for more general problems such as estimating a Gaussian distribution [22]. These studies consider the static problem of learning from samples, and generally find that additional training data exhibits decreasing marginal value. Koh and Liang [25] introduced the use of influence functions to quantify how the performance of a model depends on individual training examples.

While we assume samples are of uniform quality, other work has studied agents who have data of different quality or cost [29, 7, 16]. Another line studies the way that data is sold in current marketplaces [32], as well as proposing new market designs [28]. This includes going beyond markets for raw data to markets which acquire and combine the outputs of machine learning models [33].

Our work is also related to statistical and algorithmic aspects of learning a distribution from samples. A significant body of recent work has considered problems of learning Gaussians using a minimal number of noisy and/or adversarial samples [21, 13, 14, 26, 15]. In comparison, we are likewise interested in learning a hidden Gaussian from which we obtain noisy samples (as a step toward determining an optimal action), but instead of robustness to adversarial noise we are instead concerned about optimizing the split of samples across time periods in a purely stochastic setting.

Our investigation of data staleness is closely related to the issue of concept drift in streaming algorithms; see, e.g., Chapter 3 of [2]. Concept drift refers to scenarios where the data being fed to an algorithm is pulled from a model that evolves over time, so that, for example, a solution built using historical data will eventually lose accuracy. Such scenarios arise in problems of histogram maintenance [18], dynamic clustering [3], and others. One problem is to quantify the amount of drift occurring in a given data stream [1]. Given that such drift is present, one approach to handling concept drift is via sliding-window methods, which limit dependence on old data [12]. The choice of window size captures a tension between using a lot of stale data or a smaller amount of fresh data. However, in work on concept drift one typically cannot control the rate at which data is collected.

Another concept related to staleness is the “age of information.” This captures scenarios where a source generates frequent updates and a receiver wishes to keep track of the current state, but due to congestion in the transmission technology (such as a queue or database locks) it is optimal to limit the rate at which updates are sent [24, 31]. Minimizing the age of information can be captured as a limit of our model where a single sample suffices to provide perfect information. Recent work has examined variants of the model where generating updates is costly [19], but the focus in this literature is more on the management of the congestible resource. Closer to our work, several recent papers have eliminated the congestible resource and studied issues such as an energy budget that is stochastic and has limited storage capacity [37] and pricing schemes for when sampling costs are non-uniform [35, 38]. Relative to our work these papers have simpler models of the value of data and focus on features of the sampling policy given the energy technology and pricing scheme, respectively.

## 2 Model

We first describe our general framework, then describe a specific instantiation of interest in Section 2.1. Time occurs in rounds, indexed by  $t = 1, 2, \dots$ . There is a hidden state variable  $x_t \in \Omega$  that evolves over time according to a stochastic process. The initial state  $x_1$  is drawn from known distribution  $F_1$ . Write  $m_t$  for the (possibly randomized) evolution mapping applied at round  $t$ , so that  $x_{t+1} \leftarrow m_t(x_t)$ .

In every round, the decision-maker chooses an action  $y_t \in A$ , and then suffers a loss  $\ell(y_t, x_t)$  that depends on both the action and the hidden state. The evolution functions ( $m_t$ ) and loss function  $\ell$  are known to the decision-maker, but neither the state  $x_t$  nor the loss  $\ell(y_t, x_t)$  is directly observed.<sup>2</sup> Rather, on each round before choosing an action, the decision-maker can request one or more independent samples that are correlated with  $x_t$ , drawn from a known distribution  $\Gamma(x_t)$ .

Samples are costly, and the decision-maker has a budget that can be used to obtain samples. The budget is  $B$  per round, and can be banked across rounds. A sampling policy results in a number of samples  $s_t$  taken in each round  $t$ , which can depend on all previous observations. The cost of taking  $s_t$  samples in round  $t$  is  $C(s_t) \geq 0$ . We assume that  $C$  is non-decreasing and  $C(0) = 0$ . A sampling policy is *valid* if  $\sum_{t=1}^T C(s_t) \leq B \cdot T$  for all  $T$ . For example,  $C(s_t) = s_t$  corresponds to a cost of 1 per sample, and setting  $C(s_t) = s_t + z \cdot \mathbb{1}_{s_t > 0}$  adds an additional cost of  $z$  for each round in which at least one sample is collected.

To summarize: on each round, the decision-maker chooses a number of samples  $s_t$  to observe, then chooses an action  $y_t$ . Their loss  $\ell(y_t, x_t)$  is then realized, the value of  $x_t$  is updated to  $x_{t+1}$ , and the process proceeds with the next round. The goal is to minimize the expected long-run average of  $\ell(y_t, x_t)$ , in the limit as  $t \rightarrow \infty$ , subject to  $\sum_{t=0}^T C(s_t) \leq B \cdot T$  for all  $T \geq 1$ .

### 2.1 Estimation under Gaussian Drift

We will be primarily interested in the following instantiation of our general framework. The hidden state variable is a real number (i.e.,  $\Omega = \mathbb{R}$ ) and the decision-maker's goal is to estimate the hidden state in each round. The initial state is  $x_1 \sim N(0, \rho)$ , a Gaussian with mean 0 and variance  $\rho > 0$ . Moreover, the evolution process  $m_t$  sets  $x_{t+1} = x_t + \delta_t$ , where each  $\delta_t \sim N(0, \rho)$  independently. We recall that the decision-maker knows the evolution process (and hence  $\rho$ ) but does not directly observe the realizations  $\delta_t$ .

Each sample in round  $t$  is drawn from  $N(x_t, \sigma)$  where  $\sigma > 0$ . Some of our results will also allow fractional sampling, where we think of an  $\alpha \in (0, 1)$  fraction of a sample as a sample drawn from  $N(x_t, \sigma/\alpha)$ .<sup>3</sup> The action space is  $A = \mathbb{R} \cup \{\perp\}$ . If the decision-maker chooses  $y_t \in \mathbb{R}$ , her loss is the squared error of her estimate  $(y_t - x_t)^2$ . If she is too unsure of the state, she may instead take a default action  $y_t = \perp$ , which corresponds to not making a guess; this results in a constant loss of  $c > 0$ . Let  $G_t$  be a random variable whose law

<sup>2</sup> Assuming that the ground truth for  $\ell(y_t, x_t)$  is unobserved captures scenarios like our political example, and approximates settings where the decision maker only gets weak feedback, feedback at a delay, or feedback in aggregate over a long period of time. Observing the loss provides additional information about  $x_{t+1}$ , and this could be considered a variant of our model where the decision-maker gets some number of samples “for free” each round from observing a noisy version of the loss.

<sup>3</sup> One can view fractional sampling as modeling scenarios where the value of any one single sample is quite small; i.e., has high variance, so that a single “unit” of variance is derived from taking many samples. E.g., sampling a single constituent in our polling example. It also captures settings where it is possible to obtain samples of varying quality with different levels of investment.

is the decision maker's posterior after observing whatever samples are taken in round  $t$  as well as all previous samples. The decision maker's subjective expected loss when guessing  $y_t \in \mathbb{R}$  is  $E[(y_t - G_t)^2]$ . This is well known to be minimized by taking  $y_t = E[G_t]$ , and that furthermore the expected loss is  $E[(E[G_t] - G_t)^2] = \text{Var}(G_t)$ . It is therefore optimal to guess  $y_t = E[G_t]$  if and only if  $\text{Var}(G_t) < c$ , otherwise pass.

We focus on deriving approximately optimal sampling algorithms. To do so, we need to track the variance of  $G_t$  as a function of the sampling strategy. As the sample noise and random state permutations are all zero-mean Gaussians,  $G_t$  is a zero-mean Gaussian as well, and the evolution of its variance has a simple form.

► **Lemma 1.** *Let  $v_t$  be the variance of  $G_t$  and suppose each  $\delta_t \sim N(0, \rho)$  independently, and that each sample is subject to zero-mean Gaussian noise with variance  $\sigma$ . Then, if the decision-maker takes  $s$  samples in round  $t + 1$ , the variance of  $G_{t+1}$  is*

$$v_{t+1} = \frac{v_t + \rho}{1 + \frac{s}{\sigma}(v_t + \rho)}.$$

The proof, which is deferred to the full version of the paper along with all other proofs, follows from our model being a special case of the model underlying a Kalman filter.

The optimization problem therefore reduces to choosing a number of samples  $s_t$  to take in each round  $t$  in order to minimize the long-run average of  $\min(v_t, c)$ , the loss of the optimal action. That is, the goal is to minimize  $\limsup_{T \rightarrow \infty} \frac{1}{T} \sum_{t=1}^T \min(v_t, c)$ , where we take the superior limit so that the quantity is defined even when the average is not convergent. We choose  $C(s_t) = s_t + z \cdot \mathbb{1}_{s_t > 0}$ , so this optimization is subject to the budget constraint that, at each time  $T \geq 1$ ,  $\sum_{t=1}^T s_t + z \cdot \mathbb{1}_{s_t > 0} \leq BT$ . This captures two kinds of information acquisition costs faced by the decision-maker. First she faces a cost per sample, which we have normalized to one. Second, she faces a fixed cost  $z$  (which may be 0) on each day she chooses to take samples, expressed in terms of the number of samples that could instead have been taken on some other day had this cost not been paid. This captures the costs associated with setting up the infrastructure to collect samples on a given round, such as getting data collectors to the location where they are needed, hiring a polling firm which uses a two-part tariff, or establishing a satellite connection to begin using a phone's GPS.

A useful baseline performance is the cost of a policy that takes no samples and simply chooses the outside option at all times. We refer to this as the *null policy*. The *value* of a sampling policy  $s$ , denoted  $\text{Val}(s)$ , is defined to be the difference between its cost and the cost of the null policy:  $\liminf_{T \rightarrow \infty} \frac{1}{T} \sum_{t=1}^T \max(c - v_t, 0)$ . Note that maximizing value is equivalent to minimizing cost, which we illustrate in Section 3.1. We say that a policy is  $\alpha$ -approximate if its value is at least an  $\alpha$  fraction of the optimal policy's value.

### 3 Analyzing Variance Evolution

Before moving on to our main results, we show how to analyze the evolution of the variance resulting from a given sampling policy. We first illustrate our model with a particularly simple class of policies: those where  $s_t$  takes on only two possible values. We then analyze arbitrary periodic policies, and show via contraction that they result in convergence to a periodic variance evolution.

#### 3.1 Visualizing the Decision Problem

To visualize the problem, we begin by plotting the result of an example policy where the spending rate is constant for some interval of rounds, then shifts to a different constant spending rate. Figure 1 illustrates one such policy. The spending rates are indicated as

■ **Figure 1** The variance for a piecewise-constant sampling policy, and its loss and benefit.

alternating line segments, while the variance is an oscillating curve, always converging toward the current spending rate. Note that this particular policy is periodic, in the sense that the final variance is the same as the initial variance. The horizontal line gives one possible value for the cost of the outside option. Given this, the optimal policy is to guess whenever the orange curve is below the green line and take the outside option whenever it is above it. Thus, the loss associated with this spending policy is given by the orange shaded area in Figure 1. Minimizing this loss is equivalent to maximizing the green shaded area, which corresponds to the value of the spending policy. The null policy, which takes no samples and has variance greater than  $c$  always (possibly after an initial period if  $v_0 < c$ ), has value 0.

### 3.2 Periodic Policies

We next consider policies that are periodic. A *periodic policy* with period  $R$  has the property that  $s_t = s_{t+R}$  for all  $t \geq 1$ . Such policies are natural and have useful structure. In a periodic policy, the variance ( $v_t$ ) converges uniformly to being periodic in the limit as  $t \rightarrow \infty$ . This follows because the impact of sampling on variance is a contraction map.

► **Definition 2.** Given a normed space  $X$  with norm  $\|\cdot\|$ , a mapping  $\Psi: X \rightarrow X$  is a contraction map if there exists a  $k < 1$  such that, for all  $x, y \in X$ ,  $\|\Psi(x) - \Psi(y)\| \leq k\|x - y\|$ .

► **Lemma 3.** Fix a sampling policy  $s$ , and a time  $R \geq 1$ , and suppose that  $s$  takes a strictly positive number of samples in each round  $t \leq R$ . Let  $\Psi$  be the mapping defined as follows: supposing that  $v_0 = x$  and  $v$  is the variance function resulting from sampling policy  $s$ , set  $\Psi(x) := v_R$ . Then  $\Psi$  is a contraction map over the non-negative reals, under the absolute value norm.

The proof appears in the full version of the paper. It is well known that a contraction map has a unique fixed point, and repeated application will converge to that fixed point. Since we can view the impact of the periodic sampling policy as repeated application of mapping  $\Psi$  to the initial variance in order to obtain  $v_0, v_R, v_{2R}, \dots$ , we conclude that the variance will converge uniformly to a periodic function for which  $v_t = v_{t+R}$ . Thus, for the purpose of evaluating long-run average cost, it will be convenient (and equivalent) to replace the initial condition on  $v_0$  with a periodic boundary condition  $v_0 = v_R$ , and then choose  $s$  to minimize the average cost over a single period,  $\frac{1}{R} \int_0^R \min\{v_t, c\} dt$ , subject to the budget constraint that, at any round  $T \leq R$ , we have  $\sum_{t=1}^T s_t \leq BT$ .

### 3.3 Lazy Policies

Write  $\tilde{v} = v_{t-1} + \rho$  for the variance that would be obtained in round  $t$  if  $s_t = 0$ . We say that a policy is *lazy* if  $s_t = 0$  whenever  $\tilde{v}_t < c$ . That is, samples are collected only at times where the variance would otherwise be at or above the outside option value  $c$ . Intuitively, we can

think of such a policy as collecting a batch of samples in one round, then “free-riding” off of the resulting information in subsequent rounds. The free-riding occurs until the posterior variance grows large enough that it becomes better to select the outside option, at which point the policy may collect another batch of samples.

If a policy is lazy, then its variance function  $v$  increases by  $\rho$  whenever  $\tilde{v}_t < c$ , with downward steps only at times corresponding to when samples are taken. Furthermore, the value of such a policy decomposes among these sampling instances: for any  $t$  where  $s_t > 0$ , resulting in a variance of  $v_t < c$ , if we write  $h = \lfloor c - v_t \rfloor$  then we can attribute a value of  $\frac{1}{2}h(h+1) + (h+1)(c - v_t - h)$ . Geometrically, this is the area of the “discrete-step triangle” formed between the increasing sequence of variances  $v_t$  and the constant line at  $c$ , over the time steps  $t, \dots, t+h+1$ .

### 3.4 On-Off Policies

An On-Off policy is a periodic policy parameterized by a time interval  $T$  and a sampling rate  $S$ . Roughly speaking, the policy alternates between intervals where it samples at a rate of  $S$  each round, and intervals where it does not sample. The two interval lengths sum to  $T$ , and the length of the sampling interval is set as large as possible subject to budget feasibility. More formally, the policy sets  $s_t = 0$  for all  $t \leq (1 - \alpha) \cdot T$ , where  $\alpha = \min\{B/S, 1\} \in [0, 1]$  and  $s_t = S$  for all  $t$  such that  $(1 - \alpha)T < t \leq T$ . This policy is then repeated, on a cycle of length  $T$ . The fraction  $\alpha$  is chosen to be as large as possible, subject to the budget constraint.

### 3.5 Simple Example Revisited

We can now justify the simple example we presented in the introduction, where  $\rho = \sigma = 1$ ,  $B = 1$ , and  $c = 0.75$ . The policy that takes a single sample each round is periodic with period 1, and hence will converge to a variance that is likewise equal each round. This fixed point variance,  $v^*$ , satisfies  $v^* = \frac{v^*+1}{1+(v^*+1)}$  by Lemma 1. Solving for  $v^*$  yields  $v^* = \frac{\sqrt{5}-1}{2} < 0.75$ , which is the average cost per round.

If instead the policy takes  $k$  samples every  $k$  rounds, this results in a variance that is periodic of period  $k$ . After the round in which samples are taken, the fixed-point variance satisfies  $v^* = \frac{v^*+k}{1+k(v^*+k)}$ , again by Lemma 1. Solving for  $v^*$ , and noting that  $v^* + 1 \geq 1 > c$ , yields that the cost incurred by this policy is minimized when  $k = 2$ .

To solve for the policy that alternates between taking no samples for two round, followed by taking two samples on each of two rounds, suppose the long-run, periodic variances are  $v_1, v_2, v_3, v_4$ , where samples are taken on rounds 3 and 4. Then we have  $v_2 = v_1 + 1$ ,  $v_3 = \frac{v_2+1}{1+2(v_2+1)}$ ,  $v_4 = \frac{v_3+1}{1+2(v_3+1)}$ , and  $v_1 = v_4 + 1$ . Combining this sequence of equations yields  $4v_1^2 + 4v_1 - 13 = 0$ , which we can solve to find  $v_1 = \frac{-1+\sqrt{14}}{2} \approx 1.3708$ . Plugging this into the equations for  $v_2, v_3, v_4$  and taking the average of  $\min\{v_i, 0.75\}$  over  $i \in \{1, 2, 3, 4\}$  yields the reported average cost of  $\approx 0.576$ .

## 4 Solving for the Optimal Policy

In this section we show that when the cost of sampling is linear in the total number of samples taken (i.e.,  $z = 0$ )<sup>4</sup>, and when fractional sampling is allowed, then the supremum value over all on-off policies is an upper bound on the value of any policy. This supremum

<sup>4</sup> Recall that  $z$  is the fixed per-round cost of taking a positive number of samples. Even when  $z = 0$ , there is still a positive per-sample cost.

is achieved in the limit as the time interval  $T$  grows large. So, while no individual policy achieves the supremum, one can get arbitrarily close with an on-off policy of sufficiently long period. Proofs appear in the full version of the paper.

We begin with some definitions. For a given period length  $T > 0$ , write  $s^T$  for the on-off policy of period  $T$  with optimal long-run average value. Recall  $\text{Val}(s^T)$  is the value of policy  $s^T$ . We first argue that larger time horizons lead to better on-off policies.

► **Lemma 4.** *With fractional samples, for all  $T > T'$ , we have  $\text{Val}(s^T) > \text{Val}(s^{T'})$ .*

Write  $V^* = \sup_{T \rightarrow \infty} \text{Val}(s^T)$ . Lemma 4 implies that  $V^* = \lim_{T \rightarrow \infty} \text{Val}(s^T)$  as well. We show that no policy satisfying the budget constraint can achieve value greater than  $V^*$ .

► **Theorem 5.** *With fractional samples, the value of any valid policy  $s$  is at most  $V^*$ .*

The proof of Theorem 5 proceeds in two steps. First, for any given time horizon  $T$ , it is suboptimal to move from having variance below the outside option to above the outside option; one should always save up budget over the initial rounds, then keep the variance below  $c$  from that point onward. This follows because the marginal sample cost of reducing variance diminishes as variance grows, so it is more sample-efficient to recover from very high variance once than to recover from moderately high variance multiple times.

Second, one must show that it is asymptotically optimal to keep the variance not just below  $c$ , but uniform. This is done by a potential argument, illustrating that a sequence of moves aimed at “smoothing out” the sampling rate can only increase value and must terminate at a uniform policy. The difficulty is that a sample affects not only the value in the round it is taken, but in all subsequent rounds. We make use of an amortization argument that appropriately credits value to samples, and use this to construct the sequence of adjustments that increase overall value while bringing the sampling sequence closer to uniform in an appropriate metric.

We also note that it is straightforward to compute the optimal on-off policy for a given time horizon  $T$ , by choosing the sampling rate that maximizes [value per round]  $\times$  [fraction of time the policy is “on”]. One can implement a policy whose value asymptotically approaches  $V^*$  by repeated doubling of the time horizon. Alternatively, since  $\lim_{T \rightarrow \infty} \text{Val}(s^T) = V^*$ ,  $s^T$  will be an approximately optimal policy for sufficiently large  $T$ .

## 5 Approximate Optimality of Lazy Policies

In the previous section we solved for the optimal policy when  $z = 0$ , meaning that there is no fixed per-round cost when sampling. We now show that for general  $z$ , lazy policies are approximately optimal, obtaining at least  $1/2$  of the value of the optimal policy. Proofs appear in the full version of the paper.

We begin with a lemma that states that, for any valid sampling policy and any sequence of timesteps, it is possible to match the variance at those timesteps with a policy that only samples at precisely those timesteps, and the resulting policy will be valid.

► **Lemma 6.** *Fix any valid sampling policy  $s$  (not necessarily lazy) with resulting variances  $(v_t)$ , and any sequence of timesteps  $t_1 < t_2 < \dots < t_\ell < \dots$ . Then there is a valid policy  $s'$  such that  $\{t \mid s'_t > 0\} \subseteq \{t_1, \dots, t_\ell, \dots\}$ , resulting in a variances  $(\check{v}_t)$  with  $\check{v}_{t_i} \leq v_{t_i}$  for all  $i$ .*

The intuition is that if we take all the samples we would have spent between timesteps  $t_\ell$  and  $t_{\ell+1}$  and instead spend them all at  $t_{\ell+1}$  the result will be a (weakly) lower variance at  $t_{\ell+1}$ . We next show that any policy can be converted into a lazy policy at a loss of at most half of its value.

■ **Figure 2** Visualizing the construction in the proof of Theorem 7. Variance (vertical) is plotted against time (horizontal). We approximate the value of an optimal policy’s variance (orange) given  $c$  (green). The squares (drawn in blue) cover the gap between the curves, except possibly when  $|v_t - c| < \epsilon$  (for technical reasons). The lazy policy samples on rounds corresponding to the left edge of each square, bringing the variance to each square’s bottom-left corner.

► **Theorem 7.** *The optimal lazy policy is  $1/2$ -approximate.*

See Figure 2 for an illustration of the intuition behind the result. Consider an arbitrary policy  $s$ , with resulting variance sequence  $(v_t)$ . Imagine covering the area between  $(v_t)$  and  $c$  with squares, drawn left to right with their upper faces lying on the outside option line, each chosen just large enough so that  $v_t$  never falls below the area covered by the squares. The area of the squares is an upper bound on  $\text{Val}(s)$ . Consider a lazy policy that drops a single atom on the left endpoint of each square, bringing the variance to the square’s lower-left corner. The value of this policy covers at least half of each square. Moreover, Lemma 6 implies this policy is (approximately) valid, as it matches variances from the original policy, possibly shifted early by a constant number of rounds. This shifting can introduce non-validity; we fix this by delaying the policy’s start by a constant number of rounds without affecting the asymptotic behavior.

The factor  $1/2$  in Theorem 7 is tight. To see this, fix the value of  $c$  and allow the budget  $B$  to grow arbitrarily large. Then the optimal value tends to  $c$  as the budget grows, since the achievable variance on all rounds tends to 0. However, the lazy policy cannot achieve value greater than  $c/2$ , as this is what would be obtained if the variance reached 0 on the rounds on which samples are taken.

Finally, while this result is non-constructive, one can compute a policy whose value approaches an upper bound on the optimal lazy policy, in a similar manner to the optimal on-off policy. One can show the best lazy policy over any finite horizon has an “off” period (with no sampling) followed by an “on” period (where  $v_t \leq c$ ). One can then solve for the optimal number of samples to take whenever  $\tilde{v}_t > c$  by optimizing either value per unit of (fixed plus per-sample) sampling cost, or by fully exhausting the budget, whichever is better. Details appear in the full version of the paper.

## 6 Extensions and Future Directions

We describe two extensions of our model in the appendix. First, we consider a continuous-time variant where samples can be taken continuously subject to a flow cost, in addition to being requested as discrete atoms. The decision-maker selects actions continuously, and aims to minimize loss over time. All of our results carry forward to this continuous extension.

Second, returning to discrete time, we consider a non-Gaussian instance of our framework.

**Figure 3** Simulating the optimal policy for the non-Gaussian extension. The round number is on the horizontal axis. The hidden state of the world is binary and evolves stochastically (blue). The optimal policy tracks a posterior distribution over the hidden state (red), and takes samples in order to maintain a tuned level of certainty (dashed green). Note that most rounds have only a small number of samples, with occasional spikes triggered adaptively in response to uncertainty.

In this model, there is a binary hidden state of the world, which flips each round independently with some small probability  $\epsilon > 0$ . The decision-maker's action in each round is to guess the hidden state of this simple two-state Markov process, and the objective is to maximize the fraction of time that this guess is made correctly. Each sample is a binary signal correlated with the hidden state, matching the state of the world with probability  $\frac{1}{2} + \delta$  where  $\delta > 0$ . The decision-maker can adaptively request samples in each round, subject to the accumulating budget constraint, before making a guess.

In this extension, as in our Gaussian model, the optimal policy collects samples non-uniformly. In fact, the optimal policy has a simple form: it sets a threshold  $\theta > 0$  and takes samples until the entropy of the posterior distribution falls below  $\theta$ . Smaller  $\theta$  leads to higher accuracy, but also requires more samples on average, so the best policy will set  $\theta$  as low as possible subject to the budget constraint. Notably, the result of this policy is that sampling tends to occur at a slow but steady rate, keeping the entropy around  $\theta$ , except for occasional spikes of samples in response to a perceived change in the hidden state. See Figure 3 for a visualization of a numerical simulation with a budget of 6 samples (on average) per round.

More generally, whenever the state evolves in a heavy-tailed manner, it is tempting to take samples regularly in order to detect large, infrequent jumps in state value, and then adaptively take many samples when such a jump is evident. This simple model is one scenario where such behavior is optimal. More generally, can we quantify the dynamic value of data and find an (approximately) optimal data collection policy for more complex Markov chains, or other practical applications?

## Abstract

Peer prediction mechanisms incentivize agents to truthfully report their signals even in the absence of verification by comparing agents' reports with those of their peers. In the detail-free multi-task setting, agents are asked to respond to multiple independent and identically distributed tasks, and the mechanism does not know the prior distribution of agents' signals. The goal is to provide an  $\epsilon$ -strongly truthful mechanism where truth-telling rewards agents "strictly" more than any other strategy profile (with  $\epsilon$  additive error) even for heterogeneous agents, and to do so while requiring as few tasks as possible.

We design a family of mechanisms with a scoring function that maps a pair of reports to a score. The mechanism is strongly truthful if the scoring function is "prior ideal". Moreover, the mechanism is  $\epsilon$ -strongly truthful as long as the scoring function used is sufficiently close to the ideal scoring function. This reduces the above mechanism design problem to a learning problem – specifically learning an ideal scoring function. Because learning the prior distribution is sufficient (but not necessary) to learn the scoring function, we can apply standard learning theory techniques that leverage side information about the prior (e.g., that it is close to some parametric model). Furthermore, we derive a variational representation of an ideal scoring function and reduce the learning problem into an empirical risk minimization.

We leverage this reduction to obtain very general results for peer prediction in the multi-task setting. Specifically,

**Sample Complexity.** We show how to derive good bounds on the number of tasks required for different types of priors—in some cases exponentially improving previous results. In particular, we can upper bound the required number of tasks for parametric models with bounded learning complexity. Furthermore, our reduction applies to myriad continuous signal space settings. To the best of our knowledge, this is the first peer-prediction mechanism on continuous signals designed for the multi-task setting.

**Connection to Machine Learning.** We show how to turn a soft-predictor of an agent's signals (given the other agents' signals) into a mechanism. This allows the practical use of machine learning algorithms that give good results even when many agents provide noisy information.

**Stronger Properties.** In the finite setting, we obtain  $\epsilon$ -strongly truthful mechanisms for any stochastically relevant prior. Prior works either only apply to more restrictive settings, or achieve a weaker notion of truthfulness (informed truthfulness).

## 1 Introduction

Peer prediction is the problem of information elicitation without verification. Peer prediction mechanisms exploit the interdependence in agents' signals to incentive agents to report their private signal truthfully even when the reports cannot be directly verified. In *the multi-task setting* [5], each agent is asked to respond to multiple, independent tasks. For example:

► **Example 1 (Commute time).** We can collect data from drivers to estimate the commute time of a certain route. Each driver's daily commute time might be modeled in the following way: each day, the route has an expected time generated from a Gaussian distribution, and each driver's commute time is the expected time perturbed by independently distributed Gaussian noise.

Peer prediction from strategic agents has been attracting a surge of interest in economics and computer science. Several previous works [1, 16, 19] can be understood as using particular learning algorithms to learn nice payment functions that capture the interdependence in agents' reports. In this paper, we decouple these two components: mechanism design and learning algorithms. This framework provides a clean black-box reduction from learning algorithms to peer prediction mechanism.

One advantage of our framework is that we can use results from machine learning about complexity of learning parameters of priors to obtain bounds on the sample complexity (number of tasks required) of our mechanism. For instance, using our reduction, we can easily exponentially improve the required number of tasks in the previous work [28].

Two features of our mechanisms enable us to work in more complicated settings. First, our mechanisms use mutual information to pay agents. This allows us to use aggregation algorithms and pay an agent the mutual information between her reports and the aggregated outcome of the other agents. For example, suppose the agents' report's average quality is low, and a large fraction of agents report random noise. In that case, we can use aggregation to enhance the signal to noise ratio and provide a robust incentive to strategic workers. The second feature of our mechanisms is a variational formulation, which ensures one-sided error such that we can only underestimate the mutual information but not overestimate it. Thus, we can use deep learners or other rich enough functions to learn a good payment in practice.

In addition to the above contributions, we also improve previous work in two axes: the *truthfulness guarantee* and the *prior assumption*.

The truthful guarantee explains *how good the truth-telling strategy is in the mechanism* (formally defined in Sect.2.1). Is truth-telling always the best response regardless of other's strategy (dominantly truthful)? Or is truth-telling a Bayesian Nash equilibrium in which agents receive strictly higher payment than any other non-permutation equilibrium (strongly truthful) where a permutation equilibrium is one where agents report a permutation of the signals? A slightly weaker property is *informed truthful* where no strategy profile pays strictly more than truth-telling, and truth-telling pays more than any uninformative equilibrium. Our pairing mechanisms is dominantly truthful if the number of tasks is infinite and approximately strongly truthful when the number of tasks is finite.

Another axis upon which to measure a peer prediction mechanism's performance is its assumption on the prior of agents' signals. There are two motivations to understand how general the prior can be. First, in practice, we need a peer prediction mechanism that works for general settings, e.g., continuous signals in the aforementioned commute time example. Second, a mechanism's prior assumption often reveals why the mechanism works. Thus, improving prior assumptions can push our theoretical understanding of peer prediction mechanisms.

It is well-known that a necessary condition for the truth-telling strategy profile to be a strict Bayesian Nash equilibrium is that agents' signals need to be *stochastic relevant* (Definition 5) [32]. However, when is stochastic relevance a sufficient condition? Previous multi-task peer prediction mechanisms make ad hoc assumptions on agents' private signals (positively correlated [5], fine-grained [16], strictly correlated [11], or latent variable models [19]) which are discussed in Sect. 2.2. This restricts the settings in which they can be used. Moreover, all the above mechanisms only work when agents' signals are in a finite space<sup>1</sup>.

In this paper, we show stochastic relevance is also a sufficient condition in the multi-tasks setting. Our pairing mechanisms are approximately-strongly truthful as long as the prior is stochastic relevant. In particular, the space of agents' signals can be countably infinite or even continuous. To the authors' knowledge, our mechanism is the first (detail-free) multi-task mechanism that works all stochastically relevant priors.

Besides the above properties, we also require our mechanisms 1) are *minimal* which only elicit the agents' signals and no additional information; 2) are *detail-free* which do not require foreknowledge of the prior; and 3) have *low sample number*, where each agent only needs to answer a few questions for the mechanism to achieve approximately strong truthfulness.

**Our Techniques.** Prior work [16] has shown that paying agents according to the  $\Phi$  mutual information (a generalization of the Shannon mutual information) between their signals is a good idea. This is because, if agents try to strategically manipulate their signals, the  $\Phi$  mutual information can only decrease. However, a key open question is how to compute the mutual information while having access to only a few signals for each agent. Moreover, the computation needs to be done in a way that maintains the incentive guarantees of the mechanism.

We solve this issue. First, we convert the mechanism design problem into an optimization problem (Theorem 16). The  $\Phi$  mutual information of a pair of random variables can be defined as the  $\Phi$  divergence between two distributions: the joint distribution and the product of marginal distributions. The  $\Phi$  divergence is just a measure of distance between the two distributions and contains the KL-divergence as a special case. The problem of computing the  $\Phi$  divergence, using variational representation as a bridge, can be changed into the optimization problem of finding the best “distinguisher” between these two distributions. We call such a distinguisher a *scoring function*. The optimal scoring function (distinguisher) can differentiate the two distributions with a score equal to the  $\Phi$  divergence, whereas any other scoring function (distinguisher) yields a lower score. Thus, once one has this optimal scoring function, estimating the  $\Phi$  divergence (and hence  $\Phi$  mutual information) is easy – just compute its score. In this paper we call the optimal scoring function for a particular prior  $P$ , the  $(P, \Phi)$ -ideal scoring function which can be easily computed when the prior  $P$  is known.

Our mechanism will reward agents according to some scoring function. Importantly, agents' ex-ante payments under prior  $P$  are maximized when *both* the distinguisher used is the  $(P, \Phi)$ -ideal scoring function, and the agents are truth-telling. Consequently, if we already have the  $(P, \Phi)$ -ideal scoring function, the mechanism incentivizes truthful reporting. Additionally, agents will receive a smaller payout if the mechanism fails to find the optimal scoring function. Thus agents are naturally incentivized to aid the mechanism in finding it and cannot gain by deceiving the mechanism into using a suboptimal scoring function.

---

<sup>1</sup> Discretization approach is not practical in most situations. See [17] for more discussion.

Compared with Kong and Schoenebeck [16], our variational characterization provides a better truthfulness guarantee when the number of tasks is finite. We can uniformly upper bound the ex-ante payments under any non-truthful strategy profile (Definition 4) even when the learning algorithm cannot estimate the ideal scoring functions under those non-truthful strategies. This property is vital for continuous signal spaces where agents may adversarially adopt the worst possible strategy profiles to compromise the learning algorithm.

The above observations transform the problem from designing a mechanism to simply learning the  $(P, \Phi)$ -ideal scoring function given samples from a prior. We provide two algorithms to learn the scoring function. The first one is a *generative* approach which estimates the whole density function of the prior and computes a scoring function from it. In a *discriminative* approach, we formulate the estimation of the ideal scoring function as a convex optimization problem, empirical risk minimization [22], and estimate the scoring function directly. This latter approach allows us to use state-of-art convex optimization solvers to estimate good scoring functions.

**Our Contributions.** In this paper, we leverage the above insights to design a  $\Phi$ -pairing mechanism that is minimal and detail-free for heterogeneous agents. In particular:

**Sample Complexity.** We show how to derive good bounds on the number of tasks required for different types of priors—in some cases exponentially improving previous results. In particular, we can upper bound the required number of tasks for parametric models with bounded learning complexity (as measured by a continuous analog of the VC dimension). Furthermore, our reduction applies to myriad continuous signal space settings. To the best of our knowledge, this is the first peer-prediction mechanism on continuous signals designed for the multi-question setting.

**Connections to Machine Learning.** In this paper, we discuss how to convert information elicitation design into three learning problems. 1) The first one is a *generative* approach which estimates the whole density function of the prior and computes a scoring function from it. 2) We formulate the estimation of the ideal scoring function as a convex optimization problem, empirical risk minimization, and estimate the scoring function directly. 3) Finally, we show how to turn a soft-predictor of an agent’s signals (given the other agents’ signals) into a mechanism. This allows the practical use of machine learning algorithms that give good results even when many agents provide noisy information.

**Stronger Properties.** In the finite setting, we obtain  $\epsilon$ -strongly truthful mechanisms for any stochastically relevant prior. Prior works either only apply to more restrictive settings [11], or achieve a weaker notion of truthfulness (informed truthfulness) [28, 1].

## 1.1 Related Work

**Multi-task setting.** In the multi-task setting, Dasgupta and Ghosh [5] propose a *strongly truthful* mechanism when the signal space is binary and every pair of agents’ signals are assumed to be positively correlated. Both Kong and Schoenebeck [16] and Shnayder et al. [28] independently generalize Dasgupta and Ghosh [5] to discrete signal spaces, though in different manners illustrated as follows.

Kong and Schoenebeck [16] present the  $\Phi$ -**mutual information mechanism**, a multi-task peer prediction mechanism for the finite signal space setting with arbitrary interdependence between signals. Unfortunately, the sample number is infinite. They show that their mechanism is strongly truthful as long as the prior is “fine-grained” where, roughly speaking, no two signals can be interpreted as different names for the same signal. To define their mechanism they introduce the notion of  $\Phi$ -mutual information (of which Shannon mutual

information is a special case) where  $\Phi$  is any convex function. Their mechanism pays each agent the  $\Phi$ -mutual information between her reports and the reports of another randomly chosen agent. Strategic behavior is shown to not increase  $\Phi$ -mutual information by a generalized version of the data processing inequality. Unfortunately, their analysis requires infinite sample number to measure this  $\Phi$ -mutual information and does not handle errors in estimation.

Shnayder et al. [28] introduce the **Correlated Agreement (CA) mechanism** which also generalizes Dasgupta and Ghosh [5] to any finite signal space. On the one hand, the CA mechanism can assume the knowledge of the “signal structure” (which tells which signals are positively and negatively correlated). In this case they can provide a mechanism that is truthful with sample number of two.<sup>2</sup> On the other hand, when agents are homogeneous the CA mechanism can learn the signal structure, albeit with some chance of error. The CA mechanism is shown to be robust to this error, and is  $\epsilon$ -informed truthful (a slightly weaker notion than strongly truthful). Agarwal et al. [1] extend the above work [28] to a particular setting of heterogeneous agents where agents are (close to) one of a fixed number of types. They establish a  $O(n)$  sample number in this new setting where  $n$  is the number of agents.

Note that in the above works, a new robustness (error) analysis is required for each different setting of interdependence between signals. Interestingly, the CA mechanism can be viewed as a special case of the aforementioned  $\Phi$ -mutual information mechanism using the total variation distance mutual information (i.e.,  $\Phi(a) = |a - 1|/2$ ). However, instead of directly computing this mutual information, the CA mechanism obtains a consistent estimator of it [16]. Similarly, in the special case that our mechanism implements the total variation distance, we also recover the CA mechanism. However, our analysis is entirely different.

Kong [11] shows an elegant way of obtaining strongly truthful mechanisms (DMI mechanism) for the multitask setting. Our results are incommensurate with these results. In our results, the sample complexity grows with the  $\epsilon$  in the desired  $\epsilon$ -strongly truthful guarantee but is independent of the number of signals. In Kong [11], there is an exact strongly truthful guarantee but sample complexity grows in the size of the signal space. However, the prior structure needs to be strictly correlated, which is a stronger assumption than stochastic relevance. We provide a comparison in Table 1 and Sect. 2.2. In particular, her mechanism requires all agents’ report spaces are finite and have the same size. This restricts the application of an aggregation algorithm (as mentioned in the introduction and Sect. 7).

<sup>2</sup> The original paper shows it requires 3, but it actually only needs 2 tasks.

**Single task setting.** In general, agents do not (necessarily) have multiple identical and independent signals. Without this property, most of the mechanisms require knowledge of a common prior (not detail-free) or for agents to report their whole posterior distribution of other’s signals (not minimal). The later solution is especially difficult to apply to complicated signal spaces (e.g. asking agents to report their probability density function of others’ continuous signals).

Miller et al. [20] introduce the peer prediction mechanism which is the first mechanism that has truth-telling as a strict Bayesian Nash equilibrium and does not need verification. However, their mechanism requires the full knowledge of the common prior and there exist some equilibria that are paid more than truth-telling. In particular, the oblivious equilibrium pays strictly more than truth-telling. Kong et al. [12] modify the original peer prediction mechanism such that truth-telling pays strictly better than any other equilibrium but still requires the full knowledge of the common prior. Prelec [23] designs the first detail-free peer prediction mechanism – Bayesian truth serum (BTS) in the one question setting. Several other works study the one-question setting of BTS [24, 25, 31, 14, 27]. For continuous signals, Radanovic and Faltings [25] apply a discretization approach and use a new payment method, but that is also non-minimal. Goel and Faltings [10] work on a mixture of normal distributions with an infinite number of agents.

**Miscellany.** Liu and Chen [18] design a peer prediction mechanism where each agents’ responses are not compared to another agents’, but rather the output of a machine learning classifier that learns from all the other agents’ responses. Liu and Chen [19] design a non-minimal approximate dominant strategy mechanism that uses surrogate loss functions as tools to correct for the mistakes in agents’ reports. Kong and Schoenebeck [15] studies the related goal for forecast elicitation, and like the present work uses Fenchel’s duality to reward truth-telling (though in a different manner).

One interesting, but orthogonal, line of work looks at “cheap” signals, where agents can coordinate on less useful information. For example, instead of grading an assignment based on correctness, a grader could only spot check the grammar. Gao et al. [9] introduces the issue, while Kong and Schoenebeck [13] shows a partial solution using conditional mutual information.

The recent book [7] surveys additional results from this area.

## 1.2 Structure of Paper

Sect. 2 introduces some basic notions. In particular, Sect. 2.2 defines scoring functions, which will play an important role in this paper.

At the beginning of Sect. 3, we define a central component of our  $\Phi$ -pairing mechanism, Mechanism 1, which takes agents’ report and a scoring function  $K$  as input. In Sect. 4, we consider the full information setting. We show, in the Mechanism 1 with an ideal scoring function, agents are incentivized to report their signals truthfully. In Sect. 5, we prove Theorem 11, and main technical lemmas. In Sect. 6, we define a notion of approximation of an ideal scoring function and introduce our framework that reduces the mechanism problem for information elicitation to a learning problem for an ideal scoring function (Theorem 16). In Sect. 6.3, we focus on the learning problem introduced in Sect. 6. We first show two sufficient conditions for approximating an ideal scoring function in Sect. 6.3.1. Then, we present two algorithms to derive approximately ideal scoring functions from agents’ reports in Sect. 6.3.2.

In Sect. 7, we generalize Mechanism 1 to more than two agents. We show how machine learning techniques can be naturally integrated with our mechanism.

## 2 Preliminaries

We use  $(\Omega, \mathcal{F}, \mu)$  to denote a measure space where  $\mathcal{F}$  is a  $\sigma$ -algebra on the outcome space  $\Omega$  and  $\mu$  is a measure. Let  $\Delta_\Omega$  denote the set of distributions of over  $(\Omega, \mathcal{F})$ ,<sup>3</sup> and  $\mathcal{P}$  as a subset of distributions in  $\Delta_\Omega$ . Given a distribution  $P$ , we also use  $P$  to denote the density function where  $P(\omega)$  is the probability density of outcome  $\omega \in \Omega$ . We use uppercase for a random object  $X$  and lowercase for the outcome  $x$ . In this paper we consider  $\Phi$  to be a convex continuous function and use  $\text{dom}(\Phi)$  to denote its domain.

### 2.1 Mechanism Design for Information Elicitation

For simplicity we first consider two agents, Alice and Bob, who work on a set of  $m$  tasks denoted as  $[m]$ . For each task  $s \in [m]$ , Alice receives a signal  $x_s$  in  $\mathcal{X}$  and Bob a signal  $y_s$  in  $\mathcal{Y}$ . We use  $(\mathbf{X}, \mathbf{Y}) \in (\mathcal{X} \times \mathcal{Y})^m$  to denote the *signal profile* of Alice and Bob which is generated from a prior distribution  $\mathbb{P}$ . In this paper, we make the following assumption:

► **Assumption 2** (A priori similar tasks [5]).  *$\mathbb{P}$  is a prior, and each task is identically and independently (i.i.d.) generated: there exists a distribution  $P_{X,Y}$  over  $\mathcal{X} \times \mathcal{Y}$  such that  $\mathbb{P} = P_{X,Y}^m$ . Moreover, we assume the marginal distributions have full supports,  $P_X(x) > 0$  and  $P_Y(y) > 0$  for all  $x \in \mathcal{X}$  and  $y \in \mathcal{Y}$ .*

Given a report profile of Alice,  $\hat{\mathbf{x}} \in \mathcal{X}^m$  and Bob,  $\hat{\mathbf{y}} \in \mathcal{Y}^m$ , an *information elicitation mechanism*  $\mathcal{M} = (M_A, M_B)$  with  $m$  tasks pays  $M_A(\hat{\mathbf{x}}, \hat{\mathbf{y}}) \in \mathbb{R}$  to Alice, and  $M_B(\hat{\mathbf{x}}, \hat{\mathbf{y}}) \in \mathbb{R}$  to Bob. In the rest of the paper we often only define notions for Alice, and define Bob's in the symmetric way.

Besides Assumption 2, we assume their strategies are uniform and independent across different tasks which is also made in previous work [5, 28, 16].

► **Assumption 3** (Uniform strategy). *Formally, the strategy of Alice is a random function  $\theta_A : \mathcal{X} \rightarrow \Delta_{\mathcal{X}}$  where  $\theta_A(x, \hat{x})$  is the probability that Alice reports  $\hat{x}$  conditioning on her private information  $x$ . That is, each report only depends on the corresponding signal.*

For instance, given Alice receiving  $\mathbf{x} \in \mathcal{X}^m$  the probability that Alice reports  $\hat{\mathbf{x}} \in \mathcal{X}^m$  is  $\Pr[\hat{\mathbf{X}} = \hat{\mathbf{x}}] = \prod_{s \in [m]} \theta_A(x_s, \hat{x}_s)$ . We call  $\boldsymbol{\theta} = (\theta_A, \theta_B)$  a the *strategy profile*. The *ex-ante payment* to Alice under a strategy profile  $\boldsymbol{\theta}$  and a prior  $\mathbb{P}$  in mechanism  $\mathcal{M}$  is  $u_A(\boldsymbol{\theta}; \mathbb{P}, \mathcal{M}) \triangleq \mathbb{E}_{(\mathbf{X}, \mathbf{Y})} [\mathbb{E}_{(\hat{\mathbf{X}}, \hat{\mathbf{Y}})} [M_A(\hat{\mathbf{x}}, \hat{\mathbf{y}})] \mid (\mathbf{x}, \mathbf{y})]$  where we use a semicolon to separate the variable,  $\boldsymbol{\theta}$ , and parameters  $\mathbb{P}$  and  $\mathcal{M}$ . Note that a strategy profile  $\boldsymbol{\theta}$  can be seen as a Markov operator on the signal space  $\mathcal{X} \times \mathcal{Y}$ , so that Alice and Bob's reports,  $\boldsymbol{\theta} \circ P$ , is also a distribution on the signal space  $\mathcal{X} \times \mathcal{Y}$ .

In the literature on peer-prediction, there are three important classes of strategies. We use  $\boldsymbol{\tau}$  to denote the **truth-telling strategy profile** where both agents' reports are equal to their private signals with probability 1, e.g., Alice's strategy is  $\tau_A(x, \hat{x}) = \mathbb{I}[x = \hat{x}]$ . A strategy profile is a **permutation strategy profile** if both agents' strategy are a (deterministic) permutation, a bijection between signals and reports. Finally, a strategy profile is **oblivious** or *uninformed* if even one of the agents' strategies does not depend on their signal: that is for Alice  $\theta_A(x, \hat{x}) = \theta_A(x', \hat{x})$  for all  $x, x'$ , and  $\hat{x}$  in  $\mathcal{X}$ . Note that the set of permutation strategy profiles includes the truth-telling strategy profile  $\boldsymbol{\tau}$  but does not include any oblivious strategy profiles.

<sup>3</sup> We assume these distribution has a density function with respect to the  $\mu$ ,  $P \ll \mu$  for all  $P \in \Delta_\Omega$ . The distributions in  $\Delta_\Omega$  depend on  $\mathcal{F}$  and  $\mu$ , but we omit it to simplify the notation. The density is defined as the Radon–Nikodym derivative  $\frac{dP}{d\mu}$  which exists because  $P$  is dominated by  $\mu$ .

**Truthful Guarantees.** We now define some truthfulness guarantees for our mechanism  $\mathcal{M}$  that differ in how unique the high payoff of truth-telling strategy profile is:

**Truthful:** the truth-telling strategy profile  $\tau$  is a Bayesian Nash Equilibrium, and has the highest payment to both Alice and Bob.

**Informed-truthful [28]:** Truthful and also for each agent  $\tau$  is strictly better than any oblivious strategy profiles. For any oblivious strategy profile  $\theta$ ,  $u_A(\tau; \mathbb{P}, \mathcal{M}) > u_A(\theta; \mathbb{P}, \mathcal{M})$  and  $u_B(\tau; \mathbb{P}, \mathcal{M}) > u_B(\theta; \mathbb{P}, \mathcal{M})$ .

**Strongly truthful [28, 16]:** Truthful and also for each agent  $\tau$  is strictly better than all non-permutation strategy profiles. For any non-permutation strategy profile  $\theta$ ,  $u_A(\tau; \mathbb{P}, \mathcal{M}) > u_A(\theta; \mathbb{P}, \mathcal{M})$  and  $u_B(\tau; \mathbb{P}, \mathcal{M}) > u_B(\theta; \mathbb{P}, \mathcal{M})$ .

**Dominant truthful:** Each agent report truthfully leads to higher expected payoff than other strategies, regardless of other agent's reporting strategies. For any strategy profile  $\theta$ , we have  $u_A(\tau; \mathbb{P}, \mathcal{M}) > u_A(\theta; \mathbb{P}, \mathcal{M})$  and  $u_B(\tau; \mathbb{P}, \mathcal{M}) > u_B(\theta; \mathbb{P}, \mathcal{M})$ .

We can also call a general mapping truthful, informed-truthful, strongly truthful, dominant truthful when it satisfy the corresponding property.

In this work, we consider an approximate version of above statements with low sample number. For example, given  $\epsilon > 0$ , a mechanism  $\mathcal{M}$  with  $m(\epsilon)$  tasks (the sample number)<sup>4</sup> is  $\epsilon$ -strongly truthful with  $m(\epsilon)$  tasks if there exists a mapping from strategy profiles to ex-ante payments such that 1) this mapping is strongly truthful; 2) for all  $\epsilon$  the ex-ante payments of our mechanism with  $m(\epsilon)$  tasks is within  $\epsilon$  of this mapping.

Now we define the sample number for approximately truthfulness guarantees.

► **Definition 4.** Given a family of joint signal distributions  $\mathcal{P}$  and a function  $S : \mathbb{R}_{>0} \rightarrow \mathbb{N}$  we say a mechanism  $\mathcal{M}$  is  $\epsilon$ -strongly truthful on  $\mathcal{P}$  with  $S(\epsilon)$  number of tasks, if there exists a strongly truthful mapping  $F = (F_A, F_B)$  from joint signal distributions and strategy profiles to payments such that for all  $\epsilon > 0$  and  $m \geq S(\epsilon)$

- the ex-ante payment under the truth-telling strategy profile in  $\mathcal{M}$  with  $m$  number of tasks is within  $\epsilon$  additive error from  $F$ : for all  $P \in \mathcal{P}$ ,  $u_A(\tau; P, \mathcal{M}) \geq F_A(\tau, P) - \epsilon$ ;
- and the ex-ante payment under any strategy profile  $\theta$  in  $\mathcal{M}$  with  $m$  number of tasks is bounded above by  $F$ : for all  $P \in \mathcal{P}$ , and  $\theta$ ,  $u_A(\theta; P, \mathcal{M}) \leq F_A(\theta, P)$ .

And the inequality also holds for Bob's ex-ante payment. Furthermore, we say  $\mathcal{M}$  is  $(\delta, \epsilon)$ -strongly truthful on  $\mathcal{P}$  with  $S(\delta, \epsilon)$  if the above conditions holds with probability  $1 - \delta$  for all  $\delta \in (0, 1)$  and  $\epsilon > 0$ . Additionally, we say  $\mathcal{M}$  is  $\epsilon$ -informed-truthful ( $\epsilon$ -truthful) with  $S(\epsilon)$  number of tasks if it is  $\epsilon$  close to an informed-truthful (truthful) mapping.

Note that our notion of  $\epsilon$ -truthfulness guarantee is quite strong. In particular, the second item requires for any strategy profile  $\theta$ , the ex-ante payment is upper bounded by a strongly truthful (informed-truthful, truthful) mapping.

## 2.2 Prior Assumptions

There are two axes to compare these peer prediction mechanism: *truthful guarantee* and *prior assumption*. Truthful guarantee asks how good the truth-telling strategy is. Prior assumption addresses how general these mechanisms are. We first introduce the weakest possible notion of interdependence that we used in our paper. Then we survey other notions proposed in previous works. Finally, we provide concrete examples to show the distinction between those notions of interdependence.

<sup>4</sup> Here mechanism which can take different length of report  $m$ . Or we can consider a family of mechanisms  $(\mathcal{M}_m)$  parameterized by the sample number (the number of tasks)  $m$ .

► **Definition 5** (Stochastic Relevant [28]). *We call  $P_{X,Y}$  stochastic relevant if for any two distinct signals  $x, x' \in \mathcal{X}$   $P_{X,Y}[Y | X = x] \neq P_{X,Y}[Y | X = x']$ . That is, Alice's posteriors on Bob's signals are different when Alice receives signal  $x$  or  $x'$ . And symmetrically, the same holds for Bob's posterior on Alice's signals.*

Stochastic relevancy is the weakest assumption we can hope for designing peer prediction mechanisms. Proposition 6 shows that if agent's signal are not stochastic relevant an agent can always misreport regardless other agents' reports even if the mechanism knows the information structure.

► **Proposition 6** (Elicitability [32]). *If the prior  $P_{X,Y}$  is not stochastic relevant, there is no mechanism that has truth-telling as a strict Bayesian Nash equilibrium.*

Besides the above notion, previous peer prediction mechanisms make ad hoc assumptions on agents' private signals.

Kong and Schoenebeck [16] studies *fine-grained* joint distributions. A joint distribution  $P_{X,Y}$  is *fine-grained* if for any distinct pairs of signals  $(x, y)$  and  $(x', y')$ ,  $\frac{P_{X,Y}(x, y)}{P_X(x)P_Y(y)} \neq \frac{P_{X,Y}(x', y')}{P_X(x')P_Y(y')}$ . Kong [11] considers *strictly correlated* distributions. A joint distribution  $P$  on a finite space  $\mathcal{X}^2$  is strictly correlated if the determinant of distribution  $P \in \mathbb{R}^{|\mathcal{X}| \times |\mathcal{X}|}$  is nonzero. Those two notions are both stronger than stochastic relevance.

### 2.3 Convex Analysis and $\Phi$ -divergence

Informally,  $\Phi$ -divergences quantify the difference between a pair of distributions over a common measurable space.

► **Definition 7** ( $\Phi$ -divergence [3, 21, 2]). *Let  $\Phi : [0, \infty) \rightarrow \mathbb{R}$  be a convex function with  $\Phi(1) = 0$ . Let  $P$  and  $Q$  be two probability distributions on a common measurable space  $(\Omega, \mathcal{F})$ . The  $\Phi$ -divergence of  $Q$  from  $P$  where  $P \ll Q$  is defined as  $D_\Phi(P||Q) \triangleq \mathbb{E}_Q[\Phi(P/Q)]$ .<sup>5</sup>*

We can use these divergences to measure interdependency between two random variables  $X$  and  $Y$ . Formally, Let  $P_{X,Y}$  be a distribution over  $(x, y) \in \mathcal{X} \times \mathcal{Y}$ , and  $P_X$  and  $P_Y$  be marginal distributions of  $X$  and  $Y$  respectively. We set  $P_X P_Y$  be the tensor product between  $P_X$  and  $P_Y$  such that  $P_X P_Y(x, y) = P_X(x)P_Y(y)$ . We call  $D_\Phi(P_{X,Y}||P_X P_Y)$  the  $\Phi$ -mutual information between  $X$  and  $Y$ .

Given a joint distribution  $P_{X,Y}$ , let **joint to marginal product ratio** at  $(x, y)$  on  $P_{X,Y}$  be  $JP_P(x, y) := \frac{P_{X,Y}(x, y)}{P_X(x)P_Y(y)}$  which is ratio between joint probability divided by the product of the probabilities at  $(x, y)$ . We will omit subscript  $P$  when there is no ambiguity. This ratio widely studied. For instance, it's called *observed to expected ratio* in life sciences literature, or *lift* in data mining for binary random variable. Additionally,  $\log JP(x, y)$  is called point-wise mutual information. Finally, note that  $\Phi$  mutual information is the average of joint to marginal product ratio applied to  $\Phi$ .

Now, we introduce some basic notions in convex analysis [26]. Let  $\Phi : [0, +\infty) \rightarrow \mathbb{R}$  be a convex function. The *convex conjugate*  $\Phi^*$  of  $\Phi$  is defined as:  $\Phi^*(b) = \sup_{a \in \text{dom}(\Phi)} \{ab - \Phi(a)\}$ . Moreover  $\Phi = \Phi^{**}$  if  $\Phi$  is continuous.

By Young-Fenchel inequality [8], we can rewrite the  $\Phi$ -divergence of  $Q$  from  $P$  in a variational form. This formulation is important to understand our mechanisms.

<sup>5</sup>  $P/Q$  is the Radon-Nikodym derivative between measures  $P$  and  $Q$ , and it is equal to the ratio of density function.

► **Theorem 8** (Variational representation [22]).

$$D_\Phi(P\|Q) = \sup_{k:\Omega \rightarrow \text{dom}(\Phi^*)} \left\{ \mathbb{E}_{\omega \sim P}[k(\omega)] - \mathbb{E}_{\omega \sim Q}[\Phi^*(k(\omega))] \right\},^6$$

and the equality holds  $D_\Phi(P\|Q) = \mathbb{E}_{\omega \sim P}[k(\omega)] - \mathbb{E}_{\omega \sim Q}[\Phi^*(k(\omega))]$  if and only if  $k \in \partial\Phi(P/Q)$  almost everywhere on  $Q$ .<sup>7</sup>

## 2.4 Scoring Function

Our constructions and analysis will make heavy use of the following functionals – scoring functions.

► **Definition 9** (Scoring function). A **scoring function**  $K : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}$  is a functional (real-valued function) that maps from a pair of reports to a real value. Given a convex function  $\Phi$ , a scoring function  $K_{P,\Phi}^*$  is a  $(P_{X,Y}, \Phi)$ -**ideal scoring function** if

$$K_{P,\Phi}^*(x, y) \in \partial\Phi\left(\frac{P_{X,Y}(x, y)}{P_X(x)P_Y(y)}\right) = \partial\Phi(\text{JP}_P(x, y)). \quad (1)$$

We will use  $P$  and  $P_{X,Y}$  interchangeably later, and say  $K^*$  is ideal without specifying  $P$  and  $\Phi$  when it's clear.

A  $(P, \Phi)$ -ideal scoring function is the joint to marginal product ratio applied to  $\partial\Phi$  which is a monotone increasing function if  $\Phi$  is differentiable. joint to marginal product ratio encodes the signal structure of  $P_{X,Y}$  which measure how interdependent  $x$  and  $y$  is. Alternatively, the scoring function serves as a “distinguisher” which tries to decide whether a pair of reports came from the joint distribution or the product of the marginal distributions.

Furthermore, the ideal scoring function can also be easily computed from the density function  $P_{X,Y}$ .

## 2.5 Functional Complexity

In this section, we provide some standard notions to characterize the complexity of learning functionals which are standard [29, 30]. We will use these notions to characterize the complexity of learning an ideal scoring function.

Let  $\mathcal{K}$  be a pre-specified class of functionals  $k : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}$ . Given  $k \in \mathcal{K}$ ,  $L > 0$ , and a distribution  $P_{X,Y}$ , we define the *Bernstein norm* as  $\rho_L^2(k; P) \triangleq 2L^2 \mathbb{E}_P[\exp(|k|/L) - 1 - |k|/L]$ , and  $\rho_L(\mathcal{K}; P) \triangleq \sup_{k \in \mathcal{K}} \rho_L(k, P)$ . Let  $\mathcal{N}_{[],L}(\delta, \mathcal{K}, P)$  be the smallest value of  $n$  for which there exists  $n$  pairs of functions  $\{(k_j^L, k_j^U)\}$  such that 1)  $\rho_L(k_j^U - k_j^L; P) \leq \delta$  for all  $j$  and 2) for all  $k \in \mathcal{K}$  there is a  $j$ ,  $k_j^L(x, y) \leq k(x, y) \leq k_j^U(x, y)$  for all  $(x, y) \in \mathcal{X} \times \mathcal{Y}$ . Then  $\mathcal{H}_{[],L}(\delta, \mathcal{K}, P) \triangleq \log \mathcal{N}_{[],L}(\delta, \mathcal{K}, P)$  is called the *generalized entropy with bracketing*. We further define the entropy integral as  $J_{[],L}(R, \mathcal{K}, P) \triangleq \int_0^R \sqrt{\mathcal{H}_{[],L}(u, \mathcal{K}, P)} du$ .

Our results will show that constant number of questions suffice as long as the ideal scoring functions is in some bounded complexity space  $\mathcal{K}$  where  $J_{[],L}(R, \mathcal{K}, P)$  and  $\rho_L(\mathcal{K}; P)$  are bounded.

<sup>6</sup> The sup is taken over  $k$  with finite  $\mathbb{E}_{\omega \sim P}[k(\omega)]$  and  $\mathbb{E}_{\omega \sim Q}[\Phi^*(k(\omega))]$ .

<sup>7</sup>  $\partial\Phi$  is the subgradient of  $\Phi$ , and the formal definition can be found in [26]. Here we only use the equality condition when  $\Omega$  is finite.

### 3 $\Phi$ -Divergence Pairing Mechanisms

In this section, we first define a class of multi-task peer-prediction mechanisms  $\mathcal{M}^{\Phi, K}$ . The mechanism is parametrized by a convex function  $\Phi$  and a scoring function  $K$  (Definition 9). Then we briefly discuss how to obtain a good scoring function, and develop algorithms for estimating good scoring function.

The process of this mechanism is quite simple. Given a scoring function  $K$  and  $\Phi$ , we arbitrarily choose one task  $b$ , and two distinct tasks  $p$  and  $q$  from  $m \geq 2$  tasks. Alice gets paid by Eqn. (2) the scoring function on her and Bob's reports on task  $b$  minus the  $\Phi^*$  applied to the scoring function on her report on  $p$  and Bob's report on  $q$ . In this way, agents are paid by a scoring function on a *correlated task* minus a regularized scoring function on two *uncorrelated tasks*.

■ **Algorithm 1**  $\Phi$ -divergence pairing mechanism with a scoring function  $K$  for two agents,  $\mathcal{M}^{\Phi, K}$ .

**Input:** A report profile  $(\hat{\mathbf{x}}, \hat{\mathbf{y}})$  where both Alice and Bob submit report for all  $m \geq 2$  tasks.

**Parameters:** A convex function  $\Phi : [0, \infty) \rightarrow \mathbb{R}$ , its conjugate  $\Phi^*$ , and a scoring function  $K : \mathcal{X} \times \mathcal{Y} \rightarrow \text{dom}(\Phi^*) \subseteq \mathbb{R}$ .

- 1: For Alice, arbitrarily pick three tasks  $b, p$  and  $q$  where  $p$  and  $q$  are distinct. We call  $b$  the *bonus task*,  $p$  the *penalty task to Alice*, and  $q$  the *penalty task to Bob*.
- 2: Based on Alice's reports on  $b$  and  $p$  ( $\hat{x}_b$  and  $\hat{x}_p$ ) and Bob's reports on  $b$  and  $q$  ( $\hat{y}_b$  and  $\hat{y}_q$ ), the payment to Alice is

$$M_A^{\Phi, K}(\hat{\mathbf{x}}, \hat{\mathbf{y}}) \triangleq K(\hat{x}_b, \hat{y}_b) - \Phi^*(K(\hat{x}_p, \hat{y}_q)). \quad (2)$$

- 3: The payment of Bob is defined similarly.

To simplify the notion, we use  $u_A$  or  $u_A(\boldsymbol{\theta}, P, K)$  to denote the ex-ante payment to Alice under a strategy profile  $\boldsymbol{\theta}$  and a joint signal distribution  $P$  in pairing mechanism with a scoring function  $K$ .

In general, the truthfulness guarantees of Mechanism 1 depends on the degeneracy of Alice's and Bob's signal distribution  $P$  and convex function  $\Phi$ . In this paper, we consider three different conditions which will be used in the statement of our results.

► **Assumption 10.** *In this paper, we consider the following three different settings.*

1. *no assumption;*
2.  *$P_{X,Y}$  is stochastic relevant;*
3. *Besides the above conditions,  $\mathcal{X}$  and  $\mathcal{Y}$  are finite sets,  $\Phi$  is strictly convex and differentiable, and  $\Phi^*$  is strictly convex.*

#### 3.1 Obtaining a Good Scoring Function

The  $\Phi$ -pairing mechanism  $\mathcal{M}^{\Phi, K}$  is not stand-alone mechanism for information elicitation, because it requires a scoring function  $K$  as a parameter. We will see shortly in Sect. 4 and 6, the truthfulness guarantees of the pairing mechanism depends on the quality of the scoring function. In this paper, we consider three different models for mechanism designers to estimate good scoring functions which are discussed in the rest of the sections:

**Direct access of  $K_{P, \Phi}^*$ .** In Sect. 4, we first consider the mechanism knows a  $(P, \Phi)$ -ideal scoring function  $K_{P, \Phi}^*$ . Note that if the mechanism knows the prior  $P$ , it can compute the  $(P, \Phi)$ -ideal scoring function, but the converse is not necessarily true.

**General reduction to a learning problem.** In Sect. 6, besides the reports from Alice and Bob, mechanism may exploit Alice and Bob's previous scoring function and other side information. For example the joint distribution between Alice and Bob can be approximated by some parametric model, say joint Gaussian distributions. We introduce our framework (Mechanism 2) that reduces the problem into a learning problem.

**Estimation from samples.** Finally, in the multi-task setting, if Alice and Bob truthfully report their signals, it is possible to estimate the  $(P, \Phi)$ -ideal scoring function from those reports. However, the mechanism needs to incentive them to be truthful. In Sect. 6.3, we propose two learning methods to estimate good scoring functions. Combining them with our framework (Mechanism 2), we can have detail-free  $\epsilon$ -strongly truthful mechanisms with high probability.

#### 4 Pairing Mechanisms in the Known Prior Setting

If the mechanism  $\mathcal{M}^{\Phi, K^*}$  has an  $(P, \Phi)$ -ideal scoring function  $K^*$  where  $P$  is the joint distribution to Alice's and Bob's signals, the mechanism has the following properties. We defer the proof to Sect. 5.

► **Theorem 11.** *Let an integer  $m$  be greater than 2, a functional  $\Phi$  be a continuous convex function with  $[0, \infty) \subseteq \text{dom}(\Phi)$ ,  $\mathbb{P}$  with  $P_{X,Y}$  be a common prior between Alice and Bob satisfying Assumption 2. Let  $\tau$  be the truth-telling strategy profile, and  $K^*$  be a  $(P, \Phi)$ -ideal scoring function.*

*The  $\Phi$ -pairing mechanism with  $K^*$ ,  $\mathcal{M}^{\Phi, K^*}$  has the following properties: For any strategy profile  $\theta$ ,<sup>8</sup>*

$$u_A(\theta, P, K^*) \leq u_A(\tau, P, K^*). \quad (3)$$

*Furthermore, under the four conditions in Assumption 10 respectively, the mechanism  $\mathcal{M}^{\Phi, K^*}$  is*

1. *truthful,*
2. *informed-truthful, or*
3. *strongly truthful.*

In the following example, we show how Mechanism 1 with a  $(P, \Phi)$ -ideal scoring function works, and illustrate the difference between informed-truthful and strongly truthful.

#### 5 Main Technical Lemmas and Proof of Theorem 11

To prove Theorem 11, we use the following lemmas which are also important in the rest of the paper.

We first show the ex-ante payment under the truth-telling strategy profile in the  $\Phi$ -pairing mechanism with  $(P, \Phi)$ -ideal scoring function is the  $\Phi$ -mutual information between Alice's and Bob's signals.

► **Lemma 12 (Truth-telling).** *If  $K^*$  is a  $(P_{X,Y}, \Phi)$ -ideal scoring function,*

$$u_A(\tau, P, K^*) = D_\Phi(P_{X,Y} \| P_X P_Y).$$

<sup>8</sup> There are some minor details when  $\mathcal{X}$  and  $\mathcal{Y}$  are not finite set. Here we require  $\theta$  to have finite  $\int K^* d\theta_A d\theta_B dP_{X,Y}$ , and  $\int \Phi^*(K^*) d\theta_A d\theta_B dP_X P_Y$ .

Moreover, if  $P_{X,Y}$  is stochastic relevant,  $D_\Phi(P_{X,Y} \| P_X P_Y) > 0$ .

Then we show any deviation from the truth-telling strategy profile or an ideal scoring function cannot improve Alice (and Bob's) ex-ante payment. The proof uses the variational representation of  $\Phi$ -divergence (Theorem 8).

► **Lemma 13** (Manipulation). *For any strategy profile  $\theta$  and scoring function  $K$ ,  $u_A(\theta, P, K) \leq D_\Phi(P_{X,Y} \| P_X P_Y)$ .*

Note that combining these two lemmas we have an even stronger result than inequality (3) which is a key tool in this paper: For any scoring function  $K$  and strategy profile  $\theta$ ,

$$u_A(\theta, P, K) \leq u_A(\tau, P, K^*). \quad (4)$$

► **Lemma 14** (Oblivious strategy). *If  $\theta$  is an oblivious strategy profile, for any scoring function  $K$ ,  $u_A(\theta, P, K) \leq 0$ .*

► **Lemma 15**. *Moreover, given Conditions 3 in Assumption 10, the equality in (4) for Alice or Bob occurs if and only if*

1.  $\theta = (\pi_A, \pi_B)$  which is a permutation strategy profile, and
2. For all  $x \in \mathcal{X}$  and  $y \in \mathcal{Y}$ ,  $K(\pi_A(x), \pi_B(y)) = \Phi'(\text{JP}(x, y))$ .

Informally, Lemma 15 shows if the pair of a strategy profile and a scoring function  $(\theta, K)$  have (4) equal only if there is a “conjugated” structure between the strategy and the scoring function. The proof uses the pigeonhole principle on the finite signal spaces and shows if the equality holds under a non permutation strategy profile,  $P$  is not stochastic relevant.

With the above four lemmas, we are ready to prove Theorem 11.

**Proof of Theorem 11.** There are four statements to show.

First, (3) is a direct result of (4). Furthermore, (3) proves that truth-telling is a Bayesian Nash equilibrium, and has highest ex-ante payment to Alice. This shows the mechanism is truthful.

By Lemma 14, the ex-ante payment to Alice (and Bob) is non-positive. Combining this and Lemma 12, we prove the  $\Phi$ -pairing mechanism with  $(P, \Phi)$ -ideal scoring function is informed-truthful when  $P$  is stochastic relevant.

To show our mechanism is strongly truthful, under Condition 3 in Assumption 10, we use the first part of Lemma 15. If the ex-ante payment under some strategy profile is equal to the ex-ante payment under the truth-telling strategy profile, the strategy profile is a permutation strategy profile. ◀

## 6 The Pairing Mechanism in the Detail Free Settings

With Sect. 5, we can see that to achieve the truthfulness guarantees, it suffices to have a “good” scoring function. That is if the ex-ante payment to Alice under the truth-telling strategy profile is close to the  $\Phi$ -mutual information between Alice's and Bob's signals, by (4), the ex-ante payment under an untruthful-strategy is less than the ex-ante payment under the truth-telling strategy profile.

In Sect. 6.1 we formalize the notions of a *good* scoring function and of the *accuracy* of a learning algorithm  $\mathcal{L}$  for scoring functions. In Sect. 6.2, we state our main result, Theorem 16, which reduces the mechanism design problem to a learning problem for an ideal scoring function, and provides some intuition about the proof of the theorem.

## 6.1 Accuracy of Scoring Rules and Learning Algorithms

Now we define a *good* scoring function, and the *accuracy* of a learning algorithm  $\mathcal{L}$ . Given  $\Phi$ , a prior  $P_{X,Y}$  and  $\epsilon > 0$ , we say that a scoring function  $K$  is  $\epsilon$ -ideal on  $(P_{X,Y}, \Phi)$ , if for Alice

$$u_A(\tau, P, K) \geq u_A(\tau, P, K_{P,\Phi}^*) - \epsilon = D_\Phi(P_{X,Y} \| P_X P_Y) - \epsilon, \quad (5)$$

and the similar inequality holds for Bob. Additionally, For  $m_L \in \mathbb{N}$ , we say a *learning algorithm for scoring functions with  $m_L$  samples*, as a function from  $(\mathbf{x}_L, \mathbf{y}_L) \in (\mathcal{X} \times \mathcal{Y})^{m_L}$  to a scoring function  $K$ . Given  $\mathcal{P}$ , a set of distributions on  $\mathcal{X} \times \mathcal{Y}$ , and a function  $S_L : \mathbb{R} \times \mathbb{R} \rightarrow \mathbb{N}$ , we say such a learning algorithm  $\mathcal{L}$  is  $(\delta, \epsilon)$ -accurate on  $(\mathcal{P}, \Phi)$  with  $S_L(\delta, \epsilon)$  samples, if for all  $P_{X,Y} \in \mathcal{P}$ ,  $\delta \in (0, 1)$ ,  $\epsilon > 0$ , and  $m_L \geq S_L(\delta, \epsilon)$ :

$$\Pr_{(\mathbf{x}_L, \mathbf{y}_L) \sim P_{X,Y}^{m_L}} [u_A(\tau, P, \mathcal{L}(\mathbf{x}_L, \mathbf{y}_L)) > D_\Phi(P_{X,Y} \| P_X P_Y) - \epsilon] \geq 1 - \delta.$$

That is, given  $m_L$  i.i.d. samples from  $P_{X,Y}$ , the probability that the output,  $\mathcal{L}(\mathbf{x}_L, \mathbf{y}_L)$ , is  $\epsilon$ -ideal on  $(P, \Phi)$  is greater than  $1 - \delta$ . Note that we require the algorithm  $\mathcal{L}$  to approximate the ideal scoring *uniformly* on all distributions in  $\mathcal{P}$ .

## 6.2 Pairing Mechanism with Learning Algorithms

Now we replace a fixed scoring function with an accurate learning algorithm  $\mathcal{L}$  in Mechanism 1. Intuitively, in the detail-free setting, the Mechanism 2 first runs a learning algorithm on Alice's and Bob's report profile to derive a scoring function, and then pays Alice and Bob by Mechanism 1.

■ **Algorithm 2**  $\Phi$ -divergence pairing mechanism with a learning algorithm  $\mathcal{M}^{\Phi, \mathcal{L}}$ .

**Parameters:** A convex function  $\Phi$ , and a learning algorithm  $\mathcal{L}$  with  $m_L$  samples.

**Input:** A report profile  $(\hat{\mathbf{x}}, \hat{\mathbf{y}})$  from Alice and Bob on  $m$  tasks where  $m \geq 2 + m_L$ .

- 1: Partition  $m$  tasks (arbitrarily) into a set of learning tasks  $M_L$  and a set of scoring tasks  $M_S$  where  $|M_L| \geq m_L$  and  $|M_S| \geq 2$ . Let  $(\hat{\mathbf{x}}_L, \hat{\mathbf{y}}_L)$  be the reports from Alice and Bob on the learning tasks  $M_L$ , and  $(\hat{\mathbf{x}}_S, \hat{\mathbf{y}}_S)$  be the reports on the scoring tasks.
- 2: Run the learning algorithm and derive  $K_{\text{est}} = \mathcal{L}(\hat{\mathbf{x}}_L, \hat{\mathbf{y}}_L)$ .
- 3: Run the  $\Phi$ -pairing mechanism (Mechanism 1) with the scoring function  $K_{\text{est}}$ , and pay Alice and Bob accordingly.

► **Theorem 16.** Let  $\Phi$  be a continuous convex function with  $[0, \infty) \subseteq \text{dom}(\Phi)$ ,  $m_L$  be an integer,  $\mathcal{L}$  be a learning algorithm on  $m_L$  samples, a function  $S_L : \mathbb{R} \times \mathbb{R} \rightarrow \mathbb{N}$ , and  $\mathcal{P}$  be a set of joint distributions on  $\mathcal{X} \times \mathcal{Y}$ .

Suppose the common prior between Alice and Bob satisfying Assumption 2 with  $P_{X,Y} \in \mathcal{P}$ , and  $\mathcal{L}$  is  $(\delta, \epsilon)$ -accurate on  $(\mathcal{P}, \Phi)$  with  $S_L(\delta, \epsilon)$  samples. Under three conditions in Assumption 10 respectively, Mechanism 2 is

1.  $(\delta, \epsilon)$ -truthful on  $\mathcal{P}$  with a  $2 + S_L(\delta, \epsilon)$  number of tasks;
2.  $(\delta, \epsilon)$ -informed-truthful on  $\mathcal{P}$  with a  $2 + S_L(\delta, \epsilon)$  number of tasks;
3.  $(\delta, \epsilon)$ -strongly truthful on  $\mathcal{P}$  with a  $2 + S_L(\delta, \epsilon)$  number of tasks.

Here  $\mathcal{L}$  only outputs an  $\epsilon$ -ideal scoring function on the joint distribution of agents' signals. Still, the algorithm can have an arbitrarily large error when agents are not truthtelling. For instance, there may exists a non-truth-telling strategy profile  $\theta$  such that  $\theta \circ P$  is not in  $\mathcal{P}$ ,

and the output of  $\mathcal{L}$  is not  $\epsilon$ -ideal on  $(\theta \circ P, \Phi)$ . Nevertheless, Mechanism 2 still can upper bound their ex-ante payment under such non-truth-telling strategy profiles. Furthermore, if the learning algorithm is  $\epsilon$ -ideal on  $(\theta \circ P, \Phi)$  for all strategy profile  $\theta$ , the pairing mechanism is indeed approximately dominantly truthful.

### 6.3 Learning Ideal Scoring Functions

Theorem 16 reduces the mechanism design problem to a learning problem for an ideal scoring function. However, Eqn. (5) may be hard to verify. We provide two natural sufficient conditions for  $\epsilon$ -ideal scoring functions in Sect. 6.3.1, and we will provide two concrete learning algorithms for scoring function in Sect. 6.3.2.

#### 6.3.1 Sufficient Conditions for Approximately $\Phi$ -Ideal Scoring Functions

**Bregman divergence.** Given  $a, b \in \mathbb{R}$  and a strictly convex and twice differentiable  $\Phi : \mathbb{R} \rightarrow \mathbb{R}$ , the standard Bregman divergence is  $\Phi(a) - \Phi(b) - \nabla \Phi(b)^\top (a - b)$ . It can be extended to **Bregman divergence** between two functionals  $f$  and  $g$  over a probability space  $(\Omega, \mathcal{F}, P)$  [4]

$$B_{\Phi, P}(f, g) = \int \Phi(f(\omega)) - \Phi(g(\omega)) - \nabla \Phi(g(\omega))^\top (f(\omega) - g(\omega)) dP(\omega).$$

► **Lemma 17** (Bregman divergence and accuracy). *If  $\Phi$  is strictly convex and twice differentiable on  $[0, \infty)$ ,  $D_\Phi(P_{X,Y} \| P_X P_Y) - u_A(\tau, P, K) = B_{\Phi^*, P_X P_Y}(K, K^*)$ . Therefore, if  $B_{\Phi^*, P_X P_Y}(K, K^*) \leq \epsilon$ ,  $K$  is an  $\epsilon$ -ideal scoring function on  $(\Phi, P)$ .*

Since Bregman divergence capture an *average distance* between a scoring function  $K$  and the ideal one, if the scoring function  $K$  is uniformly close to the ideal one  $K^*$ , the Bergman divergence between  $K$  and  $K^*$  is also small.

**Total variation distance.** On the other hand, we may first learn the prior  $P$  and compute an approximately ideal scoring function afterward. This indirect method is also useful, because estimating the probability density function is a much well studied problem.

► **Theorem 18** (Total variation to accuracy). *Given  $\Phi$  is a convex function and a prior  $P_{X,Y}$  over a finite space  $\mathcal{X} \times \mathcal{Y}$ , suppose there exist constants  $0 < \alpha < 1$  and  $c_L$  such that*

$$\forall x \in \mathcal{X}, y \in \mathcal{Y}, P_{X,Y}(x, y) > 2\alpha \text{ or } P_{X,Y}(x, y) = 0, \quad (6)$$

$$\forall z, w \in [\alpha, 1/\alpha], |\Phi(z) - \Phi(w)| \leq c_L |z - w|. \quad (7)$$

*If  $\|\hat{P}_{X,Y} - P_{X,Y}\|_{TV} \leq \delta < \alpha$ ,<sup>9</sup>  $\hat{K}(x, y) \in \partial \Phi \left( \frac{\hat{P}_{X,Y}}{\hat{P}_X \otimes \hat{P}_Y} \right)$  is a  $\frac{6c_L}{\alpha^2} \delta$ -ideal scoring function.*

The first condition says the smallest nonzero probability  $P_{X,Y}(x, y)$  is either constantly away from zero or equal to zero, and the second condition requires the function  $\Phi$  is Lipschitz in  $[\alpha, 1/\alpha]$ . With these conditions, if we have a good estimation  $\hat{P}$  for  $P$  with small total variation distance, we can compute a very accurate scoring function  $\hat{K}$  from  $\hat{P}$ . As we will see in Sect. 6.3.2, the empirical distributions with  $m_L$  samples satisfies this condition with high probability for large enough  $m_L$ .

<sup>9</sup>  $\|\hat{P} - \hat{P}\|_{TV} = \sum_{\omega \in \Omega} |P(\omega) - \hat{P}(\omega)|$  is the total variation distance between  $P$  and  $\hat{P}$ .

### 6.3.2 Learning Algorithms for Scoring Functions

**Generative approach.** Recall that if  $P$  is known, the ideal scoring function can be computed directly. In a generative approach, we try to estimate the probability density function  $P$  from reports and derive the scoring function afterward under the truth-telling strategy profile. In general this generative approach is useful when  $\mathcal{P}$  is on a finite space, or  $\mathcal{P}$  is a parametric model by Theorem 18. Here we provide an example of a generative approach.

A standard way of learning probability density function is to use empirical distribution on  $m_L$  samples. The following theorem shows that the empirical distribution gives a good estimation in terms of total variation distance.

► **Lemma 19** (Theorem 3.1 in [6]). *For all  $\epsilon > 0$ ,  $\delta > 0$ , finite domain  $\Omega$ , and distribution in  $P$  in  $\Delta_\Omega$ , there exists  $M = O\left(\frac{1}{\epsilon^2} \max(|\Omega|, \log(1/\delta))\right)$  such that for all  $m_L \geq M$  the empirical distribution  $\hat{P}_{m_L}$  with  $m_L$  i.i.d. samples,  $\|P - \hat{P}_{m_L}\|_{TV} \leq \epsilon$  with probability at least  $1 - \delta$ .*

Therefore, we can design a learning algorithm  $\mathcal{L}_{\text{emp}}$  as follows: estimate joint distribution  $P_{X,Y}$  by their empirical distributions  $\hat{P}_{X,Y}$  and derive  $\hat{K}$  from Theorem 18. By Theorem 18 and Lemma 19, such algorithm is  $\epsilon$ -accurate with  $1 - \delta$  probability.

**Discriminative approach.** Instead of density estimation, a discriminative approach estimates an ideal scoring functions directly. This enables more freedom of algorithm design. Here we use the variational representation (Theorem 8), and give an optimization characterization of an ideal scoring function.

Given the assumption 2, under the truth-telling strategy profile we can have i.i.d. samples of  $(u, v)$  where  $u$  is sampled from  $P_{X,Y}$  and  $v$  is sampled from  $P_X P_Y$  independently. Taking  $L^\Phi(a, b) \triangleq a - \Phi^*(b)$  as the risk function, we can convert the estimation of the ideal scoring functions to empirical risk minimization (maximization) over a training set  $(u_t, v_t)$  with  $t = 1, 2, \dots, \lfloor m_L/3 \rfloor$ ,

$$\tilde{K} = \arg \max_{k \in \mathcal{K}} \sum_t L^\Phi(k(u_t), k(v_t)) = \arg \max_{k \in \mathcal{K}} \left\{ \int k(\omega) d\hat{P}_{X,Y}(\omega) - \int \Phi^*(k(\omega)) dP_X \hat{P}_Y(\omega) \right\} \quad (8)$$

where  $\mathcal{K}$  is a pre-specified class of functionals  $k : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}$ ,  $\hat{P}_{X,Y}$  and  $P_X \hat{P}_Y$  are empirical distributions on  $\lfloor m_L/3 \rfloor$  samples from distributions  $P_{X,Y}$  and  $P_X P_Y$  respectively.

Assuming that  $\mathcal{K}$  is a convex set of functionals, the implementation of (8) only requires solving a convex optimization problem over function space  $\mathcal{K}$  which is well studied [22]. With these results, we show the empirical risk maximizer  $\tilde{K}$  with respect to  $L^\Phi$  is  $\epsilon$ -accurate with large probability under some conditions on  $\mathcal{K}$  and prior  $P_{X,Y}$ . Furthermore, this error can be seen as the generalized error of the empirical risk maximizer.

► **Theorem 20.** *Consider a distribution  $P$  over  $\mathcal{X} \times \mathcal{Y}$ ; a strictly convex and a twice differentiable function  $\Phi$  on  $[0, \infty)$  with its gradient  $\Phi'$  and conjugate  $\Phi^*$ ; a family of functional  $\mathcal{K}$  from  $\mathcal{X} \times \mathcal{Y}$  to  $\text{dom}(\Phi^*)$ ; and  $\Phi^*(\mathcal{K}) = \{\Phi^*(k) : k \in \mathcal{K}\}$ . Suppose*

1. *the  $(P, \Phi)$ -ideal scoring function  $K^* = \Phi' \left( \frac{P_{X,Y}}{P_X P_Y} \right)$  is in  $\mathcal{K}$ , and*
2. *there exist constants  $(L_l, R_l, D_l)_{l=1,2}$* 
  - a.  $\sup_{k \in \mathcal{K}} \rho_{L_1}(k, P_{X,Y}) \leq R_1$ , and  $\int_0^{R_1} \sqrt{\mathcal{H}_{[\cdot], L_1}(u, \mathcal{K}, P_{X,Y})} du \leq D_1$
  - b.  $\sup_{l \in \Phi^*(\mathcal{K})} \rho_{L_2}(l, P_X P_Y) \leq R_2$  and  $\int_0^{R_2} \sqrt{\mathcal{H}_{[\cdot], L_2}(u, \Phi^*(\mathcal{K}), P_X P_Y)} du \leq D_2$

*There exists  $M = O\left(\frac{1}{\epsilon^2} \log \frac{1}{\delta}\right)$ , such that for all  $m_L \geq M$ ,  $\tilde{K}$  is  $\epsilon$ -accurate on prior  $P$  with probability  $1 - \delta$ .*

Informally, Theorem 20 requires the functional class  $\mathcal{K}$  contains an ideal scoring function and it has a constant complexity (generalized entropy with bracketing). Under these conditions, the empirical risk minimizer (maximizer) can estimate the ideal scoring function accurately even when the signal space can be integers, real numbers, or Euclidean spaces.

Here we give a outline of the proof. By Lemma 17, it is sufficient to show the empirical risk minimizer  $\tilde{K}$  has small Bregman divergence from the ideal one. Moreover, if the estimation  $K$  is the empirical risk maximizer, this error can be upper bounded by the distance between the empirical distribution and the real distribution (Lemma 21). Therefore, we can use functional form of Central Limit Theorem to upper bound the error. We defer the proof to the full version.

► **Lemma 21.** *Let  $\tilde{K}$  be the estimate of  $K^*$  obtained by solving Eqn. (8), and  $K^* \in \mathcal{K}$ . Then*

$$B_{\Phi^*, P_X P_Y}(\tilde{K}, K^*) \leq \sup_{k \in \mathcal{K}} \left| \int \Phi^*(k - \Phi^*(K^*)) d(\tilde{P}_X \tilde{P}_Y - P_X P_Y) - \int (k - K^*) d(\tilde{P}_{X,Y} - P_{X,Y}) \right|.$$

## 7 Machine Learning and Multiple Agents

We have discussed the  $\Phi$ -pairing mechanisms on two agents, Alice and Bob. What can we do if there are more than two agents, Alice, Bob, ...? We first discuss a naive approach that reduces the multiple agents setting to the two agent setting: Randomly select two agents, pay them according to a two agent mechanism, and pay the other agents 0. In this mechanism, as long as the mutual information between any two agents' signals is lower bounded, the sample complexity does not grow with the number of agents.

This naive approach is clearly wasteful and not useful in practice. It throws away nearly all the information agents provide, and will yield payments with high variance. Nonetheless it can provide some strong theoretical guarantees if the sole goal is obtaining approximately informed truthful mechanisms. In a way, this improves the sample complexity of Agarwal et al. [1] from  $O(n)$  to constant with an almost trivial analysis.

Yet, the progression of these papers does provide key insights. In Shnayder et al. [28], agents are paired up with every other agent, enough samples are drawn to estimate the pairwise joint distributions and this is used to (in our parlance) learn an ideal scoring function. Agarwal et al. [1] then assumes structure on the joint prior of all agents, and leverages this particular structure to better learn the ideal scoring function.

These approaches seem much more promising in practice. In the case where the mutual information between any two agents is lower bounded by a constant, they will not asymptotically improve the sample complexity, but in real life, constants matter.

Moreover, these technique may lead to better asymptotic analysis when the average pair-wise mutual information goes to zero. For example, say only Alice and Bob work on the tasks and the rest of agents report random noise. Alice will now only have positive expected payment if she and Bob are both randomly selected. As the number of agents increases, her expected payment will go to zero. However, if the sample complexity is large enough that a learning algorithm can pick out Alice and Bob from the crowd of noise, a mechanism might be able to appropriately reward them.

Intuitively, in such a case, we can pair Alice simultaneously with all other agents, and run our mechanism using the concatenation of all other agent's signals as "Bob"'s signal. As the number of agents increases, this approach ensures Alice's expected payment is non-decreasing because the mutual information does not decrease by adding more information – the additional agents' reports. However, the sample complexity for ideal scoring function will increase, perhaps even exponentially.

We propose two novel approaches that exploit the power of current machine learning algorithms to compute the mutual information between Alice’s signal and the rest of the agents with limited sample complexity.

**Computing the  $\Phi$ -Mutual Information between  $X_i$  and  $X_{-i}$ .** Our variation method is well suited to the challenge of reliably computing the  $\Phi$ -mutual information between Alice’s reports,  $X_i$ , and those of the other agents,  $X_{-i}$ .

Recall that Mechanism 2 reduces the mechanism design problem to learning a scoring rule, which Eqn. (1) reduces to learning

$$\text{JP}_P(x_i, x_{-i}) = \frac{P_{X_i, X_{-i}}(x_i, x_{-i})}{P_{X_i}(x_i)P_Y(x_{-i})} = \frac{P_{X_i|X_{-i}}(x_i | x_{-i})}{P_{X_i}(x_i)}.$$

Therefore, it is enough to learn both the marginal distribution,  $P_{X_i}(x_i)$  and  $P_{X_i|X_{-i}}(x_i | x_{-i})$ . The former can be estimated empirically. However, when the number of agents is large, the later is high dimensional and must be learned. Fortunately, this is just a soft-classifier which produces a forecast to predict her report rather than a single report. which, given the reports of every agent but Alice on a particular task, (soft) predicts Alice’s report on the same task.

Therefore, we can derive an approximate ideal scoring rule by using machine learning techniques to produce a (soft) prediction of Alice’s report for an answer given the reports of the other agents. Specifically, the machine learning algorithm outputs  $f(\cdot, \cdot)$  such that  $f(x_i, x_{-i}) = P_{X_i|X_{-i}}(x_i | x_{-i})$ .

Using Mechanism 2, we can divide the tasks into training and testing tasks. The training tasks are used to learn  $f$  and to estimate  $P_X(x)$ . We can compute  $K_{\text{est}}$  from  $f$  and  $P_X(x)$ , and then use Mechanism 2 to pay the agents.

Note that for the guarantees of Theorem 16 to hold, it is required that  $f$  is learned accurately on truthful strategy profiles. However, we do not require the learning algorithms perform well on non-truthful strategy profiles.

**Latent Variable Models.** Our pairing mechanisms are particularly powerful when the prior  $P$  on agents’ signals is a latent variable model. In a latent variable model, signals are mutually independent conditioned on the latent variables. Examples include Dawid-Skene models, Gaussian mixture models, hidden Markov models, and latent Dirichlet allocations. When  $P$  is a latent variable model, we can pay Alice the (approximate) mutual information between her report and each task’s latent variable.

1. Given a latent label recovery algorithm, e.g., [33], we run such algorithm on all reports except Alice’s, and get estimate of latent label for each tasks  $(Y_1, \dots, Y_m)$ ;
2. Then, using Alice’s report  $(X_1, \dots, X_m)$  and the estimated latent label  $(Y_1, \dots, Y_m)$  we can run Mechanism 2 with the generated method to pay Alice the mutual information between Alice’s report and the latent labels.

This mechanism is (approximate) strongly truthful, because the  $\Phi$ -mutual information between Alice and the others’ reports is less than the  $\Phi$ -mutual information between her reports and the tasks’ latent variable due to data processing inequality. This approach has the following advantages. First, this provides a reduction from aggregation to elicitation. Second, paying mutual information between Alice’s reports and the latent variable resolves the problems that the above naive approaches have. Alice’s payment increases as the number of agents increases by the data processing inequality and the sample complexity of scoring function mirrors that of the latent label algorithm, which typically will not increase.

## Abstract

Inspired by applications on search engines and web servers, we consider a load balancing problem with a general *convex* objective function. In this problem, we are given a bipartite graph on a set of sources  $S$  and a set of workers  $W$  and the goal is to distribute the load from each source among its neighboring workers such that the total load of workers are as balanced as possible. We present a new distributed algorithm that works with *any* symmetric non-decreasing convex function for evaluating the balancedness of the workers' load. Our algorithm computes a nearly optimal allocation of loads in  $O(\log n \log^2 d / \epsilon^3)$  rounds where  $n$  is the number of nodes,  $d$  is the maximum degree, and  $\epsilon$  is the desired precision. If the objective is to minimize the maximum load, we modify the algorithm to obtain a nearly optimal solution in  $O(\log n \log d / \epsilon^2)$  rounds. This improves a line of algorithms that require a polynomial number of rounds in  $n$  and  $d$  and appear to encounter a fundamental barrier that prevents them from obtaining poly-logarithmic runtime [6, 7, 13, 15]. In our paper, we introduce a novel primal-dual approach with multiplicative weight updates that allows us to circumvent this barrier. Our algorithm is inspired by [1] and other distributed algorithms for optimizing linear objectives but introduces several new twists to deal with general convex objectives.

## 1 Introduction

Emerging web based services including commercial web search engines face challenging resource efficiency targets in their serving data centers. Motivated by the growing demand in fast responding services, they aim for sub-second latency targets. Therefore they replicate the data across distributed machines in data centers to allow for serving queries in parallel as well as cloning the search algorithm to expedite computation tasks. With billions of queries to serve on a daily basis [14], load balancing becomes a critical challenge in resource efficiency and optimizing the computation fleet.

From the combinatorial optimization perspective, one can formulate the serving requirements with packing and covering constraints and model this problem as an allocation/matching instance in a bipartite graph. Although feasibility of the allocation is the first problem to study, in practice, we face a wider range of objectives to optimize. Emergency mechanisms in data centers allow the excess load to be served with the buffer capacities locally or be shifted to alternative data centers globally with services like Global Server Load Balancing.

This motivates service level objectives (SLO) in terms of quantile statistics of machine utilization values or other convex functions that are much more sensitive to higher utilization values instead of standard linear objective functions in matching theory that have uniform partial derivatives across the whole range of valid utilization values. One particular frequently occurring scenario is when the underlying properties of the load balancing instance determines some phase transition utilization threshold (say 0.95) beyond which the service starts to deteriorate. Thus, the cost objective function we are trying to minimize should have completely different behaviours on the two sides of this threshold and linear functions are unable to capture this exponential growth in the cost function.

To accommodate this wide range of objectives, in this paper we focus on the load balancing problem with a general *convex* objective function. The problem is defined on a bipartite graph, with a set of sources  $S$  on one side, and a set of workers  $W$  on the other. For each source, we must distribute its load among its neighboring workers. The goal is to minimize a convex function of the workers' loads (where the load of a worker is the total load it receives from all incoming sources). Fractional allocations are allowed, as in the real-world setting, there are usually huge amounts of query requests coming from each source.

The problem described above can be solved as a convex program. However, in real-world settings, the graph could contain billions of nodes and be too large to store in one piece. Thus, for an algorithm to be scalable, it has to be implementable in a *distributed* manner. In this paper, we work in the CONGEST model that is standard in distributed algorithms literature (see e.g. [4]). Under this model, computation proceeds in rounds and in each round, each node may send a logarithmic number of bits to each of its neighbors. Previous distributed algorithms for load balancing (with a convex objective), such as [6, 7, 13, 15], require a number of distributed rounds that is *polynomial* in the number of nodes or the maximum degree of a node. This could still be prohibitive for real-world applications where each node could have a large number of neighbors. The main contribution of this paper is to provide *the first distributed algorithm* that computes an approximately optimal solution to the load balancing problem with a convex objective and runs in a *poly-logarithmic* number of distributed rounds. Our main theorem is stated below.

► **Theorem 1 (Informal).** *Assume the objective function  $\Phi$  is convex, symmetric, and non-decreasing in each variable. Then for any  $\epsilon < 1$ , our algorithm computes a  $(1 + \epsilon)$ -approximation to the optimal solution in  $O\left(\frac{\log n \log^2 d}{\epsilon^3}\right)$  rounds, where  $n, d$  denote the number of nodes and the maximum degree respectively.*<sup>1</sup>

In the special case where the objective is the max function, i.e. the goal is to minimize the maximum load, we obtain a distributed algorithm with an improved round complexity of  $O\left(\frac{\log n \log d}{\epsilon^2}\right)$ , which is faster than a direct application of a parallel mixed positive LP solver (see [11]) by an  $O\left(\frac{\log n}{\epsilon}\right)$  factor.

---

<sup>1</sup> Technically, we need a few additional assumptions on the objective function  $\Phi$  in order to obtain a  $(1 + \epsilon)$ -approximation in terms of objective value. Formally, our theorem is stated in terms of an  $\epsilon$ -approximate solution which is defined in the main body but for natural objective functions such as  $L^p$  norms for  $p > 1$ , our algorithm obtains a  $(1 + \epsilon)$ -approximation in objective value. See the remark at the end of Section 2 for more details.

► **Theorem 2** (Informal). *When the objective is the max function, our algorithm computes a  $(1 + \epsilon)$ -approximation to the optimal solution and runs in  $O\left(\frac{\log n \log d}{\epsilon^2}\right)$  rounds.*

## 1.1 Related work

There is extensive work on distributed algorithms for optimizing linear objective functions such as packing, covering and positive LPs [2, 3, 5, 10, 11, 17, 18]. In these settings, distributed algorithms with poly-logarithmic convergence rates are known. In particular, for general positive LPs, there is a distributed algorithm that computes a  $(1 + \epsilon)$ -approximation in  $O\left(\frac{\log^3 n}{\epsilon^3}\right)$  rounds; for the special case of pure packing and pure covering LPs, a better runtime of  $O\left(\frac{\log^2 n}{\epsilon^2}\right)$  is known [11]. We refer the interested reader to the thesis [16] for a more detailed survey. While the techniques in these works can be applied to our problem when the objective function is linear, optimizing a general convex objective is significantly different. Whereas for a linear objective, the optimum always occurs at one of the vertices of the feasible polytope, for a convex objective, the optimum may be in the interior. Therefore, it seems that existing algorithms for optimizing linear objectives cannot be directly applied.

As mentioned previously, there are works that study a convex load balancing objective [6, 7, 13, 15]. The algorithms proposed in these works have distributed runtime that depends polynomially on the number of nodes or the maximum degree whereas our algorithm has only polylogarithmic dependence on these parameters.

There has also been work on discrete load balancing i.e. when the sources are not divisible (so fractional allocations are not allowed). A recent line of work [4, 8, 9] obtains constant-factor approximation algorithms in the local and congest models. More specifically, Czygrinow et al. [8] give a distributed 2-approximation algorithm that runs in  $O(d^5)$  rounds. Assadi et al. [4] gives an  $O(1)$ -approximation algorithm for unweighted loads and an  $O(\log n)$  approximation algorithm for weighted loads with polylogarithmic round complexity in the congest model. For the less restrictive local model, they present an  $O(1)$ -approximation algorithm for weighted loads with polylogarithmic round complexity. In general, when the sources are not divisible, one cannot hope to compute, say, a  $(1 + \epsilon)$ -approximation efficiently. Thus, these works focus on constant-factor approximation, whereas in our setting, we focus on computing a nearly optimal solution.

## 1.2 Technical Overview

One key limitation for previous works on (continuous) load balancing [6, 7, 13, 15] is that they rely on an algorithm that, for each source, additively shifts load from higher-loaded neighbors to lower-loaded neighbors. However, the step size must be set to  $O(1/d)$  in order for the algorithm to be stable and thus the number of rounds required depends linearly (or even worse) on the maximum degree  $d$ .

Since the load balancing problem is convex, another natural approach is to apply general convex optimization algorithms that can be implemented in a distributed manner. However, straight-forward applications of first-order convex optimization algorithms also get stuck with a linear dependence on  $d$  because both the diameter of the feasible polytope and the condition number of the convex optimization problem can depend linearly on the maximum degree.

We circumvent the aforementioned limitations by adopting a different algorithmic framework and we introduce a novel algorithm based on a primal-dual approach with multiplicative-weight updates. One of the central insights in our algorithm is that if we know the target

capacities in the optimal solution, then we can compute the allocation of the sources that achieves the optimum as this essentially reduces to solving a linear problem. More generally, for a given set of target capacities, we can essentially test whether it is achievable. This motivates the following iterative procedure: we start with very high target capacities and iteratively update the target capacities downwards while checking feasibility until we reach a solution that is barely feasible.

For checking feasibility, we use a proportional allocation algorithm based on the work in [1] for maximum matching. We update the load assignment according to the proportional allocation algorithm and then update the target capacities based on whether each worker has too much or too little load. We start our algorithm with a feasible solution (by setting the target capacities to be very high) and can easily maintain feasibility throughout the entire process. The difficulty lies in proving optimality. An important observation is that after running the proportional allocation algorithm for a sufficient number of iterations, if there are workers whose load differs significantly from their target capacity, then it is possible to (implicitly) construct a certificate that this imbalance must happen in any feasible allocation. For the special case when the objective is the max function, it is not too difficult to complete the proof using the above ideas as it suffices to maintain the same target capacity for all the workers and decrease all capacities together. When the algorithm stops, we only need to show that there exists a set of workers that is *saturated*, in the sense that their total capacity is roughly equal to the total load of the sources whose neighbors are all included in this set. For general convex objectives, we will need a more refined analysis since the workers may have different target capacities. We will prove that the solution that we compute is optimal at multiple levels. In particular, our algorithm allows us to (implicitly) construct a multi-level cut that serves as a hierarchy of certificates that, when combined, imply that the entire solution is nearly optimal.

## 2 Preliminary

We now formalize our problem and introduce notation. In the load balancing problem, the input is a bipartite graph  $G(S, W, E)$ , where we use  $S$  ( $|S| = n_S$ ) to denote the set of sources and  $W$  ( $|W| = n_W$ ) to denote the set of workers. We write  $n = n_S + n_W$ . We assume there is a load associated with each source  $s \in S$ . For simplicity of presentation, we assume each source has one unit of load, although following the same proof method, the results obtained in this paper can be generalized to arbitrary weighted loads. For each source  $s \in S$ , we use  $N_s$  to denote the set of workers that are connected to the source  $s$ . Similarly, we use  $N_w$  to denote all the sources that are connected to worker  $w$ . We use  $d$  to denote the maximum degree of a node (source or worker) in the graph. For a subset of workers  $X \subset W$ , let  $N(X) \subset S$  be the set of sources  $s$  with the property that all of the neighbors of  $s$  are in  $X$ .

We want to assign loads along the edges of the graph such that all of the sources are served and the loads of the workers are as balanced as possible. We use  $x_{s,w}$  to denote the amount of load assigned from source  $s$  to worker  $w$ . We assume the load is splittable and fractional allocations are allowed. For each worker  $w$ , define its load  $L_w$  to be

$$L_w = \sum_{s \in N_w} x_{s,w}.$$

In this paper, our objective is to minimize some convex function of the loads. We assume the objective function  $\Phi : \mathbb{R}^{n_W} \rightarrow \mathbb{R}$  is symmetric, convex, and non-decreasing in each variable. Formally, we aim to solve the following optimization problem in a distributed manner:

$$\begin{aligned}
& \text{minimize} && \Phi(L_1, \dots, L_{n_W}) \\
& \text{subject to} && \sum_{w \in N_s} x_{s,w} = 1 \quad \forall s \in S \\
& && L_w = \sum_{s \in N_w} x_{s,w} \quad \forall w \in W \\
& && x_{s,w} \geq 0 \quad \forall s \in S, w \in W \\
& && x_{s,w} = 0 \quad \forall (s, w) \notin E
\end{aligned} \tag{1}$$

Given any load vector  $L = (L_1, \dots, L_{n_W}) \in \mathbb{R}^{n_W}$ , we say it is *feasible* if there exists a feasible assignment  $\{x_{s,w}\}_{s \in S, w \in W}$  that satisfies the constraints of Eq. (1). Our algorithm will find an  $\epsilon$ -approximate solution as defined below.

► **Definition 3** ( $\epsilon$ -approximate solution). *We say  $L = (L_1, \dots, L_{n_W})$  is an  $\epsilon$ -approximate solution, if  $L$  is feasible and for any other feasible solution  $(L'_1, \dots, L'_{n_W})$ , we have*

$$\Phi(L_1, \dots, L_{n_W}) \leq \Phi((1 + \epsilon)L'_1, \dots, (1 + \epsilon)L'_{n_W}).$$

We are primarily interested in the case where  $1/\epsilon$  is constant or poly-logarithmic in  $n$  so runtime that is polynomial in  $1/\epsilon$  is acceptable.

► **Remark 4.** The definition of  $\epsilon$ -approximate solution is stated in terms of scaling the *inputs* of the convex function rather than scaling the *value* of the convex function itself. An  $\epsilon$ -approximate solution would directly imply a  $(1 + O(\epsilon))$  approximation on the optimal value for any Lipschitz continuous function together with a mild lower bound assumption on the optimal value. In particular, it implies  $(1 + \epsilon)$ -approximation (in terms of objective value) for widely used functions such as  $L_p$  norms for  $p \geq 1$ .

In general, it is impossible to achieve a multiplicative approximation without additional assumptions on the objective. For instance, if we take  $\Phi = \max(\max(L_1, \dots, L_{n_W}) - \text{OPT}, 0)$  where  $\text{OPT}$  is the minimum possible value of  $\max(L_1, \dots, L_{n_W})$ , then achieving a multiplicative approximation would require solving the problem exactly.

### 3 Algorithm

We first give a high level overview of our main algorithm (the pseudocode is given in Algorithm 1). The algorithm maintains a target capacity  $C_w$  and a weight  $a_w$  for each worker  $w \in W$ . For any source  $s \in S$ , the amount of load it assigns to its neighbor worker  $w$  ( $w \in N_w$ ) is proportional to the weight  $a_w$  (see Line 13). Our algorithm always maintains a (near) feasible solution under the target capacity. It gradually decreases the target capacity and adjusts the weights, until reaching a nearly optimal solution. The algorithm updates the capacity once per epoch (see Line 8 to Line 12). While in each epoch, the algorithm freezes the target capacity and attempts to find a feasible assignment via the PROPORTIONAL ALLOCATION algorithm (see Algorithm 2). The PROPORTIONAL ALLOCATION algorithm was originally proposed in [1] for finding an approximate maximum matching. It adjusts the weight of workers based on the following rules: If the current load exceeds the target capacity, it decreases the weight by a multiplicative factor of  $(1 + \epsilon)$ ; it increases the weight otherwise. After repeating the weight updating rules for  $\tilde{O}\left(\frac{\log n \log d}{\epsilon^2}\right)$  steps, our algorithm updates the target capacities on workers based on the gap between the target capacity and the current load. The algorithm will *fix* workers whose load significantly exceeds the target capacity meaning that for these workers, the target capacity never changes anymore.

---

**Algorithm 1** GENERAL LOAD BALANCING.

---

```

1: Input: Graph  $G$ , set of workers  $W$ , set of sources  $S$ 
2: Initialize weights  $a_w = 1$  for all workers  $w \in W$ .
3: Initialize capacity upper bounds  $C_w = d$  for all workers  $w \in W$ 
4: Set all workers  $w$  to be unfixed
5: Set  $A = \frac{2 \log(d/\epsilon)}{\epsilon}$  and  $B = \frac{100 \log(n/\epsilon) \cdot \log(d/\epsilon)}{\epsilon^2}$ 
6: for  $r = 0, 1, \dots, A - 1$  do
7:    $x \leftarrow \text{PROPORTIONAL\_ALLOCATION}(G, C, a, \epsilon, B)$ 
8:   for  $w \in W$  do
9:     if  $w$  is unfixed and  $L_w < (1 + 10\epsilon)C_w$  then
10:      Set  $C_w \leftarrow \frac{C_w}{1+\epsilon}$ 
11:     else
12:      Set  $w$  to fixed
13: return  $x_{s,w} = \frac{a_w}{\sum_{w \in N_s} a_w}$ 

```

---

The pseudocode of the PROPORTIONAL ALLOCATION algorithm is given in Algorithm 2. We note that each time we run PROPORTIONAL ALLOCATION and update the weights  $a_w$ , we *do not* reinitialize the weights. We continue updating from the weights computed in the previous step.

---

**Algorithm 2** PROPORTIONAL ALLOCATION [1] ( $G, C, a, \epsilon, B$ ).

---

```

Input: Graph  $G$ , set of workers  $W$ , set of sources  $S$ 
Input: Target capacity  $C_w$  for each worker
Input: Initial weight  $a_w$  for each worker
Input: Precision  $\epsilon$ 
input: Number of rounds  $B$ 
for  $t = 0, 1, \dots, B - 1$  do
  Set  $x_{s,w} = \frac{a_w}{\sum_{w \in N_s} a_w}$  for all edge variables  $x_{s,w}$ 
  for  $w \in W$  do
    If  $L_w > C_w$  then update  $a_w \leftarrow \frac{a_w}{1+\epsilon}$ 
    If  $L_w < C_w$  then update  $a_w \leftarrow (1 + \epsilon)a_w$ 
return  $x_{s,w} = \frac{a_w}{\sum_{w \in N_s} a_w}$ 

```

---

## 4 Analysis

Our main result is formally stated in Theorem 5, we sketch the high-level idea of the proof here. The main idea in the proof of Theorem 5 is to show that if we have fixed the sets of workers  $W_1, W_2, \dots, W_r$  in iterations  $1, 2, \dots, r$ , then the number of sources whose only neighbors are in the set  $W_1 \cup \dots \cup W_r$  is at least  $(1 - O(\epsilon)) \sum_{w \in W_1 \cup \dots \cup W_r} C_w$ . This would then certify that our solution is essentially optimal for the total load among the set of workers in  $W_1 \cup \dots \cup W_r$ . While this claim is not technically true, Lemma 12 is a slight modification that involves considering a superset of  $W_1 \cup \dots \cup W_r$  and it suffices for our purposes. Once we have a hierarchy of certificates for  $r = 1, 2, \dots, A - 1$  we can prove that the solution computed by our algorithm is essentially optimal overall.

► **Theorem 5.** Assume the objective function  $\Phi : \mathbb{R}^{nw} \rightarrow \mathbb{R}^+$  is convex, symmetric, and non-decreasing in each variable. For  $0 < \epsilon < 1$ , Algorithm 1 computes an  $O(\epsilon)$ -approximate solution in  $O\left(\frac{\log n \log^2 d}{\epsilon^3}\right)$  distributed rounds.

In the proof of Theorem 5, the bulk of the work is in proving Lemma 12. We will first prove some basic facts about the behavior of the loads and target capacities throughout the execution of Algorithm 1 in Section 4.1. We then introduce the concept of majorization for analyzing convex functions in Section 4.2. In Section 4.3, we prove Lemma 12. A key observation about the proportional allocation algorithm of [1] is that at the end, if the load on a worker is significantly less than the target capacity, its weight  $a_w$  must be increased at every round and if the load on a worker is significantly more than the target capacity, its weight  $a_w$  must be decreased at every round. Thus, there must be a large multiplicative gap between weights on underallocated and overallocated workers. Since loads are allocated proportionally, if some source is connected to both underallocated workers and overallocated workers, almost all of the load is actually being sent to the underallocated workers. Exploiting this intuition (we will need a slightly more precise statement in the proof), we can construct the desired certificate and complete the proof of Lemma 12. Finally, combining Lemma 12 with the tools introduced in Section 4.2 for analyzing convex functions, we complete the proof of Theorem 5.

## 4.1 Basic Observations

### Notation

For a load variable  $L_w$  and indices  $0 \leq r < A, 0 \leq t \leq B$ , we let  $L_w^{r,t}$  denote its value when the algorithm is executed to the timestep  $r, t$  i.e. we have completed  $r$  full iterations of PROPORTIONAL ALLOCATION and  $t$  rounds within the next iteration of PROPORTIONAL ALLOCATION. We adopt the same notation for  $x_{s,w}$ ,  $s_w$  and  $C_w$ .

Below is an informal summary of the properties that we will prove in this section.

- Loads gradually move toward the target capacities
- Loads never significantly exceed the target capacity
- For fixed workers, their load is roughly equal to their target capacity
- Any significantly underallocated workers must have their weight increased at every previous timestep

We begin with a simple observation that after each weight update, the load on each worker moves toward the target capacity.

► **Lemma 6.** Consider indices  $0 \leq r < A, 0 \leq t < B$  then

- If  $L_w^{r,t} > C_w^{r,t}$  then  $\frac{L_w^{r,t}}{(1+\epsilon)^2} \leq L_w^{r,t+1} \leq L_w^{r,t}$
- If  $L_w^{r,t} < C_w^{r,t}$  then  $L_w^{r,t} \leq L_w^{r,t+1} \leq (1+\epsilon)^2 L_w^{r,t}$

**Proof.** We prove the first claim and the second one follows from the same argument. Suppose  $L_w^{r,t} > C_w^{r,t}$ , then we know that  $a_w^{r,t+1} = a_w^{r,t}/(1+\epsilon)$ . Together with the fact that  $a_{w'}^{r,t} \in [(1+\epsilon)^{-1}a_w^{r,t}, (1+\epsilon)a_w^{r,t}]$  holds for all worker  $w' \in W$ , we have

$$L_w^{r,t+1} = \sum_{s \in N_w} \frac{a_w^{r,t+1}}{\sum_{w' \in N_s} a_{w'}^{r,t+1}} \leq \sum_{s \in N_w} \frac{a_w^{r,t} \cdot (1+\epsilon)^{-1}}{\sum_{w' \in N_s} a_{w'}^{r,t} \cdot (1+\epsilon)^{-1}} = L_w^{r,t}$$

and

$$L_w^{r,t+1} = \sum_{s \in N_w} \frac{a_w^{r,t+1}}{\sum_{w' \in N_s} a_{w'}^{r,t+1}} \geq \sum_{s \in N_w} \frac{a_w^{r,t} \cdot (1+\epsilon)^{-1}}{\sum_{w' \in N_s} a_{w'}^{r,t} \cdot (1+\epsilon)} = \frac{L_w^{r,t}}{(1+\epsilon)^2}. \quad \blacktriangleleft$$

## 79:8 Distributed Load Balancing

Next, we observe that the load on any worker can never significantly exceed its target capacity.

► **Lemma 7.** *For all workers  $w$ , we have at all timesteps  $r, t$ ,*

$$L_w^{r,t} \leq (1 + 10\epsilon)(1 + \epsilon)C_w^{r,t}.$$

**Proof.** We prove the claim by induction on  $r$  and  $t$ . The base case is clearly true as

$$L_w^{0,0} \leq d = C_w^{0,0}.$$

Suppose the claim holds up to  $r, t$ . If  $0 \leq t < B$ , then Lemma 6 implies the desired for  $r, t + 1$ . If  $t = B$ , then we are in one of the following two cases

- $L_w^{r,B} < (1 + 10\epsilon)C_w^{r,B}$ , which implies  $L_w^{r+1,0} < (1 + 10\epsilon)(1 + \epsilon)C_w^{r+1,0}$
- $L_w^{r,B} \geq (1 + 10\epsilon)C_w^{r,B}$ , which implies  $C_w^{r+1,0} = C_w^{r,B}$

The first case is clearly resolved. For the second case, we can use the induction hypothesis to get the desired. ◀

When a worker becomes *fixed*, we observe that at all future timesteps, its load is close to its target capacity.

► **Lemma 8.** *For a worker  $w$ , once  $w$  is fixed, we have*

$$L_w^{r,t} \geq \frac{C_w^{r,t}}{(1 + \epsilon)^2}$$

*holds for all **future** timesteps.*

**Proof.** When  $w$  is *fixed*, we must have  $L_w > C_w$ . Combining Lemma 6 with the fact that we no longer update  $C_w$ , we get the desired. ◀

For any worker whose load is significantly lower than its capacity, we note that its weight  $a_w$  must have been increased at **every** previous timestep.

► **Lemma 9.** *Consider a worker  $w$  such that for some  $0 \leq r < A$ , if*

$$L_w^{r,B} \leq \frac{C_w^{r,B}}{(1 + \epsilon)^2},$$

*then*

$$a_w = (1 + \epsilon)^{(r+1)B},$$

*i.e. if a worker is significantly underallocated when we reach the capacity update step, then its weight must have been increased at every step.*

**Proof.** This follows immediately from Lemma 6 and the fact that the capacities  $C_w$  are weakly decreasing. ◀

## 4.2 Majorization

We present a basic inequality about convex functions that will be useful later on for bounding the objective value. We first introduce the concept of *majorization*.

► **Definition 10** (Majorization). For two sequences of real numbers  $(x_1, \dots, x_n)$  and  $(y_1, \dots, y_n)$ , let  $\pi, \sigma$  be permutations such that

$$x_{\pi(1)} \geq \dots \geq x_{\pi(n)}, y_{\sigma(1)} \geq \dots \geq y_{\sigma(n)}.$$

We say  $(x_1, \dots, x_n)$  **weakly majorizes**  $(y_1, \dots, y_n)$  if for all  $1 \leq k \leq n$

$$\sum_{i=1}^k x_{\pi(i)} \geq \sum_{i=1}^k y_{\sigma(i)}.$$

If we also have that

$$\sum_{i=1}^n x_{\pi(i)} = \sum_{i=1}^n y_{\sigma(i)}$$

then we say  $(x_1, \dots, x_n)$  **majorizes**  $(y_1, \dots, y_n)$

Intuitively, a sequence  $(x_1, \dots, x_n)$  majorizes a sequence  $(y_1, \dots, y_n)$  if the terms of  $(x_1, \dots, x_n)$  are more imbalanced. The following inequality states that a symmetric convex function takes larger values when the inputs are more imbalanced:

► **Lemma 11.** Let  $f$  be a convex function that is symmetric and non-decreasing in each of the variables. Given sequences  $(x_1, \dots, x_n)$  and  $(y_1, \dots, y_n)$  such that  $(x_1, \dots, x_n)$  weakly majorizes  $(y_1, \dots, y_n)$ , we have

$$f(x_1, \dots, x_n) \geq f(y_1, \dots, y_n).$$

If  $(x_1, \dots, x_n)$  majorizes  $(y_1, \dots, y_n)$  then the above inequality holds without the assumption that  $f$  is non-decreasing.

**Proof.** [12] proves the above inequality when  $(x_1, \dots, x_n)$  majorizes  $(y_1, \dots, y_n)$ , we adapt it to the case that  $(x_1, \dots, x_n)$  weakly majorizes  $(y_1, \dots, y_n)$ . In particular, we prove that there exists a sequence  $(y'_1, \dots, y'_n)$  such that  $y'_i \geq y_i$  for all  $1 \leq i \leq n$  and  $(x_1, \dots, x_n)$  majorizes  $(y'_1, \dots, y'_n)$ . WLOG, we assume  $x_1 \geq \dots \geq x_n$  and  $y_1 \geq \dots \geq y_n$ . We construct the sequence as follows. We first set  $y'_1$  to be the largest value so that  $(x_1, \dots, x_n)$  weakly majorizes  $(y'_1, y_2, \dots, y_n)$ . After determining the value of  $y'_1$ , we set  $y'_2$  to be the largest value so that  $(x_1, \dots, x_n)$  weakly majorizes  $(y'_1, y'_2, y_3, \dots, y_n)$ . We repeat this process to set all of  $y'_3, \dots, y'_n$ . Now, for each index  $i \in [n]$ , there exists an index  $j$  with  $j \geq i$  such that

$$x_1 + \dots + x_j = y'_1 + \dots + y'_i + y_{i+1} + \dots + y_j,$$

as otherwise, this would contradict the maximality of  $y'_i$ . Hence, we conclude that

$$x_1 + \dots + x_n = y'_1 + \dots + y'_n,$$

so  $(x_1, \dots, x_n)$  majorizes  $(y'_1, \dots, y'_n)$ , as desired. ◀

### 4.3 Main Proof

Now we are ready to analyze the performance of the algorithm. The following lemma is essential to our proof. Intuitively, it allows us to construct a set of cuts that “certify” that the solution computed by the algorithm is essentially optimal.

## 79:10 Distributed Load Balancing

► **Lemma 12.** *Let  $X_0 = \emptyset$ . We can construct sets  $X_1, \dots, X_A \subset W$  with the following properties:*

- $X_1 \subset X_2 \subset \dots \subset X_A$
- $|N(X_r)| \geq \sum_{i=0}^{r-1} |X_{i+1} \setminus X_i| \cdot \frac{d}{(1+\epsilon)^{i+10}}$
- $X_i$  contains all of the workers that are fixed after executing PROPORTIONAL ALLOCATION and capacity updates for  $r = 0, 1, \dots, i-1$

**Proof.** We prove the claim by induction. Assume that we have already constructed  $X_1, \dots, X_{i-1}$ . Let  $F^i$  be the set of workers that become *fixed* after completing the capacity updates for  $r = i-1$  but are not fixed before this. For any worker  $w \in F^i$ , we must have

$$a_w^{i-1,t+1} = \frac{a_w^{i-1,t}}{1+\epsilon} \quad \forall 0 \leq t < B.$$

This is because if this was not the case, we must have  $L_w^{i-1,t_0} < C_w^{i-1,t_0}$  for some  $t_0$  and by Lemma 6, this implies  $L_w^{i-1,t} \leq (1+\epsilon)^2 C_w^{i-1,t}$  holds for all  $t \geq t_0$ . This contradicts the fact that worker  $w$  gets fixed in the execution of the capacity updates for  $r = i-1$ . Thus, we conclude for any  $w \in F^i$

$$a_w^{i-1,B} \leq (1+\epsilon)^{(i-1)B}.$$

Let  $Y = F^i \setminus (F^i \cap X_{i-1})$ . If  $Y$  is empty then it suffices to set  $X_i = X_{i-1}$ . Assume  $Y$  is not empty, then for any integer  $0 \leq j \leq B$ , define  $Z_j$  as

$$Z_j := \{w | w \in W, a_w \leq (1+\epsilon)^{(i-1)B+j}\}.$$

We note that  $Y \subseteq Z_0 \subseteq Z_1 \subseteq \dots \subseteq Z_B$  and therefore  $Z_0 \neq \emptyset$ .

Since  $B \geq \frac{100 \log(n/\epsilon) \cdot \log(d/\epsilon)}{\epsilon^2}$ , there must exist some index  $j$  satisfying

$$10 \log\left(\frac{d}{\epsilon}\right) \cdot \frac{1}{\epsilon} \leq j < B$$

and

$$|Z_j \setminus X_{i-1}| \leq (1+\epsilon) \cdot \left| Z_{j-10 \log(\frac{d}{\epsilon}) \cdot \frac{1}{\epsilon}} \setminus X_{i-1} \right|. \quad (2)$$

We set  $X_i = Z_j \cup X_{i-1}$  and prove it satisfies all three properties in the rest of the proof. The first and third properties are clearly satisfied, i.e.,  $Z_j \cup X_{i-1}$  is a superset of  $X_{i-1}$  and it contains all of the workers that are fixed after  $i$  executions of PROPORTIONAL ALLOCATION. It remains to verify the second one

For any worker  $w \in Z_{j-10 \log(\frac{d_{\max}}{\epsilon}) \cdot \frac{1}{\epsilon}}$ , if the worker  $w$  is connected to some source  $s$ , such that  $s$  has another neighbor worker  $w'$  with  $w' \notin Z_j$ , then we have

$$x_{s,w}^{i-1,B} \leq \frac{a_w^{i-1,B}}{a_w^{i-1,B} + a_{w'}^{i-1,B}} < \frac{(1+\epsilon)^{(i-1)B+j-10 \log(\frac{d}{\epsilon}) \cdot \frac{1}{\epsilon}}}{(1+\epsilon)^{(i-1)B+j}} \leq \left(\frac{\epsilon}{d}\right)^{10}$$

Therefore, the total contributions  $x_{s,w}^{i-1,B}$  from all sources  $s$  with a neighbor not in  $Z_j$  to the worker  $w$  is at most

$$\sum_{\substack{s \in N_w \\ N_s \cap (W \setminus Z_j) \neq \emptyset}} x_{s,w}^{i-1,B} \leq \left(\frac{\epsilon}{d}\right)^{10} \cdot d \leq \left(\frac{\epsilon}{d}\right)^9. \quad (3)$$

Now we bound the changes of  $|N(X_i)|$  comparing to  $|N(X_{i-1})|$ . Consider the graph  $G^{i-1,B}$  at timestep  $(i-1, B)$ . We restrict the graph to the one induced by the set of workers  $Z_j$  and the set of sources  $N(Z_j)$ . For each worker  $w \in Z_{j-10 \log(\frac{d}{\epsilon}) \cdot \frac{1}{\epsilon}} \setminus X_{i-1}$ , its load in  $G^{i-1,B}$  satisfies

$$L_w^{i-1,B} \geq \frac{C_w^{i-1,B}}{(1+\epsilon)^2} \geq \frac{d}{(1+\epsilon)^{i+1}} \quad (4)$$

The first step comes from Lemma 9, the second step comes from the fact that  $C_w^{i-1,B} = d/(1+\epsilon)^{i-1}$ .

Thus the load of worker  $w$  in the restricted graph is at least

$$\begin{aligned} \sum_{\substack{s \in N_w \\ N_s \cap (W \setminus Z_j) = \emptyset}} x_{s,w}^{r, A_r-1, B_r} &= L_w^{r, A_r-1, B_r} - \sum_{\substack{s \in N_w \\ N_s \cap (W \setminus Z_j) \neq \emptyset}} x_{s,w}^{r, A_r-1, B_r} \\ &\geq \frac{d}{(1+\epsilon)^{i+1}} - \left(\frac{\epsilon}{d}\right)^9 \\ &\geq \frac{d}{(1+\epsilon)^{i+2}}. \end{aligned} \quad (5)$$

The second step comes from Eq. (3)(4).

Consequently, we have

$$\begin{aligned} |N(X_i)| - |N(X_{i-1})| &= |N(Z_j \cup X_{i-1})| - |N(X_{i-1})| \\ &\geq \sum_{w \in Z_j \setminus X_{i-1}} \sum_{\substack{s \in N_w \\ N_s \cap (W \setminus Z_j) = \emptyset}} x_{s,w}^{r, A_r-1, B_r} \\ &\geq \frac{d}{(1+\epsilon)^{i+2}} |Z_{j-10 \log(\frac{d}{\epsilon}) \cdot \frac{1}{\epsilon}} \setminus X_{i-1}| \\ &\geq \frac{d}{(1+\epsilon)^{i+3}} |Z_j \setminus X_{i-1}| \\ &= \frac{d}{(1+\epsilon)^{i+3}} |X_i \setminus X_{i-1}|. \end{aligned}$$

The third step follows from Eq. (5), the fourth step follows from Eq. (2) We complete the induction here.  $\blacktriangleleft$

Let  $X_0 = \emptyset, X_1, \dots, X_A$  be the sets constructed in Lemma 12. In the following two lemmas, we will compare our solution with the optimal solution using the hierarchy of certificates given by Lemma 12.

► **Lemma 13.** *Consider a feasible assignment and suppose the loads on the workers are  $L_1, \dots, L_{n_W}$ . Then the sequence  $(L_1, \dots, L_{n_W})$  weakly majorizes the following sequence  $\Gamma_1$ :*

- $|X_1 \setminus X_0|$  copies of  $\frac{d}{(1+\epsilon)^{11}}$
- $|X_2 \setminus X_1|$  copies of  $\frac{d}{(1+\epsilon)^{12}}$
- $\vdots$
- $|X_A \setminus X_{A-1}|$  copies of  $\frac{d}{(1+\epsilon)^{10+A}}$
- All remaining terms are set to 0

## 79:12 Distributed Load Balancing

**Proof.** Since the last  $n_W - |X_A|$  term of  $\Gamma_1$  is 0, it suffices to prove majorization for the first  $n_W - |X_A|$  indices. For any index  $1 \leq j \leq n_W - |X_A|$ , suppose  $|X_r| < j \leq |X_{r+1}|$  holds for some  $r$  ( $0 \leq r \leq A-1$ ). By Lemma 12, we have

$$\sum_{w \in X_{r+1}} L_w \geq \sum_{i=0}^r |X_{i+1} \setminus X_i| \cdot \frac{d}{(1+\epsilon)^{i+10}}$$

and

$$\sum_{w \in X_r} L_w \geq \sum_{i=0}^{r-1} |X_{i+1} \setminus X_i| \cdot \frac{d}{(1+\epsilon)^{i+10}}$$

Suppose  $G(r, j)$  consists of the largest  $j - |X_r|$  workers in  $X_{r+1} \setminus X_r$ , then we have

$$\begin{aligned} \sum_{w \in X_r \cup G(r, j)} L_w &\geq \sum_{w \in X_r} L_w + \frac{j - |X_r|}{|X_{r+1}| - |X_r|} \sum_{w \in X_{r+1} \setminus X_r} L_w \\ &= \frac{j - |X_r|}{|X_{r+1}| - |X_r|} \sum_{w \in X_{r+1}} L_w + \frac{|X_{r+1}| - j}{|X_{r+1}| - |X_r|} \sum_{w \in X_r} L_w \\ &\geq \frac{j - |X_r|}{|X_{r+1}| - |X_r|} \cdot \sum_{i=0}^r |X_{i+1} \setminus X_i| \cdot \frac{d}{(1+\epsilon)^{i+10}} \\ &\quad + \frac{|X_{r+1}| - j}{|X_{r+1}| - |X_r|} \sum_{i=0}^{r-1} |X_{i+1} \setminus X_i| \cdot \frac{d}{(1+\epsilon)^{i+10}} \\ &= \sum_{i=0}^{r-1} |X_{i+1} \setminus X_i| \cdot \frac{d}{(1+\epsilon)^{i+10}} + (j - |X_r|) \cdot \frac{d}{(1+\epsilon)^{r+10}} \end{aligned}$$

Thus completing the proof. ◀

► **Lemma 14.** Consider the assignment returned by our algorithm and suppose the loads on the workers are  $L'_1, L'_2, \dots, L'_{n_W}$ . Then the sequence  $(L'_1, \dots, L'_{n_W})$  is weakly majorized by the following sequence  $\Gamma_2$

- $|X_1 \setminus X_0|$  copies of  $\frac{(1+50\epsilon)d}{(1+\epsilon)^1}$
- $|X_2 \setminus X_1|$  copies of  $\frac{(1+50\epsilon)d}{(1+\epsilon)^2}$
- ⋮
- $|X_A \setminus X_{A-1}|$  copies of  $\frac{(1+50\epsilon)d}{(1+\epsilon)^A}$
- All remaining terms set to 0

**Proof.** For each index  $1 \leq i \leq A$ , define  $W^i$  to be the set of workers that are fixed after completing  $i$  full executions of PROPORTIONAL ALLOCATION and capacity update step. Consider any worker  $w$  that satisfies

$$L_w \geq \frac{(1+40\epsilon)d}{(1+\epsilon)^i}.$$

By Lemma 7, the capacity of worker  $w$  can be bounded as

$$C_w \geq \frac{(1+20\epsilon)d}{(1+\epsilon)^i}.$$

Now it is clear that this can only happen if the worker  $w$  is fixed before round  $i$ . In particular, the number of such workers is at most  $|W^i|$ . Meanwhile, we know that  $|X_i| \geq |W^i|$  by Lemma 12. Thus, if we only consider the  $|X_A|$  largest terms of the sequence  $(L'_1, \dots, L'_{n_W})$ , they are entry-wise dominated by the terms of  $\Gamma_2$ .

Since all terms after the  $|X_A|^{\text{th}}$  term of  $\Gamma_2$  are 0, to complete the proof of the weak majorization, it suffices to show that the sum of all of the terms of  $\Gamma_2$  is at least  $L'_1 + \dots + L'_{n_W}$ . Let  $U$  be the set of workers that are not *fixed* at the end of the execution of the algorithm. For all worker  $w \in U$ , due to the choice of  $A$ , we have

$$L'_w \leq (1 + 10\epsilon)C_w^{A-1, B} = \frac{(1 + 10\epsilon)d}{(1 + \epsilon)^{A-1}} \leq \frac{\epsilon}{d},$$

and therefore,

$$\sum_{w \in U} L'_w \leq \frac{\epsilon n_W}{d}. \quad (6)$$

Since the number of sources is at least  $\frac{n_W}{d}$ , we have

$$\sum_{w \in W} L'_w \geq \frac{n_W}{d}. \quad (7)$$

WLOG, we can assume  $L'_1 \geq L'_2 \geq \dots \geq L'_{n_W}$ . We then have

$$\sum_{i=0}^{A-1} |X_{i+1} \setminus X_i| \cdot \frac{(1 + 40\epsilon)d}{(1 + \epsilon)^i} \geq \sum_{j=1}^{|X_A|} L'_j \geq \sum_{w \in W \setminus U} L'_w \geq (1 - \epsilon) \sum_{w \in W} L'_w.$$

The second step holds due to the fact that the total number of workers that are fixed by the end of the algorithm is at most  $|X_A|$  (see Lemma 12). The last step follows from Eq. (6)(7).

Consequently, we have

$$\sum_{i=0}^{A-1} |X_{i+1} \setminus X_i| \cdot \frac{(1 + 50\epsilon)d}{(1 + \epsilon)^i} \geq \sum_{w \in W} L'_w,$$

which completes the proof.  $\blacktriangleleft$

Combining Lemma 13 and Lemma 14, we get

► **Corollary 15.** *Consider the assignment returned by our algorithm, and suppose the loads are  $L'_1, \dots, L'_{n_W}$ . For any feasible allocation, the loads  $L_1, \dots, L_{n_W}$  must satisfy that  $(L_1, \dots, L_{n_W})$  weakly majorizes  $\left(\frac{L'_1}{1+100\epsilon}, \dots, \frac{L'_{n_W}}{1+100\epsilon}\right)$*

Now we can easily wrap up the proof of Theorem 5.

**Proof of Theorem 5.** Let the loads in the output of our algorithm be  $L'_1, \dots, L'_{n_W}$  and let the loads in the optimal solution be  $L_1, \dots, L_{n_W}$ . Then

$$\Phi(L'_1, \dots, L'_{n_W}) \leq \Phi((1 + 100\epsilon)L_1, \dots, (1 + 100\epsilon)L_{n_W})$$

where we use Corollary 15 and Lemma 11. The above inequality immediately implies the desired.  $\blacktriangleleft$

## 5 Improved algorithm for minimizing max load

If the objective is the max function, i.e., we want to minimize the maximum load on workers, we can further reduce the number of distributed rounds to  $O\left(\frac{\log n \log d}{\epsilon^2}\right)$ . The idea is to start with a coarse estimation and gradually decrease the precision parameter down to  $\epsilon$ . The key observation is that each time we decrease the precision value, we only need to run a constant number of rounds of PROPORTIONAL ALLOCATION to refine our estimation and the number of distributed rounds of the algorithm is dominated by the number of rounds for the smallest precision parameter, which is  $O\left(\frac{\log n \log d}{\epsilon^2}\right)$ .

In Appendix B, we present an example showing that our analysis of our algorithm is tight. More specifically, we show that any proportional allocation based algorithm that starts from a uniform initialization and has step size bounded by  $\epsilon$  must run at least  $\Omega\left(\frac{\log n \log d}{\epsilon^2}\right)$  rounds to compute a  $1 + \epsilon$ -approximation.

To facilitate the presentation, we first define the precision sequence we use in the algorithm.

► **Definition 16.** We define the sequence  $\{\epsilon_r\}_{r \in \mathbb{N}}$  and  $\{B_r\}_{r \in \mathbb{N}}$  as follow.

■ For any  $r \geq 0$ ,  $\epsilon_{r+1} = (1 + \epsilon_r)^{1/2} - 1$  and  $\epsilon_0 = d - 1$ .

■ For any  $r \geq 0$ ,  $B_r = 2 \log_{1+\epsilon_r}(n) \log_{1+\epsilon_r}(d/\epsilon) + 8 \log_{1+\epsilon_r}(n)$

We further define  $R(n, \epsilon)$  to be the smallest index such that  $(1 + \epsilon_r)^5 \leq 1 + \epsilon$ .

### Algorithm 3 LOAD BALANCING FOR THE MAX OBJECTIVE.

---

```

1: Initialize weights  $a_w = 1$  for all workers  $w \in W$ .
2: Initialize capacity upper bounds  $C = d_{\max}$ .
3: Set  $R = R(n, \epsilon)$ .
4: for  $r = 0, 1, \dots, R - 1$  do
5:   Reset  $a_w = 1, \forall w \in W$ 
6:   while True do
7:     Run PROPORTIONAL ALLOCATION for  $B_r$  rounds with initial parameters  $a_w, \epsilon_r$ ,
        $C_w = C \forall w$ ,
8:     if  $\exists w \in W$  such that  $L_w \geq (1 + \epsilon_r)^4 C$  then
9:       Break the while loop
10:    else
11:       $C \leftarrow \frac{C}{1 + \epsilon_r}$ 
12:     $C \leftarrow C(1 + \epsilon_r)^8$ 
13: for  $s, w$  do
14:   Output  $x_{s,w} = \frac{a_w}{\sum_{w \in N_s} a_w}$ 

```

---

► **Theorem 17.** When the objective is the max function, Algorithm 3 returns an  $(1 + \epsilon)$  approximate solution to the load balancing problem after  $O\left(\frac{\log(n) \log(d/\epsilon)}{\epsilon^2}\right)$  iterations.

### Notations

For any  $0 \leq r \leq R - 1$ , we use  $A_r$  to denote the number of calls we make to PROPORTIONAL ALLOCATION within the while loop of round  $r$ . For the load variable  $L_w$ , we slightly abuse of notation and for any  $0 \leq r \leq R - 1, 0 \leq a \leq A_r - 1, 0 \leq t \leq B_r$ , we use  $L_w^{r,a,t}$  to denote

the load on worker  $w$  when the algorithm is executed to the timestep  $r, a, t$ , i.e. we finished  $r$  outer loops and completed  $a$  full iterations of PROPORTIONAL ALLOCATION, and then  $t$  rounds within the next iteration of PROPORTIONAL ALLOCATION. We apply the same notation for  $a_w$  and  $x_{s,w}$ . For the capacity variable, since we maintain the same capacity over all workers and the capacity does not change during the execution of PROPORTIONAL ALLOCATION, we simplify the notation and use  $C^{r,a}$  to denote the capacity on the worker side right after we finished  $r$  outer loops and completed  $a$  full iterations of PROPORTIONAL ALLOCATION *but before we perform the update on the capacity*.

The following observation, a restatement of Lemma 6, still holds.

- **Lemma 18.** *For any  $0 \leq r \leq R-1, 0 \leq a \leq A_r-1, 0 \leq t \leq B_r-1$*
- *If  $L_w^{r,a,t} > C^{r,a}$  then  $\frac{L_w^{r,a,t}}{(1+\epsilon_r)^2} \leq L_w^{r,a,t+1} \leq L_w^{r,a,t}$*
  - *If  $L_w^{r,a,t} < C^{r,a}$  then  $L_w^{r,a,t} \leq L_w^{r,a,t+1} \leq (1+\epsilon_r)^2 L_w^{r,a,t}$*

The following Lemma follows immediately from Lemma 18.

- **Lemma 19.** *Consider a worker  $w$  such that for some  $0 \leq r < R, 0 \leq a < A_r$ ,*

$$L_w^{r,a,B_r} \leq \frac{C_w^{r,a}}{(1+\epsilon_r)^2}$$

*then*

$$a_w = (1+\epsilon_r)^{(a+1)B_r}$$

*i.e. if a worker is significantly underallocated then its weight must have been increased at every step.*

We proceed next to the following key lemma, which says when we break the while loop for any round  $r$ , we actually find a certificate lower bound on the optimal value. The proof of Lemma 20 bares some similarities with Lemma 12, the difference is that we need to deal with the case that  $\epsilon_r$  is large. The detailed proof is provided in Appendix A for completeness.

- **Lemma 20.** *For any  $0 \leq r < R$ , we can find a subset of worker  $W_r \subseteq W$  such that*

$$|N(W_r)| \geq |W_r| \cdot \frac{C^{r,A_r}}{(1+\epsilon_r)^4}.$$

We next show that at the end of each round of PROPORTIONAL ALLOCATION, the load on any worker can never significantly exceed its target capacity.

- **Lemma 21.** *For all workers  $w$ , we have at all timesteps  $r, a$  with  $0 \leq r < R, 0 \leq a \leq A_r-1$*

$$L_w^{r,a,B_r} \leq (1+\epsilon_r)^5 C^{r,a+1}.$$

**Proof.** We prove by induction on  $(r, a)$ . The base case hold trivially as  $L_w^{0,0,B_r} \leq d_{\max} = C^{0,1}(1+\epsilon_0)$ . Suppose the claim holds up to  $(r, a)$ , it is easy to see it holds for  $(r, a+1)$ . This is due to Lemma 18 and the fact that we stop if  $L_w \geq (1+\epsilon_r)^4 C$  for any worker.

It remains to show that if the claim holds up to  $(r, A_r-1)$ , then it also holds for  $(r+1, 0)$ . This would complete the proof. We prove by contradiction. Suppose  $L_w^{r+1,0,B_r} \geq (1+\epsilon_r)^5 C^{r+1,1}$ , then we know that we need to break out the loop and followed by Lemma 20, there exists a subset of workers  $W_{r+1} \subseteq W$  such that

$$|N(W_{r+1})| \geq |W_{r+1}| \cdot \frac{C^{r+1,1}}{(1+\epsilon_{r+1})^4}$$

This actually says that the optimal solution is at least

$$\text{OPT} \geq \frac{C^{r+1,1}}{(1+\epsilon_{r+1})^4} = \frac{C^{r+1,1}}{(1+\epsilon_r)^2} = C^{r,A_r}(1+\epsilon_r)^6.$$

However, by induction, we have that  $L_w^{r,A_r-1,B_r} \leq (1+\epsilon_r)^5 C^{r,A_r}$ . this says that we actually have a solution with max load bounded by  $(1+\epsilon_r)^5 C^{r,A_r}$ , i.e.,  $\text{OPT} \leq (1+\epsilon_r)^5 C^{r,A_r}$ . This comes to a contradiction and we conclude the proof here.  $\blacktriangleleft$

► **Lemma 22.** For  $0 \leq r < R$ , the optimal solution satisfies

$$\text{OPT} \in [(1+\epsilon_r)^{-4} C^{r,A_r}, (1+\epsilon_r)^5 C^{r,A_r}]$$

**Proof.** The lower bound comes from Lemma 20. The upper bound comes from Lemma 21.  $\blacktriangleleft$

We can now wrap up the proof of Theorem 17

**Proof of Theorem 17.** The correctness of the algorithm comes as a direct corollary of Lemma 22. For the running time, for any  $0 \leq r < R$ , we claim that  $A_r \leq 30$ . The claim holds trivially for  $r = 0$  and for  $r \geq 1$ , we have

$$\begin{aligned} \text{OPT} &< (1+\epsilon_r)^6 C^{r,A_r} = (1+\epsilon_r)^{6-A_r} C^{r,0} = (1+\epsilon_{r-1})^{3-A_r/2} C^{r,0} \\ &= (1+\epsilon_{r-1})^{11-A_r/2} C^{r-1,A_{r-1}} \leq (1+\epsilon_{r-1})^{15-A_r/2} \text{OPT} \end{aligned}$$

The first inequality follows from the upper bound of Lemma 21, the second step follows from  $C^{r,A_r} = (1+\epsilon)^{-A_r} C^{r,0}$ . The third step follows from the fact that  $(1+\epsilon_r) = (1+\epsilon_{r-1})^{1/2}$ , the fourth step follows from the fact that  $C^{r,0} = (1+\epsilon_{r-1})^8 C^{r-1,A_{r-1}}$ , the last inequality follows from the lower bound of Lemma 21.

The total number of iterations is then bounded by

$$\begin{aligned} \sum_{r=0}^R A_r B_r &\leq 30 \sum_{r=0}^R B_r \lesssim \sum_{r=0}^R \log_{1+\epsilon_r}(n) \log_{1+\epsilon_r}(d/\epsilon_r) + \log_{1+\epsilon_r}(n) \\ &= \sum_{r=0}^{\epsilon_r \geq 1} \log_{1+\epsilon_r}(n) \log_{1+\epsilon_r}(d/\epsilon_r) + \sum_{r:\epsilon_r \leq 1}^R \log_{1+\epsilon_r}(n) \log_{1+\epsilon_r}(d/\epsilon_r) \\ &\lesssim \sum_{r=0}^{\epsilon_r \geq 1} \log_{1+\epsilon_r}(n) \log_{1+\epsilon_r}(d/\epsilon_r) + \sum_{r:\epsilon_r \leq 1}^R \frac{\log n \log(d/\epsilon)}{\epsilon_r^2} \\ &\lesssim \log n \log d + \frac{\log n \log(d/\epsilon)}{\epsilon^2} \\ &= O\left(\frac{\log n \log(d/\epsilon)}{\epsilon^2}\right) \end{aligned}$$

Thus completing the proof.  $\blacktriangleleft$

## A

 Missing proof from Section 5

**Proof of Lemma 20.** We prove the lemma for a fixed  $r$ . Define

$$F := \{w | w \in W, L_w^{r, A_r-1, B_r} > (1 + \epsilon_r)^4 C^{r, A_r}\},$$

i.e.,  $F$  is the subset of workers whose load significantly outweigh the target capacity and break the while loop. For any worker  $w \in F$ , we assert that its weight  $a_w$  must decrease every timestep during the last call to PROPORTIONAL ALLOCATION, i.e.,

$$a_w^{r, A_r-1, t+1} = \frac{a_w^{r, A_r-1, t}}{1 + \epsilon_r} \quad \forall 0 \leq t < B_r.$$

This is because if  $L_w^{r, A_r-1, t_0} < C^{r, A_r-1}$  for some  $t_0$ , then by Lemma 18, we know that  $L_w^{r, A_r-1, t} \leq (1 + \epsilon_r)^2 C^{r, A_r-1}$  holds for all  $t \geq t_0$ , which contradicts with the fact that  $L_w^{r, A_r-1, B_r} > (1 + \epsilon_r)^4 C^{r, A_r}$ . Thus we conclude that

$$a_w^{A_r-1, B_r} \leq (1 + \epsilon_r)^{(A_r-1)B_r} \quad \forall w \in F.$$

For any  $0 \leq j \leq B_r$ , define

$$Z_j = \left\{ w | w \in W, a_w^{A_r-1, B_r} \leq (1 + \epsilon_r)^{(A_r-1)B_r+j} \right\}.$$

We note that  $F \subseteq Z_0 \subseteq Z_1 \cdots \subseteq Z_{B_r} = W$  and therefore  $Z_0 \neq \emptyset$ .

Since  $B_r = 2 \log_{1+\epsilon_r}(n) \log_{1+\epsilon_r}(d/\epsilon) + 8 \log_{1+\epsilon_r}(n)$ , there must exist some index  $j$  satisfies

$$2 \log_{1+\epsilon_r}(d/\epsilon) + 8 \leq j < B_r$$

and

$$|Z_j| \leq (1 + \epsilon_r)^{|Z_{j-2 \log_{1+\epsilon_r}(d/\epsilon)-8}|}. \quad (8)$$

We set  $W_r = Z_j$  and will show that  $|N(Z_j)| \geq |Z_j| \cdot C^{r, A_r} / (1 + \epsilon_r)^4$  in the rest of the proof. For any worker  $w \in Z_{j-2 \log_{1+\epsilon_r}(d/\epsilon)-8}$ , if worker  $w$  is connected to some source  $s$  such that  $s$  has another neighbor  $w'$  with  $w' \notin Z_j$ . Then we have

$$\begin{aligned} x_{s,w}^{r, A_r-1, B_r} &\leq \frac{a_w^{r, A_r-1, B_r}}{a_w^{r, A_r-1, B_r} + a_{w'}^{r, A_r-1, B_r}} \leq \frac{(1 + \epsilon_r)^{(A_r-1)B_r+j-2 \log_{1+\epsilon_r}(d/\epsilon)-8}}{(1 + \epsilon_r)^{(A_r-1)B_r+j+1}} \\ &\leq \frac{\epsilon_r^2}{d^2(1 + \epsilon_r)^9} \leq \frac{\epsilon_r}{d^2(1 + \epsilon_r)^8}. \end{aligned}$$

Hence, the total contributions  $x_{s,w}^{r, A_r-1, B_r}$  from all sources  $s$  with a neighbor not in  $Z_j$  to worker  $w$  is at most

$$\sum_{\substack{s \in N_w \\ N_s \cap (W \setminus Z_j) \neq \emptyset}} x_{s,w}^{r, A_r-1, B_r} \leq \frac{\epsilon_r}{d^2(1 + \epsilon_r)^8} \cdot d \leq \frac{\epsilon_r}{d(1 + \epsilon_r)^8}. \quad (9)$$

Consider the restricted graph between the source set  $N(Z_j)$  and the worker set  $Z_j$ , for each worker  $w \in Z_{j-2 \log_{1+\epsilon_r}(d/\epsilon)-8}$ , by Lemma 19, we know that its load satisfies

$$L_w^{r, A_r-1, B_r} \geq \frac{C^{r, A_r-1}}{(1 + \epsilon_r)^2}.$$

Hence the load of worker  $w$  in the restricted graph is at least

$$\begin{aligned}
\sum_{\substack{s \in N_w \\ N_s \cap (W \setminus Z_j) = \emptyset}} x_{s,w}^{r, A_r-1, B_r} &= L_w^{r, A_r-1, B_r} - \sum_{\substack{s \in N_w \\ N_s \cap (W \setminus Z_j) \neq \emptyset}} x_{s,w}^{r, A_r-1, B_r} \\
&\geq \frac{C^{r, A_r}}{(1 + \epsilon_r)^2} - \frac{\epsilon_r}{d_{\max}(1 + \epsilon_r)^8} \\
&\geq \frac{C^{r, A_r}}{(1 + \epsilon_r)^3}
\end{aligned} \tag{10}$$

The second step follows from Eq. (9), the last step follows from  $C^{r, A_r} \geq (1 + \epsilon_r)^{-5}$  holds all the time.

Thus, we have

$$\begin{aligned}
|N(Z_j)| &= \sum_{w \in Z_j} \sum_{\substack{s \in N_w \\ N_s \cap (W \setminus Z_j) = \emptyset}} x_{s,w}^{r, A_r-1, B_r} \\
&\geq \sum_{w \in Z_j - 2 \log_{1+\epsilon_r}(d_{\max}/\epsilon) - 4} \sum_{\substack{s \in N_w \\ N_s \cap (W \setminus Z_j) = \emptyset}} x_{s,w}^{r, A_r-1, B_r} \\
&\geq |Z_j - 2 \log_{1+\epsilon_r}(d_{\max}/\epsilon) - 4| \cdot \frac{C^{r, A_r}}{(1 + \epsilon_r)^3} \\
&\geq \frac{C^{r, A_r}}{(1 + \epsilon_r)^4} \cdot |Z_j|.
\end{aligned}$$

The third step follows from Eq. (10), the last step follows from Eq. (9). We complete the proof here.  $\blacktriangleleft$

## B Tightness

Here we present an example showing that our analysis of our algorithm is tight for the case of the max function even if we know the optimum value in advance. More formally, we show that starting from a state where all of the weights are initialized to 1 and the precision parameter is set to  $\epsilon$ , running  $\Omega\left(\frac{\log^2 n}{\epsilon^2}\right)$  iterations of proportional allocation is actually necessary.

Note here we assume  $1/\epsilon = n^{o(1)}$  i.e. the desired tolerance is much larger than  $n^{-1}$ .

Consider the following graph  $G$ . Let  $k = 0.5 \log n / \epsilon$ . We have sets  $S_1, S_2, \dots, S_k$  of sources and sets  $W_1, W_2, \dots, W_k$  of workers. For all  $i$  let

$$|S_i| = |W_i| = (1 - \epsilon)^i \epsilon n.$$

In  $G$ , there is a perfect matching between the vertices of  $W_i$  and the vertices of  $S_i$  for all  $1 \leq i \leq k$ . Also, there is a complete bipartite graph between the vertices of  $S_i$  and  $W_{i+1}$  for  $1 \leq i \leq k - 1$ .

Consider the initial state where all of the sources distribute their load uniformly among the adjacent workers. In this case the maximum load among all of the workers is

$$1 + \frac{|S_{k-1}| \cdot |W_k|}{|W_k| + 1} \geq 2.$$

## 79:20 Distributed Load Balancing

However, in the optimal allocation, each set of sources  $S_i$  assigns all of its load to the workers in  $W_i$  according to the perfect matching and the maximum load among all of the workers is 1. Now we will show that for some positive constant  $c$ , starting from the initial state where all sources distribute their load uniformly, after  $\frac{c \log^2 n}{\epsilon^2}$  iterations of proportional allocation, the maximum load among all of the workers is at least  $1 + 0.1\epsilon$ .

First observe that within each set  $W_i$ , by symmetry, all of the weights of the workers are equal at all times. Let  $w_i^t$  denote the weight of a worker in  $W_i$  after  $t$  rounds. If there exists an  $i$  such that

$$w_i^t \geq w_{i-1}^t n^{-0.1}$$

then consider the sources in  $S_{i-1}$ . The amount of their load going to the workers in  $W_i$  is at least  $\frac{|S_{i-1}| \cdot |W_i|}{|W_i| + n^{0.1}} \geq |S_i|$ . Thus the total load going to workers in  $W_k \cup W_{k-1} \cup \dots \cup W_i$  is at least

$$|S_k| + \dots + |S_i| + |S_i|.$$

Note that  $|S_k|, |S_{k-1}|, \dots, |S_i|$  is a geometric series with ratio  $\frac{1}{1-\epsilon}$  so

$$|S_i| \geq 0.1\epsilon(|S_k| + \dots + |S_i|).$$

Thus, there is some worker among  $W_k \cup W_{k-1} \cup \dots \cup W_i$  with load at least

$$\frac{(1 + 0.1\epsilon)(|S_k| + \dots + |S_i|)}{(|W_k| + \dots + |W_i|)} = 1 + 0.1\epsilon.$$

On the other hand, if we have

$$w_i^t \leq w_{i-1}^t n^{-0.1}$$

for all  $i$ , then the ratio between the smallest and largest weight among all of the workers must be at least  $n^{0.1k}$ . However, this ratio is 1 at the beginning and increases by a factor of at most  $(1 + \epsilon)^2$  each round so the number of rounds must be at least

$$\Omega\left(\frac{\log n}{\epsilon} k\right) = \Omega\left(\frac{\log^2 n}{\epsilon^2}\right).$$

► **Remark 23.** Based on this example, an obvious modification would be to adaptively increase the step size of the proportional allocation updates for certain workers depending on their current load. However, note that initially all workers that are not in  $W_1$  or  $W_k$  have load very close to 1. In other words, for every worker, there is another worker in its two-hop neighborhood whose load is very close to the optimal load of 1. If we significantly increased the step size, then we would no longer have the stability conditions (Lemma 7 and Lemma 21) and our analysis would have to be quite different.

## Abstract

We investigate sublinear-time algorithms that take partially erased graphs represented by adjacency lists as input. Our algorithms make degree and neighbor queries to the input graph and work with a specified fraction of adversarial erasures in adjacency entries. We focus on two computational tasks: testing if a graph is connected or  $\varepsilon$ -far from connected and estimating the average degree. For testing connectedness, we discover a threshold phenomenon: when the fraction of erasures is less than  $\varepsilon$ , this property can be tested efficiently (in time independent of the size of the graph); when the fraction of erasures is at least  $\varepsilon$ , then a number of queries linear in the size of the graph representation is required. Our erasure-resilient algorithm (for the special case with no erasures) is an improvement over the previously known algorithm for connectedness in the standard property testing model and has optimal dependence on the proximity parameter  $\varepsilon$ . For estimating the average degree, our results provide an “interpolation” between the query complexity for this computational task in the model with no erasures in two different settings: with only degree queries, investigated by Feige (SIAM J. Comput. ‘06), and with degree queries and neighbor queries, investigated by Goldreich and Ron (Random Struct. Algorithms ‘08) and Eden et al. (ICALP ‘17). We conclude with a discussion of our model and open questions raised by our work.

## 1 Introduction

The goal of this work is to model and investigate sublinear-time algorithms that run on graphs with incomplete information. Typically, sublinear-time models assume that algorithms have query or sample access to an input graph. However, this assumption does not accurately reflect reality in some situations. Consider, for example, the case of a social network where vertices represent individuals and edges represent friendships. Individuals might want to hide their friendship relations for privacy reasons. When input graphs are represented by their adjacency lists, such missing information can be modeled as *erased* entries in the lists. In this work, we initiate an investigation of sublinear-time algorithms whose inputs are graphs represented by the adjacency lists with some of the entries adversarially erased.

In our erasure-resilient model of sublinear-time graph algorithms, an algorithm gets a parameter  $\alpha \in [0, 1]$  and query access to the adjacency lists of a graph with at most an  $\alpha$  fraction of the entries in the adjacency lists erased. We call such a graph  $\alpha$ -*erased* or, when  $\alpha$  is clear from the context, *partially erased*. Algorithms access partially erased graphs via degree and neighbor queries. The answer to a degree query  $v$  is the degree of the vertex  $v$ . A neighbor query is of the form  $(v, i)$ , and the answer is the  $i^{\text{th}}$  entry in the adjacency list of  $v$ . If the  $i^{\text{th}}$  entry is erased<sup>1</sup>, the answer is a special symbol  $\perp$ . A *completion* of a partially erased graph  $G$  is a valid graph represented by adjacency lists (with no erasures) that coincide with the adjacency lists of  $G$  on all nonerased entries. We formulate our computational tasks in terms of valid completions of partially erased input graphs and analyze the performance of our erasure-resilient algorithms in the *worst case* over all  $\alpha$ -erased graphs. We investigate representative problems from two fundamental classes of computational tasks in our model: graph property testing and estimating a graph parameter.

In the context of graph property testing [15], we study the problem of testing whether a partially erased graph is connected. Our model is a generalization of the *general graph model* of Parnas and Ron [23] (which is in turn a generalization of the *bounded degree model* of Goldreich and Ron [16]) to the setting with erasures. A partially erased graph  $G$  has property  $\mathcal{P}$  (in our case, is connected) if there exists a completion of  $G$  that has the property. For  $\varepsilon \in (0, 1)$ , such a graph with  $m$  edges (more precisely,  $2m$  entries in its adjacency lists) is  $\varepsilon$ -far from  $\mathcal{P}$  (in our case, from being connected) if every completion of  $G$  is different in at least  $\varepsilon m$  edges from every graph with the property. The goal of a testing algorithm is to distinguish, with high probability,  $\alpha$ -erased graphs that have the property from those that are  $\varepsilon$ -far. For testing connectedness in our erasure-resilient model, we discover a threshold phenomenon: when the fraction of erasures is less than  $\varepsilon$ , this property can be tested efficiently (in time independent of the size of the graph); when the fraction of erasures is at least  $\varepsilon$ , then a number of queries linear in the size of the graph is required to test connectedness. Additionally, when there are no erasures, our tester has better query complexity than the best previously known standard tester for connectedness [23, 5], also mentioned in the book on property testing by Goldreich [14]. Our tester has optimal dependence on  $\varepsilon$ , as evidenced by a recent lower bound in [21] for this fundamental property.

Next, we study erasure-resilient algorithms for estimating the average degree of a graph. The problem of estimating the average degree of a graph, in the case with no erasures, was studied by Feige [13], Goldreich and Ron [17], and Eden et al. [9, 10]. Feige designed an algorithm that, for all  $\varepsilon > 0$ , makes  $O(\sqrt{n}/\varepsilon)$  degree queries to an  $n$ -node graph and outputs, with high probability, an estimate that is within a factor of  $2 + \varepsilon$  of the average

<sup>1</sup> One can consider a more general model where the degrees of some vertices can also be erased. Our algorithms continue to work in this model, since one can determine the degree of a vertex using  $O(\log n)$  neighbor queries (irrespective of whether these queries are made to erased adjacency entries).

degree. He also showed that to get a 2-approximation, one needs  $\Omega(n)$  degree queries. Goldreich and Ron proved that if an algorithm can make uniformly random neighbor queries (that is, obtain a uniformly random neighbor of a specified vertex) then, for all  $\varepsilon > 0$ , the average degree can be estimated to within a factor of  $1 + \varepsilon$  using  $O(\sqrt{n} \cdot \text{poly}(\log n, 1/\varepsilon))$  queries. Eden et al. proved a tighter bound of  $O(\sqrt{n} \cdot \log \log n \cdot \text{poly}(1/\varepsilon))$  on the query complexity of this problem and provided a simpler analysis. We describe an algorithm that estimates the average degree of  $\alpha$ -erased graphs to within a factor of  $1 + \min(2\alpha, 1) + \varepsilon$  using  $O(\sqrt{n} \cdot \log \log n \cdot \text{poly}(1/\varepsilon))$  queries. Our result can be thought of as an interpolation between the results in [13] and [17, 9, 10]. In particular, when there are no erasures, that is, when  $\alpha = 0$ , we get a  $(1 + \varepsilon)$ -approximation; when all adjacency entries are erased, and only the degree queries are useful, that is, when  $\alpha = 1$ , we obtain a  $(2 + \varepsilon)$ -approximation. We also show that our result cannot be improved significantly: to get a  $(1 + \alpha)$ -approximation,  $\Omega(n)$  queries are necessary.

## Discussion of our model

For the case of graph property testing, our model is an adaptation of the erasure-resilient model for testing properties of functions by Dixit et al. [7]. Dixit et al. designed erasure-resilient testers for many properties of functions, including monotonicity, the Lipschitz property, and convexity. The conceptual difference between the two models is that the adjacency lists representation of a graph cannot be viewed as a function. (This is not the case for the adjacency matrix representation.) For a function, erased entries can be filled in arbitrarily and, as a result, they never contribute to the distance to the property. For the adjacency lists representation, this is not the case: erasures have to be filled so that the resulting completion is a valid graph. The restrictions on how they can be filled may result in some contribution to the distance coming from the erased entries<sup>2</sup>. For example, consider the property of bipartiteness. Let  $B$  be a complete balanced bipartite graph  $(U, V; E)$ , and let  $B'$  be obtained from  $B$  by adding an erased entry to the adjacency list of every vertex in  $U$ . Then, in every completion of  $B'$ , all formerly erased entries have to be changed to make the graph bipartite.

Furthermore, Dixit et al. [7] gave results only on property testing in the erasure-resilient model. We go beyond property testing in our exploration of erasure-resilient algorithms by considering more general computational tasks.

Finally, our model opens up many new research directions, some of which are discussed in Section 4.

## 1.1 The Model

We consider simple undirected graphs  $G = (V, E)$  represented by adjacency lists, where some entries in the adjacency lists could be adversarially erased (these entries are denoted by  $\perp$ ).

► **Definition 1.1** ( $\alpha$ -erased graph; completion). *Let  $\alpha \in [0, 1]$  be a parameter. An  $\alpha$ -erased graph on a vertex set  $V$  is a concatenation of the adjacency lists of a simple undirected graph  $(V, E)$  with at most an  $\alpha$  fraction of all entries (that is, at most  $2\alpha|E|$  entries) in the lists erased. A completion of an  $\alpha$ -erased graph  $G$  is the adjacency lists representation of a simple undirected graph  $G'$  that coincides with  $G$  on all nonerased entries.*

<sup>2</sup> Because of this, we make an adjustment to the model of Dixit et al. [7]: we measure the distance to the property as a fraction of the completion representation that needs to be changed, as opposed to the fraction of the nonerased representation that needs to be changed.

By definition, every partially erased graph has a completion, because it was obtained by erasing entries in a valid graph.

Given a partially erased graph  $G$  over a vertex set  $V$ , we use  $n$  to denote  $|V|$  and  $m$  to denote the number of edges in any completion of  $G$ , that is, half the sum of lengths of the adjacency lists of all the vertices in  $G$ . The average degree, that is,  $2m/n$ , is denoted by  $\bar{d}$ . For  $u \in V$ , we use  $\text{Adj}(u)$  to denote the adjacency list of  $u$ . The degree  $u$ , denoted  $\deg(u)$ , is the length of  $\text{Adj}(u)$ .

► **Definition 1.2** (Nonerased and half-erased edges). *Let  $G$  be a partially erased graph over a vertex set  $V$ . For vertices  $u, v \in V$ , the set  $\{u, v\}$  is a nonerased edge in  $G$  if  $u$  is present in  $\text{Adj}(v)$  and vice versa. The set  $\{u, v\}$  is a half-erased edge if  $u$  is in  $\text{Adj}(v)$  but  $v$  is not in  $\text{Adj}(u)$ , or vice versa.*

Our algorithms make two types of queries: *degree queries* and *neighbor queries*. A degree query specifies a vertex  $v$ , and the answer is  $\deg(v)$ . A neighbor query specifies  $(v, i)$ , and the answer is the  $i^{\text{th}}$  entry in  $\text{Adj}(v)$ .

► **Definition 1.3** (Distance to a property; erasure-resilient property tester). *Let  $\alpha \in [0, 1]$ ,  $\varepsilon \in (0, 1)$  be parameters. An  $\alpha$ -erased graph  $G$  satisfies a property  $\mathcal{P}$  if there exists a completion of  $G$  that satisfies  $\mathcal{P}$ . An  $\alpha$ -erased graph  $G$  is  $\varepsilon$ -far from a property  $\mathcal{P}$  if every completion  $G'$  of  $G$  is different in at least  $\varepsilon m$  edges from every graph that satisfies  $\mathcal{P}$ .*

*An  $\alpha$ -erasure-resilient  $\varepsilon$ -tester for a property  $\mathcal{P}$  gets parameters  $\alpha \in [0, 1]$ ,  $\varepsilon \in (0, 1)$  and query access to an  $\alpha$ -erased graph  $G$ . The tester accepts, with probability at least  $2/3$ , if  $G$  satisfies  $\mathcal{P}$ . The tester rejects, with probability at least  $2/3$ , if  $G$  is  $\varepsilon$ -far from  $\mathcal{P}$ .*

## 1.2 Our Results

In this section, we state our main results for the erasure-resilient model of sublinear-time algorithms.

### 1.2.1 Testing Connectedness

The problem of testing connectedness in the *general graph model* (that we further generalize to the erasure-resilient setting) was studied by Parnas and Ron [23]. The results on this fundamental problem are described in Section 10.2.1 in [14]. The best tester for this problem to date, due to [5], had query complexity  $O(\frac{1}{(\varepsilon \bar{d})^2})$ .

We give two erasure-resilient testers for connectedness: one for small values of  $\alpha$  and another for intermediate values of  $\alpha$ . Both testers work for all<sup>3</sup> values of the proximity parameter,  $\varepsilon$ . We first give a tester that works for all  $\alpha < \varepsilon/2$ . (This tester is presented in Section 2.1.)

► **Theorem 1.4.** *There exists an  $\alpha$ -erasure-resilient  $\varepsilon$ -tester for connectedness of graphs with the average degree  $\bar{d}$  that has  $O(\min\{\frac{1}{((\varepsilon-2\alpha)\bar{d})^2}, \frac{1}{\varepsilon-2\alpha} \log \frac{1}{(\varepsilon-2\alpha)\bar{d}}\})$  query and time complexity and works for every  $\varepsilon \in (0, 2/\bar{d})$  and  $\alpha \in [0, \varepsilon/2)$ . The tester has 1-sided error. When the average degree  $\bar{d}$  of the input graph is unknown,  $\alpha$ -erasure-resilient  $\varepsilon$ -testing of connectedness (with 1-sided error) has query and time complexity  $O(\frac{1}{\varepsilon-2\alpha} \log \frac{1}{\varepsilon-2\alpha})$ .*

<sup>3</sup> For  $\varepsilon \geq 2/\bar{d}$ , we have  $\varepsilon m \geq n$ . Then testing connectedness is trivial, since every graph can be made connected by adding at most  $n - 1$  edges.

Importantly, when the input adjacency lists have no erasures (i.e., when  $\alpha = 0$ ), our tester has better query complexity than the previously known best (standard) tester for connectedness, which was due to [5]. We present a standalone algorithm for this important special case in the full version of this article [20]. By substituting  $\alpha = 0$  in Theorem 1.4, we get  $O(\min\{\frac{1}{(\varepsilon\bar{d})^2}, \frac{1}{\varepsilon} \log \frac{1}{\varepsilon\bar{d}}\})$  query complexity for the case when  $\bar{d}$  is known and  $O(\frac{1}{\varepsilon} \log \frac{1}{\varepsilon})$  query complexity when  $\bar{d}$  is unknown. For the case with no erasures, the improvement in query complexity as a function of  $\varepsilon$  is from  $O(\frac{1}{\varepsilon^2})$  to  $O(\frac{1}{\varepsilon} \log \frac{1}{\varepsilon})$ . The latter is optimal, as evidenced by an  $\Omega(\frac{1}{\varepsilon} \log \frac{1}{\varepsilon})$  lower bound for testing connectedness of graphs of degree 2 in [21]. We note that Berman et al. [5] already proved that testing connectedness of graphs (with no erasures) in the bounded degree graph model of [16] has query complexity  $O(\frac{1}{\varepsilon} \log \frac{1}{\varepsilon D})$  where  $D$  denotes the degree bound. Our result shows that the same query complexity (with  $D$  replaced by  $\bar{d}$ ) is attainable in the general graph model.

Our first tester looks for small connected components that do not have any erasures. When  $\alpha \in [\varepsilon/2, \varepsilon)$ , some  $\alpha$ -erased graphs that are  $\varepsilon$ -far from connected may not have any connected component that is free of erasures. Consequently, our first tester fails to reject such graphs. We give a different algorithm (presented in Section 2.2) which works by looking for a subset of vertices that has at most one erasure and gets completed to a unique connected component in every completion of the partially erased graph. (In the beginning of Section 2.2, we give an explanation, illustrated by Figure 1, of why two erasures in a witness may render it not detectable from a local view obtained by a sublinear algorithm.)

► **Theorem 1.5.** *There exists an  $\alpha$ -erasure-resilient  $\varepsilon$ -tester for connectedness of graphs with the average degree  $\bar{d}$  that has  $O(\frac{1}{(\varepsilon-\alpha)^2 \cdot \bar{d}} \cdot \min\{\frac{1}{(\varepsilon-\alpha) \cdot \bar{d}}, 1\})$  query and time complexity and works for every  $\varepsilon \in (0, 2/\bar{d})$  and  $\alpha \in [0, \varepsilon)$ . The tester has 1-sided error.*

Finally, we show that when  $\alpha \geq \varepsilon$ , the task of  $\alpha$ -erasure-resilient  $\varepsilon$ -testing of connectedness requires examining a linear portion of the graph representation. That is, we discover a phase transition in the complexity of this problem when the fraction of erasures  $\alpha$  reaches the proximity parameter  $\varepsilon$ .

► **Theorem 1.6.** *For all  $\varepsilon \in (0, 1/7]$ , every  $\varepsilon$ -erasure-resilient  $\varepsilon$ -tester for connectedness that makes only degree and neighbor queries requires a number of queries linear in the size of the graph representation.*

To prove this theorem, we construct (in Section 2.3) a family of partially erased graphs for which it is hard to distinguish connected graphs from graphs that are far from connected. The average degree of the graphs in our constructions is constant. So, the lower bound for this graph family is  $\Omega(n) = \Omega(m)$ .

## 1.2.2 Estimating the Average Degree

In Section 3.1, we give an erasure-resilient algorithm for estimating the average degree by generalizing the algorithm of Eden et al. [9, 10] to work for the case with erasures.

► **Theorem 1.7.** *Let  $\alpha \in [0, 1]$  and  $\varepsilon \in (0, 1/2)$ . There exists an algorithm that makes  $O(\sqrt{n} \cdot \log \log n \cdot \text{poly}(1/\varepsilon))$  degree queries and uniformly random neighbor queries to an  $\alpha$ -erased input graph of average degree  $\bar{d} \geq 1$  and outputs, with probability at least  $2/3$ , an estimate  $\tilde{d}$  satisfying  $(1 - \varepsilon) \cdot \bar{d} < \tilde{d} < (1 + 2 \min(\alpha, \frac{1}{2}) + \varepsilon) \cdot \bar{d}$ . The running time of the algorithm is the same as its query complexity.*

For graphs with no erasures, a good estimate of the number of edges gives a good estimate of the average degree. Feige’s algorithm [13] (that has access only to degree queries) counts some edges twice and gets an estimate of the average degree that is within a factor of  $2 + \varepsilon$ . Goldreich and Ron [17] and Eden et al. [9, 10] avoid the issue of double-counting by ranking vertices according to their degrees and estimating, within a factor of  $1 + \varepsilon$ , the number of edges going from lower-ranked to higher-ranked vertices. These algorithms use degree queries and uniformly random neighbor queries. Having erasures in the adjacency lists is, in a rough sense, equivalent to not having access to *some* of the neighbor queries. This results in the additional  $2\alpha$  error term in the approximation guarantee. Consequently, when the fraction of erasures approaches  $1/2$ , all the “relevant” entries in the adjacency lists of the input graph could be erased, and we enter the regime of having access only to degree queries.

In Section 3.2, we show that, for any fraction  $\alpha \in (0, 1]$ , estimating the average degree of an  $\alpha$ -erased graph to within a factor of  $(1 + \alpha)$  requires  $\Omega(n)$  queries. In other words, the approximation ratio of our erasure-resilient algorithm for estimating the average degree cannot be improved significantly.

► **Theorem 1.8.** *Let  $\alpha \in (0, 1]$  be rational. For all  $\gamma < \alpha$ , at least  $\Omega(n)$  queries are necessary for every algorithm that makes degree and neighbor queries to an  $\alpha$ -erased graph with the average degree  $\bar{d}$  and outputs, with probability at least  $2/3$ , an estimate  $\tilde{d} \in [\bar{d}, (1 + \gamma)\bar{d}]$ .*

### 1.3 Research Directions and Further Observations

There are numerous research questions that arise from our work. In Section 4, we discuss some of them and also give additional observations about variants of our model. We mention open questions about another (weaker) threshold in erasure-resilient testing of connectedness, about erasure-resilient testing of monotone graph properties, about the relationship between testing with erasures and testing with errors, and about the variant of our model that allows only symmetric erasures. We show that some of the questions we discuss are open in our model, but easy in the bounded-degree version of our model.

### 1.4 Related Work

Erasure-resilient sublinear-time algorithms, in the context of testing properties of functions, were first investigated by Dixit et al. [7], and further studied by Raskhodnikova et al. [25], Pallavoor et al. [22], and Ben-Eliezer et al. [3].

Property testing in the general graph model was first studied by Parnas and Ron [23], who considered a relaxed version of the problem of testing whether the input graph has small diameter. Kaufman et al. [19] studied the problem of testing bipartiteness in the general graph model and obtained tight upper and lower bounds on its complexity.

Sublinear-time algorithms for estimating various graph parameters have also received significant attention. There are sublinear-time algorithms for estimating the weight of a minimum weight spanning tree [6], the number of connected components [6, 4], the average degree [13, 17], the average pairwise distance [17], moments of the degree distribution [18, 9], and subgraph counts [18, 8, 11, 12, 1, 2].

## 2 Erasure-Resilient Testing of Connectedness

In this section, we present our results on erasure-resilient testing of connectedness in graphs.

### 2.1 An Erasure-Resilient Connectedness Tester for $\alpha < \varepsilon/2$

In this section, we present our connectedness tester for small  $\alpha$  and prove Theorem 1.4. The tester looks for witnesses to disconnectedness in the form of connected components with no erasures. It repeatedly performs a breadth first search (BFS) from a random vertex until it finds a witness to disconnectedness or exceeds a specified query budget.

A simple counting argument shows that if a partially erased graph is far from connected then it has many small witnesses to disconnectedness. Moreover, the size of the average witness among them is at most some bound  $b$  (that we calculate later). Our tester uses BFS to detect a witness to disconnectedness of size at most  $b$ .

The best tester for connectedness to date, by Berman et al. [5], uses a technique called the *work investment strategy*. Specifically, their algorithm repeatedly samples a uniformly random vertex  $v$ , guesses the size of the witness to disconnectedness  $C_{(v)}$  containing  $v$ , and then performs a BFS from  $v$  for  $|C_{(v)}|^2$  queries. Clearly,  $|C_{(v)}|^2$  queries are enough to detect  $C_{(v)}$ . Using the fact that the expected size of a witness is  $b$ , they argue that their algorithm has complexity  $O(b^2)$ .

The new idea in our connectedness tester is to perform the BFS from a uniformly random vertex  $v$  for  $|C_{(v)}| \cdot \deg(v)/2$  queries. The expected value of the latter quantity is bounded by  $E_{(v)}$ , where  $E_{(v)}$  denotes the number of edges in the witness containing  $v$ , and the expectation is over the choice of a uniformly random vertex from  $C_{(v)}$ . That is, in expectation, the number of queries that we *invest* into the BFS from  $v$  is enough to detect  $C_{(v)}$ . We show that, overall, the expected complexity of this algorithm is  $\tilde{O}(b \cdot \bar{d})$ , which is smaller than  $O(b^2)$  when  $b > \bar{d}$ .

Our erasure-resilient tester is Algorithm 1, with a small standard modification to ensure that the stated complexity bounds hold in the worst case (not just in expectation). It is obtained by running the algorithm of Berman et al. (generalized to handle erasures) when  $b < \bar{d}$  and running the above algorithm otherwise.

Before stating the algorithm, we formalize the notion of the witness to disconnectedness and argue that partially erased graphs that are far from being connected have many witnesses to disconnectedness.

► **Definition 2.1** (Witness to disconnectedness). *A set  $C$  of vertices is a witness to disconnectedness in a partially erased graph  $G$  if the adjacency lists of vertices in  $C$  have no erasures, and  $C$  forms a connected component in every completion of  $G$ .*

► **Observation 2.2.** *Let  $\varepsilon \in (0, 2/\bar{d})$  and  $G'$  be an  $m$ -edge graph (with no erasures) that is  $\varepsilon$ -far from connected. Then  $G'$  has at least  $\varepsilon m + 1$  connected components.*

Next, in Claim 2.3, we argue that if the fraction of erasures is *small*, *many* of the connected components present in a completion  $G'$  are also present as witnesses to disconnectedness in  $G$ .

▷ **Claim 2.3.** *Let  $\varepsilon \in (0, 2/\bar{d})$  and  $\alpha \in [0, \varepsilon/2)$ . The number of witnesses to disconnectedness in an  $\alpha$ -erased graph  $G$  that is  $\varepsilon$ -far from connected is at least  $(\varepsilon - 2\alpha)m$ .*

*Proof.* By Observation 2.2, every completion  $G'$  of  $G$  has at least  $\varepsilon m + 1$  connected components. The number of connected components in  $G'$  with at least one erased entry in the union of its adjacency lists (with respect to  $G$ ) is at most  $2\alpha m$ . Hence, the number of connected components in  $G'$  that do not have any erased entry in the union of its adjacency lists (with respect to  $G$ ) is at least  $\varepsilon m - 2\alpha m = (\varepsilon - 2\alpha)m$ . The claim follows. ◁

Let  $b = 2/((\varepsilon - 2\alpha) \cdot \bar{d})$ . By Claim 2.3, the size of the average witness to disconnectedness is at most  $b$ . Now we are ready to state Algorithm 1.

■ **Algorithm 1** Erasure-Resilient Connectedness Tester for  $\alpha < \varepsilon/2$ .

---

**input** : The average degree  $\bar{d}$ , parameters  $\varepsilon \in (0, 2/\bar{d})$ ,  $\alpha \in [0, \varepsilon/2)$ ; query access to an  $\alpha$ -erased graph  $G$ .

- 1 Let  $b \leftarrow 2/((\varepsilon - 2\alpha) \cdot \bar{d})$ . // the average size of a witness is at most  $b$
- 2 **for**  $i \in [\lceil \log(4b) \rceil]$  **do**
- 3    **repeat**  $\lceil \frac{4b \ln 6}{2^i} \rceil$  **times**
- 4     Sample a vertex  $v$  uniformly and independently at random.
- 5     **if**  $b \leq \bar{d} \log b$  **then**
- 6       Run a BFS from  $v$  until it encounters an erased entry or  $(2^i + 1)$  vertices.
- 7       **else**
- 8          Query  $\deg(v)$ ;
- 9          Run a BFS from  $v$  until it encounters an erased entry or  $(2^{i-1} \cdot \deg(v) + 1)$  edges.
- 10      **if** the BFS explored an entire connected component and didn't encounter an erasure **then reject**.
- 11 **Accept**.

---

Clearly, Algorithm 1 accepts all connected partially erased graphs.

► **Lemma 2.4.** *Let  $\varepsilon \in (0, 2/\bar{d})$  and  $\alpha \in [0, \varepsilon/2)$ . Let  $G$  be an  $\alpha$ -erased graph that is  $\varepsilon$ -far from connected. Then Algorithm 1 rejects  $G$  with probability at least  $5/6$ .*

**Proof.** Let  $V$  be the vertex set of  $G$ . We start by defining the quality of a vertex  $v \in V$ . The definition is different for the two cases, corresponding to the two stopping conditions Algorithm 1 uses for BFS. First, we consider the case when  $b \leq \bar{d} \cdot \log b$ , that is, when Algorithm 1 runs the version of BFS specified in Step 6.

► **Definition 2.5** (Quality of a vertex when  $b \leq \bar{d} \cdot \log b$ ). *The quality of a vertex  $v$ , denoted  $q(v)$ , is defined as follows. If  $v$  belongs to a witness to disconnectedness in  $G$  then  $q(v) = 1/|C_{(v)}|$ , where  $C_{(v)}$  denotes the witness to disconnectedness that  $v$  belongs to. Otherwise,  $q(v) = 0$ .*

The important feature of  $q(v)$  is that, for a witness  $C$  to disconnectedness,  $\sum_{v \in C} q(v) = 1$ .

Next, we define the quality of a vertex for the case when  $b > \bar{d} \cdot \log b$ , that is, when Algorithm 1 runs the version of BFS specified in Step 8.

► **Definition 2.6** (Quality of a vertex when  $b > \bar{d} \cdot \log b$ ). *Fix a completion  $G'$  of  $G$ . For a vertex  $v \in V$ , let  $C_{(v)}$  denote the connected component (in  $G'$ ) containing  $v$ , and let  $E_{(v)}$  denote the number of edges in  $C_{(v)}$ . The quality of a vertex  $v$ , denoted  $q(v)$ , is defined as*

$$q(v) = \begin{cases} 0 & \text{if } C_{(v)} \text{ contains at least one erased entry in } G, \\ \frac{\deg(v)}{2E_{(v)}} & \text{if } E_{(v)} > 0, \\ 1 & \text{if } E_{(v)} = 0. \end{cases}$$

Like for  $q(v)$  from Definition 2.5, for a witness  $C$  to disconnectedness,  $\sum_{v \in C} q(v) = 1$ .

The rest of the proof of Lemma 2.4 is the same for both cases. We analyze the expected quality of a uniformly random vertex  $v \in V$ . Since  $\sum_{v \in C} q(v) = 1$ , by Claim 2.3,

$$\mathbb{E}_{v \in V}[q(v)] = \frac{1}{n} \sum_{v \in V} q(v) = \frac{1}{n} \sum_{\substack{C: C \text{ is a witness} \\ \text{to disconnectedness}}} 1 \geq \frac{(\varepsilon - 2\alpha)m}{n} = \frac{1}{b}.$$

Finally, we apply the following work investment strategy lemma [5, Lemma 2.5].

► **Lemma 2.7** ([5]). *Let  $X$  be a random variable that takes values in  $[0, 1]$ . Suppose  $\mathbb{E}[X] \geq \beta$ , and let  $t = \lceil \log(4/\beta) \rceil$ . For all  $i \in [t]$ , let  $p_i = \Pr[X \geq 2^{-i}]$  and  $k_i = \frac{4 \ln 6}{2^i \beta}$ . Then  $\prod_{i=1}^t (1 - p_i)^{k_i} \leq \frac{1}{6}$ .*

We apply Lemma 2.7 with  $X$  equal to  $q(v)$  for a uniformly random  $v \in V$ . Set  $\beta = 1/b$  and  $t = \lceil \log(4/\beta) \rceil$ . For  $i \in [t]$ , set  $p_i$  to be the probability that a vertex  $v$  sampled uniformly at random belongs to a witness to disconnectedness of  $G$  that has at most (i)  $2^i$  vertices, when  $b \leq \bar{d} \cdot \log b$ ; (ii)  $2^{i-1} \cdot \deg(v)$  edges, otherwise. That is,  $p_i = \Pr[X \geq 2^{-i}]$ . Similarly, for  $i \in [t]$ , let  $k_i = \frac{4 \ln 6}{2^i \beta}$ . Then the probability that Step 9 of the tester does not reject is  $\prod_{i=1}^t (1 - p_i)^{k_i}$ . By Lemma 2.7, this step rejects with probability at least  $5/6$ . ◀

**Proof of Theorem 1.4.** We start by analyzing the query and time complexity of Algorithm 1.

**Case 1:** When  $b \leq \bar{d} \cdot \log b$ , the query and time complexity of Algorithm 1 is

$$\sum_{i \in [\lceil \log(4b) \rceil]} \left\lceil \frac{4b \ln 6}{2^i} \right\rceil \cdot 2^{2i} = O(b^2) = O(\min\{b^2, b\bar{d} \cdot \log b\}).$$

**Case 2:** When  $b > \bar{d} \cdot \log b$ , the expected query and time complexity of Algorithm 1 is

$$\sum_{i \in [\lceil \log 4b \rceil]} \left\lceil \frac{4b \ln 6}{2^i} \right\rceil \cdot 2^i \cdot \mathbb{E}_{s \in V}[\deg(s)] = O(b\bar{d} \log b) = O(\min\{b^2, b\bar{d} \cdot \log b\}).$$

Substituting the value of  $b$ , we get

$$O(\min\{b^2, b\bar{d} \cdot \log b\}) = O\left(\min\left\{\frac{1}{((\varepsilon - 2\alpha)\bar{d})^2}, \frac{1}{\varepsilon - 2\alpha} \log \frac{1}{(\varepsilon - 2\alpha)\bar{d}}\right\}\right).$$

The final tester is obtained by running Algorithm 1 and then aborting and accepting if the number of queries exceeds six times its expectation. The final tester then has the query complexity and the running time stated in Theorem 1.4.

The final tester never rejects a connected partially erased graph. However, a partially erased graph that is  $\varepsilon$ -far from connected can get accepted incorrectly if Algorithm 1 accepts it or if the final algorithm aborts. The probability of the former event is at most  $1/6$ , by Lemma 2.4. The probability of aborting is also at most  $1/6$ , by Markov's inequality. By a union bound, the final algorithm accepts incorrectly with probability at most  $1/3$ , completing the proof of the theorem for the case when  $\bar{d}$  is given to the algorithm.

We can adjust the algorithm to work without access to the average degree at a small cost in query and time complexity. The details appear in the full version [20]. ◀

## 2.2 Our Erasure-Resilient Connectedness Tester for $\alpha \in [\varepsilon/2, \varepsilon]$

In this section, we prove Theorem 1.5. We describe and analyze a 1-sided error  $\alpha$ -erasure-resilient  $\varepsilon$ -tester for connectedness that can work with more erasures in the input graph than Algorithm 1 can handle. Specifically, the tester works for all  $\alpha < \varepsilon$ . However, it has better performance than Algorithm 1 only for  $\alpha \in [\varepsilon/2, \varepsilon]$ .

■ **Figure 1** An example of a component with two erasures, where a BFS from any vertex fails to detect that this component is disconnected from the rest of the graph.

■ **Figure 2** An example of a generalized witness to disconnectedness, where only a BFS from  $v_1$  (but not from any other vertex) detects the generalized witness.

A dotted line represents an erasure in the adjacency list of the corresponding vertex. An arrow pointing from a vertex  $a$  in the direction of a vertex  $b$  represents that  $b \in \text{Adj}(a)$ , but  $a \notin \text{Adj}(b)$ .

When  $\alpha > \varepsilon/2$ , an  $\alpha$ -erased graph that is  $\varepsilon$ -far from being connected may not contain any witnesses to disconnectedness as defined in Section 2.1. Specifically, every set  $C$  of nodes that gets completed to a connected component could have an erasure in the union of the adjacency lists of the nodes in  $C$ . To get around this issue, our tester looks for a *generalized witness to disconnectedness*, which is, intuitively, a connected component with at most one erasure. Observe that a component with two erasures could have a unique completion, but impossible to certify as a separate connected component from the local view from any of its vertices. Figure 1 shows an example of a small component, where a BFS from any vertex will be unable to certify that the graph is disconnected.

Our tester repeatedly performs a BFS from a random vertex until it detects a generalized witness to disconnectedness, or exceeds a specified query budget. We show, by a counting argument, that every partially erased graph that is far from connected has several *small* generalized witnesses to disconnectedness. The correctness of the tester is ensured by the observation that each such witness  $C$  contains at least one vertex from which all the other vertices in  $C$  are reachable. (It is possible to have *exactly* one vertex in  $C$  from which all the other vertices are reachable. Figure 2 shows an example of a connected component, where a BFS can detect the generalized witness to disconnectedness only if started at vertex  $v_1$ , but will fail to do so from all other vertices.)

Before we state our tester, we formalize the notion of generalized witnesses.

► **Definition 2.8** (Generalized witness to disconnectedness). *Given a partially erased graph  $G$  over a vertex set  $V$ , a set  $C \subset V$  is a generalized witness to disconnectedness of  $G$  if*

1. *there is at most one erased entry ( $\perp$ ) in  $\bigcup_{v \in C} \text{Adj}(v)$ ,*
2. *every nonerased entry in  $\bigcup_{v \in C} \text{Adj}(v)$  is a vertex from  $C$ ,*
3. *if  $\perp \in \text{Adj}(u)$  for some  $u \in C$  then  $u \in \text{Adj}(v)$  but  $v \notin \text{Adj}(u)$  for some  $v \in C$ ; moreover, each node in  $C$  is reachable via a BFS from  $v$ .*

Definition 2.8 implies that the only erasure, if any, in the union of the adjacency lists of the nodes in  $C$  is part of a half-erased edge within  $C$ , and that  $C$  forms a connected component in every completion of  $G$ .

Let  $b = 4/((\varepsilon - \alpha)\bar{d})$ . Our tester is presented in Algorithm 2. In the rest of the section, we analyze the correctness and complexity of the tester.

► **Definition 2.9** (Small and big sets). *Let  $G$  be a partially erased graph and let  $\varepsilon^* \in (0, 2/\bar{d})$  be a parameter. The representation length of a set  $C$  of nodes is the sum of lengths of the adjacency lists of nodes in  $C$ . The set  $C$  is  $\varepsilon^*$ -small if either*

- $\varepsilon^* \geq 4/\bar{d}^2$  and  $C$  contains at most  $4/(\varepsilon^* \cdot \bar{d})$  vertices, or
- $\varepsilon^* < 4/\bar{d}^2$  and  $C$  has representation length at most  $4/\varepsilon^*$ .

*The set  $C$  is  $\varepsilon^*$ -big otherwise.*

Claim 2.10 shows that a partially erased graph that is far from connected has sufficiently many small generalized witnesses to disconnectedness.

**Algorithm 2** Erasure-Resilient Connectedness Tester for  $\alpha \in [\varepsilon/2, \varepsilon)$ .

---

**input** : The average degree  $\bar{d}$ , parameters  $\varepsilon \in (0, 2/\bar{d})$ ,  $\alpha \in [0, \varepsilon)$ ; query access to an  $\alpha$ -erased graph  $G$ .

- 1 Let  $b \leftarrow 4/((\varepsilon - \alpha)\bar{d})$ .
- 2 **repeat**  $\lceil b \ln 3 \rceil$  **times**
- 3   Sample a vertex  $s$  uniformly and independently at random.
- 4   Run a BFS starting from  $s$  using at most  $\min\{b^2, b \cdot \bar{d}\}$  neighbor queries.
- 5   **if** *Step 4 detected a generalized witness to disconnectedness* **then**
- 6     **Reject**.
- 7 **Accept**.

---

▷ **Claim 2.10.** Let  $\varepsilon \in (0, 2/\bar{d})$ ,  $\alpha \in [0, \varepsilon)$ . Let  $G$  be an  $\alpha$ -erased graph that is  $\varepsilon$ -far from connected. The number of  $(\varepsilon - \alpha)$ -small generalized witnesses to disconnectedness of  $G$  is at least  $(\varepsilon - \alpha)m/2$ .

*Proof.* We first argue that there are many small connected components in every completion  $G'$  of  $G$  and then prove that many of these are generalized witnesses in  $G$ .

Consider a completion  $G'$  of  $G$ . If  $\varepsilon - \alpha \geq 4/\bar{d}^2$ , the number of  $(\varepsilon - \alpha)$ -big connected components in  $G'$  is at most  $n/b = (\varepsilon - \alpha)m/2$ . If  $\varepsilon - \alpha < 4/\bar{d}^2$ , the number of  $(\varepsilon - \alpha)$ -big connected components in  $G'$  is at most  $2m/(b \cdot \bar{d}) = (\varepsilon - \alpha)m/2$ , since the representation length of the vertex set  $V$  of  $G$  is  $2m$ . By Observation 2.2, the total number of connected components in  $G'$  is at least  $\varepsilon m + 1$ . Hence, the number of  $(\varepsilon - \alpha)$ -small connected components in  $G'$  is at least  $(\varepsilon + \alpha)m/2$ .

Let  $C \subset V$  denote the set of vertices corresponding to an  $(\varepsilon - \alpha)$ -small connected component in  $G'$ . If  $\bigcup_{v \in C} \text{Adj}(v)$  has no erasures, then  $C$  is a generalized witness to disconnectedness of  $G$ . Next, assume that  $\bigcup_{v \in C} \text{Adj}(v)$  has exactly one erasure. We show that the set  $C$  is a generalized witness to disconnectedness of  $G$ . Condition 1 is satisfied by definition. Condition 2 is true since  $C$  forms a connected component in  $G'$ . To see that Condition 3 holds, let  $u \in C$  be the vertex with  $\perp \in \text{Adj}(u)$ . Since  $C$  is a connected component in  $G'$ , this erased entry was completed with the label of another vertex  $v \in C$ . Moreover, every vertex in  $C$  is reachable by a BFS from  $v$ , since  $C$  forms a connected component in  $G'$ , and the erased entry is not needed for these searches because it would lead back to  $v$ . Therefore,  $C$  is a generalized witness to disconnectedness of  $G$  if  $\bigcup_{v \in C} \text{Adj}(v)$  has exactly one erasure.

Among the  $(\varepsilon - \alpha)$ -small connected components in  $G'$ , at most  $\alpha m$  have at least 2 erased entries in the union of their adjacency lists. Hence, the number of  $(\varepsilon - \alpha)$ -small generalized witnesses to disconnectedness of  $G$  is at least  $((\varepsilon + \alpha)m/2) - \alpha m = (\varepsilon - \alpha)m/2$ . ◁

Lemma 2.11 below implies Theorem 1.5.

► **Lemma 2.11.** For every  $\varepsilon \in (0, 2/\bar{d})$  and  $\alpha \in [0, \varepsilon)$ , Algorithm 2 is an  $\alpha$ -erasure-resilient  $\varepsilon$ -tester for connectedness of graphs with the average degree  $\bar{d}$ . It has  $O(b^2 \bar{d} \cdot \min\{b/\bar{d}, 1\})$  query and time complexity.

**Proof.** Consider an  $\alpha$ -erased graph  $G$  over a vertex set  $V$ . Assume that  $G$  is connected, that is, there exists a connected completion  $G'$  of  $G$ . Consider an arbitrary  $C \subset V$ . There exist vertices  $u \in C$  and  $v \in V \setminus C$  such that  $\text{Adj}(u)$  in  $G'$  contains  $v$ . Hence,  $C$  is not a generalized witness to disconnectedness of  $G$ . Therefore, the tester accepts  $G$ .

■ **Figure 3** The partially erased graphs  $G^+$  and  $G^-$  described in the proof of Theorem 1.6. The dotted lines represent erased entries in the adjacency lists of the corresponding vertices. In  $G^+$ , the directed edges from  $v^*$  point to the vertices in its adjacency list. The circles represent cycles.

Next, assume that  $G$  is  $\varepsilon$ -far from connected. Let  $\mathcal{W}$  denote the family of all  $(\varepsilon - \alpha)$ -small generalized witnesses to disconnectedness of  $G$ . Let  $C \subset V$  be an element of  $\mathcal{W}$ . If  $\varepsilon - \alpha \geq 4/\bar{d}^2$ , the representation length of  $C$  is at most  $b^2 \leq b \cdot \bar{d}$ . If  $\varepsilon - \alpha < 4/\bar{d}^2$ , the representation length of  $C$  is at most  $b \cdot \bar{d} < b^2$ . Hence, the representation length of  $C$  is at most  $\min\{b^2, b \cdot \bar{d}\}$ . If  $\bigcup_{v \in C} \text{Adj}(v)$  has no erasures then every vertex in  $C$  is reachable from every other vertex in  $C$ . Otherwise, the vertex  $v$  in Condition 3 of Definition 2.8 is such a vertex. If Algorithm 2 performs a BFS from  $v$ , it will detect a generalized witness to disconnectedness after at most  $\min\{b^2, b \cdot \bar{d}\}$  queries and reject. Since  $|\mathcal{W}| \geq (\varepsilon - \alpha)m/2$  and each generalized witness in  $\mathcal{W}$  has at least one vertex from which the generalized witness is detectable by a BFS, a single iteration of Algorithm 2 rejects with probability at least  $|\mathcal{W}|/n = 1/b$ . Hence, Algorithm 2 rejects with probability at least  $1 - (1 - (1/b))^{\lceil b \ln 3 \rceil} \geq 1 - \exp(-\ln 3) = 2/3$ .

Step 4 of Algorithm 2 makes at most  $\min\{b^2, b\bar{d}\}$  queries. Thus, the query complexity of Algorithm 2 is  $O(b \cdot \min\{b^2, b\bar{d}\})$ , which simplifies to the claimed expression. Checking (in Step 5) whether a set  $C$  is a generalized witness to disconnectedness can be done with a constant number of passes over the adjacency lists of vertices in  $C$ . Since the algorithm queried all entries in them, its running time is asymptotically equal to its query complexity. ◀

### 2.3 A Lower Bound for Erasure-Resilient Connectedness Testing

In this section, we prove Theorem 1.6. We note that hard graphs in our construction have constant average degree. That is, for those graphs, our lower bound is  $\Omega(n) = \Omega(m)$ .

**Proof of Theorem 1.6.** We apply Yao's minimax principle, as stated in [26]. Specifically, we construct distributions  $\mathcal{D}^+$  and  $\mathcal{D}^-$ , the former over connected graphs and the latter over graphs that are  $\varepsilon$ -far from connected, such that every deterministic  $\varepsilon$ -erasure-resilient  $\varepsilon$ -tester for connectedness makes  $\Omega(m)$  queries to distinguish the two distributions.

Without loss of generality, assume that  $t = (1 - \varepsilon)/(2\varepsilon)$  is an integer. Observe that  $t \geq 3$  as  $\varepsilon \leq 1/7$ . Let  $k$  be an even number and  $n = kt + 1$ . We first construct two partially erased  $n$ -node graphs  $G^+$  and  $G^-$ , depicted in Figure 3. The vertices of  $G^+$  are partitioned into  $k + 1$  sets. Each of the first  $k$  sets induces a  $t$ -node cycle. Exactly one node in each cycle has degree 3 and has an erasure in its adjacency list, in addition to its two neighbors on the cycle. The last set contains a single node  $v^*$  of degree  $k$ . Its adjacency list contains the labels of the degree-3 vertices in the cycles. The graph  $G^-$  is the same as  $G^+$ , except that in  $G^-$ , we have that  $\text{Adj}(v^*)$  is empty, that is,  $v^*$  is isolated.

We can obtain a connected completion of  $G^+$  by connecting the vertex  $v^*$  to all the degree-3 vertices. In contrast, at least  $k/2$  edges need to be added to every completion of  $G^-$  to make it connected. Hence, the distance from  $G^-$  to connectedness is  $(k/2)/(kt+k/2) = 1/(2t+1) = \varepsilon$ .

The fraction of erased entries in the adjacency lists of  $G^+$  and  $G^-$  are  $1/(2t+2)$  and  $1/(2t+1)$ , respectively. That is,  $G^+$  and  $G^-$  are both  $\alpha$ -erased graphs for  $\alpha = 1/(2t+1) = \varepsilon$ .

The distributions  $\mathcal{D}^+$  and  $\mathcal{D}^-$  are uniform over the sets of all partially erased graphs isomorphic to  $G^+$  and  $G^-$ , respectively. Each partially erased graph sampled from  $\mathcal{D}^+$  is connected. Each partially erased graph sampled from  $\mathcal{D}^-$  is  $\varepsilon$ -far from connected.

▷ **Claim 2.12.** Every deterministic algorithm  $A$  has to make  $\Omega(n)$  queries to distinguish  $\mathcal{D}^+$  and  $\mathcal{D}^-$  with probability at least  $2/3$ .

*Proof.* Let  $q$  denote the number of queries made by  $A$  and assume  $q \leq n/6$ . In this proof, we use  $v^*$  as a shorthand for the vertex from the singleton set in the construction of  $\mathcal{D}^+$  and  $\mathcal{D}^-$ , as opposed to the label of that vertex. Since  $\mathcal{D}^+$  and  $\mathcal{D}^-$  differ only on  $v^*$ , it is important to understand when  $A$  gets any information about  $v^*$ .

► **Definition 2.13 (Node status).** *Given a sequence of queries made by  $A$  and answers it has received so far, a node  $v$  is known if it has been queried (via a degree or neighbor query) or received as an answer to a (neighbor) query; otherwise, it is unknown.*

The node  $v^*$  is *unknown* before  $A$  makes its first query. Since  $v^*$  cannot be received as an answer to a query for the graphs in the support of  $\mathcal{D}^+$  and  $\mathcal{D}^-$ , it can become *known* only if  $A$  queries an *unknown* node that happens to be  $v^*$ . At most two new nodes become *known* per query. So, the probability (over the distribution  $\mathcal{D}^+$  or  $\mathcal{D}^-$ ) that a specific *unknown* node queried by  $A$  turns out to be  $v^*$  is at most  $1/(n-2q)$ . Let  $p$  denote the probability that  $v^*$  becomes *known* by the end of an execution of  $A$ . By a union bound over all queries made by  $A$ , we have,  $p \leq \frac{q}{n-2q} \leq \frac{n/6}{n-n/3} = \frac{1}{4}$ .

If  $v^*$  is *unknown* by the end of a particular execution then the view of the partially erased graph obtained by  $A$  in that execution arises with the same probability under  $\mathcal{D}^+$  and under  $\mathcal{D}^-$ . Such an execution of  $A$  can distinguish  $\mathcal{D}^+$  and  $\mathcal{D}^-$  with probability at most  $1/2$ . Therefore, the probability that  $A$  distinguishes  $\mathcal{D}^+$  and  $\mathcal{D}^-$  is at most  $p + (1-p) \cdot \frac{1}{2} = \frac{1}{2} + \frac{p}{2} < \frac{2}{3}$ . ◁

In our construction,  $m = \Theta(n)$ . Thus, every  $\varepsilon$ -erasure-resilient  $\varepsilon$ -tester for connectedness that uses only degree and neighbor queries must make  $\Omega(m)$  queries in the worst case over the input graph, completing the proof of Theorem 1.6. ◀

### 3 Estimating the Average Degree of a Graph

In this section, we present our results on erasure-resilient estimation of the average degree of graphs.

#### 3.1 An Algorithm for Estimating the Average Degree

In this section, we describe and analyze the algorithm (claimed in Theorem 1.7) for estimating the average degree of (or, equivalently, the number of edges in) a partially erased graph. Our algorithm is a generalization of the algorithm for counting the number of edges in graphs by Eden et al. [9, 10] to the case of partially erased graphs. We first give an algorithm (Algorithm 3) that takes a crude estimate of the average degree as input and outputs a more accurate estimate. Using a standard technique similar to the binary search, our final algorithm uses Algorithm 3 as a subroutine to gradually refine its estimate of the average degree. The final algorithm and the complete proof of Theorem 1.7 appear in the full version.

Algorithm 3, like the algorithm of Eden et al. [9, 10], works by empirically estimating a random variable whose expectation is close to the number of edges in the graph. We first rank vertices according to their degrees, breaking ties arbitrarily. Then we orient the nonerased edges of the graph from lower-ranked to higher-ranked endpoints. This orientation allows us to attribute each nonerased edge to its lower-ranked endpoint in order to avoid double-counting the edge. Since the number of edges between high-degree vertices is small, we ignore such edges. Algorithm 3 samples low-degree vertices uniformly at random and estimates, via sampling, the number of edges “credited” to them.

The crucial difference in the behavior of the algorithm in the case of partially erased graphs is the following. When we sample an erased entry from the adjacency list of a low-degree vertex  $u$ , we assume that it gets completed to a vertex ranked higher than  $u$  and, therefore, attribute the corresponding edge to  $u$ . Consequently, some erased edges get counted twice. This results in the additional term depending on the fraction of erasures in the approximation guarantee.

The ranking of (or the total ordering on) the vertices of a graph is defined below.

► **Definition 3.1** (Total ordering  $\prec$ ). *In a partially erased graph  $G$ , for any two vertices  $u, v$ , we write  $u \prec v$  if either  $\deg(u) < \deg(v)$ , or  $\deg(u) = \deg(v)$  and  $u$  is lexicographically smaller than  $v$ .*

■ **Algorithm 3** Erasure-Resilient Algorithm for Improving an Estimate of Average Degree.

---

**input** : Parameters  $\varepsilon \in (0, 1/2)$ ,  $\delta \in (0, 1/3)$ ; query access to a partially erased graph  $G$  on  $n$  nodes; a crude estimate  $\widehat{d}$  of the average degree of  $G$ .

- 1 Set  $s \leftarrow \left\lceil 660 \ln(2/\delta) \sqrt{\frac{n}{\varepsilon^5 \widehat{d}}} \right\rceil$ .
- 2 **for**  $i = 1$  **to**  $s$  **do**
- 3     Sample a node  $u$  from  $V$  uniformly at random and query its degree,  $\deg(u)$ .
- 4     Query a uniformly random entry from  $\text{Adj}(u)$  and let  $v$  be the answer.
- 5     If  $v \neq \perp$  then query its degree,  $\deg(v)$ .
- 6     **if**  $\deg(u) \leq 4\sqrt{n\widehat{d}/\varepsilon}$  **and** either  $v = \perp$  or  $u \prec v$  **then**
- 7          $\chi_i \leftarrow \deg(u)$
- 8     **else**
- 9          $\chi_i \leftarrow 0$
- 9 **return**  $\widetilde{d} = 2 \cdot \frac{1}{s} \sum_{i=1}^s \chi_i$ .

---

► **Lemma 3.2.** *Let  $G$  be an  $\alpha$ -erased  $n$ -node graph with the average degree  $\bar{d} \geq 1$ . Let  $\widehat{d}$  be a crude estimate of the average degree, given as an input to Algorithm 3. Then the output  $\widetilde{d}$  of Algorithm 3 satisfies the following:*

1. *If  $\widehat{d} \geq \frac{\bar{d}}{8}$  then, with probability at least  $3/4$ , we have  $\widetilde{d} \leq 8\bar{d}$ .*
2. *Furthermore, if  $\frac{\bar{d}}{8} \leq \widehat{d} \leq 8\bar{d}$  then with probability at least  $1 - \delta$ ,*

$$(1 - \varepsilon) \cdot \bar{d} < \widetilde{d} < (1 + \varepsilon + 2 \min(\alpha, \frac{1}{2})) \cdot \bar{d}.$$

*The query complexity of the algorithm is  $\Theta\left(\sqrt{\frac{n}{\varepsilon^5 \widehat{d}}} \cdot \log \frac{1}{\delta}\right)$ .*

**Proof.** The algorithm makes at most two degree queries and one neighbor query in each iteration, and it runs for  $\Theta\left(\sqrt{\frac{n}{\varepsilon^5 \cdot \bar{d}}} \cdot \log \frac{1}{\delta}\right)$  iterations. Hence, the bound on its query complexity is as claimed in the lemma.

To prove the guarantees on the output estimate  $\tilde{d}$ , we first show that for all  $i \in [s]$ , the expected value of  $\chi_i$  is a good estimate to the average degree of the partially erased graph, where  $s$  is the number of samples taken by Algorithm 3. We then apply Markov's inequality and Chernoff bound to prove parts 1 and 2 of the lemma, respectively. For all  $i \in [s]$ , the random variables  $\chi_i$  set by the algorithm are mutually independent and identically distributed. Hence, it suffices to bound  $\mathbb{E}[\chi_1]$ .

▷ **Claim 3.3.** If  $\hat{d} \geq \frac{\bar{d}}{8}$  then

$$\left(1 - \frac{\varepsilon}{2}\right) \cdot \frac{\bar{d}}{2} < \mathbb{E}[\chi_1] \leq \left(1 + 2 \min\left(\alpha, \frac{1}{2}\right)\right) \cdot \frac{\bar{d}}{2}.$$

**Proof.** Let  $m = n\bar{d}/2$  denote the total number of edges in the graph, and

$$\mathcal{H} = \left\{u \in V \mid \deg(u) > 4\sqrt{n\hat{d}/\varepsilon}\right\}$$

denote the set of high degree vertices. Let  $\hat{m} = n\hat{d}/2$  be the number of edges in the graph estimated from the input parameter  $\hat{d}$ . Since  $\hat{d} \geq \bar{d}/8$ , we have  $\hat{m} \geq m/8$ . Hence,

$$|\mathcal{H}| < \frac{2m}{4\sqrt{n\hat{d}/\varepsilon}} = \frac{m}{2\sqrt{2\hat{m}/\varepsilon}} \leq \frac{m}{\sqrt{m/\varepsilon}} = \sqrt{\varepsilon m}, \quad (1)$$

where the first inequality holds because the sum of degrees of high-degree vertices is at most  $2m$ , and the second inequality follows from  $\hat{m} \geq m/8$ .

The following quantity,  $d^+(u)$ , was defined in [10] for (standard) graphs. We extend their definition to partially erased graphs.

► **Definition 3.4.** For a vertex  $u$  in a partially erased graph  $G$ , let  $N(u)$  denote the set of (nonerased) neighbors present in  $\text{Adj}(u)$ . Let  $d^+(u) = |\{v \in N(u) \mid u \prec v\}|$  denote the number of nonerased neighbors of  $u$  that are higher than  $u$  w.r.t. the ordering on vertices (as in Definition 3.1).

Roughly,  $d^+(u)$  denotes the number of nonerased neighbors of  $u$  with the degree higher than that of  $u$ . The following fact is based on an observation by [10].

► **Fact 3.5.** For a partially erased graph  $G$  over a vertex set  $V$ , the sum  $\sum_{u \in V} d^+(u) \leq m$ . The inequality can be replaced with equality when  $G$  has no erasures.

The fact holds because each nonerased and half-erased edge in  $G$  is counted exactly once and at most once, respectively, in the sum  $\sum_{u \in V} d^+(u)$ .

Let  $u_1, u_2, \dots, u_{|\mathcal{H}|}$  be a labeling of the high degree vertices such that  $u_1 \prec u_2 \prec \dots \prec u_{|\mathcal{H}|}$ . For each  $j \in [|\mathcal{H}|]$ , observe that  $d^+(u_j) \leq |\mathcal{H}| - j$ , as  $d^+(u_j)$  is at most the number of vertices that are higher than  $u_j$  in the ordering. Hence,

$$\sum_{u \in \mathcal{H}} d^+(u) \leq \sum_{j=1}^{|\mathcal{H}|} (|\mathcal{H}| - j) = \sum_{k=0}^{|\mathcal{H}|-1} k < \frac{|\mathcal{H}|^2}{2} < \frac{\varepsilon m}{2}, \quad (2)$$

where the last inequality follows from (1).

Let  $d^\perp(u)$  denote the number of erased entries in  $\text{Adj}(u)$ . The expectation

$$\mathbb{E}[\chi_1] = \frac{1}{n} \sum_{u \in V \setminus \mathcal{H}} \frac{d^+(u) + d^\perp(u)}{\deg(u)} \cdot \deg(u) = \frac{1}{n} \sum_{u \in V \setminus \mathcal{H}} (d^+(u) + d^\perp(u)) \quad (3)$$

since the degree of the sampled vertex  $u$  is assigned to  $\chi_1$  if and only if

1.  $\deg(u) \leq 4\sqrt{n\widehat{d}}/\varepsilon$ , i.e.,  $u \in V \setminus \mathcal{H}$ ; and
2. the queried entry from  $\text{Adj}(u)$  is either a vertex  $v \succ u$  or  $\perp$ .

We now bound the quantity on the right hand side of (3) from below and above. Let  $G'$  be an arbitrary completion of  $G$ , and let  $d_{G'}^+(\cdot)$  denote the quantity defined in Definition 3.4 with respect to  $G'$  (instead of  $G$ ). For each  $u \in V$ , observe that  $d^+(u) + d^\perp(u) \geq d_{G'}^+(u)$ . Note that the upper bound in (2) still holds if we replace  $d^+(\cdot)$  with  $d_{G'}^+(\cdot)$ . Hence, by (3),

$$\mathbb{E}[\chi_1] \geq \frac{1}{n} \sum_{u \in V \setminus \mathcal{H}} d_{G'}^+(u) = \frac{1}{n} \left( m - \sum_{u \in \mathcal{H}} d_{G'}^+(u) \right) > \left( 1 - \frac{\varepsilon}{2} \right) \frac{m}{n}. \quad (4)$$

On the other hand, by (3),

$$\mathbb{E}[\chi_1] \leq \frac{1}{n} \sum_{u \in V} (d^+(u) + d^\perp(u)) \leq (1 + 2\alpha) \frac{m}{n}, \quad (5)$$

where the last inequality uses Fact 3.5 and  $\sum_{u \in V} d^\perp(u) \leq 2\alpha m$ . Since  $d^+(u) + d^\perp(u) \leq \deg(u)$  for all  $u \in V$ , by (3),

$$\mathbb{E}[\chi_1] \leq \frac{1}{n} \sum_{u \in V} \deg(u) = \frac{2m}{n}. \quad (6)$$

This completes the proof of Claim 3.3 because, using (4),(5) and (6), we get

$$\left( 1 - \frac{\varepsilon}{2} \right) \cdot \frac{m}{n} < \mathbb{E}[\chi_1] \leq \left( 1 + 2 \min \left( \alpha, \frac{1}{2} \right) \right) \cdot \frac{m}{n}. \quad \triangleleft$$

Let random variable  $\chi = \frac{1}{s} \sum_{i=1}^s \chi_i$  denote the mean of  $\chi_i$ 's calculated in Step 9 of Algorithm 3. Since all  $\chi_i$ 's are independent and identically distributed,  $\mathbb{E}[\chi] = \mathbb{E}[\chi_1]$ . Furthermore, the output  $\widehat{d}$  of the algorithm is  $2\chi$  and hence,  $\mathbb{E}[\widehat{d}] = 2\mathbb{E}[\chi]$ . By Claim 3.3, if  $\widehat{d} \geq \bar{d}/8$  then  $\mathbb{E}[\widehat{d}] \leq 2\bar{d}$ . By Markov's inequality,  $\Pr[\widehat{d} > 8\bar{d}] \leq \Pr[\widehat{d} > 4\mathbb{E}[\widehat{d}]] \leq 1/4$ . This completes the proof of part 1 of Lemma 3.2.

Now consider the case when  $\frac{\bar{d}}{8} \leq \widehat{d} \leq 8\bar{d}$ . Observe that  $0 \leq \chi_i \leq 4\sqrt{n\widehat{d}}/\varepsilon$  for all  $i \in [s]$  by Step 6. Hence, by an application of the Hoeffding bound,

$$\Pr \left[ |\chi - \mathbb{E}[\chi]| \geq \frac{\varepsilon}{2} \cdot \mathbb{E}[\chi] \right] \leq 2 \exp \left( -\frac{\varepsilon^2/4}{2 + \varepsilon/2} \cdot \frac{s \mathbb{E}[\chi]}{4} \sqrt{\frac{\varepsilon}{n\widehat{d}}} \right) < \delta,$$

where we used  $\varepsilon < 1/2$  and  $\widehat{d} \leq 8\bar{d}$  in the simplification. Hence, with probability at least  $1 - \delta$ , we have,  $(1 - \frac{\varepsilon}{2}) \cdot \mathbb{E}[\chi_1] < \chi < (1 + \frac{\varepsilon}{2}) \cdot \mathbb{E}[\chi_1]$ . Since  $\bar{d} = 2\mathbb{E}[\chi]$ , by Claim 3.3, we get that with probability at least  $1 - \delta$ ,

$$\left( 1 - \frac{\varepsilon}{2} \right) \left( 1 - \frac{\varepsilon}{2} \right) \cdot \bar{d} < \widehat{d} < \left( 1 + \frac{\varepsilon}{2} \right) \left( 1 + 2 \min \left( \alpha, \frac{1}{2} \right) \right) \cdot \bar{d},$$

proving part 2 of Lemma 3.2. ◀

The rest of the proof of Theorem 1.7 appears in the full version of this article [20].

■ **Figure 4** The partially erased graphs  $G_1$  and  $G_2$  described in the proof of Theorem 1.8. The dotted lines represent erased entries in the adjacency lists of corresponding vertices. The lines with arrows indicate that the entry corresponds to the vertex to which the arrow points to. The circles represent the  $(1-\lambda)(n-1)$ -cycles.

### 3.2 A Lower Bound for Estimating the Average Degree

In this section, we prove Theorem 1.8.

**Proof of Theorem 1.8.** Fix  $\lambda = \frac{2\alpha}{1+\alpha}$ . Note that  $\lambda \in (0, 1]$  since  $\alpha \in (0, 1]$ . Consider any integer  $n$  such that  $\lambda(n-1)$  is an even integer. Since  $\alpha$  is rational, there are infinitely many such  $n$ . We define two  $n$ -node graphs,  $G_1$  and  $G_2$  (see Figure 4). Both graphs contain a cycle consisting of  $(1-\lambda)(n-1)$  vertices. Of the remaining  $\lambda(n-1) + 1$  vertices, both graphs have  $\lambda(n-1)$  vertices of degree 1, with the only entry in the adjacency list of each such vertex erased. The last vertex, called  $v^*$ , is where  $G_1$  and  $G_2$  differ. In  $G_1$ , we have that  $\text{Adj}(v^*)$  consists of the labels of the  $\lambda(n-1)$  degree-1 vertices. In contrast, in  $G_2$ , the vertex  $v^*$  is isolated.

The graph  $G_1$  can only be completed to a graph consisting of two components: a cycle of length  $(1-\lambda)(n-1)$  and a star consisting of  $\lambda(n-1)$  edges. The graph  $G_2$  can only be completed to a graph consisting of a cycle of length  $(1-\lambda)(n-1)$ , one isolated vertex, and a matching of size  $\lambda(n-1)/2$ . Hence, the total lengths of the adjacency lists of  $G_1$  and  $G_2$  are  $2(n-1)$  and  $(2-\lambda)(n-1)$ , respectively. The number of entries erased in both graphs is  $\lambda(n-1)$ . So, the fraction of erased entries in the adjacency lists of  $G_1$  and  $G_2$  are  $\frac{\lambda}{2}$  and  $\frac{\lambda}{2-\lambda}$ , respectively. Hence, both  $G_1$  and  $G_2$  are  $\alpha$ -erased, as  $\frac{\lambda}{2-\lambda} = \alpha$ . The average degree of  $G_1$  and  $G_2$  are  $\frac{2(n-1)}{n}$  and  $\frac{(2-\lambda)(n-1)}{n}$ , respectively. The ratio of the average degrees is  $\frac{2}{2-\lambda} = 1 + \alpha$ .

The rest of the proof is similar to that of Theorem 1.6. We define two distributions  $\mathcal{D}_1$  and  $\mathcal{D}_2$  as the uniform distributions over the set of all graphs isomorphic to  $G_1$  and  $G_2$ , respectively. To differentiate between the two distributions, any tester must necessarily query  $v^*$  which requires  $\Omega(n)$  queries. The ratio of the average degrees of the two distributions is  $1 + \alpha$ . Hence, to approximate the average degree within a factor of  $(1 + \gamma)$ , where  $\gamma < \alpha$ , any tester must query  $\Omega(n)$  vertices. ◀

## 4 Conclusion and Open Questions

In this work, we initiate the study of sublinear-time algorithms for problems on partially erased graphs. Our investigation opens up a plethora of research directions and possibilities for future work. Next, we discuss several specific open questions arising from our work.

### Phase Transitions in the Complexity of Erasure-Resilient Connectedness Testing

As shown in Section 2, there is a phase transition in the complexity of connectedness testing at  $\alpha = \varepsilon$  from time independent of the size of the graph to  $\Omega(n)$ . Our upper bound on the complexity of this problem exhibits another, less drastic phase transition at  $\alpha = \varepsilon/2$ , when the asymptotic dependence of the running time on  $\varepsilon$  and  $\alpha$  changes. We conjecture that this second phase transition is inherent (and not an artifact of our techniques). It would be interesting to investigate whether connectedness testing when  $\alpha \in [\varepsilon/2, \varepsilon)$  is fundamentally different from the same problem when  $\alpha \in [0, \varepsilon/2)$ .

### Erasure-Resilient Testing of Monotone Properties in the Bounded-Degree Model

A property of a graph is *monotone* if it is preserved under deletion of edges and vertices. That is, if  $G$  satisfies a monotone property then so does every subgraph of  $G$ . Many important graph properties, including bipartiteness, 3-colorability, and triangle-freeness, are monotone.

In the bounded-degree property testing model [16], an  $n$ -node graph  $G$  with the degree bound  $D$  is represented as a concatenation of  $n$  adjacency lists, each of length  $D$ . For a vertex  $v \in G$  and an index  $i \in [D]$ , a neighbor query  $(v, i)$  returns a valid vertex in the graph if  $i \leq \deg(v)$  and a special symbol, say  $\sqcup$ , if  $i > \deg(v)$ . The graph  $G$  is  $\varepsilon$ -far from satisfying a property  $\mathcal{P}$  if at least  $\varepsilon n D$  entries in the adjacency lists of  $G$  need to be modified to make it satisfy  $\mathcal{P}$ .

Bounded-degree property testing can be generalized in a natural way to account for erased entries in adjacency lists. A bounded-degree graph is  $\alpha$ -erased if at most  $\alpha n D$  entries of its adjacency lists are erased. We observe that a tester for a monotone property of bounded-degree graphs can be made erasure-resilient via a simple transformation.

► **Observation 4.1.** *Let  $\mathcal{P}$  be a monotone property of graphs. Suppose there exists an  $\varepsilon$ -tester for  $\mathcal{P}$  in the bounded-degree model that makes  $q(\varepsilon, n, D)$  queries. Then there exists an  $\alpha$ -erasure-resilient  $\varepsilon$ -tester for  $\mathcal{P}$  in the bounded-degree model that makes at most  $D^2 \cdot q(\varepsilon - 2\alpha, n, D)$  queries and works for all  $\alpha \in (0, \varepsilon/2)$ .*

This transformation is not efficient for general graphs, as the maximum degree of a graph can be  $n - 1$ . It is interesting to understand how much erasure-resilience affects query complexity of testing monotone properties in our erasure-resilient model for general graphs.

### Erasure-Resilient vs. Tolerant Testing of Graphs

For  $0 \leq \varepsilon_1 < \varepsilon_2 < 1$ , an  $(\varepsilon_1, \varepsilon_2)$ -tolerant tester for a property  $\mathcal{P}$  must accept, with high probability, if the input is  $\varepsilon_1$ -close<sup>4</sup> to  $\mathcal{P}$  and reject, with high probability, if the input is  $\varepsilon_2$ -far from  $\mathcal{P}$  [24]. Dixit et al. [7] observed that, for properties of functions, erasure-resilient testing is no harder than tolerant testing. Specifically, a tolerant tester for a property of functions can be easily converted to an erasure-resilient tester with the same complexity.

---

<sup>4</sup> An object is  $\varepsilon_1$ -close to a property  $\mathcal{P}$  if it is not  $\varepsilon_1$ -far from  $\mathcal{P}$ .

The new tester can run the tolerant tester, filling in the queried erasures with arbitrary values. However, this argument fails in the case of testing properties of graphs represented as adjacency lists, since the erased entries have to be filled in so that the resulting completion is a valid graph. In the bounded-degree model, we can use a  $(2\alpha, \varepsilon - 2\alpha)$ -tolerant tester for a property  $\mathcal{P}$  to obtain an  $\alpha$ -erasure-resilient  $\varepsilon$ -tester for  $\mathcal{P}$  with an overhead  $O(D^2)$  in query complexity via a transformation similar to the one explained in our discussion of monotone properties. It is an important open question to understand the relationship between erasure-resilient and tolerant testing in the general graph model.

### Symmetric vs. Asymmetric Erasures

Our definition of partially erased graphs is general in the sense that erased entries may be *asymmetric*: an edge  $(u, v)$  can be erased in  $\text{Adj}(u)$ , but not in  $\text{Adj}(v)$ . A partially erased graph has only *symmetric* erasures if it has no half-erased edges, that is,  $u \in \text{Adj}(v)$  iff  $v \in \text{Adj}(u)$  for any two nodes  $u, v$ . It is an interesting direction to investigate which computational tasks are strictly easier in the model with symmetric erasures compared to the model with asymmetric erasures.

## Abstract

We investigate the algorithmic problem of selling information to agents who face a decision-making problem under uncertainty. We adopt the model recently proposed by Bergemann et al. [4], in which information is revealed through signaling schemes called *experiments*. In the single-agent setting, any mechanism can be represented as a menu of experiments. Our results show that the computational complexity of designing the revenue-optimal menu depends heavily on the way the model is specified. When all the parameters of the problem are given explicitly, we provide a polynomial time algorithm that computes the revenue-optimal menu. For cases where the model is specified with a succinct implicit description, we show that the tractability of the problem is tightly related to the efficient implementation of a *Best Response Oracle*: when it can be implemented efficiently, we provide an additive FPTAS whose running time is independent of the number of actions. On the other hand, we provide a family of problems, where it is computationally intractable to construct a best response oracle, and we show that it is NP-hard to get even a constant fraction of the optimal revenue. Moreover, we investigate a generalization of the original model by Bergemann et al. [4] that allows multiple agents to compete for useful information. We leverage techniques developed in the study of auction design (see e.g. [5, 1, 6, 7, 8]) to design a polynomial time algorithm that computes the revenue-optimal mechanism for selling information.

## 1 Introduction

Decision-making heavily relies on information availability. The uneven distribution of information thus enables markets for trading information. Imagine a bank reviewing a loan application. Information about the borrower's financial status clearly influences the bank's lending decisions. In this setting, the bank already has some private knowledge about the borrower, i.e., through prior interactions, but may still be willing to pay to acquire supplemental information to guide its decision-making. Indeed, Equifax, the credit report

agency, provides its business consumers, e.g., banks and credit card companies, a product called Undisclosed Debt Monitoring, that tracks negative information about individual borrowers.<sup>1</sup>

How should the information owner reveal and price the information? We adopt the model introduced by Bergemann et al. [4] to study this problem. Their model involves a data buyer and a data seller. The data buyer faces a decision under uncertainty, and his payoff depends on the *action* he decides to take and the underlying *state* of the world. Initially, the buyer only has some *imperfect* knowledge about the state, i.e. a prior distribution over the possible states. This piece of information is private to the buyer. On the contrary, the data seller knows the state of the world and can sell supplemental information to the buyer. Since the buyer's willingness to pay for supplemental information is determined by the precision of his own prior belief, we refer to the buyer's prior belief as his type. How does the seller optimize her revenue if the buyer's type is assumed to be drawn from a known distribution? To screen heterogeneous buyer types, the seller offers a menu of information products. Each product has the form of a *statistical experiment*, whose result reveals a signal that is correlated with the underlying state. Bergemann et al. [4] investigate what experiments should be included and how to price them. They obtain analytic solution of the revenue-optimal menu in two special cases: (i) the case with only two possible buyer types and (ii) the case with two states and two possible actions for the buyer to choose from. However, general characterization of the revenue-optimal menu remains elusive. In this paper, we initiate the algorithmic study of this problem and investigate the computational complexity for finding the revenue-optimal menu.

Our first result considers an explicit representation of the problem, where the input contains the buyer's type distribution and his payoff for each action and state pair.

**Result 1:** We design an algorithm that computes the revenue-optimal menu in time polynomial in the number of buyer types, the number of buyer actions, and the number of underlying states. (Theorem 3)

For many settings of interest, the model is too expensive to be specified explicitly but has a natural succinct implicit description. Consider the following motivating example. Suppose there is a traffic network  $G$ , and a binary state  $\omega$  that indicates the level of congestion on the edges of  $G$ . A driver wants to go from a vertex  $s$  to another vertex  $t$ , and his payoff is  $H$  minus the expected travel time from  $s$  to  $t$  using the path he picks.<sup>2</sup> Of course, which path is the fastest depends on the driver's belief of the state  $\omega$ . Suppose Waze is offering a service that provides the driver supplemental information about the congestion. How should Waze price its service? In this setting, the driver is the data buyer and the number of actions available to him is exactly the number of  $s - t$  paths, which can be exponential in the size of the network  $G$ . Applying our first result is thus computationally inefficient in this setting. Our second result concerns exactly these settings with succinct implicit descriptions. We show that the key to tractability is the existence of a computationally efficient *Best Response Oracle*, that is, an oracle that accepts a distribution over the underlying state as input and outputs an action with the highest expected payoff. Clearly, in the example above, it is straightforward to construct a computationally efficient best response oracle – simply assign the expected congestion on each edge as its length and run any shortest path algorithm on the graph  $G$ . We show that finding the revenue-optimal menu is tractable as long as there exists a best response oracle.

---

<sup>1</sup> <https://www.equifax.com/business/undisclosed-debt-monitoring/>

<sup>2</sup>  $H$  is a sufficiently large constant so that the payoff is always nonnegative.

**Result II:** For any setting with a constant number of possible underlying states, we design an FPTAS to compute an *up-to- $\varepsilon$  optimal menu*, i.e., a menu whose revenue is at most  $\varepsilon$  less than the optimum, given access to a best response oracle.<sup>3</sup> (Theorem 9)

Without the best response oracle, we show that it is NP-hard to even find a constant factor approximation to the optimal revenue for a family of succinctly describable instances with only two underlying states and one buyer type. (Theorem 12)

We also investigate extensions of the basic model studied in Bergemann et al. [4]. First, we consider the setting where multiple data buyers are competing with each other to receive an informative signal from the data seller. We obtain the following generalization of Result I.

**Result III:** We design an algorithm that computes the revenue-optimal mechanism in time polynomial in the *total number of buyer types*, the number of buyer actions, and the number of underlying states. (Theorem 19)

Note that the straightforward generalization of Result I only gives an algorithm that runs in time polynomial in the *total number of buyer type profiles*, which is exponential in the number of buyers. Our algorithm in Result III runs in time polynomial in the *total number of buyer types*, which is the description size for specifying each buyer's type distribution.

In Section 5, we discuss another natural extension. We can treat a buyer's payoffs for taking actions in various states as the buyer's private information and may be different across buyers. In other words, a buyer type is no longer just the buyer's prior belief of the underlying state but also his payoff function. We show that all our results (c.f. Result I, II, and III) can be easily extended to handle this case, and the modification is summarized in Section 5.

## Our Approach

In the explicit model, we first show that the revenue-optimal menu can be captured by a LP with polynomially many decision variables but exponentially many constraints. We leverage a technique introduced by Chen et al. [15] to transform it to an equivalent LP with polynomially many constraints. In the implicit model with a best response oracle, the main difficulty is that the optimal menu may contain experiments that use an arbitrary number of signals, and as a result the menu cannot even be represented in polynomial time. To overcome this difficulty, we first argue that there always exists an up-to- $\varepsilon$  optimal menu that only contains experiments that use a small number of signals, then apply an algorithm similar to the one in the explicit model to find such a menu. For the multi-agent setting, one can use a LP similar to the one in the explicit model to capture the optimal mechanism. The issue with this approach is that both of the number of variables and constraints are exponential in the number of agents, which is too large to solve. Our solution is inspired by an approach used to computing the revenue-optimal multi-item auctions [5, 1, 6, 7, 8]. The key idea is to first represent mechanisms in a succinct way known as the “reduced forms” and use a LP to search for the revenue-optimal reduced form. However, as a reduced form is only a succinct description, given a reduced form, it is not obvious what mechanism it corresponds to. Indeed, it is not even clear whether it corresponds to any mechanism. The main technical barrier we overcome is to design efficient algorithms to (i) check the feasibility of a reduced form and (ii) to implement a feasible reduced form as an actual mechanism.

---

<sup>3</sup> Our algorithm runs in time polynomial in the total number of buyer types and  $1/\varepsilon$ .

## 1.1 Related Work

### Relationship with Monopoly Pricing

A well-studied problem from mechanism design, the *monopoly pricing problem*, bears some resemblance to our problem. The monopoly pricing problem asks what is the revenue-optimal mechanism to sell one or more items to a buyer, whose valuation/willingness to pay for the items is drawn from a known distribution. In single-dimensional settings, the problem is completely resolved by [35, 36]. In multi-dimensional settings, complete characterizations are known only in several special cases [27, 28, 30, 18, 26, 22, 21], but simple and approximately optimal mechanisms [13, 14, 31, 2, 34, 37, 9, 12], as well as algorithmic characterizations [5, 1, 6, 7, 8] have been discovered in fairly general settings. The nature of information goods adds an extra layer of difficulty to the pricing problem. The value of information is determined by how much such information can improve the quality of decision-making. Buyers with different beliefs do not simply have different values for different experiments, but they may even disagree on their ranking. This richness in buyer valuations does not happen in single-dimensional monopoly pricing, but already exists in single-dimensional information pricing, where there are only two possible underlying states.<sup>4</sup> As a result, the optimal menu in information pricing has a more complex structure. For example, Bergemann et al. [4] showed that even in the two-state case, the seller sometimes needs to use randomized experiments to maximize her revenue. In this work, we show that despite the new challenges of selling information products, some of the algorithmic ideas from monopoly pricing are still useful.

### Relationship with Information Design

Similar to our problem, the designer constructs a signaling scheme that reveals partial information about the underlying state to influence the action of the agents in information design [32]. There has been growing interest in the algorithmic study of information design [24, 23, 25, 16, 19, 10]. The fundamental difference between our setting and information design is that, in our setting, the buyer's action does not have direct effect on the seller's utility. The seller only derives utility from the monetary transfers received from the buyer.

### Relationship with other Information-Selling Models

The work that is most related to the problem we are studying is by Babaioff et al. [3]. Similar to us, they consider a seller who knows the state of the world  $\omega$  and wants to sell information to a buyer whose prior is drawn from some distribution  $\Theta$ . However, there is a subtle but crucial difference between our models. In their work, the seller's information disclosure strategy and the price are allowed to be dependent on the realized state of the world  $\omega$ . By contrast, our model requires the seller to commit to a mechanism before the realization of the state  $\omega$ . Their main results state that (i) when  $\omega$  and the buyer's type are independently distributed, revelation principle holds, i.e., a single-round interaction suffices; and (ii) when  $\omega$  and the buyer's type are correlated, a full surplus extraction mechanism, similar to Crémer and McLean [17], exists and can be computed efficiently. These results differ quite substantially from the structural results for the model we study here [4]. For instance, full surplus extraction is in general impossible in our model. In a recent work, Chen et al. [15] extends the results by Babaioff et al. [3] to the setting where the buyer is budget-constrained, and improves upon some of the algorithmic results.

---

<sup>4</sup> In this case, the buyer's prior belief can be represented using a single real number in  $[0, 1]$ .

## 2 Preliminaries

### Model and Notation

The data buyer faces a decision problem under uncertainty. The state of the world  $\omega$  is drawn from a state space  $\Omega$ . The buyer chooses an action  $a$  from an action space  $A$ . Throughout the paper, we use  $m$  to denote the size of  $A$ . The buyer's **ex-post utility** for choosing action  $a$  under state  $\omega$  is defined to be  $u_{\omega,a}$  and is assumed to lie in  $[0, 1]$ . The buyer has some prior information about the state of the world which is denoted by  $\theta$  and comes from a set  $\Theta \subseteq \Delta\Omega$ . We call  $\theta$  the *type* of the buyer, and use  $\theta_\omega$  to denote the probability that the buyer assigns to the event that the state of the world is  $\omega$ . The type of the buyer is distributed according to  $F$ . Apart from the buyer, there is also a *seller* who observes the state of the world and is willing to sell supplemental information to the buyer. We refer to the buyer as he and to the seller as she.

### Experiment

The seller provides supplemental information to the buyer via a *signaling scheme* which we call *experiment*. A signaling scheme is a commitment to  $|\Omega|$  probability distributions over a set of different signals  $S$ , such that when the state of the world is realized, the seller draws a signal from the corresponding distribution and sends it to the buyer. We denote such an experiment by  $E = (S, \pi(E))$ , where  $\pi(E) : \Omega \rightarrow \Delta S$  denotes the distributions that experiment  $E$  is using. We denote the probability that experiment  $E$  sends signal  $s_k$  when the state of the world is  $\omega$  by  $\pi_{\omega,k}(E) = \Pr[s_k|\omega]$ . In this work, it is useful to think of the experiment  $\pi(E)$  as a matrix whose rows are indexed by the states of the world and columns are indexed by the signals. A *menu* of experiments is a collection  $\mathcal{M} = \{(E, t(E))\}$ , where  $t(E) \in [0, 1]$  is the payment the buyer has to make when he purchases experiment  $E$ . In the multi-agent setting, a menu is insufficient to generate the optimal revenue, and our goal there is to compute the revenue-optimal *mechanism*. In the single-agent setting, the interaction between the seller and the buyer works as follows:

1. The seller posts a menu  $\mathcal{M}$ .
2. The state of the world  $\omega$  and the type of the buyer  $\theta$  are realized.
3. The buyer chooses some experiment  $E$  from the menu based on his type and pays  $t(E)$ .
4. The seller sends the buyer a signal  $s$  that is drawn from  $\pi_{\omega,\cdot}(E)$ .
5. The buyer chooses an action  $a$ , based on his original belief  $\theta$  and the signal  $s$ , and receives utility  $u_{\omega,a}$ .

### The Value of an Experiment

To understand the behavior of the buyer, we first explain how the buyer evaluates an experiment. We first explain how the buyer would act if the only information available to him was his type  $\theta$ . Since the buyer picks an action that maximizes his expected utility, his best move without receiving any additional information from the seller is  $a(\theta) = \arg \max_a \sum_{\omega} \theta_{\omega} u_{\omega,a}$  and his **base utility** following that move is  $u(\theta) = \max_a \sum_{\omega} \theta_{\omega} u_{\omega,a}$ . If he receives extra information from the seller, he updates his beliefs and may choose a new action that induces higher expected value based on his posterior distribution over the states. After receiving signal  $s_k$  from experiment  $E$  his belief about the state of the world is

$$\Pr[\omega|s_k, \theta] = \frac{\theta_{\omega} \pi_{\omega,k}(E)}{\sum_{\omega' \in \Omega} \theta_{\omega'} \pi_{\omega',k}(E)}.$$

Hence, the best action is

$$a(s_k|\theta) \in \arg \max_a \sum_{\omega} \left( \frac{\theta_{\omega} \pi_{\omega,k}(E)}{\sum_{\omega' \in \Omega} \theta_{\omega'} \pi_{\omega',k}(E)} \right) u_{\omega,a},$$

which yields **conditional expected utility**

$$u(s_k|\theta) := \max_a \sum_{\omega} \left( \frac{\theta_{\omega} \pi_{\omega,k}(E)}{\sum_{\omega'} \theta_{\omega'} \pi_{\omega',k}(E)} \right) u_{\omega,a}.$$

When it is clear from the context, we might drop  $\theta$  in the previous expressions. Notice that after computing his posterior, the buyer's conditional expected utility is linear in the actions so we can assume w.l.o.g. that he picks a single action and not a distribution over actions. Taking the expectation over the signal he will receive, we denote the **value of the experiment**  $E$  for type  $\theta$  to be

$$V_{\theta}(E) = \sum_{s_k \in S} \max_a \left\{ \sum_{\omega} \theta_{\omega} \pi_{\omega,k}(E) u_{\omega,a} \right\}.$$

We assume that the buyer is quasilinear. We denote the **expected net utility** of type  $\theta$  for experiment  $E$  as  $V_{\theta}(E) - t(E)$ .

Notice that two different types  $\theta, \theta'$  may have different favorite actions under the same signal. As a result,  $V_{\theta}(E)$  is not a linear function over  $\theta$  for a fixed experiment  $E$  even when the type  $\theta$  is single-dimensional, i.e.,  $|\Omega| = 2$ . This is in sharp contrast to standard single-dimensional auction design settings, where the agent's value is always a linear function over the type when the allocation is fixed.<sup>5</sup>

## IC and IR Menu

The buyer chooses the experiment that gives him the highest net utility, and we slightly abuse notation and denote by  $E(\theta)$  the experiment of the menu  $\mathcal{M}$  that type  $\theta$  prefers

$$E(\theta) = \arg \max_E V_{\theta}(E) - t(E).$$

If all experiments give him expected net utility smaller than his base utility  $u(\theta)$ , he will not purchase any experiment. For convenience, we assume that there is a null experiment that provides no information offered at price 0, so now without loss of generality every type takes an experiment from the menu. We sometimes abuse notation to call a menu *Incentive Compatible* (IC) and *Individually Rational* (IR). By that, we mean that every buyer type  $\theta$  selects the experiment  $(E(\theta), t(\theta))$  that maximizes his expected net utility. Formally, these constraints are captured by the following two sets of inequalities:

$$\begin{aligned} V_{\theta}(E(\theta)) - t(\theta) &\geq V_{\theta}(E(\theta')) - t(\theta'), \quad \forall \theta, \theta' \in \Theta, \\ V_{\theta}(E(\theta)) - t(\theta) &\geq u(\theta), \quad \forall \theta \in \Theta. \end{aligned}$$

Once we have fixed the parameters of the model, we denote by  $\text{REV}(\mathcal{M})$  the revenue that menu  $\mathcal{M}$  generates and by  $\text{OPT}$  the optimal revenue in this setting.

---

<sup>5</sup> Indeed, this linearity even holds for quite general multi-dimensional settings in auction design, for example, when the buyer has additive valuations.

### 3 Optimal Menu for a Single Agent

In this section, we consider the problem of computing the optimal menu for a single agent. As we will show, the computational complexity of the problem is tightly related to the way that the problem is specified. We consider three different models.

- **Explicit model:** the distribution  $F$  and the ex-post utility matrix  $U$  are given explicitly in the input.
- **Implicit model with a best response (BR) oracle:** the distribution  $F$  is given along with a best response oracle. The best response oracle accepts a distribution over the states as input and outputs the action that generates the highest expected utility w.r.t. the input distribution.
- **Implicit model with succinct description:** the distribution  $F$  is given along with the description of a Turing Machine that computes the ex-post utility of any pair of state and action in time polynomial in the description size.

We summarize our results with respect to the three different models: (i) we show that computing the optimal menu in the explicit model is captured by a polynomial size LP; (ii) even though the number of actions in the implicit model with BR oracle may be arbitrarily large, we provide an FPTAS to find an up-to- $\varepsilon$  optimal menu for settings with a constant number of underlying states; (iii) we construct a succinctly representable instance of the problem such that computing a constant factor approximation or an up-to- $\varepsilon$  optimal menu is NP-hard.

#### 3.1 Explicit Model

In this section, we discuss the basic setting where the model is explicitly given. First, we state a structural result of the optimal menu that allows us to restrict the number of signals.

► **Definition 1** (Responsive Experiment). *A buyer type  $\theta$  is responsive to an experiment  $E$  if every signal  $s$  of  $E$  leads  $\theta$  to a different optimal choice of action and, in particular  $a(s_k | \theta) = a_k$  for all  $s_k \in S$ .*

Note that if an experiment  $E$  is responsive to any buyer type,  $E$  has exactly  $m$  signals. An intuitive way to think about Definition 1 is that signal  $s_i$  of  $E$  recommends the buyer to take an action  $a_i$ , and type  $\theta$  is responsive to  $E$  if  $\theta$  always follows the recommendation. Importantly, a different type  $\theta'$  may not be responsive to experiment  $E$  and does not follow the recommendations. We now state the structural result from [4] that states that it is without loss of generality to consider a menu where each buyer type purchases a responsive experiment.

► **Lemma 2** (Adapted from Proposition 1 from [4]). *A menu  $\mathcal{M}$  is responsive if for every buyer type  $\theta$ , it chooses a responsive experiment  $E(\theta)$  from the menu. We define the outcome of a menu as the joint distribution of states, actions, and monetary transfers resulting from every buyer type's optimal choice of experiment and subsequent choice of action. The outcome of every menu can be attained by a responsive menu.*

The proof of Lemma 2 is based on a revelation-principle type of argument. More precisely, assume that some type  $\theta$  prefers an experiment  $E(\theta)$  for which he is not responsive. Then, we can merge all the signals  $s_{i_1}, \dots, s_{i_\ell}$  of  $E(\theta)$  that lead the type to take the same action  $a_k$  and just send the merged signal as the new  $k$ -th signal  $s_k$ . Equipped with the structural result, we are ready to show how to capture the design of the optimal menu as a LP. Since

there exists an optimal menu that is responsive, every experiment in this menu has at most  $m$  signals. For every buyer type  $\theta$ , we use  $\pi(\theta)$  to denote the experiment type  $\theta$  purchases, where  $\pi_{\omega,i}(\theta)$  is the probability to send signal  $s_i$  when the state is  $\omega$ .  $\{\pi_{\omega,i}(\theta)\}_{\omega \in \Omega, i \in [m], \theta \in \Theta}$  is the first set of variables. We also have the prices for each experiment  $\{t(\theta)\}_{\theta \in \Theta}$  as variables. The main difference between selling experiments and selling items is that different types may interpret the same experiment differently. More specifically, for a responsive experiment  $(\pi(\theta), t(\theta))$ , the optimal choice of action for type  $\theta$  after receiving signal  $s_i$  is simply action  $a_i$ ; while for a different type  $\theta'$ , the best action after receiving signal  $s_i$  can be a completely different action  $a_j$  due to a different induced posterior. As our LP is designed to compute the optimal and responsive menu, we need to guarantee that for any type  $\theta$ , purchasing experiment  $(\pi(\theta), t(\theta))$  and following the recommendation is better than purchasing any experiment  $(\pi(\theta'), t(\theta'))$  for a different type  $\theta'$  and subsequently choosing the optimal action based on the induced posterior. We remark that the straightforward formulation of the previous constraints requires one to consider all the possible mappings from signals to actions, resulting in a LP that has exponentially many constraints in  $m$ . Although this huge LP can be solved using the ellipsoid algorithm, we use a technique inspired by Chen et al. [15] that allows us to formulate it using only polynomially many constraints in  $m$ .

See Figure 1 for our LP. Besides the variables representing the experiments and prices, we introduce a new set of variables  $\{z_i(\theta, \theta')\}_{i \in [m], \theta, \theta' \in \Theta}$ .  $z_i(\theta, \theta')$  serves as an upper bound of the conditional expected utility that  $\theta$  gets when he considers misreporting as  $\theta'$  and receives signal  $s_i$ , which is guaranteed by the second set of constraints. The first set of constraints make sure that for any type  $\theta$ , the net utility of purchasing experiment  $E(\theta)$  and following its recommendations is no worse than the utility of purchasing any other experiment and subsequently choosing the best action under each signal. Note that we allow  $\theta'$  to be the same  $\theta$  in the first set of constraints, which guarantees that the menu is responsive. The third set of constraints guarantees that purchasing experiment  $(\pi(\theta), t(\theta))$  is no worse than  $\theta$ 's base utility. We refer to these constraints as the individual rationality (IR) constraints. The last two constraints guarantee that  $\pi(\theta)$  is indeed an experiment.

► **Theorem 3.** *The LP in Figure 1 can be solved in time polynomial in  $m = |A|$ ,  $|\Omega|$ , and  $|\Theta|$ , and its optimal solution is the revenue-optimal menu.*

**Proof of Theorem 3.** The number of constraints and the number of variables of the LP in Figure 1 is polynomial in  $m, |\Omega|, |\Theta|$ , so it is clear that it can be solved in polynomial time. We now argue that its solution is indeed the optimal responsive menu, hence the optimal menu as guaranteed by Lemma 2. Observe that every responsive menu corresponds to a feasible solution of the LP. This is because if  $\{(\pi(\theta), t(\theta))\}_{\theta \in \Theta}$  is a responsive menu, then we can satisfy all the constraints by setting  $z_i(\theta, \theta') = \max_{a_j} \sum_{\omega} \theta_{\omega} \pi_{\omega,i}(\theta') u_{\omega,a_j}$ . Conversely, note that every feasible solution of the LP induces a responsive menu that simply chooses the experiment  $E(\theta)$  as  $(\pi(\theta), t(\theta))$  for each type  $\theta \in \Theta$ . This is because (i) the first and second sets of constraints guarantee that  $E(\theta)$  is a responsive experiment for  $\theta$  (this follows from setting  $\theta'$  to be  $\theta$  in both the first and second set of constraints) and  $V_{\theta}(E(\theta)) - t(\theta) \geq V_{\theta}(E(\theta')) - t(\theta')$ ; (ii) the IR constraints ensure that  $V(E(\theta)) - t(\theta) \geq u(\theta)$ . Hence, the optimal solution corresponds to the revenue-optimal menu. ◀

### 3.2 Implicit Model with a Best Response Oracle

In this section, we study the case where the model is provided implicitly. We prove that, given access to a best response oracle, our algorithm can compute an up-to- $\varepsilon$  optimal menu in time  $\text{poly}\left(|\Theta|, \frac{|\Omega||\Omega|^2}{\varepsilon|\Omega|^2 + |\Omega|}\right)$ , which is independent of the number of actions.

**Variables:**

- $\{\pi_{\omega,i}(\theta)\}_{\omega \in \Omega, i \in [m], \theta \in \Theta}$ , denoting the experiments in the menu.
- $\{t(\theta)\}_{\theta \in \Theta}$ , denoting the prices of the experiments.
- $\{z_i(\theta, \theta')\}_{i \in [m], \theta, \theta' \in \Theta}$ , helper variables.  $z_i(\theta, \theta')$  represents an upper bound of the conditional expected utility of signal  $s_i$  from experiment  $E(\theta')$  for type  $\theta$ .

**Linear Program:**

$$\begin{aligned}
& \max \quad \sum_{\theta \in \Theta} F(\theta) t(\theta) \\
& \text{s.t.} \quad \sum_{i \in [m]} \sum_{\omega \in \Omega} \theta_{\omega} \pi_{\omega,i}(\theta) u_{\omega,a_i} - t(\theta) \geq \sum_{i \in [m]} z_i(\theta, \theta') - t(\theta'), \quad \forall \theta, \theta' \in \Theta \quad (\text{IC}) \\
& \quad \quad z_i(\theta, \theta') \geq \sum_{\omega} \theta_{\omega} \pi_{\omega,i}(\theta') u_{\omega,a_j}, \quad \forall \theta, \theta' \in \Theta, \forall i, j \in [m] \\
& \quad \quad \sum_{i \in [m]} \sum_{\omega \in \Omega} \theta_{\omega} \pi_{\omega,i}(\theta) u_{\omega,a_i} - t(\theta) \geq u(\theta), \quad \forall \theta \in \Theta \quad (\text{IR}) \\
& \quad \quad \sum_{i \in [m]} \pi_{\omega,i}(\theta) = 1, \quad \forall \theta \in \Theta, \omega \in \Omega \\
& \quad \quad \pi_{\omega,i}(\theta) \geq 0, \quad \forall \theta \in \Theta, \forall \omega \in \Omega, \forall i \in [m]
\end{aligned}$$

■ **Figure 1** A linear program to find the revenue-optimal menu in the explicit model.

We first prove a structural result which shows that no matter how large the actual action set  $A$  may be, there is some  $A' \subseteq A$  such that a menu  $\mathcal{M}$  that recommends actions only from  $A'$  has negligible revenue loss compared to  $\text{OPT}$ . Moreover,  $|A'|$  depends only on  $|\Omega|$  and the additive approximation error. We also show that these sets can be computed efficiently.

► **Theorem 4.** *For any constant  $\varepsilon > 0$ , given access to a BR oracle we can compute for each type  $\theta \in \Theta$  a set of actions  $A_{\theta}$  by querying  $O\left(\frac{|\Omega||\Omega|^2}{\varepsilon|\Omega|^2 + |\Omega|}\right)$  times the BR oracle, so that there exists an IC and IR menu  $\mathcal{M}$ , whose experiments all contain no more than  $O\left(\frac{|\Omega||\Omega|^2}{\varepsilon|\Omega|^2 + |\Omega|}\right)$  many signals. Moreover, every type  $\theta$  only uses actions from  $A_{\theta}$  upon receiving any of these signals generated by his experiment. Finally, the revenue of  $\mathcal{M}$  is at least  $\text{OPT} - O(\sqrt{\varepsilon})$ .*

We present some lemmas that are used in the proof of Theorem 4. Firstly, we show that given a menu  $\mathcal{M}$  and  $\varepsilon$ , we can create a menu  $\mathcal{M}'$  with the following two properties: (i) the number of signals that  $\mathcal{M}'$  uses depends only on  $|\Omega|$  and  $\varepsilon$ , and every type  $\theta$  values the new experiment he gets at most  $O(\varepsilon)$  less than his original experiment. The proof is based on the idea that merging signals of an experiment  $E$  that are close does not decrease the value of the experiment by much.

► **Lemma 5.** *Let  $\varepsilon > 0$  be some given constant and let  $E = \{E(\theta)\}_{\theta \in \Theta}$  be a set of experiments, where each  $E(\theta)$  uses an arbitrary number of signals. Then, we can create a set of experiments  $E' = \{E'(\theta)\}_{\theta \in \Theta}$  that uses  $O\left(\left(\frac{|\Omega|}{\varepsilon}\right)^{|\Omega|}\right)$  signals per player such that  $V_{\theta}(E'(\theta)) \geq V_{\theta}(E(\theta)) - 2\varepsilon$ .*

We now argue that when we merge two signals, no type can value any experiment more than he did before.

▷ **Claim 6.** Let  $E(\theta)$  be the initial experiment that is offered to type  $\theta$  and  $E'(\theta)$  the experiment that is offered to  $\theta$  after the merge. Then, for any type  $\theta' \in \Theta$  it holds that  $V_{\theta}(E'(\theta')) \leq V_{\theta}(E(\theta'))$ .

So far we have established the existence of a menu  $\mathcal{M}'$  whose number of signals is significantly smaller than the initial one. However, if we do not have access to  $\mathcal{M}$  we cannot compute  $\mathcal{M}'$ . Lemma 7 shows that we can overcome this issue. By “rounding” the entries of the experiment so that for any type the value this experiment generates does not change much. Now, since there is a small number of signals, and the size of every experiment depends only on  $\varepsilon$  and  $|\Omega|$ , we can do an exhaustive search over the discretized entries.

► **Lemma 7.** *Let  $\{E(\theta)\}_{\theta \in \Theta}$  be a set of experiments, where each  $E(\theta)$  uses signals from  $S$ . We also let  $0 < \delta < 1$  be a given number such that  $1/\delta \in \mathbb{N}$ . Then, we can create a set of experiments  $\{E'(\theta)\}_{\theta \in \Theta}$  that uses signals from  $S'$  with  $|S'| = |S|$ , such that  $E'(\theta)$  is a valid experiment with  $\pi_{\omega, s'}(E'(\theta))$  being a multiple of  $\delta$  for all  $\omega \in \Omega, s' \in S', \theta \in \Theta$ , and  $|V_\theta(E'(\theta')) - V_\theta(E(\theta'))| \leq \delta|S|$ , for all  $\theta, \theta' \in \Theta$ .*

One construction that will be useful in our proofs is the  $\varepsilon$ -IC to IC transformation. Lemma 8 shows that if we have a menu whose IC, IR constraints are violated by at most  $\varepsilon$ , we can modify the prices so that it becomes IC, IR and has negligible  $O(\sqrt{\varepsilon})$  revenue loss. The construction is based on a technique developed [20, 11] and frequently used in the Mechanism Design literature. In the single agent setting, the idea is to offer a small multiplicative discount to all types to make sure that if they want to deviate to some other experiment, this will not be much cheaper than the one they were buying in the initial  $\varepsilon$ -IC menu.

► **Lemma 8.** *Let  $\mathcal{M} = \{E_i, t(E_i)\}_{i \in [k]}$  be a menu with  $k$  experiments. Suppose that the IC, IR constraints are violated by at most  $\varepsilon$ . Then, we can compute a new set of prices  $\{\tilde{t}(E_i)\}_{i \in [k]}$  such that the menu  $\tilde{\mathcal{M}} = \{E_i, \tilde{t}(E_i)\}_{i \in [k]}$  is IR, IC and  $\text{REV}(\tilde{\mathcal{M}}) \geq (1 - \sqrt{\varepsilon})\text{REV}(\mathcal{M}) - \sqrt{\varepsilon} - \varepsilon$ , in time  $O(k)$ .*

We are now ready to present a sketch of the proof for Theorem 4. Assume that we start with the optimal menu  $\mathcal{M}^*$ . By Lemma 5, Claim 6, and Lemma 7, we know that we can modify the experiments in  $\mathcal{M}^*$  so that they use only discretized signals. Moreover, the new menu is approximately IC and IR. We then apply Lemma 8 to obtain a menu that is IC and IR by sacrificing a negligible amount of revenue. Finally, to compute the collection of action sets that the types will choose after receiving the signals, we query BR oracle on all the possible discretized distributions where the signals are drawn from.

So far we have only shown a structural result about the existence of a menu that uses  $O\left(\frac{|\Omega||\Omega|^2}{\varepsilon|\Omega|^2 + |\Omega|}\right)$  signals and gives an additive  $O(\sqrt{\varepsilon})$ -approximation to the optimal revenue. We now argue that we can use a LP (Figure 2) to find such a menu. This is done by combining the result of Theorem 4 and modifying the LP we used in Section 3.1.

► **Theorem 9.** *For any  $\varepsilon > 0$ , any set  $\Theta$  of types, given access to a BR oracle, we can use the LP in Figure 2 to compute a menu  $\mathcal{M}$  that achieves  $\text{REV}(\mathcal{M}) \geq \text{OPT} - O(\sqrt{\varepsilon})$ . The number of queries to the BR oracle is poly  $\left(|\Theta|, \frac{|\Omega||\Omega|^2}{\varepsilon|\Omega|^2 + |\Omega|}\right)$  and the running time is poly  $\left(|\Theta|, \frac{|\Omega||\Omega|^2}{\varepsilon|\Omega|^2 + |\Omega|}\right)$ . Moreover, each experiment contains at most  $O\left(\frac{|\Omega||\Omega|^2}{\varepsilon|\Omega|^2 + |\Omega|}\right)$  many signals, and each type  $\theta$  only chooses actions from a set of actions  $A_\theta$  with size  $O\left(\frac{|\Omega||\Omega|^2}{\varepsilon|\Omega|^2 + |\Omega|}\right)$ .*

So far, the number of experiments in our constructions depends on the number of types  $|\Theta|$ . We show that the number of experiments needed for an up-to- $\varepsilon$  optimal menu is independent of  $|\Theta|$ . We achieve this by dropping experiments that are offered to types who are close in

**Variables:**

- $\{\pi_{\omega,i}(\theta)\}_{\omega \in \Omega, i \in [|A_\theta|], \theta \in \Theta}$ , denoting the experiments in the menu.
- $\{t(\theta)\}_{\theta \in \Theta}$ , denoting the prices of the experiments.
- $\{z_i(\theta, \theta')\}_{i \in [|A_{\theta'}|], \theta, \theta' \in \Theta}$ , helper variables.  $z_i(\theta, \theta')$  represents an upper bound of the conditional expected utility of signal  $s_i$  from experiment  $E(\theta')$  for type  $\theta$ .

**Linear Program:**

$$\begin{aligned}
& \max \quad \sum_{\theta \in \Theta} F(\theta) t(\theta) \\
& \text{s.t.} \quad \sum_{i \in [|A_\theta|]} \sum_{\omega \in \Omega} \theta_{\omega} \pi_{\omega,i}(\theta) u_{\omega, a_{\tau_\theta(i)}} - t(\theta) \geq \sum_{i \in [|A_{\theta'}|]} z_i(\theta, \theta') - t(\theta'), \quad \forall \theta, \theta' \in \Theta \quad (\text{IC}) \\
& \quad z_i(\theta, \theta') \geq \sum_{\omega} \theta_{\omega} \pi_{\omega,i}(\theta') u_{\omega, a_j}, \quad \forall \theta, \theta' \in \Theta, \forall i \in [|A_{\theta'}|], \forall a_j \in A \\
& \quad \sum_{i \in [|A_\theta|]} \sum_{\omega \in \Omega} \theta_{\omega} \pi_{\omega,i}(\theta) u_{\omega, a_{\tau_\theta(i)}} - t(\theta) \geq u(\theta), \quad \forall \theta \in \Theta \quad (\text{IR}) \\
& \quad \sum_{i \in [|A_\theta|]} \pi_{\omega,i}(\theta) = 1, \quad \forall \theta \in \Theta, \omega \in \Omega \\
& \quad \pi_{\omega,i}(\theta) \geq 0, \quad \forall \theta \in \Theta, \forall \omega \in \Omega, \forall i \in [|A_\theta|]
\end{aligned}$$

■ **Figure 2** A linear program to find an approximately revenue-optimal menu in the implicit model.

TV-distance. We show that this leads to a menu that preserves the revenue, is  $O(|\Omega|\varepsilon)$ -IC, IR and has  $O\left(\frac{|\Omega|^{2|\Omega|}}{\varepsilon^{|\Omega|}}\right)$  different experiments. Finally, we apply the  $\varepsilon$ -IC to IC transformation to the modified menu.

► **Lemma 10.** *Let  $\mathcal{M} = \{E(\theta), t(\theta)\}_{\theta \in \Theta}$  be a menu of experiments. Then, for any  $\theta, \theta' \in \Theta$  with  $d_{TV}(\theta, \theta') \leq \varepsilon$  it holds that  $V_\theta(E(\theta')) - t(\theta') \geq V_\theta(E(\theta)) - t(\theta) - 2|\Omega|\varepsilon$ .*

We are now ready to prove that we can create a menu that offers a small number of experiments and loses negligible revenue compared to OPT. We do that in two steps, since we are dealing with an action space and type space that are arbitrary. The first step is to shrink the action space that we are considering. In order to do that, we use Theorem 4 that guarantees the existence of a menu which loses negligible revenue and only considers actions from smaller action spaces. The next step is to divide the state space into regions in which all the types are within  $\varepsilon$  in TV-distance. Lemma 10 shows us that if we consider offering a single experiment to all the types in the same region, their values for the new experiment will not change much compared to the one they were getting. Finally, we apply Lemma 8 to solve the issue that the menu resulting from dropping experiments might not be IC, IR.

► **Theorem 11.** *Consider an environment with a type space  $\Theta$ , action space  $A$  and state space  $\Omega$ . Then, given some  $\varepsilon > 0$  and access to a BR oracle we can find a menu  $\mathcal{M}$  that generates revenue at least  $\text{OPT} - O(\sqrt{\varepsilon})$  and offers at most  $O\left(\frac{|\Omega|^{2|\Omega|}}{\varepsilon^{|\Omega|}}\right)$  experiments, in time  $\text{poly}\left(|\Theta|, \frac{|\Omega|^{|\Omega|^2}}{\varepsilon^{|\Omega|^2+|\Omega|}}\right)$ .*

### 3.3 Implicit Model with Succinct Description

In this section, we consider a setting where the model has a succinct implicit description. We show that no algorithm can obtain even a constant factor approximation to the optimal revenue for this setting, unless  $P = NP$ . To be more precise, we consider the following problem.

**Information Pricing SAT (IP-SAT):** find the revenue-optimal menu in the following setting:

- State space  $\Omega$ , type space  $\Theta$ .
- for each state  $\omega$ ,  $\Phi_\omega$  is a boolean formula in CNF over variables in  $X = \{x_1, \dots, x_n\}$
- Action space  $A$ : all the possible truth assignments of the variables in  $X$
- $u_{\omega,a} = \frac{\# \text{ satisfied clauses of } \Phi_\omega \text{ with assignment } a}{\# \text{ clauses of } \Phi_\omega}$

IP-SAT is a hard problem for the buyer in general, as maximizing his net utility requires solving an NP-hard problem. We show here that designing an approximately revenue-optimal menu for IP-SAT is also computationally intractable for the seller. Of course, it is not even clear what the optimal menu looks like in general for IP-SAT as we only have a limited characterization of the optimal menu. In Theorem 12, we construct a special family of IP-SAT instances with 2 states and 1 buyer type, and show how to reduce SAT to it.

► **Theorem 12.** *For any constant  $\varepsilon > 0$ , there does not exist a polynomial time algorithm  $\mathcal{A}$  that computes an menu with revenue at least  $(1/2 + \varepsilon)OPT - \frac{\varepsilon}{2m+4}$  in the IP-SAT problem with  $m+2$  clauses, unless  $P = NP$ .*

**Proof of Theorem 12.** Let  $\Phi = C_1 \wedge \dots \wedge C_m$  be any SAT instance over variables  $x_1, \dots, x_n$ . We show that given  $\mathcal{A}$  we can decide whether  $\Phi$  is satisfiable. We create the following IP-SAT instance: there are two states  $\omega_1, \omega_2$ , a single type  $\theta = (\frac{1}{2}, \frac{1}{2})$  and we set  $\Phi_{\omega_1} = (C_1 \vee y) \wedge \dots \wedge (C_m \vee y) \wedge (x_1 \vee y) \wedge (\neg x_1 \vee y)$ ,  $\Phi_{\omega_2} = (C_1 \vee \neg y) \wedge \dots \wedge (C_m \vee \neg y) \wedge (x_1 \vee \neg y) \wedge (\neg x_1 \vee \neg y)$  to be the two SAT instances with  $m+2$  clauses that the buyer faces. At each state, the actions are the possible assignments of the variables  $x_1, \dots, x_n, y$ . Let  $\Psi$  be some boolean formula in CNF and  $a$  some assignment of its variables. We define  $z_a(\Psi)$  to be the number of clauses in  $\Psi$  that  $a$  satisfies and  $w(\Psi)$  the total number of clauses in  $\Psi$ . Then, at each state  $\omega$  when the agent chooses assignment  $a$  we define his ex-post utility to be  $u_{\omega,a} = \frac{z_a(\Phi_\omega)}{w(\Phi_\omega)}$ .

From Bergemann et al. [4], we know the optimal menu should contain only the fully informative experiment  $E^*$ , and the price for this experiment is  $V_\theta(E^*) - u(\theta)$ .<sup>6</sup> Clearly,  $V_\theta(E^*) = 1$ , because the buyer can pick  $y$  to be  $T$  and  $F$  in states  $\omega_1, \omega_2$  respectively and satisfy all clauses. We now focus our attention on  $u(\theta)$ . Assume that without receiving any information the buyer decides to set  $y = T$ . This is w.l.o.g. since it is symmetric with the case he decides to set  $y = F$ . When the state is  $\omega_1$ , he satisfies all the clauses. According to his prior, this happens  $1/2$  of the time, so we see that so far  $u(\theta) \geq 1/2$ . Let us consider which assignment he should pick when the state is  $\omega_2$ . Observe that no matter which value he picks for  $x_1$ , he will always satisfy exactly one of the last two clauses in  $\Phi_2$ . Hence, for variables  $x_1, \dots, x_n$  he better pick the assignment  $a$  that maximizes  $z_a(\Phi)$ . Let  $k = \max_a z_a(\Phi)$ . Then  $u(\theta) = 1/2 + (k+1)/(2m+4) = \frac{m+k+3}{2m+4}$ . Hence, the optimal revenue is  $V_\theta(E^*) - u(\theta) = 1 - \frac{m+k+3}{2m+4} = \frac{m-k+1}{2m+4}$ . If  $\Phi$  is satisfiable, then  $k = m$ , so  $OPT = \frac{1}{2m+4}$ . If  $\Phi$  is not satisfiable then  $k \leq m-1$  so  $OPT \geq \frac{2}{2m+4}$ . Now assume that there is such an algorithm  $\mathcal{A}$  and denote  $REV(\mathcal{A})$  the revenue generated by the mechanism output by  $\mathcal{A}$ . If  $\Phi$  is not satisfiable, since  $OPT \geq \frac{2}{2m+4}$ , it must be that  $REV(\mathcal{A}) > \frac{1}{2m+4}$ . On the other hand, if  $\Phi$  is not satisfiable we have that  $REV(\mathcal{A}) \leq \frac{1}{2m+4}$ . Hence, the existence of  $\mathcal{A}$  allows us to distinguish between satisfiable and unsatisfiable SAT formulas. ◀

<sup>6</sup> The fully informative experiment simply sends out a signal to reveal the state.

► **Remark 13.** Since  $m$  is linear in the description length of the problem, given access to a BR oracle, for any  $\varepsilon > 0$  we can set  $\varepsilon' = c(m\varepsilon)^2$ , for some appropriate constant  $c > 0$ , and then apply Theorem 9. Since  $|\Omega| = 2$  and  $|\Theta| = 1$ , the revenue we get is at least  $\text{OPT} - \varepsilon$  and the running time is  $O\left(\frac{1}{(m\varepsilon)^{10}}\right)$ . However, this does not contradict with the result of Theorem 12, since in this setting the BR oracle solves an NP-hard problem.

## 4 Multi-Agent Setting

In this section, we consider a multi-agent generalization of the model by Bergemann et al. [4]. More specifically, we assume that there are  $n$  buyers who are interested in acquiring extra information from the seller and each buyer's ex-post utility only depends on the state of the world and his own action. We further assume that the types of the buyers are drawn independently from their own type distributions. If there is no competition among them, the solution to the problem follows immediately from the single-agent setting, since the seller can offer each agent his optimal menu separately. Thus, we focus on a more interesting case where the buyers are competitors and only *one* of them can receive an informative signal.

### Input Model and New Notation

We first need to introduce some new notation. We use  $\Theta^i$  to denote the type space of buyer  $i$  and  $F^i(\theta^i)$  to denote the probability that buyer  $i$ 's type is  $\theta^i$ . We use  $\Theta$  to denote the set of all type profiles and  $F(\theta)$  to denote  $\times_{i \in [n]} F^i(\theta^i)$ . We assume the action space  $A$  is the same for each buyer  $i$ , but the ex-post utility  $u_{\omega,a}^i$  for choosing action  $a$  under state  $\omega$  may be different for different buyers. We consider the *explicit model*, that is, for each buyer  $i$ , both  $F^i$  and the ex-post utility matrix  $U^i = \{u_{\omega,a}^i\}_{\omega \in \Omega, a \in A}$  are given as input. We use  $u^i(\theta^i)$  to denote the base utility of buyer  $i$  for choosing the best action under distribution  $\theta^i$ .

### Interaction between the Seller and Buyers

The interaction happens in the following order:

1. The seller commits to a mechanism  $\{(\Pi(\theta) = (\Pi^1(\theta), \dots, \Pi^n(\theta))), \{t(\theta) = (t^1(\theta), \dots, t^n(\theta))\}\}_{\theta \in \Theta}$ , and announces the mechanism to all buyers.
2. The types of the buyers  $\theta = (\theta^1, \dots, \theta^n)$  are realized.
3. Each buyer  $i$  **privately** submits his type  $\theta^i$  to the seller.
4. The seller chooses buyer  $i$  as the winner with probability  $p^i(\theta)$ .
5. The seller observes the state of the world  $\omega$  and sends buyer  $i$  a signal  $s$  according to the signaling scheme  $\Pi^i(\theta)$  and charges buyer  $i$  price  $t^i(\theta)$ .
6. Each buyer  $i$  chooses an action  $a^i$  and receives ex-post utility  $u_{\omega,a^i}^i$ .

There are some subtle issues in our model that require further clarification. The most important of them being the following. After the winner has been chosen, does he observe the signaling scheme  $\Pi^i(\theta)$  that the seller uses to generate the signal  $s$ ? In this work, we consider the setting where the signaling scheme  $\Pi^i(\theta)$  is **not revealed** and the winner only observes the realized signal.<sup>7</sup> Some remarks are in order. Firstly, the seller may want to

<sup>7</sup> One may worry that the winner can obtain extra information from the price  $t^i(\theta)$ . To avoid this, we will design a mechanism so that the price for buyer  $i$  only depends on  $i$ 's type  $\theta^i$ . This is without loss of generality, as we can simply set the price to be  $\mathbb{E}_{\theta^{-i}}[t^i(\theta)]$ .

preserve the privacy of the buyers, and revealing  $\Pi^i(\theta)$  allows the winner  $i$  to infer the other buyers' priors. Secondly, hiding the implemented signaling scheme  $\Pi^i(\theta)$  from the winner allows the seller to design a mechanism with less stringent IC constraints and thus generates higher revenue for the seller. This is because the winner does not know the exact experiment he is getting, if he wants to deviate from the recommendation he must map the same signal to the same action for all potential experiments that he may win. Therefore, he would map the signal to an action that induces the highest *expected utility*, where the expectation is over the other bidders' types and the chosen experiment. On the other hand, if the buyer knew which experiment the signal is drawn from, he could use a mapping that is the best for each particular experiment.

Our goal in this section is to design a polynomial time algorithm to find the Bayesian Incentive Compatible (BIC) and Interim Individually Rational (IIR) mechanism that achieves the highest revenue among all BIC and IIR mechanisms for our model. It is not hard to see that Lemma 2 generalizes to our multi-agent setting. We begin by introducing an extension of the LP in Figure 1 to the multi-agent setting. Define  $\Pi^i(\theta) = (\pi_{\omega,j}^i(\theta))_{\omega \in \Omega, j \in [m]}$ ,  $p^i(\theta)$ , and  $t^i(\theta)$  as the decision variables for every buyer  $i$  and type profile  $\theta$ . Recall that  $m = |A|$ .

$$\begin{aligned}
& \max \quad \sum_{\theta \in \Theta} F(\theta) \sum_{i \in [n]} t^i(\theta) \\
& \text{s.t.} \quad \sum_{\theta^{-i}} F^{-i}(\theta^{-i}) \left( \sum_{\substack{\omega \in \Omega, \\ j \in [m]}} \theta_{\omega}^i \pi_{\omega,j}^i(\theta^i, \theta^{-i}) u_{\omega,a_j}^i + (1 - p^i(\theta)) u^i(\theta^i) - t^i(\theta^i, \theta^{-i}) \right) \geq \\
& \quad \sum_{\theta^{-i}} F^{-i}(\theta^{-i}) \left( \sum_{j \in [m]} z_j^i(\theta^i, \tilde{\theta}^i, \theta^{-i}) + (1 - p^i(\tilde{\theta}^i, \theta^{-i})) u^i(\theta^i) - t^i(\tilde{\theta}^i, \theta^{-i}) \right), \quad \forall i, \forall \theta^i, \tilde{\theta}^i \text{ (BIC)} \\
& \quad \sum_{\theta^{-i}} F^{-i}(\theta^{-i}) z_j^i(\theta^i, \tilde{\theta}^i, \theta^{-i}) \geq \sum_{\theta^{-i}} F^{-i}(\theta^{-i}) \sum_{\omega} \theta_{\omega}^i \pi_{\omega,j}^i(\tilde{\theta}^i, \theta^{-i}) u_{\omega,a_k}, \quad \forall i, \forall j, k, \forall \theta^i, \tilde{\theta}^i \\
& \quad \sum_{\theta^{-i}} F^{-i}(\theta^{-i}) \left( \sum_{\substack{\omega \in \Omega, \\ j \in [m]}} \theta_{\omega}^i \pi_{\omega,j}^i(\theta) u_{\omega,a_j}^i + (1 - p^i(\theta)) u^i(\theta^i) - t^i(\theta) \right) \geq u^i(\theta^i), \quad \forall i, \theta^i \text{ (IIR)} \\
& \quad \sum_{j \in [m]} \pi_{\omega,j}^i(\theta) = p^i(\theta), \quad \forall i, \forall \theta, \forall \omega \text{ (feasibility)} \\
& \quad \sum_{i \in [n]} p^i(\theta) \leq 1, \quad \forall \theta \text{ (feasibility)} \\
& \quad \pi_{\omega,j}^i(\theta) \geq 0, \quad \forall i, \forall \theta, \forall \omega, \forall j \text{ (feasibility)}
\end{aligned}$$

Observe that the number of variables is exponential in  $n$  and the number of constraints is exponential in both  $n$  and  $m$ . There is no hope to solve this LP in polynomial time. The main challenge is how to remove the exponential dependence on  $n$ . To overcome this obstacle, we use a method that is powerful in the study of multi-item auctions, that is, rewriting the LP using a more succinct representation of the mechanism known as the reduced form [5, 1, 6, 7, 8]. We first define the reduced form of a mechanism.

► **Definition 14 (Reduced Form).** *Given a mechanism  $\mathcal{M} = (\{\Pi(\theta)\}_{\theta \in \Theta}, \{t(\theta)\}_{\theta \in \Theta})$ , we define its reduced form  $\{\hat{\Pi}^i(\theta^i)\}_{i \in [n], \theta^i \in \Theta^i}$ , where  $\hat{\Pi}^i(\theta^i) = \{\hat{\pi}_{\omega,j}^i(\theta^i)\}_{\omega \in \Omega, j \in [m]}$  and  $\hat{\pi}_{\omega,j}^i(\theta^i) = \mathbb{E}_{\theta^{-i}}[\pi_{\omega,j}^i(\theta)]$  for each state  $\omega$  and  $j \in [m]$ , and its interim prices  $\{\hat{t}^i(\theta^i)\}_{i \in [n], \theta^i \in \Theta^i}$ , where  $\hat{t}^i(\theta^i) = \mathbb{E}_{\theta^{-i}}[t^i(\theta)]$ . We use  $\mathcal{P}(F)$  to denote the set of all reduced forms for a particular type distribution  $F$ .*

It is not hard to see that  $\mathcal{P}(F)$  is a closed convex set, as the set of all mechanisms is clearly closed and convex, and  $\mathcal{P}(F)$  is simply a linear transformation of that set. Intuitively, the reduced form is the “expected experiment and price” that the each buyer believes he will be allocated when his type is realized, and the expectation is taken over the randomness of the other buyers’ types.

► **Lemma 15.** *For any type distribution  $F$ ,  $\mathcal{P}(F)$  is a closed convex set.*

The LP in Figure 3 searches for the reduced form of the revenue-optimal mechanism. Notice that the size of the reduced-form LP is substantially smaller than the original one, and the number of variables is polynomial in the number of agents. With these new variables we can still express the BIC and IIR constraints of the initial LP. However, it is not yet clear how to check whether these variables correspond to an actual feasible mechanism. In the next section, we show how to design a separation oracle that checks the feasibility efficiently.

#### Variables:

- $\{\hat{\pi}_{\omega,j}^i(\theta^i)\}_{\omega \in \Omega, i \in [n], \theta^i \in \Theta^i, j \in [m]}$ , denoting the reduced form of the mechanism.
- $\{\hat{t}^i(\theta^i)\}_{i \in [n], \theta^i \in \Theta^i}$ , denoting the interim prices.
- $\{\hat{p}^i(\theta^i)\}_{i \in [n], \theta^i \in \Theta^i}$ , denoting the allocation probabilities of the experiment
- $\{\hat{z}_j^i(\theta^i, \tilde{\theta}^i)\}_{i \in [n], j \in [m], \theta^i, \tilde{\theta}^i \in \Theta^i}$ , helper variables.  $\hat{z}_j^i(\theta^i, \tilde{\theta}^i)$  represents an upper bound of the conditional expected utility of signal  $s_j$  for type  $\theta^i$ .

#### Linear Program:

$$\begin{aligned}
 \max \quad & \sum_{i \in [n]} \sum_{\theta^i \in \Theta^i} F^i(\theta^i) \hat{t}^i(\theta^i) \\
 \text{subject to} \quad & \sum_{j \in [m]} \sum_{\omega \in \Omega} \theta_{\omega}^i \hat{\pi}_{\omega,j}^i(\theta^i) u_{\omega,a_j}^i + (1 - \hat{p}^i(\theta^i)) u^i(\theta^i) - \hat{t}^i(\theta^i) \geq \\
 & \sum_{j \in [m]} \hat{z}_j^i(\theta^i, \tilde{\theta}^i) + (1 - \hat{p}^i(\tilde{\theta}^i)) u^i(\theta^i) - \hat{t}^i(\tilde{\theta}^i), \quad \forall i, \forall \theta^i, \tilde{\theta}^i \quad (\text{BIC}) \\
 & \hat{z}_j^i(\theta^i, \tilde{\theta}^i) \geq \sum_{\omega \in \Omega} \theta_{\omega}^i \hat{\pi}_{\omega,j}^i(\tilde{\theta}^i) u_{\omega,a_k}^i \quad \forall i, \forall \theta^i, \tilde{\theta}^i, \forall j, k \\
 & \sum_{j \in [m]} \sum_{\omega \in \Omega} \theta_{\omega}^i \hat{\pi}_{\omega,j}^i(\theta^i) u_{\omega,a_j}^i + (1 - \hat{p}^i(\theta^i)) u^i(\theta^i) - \hat{t}^i(\theta^i) \geq u^i(\theta^i), \quad \forall i, \forall \theta^i \quad (\text{IIR}) \\
 & \hat{p}^i(\theta^i) = \sum_{j \in [m]} \hat{\pi}_{\omega,j}^i(\theta^i) \quad \forall i, \forall \omega, \forall \theta^i \\
 & \{\hat{\pi}_{\omega,j}^i(\theta^i)\}_{\omega \in \Omega, i \in [n], \theta^i \in \Theta^i, j \in [m]} \in \mathcal{P}(F) \quad (\text{Feasibility})
 \end{aligned}$$

■ **Figure 3** A linear program to find the reduced form of the revenue-optimal mechanism in the multi-agent setting.

## 4.1 Feasibility of Reduced Forms

To design a separation oracle for the set  $\mathcal{P}(F)$ , we invoke the equivalence between Optimization and Separation in Linear Programming [29, 33], which states that being able to optimize any linear function over a convex set  $P$  is equivalent to having a separation oracle for  $P$ . It is a well-known fact that given a separation oracle for  $P$  one can optimize any linear function using the ellipsoid method. Interestingly, the reverse is also true. If there is an algorithm to optimize any linear function over  $P$ , one can construct a separation oracle for  $P$  using the ellipsoid method. We state a strengthened version of the equivalence due to Cai et al. [7].

The reason that we need to be able to decompose a feasible point into corners of the polytope is that we eventually need to be able to implement the reduced forms as a feasible mechanism. We elaborate more on this later.

► **Theorem 16** (Adapted from Theorem H.1 of [7]). *Let  $P$  be a  $d$ -dimensional closed convex region, and let  $\mathcal{A}$  be any polynomial-time algorithm that takes any direction  $w \in \mathbb{R}^d$  as input and outputs the extreme point  $\mathcal{A}(w) \in P$  in direction  $w$  such that  $\mathcal{A}(w) \cdot w \geq \max_{x \in P} x \cdot w$ . Then we can design a polynomial time separation oracle  $SO$  for  $P$  such that, whenever  $SO(x) = \text{“yes”}$ , the execution of  $SO$  explicitly finds directions  $w_1, \dots, w_k$  such that  $x$  lies in the convex hull of  $\{\mathcal{A}(w_1), \dots, \mathcal{A}(w_k)\}$ .*

To apply this equivalence, we need to show how we can optimize a linear function over the set of feasible reduced-form variables. Recall that we use  $\Pi^i(\theta) = (\pi_{\omega,j}^i(\theta))_{\omega \in \Omega, j \in [m]}$  and  $\hat{\Pi}^i(\theta^i) = (\hat{\pi}_{\omega,j}^i(\theta^i))_{\omega \in \Omega, j \in [m]}$  to denote the ex-post signaling scheme and its reduced form. We will treat  $\Pi^i(\theta)$  and  $\hat{\Pi}^i(\theta^i)$  as  $m|\Omega|$ -dimensional vectors. The following maximization problem plays a crucial role in our approach.

► **Definition 17.** *Consider any type profile  $\theta$ . Let  $\{X^i(\theta^i)\}_{i \in [n], \theta^i \in \Theta^i}$  be a collection of  $m|\Omega|$ -dimensional vectors. We define a Virtual Payoff Maximizer (VPM) w.r.t. these weight vectors  $VPM(\{X^i(\theta^i)\}_{i \in [n], \theta^i \in \Theta^i})$  to be the ex-post signaling scheme  $\Pi(\theta)$  that maximizes the following quantity  $\sum_i \Pi^i(\theta^i) \cdot X^i(\theta^i)$  for every type profile  $\theta$ . The corresponding reduced form  $\hat{\Pi}(\theta)$  is called  $rVPM(\{X^i(\theta^i)\}_{i \in [n], \theta^i \in \Theta^i})$ . In order to ensure that the maximizer is unique, we break ties lexicographically.*

When there is no confusion, we also write  $VPM(w), rVPM(w)$  as the maximizers for the weight vector  $w$ .

► **Lemma 18.** *Given an arbitrary collection of weights  $\{X^i(\theta^i)\}_{i \in [n], \theta^i \in \Theta^i}$  we can find the exact optimal solution of*

$$\max_{\hat{\Pi} \in \mathcal{P}(F)} \sum_{i \in [n]} \sum_{\theta^i \in \Theta^i} \hat{\Pi}^i(\theta^i) \cdot X^i(\theta^i) \text{ in time } O\left(m|\Omega| \left(\sum_{i \in [n]} |\Theta^i|\right) + \left(\sum_{i \in [n]} |\Theta^i|\right)^2\right).$$

**Proof of Lemma 18.** We first rewrite the maximization problem

$$\begin{aligned} \max_{\hat{\Pi} \in \mathcal{P}(F)} \sum_{i \in [n]} \sum_{\theta^i \in \Theta^i} \hat{\Pi}^i(\theta^i) \cdot X^i(\theta^i) &= \max_{\Pi} \sum_{i, \theta^i, \theta^{-i}} F^{-i}(\theta^{-i}) \Pi^i(\theta^i, \theta^{-i}) \cdot X^i(\theta^i) = \\ &= \max_{\Pi} \sum_{i, \theta} F(\theta) \Pi^i(\theta) \cdot \frac{X^i(\theta^i)}{F^i(\theta^i)} = \max_{\Pi} \sum_{\theta} F(\theta) \sum_i \Pi^i(\theta) \cdot \tilde{X}^i(\theta^i), \end{aligned}$$

where  $\tilde{X}^i(\theta^i) = \frac{X^i(\theta^i)}{F^i(\theta^i)}$ .

Let  $\theta$  be a type profile. We now characterize the solution of  $\max_{\Pi(\theta)} \sum_i \Pi^i(\theta) \cdot \tilde{X}^i(\theta^i)$ . If we allocate the experiment to buyer  $i$ , the maximum value we can derive is  $v^i(\theta^i) = \sum_{\omega} \max_a \tilde{X}_{\omega,a}^i(\theta^i)$ . Clearly, the optimal solution of the linear function above is to always allocate the experiment to the buyer with the largest  $v^i(\theta^i)$ .

The ex-post signaling scheme that maximizes  $\sum_{\theta} F(\theta) \sum_i \Pi^i(\theta) \cdot \tilde{X}^i(\theta^i)$  is the one that always allocates the experiment to the buyer with the largest  $v^i(\theta^i)$  for every type profile  $\theta$ . To solve  $\max_{\hat{\Pi} \in \mathcal{P}(F)} \sum_{i \in [n]} \sum_{\theta^i \in \Theta^i} \hat{\Pi}^i(\theta^i) \cdot X^i(\theta^i)$ , we only need to calculate the reduced form of this ex-post signaling scheme and we denote it using  $\hat{\Pi}_*$ .

We first compute  $v^i(\theta^i) = \sum_{\omega} \max_a x_{\omega,a}^i(\theta^i)$  for every buyer  $i$  and every type  $\theta^i$ . This step takes time  $O\left(m|\Omega| \left(\sum_{i \in [n]} |\Theta^i|\right)\right)$ , and there are  $\sum_{i \in [n]} |\Theta^i|$  different such values. Next, for each buyer, we sort  $v^i(\theta^i)$ . This step takes time  $O\left(\sum_{i \in [n]} |\Theta^i| \log |\Theta^i|\right)$ . To compute  $\hat{\Pi}_*^i(\theta^i)$ , we only need to calculate the probability of the event that over the random draws of  $\theta_{-i}$ , there exists another buyer  $\ell \neq i$  either  $v_{\ell}(\theta^{\ell}) > v^i(\theta^i)$  or  $\ell < i$  and  $v_{\ell}(\theta^{\ell}) = v^i(\theta^i)$ . This probability can be computed in time  $O\left(\sum_{i \in [n]} |\Theta^i|\right)$  for each buyer  $i$  and type  $\theta^i$ . Hence, in total we can optimize the linear function in time  $O\left(m|\Omega| \left(\sum_{i \in [n]} |\Theta^i|\right) + \left(\sum_{i \in [n]} |\Theta^i|\right)^2\right)$ . ◀

Combining Theorem 16 and Lemma 18, we have a polynomial time algorithm to solve the LP in Figure 3, but we still need to turn the reduced form into an ex-post signaling scheme. We again use an idea from computing the optimal multi-item auctions, that is, first decomposing the optimal reduced form into a distribution over extreme points of  $\mathcal{P}(F)$ , then implementing all the extreme points that appear in the distribution using a VPM ex-post signaling scheme.

► **Theorem 19.** *We design an algorithm to compute the revenue-optimal mechanism in time  $\text{poly}\left(n, m, |\Omega|, \sum_{i \in [n]} |\Theta^i|\right)$ . Moreover, the mechanism can be implemented as a distribution over  $m|\Omega| \left(\sum_{i \in [n]} |\Theta^i|\right) + 1$  VPM ex-post signaling schemes.*

## 5 Further Extensions and Future Directions

In this section, we discuss further generalizations of the model by Bergemann et al. [4] and future research directions that we believe are interesting to pursue.

### 5.1 Extensions of the Original Model

#### Enlarged Buyer Type

Recall that in the original model the only private information of the buyer is his private belief of the underlying state, which is realized at the beginning of the interaction with the seller. Importantly, the payoffs are public knowledge and remain the same across different buyers. A natural generalization one can consider is to allow the buyer to draw not only his prior belief  $\theta$ , but also his payoff function  $u : \Omega \times A \rightarrow [0, 1]$  from some distribution.

To be more specific, we consider the setting where a buyer's type  $\rho = (\theta, u)$  is drawn from some distribution  $F$  at the beginning of the interaction between the buyer and the seller, and  $\rho$  is private to the buyer. As in the original model, we assume that the seller has access to this distribution. We remark that all of our positive results from Section 3 and Section 4, except for Theorem 11, hold in this extended model as well. The only difference in our constructions is that instead of indexing the variables by  $\theta$  we now index them by  $\rho$ .

#### Misspecified Model

Another generalization we consider in the single-agent setting is the *misspecified* model. In this model the seller has access to some type distribution  $\tilde{F}$  which is within  $\varepsilon$  in TV-distance with the real type distribution  $F$ . Moreover, the seller has access to a type space  $\tilde{\Theta}$  with the following two properties:  $|\tilde{\Theta}| = |\Theta|$ , for all  $\tilde{\theta} \in \tilde{\Theta}$  there is some  $\theta \in \Theta$  for which  $d_{TV}(\tilde{\theta}, \theta) \leq \varepsilon$ . Then, the menu that the seller designs for the misspecified distributions can be modified so that it guarantees only a negligible revenue loss when it is evaluated in the true setting. Lemma 20 formalizes this claim.

► **Lemma 20.** *Let  $\tilde{F}, F$  be the distributions of the types that the seller has access to and the true distribution of the types, respectively. Let also  $\{\tilde{\theta}_i\}_{i \in [k]}, \{\theta_i\}_{i \in [k]}$  be the types that the seller has access to and the true types, respectively. Assume that  $d_{TV}(\tilde{F}, F) \leq \varepsilon_1, d_{TV}(\tilde{\theta}_i, \theta_i) \leq \varepsilon_2, \forall i \in [k]$ . We also let  $\tilde{\mathcal{M}} = \{\tilde{E}(\tilde{\theta}_i), \tilde{t}(\tilde{\theta}_i)\}_{i \in [k]}$  be an IC, IR menu that has revenue  $REV(\tilde{\mathcal{M}})$  under the misspecified distributions and uses at most  $|S|$  signals. Then, we can compute a set of prices  $\{t(\tilde{\theta}_i)\}_{i \in [k]}$  so that  $\mathcal{M} = \{\tilde{E}(\theta_i), t(\theta_i)\}_{i \in [k]}$  is IR, IC and has  $REV(\mathcal{M}) \geq REV(\tilde{\mathcal{M}}) - O\left(\varepsilon_1 + \sqrt{|\Omega|\varepsilon_2}\right)$  under the true distributions.*

Note that Lemma 20 allows us to generalize our results and obtain approximately-optimal menus when we only have black-box access to the distribution of the types. That is, we take enough samples to learn the distribution within Total Variation distance  $\varepsilon$  and then apply Lemma 20.

## 5.2 Future Directions

We believe that the design of Information Markets is a very important problem that has not received sufficient attention by the Theory of Computation community. There are many interesting questions waiting to be addressed.

1. In the single-buyer setting where we only have access to the action space via a BR oracle the running time of our algorithms is exponential in the number of states. An immediate question to ask is whether we can get an FPTAS or even a PTAS that has a better dependence on the number of states.
2. In the multi-agent setting, we consider the case in which the seller does not reveal the signaling scheme that she uses to send a signal to the winner. An interesting question is whether we can have efficient algorithms in the setting where the seller reveals the signaling scheme to the buyer.
3. Currently, in the multi-agent setting we assume that the ex-post utility of each buyer depends only on the state of the world and the action he takes. Is the problem of designing the optimal mechanism when the ex-post utilities also depend on the actions of the other buyers tractable?

## Abstract

We study the  $n$ -party *noisy broadcast channel* with a constant fraction of *malicious parties*. Specifically, we assume that each non-malicious party holds an input bit, and communicates with the others in order to learn the input bits of all non-malicious parties. In each communication round, one of the parties broadcasts a bit to all other parties, and the bit received by each party is flipped with a fixed constant probability (independently for each recipient). How many rounds are needed?

Assuming there are no malicious parties, Gallager gave an  $\mathcal{O}(n \log \log n)$ -round protocol for the above problem, which was later shown to be optimal. This protocol, however, inherently breaks down in the presence of malicious parties.

We present a novel  $n \cdot \tilde{\mathcal{O}}(\sqrt{\log n})$ -round protocol, that solves this problem even when almost half of the parties are malicious. Our protocol uses a new type of error correcting code, which we call a *locality sensitive code* and which may be of independent interest. Roughly speaking, these codes map “close” messages to “close” codewords, while messages that are not close are mapped to codewords that are very far apart.

We view our result as a first step towards a theory of *property preserving interactive coding*, i.e., interactive codes that preserve useful properties of the protocol being encoded. In our case, the naive protocol over the noiseless broadcast channel, where all the parties broadcast their input bit and output all the bits received, works even in the presence of malicious parties. Our simulation of this protocol, unlike Gallager’s, preserves this property of the original protocol.

## 1 Introduction

The field of *interactive coding*, pioneered by Schulman [16, 17, 18], asks the following question:

*Let  $\Pi$  be a communication protocol designed to work over a noiseless channel. Can  $\Pi$  be converted to a noise resilient protocol  $\Pi'$  with similar communication complexity?*

Many works, mainly over the last decade, give affirmative answers to this question for the two-party channel, as well as various multi-party distributed channels. For example, it was shown that protocols in the extensively studied message passing model (peer-to-peer channels) and in the shared blackboard model (broadcast channel), can be *simulated* by protocols that tolerate stochastic noise, i.e., noise that flips each of the communicated bits with constant probability [15, 1, 4, 7, 12, 6, 13, 5]. These only incur a small (sub-logarithmic and in many cases, even constant) multiplicative overhead to the communication. Here, by “simulate” we mean that the new protocols retain the same input-output behavior as the original protocols<sup>1</sup>.

**Property preserving interactive coding.** While the simulation protocols  $\Pi'$ , designed by the aforementioned interactive coding works, are communication efficient and preserve the input-output behavior of the original protocols  $\Pi$ , they often lose the “structure” of the original protocols together with some of the basic properties making the original protocols useful. For instance, the importance of celebrated distributed protocols for the *consensus* and the *leader election* problems stems from their fault tolerance properties – the fact that they keep the same input-output behavior, even in the presence of *malicious parties* that may exhibit crashes or even Byzantine failures<sup>2</sup>.

We study the above interactive coding question in a different light: Assume that the original communication protocol  $\Pi$  satisfies a special property  $P$ , can  $\Pi$  be converted to a noise resilient protocol  $\Pi'$  that still satisfies  $P$ ? Specifically, we focus on protocols with the property  $P = “\Pi$  is resilient to a constant fraction of malicious parties”, and give a simulation protocol  $\Pi'$  over a noisy channel that also satisfies  $P$ .

**The noisy broadcast channel.** In this paper, we consider this new “property preserving” interactive coding question in the *noisy broadcast model*, a noisy version of the shared blackboard model, first suggested by El Gamal in 1984 [8]. In this model, a set of  $n$  parties, each holding a private input, communicate over a noisy broadcast channel. In each round, one of the parties broadcasts a bit to all the other parties, and the bit received by each of the other parties is flipped with some constant probability  $\epsilon > 0$  (independently for each recipient).

We revisit the basic problem suggested by El Gamal, regarding the computation of the *identity function* over the noisy broadcast channel: assume that each party receives a single bit as an input and that the parties’ mutual goal is for all parties to learn all input bits. That is, party  $i$  gets a bit  $x^i \in \{0, 1\}$  and needs to output  $f(x^1, x^2, \dots, x^n) = (x^1, x^2, \dots, x^n)$ . How many communication rounds are needed? Observe that, over the noiseless broadcast

<sup>1</sup> The parties participating in the distributed protocol are assumed to each have an input at the beginning of the protocol and give an output when the protocol terminates. We often think of the entire transcript received by a party as its output.

<sup>2</sup> Recall, for example, that in the consensus problem, each party gets an input bit and all parties need to output the input bit of one of the parties (and, in particular, all parties need to output the same bit). Indeed, there are short trivial protocols with the required input-output behavior, but these are not resilient to malicious parties.

channel, this can be done in  $n$  rounds by simply having each party broadcast its bit. In 1988, Gallager [7] showed that  $\mathcal{O}(n \log \log n)$  broadcast rounds suffice to solve the problem over the noisy broadcast channel, with polynomially small error probability. Note that this also means that any function on  $n$  input bits can be computed over the noisy broadcast channel in  $\mathcal{O}(n \log \log n)$  rounds<sup>3</sup>, making the identity function “complete” for the computation of such functions. Gallager’s result was shown to be tight in the beautiful 2005 paper by Goyal, Kindler, and Saks [10].

**The noisy broadcast channel with malicious parties.** We consider El Gamal’s question in the presence of malicious parties. Specifically, assume that a constant fraction of the parties participating in the protocol are malicious. These parties are controlled by a know-it-all adversary that sees all inputs, as well as all the sent and received bits. The rest of the parties are assumed to be honest and following the protocol, and they may not know the identity of the malicious parties.

Due to the presence of malicious parties, it is unrealistic to expect all parties to compute the identity function (neither over the noiseless broadcast channel, nor over the noisy broadcast channel) for two reasons: (i) the malicious parties will deliberately give incorrect outputs; (ii) a malicious party with an input  $x^i$  can behave as if it is holding the input  $1 - x^i$ , preventing the honest parties from learning its input. Therefore, we relax our requirement and only ask that each *honest* party outputs the input bits of all other *honest* parties. Specifically, we want that for every input  $x$ , the following condition is satisfied with high probability:

(\*) *Each party  $i$  outputs  $(\tilde{x}_1^i, \tilde{x}_2^i, \dots, \tilde{x}_n^i)$ , where if both  $i$  and  $i'$  are honest, then  $\tilde{x}_{i'}^i = x^{i'}$  (otherwise,  $\tilde{x}_{i'}^i$  can be arbitrary).*

Over the noiseless broadcast channel, it is easy to see that the simple aforementioned  $n$ -round protocol, where each party broadcasts its bit once and outputs all the bits it received, satisfies this relaxed condition. How many rounds of communication are needed when we work over the noisy broadcast channel?

## 1.1 Our Results

The main result of this paper is a novel  $n \cdot \tilde{\mathcal{O}}(\sqrt{\log n})$ -round protocol for computing the identity function under the relaxed condition (\*), in the presence of a constant fraction of malicious parties and stochastic noise. While more costly than Gallager’s protocol, which utterly breaks down in the presence of even a single malicious party (see discussion in Subsection 2.3), our protocol does beat the naive  $\mathcal{O}(n \log n)$  protocol<sup>4</sup>.

We note that our protocol assumes the *statistical* variant of the noisy broadcast channel (see, e.g., [12, 13]), where the noise flips every sent bit with probability exactly  $\epsilon$ . Generalizing the protocol for the *fault tolerant* noisy broadcast channel where the noise can flip the  $j^{\text{th}}$  bit received by the  $i^{\text{th}}$  party with a different probability for different  $i$ s and  $j$ s, as long as these probabilities are all between 0 and  $\epsilon$ , is left open (see more about this in Subsection 2.6).

<sup>3</sup> To compute the function  $g(x^1, x^2, \dots, x^n)$ , the parties run the protocol that computes the identity function. After the protocol, each party knows  $x^1, x^2, \dots, x^n$  and can evaluate  $g(\cdot)$  by itself.

<sup>4</sup> In the naive protocol, each party broadcasts its bit  $\Theta(\log n)$  times. Party  $i$  outputs  $(\tilde{x}_1^i, \tilde{x}_2^i, \dots, \tilde{x}_n^i)$ , where  $\tilde{x}_{i'}^i$  is the majority of the bits party  $i$  received from party  $i'$ . If both parties  $i$  and  $i'$  are honest, the bit  $\tilde{x}_{i'}^i$  is the input of party  $i'$ , except with polynomially small probability, and by a union bound, our relaxed property holds, except with polynomially small probability.

► **Theorem 1.** *Let  $\epsilon, \theta < 1/2$  and  $n$  be large enough. There exists an  $n \cdot \tilde{O}(\sqrt{\log n})$ -round randomized protocol with private and public randomness<sup>5</sup> over the noisy broadcast channel with noise rate exactly  $\epsilon$ , that computes the identity function in the presence of a  $\theta$ -fraction of malicious parties (i.e., satisfies condition  $(*)$ ) with error  $1/n$ . Furthermore, the protocol is computationally efficient – the algorithm for each party runs in almost-linear, i.e.,  $n^{1+o(1)}$ , time.*

As discussed above, due to the “completeness” of the identity function, our result also implies that *any*  $n$ -bit function (each party gets a single input bit) can be computed over the noisy broadcast channel in the presence of a constant fraction of malicious parties in  $n \cdot \tilde{O}(\sqrt{\log n})$  rounds.

## 1.2 Our Techniques and the Notion of Locality Sensitive Codes

The starting point of our construction is Gallager’s protocol. At the heart of this protocol is a clever trick that uses (standard) error correcting codes. While Gallager’s trick inherently breaks in the presence of malicious parties, we draw inspiration from his ideas and design a different protocol using a new type of codes that we call *locality sensitive codes*.

Roughly speaking, our locality sensitive codes map “close” messages to “close” codewords, while messages that are not close are mapped to codewords that are very far apart. In more detail, our alphabet set is the set of integers. Two messages  $m, m' \in \mathbb{Z}^k$  that are close in every coordinate ( $|m_i - m'_i| \leq \alpha$  for every  $i \in [k]$ ) will be mapped to codewords that are close in almost every coordinate, but two messages that are far apart in at least one coordinate are mapped to codewords that are far in almost all coordinates. Note that locality sensitive codes are a generalization of classical error correcting codes. Indeed, by setting  $\alpha = 0$  we can interpret “closeness” as “equality” (two messages are close only if they are identical) and retrieve the definition of standard error correcting codes – identical messages are mapped to identical codewords and non-identical messages are mapped to codewords with a large distance.

We mention that the definition of locality sensitive codes is reminiscent of that of *locality sensitive hash functions*, often used by algorithms for the *approximate nearest neighbor* problem and other related problems (see, e.g., [2, 3]). However, while locality sensitive hash functions are hash functions, and as such, are contracting the message, locality sensitive codes stretch the message. Since the problem studied in this paper is, at least seemingly, very different from other known applications of locality sensitive hash functions, devising further connections between locality sensitive codes and locality sensitive hashes will be interesting.

## 1.3 Future Directions

Our work suggests several future directions, we list a few below.

**Improving our result.** One obvious interesting question is whether our result in Theorem 1 is optimal in terms of communication complexity, or whether it can be improved. In particular, is it possible to match Gallager’s construction and design an  $\mathcal{O}(n \log \log n)$  protocol for the

---

<sup>5</sup> Observe that private and public randomness are “incomparable” in our model: the public random string is known to all parties, including the malicious parties. The private random strings are each known to a single party, and, in particular, the private random string of an honest party is not known to any of the malicious parties (see Subsection 3.3).

identity function that handles stochastic noise and also works in the presence of a constant fraction of malicious parties<sup>6</sup>? One direction towards this goal is to improve the construction of locality sensitive error correcting codes.

**Interactive codes preserving other properties.** In this paper, we consider the property  $P = \text{“}\Pi \text{ is resilient to a constant fraction of malicious parties”}$  and show that in certain cases, protocols  $\Pi$  that satisfy  $P$  can be compiled into noise resilient protocols that still respect  $P$ . Can this be done for other useful properties  $P$ ? We mention that work of [9] can be interpreted as asking a similar question with  $P = \text{“}\Pi \text{ is computing some function } f \text{ privately”}$  (and with adversarial noise), and answering it in the negative.

**General interactive coding with malicious parties.** As mentioned in Subsection 1.1, Theorem 1 implies a similar simulation for any  $n$ -bit function. Thus, one could have hoped that our simulation would also extend to functions with more than  $n$  input bits (i.e., the case where parties get long inputs), allowing us to convert any  $t$ -round noiseless protocol with malicious parties to a  $t \cdot \tilde{O}(\sqrt{\log n})$ -round protocol over the noisy broadcast channel with malicious parties. However, even without the presence of malicious parties, we suspect that the overhead in making a broadcast protocol noise resilient can be a multiplicative factor of  $\tilde{\Omega}(\log n)$  (and, in particular, a multiplicative  $\mathcal{O}(\log \log n)$  overhead à la Gallager does not always suffice).

**Interactive coding with malicious parties over different models.** While we believe that there is no scheme with a small overhead that converts protocols in the noiseless broadcast channel that are resilient to malicious parties to protocols in the noisy broadcast channel that are resilient to malicious parties, such a scheme may exist for other channels, such as the (synchronous or asynchronous) peer-to-peer model. If it does, this scheme would imply noise resilient consensus and leader election protocols in the respective models. We mention that noise resilient consensus is considered in [11], under a different noise model.

**Better than optimal interactive coding with adversarial noise.** Another interesting direction is further exploring the relaxed requirement (\*). In this paper, we design a protocol for the identity function that satisfies (\*) even in the presence of a constant fraction of malicious parties and stochastic noise. Does such a protocol exist in the presence of a more general type of noise – say, if we allow the adversary to corrupt a different set of parties in each round or if we allow general adversarial noise, where the adversary can corrupt a constant fraction of the received bits? While prior works argue that in multi-party settings it is impossible to handle more than a  $1/n$  fraction of adversarial noise, as with this budget, the adversary can corrupt one of the parties completely, this may be possible under a relaxed definition along the lines of (\*).

## 2 Overview of Our Protocol

In this section, we build up to our protocol step by step, covering our main ideas.

### 2.1 The Identity Problem Over the Broadcast Channel

In the broadcast channel, there are  $n$  parties that communicate with one another. This communication happens through bit “broadcasts”, namely, bits sent from one of the  $n$  parties to *all* the parties. The party sending these bits computes them using the bits it

<sup>6</sup> Goyal et al. [10], proved their lower bounds for the statistical model assumed in this paper, where each received bit is flipped with probability exactly  $\epsilon$ . Therefore, our result cannot be improved to an  $o(n \log \log n)$ -round protocol.

received during the communication that happened so far and its own private input. The end-goal of this communication is to compute a joint function of all the private inputs while communicating as few bits as possible.

An important setting (indeed, complete in certain respects) is when all the  $n$  parties have a bit as their input, and they want to know the inputs of all the other parties. Formally, party  $i \in [n]$  has a bit  $x^i$  and should output the bit string  $x^1, x^2, \dots, x^n$  after the communication. We shall call this problem the identity problem in the rest of this document.

The identity problem admits a simple and optimal  $n$  round communication protocol over the broadcast channel: In round  $i \in [n]$ , party  $i$  broadcasts their bit  $x^i$  to all the parties. After  $n$  rounds, all the parties would have received all the bits and can output the string  $x^1, x^2, \dots, x^n$ .

This simple protocol boasts of some nice and non-trivial properties. For example, even if an (arbitrarily large) subset of parties do not follow the protocol and are malicious, we still have the guarantee that all non-malicious parties will output the bit of all other non-malicious parties correctly. This property makes sure that, when this protocol is run on a large distributed system, it will be resilient to a subset of the parties failing or being taken over by an adversary. Moreover, the protocol described is also communicationally and computationally efficient.

However, this protocol also has a major weakness in that it crucially relies on the fact that the channel does not corrupt any of the bits sent, which are received exactly by all the parties. Is it possible to have a protocol that is resilient to both malicious parties and channel corruptions?

## 2.2 The Noisy Broadcast Channel and Gallager's Protocol

To study the above question, one needs to move to the noisy broadcast channel. This channel is identical to the broadcast channel except that it has stochastic noise, namely, there is a parameter  $0 < \epsilon < \frac{1}{2}$  such that when any of the parties broadcasts a bit  $b$  over the channel, all the parties may either receive  $b$ , with (independent) probability  $1 - \epsilon$ , or may receive the bit  $1 - b$ , with probability  $\epsilon$ .

The protocol for the identity problem described above can even be simulated over the noisy broadcast channel, albeit with higher communication. For example, one may repeat each bit broadcast during the protocol  $\mathcal{O}(\log n)$  times, and this will ensure that all the parties receive the bit sent except with probability polynomially small in  $n$ . A simple union bound over all the  $n$  parties and all the  $n$  bits shows that the protocol does solve the identity problem except with probability polynomially small in  $n$ .

In fact, not only does this protocol solve the identity problem in a way that is resilient to channel corruptions, it also preserves the property of the original protocol of being resilient to malicious parties. Indeed, even if an arbitrarily large subset of parties in the protocol are malicious, all the non-malicious parties will output the bits of all the malicious parties with high probability.

### 2.2.1 Gallager's Protocol [7]

The main drawback of this protocol is that it communicates  $\mathcal{O}(n \log n)$  bits and it is not immediately clear if this is optimal in terms of communication. In fact, without the restriction of being resilient to malicious parties, Gallager, in his elegant work [7], showed that it is provably not so, exhibiting a protocol that communicates  $\mathcal{O}(n \log \log n)$  bits and is resilient to channel corruptions<sup>7</sup>.

<sup>7</sup> [10] later showed that Gallager's protocol is optimal up to constant factors.

The main idea behind Gallager’s improved protocol can be easily understood from an information theoretic viewpoint. Consider the  $\mathcal{O}(\log n)$  rounds where a given party broadcasts in the simple  $\mathcal{O}(n \log n)$  communication protocol. In the first few rounds when this party broadcasts, each bit broadcast gives a relatively large amount of information about its input to all the other parties. However, as the number of repetitions increases, the other parties already know the input bit with significant probability and each bit sent starts to give lesser and lesser information about the party’s input. Thus, by independently repeating their inputs later in the protocol, the parties are wasting a lot of communication to convey a small amount of information about their inputs. This is clearly suboptimal and a more sensible approach is to “combine” the inputs of several of the parties into fewer bits, while maintaining that the information conveyed is the same.

Actually implementing this idea requires ingenuity, and [7] does it by having a protocol with three stages as described below<sup>8</sup>:

- **Stage Broadcast:** This stage of Gallager’s protocol has  $\mathcal{O}(n \log \log n)$  rounds and in this stage, all the parties broadcast their input  $\mathcal{O}(\log \log n)$  times. As the total number of broadcasts per party is small (only  $\mathcal{O}(\log \log n)$ ), all the broadcasts in this stage convey a large amount of information to the other parties.

Because all the parties broadcast  $\mathcal{O}(\log \log n)$  times in stage **Broadcast**, after this stage, any party can decode (by simple majority based decoding) the input of any other party correctly, except with probability at most  $\frac{1}{\text{polylog}(n)}$ .

- **Stage Guess:** In this stage, the parties divide themselves into families of size  $A = \Theta(\log n)$ . As the size of the families is  $\Theta(\log n)$ , a simple union bound shows that any party in a family can decode the inputs of all other parties in the family correctly, except with probability at most  $\frac{1}{\text{polylog}(n)}$ .

In fact, as the noise received by all the parties is independent, we also have concentration and, except with probability polynomially small in  $n$ , we have that at least 90% of the parties in a family correctly decode the inputs of all the parties in the family.

- **Stage Boost:** This is the most important stage of the protocol, where the parties “combine” multiple input bits and give information about all of the combined bits in the same communication bit. Recall that before this stage, the parties are divided into families of size  $A$ , and, except with probability polynomially small in  $n$ , at least 90% of the parties in a family know the input of all the parties in the family.

We describe stage **Boost** from the perspective of a single family, noting that the behavior of all the families is symmetric. Party  $i$  in this family, for all  $i \in [A]$ , takes the vector of bits it decoded for all the parties in the family, encodes this vector using a constant rate error correcting code, and broadcasts the  $i^{\text{th}}$  coordinate of this encoding<sup>9</sup>. Observe that as this coordinate depends on all the decoded bits, transmitting it conveys information about all the  $A$  bits in the family. Indeed, it is this combination that reduces the failure probability (“boosts” the success probability) of the protocol from  $\frac{1}{\text{polylog}(n)}$  to  $\frac{1}{\text{poly}(n)}$  without wasting  $\Omega(\log n)$  communication per party and allows us to union bound over all parties and all bits.

Due to the fact that 90% of the parties in a family encode the same (correct) vector of inputs, at least 90% of the sent coordinates are actually coordinates from one codeword. As the channel corrupts each sent symbol with a small constant probability, for any one of the  $n$  parties, it holds, except with probability polynomially small in  $n$ , that at least

<sup>8</sup> We note that [7] does not describe his protocol in terms of these stages. However, it will be helpful for us to talk about his protocol in this framework.

<sup>9</sup> We assume in this description that the error correcting code takes a bit string to a string over a larger alphabet but of the same length, and assume for simplicity that the parties can broadcast symbols from this larger alphabet in one round.

80% of the received coordinates come from the same (correct) codeword. Because this is a codeword of a good error correcting code, these 80% of the coordinates suffice to decode the inputs of all parties in the family correctly, except with probability polynomially small in  $n$ , and a union bound over all families and all parties finishes the proof of correctness of Gallager's protocol.

## 2.3 Gallager's Protocol in the Presence of Malicious Parties

Gallager's protocol shows that if resilience to malicious parties is not required, then the simple  $\mathcal{O}(n \log n)$  bit communication protocol can be improved. Our main result is stronger, showing that it is possible to do better than the  $\mathcal{O}(n \log n)$  bit communication protocol while maintaining its resilience against malicious parties. Before we describe our ideas, however, it will be helpful to first understand where Gallager's protocol fails if some of the parties are malicious.

At first glance, one may mistakenly believe that Gallager's protocol is also resilient to malicious parties. Indeed, the bits broadcast by the parties in stage **Broadcast** do not depend on the bits received by them, no communication happens in stage **Guess**, and the argument described in Subsubsection 2.2.1 would work (with slightly different parameters) as long as no family has a lot, say more than 10%, of malicious parties. As the families are size  $A = \Theta(\log n)$ , this last property can be ensured, except with probability polynomially small in  $n$ , by, say, partitioning the parties into families randomly before the execution of the protocol.

However, delving deeper reveals a major problem. Recall that, for stage **Boost** to work, stage **Guess** must ensure that, except with probability polynomially small in  $n$ , at least 90% of the parties in any family have the same (correct) decoding for the input bits of all the parties in the family. As the parties perform majority based decoding in stage **Guess**, this is equivalent to saying that, for at least 90% of the parties in a family, the majority bit they receive for all the parties in the family in stage **Broadcast** is the same (and correct) except with probability polynomially small in  $n$ .

The last property is true if there are no malicious parties. Indeed, all parties repeatedly broadcast their input in stage **Broadcast**, and because the channel only corrupts with a small constant probability, a simple concentration argument shows that, except with probability polynomially small in  $n$ , the majority bit received by at least 90% of the parties in a family will be the same as the bit sent.

However, if one of the parties in a family is malicious, it may, in stage **Broadcast**, broadcast the bit 0 half the time and the bit 1 the other half of the time. This implies that the majority bit received by any other party is equally likely to be 0 or 1, and only around 50% of the parties in the family can agree on the inputs of all the other parties in the family. To make matters worse, if a constant fraction (and not just 1) of the parties in the family are malicious, and all of them behave this way, then no two parties in the family will agree on the inputs of all the parties in the family (with large probability).

Before describing how our protocol gets around this problem, we quickly note that the source of this problem is *not* that the parties perform majority based decoding and decode to a bit only if it is heard at least 50% of the time. Even if the parties have another threshold, say 70%, the malicious parties can simply broadcast 0 in 30% of their broadcasts in stage **Broadcast**, and 1 in the remaining 70%, and cause the same problem.

## 2.4 Our Approach: Boosting Before Guessing

We define the “true count” of a party to be the number of times it broadcasts 1 in stage **Broadcast**. The example from the foregoing section shows that, when there is a malicious party  $i$  whose true count is half of the total broadcasts by party  $i$  in stage **Broadcast**, then majority based decoding implies that no more than 50% of the parties in the family of party  $i$  agree on the bit they decoded for party  $i$ .

Nonetheless, the fact that the channel corrupts only a small constant fraction of the bits sent implies that, except with probability at most  $\frac{1}{\text{polylog}(n)}$ , all the parties in the family of party  $i$  can *approximately* decode the true count for party  $i$ . Our main idea is to run stage **Boost** on these true counts directly, without first executing stage **Guess** to decode the true counts to bits.

Indeed, if we can run stage **Boost** on the true counts, and get all the parties to agree on an approximation for the true counts that is correct except with probability polynomially small in  $n$ , we can union bound over all parties and all counts to conclude that, except with probability polynomially small in  $n$ , all the parties know all the true counts approximately correctly. Once this happens, the parties can discard all counts that are close to  $\frac{1}{2}$ , as these can only be from malicious parties, and run stage **Guess** on the remaining counts to get the input bits of all the non-malicious parties correctly.

### 2.4.1 Computing the Encodings

There is however, a key difference between boosting the true counts and boosting the guessed bits. While boosting the guessed bits, Gallager’s protocol ensured that most of the parties in a family have the same Boolean vector  $u \in \{0, 1\}^A$  of the bits guessed for parties in the family. This allowed an error correcting code of  $u$  to be computed in a distributed way, where every party  $i$  in the family contributes coordinate  $i$  by encoding its Boolean vector.

With the true counts, this is no longer possible as *no* party in the family is likely to have the vector of true counts exactly, and the parties merely possess a good approximation of it. That is, if  $p \in \mathbb{Z}^A$  denotes the vector of the true counts for the family, each party in the family now has a different approximation  $q \in \mathbb{Z}^A$  of  $p$ . The task to be solved now is to compute an encoding of  $p$  in a *distributed* manner, when parties only have access to the approximations  $q$ !

This task seems to be impossible for standard error correcting codes, for which changing any of the coordinates of the message being encoded even slightly may result in a codeword completely unrelated to the original codeword. What we need instead is an error correcting code that is also “locality sensitive”, namely, for two messages (not necessarily Boolean)  $q_1$  and  $q_2$  that are close in all the coordinates, the encodings of  $q_1$  and  $q_2$  are also close in most of the coordinates. On the other hand, if  $q_1$  and  $q_2$  are far in any of the coordinates, then their encodings must be far in almost all of the coordinates.

**Connection to locality sensitive hashing.** Our description above may remind the reader of the area of locality sensitive hashing, where vectors in  $\mathbb{R}^d$  are hashed into buckets such that vectors that are close to each other are likely to be hashed into the same bucket, while vectors that are far apart are likely to be hashed to different buckets.

Our description of locality sensitive error correcting codes is related, but different. Firstly, by definition, a hash function loses information to make the data more manageable while an error correcting code adds more redundant information to make the data resilient to corruptions. Moreover, a locality sensitive hash only requires the hash values of two inputs that are far to be different, while in our definition of locality sensitive error correcting codes,

we will require the codewords to not only be different, but also far apart, in most of the coordinates. In fact, how far they can be will be critical in determining the communication complexity of our protocol.

## 2.5 Locality Sensitive Error Correcting Codes

As described above, we desire a code  $C$  that is locality sensitive. Namely, it has the following properties:

1. (“close”  $\rightarrow$  “close”): If two messages  $q_1$  and  $q_2$  are such that their coordinate-wise difference is at most  $\alpha$  in absolute value, for some  $\alpha \geq 0$ , then the difference of most of the coordinates of  $C(q_1)$  and the corresponding coordinate of  $C(q_2)$  is at most  $\beta$ , for some  $\beta \geq 0$ .
2. (“not close”  $\rightarrow$  “far”): If there exists a coordinate where messages  $q_1$  and  $q_2$  differ by more than  $\alpha'$ , for some  $\alpha' > \alpha$ , then the difference of most of the coordinates of  $C(q_1)$  and the corresponding coordinate of  $C(q_2)$  is more than  $\beta$  in absolute value.

### 2.5.1 Constructing Locality Sensitive Error Correcting Codes

We present a randomized construction of locality sensitive error correcting codes that proceeds in two steps. First, we construct a version of the codes over the alphabet  $\mathbb{Z}$  with weak parameters by taking each coordinate of the codeword to be a random linear function of the coordinates of the messages being encoded (details later). The codes we construct in this step will satisfy the property in item 1 above for an extremely large, say 99.99% of the coordinates but will satisfy the property in item 2 for only 50% of the coordinates.

This is followed by an amplification step where we combine independent copies of the codes constructed in the previous step to get better parameters. Specifically, we take  $L$  copies, for some constant  $L$ , and construct a “joint” codeword each of whose coordinates  $\in \mathbb{Z}^L$  is a tuple consisting of the corresponding coordinate in all the codewords. A pair of such joint coordinates is considered to be far if any one of the constituent coordinates is far. By setting  $L$  to be the right amount, we can make sure that the constant in item 1 only degrades slightly, say to 99%, while the constant in item 2 improves drastically to 99%.

It remains to describe step 1, the construction of un-amplified locality sensitive error correcting codes. As mentioned earlier, every coordinate of these codes is a random linear function of the coordinates of the message being encoded. The coefficients in this linear function belong to  $\{-1, 1\}$  chosen independently and uniformly. A simple concentration argument shows that, for messages  $q_1$  and  $q_2$  of length  $k > 0$  whose coordinate-wise difference is at most  $\alpha$ , the value of such a random linear function will not differ by more than  $\mathcal{O}(\alpha\sqrt{k})$ , with high probability. Thus, setting  $\beta = \mathcal{O}(\alpha\sqrt{k})$  ensures that item 1 above is satisfied.

It remains to show why item 2 is satisfied. For this, assume that two messages  $q_1$  and  $q_2$  of length  $k$  are being encoded such that  $q_1$  and  $q_2$  differ by at least  $\alpha' > \alpha$  in at least one coordinate. Let us assume without loss of generality that this is the last coordinate. Then, for any choice of coefficients for the first  $k - 1$  coordinates, there exists a choice in  $\{-1, 1\}$  of the coefficient for the last coordinate such that the difference in the value of the linear function is at least  $\alpha'$  in magnitude. Indeed, either the difference without the last coordinate is positive, in which we can select the value in  $\{-1, 1\}$  that will make the difference increase by  $\alpha'$ , or it is negative, in which case we can select the other value and make the difference decrease by  $\alpha'$ . In either case, the resulting difference is at least  $\alpha'$  in absolute value.

This implies that, with probability at least  $\frac{1}{2}$ , setting  $\beta = \alpha'$  satisfies item 2 finishing the argument.

## 2.6 Our Protocol

Armed with locality sensitive error correcting codes, we now describe our protocol. Note that our description has parameters such as  $k$ ,  $m$ ,  $\alpha$ , etc. and we set these parameters to appropriate values later in the sketch. Recall that the  $n$  parties are divided into families of size  $A = \Theta(\log n)$  randomly and this ensures that, except with probability polynomially small in  $n$ , all families have a small fraction of malicious parties.

We divide our protocol into the same three stages as in Gallager's protocol, although the order of the stages is different.

- **Stage Broadcast:** In this stage, all the parties broadcast their input  $m$  times (we set  $m$  later in this sketch). The parameter  $m$  will be chosen so that, except with probability at most  $\frac{1}{\text{polylog}(n)}$ , all the parties in a family receive approximately the same counts of the number of 1s from all other parties in the family up to an additive error of  $\alpha$ .

As in Gallager's protocol, as the noise received by each party is independent, except with probability polynomially small in  $n$ , at least 90% of the parties in any family receive the same counts up to an additive error of  $\alpha$ .

- **Stage Boost:** Notwithstanding the high level similarity to it, in that the parties in a family join forces to convince all the parties of the approximately correct counts, stage **Boost** in our protocol is very different from stage **Boost** in Gallager's protocol.

In our protocol, we first divide the families into  $\frac{A}{k}$  groups of  $k$  parties each. Then, for all  $i$ , party  $i$  in the family computes, using a locality sensitive error correcting code, an encoding for each group in the family of the vector of counts it received from that group in stage **Broadcast**, and broadcasts coordinate  $i$  of all the  $\frac{A}{k}$  encodings.

All the parties then combine the coordinates received from the different parties in a family to get a codeword for all the  $\frac{A}{k}$  groups in the family, and decode it to get the individual counts for the parties in the group. We note that these decoded counts are within  $\alpha'$  of the true counts. Indeed, 90% of the parties in the family sent coordinates from encodings of counts that were within  $\alpha$  of the true counts. Only a small constant fraction of coordinates were altered due to corruptions, and another small number of coordinates were sent by malicious parties in each family. Therefore, most of the coordinates received are from encodings of vectors within  $\alpha$  of the true counts. Due to the property in item 1 above, these coordinates are within  $\beta$  of the corresponding coordinates in the encoding of the true counts.

Because of the large number of coordinates that are within  $\beta$  of the corresponding coordinates in the encoding of the true counts, due to item 2 above, these coordinates are unlikely to come from a vector that is not within  $\alpha'$  of the true counts. Consequently, except with probability polynomially small in  $n$ , all the parties decode to a vector of counts within  $\alpha'$  of the true counts, as desired. We will set  $\alpha'$  to be the same order of magnitude as  $m$ , but smaller, say  $\alpha' = \frac{m}{10}$ .

- **Stage Guess:** In this stage, the parties simply perform majority based decoding of the counts decoded after stage **Boost**. This results in correct outputs for non-malicious parties because their true counts are either 0, if they have input 0, or  $m$ , if they have input 1. As the decoded counts are only  $\alpha' = \frac{m}{10}$  off from the true counts, majority based decoding will work correctly for the non-malicious parties.

**Setting the parameters.** Recall the size of a family is  $A = \Theta(\log n)$ . We already explained  $\alpha' = \frac{m}{10}$ , and our construction of locality sensitive error correcting codes in Subsection 2.5 implies  $\beta = \mathcal{O}(\alpha\sqrt{k}) = \frac{m}{10}$  as well. The number of bits communicated by a given party in our protocol is  $m$  in stage **Broadcast** and (roughly)  $\frac{A}{k}$  in stage **Boost**. Thus, total communication by a party equals

$$m + \frac{A}{k} = m + \mathcal{O}\left(A \cdot \frac{\alpha^2}{m^2}\right).$$

In the fault tolerant model, where the best guarantee obtainable is  $\alpha = \Theta(m)$ , the expression above is at least  $\Omega(\log n)$  and we do not get any gains over the protocol in Subsection 2.2. However, in the statistical model, where the more predictable nature of the noise allows us to use concentration bounds and get  $\alpha = \Theta(\sqrt{m})$ , the expression above is minimized when  $m = \Theta(\sqrt{\log n})$ , and we get an improvement over the protocol in Subsection 2.2. Observe that, perhaps surprisingly, the malicious parties are weaker in the model with “more” noise, and this is because the noise is also more predictable.

**Mixability of the encodings.** We finish the section by covering one subtlety about stage Boost that we omitted from the description above. In our implementation, instead of party  $i$  in the family sending coordinate  $i$  of the encoding it computed, we have it send a random coordinate along with the identity of the coordinate. As a typical coordinate will satisfy the properties in item 1 and item 2 above, this does not affect our analysis by much, but it does help us avoid the pathological case where all parties send a coordinate that is atypical in that it does not satisfy item 1 and item 2.

We note that this pathological case never arose in Gallager’s implementation as there, the coordinates sent by different parties in a family were different coordinates from the encodings of the *same* message, and thus, only a small number of them could possibly be atypical. For us, the parties send encodings of *nearby* messages, and it is possible that all coordinates that are sent are atypical for the encoding where they came from, hence, this extra randomization step.

### 3 Models and Formal Problem Definition

#### 3.1 Noisy Copies

Let  $\epsilon \in [0, 1/2)$  be a noise parameter and  $k \in \mathbb{N}$ . An  $\epsilon$ -noise bit is a  $\{0, 1\}$ -valued random variable that takes value 1 with probability *exactly*  $\epsilon$ . An  $\epsilon$ -noise  $k$ -vector  $N$  is a sequence of  $k$  independent  $\epsilon$ -noise bits. For a bit-vector  $x \in \{0, 1\}^k$ , an  $\epsilon$ -noisy copy of  $x$  is a random variable of the form  $x \oplus N$ , where  $\oplus$  denotes the bitwise XOR, and  $N$  is an  $\epsilon$ -noise  $k$ -vector. More generally, if  $X$  is any random variable taking values in  $\{0, 1\}^k$  an  $\epsilon$ -noisy copy of  $X$  is a random variable of the form  $X \oplus N$ , where  $N$  is an  $\epsilon$ -noise  $k$ -vector chosen independently from  $X$ .

#### 3.2 The Noisy Broadcast Model

The (statistical) noisy broadcast model considers  $n$  parties  $P_1, \dots, P_n$ . Let  $\mathcal{X}$  and  $\mathcal{Y}$  be sets. The input is a vector  $x \in \mathcal{X}^n$ , and each of the parties  $P_i$  initially has coordinate  $x^i \in \mathcal{X}$ . The goal is for party  $P_i$  to evaluate a function  $f^i : \mathcal{X}^n \rightarrow \mathcal{Y}$  at  $x$ , i.e., output  $y^i = f^i(x)$ . This goal is to be accomplished by a noisy broadcast protocol.

The specification of a (deterministic) protocol over the noisy broadcast model with noise rate *exactly*  $\epsilon$  consists of:

1. The number  $s \in \{0\} \cup \mathbb{N}$  of broadcasts used in the protocol.
2. A sequence  $i_1, \dots, i_s \in [n]$  of indices of parties (with repetitions allowed).
3. A sequence  $g_1, \dots, g_s$  of broadcast functions, where  $g_j : \mathcal{X} \times \{0, 1\}^{j-1} \rightarrow \{0, 1\}$ .
4. For all  $i$ , an output function  $h^i : \mathcal{X} \times \{0, 1\}^s \rightarrow \mathcal{Y}$  for  $P_i$ .

**Running a protocol.** The execution of a noisy broadcast protocol  $\Pi$  depends on the input  $x$ , and on a noise vector  $N$ . We will think of  $N$  as a concatenation of  $s$  independent  $\epsilon$ -noise  $n$ -vectors  $N_1, \dots, N_s$ . Let  $j \in [s]$ . In the  $j^{\text{th}}$  step of the execution of  $\Pi$ , party  $P_{i_j}$  broadcasts a bit  $b_j$  and all the parties  $i \in [n]$ , receive  $b_j^i = b_j \oplus N_j[i]$ , an independent noisy copy of  $b_j$ . Formally, the bit broadcast by  $P_{i_j}$  at step  $j$  is  $b_j = g_j(x^{i_j}, b_1^{i_j}, b_2^{i_j}, \dots, b_{j-1}^{i_j})$ , that is, the value of  $g_j$  on the input of  $P_{i_j}$  and the  $j-1$  bits received by  $P_{i_j}$  during the first  $j-1$  rounds. The output of  $P_i$  is  $y^i = h^i(x^i, b_1^i, \dots, b_s^i)$ , that is, the value of  $h^i$  on the input of  $P_i$  and the  $s$ -vector of bits received by  $P_i$ .

Note that the assumed model is *non-adaptive* or *oblivious*: the sequence of parties who broadcast is fixed in advance and does not depend on the execution. Without this requirement, the noise could lead to several parties speaking at the same time (a *collision*). Moreover, this problem will be more serious when we introduce malicious parties, who may decide to speak all the time causing collisions in every round. Finally, note that the model rules out *communication by silence*: when it is the turn of a party to speak, it must speak.

### 3.3 The Noisy Broadcast Model with Malicious Parties

So far, we assumed that all participating parties are collaborating and following the protocol. We now consider the model where a subset  $\text{Mal} \subset [n]$  of the parties, called the *malicious parties*, are controlled by an adversary and may not follow the protocol. The set of malicious parties is determined prior to the execution of the protocol and is unchanged throughout the duration of the execution. We consider randomized protocols in this malicious setting and allow parties to use both private randomness (known to a single party) and public randomness (known to all parties). Observe that in the standard (non-malicious) setting, public randomness can always be used in lieu of private randomness. This is no longer possible in our malicious setting, as will be apparent next.

The adversary controlling the malicious parties is assumed to know the inputs of all the parties, the shared random string, and the private random strings of the parties in  $\text{Mal}$ . In addition, in round  $j \in [s]$ , the adversary knows the channel's prior noise vectors  $N_1, N_2, \dots, N_{j-1}$ , and thus also knows all the bits that were sent and received by all the parties in all the previous rounds. (Note that the adversary does not know either the private random strings of the honest parties or the noise in the channel in future rounds). The parties in  $[n] \setminus \text{Mal}$  are still assumed to be following the protocol and are called *honest parties*.

**Computing functions.** Let  $x \in \mathcal{X}^n$  be an input for the parties and let  $\text{Mal}$  be the set of malicious parties. We say that the input  $x' \in \mathcal{X}^n$  is *consistent* with  $x$  and  $\text{Mal}$  if  $\hat{x}^i = x^i$  for every  $i \in [n] \setminus \text{Mal}$ .

Let  $\theta \in [0, 1/2)$  and assume that  $n$  is a sufficiently large function of  $\theta$ . Let  $\delta \geq 0$ . We say that a randomized protocol  $\Pi$  over the noisy broadcast channel with noise rate exactly  $\epsilon$  *computes the functions  $\{f^i\}_{i \in [n]}$  in the presence of  $\theta$ -fraction of malicious parties with error  $\delta$*  if whenever the set of malicious parties  $\text{Mal}$  satisfies  $|\text{Mal}| \leq \theta n$ , then for every  $x \in \mathcal{X}^n$ , with probability at least  $1 - \delta$ , the following holds: For every  $i \in [n] \setminus \text{Mal}$ , there exists  $\hat{x} \in \mathcal{X}^n$  that is consistent with  $x$  and  $\text{Mal}$ , such that the output of  $P_i$  in  $\Pi$  is  $y^i = f^i(\hat{x})$ . Here, the probability is over the private and public randomness and the noise in the channel.

We say that a randomized protocol  $\Pi$  over the noisy broadcast channel with noise rate exactly  $\epsilon$  *computes the identity function in the presence of  $\theta$ -fraction of malicious parties with error  $\delta$*  if  $\mathcal{X} = \{0, 1\}$  and  $\mathcal{Y} = \{0, 1\}^n$  and  $\Pi$  computes the functions  $\{f^i\}_{i \in [n]}$  in the presence of  $\theta$ -fraction of malicious parties with error  $\delta$ , where  $f^i : \{0, 1\}^n \rightarrow \{0, 1\}^n$  is given by  $f^i(x) = x$ . Simplified for the identity function, the above means that whenever  $|\text{Mal}| \leq \theta n$ ,

then, for every input  $x$ , with probability at least  $1 - \delta$ , the following holds: For all  $i \in [n]$ ,  $P_i$  outputs a vectors  $y^i = (\hat{x}_1^i, \hat{x}_2^i, \dots, \hat{x}_n^i)$ , where if  $i, i' \in [n] \setminus \text{Mal}$ , then  $\hat{x}_{i'}^i = x^{i'}$  (otherwise,  $\hat{x}_{i'}^i$  can be arbitrary), as suggested by  $(*)$ .

## 4 Preliminaries

Please refer to the full version for the missing proofs.

### 4.1 Concentration Inequalities

► **Lemma 2** (Multiplicative Chernoff bound). *Suppose  $X_1, \dots, X_n$  are independent random variables taking values in  $[0, 1]$ . Let  $X$  denote their sum and let  $\mu = \mathbb{E}[X]$  denote the sum's expected value. Then,*

$$\begin{aligned} \Pr(X \geq (1 + \delta)\mu) &\leq e^{-\frac{\delta^2 \mu}{2 + \delta}}, & \forall 0 \leq \delta, \\ \Pr(X \leq (1 - \delta)\mu) &\leq e^{-\frac{\delta^2 \mu}{2}}, & \forall 0 \leq \delta \leq 1. \end{aligned}$$

In particular, we have that:

$$\begin{aligned} \Pr(X \geq (1 + \delta)\mu) &\leq e^{-\frac{\delta \mu}{3} \cdot \min(\delta, 1)}, & \forall 0 \leq \delta, \\ \Pr(|X - \mu| \geq \delta \mu) &\leq 2 \cdot e^{-\frac{\delta^2 \mu}{3}}, & \forall 0 \leq \delta \leq 1. \end{aligned}$$

We derive a couple of corollaries of Lemma 2, that will be convenient for us to use.

► **Corollary 3.** *Suppose  $X_1, \dots, X_n$  are independent random variables taking values in  $[0, 1]$ . Let  $X$  denote their sum and let  $\mu = \mathbb{E}[X]$  denote the sum's expected value. Then, for all  $\Delta \geq 2\mu$ , we have:*

$$\Pr(X \geq \Delta) \leq e^{-\frac{\Delta}{6}}.$$

**Proof.** As  $\Delta \geq 2\mu$ , we have  $\Delta = (1 + \delta)\mu$  for some  $\delta \geq 1$ . Applying Lemma 2 with this  $\delta$ , we get  $\Pr(X \geq \Delta) \leq e^{-\frac{\Delta}{3}} \leq e^{-\frac{\Delta}{6}}$ , as desired. ◀

► **Corollary 4.** *Suppose  $X_1, \dots, X_n$  are independent random variables taking values in  $[-1, 1]$  such that  $\mathbb{E}[X_i] = 0$  for all  $i \in [n]$ . If  $X = \sum_{i=1}^n X_i$  denotes their sum, then, for all  $0 \leq \delta \leq 1$ , we have*

$$\Pr(|X| \geq \delta n) \leq 2 \cdot e^{-\frac{\delta^2 n}{6}}.$$

**Proof.** Apply Lemma 2 on the variables  $\frac{X_i + 1}{2}$ . ◀

We shall also use the following version of Chernoff bound for negatively correlated random variables:

► **Definition 5** (Negatively Correlated Random Variables). *For  $n > 0$ , let  $X_1, \dots, X_n$  be random variables that take values in  $\{0, 1\}$ . We say that the random variables  $X_1, \dots, X_n$  are negatively correlated if for all subsets  $S \subseteq [n]$ , we have  $\Pr(\forall i \in S : X_i = 1) \leq \prod_{i \in S} \Pr(X_i = 1)$ .*

► **Lemma 6** (Generalized Chernoff Bound; cf. [14]). *For  $n > 0$ , let  $X_1, \dots, X_n$  be negatively correlated random variables that take values in  $\{0, 1\}$ . Let  $X$  denote their sum and let  $\mu = \mathbb{E}[X]$  denote the sum's expected value. Then, for any  $\delta \geq 0$ , we have:*

$$\Pr(X > (1 + \delta) \cdot \mu) \leq e^{-\frac{\delta^2 \mu}{2 + \delta}}.$$

In particular, we have that:

$$\Pr(X > (1 + \delta)\mu) \leq e^{-\frac{\delta \mu}{3} \cdot \min(\delta, 1)}, \quad \forall \delta \geq 0.$$

## 4.2 Results From Coding Theory

We use the following standard result for error-correcting codes, and include a proof for completeness.

► **Lemma 7.** *Let  $\delta > 0$  and define  $K_0 = \lceil 10/\delta^2 \rceil$ . For all  $n > 0$ , there exists a function  $\text{ECC}_{n,\delta} : \{0,1\}^n \rightarrow \{0,1\}^{K_0 n}$  such that for all  $s \neq t \in \{0,1\}^n$ , we have*

$$\Delta(\text{ECC}_{n,\delta}(s), \text{ECC}_{n,\delta}(t)) > \left(\frac{1}{2} - \delta\right) \cdot K_0 n.$$

## 5 Locality Sensitive Error Correcting Codes

Let  $n > 0$  and  $x, y \in \mathbb{Z}^n$  be vectors. For  $z \in \mathbb{Z}$ , define

$$\text{sep}_z(x, y) = \{i \in [n] \mid |x_i - y_i| > z\}.$$

Observe that  $|\text{sep}_0(\cdot)|$  is simply the Hamming distance between the vectors  $x$  and  $y$ , and is therefore, a metric. For general  $z \in \mathbb{Z}$  however, the function  $|\text{sep}_z(\cdot)|$  may not be a metric. In this paper, we work with the following generalization of the function  $\text{sep}(\cdot)$ .

► **Definition 8.** *Let  $n, L > 0$  and  $x, y \in (\mathbb{Z}^L)^n$  be vectors. For  $z \in \mathbb{Z}$ , define*

$$\text{sep}_z(x, y) = \{i \in [n] \mid \exists l \in [L] : |x_{i,l} - y_{i,l}| > z\}.$$

► **Lemma 9.** *Let  $n, L > 0$  and  $x_1, x_2, y \in (\mathbb{Z}^L)^n$  be vectors. For  $z_1, z_2 \in \mathbb{Z}$ , we have*

$$\text{sep}_{z_1}(x_1, y) = \emptyset \wedge \text{sep}_{z_1+z_2}(x_2, y) \neq \emptyset \implies \text{sep}_{z_2}(x_1, x_2) \neq \emptyset.$$

### 5.1 Definition

We now define locality sensitive error correcting codes. Throughout this section and the next, we fix integers  $m, k > 100$ .

► **Definition 10.** *Let  $n, L > 0$  and  $C : (\{0\} \cup [m])^k \rightarrow (\mathbb{Z}^L)^n$ . Let  $\alpha, \alpha', \beta, \mu, \mu' > 0$  be parameters. We say that the function  $C$  is an  $(n, L, \alpha, \alpha', \beta, \mu, \mu')$ -locality sensitive error correcting code if it has the following two properties:*

■  **$(\alpha, \beta, \mu)$ -locality sensitive:** *For all  $x, y \in (\{0\} \cup [m])^k$ , we have:*

$$\text{sep}_\alpha(x, y) = \emptyset \implies |\text{sep}_\beta(C(x), C(y))| \leq (1 - \mu)n.$$

■  **$(\alpha', \beta, \mu')$ -error correcting:** *For all  $x, y \in (\{0\} \cup [m])^k$ , we have:*

$$\text{sep}_{\alpha'}(x, y) \neq \emptyset \implies |\text{sep}_\beta(C(x), C(y))| \geq \mu'n.$$

We sometimes say  $C$  is a locality sensitive error correcting code or  $C$  is an  $(n, L)$ -locality sensitive error correcting code if we do not wish to emphasize the other parameters. Our protocol requires  $C$  to have a short representation as stated below:

► **Definition 11 (Representation Length).** *Let  $n, L > 0$  and  $C$  be an  $(n, L)$ -locality sensitive error correcting code. Define:*

$$\|C\| = \max_{x \in (\{0\} \cup [m])^k} \max_{i \in [n]} \max_{l \in [L]} |C_{i,l}(x)|.$$

Observe that for all  $x \in (\{0\} \cup [m])^k$ , the value of  $C(x)$ , can be encoded using  $10 \cdot \log(10 \cdot \|C\| + 10)$  bits. We shall use this to show that our protocol does not communicate a lot of bits.

## 5.2 Proof of Existence

We have:

► **Theorem 12.** *Let  $\theta < \frac{1}{2}$  and  $n \geq \left(\frac{100}{1-2\theta}\right)^3 \cdot k \log m$ . There exists a locality sensitive error correcting code  $\mathcal{C}$  with parameters:*

$$\left(n, 10 \cdot \log \frac{10}{1-2\theta}, 4\sqrt{m \log k}, \beta, \beta, \frac{1}{2} + \theta, \frac{1}{2} + \theta\right),$$

where  $\beta = 24\sqrt{mk \cdot \log k \cdot \log \frac{10}{1-2\theta}}$ . Moreover,  $\mathcal{C}$  satisfies  $\|\mathcal{C}\| \leq mk$  and  $\mathcal{C}$  can be computed in time polynomial in  $(m, k, n, L)$ <sup>10</sup>

## 6 Mixability of Codewords

We show that the encodings of similar (but not identical) inputs under a locality sensitive error correcting code can be “mixed” together while maintaining properties similar to the original codewords. In order to formalize this, we first generalize the function  $\text{sep}(\cdot)$  from Definition 8.

► **Definition 13.** *Let  $n, L > 0$ ,  $x \in (\mathbb{Z}^L)^n$ , and  $z \in \mathbb{Z}$ . For  $n' > 0$  and a vector of pairs  $y \in ([n] \times (\mathbb{Z}^L))^{n'}$ , define*

$$\text{sep-mix}_z(x, y) = \{i \in [n'] \mid \exists l \in [L] : |x_{y_{i,1},l} - (y_{i,2})_l| > z\}.$$

Intuitively, every coordinate in  $y$  has two components, the first points to a coordinate in  $x$  and the second one is a value in  $\mathbb{Z}^L$  (a symbol in the code’s alphabet). The function  $\text{sep-mix}_z(\cdot)$  compares each coordinate in  $y$  to the coordinate it points to in  $x$  and checks if they “differ” by more than  $z$ .

An easy corollary of the above definition is the following where for a set  $S \subseteq [n']$ , we use the notation  $y|_S$  to denote the vector  $y$  restricted to the coordinates in  $S$ .

► **Corollary 14.** *Let  $n, L > 0$ ,  $x \in (\mathbb{Z}^L)^n$ , and  $z \in \mathbb{Z}$ . Also, let  $n' > 0$  and  $y \in ([n] \times (\mathbb{Z}^L))^{n'}$ . We have for all  $S \subseteq [n']$  that:*

$$\text{sep-mix}_z(x, y) \cap S = \text{sep-mix}_z(x, y|_S).$$

Fix an  $(n, L, \alpha, \alpha', \beta, \mu, \mu')$ -locality sensitive error correcting code  $\mathcal{C}$  for the rest of this section. We show that:

► **Lemma 15.** *Let  $x \in (\{0\} \cup [m])^k$  and  $n' > 0$ . For  $i' \in [n']$ , let  $y_{i'} \in (\{0\} \cup [m])^k$  be given. If, for  $j_1, j_2, \dots, j_{n'} \in [n]$ , we have*

$$Y(j_1, j_2, \dots, j_{n'}) = ((j_1, \mathcal{C}_{j_1}(y_1)), (j_2, \mathcal{C}_{j_2}(y_2)), \dots, (j_{n'}, \mathcal{C}_{j_{n'}}(y_{n'}))),$$

then, when  $j_1, j_2, \dots, j_{n'}$  are sampled uniformly at random, we have for all  $\Delta_1 \geq 2 \cdot \left(n' - \frac{n'}{n} \cdot \min_{i' \in [n']} |\text{sep}_\beta(\mathcal{C}(x), \mathcal{C}(y_{i'}))|\right)$  that:

$$\Pr\left(n' - |\text{sep-mix}_\beta(\mathcal{C}(x), Y(j_1, j_2, \dots, j_{n'}))| \geq \Delta_1\right) \leq \exp\left(-\frac{\Delta_1}{6}\right).$$

We also have, for all  $\Delta_2 \geq 2 \cdot \frac{n'}{n} \cdot \max_{i' \in [n']} |\text{sep}_\beta(\mathcal{C}(x), \mathcal{C}(y_{i'}))|$  that

$$\Pr\left(|\text{sep-mix}_\beta(\mathcal{C}(x), Y(j_1, j_2, \dots, j_{n'}))| \geq \Delta_2\right) \leq \exp\left(-\frac{\Delta_2}{6}\right).$$

<sup>10</sup> In fact, as  $\mathcal{C}$  will only encode messages of logarithmic length in our protocol, the running time of our protocol will be almost-linear even if encoding  $\mathcal{C}$  took sub-exponential time.

## 7 Our Protocol

We are now ready to state our protocol. Recall that there are  $n$  parties amongst which at most  $\theta n$  are malicious. The following hold:

$$\theta < \frac{1}{2}, \quad \epsilon = \frac{1}{10}, \quad n > 100^{100 \frac{100}{1-2\theta}}. \quad (1)$$

We define the following parameters:

$$\begin{aligned} k &= \frac{\sqrt{\log n}}{\left(\frac{1}{2} - \theta\right)^2} \cdot \frac{1}{\left(\log \frac{10}{1-2\theta}\right)^2}, & m &= 50000k \cdot \left(\log \frac{10}{1-2\theta}\right)^2 \cdot \log \log n, \\ \alpha &= 4\sqrt{m \log k}, & \beta &= 24\sqrt{mk \cdot \log k \cdot \log \frac{10}{1-2\theta}} < \frac{m}{6}, \\ L &= 10 \cdot \log \frac{10}{1-2\theta}, & A &= 10^{20} \cdot \frac{\log n}{\left(\frac{1}{2} - \theta\right)^3} \cdot \frac{4\theta}{\min(4\theta, 1-2\theta)}, \\ \ell &= 10^{10} \cdot \log \left(\frac{\log n}{\frac{1}{2} - \theta}\right). \end{aligned} \quad (2)$$

For the rest of this paper, we reserve  $\mathbf{C} : (\{0\} \cup [m])^k \rightarrow (\mathbb{Z}^L)^A$  to be a locality sensitive error correcting code with parameters:

$$\left(A, L, \alpha, \beta, \beta, \frac{199+2\theta}{200}, \frac{199+2\theta}{200}\right).$$

Such a code is promised by Theorem 12. We have by Definition 10 that, for all  $x, y \in [m]^k$ ,

$$\begin{aligned} \text{sep}_\alpha(x, y) = \emptyset &\implies |\text{sep}_\beta(\mathbf{C}(x), \mathbf{C}(y))| \leq A \cdot \left(\frac{1-2\theta}{200}\right). \\ \text{sep}_\beta(x, y) \neq \emptyset &\implies |\text{sep}_\beta(\mathbf{C}(x), \mathbf{C}(y))| \geq A \cdot \left(\frac{199+2\theta}{200}\right). \end{aligned} \quad (3)$$

Additionally, we reserve ECC to be the one promised by Lemma 7 for  $n \leftarrow \ell$  and  $\delta \leftarrow \frac{1}{10}$ . By Lemma 7, we have  $s \neq t \in \{0, 1\}^\ell$  that:

$$\Delta(\text{ECC}(s), \text{ECC}(t)) > \frac{2}{5} \cdot 1000\ell = 400\ell. \quad (4)$$

### 7.1 Partitioning the Parties

The  $n$  parties are randomly divided into  $n/A$  families of  $A$  parties each. Each family is further divided into  $A/k$  groups of  $k$  parties each. Formally, this division is performed using the following random process: First, sample a permutation uniformly at random from the set  $\mathbf{S}_n$  of permutations on  $[n]$ . Then, for  $a \in [n/A]$ , family  $a$  is the set of parties

$$F_a = \{\sigma(A(a-1) + 1), \sigma(A(a-1) + 2), \dots, \sigma(A(a-1) + A)\}.$$

For  $b \in [A/k]$ , group  $b$  in family  $F_a$  is the set of parties

$$G_{a,b} = \{\sigma(A(a-1) + k(b-1) + 1), \dots, \sigma(A(a-1) + k(b-1) + k)\}$$

As the families are chosen randomly, no family has a lot of malicious parties with high probability. Formally,

► **Lemma 16.** *It holds that:*

$$\Pr_{\sigma \sim \mathbf{S}_n} \left( \exists a \in [n/A] : |F_a \cap \text{Mal}| \geq A \cdot \frac{1+2\theta}{4} \right) \leq \frac{1}{n^{30}}.$$

## 7.2 Our Protocol

For the rest of this section and the analysis, fix a partition of the parties into families such that no family has more than  $\frac{1+2\theta}{4}$  fraction of malicious parties. Due to Lemma 16, this happens except with probability at most  $\frac{1}{n^{30}}$ . We note that this partition allows us to denote a party  $i \in [n]$  using either  $(a, j) \in [n/A] \times [A]$ , emphasizing its family and index within the family, or  $(a, b, c) \in [n/A] \times [A/k] \times [k]$ , emphasizing its family, its group, and the index within the groups. These ways to denote a party  $i$  are equivalent and we use them interchangeably.

Our protocol is symmetric for all the parties and is described in Algorithm 1 from the perspective of party  $i$ . In the algorithm, we sometimes use “partial indexing”, e.g., we write  $q_{a,b'}$  to mean the concatenation of the values  $q_{a,b',c'}$  for all possible values of  $c'$ .

Please refer to the full version for details about the analysis.

■ **Algorithm 1** Our protocol from the perspective of party  $i = (a, j) = (a, b, c)$ .

---

### Stage Broadcast:

- 1: Broadcast input  $x^i$  a total of  $m$  times.
- 2: For  $b' \in [A/k]$  and  $c' \in [k]$ , let  $q_{a,b',c'} \leftarrow$  number of 1s received from party  $(a, b', c')$ .

### Stage Boost:

- 3: For  $b' \in [A/k]$ , sample  $z_{a,b'}$  privately and uniformly from  $[A]$ . Let  $v_{a,b'} \leftarrow C_{z_{a,b'}}(q_{a,b'})$ . Broadcast  $\text{ECC}((z_{a,b'}, v_{a,b'}))$  (note that  $\ell$  bits suffice to encode  $(z_{a,b'}, v_{a,b'})$ ).
- 4: For  $a' \in [n/A]$ ,  $j' \in [A]$ , and  $b'' \in [A/k]$ , decode the  $b''^{\text{th}}$  value received from party  $(a', j')$  to get  $\tilde{C}_{a',b'',j'} = (\tilde{z}_{a',b'',j'}, \tilde{v}_{a',b'',j'})$ .

### Stage Guess:

- 5: For  $a' \in [n/A]$  and  $b' \in [A/k]$ ,  $\tilde{p}_{a',b'} \leftarrow \arg \min_{p' \in (\{0\} \cup [m])^k} |\text{sep-mix}_\beta(C(p'), \tilde{C}_{a',b'})|$ .
  - 6: For  $i' = (a', b', c') \in [n]$ , output  $\tilde{x}_{i'} = \mathbf{1}(\tilde{p}_{a',b',c'} \geq \frac{m}{2})$ .
-

## Abstract

We study the problem of sampling a uniformly random directed rooted spanning tree, also known as an arborescence, from a possibly weighted directed graph. Classically, this problem has long been known to be polynomial-time solvable; the exact number of arborescences can be computed by a determinant [33], and sampling can be reduced to counting [18, 16]. However, the classic reduction from sampling to counting seems to be inherently sequential. This raises the question of designing efficient parallel algorithms for sampling. We show that sampling arborescences can be done in RNC.

For several well-studied combinatorial structures, counting can be reduced to the computation of a determinant, which is known to be in NC [9]. These include arborescences, planar graph perfect matchings, Eulerian tours in digraphs, and determinantal point processes. However, not much is known about efficient parallel sampling of these structures. Our work is a step towards resolving this mystery.

## 1 Introduction

Algorithms for (approximately) counting various combinatorial structures are often based on the equivalence between (approximate) counting and sampling [18, 16]. This is indeed the basis of the Markov Chain Monte Carlo (MCMC) method to approximate counting, which is arguably the most successful approach to counting, resolving long-standing problems such as approximating the permanent [17] and computing the volume of convex sets [13].

Approximate sampling and counting are known to be equivalent for a wide class of problems, including the so-called self-reducible ones [18, 16]. This equivalence is nontrivial and most useful in the direction of reducing counting to sampling. However, for some problems, the “easier” direction of this equivalence, namely the reduction from sampling to counting, proves useful. For these problems, almost by definition, we can count via approaches other than MCMC.

One of the mysterious approaches to counting is via determinant computations. A range of counting problems can be (exactly) solved by simply computing a determinant. A non-exhaustive list is provided below.

- Spanning trees in a graph can be counted by computing a determinant related to the Laplacian of the graph, a result known as the matrix-tree theorem [22].
- Arborescences in a directed graph can be counted by computing a determinant related to the directed Laplacian [33].
- The number of perfect matchings in a planar graph can be computed as the Pfaffian (square root of the determinant) of an appropriately signed version of the adjacency matrix, a.k.a. the Tutte matrix [20].
- The number of Eulerian tours in an Eulerian digraph is directly connected to the number of arborescences, and consequently the determinant related to the directed Laplacian [1, 34].
- Given vectors  $v_1, \dots, v_n \in \mathbb{R}^d$ , the volume sampling distribution on subsets  $S \in \binom{[n]}{d}$  can be defined as follows:

$$\mathbb{P}[S] \propto \det([v_i]_{i \in S})^2.$$

The partition function of this distribution is simply  $\det(\sum_i v_i v_i^T)$  (see, e.g., [10]).

- The number of non-intersecting paths between specified terminals in a lattice, and more generally applications of the Lindström-Gessel-Viennot lemma [24, 14].

Efficient counting for these problems follows the polynomial-time computability of the associated determinants. In turn, one obtains efficient sampling algorithms for all of these problems; we remark that of all of these problems are known to be self-reducible, but nevertheless “easy” slightly varied sampling to counting reductions exist for all of them.

While polynomial-time sampling for all of these problems has long been settled, we reopen the investigation of these problems by considering *efficient parallel sampling* algorithms. We focus on the computational model of PRAM, and specifically on the complexity classes NC and RNC. Here, a polynomially bounded number of processors are allowed access to a shared memory, and the goal is for the running time to be polylogarithmically bounded; the class RNC has additionally access to random bits. Determinants can be computed efficiently in parallel, in the class NC [9], and as a result there are NC counting algorithms for all of aforementioned problems. However, the sampling to counting reductions completely break down for parallel algorithms, as there seems to be an inherent sequentiality in these reductions.

Take spanning trees in a graph as an example. The classic reduction from sampling to counting proceeds as follows:

```

for each edge  $e$  do
     $A \leftarrow$  number of spanning trees containing  $e$ 
     $B \leftarrow$  total number spanning trees
    Flipping a coin with bias  $A/B$ , decide whether  $e$  should be part of the tree.
    Either contract or delete the edge  $e$  based on this decision.
  
```

Each iteration of this loop uses a counting oracle to compute  $A, B$ . However the decision of whether to include an edge  $e$  as part of the tree affects future values of  $A, B$  for other edges, and this seems to be the inherent sequentiality in this algorithm. The sampling-to-counting reduction for all other listed problems encounters the same sequentiality obstacle.

In this paper, we take a step towards resolving the mysterious disparity between counting and sampling in the parallel algorithms world. We resolve the question of sampling arborescences in weighted directed graphs, and as a special case spanning trees in weighted undirected graphs, using efficient parallel algorithms with access to randomness, a.k.a. the class RNC.

We remark that the special case of sampling spanning trees in unweighted undirected graphs was implicitly solved by the work of Teng [30], who showed how to simulate random walks in RNC. When combined with earlier work of Aldous [2] and Broder [6], this algorithm would simulate a random walk on the graph, and from its transcript extract a random spanning tree. However, adding either weights or directions to the graph results in the need for potentially exponentially large random walks, which cannot be done in RNC. Our work removes this obstacle.

► **Theorem 1.** *There is an RNC algorithm which takes a directed graph  $G = (V, E)$  together with edge weights  $w : E \rightarrow \mathbb{R}_{\geq 0}$  as input and outputs a random directed rooted tree  $T$ , a.k.a. an arborescence. The output  $T$  follows the distribution*

$$\mathbb{P}[T] \propto \prod_{e \in T} w(e).$$

## 1.1 Related Work and Techniques

There is a long line of research on algorithms for sampling and counting spanning trees and more generally arborescences. The matrix-tree theorem of Kirchhof [22] showed how to count spanning trees in undirected graphs, and later Tutte [33] generalized this to arborescences in digraphs. Somewhat surprisingly Aldous [2] and Broder [6] showed that random spanning trees and more generally random arborescences of a graph can be extracted from the transcript of a random walk on the graph itself. The main focus of subsequent work on this problem has been on improving the total running time of sequential algorithms for sampling. After a long line of work [35, 7, 21, 25, 12, 11], Schild [28] obtained the first almost-linear time algorithm for sampling spanning trees. More recently Anari, Liu, Oveis Gharan, and Vinzant [3] improved this to nearly-linear time. Many of these works are based on speeding up the Aldous-Broder algorithm. Our main result, Theorem 1, is also built on the Aldous-Broder algorithm, but we focus on parallelizing it instead of optimizing the total running time.

No almost-linear time algorithm is yet known for sampling arborescences in digraphs, as opposed to spanning trees in undirected graphs. While sampling spanning trees has a multitude of application (see [28]), there are a number of applications for the directed graph generalization. Most notably, there is a many-to-one direct correspondence between Eulerian tours in an Eulerian digraph and arborescences of the graph. This correspondence, known as the BEST theorem [1, 34] allows one to generate random Eulerian tours by generating random arborescences (see [8]). We leave the question of whether the correspondence in the BEST theorem is implementable in NC to future work, but note that sampling Eulerian tours has interesting applications in biology and sequence processing [19, 27]. We remark that, unlike directed graphs, generating random Eulerian tours of *undirected* Eulerian graphs in polynomial time is a major open problem [32].

In a slightly different direction related to this work, Balaji and Datta [4] considered the space complexity of counting arborescences. They showed this problem is in L for graphs of bounded tree-width, obtaining algorithms for counting Eulerian tours in these digraphs as well.

■ **Figure 1** Starting from left it takes  $\Theta(W)$  steps to cover.

■ **Figure 2** A random walk started from the left node covers all  $n$  nodes in time  $\Theta(2^n)$ .

Perhaps in the first major result of its kind in the search for RNC sampling algorithms, Teng [31] showed implicitly how to sample spanning trees in undirected graphs in RNC. Teng [31] showed how to parallelize the simulation of a random walk on a graph; more precisely, he showed how to output a length  $L$  trace of a walk on size  $n$  Markov chains in parallel running time  $\text{polylog}(L, n)$  using only  $\text{poly}(L, n)$  many processors. The Aldous-Broder algorithm extracts an arborescence from the trace of a random walk by extracting the so-called first-visit edge to each vertex. If a random walk is simulated until all vertices are visited at least once, the trace of the random walk has enough information to extract all such first-visit edges. This allows RNC sampling of arborescences in graphs where the number of steps needed to visit all vertices, known as the cover time, is polynomially bounded. While the cover time of a random walk on an undirected unweighted graph is polynomially bounded in the size of the graph (see, e.g., [23]), adding either weights or directions can make the cover time exponentially large. See Figures 1 and 2.

We overcome the obstacle of exponentially large cover times, by taking a page from some of the recent advances on the sequential sampling algorithms for spanning trees. Instead of simulating the entirety of the random walk until cover time, we extract only the first-visit edges to each vertex. We use the same insight used in several prior works that once a region of the graph has been visited, subsequent visits of the random walk can be *shortcut* to the first edge that exits this region. However, this involves a careful construction of a hierarchy of “regions”, and bounding the number of steps needed inside each region to fully cover it. Unlike undirected graphs, in directed graphs arguing about the covering time of a region becomes complicated. We build on some of the techniques developed by Boczkowski, Peres, and Sousi [5] to bound these covering times in the case of Eulerian digraphs. We then reduce the arborescence sampling problem for arbitrary digraphs to that of Eulerian digraphs.

## 1.2 Overview of the Algorithm

At a high-level, our algorithm first proceeds by reducing the problem to sampling an arborescence from an Eulerian graph. We then construct a “loose decomposition” of the Eulerian graph into weighted cycles. We then construct a hierarchy of vertex sets by starting with the empty graph and adding the weighted cycles one by one, from the lowest weight to the highest, adding the connected components in each iteration to the hierarchy. This results in a hierarchical clustering of vertices, with the intuitive property that once we enter a cluster, we spend a lot of time exploring inside before exiting. Our algorithm proceeds by “simulating” polynomially many jumps between the children of each cluster, before exiting that cluster. The resulting jumps are then stitched together at all levels of the hierarchy to form a partial subset of the transcript of a random walk.

The shallow “simulation” of edges jumping across children of a cluster in the hierarchy can be done in RNC by using a doubling trick as in the work of Teng [31]; in order to “simulate”  $L$  jumping edges, we combine the first  $L/2$  with the last  $L/2$  in a recursive fashion. A naive

implementation of this is not parallelizable however, as one needs to know *where* the first  $L/2$  jumps eventually land before “simulating” the rest. However since the number of locations is polynomially bounded, one can precompute an answer for each possible landing location in parallel to simulating the first  $L/2$  edges. Once shallow jumps are simulated, our algorithm then proceeds by stitching these jumping edges with jumping edges of one level lower (i.e., inside of the children clusters), and so on. Again, a naive implementation of this stitching is not in RNC, but we employ a similar doubling trick and an additional caching trick to parallelize everything. We then argue that with high probability all of the edges extracted by this algorithm contain the first-visit edges to every vertex.

## 2 Preliminaries

We use the notation  $[n]$  to denote the set  $\{1, \dots, n\}$ . We use the notation  $\tilde{O}(\cdot)$  to hide polylogarithmic factors. When we use the term high probability, we mean with probability  $1 - \text{poly}(\frac{1}{n})$ , where  $n$  is the size of the input, and the polynomial can be taken arbitrarily large by appropriately setting parameters.

### 2.1 Graph Theory Notations

When a graph  $G = (V, E)$  is clear from the context, we use  $n$  to refer to  $|V|$  and  $m$  to refer to  $|E|$ .

For a subset of vertices  $S \subset V$ ,  $\delta^+(S)$  denotes the set all incoming edges  $\{e = (u, v) \mid v \in S, u \notin S\}$ . Similarly,  $\delta^-(S)$  will denote the set of all outgoing edges  $\{e = (u, v) \mid u \in S, v \notin S\}$ . Lastly, let  $G(S)$  denote the subgraph induced by  $S$ .

► **Definition 2.** *Given a weighed graph  $G = (V, E)$  with weights  $w : E \rightarrow \mathbb{R}_{\geq 0}$ , a subset of the vertices  $S \subseteq V$  is said to be strongly connected by edges of weight  $w_c$  if for every  $s, t \in S$ , there exists a path of edges inside  $S$  connecting  $s$  to  $t$  such that every edge  $e$  of the path has weight  $w(e) \geq w_c$ .*

► **Definition 3.** *An arborescence is a directed graph rooted at vertex  $r$  such that for any other vertex  $v$ , there is exactly one path from  $v$  to  $r$ .*

Arborescences are also known as directed rooted trees and are a natural analog of spanning trees in directed graphs. When a background graph  $G = (V, E)$  is clear from context, by an arborescence we mean a subgraph of  $G$  that is an arborescence.

Given digraph  $G = (V, E)$  together with a weight function  $w : E \rightarrow \mathbb{R}_{> 0}$ , the random arborescence distribution is the distribution that assigns to each arborescence  $T$  probability

$$\mathbb{P}[T] \propto \prod_{e \in T} w(e).$$

When  $w$  is not given, it is assumed to be the constant 1 function, and the random arborescence distribution becomes uniformly distributed over all arborescences. We view an undirected graph  $G = (V, E)$  as a directed graph with double the number of edges, with each undirected edge producing two directed copies in the two possible directions. It is easy to see that the weighted/uniform random arborescence distribution on the directed version of an undirected graph is the same as the weighted/uniform spanning tree distribution on the original graph; viewing each arborescence without directions yields the corresponding spanning tree.

We call a (possibly weighted) digraph  $G = (V, E)$  Eulerian if

$$\sum_{e \in \delta^+(v)} w(e) = \sum_{e \in \delta^-(v)} w(e)$$

for all vertices  $v$ . Note that the directed version of an undirected graph is automatically Eulerian.

## 2.2 Random Walks and Arborescences

Our approach centers around the Aldous-Broder algorithm on directed graphs [2, 6]. Their work reduces the task of randomly generating a spanning tree or arborescence to simulating a random walk on the graph until all vertices have been visited. While most famously known for generating spanning trees, this algorithm can be used to generate arborescences as well.

A weighted digraph defines a natural random walk. This is a Markov process  $X_0, X_1, \dots$ , where each  $X_i$  is obtained as a random neighbor of  $X_{i-1}$  by choosing an outgoing edge with probability proportional to its weight, and transitioning to its endpoint.

$$\mathbb{P}[X_i \mid X_{i-1}] \propto w(X_{i-1}, X_i).$$

A stationary distribution  $\pi$  is a distribution on the vertices such that if  $X_0$  is chosen according to  $\pi$ , then all  $X_i$  are distributed as  $\pi$ . Under mild conditions, namely strong connectivity and aperiodicity, the stationary distribution is unique.

A random walk on an undirected graph is known to be time-reversible. That is if  $X_0$  is started from the stationary distribution, then  $(X_i, X_{i+1})$  is identical in distribution to  $(X_{i+1}, X_i)$ . This does not hold for directed graphs. However the time reversal of the process  $\dots, X_i, X_{i+1}, \dots$  corresponds to a random walk on a different digraph.

► **Definition 4.** For a weighted digraph  $G = (V, E)$  with weights  $w : E \rightarrow \mathbb{R}_{\geq 0}$  and stationary distribution  $\pi$ , define the time-reversal to be the graph  $G' = (V, E')$  on the same set of vertices, with edges reversed in direction, and weights given by

$$w'(v, u) = \pi(u)w(u, v)/\pi(v).$$

The random walk on  $G'$  shares the same stationary distribution  $\pi$  as  $G$ . The random walk on  $G'$  (started from  $\pi$ ) is identical in distribution to the time-reversed random walk on  $G$  (started from  $\pi$ ); see [23].

► **Theorem 5** ([2, 6]). Suppose that  $G = (V, E)$  is a strongly connected weighted graph, with weights given by  $w : E \rightarrow \mathbb{R}_{> 0}$ . Perform a time-reversed random walk, starting from a vertex  $r$ , until all vertices are visited at least once. For each vertex  $v \in V \setminus \{r\}$ , record the edge used in the random walk to reach  $v$  for the first time. Let  $T$  be the collection of all these first-visit edges (with directions reversed). Then  $T$  is an arborescence of  $G$  rooted at  $r$ , and

$$\mathbb{P}[T] \propto \prod_{e \in T} w(e)$$

This allows us to sample  $r$ -rooted arborescence from a digraph by performing a random walk on the time-reversal. It is also known that among all arborescences, the total weight of those rooted at  $r$  is proportional to  $\pi(r)$ , where  $\pi$  is the stationary distribution [2, 6]. Therefore to resolve Theorem 1, it is enough to show how to sample  $r$ -rooted arborescences.

► **Theorem 6.** There is an RNC algorithm which takes a directed graph  $G = (V, E)$  together with edge weights  $w : E \rightarrow \mathbb{R}_{\geq 0}$  and a root vertex  $r \in V$  as input and outputs a random  $r$ -rooted arborescence, where

$$\mathbb{P}[T] \propto \prod_{e \in T} w(e).$$

We can fix the root because the stationary distribution  $\pi$  can be computed in NC, by solving a system of linear equations.

## 2.3 Parallel Algorithms

In this paper we consider parallel algorithms run on the PRAM model, and we will construct algorithms to show that sampling problems are in the class RNC, the randomized version of NC. In this class, we are allowed to use polynomially (in the input size) many processors who share access to a common random access memory, and also have access to random bits. The running time of our algorithms must be polylogarithmic in the input size.

While our work hinges upon the simulation of a random walk, a process which is inherently sequential, for polynomially many steps, such a task is known to be in RNC through the use of a “doubling trick.”

► **Theorem 7** ([31]). *Suppose that  $G = (V, E)$  is a directed graph, with weights given by  $w : E \rightarrow \mathbb{R}_{\geq 0}$ . The transcript of a random walk starting from a given vertex  $v_0 \in V$  and running for  $L$  time steps can be produced in the PRAM model using  $\text{poly}(|E|, L)$  processors in  $\text{polylog}(|E|, L)$  time.*

Theorem 5 and Theorem 7 naturally lead to a parallel algorithm that randomly samples arborescences using  $\text{poly}(|E|, L)$  processors and  $\text{polylog}(|E|, L)$  time where  $L$  is the cover time of the digraph. However,  $L$  can be exponential in the size of the graph as the cover time depends closely on the edge weights of a graph. In directed graphs, the cover time can be exponential even if we do not allow weights. See Figures 1 and 2.

Luckily, Theorem 5 only needs the first-visit edges to produce the random arborescence. This insight has been heavily used to improve the running time of sequential algorithms for sampling spanning trees [21, 25, 28], by *shortcutting* the random walk. Here we use the same insight to design an RNC algorithm. Our algorithm identifies a hierarchy of clusters of vertices  $S \subseteq V$  and will only simulate incoming and outgoing edges of each cluster as opposed to the entire walk. To do this, we will use a well-known primitive that the probability of entering or exiting a cluster through any edge can be computed using a system of linear equations.

► **Lemma 8** (see, e.g., [28]). *Given a set  $S \subset V$  and vertex  $v \in S$ , the probability of a random walk started at  $v$  exiting  $S$  through any particular edge  $e \in \delta^-(S)$  can be computed by solving a system of linear equations involving the Laplacian.*

Some of the most powerful primitives for NC algorithms come from linear algebra. In particular, multiplying matrices, computing determinants, and inverting matrices all have NC algorithms [9]. Combining this with Lemma 8 we obtain the following folklore result.

► **Lemma 9.** *Given a set  $S \subseteq V$  and vertex  $v \in S$ , the probability of a random walk started at  $v$  exiting  $S$  through any particular edge  $e \in \delta^-(S)$  can be computed in NC.*

## 2.4 Schur Complements

A key tool which we shall use in our analysis of random walks is Schur complements.

► **Definition 10.** *For any weighted digraph  $G = (V, E)$ , for any subset of the vertices  $S \subseteq V$ , we define the graph  $G_S$  to be the Schur complement of  $\bar{S}$ .  $G_S$  is the directed graph formed by starting with the induced sub-graph of  $S$ . Then, for every pair of vertices  $(u, v)$  in  $S$ , add an edge from  $u$  to  $v$  with weight  $\deg(u) \mathbb{P}[u \rightarrow v]$ , where  $\mathbb{P}[u \rightarrow v]$  is the probability that a random walk on  $G$  currently at  $u$  exits  $S$  with the next move and its first return to  $S$  is at the vertex  $v$ .*

Then, it is easy to see that for any starting vertex  $v_0 \in S$ , the distribution over random walk transcripts in  $G_S$  starting at  $v_0$  is the same as the distribution over random walk transcripts in  $G$  starting at  $v_0$  with all vertices outside of  $S$  removed. We also observe that:

► **Proposition 11.** *For any Eulerian weighted digraph  $G = (V, E)$ , for any subset of the vertices  $S \subset V$ , the Schur complement  $G_S$  is also an Eulerian weighted digraph and the degree of any vertex in  $S$  is the same in  $G_S$  as in  $G$ .*

### 3 Reduction to Eulerian Graphs

A key part of our algorithm is the analysis of the time it takes for random walks to cover regions of a digraph. Cover times are in general difficult to analyze on directed graphs, but the situation becomes much easier on Eulerian graphs. For more precise statements, see Section 6. As a first step in our algorithm, we show how to reduce the design of sampling algorithms on arbitrary digraphs to Eulerian ones.

We can reduce the problem of sampling an arborescence of digraph  $G$  to sampling a random arborescence rooted at vertex  $r$  on strongly connected Eulerian digraph  $G''$  as follows in Algorithm 1. We begin by selecting the vertex at which the arborescence is rooted, using the Markov chain tree theorem [2, 6].

► **Theorem 12** (The Markov chain tree theorem). *Let  $G = (V, E)$  be a weighted directed graph. Assume that the natural Markov chain associated with  $G$  has stationary distribution  $\pi = (\pi_1, \dots, \pi_n)$ . Then we have the following relationship between  $\pi$  and the arborescences of  $G$ :*

$$\pi_i = \frac{\sum \{w(T) \mid T \text{ arborescence rooted at } i\}}{\sum \{w(T) \mid T \text{ arborescence}\}},$$

where  $w(T)$  is product of edge weights in  $T$ .

Finding the stationary distribution of a random walk on some graph  $G$  reduces to solving a system of  $n$  linear equations and can be done in NC.

After the root  $r \in V$  of an arborescence is selected, we can add outgoing edges from  $r$  to graph  $G$  to guarantee that  $G$  is strongly connected. As no arborescence rooted at  $r$  will contain these new edges, the addition of such edges does not affect the distribution of arborescences rooted at  $r$ . Then, we note that for any vertex  $v$ , if we multiply the weights of all edges in  $\delta^-(v)$  by some constant, the distribution of arborescences rooted at any vertex does not change. We can therefore rescale edges to ensure that the resulting graph is Eulerian.

► **Proposition 13.** *Graph  $G''$  is Eulerian.*

**Proof.** We have that, for all  $v$  in  $G'$

$$\sum_{(u,v) \in \delta^+(v)} \pi'(u) \frac{w'(u,v)}{\deg'_{\text{out}}(u)} = \pi'(v)$$

Then, considering  $G''$  :

$$\begin{aligned} \deg''_{\text{in}}(v) &= \sum_{(u,v) \in \delta^+(v)} w''(u,v) = \sum_{(u,v) \in \delta^+(v)} \frac{w'(u,v)\pi'(u)}{\deg'_{\text{out}}(u)} = \pi'(v) \\ &= \pi'(v) \sum_{(v,x) \in \delta^-(v)} \frac{w'(v,x)}{\deg'_{\text{out}}(v)} = \sum_{(v,x) \in \delta^-(v)} w''(v,x) = \deg''_{\text{out}}(v) \end{aligned} \quad \blacktriangleleft$$

---

**Algorithm 1** Reduction to strongly-connected Eulerian graphs.
 

---

```

Compute the stationary distribution  $\pi(v)$  of a random walk on  $G$ 
Choose vertex  $r$  to be the root of the arborescence with probability  $\pi(r)$ 
 $G' = (V, E') \leftarrow G$ 
for  $v \in V \setminus \{r\}$  in parallel do
  if  $e' = (r, v) \notin E$  then
    Add  $e'$  to  $E'$  with weight  $w'(e) = 1$ 
Compute the stationary distribution  $\pi'(v)$  of a random walk on  $G'$ 
 $G'' = (V, E'') \leftarrow G'$ 
for  $v \in V$  do
  for  $e = (v, u) \in E''$  do
     $w''(e) \leftarrow \frac{w'(e)}{\deg_{out}(v)} \pi'(v)$ 
Randomly sample an arborescence rooted at  $r$  from  $G''$ 

```

---

Thus, in RNC, the task of randomly sampling an arborescence in some digraph can be reduced to the task of randomly sampling an arborescence rooted at some vertex  $r$  from a strongly connected Eulerian digraph.

## 4 Cycle Decomposition

Because Theorem 5 only needs the first-visit edges to produce a random arborescence, our main idea is to create a hierarchical clustering of the graph that we call  $\mathcal{T}$ . Every element  $\mathcal{S} \in \mathcal{T}$  in the clustering is a subset of  $V$  which is strongly connected by edges of relatively high weight compared to the edges in  $\delta^-(\mathcal{S})$ . Intuitively, a random walk will spend much time traversing edges inside a cluster, before venturing out. Aside from first visit edges, any other traversals do not need to be simulated, thus much of the work can be avoided by only simulating the first few edges which enter or exit a cluster. Consider the pseudocode in Algorithm 2 for generating one such decomposition:

---

**Algorithm 2** Generating a hierarchical decomposition.
 

---

```

for edge  $e \in G$  in parallel do
  Find a cycle  $C_e$  of edges such that  $e \in C_e$  and for every  $e' \in C_e$ ,  $w_{e'} \geq \frac{w_e}{m}$  using
    Algorithm 3
Sort the cycles found by minimum edge weight in decreasing order  $C_1, C_2, \dots, C_m$ 
 $\mathcal{T} \leftarrow \{\}$ 
for  $i = 1, 2, \dots, m$  in parallel do
  Find  $\mathcal{S}_{i,1}, \mathcal{S}_{i,2}, \dots, \mathcal{S}_{i,j}$ , the vertex sets of the connected components in
     $(V, C_1 \cup C_2 \cup \dots \cup C_i)$ 
  Add all elements found to  $\mathcal{T}$ 
for  $\mathcal{S}_{i,j} \in \mathcal{T} \setminus \mathcal{S}_{m,1}$  in parallel do
  Find the node of the form  $\mathcal{S}_{i+1,k}$  such that  $\mathcal{S}_{i,j} \subset \mathcal{S}_{i+1,k}$  and assign  $\mathcal{S}_{i+1,k}$  as the
    parent of  $\mathcal{S}_{i,j}$ 
Contract duplicate nodes in  $\mathcal{T}$ 

```

---

■ **Algorithm 3** FindCycle( $e = (e_0, e_1), G = (E, V)$ ).

---

```

Construct  $G' = (V, E')$ , where  $E' = \{e' \in E : w_{e'} \geq \frac{w_e}{m}\}$ 
for  $v_1, v_2 \in V$  in parallel do
    if  $(v_1, v_2) \in E'$  then
         $R(v_1, v_2, 1) \leftarrow \text{True}$ 
for  $v \in V$  in parallel do
     $R(v, v, 0) \leftarrow \text{True}$ 
     $R(v, v, 1) \leftarrow \text{True}$ 
for  $l \in \{2, 4, \dots, 2^{\lceil \ln n \rceil}\}$  do
    for  $v_1, v_2, v_3 \in V$  in parallel do
        if  $R(v_1, v_2, l/2)$  and  $R(v_2, v_3, l/2)$  then
             $R(v_1, v_3, l) \leftarrow \text{True}$ 
 $c_0 \leftarrow e_1, c_{2^{\lceil \ln n \rceil}} \leftarrow e_0$ 
for  $l \in \{2^{\lceil \ln n \rceil - 1}, 2^{\lceil \ln n \rceil - 2}, \dots, 1\}$  do
    for  $i \in [2^{\lceil \ln n \rceil}]$  such that  $l$  is the largest power of 2 which divides  $i$  in parallel
        do
             $\text{Set } c_i \text{ to be some vertex such that } R(c_{i-l}, c_i, l) \text{ and } R(c_i, c_{i+l}, l)$ 
Prune the transcript of vertices  $\{c_0, c_1, \dots, c_{2^{\lceil \ln n \rceil}}\}$  to remove any duplicates and
return the resulting cycle.

```

---

We use Algorithm 3 to construct a cycle of comparably high-weight edges containing a given edge  $e$ . The collection of these cycles is a “loose decomposition” of the Eulerian graph into cycles. While an Eulerian graph can be decomposed into cycles in general, we do not know if this can be done in NC. Instead we find a collection of cycles whose sum and  $\text{poly}(m)$  times it sandwich the Eulerian graph.

For each edge  $e$ , Algorithm 3 successfully returns a cycle since,

► **Proposition 14.** *In directed weighted Eulerian graph  $G = (V, E)$  for any edge  $e \in E$ , there exists a cycle of edges  $C_e$  such that  $e \in C_e$  and for all  $e' \in C_e, w_{e'} \geq \frac{w_e}{m}$*

**Proof.** Note that any Eulerian digraph can be decomposed into at most  $m$  cycles where each cycle contains edges of uniform weight. Then, for any edge  $e$ , one of these cycles must have weight at least  $\frac{w_e}{m}$ . ◀

Given that a cycle is found containing every edge in  $G$ , it follows that Algorithm 2 successfully generates a hierarchical decomposition which satisfies:

► **Proposition 15.**  *$\mathcal{T}$  is a laminar family, i.e. has the following properties:*

1. Every node  $\mathcal{S}$  of  $\mathcal{T}$  is a subset of  $V$  and is the vertex set of a connected component of  $G$ .
2. Children of any node in  $\mathcal{T}$  are proper subsets of it.
3.  $|\mathcal{T}| \leq 2n$ .

Given this clustering  $\mathcal{T}$ , for any  $\mathcal{S} \in \mathcal{T}$ , we say an edge  $e \in E$  jumps between children of  $\mathcal{S}$  if  $\mathcal{S}$  is the lowest node in  $\mathcal{T}$  which contains both endpoints of  $e$ . We call  $e$  a *jumping edge* of  $\mathcal{S}$ .

In addition, we note that

► **Lemma 16.** *For any  $\mathcal{S} \in \mathcal{T}$ , let  $w_{\max}(\mathcal{S})$  be the maximum weight among the jumping edges of  $\mathcal{S}$ .  $G(\mathcal{S})$  is strongly connected by edges of weight  $\frac{w_{\max}(\mathcal{S})}{m}$ .*

**Proof.** We prove by contradiction. Assume that there is some edge  $e$  jumping between children of  $\mathcal{S}$  and two vertices  $u, v \in \mathcal{S}$  such that every path between  $u, v$  contains an edge of weight less than  $\frac{w_e}{m}$ . Let the cycles which connect  $\mathcal{S}$  in Algorithm 2 be  $C_1, \dots, C_k$ , with  $C_k$  being the cycle with an edge of minimum weight. Then, consider the path of edges connecting  $u$  to  $v$  only containing edges in these cycles. The weight of every edge in the path must be greater than  $w(C_k)$ , the weight of the minimum weight edge in  $C_k$ . Thus by our assumption we must have that  $\frac{w_e}{m} > w(C_k)$ .

But now consider  $C_e$ , the cycle found containing edge  $e$  with minimum edge weight  $w(C_e) \geq \frac{w_e}{m}$ . As  $w(C_e) > w(C_k)$ , this cycle must have been used to construct a child of  $\mathcal{S}$  in  $\mathcal{T}$ . This implies the  $e$  is contained in a child of  $\mathcal{S}$  and is therefore not a jumping edge of  $\mathcal{S}$ , a contradiction.  $\blacktriangleleft$

Lemma 16 intuitively states that the nodes in  $\mathcal{T}$  are tightly connected by edges of relatively high weight compared to incoming or outgoing edges. This will be critical in bounding the number of edges which need to be simulated.

## 5 Parallel Sampling

For clarity, a partially sampled random walk shall be represented as an alternating series of clusters and edges:  $\mathcal{S}_1, e_1, \mathcal{S}_2, e_2, \dots$ , where each  $\mathcal{S}_i \in \mathcal{T}$  and  $e_i \in \delta^-(\mathcal{S}_i) \cap \delta^+(\mathcal{S}_{i+1})$ . The sequence has a natural interpretation of a random walk in  $\mathcal{S}_i$  which then exits  $\mathcal{S}_i$  through  $e_i$  to continue in  $\mathcal{S}_{i+1}$  before traversing  $e_{i+1}$  and so on.

Once we have a hierarchical decomposition  $\mathcal{T}$  found in Section 4, a natural way to use such a decomposition is to simulate a random walk as follows:

1. Simulate just the edges jumping between high-level clusters of a random walk, producing a transcript of the form  $\mathcal{S}_1, e_1, \mathcal{S}_2, e_2, \dots$ .
2. For each  $i$ , recursively simulate a random walk on  $\mathcal{S}_i$  conditioned on exiting  $\mathcal{S}_i$  through edge  $e_i$ .

While this recursive procedure as described is not in RNC, using doubling tricks and memoization, we show how to perform this in RNC. One can view this as a generalization of the doubling trick used by Teng [31].

### 5.1 Simulating Jumping Edges

To simulate edges jumping across children of a node, we generalize the techniques of [31] to the following:

► **Theorem 17.** *Suppose that  $G = (V, E)$  is a directed graph, with weights given by  $w : E \rightarrow \mathbb{R}_{\geq 0}$ . Let  $\mathcal{S} \subseteq V$  be the disjoint union of  $\mathcal{S}_1, \mathcal{S}_2, \dots, \mathcal{S}_k$ , where  $\mathcal{S}$  and each  $\mathcal{S}_i$  is strongly connected. The transcript of first  $L$  edges jumping across different  $\mathcal{S}_i$  in a random walk starting from a given vertex  $v_0 \in \mathcal{S}$  and conditioned on exiting  $\mathcal{S}$  through some edge  $e \in \delta^-(\mathcal{S})$  can be produced in the PRAM model using  $\text{poly}(|E|, L)$  processors and  $\text{polylog}(|E|, L)$  time.*

**Proof.** We denote this function  $\text{JumpingEdges}(\mathcal{S}, v_0, e, L)$ . See Algorithm 4 for pseudocode. Note that we can condition a walk on  $\mathcal{S}$  to exit via some edge  $e \in \delta^-(\mathcal{S})$  by considering a random walk on the graph induced by  $\mathcal{S}$  with an additional edge  $e$  and an absorbing state at the endpoint of  $e$ . For any vertex  $v \in \mathcal{S}$ , let  $\mathcal{S}_v$  denote the unique  $\mathcal{S}_i$  which contains  $v$ .

From Lemma 9, for any  $v \in \mathcal{S}$ , the probability that a random walk currently at  $v$  exits  $\mathcal{S}_v$  through each edge in  $\delta^-(\mathcal{S}_v)$  can be computed in NC. Thus, after using  $\text{poly}(|E|, L)$  processors and  $\text{polylog}(|E|, L)$  time to compute all such probabilities for every vertex  $v \in \mathcal{S}$ ,

### 83:12 Sampling Arborescences in Parallel

we can assume access to a deterministic function  $\text{Next}(v, X)$  which takes a vertex  $v \in \mathcal{S}$  and number  $X \in [0, 1]$  and outputs an edge  $e \in \delta^-(\mathcal{S}_v)$  such that if  $X$  is chosen uniformly from  $[0, 1]$ , then the probability that  $\text{Next}(v, X)$  returns some edge  $e \in \delta^-(\mathcal{S}_v)$  is the probability a random walk currently at  $v$  exits  $\mathcal{S}_v$  through edge  $e$ .

Given this function, if we generate independent uniformly random numbers  $X_1, \dots, X_L \in [0, 1]$ , the transcript of the jumping edges in random walk can be extracted by starting at  $v = v_0$  and repeatedly applying  $\text{Next}(v, X_i)$  to get the next vertex  $v$ , for  $i \in [L]$ . Of course, a naive implementation does not leverage parallelism, so we instead use a doubling trick.

We compute the values  $\text{End}(v, t, l)$  which would be the final edge jumping between children of  $\mathcal{S}$  when we run a random walk starting at  $v$ , and applying  $\text{Next}$  with random inputs  $X_t, X_{t+1}, \dots, X_{t+l-1}$ . For  $l = 1$ , these are 1-step random walks and we use  $\text{Next}$  to compute them. For simplicity, we allow the first argument of  $\text{End}$  to also be an edge, in which case the random walk starts at the ending vertex of that edge. Then we use the following identity, which allows us to compute  $\text{End}$  values for a particular  $l$  from  $\text{End}$  values for  $\frac{l}{2}$ .

$$\text{End}(v, t, l) = \text{End}(\text{End}(v, t, l/2), t, l/2)$$

This is because we can break an  $l$ -step random walk into two  $l/2$ -step random walks. So we can compute all  $\text{End}$  values when  $l$  ranges over powers of 2, in  $\log(L)$  steps.

Finally to compute the edge taken by the random walk at any time  $l = 1, \dots, L$ , we simply write down  $l$  as a sum of powers of 2, and repeatedly use the  $\text{End}$  function to compute the  $l$ -th edge of the random walk which jumps between children of  $\mathcal{S}$ . ◀

---

■ **Algorithm 4**  $\text{JumpingEdges}(\mathcal{S}, v_0, e_{\text{end}}, L)$ .

---

```

for  $t \in \{1, 2, \dots, L\}$  in parallel do
    Let  $X_t$  be a uniformly random number sampled from  $[0, 1]$ 
    for  $v \in \mathcal{S}$  in parallel do
         $\text{End}(v, t, 1) \leftarrow \text{Next}(v, X_t)$ 
for  $l \in \{2, 4, 8, \dots, 2^{\lfloor \ln L \rfloor}\}$  do
    for  $v \in \mathcal{S}, t \in \{0, 1, \dots, L - 1 - l\}$  in parallel do
         $\text{End}(v, t, l) \leftarrow \text{End}(\text{End}(v, t, \frac{l}{2}), t, \frac{l}{2})$ 
for  $l \in 1, 2, \dots, L$  in parallel do
    Decompose  $l$  as a sum of subset  $S \subset \{1, 2, \dots, 2^{\lfloor \ln L \rfloor - 1}\}$ 
     $e \leftarrow (*, v_0)$ 
     $t \leftarrow 0$ 
    for  $s \in S$  do
         $e \leftarrow \text{End}(e, t, s)$ 
         $t \leftarrow t + s$ 
     $e_l \leftarrow e$ 
     $v_l \leftarrow$  the ending vertex of  $e_l$ 
if  $e_k = e_{\text{end}}$  for some  $k$  then
     $\text{return } \mathcal{S}_{v_0}, e_1, \mathcal{S}_{v_1}, e_2, \dots, \mathcal{S}_{v_{k-1}}, e_k = e_{\text{end}}$ 
else
     $\text{return } \mathcal{S}_{v_0}, e_1, \mathcal{S}_{v_1}, e_2, \dots, \mathcal{S}_{v_{L-1}}, e_L, \mathcal{S}, e_{\text{end}}$ 

```

---

► **Remark 18.** For clarity of exposition, we allow sampling numbers from  $[0, 1]$ . However sampling a number with polynomially many bits is enough for our purposes. In our algorithms, we only need to compare our samples  $X_t$  with deterministic numbers derived from the input. To this end, we can simply sample the first  $N$  digits of the binary expansion of  $X_t$  for some large  $N$ . The probability that the comparison of  $X_t$  and a fixed number is not determined from the first  $N$  digits is  $2^{-N}$ . By taking  $N$  to be polynomially large, the probability of failure will be bounded by an exponentially small number. If one insists on avoiding even this small probability of failure, we can continue sampling digits of  $X_t$  whenever we run into a situation where the first  $N$  are not enough. Since the probability of running into failure is very small, the overall expected running time still remains polylogarithmic.

## 5.2 Extracting First-Visit Edges

For a cluster, once we know which edges jump across its children, we can recursively fill in the transcript of the walk. This is because we now have a similar subproblem for each child node, where we have a starting vertex, and a prespecified exit edge. However, a naive implementation of this is not in RNC.

Instead our strategy is to again use a doubling trick. Consider a node  $\mathcal{S}$  of  $\mathcal{T}$  and a vertex  $v \in \mathcal{S}$ . Using the algorithm **JumpingEdges**, we can extract the edges that jump across children of  $\mathcal{S}$ . We can then extend these to include edges that jump across children of children of  $\mathcal{S}$  by more applications of **JumpingEdges**. We will construct a function **AllEdges** $(\mathcal{S}, v, e, L, l)$  that besides the arguments to **JumpingEdges** also takes an integer  $l \geq 1$ . The goal of this function is to extract from the transcript of a random walk started at  $v$  and conditioned on exiting  $\mathcal{S}$  through  $e$ , the first  $L$  edges which jump between descendants of depth at most  $l$  below  $\mathcal{S}$  in  $\mathcal{T}$ . Then, each intermediate node in the transcript is either an individual vertex, an  $l$ th descendant of  $\mathcal{S}$ , or a cluster for which  $L$  edges jumping between its children have already been found. We will show that for polynomially large  $L$ , this transcript will contain all first-visit edges with high probability.

A natural approach for computing **AllEdges** is as follows. We already know how to compute **AllEdges** for  $l = 1$ ; that is just a call to **JumpingEdges**. Once the value of **AllEdges** has been computed for all settings of parameters for a particular  $l$ , we can compute it for  $2l$  by the following procedure:

1. Let the transcript returned by **AllEdges** $(\mathcal{S}, v, e, L, l)$  be  $\mathcal{S}_1, e_1, \mathcal{S}_2, e_2, \dots, \mathcal{S}_k, e_k$ .
2. For each intermediate node  $\mathcal{S}_i$  that is not a single vertex, if the transcript does not already contain  $L$  edges jumping between children of  $\mathcal{S}_i$ , let  $u$  be the endpoint of  $e_{i-1}$  and replace  $\mathcal{S}_i, e_i$  with **AllEdges** $(\mathcal{S}_i, u, e, L, l)$
3. Trim the transcript to only contain at most the first  $L$  edges jumping between children of any node

There is one key problem with this approach. We cannot precompute **AllEdges** $(\cdot, \cdot, \cdot, \cdot, l)$  and use the same precomputed answer to fill in the gaps for larger values of  $l$ . Each time we need to use **AllEdges** for a particular setting of its input parameters, we really need to use fresh randomness; otherwise the transcript we extract will not be from a true random walk.

We resolve this by using a caching trick. Instead of computing **AllEdges** $(\mathcal{S}, v, e, L, l)$  for each setting of parameters once and reusing the same output for larger subproblems, we compute  $M$  possible answers for a large enough  $M$  and store all  $M$  answers. For larger subproblems, every time that we need to use the values of a smaller subproblem, we randomly pick one of the stored  $M$  answers. We will inevitably reuse some of the answers in this process; however when we restrict our attention to the unraveling of a particular answer for a subproblem there is a high probability of not having reused any answers. We will formalize this in Lemma 19.

Pseudocode for computing **AllEdges** can be found in Algorithm 5. In the end we use  $\text{AllEdges}(V, v, \emptyset, L, |V|)$  to extract a list of edges, and with high probability all first-visit edges will be among this list

■ **Algorithm 5** Computing the random walk transcript extracts.

---

```

for  $\mathcal{S} \in \mathcal{T}, e \in \delta^-(\mathcal{S}) \cup \{\emptyset\}, v \in \mathcal{S}, i \in [M]$  in parallel do
   $\text{AllEdges}(\mathcal{S}, v, e, L, 1)[i] \leftarrow \text{JumpingEdges}(\mathcal{S}, v, e, L)$ 
for  $l \in \{1, 2, \dots, 2^{\lceil \lg L \rceil - 1}\}$  do
  for  $\mathcal{S} \in \mathcal{T}, e \in \delta^-(\mathcal{S}) \cup \{\emptyset\}, v \in \mathcal{S}, i \in [M]$  in parallel do
    if  $l$  is greater than depth of the deepest child of  $\mathcal{S}$  then
       $\text{AllEdges}(\mathcal{S}, v, e, L, 2l)[i] \leftarrow \text{AllEdges}(\mathcal{S}, v, e, L, l)[i]$ 
    else
      Let  $\mathcal{S}_1, e_1, \mathcal{S}_2, e_2, \dots, \mathcal{S}_k$  be the output of  $\text{AllEdges}(\mathcal{S}, v, e, L, l)[i]$ 
      for  $j \in [k]$  in parallel do
        if the transcript does not already contain  $L$  edges jumping between
          children of  $\mathcal{S}_j$  then
          Replace  $\mathcal{S}_j, e_j$  with a randomly chosen instance of
             $\text{AllEdges}(\mathcal{S}_j, v', e_j, L, l)$  where  $v'$  is the endpoint of  $e_{j-1}$ 
      Trim the resulting transcript to only contain at most the first  $L$  edges
        jumping between children of any node. Save the resulting transcript as a
        solution to  $\text{AllEdges}(\mathcal{S}, v, e, L, 2l)[i]$ 
  if the final transcript of  $\text{AllEdges}(V, v, \emptyset, L, |V|)$  contain multiple subsequences
    which depend on the same call to JumpingEdges then
      Replace all but the first subsequence with a freshly sampled transcript

```

---

► **Lemma 19.** *For  $M = \text{poly}(L)$ , when we unravel the recursion tree for the computation of the value  $\text{AllEdges}(V, v, \emptyset, L, |V|)$ , no stored answer of **AllEdges** for any of the subproblems will be used more than once with high probability.*

**Proof.** Note that for any  $\mathcal{S} \in \mathcal{T}, v \in \mathcal{S}, e \in \delta^-(\mathcal{S})$ , the recursion tree for an answer to  $\text{AllEdges}(V, v, \emptyset, L, |V|)$  will rely on at most  $L$  calls to  $\text{JumpingEdges}(\mathcal{S}, v, e, L)$  since each call to  $\text{JumpingEdges}(\mathcal{S}, v, e, L)$  corresponds to a subsequence of the final transcript which ends in  $e$ , and  $e$  can only occur  $L$  times in the transcript by the definition of **AllEdges**. As each sample of  $\text{JumpingEdges}(\mathcal{S}, v, e, L)$  is chosen uniformly at random from  $M$  samples, for polynomially large  $M$ , the probability of the same sample being chosen twice can be made small and of the form  $\frac{1}{\text{poly}(n)}$ . Lastly via a union bound over polynomially many possible combinations of arguments for **JumpingEdges**, we have that for polynomially large  $M$ , which high probability no stored answer of **JumpingEdges** or **AllEdges** will be used more than once. ◀

Putting everything together, we have shown that:

► **Theorem 20.** *Suppose that  $G = (V, E)$  is a directed graph, with weights given by  $w : E \rightarrow \mathbb{R}_{>0}$ . Let  $\mathcal{T}$  denote a hierarchical decomposition of  $G$ . The transcript of a random walk starting at  $v_0 \in V$  which contains first  $L$  edges jumping between children of  $\mathcal{S}$  for any  $\mathcal{S} \in \mathcal{T}$  can be produced in the PRAM model using  $\text{poly}(|E|, L)$  processors in  $\text{polylog}(|E|, L)$  expected time.*

## 6 Hierarchical Exploration Time

The last element needed to obtain an RNC algorithm for the random sampling of arborescences is to show that for the decomposition achieved above, for polynomially large  $L$ , simulating the first  $L$  edges which jump across each node  $S \in \mathcal{T}$  will contain all first-visit edges to each vertex with high probability. We do this by bounding the number of edge traversals between children of each node before that node is covered. We build on techniques developed by Boczkowski, Peres, and Sousi [5].

We start by bounding the number of times a given vertex is visited before cover time. For any  $v, s, t \in V$ , let  $H_v(s, t)$  denote the expected number of times a random walk starting at  $s$  visits  $v$  before reaching  $t$ ; in the case that  $s = t$ ,  $H_v(s, s)$  denotes the number of times a walk starting at  $s$  reaches  $v$  before returning to  $s$ .

It is easy to see that  $H_v$  satisfies a triangle inequality, namely:

► **Proposition 21.** *On any directed graph  $G = (V, E)$ , for any  $v, s, t, u \in V$ :  $H_v(s, t) \leq H_v(s, u) + H_v(u, t)$ .*

Additionally, as the stationary distribution of vertices on an Eulerian graph is proportional to the degree of a vertex, it follows that:

► **Proposition 22.** *On any directed Eulerian graph  $G = (V, E)$ , for any  $v, s \in V$ :  $H_v(s, s) = \frac{1}{\pi(s)} \pi(v) = \frac{\deg(v)}{\deg(s)}$*

**Proof.** Consider the Schur complement  $G_S$  where  $S = \{v, s\}$ . Since  $G$  is Eulerian, so is  $G_S$  and the degrees of  $v, s$  are the same in  $G$  and  $G_S$ . Letting the weights of edges in  $G_S$  be  $w(v, s)$ ,  $w(s, v)$ ,  $w(v, v)$ ,  $w(s, s)$ , we must have  $w(s, v) = w(v, s)$  for  $G_S$  to be Eulerian. As random walks on  $G_S$  are distributed like random walks on  $G$  whose transcripts have been restricted to only contain vertices in  $S$ , the values of  $H_v(s, s)$ ,  $H_v(v, s)$  are the same for a walk on  $G$  as for one on  $G_S$ . Considering one-step transitions, we can construct the following system of equations:

$$\begin{aligned} H_v(s, s) &= \frac{w(s, v)}{\deg(s)} (H_v(v, s) + 1) + \frac{w(s, s)}{\deg(s)} 0, \\ H_v(v, s) &= \frac{w(v, v)}{\deg(v)} (H_v(v, s) + 1) + \frac{w(v, s)}{\deg(v)} 0. \end{aligned}$$

Solving yields  $H_v(v, s) = \frac{w(v, v)}{w(v, s)}$  and  $H_v(s, s) = \frac{w(s, v)}{\deg(s)} \left( \frac{w(v, v)}{w(v, s)} + 1 \right) = \frac{w(s, v)}{\deg(s)} \frac{\deg(v)}{w(v, s)} = \frac{\deg(v)}{\deg(s)}$ . ◀

For any two vertices which are connected by an edge, we have:

► **Lemma 23.** *On any directed Eulerian graph  $G = (V, E)$ , for any  $v, s, t \in V$  such that  $e = (s, t) \in E$ ,  $H_v(s, t) \leq \frac{\deg(v)}{w(s, t)}$*

**Proof.** Note that every time the walk is currently at  $s$ , there is a  $\frac{w(s, t)}{\deg(s)}$  chance of moving to  $t$ , thus, in expectation, the expected number of times the walk returns to  $s$  before reaching  $t$  is at most  $\frac{\deg(s)}{w(s, t)}$ . Between each return to  $s$ , the expected number of visits to  $v$  is  $\frac{\deg(v)}{\deg(s)}$  by Proposition 22. Thus, we conclude that:

$$H_v(s, t) \leq \frac{\deg(s)}{w(s, t)} \frac{\deg(v)}{\deg(s)} = \frac{\deg(v)}{w(s, t)}. \quad \blacktriangleleft$$

On graphs which are strongly connected by edges of some weight  $w_c$ , this observation leads to the conclusion that:

► **Lemma 24.** *On an Eulerian directed graph  $G = (V, E)$  strongly connected by edges of weight  $w_c$ , for any  $s, t \in V$ ,  $H_s(s, t) \leq \frac{\deg(s)n}{w_c}$*

**Proof.** By connectivity assumptions, there exists a sequence of at most  $n$  vertices  $s = v_0, v_1, \dots, v_k = t$  which form a path connecting  $s$  and  $t$  such that  $w(v_{i-1}, v_i) \geq w_c$  for all  $i \in [k]$ . Then, combining Proposition 21 with Lemma 23,

$$H_s(s, t) \leq \sum_{i=1}^k H_s(v_{i-1}, v_i) \leq \sum_{i=1}^k \frac{\deg(s)}{w(v_{i-1}, v_i)} \leq \frac{n \deg(s)}{w_c}. \quad \blacktriangleleft$$

This trivially bounds the expected number of returns to a vertex  $s$  before a graph  $G$  is covered by a random walk by  $\frac{n^2 \deg(s)}{w_c}$ .

► **Remark 25.** While this bound is sufficient for our purposes, using Matthew's trick, this bound can be further tightened to  $\frac{n \log n \deg(s)}{w_c}$  [26].

► **Lemma 26.** *For any node  $\mathcal{S} \in \mathcal{T}$  in the decomposition obtained by Algorithm 2, the expected number of edges traversed between children of  $\mathcal{S}$  before every vertex in  $\mathcal{S}$  has been visited is at most  $n^2 m^2$ .*

**Proof.** For each edge  $e = (u, v)$  which jumps between children of  $\mathcal{S}$ , the expected number of times edge  $e$  is traversed is  $\frac{w_e}{\deg(u)}$  times the expected number of times vertex  $u$  is reached by a random walk before all vertices in  $\mathcal{S}$  are reached. To bound the number of times  $u$  is reached before  $\mathcal{S}$  is covered, consider a random walk on the Schur complement  $G_{\mathcal{S}}$ . The expected number of times  $u$  is reached in a random walk on  $G$  before  $\mathcal{S}$  is covered is the same as the expected number of times  $u$  is reached by a random walk on  $G_{\mathcal{S}}$  before  $G_{\mathcal{S}}$  is covered.

By Proposition 11,  $G_{\mathcal{S}}$  will be Eulerian and the degrees of all vertices in  $\mathcal{S}$  will be the same in  $G$  and  $G_{\mathcal{S}}$ . By Lemma 16,  $\mathcal{S}$  is strongly connected by edges of weight  $\frac{w_{\max}(\mathcal{S})}{m}$ , and so  $G_{\mathcal{S}}$  is as well. Then, by Lemma 24, the expected number of times  $u$  is hit before  $G_{\mathcal{S}}$  is covered is at most by  $\frac{\deg(u)n^2 m}{w_{\max}}$ . Thus, the expected number of times edge  $e$  is traversed before  $\mathcal{S}$  is covered is at most

$$\frac{\deg(u)n^2 m}{w_{\max}} \frac{w_e}{\deg(u)} \leq n^2 m$$

since  $w_c \geq \frac{w_e}{m}$ . As there are at most  $m$  jumping edges of  $\mathcal{S}$ , in expectation, at most  $n^2 m^2$  edge traversals between children of  $\mathcal{S}$  will occur before every vertex in  $\mathcal{S}$  has been reached.  $\blacktriangleleft$

Thus, for large enough  $L = \text{poly}(n, m)$ , by Markov's inequality, with high probability every node  $\mathcal{S} \in \mathcal{T}$  is covered by the time  $L$  edges have jumped across  $\mathcal{S}$ . This means the transcript returned by `AllEdges` will contain all first visit edges with high probability. As this transcript is polynomial in length, all first visit edges and the corresponding arborescence they form can be extracted and returned in NC.

## 7 Discussion and Open Problems

We showed how to sample arborescences, and as a special case spanning trees, from a given weighted graph using an RNC algorithm. While this is a step in resolving the disparity between parallel sampling and parallel counting algorithms, more investigation is needed. In particular, for the list of problems with determinant-based counting in Section 1, designing RNC sampling algorithms remains open.

One of these problems in particular, namely sampling Eulerian tours from an Eulerian digraph, is intimately connected to sampling arborescences, due to the BEST theorem [1, 34]. However the reduction, while polynomial-time implementable, is not known to be in NC.

► **Question 27.** Is there an algorithm for sampling Eulerian tours uniformly at random in Eulerian digraphs?

The important tool our result relied on was the Aldous-Broder algorithm. So it is natural to ask whether there are generalizations of the Aldous-Broder result to settings beyond spanning trees and arborescences. In particular the bases of a *regular matroid* are a proper generalization of spanning trees in a graph, and they have a decomposition in terms of graphic, co-graphic, and some special constant-sized matroids [29].

► **Question 28.** Can we sample from a regular matroid, or equivalently from a volume-based distribution defined by totally unimodular vectors in RNC?

Yet another direction for generalization are higher-dimensional equivalents of spanning trees and arborescences. For example, Gorodezky and Pak [15] provided a generalization of the algorithm of Wilson [35] for sampling arborescences from graphs to hypergraphs. While Wilson’s algorithm is different from that of Aldous-Broder, it is closely related. Can these generalizations be efficiently parallelized?

## Abstract

Mechanisms with money are commonly designed under the assumption that agents are quasi-linear, meaning they have linear disutility for spending money. We study the implications when agents with non-linear (specifically, convex) disutility for payments participate in mechanisms designed for quasi-linear agents. We first show that any mechanism that is truthful for quasi-linear buyers has a simple best response function for buyers with non-linear disutility from payments, in which each bidder simply scales down her value for each potential outcome by a fixed factor, equal to her target return on investment (ROI). We call such a strategy ROI-optimal. We prove the existence of a Nash equilibrium in which agents use ROI-optimal strategies for a general class of allocation problems. Motivated by online marketplaces, we then focus on simultaneous second-price auctions for additive bidders and show that all ROI-optimal equilibria in this setting achieve constant-factor approximations to suitable welfare and revenue benchmarks.

## Abstract

We introduce a model for ant trail formation, building upon previous work on biologically feasible local algorithms that plausibly describe how ants maintain trail networks. The model is a variant of a reinforced random walk on a directed graph, where ants lay pheromone on edges as they traverse them and the next edge to traverse is chosen based on the level of pheromone; this pheromone decays with time. There is a bidirectional flow of ants in the network: the forward flow proceeds along forward edges from source (e.g. the nest) to sink (e.g. a food source), and the backward flow in the opposite direction. Some fraction of ants are lost as they pass through each node (modeling the loss of ants due to exploration observed in the field). We initiate a theoretical study of this model. We note that ant navigation has inspired the field of ant colony optimization, heuristics that have been applied to several combinatorial optimization problems; however the algorithms developed there are considerably more complex and not constrained to being biologically feasible.

We first consider the linear decision rule, where the flow divides itself among the next set of edges in proportion to their pheromone level. Here, we show that the process converges to the path with minimum leakage when the forward and backward flows do not change over time. On the other hand, when the forward and backward flows increase over time (caused by positive reinforcement from the discovery of a food source, for example), we show that the process converges to the shortest path. These results are for graphs consisting of two parallel paths (a case that has been investigated before in experiments). Through simulations, we show that these results hold for more general graphs drawn from various random graph models; proving this convergence in the general case is an interesting open problem. Further, to understand the behaviour of other decision rules beyond the linear rule, we consider a general family of decision rules. For this family, we show that there is no advantage of using a non-linear decision rule, if the goal is to find the shortest or the minimum leakage path. We also show that bidirectional flow is necessary for convergence to such paths. Our results provide a plausible explanation for field observations, and open up new avenues for further theoretical and experimental investigation.

## Abstract

A prophet inequality states, for some  $\alpha \in [0, 1]$ , that the expected value achievable by a gambler who sequentially observes random variables  $X_1, \dots, X_n$  and selects one of them is at least an  $\alpha$  fraction of the maximum value in the sequence. We obtain three distinct improvements for a setting that was first studied by Correa et al. (EC, 2019) and is particularly relevant to modern applications in algorithmic pricing. In this setting, the random variables are i.i.d. from an unknown distribution and the gambler has access to an additional  $\beta n$  samples for some  $\beta \geq 0$ . We first give improved lower bounds on  $\alpha$  for a wide range of values of  $\beta$ ; specifically,  $\alpha \geq (1 + \beta)/e$  when  $\beta \leq 1/(e - 1)$ , which is tight, and  $\alpha \geq 0.648$  when  $\beta = 1$ , which improves on a bound of around 0.635 due to Correa et al. (SODA, 2020). Adding to their practical appeal, specifically in the context of algorithmic pricing, we then show that the new bounds can be obtained even in a streaming model of computation and thus in situations where the use of relevant data is complicated by the sheer amount of data available. We finally establish that the upper bound of  $1/e$  for the case without samples is robust to additional information about the distribution, and applies also to sequences of i.i.d. random variables whose distribution is itself drawn, according to a known distribution, from a finite set of known candidate distributions. This implies a tight prophet inequality for exchangeable sequences of random variables, answering a question of Hill and Kertz (Contemporary Mathematics, 1992), but leaves open the possibility of better guarantees when the number of candidate distributions is small, a setting we believe is of strong interest to applications.

## Abstract

We extend the definitions of complexity measures of functions to domains such as the symmetric group. The complexity measures we consider include degree, approximate degree, decision tree complexity, sensitivity, block sensitivity, and a few others. We show that these complexity measures are polynomially related for the symmetric group and for many other domains.

To show that all measures but sensitivity are polynomially related, we generalize classical arguments of Nisan and others. To add sensitivity to the mix, we reduce to Huang’s sensitivity theorem using “pseudo-characters”, which witness the degree of a function.

Using similar ideas, we extend the characterization of Boolean degree 1 functions on the symmetric group due to Ellis, Friedgut and Pilpel to the perfect matching scheme. As another application of our ideas, we simplify the characterization of maximum-size  $t$ -intersecting families in the symmetric group and the perfect matching scheme.

## 1 Introduction

A classical result in complexity theory states that a Boolean function  $f: \{0, 1\}^n \rightarrow \{0, 1\}$  of degree  $d$  can be computed using a decision tree of depth  $\text{poly}(d)$ . Conversely, a Boolean function computed by a decision tree of depth  $d$  has degree at most  $d$ . Thus degree and decision tree complexity are polynomially related. Other complexity measures which are polynomially related to the degree include approximate degree, certificate complexity, and block sensitivity. Recently, Huang [9] added sensitivity to the list.

Can we prove similar results for Boolean functions on other domains? Such domains have been introduced to complexity theory in recent years: for example, O'Donnell and Wimmer [13] used Boolean functions on the so-called “slice” to construct optimal nets for monotone functions; Barak et al. [1] used Boolean functions on the Reed–Muller code to construct and analyze the influential “short code”; and recently, Khot, Minzer and Safra [10] proved the 2-to-2 conjecture using Boolean functions on the Grassmann scheme.

Although yet to see applications to complexity theory, perhaps the most appealing domain is the symmetric group. We say that a function  $f: S_n \rightarrow \mathbb{R}$  has degree at most  $d$  if any of the following equivalent conditions hold:

1.  $f(\pi)$  can be written as a linear combination of  $d$ -juntas, which are functions depending on  $\pi(i_1), \dots, \pi(i_d)$  for some  $i_1, \dots, i_d \in [n]$ .
2. Representing the input as a permutation matrix,  $f$  can be written as a degree  $d$  polynomial in the entries of the matrix.
3.  $f$  has Fourier-degree  $d$ , that is, it is supported on isotypic components corresponding to partitions  $\lambda$  with  $\lambda_1 \geq n - d$ .

(The reader who is not familiar with representation theory can ignore the last definition.)

What is the correct generalization of decision tree? We take our inspiration from the work of Ellis, Friedgut and Pilpel [4], which characterized the Boolean degree 1 functions on  $S_n$ . These are functions that depend on some  $\pi(i)$  or on some  $\pi^{-1}(j)$ . This suggests the following definition: a decision tree for functions on  $S_n$  is a decision tree with queries of the form “ $\pi(i) = ?$ ” and “ $\pi^{-1}(j) = ?$ ”. Essentially the same definition (“matching decision trees”) is used in lower bounds on the pigeonhole principle [14].

We show that this is a good definition by proving that degree and decision tree complexity are polynomially related for the symmetric group. In fact, we are able to generalize many other complexity measures to the symmetric group, and show that all of them are polynomially related:

► **Theorem 1.** *The following complexity measures (appropriately defined) are all polynomially related for Boolean functions over the symmetric group: degree, approximate degree, decision tree complexity, certificate complexity, unambiguous certificate complexity, sensitivity, block sensitivity, fractional block sensitivity, quantum query complexity.*

Our results hold for many other domains, such as the perfect matching scheme (the set of all perfect matchings in  $K_{2n}$ ) and balanced slices (the balanced slice consists of all vectors in  $\{0, 1\}^{2n}$  with equally many 0s and 1s, and is also known as the Johnson scheme  $J(2n, n)$ ).

We prove Theorem 1 and its generalizations in an abstract framework based on simplicial complexes. In this framework, every point in the domain is a set. For example:

1. Boolean cube: We identify each vector  $x \in \{0, 1\}^n$  with the set  $\{(i, x_i) : i \in [n]\}$ .
2. Symmetric group: We identify each permutation  $\pi \in S_n$  with the set  $\{(i, \pi(i)) : i \in [n]\}$ .

A function has degree  $d$  if it can be written as a linear combination of functions of the form “the input set contains  $S$ ”, where  $|S| \leq d$ ; this generalizes the usual notion of degree in these two domains. Our decision trees allow any queries of the form “which element of the set  $Q$  does the input set contain?”, as long as there is a unique answer for every input.

With this setup in place, we are able to polynomially relate all complexity measures other than sensitivity by generalizing classical arguments, as presented by Buhrman and de Wolf [2], for example. To add sensitivity to the mix, we reduce to Huang’s sensitivity theorem [9] using basic representation theory.

Generalizing ideas of Gopalan et al. [8], we also prove the following simple result:

► **Theorem 2.** *If a function on the symmetric group has sensitivity  $s$ , then it can be recovered from its evaluation on a ball of radius  $O(s)$  around an arbitrary permutation.*

Using this, we show that low sensitivity functions can be computed efficiently:

► **Theorem 3.** *If a function on the symmetric group has sensitivity  $s$ , then it can be computed using a circuit of size  $n^{O(s)}$ .*

This should be compared to a decision tree for the function, which corresponds to a balanced formula of size  $n^{O(D)}$ , where  $D \geq s$  is the decision tree complexity.

## 1.1 Degree 1 functions

Our results show that in a wide variety of domains, Boolean degree 1 functions can be computed by constant depth decision trees. Can we say more?

Boolean degree 1 functions on the Boolean cube are *dictators*, that is, depend on a single coordinate, and the same holds for functions on the balanced slice. Ellis, Friedgut and Pilpel [4] showed that the same holds for the symmetric group, with the correct interpretation of “dictator”: a function depending only on some  $\pi(i)$ , or only on some  $\pi^{-1}(j)$ . In contrast, Filmus and Ihringer [6] showed that Boolean degree 1 functions on the Grassmann scheme ( $k$ -dimensional subspaces of an  $n$ -dimensional vector space over a finite field) could depend on two different “data points”.

Among the domains we consider, in many cases Boolean degree 1 functions are trivially dictators. In some other cases, describing all Boolean degree 1 functions seems difficult. We identify one case in which the problem is feasible:

► **Theorem 4.** *A Boolean function on the perfect matching scheme has degree at most 1 if and only if it is one of the following: a constant function; a function depending on the match of some vertex  $i$ ; or a function depending on whether the perfect matching intersects some triangle.*

Incidentally, this is another example in which there are non-dictatorial degree 1 functions, namely those depending on intersections with a triangle.

We prove Theorem 4 using polyhedral techniques. As in the proof of the corresponding result for the symmetric group by Ellis, Friedgut and Pilpel (which we paraphrase using our methods), we first characterize all *nonnegative* degree 1 functions, using the classical characterization of supporting hyperplanes of the perfect matching polytope. To deduce the result for Boolean functions, we use a simple result from the theory of complexity measures: a degree 1 function has sensitivity at most 1.

The reader is perhaps wondering about nonnegative functions of higher degree. Can we say anything intelligent about them? It turns out that the answer is negative already for the Boolean cube: classical results on the Sherali–Adams hierarchy [7] show that there exist nonnegative degree 2 functions which, if written as nonnegative linear combinations of monomials over literals (that is, products of factors of the form  $x_i$  and  $1 - x_j$ ), require degree  $\Omega(n)$ .

## 1.2 Application to Erdős–Ko–Rado theory

The work of Ellis, Friedgut and Pilpel, which has already been mentioned several times, is about intersecting families of permutations. A subset  $\mathcal{F} \subseteq S_n$  is *t-intersecting* if any two  $\pi_1, \pi_2 \in \mathcal{F}$  agree on the image of at least  $t$  points. In other words, if we think of  $\pi_1, \pi_2$  as sets (as in our setup), then  $|\pi_1 \cap \pi_2| \geq t$ . How large can a  $t$ -intersecting family be? One construction is a *t-star*:

$$\mathcal{F} = \{\pi \in S_n : \pi(i_1) = j_1, \dots, \pi(i_t) = j_t\}.$$

Ellis et al. show that for large enough  $n$  (depending on  $t$ ), these families have the maximum possible size, and moreover uniquely so: every  $t$ -intersecting family of the maximum size  $(n - t)!$  is a  $t$ -star. Unfortunately, their argument for the uniqueness claim is wrong, see [5]. Uniqueness can be recovered from the work of Ellis [3], which proves a much stronger result, and is quite complicated.

We give a much simpler proof of uniqueness, using the connection between degree and certificate complexity:

► **Theorem 5.** *For every  $t, d$ , the following holds for large enough  $n$ . If  $f$  is the characteristic vector of a  $t$ -intersecting family and  $\deg f \leq d$ , then either  $f$  is contained in a  $t$ -star, or the corresponding family contains  $O((n - t - 1)!)$  permutations.*

Ellis et al. show that a  $t$ -intersecting family of size  $(n - t)!$  must have degree  $t$  (for large enough  $n$ ), and so Theorem 5 shows that for large enough  $n$ , such a family must be a  $t$ -star.

Theorem 5 generalizes to other domains for which similar intersection theorems are known, such as the perfect matching scheme [11, 12], and to cross- $t$ -intersecting families.

We see Theorem 5 as a contribution of theoretical computer science to extremal combinatorics. It illustrates the usefulness of the theory developed in this work.

---

## Abstract

In several applications of real-time matching of demand to supply in online marketplaces, the platform can allow for some latency to batch the demand and improve the matching's efficiency. Motivated by these scenarios, we study the optimal trade-off between batching and inefficiency in online allocations. In particular, we consider  $K$ -stage variants of the classic vertex weighted bipartite b-matching and AdWords problems, where online vertices arrive in  $K$  batches. Our main result for both problems is an optimal  $(1 - (1 - 1/K)^K)$ -competitive (fractional) matching algorithm, improving the classic  $(1 - 1/e)$  competitive ratios known for the online variant of these problems [2, 1].

Our main technique is using a family of convex-programming based matchings that distribute the demand in a particularly balanced way among supply in different stages. More precisely, we identify a sequence of *polynomials with decreasing degrees* that can be used as strictly concave regularizers of the optimal matching linear program to form this family. By providing structural decompositions of the underlying graph using the optimal solutions of these convex programs, we develop a new multi-stage primal-dual framework to analyze the fractional multi-stage algorithm that returns the corresponding regularized optimal matching in each stage (by solving the stage's convex program). We further show a matching upper-bound by providing an unweighted instance of the problem in which no online algorithm obtains a competitive ratio better than  $(1 - (1 - 1/K)^K)$ . We extend our results to integral allocations in the vertex weighted b-matching problem with large budgets, and in the AdWords problem with small bid over budget ratios.

## Abstract

Håstad showed that any De Morgan formula (composed of AND, OR and NOT gates) shrinks by a factor of  $O(p^2)$  under a random restriction that leaves each variable alive independently with probability  $p$  [SICOMP, 1998]. Using this result, he gave an  $\tilde{\Omega}(n^3)$  formula size lower bound for the Andreev function, which, up to lower order improvements, remains the state-of-the-art lower bound for any explicit function.

In this work, we extend the shrinkage result of Håstad to hold under a far wider family of random restrictions and their generalization – random projections. Based on our shrinkage results, we obtain an  $\tilde{\Omega}(n^3)$  formula size lower bound for an explicit function computed in  $\mathbf{AC}^0$ . This improves upon the best known formula size lower bounds for  $\mathbf{AC}^0$ , that were only quadratic prior to our work. In addition, we prove that the KRW conjecture [Karchmer et al., Computational Complexity 5(3/4), 1995] holds for inner functions for which the unweighted quantum adversary bound is tight. In particular, this holds for inner functions with a tight Khrapchenko bound.

Our random projections are tailor-made to the function's structure so that the function maintains structure even under projection – using such projections is necessary, as standard random restrictions simplify  $\mathbf{AC}^0$  circuits. In contrast, we show that any De Morgan formula shrinks by a quadratic factor under our random projections, allowing us to prove the cubic lower bound.

Our proof techniques build on the proof of Håstad for the simpler case of balanced formulas. This allows for a significantly simpler proof at the cost of slightly worse parameters. As such, when specialized to the case of  $p$ -random restrictions, our proof can be used as an exposition of Håstad's result.

## 1 Introduction

### 1.1 Background

Is there an efficient computational task that cannot be perfectly parallelized? Equivalently, is  $\mathbf{P} \not\subseteq \mathbf{NC}^1$ ? The answer is still unknown. The question can be rephrased as follows: is there a function in  $\mathbf{P}$  that does not have a (De Morgan) formula of polynomial size?

The history of formula lower bounds for functions in  $\mathbf{P}$  goes back to the 1960s, with the seminal result of Subbotovskaya [30] that introduced the technique of random restrictions. Subbotovskaya showed that the Parity function on  $n$  variables requires formulas of size at least  $\Omega(n^{1.5})$ . Khrapchenko [22], using a different proof technique, showed that in fact the Parity function on  $n$  variables requires formulas of size  $\Theta(n^2)$ . Later, Andreev [3] came up with a new explicit function (now known as the Andreev function) for which he was able to obtain an  $\Omega(n^{2.5})$  size lower bound. This lower bound was subsequently improved by [18, 25, 14, 31] to  $n^{3-o(1)}$ .

The line of work initiated by Subbotovskaya and Andreev relies on the *shrinkage* of formulas under  $p$ -random restrictions. A  $p$ -random restriction is a randomly chosen partial assignment to the inputs of a function. Set a parameter  $p \in (0, 1)$ . We fix each variable independently with probability  $1 - p$  to a uniformly random bit, and we keep the variable alive with probability  $p$ . Under such a restriction, formulas shrink (in expectation) by a factor more significant than  $p$ . Subbotovskaya showed that De Morgan formulas shrink to at most  $p^{1.5}$  times their original size, whereas subsequent works of [25, 18] improved the bound to  $p^{1.55}$  and  $p^{1.63}$ , respectively. Finally, Håstad [14] showed that the shrinkage exponent of De Morgan formulas is 2, or in other words, that De Morgan formulas shrink by a factor of  $p^{2-o(1)}$  under  $p$ -random restrictions. Tal [31] improved the shrinkage factor to  $O(p^2)$  – obtaining a tight result, as exhibited by the Parity function.

In a nutshell, shrinkage results are useful to proving lower bounds as long as the explicit function being analyzed maintains structure under such restrictions and does not trivialize. For example, the Parity function does not become constant as long as at least one variable remains alive. Thus any formula  $F$  that computes Parity must be of at least quadratic size, or else the formula  $F$  under restriction, keeping each variable alive with probability  $100/n$ , would likely become a constant function, whereas Parity would not. Andreev’s idea is similar, though he manages to construct a function such that under a random restriction keeping only  $\Theta(\log n)$  of the variables, the formula size should be at least  $\tilde{\Omega}(n)$  (in expectation). This ultimately gives the nearly cubic lower bound.

### The KRW Conjecture

Despite much effort, proving  $\mathbf{P} \not\subseteq \mathbf{NC}^1$ , and even just breaking the cubic barrier in formula lower bounds, have remained a challenge for more than two decades. An approach to solve the  $\mathbf{P}$  versus  $\mathbf{NC}^1$  problem was suggested by Karchmer, Raz and Wigderson [20]. They conjectured that when composing two Boolean functions,  $f$  and  $g$ , the formula size of the

resulting function,  $f \diamond g$ , is (roughly) the product of the formula sizes of  $f$  and  $g$ .<sup>1</sup> We will refer to this conjecture as the “KRW conjecture”. Under the KRW conjecture (and even under weaker variants of it), [20] constructed a function in  $\mathbf{P}$  with no polynomial-size formulas. It remains a major open challenge to settle the KRW conjecture.

A few special cases of the KRW conjecture are known to be true. The conjecture holds when either  $f$  or  $g$  is the AND or the OR function. Håstad’s result [14] and its improvement [31] show that the conjecture holds when the inner function  $g$  is the Parity function and the outer function  $f$  is any function. This gives an alternative explanation to the  $n^{3-o(1)}$  lower bound for the Andreev function. Indeed, the Andreev function is at least as hard as the composition of a maximally-hard function  $f$  on  $\log n$  bits and  $g = \text{Parity}_{n/\log n}$ , where the formula size of  $f$  is  $\tilde{\Omega}(n)$  and the formula size of  $\text{Parity}_{n/\log n}$  is  $\Theta(n^2/\log^2 n)$ . Since the KRW conjecture holds for this special case, the formula size of the Andreev function is at least  $\tilde{\Omega}(n^3)$ . In other words, the state-of-the-art formula size lower bounds for explicit functions follow from a special case of the KRW conjecture – the case in which  $g$  is the Parity function. Moreover, this special case follows from the shrinkage of De Morgan formulas under  $p$ -random restrictions.

### Bottom-Up versus Top-Down Techniques

Whereas random restrictions are a “bottom-up” proof technique [15], a different line of work suggested a “top-down” approach using the language of communication complexity. The connection between formula size and communication complexity was introduced in the seminal work of Karchmer and Wigderson [21]. They defined for any Boolean function  $f$  a two-party communication problem  $KW_f$ : Alice gets an input  $x$  such that  $f(x) = 1$ , and Bob gets an input  $y$  such that  $f(y) = 0$ . Their goal is to identify a coordinate  $i$  on which  $x_i \neq y_i$ , while minimizing their communication. It turns out that there is a one-to-one correspondence between any protocol tree solving  $KW_f$  and any formula computing the function  $f$ . Since protocols naturally traverse the tree from root to leaf, proving lower bounds on their size or depth is done usually in a top-down fashion. This framework has proven to be very useful in proving formula lower bounds in the monotone setting (see, e.g., [21, 10, 28, 20, 27, 11, 26]). Moreover, a recent work by Dinur and Meir [6] was able to reprove Håstad’s cubic lower bound using the framework of Karchmer and Wigderson. As Dinur and Meir’s proof showed that top-down techniques can replicate Håstad’s cubic lower bound, a natural question (which motivated this project) arose:

*Are top-down techniques superior to bottom-up techniques?*

Towards that, we focused on a candidate problem: prove a cubic lower bound for an explicit function in  $\mathbf{AC}^0$ .<sup>2</sup> Based on the work of Dinur and Meir [6], we suspected that such a lower bound could be achieved using top-down techniques. We were also *certain* that the problem cannot be solved using the random restriction technique. Indeed, in order to prove a lower bound on a function  $f$  using random restrictions, one should argue that  $f$  remains hard under a random restriction, however, it is well-known that functions in  $\mathbf{AC}^0$  trivialize under  $p$ -random restrictions [7, 1, 32, 12]. Based on this intuition, surely random restrictions cannot show that a function in  $\mathbf{AC}^0$  requires cubic size. Our intuition turned out to be false.

<sup>1</sup> More precisely, the original KRW conjecture [20] concerns depth complexity rather than formula complexity. The variant of the conjecture for formula complexity, which is discussed above, was posed in [9].

<sup>2</sup> Recall that  $\mathbf{AC}^0$  is the class of functions computed by constant depth polynomial size circuits composed of AND and OR gates of unbounded fan-in, with variables or their negation at the leaves.

## 1.2 Our results

In this work, we construct an explicit function in  $\mathbf{AC}^0$  which requires De Morgan formulas of size  $n^{3-o(1)}$ . Surprisingly, our proof is conducted via the bottom-up technique of random projections, which is a generalization of random restrictions (more details below).

► **Theorem 1.** *There exists a family of Boolean functions  $h_n : \{0, 1\}^n \rightarrow \{0, 1\}$  for  $n \in \mathbb{N}$  such that*

1.  $h_n$  can be computed by uniform depth-4 unbounded fan-in formulas of size  $O(n^3)$ .
2. The formula size of  $h_n$  is at least  $n^{3-o(1)}$ .

Prior to our work, the best formula size lower bounds on an explicit function in  $\mathbf{AC}^0$  were only quadratic [24, 5, 19, 4].

Our hard function is a variant of the Andreev function. More specifically, recall that the Andreev function is based on the composition  $f \diamond g$ , where  $f$  is a maximally-hard function and  $g$  is the Parity function. Since Parity is not in  $\mathbf{AC}^0$ , we cannot take  $g$  to be the Parity function in our construction. Instead, our hard function is obtained by replacing the Parity function with the Surjectivity function of [4].

As in the case of the Andreev function, we establish the hardness of our function by proving an appropriate special case of the KRW conjecture. To this end, we introduce a generalization of the complexity measure of Khrapchenko [22], called the *min-entropy Khrapchenko bound*. We prove the KRW conjecture for the special case in which the outer function  $f$  is any function, and  $g$  is a function whose formula complexity is bounded tightly by the min-entropy Khrapchenko bound. We then obtain Theorem 1 by applying this version of the KRW conjecture to the case where  $g$  is the Surjectivity function. We note that our KRW result also implies the known lower bounds in the cases where  $g$  is the Parity function [14] and the Majority function [8].

Our KRW result in fact applies more generally, to functions  $g$  whose formula complexity is bounded tightly by the “soft-adversary method”, denoted  $\text{Adv}_s(g)$ , which is a generalization of Ambainis’ unweighted adversary method [2].

Our proof of the special case of the KRW conjecture follows the methodology of Håstad [13], who proved the special case in which  $g$  is Parity on  $m$  variables. Håstad proved that De Morgan formulas shrink by a factor of (roughly)  $p^2$  under  $p$ -random restrictions. Choosing  $p = 1/m$  shrinks a formula for  $f \diamond g$  by a factor of roughly  $m^2$ , which coincides with the formula complexity of  $g$ . On the other hand, on average each copy of  $g$  simplifies to a single input variable, and so  $f \diamond g$  simplifies to  $f$ . This shows that  $L(f \diamond g) \gtrsim L(f) \cdot L(g)$ .

Our main technical contribution is a new shrinkage theorem that works in a far wider range of scenarios than just  $p$ -random restrictions. Given a function  $g$  with soft-adversary bound  $\text{Adv}_s(g)$ , we construct a random projection<sup>3</sup> which, on the one hand, shrinks De Morgan formulas by a factor of  $\text{Adv}_s(g)$ , and on the other hand, simplifies  $f \diamond g$  to  $f$ . We thus show that  $L(f \diamond g) \gtrsim L(f) \cdot \text{Adv}_s(g)$ , and in particular, if  $\text{Adv}_s(g) \approx L(g)$ , then  $L(f \diamond g) \gtrsim L(f) \cdot L(g)$ , just as in Håstad’s proof. Using these random projections, that are tailored specifically to the structure of the function  $f \diamond g$  so that  $f \diamond g$  simplifies to  $f$  under projection, enables us to overcome the aforementioned difficulty. In contrast,  $p$ -random restrictions that do not respect the structure of  $f \diamond g$  would likely result in a restricted function that is much simpler than  $f$  and in fact would be a constant function with high probability.

<sup>3</sup> A projection is a mapping from the set of the variables  $\{x_1, \dots, x_n\}$  to the set  $\{y_1, \dots, y_m, \overline{y_1}, \dots, \overline{y_m}, 0, 1\}$ , where  $y_1, \dots, y_m$  are formal variables.

Our shrinkage theorem applies more generally to two types of random projections, which we call *fixing projections* and *hiding projections*. Fixing projections are random projections in which fixing the value of a variable results in a projection which is much more probable. Hiding projections are random projections in which fixing the value of a variable hides which coordinates it appeared on. We note that our shrinkage theorem for fixing projections captures Håstad's result for  $p$ -random restrictions as a special case.

The proof of our shrinkage theorem is based on Håstad's proof [14], but also simplifies it. In particular, we take the simpler argument that Håstad uses for the special case of completely balanced trees, and adapt it to the general case. As such, our proof avoids a complicated case analysis, at the cost of slightly worse bounds. Using our bounds, it is nevertheless easy to obtain the  $n^{3-o(1)}$  lower bound for the Andreev function. Therefore, one can see the specialization of our shrinkage result to  $p$ -random restrictions as an exposition of Håstad's cubic lower bound.

### An example: our techniques when specialized to $f \diamond \text{Majority}_m$

To illustrate our choice of random projections, we present its instantiation to the special case of  $f \diamond g$  where  $f : \{0, 1\}^k \rightarrow \{0, 1\}$  is non-constant and  $g = \text{Majority}_m$  for some odd integer  $m$ . In this case, the input variables to  $f \diamond g$  are composed of  $k$  disjoint blocks,  $B_1, \dots, B_k$ , each containing  $m$  variables. We use the random projection that for each block  $B_i = \{x_{m(i-1)+1}, \dots, x_{mi}\}$ , picks one variable in the block  $B_i$  uniformly at random, projects this variable to the new variable  $y_i$ , and fixes the rest of the variables in the block in a balanced way so that the number of zeros and ones in the block is equal (i.e., we have exactly  $(m-1)/2$  zeros and  $(m-1)/2$  ones). It is not hard to see that under this choice,  $f \diamond g$  simplifies to  $f$ . On the other hand, we show that this choice of random projections shrinks the formula complexity by a factor of  $\approx 1/m^2$ . Combining the two together, we get that  $L(f \diamond \text{Majority}_m) \gtrsim L(f) \cdot m^2$ . Note that in this distribution of random projections, the different coordinates are not independent of one another, and this feature allows us to maintain structure.

## 1.3 Related work

Our technique of using tailor-made random projections was inspired by the celebrated result of Rossman, Servedio, and Tan [29, 16] that proved an average-case depth hierarchy. In fact, the idea to use tailor-made random restrictions goes back to Håstad's thesis [17, Chapter 6.2]. Similar to our case, in [17, 29, 16],  $p$ -random restrictions are too crude to separate depth  $d$  from depth  $d+1$  circuits. Given a circuit  $C$  of depth  $d+1$ , the main challenge is to construct a distribution of random restrictions or projections (tailored to the circuit  $C$ ) that on the one hand maintains structure for  $C$ , but on the other hand simplify any depth  $d$  circuit  $C'$ .
